PREPARATION, PROPERTIES AND STRUCTURES OF ESTERTIN(IV) SULPHIDES

OK-SANG JUNG, JONG HWA JEONG and YOUN SOO SOHN*

Division of Chemistry, Korea Advanced Institute of Science & Technology, Seoul 136-791, Korea

(*Received* 8 *May* 1989; *accepted* 5 *June* 1989)

Abstract—Estertin(IV) sulphides $[CH_3OOCCH_2CH_2(L)SnS]_n$ (**1a**: L = Me_2NCS_2—, $n = 2$; **1b**: L = Et_2NCS_2—, $n = 2$; **2**: L = $CH_3OOCCH_2CH_2$—, $n = 3$) have been prepared and characterized. In the crystal, the structure of **1a**·$2CHCl_3$ ($P\bar{1}$; $a = 10.739(1)$, $b = 11.801(1)$, $c = 7.7173(9)$ Å, $\alpha = 107.036(8)$, $\beta = 97.93(1)$ and $\gamma = 105.350(9)°$; $R = 0.0600$) is a centrosymmetric four-membered dimer in which the dithiocarbamate ligand is anisobidentate and each tin atom is pentacoordinate with local geometry of a distorted trigonal bipyramid, whereas the structure of **2** ($P\bar{1}$; $a = 11.453(3)$, $b = 12.513(3)$, $c = 13.349(3)$ Å, $\alpha = 97.07(2)$, $\beta = 99.77(2)$, $\gamma = 97.48(2)°$; $R = 0.0369$) shows a six-membered trimer in the boat conformation with tetracoordinated tin atoms. Spectral data of IR, and ^1H, ^{13}C and ^{119}Sn NMR along with the cryoscopic data indicate that the complexes have the same structure in the solid state and in solution.

Diorganotin sulphides revealed a variety of structures depending on the organic groups bonded to the tin atom. Ph_2SnS[1] and Me_2SnS[2] have been found as a cyclic trimer with a Sn_3S_3 six-membered puckered ring, whereas $(t\text{-Bu})_2SnS$[3] and MeN $(CH_2CH_2CH_2)_2SnS$[4] are found as a cyclic dimer with a Sn_2S_2 four-membered ring structure. Besides these cyclic species, $(i\text{-Pr})_2SnS$[5] shows a polymeric chain structure in which tin and sulphur atoms are coupled alternatively. In these diorganotin(IV) chalcogenides, the tin atom is tetracoordinate except in the compound of a cyclic ligand with a nitrogen donor atom.[4]

On the other hand, crystal structures of estertin(IV) compounds, $(CH_3OOCCH_2CH_2)_2SnCl_2$[6] and $CH_3OOCCH_2CH_2(Me_2NCS_2)SnCl_2$,[7] have shown that the central tin atom is hexacoordinated via carbonyl oxygen-to-tin coordination.

In order to understand the structural variety of organotin(IV) chalcogenides, we have prepared mono- and diestertin(IV) sulphides and examined them by means of X-ray crystallography and various spectroscopies.

EXPERIMENTAL

All chemicals were of reagent grade from commercial sources and used without further purification. All solvents were either used directly from freshly opened bottles or dried prior to use. Estertin chlorides were prepared by the literature method.[8] Sodium dithiocarbamates were prepared in the standard manner.[9] Chemical analyses were carried out by the Chemical Analysis Laboratory at KAIST and the molecular weights were determined cryoscopically in benzene using a Cryette A Automatic Cryoscope. The IR spectra in the 4000–400 cm^{-1} region were measured on KBr pellets with an Analect Instrument fx 6160 FT-IR spectrometer. All the NMR spectra were measured in chloroform solution. ^1H NMR spectra were recorded on a JEOL JNM DMX 60 spectrometer, and ^{13}C and ^{119}Sn NMR spectra on a Bruker AM-200 operating at 50.32 (^{13}C) and 74.63 MHz(^{119}Sn) in the pulse mode with Fourier transform at ambient temperature (23 ± 2°C). The chemical shifts are relative

to external Me_4Si (^{13}C) and Me_4Sn (^{119}Sn) for the indicated nuclei.

Preparation of $CH_3OOCCH_2CH_2(Me_2NCS_2)SnCl_2$

This compound was prepared by the authors' procedure.[7]

Preparation of $CH_3OOCCH_2CH_2(Et_2NCS_2)SnCl_2$

$Na \cdot S_2CNEt_2 \cdot 3H_2O$ (1.13 g, 5 mmol) in 50 cm^3 of ethanol was reacted with $CH_3OOCCH_2CH_2SnCl_3$ (1.56 g, 5 mmol) in 50 cm^3 of ethanol in the same manner as used for the preparation of $CH_3OOCCH_2CH_2(Me_2NCS_2)SnCl_2$. The resultant solid was recrystallized from a solvent pair of chloroform–petroleum ether (1 : 1). The crystalline solid (m.p. 80–81°C) was obtained in 81% yield. Found: C, 25.1; H, 4.0; N, 3.3. Calc. for $C_9H_{12}NCl_2O_2S_2Sn$: C, 25.4; H, 4.0; N, 3.3%. ^1H NMR (δ, ppm): 1.4 (t, CH_3—), 1.9 (t, —CH_2Sn), 2.9 (t, —CH_2—), 3.7 (q, —CH_2N), 4.0 (s, CH_3O—). IR (cm^{-1}): ν(C=O), 1673; ν(C—N), 1519; ν(C—S), 992.

Preparation of $[CH_3OOCCH_2CH_2(Me_2NCS_2)SnS]_2$ **(1a)**

A solution of $Na_2S \cdot 9H_2O$ (2.40 g, 10 mmol) dissolved in 50 cm^3 of water was added dropwise to an equimolar solution of $CH_3OOCCH_2CH_2(Me_2NCS_2)SnCl_2$ (3.97 g, 10 mmol) in 50 cm^3 of chloroform, and the resultant solution was stirred at room temperature for 30 min. The chloroform layer was separated and evaporated to produce a thin yellow solid. Recrystallization of the crude product from a chloroform–petroleum ether solvent pair (1 : 1) at 0°C gave a colourless chloroform-solvated crystalline solid (m.p. 163–165°C) in 85% yield. Found: C, 19.8; H, 2.9; N, 2.9. Calc. for $C_{14}H_{26}N_2O_4S_6Sn_2 \cdot 2CHCl_3$: C, 20.0; H, 2.9; N, 2.9%.

Preparation of $[CH_3OOCCH_2CH_2(Et_2NCS_2)SnS]_2$ **(1b)**

Reaction of $CH_3OOCCH_2CH_2(Et_2NCS_2)SnCl_2$ (4.25 g, 10 mmol) with $Na_2S \cdot 9H_2O$ (2.40 g, 10 mmol) using the same method as used for the preparation of **1a**, followed by recrystallization from a benzene–petroleum ether solvent pair (1 : 1), resulted in a thin yellow solid (m.p. 98–100°C) in 83% yield. Molecular weight measured: 758.4 (theory: 778.2). Found: C, 27.5; H, 4.3; N, 3.6. Calc. for $C_{18}H_{34}N_2O_2S_6Sn_2$: C, 27.8; H, 4.4; N, 3.6%.

Preparation of $[(CH_3OOCCH_2CH_2)_2SnS]_3$ **(2)**

This compound was prepared by the literature method.[10] The white solid was recrystallized from a chloroform–petroleum ether solvent pair (1 : 2). The colourless crystalline solid (m.p. 72–73°C) was obtained in 80% yield. Molecular weight measured: 940.5 (theory: 974.9). Found: C, 29.6; H, 4.4; S, 9.2. Calc. for $C_{28}H_{42}O_{12}S_3Sn_3$: C, 29.6; H, 4.3; S, 9.9%.

Crystallographic analysis of complexes **1a** *and* **2**

All the crystallographic data were obtained on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated molybdenum radiation ($\lambda(K_{\alpha 1}) = 0.70930$, $\lambda(K_{\alpha 2}) = 0.71359$ Å) at an ambient temperature of 23 ± 2°C. The chloroform-solvated crystal of **1a** was unstable when removed from the mother liquor and, therefore, the crystal used for X-ray study was wedged, wet with mother liquor, into a glass capillary which was then sealed. The crystal of **2** was glued to the interior of a thin walled glass capillary. Preliminary diffractometric investigations indicated that both **1a** and **2** belong to the same space group $P\bar{1}$ (C_i^1, no. 2).[11] The lattice constants were determined by the least-square refinement of the diffraction geometry for 25 intense reflections having $12 < \theta_{Mo\text{-}K} < 16$ for **1a** and $8 < \theta_{Mo\text{-}K} < 13$ for **2**. Crystal parameters and procedural information corresponding to data collection and structure refinement for the complexes are given in Table 1. The structures were solved by use of the conventional heavy-atom method and difference Fourier techniques, and were refined by means of full-matrix least-squares procedures using SHELX-76.[12] The non-hydrogen atoms were refined anisotropically, except for those comprising chloroform of solvation which were refined isotropically. Hydrogen atoms were omitted from the refinement. Tables of atomic positional and thermal parameters and F_o/F_c values have been deposited as Supplementary Material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The reaction of dithiocarbamatoestertin chlorides, $CH_3OOCCH_2CH_2(R_2NCS_2)SnCl_2$ (R = Me, Et), with sodium sulphide resulted in the dimeric complexes **1a** and **1b**, whereas the cognate reaction of diestertin chlorides, $(CH_3OOCCH_2CH_2)_2SnCl_2$, gave a trimeric complex **2** as established by chemical analysis, cryoscopic data, and X-ray crystal-

lography, as will be shown below. The product were obtained as crystalline solids with sharp melting points, and are soluble in polar organic solvents such as chloroform, dichloromethane, dimethyl sulphoxide and acetone, but insoluble in water and saturated aliphatic hydrocarbons. It is noticeable that **1a** is not soluble but **1b** is soluble in benzene, which allows cryoscopic measurement.

Crystal structure of complexes **1a** *and* **2**

The molecular geometry and labelling scheme for complex **1a** is shown in Fig. 1. The bond distances and angles are tabulated in Table 2. The chloroform molecules solvated are not shown in the structure and do not interact with the complex **1a**. Complex **1a** is a centrosymmetric dimer consisting of a planar four-membered ring, Sn_2S_2, in which the dithiocarbamate ligand is bidentate and thus each tin atom is pentacoordinate, with S(1), S(2) and C(4) in equatorial positions and with S(3) and S(1)′ in axial positions in a distorted trigonal bipyramidal arrangement. The Sn_2S_2 four-membered ring is a slightly distorted rectangle with different Sn—S bond lengths: Sn—S(1) and Sn—S(1)′ distances of 2.381(2) and 2.509(3) Å are similar to those of 2.40 and 2.53 Å in $[MeN(CH_2CH_2CH_2)SnS]_2$.[4] The dithiocarbamate ligand is bonded to the tin atom in an anisobidentate fashion: Sn—S(2) and Sn—S(3) distances of 2.487(3) and 2.752(3) Å are comparable with those of $(t\text{-Bu})_2Sn(S_2CNMe_2)_2$[13] (2.489(1), 2.795(1) Å) and $BuPhSn(S_2CNEt_2)Cl$[14] (2.454(1), 2.764(1) Å). The axial Sn—S(3) and Sn—S(1)′ bond lengths are longer than the equatorial ones. The small bite angle (68.6(1)°) of the dithiocarbamate

		C(7)—O(2)—C(6)	115.9(10)

ligand is in part responsible for the distortion of the trigonal bipyramid. Another aspect noteworthy in the structure of **1a** is that the ester carbonyl group does not coordinate to the tin (Sn---O(1), 3.19(1) Å) in spite of its favourable position as shown in Fig. 1, in contrast to its halide analogue, $CH_3OOCCH_2CH_2(Me_2NCS_2)SnCl_2$,[7] which includes a five-membered chelate ring via a carbonyl oxygen-to-tin coordination of the ester group. The free ester group in complex **1a** is presumably due to a decrease of Lewis acidity of the tin atom by the partial change of donor atoms.

The molecular geometry of **2** is depicted in Fig. 2, where the atomic numbering scheme is defined. The selected bond distances and angles appear in Table 3. In contrast to **1a**, the crystal structure of **2** shows that three tin and three sulphur atoms form a trimeric six-membered ring in somewhat distorted boat conformation. The structure is quite similar to the structures of $[Ph_2SnS]_3$ and $[Me_2SnS]_3$ reported by Schumann[1] and Jacobsen and Kress,[2] respectively. The complex also indicates free ester groups which are different from those of its starting material $(CH_3OOCCH_2CH_2)_2SnCl_2$,[6] probably due to a decrease of the acceptor properties of the tin atom by changing the donor atoms, and an approximate tetrahedral geometry around the tin atom results. The S(1)—Sn(1)—S(3), S(1)—Sn(2)—S(2) and S(2)—Sn(3)—S(3) bond angles of 111.0(1), 104.7(1) and 104.0(1)° deviate from those expected for a tetrahedral sp^3-hybridized tin atom, presumably owing to the ester groups. The Sn—S—Sn angles of 102.8(1), 106.9(1) and 100.7(1)° also deviate slightly from that (104°) calculated by Kriegsmann *et al.*[15] The Sn—S (2.404(2)–2.442(2) Å) and Sn—C (2.140(9)–2.168(7) Å) distances in this compound correspond to those expected on the basis of covalent single bonds between Sn—S and Sn—C.

Why complex **1a** is dimeric, rather than trimeric, is not clear. There is a temptation to invoke steric hindrance. Thus the bulky pentacoordinate tin complexes, **1a** and **1b**, are capable of forming dimeric Sn_2S_2 four-membered rings as in [MeN-

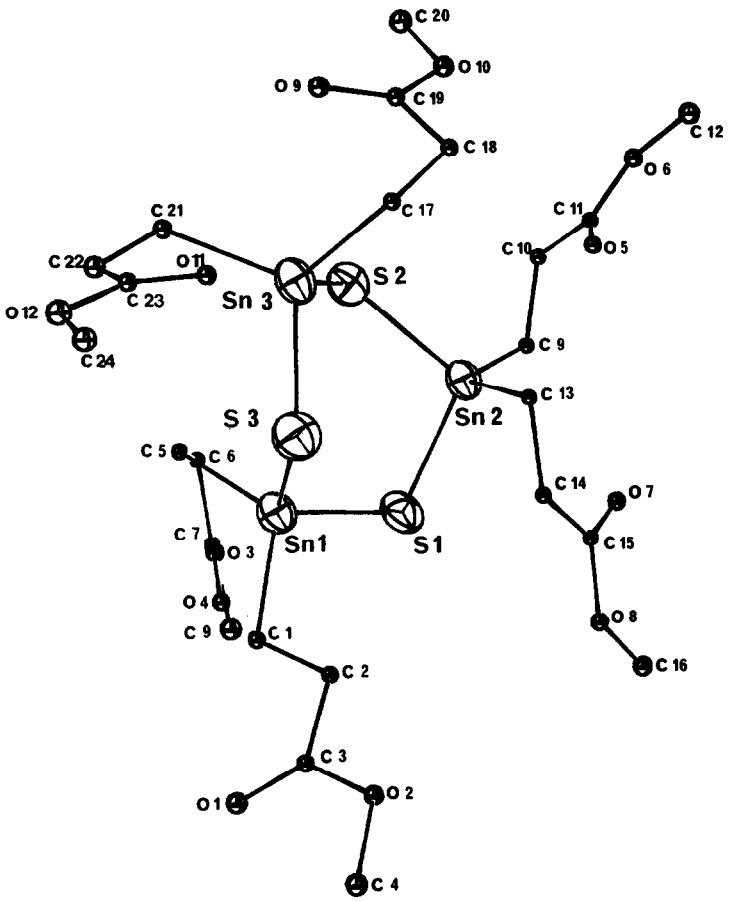

Fig. 2. ORTEP drawing of $[(CH_3OOCCH_2CH_2)_2SnS]_3$ along with the atomic labelling scheme. Thermal ellipsoids of C and O were reduced for clarity.

Table 4. Relevant IR bands for $[CH_3OOCCH_2CH_2(L)SnS]_n$[a]

Compound	ν(C═O) (cm^{-1})	ν(C—N) (cm^{-1})	ν(C—S) (cm^{-1})
1a	1730(vs)	1528(vs)	973(s)
1b	1730(vs)	1507(vs)	988(s)
2	1713(vs)	—	—

[a] **1a**: L = Me_2NCS_2—, $n = 2$; **1b**: L = Et_2NCS_2—, $n = 2$; **2**: L = $CH_3OOCCH_2CH_2$—, $n = 3$. vs, very strong; s, strong.

$(CH_2CH_2CH_2)SnS]_2$,[4] whereas the tetracoordinate tin complex, **2**, seems to favour a trimeric Sn_3S_3 six-membered ring.

Spectroscopic properties of complexes **1a**, **1b** *and* **2**

The characteristic IR bands of the complexes relevant to their molecular structures are listed in Table 4. Among the stretching modes, the ν(C═O) band is known to depend on the type of coordination of the carbonyl group.[16–18] The ν(C═O) bands of complexes **1a** (1730 cm^{-1}), **1b** (1730 cm^{-1}) and **2** (1713 cm^{-1}) exhibit a remarkable blue shift from that (1652 cm^{-1}) of the carbonyl oxygen-to-tin coodinated complex, $CH_3OOCCH_2CH_2(Me_2NCS_2)SnCl_2$.[7] This fact clearly indicates the non-chelating nature of the carbonyl group in the present chalcogenides. The ν(C—N) and ν(C—S) bands in the regions 1450–1550 and 950–1050 cm^{-1}, respectively, are known to depend on the nature of coordination of the dithiocarbamate ligand. A single band for complexes **1a** and **1b** in each region is indicative of bidentate chelation of the dithiocarbamate ligand.[19,20]

The ^1H, ^{13}C and ^{119}Sn NMR data are listed in Table 5. In particular, ^1H and ^{13}C NMR data also support the absence of carbonyl oxygen-to-tin coordination for the chalcogenides in solution: $\delta(^1H) = 3.7$ ppm for CH_3O— and $\delta(^{13}C)$ values for C═O (174.5–176.1 ppm) and CH_3O— (51.7–52.0 ppm) in the chalcogenides were shielded by about 0.3, 6 and 3 ppm, respectively, relative to those of the carbonyl oxygen-to-tin coordinated complex, $CH_3OOCCH_2CH_2(Me_2NCS_2)SnCl_2$.[7]

^{119}Sn NMR spectroscopy has been found to have an approximately linear relationship between the $\delta(^{119}Sn)$ values and the coordination numbers of dithiocarbamatotin(IV) complexes:[21–27] the $\delta(^{119}Sn)$ value has been found to lie between −150 and −250 ppm in pentacoordinate complexes and between −300 and −500 ppm in hexacoordinate complexes. From this relationship $\delta(^{119}Sn)$ values for complexes **1a** ($\delta(^{119}Sn) = -229.8$, −232.0 ppm) and **1b** ($\delta(^{119}Sn) = -232.9$, −235.1 ppm) indicate that the tin atoms in **1a** and **1b** are pentacoordinate. Assuming from the above-mentioned spectroscopic data that the ester group acts as monodentate, then the $\delta(^{119}Sn)$ values of complexes **1a** and **1b** suggest that the dithiocarbamate ligand is bidentate. It seems worthwhile to point out that the ^{119}Sn signals appear at slightly different chemical shifts in the dimeric chalcogenides, **1a** and **1b**, implying slightly different chemical environments around the tin atom. On the other hand, a drastic deshielding of the tin chemical shift for complex

Table 5. ^1H, ^{13}C and ^{119}Sn NMR data for $[CH_3OOCCH_2CH_2(L)SnS]_n$[a]

Compound	$^1H(\delta,ppm)$	$^{13}C(\delta,ppm)$	$^{119}Sn(\delta,ppm)$

(*Received* 16 *May* 1989; *accepted* 7 *June* 1989)

Abstract—The synthesis and structure of the tetragonal pyramidal complex $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ are reported. This complex has a *cis*-disposition of basal ligands with an apical nitrosyl group inclined towards the bromide ligands. $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ readily and irreversibly takes up atmospheric dioxygen to form the nitrato complex $[RhBr_2(NO_3)\{P(C_6H_{11})_2H\}_2]$, whose structure is also described. In this complex the bromide and phosphine ligands are *trans*- and *cis*-disposed, respectively.

Several structures of pentacoordinate nitrosyl complexes $[RhX_2(NO)\{PR_3\}_2]$ (X = Cl or Br, and R represents various organic groups) have been reported.[1–3] We have suggested[3] two possible explanations for the structures adopted by this series of compounds—the one based on a general molecular orbital model for pentacoordinate metal nitrosyl complexes proposed by Hoffmann *et al.*,[4] and the other, a simpler picture relying on molecular mechanical ideas. In this paper a nitrosyl complex, $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ is described, aspects of whose structure can be explained using the simple mechanical model, but which are difficult to account for otherwise. Interestingly, a proposal that "steric interactions in molecules and crystals must be described by simple mechanical models and not by quantum theory"[5] appeared recently.

The reactivity of $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ in solution towards atmospheric oxygen differs from that of other complexes of this class, which are either air-stable and very insoluble, or air-sensitive and decompose forming uncharacterisable products: $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ reacts irreversibly with dioxygen to form the stable complex $[RhBr_2(NO_3)\{P(C_6H_{11})_2H\}_2]$. The formation and structure of this nitrato complex are also described in this paper.

EXPERIMENTAL

$[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ was prepared by reacting $[\{Rh(NO)Br_2\}_n]$[6] with dicyclohexylphosphine, following the procedure described in the literature.[7] The complex crystallized as dark green prisms [ν(N—O) 1651 cm^{-1}, in Nujol] from dichloromethane–methanol at 0°C: yield *ca* 40%. Microanalysis indicated the presence of a molecule of dichloromethane of solvation (Found: C, 39.0; H, 6.4; N, 1.8; Cl, 9.0. $C_{25}H_{48}Br_2Cl_2NOP_2Rh$ requires C, 38.8; H, 6.3; N, 1.8; Cl, 9.2%). During recrystallization air was not excluded, and from the dark red–brown supernatant solution, $[RhBr_2(NO_3)\{P(C_6H_{11})_2H\}_2]$ was isolated in *ca* 15% yield based on $[\{Rh(NO)Br_2\}_n]$ as orange lozenges of the 1:1 dichloromethane solvate (Found: C, 37.3; H, 6.0; N, 1.8; Cl, 8.7. $C_{25}H_{48}Br_2Cl_2NO_3P_2Rh$ requires C, 37.2; H, 6.0; N, 1.7; Cl, 8.8%). IR bands due to the NO_3 ligand were not assigned.

unit cell dimensions based on 25 low θ reflections; crystal stability monitored and confirmed; structure solution and refinement details have been described previously.[7] With the exception of carbon, hydrogen and solvent atoms, the model structures were refined anisotropically. Solvent atoms (no hydrogens) were refined as rigid groups with C—Cl 1.75 Å, Cl—C—Cl 109.5°. Hydrogen atoms were included at calculated positions with common temperature factors.* Crystal data, data collection and refinement details are summarized in Table 1, and selected bond lengths and angles are given in Table 2.

RESULTS AND DISCUSSION

$[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$, whose structure is depicted in Fig. 1, displays a tetragonal pyramidal coordination geometry with the phosphine and bromide ligands constituting the basal square and the nitrosyl group the apex. In common with other complexes of this type, the nitrosyl group is bent; this mode of coordination is a consequence of the good electron-donating capabilities, and weak π-acceptor qualities of the basal ligands.[4] The features of the molecule which invite comment are firstly the *cis*-disposition of the basal ligands; secondly the direction in which the NO ligand bends and finally the unusual reactivity towards O_2.

We have remarked previously that the preferred arrangement of basal ligands appears to be *cis*; only in the cases of PPh_3 and $P(OPr^i)Ph_2$ is the *trans*-arrangement observed.[1,3] We proposed the critical ligand cone angle (the apical angle of the cone whose apex is the metal atom and which envelops the van der Waals' volume of the ligand[8]) which would force a *trans*-geometry, lies somewhere between 132 and 140°. On this basis, the cone angle of the dicyclohexylphosphine ligand should be 132° or less. Can this parameter be estimated from first principles?

Using the mean bond lengths of P—C 1.835, C—C 1.51 and C—H 1.08 Å, with a van der Waals' radius for hydrogen of 1.2 Å[9] and tetrahedral geometry around carbon, a simple calculation shows that the van der Waals' contact cone angle subtended at a phosphorus atom by a cyclohexyl group free to rotate is 143°. However, the C—P—C angles found in this analysis are approximately tetrahedral, so the cyclohexyl groups are intermeshed to the extent that their contact cones interpenetrate by $143-109.5°$ i.e. 33.5°. For perfect tetrahedral geometry around phosphorus P, and a

Rh—P distance of 2.30 Å, and given this degree of interpenetration, one may estimate the cone angle of the strain-free tricyclohexylphosphine ligand bound to rhodium to be 164°. (Tolman[8] gives a figure of 179(10)°, significantly larger, based on a phosphine–metal (Ni) distance of 2.28 Å, and measured on a model.) The corresponding cone angle of PH_3 is 99° based on a P—H bond length of 1.3 Å (Tolman quotes 87(2)°). Consequently, using Tolman's equation, the cone angle of the $P(C_6H_{11})_2H$ ligand will be 2/3 of $(2\times 164/2+99/2)$, i.e. 142° (considerably greater if Tolman's figures are used).

According to our previous suggestion this angle is large enough to force a *trans*-ligand geometry. The reason it does not, and that the two $P(C_6H_{11})_2H$ ligands can bond *cis*, is apparent from inspection of Fig. 2, which depicts the molecule with atoms plotted in space-filling style, i.e. as spheres with corresponding van der Waals' radii.[9] It is clear that the two secondary phosphine hydrogens are in close contact—the H—H distance is 2.3(1) Å,

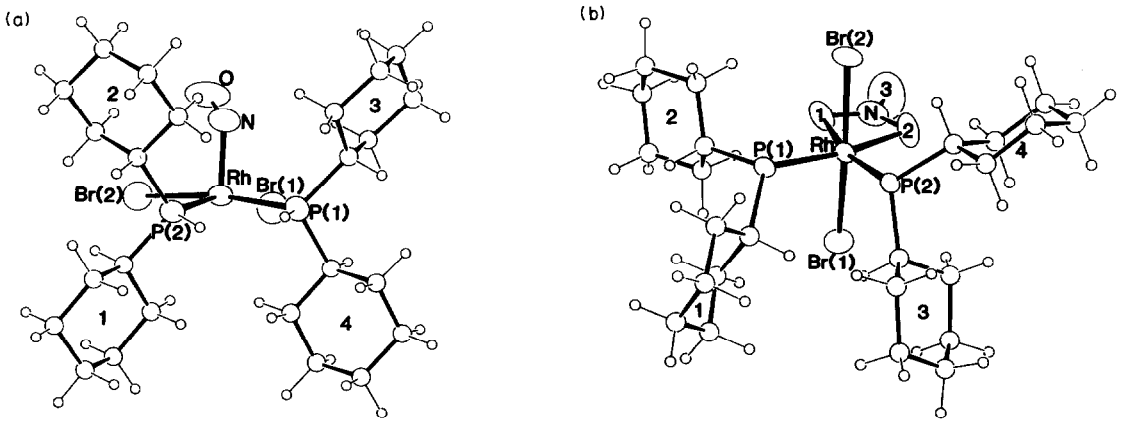

Fig. 1. The molecular structures of (a) $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ and (b) $[RhBr_2(NO_3)\{P(C_6H_{11})_2H\}_2]$.

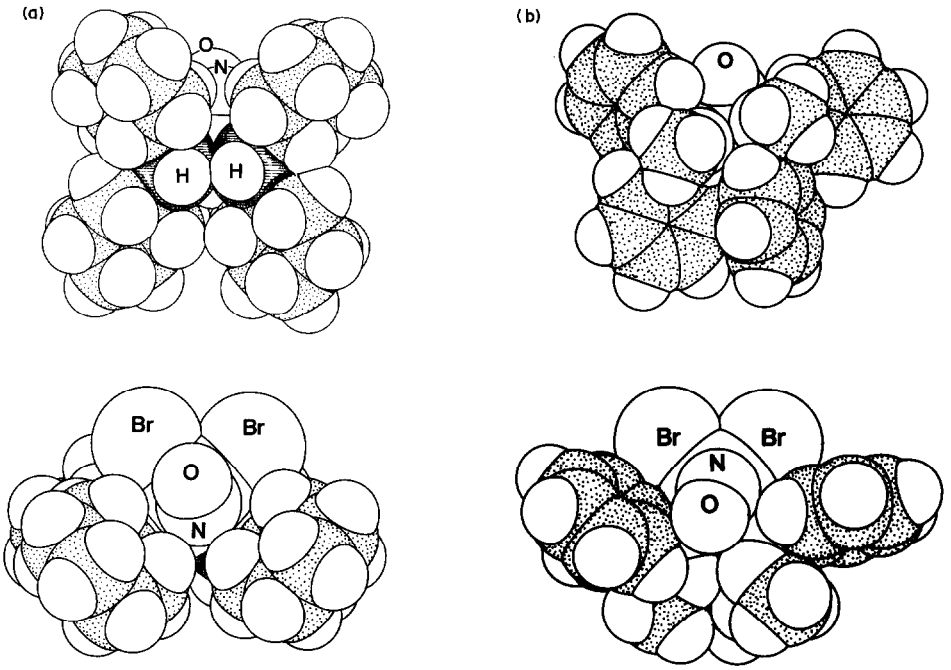

Fig. 2. (a) Space-filling diagrams of $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ viewed (top) perpendicular to the Rh—N vector and (bottom) down the Rh—N vector. (b) Corresponding diagrams of $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$ for comparative purposes.

compared to the sum of the van der Waals' radii of 2.4 Å—and that the cone angle as a measure of ligand bulk is inappropriate in the case of dicyclohexylphosphine, where the sizes of the hydrogen and cycohexyl groups attached to the phosphorus atom are so disparate. The $P(C_6H_{11})_2H$ ligands are able to bond *cis* by juxtaposing the sterically undemanding P—H moieties.

It is also interesting to note that the NO group bends in the opposite sense to that observed in $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$;[3] we suggested a simple explanation for the conformation of the NO group in this complex in terms of dipole–dipole interactions between the NO and the rest of the molecule: this explanation clearly will not hold water for $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$. Once again, Fig. 2 shows that it is not possible for the NO group to incline towards the phosphine ligands in $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$, as this region is occupied by the bulky cyclohexyl groups; such is not the case with $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$.

It appears, therefore, that the *cis*-arrangement of basal ligands in $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$, $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$ and $[RhBr_2(NO)\{P(OC_6H_5)_3\}_2]$ is the favoured configuration. This is surprising considering the steric demands of the phosphine ligands. A mechanistic rather than energetic explanation for this result seems preferable: one rather along the lines of that advanced to explain the formation of the dimer $[\{RhBr(NO)[PPh_2O)_2H]\}_2]$[7] from $[\{Rh(NO)Br_2\}_n]$ *via* a dinuclear bromide-bridged *solvento*-intermediate. The conformation of the NO ligand is then easily accounted for on the basis of simple molecular mechanical arguments; however the general molecular orbital model does not predict the observed structure.

The reactivity of the NO group towards oxidation by atmospheric dioxygen is unexpected. Kubota and Phillips[10] have described reactions of $[Ir(PPh_3)_2(CO)ClX(NO)]$ with dioxygen to give the nitrato complexes $[Ir(PPh_3)_2(CO)ClX(NO_3)]$, and suggest that the reaction proceeds by *electrophilic* attack of O_2 on the NO^- ligand, as has been proposed for reactions of cobalt nitrosyls, followed by rearrangement of the N-coordinated O—N—O—O group. However, the complexes $[RhX_2(NO)\{PR_3\}_2]$ hitherto reported do not show any tendency to oxidation of the NO ligand to NO_3, and it may be that the particular conformation of the NO in, and the structure of, $[RhBr_2(NO)\{P(C_6H_{11})_2H\}_2]$ is the source of this susceptibility.

The structure of $[RhBr_2(NO_3)\{P(C_6H_{11})_2H\}_2]$ is shown in Fig. 1. It is a slightly distorted octahedral molecule with a bidentate NO_3 ligand. During the oxidation and rearrangement of ligands it is sur-

prisingly the bromide ligands which end up *trans*-disposed, not the much more bulky $P(C_6H_{11})_2H$ groups. A search through a somewhat out-of-date version (Jan 1986) of the Cambridge Data File did not reveal any other octahedral rhodium(III) nitrato complexes; however, apart from this claim to uniqueness, $[RhBr_2(NO_3)\{P(C_6H_{11})_2H\}_2]$ is structurally unremarkable.

(*Received* 3 *February* 1989; *accepted* 7 *June* 1989)

Abstract—The compounds $\{Ru_2(\mu\text{-}O_2CCH_3)_4[OP(p\text{-}RC_6H_4)_3]_2\}PF_6$ (R = H, F, CH_3O, Cl) containing the Ru_2^{5+} unit have been prepared by the reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ and $P(p\text{-}RC_6H_4)_3$ (R = H, F, CH_3O, Cl) in the presence of $NOPF_6$ in methanol. In all cases the oxidation of triarylphosphine to triarylphosphine oxide is observed and the $Ru_2(\mu\text{-}O_2CCH_3)_4^+$ unit remains unaltered. The X-ray structure of $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]PF_6 \cdot CH_2ClCH_2Cl$ has been determined; this compound crystallizes in the space group $P\bar{1}$, with $a = 8.46(2)$, $b = 12.399(2)$, $c = 13.017(4)$ Å, $\alpha = 105.18(2)$, $\beta = 92.64(5)$, $\gamma = 108.81(5)°$, $V = 1234(3)$ Å^3. There are two half ruthenium dimers, one anion and an uncoordinated solvent CH_2ClCH_2Cl molecule per unit cell. Final $R = 0.07$ for 6591 observed reflections.

The reactions of oxygen atom transfer in the presence of transition metal compounds have received considerable attention due to their relevance in enzymatic processes.[1-2] Among these reactions, the oxidation of triphenylphosphine to triphenylphosphine oxide has been the subject of numerous investigations.[3-12] Several oxygen atom transfer reactions with mononuclear ruthenium complexes have been reported; thus, complexes such as $Ru(EDTA)(H_2O)$,[10] $[Ru(O)(bpy)_2(py)]^{2+}$,[11] $Ru(SCN)(NO)(PPh_3)_2$[12] and others have been used in the catalytic and non-catalytic oxygen transfer to triphenylphosphine. However, similar oxidation reactions of PPh_3 in the presence of carboxylate dimers of ruthenium are unknown. We have recently shown[13] that the oxidation of triphenylphosphine to triphenylphosphine oxide in the presence of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ and $NOPF_6$ is preferred to the oxidation of the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ unit.

In this paper we describe the synthesis and characterization of some new complexes of the type $\{Ru_2(\mu\text{-}O_2CCH_3)_4[OP(p\text{-}RC_6H_4)_3]_2\}PF_6$ obtained from $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$, $NOPF_6$ and $P(p\text{-}RC_6H_4)_3$ [R = H (**I**), F (**II**), CH_3O (**III**), Cl (**IV**)], with simultaneous oxidation of triarylphosphine to triarylphosphine oxide. The X-ray crystal structure of $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]PF_6 \cdot CH_2ClCH_2Cl$ has been determined.

RESULTS AND DISCUSSION

The reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with $NOPF_6$ and $P(p\text{-}RC_6H_4)_3$ [R = H (**I**), F (**II**), CH_3O

* Author to whom correspondence should be addressed.

(**III**), Cl (**IV**)] in methanol at room temperature leads to formation of the $\{Ru_2(\mu\text{-}O_2CCH_3)_4[OP(p\text{-}RC_6H_4)_3]_2\}PF_6$ compounds. These reactions carried out in refluxing methanol give the same products in shorter periods of time.

In all cases the oxidation of triarylphosphine to triarylphosphine oxide is observed. We do not know the mechanism of these reactions, but we can affirm that the metal centre plays an important role because the oxidation of the triarylphosphine by $NOPF_6$ does not occur in the absence of the $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ compound.

The complexes have been obtained as brown–yellow solids, stable to air and soluble in the most common polar organic solvents. The stability of these compounds in solution (i.e. CH_2Cl_2, THF, etc.) varies in the order **I** > **II** > **III** ≫ **IV**; thus, the solutions of **I** are stable almost indefinitely, whereas the solutions of **IV** decompose over short periods of time. Compounds **I** and **II** can be recrystallized from dichloromethane–petroleum ether (40–60°C) or 1,2-dichloroethane–petroleum ether (40–60°C). Crystals of **I** suitable for X-ray structural determination were obtained from 1,2-dichloroethane–petroleum ether (40–60°C) as $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]PF_6 \cdot CH_2ClCH_2Cl$. Compound **III** does not crystallize from several mixtures of solvents (dichloromethane–petroleum ether (40–60°C), tetrahydrofuran–petroleum ether (40–60°C), etc.). Compound **IV** can not be crystallized from several solvents (dichloromethane, tetrahydrofuran, diethylether, etc.) because it decomposes in solution.

The elemental analyses of these compounds are in accordance with the proposed stoichiometries (see Table 1).

Table 1. Physical properties of compounds **I**–**IV**

Compound	Analysis (%) Found (Calc.)	Magnetic moment (BM)	Conductivity (Ω^{-1} cm^2 mol^{-1})
I[a]	C, 45.3 (44.6) H, 3.7 (3.7)	4.03	125.7
II[b]	C, 40.6 (40.6) H, 2.7 (2.9)	4.68	143.3
III	C, 46.5 (45.5) H, 3.8 (4.1)	3.36	110.9
IV	C, 40.7 (39.3) H, 2.9 (2.7)	3.14	131.5

[a] Physical data for the compound with one molecule of 1,2-dichloroethane.

[b] Physical data for the compound with one molecule of dichloromethane.

Conductivity measurements show, in all cases, the presence of a 1 : 1 electrolyte in acetone solution (10^{-3} M)[14] (see Table 1).

Spectroscopic studies

The IR spectra of these complexes show the absorptions due to bridging carboxylate groups as strong bands between 1400 and 1450 cm^{-1}, similar to those observed in the starting $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ compound; the ν_{st}(P—F) signal corresponding to the PF_6^- group appears as a broad, strong absorption at 840 cm^{-1}. In addition to the $P(p\text{-}RC_6H_4)_3$ bands, an absorption at about 1140 cm^{-1}, assigned to the ν_{st}(P═O) vibration, is observed.

The electronic spectra (range 300–800 nm) of the complexes in dichloromethane solution show, in all cases, a single absorption band in the region λ_{max} = 432–437 nm; ε_{max} = 659–1240 dm^3 mol^{-1} cm^{-1}. This band has been assigned to an $O(\pi) \rightarrow Ru\text{—}Ru(\pi^*)$ transition, in agreement with Norman *et al.*[15]

The IR and electronic spectra data are summarized in Table 2.

Magnetic studies

Magnetic measurements were carried out from room temperature to 70 K. The variation of the magnetic susceptibilities with temperature obeys the Curie–Weiss law (see Table 3). Magnetic moments for the complexes are in the range μ_{eff} = 3.14–4.68 BM per dimer (see Table 1). The values are consistent with species containing three unpaired electrons per dimer, in accordance[15] with the ground electronic configuration of $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$.

Crystal structure of $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]PF_6 \cdot CH_2ClCH_2Cl$

Selected bond distances and angles are presented in Table 4. Figure 1 shows the ORTEP view of the complex with the atomic labelling used. The structure consists of discrete $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]^+$ cations and PF_6^- anions; one molecule of CH_2ClCH_2Cl solvent per dimer is also present and does not interact with the complex. The phosphorus atom [P(2)] of the PF_6^- anion is situated at an inversion centre. The asymmetric unit consists of only one half of the dimeric centrosymmetric unit.

The X-ray structure of the compound confirms the existence of the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ unit with two $OPPh_3$ ligands occupying the axial positions.

Table 2. IR and UV–vis data of compounds I–IV

Compound	IR data (cm^{-1})				UV–vis data	
	ν_a(COO)	ν_s(COO)	ν_{st}(P=O)	ν(P—F)	λ (nm)	ε ($dm^3\ mol^{-1}\ cm^{-1}$)
I	1445 vs	1400 s	1140 s	840 vs	435	1240
II	1440 vs	1400 s	1150 s	840 vs	435	1171
III	1450 vs	1400 s	1140 s	840 vs	432	838
IV	1450 vs	1400 s	1130 s	840 vs	437	659

s—strong.
vs—very strong.

The coordination polyhedra of the two metal atoms are distorted with respect to the regular octahedral arrangement. Each ruthenium atom is coordinated by four oxygen atoms of the bridged acetate groups, by one oxygen corresponding to the triphenylphosphine oxide and by the other ruthenium atom of the dimer unit.

The bond distances and angles in the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ unit are similar to those observed in related compounds.[16–19] The Ru—Ru distance for compound I is slightly longer (*ca* 0.019 Å) than that for its closest Ru_2^{5+} core analogue, $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]BF_4$.[16] On the other hand, there are no important differences between the Ru—Ru distances in compound I (2.267 Å) and other compounds with the Ru_2^{5+} core, *viz.* $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (2.281 Å),[16] $Ru_2Cl(\mu\text{-}O_2CCH_3)_4 \cdot 2H_2O$ (2.267 Å),[17] the Ru_2^{4+} core, *viz.* $Ru_2(\mu\text{-}O_2CCH_3)_4(THF)_2$ (2.260 Å)[18] or the Ru_2^{6+} core, *viz.* $Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2 \cdot 0.7H_2O$ (2.265 Å),[19] although

this compound has been reformulated by Cotton *et al.*[20] as $Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2H \cdot 0.7H_2O$ containing the Ru_2^{5+} unit.

EXPERIMENTAL

All reactions were carried out in an inert atmosphere, using standard Schlenk techniques. $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ was prepared by a literature procedure.[21] $RuCl_3 \cdot 3H_2O$, $NOPF_6$, PPh_3 and $P(p\text{-}RC_6H_4)_3$ (R = F, CH_3O, Cl) were obtained from Engelhard, Alfa, Probus and Maybridge, respectively. Solvents were purified and distilled by standard methods. Methanol was used without previous purification.

Elemental microanalysis for carbon and hydrogen were performed with a Perkin–Elmer 240 B microanalyser. IR spectra in the region 4000–200 cm^{-1} were recorded as KBr disks on a Perkin–Elmer 1330 IR spectrophotometer. Electronic spectra in the region 300–800 nm were registered on a Pye Unicam SP8-200 UV–vis spectrophotometer. Magnetic measurements were made with a magnetometer DSM 5 in the range 70–290 K. Molar

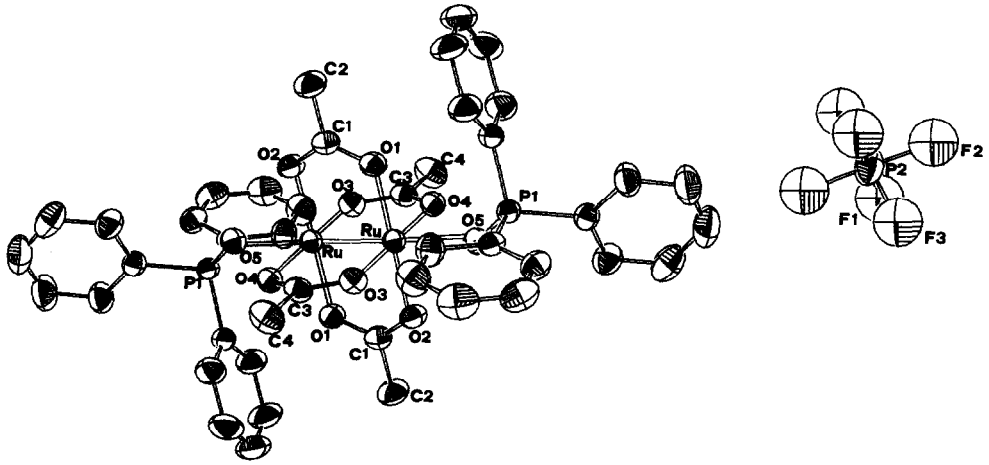

Fig. 1. ORTEP drawing of $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]PF_6 \cdot CH_2ClCH_2Cl$.

conductivities were measured with a Philips PW 9526 digital conductivity meter, using a Philips PW 9512/60 conductivity measuring cell.

Synthesis of $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]PF_6$ **(I)**

This compound was prepared by reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$, $NOPF_6$ and PPh_3 in methanol, as previously described.[13] When the reaction was carried out in refluxing methanol, the process was completed in 1 h.

The complex was crystallized from 1,2-dichloroethane–petroleum ether (40–60°C) to give red crystals of $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]PF_6 \cdot CH_2ClCH_2Cl$.

Synthesis of $\{Ru_2(\mu\text{-}O_2CCH_3)_4[OP(p\text{-}FC_6H_4)_3]_2\}PF_6$ **(II)**

To $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (0.20 g, 0.42 mmol) in methanol (40 cm^3) was added an excess of $NOPF_6$ (0.22 g, 1.27 mmol) and $P(p\text{-}FC_6H_4)_3$ (0.67 g, 2.11 mmol). The reaction mixture was stirred at room temperature for 6 h (or under reflux for 3 h). The solvent was pumped to dryness giving an oil, which was treated with cold petroleum ether (40–60°C) to obtain a brown–yellow solid. The solid was washed with diethylether–petroleum ether (40–60°C) (1 : 1).

The solid product was crystallized from dichloromethane–petroleum ether (40–60°C) to give red–brown crystals of $\{Ru_2(\mu\text{-}O_2CCH_3)_4[OP(p\text{-}FC_6H_4)_3]_2\} \cdot CH_2Cl_2$. Yield 0.28 g, 54%.

Synthesis of $\{Ru_2(\mu\text{-}O_2CCH_3)_4[OP(p\text{-}CH_3OC_6H_4)_3]_2\}PF_6$ **(III)**

To $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (0.20 g, 0.42 mmol) in methanol (40 cm^3) was added an excess of $NOPF_6$ (0.22 g, 1.27 mmol) and $P(p\text{-}CH_3OC_6H_4)_3$ (0.75 g, 2.11 mmol). The reaction mixture was stirred at room temperature for 6 h (or under reflux for 3 h). The solvent was pumped to dryness giving a golden, spumy solid. This solid did not crystallize from several mixtures of solvents, such as dichloromethane–petroleum ether (40–60°C), THF–petroleum ether (40–60°C), etc. For this reason the solid was purified by precipitation with petroleum ether (40–60°C) from a solution of dichloromethane. Yield 0.34 g, 61%.

Synthesis of $\{Ru_2(\mu\text{-}O_2CCH_3)_4[OP(p\text{-}ClC_6H_4)_3]_2\}PF_6$ **(IV)**

To $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (0.20 g, 0.42 mmol) in methanol (40 cm^3) was added an excess of $NOPF_6$ (0.22 g, 1.27 mmol) and $P(p\text{-}ClC_6H_4)_3$ (0.77 g, 2.11 mmol). The reaction mixture was stirred at room temperature for 6 h (or under reflux for 3 h). The solution was pumped to dryness giving an oil, which was treated with cold petroleum ether (40–60°C) to give a brown–yellow solid. The compound could not be crystallized from several mixtures of solvents, because it decomposes over short periods of time. For this reason the product was purified by precipitation with petroleum ether (40–60°C) from a solution of dichloromethane. Yield 0.28 g, 49%.

X-ray crystallographic procedures

A prismatic crystal was mounted on an Enraf–Nonius CAD4-F automatic diffractometer. The cell dimensions were refined by least-squares fitting of the setting angles of 25 reflections. The intensities of all 7745 reflections with $1 < \theta < 30$ and the range from $(-11, -17, 0)$ to (11, 17, 18) were measured at 295 K with monochromatic Mo-K_α radiation ($\lambda = 0.71069$ Å) and an ω–2θ scan technique.

Three reflections monitored periodically during data collection revealed no crystal decomposition. The intensities were corrected for Lorentz and for polarization effects; 6591 reflections were considered as observed with $I > 2\sigma(I)$. Scattering factors for neutral atoms and anomalous dispersion corrections for ruthenium, fluorine and chlorine were taken from the *International Tables for X-Ray Crystallography*.[22] The structure was solved by Patterson and Fourier methods. An empirical absorption correction[23] was applied at the end of the isotropic refinement. Some positional disorder was found around the CH_2ClCH_2Cl molecule of crystallization and the PF_6^- anion, and because of this, the atoms involved in these groups, F, Cl and C(23) have been refined only isotropically. Mixed full-matrix least-squares refinement with unit weights minimizing $[F_o - F_c]$ gave $R = 0.072$. Final refinement with fixed isotropic temperature factors and coodinates for hydrogen atoms gave $R = 0.07$. Most of the calculations were carried out with XRAY80.[24] Crystallographic data and other basic information pertaining to the data collection are summarized in Table 5.

Complete tables of distances and angles as well as atomic positional and anisotropic thermal parameters and structure factors have been deposited as supplementary material.

Acknowledgements—We are grateful to the Comision Asesora de Investigacion Cientifica y Tecnica (CAICYT) (Spain) for financial support (project PR84-0367). Thanks are due to Dr Saez and colleagues for their help in obtaining the magnetic measurements.

FORMATION OF SILICO–ANTIMONIC CORE-SHELL PARTICLES WITH AN ANTIMONIC ACID CORE ENCAPSULATED WITH SILICA

M. KONE, P. COURTIN and J. LEMERLE*

Laboratoire de Chimie des Polymères Inorganiques, Université Pierre et Marie Curie, 4 Place Jussieu, 75252 Paris Cedex 05, France

(*Received* 7 *March* 1989; *accepted* 12 *June* 1989)

Abstract—Core-shell particles were formed from aqueous solutions of antimonic and silicic acids. Three methods were developed for preparing the particles: (i) mixing freshly prepared antimonic and silicic acids (A); (ii) mixing potassium salts of antimonic and silicic acids followed by protonation by ion exchange (B); (iii) hydrolysis of a tetraethoxysilane solution in ethanol by an aqueous antimonic acid solution (C). Methods (A) and (B) led to three-dimensional core-shell particles with the β-antimonic acid structure. Three-dimensional core-shell particles were formed only through route (C) when alkoxysilane was in excess. Without an excess of alkoxysilane, fibrous silicic particles including antimony were obtained. The nature and size of the particles are closely dependent upon the reaction rates (polymerization, mixed compound formation).

Particles of inorganic oxides of colloidal size can be prepared by spontaneous polymerization of an inorganic acid in aqueous solution. In previous works[1,2] inorganic polymers containing antimony have been prepared by ion exchange. The β-antimonic acid forms particles with a cubic close-packing structure (c.c.p.). Polymerization of antimonic acid in the presence of other inorganic acids leads to mixed polymers. Hexacoordinated anions can substitute the SbO_6 groups to form particles with a c.c.p. structure.[3,4] With tetracoordinated anions, the substitution prevents the extension of the structure to give amorphous particles.[5,6] Silica gels have been prepared by various routes such as protonation of a silicate,[7] or the hydrolysis of an alkoxysilane.[8] Silica gels including a heteroelement have been obtained by hydrolysis of a mixture of an alkoxysilane with another alkoxide or ethoxide.[9] In this work we describe the formation of particles including both antimony and silicon. Different routes of synthesis are used to show the importance of the polymerization rate on the formation of the compounds.

EXPERIMENTAL

Preparation of the sols

Preparation (A). The antimonic acid was prepared by ion exchange in a resin (DOWEX 50 WX2 100–200 mesh) from potassium hexahydroxoantimonate solutions (Merck).[1] The silicic acid was prepared according to Alexander's method:[10] solid sodium metasilicate (Na_2SiO_3, 5 H_2O) was slowly added to an excess of resin (DOWEX 50 WX8 100–200 mesh, H^+ form), dispersed in water. During the addition the mixture was vigorously stirred and kept at 0°C. After filtration, the proportion of oligomers in silicic acid (17%), determined according to the Coudurier's method,[11] showed the main silicic species to be monomeric. The antimonic and silicic acids were mixed in various ratios ($0.059 \leqslant Si/Sb \leqslant 3.53$) just after preparation. In the mixtures, the antimony concentration is constant (3.9×10^{-2} mol dm^{-3}).

Preparation (B). Potassium hexahydroxoantimonate and potassium silicate solutions were mixed in various ratios ($0.06 \leqslant Si/Sb \leqslant 3.06$). Potassium salts prevented sodium antimonate precipitation; the antimony concentration was

constant (8.5×10^{-2} mol dm^{-3}). The potassium silicate solutions were prepared by ion exchange on a resin (DOWEX 50 WX2 50–100 mesh, K^+ form) and then the mixture was protonated on another resin (DOWEX 50 WX2 50–100 mesh, H^+ form). The resin was poured into a column with a cooled jacket to maintain a constant temperature (5°C). During the acidification the antimony concentration decreased slightly.

Preparation (C). A solution of tetraethoxysilane in ethanol was slowly added under stirring to a freshly prepared aqueous antimonic acid solution (α-antimonic acid)[1] ($0.067 \leqslant Si/Sb \leqslant 4.01$). The antimony concentration was constant (3.68×10^{-2} mol dm^{-3}). Under these conditions the silane is hydrolysed in the presence of antimonic acid.

Physicochemical measurements

For all the samples the concentrations of the antimony and silicon were measured by atomic absorption, with an air–acetylene flame for antimony, and a nitrous–acetylene flame for silicon.

Ultracentrifuge measurements were carried out with a Beckman model E ultracentrifuge equipped with schlieren optics. The solvents were water [samples (C)] or LiCl solutions, 5×10^{-2} mol dm^{-3} [samples (A) and (B)]. The electrolytes were slowly added just before the runs. Preparative centrifugations were monitored in the same ultracentrifuge equipped with a swinging bucket rotor SW65E.

Density measurements were carried out with a DMA_2 PAAR automatic densimeter.

The particles which packed down to the bottom of the centrifugation tube were studied by electron microscopy, X-ray and NMR spectroscopies. Electron microscopy was carried out with a Jeol 100 CXII microscope at a magnification of 63,000. Samples were prepared by deposition of the dilute sol containing the particles on a grid. Analytical electronic microscopy was carried out with Link equipment. Powder patterns were obtained by diffractometry with a CGR Theta 60 diffractometer using Cu-K_α radiation. Analytical grade NaCl was added to the powders as an internal standard in order to obtain accurate d-spacing.[12]

^{29}Si NMR spectra of the solids were obtained at room temperature with a MSL 400 Bruker spectrometer, using the MAS technique.

RESULTS

Study of the sols

All the aged samples (3 months) scatter light, the (C) samples gelled. In analytical ultracentrifuge experiments free sedimenting species were observed. The sedimentation coefficients corresponding to samples (A), (B) and (C) are reported in the Tables 1, 2 and 3, respectively. Only one sedimentation peak is observed for $Si/Sb \leqslant 1$, while two peaks are present for higher Si/Sb ratios. The particles having the higher sedimentation coefficient are labelled "high polymers".

By assuming that the particles are rigid and spherical, the friction coefficient can be evaluated from Stokes' law. Under these conditions the particle size can be obtained from the sedimentation velocity, S.[13]

$$D = 2\sqrt{\frac{9S\eta}{2(\rho - \rho_0)}}$$

D is the diameter of the particle, η is the solvent viscosity, ρ is the particle density and ρ_0 is the solvent density; ρ and ρ_0 were obtained from density measurements.

The particle size values are reported in Tables 1 and 2.

For each sample the cumulative distribution curves of the sedimentation coefficients of the "high polymers" are shown in Fig. 1. Within each group of samples the polydispersity of the high polymers increases with the initial Si/Sb ratio. The high polymeric species can be easily obtained by preparative ultracentrifugation of the aged sols. The samples prepared by routes (A) and (B) were centrifuged at 20,000 r.p.m. over 30 min, while (C) samples were centrifuged at 30,000 r.p.m. over 1 h. Antimony and silicon present in the supernatant solutions were titrated. The high polymers which packed down to the bottom of the centrifugation tube were separated from the supernatant solution and their silicon and antimony content determined. The results are reported in the Tables 1, 2 and 3.

The supernatant solutions and high polymers contain both silicon and antimony with a higher proportion of antimony in the high polymer fractions (samples (B) gave high polymers with higher silicon content). No EtO groups were found in the high polymers [sample (C)] (Ir spectra, carbon microanalysis).

Study of the high polymers

The composition of the high polymers [samples (A) and (B)] is homogeneous, as shown by analytical electron microscopy. Thus the particles differ only in their size.

Electronic micrographs (TEM) of high polymers show that the shape of the particles is dependent on the route of preparation. The particles of samples (A) are spherical (Fig. 2), the particles of the samples (B) are hexagonal, square or diamond shaped (Fig. 3). These shapes can be considered as the projections of an octahedron onto a plane. These assumptions are confirmed by the STEM micrographs.

For particles of the (C) samples the shape depends on the initial Si/Sb ratio. For Si/Sb $\leqslant 3$ (silicon content of the high polymer <0.1), the electron micrographs appear to be blurred. When the silicon content increases, a fibrous structure is observed, similar to silicic acid xerogels.[14] In addition to this fibrous structure some large octahedral particles are observed for an initial Si/Sb ratio >3 (Fig. 4).

All of the (A) and (B) samples are approximately homogeneous in size. The size distribution curves corresponding to sample (A) is shown in the Fig. 5. The diameter of the particles decreases when the silicon content of the high polymers increases and

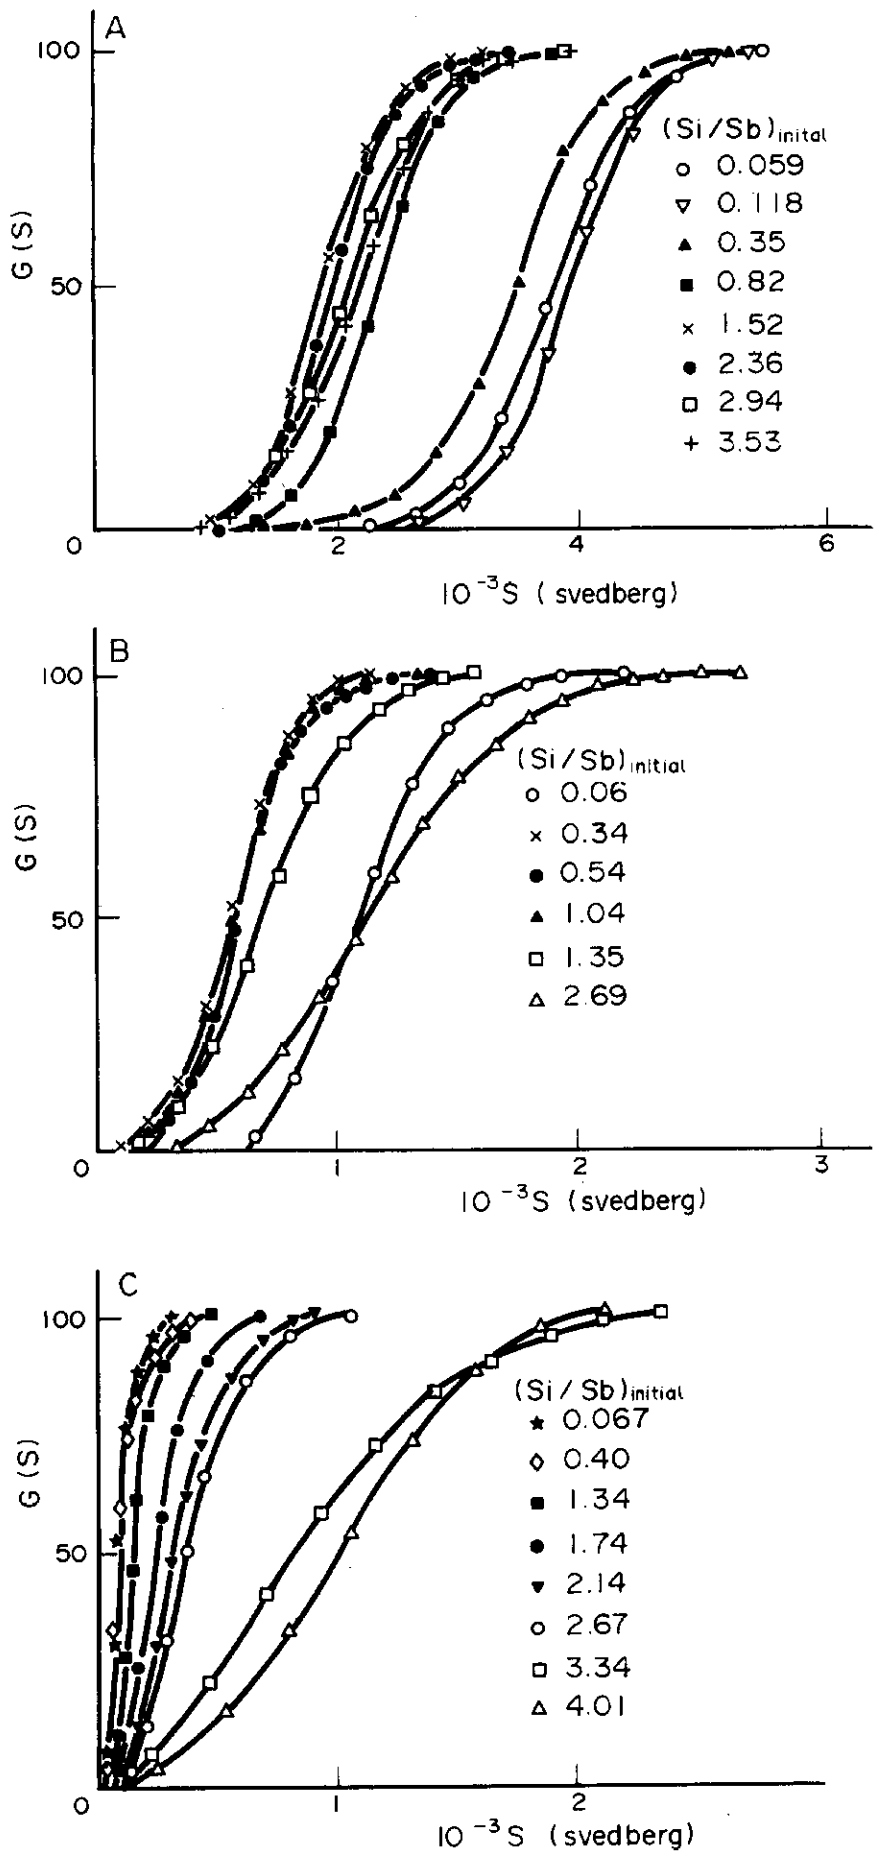

Fig. 1. Cumulative distribution curves of sedimentation coefficients of high polymers.

the size polydispersity slightly increases (Table 1). For (B) particles the size is characterized by their octahedron edges. The mean size of these particles (about 200 Å) is nearly independent of the silicon content. The size of the sample (C) particles can only be measured for the large octahedral particles for an initial Si/Sb ratio >3. The high polydispersity observed is within the 780–1960 Å range.

Powder diffraction patterns of samples (A) and (B) agree with a cubic close-packing structure (pyrochlore type, $a = 10.40$ Å) like that in the β-antimonic acid.[1] The unit cell is independent of the silicon content. The peak width gives the mean size of the crystals, with the mean values close to the electronic microscopy results.

NMR spectra are shown in the Fig. 6. For the (B) samples the peak corresponding to a chemical shift of about -112 ppm is present only when the silicon content of the high polymers is greater than 0.3. For (C) samples this peak is extremely broad and is absent in the (A) samples.

DISCUSSION

The particle sizes, measured by ultracentrifugation, electron microscopy and diffractometry, are in good agreement. Ultracentrifugation gives the hydrodynamic diameter, and electron microscopy and X-ray determine the diameter in the solid state. As these two values are close, we conclude that no noticeable particle association occurs in the aqueous solutions.

During ageing, antimonic acid solutions spontaneously transform into insoluble β-antimonic acid,[1] while silic acid solutions gel. Since the samples do not precipitate, the antimonic acid must combine with silicic acid leading to a stabilized sol. In previous work,[3] soluble compounds prepared with antimonic acid have been described. In the c.c.p. structure of the antimonic acid, antimony atoms can be substituted by octahedral atoms[3,4] and the c.c.p. structure is maintained without any dislocations. If the substitution is made by tetrahedral atoms[5,6] the c.c.p. structure is broken and no long distance order is observed in the solid materials. Even with a high silicon content, all the particles of the high polymers prepared by routes (A) and (B) have the same composition for a given initial Si/Sb ratio. The c.c.p. structure of the antimonic acid and the unit cell dimensions are conserved. Antimony atoms are substituted by tetrahedral silicon atoms. Silicons are probably located at the surface of the particles leading to core-shell particles with a narrow and/or amorphous silica shell. Thus, no additional X-ray diffraction patterns are observed.

From these assumptions the thickness Δr of the silica shell can be estimated. The core is supposed to be β-antimonic acid: $HSbO_3,1H_2O$ (molecular weight M_1, specific gravity ρ_1) and the shell silica SiO_2 (molecular weight M_2, specific gravity ρ_2). The Si/Sb ratio in the particle is x. For one mole of antimony the total volume, V, of the particle is

$$V = \frac{M_1}{\rho_1} + \frac{M_2 x}{\rho_2}.$$

The total volume of the particle is related to the

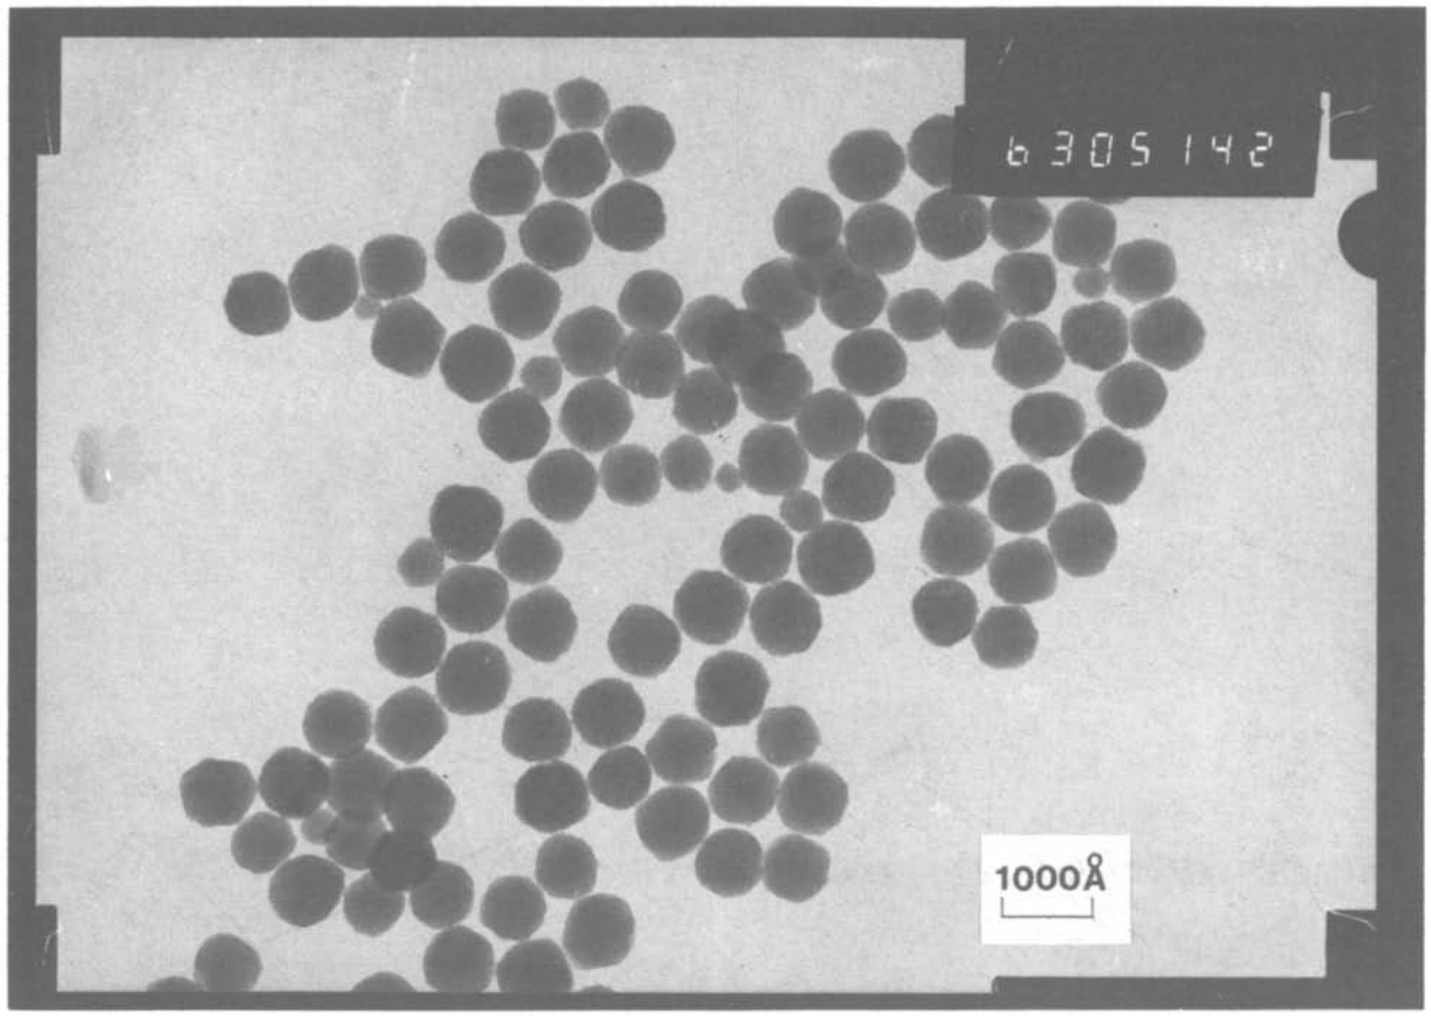

Fig. 2. Electron micrograph (TEM) of high polymers : samples (A).

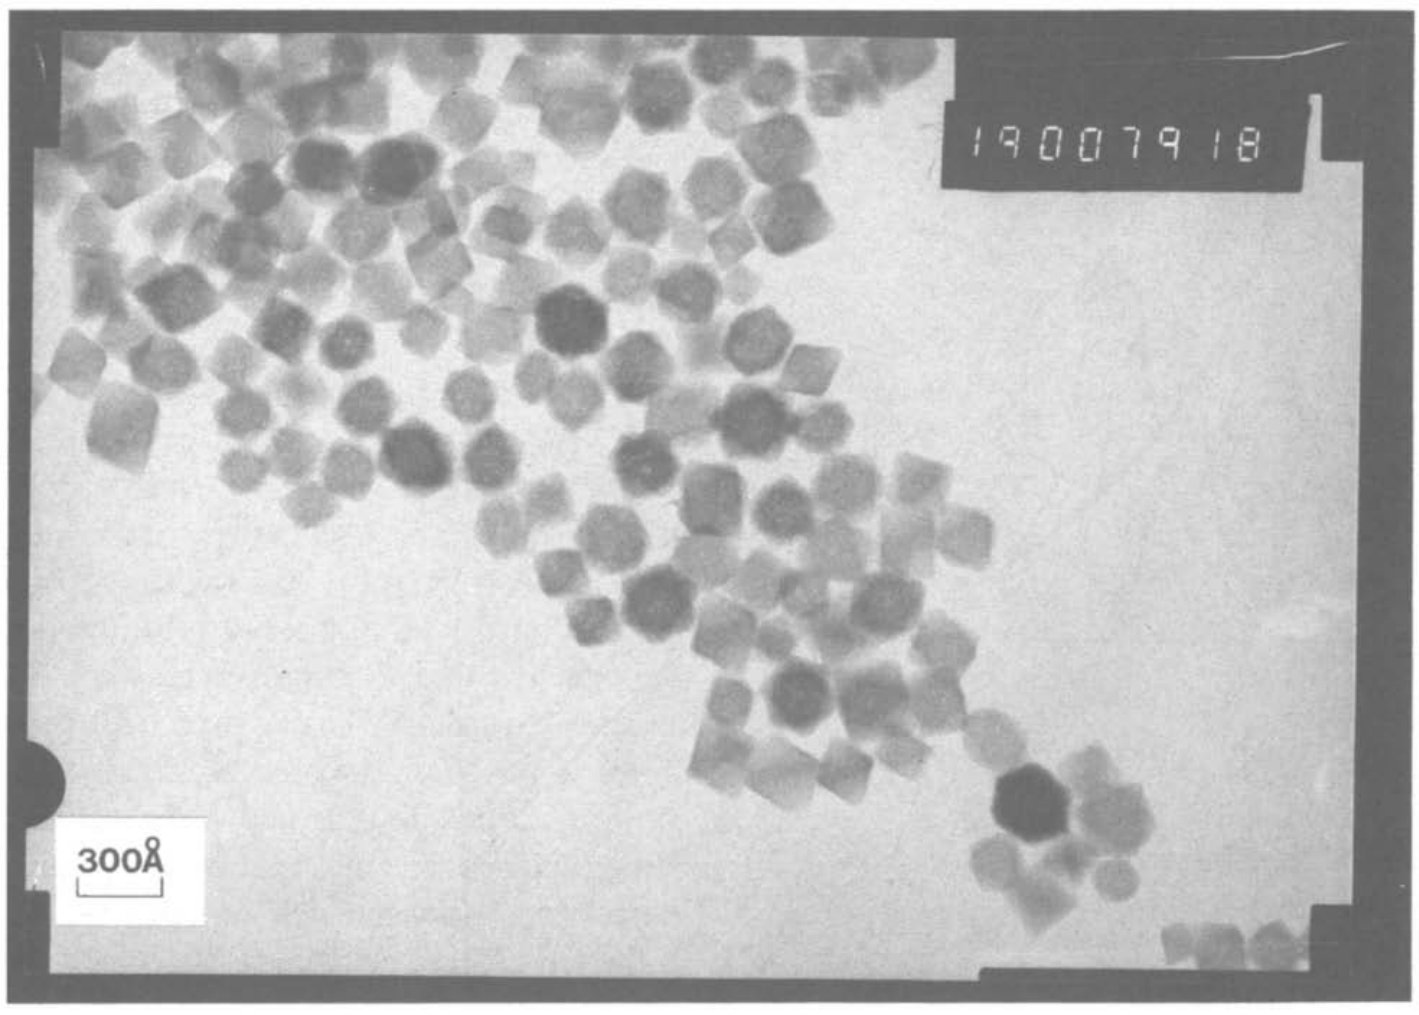

Fig. 3. Electron micrograph (TEM) of high polymers : samples (B).

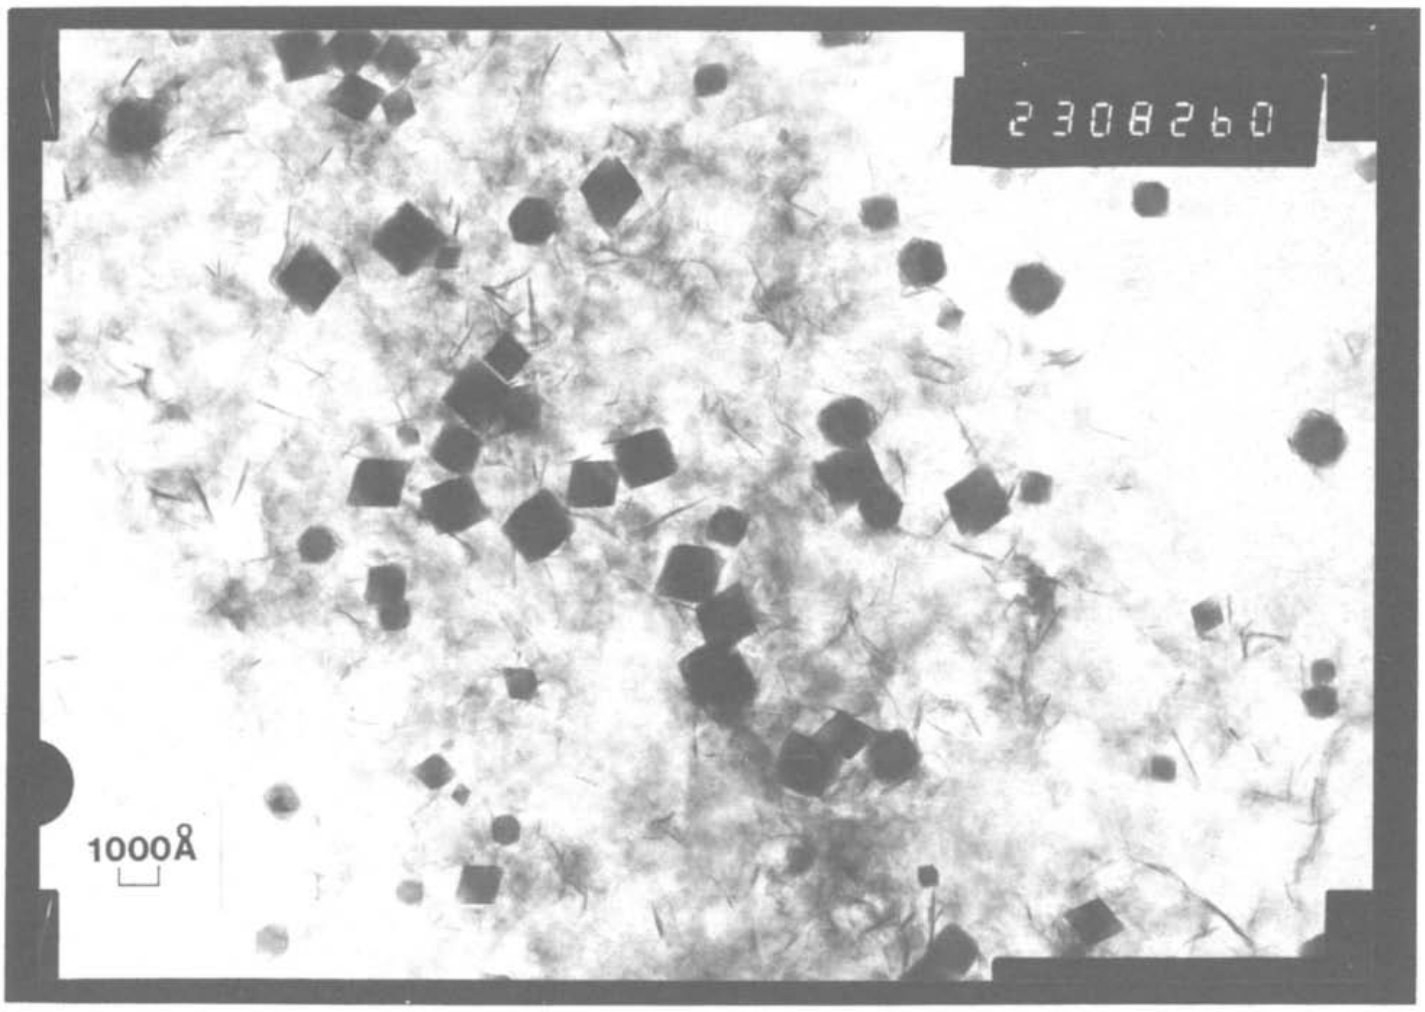

Fig. 4. Electron micrograph (TEM) of high polymers: samples (C).

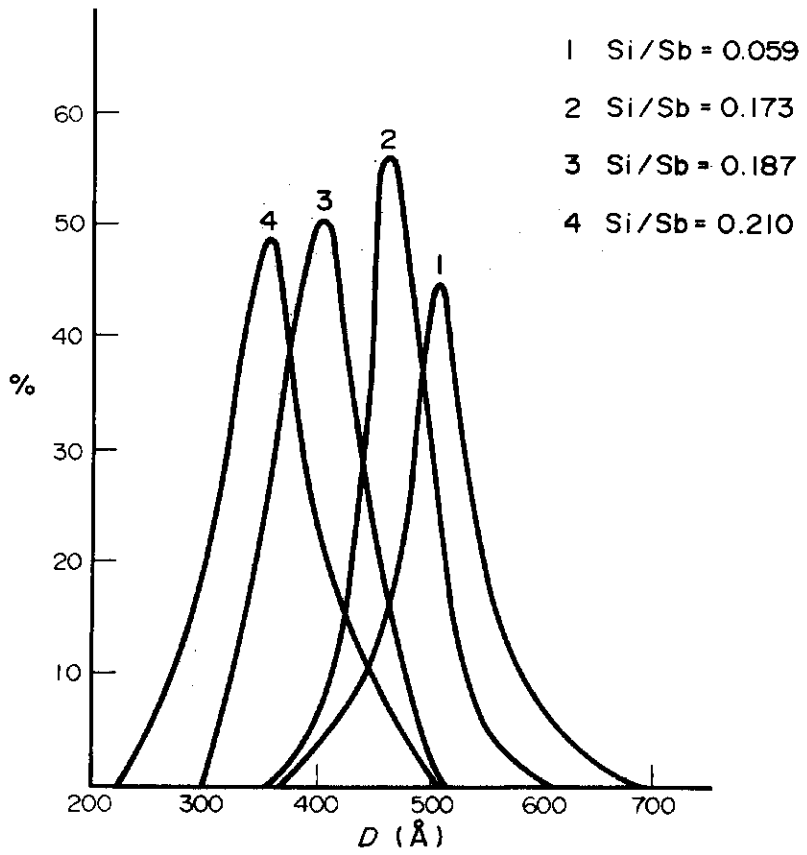

Fig. 5. Size distribution curves: samples (A).

core volume, V_1 by the expression:

$$\frac{V}{V_1} = \frac{M_1\rho_2 + M_2 x \rho_1}{M_1\rho_2} = \frac{D^3}{D_1^3},$$

where D and D_1 are, respectively, the outer and inner diameters of the particle.

If ρ_1, ρ_2 and D are known, D_1 can be obtained, and the shell thickness, $\Delta r = (D - D_1)/2$, calculated.

The diameter measured by ultracentrifugation can be considered as the outer diameter. The experimental value of ρ_1 is 4.49 g cm^{-3} (specific gravity of pure antimonic acid). The approximate value of the specific gravity of the shell is 2.2 g cm^{-3}, close to the given values for silica gels obtained through an ion exchange process.[7]* The Δr values are reported in Tables 1 and 2. Even with a high silicon content the particles have a very thin shell which cannot be seen in the X-ray diffraction experiments.

NMR spectra agree with these assumptions. Lippmaa and co-workers[15] have applied this technique to crystalline silicates and found that the ^{29}Si NMR spectra exhibit peaks whose position depends on the nature of the silicate anion. In particular, the spectra can distinguish between isolated SiO_4 tetrahedra and SiO_4 tetrahedra linked by sharing common corners (oxygen atoms) to one, two, three or four adjacent tetrahedra. In order to facilitate the discussion, it is customary to assign to each silicon a Q value which represents the number of adjacent SiO_4 tetrahedra to which it is directly bonded. Q values range from 0 (in *ortho*-silicates) to 4 in a three-dimensional framework structure (SiO_2). The position of the ^{29}Si NMR peaks, i.e. the chemical shifts relative to the internal standard (TMS) depend approximately on the Q value. Moreover, the chemical shift depends on the nature and the number of adjacent atoms bonded to the

* If the specific gravity of the shell is taken in the range 2–2.4 g cm^{-3}, the shell thickness value is kept approximately constant.

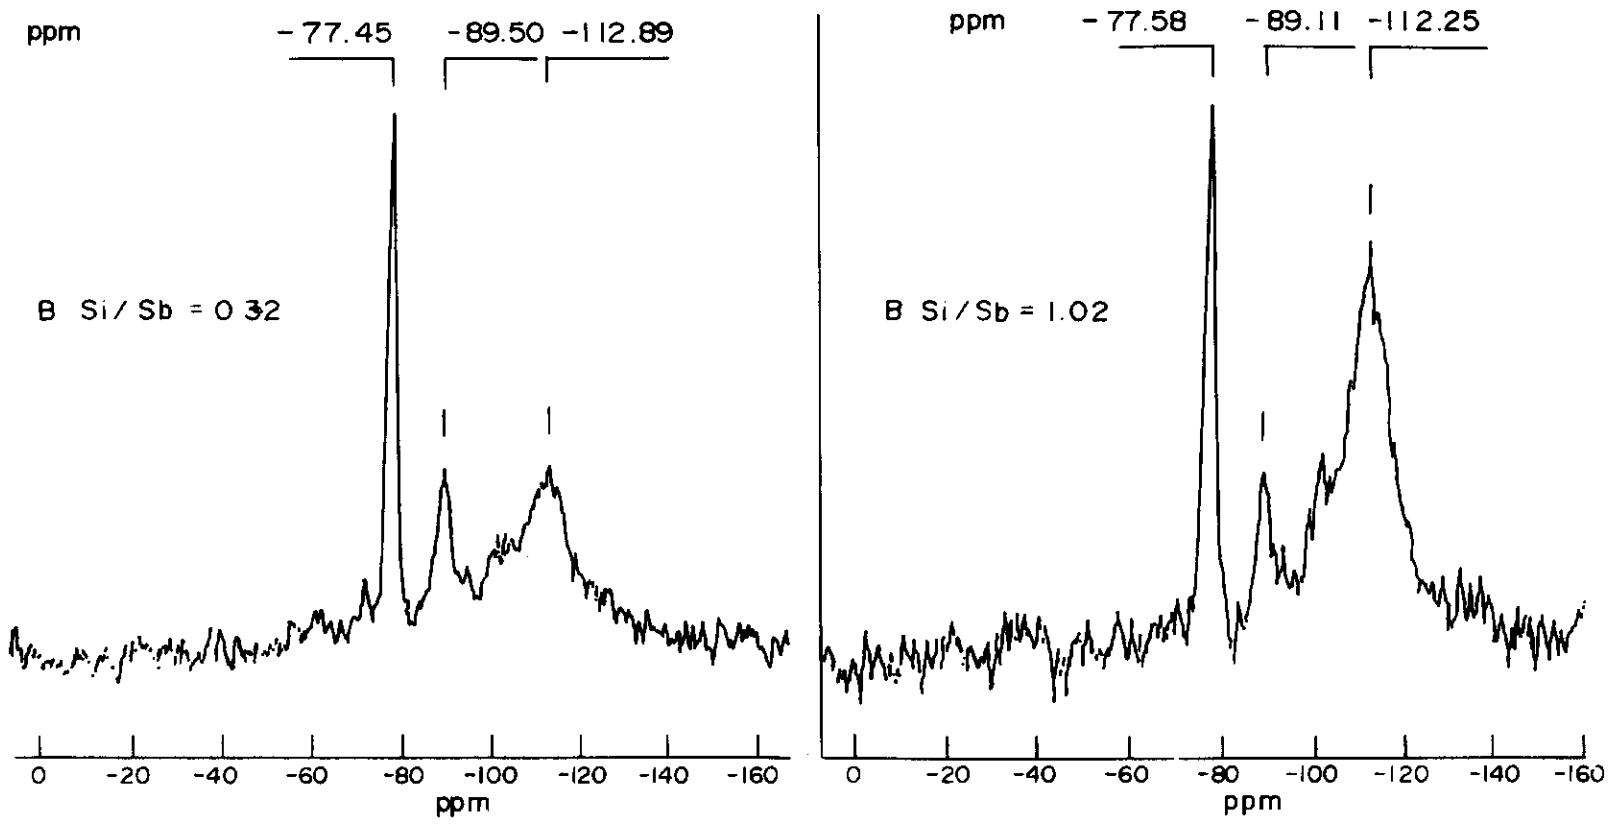

Fig. 6. ^{29}Si NMR spectra of the solid high polymer.

SiO_4 tetrahedra if they are not silicon atoms.[16] The changes in electronic density surrounding one silicon atom influence the chemical shift value corresponding to a given configuration. The chemical shift is decreased if the electronic density near the silicon atom is increased, as it is for the related alumino silicates structures.[17]

Samples (A) and (B) have a small calculated thickness ($\Delta r < 9$ Å), the NMR spectra exhibit two peaks corresponding to chemical shift values near to -78 and -89 ppm which agree with slightly bonded Q^1 and Q^2 silicon. Nevertheless this Q^2 chemical shift is slightly modified[15] and the peak is broadened. This can be attributed to silicon atoms which are two-fold bonded. Among silica atoms one can be bonded to an antimony atom.

Δr increases ($\Delta r > 9$ Å) with the silicon content of the sample (B) polymers. Three-dimensional frameworks are obtained which are characterized by a Q^4 peak. A third peak corresponding to a chemical shift of about -112 ppm is observed as expected for the Q^4 configuration.

For the (C) samples, only one broad peak, located at about -112 ppm corresponding to a Q^4 configuration, is observed. The fibrous structure revealed by the electron microscopy corresponds to thick silica fibres including antimony atoms statistically distributed. The Q^4 peak is broadened.

All the sols contain two types of particles (large and small polymers) irrespective of the preparation. On the other hand, the size, the polydispersity and the composition of the high polymer are governed by the method of preparation. Equilibria can be displaced and/or polymerization rates modified, to favour the formation of one type of particle. In (A), the protonation is carried out before the mixing. The sol contains two compounds, with different silicon contents and different molecular weights. In (B), the protonation is carried out after the mixing. The sol contains two compounds of different molecular weight but with approximately the same silicon content for an initial ratio of $Si/Sb \leqslant 1$ or a different silicon content for $Si/Sb > 1$. In (C), the protonation of antimony is carried out before the mixing and the protonation of silicon after. The sol contains two (or more) compounds of different molecular weight and different silicon content.

In previous works,[2,3] the formation process of such high polymers was described. When inorganic acids which spontaneously polymerize are mixed, the first step of the chemical reaction is the depolymerization of the reactants, α-antimonic acid and oligomers of silicic acid. The second step is the formation of an oxo bridge by elimination of water between two monomers. These oxo bridges can be formed between two antimonic octahedra, two silicic tetrahedra, or one antimonic octahedron and one silicic tetrahedron. Assuming that the structure consists of the same type of atoms, the formation of an oxo bridge between an atom of this structure and a heteroatom of different symmetry prevent the extention of the network. Nevertheless, a few heteroatoms can be bonded together through oxo bridges. If the first structure has the critical size, core-shell particles are formed.

The silicic acid reacts slowly with respect to the α-antimonic acid polymerization rate.[1,3,7,11] For the (A) samples, monomer units of antimony react with monomers or oligomers of silicic acid before they are depolymerized. The free antimony atoms (monomer units or α-acid) polymerize to reach the critical size which then catalyses their own formation.[1] Addition of an excess of silicon rapidly limits the polymerization of antimony to yield small core-shell particles. With lower silicon concentrations large core-shell particles are observed because the polymerization rate of antimony is less limited.

For the (B) samples, the protonation is carried out after the mixing, so no polymerized species are present in solution when antimony and silicon are mixed. Thus the growth of the antimony particles is stopped earlier than for the (A) samples: the particle size is approximately independent of the initial ratio Si/Sb. If silicon is in excess ($Si/Sb > 1$), it is preferentially fixed upon the small particles and the silicon content of the high polymers is lowered.

In the (C) samples, the hydrolysis of tetraethoxysilane leads to polydisperse polymeric silica compounds.[10,14] Under weak acidic conditions, the hydrolysis of $(EtO)_4Si$ leads to a low concentration of $(EtO)_3SiOH$. The excess of antimonic acid catalyses the hydrolysis of $(EtO)_4Si$. Thus the polymerization rate of silica is enhanced.[14] Antimony is then entirely included in the amorphous silica polymers, the β-antimonic structure is not formed. When the silicon concentration increases in the medium, the hydrolysis rate is decreased, lowering the silica polymerization rate. Particles of β-antimony structure can be formed.

For (A), (B) and (C), the main factor for preparing core-shell particles is that the polymerization rate of the silicon particles has to be lower than the antimony one.

CONCLUSION

Core-shell particles having a c.c.p. structure of β-antimonic acid can be formed through a polymerization process in aqueous medium. The silicon content and the size of these particles is only governed by the route of protonation of the reactants related to their mixing order.

Acknowledgements—NMR measurements were made by P. Tougne and F. Taulelle and electronic microscopies were carried out by P. Baunier and M. Lavergne. The authors express their thanks to all of them for experimental assistance and helpful discussions.

THE SYNTHESIS OF THE NOVEL MIXED HALIDE SEVEN-COORDINATE COMPLEX $[WBrI(CO)_3(NCMe)_2]$ AND ITS REACTIONS WITH ALKYNES

PAUL K. BAKER,* ADRIAN BURY and KEVIN R. FLOWER

Department of Chemistry, University College of North Wales, Bangor, Gwynedd LL57 2UW, Wales, U.K.

(*Received* 4 *April* 1989; *accepted* 12 *June* 1989)

Abstract—The tris-acetonitrile complex $[W(CO)_3(NCMe)_3]$ reacts *in situ* with an equimolar quantity of BrI at 0°C to afford a quantitative yield of the seven-coordinate complex $[WBrI(CO)_3(NCMe)_2]$. Reaction of $[WBrI(CO)_3(NCMe)_2]$ with one equivalent of RC_2R' (R = R′ = Ph or CH_2Cl; R = Me, R′ = Ph), in CH_2Cl_2 at room temperature, rapidly gave the dimeric complexes $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$ in good yield. ^{13}C NMR spectroscopy suggests that the alkynes are acting as four-electron donors in the dimeric compounds $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$. Two equivalents of RC_2R' (R = R′ = Me, Ph or CH_2Cl; R = Me, R′ = Ph) react with $[WBrI(CO)_3(NCMe)_2]$, in CH_2Cl_2 at room temperature, to give the bis-alkyne complexes $[WBrI(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ in high yield. The bis-diphenylacetylene complex, $[WBrI(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$, can also be prepared by reacting the iodo-bridged dimer $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)]_2$ in CH_2Cl_2 at room temperature, with two equivalents of diphenylacetylene. The alkyne ligands are donating an average of three electrons each to the tungsten in these complexes.

The reactions of seven-coordinate halocarbonyls of molybdenum(II) and tungsten(II) with alkynes have received considerable attention in recent years. In 1982, Davidson and co-workers[1] described the reaction of the bromo-bridged dimer $[W(\mu\text{-}Br)Br(CO)_4]_2$ with $CF_3C_2CF_3$ to give the bis-alkyne complex, $[WBr_2(CO)(\eta^2\text{-}CF_3C_2CF_3)_2]$. In the same year Umland and Vahrenkamp[2] reported the preparation of the diiodo–alkyne complexes $[WI_2(CO)_2L(\eta^2\text{-}HC_2H)]$ (L = PMe_3 or $AsMe_3$) or $[WI_2(CO)_2L(\eta^2\text{-}PhC_2H)]$ (L = PMe_3, $AsMe_3$ or $CNBu^t$) from reaction of $[WI_2(CO)_4L]$ with HC_2R (R = H or Ph). In 1983, Templeton and co-workers[3] described the preparation of $[MX_2(CO)L_2(\eta^2\text{-}RC_2R')]$ [X = Cl or Br; L = PPh_3, PEt_3 or py; $L_2 = Ph_2P(CH_2)_2PPh_2$] by reacting $[MX_2(CO)_nL_2]$ (n = 2 or 3) with alkyne, and Davidson and Vasapollo[4] reported the reactions of $[W(\mu\text{-}Br)Br(CO)_4]_2$ with RC_2R' (R = R′ = Me or Ph and PhC_2Me) to give the dimeric complexes $[W(\mu\text{-}Br)Br(CO)(\eta^2\text{-}RC_2R')_2]_2$. In 1985, Bennett and Boyd[5] reacted $[MBr_2(CO)_3(PEt_3)_2]$ (M = Mo or W) with cyclooctyne to give $[MBr_2(CO)(PEt_3)_2(\eta^2\text{-}C_8H_{12})]$. More recently we have described the reactions of the bis-acetonitrile diiodo seven-coordinate complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with either one equivalent of RC_2R' (R = R′ = Me, Ph or CH_2Cl; R = Ph, R′ = Me and CH_2OH; R = Me, R′ = PhS and *p*-tolS) to give eventually $[M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$[6] or two equivalents of RC_2R' (R = R′ = Me or Ph; R = Me, R′ = Ph; for M = W only, R = R′ = Me, CH_2Cl or *p*-tol; R = Ph, R′ = CH_2OH) to give the mononuclear complexes $[MI_2(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ or the dinuclear compound $[Mo(\mu\text{-}I)I(CO)(\eta^2\text{-}MeC_2Me)_2]_2$.[7] Hitherto, no mixed halide–alkyne complexes of this type have been described. In this paper we wish to report the synthesis of the new mixed halide, seven-coordinate complex $[WBrI(CO)_3(NCMe)_2]$ and its reactions with alkynes.

EXPERIMENTAL

All reactions described in this paper were carried out under nitrogen using standard Schlenk apparatus. CH_2Cl_2 was dried and distilled before use. BrI

* Author to whom correspondence should be addressed.

was prepared by the literature method,[8] and all other chemicals used were purchased from commercial sources. Elemental analyses were determined using a Carlo Erba Elemental Analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded as $CHCl_3$ films between NaCl plates on a Perkin–Elmer ratio recording 1430 IR spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC 250 CP/MAS NMR spectrometer (all spectra were calibrated against tetramethylsilane).

Preparation of $[WBrI(CO)_3(NCMe)_2]$ **(1)**

A suspension of $[W(CO)_6]$ (4.00 g, 11.4 mmol) in degassed acetonitrile (120 cm^3) was refluxed under nitrogen for 72 h. The solution was then cooled to 0°C and BrI (2.36 g, 11.4 mmol) was added, which resulted in the immediate formation of a red–brown solution. After stirring for 30 min, the solvent was removed *in vacuo* to afford the analytically pure red–brown crystalline complex $[WBrI(CO)_3(NCMe)_2]$ **(1)** in quantitative yield.

Preparation of $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)]_2$ **(2)**

To $[WBrI(CO)_3(NCMe)_2]$ (0.56 g, 1 mmol) dissolved in CH_2Cl_2 (12 cm^3), with continuous stirring under a stream of dry nitrogen, was added PhC_2Ph (0.18 g, 1 mmol). After stirring for 4 h, the solution was filtered and removal of the solvent *in vacuo* gave dark green crystals of $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)]_2$ **(2)** which were recrystallized from CH_2Cl_2; yield of pure product = 0.54 g, 84%. Similar reactions of $[WBrI(CO)_3(NCMe)_2]$ with an equimolar quantity of RC_2R' (R = R′ = CH_2Cl; R = Me, R′ = Ph) afforded the new complexes $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$ **(3** and **4)**.

Preparation of $[WBrI(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]\cdot\frac{1}{2}CH_2Cl_2$ **(5)**

To $[WBrI(CO)_3(NCMe)_2]$ (0.56 g, 1 mmol) dissolved in CH_2Cl_2 (15 cm^3), with continuous stirring under a stream of dry nitrogen, was added MeC_2Me (0.16 g, 3 mmol). After stirring for 19 h, the solution was filtered and removal of solvent *in vacuo* gave yellow crystals of $[WBrI(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]\cdot\frac{1}{2}CH_2Cl_2$ **(5)**, which were recrystallized from CH_2Cl_2; yield of pure product = 0.44 g, 72%. Similar reactions of $[WBrI(CO)_3(NCMe)_2]$ with two equivalents of RC_2R' (R = R′ = Ph and CH_2Cl; R = Me, R′ = Ph) gave the new complexes $[WBrI(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ **(6–8)** (see Table 1 for colours and yields).

Reaction of $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)]_2$ *with two equivalents of* PhC_2Ph

To $[W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)]_2$ (0.26 g, 0.2 mmol) dissolved in CH_2Cl_2 (15 cm^3), with continuous stirring under a stream of dry nitrogen, was added PhC_2Ph (0.071 g, 0.4 mmol). After stirring for 19 h, the solution was filtered and removal of the solvent *in vacuo* gave yellow crystals of

[WBrI(CO)(NCMe)(η^2-PhC$_2$Ph)$_2$], which were recrystallized from CH_2Cl_2; yield of pure product = 0.31 g, 95% (Found: C, 46.2; H, 3.5; N, 1.5. Calc. for $C_{31}H_{23}NOBrIW$: C, 45.6; H, 2.8; N, 1.7%). The IR and ^{1}H NMR spectral properties were identical to those of compound **6**.

RESULTS AND DISCUSSION

Addition of an equimolar amount of BrI to a solution of the tris-acetonitrile compound [W(CO)$_3$(NCMe)$_3$] {prepared *in situ* by reacting [W(CO)$_6$] in refluxing acetonitrile for 72 h[9]} at 0°C, immediately affords a deep red–brown solution, which after removal of the solvent *in vacuo* afforded a quantitative yield of the new seven-coordinate compound [WBrI(CO)$_3$(NCMe)$_2$] (**1**). The complex is soluble in chlorinated solvents, such as CH_2Cl_2 and $CHCl_3$ etc., but only slightly soluble in diethyl ether and hydrocarbon solvents. The compound is stable in the solid state for several days when stored in the dark under an atmosphere of nitrogen, however it is very air-sensitive in solution. The complex [WBrI(CO)$_3$(NCMe)$_2$] (**1**) reacts with one equivalent of RC$_2$R′ (R = R′ = Ph or CH_2Cl; R = Me, R′ = Ph) to rapidly afford the iodo-bridged dimers [W(μ-I)Br(CO)(NCMe)(η^2-RC$_2$R′)]$_2$ (**2–4**) in good yield. Reaction of **1** with two equivalents of RC$_2$R′ (R = R′ = Me, Ph or CH_2Cl; R = Me, R′ = Ph) gives the bis-alkyne compounds [WBrI(CO)(NCMe)(η^2-RC$_2$R′)$_2$] (**5–8**). The dimeric complexes, **2–4**, are very unstable, however, they can be stored in the dark for several hours. They are very air-sensitive in solution, particularly the $CH_2ClC_2CH_2Cl$ derivative. The bis-alkyne compounds, **5–8**, are much more stable than the dimers, **2–4**, but must be stored under an inert atmosphere in the dark. All the alkyne complexes are soluble in CH_2Cl_2 and $CHCl_3$, but are much less soluble in diethyl ether and hydrocarbon solvents. All the new complexes described in this paper were fully characterized by elemental analysis (C, H and N) (Table 1), IR spectroscopy (Table 2), ^{1}H NMR and in selected cases ^{13}C NMR spectroscopy (Tables 3 and 4). The complex [WBrI(CO)(NCMe)(η^2-MeC$_2$Me)$_2$]·$\frac{1}{2}$CH$_2$Cl$_2$ was confirmed as a $\frac{1}{2}CH_2Cl_2$ solvate by repeated elemental analyses and ^{1}H and ^{13}C NMR spectroscopy. It is interesting to note that this is similar to the diiodo complex,

$[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]\cdot\frac{1}{2}CH_2Cl_2$, which showed a $\frac{1}{2}CH_2Cl_2$ solvate in the X-ray structural determination.[7]

Reaction of $[W(CO)_3(NCMe)_3]$ *in situ* with one equivalent of BrI is similar to our previously reported reactions of $[M(CO)_3(NCMe)_3]$ (M = Mo or W) with an equimolar quantity of X_2 (X = Br or I).[10] It is interesting to note that Tate *et al.* reported in 1962[9] that reaction of $[W(CO)_3(NCMe)_3]$ with one equivalent of I_2 in methanol gave a non-carbonyl-containing product. Hence, simply by carrying out the reaction *in situ* in a different solvent, i.e. acetonitrile, we obtain the highly reactive seven-coordinate halocarbonyl bis-acetonitrile compounds. The colour and IR spectral properties of the $[WBrI(CO)_3(NCMe)_2]$ complex are very similar to the analogous dibromo and diiodo complexes.[10] Surprisingly, the mixed halide complex $[WBrI(CO)_3(NCMe)_2]$ showed little propensity to disproportionate to give the dibromo and diiodo complexes. Since the X-ray crystal structure of $[WI_2(CO)_3(NCMe)_2]$ has been determined by Drew *et al.*,[11] and the colour and spectral properties of $[WBrI(CO)_3(NCMe)_2]$ (**1**) and $[WI_2(CO)_3(NCMe)_2]$ are very similar, the most likely structure for **1** is capped octahedral. We were unable to grow suitable single crystals for X-ray crystallography of $[WBrI(CO)_3(NCMe)_2]$ (**1**).

Equimolar quantities of the complex $[WBrI(CO)_3(NCMe)_2]$ and RC_2R' (R = R′ = Ph and CH_2Cl; R = Me, R′ = Ph) are likely to initially give the mononuclear complexes $[WBrI(CO)(NCMe)_2(\eta^2\text{-}RC_2R')]$, which rapidly dimerize to give the iodo-bridged dimers, $[W(\mu\text{-I})Br(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$, with loss of acetonitrile. It is likely that the tungsten atoms are bridged by iodide ligands, since iodides have a greater affinity for dative bridging compared to bromides. It is likely that these complexes are dimeric, since the analogous diiodide compounds $[M(\mu\text{-I})I(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$ were found to be iodo-bridged dimers.[6] Attempts to follow the reactions of $[WBrI(CO)_3(NCMe)_2]$ with one equivalent of RC_2R' by IR spectroscopy were made, however after 30 s only the carbonyl bands due to the dimer were observed. This is in contrast to the reactions of the diiodide complexes $[MI_2(CO)_3(NCMe)_2]$ with an equimolar amount of RC_2R', whereby for example, the reaction of equimolar quantities of PhC_2Ph and $[WI_2(CO)_3(NCMe)_2]$ took 12 h to go to completion, and a carbonyl band at 1948 cm^{-1} was observed which is due to $[WI_2(CO)(NCMe)_2(\eta^2\text{-}PhC_2Ph)]$.[6] This greater ease of dimerization of the mixed halide complexes $[WBrI(CO)(NCMe)_2(\eta^2\text{-}RC_2R')]$ may be due to the smaller size of the bromide ion allowing easier attack of the iodide by an associative mechanism. The alkyne can switch from a four-electron donor to a two-electron donor during associative attack by the iodide, rapidly switching back to a four-electron donor resulting in loss of acetonitrile. Associative mechanisms have been previously described for reaction of donor ligands with four-electron alkyne complexes of molybdenum(II) and tungsten(II).[12,13] The structure of the dimers $[W(\mu\text{-I})Br(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$ is likely to have *cis*-carbonyls in view of the closely spaced, equally intense carbonyl bands, with the alkyne ligands *cis* and parallel to the carbonyl groups, which has been previously observed.[14–17] However, in view of the complexity of the NMR spectra of the dimers $[W(\mu\text{-I})Br(CO)(NCMe)(\eta^2\text{-}RC_2R')]$ (**2–4**) it is likely that several isomers exist in solution. The ^1H NMR spectra (Table 3) show the expected features for the dimers (**2**→**4**). The ^{13}C NMR spectra for both **3** and **4** show several resonances above 200 ppm for both the alkyne-contact carbons and the carbonyl ligands. The lower field resonances have been assigned to the alkyne-contact carbon resonances which have been previously reported[12] for other four-electron alkyne complexes of molybdenum(II). Templeton and Ward[18] have suggested that alkyne carbons above 200 ppm indicate that the alkyne ligand is utilizing both its filled $p\pi$-orbitals and donating four electrons to the metal, which allows these complexes to obey the eighteen-electron rule.

The seven-coordinate complex $[WBrI(CO)_3(NCMe)_2]$ reacts with two equivalents of RC_2R' (R = R′ = Me, Ph or CH_2Cl; R = Me, R′ = Ph),

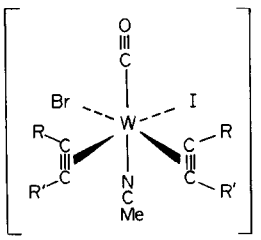

Fig. 1. Proposed structure for the complexes [WBrI(CO)(NCMe)(η^2-RC$_2$R')$_2$].

in CH_2Cl_2 at room temperature, to eventually afford the bis-alkyne complexes [WBrI(CO)(NCMe)(η^2-RC$_2$R')$_2$] (**5–8**) in high yield. The bis-diphenylacetylene compound can also be prepared by reacting the iodo-bridged dimer [W(μ-I)Br(CO)(NCMe)(η^2-PhC$_2$Ph)]$_2$ with two equivalents of diphenylacetylene (see Experimental). The bis-alkyne complexes, **5–8**, are similar in colour (yellow) to their diiodo analogues. The mixed halogeno complexes have a strong single carbonyl band well above 2000 cm^{-1} (see Table 2). The structures of the bis-alkyne complexes [WI$_2$(CO)(NCMe)(η^2-RC$_2$R)$_2$] (R = Me and Ph)[7] and [WI$_2$(CO)$_2$(η^2-MeC$_2$Me)$_2$][19] have been determined by X-ray crystallography, hence in view of the similar colours and spectral properties of the mixed halogeno complexes, **5–8**, to the diiodo compounds [WI$_2$(CO)(NCMe)(η^2-RC$_2$R)$_2$],[7] it is likely that the structures of **5–8** will be similar. The proposed structure of these bis-alkyne complexes is shown in Fig. 1. The ^{1}H NMR spectra (Table 3) conform with the structure shown in Fig. 1. The ^{13}C NMR spectrum of the bis-but-2-yne complex [WBrI(CO)(NCMe)(η^2-MeC$_2$Me)$_2$]·$\frac{1}{2}$CH$_2$Cl$_2$ (**5**) show alkyne-contact carbon resonances at 167.45 and 151.91 ppm. In view of Templeton and Ward's[18] correlation between alkyne-contact carbon shifts and the number of electrons donated to the metal, the range of values for this bis-alkyne complex suggest that the alkynes are donating an average of three electrons each to this tungsten in this complex.

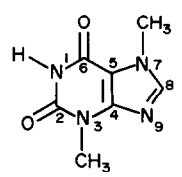
Abstract—Copper(II) amine complexes of theobromine (TbH) having the general formula $Cu(Tb)_2(Amine)_2$ [where Amine = ethylamine ($EtNH_2$) and *n*-butylamine (*n*-$BuNH_2$)] were synthesized. In addition, copper(II) and zinc(II) halide adducts of theobromine were prepared with the general formula $M(TbH)_2X_2 \cdot nH_2O$ (where X = Cl or Br and $n = 0$, 1 or 2). The amine complexes experience large carbonyl IR shifts and the loss of the N(1) theobromine proton, suggesting copper(II) complexation at the N(1) position, while the halide compounds do not exhibit theobromine N(1) proton loss and are proposed to bind at the N(9) position. $Zn(TbH)_2Cl_2$ can be assigned a tetrahedral geometry on the basis of low frequency IR evidence, while the low magnetic susceptibilities and lack of M—X vibrations above 200 cm^{-1} suggest that the copper centres in $Cu(TbH)_2Cl_2 \cdot 2H_2O$ and $Cu(TbH)_2Br_2 \cdot H_2O$ are antiferromagnetically coupled and that these complexes exist as halogen-bridged dimers or larger aggregates.

Theobromine (TbH) is a purine derivative found in significant concentrations in a number of plant products, including cocoa and coffee beans. Many studies have been undertaken on metal ion complexes with other biologically important purines, including adenine, guanine, xanthine, hypoxanthine, theophylline and caffeine,[1–12] yet fewer references can be found to compounds of theobromine with metal ions. For example, Beck and Kottmair[13] reported the preparation of $Rh(CO)(PPh_3)_2(Tb)$, while Mikulski *et al.* have synthesized $Cu(TbH)_2(ClO_4)_2$,[14] $Pd(TbH)(Tb)Cl$[15] and $ZrO(TbH)_2(Tb)Cl \cdot H_2O$.[16] Recently, Mikulski *et al.* have expanded their work to include theobromine adducts with perchlorate salts of chromium(III), manganese(II), iron(II), iron(III), cobalt(II), nickel(II) and zinc(II).[17] In addition, the crystal structure determination of $K[Pt(TbH)Cl_3] \cdot H_2O$ has been accomplished.[18]

Neutral theobromine is protonated at the N(1) position.[19,20] The crystal structure of $K[Pt(TbH)Cl_3] \cdot H_2O$ shows theobromine binding through the N(9) imidazole nitrogen to the platinum centre.[18] This may not be the exclusive binding site for the theobromine in all complexes, however, as $K[Pt(TbH)Cl_3] \cdot H_2O$ was prepared under acid conditions, which prevented ionization of the proton at N(1), where metal bonding could also occur. Hodgson[2] has noted that the binding site of transition metal ions to the purines, which contain both pyrimidine and imidazole moieties, is almost always an imidazole nitrogen atom, and therefore states that the pyrimidine N(1) and N(3) atoms are poorer ligating atoms than are the imidazole N(7) and N(9) atoms. Recent workers have concluded that N(1) and N(9) would be about equally likely to act as the binding site of terminal unidentate theobromine, however, under neutral conditions.[14,17]



Theobromine

We have prepared metal ion complexes with other purines of biological interest, including adducts of copper(II), cadmium(II) and zinc(II) with theophylline,[21] guanine and xanthine,[22] and

* Author to whom correspondence should be addressed.

kinetin and 6-benzylaminopurine.[23] Some of these compounds also contain various primary amines while others contain various halide atoms. In the present study, we have synthesized copper(II) complexes of theobromine with primary amines having the general formula $Cu(Tb)_2(Amine)_2$, [where Amine = ethylamine ($EtNH_2$) and *n*-butylamine (*n*-$BuNH_2$)], and copper(II) and zinc(II) halide adducts of theobromine with the general formula $M(TbH)_2X_2 \cdot nH_2O$ (where X = Cl or Br and $n = 0$, 1 or 2). IR (4000–200 cm^{-1}) and room-temperature magnetic susceptibility measurements have been employed to study these new complexes.

EXPERIMENTAL

Preparation of $Cu(Tb)_2(EtNH_2)_2$ *and* $Cu(Tb)_2$ (*n*-$BuNH_2)_2$

The synthetic procedure was similar to that used for a previously reported copper–guanine primary amine complex.[22] $CuSO_4 \cdot 5H_2O$ (5.0 mmol) and TbH (5.0 mmol) were slurried in 50 cm^3 of 35% ethylamine–H_2O and 50% *n*-butylamine–H_2O, respectively, to yield purple powders. The products were filtered by vacuum, washed with the respective aqueous amines and dried with acetone. They were air stable but spontaneously decomposed in water to yield theobromine and aqueous copper(II), and were insoluble in common aprotic solvents. Elemental analyses are listed in Table 1.

Preparation of $Cu(TbH)_2Cl_2 \cdot 2H_2O$, $Cu(TbH)_2Br_2 \cdot H_2O$ *and* $Zn(TbH)_2Cl_2$

The synthetic procedure was similar to that used in previously reported copper halide–purine complexes,[21–23] with the difference that acetone was used as the solvent rather than methanol. 5.0 mmol of either $CuCl_2 \cdot 2H_2O$, $CuBr_2$ or $ZnCl_2$ were refluxed with TbH (5.0 mmol) in acetone for 24 h, filtered by vacuum and washed with acetone. The grey copper and white zinc adducts were obtained as powders and were insoluble in water and common aprotic solvents. Elemental analyses are listed in Table 1.

IR spectra were obtained as Nujol mulls between high-density polyethylene windows (600–200 cm^{-1}) and as KBr pellets (4000–400 cm^{-1}) on a Perkin–Elmer 1430 spectrometer. Room-temperature magnetic susceptibility measurements were conducted on a Gouy balance of standard design. Elemental analyses (C, H, N) were performed by Galbraith Laboratories.

RESULTS AND DISCUSSION

Theobromine exhibits four prominent IR absorbances in the 2800–3200 cm^{-1} region (Table 2). The peaks at 3160 and 3030 cm^{-1} have been assigned to N(1)—H, while those at 3115 and 2830 cm^{-1} include absorbances from C(8)—H.[14,17] $Cu(Tb)_2(EtNH_2)_2$ and $Cu(Tb)_2$(*n*-$BuNH_2)_2$ complexes exhibit symmetric and asymmetric primary amine N—H stretching at 3170 and 3264 cm^{-1} and 3180 and 3270 cm^{-1}, respectively, while ring N(1)—H vibrations are absent in these two complexes. Theobromine carbonyl absorbances experience large shifts of over 50 cm^{-1} to lower frequencies upon complexation, while skeletal ring C=C and C=N bands also shift to lower frequencies to a lesser extent. The IR evidence thus suggests complexation to the theobromine ring with carbonyl involvement in bonding, probably through hydrogen bonding to

the coordinated primary amine groups since their N—H absorbances also occur at longer wavelengths than free, non-hydrogen bonded asymmetric and symmetric N—H stretching modes. Hydrogen bonding by purine ring carbonyl groups has been suggested for other complexes of this type.[22,24] Changes in intensity of theobromine ligand bands are observed in the 600–200 cm^{-1} region, and a new absorbance appears at 245 cm^{-1}. This is a region where metal–nitrogen vibrations have been observed in copper(II) complexes of various imidazoles,[25–26] and so may be a copper–theobromine nitrogen vibration. Room temperature magnetic susceptibility measurements gave values of 1.64 BM for both primary amine complexes. These values are slightly lower than those usually found for mononuclear copper(II) compounds, but are consistent with numerous reported examples of copper(II)–purine complexes.[3,4,7,27–30]

C—H and N—H vibrations in the 2800–3200 cm^{-1} region do not change appreciably in $Cu(TbH)_2Cl_2 \cdot 2H_2O$, $Cu(TbH)_2Br_2 \cdot H_2O$ and $Zn(TbH)_2Cl_2$, suggesting that neutral theobromine ligands are present in these complexes. Further, carbonyl absorbances are relatively unaffected in these compounds, indicating that bonding through a C=O oxygen atom does not occur. Mikulski *et al.*[17] note similar effects for a series of metal perchlorate complexes of theobromine, including $Cu(TbH)_2(ClO_4)_2$. Slight changes are observed for skeletal ring C=C and C=N bands in the 1500–1600 cm^{-1} region, while significant ring vibrational mode changes from those of free theobromine occur at frequencies lower than 1600 cm^{-1}. The spectra of $Cu(TbH)_2Cl_2 \cdot 2H_2O$ and $Cu(TbH)_2Br_2 \cdot H_2O$ are very similar, suggesting that they are isomorphous; no copper halide vibrations are observed at frequencies above 200 cm^{-1} in these compounds. Room-temperature magnetic susceptibility measurements for $Cu(TbH)_2Cl_2 \cdot 2H_2O$ and $Cu(TbH)_2Br_2 \cdot H_2O$ gave values of 0.65 and 0.88 BM, respectively. These values are below those found for magnetically dilute copper(II) compounds and indicate that antiferromagnetic coupling occurs between copper centres.[31] If halogen bridges link metal atoms to form dimers or larger aggregates, this conclusion could also explain the absence of Cu—Cl and Cu—Br stretches in the region near 300 cm^{-1}. $Zn(TbH)_2Cl_2$, however, exhibits a well-defined Zn—Cl doublet at 330 and 312 cm^{-1}, which suggests a tetrahedral coordination geometry around the metal centre.[21,22,32] Absorbances at 245, 242 and 240 cm^{-1} for $Cu(TbH)_2Cl_2 \cdot 2H_2O$, $Cu(TbH)_2Br_2 \cdot H_2O$ and $Zn(TbH)_2Cl_2$, respectively, could result from metal–theobromine nitrogen vibrations.

It is not possible from the information obtained for the present complexes to determine unambiguously whether metal binding occurs to the N(1) or N(9) theobromine ring nitrogen. In the cases of $Cu(Tb)_2(EtNH_2)$ and $Cu(TbH)_2(n\text{-}BuNH_2)_2$, prepared in basic solution, IR evidence indicates that ionization of the N(1) protons has occurred and the resulting complexes experience large carbonyl shifts most likely due to hydrogen bonding to coordinated primary amine groups. This suggests that coordination may occur at N(1) in these compounds, although intermolecular hydrogen bonding between carbonyl and primary amine groups on separate monomeric adducts cannot be discounted. The IR evidence suggests tetrahedral coordination for $Zn(TbH)_2Cl_2$, probably through the theobromine N(9), as the N(1) proton is undisturbed. N(9) bonding to the copper centre is also indicated for $Cu(TbH)_2Cl_2 \cdot 2H_2O$ and $Cu(TbH)_2Br_2 \cdot H_2O$ for the same reason, while magnetic susceptibility data indicate that these compounds are dimers or larger aggregates.

The present work presents facile methods for the preparation of metal ion–theobromine complexes using modified procedures employed for other purine–metal ion adducts.[21–23] Efforts are continuing to synthesize additional theobromine halide and primary amine complexes with a wider range of metal ions.

SOME 1,2-BIS(DIPHENYLPHOSPHINO)ETHANE COMPLEXES OF MOLYBDENUM(0) AND (II)

ANDREW R. BARRON, SIMON J. ANDERSON, KEITH McGREGOR and GEOFFREY WILKINSON*

Chemistry Department, Imperial College of Science and Technology, London SW7 2AY, U.K.

(*Received* 21 *May* 1989; *accepted* 15 *June* 1989)

Abstract—Reactions of the allylhydrido complex, $MoH(\eta^3\text{-}C_3H_5)(dppe)_2$ [dppe = 1,2-bis(diphenylphosphino)ethane], with various small molecules have been studied. New complexes isolated were the molybdenum(0), $Mo(2,6\text{-}Me_2C_6H_3NC)_2(dppe)_2$ and the molybdenum(II) compounds, $MoCl(\eta^3\text{-}C_3H_5)(dppe)_2$, $[Mo(MeCN)(\eta^3\text{-}C_3H_5)(dppe)_2]BF_4$, $Mo(CH_3)(\eta^3\text{-}C_3H_5)(dppe)_2$ and $Mo(CH_2SiMe_3)(\eta^3\text{-}C_3H_5)(dppe)_2$.

The allyl hydride complex,[1] $MoH(\eta^3\text{-}C_3H_5)(dppe)_2$, made by reduction of $MoCl_3(THF)_3$ with Na–Hg in THF under propylene, was reported to be stable thermally to *ca* 110°C.[1] No details or reactions were reported, although NMR spectra at +5°C confirmed the structure and at elevated temperatures showed metal hydride exchange with terminal hydrogen on the η^3-allyl group.[1]

In the hope that insertion reactions typical for M—H species could be carried out, possibly, subsequently leading to functionalized alkenes, we have studied the reaction of the complex with some small molecules. Analytical and other data for new compounds are given in Table 1.

RESULTS AND DISCUSSION

The hydrido allyl was made by Osborn's method but using $MoCl_4(THF)_2$ rather than $MoCl_3(THF)_3$. The IR spectrum, not previously reported, shows (in addition to bands due to dppe) bands at 1410, 930 and 870 cm^{-1} which can be assigned to the allyl vibration.[2] The mass spectrum shows no parent ion, but peaks due to $[Mo(dppe)_2]^+$ and $[C_3H_6]^+$ are present. These data are in agreement with the structure reported on the basis of NMR spectra.[1]

The hydrido allyl rapidly reacts in solution with N_2 to yield the known complex *trans*-$Mo(N_2)_2(dppe)_2$.[3] It also reacts in THF with CO (3 atm) and H_2 (5 atm) to yield *trans*-$Mo(CO)_2(dppe)_2$[4] and $MoH_4(dppe)_2$,[5] respectively. Although the compound reacts with CO_2 and CS_2 we have been unable to isolate any well-defined products.

The attempted insertion of the isocyanide, 2,6-$Me_2C_6H_3NC$, into the Mo—H bond at low temperatures resulted in loss of propylene to yield *trans*-$Mo(2,6\text{-}Me_2C_6H_3NC)_2(dppe)_2$ (**1**) in high yield. The spectroscopic data resemble those for similar isocyanide compounds of molybdenum and tungsten, $M(RNC)_2(dppe)_2$.[6]

If only 1 equivalent of isocyanide was used under a propylene atmosphere, the bis-isocyanide was still formed although in lower yield. The remaining product being unreacted hydride.

Addition of CCl_4 to a THF solution of the hydride yields the bright yellow allyl complex, $MoCl(\eta^3\text{-}C_3H_5)(dppe)_2$ (**2**), and $CHCl_3$ in virtually quantitative yield. The IR spectrum of **2** shows a band at 310 cm^{-1} due to ν(Mo—Cl). In $CHCl_3$ solution at room temperature the chloride is undissociated but on warming to *ca* 40°C the orange colour changes to pale yellow and there is dissociation to form the ionic species $[Mo(\eta^3\text{-}C_3H_5)(dppe)_2]Cl$. This dissociation in $CHCl_3$ is reversible and on cooling the neutral complex is reformed. In acetonitrile the chloride is a 1:1 electrolyte and the addition of KBF_4 to the MeCN solution leads to the salt $[Mo(MeCN)(\eta^3\text{-}C_3H_5)(dppe)_2]BF_4$ (**3**). This yellow solid can also be made directly from the hydride by addition of HBF_4 in acetonitrile; such acidolyses are well known.[7]

$Mo(CH_2SiMe_3)(\eta^3\text{-}C_3H_5)(dppe)_2$ (**5**)	210 (dec)	2.35	70.0 (70.6)	6.5 (6.4)	12.0 (12.4)

[a] Required values in parentheses.
[b] N, 2.4 (2.4).
[c] Cl, 3.8 (3.7).
[d] N, 1.2 (1.3).

Alkylation of the chloride, **2**, with RLi in THF produces the yellow alkyl complexes, $MoR(\eta^3\text{-}C_3H_5)(dppe)_2$ [R = Me (**4**) and CH_2SiMe_3 (**5**)] in moderate yields.

The halide and alkyl compounds are paramagnetic in the solid state with magnetic moments somewhat lower than the spin-only value (2.83 BM) for octahedral d^4 complexes. No ESR spectra could be observed since octahedral molybdenum(II), $S = 1$ is ESR silent. Despite their paramagnetism, the compounds have moderately sharp ^1H NMR spectra which are shifted only a little compared to typical diamagnetic η^3-allyls.[8] This type of behaviour has been observed[9] for other paramagnetic d^4 complexes such as $ReX_3(PR_3)_3$.

For neither compound **4** and **5** is there any evidence of 1,3-shifts comparable to the hydride shift[1] on heating in solution to yield substituted propylenes, nor do they show any significant reactivity towards CO even at elevated temperature and pressure. The absence of migration, for even the methyl complex, may indicate that the complex adopts a "*trans*" configuration as opposed to the "*cis*" configuration, probably present in the allyl hydride. Crystals of the various compounds suitable for X-ray study could not be obtained.

Although *no* substituted propylene species could be isolated, the mass spectra show peaks due to C_3H_5X (X = Cl, Me and CH_2SiMe), indicating that elimination does occur at high temperatures in the vapour phase (> 180°C).

Thus, except for the reaction with CCl_4 the complex $MoH(\eta^3\text{-}C_3H_5)(dppe)_2$ appears to react as the isomeric molybdenum(0) propylene complex, which having a vacant coordination site on the metal enables coordination of a donor ligand with facile displacement of propylene.

EXPERIMENTAL

Experimental methods and instruments are as given previously.[10] Magnetic susceptibilities in the solid state were determined using an Evans' balance and were corrected for diamagnetism at ligands. $MoCl_4(THF)_2$ was prepared by a literature method.[11]

Hydrido(η^3 - allyl)bis[1,2 - bis(diphenylphosphino) ethane]molybdenum(II)

$MoCl_4(THF)_3$ (1.19 g, 3.12 mmol) was added to a solution of dppe (2.49 g, 6.26 mmol) in THF (80 cm^3) over Na(Hg) amalgam (0.40 g in 5 cm^3) under propylene (1 atm). The solution was stirred for 12 h, filtered, concentrated and cooled to −20°C to give a red microcrystalline solid which was collected, washed with hexane (2 × 10 cm^3) and dried *in vacuo*. Yield: 2.34 g, 82%. IR: 3050m, 1965m, 1585m, 1470s, 1430s, 1410m, 1300w, 1260m, 1190m, 1150w, 1115m, 1090s, 1075m, 1025m, 930w, 910w, 870m, 840w, 800s, 740s, 720s, 698s, 650s, 620s, 610w, 520s, 510s, 500w, 490m, 470w, 440m, 420m, 400m.

Trans - *bis*(2,6 - *dimethylphenylisocyanide)bis*[1,2-*bis*(*diphenylphosphino*)*ethane*]*molybdenum*(0) (**1**)

To a stirred solution of the allyl hydride (0.34 g, 0.36 mmol) in THF (30 cm^3), at −20°C, was added 2,6-$Me_2C_6H_3NC$ (0.1 g, 0.76 mmol). The solution was allowed to warm to room temperature and stirred for 6 h. The deep red solution was concentrated *in vacuo*, and on cooling (−20°C) gave red diamond-shaped crystals. Yield: 0.38 g, 91%. IR: 1879vs, 1587s, 1432s, 1308w, 1262w, 1190w, 1155w, 1091m, 1027m, 920m, 859m, 791s, 772m, 745w, 739m, 720m, 694s, 653s, 625w, 616m, 539w, 530w, 518m, 505w, 495m. NMR ^1H: 0.9 (12H, s, CH_3); 2.2–2.6 (8Hm, PCH_2); 6.9–8.0 (46Hm arom. H). ^{31}P: 78.6s. Mass spectrum: *m/z* 1156 [Mo$(Me_2C_6H_3NC)_2(dppe)_2]^+$; 1025 [Mo$(Me_2C_6H_3NC)(dppe)_2]^+$.

Chloro(η^3 - *allyl*)*bis*[1,2 - *bis*(*diphenylphosphino*)*ethane*]*molybdenum*(II) (**2**)

To a stirred solution of the allyl hydride (2 g, 2.18 mmol in 100 cm^3 of THF) was added CCl_4 (20 cm^3). A yellow precipitate formed after stirring for 1 h. The solid was collected, washed with hexane (2 × 20 cm^3) and dried *in vacuo*. Yield: 2.07 g, *ca* 100%. IR: 3050m, 1595m, 1570s, 1480m, 1430s, 1410m, 1190m, 1160m, 1120m, 1110m, 1070m, 1030m, 1000m, 870m, 790s, 740s, 695s, 660s, 545m, 530m, 520s, 510s, 500m, 485m, 310m. NMR ^1H: 0.66 (2H, s), 1.12 (2H, s), (allyl CH_2); 1.30 (8H, s, PCH_2); 3.80s (^1H, s, allyl C*H*). Mass spectrum: *m/z* 892 $[Mo(dppe)_2]^+$; 76 $[C_3H_5Cl]^+$.

The conductivity of **2** in $CHCl_3$ at 25°C showed the complex to be unionized ($\Lambda_M = 0.67\ \Omega^{-1}\ cm^3\ mol^{-1}$), but at 40°C the conductivity increased to 2.86 $\Omega^{-1}\ cm^3\ mol^{-1}$ and on cooling returned to the original value. The cycle could be repeated several times. Addition of KBF_4 stabilizes the conductivity at the higher value. The cation has been isolated from acetonitrile as below.

Acetonitrile(η^3 - *allyl*)*bis*[1,2 - *bis*(*diphenylphosphino*)*ethane*]*molybdenum*(II) *tetrafluoroborate* (**3**)

(a) To a solution of the chloride, **2** (0.24 g, 0.25 mmol), in MeCN (30 cm^3) was added KBF_4 (0.03 g, 0.25 mmol). After stirring for 1 h the solvent was removed and the yellow solid washed with MeOH (2 × 20 cm^3) and recrystallized from MeCN–Et_2O (1:1, 20 cm^3). Yield: 0.16, 63%. IR: 3050m, 2305m, 1598m, 1570w, 1480, 1430s, 1410, 1190m, 1120sh, 1050br.s, 1000sh, 870m, 780s, 740s, 660s, 550m, 520m, 510s, 500m, 490w. NMR ^1H: 0.4 (2H, s), 1.2 (2H, s), (allyl CH_2); 1.30 (8H, s, PCH_2); 2.1 (3H, s, $NCCH_3$). Conductivity (MeCN): Λ_M 136 $\Omega^{-1}\ cm^3\ mol^{-1}$.

(b) To a solution of the allyl hydride (0.25 g, 0.28 mmol) in MeCN (30 cm^3) was added an excess of an Et_2O solution of $HBF_4 \cdot OEt_2$ (1 cm^3, 52%). After stirring for 6 h, the solvent was removed and the residue washed with Et_2O (3 × 10 cm^3), then extracted into MeCN–Et_2O (1:1, 20 cm^3); cooling (−20°C) produced a yellow solid identical to that in (a). Yield: 0.10 g, 40%.

Methyl(η^3 - *allyl*)*bis*[1,2-*bis*(*biphenylphosphino*)*ethane*]*molybdenum*(II) (**4**)

To a suspension of Mo$Cl(\eta^3$-$C_3H_5)(dppe)_2$ (0.5 g, 0.53 mmol) in THF (100 cm^3), at −78°C, was added MeLi (1.0 cm^3, 0.69 mmol). The solution was allowed to warm to room temperature and stirred for 2 h. The deep golden solution was filtered, the volume reduced to *ca* 20 cm^3 and cooled (−20°C) to give a dark yellow solid, which was recrystallized from toluene. Yield 0.35 g, 71%. IR: 3050m, 1585m, 1410m, 1310w, 1260m, 1100s, 1090s, 1060s, 1025m, 900m, 870m, 800m, 755m, 740s, 695s, 650s, 635m, 510s, 505m, 495w, 485m, 420m, 370m. NMR ^1H: 0.88 (2H, s), 1.12 (2H, s) (allyl CH_2); 1.30 (8H, s, PCH_2); 2.90 (3H, s, CH_3); 3.55 (^1H, s, allyl C*H*). Mass spectrum: *m/z* 892 $[Mo(dppe)_2]^+$; 56 $[C_4H_8]^+$.

(η^3 - *Allyl*)*trimethylsilylmethylbis*[1,2 - *bis*(*diphenylphosphino*)*ethane*]*molybdenum*(II) (**5**)

As for **4** but using 1 equivalent of Me_3SiCH_2Li. Yield: *ca* 65%. IR: 3050m, 1566s, 1475m, 1430s, 1408m, 1310m, 1270m, 1260m, 1190m, 1160m, 1130m, 1100s, 1090, 1071m, 1030m, 870m, 800m, 750m, 695s, 610s, 560m, 485m, 420w. NMR ^1H: 0.15 (9H, s) ($SiMe_3$); 0.89 (2H, s), 1.18 (2H, s) (allyl CH_2); 1.30 (8H, s, PCH_2); 2.93 (2H, s, $SiCH_2$) 3.61 (^1H, s, allyl C*H*). Mass spectrum: *m/z* 892 $[Mo(dppe)_2]^+$; 128 $[C_7H_{16}Si]^+$.

CHEMICAL, SPECTROSCOPIC AND ELECTRICAL CONDUCTION PROPERTIES OF IODINATED NICKEL DIIMINE COMPLEXES

FRANCESCO LELJ,* GIANCARLO MORELLI, GIAMPAOLO RICCIARDI, MARIA F. BRIGATTI and ANGELA ROSA

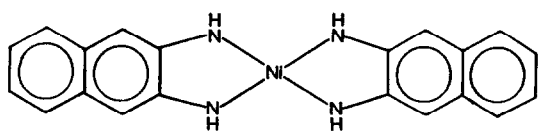
Istituto di Chimica, Universita' della Basilicata, Via N. Sauro 85, 85100 Potenza, Italy

(*Received* 16 *May* 1989; *accepted* 16 *June* 1989)

Abstract—Bis(diimine)nickel complexes [diimine = 2,3-diiminonaphthalene (din) and 9,10-diiminophenanthrene (dip)] have been prepared by oxidation of a solution of Ni^{2+} and the appropriate diamine. The complexes were studied by UV–vis spectroscopy and compared with the well-known bis(*o*-phenylenediimine)nickel complex. Oxidation with iodine gave $Ni(din)_2I_x$ and $Ni(dip)_2I_x$ (where $x = 0.13$–3.30). Thermogravimetric analyses (TGA) provided quantitative information on the iodine content. Weight losses at 100°C were observed for highly iodinated compounds involving the decomposition of I_5^- to I_3^- and for all species above 260°C. Raman and IR spectroscopy were used to characterize the iodine-doped complexes. The Raman spectra showed strong scattering attributable to I_3^- (107 cm^{-1}) and I_5^- (160 cm^{-1}), the latter only for highly iodinated complexes. The conductivity of iodine-doped materials was studied by using linear two-probe (300 K) and variable temperature (77–300 K) van der Pauw methods on pressed pellets. The conductivity is thermally activated, with an apparent activation energy of 0.25 and 0.075 eV for $Ni(din)_2I_x$ and $Ni(dip)_2I_x$, respectively. A large increase of the conductivity for more extended molecules is observed.

Many classes of mixed-valence and partially oxidized metallo-organic complexes have been studied during recent years. Most studies[1] concern: (i) glyoximate complexes of nickel(II) and palladium(II);[2] (ii) 16 π-electron tetra-azaannulene complexes of cobalt(II), nickel(II) and palladium(II);[3] (iii) 16 π-electron phthalocyanine[4] or porphyrin[5] complexes of a large variety of metals, all these compounds being partially oxidized by different amounts of iodine or other oxidants. The great interest in these compounds is due to the anisotropic conducting properties associated with the one-dimensionality of these systems. The conducting behaviour of these stacked materials depends on electronic features of both the ligand and metal, structural organization (interplanar spacing) and crystal packing, nature and amount of the oxidant.

In attempts to obtain a new class of metallo-organic conducting materials using the well-known bis(*o*-phenylenediimine)nickel complex, $Ni(opd)_2$, has been investigated in recent years. Conductivity data are reported for: $Ni(opd)_2 \cdot A$ species (where A is a strong electron acceptor);[6] $[Ni(opd)_2]_n^+$ salts;[7] and finally for the iodinated species $Ni(opd)_2I_x$.[8] These partially oxidized $Ni(opd)_2I_x$ species show[8] modest conducting properties compared with phthalocyanine or tetra-azaannulene iodinated complexes.

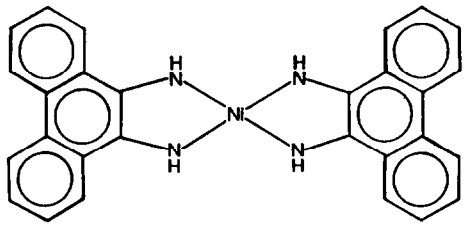


$Ni(din)_2$

In this paper we present the preparation and characterization of a series of new nickel complexes with aromatic diamines: bis(2,3-diiminonaphthalene)nickel, $Ni(din)_2$, and bis(9,10-diiminophenan-

* Author to whom correspondence should be addressed.

threne)nickel, $Ni(dip)_2$, and their partially oxidized iodine counterparts.



$Ni(dip)_2$

The conducting behaviour of these complexes was studied in order to correlate the conducting properties of the bulk materials within a homologous series of ligand molecules, on going from the $Ni(opd)_2$ species to $Ni(din)_2$ and finally to $Ni(dip)_2$. The rôle played by the metal, the ligand and the iodine in the conducting phenomenon was also investigated.

EXPERIMENTAL

Reagents

2,3-Diaminonaphthalene and 9,10-diaminophenanthrene were obtained commercially (Aldrich) and purified by sublimation (10^{-2} mm Hg). I_2, crystals, resublimated 99.8% A.C.G. reagent was used. Solvents were of analytical reagent or spectrograde quality. Elemental analyses were performed by the Analytical Laboratory, Faculty of Engineering, Potenza.

Synthesis of bis(diimine)nickel complexes

(a) *Bis(2,3-diiminonaphthalene)nickel*, $Ni(din)_2$. 2,3-diaminonaphthalene (1.0 g, 2.7 mmol) was dissolved by stirring at 70°C in 100 cm^3 of an ethanol–water (4 : 1) solution and treated with $NiCl_2 \cdot 6H_2O$ (1.2 g, 5.0 mmol) dissolved in 3.0 cm^3 of water and 3.0 cm^3 of concentrated ammonia. A stream of a O_2–N_2 (1 : 1) mixture was bubbled into the flask until the solution became a deep blue–green colour (*ca* 1.5 h). Ethanol was removed *in vacuo* and the green–black solid was filtered and washed well with water and acetone until the washings were colourless. After drying at 60°C and 25 mm Hg, the compound was purified by prolonged Soxhlet extraction with acetone under a nitrogen atmosphere. The first extract was not used, but the others afforded green–black pure microcrystalline powder in 20% yield. The compound is air-stable but it undergoes slow decomposition in solution when solvents other than acetone are used. Found: C, 63.8; H, 4.9; N, 14.7. Calc. for $C_{20}H_{16}N_4Ni$: C, 64.7; H, 4.3; N, 15.1%. UV–vis (acetone, 10^{-5} M): 742(7100), 460(2180)sh, 422(3310)sh, 390(4320)sh, 355(8350), 332(6350) nm (mol cm^{-1}).

(b) *Bis(9,10-diiminophenanthrene)nickel*, $Ni(dip)_2$. 9,10-Diaminophenanthrene (1.0 g, 2.1 mmol) which was completely dissolved in ethanol (100 cm^3) by stirring at 65°C, was treated with $NiCl_2 \cdot 6H_2O$ (1.0 g, 4.2 mmol) in 3.0 cm^3 of water and 3.0 cm^3 of concentrated ammonia. The solution was slowly stirred for 24 h in a flask open to the air but a pink–red colour was observed within a few minutes. Ethanol was removed *in vacuo* and the pink–red solid was treated and purified as described for $Ni(din)_2$. The air-stable complex was obtained in 40% yield as a pink–red microcrystalline powder. Found: C, 70.1; H, 4.6; N, 11.1. Calc. for $C_{28}H_{20}N_4Ni$: C, 71.4; H, 4.2; N, 11.9%. UV–vis (acetone, 10^{-5} M): 560(2120), 415(5500), 402(3601), 388(3805), 380(2504), 368(2400), 360(2385)sh nm (mol cm^{-1}).

Iodination of $Ni(din)_2$ *and* $Ni(dip)_2$ *complexes*

In order to prepare polycrystalline samples of various stoichiometries, finely powdered $Ni(din)_2$ and $Ni(dip)_2$, in acetone, were treated with increasing amounts of iodine dissolved in acetone, in the dark. The reactions were performed by stirring for 18 h at room temperature in a flask sealed with a septum. In a typical experiment $Ni(din)_2$ (0.156 g, 0.42 mmol) in 20 cm^3 of acetone was treated with I_2 (0.106 g, 0.42 mmol) dissolved in 15 cm^3 of acetone. The green–gold compound obtained was purified by removing the solvent and the unreacted iodine under a stream of nitrogen. The compound, washed twice with acetone and dried at 40°C and 25 mm Hg, was characterized as $Ni(din)_2I_{0.55}$. The iodine content was monitored by TGA and was consistent with the elemental analysis.

Physical measurements

Thermogravimetric analysis

TGA data were obtained by using a B85 Setaram thermal analyser, equipped with a TGC 85 controller module and a BBC(Goerz Metrawatt) Servogor 120 recorder. Measurements were carried out using a platinum sample boat under a nitrogen atmosphere. A nitrogen flow rate of 50 cm^3 min^{-1} and a programmed heating rate of 20°C min^{-1} were employed. Scans were made from room temperature to approximately 350°C. The initial sample mass was nominally 8.0 mg. Iodine contents were directly determined from the thermograms. All the

data obtained were in good agreement with the elemental analyses.

Spectroscopy

IR spectra were recorded on Nujol mulls with a Perkin–Elmer Model 883 spectrophotometer. UV–vis spectra in solution (acetone, 10 cm path length cells) were obtained using a Cary 2300 spectrophotometer. Raman spectra were obtained with a Ramanor HG2S spectrometer employing 514.5 nm excitation (250 mW argon ion laser power filtered at 30%). Samples, in glass capillaries, were spun at 300 r.p.m.

Conductivity measurements

Electrical conductivity data by both the linear two-probe and the four-probe van der Pauw[9] methods were obtained. With the linear two-probe technique only room temperature data were acquired. Micropellets, 1 mm in diameter and *ca* 1 mm thick, were introduced into a glass capillary. In the case of van der Pauw[9] measurements sample discs (13 mm diameter, approx. 0.5 mm thick) were used. The discs were formed using an evacuable die and a Carver press. The thickness and diameter of samples and probe spacing were determined with the aid of a microscope. Electrical current to the samples was supplied by a Hewlett–Packard precision DC current source 6186C. Output DC voltages were detected by a Hewlett–Packard 3478 A multimeter. Electrical contacts to the samples were made with Silver Paint AG 121, Bitronic (Italy). For provision of strain-free mounting, the discs were secured to the anodized aluminium mount by a tuft of cotton over which was wrapped a strip of Teflon tape. The sample holder was contained in a gas-tight brass can which fitted into a liquid nitrogen Dewar and was cooled by a stream of nitrogen. The temperature (± 0.1°C) was monitored by a Au–Chromel thermocouple located *ca* 1 mm from the sample. The investigated temperature range was between 77 K and room temperature. At temperatures above 30–40°C, highly iodinated samples released iodine slowly and stable voltages could not be recorded. The measurement procedure included: (i) verification of electrical isolation between the sample and mount; (ii) resistance measurements between all four electrodes as a function of current to check for non-ohmic behaviour, contact resistance and sample integrity; (iii) measurements at zero current to the sample to check for stray voltages.

RESULTS AND DISCUSSION

The two complexes $Ni(din)_2$ and $Ni(dip)_2$ were synthesized following a slightly modified procedure of Feigl and Furth[10] for $Ni(opd)_2$. By oxidation of a solution of Ni^{2+} and of the appropriate diamine in aqueous ammonia, the complexes are isolated as solids which display very low solubility in most solvents. $Ni(din)_2$ requires a more oxidative atmosphere and prolonged reaction time; moreover, by using a more water-rich solvent in the preparation of $Ni(din)_2$, amine polymerization can occur. Furthermore, owing to the fact that the reactions have low yields, the products have to be purified from large amounts of unreacted amine.

Concerning the electronic structure of the complexes and the oxidation state of the metal, different possibilities can be formally considered:[11,12]

(1) the ligands are in the deprotonated form (L^{2-}) and nickel is in the +IV oxidation state;
(2) the ligands have a radical anionic structure (L^{-}) and nickel has an oxidation number of +II;
(3) the ligands are in the fully oxidized form (L) with an oxidation number of zero assigned to the metal.

In recent papers we have presented investigations on the ground-state electronic structure of $Ni(opd)_2$[13] (a DV-Xα study with comparison to previous MS-Xα calculations[12]) and on the spectroscopic behaviour[14] of this complex. The reported results confirm the α-diimine character of the ligands and suggest a structural situation, intermediate between the formal structures (2) and (3), with the nickel atom having a positive charge of +1. By analogy with the $Ni(opd)_2$ species a similar structure for $Ni(din)_2$ and $Ni(dip)_2$ can be postulated; moreover, the similar spectroscopic behaviour for these three complexes (*vide infra*) suggests an α-diimine character of the ligands also in the $Ni(din)_2$ and $Ni(dip)_2$ species.

UV–vis characterization of $Ni(din)_2$ *and* $Ni(dip)_2$

The UV–vis spectra of $Ni(din)_2$ and $Ni(dip)_2$ can be interpreted by analogy with the spectroscopic behaviour of bis(*o*-phenylenediimine)nickel.[14] Figure 1 shows the UV–vis spectra at room temperature of $Ni(din)_2$ and $Ni(dip)_2$ in acetone solutions. For $Ni(din)_2$, the spectrum shape is similar to that of bis(*o*-phenylenediimine)nickel with an intense band ($\varepsilon_{max} = 7100$) at 742 nm. This band, responsible for the green–blue colour of the solution, suggests intermolecular interactions in solution depending on the concentration and the nature

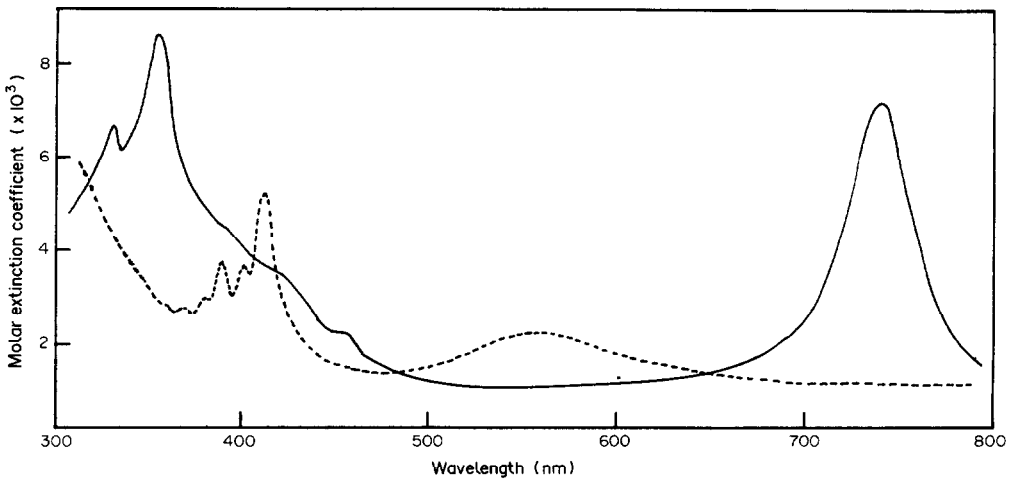


Fig. 1. UV–vis spectra in acetone solution for $Ni(din)_2$ (solid line) and $Ni(dip)_2$ (dotted line).

of the solvent.[14] For the less soluble complex, $Ni(dip)_2$, only very dilute (less than 5×10^{-5} M) pink–violet solutions in acetone were obtained. Under these conditions the spectrum shows a moderately intense band ($\varepsilon_{max} = 2120$) at *ca* 560 nm, as observed for dilute solutions of bis(*o*-phenylenediimine)nickel. This spectroscopic feature rules out strong intermolecular interactions for $Ni(dip)_2$ species under these experimental conditions.

Iodination chemistry: IR, Raman and TGA data

Iodination at room temperature of $Ni(din)_2$ and $Ni(dip)_2$ gives, respectively, green–gold and red–black microcrystalline powders. The iodine content, determined by TGA, is in good agreement with elemental analyses. For both compounds the iodine uptake is approximately 0.25–0.33 the amount of I_2 used in the reaction and depends on the reaction conditions. The reaction rate is dependent on the oxidant concentration, and the iodine uptake occurs slowly. No significant loss of iodine was observed during the drying operation. The $Ni(din)_2I_x$ and $Ni(dip)_2I_x$ species with maximum iodine content are not stable *in vacuo* (10^{-1} mm Hg) and slowly lose I_2 over a period of 1 week, finally giving stable compositions. At an elevated temperature (200°C) and under dynamic vacuum, complete removal of I_2 occurs leaving the starting $Ni(din)_2$ and $Ni(dip)_2$ species. A list of the complexes obtained, together with synthetic information and analytical data, are presented in Table 1.

The IR spectra of $Ni(din)_2$ and $Ni(dip)_2$ and of the iodinated compounds show characteristic absorptions for nickel complexes with aromatic diiminic ligands.[8] In fact all the compounds exhibit a strong N—H stretch around 3250–3300 cm^{-1}, C=C, C=N stretches in the 1400–1600 cm^{-1} region and an out-of-plane bending of the aromatic C—H in the region 740–900 cm^{-1}: the latter absorption's wavenumber is strongly dependent on the I/Ni ratio. Moreover, a series of bands in the region 1200–1400 cm^{-1} can be observed for the

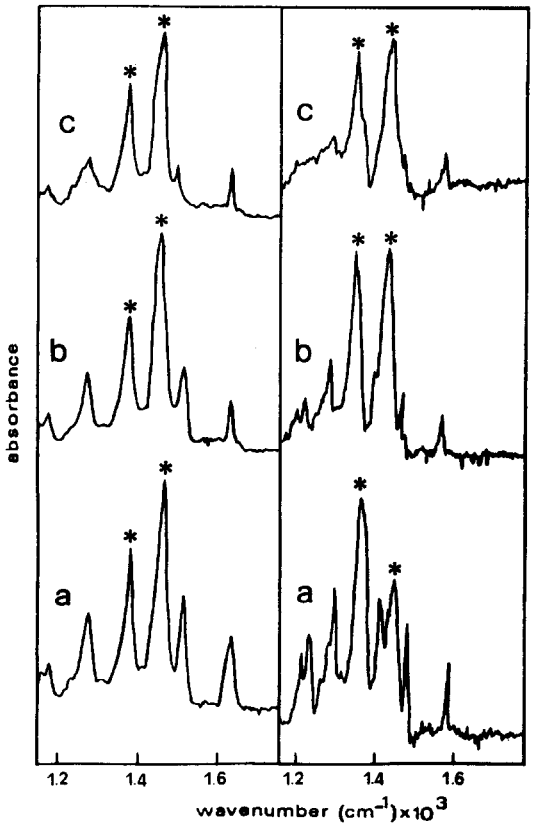

Fig. 2. IR spectra in the 1200–1800 region (cm^{-1}) as a function of iodine content. Left: $Ni(din)_2I_x$ (a, $x = 0$; b, $x = 0.55$; c, $x = 3.30$). Right: $Ni(dip)_2I_x$ (a, $x = 0$; b, $x = 0.56$; c, $x = 3.25$). Nujol absorption bands are marked by asterisks.

unoxidized complexes. As the iodine content increased, the IR peaks broadened and were finally obscured due to the superposition of the electronic excitation absorption.[15,16] This phenomenon is shown in Fig. 2.

Raman spectra (50–450 cm^{-1}) for $Ni(din)_2I_x$ and for $Ni(dip)_2I_x$ are shown in Fig. 3. Contributions from non-iodinated compounds in this region are negligible if compared with the resonances enhanced by the polyiodide modes. All iodinated compounds exhibit intense scattering at *ca* 107 cm^{-1}. According to previous spectroscopic studies on iodine-doped mixed-valence inorganic salts[17] and polyacetylene,[18] this band is assigned to the I_3^- fundamental symmetric stretching. Overtones are also observed at 214 cm^{-1} and 320–340 cm^{-1}. The band at 160 cm^{-1}, observed only for highly iodinated $Ni(din)_2I_x$ ($x > 0.55$) and $Ni(dip)_2I_x$ ($x > 0.21$), is assigned to I_5^-, in agreement with earlier works on iodine-doped fluorogallium

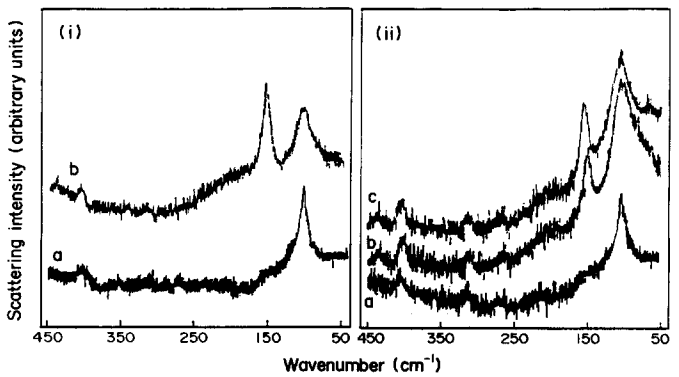

Fig. 3. Raman spectra in the range 50–450 cm^{-1}. (i) $Ni(din)_2I_x$ (a, $x = 0.15$; b, $x = 1.25$). (ii) $Ni(dip)_2I_x$ (a, $x = 0.13$; b, $x = 0.56$; c, $x = 1.20$).

and fluoroaluminium phthalocyanines[17] and polyacetylene.[19] No evidence for the presence of I_2 is obtained due to the lack of any bands around 207 cm^{-1}. Previous works[20,21] on iodinated molecular crystals do not provide any evidence for the presence of I^-. Anyway, this species is undetectable by any of the spectroscopic techniques utilized in this study.

Thermogravimetric analyses for $Ni(din)_2I_x$ and $Ni(dip)_2I_x$ reveal some most interesting features between room temperature and 260°C. Above this temperature range the thermograms are identical with those for non-iodinated complexes, showing weight losses at 400°C [$Ni(din)_2$] and 450°C [$Ni(dip)_2$] due to their decomposition. The thermograms for iodinated $Ni(din)_2I_x$ and $Ni(dip)_2I_x$ species with I/Ni ratios higher than 0.55 and 0.21, respectively, present two weight loss processes between 60 and 120°C, and 180 and 270°C, with a maximum of DTGA centred at 100 and 220°C (see Figs 4 and 5 for the $Ni(dip)_2I_x$ series). The weight loss at 100°C, according to the Raman spectra which show intense scattering at 160 cm^{-1} imputable to the presence of I_5^- polyiodide, is interpreted as decomposition of I_5^- to I_3^-. For the less iodinated complexes only one weight loss is observed (260°C) and attributed to the complex removal of I_3^-. These data are in agreement with the previous evidence[17] concerning the presence of I_5^- only in the highly iodinated species.

Electrical conductivity

Conductivity data at room temperature by both the linear two-probe technique on micropellets and the van der Pauw method on pressed discs are in excellent agreement for all the samples. At low temperature only the van der Pauw technique was used. Data at room temperature for all the species are reported in Table 1. Temperature dependence of the conductivity (plotted in Fig. 6 for three $Ni(dip)_2I_x$ complexes and for $Ni(din)_2I_{0.55}$) was investigated: the data fit the function $\sigma = \sigma_\infty \exp(-E_a/KT)$ and indicated a semiconducting behaviour for all the samples in the investigated temperature range from 77 K to room temperature. Activation energy depends on the ligands but is independent of iodine content. In fact E_a values of 0.25 and 0.075 eV for $Ni(din)_2I_{0.55}$ and for the three $Ni(dip)_2I_x$ complexes, respectively, are found, against an E_a value of 0.87 eV reported[6] for $Ni(opd)_2I$. The conductivity trend as a function of iodine content is plotted in Fig. 7 for both $Ni(dip)_2I_x$ and $Ni(din)_2I_x$ species. The data[8] concerning the $Ni(opd)_2I_x$ species are also reported for comparison. The main features of the reported data can be summarized:

(i) on increasing the iodine content, the conductivity of all the complexes first rises rapidly until a value of σ_{max}, and then decreases moderately;

(ii) the I/Ni ratio corresponding to the higher conductivity decreases on going from $Ni(opd)_2I_x$

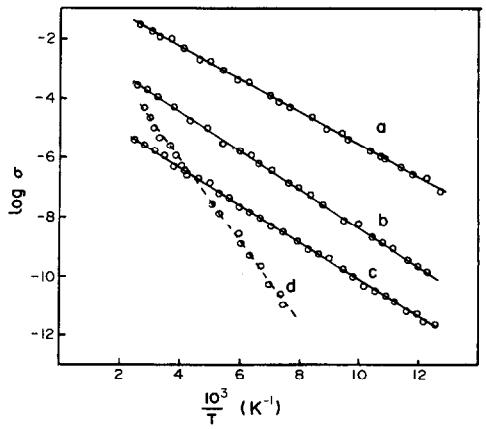

Fig. 6. Temperature dependence of the conductivity: (a) $Ni(dip)_2I_{1.20}$; (b) $Ni(dip)_2I_{0.30}$; (c) $Ni(dip)_2I_{0.21}$; (d) $Ni(din)_2I_{1.25}$.

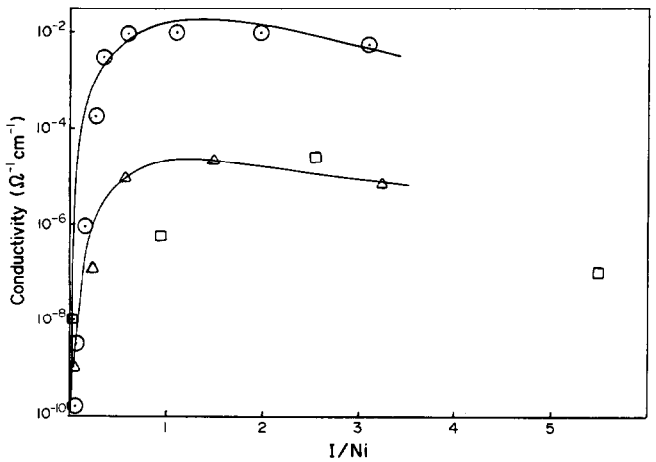

Fig. 7. Variation of the conductivity as a function of iodine content. (Δ, $Ni(din)_2I_x$; ⊙, $Ni(dip)_2I_x$; □, $Ni(opd)_2I_x$, ref. 8).

to $Ni(din)_2I_x$ and finally to $Ni(dip)_2I_x$. The highest conductivity ($10^{-2}\,\Omega\,cm^{-1}$) is observed at an I/Ni ratio of 0.56 in the case of $Ni(dip)_2I_x$;

(iii) for more extended complexes ($Ni(dip)_2I_x$ vs $Ni(opd)_2I_x$) an increase of the conductivity by a factor of 10^3–10^4 is observed.

These results, and in particular the observed trend that the increase of the molecular surface raises the electrical conductivity, suggest the influence of the ligands on the packing in the stacks. In fact, although structural analyses on these iodinated complexes were not performed, an X-ray structure determination on the unoxidized $Ni(opd)_2$ complex[22] shows a stacked packing with very large Ni—Ni distances (4.65 Å) and not a parallel stacking of the molecular planes. These packing features should be responsible for the modest conductivity of the $Ni(opd)_2I_x$ compounds. The diimines in $Ni(din)_2$ and in $Ni(dip)_2$, more extended than *o*-phenylenediimine, should favour a stacked packing with a large parallelism between the molecular planes and consequently a better overlapping of the π-system. X-ray measurements to understand better the steric role are in progress.

In conclusion, the results of this study demonstrate that partial iodine oxidation of nickel–aromatic diimine complexes provides an interesting new class of molecular conductors. All the chemical and physical properties of these compounds, including electrical conductivity, are comparable with that of the best known stacked molecular conductors. Moreover, to the best of our knowledge, $Ni(dip)_2I_{0.56}$ shows the higher conductivity value for open-ring $M—N_4$ partially oxidized systems.

THERMAL AND KINETIC STUDIES ON THE ADDUCTS WITH PYRIDINES OF BIS(ACETYLACETONATE)OXOVANADIUM(IV)

R. LOZANO,* J. MARTINEZ, A. MARTINEZ, J. ROMAN and F. DE JESUS

Departamento de Química Inorgánica y Bioinorgánica, Facultad de Farmacia, Universidad Complutense, 28040 Madrid, Spain

(*Received* 31 *March* 1989; *accepted* 16 *June* 1989)

Abstract—The kinetics of the thermal decomposition, under nitrogen, of several adducts with pyridine or substituted pyridines of bis(acetylacetonate)oxovanadium(IV), {[$VO(acac)_2$,B] where acac = acetylacetonate and B = pyridine (Py), 3-methyl-pyridine (3-MP), 4-methylpyridine (4-MP), 3,5-dimethylpyridine (3,5-DMP), 3-aminopyridine (3-AP) and 4-aminopyridine (4-AP)}, have been studied by differential scanning calorimetry (DSC). Activation energies and pre-exponential Arrhenius factors, for the endothermic process of the loss of one mole of coordinated base, have been calculated using a new method, and the mechanism of this reaction has been determined. A relationship between activation energies and the properties of the ligands has also been determined.

The determination of kinetic parameters by non-isothermal methods offers interesting advantages over conventional isothermal studies.[1] However, the methods usually employed for kinetic analysis[2–9] lead to ambiguous results, especially if the reaction studied follows a diffusion-controlled kinetic law.

In others papers, we have studied the synthesis, thermal behaviour and kinetic parameters, by Thomas and Clarke's procedure,[10] of several vanadium(IV) and molybdenum(IV) complexes with pyridine or substituted pyridines.[11–14] However, the results obtained, only have validity in a narrow range of the reaction. Lastly, we have reported a new method to carry out the kinetic analysis of non-isothermal decomposition reactions of inorganic compounds by means of differential scanning calorimetry (DSC).[15–18]

The primary objectives of the present paper were to apply this previously reported method to determine the mechanism of the process of thermal decomposition of several adducts with pyridine or substituted pyridines of [$VO(acac)_2$,B] [where acac = acetylacetonate and B = pyridine (Py), 3-methylpyridine (3-MP), 4-methylpyridine (4-MP), 3,5-dimethylpyridine (3,5-DMP), 3-aminopyridine (3-AP) and 4-amino-pyridine (4-AP)] which takes place.

We have determined the mechanism of the process to be:

$$[VO(acac)_2,B]\,(solid) \rightarrow VO(acac)_2\,(solid) + B\,(gas),$$

and we have calculated the activation energy and the pre-exponential Arrhenius factor, in all the adducts synthesized.

A comparison between the activation energies and the steric or inductive factors and pK_b values of the coordinated bases has also been explored.

EXPERIMENTAL

Preparation of complexes

The complex $VO(acac)_2$ and its adducts with pyridine or substituted pyridines, were prepared as previously reported.[12]

Thermogravimetric analysis

Thermogravimetric analysis was performed on a Mettler HE-20 thermobalance. The analytical constants were: heating rate, 5°C min^{-1}; TG range, 20 mV; record rate, 20 cm h^{-1}; sample mass, 20 mg; reference, Al_2O_3; thermocouple, Pt/Pt—Rh 80%. The analysis was made in a dynamic nitrogen atmosphere between 25 and 300°C. A platinum pan was used.

* Author to whom correspondence should be addressed.

Differential scanning calorimetry

Differential scanning calorimetry was performed using a Mettler TA 3000 system with a Mettler DSC-20 differential scanning calorimeter. The scanning rate used was 2°C min^{-1} and samples of about 5 mg were used, so as to render insignificant the temperature non-uniformity within the sample. An aluminium pan was used under a dynamic nitrogen atmosphere. The instrument calibration was checked periodically with standard samples of indium (99.99% purity). Several runs were made.

RESULTS AND DISCUSSION

The DSC curves of all the compounds, show a first endothermic peak. The mass loss accompanying this transition, corresponds, on the TG curves, to the loss of pyridine or substituted pyridine coordinated to vanadium, the residue, identified by IR spectroscopy, being $VO(acac)_2$ in all cases.

The DSC study of this endothermic process has allowed us to determine the activation energy and the pre-exponential Arrhenius factor by the method proposed previously.[15–18]

From the DSC curve of the adduct $[VO(acac)_2,3,5\text{-DMP}]$, we have constructed Table 1. In this table, α is the reacted fraction at time t and $\alpha' = d\alpha/dt$.

The reactions of thermal decomposition of solids can be expressed by the Arrhenius equation:

$$\frac{d\alpha}{dt} = A e^{-E_a/RT} f(\alpha).$$

In this equation, α is the fraction of material that has reacted at time t, E_a is the activation energy, $f(\alpha)$ is a function which depends on the actual reaction mechanism and A is the pre-exponential Arrhenius factor.

When the temperature of the sample is increased at a constant rate, we can write eq. (1), where β is the heating rate, dT/dt

$$\frac{d\alpha}{dT} = \alpha' = \frac{A}{\beta} e^{-E_a/RT} f(\alpha). \quad (1)$$

Table 1. ΔH, α, T and α' obtained from the DSC curve of the complex $[VO(acac)_2,3,5\text{-DMP}]$

We have collected in Table 2 the mathematical expressions of the functions $f(\alpha)$ corresponding to some of the mechanisms of thermal decomposition found in the literature.[1]

By differentiating the logarithmic form of eq. (1) with respect to $d \ln (1-\alpha)$, we obtain:

$$\frac{d \ln \alpha'}{d \ln (1-\alpha)} = -\frac{E_a}{R} \frac{d(1/T)}{d \ln (1-\alpha)} + \frac{d \ln f(\alpha)}{d \ln (1-\alpha)}$$

or

$$\frac{\Delta \ln \alpha'}{\Delta \ln (1-\alpha)} = -\frac{E_a}{R} \frac{\Delta(1/T)}{\Delta \ln (1-\alpha)} + \frac{\Delta \ln f(\alpha)}{\Delta \ln (1-\alpha)}$$

and

$$\frac{\Delta \ln \alpha' - \Delta \ln f(\alpha)}{\Delta \ln (1-\alpha)} = -\frac{E_a}{R} \frac{\Delta(1/T)}{\Delta \ln (1-\alpha)}. \quad (2)$$

Table 2. Kinetic equations

Mechanism (Rate-controlling process)		$f(\alpha)$
D1	(One-dimensional diffusion)	$(1/2\alpha)$
D2	(Two-dimensional diffusion)	$[-\ln(1-\alpha)]^{-1}$
D3	(Three-dimensional diffusion: Jander equation)	$(3/2)(1-\alpha)^{2/3}[1-(1-\alpha)^{1/3}]^{-1}$
D4	(Three-dimensional diffusion: Ginstling–Brounshtein equation)	$3/[2(1-\alpha)^{1/3}-1]$
F1	(Random nucleation)	$(1-\alpha)$
R2	(Phase-boundary reaction: Cylindrical symmetry)	$2(1-\alpha)^{1/2}$
R3	(Phase-boundary reaction: Spherical symmetry)	$3(1-\alpha)^{2/3}$

Table 3. Results obtained by using the seven mechanisms for the plot of $\Delta \ln \alpha' - \Delta \ln f(\alpha)/\Delta \ln(1-\alpha)$ vs $\Delta(1/T)/\Delta \ln(1-\alpha)$, for the complex [VO(acac)$_2$, 3,5-DMP]

Mechanism	Correlation coefficient (r)	Slope (m)	Intercept value (i)	Activation energy (kJ mol^{-1}) (E_a)
D1	−0.99998	−25927.34	0.91463	216±2
D2	−0.99998	−26105.84	0.50112	217±3
D3	−0.99999	−26085.44	−0.00870	217±2
D4	−0.99999	−26085.47	0.32464	217±2
F1	−0.99769	−11868.40	−0.44742	99±1
R2	−0.99768	−11868.40	0.05258	99±2
R3	−0.99769	−11868.41	−0.11409	99±1

Thus the plot of $[\Delta \ln \alpha' - \Delta \ln f(\alpha)]/[\Delta(1/T)]$ vs $\Delta(1/T)/[\Delta \ln(1-\alpha)]$ should be a straight line with a slope of $-E_a/R$, irrespective of the $f(\alpha)$ value employed. However, we can select the $f(\alpha)$ value that best fits the actual mechanism of the reaction studied using the intercept value; this should be zero from eq. (2).

Using the seven mechanisms listed in Table 2, we have plotted:

$$\frac{\Delta \ln \alpha' - \Delta \ln f(\alpha)}{\Delta \ln(1-\alpha)} \text{ vs } \frac{\Delta(1/T)}{\Delta \ln(1-\alpha)},$$

for the five adducts studied.

Table 3 shows the results, for the complex [VO(acac)$_2$,3,5-DMP] with r (correlation coefficient), m (slope), i (intercept value) and E_a (activation energy) obtained for the seven mechanisms.

We can observe that in all cases the correlation coefficients (r) are very near to unity, consistent with the results of Criado *et al.*[19] Nevertheless, only when the analysis was performed with mechanism D3 does the straight line present a low intercept value. Figure 1 reflects the representation of this line.

Therefore, we deduce that the mechanism of the thermal decomposition of the complex [VO(acac)$_2$,3,5-DMP] and loss of 3,5-dimethylpyridine, is by mechanism D3 (Three-dimensional diffusion: Jander equation) with a function $f(\alpha) = (3/2)(1-\alpha)^{2/3}[1-(1-\alpha)^{1/3}]^{-1}$, an activation energy $E_a = 217 \pm 2$ kJ mol^{-1} and a pre-exponential Arrhenius factor $A = (4.1 \pm 0.3) \times 10^{25}$ s^{-1}. The results obtained for the complexes studied in this paper, are listed in Table 4.

We can assume that the thermal decomposition of the adducts with pyridine or substituted pyridines follows a D3 mechanism.

If we compare the results, in general, as can be seen from the data in Table 4, the greater the basicity of the base employed, the higher the activation energy and the pre-exponential Arrhenius factor for the process of the loss of the base. The

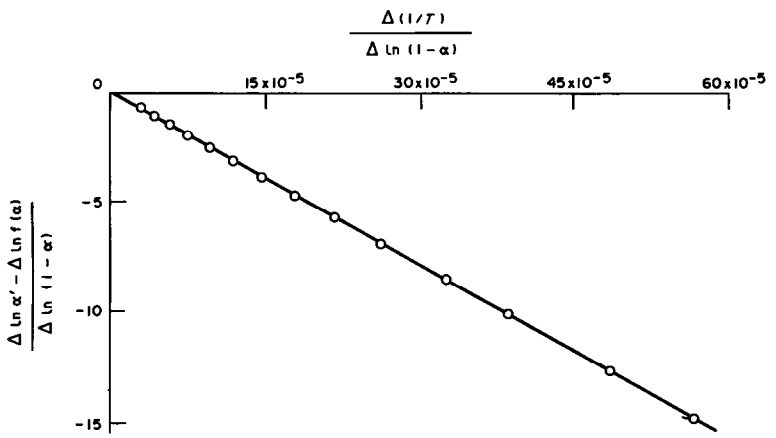

Fig. 1. Plot of $\Delta \ln \alpha' - \Delta \ln f(\alpha)/\Delta \ln(1-\alpha)$ vs $\Delta(1/T)/\Delta \ln(1-\alpha)$, for mechanism D3, for the adduct [VO(acac)$_2$,3,5-DMP].

Table 4. Thermal and kinetic parameters for the complexes [VO(acac)$_2$,B]

Complex	ΔH (kJ mol^{-1})	E_a (kJ mol^{-1})	A (s^{-1})	pK_b
[VO(acac)$_2$,Py]	56.4±0.7	144±2	(6.1±0.5)×10^{13}	8.87
[VO(acac)$_2$,3-MP]	43.9±0.5	182±2	(6.8±0.7)×10^{21}	8.32
[VO(acac)$_2$,4-MP]	63.9±0.7	205±3	(2.9±0.3)×10^{25}	7.98
[VO(acac)$_2$,3,5-DMP]	72.6±0.8	217±2	(4.1±0.3)×10^{25}	7.85
[VO(acac)$_2$,3-AP]	86.3±0.8	239±3	(3.3±0.4)×10^{29}	7.49
[VO(acac)$_2$,4-AP]	47.2±0.5	185±2	(1.3±0.2)×10^{23}	4.88

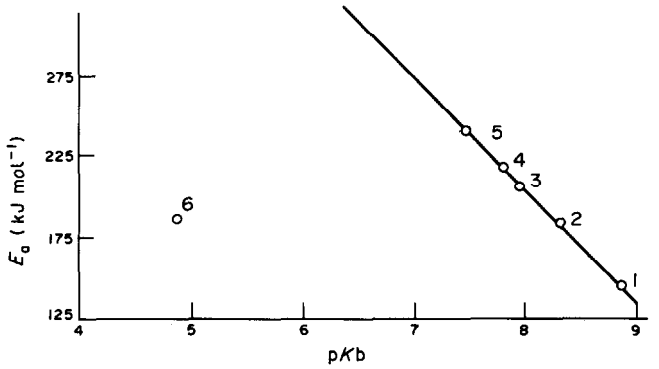

Fig. 2. Activation energy for decomposition of [VO(acac)$_2$,B] complexes as a function of pK_b. Points 1–6 correspond to complexes of Py, 3-MP, 4-MP, 3,5-DMP, 3-AP and 4-AP, respectively.

outstanding exception is the 4-AP adduct, which can be attributed to the existence of resonance structures and a pronounced effect on the stability of the complex.[11] It can be seen that the steric impediment of the 3,5-DMP does not modify the kinetic parameters.

The plot of pK_b vs activation energy presented in Fig. 2, shows that, except for the 4-AP adduct, a very satisfactory correlation was obtained. It is obvious from this figure that activation energy is linearly related to the basicity of the ligands.

CONTROLLED SYNTHESIS OF SOME MIXED DIIMINE RUTHENIUM(II) COMPLEXES

IBRAHIM JIBRIL,* TALAL S. AKASHEH and AMJAD M. SHRAIM

Department of Chemistry, Yarmouk University, Irbid, Jordan

(*Received* 14 *April* 1989; *accepted* 26 *June* 1989)

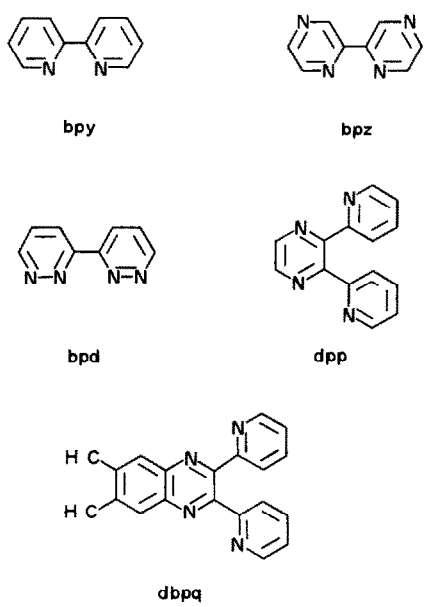
Abstract—Complexes of a series of mixed ligands with ruthenium have been prepared and characterized through dihalide replacement in $Ru(bpy)_2Cl_2$, $Ru(bpz)_2Cl_2$ and tetrahalide replacement in $HRu(bpy)Cl_4$ (bpy = 2,2′-bipyridine; bpz = 2,2′-bipyrazine) by one or two bidentate ligands of the diimine type namely, bpd, dbpq and dpp (bpd = 3,3′bipyridazine; dbpq = 6,7-dimethyl-2,3-bis-(2′-pyridyl)-quinoxaline; dpp = 2,3-bis-(2-pyridyl)-pyrazine). The ruthenium dimer $[(bpy)_2Ru(dbpq)Ru(bpy)_2](PF_6)_4 \cdot 3H_2O$, as well as the tris-complex $[Ru(dbpq)_3](PF_6)_2 \cdot H_2O$, were also prepared and characterized.

Ruthenium diimine complexes have been the centre of great interest due to their potential application in the chemical use of solar energy conversion.[1,2] Moreover, the use of ligand diimine complexes of ruthenium is of special interest because of the ability of ligands to modify their photophysical properties.

In view of the advantages of such complexes we have recently reported the synthesis of some ruthenium mixed-diimine complexes.[3] In continuation of our interest in this area we report herein the synthesis of a new series of similar complexes.

In a relatively simple and controlled reaction, a bidentate diimine ligand L (L = bpd, dbpq and dpp) replaces the two chloride atoms of the complexes $Ru(bpy)_2Cl_2$ or $Ru(bpz)_2Cl_2$ and the four chloride atoms of the $H[Ru(bpy)Cl_4]$ complex to produce the new mixed diimine complexes $[Ru(bpy)_2L](PF_6)_2$ (L = bpd, dbpq), $[Ru(bpz)_2L](PF_6)_2$ (L = bpd) and $[Ru(bpy)L_2](PF_6)_2$ (L = dbpq, dpp). The tris-complex $[Ru(dbpq)_3](PF_6)_2$ was prepared by reaction of $Ru(DMSO)_4Cl_2$ with dbpq (DMSO = dimethyl sulphoxide).

The dinuclear complex $[(bpy)_2Ru(dbpq)Ru(bpy)_2](PF_6)_4$ was obtained by the reaction of $Ru(bpy)_2Cl_2$ with dbpq when the ligand-to-complex ratio was 2 : 1.



EXPERIMENTAL

Materials

$Ru(bpy)_2Cl_2 \cdot 2H_2O$ was prepared according to the method of Sullivan *et al.*[4] $Ru(bpz)_2Cl_2 \cdot 2H_2O$ was prepared according to Lever's method.[5] $H[Ru(bpy)Cl_4]$ and $Ru(DMSO)_4Cl_2$ were prepared according to the method of Evans *et al.*[6] bpd was prepared according to Lafferty's method[7] and dbpq

* Author to whom correspondence should be addressed.

was prepared according to the method used to prepare 2,3-bis-(2-pyridyl)-quinoxaline.[8] dpp was prepared according to the method of Goodwin and Lions.[8]

Elemental analyses

These were carried out by M.H.W. Laboratories (P.O.Box 15853, Phoenix, AZ 85018, U.S.A.).

Physical measurements

UV-vis spectra were recorded with a CARY 2390 spectrophotometer. KBr disc IR spectra were taken on a Pye–Unicam SP3-300 spectrophotometer. Solution conductance, at 25°C in acetonitrile, was measured for 1×10^{-3} M concentration using a Harris conductivity meter. Cyclic voltammetry of the dimer on a Hi-Tek potentiostat was carried out in acetonitrile for oxidations and in DMF for reductions on a platinum working electrode against a platinum counter electrode and a SSCE reference electrode. The concentration of the dimer was 10^{-3} M and tetra-*n*-butylammonium hexafluorophosphate (0.1 M) was the supporting electrolyte.

Synthesis of complexes

General procedure. Two separate ethanol–water solutions (30%) containing stoichiometric amounts of the diimine ligand and the ruthenium complex, RuL_nX_{6-2n}, were mixed, and the reaction mixture was refluxed for 2–72 h (see Table 1). The product was precipitated by slowly adding a water solution of NH_4PF_6 to the reaction mixture while hot. After cooling in the refrigerator overnight, the precipitate was collected by filtration, washed with cold water, then washed with ether.

Purification of the product was performed by dissolving it in the minimum volume of acetone or acetonitrile and then precipitating with ether. This process was repeated several times. Further purification of the complexes was carried out by column chromatography using alumina columns made up in acetone. The eluted fraction containing the pure product, as checked by the quality of the luminescence spectra, was concentrated to $< 10\ cm^3$ and the product was precipitated with ether, collected by filtration, washed with ether and finally dried under vacuum. (Table 1 summarizes the details of the synthesis of each complex and their yields.)

Table 1. Reactions used for the synthesis of ruthenium diimine complexes

and the conductivity data given in Table 2. All the complexes except for the dimer (1 : 4) are 1 : 2 electrolytes as expected from their formula.[9]

The IR results are given in Table 3. The IR spectra for these complexes exhibit bands characteristic of the ligands. In particular, bands roughly in the range 1570–1615 cm^{-1} and 1545–1565 cm^{-1}[10,11] are assigned to the C=N and C=C stretchings in the ring of the bidentate ligands, respectively.

It is worth noting that the C=N stretching frequency in almost all the complexes reported here is higher than that of the free ligands.

Superscripts: $a = \nu$(OH); $b = \nu$(C=N); $c = \nu$(C=C); $d = PF_6$ peak.

Similar results have recently been observed[12] and an acceptable explanation[3] for this observation is due to the interplay of the σ- and π-bonding effects on the diimine ligands when complexed with transition metals. In such complexes, σ-bonding through normal donation from ligand-to-metal tends to strengthen the C=N by attracting the ring π-electrons towards the nitrogen atom, while π-bonding through back donation from metal-to-ligand weakens the C=N by adding electrons into the π^*-orbitals of the ring. In all cases, here, π-bonding seems to dominate the complexation effect of the C=N stretching frequency.

Unfortunately identification of the complexes' C=N frequency when nitrogen is not complexed has proved difficult due to the broadness and overlap of the peaks in both the free ligands and complexes.

Moreover, the strong bands around 830–840 cm^{-1} are assigned to the stretching frequency for the PF_6^- counter anions.[13]

The UV–vis results in Table 4 exhibit sharp peaks in the region 275–290 nm in all the complexes. These are attributed to ligand-centred π,π^* or n,π^* transitions. The broad shoulders below 390 nm in some complexes may be *d–d*, MLCT or LMCT bands.

The strong, very broad peaks in the visible region for the complexes are a superposition of many MLCT (metal-to-ligand charge-transfer) bands from the metal *d*-orbital to the diimine π^*-ligand orbitals. The red tailing region is often attributed to an absorption by the emissive, highly triplet in character, state (MLCT) responsible for most of the photochemical and photosensitizating behaviour of such complexes.[13,14] In the dimer a red shift of the lowest energy peak (592 vs 510 nm in $Ru(bpy)_2$ dbpq) is observed. This peak is assignable to an MLCT absorption into the bridging ligand π^*-orbital which gains additional stabilization by the

Values in parentheses are $\varepsilon \times 10^{-4}$ ($dm^3\ mol^{-1}\ cm^{-1}$).

introduction of the second metal atom.[15] The existence of the two metal centres is immediately noticed in the cyclic voltammogram of the dimer. Two quasi-reversible oxidation peaks [Fig. 1(a)] at 1.51 and 1.68 V correspond to two consecutive Ru^{II}/Ru^{III} oxidation steps of the metal centres. Five reduction quasi-reversible peaks [Fig. 1(b)] (−0.36, −1.06, −1.22, −1.61 and −1.80 V) correspond to the consecutive introduction of one electron into the π^*-orbitals of each ligand. The stabilization of the π^*-orbital of the bridging ligand (dbpq) is evident from the first reduction peak (−0.36 V) compared to −0.77 V for the π^*-orbital of dbpq in $[Ru(bpy)_2dbpq]^{2+}$.[16]

THE MOLAR ABSORPTIVITY OF SODIUM HYPONITRITE

CHARLOTTE N. CONNER, CAROLINE E. DONALD, MARTIN N. HUGHES* and CHRISTINA SAMI

Department of Chemistry, King's College London, Strand, London WC2R 2LS, U.K.

(*Received* 13 *June* 1989; *accepted* 26 *June* 1989)

Abstract—The molar absorptivity of sodium hyponitrite at 248 nm (λ_{max}) has been redetermined as 6550 ± 100 dm^3 mol^{-1} cm^{-1}.

The molar absorptivity of sodium hyponitrite at 248 nm (λ_{max}) is usually quoted[1] as 3980 dm^3 mol^{-1} cm^{-1}. However, we have frequently prepared sodium hyponitrite with substantially higher molar absorptivities than this. A value of 6550 ± 200 dm^3 mol^{-1} cm^{-1}, reported by Polydoropoulos and Voliotis,[2] is not widely cited. These observations suggest that studies on hyponitrite chemistry have usually been carried out on highly impure material. This is probably due to the presence of sodium carbonate formed by absorption of CO_2 during work-up of the product and by reaction of CO_2 with solid sodium hyponitrite.[3] Recently it has been shown that the decomposition of hyponitrite in solution is catalysed by CO_2 which forms an adduct at nitrogen, followed by rate-determining isomerization to give the unstable *cis*-hyponitrite ion.[4]

We have now redetermined the molar absorptivity of sodium hyponitrite.

EXPERIMENTAL

Sodium hyponitrite was prepared by the reduction of nitrite with sodium amalgam[1] under an atmosphere of nitrogen, either in a glove box or a plastic bag. A solution of sodium nitrite (12.5 g) in water (20 cm^3) was added to the continuously-swirled amalgam (prepared, with appropriate precautions, from 70 cm^3 of mercury and 12 g of sodium metal) in a 500 cm^3 conical flask cooled in ice. After the initial vigorous reaction had subsided, the mixture was transferred to a thick-walled 250 cm^3 separating funnel and shaken until gas evolution had ceased. The aqueous layer was run into 400 cm^3 absolute ethanol. The residues in the funnel were washed into the ethanol with 2 cm^3 of dilute alkali. Crystalline, hydrated sodium hyponitrite was precipitated on vigorous stirring and filtered off under nitrogen. The off-white product was dissolved in the minimum volume of dilute alkali (no more than 3 cm^3), the solution filtered and the filtrate added to 400 cm^3 of absolute ethanol, with vigorous stirring. The hydrated sodium hyponitrite was filtered off under nitrogen and stored in a vacuum desiccator over P_4O_{10}. The anhydrous product was formed over several days, and stored in a vacuum desiccator or in sealed ampoules.

Preparations of sodium hyponitrite were analysed for carbon and hydrogen (reproducible values for nitrogen could not be obtained), for sodium by atomic emission spectroscopy (Perkin–Elmer 2380 instrument), and for nitrite by a standard colorimetric method involving the diazotization of sulphanilic acid and coupling to β-naphthol. IR spectra were recorded as Nujol mulls, prepared under nitrogen (Perkin–Elmer 1310 instrument). UV spectra were measured for solutions of sodium hyponitrite in 1 mol dm^{-3} alkali (to limit self-decomposition) in 1 cm matched silica cells on Perkin–Elmer Lambda 3 and SP5-600 spectrometers. Spectra were remeasured after 5 and 10 min to check the stability of the solutions.

RESULTS AND DISCUSSION

Data for seven samples of sodium hyponitrite are given in Table 1, including the measured values of the molar absorptivity at 248 nm (ε_m) and values corrected to allow for the impurity of the sample (ε_c).

All samples of sodium hyponitrite contained negligible or undetectable amounts of nitrite, the highest amount being less than 0.1% by weight. The IR spectra showed that most samples contained traces

1	6020	0.39	0.33	42.3	3.45[b]	2.97[b]	6440
2	6320	0.55	0		4.86[b]	0	6645
3	5960	1.03	0		9.10[b]	0	6560
4	6150			41.7	[b]	4.00[b]	> 6410
5	6390				[b]		> 6390
6	6310				[b]		> 6310
7	6000				[b]	[b]	> 6000

[a] Mean value for samples 1–3 is $6550 \pm 100\ dm^3\ mol^{-1}\ cm^{-1}$.
[b] Detected in the IR spectrum of the sample.

of carbonate and/or water, which was confirmed by elemental analysis. Table 1 lists the amounts of sodium carbonate and water present in the samples calculated from these data. The analytical data for sodium is not sensitive to contamination by sodium carbonate.

The measured values of the molar absorptivities lie in the range 5960–6390 $dm^3\ mol^{-1}\ cm^{-1}$. For three of these samples, with extinction coefficients 6000, 6310 and 6390, elemental analyses were not carried out as decomposition of the samples occurred, but their IR spectra showed the presence of carbonate and/or water. These values must be lower than the true value. The sodium carbonate present in some samples appears to have been formed during the work-up procedure rather than during subsequent measurements, as repeat spectroscopic and elemental analyses were reproducible provided the sample was not exposed to the atmosphere. It appears, therefore, that all measurements on a particular sample have been carried out at a constant level of carbonate and may be related to each other. Table 1 contains values of the molar absorptivities corrected to allow for the impurities of water and sodium carbonate, where present (ε_c). The mean value for samples 1–3 is $6550 \pm 100\ dm^3\ mol^{-1}\ cm^{-1}$, in agreement with that reported by Polydoropoulos and Voliotis.[2] The remaining values in Table 1 represent uncorrected values but confirm the overall picture.

Samples of sodium hyponitrite left on a watch glass exposed to the atmosphere showed a substantial fall (up to 60%) in absorptivity over a few hours, emphasizing the need to store sodium hyponitrite under conditions where CO_2 is excluded. In a separate experiment, a sample stored in a vacuum desiccator showed a fall in molar absorptivity of between 5–10% on each measurement if no precautions were taken to exclude water and CO_2 during the preparation of the solution for optical density measurement.

It is clear from these experiments that it is very difficult to prepare and maintain pure samples of sodium hyponitrite and that the bulk of all published work on hyponitrite has been carried out on material that was probably at best only about 60% pure. Most kinetic studies[5] appear to have involved conditions where the rate law is first-order or pseudo-first-order in hyponitrite, so that the lack of purity will not have had any major effects on rate constants. However, it is possible that the use of hyponitrite of purity close to 50% could lead to misleading conclusions about the stoichiometries of reaction.

REACTIONS OF SOME DIMETHYLAMINOPHOSPHONIUM SALTS WITH LIQUID HYDROGEN CHLORIDE

KEITH B. DILLON,* NABIL D. A. H. KHABBASS and CLIFFORD J. LUDMAN*

Chemistry Department, University of Durham, South Road, Durham DH1 3LE, U.K.

(*Received* 19 *April* 1989; *accepted after revision* 30 *June* 1989)

Abstract—The reactions of the dimethylaminophosphonium ions $[P(NMe_2)_xPh_{4-x}]^+$ ($x = 1$–3), $[P(NMe_2)_xCl_{4-x}]^+$ ($x = 2$ or 3), $[P(NMe_2)Me_xCl_{3-x}]^+$ ($x = 1$ or 2) and of $P(NMe_2)_3O$ with liquid hydrogen chloride have been investigated by means of ^{31}P NMR spectroscopy. In most instances cleavage of one (or more) of the P—N bonds is observed, although the rate of reaction varies considerably with the other substituents on phosphorus.

Comparatively few reactions of organophosphorus(V) compounds with liquid hydrogen chloride have been described.[1] Compounds containing P=O double bonds were found by means of ^{31}P NMR spectroscopy to protonate to some extent on the phosphoryl oxygen, and the order of base strengths of the phosphorus species could be deduced from analysis of the results.[1] None of the compounds examined had nitrogen substituents on phosphorus, however. A preliminary experiment on the aminophosphonium salt $[P(NMe_2)Cl_3]_2^+PCl_6^-$, Cl^- suggested that the cation was stable to liquid HCl.[2] In the presence of BCl_3, however, the P—N bond was broken, and the PCl_4^+ ion was identified by ^{31}P NMR[3] as the only phosphorus-containing product. The reaction was formulated[2] as

$$[P(NMe_2)Cl_3]_2^+PCl_6^-,Cl^- + 4HCl + 5BCl_3 \longrightarrow 2Me_2NH_2^+BCl_4^- + 3PCl_4^+BCl_4^- \quad (1)$$

We have now carried out a systematic investigation of the behaviour of several dimethylaminophosphonium salts and related compounds in liquid hydrogen chloride, with various substituents on phosphorus. Cleavage of one (or more) P—N bonds is usually observed, although the reactions are very slow if no organo-substituents are present on phosphorus. The reaction products have been identified by ^{31}P NMR spectroscopy; shifts obtained are in good agreement with independent data.

* Authors to whom correspondence should be addressed.

EXPERIMENTAL

All manipulations including NMR sample preparation were carried out either *in vacuo* or under an inert atmosphere of dry nitrogen. The dimethylaminophosphonium salts were prepared by the action of dimethylchloramine, Me_2NCl, on the appropriate phosphine; these preparations will be described in detail elsewhere.[4] Hydrogen chloride was purified as described in previous publications.[5] Other chemicals were obtained commercially and were used without further purification. NMR samples in liquid HCl, as solvent, were prepared as in earlier work;[1] the tubes were sealed and allowed to warm to 313 K in a water thermostat bath behind protective bricks in a fume cupboard, to make sure that they would withstand the pressure at the spectrometer operating temperature. ^{31}P NMR spectra were recorded at 307.2 K on the Fourier transform spectrometer operating at 24.29 MHz, as described previously.[6] Chemical shifts are quoted relative to external 85% H_3PO_4, with the downfield (higher frequency) direction taken as positive.

RESULTS AND DISCUSSION

The results for individual compounds are discussed separately.

(a) $[P(NMe_2)Ph_3]^+Cl^-$

A clear, colourless solution was obtained from reaction of this compound with liquid HCl. Its ^{31}P

NMR spectrum showed a single sharp resonance at 66.2 ppm, readily ascribed to the $[PPh_3Cl]^+$ cation.[7-15] Hence, liquid HCl cleaves the P—N bond, and the probable reaction is

$$[P(NMe_2)Ph_3]^+Cl^- + 4HCl \longrightarrow [PPh_3Cl]^+HCl_2^- + Me_2NH_2^+HCl_2^- \quad (2)$$

(b) $[P(NMe_2)_2Ph_2]^+Cl^-$

Again one sharp resonance, at 71.5 ppm, was observed, after the sample had been kept at room temperature for 3 h, and was assigned to the $[P(NMe_2)Ph_2Cl]^+$ cation. This species was obtained independently by chlorination of $P(NMe_2)Ph_2$, and gave a shift of 70.9 ppm in CH_2Cl_2 as solvent. A value of 72.5 ppm has also been reported for $[P(NMe_2)Ph_2Cl]^+SbCl_6^-$ in $MeNO_2$ solution.[16] When the tube was kept at room temperature for a further 15 h and its spectrum re-recorded, this resonance had disappeared, and had been replaced by a signal at 93.5 ppm, due to the formation of $[PPh_2Cl_2]^+$.[8,9,13-15] Thus cleavage of both P—N bonds occurs within 1 day, and the overall reaction may be represented as

$$[P(NMe_2)_2Ph_2]^+Cl^- + 7HCl \longrightarrow [PPh_2Cl_2]^+HCl_2^- + 2Me_2NH_2^+HCl_2^- \quad (3)$$

(c) $[P(NMe_2)_3Ph]^+Cl^-$

A single ^{31}P NMR resonance at 51.6 ppm was observed when the spectrum was run shortly after the tube had been warmed to room temperature. This was ascribed to the starting material, which gives a shift of 51.6 ppm in CH_2Cl_2; the bromide $[P(NMe_2)_3Ph]^+Br^-$ gives a value of 51.4 ppm in the same solvent. After 2 days, the ^{31}P NMR spectrum showed two resonances, a major one at 51.6 ppm (starting material), and a minor one at 72.1 ppm, assigned to $[P(NMe_2)_2PhCl]^+$. The latter was obtained independently by chlorination of $P(NMe_2)_2Ph$, and gave a signal at 67.8 ppm in CH_2Cl_2. After the sample had been kept for 14 days at room temperature, a single sharp resonance was observed at 101.0 ppm, readily attributed to the $[PPhCl_3]^+$ ion.[8,9,12-15,17] Thus, slow cleavage of the P—N bonds takes place in this system. The intermediate ion $[P(NMe_2)PhCl_2]^+$ was not detected, but may be presumed to have formed and then undergone solvolysis during the 14 day period. The overall reaction is

$$[P(NMe_2)_3Ph]^+Cl^- + 10HCl \longrightarrow [PPhCl_3]^+HCl_2^- + 3Me_2NH_2^+HCl_2^- \quad (4)$$

(d) $[P(NMe_2)_3Cl]^+Cl^-$

The clear, colourless solution showed one resonance only, at 53.3 ppm, from the starting material. No change was detected after 16 h at room temperature, and again after 35 days. This result implies that the P—N bonds of this compound are not cleaved by liquid HCl.

(e) $P(NMe_2)_3O$

The purity of the commercial material was checked by ^{31}P NMR. The spectrum of the solution in liquid HCl showed one sharp signal at 30.3 ppm, ascribed to the formation of $P(NMe_2)_2ClO$.[18-20] After the solution had been kept at room temperature for 1 day, its ^{31}P NMR spectrum showed two resonances, a major one at 33.3 ppm ($P(NMe_2)_2ClO$), and a minor one at 15.8 ppm, assigned to $P(NMe_2)Cl_2O$.[20,21] After 5 days, only one signal was detected, at 15.6 ppm, but after 21 days a single resonance was found at 1.6 ppm, ascribed to PCl_3O.[22] Hence, the three P—N bonds are cleaved by liquid HCl, the rate of reaction decreasing with successive replacement of Me_2N groups by Cl groups. The overall reaction is

$$P(NMe_2)_3O + 9HCl \longrightarrow PCl_3O + 3Me_2NH_2^+HCl_2^- \quad (5)$$

(f) $[P(NMe_2)_2Cl_2]^+Cl^-$

The solution gave a single peak at 51.6 ppm, due to the starting material. After the solution had been kept for 6 days at room temperature, an additional minor resonance was detected at 61.3 ppm from the $[P(NMe_2)Cl_3]^+$ ion. After 1 month, two equally intense resonances at 51.6 and 60.3 ppm were observed. Hence very slow cleavage of one of the P—N bonds takes place, according to the equation:

$$[P(NMe_2)_2Cl_2]^+Cl^- + 4HCl \longrightarrow [P(NMe_2)Cl_3]^+HCl_2^- + Me_2NH_2^+HCl_2^- \quad (6)$$

After a further 14 days, the deposition of a large quantity of a white, crystalline solid was seen on the walls of the tube. The ^{31}P NMR spectrum showed three broad signals, at 51.6 (starting material), 60.3 ($[P(NMe_2)Cl_3]^+$) and -302.1 ppm, attributed to the PCl_6^- ion.[11,22] The second P—N bond of the starting material is thus cleaved eventually, and a hexachlorophosphate is produced, reaction (7):

$$[P(NMe_2)Cl_3]^+HCl_2^- + HCl \longrightarrow Me_2NH_2^+PCl_6^- \quad (7)$$

The six-coordinate species is presumably stabilized by the insolubility of the dimethylammonium salt, since the PCl_6^- ion has been reported to break up in liquid HCl to give the PCl_4^+ ion.[23] There was no evidence for such a reaction here, however.

(g) $[P(NMe_2)Me_2Cl]^+Cl^-$

When the ^{31}P NMR spectrum was recorded as soon as possible after completion of the safety check (Experimental), one resonance only, at 131.6 ppm, was detected from the clear solution, readily assigned to the $[PMe_2Cl_2]^+$ ion.[15,24] The P—N bond is readily cleaved in this reaction, eq. (8):

$$[P(NMe_2)Me_2Cl]^+Cl^- + 4HCl \longrightarrow [PMe_2Cl_2]^+HCl_2^- + Me_2NH_2^+HCl_2^- \quad (8)$$

(h) $[P(NMe_2)MeCl_2]^+Cl^-$

As in the previous system, only one signal was observed under similar conditions, at 122.1 ppm, due to the $[PMeCl_3]^+$ ion.[15,17,24,25] The course of this reaction is therefore similar, as shown in eq. (9):

$$[P(NMe_2)MeCl_2]^+Cl^- + 4HCl \longrightarrow [PMeCl_3]^+HCl_2^- + Me_2NH_2^+HCl_2^- \quad (9)$$

(i) *General discussion*

Liquid HCl reacts with most of the dimethylaminophosphorus(V) derivatives studied to cleave one or more P—N bonds and introduce chlorine on phosphorus, though the rate of reaction varies greatly with the other substituents present. Organo-groups, both aliphatic (Me) and aromatic (Ph), seem to increase the rate of reaction compared with similar species with no organo-groups present. The rate decreases, however, with increasing numbers of NMe_2 groups, and is slower for phenyl than for methyl substituents. The $[P(NMe_2)_3Cl]^+$ ion appears to be stable in this medium. The initial reaction in each case may be a protonation of one of the NMe_2 groups, followed by an S_N2 attack by the chloride ion on the resultant complex.

Protonation will be favoured by electron-supplying groups on phosphorus such as methyl, thus accounting for the observed rate increase. The dimethylamino-groups are also electron-donating, and will assist in delocalizing the formal positive charge on phosphorus in the aminophosphonium salts. Donation is possible from a nitrogen lone pair into a vacant *d*-orbital on phosphorus, giving some π-character to the P—N bond and increasing its strength. Protonation at nitrogen will destroy any such π-interaction, however, and render the P—N bond liable to cleavage by a stronger ligand such as chloride. With more NMe_2 groups present, the possibilities of π-interactions are increased, and protonation may not take place as readily. The positive charge will also be delocalized over more atoms, making the phosphorus less susceptible to nucleophilic attack. A combination of these two factors may thus account for the enhanced stability of the $[P(NMe_2)_3Cl]^+$ ion to bond cleavage by HCl.

SULPHUR TRANSFER TO CYANIDE: THE RÔLE OF RHODANESE

ANTHONY R. BUTLER,* CHRISTOPHER GLIDEWELL and ANNE E. WADDON

Chemistry Department, University of St. Andrews, Fife KY16 9ST, Scotland, U.K.

(*Received* 10 *May* 1989; *accepted* 24 *July* 1989)

Abstract—High thiocyanate levels are found in the blood of patients receiving nitroprusside. NMR evidence is presented which suggests that this is not due to the action of rhodanese on cyano-ligands or on free cyanide released from nitroprusside. Although there is no sulphur transfer from thiocyanate to cyanide, even in the presence of rhodanese, the analogous reaction with selenocyanate occurs.

^{13}C NMR is a convenient means of detecting sulphur, and other chalcogen, transfer to cyanide either as a spontaneous reaction or catalysed by the enzyme rhodanese (thiosulphate: cyanide sulphur transferase, EC 2.8.1.1). This enzyme is active in the liver and is the body's means of detoxifying cyanide to give innocuous thiocyanate, which can be excreted. For *in vitro* experiments, thiosulphate is a ready source of sulphur which can be utilized by the enzyme. The mechanism of rhodanese action has been extensively reviewed by Westley.[1]

Our interest in the action of this enzyme was occasioned by reports[2–6] that patients to whom sodium nitroprusside $\{Na_2[Fe(CN)_5NO]\}$ had been administered as a hypotensive agent had elevated plasma thiocyanate levels. This was taken as evidence that nitroprusside had broken down *in vivo* to give free cyanide which had then been detoxified to thiocyanate. This evidence for *in vivo* formation of free cyanide conflicts with our studies,[7,8] indicating the stability of the $[Fe(CN)_5]$ moiety. So we examined the ability of rhodanese to convert cyanide ligands into free thiocyanate to see if thiocyanate could be formed without the intermediacy of free cyanide.

RESULTS AND DISCUSSION

In aqueous TRIS buffer, pH 8.6, dilute solutions of KCN and KSCN have, from natural abundance ^{13}C NMR spectra, chemical shifts of 163.9 and 13.56 ppm, respectively, due to the presence, at that pH, of HCN (pK_a 9.2) and $[SCN]^-$ (pK_a of HSCN is −1.8). In the same medium the axial and equatorial cyanide ligands of nitroprusside have shifts of 134.8 and 136.7 ppm. Addition of sodium thiosulphate had no effect on these NMR spectra, showing that there is no non-enzymic transfer of sulphur to free cyanide or cyanide ligand. Also, addition of cyanide to the nitroprusside solution had no effect, confirming the absence of cyanide exchange in this substitution inert d^6 complex.

When 90% of ^{13}C-enriched sodium cyanide was mixed with a 50% molar excess of sodium thiosulphate, the ^{13}C NMR spectrum showed the presence of only $H^{13}CN$. However, on addition of rhodanese the spectrum of $H^{13}CN$ was gradually replaced by that of $[S^{13}CN]^-$ (Fig. 1), showing complete and quantitative sulphur transfer from thiosulphate to cyanide, eq. (1):

$$H^{13}CN + S_2O_3^{2-} \rightarrow H^+ + S^{13}CN^- + SO_3^- . \quad (1)$$

Reaction was complete in 2 h. In similar experiments using $Na_2[Fe(^{13}CN)_5NO]$ instead of $Na[^{13}CN]$, no transfer of sulphur from thiosulphate to give $[S^{13}CN]^-$ was observed, even after an incubation time of 24 h, indicating the inertness of cyanide as a ligand to iron. However, it is known[9] that a number of cyanometallate anions, including $[Au(CN)_2]^-$, $[Ni(CN)_4]^{2-}$, $[Zn(CN)_4]^{2-}$ and $[Pt(CN)_4]^{2-}$, bind to rhodanese at a site adjacent to the active site pocket and thereby inhibit binding of the thiolating agent. However, repetition of the reaction between $Na[^{13}CN]$ and sodium thiosulphate, in the presence of unlabelled sodium nitroprusside, again showed quantitative sulphur transfer according to eq. (1). Thus nitroprusside is not an inhibitor of rhodanese. The NMR spectrum of

* Author to whom correspondence should be addressed.

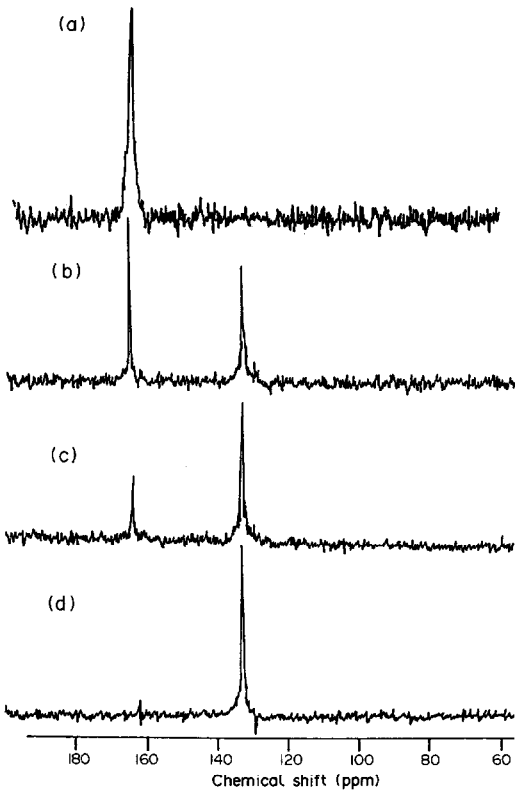

Fig. 1. ^{13}C NMR spectral changes occurring on incubation of 1 M Na[^{13}CN] with 3 M sodium thiosulphate in the presence of rhodanese; (a) start, (b) 30 min, (c) 90 min, (d) 150 min. The accumulation time was 5 min.

$Na_2[Fe(^{13}CN)_5NO]$ in TRIS buffer was unchanged by addition of rhodanese, indicating that nitroprusside does not bind strongly to the enzyme. Binding to vitamin B_{12} produces considerable spectral changes.[10]

The possibility that a blood component might mediate sulphur transfer to the cyano-ligands of nitroprusside was investigated. Two components, haemoglobin and glutathione, are known[11–13] to effect reduction of nitroprusside with formation of $[Fe(CN)_6]^{4-}$ via the substitution-labile d^7 complex $[Fe(CN)_4NO]^{2-}$, although no free cyanide is formed in these reactions. Incubation of 5×10^{-3} M ^{13}C-labelled sodium nitroprusside with sodium thiosulphate and rhodanese, using whole blood as solvent rather than TRIS buffer, gave no indication of thiocyanate formation even after 24 h although the ^{13}C NMR signal was strong. This confirms our belief that no free cyanide is formed on interaction of nitroprusside with whole blood, but leaves open the question of why patients receiving nitroprusside have high plasma thiocyanate levels.

In vivo, the probable source of sulphur for transfer to cyanide is thiosulphate, as it was in the experiments described above. It is formed enzymatically in the liver and kidney from a reaction between β-mercaptopyruvic acid and inorganic sulphite,[14] both of which arise from the metabolism of L-cysteine. In view of the simplicity of our method it was easy to see if, *in vitro*, the enzyme can use other sources of sulphur. We confirmed that thiocyanate cannot act as a source of sulphur[15] and so the equilibrium of eq. (2) does not occur, either

$$[^{13}CN]^- + [SCN]^- \rightleftharpoons [S^{13}CN]^- + [CN]^- \quad (2)$$

spontaneously or in the presence of rhodanese. In a similar way, no sulphur transfer occurs from thiourea. Rhodanese is thought to act by formation of a persulphide bond within the enzyme by capturing a sulphur from the donating agent; it appears that this occurs only with agents which can readily donate a sulphur, such as thiosulphate.

On the other hand, a mixture of $[^{13}CN]^-$ and $[SeCN]^-$ showed two equally strong signals with chemical shifts of 119.5 and 163.9 ppm, assigned to $[Se^{13}CN]^-$ and H[^{13}CN], respectively, within a few minutes of mixing. The equilibrium in eq. (3) is set up rapidly but it is

$$[SeCN]^- + [^{13}CN]^- \rightleftharpoons [CN]^- + [Se^{13}CN]^- \quad (3)$$

not so fast that it gives only an averaged signal in the NMR spectrum. The spectrum was unaffected by addition of rhodanese. It is probable that the much faster transfer of selenium from $[SeCN]^-$ compared with the corresponding transfer of sulphur from $[SCN]^-$ is related to the much larger atomic size of selenium and the corresponding longer bond to carbon: Se—C distances are typically 1.90–2.00 Å, while S—C distances are some 0.10–0.15 Å shorter. Bonding interactions in the intermediate $[X(CN)_2]^{2-}$ are therefore significant at longer separations between $[CN]^-$ and $[XCN]^-$, when X = Se than when X = S, so reducing the repulsive forces between the two negatively charged reactants. Selenourea does not act as a source of selenium, either spontaneously or in the presence of rhodanese.

EXPERIMENTAL

[^{13}C]-sodium cyanide at 90% enrichment was purchased from MSD Isotopes and was used as received. The preparation of ^{13}C-labelled nitroprusside has been described previously.[16] All manipulations involving nitroprusside were carried out in the absence of light. Other materials were AnalaR grade. Rhodanese with a specific activity of 10 units mg^{-1} was purchased from Sigma. All reactions involving rhodanese were carried out in TRIS buffer pH 8.6.

The NMR spectra were taken on a Bruker AM

300 spectrometer in the FT mode at 25°C with a field of 7.04 T. The lock was D_2O.

Blood was donated by A.R.B.

(*Received* 17 *May* 1989; *accepted* 31 *July* 1989)

Abstract—The structure of tetrasulphur tetranitride, S_4N_4, determined by gas-phase electron diffraction has D_{2d} symmetry with four nitrogen atoms at the corners of a square, bridging four of the six edges of an approximately tetrahedral S_4 unit. The bonded sulphur–nitrogen distance $\{r_a[S(1)—N(1)]\}$ is 1.623(4) Å while the short unbridged sulphur–sulphur distance $\{r_a[S(1)\cdots S(2)]\}$ is 2.666(14) Å. The longer nitrogen-bridged sulphur–sulphur distance $\{r_a[S(1)\cdots S(3)]\}$ is 2.725(10) Å which is almost as short as the unbridged distance. The important angles in the molecule are $\angle$N(1)—S(1)—N(3) at 105.3(7)°, $\angle$S(1)—N(1)—S(3) at 114.2(6)°, $\angle$S(2)$\cdots$S(1)—N(1) at 88.4(9)°, and the interplanar angle between the plane of the four nitrogen atoms and the S(1)—N(1)—N(3) plane which is 92.5(3)°.

As elsewhere, fashions in chemical research come and go. Thus sulphur–nitrogen chemistry—a field initiated in 1835 when S_4N_4 was first isolated[1]—proceeded in fits and starts until 1973 when it was shown that polythiazyl, $[SN]_x$, a compound first prepared in 1910,[2] is a species capable of exhibiting metallic, and even super conductivity.[3] There then followed a flurry of research activity with new routes to thin films of $[SN]_x$ being avidly sought. Of the published routes, most require S_4N_4 as the starting material. Two of the commonly used methods involve the pyrolysis of S_4N_4, either over silver wool[3,4] or over Pyrex/quartz wool at *ca* 275°C.[5] A third route is via the polymerization of the red material that is formed when S_4N_4 is pyrolysed over silver wool[6] or silver selenide.[7] All of these routes involve reactions of gaseous S_4N_4. Accordingly, the vapour transport of S_4N_4 is of current interest, as is its structure in the gas phase.

Many years after its discovery, S_4N_4 was shown to be tetrameric[8] and there have been two reports of structural investigations by electron diffraction using the visual method. Both reports state that S_4N_4 exists as a molecular species of D_{2d} symmetry.[9,10] They differ in the nature of the conformations proposed for the S_4N_4 array. In the first study, it was suggested that the structure consists of a square plane of four sulphur atoms linked to a tetrahedron of four nitrogen atoms, a structure

*Author to whom correspondence should be addressed.

analogous to that found in β-realgar, As_4S_4.[9] In the second study[10] the molecule was said to have a plane of four nitrogen atoms linked to an approximate tetrahedron of four sulphur atoms, an arrangement in accord with the solid-state structure of S_4N_4 which has been determined by X-ray diffraction both at room temperature[11] and at 120 K.[12] However, in adducts formed with BF_3,[13] $SbCl_5$,[14] or SO_3,[15] the S_4N_4 unit adopts the β-realgar form. As the energy barrier between the two molecular forms of S_4N_4 having D_{2d} symmetry is likely to be small, a mixture of forms may be present in the gas phase, especially at the elevated temperatures needed to vaporize the compound (approximately 150°C). Accordingly, it was decided to re-investigate the gas-phase structure by electron diffraction using the methods that have superseded the visual method.

EXPERIMENTAL

Tetrasulphur tetranitride was prepared from S_2Cl_2 and NH_4Cl via thiotrithiazyl chloride, S_4N_3Cl,[16,17] and recrystallized from either chloroform or liquid sulphur dioxide. Samples were placed in sealed ampoules which were loaded into the nozzle arrangement of the electron-diffraction apparatus and opened *in situ*.

Electron-diffraction photographs were obtained from the Reading University apparatus,[18] which is fitted with a rotating sector whose angular opening is proportional to r^3. The nozzle-to-plate distances were 494.88 and 244.40 mm, and the data were obtained with the nozzle in the temperature range 139–175°C. The electron wavelength, approximately 0.062 Å, was calibrated against diffraction pictures of benzene.[19] Two plates from the long and two from the short camera distance were selected for use in the final analysis. The data spanned the ranges $3.25 \leqslant s \leqslant 14.75$ Å^{-1} and $9.00 \leqslant s \leqslant 29.00$ Å^{-1} at intervals of $\Delta s = 0.25$ Å^{-1}. The experimental data were processed as described previously[18] with scattering factors being taken from refs 20 and 21. Average curves were produced for each camera distance, and these are depicted in Fig. 1.

Root-mean-square vibrational amplitudes (l), perpendicular amplitude corrections (K) and centrifugal distortions (δr) were calculated from an assumed valence force field using values for the force constants (see Table 1) obtained from studies of S_4N_4.[22,23]

Analysis of the structure

The refinements of the structure were based upon the molecule depicted in Fig. 2, which contains the atom numbering scheme. As shown, the molecule has D_{2d} symmetry with the four nitrogen atoms forming a square, while the sulphur atoms form an approximate tetrahedron. As the molecule has such relatively high symmetry, it is necessary only to

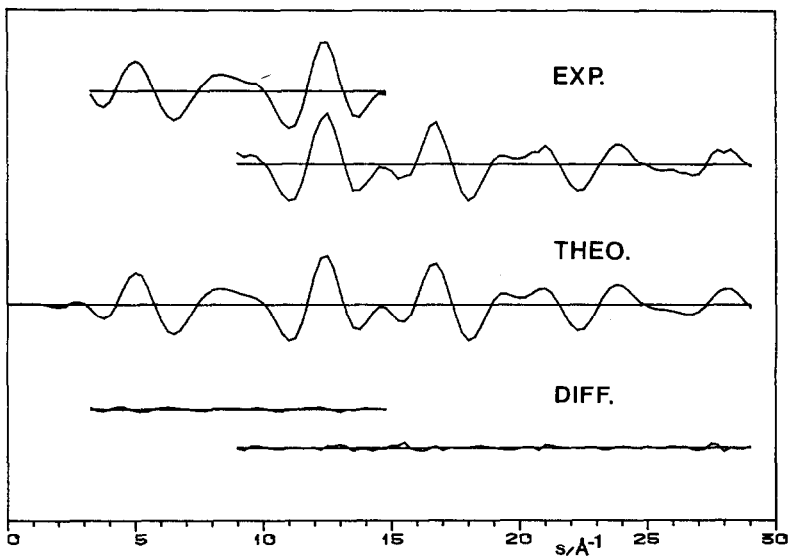

Fig. 1. Intensity curves $sI_m(s)$ for S_4N_4. Experimental curves (EXP) are averages of all the data from the plates for the two camera distances. The theoretical curves (THEO) were calculated from the structural parameters shown in Table 1 for model 1. The difference curves (DIFF) result from subtracting the relevant part of the theoretical curve from the experimental curves.

Table 1. Force constants used in the calculation of l, K and δr values for tetrasulphur tetranitride[22,23]

S(1)—N(1) stretch	3.76
S(1)···S(2) stretch	0.25
S(1)—N(1)—S(3) bend	1.78
N(1)—S(1)—N(3) bend	1.39
S(1)—N(1)/S(3)—N(2) torsion	0.31
S(1)—N(1)/S(1)—N(3) interaction	−0.64
S(1)—N(1)/N(1)—S(1)—N(3) interaction	0.10
S(1)—N(1)/S(1)—N(1)—S(3) interaction	0.52

Units for force constants: mdyne $Å^{-1}$, stretch, stretch–stretch interaction; mdyne, stretch–bend interaction; mdyne Å, bend, torsional.

define the positions of one sulphur and one nitrogen atom relative to an axis system to define the whole molecule. A suitable axis system has the centre of the square of the nitrogen atoms as its origin with the x- and y-axes bisecting the sides of the square. Thus, all the atoms are defined by three coordinates. The nitrogen atoms, which lie in the xy-plane, are defined by one coordinate which is equal to half the length of the side of the N_4 square. The sulphur atoms are defined by two coordinates. If the x-axis is chosen to bisect the N(1)···N(3) distance (see Fig. 2), the S(1) atom is defined by an x- and a z-coordinate.

To define the folding of the S_4N_4 unit a dependent dihedral angle, Φ, was calculated. This describes the angle between the N—S—N plane and the plane of the nitrogen atoms. The angle was defined so that, if the x-coordinate of S(1) is greater than that of N(1), Φ is greater than 90°. For reference purposes this model is called model 1. The most likely possible alternative model is obtained by interchanging the positions of the sulphur and nitrogen atoms

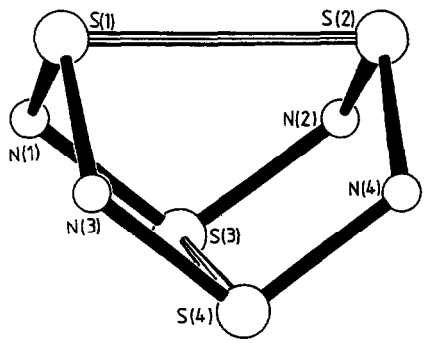

Fig. 2. The S_4N_4 molecule (model 1) with the atom numbering scheme.

from those shown in Fig. 2. As stated in the introduction, this model, called model 2, is related to that of β-realgar and is shown by S_4N_4 in certain of its coordination compounds.[13–15]

Refinements of the structures defined by models 1 and 2 were carried out by the least-squares procedure based on the intensity curves by adjusting one theoretical curve to the two averaged experimental curves (one from each nozzle-to-plate distance) using a unit weight matrix.[18] For model 1 it was possible to refine all of the vibrational amplitudes {the amplitude l[N(2)···N(4)] was tied to amplitude l[N(2)···N(3)]}, together with all the geometric parameters. For model 2 it was necessary to tie the two S···S amplitudes as well as the two N···N amplitudes in order to prevent them from having unrealistic values. Results from the final refinements for models 1 and 2 are recorded in Table 2. The average experimental and theoretical curves are shown in Fig. 1, while the radial distribution (RD) curves for models 1 and 2, calculated in the usual manner by Fourier transformation of the $s[I_m(s)]$ values after multiplication by $(Z_N Z_S/f_N f_S)\exp(-0.0025s^2)$, are shown in Fig. 3, together with the appropriate difference curves.

RESULTS AND DISCUSSION

To interpret electron-diffraction data, it is necessary to propose a model for the structure of the molecule under investigation, and to carry out refinements on the model to ascertain if it can be fitted to the experimental data. Thus the choice of model is all-important, and in selecting such a model attention must obviously be given to the known chemistry of the species, as more than one model can often be fitted to the data. If a single unambiguous model cannot be proposed, a number of models must be investigated. As S_4N_4 is known to adopt two structural forms in its various derivatives, refinements were carried out to ascertain which structural form is adopted in the gas phase, or, alternatively, if a mixture of the two forms is present. The structure found for S_4N_4 in the solid phase,[11,12] is related to that in Fig. 2 and this was refined as model 1. The alternative form, found in certain coordination compounds of S_4N_4 (model 2),[13–15] differs from that in model 1 by having the sulphur and nitrogen atoms transposed. Refinements of both models were carried out (see Table 2), and the resulting radial distribution curves for both models, together with the experimental radial distribution curve, and the difference curves, are shown in Fig. 3. It is obvious that model 2 does not fit the experimental data. The difference between the experimental and theoretical radial distribution

		0.082				0.22	

[a] Distances (r_α and r_g) and amplitudes (l) in Ångstroms, and angles ($\angle_\alpha$) in degrees. Parenthesized uncertainties are 2σ and include estimates of systematic errors and correlation in the experimental data.

[b] Model 1 is the molecule as depicted in Fig. 2.

[c] Model 2 is the molecule as depicted in Fig. 2 with the nitrogen and sulphur atoms transposed.

[d] The N···N amplitudes were tied during the refinement.

[e] The N···N amplitudes were tied as a pair during the refinement and the S···S amplitudes were similarly treated.

[f] ∠Φ is an interplanar angle which in model 1 is the angle between the plane of the four nitrogen atoms and the N(1)—S(1)—N(3) plane.

[g] $R = [\Sigma w_i \Delta_i^2 / \Sigma w_i (s_i I_i(\text{obs.}))^2]^{1/2}$, where $\Delta_i = s_i I_i(\text{obs.}) - s_i I_i(\text{calc.})$.

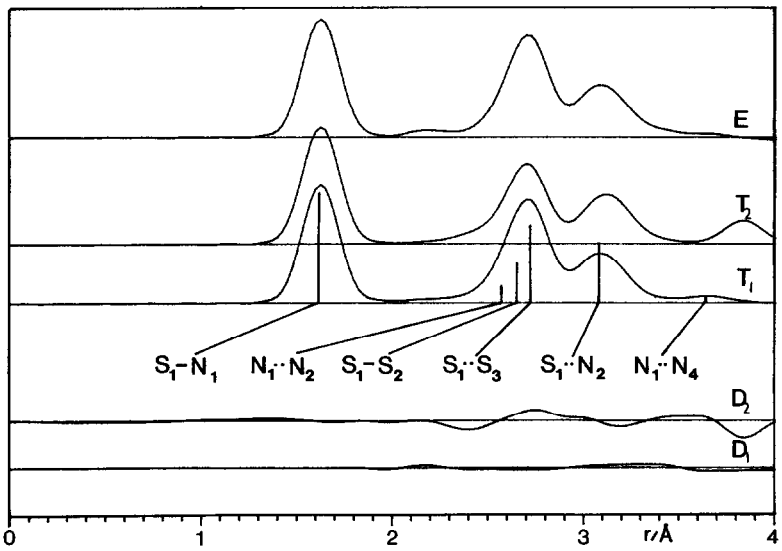

Fig. 3. Radial distribution curves for S_4N_4 showing the experimental (E), theoretical (T_1 for model 1 and T_2 for model 2) and the difference (D_1 for model 1 and D_2 for model 2) curves. The radial distribution curves were calculated using the theoretical curves that yielded the data contained in Table 2. To obtain the radial distribution curves the theoretical curves were first multiplied by $Z_N Z_S / f_N f_S \exp(-0.0025 s^2)$, and theoretical data were used for the unobserved area, $s < 3.75$ Å^{-1}.

curves is particularly apparent around 3.8 Å where model 2 requires a S···S distance (Table 2) which is not seen in the experimental data. The possibility that the vapour consists of a mixture of the two forms (models 1 and 2) was investigated by allowing the structural parameters, and the relative percentages of the two models, to refine. The R factor varies with the percentage composition of the two isomers (models 1 and 2) as follows: 100% model 1, $R = 0.082$; 95% model 1 and 5% model 2, $R = 0.085$; 90% model 1 and 10% model 2, $R = 0.089$; 85% model 1 and 15% model 2, $R = 0.094$. Thus the best fit to the experimental data was obtained with 100% of model 1. We can conclude that, in the gas phase, S_4N_4 has the structural form depicted in Fig. 2. There is a slight difference between the radial distribution curve for model 1 and the experimental data (see Fig. 3), although a satisfactory R factor of 0.082 was obtained. It is known that the thermal decomposition of S_4N_4 gives rise to S_4N_2[24] and S_2N_2.[25] Thus it is possible that the presence, in the gas phase, of trace amounts of these other sulphur–nitrogen compounds may account for the small differences observed between the experimental curves and the theoretical ones for model 1 (see Figs 1 and 3). Accordingly, refinements were carried out to ascertain if such impurities were present in the gas phase by adopting a procedure similar to that used to investigate the model 1/model 2 ratio. In these investigations, the S_4N_4/S_4N_2 or S_4N_4/S_2N_2 ratio and the parameters for S_4N_4 were refined, while the molecular parameters of the impurity under examination were set at the values obtained by X-ray crystallography.[26,27] No improvement in the fit between the experimental and theoretical curves was obtained on the introduction of either impurity. We are therefore confident that, under the conditions of our experiments, S_4N_4 volatilizes without decomposition, and adopts the structure shown in Fig. 2, namely model 1.

In any analysis of electron- and X-ray diffraction data, it is the r_α distances from the electron-diffraction studies that provide the best basis for comparison. The r_α[S(1)—N(1)] bonded distance (1.623(4) Å) is close to that reported in X-ray diffraction studies, whether at room temperature (mean value 1.616(17) Å)[11] or at 120 K (mean value 1.630 Å).[12] The angle between the plane of the four nitrogen atoms and that formed by N(1), S(1) and N(3) is 92.5(3)° and so r_α[S(1)···S(2)] (2.666(14) Å) is greater than r_α[N(1)···N(2)] (2.580(14) Å), whereas the reverse situation occurs in the solid phase. Thus the r_α[S(1)···S(2)] distance is slightly larger than that found in the solid phase (mean values 2.582(8) Å[11] at room temperature and 2.599 Å[12] at 120 K), although close to the value calculated in the earlier electron-diffraction study by Lu and Donohue[10] (2.69 Å). All attempts to refine r_α[S(1)···S(2)] to a value closer to that seen in the crystal failed. The larger S(1)···S(2) distance in the gas-phase structure of S_4N_4 is ascribable to the lack of close intermolecular contacts that impart packing forces. In the crystal structure, there are several non-bonded contacts below 3.3 Å involving interactions between either sulphur and nitrogen or nitrogen and nitrogen atoms,[12] and this, along with other crystal packing effects, results in a more compact structure in the solid phase than in the gas phase.

The angles in the ring, namely ∠[S(1)—N(1)—S(3)] 114.2(6)°) and ∠[N(1)—S(3)—N(2)] (105.3(7)°), are comparable with the mean values observed in the solid state (∠S—N—S angles: 113.1(7)[11] and 112.6(9)°;[12] ∠N—S—N: 104.5(15)[11] and 104.5(8)°[12]).

The observed structure cannot be represented in a simple single model based on classical notions of bonding. There have been numerous papers devoted to the problem of the bonding in S_4N_4,[28–31] and to the relative stabilities of the two possible conformations (models 1 and 2) for S_4N_4.[32,33] We do not wish to amplify the discussion here. However, comments on the size of r_α[S(1)···S(2)] and r_α[S(1)···S(3)] are appropriate. At 2.666(14) Å, the r_α[S(1)···S(2)] distance, while longer than the S—S distance in S_8 (2.04 Å),[34] is much shorter than twice the van der Waals radius for sulphur (3.70 Å), implying that there is a bonding interaction between S(1) and S(2). The second S—S distance, r_α[S(1)···S(3)] (2.725(10) Å), is almost as short as the unbridged S—S distance. So the question arises; does this distance also represent a S—S bonding interaction? If it does, then S_4N_4 can be visualized as an S_4 tetrahedron with four of its six edges bridged by nitrogen atoms. Alternatively, the shortness of r_α[S(1)···S(3)] could be assumed to be primarily a consequence of the angle subtended at the nitrogen atom. Then we must ask: why should such a small angle be subtended? It is interesting to compare the structure of S_4N_4 with that of $S_4N_4 \cdot SO_3$,[15] where the S_4N_4 fragment has a structure similar to that of β-realgar. Here the S—N—S angles range from 116 (the angle subtended at the nitrogen atom bound to SO_3) to 138 and 140°. There seems, therefore, to be no *a priori* reason, other than to form a short r_α[S(1)···S(3)] interaction, for the adoption of the small S—N—S angles reported here for S_4N_4. Such a model for S_4N_4 contrasts with that seen for the α-form of P_4S_4,[35] where the phosphorus atoms form an approximate tetrahedron, while the sulphur atoms, that are all in a plane, bridge four of the six edges of the P_4 tetrahedron. The two types

of P—P distance are 2.360(3) Å (unbridged) and 3.218(5) Å (sulphur-bridged), and so exhibit a much greater dissimilarity than the two types of S—S distance in S_4N_4. Therefore the S_4 unit in S_4N_4 has a structure that is closer to a tetrahedron than is the P_4 moiety in P_4S_4.

Abstract—The N-alkyldithiocarbamate ligands when bidentately-coordinated to the nickel triad elements undergo facile electrophilic substitution reactions with a diversity of electrophiles affording novel carbodithioato derivatives of weak nitrogenous bases, not available by other methods.

In the course of our investigations on the reactions of the square-planar d^8 bis(N-alkyldithiocarbamato)metal(II) complexes with Lewis bases (L), we have demonstrated that dithiocarbimato complexes formulated as $[M(S_2C{=}NR)L_2]$ and $[M(S_2C{=}NR)_2]^{2-}$ can be isolated.[1–4] The mechanism of these reactions at the level of the frontier molecular orbital approach of chemical reactivity has been fully investigated by EHMO–SCCC calculations.[5] According to these investigations, the acidic character of the hydrogen atom of the bidentately-coordinated parent N-alkyldithiocarbamate ligands, as well as the high nucleophilicity of the nitrogen atom of the resulted dithiocarbimate ligands, have been verified. It is readily apparent from these reactivity patterns that the square-planar d^8 $[M(S_2CNHR)_2]$ complexes could easily undergo electrophilic substitution reactions, affording new classes of carbodithioato complexes, according to Scheme 1.

Taking advantage of this reactivity pattern, convenient, straightforward routes to carbodithioato derivatives of weak nitrogenous bases, such as secondary amides, ureas, amino acid esters, carbamic esters and sulphonamides, have emerged. In this respect, some of the resulting novel carbodithioate ligands are shown in Table 1. The direct preparation of such ligands by the reaction of the corresponding weak nitrogenous base with carbon disulphide in alkaline media is difficult or impossible to achieve, although some examples concerning the formation of N-formyl and N-methyl N-formyl dithiocarbamates and their thioformyl analogues have already been published.[6–10] However, no reports on their corresponding coordination compounds with transition metals have been found by us to date. Therefore, the novel nickel(II) complexes of the aforesaid carbodithioate ligands reported herein are probably some of the first examples in the pure chemistry of the dithiocarbamate ligands which may be considered as derivatives of weak nitrogenous bases. It is important to note, at this point, that all our efforts to prepare the corresponding free ligands according to the procedure described by Gattow *et al.*[6] were unsuccessful, leading to unstable easily oxidized species.

In a typical reaction concerning the synthesis of the bis(N-alkyl N-acetyldithiocarbamato)nickel(II)

complexes,[11] $[Ni\{S_2CN(COMe)R\}_2]$ (R = Me, Et, Bu^i, Bz, Ph, *p*-MePh, *p*-ClPh), the following procedure was adopted: 1 mmol of the appropriate $[Ni(S_2CNHR)_2]$ complex was dissolved in acetone and treated with 2 mmol of triethylamine and 2 mmol of acetic anhydride. In the resulting solution a solid material was formed, which on addition of water was quantitatively separated. Purification was achieved by dissolving the solid in chloroform and re-precipitating with ethanol (yield: 75%). It should be noted that by changing the molar ratio of the reactants to 1:1:1, the mixed-ligand (N-alkyldithiocarbamato)(N-alkyl N-acetyldithiocarbamato)nickel(II) complexes can also be isolated in relatively high yields. A similar procedure was followed for the synthesis of the rest of the carbodithioato nickel(II) complexes by using the appropriate precursor of the corresponding electrophile. Obviously, in the case of $[Ni\{S_2CN(PhHNCO)R\}_2]$ complexes, the presence of triethylamine as the deprotonating agent was unnecessary. All of these compounds are non-conducting, diamagnetic, and quite stable both in solid and solution states.

Inspection of the spectroscopic (Table 2) and magnetic data of the compounds under study clearly indicates the bidentate bonding mode of the carbodithioate ligands in the complexes and their

square-planar configuration. Although all the ligands also possess an oxygen donor atom capable of bonding to the central atom forming a six-membered chelate ring, involving O- and S-coordination, such bonding has been excluded on the basis of spectroscopic data. Therefore, all these new compounds have broadly similar structures, involving the square-planar NiS_4 chromophore. However, in order to establish further their geometries, an X-ray diffraction study has been carried out on a member of this series, namely the $[Ni\{S_2CN(COMe)Bz\}_2]$ complex.[12]

Obviously, any attempt to further extend these electrophilic substitution reactions by using a great diversity of electrophiles, as well as other transition metal ions, would be of great importance, for it is possible to obtain novel compounds whose structures, chemical reactivities and applications are worth studying. Some of them, especially those of iron(III), are expected to extend further the area of six-coordinated iron complexes exhibiting either the low-spin configuration or intermediate spin states. Moreover, it is possible to obtain indirectly, via degradation of the complexes, organic and bioorganic compounds involving peptide-type bonds. Work along these lines is continuing in our laboratory.

USE OF ^{14}N AND ^{73}Ge NMR SPECTROSCOPY FOR ELUCIDATION OF PRODUCTS OF THE REACTION BETWEEN $GeCl_4$ AND KSCN IN ACETONE

Ē. KUPČE, E. UPENA, M. TRUŠULE and E. LUKEVICS*

Institute of Organic Synthesis, Latvian SSR Academy of Sciences, Riga, 226006, U.S.S.R.

(*Received* 19 *December* 1988; *accepted* 19 *May* 1989)

Abstract—^{73}Ge and ^{14}N NMR spectra were used to study reaction products and chemical exchange processes in the system $GeCl_4$+KSCN+acetone-d_6. At the $GeCl_4$ to KSCN ratios from 2 : 1 to 1 : 4, germanium(IV) derivatives of the type $Ge(NCS)_nCl_{4-n}$ were formed. Rapid intermolecular exchange with Cl and NCS groups was observed between the $Ge(NCS)_nCl_{4-n}$ (n = 0–4) molecules with varying n. The formation of dimeric and/or larger intermediate complexes has been suggested. This is accompanied by simultaneous formation of $[Ge(NCS)_nCl_{6-n}]^{2-}$ anions (n = 4–6). The 2D phase sensitive ^{14}N NOESY spectrum has indicated the existence of relatively slow intermolecular exchange between $Ge(NCS)_nCl_{4-n}$ (n = 1–4) and $[Ge(NCS)_4Cl_2]^{2-}$ species in solution. The content of $[Ge(NCS)_6]^{2-}$ increased with the amount of KSCN added. At a ratio of 1 : 6 this was practically the only product found in solution. A further increase in the amount of KSCN apparently resulted in a germanium derivative with a higher coordination number involved in rapid intermolecular exchange with free NCS^- ions in the solution.

^{73}Ge NMR studies are scarce because of the low resonance frequency (3.49 MHz at B_0 = 2.35 T) involved and due to the quadrupole moment of the ^{73}Ge nuclei (spin I = 9/2) impeding the recording of NMR spectra.[1,2] For this reason, investigations mainly involve symmetrically-substituted derivatives of tetracoordinate germanium (GeR_4 for R = H, Alk, Ar, OR, NR_2, SR, Hal),[3,4] as well as some germatranes containing pentacoordinate germanium atoms.[5,6] Only one paper reports the use of ^{73}Ge NMR for studying reaction products.[7] Recently, we have reported for the first time the ^{73}Ge spectra for hexacoordinate germanium in the $[Ge(NCS)_6]^{2-}$ anion.[8,9] The present communication demonstrates that the combined use of ^{73}Ge and ^{14}N NMR facilitates a more detailed analysis of reaction products and chemical exchange processes in the system $GeCl_4$+KSCN+acetone-d_6.

DISCUSSION

The ^{14}N chemical shift of a KSCN solution in acetone-d_6 (−171 ppm, see Table 1) occupies an intermediate position between that observed for the covalent derivatives RSCN (−100±10 ppm) and RNCS (−275±20 ppm),[10] indicating that KSCN occurs in the ionic form in the solution. Pure $GeCl_4$ shows a relatively narrow ^{73}Ge NMR signal (line width at half height $\Delta\nu_{1/2}$ = 2.1 Hz) at 30.9 ppm.[7]

Addition of a KSCN solution in acetone-d_6 to $GeCl_4$ results in the considerable broadening of the ^{73}Ge signal and its displacement to higher fields (see Table 1). This is accompanied by the occurrence of a ^{73}Ge signal at −443 ppm corresponding to $[Ge(NCS)_6]^{2-}$ ion (see Fig. 1). Two major signals are also observed in the ^{14}N spectra of these solutions (see Fig. 2) at *ca* −225 and −270 ppm, respectively. The chemical shifts of these resonances suggest the bonding of the NCS fragments to the germanium atom via N but not via S.

The ^{14}N signal at −225 ppm corresponds to the

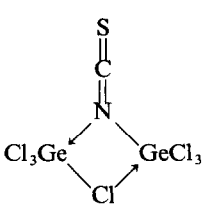
[a] Chemical shifts (δ) in ppm, line width at half height ($\Delta\nu_{1/2}$) in Hz, relative signal intensities (A) are rough estimates, as at significant difference in line widths the intensity of broad signals is decreased due to relaxation in the pre-acquisition delay.[11]

$[Ge(NCS)_6]^{2-}$ ion.[8,9] The downfield shift of this signal relative to the range characteristic of covalent derivatives of the type RNCS indicates enhanced polarity of the Ge—M bond in the anion $[Ge(NCS)_6]^{2-}$. The ^{14}N signal observed at −270 ppm suggests the formation of a germanium(IV) derivative of the type $Ge(NCS)_nCl_{4-n}$ in solution. ^{73}Ge chemical shifts for $Ge(NCO)_4$ ($\delta = -88.9$ ppm[8,9]) suggest that the ^{73}Ge resonance for $Ge(NCS)_nCl_{4-n}$ ($n = 1$–4) must be observed at higher fields than for $GeCl_4$. On the other hand, the lack of the narrow ^{73}Ge signal characteristic of $GeCl_4$ in an excess of the latter indicates that the broad ^{73}Ge resonance observed at 14–25 ppm is an averaged signal. This suggests the presence of rapid intermolecular exchange between $GeCl_4$ and $Ge(NCS)_nCl_{4-n}$, the upfield shift of ^{73}Ge signal reflecting an altered ratio of various $Ge(NCS)_nCl_{4-n}$ derivatives in favour of larger n. A certain narrowing of the ^{73}Ge resonance at the $GeCl_4$ to KSCN ratio of 1:1 indicates the predominance of one derivative, apparently $GeCl_3NCS$, in solution.

The most plausible mechanism for the observed exchange is the formation of dimeric and/or larger intermediate structures of type **I**. The involvement



I

X = Cl, NCS

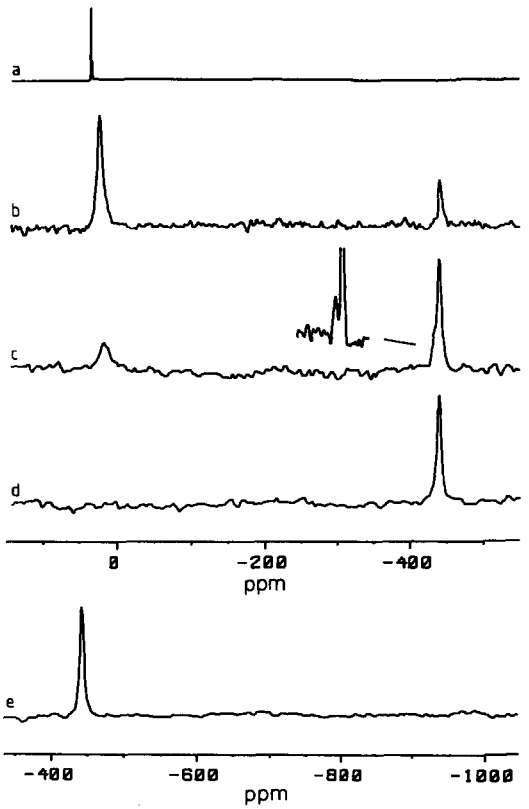


Fig. 1. ^{73}Ge NMR spectra of $GeCl_4$+KSCN in acetone-d_6 at (a) 1:0, (b) 1:1, (c) 1:2, (d) 1:6 and (e) 1:20 ratios.

of the $[Ge(NCS)_6]^{2-}$ anion in this exchange is insignificant, as the chemical shift and the corresponding ^{14}N signal line width were not subject to appreciable variation.

The low intensity signals also detected in the ^{14}N and ^{73}Ge spectra (see Table 1 and Figs 1 and 2) indicate the formation of small amounts of $[Ge(NCS)_nCl_{6-n}]^{2-}$ (n = 5–6) type derivatives.

The phase sensitive 2D ^{14}N NOESY spectrum of a 1:2 mixture of $GeCl_4$+KSCN (see Fig. 3) showing cross-peaks between the signals corresponding to $Ge(NCS)_nCl_{4-n}$ and $[Ge(NCS)_4Cl_2]^{2-}$ molecules, indicates the existence of intermolecular exchange between these species. To our knowledge this is the first application of 2D techniques in the ^{14}N NMR spectroscopy.

A further increase in KSCN content in the reaction mixture leads to some broadening and subsequent disappearance of the ^{73}Ge signal corresponding to germanium(IV) derivatives, as well as to enhanced intensity of the signal corresponding to the $[Ge(NCS)_6]^{2-}$ anion. The ^{14}N spectra indicate that this may be due not only to decreased content of $Ge(NCS)_nCl_{4-n}$ in solution, but also to decreased symmetry of charge distribution around the ^{73}Ge nuclei.

At the ratio 1:6 the ^{14}N and ^{73}Ge spectra practically show only one signal corresponding to the $[Ge(NCS)_6]^{2-}$ anion. Further addition of KSCN

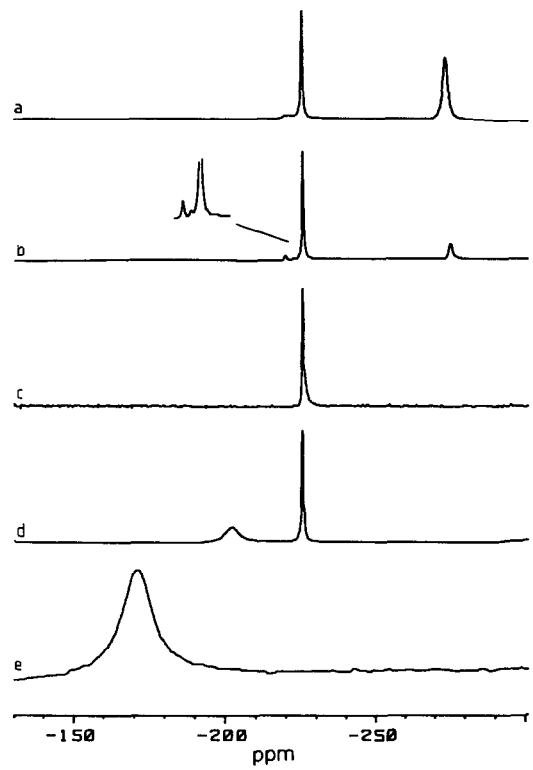

Fig. 2. ^{14}N NMR spectra of $GeCl_4$+KSCN in acetone-d_6 at (a) 2:1, (b) 1:3, (c) 1:6, (d) 1:10 and (e) 0:1 ratios.

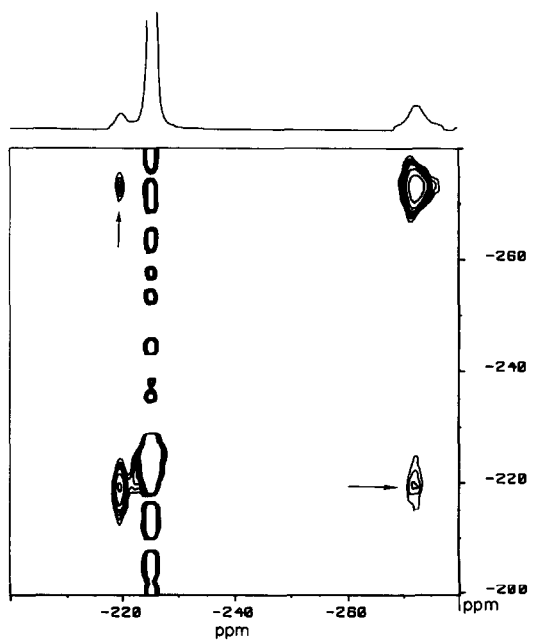

Fig. 3. The 2D phase sensitive ^{14}N NOESY spectrum of $GeCl_4$+KSCN in acetone-d_6 at a 1:2 ratio showing cross-peaks due to the intermolecular exchange between $Ge(NCS)_nCl_{4-n}$ and $[Ge(NCS)_4Cl_2]^{2-}$ species.

leads to the occurrence of a broad signal in the ^{14}N spectra, depending essentially on the amount of KSCN added. The ^{14}N line width and chemical shift corresponding to $[Ge(NCS)_6]^{2-}$ are not subject to variation. This demonstrates that intermolecular exchange between the anion $[Ge(NCS)_6]^{2-}$ and the free NCS^- ions in solution occurs rather slowly. At the same time, the ^{14}N signal expected for free NCS^- ions at −171 pm was not observed. This leads us to assume that the occurrence of the broad signal in the ^{14}N spectra may be attributed to a germanium derivative of higher coordination, apparently $[Ge(NCS)_7]^{3-}$ or $[Ge(NCS)_8]^{4-}$ involved in rapid (in NMR time scale) intermolecular exchange with free NCS^- ions. The absence of an appropriate signal in the ^{73}Ge spectrum may be explained by the lack of spherical symmetry of charge distribution around the ^{73}Ge nuclei or by the presence of intermolecular exchange between various structures.

EXPERIMENTAL

Solutions studied were prepared by adding 1 M KSCN in acetone + acetone-d_6 to $GeCl_4$ at various molar ratios. The KCl precipitate formed was removed by filtration. Acetone-d_6 was dried over molecular sieves (4 Å).

^{14}N and ^{73}Ge NMR spectra of solutions were recorded at 303 K on a Bruker WM-360 spectrometer in 5 mm sample tubes at 26.02 and 12.56 MHz, respectively. Chemical shifts were measured relative to internal references, Me_4Ge (^{73}Ge) and $MeNO_2$ (^{14}N).

For the phase sensitive 2D ^{14}N NOESY experiment, data were collected and processed by means of the standard DISNMR software package. In a typical experiment 256 FIDs (of 512 scans each) consisting of 1 K data points were accumulated using a mixing time of 10 ms. Sine bell resolution enhancement was used in both directions.

COMPLEXATION OF PUTRESCINE WITH COPPER(II), ZINC(II), LEAD(II) AND MAGNESIUM(II) IN AQUEOUS SOLUTION

LECHOSŁAW ŁOMOZIK* and ANNA WOJCIECHOWSKA

Faculty of Chemistry, Adam Mickiewicz University, Grunwaldzka 6, 60-780 Poznań, Poland

(*Received* 23 *January* 1989; *accepted* 19 *May* 1989)

Abstract—On the basis of potentiometric and spectral studies the presence of two types of the $CuL_2(OH)^+$ complex, where L = putrescine, was detected. In one complex two nitrogen atoms of the first ligand and one nitrogen atom of the second ligand are involved in the coordination, whereas in the other complex both nitrogen atoms of each amine take part in the coordination. At pH *ca* 7, the formation of the $CuHL^{3+}$ complex was proved. The stability constant of the $CuL_2(OH)^+$ complex was determined.

Putrescine (1,4-diaminobutane), spermidine (4-azooctane-1,8-diamine) and spermine (4,9-diazododecane-1,12-diamine) are biogenic amines which occur in the cells of living organisms and participate in the genetic information transfer, interacting in the protonated forms (as cations) with negatively-charged fragments of nucleic acid chains.[1–7] However, the mechanism of this reaction still remains to be explained, as well as the character of the processes between the metal ions and nucleic acid molecules. Moreover, the possibilities of formation of metal–polyamine complexes and the reactions of such compounds with electron-donor fragments of DNA and RNA should also be considered.

In the cases of spermine and spermidine it was found that they formed coordination compounds with metals in aqueous solution,[5–7] yet it is still uncertain whether these compounds can also be given by putrescine. Some authors would rather suggest that putrescine does not coordinate metal ions in solution,[7,8] though its complex compounds were isolated from absolute ethanol.[9] Results of our studies on complexing properties of this amine with some metal cations contradict such a suggestion. Instead they testify to the fact that under certain conditions putrescine forms coordination compounds in aqueous solution.

Results of the studies on complex formation of putrescine with Cu^{2+}, Zn^{2+}, Pb^{2+} and Mg^{2+} are presented in this work.

EXPERIMENTAL

Putrescine dihydrochloride (Institute of Bioorganic Chemistry of Polish Academy of Sciences in Poznań) was used in these studies. Results of the elementary analysis are in agreement with the theoretical composition of the compound.

Copper was used in the form of the perchlorate, the preparation of which was described earlier.[10] Perchlorates of the other metals used in these studies were obtained likewise.

Potentiometric measurements were carried out using a Radiometer TTT85 titrator with an autobiurette ABU80; a previously calibrated electrode GK 2401C[11] was also applied. The concentration of putrescine in all the titration systems was 1.00×10^{-3} mol dm^{-3}. All titrations were performed under an argon atmosphere at ionic strength $\mu = 0.1$ ($NaClO_4$), at 293 ± 1 K. NaOH (0.0465 mol dm^{-3}) free of CO_2 was used as the titrant.

The pH values at which turbidity appears for the systems with copper(II), zinc(II), lead(II), magnesium(II) and putrescine were measured on a spectral colorimeter SPECOL–Carl Zeiss Jena fitted with an attachment TK for solutions with composition and concentrations identical to those used in the potentiometric studies.

* Author to whom correspondence should be addressed.

In turbidity measurements, ligand solutions of the same concentration as those of metal-containing systems were used as reference. The turbidity was assumed to appear at a pH value for which the declination of a pointer was observed at a maximum amplification obtainable with this equipment.

UV–vis measurements were performed on a UV–vis SHIMADZU 160 spectrometer. The concentrations of putrescine and Cu^{2+} in the samples were $c_{Put} = 3.00 \times 10^{-3}$ mol dm^{-3}, $c_{Cu^{2+}} = 5.19 \times 10^{-4}$ mol dm^{-3}; $c_{Put} = 3.00 \times 10^{-3}$ mol dm^{-3}, $c_{Cu^{2+}} = 1.14 \times 10^{-3}$ mol dm^{-3}.

The model discrimination and determination of complex stability constants were carried out on EMC-RIAD 32 and AMSTRAD PC-1512 computers using adopted versions of SCOGS[12] and MINIQUAD[13] programs, whereas the form distribution in the system was calculated using the HALTAFALL[14] program.

RESULTS AND DISCUSSION

Complexing abilities of putrescine (Put) in comparison with other biogenic amines (spermine, spermidine) are definitely weaker. This is due to the formation of a seven-membered chelate ring, which is very unfavourable because of the spatial arrangement and also energetic reasons. However, it is difficult to agree with some authors who claim that the above facts exclude the formation of coordination compounds of 1,4-diaminobutane. Let us add that there is still a possibility of this compound forming with the participation of only one nitrogen atom in the complexation. It should be remembered that putrescine compounds may be formed with metal ions in the solid phase.[8] Moreover, during the complexation of spermine with Cu^{2+}, seven-membered rings[7] (in addition to six-membered rings) are also formed.

The first step in the studies on the putrescine–metal system was to determine the ligand association constants (Table 1). Then mixtures of putrescine (1.00×10^{-3} mol dm^{-3}) with Cu^{2+} were titrated. The studies were performed for a few concentrations of copper ions at cation–ligand ratios ranging from 1:6 to 1:8.5. Titration at relatively higher concentrations of metal prevented the application of the potentiometric method due to precipitation at a relatively low pH. In all the experiments performed, this process was observed from pH *ca* 7.0. On further addition of base the precipitate gradually dissolved (at pH *ca* 9.0 the solution became clear). For the calculations, points from a titration curve were used with a pH range for which no precipitate was recorded. Limiting values of this range were determined by measuring the turbidity described in the Experimental. The initial formation of the precipitate was also determined on the grounds of measurements of the pH. An inflection on the titration curve corresponds to the time of precipitate formation. The solid state formation is undoubtedly related to the reaction type:

$$M^{2+} + xH_2O \rightleftharpoons M(OH)_x^{2-x} + xH^+$$

(the coordination compound can also undergo hydrolysis) which results in an increase in the acidity of the medium. The above observations are consistent with the results of turbidity studies. We distinguished two sets of points on the titration curve. One set included the points within the pH range from 3.0 to 7.0 ("before precipitation") and the other set included the points for the pH range from 9 to 12 ("after precipitation"). Both sets were treated in the computer analysis as one series of measurements. The formation of only one complex: $ML_2(OH)$, $\log \beta_{1-12} = 0.065$, was detected in the system (Table 1). The complexation takes place from a pH of about 9.0 (Fig. 1). This complex practically binds all the metal from a pH of about 10.5.

A computer analysis proved no complexation at the pH before precipitation, despite the fact that in

Table 1. Stability constants $\log \beta_{pqr}$ of putrescine complexes with H^+ and Cu^{2+} for the $Cu_pH_qL_r$ type

	p	q	r	$\log \beta_{pqr}$
Put–Cu^{2+}	0	2	1	20.51 (0.01)
	0	1	1	10.83 (0.01)
	1	−1	2	0.065 (0.06)[a]

[a] The value of R obtained for MINIQUAD calculations was 0.024. For the hydroxo complex $ML_2(OH)^+$ its stability constant $\beta = \beta_{pqr}/K_w$ (in our calculations $pK_w = 14.167$).

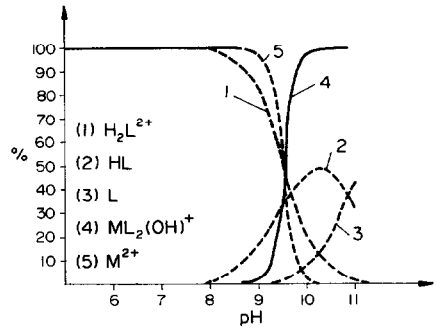

Fig. 1. Distribution diagram of the Put–Cu^{2+} system; percentages of the species refer to total metal except for the metal-free forms which refer to total ligand.

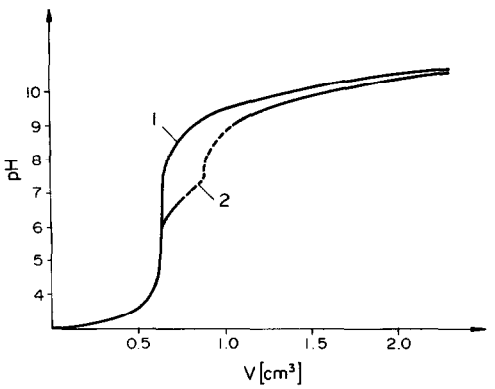

Fig. 2. Titration curves of (1) putrescine; (2) putrescine with Cu^{2+}.

this range the pH value for the titration curve of the Cu^{2+}–ligand system is lower than for the titration curve of the ligand alone (Fig. 2).

Additional information about the system was obtained by electron spectroscopy measurements. At pH 10.0 (significant concentration of $ML_2(OH)^+$, Fig. 1), the maximum absorption of the system Put–Cu was found for $\lambda = 634.5$ nm. The calculated value of the molar absorbance coefficient of the complex was $\varepsilon = 105$ dm^3 mol^{-1} cm^{-1} (Table 2). The maximum corresponds to the case of three coordinated nitrogen atoms.[5,7,15]

At pH 11.6 the maximum of absorption is shifted to $\lambda = 601$ nm ($\varepsilon = 93$ dm^3 mol^{-1} cm^{-1}). The $ML_2(OH)^+$ complex still dominates in the system (Fig. 1) but, as it follows from spectral measurements, its coordination is different. The maximum absorption at $\lambda = 601$ nm corresponds most likely to tetracoordination by the nitrogen atoms. Thus, we may conclude that putrescine forms the $ML_2(OH)$ complex with copper from a pH of *ca* 9.0. One of the attached ligands forms a seven-membered ring with the metal and the other coordinates only with one nitrogen atom. At a pH of *ca* 11.6 two chelate rings are formed in the $ML_2(OH)^+$ complex. Electron spectroscopy was also performed for the Put–Cu^{2+} system at pH ranging from 3.0 to 7.0. From a pH of *ca* 3 to *ca* 6.8 the position of the absorption maximum of this system (754 nm) indicates the presence of uncoordinated copper. At pH 7.0 (Table 2) the maximum absorption at $\lambda = 705$ nm was observed. This testifies to the presence of a complex with only one coordinated nitrogen atom, i.e. a compound of the MHL type without a chelate ring. Such a conclusion is then in agreement with the observed shift of the titration curve of Put–Cu^{2+} with respect to the titration curve of the ligand. It should be emphasized that the UV–vis measurements of the Put–Cu^{2+} system were carried out together with a study of copper(II) perchlorate alone under the same conditions as for the mixture with the ligand. The maximum absorption values for the Cu^{2+} ion (hydrated) are found at wavelengths which are markedly longer than for Put–Cu^{2+} (Table 2).

In order to solve the problem of Put–Cu^{2+} complex formation in solution over precipitate formation, the Put–Cu^{2+} system with a putrescine concentration of 3.00×10^{-3} mol dm^{-3} and a Cu^{2+} concentration of 1.14×10^{-3} mol dm^{-3} (which expanded the range of pH "with precipitate" from 6.4 to 12.0) was subjected to the UV–vis investigation. A solution of pH 11.6 was filtered and UV–vis measurements were taken. Then the solution of pH 11.6 was acidified until the required pH was reached (10.4, 10.0, 8.7, 7.0), filtered and the absorption spectra of the clear solutions were recorded (Table 2). λ_{max} values for the obtained series of results are almost the same as the results obtained

Table 2. Results of UV–vis measurements for the system Put–Cu^{2+}. (a) $c_{Put} = 3.00 \times 10^{-3}$, $c_{Cu^{2+}} = 5.19 \times 10^{-4}$ mol dm^{-3}; (b) $c_{Put} = 3.00 \times 10^{-3}$, $c_{Cu^{2+}} = 1.14 \times 10^{-3}$ mol dm^{-3}; (c) $c_{Cu^{2+}} = 5.19 \times 10^{-4}$ mol dm^{-3}.

pH	λ_{max} (nm)	A	ε (dm^3 mol^{-1} cm^{-1})	λ_{max} (nm)	A	λ_{max} (nm)

11.6	601.5	0.037	92.75	603.0	0.050	638.0

[a] At pH 7 the presence of the $CuHL^{3+}$ complex was not proved using a potentiometric method.

for a system of lower concentration of Cu^{2+} (for a smaller pH range of precipitate formation). Hence it should be assumed that the complexing equilibria for both cases examined are analogous, which means that "over the precipitate" the MHL^{3+} complex and the $ML_2(OH)^+$ complex are formed at a pH of *ca* 7.0 and a pH of *ca* 9.0, respectively.

The MHL^{3+} formation [as it can be concluded from distribution curves (Fig. 1)] proceeds as follows:

$$H_2L^{2+} + Cu^{2+} \rightleftharpoons Cu(HL)^{3+} + H^+.$$

It should be added that the results of spectral studies do not exclude the formation of the ML^{2+} complex (non-chelate with coordination by one nitrogen only).

Due to the low concentration of the compound formed at pH *ca* 7.0 it was not possible to prove the formation of a protonated compound using computer analysis, or to determine its stability constant. Consequently, we could not present it on a distribution curve. Since the value of pK for putrescine is 9.68 it is difficult to assume that a simple complex (at pH = 7.0) may be formed in which putrescine behaves as a monodentate ligand and where the other donor atom is deprotonated.

Under the conditions of $ML_2(OH)^+$ complex formation both the HL^+ (dominates at pH about 10.0) and L (dominates at pH above 11.0) forms may take part in its formation. In the latter case amine is completely deprotonated, which undoubtedly facilitates coordination with all nitrogen atoms (H^+ does not compete with a metal cation). These observations testify to the fact that two different forms of the $ML_2(OH)^+$ complex may occur (as it follows from spectral data). An attempt to determine the structure of the precipitate formed in the system led us to a conclusion that it contains mainly hydroxo-compounds of copper and a certain amount of the amine examined. However, we have failed to prove unambiguously the composition of the precipitate on the grounds of elementary analysis and spectral investigations.

Potentiometric studies on putrescine complexation with Pb^{2+}, Zn^{2+} and Mg^{2+} have also been carried out. In the case of the Mg^{2+} ion, formation of coordination compounds in solution should be excluded (titration curve of Put–Mg^{2+} system overlaps completely with the titration curve of a ligand in the whole acidity range—pH from 3.0 to *ca* 11.0). On the other hand, in the case of the Pb^{II} and Zn^{II} ions even at metal–ligand ratios equal to 1 : 9, a precipitate appears in the solution (at a pH of *ca* 7.8 and 8.2, respectively) and it does not dissolve even after further additions of NaOH.

For these two systems it seems more reasonable to conclude that the presence of Pb^{II} and Zn^{II} complexes with putrescine cannot be proved using potentiometric methods, rather than to say that such complexes do not occur in solution.

(*Received* 25 *August* 1988; *accepted* 2 *June* 1989)

Abstract—$[Ni(phen)_3]I_2 \cdot nH_2O$ forms several solid phases, both as racemate and when resolved. The most stable phase of the racemic iodide (a trihydrate) has space group $P2_1/c$, $Z = 4$. The structure is made up of complex ions containing nickel chelated by three 1,10-phenanthroline ligands, and by layers of hydrogen-bonded assemblies of iodide ions and water molecules.

Complex ions containing 1,10-phenanthroline are central in coordination chemistry. There has been increasing interest in the mechanism of the racemization of tris-phenanthroline metal salts in solid[1–5] and solution phases. Conflicting schemes have been proposed for the solid state racemization of Δ-(−)-$[Ni(phen)_3]I_2 \cdot nH_2O$ or its enantiomer.

In considering such mechanisms, a fundamental requirement is knowledge of the lattice structure. But with these compounds even such basic information as phase identification and a proper understanding of the role played by water in determining the structure is lacking. $[Ni(phen)_3]I_2 \cdot nH_2O$ is rose-pink when hydrated and changes[6] to yellow on loss of water. Further, water has been shown to depress the solid state racemization of $[Fe(phen)_3]Br_2$ at room temperature[5] and the pressure-induced racemization[7] of $[Ni(phen)_3](ClO_4)_2$.

Many salts exist in a variety of crystalline phases under "ambient" conditions. This fact has been ignored in this area and often elsewhere in solid state coordination chemistry. Such multiple phase systems are quite common among salts involving complexed phenanthroline and similar ligands, as exemplified by: $[Rh(phen)_2Cl_2]Cl \cdot nH_2O$;[8] $[Ir(phen)_2Cl_2]Cl \cdot nH_2O$;[9] $[Pt(bipy)Cl_2]$.[10]

We recently found[1] seven phases for racemic $[Ni(phen)_3]I_2 \cdot nH_2O$ and four for the same salt resolved. In this context, we heated the common chiral phase, [**B** of ref. 1]; $[Ni(phen)_3]I_2 \cdot nH_2O$ at 190°C for a week, racemizing it. The product was a *new* racemic phase, unlike any obtained by crystallizing the racemic iodide from solution.

To give a full account of such solid state reactivity, and to comment on the reasons for such widespread multiformity among these classical coordination compounds, it will be necessary to give painstaking attention to characterization of phases. For racemic and optically active tris-1,10-phenanthrolinenickel(II) salts, this process was described in the previous part[1] of this series. We now report the crystal and molecular structure of the most easily accessible form $[Ni(phen)_3]I_2 \cdot 3H_2O$ of the racemic iodides.

EXPERIMENTAL AND STRUCTURE SOLUTION

The preparation of the compound is described in the preceding part.[1]

Cell: monoclinic space group $P2_1/c$ (no. 14),

*Author to whom corresponding should be addressed.

absences *hol*, $l \neq 2n$ and $0k0$, $k \neq 2n$, $a = 20.547(3)$, $b = 16.454(2)$, $c = 10.705(3)$ Å, $\beta = 104.33(2)°$, $Z = 4$, $D_c = 1.72$, $D_o = 1.71$ g cm^{-3} (by flotation in $CHBr_3/CH_3CCl_3$).

The data set consisted of 6411 reflections: 5090 remained after those with $F_o < 3\sigma F_o$ were removed. The structure was solved using the SHELX76[11] and SHELXTL[12] programs.

Iodine and nickel atoms were located from a Patterson map, and the remaining atoms by peak searching on difference Fourier maps after a few cycles of least-squares refinement. Aromatic hydrogen atoms were allowed to ride on the carbon atoms with a bond length of 1.08 Å. Their thermal parameters were tied together to the same free variable and refined isotropically.

Atoms were refined by the least-squares method, in blocks, and refinement was terminated when the function R_g was minimized. A free weighting scheme was used with weight $= K/(\sigma^2 + gF^2)$. The final R-indices were $r = 0.045$, $R_w = 0.062$ and $R_g = 0.091$ ($K = 1.000$, $g = 0.0395$). The largest shift of any refined parameter was less than 0.19 of the estimated standard deviation, except for the isotropic thermal parameter of the hydrogens which oscillated by ± 1.25 ESD between least-squares cycles.

Bond lengths, bond angles and other structural features are given in Tables 1–5 and coordinates in the supplementary material. Planes were calculated using XRAY76 (program LSQPL),[13] and figures drawn using ORTEP.[14]

RESULTS

The crystal structure

This (Fig. 1) is composed of separate units of $[Ni(phen)_3]^{2+}$, iodide and water molecules; all atoms occupy general sites in the lattice. $[Ni(phen)_3]^{2+}$ and iodide ions, and water molecules are arranged in layers (Fig. 2). There are four such layers per unit cell, arranged parallel to the *bc* plane and containing right- and left-handed tris-chelates. Layers of complex molecules alternate with water–iodide layers, of which there are two unique layers.

Complex geometry

Because the complex ion occupies a general site in the lattice, its geometry has only approximate D_3

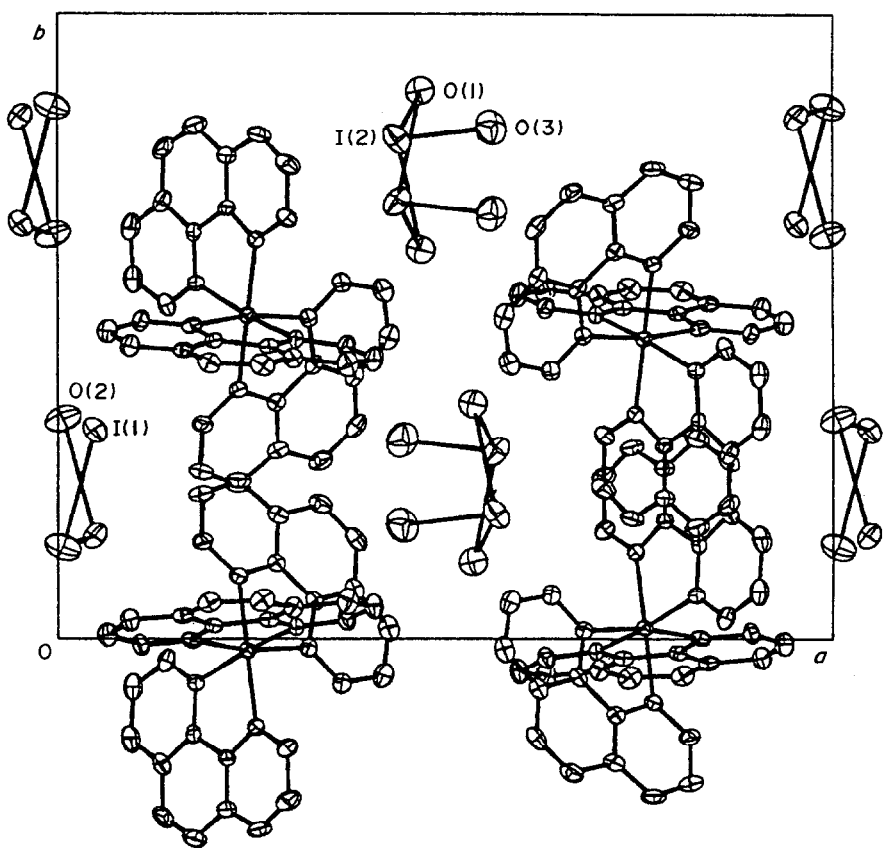

Fig. 1. Arrangement (viewed in *c*-direction) of components in the unit cell.

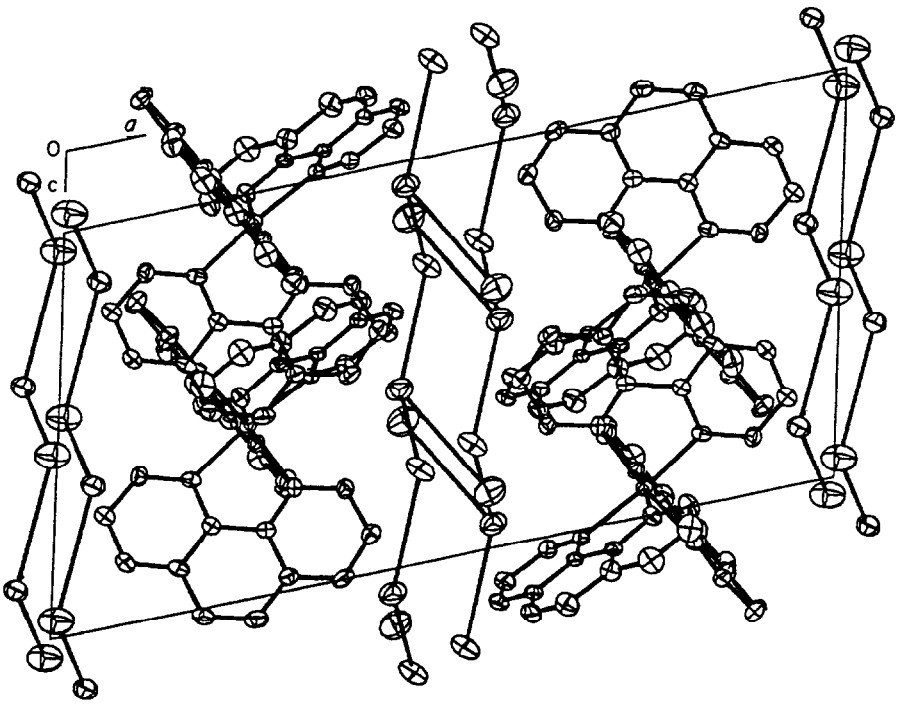

Fig. 2. Arrangement (viewed in *b*-direction) of layers of $[Ni(phen)_3]^{2+}$ ions and of (water + iodide).

symmetry, so all bond lengths, angles, etc. should be treated as independent. For the same reason, we describe its geometry by treating it as twisted (from trigonal prismatic toward regular octahedral) about the quasi-*C*3 axis. The twist is defined at each ligand by the angle between the planes defined[15] by the two centroids of the "trigonal" faces and the nitrogens of the respective phenanthroline. The average twist (θ) for the ion is 49.5(5)°, which is toward the octahedral extreme. (θ is, of course, 0 for the trigonal prism, a possible intermediate for intramolar racemization.) The calculated[16] optimum twist of 1,10-phenanthroline in this structure is ~ 48° (b = 1.28, bite/M—N bond length).

C(11)—C(12)	1.394(6)	1.412(7)	1.389(6)
C(11)—C(13)	1.423(6)	1.432(6)	1.468(6)
C(13)—C(14)	1.415(7)	1.392(6)	1.404(6)

The average lengths of Ni—N bonds (2.089(14) Å) and angles N_1—Ni—N_{10} (79.9(3)°) are similar to those found[17,18] in structures of other tris-phen nickel salts, although, in those, nickel occupies sites of higher symmetry.

The distance (d) between the "trigonal" faces (between centroids) is 2.24 Å, and the angle between the normals to the two faces is 1.9°. The nickel atom lies where expected, very close (0.016 Å) to and midway (1.11 Å from the N(1) plane) along the line joining the centroids of the "trigonal" faces.

The differences found between the internal angles of the coordination sphere are related to the slight distortions described above. The overall effect is illustrated in Fig. 3 and discussed below. The increased twist (50.0°) at ligand 3, and decreased twist (49.0°) at ligand 1 has the effect of increasing the N(10′)—Ni—N(10″) angle (95.5°) and decreasing the N(1)—Ni—N(1′) angle (93.2°). This is also reflected in the small angle (1.88°) made between the trigonal faces, and by the increased bite and N(1)—Ni—N(10) angle for ligand 1, and the converse for ligand 3. The Ni—N(10) bond length is larger (2.111 Å) than expected and may contribute to these distortions.

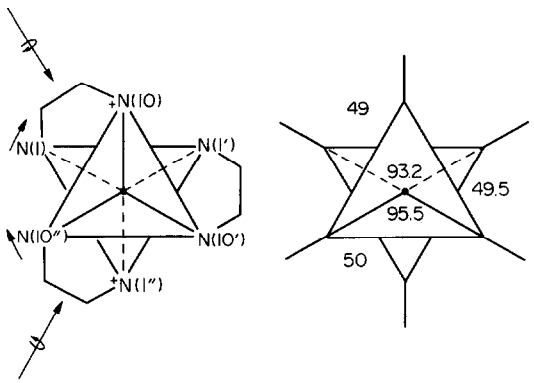

Fig. 3. View of the tris-chelated ion along the quasi-C_3 axis, and definitions of angles of twist, following ref. 15. Arrows and + symbols indicate [relative to phenanthroline(1)] the movements of atoms and the twist adopted by the other two phenanthroline ligands.

Phenanthroline

The numbering scheme for 1,10-phenanthroline is in Fig. 4. Bond lengths and angles within the ligand are similar to those[17,18] in prior reports: the average bond distances are C—C, 1.398(32) and C—N, 1.340(21) Å, consistent[17] with a bond order of ~ 1.5. The ligands are planar: no atom deviates from its respective plane by more than 0.017 Å (Table 3). Further, the nickel atom is almost coplanar with phen(3) but 0.10 and 0.13 Å from the planes of phen(1) and (2), respectively.

Water–iodide layers

Water molecules and iodide ions make hydrogen bonds to each other to form chains running parallel to the *c*-axis. Most of the O—I contacts are between 3.56 and 3.70 Å (Table 4): there is only one long contact I(2)—O(3) at 4.16 Å, a little shorter than the expected non-bonding distance (~ 4.2 Å); variations in the reported van der Waals radii make this number somewhat indefinite for a linear sequence[19–21] of atoms I(2)···H—O: hydrogen bonding is probably not involved. However, the atoms need not be linear, in which case the maximum O(3)···I(2) distance consistent with hydrogen-bonding will be shorter, and the observed contact should then be considered even less likely to involve hydrogen-bonding.

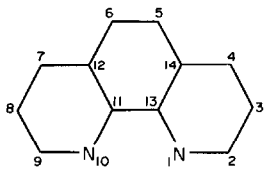

Fig. 4. Numbering of atoms in 1,10-phenanthroline.

C(5)—C(14)—C(13)	118.5(4)	117.2(4)	120.5(5)

The angles I(2)—O(*n*)—I(2) indicate that only one or perhaps no contact involves a linear sequence of atoms, because the angles are much larger than the H—O—H angle of water (105.5° in the gas phase). Conversely, in the O(2)—I(1) layer, the I(1)—O(2)—I(1) angle is 110.9° and so an almost linear sequence would be expected and both contacts considered as weak hydrogen bonds.

Oxygen–oxygen contact distances are all > 3.4 Å, too long for hydrogen bonds, and there are no short oxygen–phenanthroline contacts. The smallest are O(2)···C(2) at 3.21 Å and O(1)···H(7′) at

Angle (°) between phenanthroline planes:

2–1	86.12
3–1	88.42
3–2	84.09

2.43 Å. Water molecule O(1) lies in a pocket 4.88 Å from the nickel, close to the quasi-$C3$ axis of the complex. Relevant contacts with phenanthroline are given in Table 5. O(1) does not lie exactly on the quasi-$C3$ axis, as defined by the line joining the nickel and centroid of the plane of O(9) or H(9) atoms. The distances to this line are 0.216 and 0.252 Å, respectively. There is a bias towards H(9). The point that is the projection of O(1) onto the plane of H(9) atoms lies closer to atom H(9) than does the centroid of that plane (1.614 as opposed to 1.869 Å). However, this is probably not a hydrogen bonding interaction with phenanthroline—the contact is too long (O(1)···H(9), 2.78 Å). It more likely

arises from a combination of hydrogen-bonding to iodide outside the pocket, and packing constraints.

DISCUSSION

The present crystal structure of the most stable racemic phase, $[Ni(phen)_3]I_2 \cdot 3H_2O$, shows no unusual features. Covalent hydration was proposed[22] for this system *in solution* on the basis of new circular dichroism absorptions arising on the addition of water to dichloroethane solutions. Such modification of the ligated 1,10-phenanthroline is not present *in this particular solid.* The coordination geometry is as regular as may be expected from packing in a low symmetry site. Each ligand coordinates in a similar fashion, and the detailed geometry of the complex is consistent with the differences between them.

Among the crystal structures solved for salts containing complex ions $[M(phen)_3]^{n+}$, ferrous and ferric salts are the most extensive series. These, similar to nickel in that their coordination spheres display very little distortion, do, however, display an increase in their overall twist making them more like octahedra than is nickel(II). Iron(II)[23] $\theta = 52.8$, $d = 2.16$; iron(III)[24] $\theta = 55.7$, $d = 2.10$.

The present structure of $[Ni(phen)_3]I_2 \cdot 3H_2O$ may be considered isostructural with that[23] of $[Fe(phen)_3]I_2 \cdot 2H_2O$, apart from an additional water molecule. The unit cell dimensions and coordinates are similar, although the ferrous structure was refined in space group $P2_1/a$.

The question of whether a hole exists in the iron structure sufficiently large to accommodate another water molecule was not addressed. In view of the close similarity of coordinates, it seems likely that there is space. The third water may not be present in the ferrous crystal studied because it is mobile and was lost during or before collection of diffraction results. Alternatively, it may not have been included in the analysis although present in the lattice.

Mason has discussed[25] the ways in which chiral and racemic groups of molecules pack in crystal lattices, and identified the geometrical conditions necessary for optimal close packing. There may be a close and sometimes exact correspondence between lattice symmetry elements and the orientation of symmetry elements of the isolated molecules. To some extent, this is a consequence of the molecules occupying special positions in the lattice. The tris-chelate molecules $[M(acac)_3]$ (acac = acetylacetonate, the mono-O-anion of pentane-2,4-dione) and $[M(en)_3]^{3+}$ (en = 1,2-diaminoethane) were considered specifically. In most instances, however, when counter ions and water are also present in the lattice, optimal packing does not necessarily require a close association between complex molecules. Certainly, the present packing arrangement we find in $[Ni(phen)_3]I_2 \cdot 3H_2O$ does not correspond with the "optimal" close packing schemes for delta and lambda isomers. Close packing would be confined to the layers of complex molecules, but each $[Ni(phen)_3]^{2+}$ unit packs without interleaving with any of its neighbours. The symmetry operation that relates the molecules in a layer is the *c*-glide. This has the effect of separating the molecules. So the only operation remaining that could cause interleaving is translation in *b* or *c* directions. However the smallest dimension, *b*, is too large for effective overlap, and the molecules are orientated incorrectly for this means of achieving interleaving.

A fair number of structures are now known involving tris-1,10-phenanthroline complex ions. In a few, the metal ion exerts direct influence on the geometry of the ion, as in the tetragonal static Jahn–Teller distortion found for the one dimorph[26] of $[Cu(phen)_3](ClO_4)_2$ studied.[27] Among the more numerous diffraction studies for salts of complexed *spherical* ions, the known structures including nickel(II) are:

	Reference
$[Ni(phen)_3][Mn(CO)_5]$	17
$K\{\Lambda\text{-}(+)_{589}\text{-}[Ni(phen)_3]\}\{\Lambda\text{-}(-)_{589}\text{-}[Co(C_2O_4)_3]\}2H_2O$	18
$[Ni(phen)_3](S_2P(OCH_3)_2)_2$	28
$[Ni(phen)_3](I_3)_2$	29.

$[M(phen)_3]^{n+}$ units have been found to occupy lattice sites with three different site symmetries, in accordance with the symmetry properties of the free molecules. These are:

(i) (C_1): most common, and the structure we now find for $[Ni(phen)_3]I_2 \cdot 3H_2O$;
(ii) (C_2): $[Hg(phen)_3](CF_3SO_3)_2$[30] and Λ-(−)-$[Fe(phen)_3][Sb_2(D\text{-tart})_2] \cdot 8H_2O$;[31]
(iii) (C_3): $K\{(+)\text{-}[Ni(phen)_3]\}\{(-)\text{-}[Co(C_2O_4)_3]\} \cdot 2H_2O$.[18]

The averaged geometry of ions like $[Ni(phen)_3]^{2+}$ in solution of course has at least C_3 symmetry (and often, indeed, D_3 symmetry). That is not particularly common in the solid state and the present structure again iterates the need for caution in transferring the mechanistic concepts appropriate to solution, unmodified, to studies on solids.

Finally, the colour change observed on dehydration may be rationalized. The iodide ions are held in water–iodide sheets some way from the cations in the studied pink crystals, whose colour arises from a *d–d* transition. As water is removed or lost, the iodide ions may presumably approach the cat-

ions more closely, giving enhanced charge-transfer intensities. The same phenomenon (increase in richness of colour on dehydration) occurs in other similar systems, like $[Pt(bipy)_2]I_2 \cdot 2H_2O$ and solvated N-benzylnicotinamide iodide. We earlier showed[1] that the yellow colour of the product in eq. (1) could be "cooled out" in liquid nitrogen, giving the pink colour of the *d–d* chromophore in the NiN_6 manifold.

$$[Ni(phen)_3]I_2 \cdot 3H_2O \longrightarrow [Ni(phen)_3]I_2 \quad (1)$$

(*Received* 16 *May* 1989; *accepted* 7 *June* 1989)

Abstract—Previous studies on *t*-butylimido aryls of rhenium have been extended and the compounds $(Bu^tN)_2Re^{VII}(o\text{-tol})_3$, $(Bu^tN)_2Re^{VII}Cl_2Ph$ and $(Bu^tN)_2Re^{VI}(mes)_2$ synthesized. Electrochemical studies of the latter show reversible one-electron oxidation and reduction, and chemical oxidation leads to the cation $[(Bu^tN)_2Re^{VII}(mes)_2]^+$ isolated as PF_6^- and $CF_3SO_3^-$ salts. Although the neutral complex does not undergo insertion with isocyanides, the cation does so to give η^2-iminoacyls, $\{(Bu^tN)_2Re(mes)[\eta^2\text{-}RN{=}C(mes)]\}^+$, R = 2,6-xylyl, *t*-Bu. Reduction of $(Bu^tN)_3Re(OSiMe_3)$ in hexane by sodium gives the bridged homoleptic compound $(Bu^tN)_2Re(\mu\text{-}NBu^t)_2Re(NBu^t)_2$. The homoleptic anion $[Re(NBu^t)_4]^-$ as the $Li(tmed)^+$ complex has been synthesized via the new intermediates $(Bu^tN)_3ReCl$ and $(Bu^tN)_3Re(NHBu^t)$. X-ray crystal structures of the compounds listed in the title have been determined. The homoleptic rhenium(VI) *t*-butylimide is dimeric with four-coordinate rhenium and almost symmetrical imido bridges; the terminal imido groups have near linear geometry. The diamagnetism is consistent with a Re—Re bond, although the Re—Re distance of *ca* 2.7 Å indicates this to be weak. The rhenium(VII) siloxide is also four-coordinate distorted tetrahedral; and the geometries of the Re–imido and Re–siloxide units indicate involvement of all ligands in π-interactions. The $(Bu^tN)_3ReCl$ is also tetrahedral. The two bis-imido chloro compounds are five-coordinate with a geometry that can be conveniently described as trigonal bipyramidal where the imido groups occupy equatorial sites with unusually small inter-ligand angles of *ca* 110°.

This paper is concerned with the synthesis of *t*-butylimido compounds of rhenium, the X-ray crystal structures of four of the species and the synthesis of the first homoleptic *t*-butylimido compounds of rhenium and the crystal structure of one of them.

(1) *t*-BUTYLIMIDORHENIUM ARYL COMPOUNDS

We have previously described[1] the aryl compounds $(Bu^tN)_3ReAr$ and $(Bu^tN)_2ReCl_2Ar$, where Ar = *o*-tolyl, xylyl and mesityl. The crystal structure of $(Bu^tN)_2ReCl_2(o\text{-tol})$ showed the molecule to have square-pyramidal geometry with a bent imido group. In view of this and the use of NMR studies for assignment of structures of various rhenium

* Bis[(*t* - butylimido)(μ - *t* - butylimido)]dirhenium(VI) (Re—Re), bis(*t*-butylimido)trichlororhenium(VII), bis(*t*-butylimido)dichlorophenylrhenium(VII), tris(*t* - butylimido)(trimethylsilyloxo)rhenium(VII), tris(*t* - butylimido)chlororhenium(VII).

Abbreviations: tmed = tetramethylethylenediamine, *o*-tol = 2-MeC_6H_4; xylyl = 2,6-$Me_2C_6H_3$; mes = 2,4,6-$Me_3C_6H_2$.

† Authors to whom correspondence should be addressed.

imido alkyls and other compounds,[1,2] mostly as trigonal bipyramidal ones, two other representative five-coordinate structures have been determined, namely $(Bu^tN)_2ReCl_3$ and $(Bu^tN)_2ReCl_2Ph$, in the hope of aiding the NMR interpretations.

Bis(t-*butylimido*)*bis*(2,4,6-*trimethylphenyl*) *rhenium*(VI)

Although the interaction of $(Bu^tN)_2ReCl_3$ with Grignard reagents normally leads to trialkyl or aryl species, with mesityl magnesium bromide reduction occurs giving high yields (*ca* 70%) of the deep red paramagnetic rhenium(VI) compound, $(Bu^tN)_2Re(mes)_2$, which is the analogue of similar compounds, $(Bu^tN)_2M(mes)_2$ (M = Cr, Mo, W).[3] This reduction may result from the steric demand of the mesityl group; steric factors have been suggested for the formation of $(O)_2ReAr_2$ (Ar = *o*-xylyl and mesityl) from Re_2O_7, whereas *o*-tolyl or *o*-methoxophenyl Grignards give $(O)ReAr_4$.[4] Since $(O)Re(mes)_4$ can be made from $(O)ReCl_4$ it is possible that $(Bu^tN)_2Re(mes)_3$ may be prepared via a different route.

The rhenium(VI) compound slowly decomposes in air, both in the solid state and in solution. The mass spectrum shows the parent ions and subsequent loss of one mesityl group. The electron spin resonance spectrum at 295 K in toluene (*X*-band) shows a six-line hyperfine structure ($g_{iso} = 1.966$, $A_{iso} = 0.0133\ cm^{-1}$). On lowering the temperature, a complicated pattern appeared showing, at 78 K, more than two sets of six rhenium hyperfine lines with uneven spacing (cf. the ESR spectrum of $(O)_2ReAr_2$[1,4]); this might result from restriction of rotation about Re—C bonds.

Cyclic voltammetry study of $(Bu^tN)_2Re(mes)_2$ in 0.2 M $(Bu^n_4N)PF_6$ in THF at 22°C shows a reversible one-electron oxidation wave at −0.51 V and a reversible one-electron reduction wave at −1.80 V relative to Cp_2Fe at 0.00 V. Chemical oxidation using Cp_2FePF_6, AgO_3SCF_3 or $AgPF_6$ leads to orange–red diamagnetic crystalline salts of the $[(Bu^tN)_2Re(mes)_2]^+$ ion; these are stable in air but slowly decompose in solution in THF, acetone, CH_2Cl_2 and MeCN. The ^1H NMR spectrum shows equivalent *t*-butyl and mesityl groups with free rotation about the Re—C bond at room temperature (cf. ref. 4).

So far the anionic rhenium(V) species, $[(Bu^tN)_2Re(mes)_2]^-$, has not been isolated; the rhenium(VI) species is not reduced in THF by Cp_2Co. However, the corresponding rhenium(V) oxo aryl anions, $[(O)_2ReAr_2]^-$ (Ar = xylyl, mes), have been obtained,[1,4] as has the neopentyl,[5] $[(O)_2Re(CH_2CMe_3)_2]^-$. The latter anion is oxidized to $Re_2(O)_2(\mu\text{-}O)_2(CH_2CMe_3)_4$, from which it is formed on reduction. The bridged oxo-species is presumably formed initially rather than $(O)_2Re(CH_2CMe_3)_2$ because of the lower steric hindrance compared to the *t*-butylimido and/or aryl groups of $(Bu^tN)_2Re(mes)_2$. Cyclic voltammetry on the oxo-bridged dimer gives an ill-defined oxidation wave indicating that chemical oxidation to $[(O)_2Re(CH_2CMe_3)_2]^+$ is probably not feasible.[5] These differences in redox behaviour of the oxo versus imido systems may be due to differences in ligand electronegativity and π-donating capability.

Although $('BuN)_2Re(mes)_2$, unlike its chromium, molybdenum and tungsten analogues,[3] does not react with isocyanides, the cation, which is isoelectronic with these analogues, does so rapidly at room temperature [eq. (1)] similarly

$$[(Bu^tN)_2Re(mes)_2]^+ + RNC \longrightarrow \{(Bu^tN)_2Re(mes)[\eta^2\text{-}RN{=}C(mes)]\}^+ \quad (1)$$

giving only the mono-insertion product with 2,6-xylyl and *t*-butyl isocyanides even in presence of excess isocyanide. The pale yellow crystalline materials are stable in air. The ^1H NMR spectra show two sets of resonances for the mesityl groups, but there is free rotation about the Re—C bond at room temperature (cf. ref. 4). For the 2,6-xylyl isocyanide product the *ortho*-methyl resonances on the xylyl ring attached to nitrogen occur at the highest field (δ 1.82 ppm). The resonances for the mesityl group which remains attached to rhenium have changed relative to the starting complex, such that the *ortho*-methyl resonances fall at higher field than the *para*-methyl resonance.

The IR and NMR spectroscopic data are similar to those of the chromium, molybdenum and tungsten compounds[3] and are consistent with η^2-coordination of the iminoacyl group, which was confirmed for $(Bu^tN)_2Cr(mes)[(mes)C{=}NBu^t]$ by X-ray crystallography.

Bis(t-*butylimido*)*tris*(2-*methylphenyl*)*rhenium*(VII)

This compound arises from the interaction of the Grignard reagent with $(Bu^tN)_2ReCl_3$ and forms air-sensitive orange crystals. The ^1H NMR spectrum has two *o*-tolyl group resonances in a 2:1 ratio suggesting a *tbp* structure with equatorial imido ligands.

(2) X-RAY STUDIES

As noted earlier, Schrock *et al.*[2] have widely used NMR for characterization of rhenium imido species, generally concluding trigonal bipyramidal

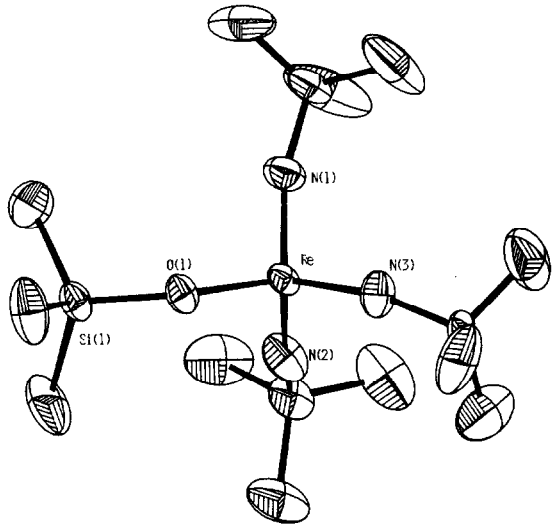

Fig. 1. The structure of $(Bu^tN)_3Re(OSiMe_3)$.

structures. Comparable oxo alkyls $Re(O)_2R_3$ (Re = Me,[6a] CH_2SiMe_3[6b]) appear to be *tbp* from spectroscopic data, while $Re(O)_2(CH_2CMe_3)$[6c] is distorted *tbp* with α-CH···O interactions from X-ray data.

$(Bu^tN)_3Re(OSiMe_3)$

The molecule has a distorted tetrahedral geometry about the rhenium atom, as shown in Fig. 1. Selected bond lengths and angles are given in Table 1. The angles at silicon are also approximately tetrahedral, with an average Si—C bond length of 1.8 Å.

The Re—N—C bonds are slightly bent (157–165°) and, as expected, the most bent imido group has the longest Re—N bond length.

With the possibility of the imido ligands acting as 4e donors, Re≡NR and the siloxo group making available up to 5e, Re≡OSiR$_3$, the metal has access to 24e. On the basis of the angles at the nitrogens, 157–165°, and at oxygen, 137°, all ligands seem to be participating in π-bonding to some extent. Not surprisingly however, the siloxide, for which the Re—O bond of 1.90 Å is only slightly shorter than a normal single bond, would seem to contribute least. It is pertinent to compare this structure with that of the analogous oxo-complex $O_3Re(OSiMe_3)$,[7] where the Re—O—Si angle is larger (167°) than in the present complex and the Re—O bond much shorter. More significantly, steric crowd-

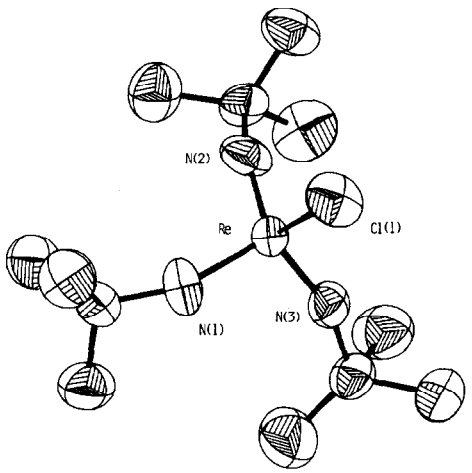

Fig. 2. The structure of $(Bu^tN)_3ReCl$.

ing in the *t*-butyl imido complex would be expected to favour a larger Re—O—Si angle, especially as metal–trimethylsiloxo links seem to be quite flexible.

$(Bu^tN)_3ReCl$

A diagram of the molecule is given in Fig. 2, bond lengths and angles in Table 2. The geometry is slightly distorted tetrahedral with small variations in Re—N distances and Re—N—C angles (see Table 2). This again is consistent with an "averaging" process between the three potentially 4e donor imido ligands in providing an 18e count for the rhenium atom.

$(Bu^tN)_2ReCl_3$

A diagram of the molecule is given in Fig. 3, with selected bond lengths and angles in Table 3. The structure of the complex is simply and logically described as a slightly distorted trigonal bipyramid with equatorial imido groups. The two axial chloride ligands are bent towards the equatorial plane, [Cl(3)—Re—Cl(2) = 165°], in the direction of the equatorial chloride ligand.

The distribution of the angles in the equatorial plane is interesting. The N—M—N angle is smaller than both N—M—Cl angles (111° vs 128 and 121°). This contrasts with most structures containing two neighbouring multiply-bonded functions where repulsion between the π-electron clouds in the two bonds causes an increase in the interbond angle from idealized values.[4] A second, surprising feature of the structure is the equivalence, within experimental error, of all Re—Cl bond lengths, whether axial or equatorial.

The imido ligands both contain "linear" M—N—R linkages (163 and 170°); the Re—N bond distances are in accord with these angles (1.71 and 1.68 Å, respectively). As such, both imido ligands are assumed to behave as 4e donors, and the formal electron count for rhenium is 18.

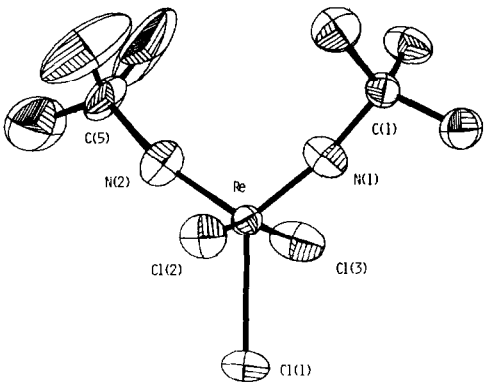

Fig. 3. The structure of $(Bu^tN)_2ReCl_3$.

$(Bu^tN)_2ReCl_2Ph$

The molecular structure is shown in Fig. 4 and selected bond lengths and angles are listed in Table 4. In this case the molecular geometry may also be described as a distorted trigonal bipyramid with the imido groups occupying equatorial positions and the phenyl ring in an axial position. In fact the structure is very similar to that of $(Bu^tN)_2ReCl_3$ above. The axial chloride and phenyl ligands are tilted slightly towards the equatorial chloride [Cl(1)—Re—C(1) = 158°], Cl(2)—Re—Cl′(2). The N—Re—N angle at 110° is similar to that in $(Bu^tN)_2ReCl_3$ and the slight bending of the imido groups (161°, 173°) parallels the geometry of the trichloride. However, the actual distribution of angles within the equatorial plane is different.

Whilst the N—Re—N angle is similar in the two structures, the close similarity between Cl—Re—N angles in the trichloride is lost in the phenyl where these two angles are now very different, at 115.5 and 134.1°. Indeed, notwithstanding the bend of the *tbp* axial Re—Cl(1) and Re—C(1) bonds *towards* Cl(2), the structure could be described as tending to tetragonal pyramid, in which the imido ligand which N(1) occupies the *tp* axial site. This ligand shows the most bending of the two present, albeit slight, and it is interesting to note that it is exactly this ligand which shows even more bending in the more recognizable *tp* structure of $(Bu^tN)_2ReCl_2$(*o*-tol).[1] The structural relationship now established for the three compounds $(Bu^tN)_2ReCl_3$, the mono phenyl and the mono *o*-tolyl has suggested a detailed theoretical investigation, which will be discussed separately.

(3) HOMOLEPTIC *t*-BUTYLIMIDO COMPOUNDS

The compounds $Li_2W(NBu^t)_4$ and Li(tmed) $Re(NBu^t)_4$ have been briefly reported;[8] these and the rhenium(VI) species now reported are the first homoleptic imido compounds of transition metals.

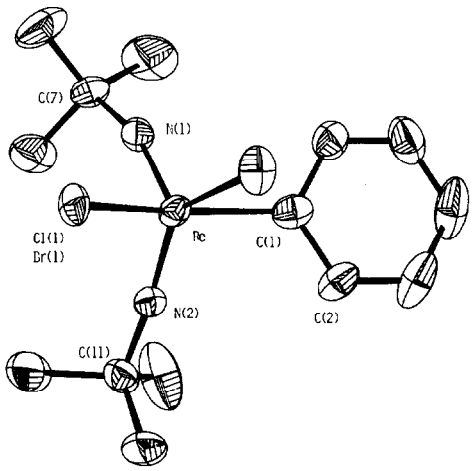

Fig. 4. The structure of $(Bu^tN)_2ReCl_2Ph$.

(a) *Bis[di(*t*-butylimido)(μ-*t*-butylimido)rhenium*(VI)]

The interaction of $(Bu^tN)_3Re(OSiMe_3)$ with an excess of Na (or Na/Hg) in hexane leads to yellow diamagnetic crystals of the title compound that slowly decompose in air. The mass spectrum of the compound shows the parent ion (*m/z* 798) and additional peaks with the intensity pattern expected from rhenium isotopic abundances. The ^1H NMR spectrum shows separate resonances for the *t*-butyl group in a 2 : 1 ratio, that are assigned, respectively, to terminal (δ 1.27) and bridging (δ 1.82) groups.

X-ray structure analysis has confirmed the dimeric nature of the molecule. Although considerable disorder occurs in all *t*-butyl group orientations, leading to difficulties in defining the correct space group and reducing the overall precision of the structure determination (see Experimental), the structure and geometry of the core is well defined. A diagram of one of the molecules is shown in Fig. 5 and a summary of the more reliable bond lengths and angles are given in Table 5.

The dimer comprises two tetrahedral rhenium(VI) atoms with bonds to two terminal and two bridging imido nitrogens (**1**). The bridges are symmetrical and the $(CN)_2Re(\mu\text{-}NC)_2Re(NC)_2$ core has approximate *mmm*($D2_h$) symmetry. As might be expected, the Re—N (terminal) distances

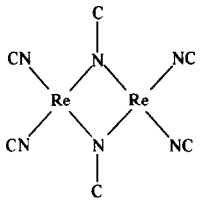
are shorter than the Re—N (bridging) distances, and, this, together with the near linearity of the terminal Re—N—C unit, is consistent with a 4e bonding mode for the ^{t}BuN group.



(1)

The Re(1)—N(3)—Re(1′) angle is 88° and the N(3)—Re(1)—N(3′) angle is 92°. Generally M—N—M angles in the range 78–84° occur when there is a metal–metal bond, and angles > 94° indicate no metal–metal interaction. The Re(1)···Re(1′) distance in this compound is 2.7 Å —this along with the intermediate M—N—M angle in the bridge suggests a weak Re—Re interaction. Rhenium–rhenium single bonds have been proposed in the binuclear d^1–d^1, rhenium(VI) oxo-bridged species $[Me_2(O)Re(\mu\text{-}O)]_2$,[9a] $[(Me_3CH_2)_2(O)Re(\mu\text{-}O)]_2$[5] and $[PhMe_2CCH_2)_2(O)Re(\mu\text{-}O)]_2$,[9b] where the Re—Re distances are 2.593(1), 2.606(1) and 2.6116(7) Å, respectively.

It may be noted that complexes containing both terminal and symmetrical bridging imido ligands are known for several other elements.[10] The crystal structure of $[(Bu^tN)_2MoMe_2]_2$ shows two terminal and two unsymmetrical imido ligands, although the reported ^{1}H NMR data indicate only one t-butyl group resonance for both this compound and its tungsten analogue.[11]

It may also be noted that the formal oxo analogue of $Re_2(NBu^t)_6$, i.e. $(ReO_3)_n$, has a structure closely related to the perovskite structure.[12]

(b) *Tetramethylethylenediaminelithiumtetra*(t-*butylimido*)*rhenate*(VII)

This compound was prepared via the route:

$$(Bu^tN)_3Re(OSiMe_3) \rightarrow (Bu^tN)_3ReCl \rightarrow (Bu^tN)_3Re(NHBu^t) \rightarrow Li(tmed)Re(NBu^t)_4.$$

The chlorination of $(Bu^tN)_3Re(OSiMe_3)$ by $PhICl_2$ in toluene at room temperature gives high yields of $(Bu^tN)_3ReCl$ on a multigram scale when the liquid product can readily be purified by fractional distillation. The compound is very soluble in hexane from which it can be crystallized at low temperature, though in somewhat low yields due to the high solubility. Chlorination by other reagents leads to mixtures which are difficult to separate (Cl_2, Me_3SiCl or Me_3SiI) or to $(Bu^tN)_2ReCl_3$[2b] ($SOCl_2$, PCl_3). In the reaction with $PhICl_2$, the silicon-containing residue (not identified) is insoluble in hexane. The $(Bu^tN)_3ReCl$ is extremely sensitive to moisture; it is miscible with organic solvents such as hydrocarbons, THF, CH_2Cl_2, etc. The ^{1}H NMR spectrum is similar to that for $(Bu^tN)_3Re(OSiMe_3)$,[13] δ 1.28 vs δ 1.36, respectively, while the difference between the ^{13}C chemical shifts of the α- and β-imido carbons, which has been suggested[14] as indicative of the electron density on the imido nitrogen atom, $\Delta = 37.8$, is also comparable to that

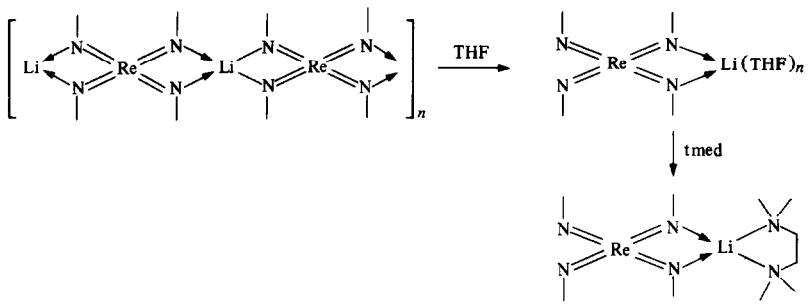
Table 5. Selected bond lengths and angles for $(Bu^tN)_6Re_2$

	Bond lengths (Å)	
Re—N(terminal),	range 1.69(3)–1.78(2),	Average 1.74
Re—N(bridge),	range 1.85(3)–1.94(2),	Average 1.91
Bond angles (°)		
M(terminal)—Re—N(terminal),	range 110(1)–112(1)	
Re—N(bridge)—Re,	range 88.4(7)—88.9(7)	
N(bridge)—Re—N(bridge),	range 91.1(8)—91.6(8)	

for (^{t}BuN)$_3$Re(OSiMe$_3$) ($\Delta = 35$). The slight difference suggests that electron donation by the ^{t}BuN group to the metal is increased, probably due to increased electron withdrawal by Cl compared to OSiMe$_3$.

The synthesis of (Bu^{t}N)$_3$Re(NHBu^t) by interaction of the chloride with LiNHBu^t gives good yields if the reagents in diethyl ether are slowly mixed at low temperature and the mixture allowed to warm slowly. A side product can be isolated by fractional crystallization but has not yet been characterized. The amide is a low melting, moisture sensitive, yellow crystalline solid with a characteristic N—H stretch in the IR at 3366 cm^{-1}. The ^{13}C-{^{1}H} spectrum shows that Δ for the α- and β-imido carbons is 35.3 ppm, suggesting that OSiMe$_3$ and NHBu^t are electronically similar ligands.

The deprotonation of the amide by MeLi in diethyl ether initially gives a product that slowly precipitates from the solution at room temperature as a yellowish solid, evidently polymeric LiRe(NBu^t)$_4$. This is insoluble in ether, hexane or toluene but slowly dissolves in THF, which is then easily displaced by Me$_2$N(CH$_2$)$_2$NMe$_2$ to give the hexane soluble Li(tmed)Re(NBu^t)$_4$ finally isolated. The reactions may be as shown in the eq. (2) (Bu^t groups omitted):



(2)

Neither the THF solution, not the THF solution of the tmed compound are electrically conducting and there is evidently no ionization in either case.

The compound Li(tmed)Re(NBu^t)$_4$ forms orange prisms that are extremely sensitive to moisture and decompose at relatively low temperatures. The X-ray crystal structure has been reported.[8] Although an 18-electron count for rhenium in the Re(NBu^t)$_4^-$ unit would be expected to lead to one bent and three linear (4e) imido ligands, in fact all four groups are non-linear, presumably because of averaging over the two terminal ligands and the two which bridge to the Li(tmed)$^+$.

The ^{1}H NMR spectrum of a solution of the complex in d^8-toluene containing THF or a slight excess of tmed (to inhibit polymerization and precipitation of the polymer at room temperature) shows a single peak at δ 1.44 ppm assignable to the *t*-butylimido group protons and two peaks due to the CH$_3$ and CH$_2$ protons of tmed at δ 1.92 and 1.76 ppm, respectively [Fig. 6(a)]. On lowering the temperature the Bu^t line starts to broaden at -30°C, and at -50°C splits into two peaks of equal intensity [Fig. 6(b)] that correspond to the two sets of non-equivalent Bu^t groups, i.e. terminal and bridging to Li$^+$ as in the solid structure.[8] At still lower temperatures (-70°C) the CH$_2$ protons of tmed started broadening, although the process responsible for this cannot be frozen out as low solubility limits the cooling.

For the exchange of the Bu^{t}N groups, using the formula[15] $\Delta G^\ddagger = \alpha T\,[10.319 + \log(T/k)]$, $\alpha = 1.914 \times 10^{-2}$, the $\Delta G^\ddagger$ value at the coalescence temperature (-40°C) is calculated to be 49.9 kJ mol^{-1} with $k = 29.7$ s^{-1}. The process is evidently intramolecular involving breaking a Li—NBu^t bond followed by rotation about the other Li—NBu^t bond and then coordination of one of the terminal NBu^t groups on rhenium.[16] Intermolecular exchange is unlikely in view of the negligible dissociation of the complex in polar solvents; association of two molecules without dissociation would require a highly hindered transition state with penta-coordination of rhenium(VII).

The second dynamic process at lower temperatures clearly involves the CH$_2$ groups and conformation changes of the puckered tmed chelate ring (see further comment below).

The ^{13}C NMR spectrum of the complex at room temperature (fast exchange limit) gives the α- and β-carbons of the *t*-butylimido group at δ 57.63 and 32.00 ppm, respectively, giving a difference, $\Delta = 25.6$ ppm, indicative of a nucleophilic imido nitrogen.[14] Although this value is qualitative, it suggests that electron donation from the imido nitrogen to the metal is reduced in comparison to Re(NBu^t)$_3$(NHBu^t) above, due to the presence of the fourth electron releasing imido group.

The structure of Li(tmed)Re(NBu^t)$_4$ at the low temperature exchange limit can be assumed to be that in the solid state[8] where the five-membered Li(tmed) ring is non-planar with a two-fold axis

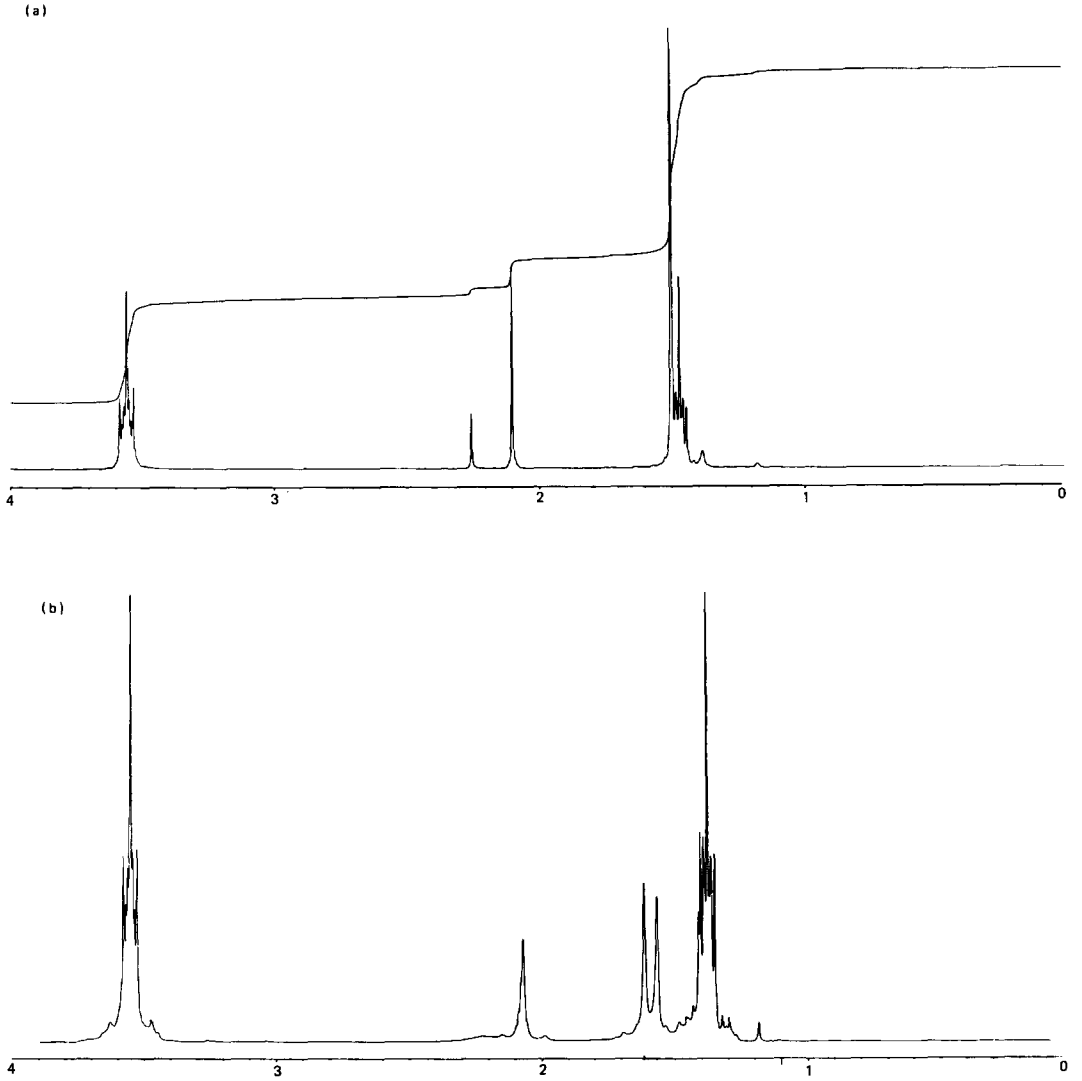


Fig. 6. NMR spectra of Li(tmed)Re(NBu^t)$_4$ (a) 25°C, (b) −60°C in d^8-toluene with additional THF.

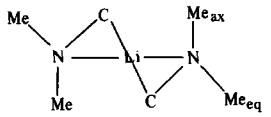
of symmetry passing through the lithium and the midpoint of the C—C bond. This results in the methyl substituents on each nitrogen atom being distinguishable as pseudo axial and equatorial (2).



(2)

The differences in their environment is clearly indicated by the torsion angles Me—N—C—C which are 73–75° for the "axial" and 12° for the equatorial substituents. Although, as noted above the exchange limit for the CH_2 groups could not be reached, nor could non-equivalence of the CH_3 groups be observed in the NMR. For extensive studies on conformation of chelate diamine rings see ref. 17.

EXPERIMENTAL

Microanalyses were by Pascher, Remagen and Imperial College Microanalytical Laboratories. Melting points were determined in sealed tubes and are uncorrected.

Spectrometers: IR, Perkin–Elmer 683 and 1720 (in Nujol mulls, values in cm^{-1}); NMR, Bruker WM-250, JEOL FX 90Q, JEOL GSX 270 (δ values in ppm relative to $SiMe_4$); ESR, Varian E12 (X-band in toluene, 22°C); mass, VG Micromass 7070 and MS-9, Kratos MS902. Magnetic moments by Evans' method in toluene.

All manipulations were carried out under purified

argon, dinitrogen or under vacuum. Solvents were dried by standard methods and degassed prior to use.

Cyclic voltammetry: OE-PP2 instrument in 0.2 M $^{n}BuNPF_6$ in THF at 22°C with platinum working, tungsten auxiliary and silver pseudo-reference electrodes. Under these conditions, Cp_2Fe was oxidized at 0.46 V with $\Delta E_p = 110$ mV. This rather high value (theoretical = 59 mV) is presumably due to uncompensated resistance in solution.[18]

$O_3Re(OSiMe_3)$,[19] $(Bu^tN)_3Re(OSiMe_3)$[13] and $(Bu^tN)_2ReCl_3$[2b] were prepared according to the literature. The last two were recrystallized from hexamethyldisiloxane and diethyl ether, respectively, to give crystals suitable for X-ray diffraction study.

(1) *Di*(t-*butylimido*)*di*(2,4,6-*trimethylphenyl*)*rhenium* (VI)

A solution of $(Bu^tN)_2ReCl_3$ (0.41 g, 0.94 mmol) in ether (30 cm^3) was cooled to −20°C. Mesitylmagnesium bromide (2.8 cm^3 of a 1.0 M solution in THF, 2.8 mmol) was added and the orange solution became instantly deep red. The solution was warmed to room temperature and stirred for 12 h, then filtered and the residue washed with ether (2 × 5 cm^3). The solvent was removed under reduced pressure and the material was extracted with hexane (20 cm^3), filtered and the volume reduced (10 cm^3). After another filtration large deep red crystals were obtained on cooling the hexane solution (−10°C). Yield 0.38 g, 71%; m.p. 128°C. Found: C, 55.0; H, 7.1; N, 5.0. Calc.: C, 55.1; H, 7.1; N, 4.9%. Mass spectrum: *m/z* 567 (100%), 565 (71%), $Re(NBu^t)_2(C_9H_{11})_2^+$; 511 (19%), 509 (9%), $(P-Bu^t)^+$; 447 (21%), 445 (11%), $(P-C_9H_{11})^+$; 119 (8%), $C_9H_{11}^+$. IR: 1591m, 1357s, 1279w, 1258s, 1235w, 1210s, 1153m, 1028br, 913br, 847s, 806m, 705m, 593w, 541w.

(2) *Di*(t - *butylimido*)*di*(2,4,6 - *trimethylphenyl*)*rhenium*(VII) *salts*

Hexafluorophosphate. Method A: to a stirred solution of $(Bu^tN)_2Re(mes)_2$ (0.5 g, 0.88 mmol) in THF (20 cm^3) was added Cp_2FePF_6 (0.29 g, 0.88 mmol). The deep red solution became bright orange and was stirred for 1 h. The solvent was removed under vacuum and the residue washed with hexane (2 × 5 cm^3) (to remove Cp_2Fe). The remaining orange powder was recrystallized from THF–ether to give bright red–orange crystals of the hexafluorophosphate. Yield 0.6 g, 95%; m.p. 158° dec. Found: C, 43.6; H, 5.7; N, 3.9. Calc.: C, 43.9; H, 5.6; N, 3.9%.

Method B: to a stirred solution of $(Bu^tN)_2Re(mes)_2$ (0.3 g, 0.53 mmol) in THF (20 cm^3) was added $AgPF_6$ (0.31 g, 0.53 mmol). The solution was stirred for 1 h, filtered (from Ag), the volume reduced (5 cm^3) and a few drops of ether added to induce crystallization of the hexafluorophosphate. Yield 0.35 g, 95%. Mass spectrum (FAB): *m/z* 567 (90%), $^{187}P^+$; 565 (53%), $^{185}P^+$; 511 (4%), $[^{185}P\text{-}C_9H_{11}]^+$. IR: 3123w, 1591s, 1366s, 1280s, 1229s, 1214m, 1179s, 1160m, 1140m, 1070w, 1032(br), 1002m, 955w, 901m, 876s, 839br, 804m, 701m, 589m, 558s, 474w, 374w, 349w. NMR: ^1H $(CD_3)_2CO$: 7.32 (4H, s, *m*-H_2—C_6); 2.54 (12H, s, *o*-CH_3); 2.38 (6H, s, *p*-CH_3); 1.86 (18H, s, CCH_3).

Trifluoromethane sulphonate. To a solution of $(Bu^tN)_2Re(mes)_2$ (0.1 g, 0.18 mmol) in THF (10 cm^3) was added AgO_3SCF_3 (0.05 g, 0.19 mmol). The deep red solution became bright orange and was stirred for 1 h, the solvent was removed under vacuum and the residue washed with hexane (2 × 5 cm^3). The orange powder was recrystallized from THF–ether to give bright orange–red crystals of the salt. Yield 0.1 g, 85%. The spectroscopic properties were similar to hexafluorophosphate except for the anion bands in the IR.

(3) *Interaction of* $[(Bu^tN)_2Re(mes)_2]^+$ *salts and isocyanides*

(a) $\{(Bu^tN)_2Re(mes)[C(mes)=N(2,6\text{ - }xylyl)]\}SO_3CF_3$. To a solution of $[(Bu^tN)_2Re(mes)_2]SO_3CF_3$ (0.3 g, 0.42 mmol) in THF (10 cm^3) was added 2,6-xylyl isocyanide (0.06 g, 0.45 mmol), and the colour changed from red–orange to pale yellow. The product was precipitated as pale yellow needles by the slow addition of hexane. Yield 0.3 g, 85%; m.p. 184°C. Found: C, 51.6; H, 6.1; N, 4.7. Calc.: C, 46.9; H, 6.2; N, 5.3%. Mass spectrum (FAB): *m/z* 698 (52%), $^{187}M^+$; 696 (31%), $^{185}M^+$; 448 (3%), $^{187}Re(NBu^t)_2(C_9H_{11})^+$; 446 (2%), $^{185}Re(NBu^t)_2(C_9H_{11})^+$. IR: 1667m, 1652w, 1608m, 1586w, 1364s, 1267s, 1224m, 1191w, 1150s, 1068m, 1032s, 925w, 895m, 879w, 794m, 753w, 705w, 572m, 517m. NMR: ^1H ($CDCl_3$): 7.23 [1H, t, *p*-*H*(xylyl)]; 7.14 [2H, s, *m*-*H*(N=Cmes)]; 7.07 [2H, d, *m*-*H* (xylyl)]; 6.98 [2H, s, *m*-*H*(mes)]; 2.44 [3H, s, *p*-*Me*(mes)]; 2.26 [3H, s, *p*-*Me*(N=Cmes)]; 2.23 [6H, s, *o*-*Me*(mes)]; 2.15 [6H, s, *o*-*Me*(N=Cmes)]; 1.82 [6H, s, *o*-*Me*(xylyl)]; 1.54 (18H, s, NBu^t).

(b) $\{(Bu^tN)_2Re(mes)[C(mes)=N(2,6\text{-}xylyl)]\}PF_6$. As above, using $[(Bu^tN)_2Re(mes)_2]PF_6$ (0.3 g, 0.42 mmol) and xylyl isocyanide (0.06 g, 0.45 mmol) in THF (10 cm^3). Yield: 0.32 g, 90%; m.p. 208°C. Found: C, 50.7; H, 5.9; N, 5.0. Calc.: C, 50.0; H, 5.8; N, 5.0%. Mass spectrum (FAB): *m/z* 698 (30%), $^{187}M^+$; 696 (16%), $^{185}M^+$; 579 (1%),

$(^{187}M-C_9H_{11})^+$; 577 (0.5%), $(^{185}M-C_9H_{11})^+$; 448 (2%), $^{187}Re(NBu^t)_2(C_9H_{11})^+$; 446 (1%), $^{185}Re(NBu^t)_2(C_9H_{11})^+$.

(c) $\{(Bu^tN)_2Re(mes)[C(mes)=NBu^t]\}PF_6$. A solution of $[(Bu^tN)_2Re(mes)_2]PF_6$ (0.1 g, 0.14 mmol) in THF (10 cm^3) was treated with *t*-butyl isocyanide (0.016 cm^3, 0.14 mmol). The red–orange solution turned pale yellow. The product was precipitated as pale yellow needles by the addition of ether. Yield: 0.1 g, 90%; m.p. 190°C. Found: C, 46.3; H, 6.1; N, 5.0. Calc.: C, 46.9; H, 6.2; N, 5.3%. Mass spectrum (FAB): *m/z* 650 (110%), $^{187}M^+$; 648 (60%), $^{185}M^+$; 474 (20%), $^{187}Re(NBu^t)_2NC(C_9H_{11})^+$; 472 (12%), $^{185}Re(NBu^t)_2NC(C_9H_{11})^+$; 448 (14%), $^{187}Re(NBu^t)_2(C_9H_{11})^+$; 446 (8%), $^{185}Re(NBu^t)_2(C_9H_{11})$. IR: 1703s, 1607m, 1597m, 1397w, 1365s, 1299w, 1286m, 1244s, 1216s, 1171s, 1144s, 1119w, 1066s, 1035w, 956w, 927w, 899m, 877m, 840vs, 735m, 705w, 667w, 654w, 582w, 558s, 526w, 468w. (4) *Di*(t - *butylimido*)*tri*(2 - *methylphenyl*)*rhenium* (VII)

A solution of $(Bu^tN)_2ReCl_3$ (0.3 g, 0.69 mmol) in ether (30 cm^3) was cooled to −20°C, *o*-tolylmagnesium bromide (2.45 cm^3 of a 0.85 mol dm^{-3} solution in ether, 2.08 mmol) was added and the orange solution became instantly dark red. The solution was warmed to room temperature and stirred for 12 h, then filtered and the residue extracted with ether (2 × 5 cm^3). The solvent was removed under reduced pressure and the material extracted with hexane (20 cm^3), filtered and the volume reduced (5 cm^3). After further filtration clumps of orange–red crystals were obtained on cooling the hexane solution (−20°C). Yield: 0.17 g, 40%; m.p. 103°C. Found: C, 57.8; H, 6.4; N, 4.7. Calc.: C, 57.9; H, 6.5; N, 4.6%. Mass spectrum: *m/z* 602 (1%), $^{187}Re(NBu^t)_2(C_7H_7)_3^+$; 600 (0.5%), $^{185}Re(NBu^t)_2(C_7H_7)_3^+$; 511 (22%), $^{187}Re(NBu^t)_2(C_7H_7)_2^+$; 509 (13%), $^{185}Re(NBu^t)_2(C_7H_7)_2^+$; 420 (3%), $^{187}Re(NBu^t)_2(C_7H_7)^+$; 418 (3%), $^{185}Re(NBu^t)_2(C_7H_7)^+$; 278 (2%), $^{187}Re(C_7H_7)^+$; 276 (1%), $^{185}Re(C_7H_7)^+$; 182 (9%), $(C_7H_7)_2^+$; 91 (100%), $(C_7H_7)^+$. IR: 1594w, 1575w, 1557w, 1359s, 1256s, 1204s, 1155m, 1141w, 1131m, 1056m, 1026w, 1014w, 804w, 745s, 731s, 708w, 638w, 578w, 447w, 408w. NMR: ^1H (C_6D_6): 807 (2H, dd, *o*-H); 7.23 (1H, d, *o*-H); 7.15–6.62 (9H, m, *m*, *p*-H); 2.59 (6H, s, *o*-Me); 2.10 (3H, s, *o*-Me); 1.21 (18H, s, CCH_3).

(5) *Di*(t-*butylimido*)*dichloro*(*phenyl*)*rhenium*(VII)

To a stirred solution of $(Bu^tN)_3Re(OSiMe_3)$ (0.5 g, 1.0 mmol) in hexane (30 cm^3) was added phenylmagnesium chloride (0.9 cm^3 of a 1.25 mol dm^{-3} solution in ether, 1.1 mmol) at −78°C. The solution was allowed to warm to room temperature and stirred for 2 h, filtered and the solvent removed under vacuum. The solid was dissolved in ether (20 cm^3) and a solution of HCl in ether (7 cm^3 of a 0.5 mol dm^{-3} solution, 3.5 mmol) was added. The solution was stirred for 1 h, filtered and the filtrate evaporated. The residue was recrystallized from Et_2O as orange–red crystals. Yield: 30%; m.p. 163°C. Found: C, 35.1; H, 4.8; N, 5.8. Calc.: C, 35.3; H, 4.8; N, 5.9%.

Note that in the preparation from which crystals for X-ray crystallography were taken, PhMgBr was used which resulted in bromide contamination (see X-ray section below). Mass spectrum: *m/z* 477 (1%), 475 M^+; 462 (0.5%), 460 (0.05%), $(P—Me)^+$; 441 (8%), 439 (4%), $(M—Cl)^+$, 57 (100%), $(Bu^t)^+$. IR: 1643w, 1570w, 1428m, 1364s, 1303w, 1250s, 1213m, 1189s, 1138m, 1067m, 1016w, 996m, 905w, 848w, 799m, 741s, 696s, 654w, 609m, 474w, 459m, 334m, 322m, 286m. NMR: ^1H (C_6D_6): 1.15 (18H, s, Bu^t); 7.1–7.3 (3H, m, *m*, *p*-$H_3C_6H_2$); 7.90 (2H, d, *o*-$H_2C_6H_3$).

(6) *Bis*[(*di* - t - *butylimido*)(μ - t - *butylimido*)*rhenium* (VI)]

A solution of $(Bu^tN)_3Re(OSiMe_3)$ (0.5 g, 1.0 mmol) in hexane (25 cm^3) was stirred with sodium amalgam (0.5 g Na in 3 cm^3 Hg) for 12 h at room temperature. The resulting red–yellow solution was filtered, evaporated to dryness and extracted with hexamethyldisiloxane (10 cm^3). Filtration and cooling of the solution to −20°C for several days gave yellow crystals which were recrystallized from hexane or $(Me_3Si)_2O$. Yield: *ca.* 20%; subl. 212°C *in vacuo*. Found: C, 36.2; H, 6.7; N, 10.3. Calc.: C, 36.1; H, 6.8; N, 10.5%. Mass spectrum: *m/z* 800 (87%), 798 (100%), M^+. IR: 1455m, 1355s, 1281m, 1243s, 1214s, 1198m, 1155w, 1069(br), 1049m, 1024m, 914m, 845s, 806m, 756w, 681w, 597w, 559w, 507w, 462w. NMR: ^1H: (d_8-toluene): 1.82 (18H, s, μ-NBu^t), 1.27 (36H, s, NBu^t).

(7) *Tris*(t-*butylimido*)*chlororhenium*(VII)

To $(Bu^tN)_3Re(OSiMe_3)$ (4.32 g, 8.85 mmol) in toluene (50 cm^3) was added $PhICl_2$[20] at room temperature and the mixture stirred for 12 h, during which time it turned from yellow to deep red then orange. Volatiles were removed in vacuum and the

residual oil extracted into hexane (30 cm^3) which was filtered and the solution transferred to a small distillation apparatus with a fractionating column (8 cm). Hexane was removed (at 1 atm) and the remainder distilled to give $(Bu^tN)_3ReCl$ as an orange liquid (b.p. 95–100°C at 0.08 mm Hg) which solidifies on cooling to room temperature. Yield: 3.7 g, 95%; m.p. *ca* 35°C. Mass spectra: *m/z* 437 (M^+ showing isotopic patterns due to ^{185}Re and ^{35}Cl); 366 $(M-NBu^t)^+$. NMR: (C_6D_6) ^1H: 1.28 s. ^{13}C: 69.1, 31.3.

The compound can alternatively be isolated by low temperature (−40°C) crystallization from concentrated hexane solution but the yield is lower due to the high solubility.

(8) *Tri*(t-*butylimido*)(t-*butylamido*)*rhenium*(VII)

To $(^tBuN)_3ReCl$ (1.73, 3.9 mmol) in diethyl ether (40 cm^3) at −40°C was slowly (5 min) added via a cannula a solution of $LiNHBu^t$ (from $^tBuNH_2$ and ^{n}BuLi in hexane; 0.32 g, 4.05 mmol) in Et_2O at −40°C. After warming the colour changed from orange to pale yellow at 0°C when LiCl precipitated; the solution was stirred for 8 h at room temperature then evaporated *in vacuo*. The residue was extracted into hexane (30 cm^3), the extracts filtered through celite, the yellow solution concentrated to *ca* 8 cm^3 and cooled to −20°C. The first yellow crystals (not identified) were moved and the supernatant cooled to −78°C for 12 h, yielding yellow prisms which were collected and dried *in vacuo*. Yield: 1.1 g, 58%; m.p. 64–66°C. The compound can be sublimed (100°C at 0.05 mmHg). Mass spectrum: *m/z*: 474 100% $(M+2)^+$; 457 $(M+2-Me)^+$; 418 $(M+2-CH_2CMe_2)^+$; 401 $(M-NBu^t)^+$. IR: *ν*(N—H), 3366. NMR: (C_6D_6) ^1H: 1.19 (9H, s, $NHBu^t$); 1.70 (27H, s, NBu^t); 3.57br (1H, s, N*H*). $^{13}C-\{^1H\}$: 67.3 ($NCMe_3$); 52.7 ($NH—CMe_3$); 32.8 [$NH—C(CH_3)_3$]; 32.0 [$N—C(CH_3)_3$].

(9) *Lithium*(*tetramethylethylenediamine*)*tetra*(t-*butylimido*)*rhenate*(VII)

To a solution of $(Bu^tN)_3Re(NHBu^t)$ (1.07 g, 2.28 mmol) in Et_2O (40 cm^3) at −40°C was added an Et_2O solution of MeLi (4.8 cm^3 of a 0.52 M solution, 12.5 mmol). During warming to room temperature the colour changed from yellow to deep orange–red; the solution was stirred for about 4 h, when a yellow–white precipitate of a polymeric lithium salt precipitated. The volatiles were removed *in vacuo* and the residue washed with hexane (2 × 20 cm^3). To the residue was added THF (30 cm^3) and the mixture stirred for 1 h to give a clear orange solution. To this solution was added dry tetramethylethylenediamine (1 cm^3, 6.6 mmol) and the solution stirred for *ca* 1 h. Volatiles were removed and the orange residue extracted into hexane (30 cm^3); the solution was filtered, concentrated to *ca* 2 cm^3 and cooled (−20°C) for 12 h to give deep orange prisms which decompose on exposure to air. Yield: 0.4 g, 28%. X-ray quality crystals were obtained by slow cooling of hexane solutions at −78°C. NMR: ^1H (d^8 toluene, 25°C): 1.44 (36H, s, Bu^tN); 1.76 (4H, s, CH_2N); 1.92 (12H, s, NCH_3). $^{13}C-\{^1H\}$ (C_6D_6 25°C): 57.63 ($NC—Me_3$); 32.00, ($NC—CH_3$); 46.67 (CH_2NMe_2); 33.83 [$CH_2N(CH_3)_2$].

X-ray crystallography

All crystallographic measurements were made at 293 K on crystals sealed under argon in thin walled glass capillaries, using a CAD4 diffractometer operating in the ω–2θ scan mode with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), following previously detailed procedures.[21] Crystal data and intensity data collected parameters are given in Table 6.

The structures were solved by application of the heavy-atom method and refined by full-matrix least-squares. Generally, all non-hydrogen atoms were refined anisotropically; hydrogens were included in idealized positions only in the case of the phenyl complex. In this complex the halogen site *trans* to the phenyl contained a mixture of chlorine and bromine, the latter almost certainly arising out of the use of a bromo-Grignard in the preparation.

The solution and refinement of the homoleptic imido dimer structure was troublesome. The data was originally and fortuitously collected on the basis of a triclinic cell, but during the subsequent analysis it was recognized that this could be transformed to a body centred orthorhombic cell. No kind of translation symmetry was indicated and so attempts were made to refine in space groups *I*222, *Imm*^{2} and *Immm*, all of which were consistent with the heavy-atom structure found using the triclinic description. However, in all cases serious disorder existed in all Bu^t orientations and eventually we found it most convenient to refine the structure in the triclinic space group $P\bar{1}$. Even here, the disorder still occurred and only the core atoms were fully identified and refined with anisotropic displacement factors. The Bu^t carbons were represented by groupings of various numbers of partial carbons, in which the tertiary carbon–methyl carbons were fixed at a standard value of 1.50 Å. Details of the refinements in the other space groups are included

PRELIMINARY CHEMICAL AND STRUCTURAL STUDY OF (1-CHLOROPHOSPHIRANE)PENTACARBONYLTUNGSTEN

BERNARD DESCHAMPS, LOUIS RICARD and FRANÇOIS MATHEY*

Laboratoire de Chimie du Phosphore et des Métaux de Transition, DCPH,
Ecole Polytechnique, 91128 Palaiseau Cedex, France

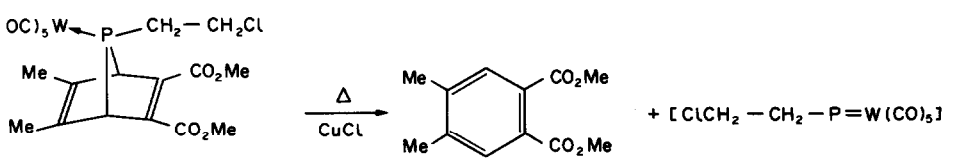
(*Received* 10 *April* 1989; *accepted* 12 *June* 1989)

Abstract—(β-Chloroethylphosphinidene)pentacarbonyltungsten, generated from the appropriate 7-phosphanorbornadiene precursor, reacts with aniline to give [(β-chloroethyl)(phenylamino)phosphane]pentacarbonyltungsten, which cyclizes upon phosphorus-metallation with *n*-butyllithium. (1-Phenylaminophosphirane)pentacarbonyltungsten, thus obtained, reacts with dry HCl to give the title compound as a stable crystalline solid which has been structurally characterized. When compared with the parent phosphirane, (1-chlorophosphirane)pentacarbonyltungsten shows much shorter P—C bonds (1.78–1.81 vs 1.867 Å) and a larger CPC intracyclic angle (49.2 vs 47.4°), which explain the enhanced stability of the complex. Normal nucleophilic substitution at the P—Cl bond is observed with EtO^- (EtOTl), O^{2-} (H_2O+DBO), $(EtO)_2P(O)^-$ and H^- ($LiAlH_4$). The opening of the ring is observed with a stronger nucleophile such as EtONa.

Presently, free unsubstituted 1-chlorophosphirane is unknown and, apparently, only 1-chlorophosphiranes with bulky substituents on the ring are stable.[1] Since the complexation of phosphorus by $M(CO)_5$ groups (M = Cr, Mo, W) has a well-documented stabilizing effect on the phosphirane ring,[2–5] we decided to study the synthesis of this interesting and fundamental species in the coordination sphere of tungsten. Two routes have been devised. We describe one of them in this paper together with some preliminary results concerning the chemistry and the structure of the complexed ring.

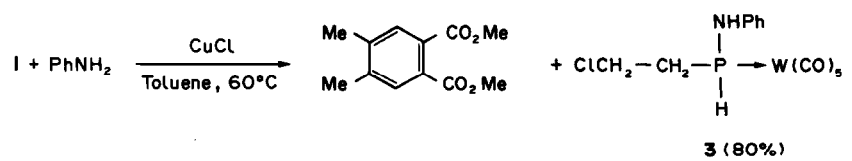
RESULTS AND DISCUSSION

Our starting point has been the readily available 7-β-chloroethyl-7-phosphanorbornadiene complex (**1**),[6] which acts as a precursor for the corresponding transient β-chloroethylphosphinidene complex (**2**) [eq. (1)]:



1 **2** (1)

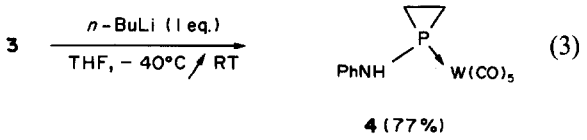
With a weakly basic amine such as aniline, the trapping of **2** occurs without side reactions[7] [eq. (2)]. (This is not the case any more with the more basic diethylamine.)



3 (80%) (2)

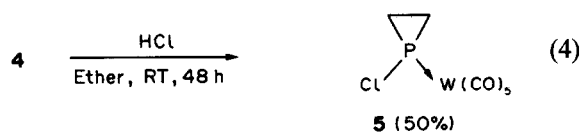
* Author to whom correspondence should be addressed.

A clean cyclization takes place upon treatment of **3** with *n*-butyllithium [eq. (3)]:



(3)

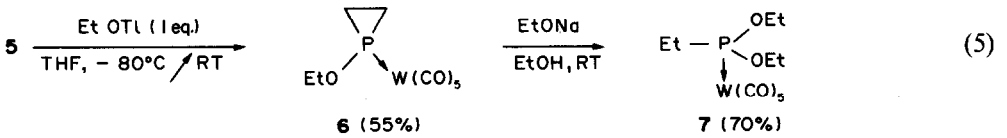
The ring closure can be monitored easily by ^{31}P NMR analysis of the reaction mixture: a characteristic upfield shift is observed and the $^{1}J(P—H)$ coupling disappears [$\delta^{31}P(\mathbf{3})$ +1.5 ppm, $^{1}J(P—H)$ 366 Hz; δ $^{31}P(\mathbf{4})$ −132 ppm]. The reaction of **4** with anhydrous HCl then affords the expected 1-chlorophosphirane complex (**5**) as a stable crystalline solid [eq. (4)]:



(4)

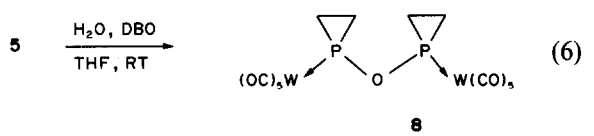
The stability of complex **5** is in sharp contrast with the very low stability of the free parent phosphirane.[8] The X-ray crystal structure analysis of **5** (Fig. 1) visualizes this stabilization of the ring upon complexation. Indeed, when comparing the structure of **5** with the structure of the parent phosphirane,[9] a striking shortening of the P—C bonds of **5** is observed: P—C bond lengths: 1.78(1) and 1.81(1) Å in **5** vs 1.867 Å in C_2H_4PH.[9] As a result, the CPC intracyclic angle increases from 47.4 ° in C_2H_4PH[9] to 49.2(5)° in **5**, suggesting a somewhat reduced cyclic strain in the complex. An easy rationalization of this phenomenon can be achieved if we use the approach of Dewar.[10] Three-membered heterocycles with weakly electronegative heteroatoms can also be viewed as π-olefinic complexes. If we consider phosphirane as a π-complex between ethylene and phosphinidene and compound **5** as a π-complex between ethylene and (chlorophosphinidene)pentacarbonyltungsten, it is clear that the phosphinidene unit is a far better electrophile as a complex than as a free species (this question is discussed in ref. 11). Thus, we expect a stronger interaction between the electron-rich ethylene and the phosphinidene subunit in the case of complex **5**. From another standpoint, it appears that 1-chlorophosphirane is a powerful ligand towards tungsten, as monitored by the short P—W bond [2.455(2) Å vs 2.496(1) Å in $(PhPC_2Ph_2)W(CO)_5$ as an example[12]]. Other structural data are given in the caption of Fig. 1.

As for other (phosphirane)pentacarbonyltungsten complexes, the ring of **5** is easily opened by strong nucleophiles.[13] Thus, some care must be taken when nucleophilic substitutions are attempted onto the P—Cl bond. For example, thallium ethoxide affords the P—OEt derivative **6**, but sodium ethoxide induces a ring opening [eq. (5)]:



(5)

This ring opening can be monitored easily by ^{31}P NMR spectroscopy: $\delta^{31}P(\mathbf{6})$ −46 ppm; $\delta^{31}P(\mathbf{7})$ +167 ppm. Similarly, minute amounts of water in the presence of a basic tertiary amine (1,4-diazabicyclo[2.2.2]octane, DBO) afford the corresponding anhydride **8** [eq. (6)]:



(6)

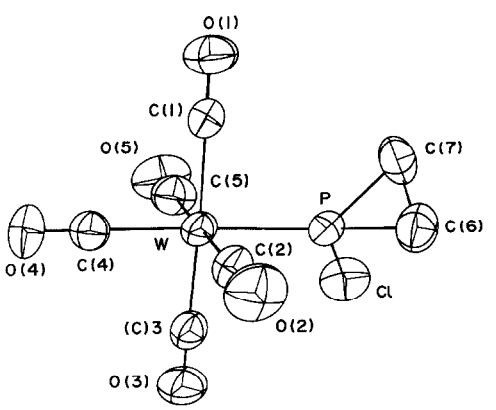


Fig. 1. ORTEP drawing of one molecule of **5**. Vibrational ellipsoids are scaled to enclose 50% of the electron density. Hydrogen atoms are omitted for clarity. Principal bond distances (Å): W—P, 2.455(2); W—C(1), 2.042(9); W—C(2), 2.023(9); W—C(3), 2.036(8); W—C(4), 2.01(1); W—C(5), 2.04(1); Cl—P, 2.037(3); P—C(6), 1.78(1); P—C(7), 1.81(1); C(6)—C(7), 1.49(1). Selected bond angles (°): P—W—C(1), 91.1(3); P—W—C(2), 88.2(3); P—W—C(3), 90.7(3); P—W—C(4), 177.8(3); P—W—C(5), 89.7(4); W—P—Cl, 118.4(1); W—P—C(6), 132.2(4); W—P—C(7), 130.8(4); Cl—P—C(6), 102.6(4); Cl—P—C(7), 104.3(4); C(6)—P—C(7), 49.2(5); P—C(6)—C(7), 66.2(6); P—C(7)—C(6), 64.6(6).

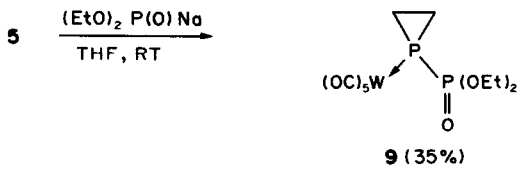
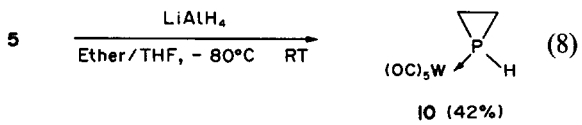
As expected, the ^{31}P chemical shifts of **6** and **8** are very close: δ ^{31}P(**8**) −45 ppm. The phosphirane ring of **5** is also preserved in the reaction with the weakly nucleophilic sodium diethylphosphite [eq. (7)]:



(7)

The resulting complex, **9**, has a very characteristic ^{31}P NMR spectrum, AB system: δ(A) −235 ppm (phosphirane), δ(B) +22.8 ppm (P=O), ^{1}J(P—P) 29.3 Hz. The chemical shifts of P_A and P_B rule out a $(EtO)_2P$—O—P (phosphirane) formulation in spite of the very low ^{1}J(P—P) coupling constant. Such low couplings have already been found in similar "phospha-Wittig" reagents.[13,14] Finally, the reduction of **5** by $LiAlH_4$ affords the complex of the parent phosphirane, **10** (a similar molybdenum complex has already been made from the free phosphirane[2]) [eq. (8)]:



(8)

Complex **10** is characterized by a ^{31}P resonance at very high field [δ^{31}P(**10**) −254 ppm] and a ^{1}J(P—H) coupling constant in the normal range for a P—$W(CO)_5$ complex (356 Hz, see refs 7 and 15). It is interesting to note here that free phosphirane is known to have an abnormally low ^{1}J(P—H) coupling,[16] contrary to its complex **10**.

EXPERIMENTAL

All reactions were performed under argon. NMR spectra were recorded on multinuclear WP 80 SY and AC 200 SY Brüker spectrometers, operating at 80.13 and 200.13 (^{1}H), 20.15 and 50.32 (^{13}C), and 32.44 (^{31}P) MHz. Chemical shifts are in ppm downfield from internal TMS (^{1}H and ^{13}C) and external 85% H_3PO_4 (^{31}P), and coupling constants are in Hz. Mass spectra were recorded on a Shimadzu GC-MS QP 1000 instrument at 70 eV under electronic impact. Elemental analyses were performed by the Service Central de Microanalyse du CNRS, France. All the new products gave correct carbon, hydrogen elemental analyses. Silica gel (70–230 mesh) was used for the chromatographic separations. All commercially available reagents were used as received from the suppliers.

[(Chloroethyl)(phenylamino)phosphane]pentacarbonyltungsten (**3**)

(7-β-chloroethyl 7-phosphanorbornadiene)pentacarbonyltungsten (**1**) (6.3 g, 10.6×10^{-3} mol) and aniline (1.01 g, 1.06×10^{-3} mol) in 15 cm^3 of toluene were heated at 60°C for 20 min in the presence of copper(I) chloride as a catalyst. After cooling and evaporation of toluene, the crude reaction mixture was chromatographed with hexane–toluene (80 : 20) as eluent. Yield of **3**: 4.0 g (80%). ^{31}P NMR (CH_2Cl_2): δ +1.5, $^{1}J(^{31}P—^{183}W)$ 254 Hz, $^{1}J(^{31}P—^{1}H)$ 366 Hz; ^{1}H NMR ($CDCl_3$): δ2.63 (m, 2H, CH_2Cl), 3.67 (m, 2H, CH_2P), 4.02 (dd, 1H, ^{3}J(H—H): 7.3 Hz, N—*H*), 7.1 (m, 1H, $^{1}J(^{31}P—^{1}H)$: 366 Hz P—*H*), 6.8–7.4 (m, 5H, Ph); ^{13}C NMR ($CDCl_3$): δ32.89 (d, ^{1}J(C—P): 25.3 Hz P—CH_2), 39.39 (s, CH_2Cl), 195.37 (d, ^{2}J(C—P) 6.3 Hz *cis*-CO) 197.63 (d, ^{2}J(C—P) 23.8 Hz, *trans*-CO). Mass spectrum (^{184}W, ^{35}Cl): *m/z*: 511 (19%), 483 (M−CO, 6%), 455 (M−2CO, 13%), 427 (M−3CO, 23%), 399 (M−4CO, 47%), 371 (M−5CO, 44%), 343 (M−5CO−C_2H_4, 100%).

(1-*Phenylaminophosphirane*)*pentacarbonyltungsten* (**4**)

Complex **3** (4.0 g, 8.4×10^{-3} mol) in 50 cm^3 of THF was cooled to *ca* −40°C. One equivalent of *n*-BuLi (5.2 cm^3 of a 1.5 N solution in hexane) was added dropwise. The crude mixture was allowed to warm to room temperature and, after evaporation of THF, was chromatographed with hexane–toluene (80 : 20) as eluent. Yield of **4**: 2.85 g (77%). ^{31}P NMR (CH_2Cl_2): δ −132 ppm, $^{1}J(^{31}P—^{183}W)$ 288 Hz; ^{1}H NMR ($CDCl_3$): δ1.17–1.63 (m, 4H, CH_2CH_2), 3.97 (broad s, 1H, N*H*), 6.88–7.24 (m, 5H, Ph); ^{13}C NMR ($CDCl_3$): δ14.0 (d, ^{1}J(C—P) 13.1 Hz, CH_2CH_2), 195.30 (d, ^{2}J(C—P): 8.5 Hz, *cis*-CO), 198.10 (d, ^{2}J(C—P) 35 Hz, *trans*-CO). Mass spectrum (^{184}W) *m/z*: 474 (M−H, 8%), 446 (M−H−CO, 23%), 418 (M−H−2CO, 15%), 390 (M−H−3CO, 6%), 362 (M−H−4CO, 100%), 334 (M−H−5CO, 43%), 306 (M−H−5CO−C_2H_4, 53%).

(1-*Chlorophosphirane*)*pentacarbonyltungsten* (**5**)

A saturated ether solution of dry HCl was first prepared. Then complex **4** (2.85 g, 6×10^{-3} mol) in HCl–ether solution (10 cm^3) was stirred at room temperature for 48 h in a sealed Erlenmeyer. The crude reaction mixture was chromatographed with hexane–toluene (80 : 20) as eluent. Yield of **5**: 1.22 g (50%). ^{31}P NMR: δ −98 ppm, $^{1}J(^{31}P—^{183}W)$ 303 Hz; ^{1}H NMR ($CDCl_3$): δ1.38–1.52 (m, 2H,

CH_2), 2.00–2.12 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$): δ14.94 (d, ^1J(C—P) 20 Hz, CH_2), 194.27 (d, ^2J(C—P) 8.9 Hz, *cis*-CO), 197.35 (d, ^2J(C—P) 44.3 Hz, *trans*-CO). Mass spectrum (^{184}W, ^{35}Cl) *m/z*: 418 (M, 27%), 390 (M − CO, 19%), 362 (M − 2CO, 21%), 334 (M − 3CO, 32%), 306 (M − 4CO, 81%), 304 (M − 4CO − 2H, 100%), 278 (M − 5CO, 70%). Experimental details of the X-ray data collection and processing are given in Table 1.

(1-*Ethoxyphosphirane*)*pentacarbonyltungsten* (**6**)

To complex **5** (1.0 g, 2.4×10^{-3} mol) in 20 cm^3 of THF was added thallous ethoxide (0.1 cm^3, 2.4×10^{-3} mol) at −80°C. The crude mixture was allowed to warm up to room temperature and after evaporation was chromatographed with hexane–toluene (80 : 20) as eluent. Yield of **6**: 0.56 g (55%). ^{31}P NMR (CH_2Cl_2): δ −46 ppm, ^1J(^{31}P—^{183}W) 303 Hz; ^{1}H NMR ($CDCl_3$): δ0.82–0.95 (m, 2H, CH_2), 1.21 (t, 3H, CH_3), 1.54–1.67 (m, 2H, CH_2), 3.56–3.71 (m, 2H, OCH_2) ppm; ^{13}C NMR ($CDCl_3$): δ10.60 (d, ^1J(C—P) 14.25 Hz, CH_2P), 16.17 (d, ^3J(C—P) 7.85, CH_3), 64.46 (d, ^2J(C—P) 2.9 Hz, OCH_2), 195.14 (d, ^2J(C—P) 9.05 Hz, *cis*-CO), 198.24 (d, ^2J(C—P) 35.8 Hz, *trans*-CO). Mass spectrum (^{184}W) *m/z*: 428 (M, 32%), 400 (M − CO, 13%), 372 (M − 2CO, 32%), 344 (M − 3CO, 32%), 316 (M − 4CO, 48%), 288 (M − 5CO, 53%), 287 (M − 4CO − C_2H_5, 100%).

[*Ethyl - bis*(*ethoxy*)*phosphane*]*pentacarbonyltungsten* (**7**)

To a solution of sodium ethoxide in ethanol (0.7×10^{-3} mol) was added complex **6** (0.3 g, 0.7×10^{-3} mol) at room temperature. After 2 h, ethanol was evaporated and the crude reaction mixture was chromatographed with hexane–toluene (80 : 20) as eluent. Yield of **7**: 0.23 g (70%). ^{31}P NMR (CH_2Cl_2): δ167 ppm, ^1J(^{31}P—^{183}W) 318 Hz; ^{1}H NMR ($CDCl_3$): δ1.06–1.25 (m, 3H, PCH_2CH_3), 1.32 (t, 6H, OCH_2CH_3), 1.95–2.09 (m, 2H, PCH_2), 3.80–4.03 (m, 4H, OCH_2); ^{13}C NMR ($CDCl_3$):

Table of Experimental Details	
Crystal description	White, paralleliped 0.30 × 0.25 × 0.22
Instrument	Enraf–Nonius CAD4 diffractometer
Corrections	Lorentz-polarization Linear decay (from 0.988 to 1.000 on *I*).[a] Reflection averaging (agreement on $I = 3.8\%$). Extinction (coefficient = 0.0000002)
Maximum 2θ	60.0°
hkl ranges	$h = 0$–9 $k = 0$–15 $l = -22$–22
Number of reflections measured	3889 total, 3617 unique
Reflections included	2384 with $F_0^2 > 3.0\sigma(F_0^2)$
Solution	Patterson method
Least-squares details:	
Hydrogen atoms	Included as fixed contribution to the structure factor
Parameters refined	137
Unweighted agreement factor	0.026
Weighted agreement factor	0.064
G.O.F.	1.33
Convergence, largest shift	0.00
Minimization function	$w(\|F_o\| - \|F_c\|)^2$
Least-squares weights	$4F_0^2/\sigma^2(F_0^2)$
Instrument instability factor (*p*)	0.080
High peak in final difference map	0.73(13) e/Å^3
Low peak in final difference map	0.00(13) e/Å^3

F.W. = 418.38; space group: *P*21/*n* (No. 14); $a = 6.832(1)$, $b = 10.893(1)$, $c = 15.993(1)$ Å, $\beta = 96.83(1)°$; $V = 1181.75(37)$ Å^3; $Z = 4$; $D_{calc} = 2.351$ g cm^{-3}; Radiation = Mo-K_α ($\lambda = 0.71073$ Å); $\mu = 103.4$ cm^{-1}; $F(000) = 768$; temperature = 18 ± 1°; final $R = 0.026$; number of unique reflections = 2384.

[a] The increase is probably due to a record low atmospheric pressure over France during data collection.

δ6.57 (s, PCH_2CH_3), 16.06 and 16.18 (s, OCH_2CH_3), 30.74 (d, ^1J(C—P) 34.7 Hz, P—CH_2), 62.00 and 62.11 (s, OCH_2), 196.21 (d, ^2J(C—P) 8.5 Hz, *cis*-CO), 198.84 (d, ^2J(C—P) 27.8 Hz, *trans*-CO). Mass spectrum (^{184}W) *m/z*: 474 (M, 25%), 446 (M−CO, 18%), 445 (M−Et, 7%), 418 (M−2CO, 32%), 416 (M−2Et, 31%), 390 (M−3CO, 99%), 388 (M−2Et−CO, 100%), 362 (M−4CO, 27%), 359 (M−3Et−CO, 27%), 334 (M−5CO, 36%).

[(Bis-phosphiran-1-yl)oxide]decacarbonylditungsten (**8**)

Complex **5** (0.21 g, 0.5×10^{-3} mol) was stirred in 10 cm^3 of THF with DBO (0.06 g, 0.5×10^{-3} mol) and a minute amount of water. The mixture was chromatographed with hexane–toluene (80 : 20) as eluent. Yield of **8**: 0.17 g (86%). ^{31}P NMR (CH_2Cl_2): δ −42.2 ppm, $^1J(^{31}P—^{183}W)$ 288.1 Hz; ^{1}H NMR ($CDCl_3$): δ1.00–1.22 (m, 4H, PCH_2), 1.76–1.98 (m, 4H, PCH_2); ^{13}C NMR ($CDCl_3$): δ12.51 (s, PCH_2), 194.45 (s, *cis*-CO). Mass spectrum (^{184}W) *m/z*: 670 (M−4CO, 8%), 642 (M−5CO, 13%), 614 (M−6CO, 28%), 586 (M−7CO, 55%), 558 (M−8CO, 51%), 530 (M−9CO, 28%), 503 (M−10CO, 36%), 474 (M−10CO−C_2H_4, 66%), 446 (W−P−O−P−W, 100%).

(1-*Diethoxyphosphorylphosphirane*)*pentacarbonyltungsten* (**9**)

Diethylphosphite (0.33 g, 2.4×10^{-3} mol) was slowly added at room temperature to NaH (0.1 g, 2.5×10^{-3} mol—60% dispersion in mineral oil) in 10 cm^3 of THF. After the H_2 evolution had ceased, complex **5** (1.0 g, 2.4×10^{-3} mol) was added. The mixture was stirred at room temperature for 2 h. Then, solvent was evaporated and the crude reaction mixture chromatographed with hexane–ether (60 : 40) as eluent. Yield of **9**: 0.44 g (35%). ^{31}P NMR (CH_2Cl_2): δ25.39 (*AB*, ^1J(P—P) 29.3 Hz, $P(O)(OEt)_2$), −233.2 (*AB*, ^1J(P—W) 253.9 Hz); ^{1}H NMR ($CDCl_3$): δ1.39 (t, 6H, CH_3), 1.40–1.57 (m, 2H, PCH_2), 1.91–2.06 (m, 2H, PCH_2), 4.12–4.27 (m, 4H, OCH_2); ^{13}C NMR ($CDCl_3$): δ9.48 (d, ^1J(C—P) 17.5 Hz, P—CH_2), 16.19 and 16.30 (s, CH_3), 63.67 and 63.81 (s, OCH_2), 194.45 (d, ^2J(C—P) 7.4 Hz, *cis*-CO), 196.28 (d, ^2J(C—P) 34.7 Hz, *trans*-CO). Mass spectrum (^{184}W) *m/z*: 520 (M, 30%), 492 (M−CO, 6%), 464 (M−2CO, 8%), 436 (M−3CO, 34%), 408 (M−4CO, 40%), 380 (M−5CO, 51%), 351 (M−5CO−Et, 100%), 290 [M−5CO−$(OEt)_2$, 54%].

(*Phosphirane*)*pentacarbonyltungsten* (**10**)

To complex **5** (2.0 g, 4.8×10^{-3} mol) in 50 cm^3 of THF was added $LiAlH_4$ (0.045 g, 1.2×10^{-3} mol) in a suspension of ether at −80°C. The reaction mixture was allowed to warm to room temperature and hydrolysed with aqueous THF. The solvent was removed and the crude mixture was chromatographed with hexane–ether (80 : 20) as eluent. Yield of **10**: 0.78 g (42%). ^{31}P NMR (CH_2Cl_2): δ −254 ppm, $^1J(^{31}P—^{183}W)$ 253.9 Hz, ^1J(P—H) 356.4 Hz; the ^{1}H NMR spectrum ($CDCl_3$) is very complicated (see ref. 16) and has not been simulated; ^{13}C NMR ($CDCl_3$): δ3.03 (d, ^1J(C—P) 10.4 Hz, CH_2), 194.80 (d, ^2J(C—P) 8.4 Hz, *cis*-CO), 197.05 (d, ^2J(C—P) 32.2 Hz, *trans*-CO). Mass spectrum (^{184}W) *m/z*: 384 (M, 81%), 383 (M−H, 51%), 356 (M−CO, 23%), 328 (M−2CO, 89%), 300 (M−3CO, 89%), 272 (M−4CO, 91%), 270 (100%), 244 (M−5CO, 49%).

X-ray structure determination for **5**

Crystals of **5**, $C_7H_4O_5PClW$, were obtained at 0°C from a dichloromethane–hexane solution of the compound. Data were collected at 18 ± 1° on an Enraf–Nonius CAD4 diffractometer. The crystal structure was solved and refined using the Enraf–Nonius supplied SDP package. The compound crystallizes in space group $P2_1/n$, $a = 6.832(1)$, $b = 10.893(1)$, $c = 15.993(1)$ Å, $\beta = 96.83(1)°$, $V = 1181.75(37)$ Å^3, $Z = 4$, $D_{calc} = 2.351$ g cm^{-3}; Mo-K_α radiation ($\lambda = 0.71073$ Å) graphite monochromator; $\mu = 103.4$ cm^{-1}; $F(000) = 768$. A total of 3617 unique reflections were recorded in the range $2 \leqslant 2\theta \leqslant 50°$ of which 1505 were considered as unobserved ($F^2 < 3\sigma(F^2)$), leaving 2384 for solution and refinement. The structure was solved by Patterson methods. The positional parameters of hydrogen atoms were included as a fixed contribution to the structure factors in the final stages of least-squares, while using anisotropic temperature factors for all other atoms. A non-Poisson weighting scheme was applied with a *p*-factor equal to 0.08. The final *R*-factors were $R = 0.026$, $R_w = 0.064$, G.O.F. = 1.33.

COBALT(III)–SALICALDEHYDE–AMINOPHENOL COMPLEXES: SOLUBILITIES, TRANSFER CHEMICAL POTENTIALS AND SOLVATION IN BINARY AQUEOUS SOLVENT MIXTURES

E. A. ABU-GHARIB and J. BURGESS*

Department of Chemistry, University of Leicester, Leicester LE1 7RH, U.K.

(*Received* 24 *May* 1989; *accepted* 15 *June* 1989)

Abstract—Solubilities are reported for four cobalt(III) complexes of Schiff bases derived from 2-aminophenol and (substituted) salicaldehydes, in aqueous methanol, and for one of these complexes also in aqueous *t*-butyl alcohol and in aqueous acetone. The derived trends of transfer chemical potentials with solvent composition are discussed in relation to the nature of the ligand and the nature of the co-solvent. Solvation characteristics for the title complexes are compared with those of other inorganic complexes, particularly of cobalt(III).

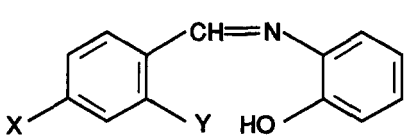
We have in recent years used transfer chemical potentials, derived from measured solubilities, as a means for probing solvation of a number of complexes in various binary aqueous mixtures.[1] The hydrophobic and hydrophilic properties of the ligands have been seen to control preferential solvation by water or the organic solvent, for example for cobalt(III) complexes in methanol–water[2,3] or acetone–water[4] mixtures or for iron(II)–diimine complexes in various mixed solvents.[2,5] In nearly all cases we have dealt with charged complexes. Very little information of this type is available for uncharged complexes, despite their advantage in avoiding the necessity for employing single-ion assumptions which bedevils the establishment of thermodynamic parameters for charged species.[6] In the present paper we report solubilities, derive transfer chemical potentials, and discuss the trends established for a series of uncharged cobalt(III) complexes of bidentate ligands, **1a**–**1d**, derived from (substituted) salicaldehydes or benzaldehyde and *o*-aminophenol (2-hydroxyaniline).[7] The binary aqueous mixtures contained the co-solvents methanol, *t*-butyl alcohol and acetone.

(1a) soap: X = H, Y = OH

(1b) MeOsoap: X = OMe, Y = OH

(1c) Me_2Nsoap: X = NMe_2, Y = OH

(1d) boap: X = H, Y = H



* Author to whom correspondence should be addressed.

EXPERIMENTAL

The complexes were prepared by established methods.[7] Their composition was checked by C, H, N microanalysis, which also served to establish that they precipitated as anhydrous compounds. Solubilities were measured using the apparatus and methods described earlier;[2] absorbance readings were obtained using a Unicam SP8-100 spectrophotometer. Wavelengths of maximum absorption and molar extinction coefficients are $\varepsilon_{422} = 17{,}800$ for $Co(soap)_3$, $\varepsilon_{434} = 27{,}200$ for $Co(MeOsoap)_3$, $\varepsilon_{433} = 22{,}400$ for $Co(Me_2Nsoap)_3$ and $\varepsilon_{433} = 22{,}000$ for $Co(boap)_3$.

RESULTS AND DISCUSSION

Solubilities are reported in Table 1; transfer chemical potentials calculated from these solubilties are listed in Table 2. The dependence of transfer chemical potentials on ligand is illustrated in Fig. 1 and on co-solvent in Fig. 2. The trends in Fig. 1 show that the nature of the ligand has only a small effect on solvation for these soap and boap complexes. As the various substituents only make minor

Table 1. Solubilities (10^5 S/mol dm^{-3}) at 298.2 K

Complex	Co-solvent	Vol. % organic solvent 0	20	40	50	60
$Co(soap)_3$	Methanol	4.0	8.9	31.2	60	155
	t-Butyl alcohol		16.7	53	84	95
	Acetone		25.3	128		440
$Co(MeOsoap)_3$	MeOH	1.2	3.0	10.8		58
	t-Butyl alcohol		7.6	79	121	154
	Acetone		11.4	84		219
$Co(Me_2Nsoap)_3$	Methanol	2.5	13.9	48		159
$Co(boap)_3$	Methanol	2.3	7.3	26		97

alterations to the surface of the complexes, this is expected. Increasing the number of methyl groups on the periphery results in a small increase in hydrophobicity and thus a small increase in stabilization as the methanol content of solvent mixtures is increased.

Figure 1 also includes transfer chemical potentials for other hydrophobic metal complexes, to put our present results into context. The trends for our present complexes are very close to those for the $[Co(phen)_3]^{3+}$ cation[3] and the *trans*-$[CoCl_2(py)_4]^+$ cation,[8] indicating similar solvation characteristics in these mixtures. The hydrophilic/hydrophobic balance for the soap and related complexes is thus similar to the resultant effect of three phen ligands and a 3+ charge, or of ligands and 1+ charge in the *trans*-$[CoCl_2(py)_4]^+$ cation. Interestingly, the introduction of ethyl groups into the latter species produces a much more marked increase in hydrophobicity[9] than the introduction of methyl groups into the soap complexes. Figure 1 suggests that $Co(acac)_3$[10] is less hydrophobic than $Co(soap)_3$—the hydrophilic properties of the OH and N in the soap ligands must be being counterbalanced by the stronger hydrophobicity of phenyl rings compared with methyl groups. Finally, the trends for the soap complexes show the expected marked difference from those for *trans*-$[CoCl_2(en)_2]^+$ and, especially, for the strongly hydrophilic $[Cr(ox)_3]^{3-}$ anion.[3]

Figure 2 shows that *t*-butyl alcohol and acetone have considerably greater stabilizing effects on these hydrophobic complexes than does methanol. This is in accord with expectation, and parallels our observations on the more complicated ternary complex $Fe(CN)_2(bipy)_2$.[11] The marked curvature in the *t*-butyl alcohol and acetone plots in Fig. 2 indicates strong preferential solvation by these organic co-solvents.

PHOTOACOUSTIC CALORIMETRY STUDIES OF LIGAND-EXCHANGE OF ALIPHATIC AMINES WITH $Cr(CO)_6$: STERIC EFFECTS AND HYDROGEN BONDING

T. J. BURKEY

Department of Chemistry, Memphis State University, Memphis, TN 38152, U.S.A.

(*Received* 10 *April* 1989; *accepted* 20 *June* 1989)

Abstract—The exchange of aliphatic amines with $Cr(CO)_6$ in heptane occurs in two steps: a CO is lost forming a solvent-coordinated complex, $Cr(CO)_5$(heptane), and then heptane is lost to form $Cr(CO)_5$(amine). The enthalpies of exchange of aliphatic amines (piperidine, *n*-butylamine, di-*n*-butylamine and tri-*n*-butylamine) with $Cr(CO)_6$ have been determined in heptane at ambient temperatures. The enthalpies of reaction determined by photoacoustic calorimetry (PAC) include contributions from hydrogen-bond formation between free amine and the pentacarbonylamine chromium, **1**. The enthalpy of hydrogen-bond formation was found to be about 4 kcal mol^{-1} and was determined from the temperature and concentration dependence of the amine NH chemical shifts of **1**. The PAC values were corrected for hydrogen-bond formation contributions to obtain only the enthalpy of ligand-exchange (ΔH_{12}). The ΔH_{12} was more endothermic for bulky amines, and this steric effect can be attributed to inhibition of Cr—N bond formation. These results, along with those in the literature, provide a detailed description of the energetics of each step of the ligand-exchange in both directions. The results suggest there is a continuum from an associative to a dissociative process for the displacement of heptane by amine that depends on the steric bulk of the amine.

Ligand-exchange reactions of group VI metal carbonyl compounds continue to be actively studied.[1] It is commonly postulated or assumed that activation enthalpies of ligand-exchange reactions that follow dissociative kinetics in alkane solvents are a good measure of the metal–ligand bond energies.[2] This requires that ligand dissociation occurs with little interaction with the solvent in the transition state; nevertheless, recent studies suggest that interactions with alkane solvent may be more important than expected. Flash photolysis studies[1a–c,3] have shown that ligand dissociation leads to an intermediate that forms an intermolecular metal–alkane bond (agostic bond),[4] and photoacoustic calorimetry (PAC) studies have shown that these agostic bonds can be quite substantial (10–13 kcal mol^{-1}).[5] Since the transition state and the solvent-coordinated intermediate it leads to are expected to have similar structures, some agostic bonding might be expected in the transition state. One method to test for agostic bonding in a transition state would be to measure ligand-exchange enthalpies. If the assumption that dissociative activation enthalpies are a good measure of bond energies is valid, then the difference in the activation enthalpies should be equal to the corresponding ligand-exchange enthalpies. If this is not the case, it indicates that at least one of the transition states is stabilized by the solvent.

Much of our current understanding of metal–ligand bond energies is based on kinetic data, since thermochemical data for organometallic compounds are scarce. In particular, few reaction enthalpies and bond energies have been documented for group VI metal carbonyl compounds. In this study we have investigated the enthalpy of ligand-exchange of aliphatic amines with $Cr(CO)_6$ [eqs (1) and (2)] by PAC.[5c,6] In addition it was discovered that **1a** hydrogen-bonded with free amine [eq. (3)]. The PAC measurement involves the determination of the amplitude of an acoustic wave from a photolysed sample. The photolysis initiates chemical and physical processes that liberate heat, producing an acoustic wave. So, the amplitude of

the acoustic wave is dependent on the amount of heat released. To better understand the effect of the amine steric bulk on the enthalpy of ligand-exchange (ΔH_{12}) and determine the "intrinsic" Cr—N bond strength, the ligand-exchange with various aliphatic amines was investigated:

$$Cr(CO)_6 + S \underset{\Delta H^{\ddagger}_{-1}}{\overset{\Delta H^{\ddagger}_{1}}{\rightleftharpoons}} Cr(CO)_5(S) + CO \quad (1)$$

S = heptane

$$Cr(CO)_5(S) + A \underset{\Delta H^{\ddagger}_{-2}}{\overset{\Delta H^{\ddagger}_{2}}{\rightleftharpoons}} Cr(CO)_5(A) + CO \quad (2)$$

1a, A = piperidine
1b, A = *n*-butylamine
1c, A = di-*n*-butylamine
1d, A = tri-*n*-butylamine

$$Cr(CO)_5(A) + A \xrightarrow{\Delta H_3} Cr(CO)_5(A)—A. \quad (3)$$

EXPERIMENTAL

The methods and equipment used have been described in detail previously.[5c] Solutions of $Cr(CO)_6$ were prepared in subdued light.

Materials

All materials were obtained from Aldrich unless otherwise noted. The $Cr(CO)_6$ was obtained from Pressure Chemical as well. "Zero"-grade argon and helium and other gases were obtained from Air Products. Heptane, amines, *o*-hydroxybenzophenone (OHB), and metal complexes were purified as before.[5c] The heptane was stored under positive helium pressure in a septum-capped bottle. Amines were refluxed over sodium or potassium until upon distillation their absorbance (neat) was insignificant for PAC: less than 0.001 for the preparation of solutions containing over 0.1 M amine and less than 0.005 for solutions containing less than 0.1 M amine (10 mm cuvette at 337.1 nm).

Preparation of **1** followed a literature method where 2 g of $Cr(CO)_6$ and 5–10 cm^3 of amine in 50–70 cm^3 THF were photolysed.[7] The solution was stirred and nitrogen purged before and during photolysis. The lamp power supply was set to dissipate 400–600 W (Hanovia 1000 W Hg–Xe short arc lamp, Schoeffel lamp housing and Kratos LPS 255HR power supply), and the beam was filtered with a 9% $NiSO_4$–$6H_2O$ solution in a 10 cm quartz cell. The photolysed solution was rotovaped, and $Cr(CO)_6$ was removed from the residue by sublimation. The residue was recrystallized several times in subdued light from cold hexane. The synthesis of **1c** has not been previously reported.

Compound **1c**: m.p. 22°C. ^{1}H NMR ($CDCl_3$): δ 2.66 (4, m, α-CH_2), 1.87 (1, br, p, 5.8 Hz, NH), 1.56 (4, m, β-CH_2), 1.31 (4, hex, 7.5 Hz, γ-CH_2), 0.96 (6, t, 7.3 Hz, CH_3). ^{13}C NMR ($CDCl_3$): δ 220.1 (*trans* CO), 214.1 (*cis* CO), 57.5 (α-CH_2), 30.6 (β-CH_2), 20.0 (γ-CH_2), 13.8 (CH_3). IR (Mattson Polaris FTIR, cyclohexane, KBr, cm^{-1}): (CO) 2065.2, 1831.7, 1913.8. Found: C, 48.61; H, 6.15; Cr, 15.95; N, 4.79. Calc. for $C_{13}H_{19}CrNO_5$: C, 48.60; H, 5.96; Cr, 16.18; N, 4.36% (Galbraith, Knoxville).

PAC experiments

Solutions for PAC measurements were prepared rapidly in a glass-stoppered flask to limit the absorption of moisture from air. Solutions containing less than 0.1 M amine were prepared under atmosphere-free conditions as before.[5c] When $Cr(CO)_6$ solutions contained 0.1 M or more of amine, amine was also added to the reference (ferrocene) solution to obtain the same amine concentration. This ensured that the acoustic properties of the sample and reference solutions were the same. All PAC solutions were purged with helium 15 min prior to photolysis. Photoacoustic measurements were obtained in a flow cell where the flow was increased until the PAC signal was independent of flow rate. The enthalpy of a reaction was calculated from eqs (4) and (5), where E_v is the energy of a mole of photons (84.8 kcal mol^{-1} for 337.1 nm), Φ is the quantum yield of reaction (1) (0.67),[8] S and R are the amplitudes of signals from the sample and reference cells, respectively. The s and r subscripts refer to measurements with a sample ($Cr(CO)_6$) and a reference (ferrocene) solution in the sample cell, respectively. The solution in the reference cell always contained OHB.

$$\Delta H = E_v(1-\phi)/\Phi \quad (4)$$

$$\phi = S_s R_r (1-T_r)/S_r R_s (1-T_s). \quad (5)$$

Absorption measurements

The absorbances of PAC solutions at 337.1 nm were determined from PAC measurements and a Gilford Response II spectrophotometer as before.[5c] Enthalpies calculated using the two methods of absorbance determination normally yielded results within 1 kcal mol^{-1} of each other with no systematic differences. An average of the two values is reported for each determination. One determination is obtained for each sample solution prepared. The

spectrophotometer cuvette was maintained to within 0.3°C of the PAC experiment. It was observed that the absorbances of solutions containing high amine concentrations were dependent on dissolved oxygen. For solutions containing 0.1 M or greater amine, absorbances by spectrophotometric measurements were obtained using one of three methods of solution preparation. These methods gave results experimentally indistinguishable from each other and the PAC absorption measurement. For the three methods, the absorbance of the $Cr(CO)_6$ or ferrocene solutions were "corrected" by subtracting the absorbance of a control solution containing the same concentration of amine. The first method involved helium purging the solutions directly in a septum-sealed 5 cm thermostatted quartz cell prior to measuring the absorbance. In the second method, the solutions were purged with air in a flask prior to measurement in the 5 cm cell. The air was dried by passing it through a 100×1.5 cm column of 4 Å molecular sieves. For the third method, the final absorbance of a solution was calculated based on the dilution of stock $Cr(CO)_6$ or ferrocene solutions. It was also found that at high amine concentrations the absorbance of $Cr(CO)_6$ increased slightly (1–2%). This required a correction to the absorbances determined by the third method.

NMR experiments

Samples of **1** for NMR spectroscopy were weighed in oven-dried 1 cm^3 flasks (calibrated to 0.4%), sealed with a septum, evacuated to < 100 microns mercury, filled with argon, and placed in a nitrogen-purged glove bag. Empty NMR tubes were similarly prepared. In the glove bag, freshly distilled amine was added to the flask with a capillary pipette (Drummond) and diluted to the mark with 0.1% TMS in cyclohexane-d_{12}. The solution was transferred to an NMR tube which was covered with foil, and kept frozen in a freezer or dry-ice chest while not in use.

All NMR spectra were obtained using a Varian VXR 300. Samples were equilibrated in the probe until the NH chemical shift of **1** was constant (10–15 min). Chemical shifts are reported relative to TMS. The variable temperature controller was calibrated at each temperature with either methanol or 1,2-dihydroxyethane, and maintained at constant temperature to within ± 0.5°C. Sample concentrations were corrected for temperature-dependent volume changes. An equilibrium constant for reaction (3) was calculated using the observed chemical shift of the NH signal of **1** when it was alone and in the presence of two different concentrations of free amine.[9] The equilibrium constants for five temperatures were used to determine the enthalpy of reaction. For four amine concentrations, an average was obtained from up to six values for the enthalpy of reaction.

RESULTS

Photolysis of $Cr(CO)_6$ yields an acoustic signal amplitude dependent on piperidine concentration. This is best demonstrated when the apparent heat calculated from the amplitude of the acoustic signal is plotted vs piperidine concentration (Fig. 1). This response is typical of a high-pass filter: the transducer responds to heat evolving at rates near or greater than the transducer frequency but not to heat evolving much slower. Photolysis of $Cr(CO)_6$ forms $Cr(CO)_5S$ in less than a nanosecond,[1a–c] and at low piperidine concentration reaction (2) is slow, so the signal is dependent on the heat liberated from reaction (1) and not reactions (2) and (3). We obtained a value near 27 kcal mol^{-1}, in agreement with results reported for other ligands at low concentrations.[5a] Near 0.1 M piperidine, the rate of reaction (2) is comparable with the frequency response of a 2.25 MHz transducer, some of the heat evolved for reactions (2) and (3) is detected, and the apparent heat increases. This is consistent with a rate constant of $\sim 10^7\ M^{-1}\ s^{-1}$ expected for eq. (2) and a diffusion controlled rate for reaction (3).[5a,10,11] At high piperidine concentration reaction (2) is fast, all the heat of reactions (1)–(3) is observed, and the amplitude is independent of piperidine concentration (0.8–2 M). At 1.0 M piperidine the same apparent heat is obtained for 1 and 2.25 MHz transducers (Fig. 1); this is consistent with the observed reactions being much faster than the transducer response at this concentration. The enthalpy of reactions (1)–(3) (ΔH_{123}) is assigned,

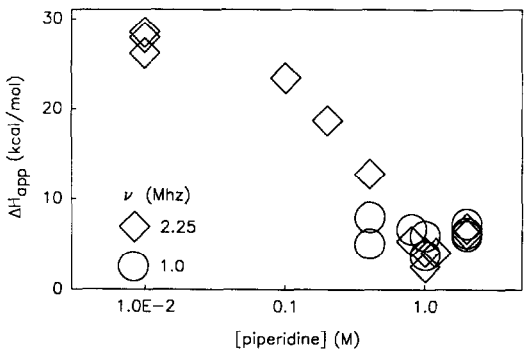

Fig. 1. PAC response (apparent ΔH) when $Cr(CO)_6$ ($\sim 9 \times 10^{-5}$ M) is photolysed in the presence of various concentrations of piperidine in heptane. The ν is the transducer frequency response.

Table 1. Enthalpy of amine exchange with $Cr(CO)_6$ in heptane

Amine	M^a	n^b	$\Delta H_{123}{}^c$

therefore, the value of 5.9 kcal mol^{-1}. Similar results were obtained for other amines and are reported in Table 1. Between 1.2 and 2.4 M di-*n*-butylamine the apparent enthalpy increased by approximately 2 kcal mol^{-1}. This may be the result of incomplete hydrogen bonding for **1c** since the equilibrium is not favourable. The reported ΔH_{123} value in this case is probably a lower limit (*vide infra*).

The chemical shift of the NH signals of **1** are dependent on the concentration of free amine and temperature. This suggested an equilibrium between free amine and **1** to form a hydrogen-bonded complex. Hydrogen bonding for **1a** has been reported previously but not to amines.[12] The hydrogen-bonding results are summarized in Table 2. The chemical shift of the NH signal for *n*-butylamine in the absence of **1** was found to be independent of temperature from 10 to 50°C (< 0.02 ppm), indicating that the hydrogen bonding between free amine is negligible. This is not surprising since aliphatic amines are good hydrogen-bond acceptors but poor donors.[13] The ΔH_3 can, therefore, be attributed primarily to hydrogen-bond formation between **1** and free amine.

DISCUSSION

The results indicate that hydrogen bonding between free amine and **1** is of the order of 4–5 kcal mol^{-1}. The establishment of the equilibrium for reaction (3) is expected to be fast relative to the transducer response, since hydrogen-bond formation is typically diffusion-controlled.[11] Equilibrium calculations from the results of Tables 1 and 2 indicate that most of **1a** (> 80%) and **1b** (> 95%) are hydrogen bonded for the conditions of the PAC experiments, while only 65% of **1c** is hydrogen bonded. Since **1** has no lone pairs on the coordinated amine, and the free amines are not good hydrogen-bond donors, we conclude that the hydrogen bond is formed between the NH protons of the coordinated amine and the lone pair of a free amine. Hydrogen bonding to the coordinated amine protons has been observed previously for **1**, as well as for molybdenum and tungsten analogues.[12,14] Furthermore, hydrogen bonding with coordinated amine protons has been detected in the solid state.[15]

The contribution of hydrogen bonding has been subtracted from ΔH_{123} to obtain the values for ΔH_{12} in Table 3.[16,17]† Previous studies show that

† Since the molecularity formally decreases in reaction (3), the reaction volume change might be expected to reduce the resultant acoustic signal. Calculations and previous PAC studies suggest the effect is not significant. The volume change upon hydrogen-bond formation is not known, but a reasonable estimate would be that it equals about 10% of the molecular volume of amine. For piperidine, this would be about 10 cm^3 mol^{-1}. The volume change due to heptane thermal expansion from 1 kcal heat is 4.7 cm^3 ($\Delta V = \alpha E/\rho C_p$,[16a] where in heptane α is the coefficient of thermal expansion (1.256×10^{-3} K^{-1}),[16b] E is 1 kcal heat, ρ is the density (0.6795 g cm^{-3}),[16c] and C_p is the heat capacity (39.5 cal K^{-1} mol^{-1})[16d] at 25°C. Therefore the volume change of reaction (3) would have the effect of −2 kcal mol^{-1} of heat. This would be an upper limit, however, since the PV work done on the reactants during the volume change is not included. The PV work will increase the internal energy of the products and result in heat deposition and a volume change due to thermal expansion. The volume increase from thermal expansion due to PV work will tend to cancel the volume decrease due to reaction volume changes. The resultant contribution to the PAC signal will be zero if the thermal expansion due to PV work is equal to the reaction volume change. In some previous PAC studies of reactions where the molecularity (and hence volume) changes, this is apparently the case: the enthalpies determined by PAC in solution were the same as the gas-phase enthalpies.[17] The same was true for aqueous solutions where the thermal expansion is much smaller than for heptane. We therefore conclude that the effect of reaction (3) volume change on the PAC signal is likely to be negligible.

the enthalpy of ligand-exchange reactions is not greatly affected by solvation effects in alkane solvents.[18] Assuming this is the case in the current study, ΔH_{12} is equal to the difference in BDE (Cr—CO) and BDE(Cr—A) ($Cr(CO)_5$—(CO) and $Cr(CO)_5$—(A) bond energies). From the value for BDE(Cr—CO), the BDE(Cr—A) values are calculated from ΔH_{12} and reported in Table 3.[19] It is clear from the trends in both ΔH_{12} and BDE (Cr—A) that the values are more endothermic as the amine becomes more substituted in spite of the fact that the bulkier amines are more basic. The results are consistent with a steric inhibition to Cr—N bond formation. A similar trend for the bonding between aliphatic amines and boranes has been observed.[20]

It is interesting that the addition of each butyl group to the amine leads to an additional 4.4–4.9 kcal mol^{-1} weakening of the Cr—A bond. This suggests that the BDE(Cr—A) for ammonia would be about 35 kcal mol^{-1} and that the ammonia derivative would be stable.[21] Such a strong bond indicates the intrinsic $Cr(CO)_5$—(A) bond is nearly as strong as the $Cr(CO)_5$—(CO) bond. This is somewhat surprising considering the fact that aliphatic amines do not backbond.

Inspection of the equilibrium constants in Table 2 reveals that the equilibrium for hydrogen bonding is more unfavourable the bulkier the amine. The fact that the trend is not reflected in the enthalpy of hydrogen-bond formation (which shows no significant change) indicates that entropy is the controlling factor.

The available kinetic and thermodynamic enthalpy parameters for exchange of piperidine with $Cr(CO)_6$ are presented in Table 4 and provide a detailed description of the reaction. It is typically assumed that ligand dissociation for $Cr(CO)_6$ and **1a** (ΔH_1^* and ΔH^*_{-2}) leads initially to $Cr(CO)_5$, which is uncoordinated by the solvent, and that the chromium–ligand bond is nearly broken in the transition state.[2a,22]† This leads to the conclusion that the two transition states are nearly the same energy as $Cr(CO)_5$ (Hammind Postulate)[23] and therefore each other. The difference in the activation enthalpies would then be equal to the enthalpy of ligand-exchange (ΔH_{12}) and the difference in Cr—A and Cr—CO bond energies. This is confirmed, within the experimental error, for the relationship between ΔH_1^*, ΔH^*_{-2} and ΔH_{12} (Table 4). Nonetheless, the recent results discussed below indicate the above conclusion cannot be considered general.

The role of the solvent in ligand-exchange reactions has been receiving intense investigation. It is well-established that $Cr(CO)_5$ forms an agostic bond with alkanes and that this bond energy is large.[1a–c,3,5,10,24] Since ΔH_1^* equals BDE(Cr—CO)[19] and $\Delta H_1^* - \Delta H^*_{-2}$ equals ΔH_{12}, ΔH^*_{-2} is taken to be equal to BDE(Cr—piperidine) (*vide supra*, Table 4). The equivalence of the activation enthalpies to bond energies and microscopic reversibility requires that solvent participation in the transition state for CO or piperidine attack of $Cr(CO)_5$ be small (ie. $\Delta H^*_{-1} = \Delta H_2^*$); therefore within experimental error, the enthalpy of solvent interaction can be taken to be zero. This is consistent with a mechanism where $Cr(CO)_5$(alkane) is in equilibrium with $Cr(CO)_5$ and the alkane dissociates to form $Cr(CO)_5$ before attack by the incoming ligand. In support of this mechanism, apparently both $Cr(CO)_5$ and $Cr(CO)_5$(cyclohexane) have been observed by picosecond IR flash photolysis.[1a,b] However, this mechanism is not consistent with the data for alkane displacement by other ligands that have been studied. Yang *et al.* have reported that the activation enthalpy for displacement of heptane by pyridine is 5 kcal mol^{-1}.[5a] This is significantly less than the chromium–heptane bond energy (10–11 kcal mol^{-1}).‡ The authors conclude that the

† The second assumption for $Cr(CO)_6$ is nicely confirmed by the similar values for BDE(Cr—CO) (ref. 19) and ΔH_1^*.

‡ BDE(Cr–heptane) = BDE(Cr—CO) − ΔH_1, see Table 4 and ref. 19. BDE(Cr–heptane) should be equal to ΔH^*_{-1} if there is no significant interaction with the solvent in the transition-state.

difference in the two values requires that the transition state be stabilized by a $Cr(CO)_5$–heptane interaction of 5 kcal mol^{-1} and that pyridine displacement of heptane be associative. A similar conclusion can be reached for the displacement of cyclohexane by THF, where the activation enthalpy is only 1 kcal mol^{-1}.[10a]†

An examination of the available data indicates that the extent of participation by the solvent in the transition state for solvent displacement may be determined by the steric bulk of the incoming ligand. For example, the activation enthalpy of 2-methylpyridine displacement of heptane (7.3 kcal mol^{-1}) is greater than for pyridine (5 kcal mol^{-1}).[5a] Likewise, the activation enthalpy for piperidine displacement of heptane (ΔH_2^*, Table 4) is greater still. The greater activation enthalpy for piperidine can be attributed to the sp^3 hybridization of the piperidine nitrogen. In light of the other data, it seems reasonable that the difference between ΔH^*_{-1} and ΔH_2^* is real, and that heptane is weakly associated in the transition state for its displacement by piperidine. In any event, it is clear that the transition state for solvent displacement by an unhindered amine favours a greater association with the solvent.

Flash photolysis data for other incoming ligands also appear to be consistent with an associative displacement of alkane solvent. The $Cr(CO)_5$ is clearly a very reactive species that reacts even with cyclohexane near the diffusion-control limit.[1a] The attack of $Cr(CO)_5$ by better ligands ought to be as fast or faster. As a result, the reaction of $Cr(CO)_5$ (cyclohexane) with ligands in a dissociative process would then be limited by the dissociation of cyclohexane and independent of the incoming ligand. This is not the case, since displacement of cyclohexane is dependent on the incoming ligand, varying from 4×10^6 to 4×10^7 M^{-1} s^{-1} (CO and THF, respectively).[10a,25] This ligand dependence is consistent with a steric effect for an associative displacement of the weakly-bonded cyclohexane.

SELECTIVITY IN MULTIPLE METHYLATION OF $MCl_n(PR_3)_m$ COMPOUNDS

ERIC G. THALER, ERIC G. LUNDQUIST and KENNETH G. CAULTON*

Department of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 5 *May* 1989; *accepted* 20 *June* 1989)

Abstract—Reaction of $RhCl_3L_3$ (L = PMe_2Ph or $PMePh_2$) with excess MeLi or MeMgCl reveals a distinct tendency to stop at the $RhMe_2ClL_3$ stage. This behaviour is attributed to the concentration of all Cl → Rh π-donation into the single remaining metal–halogen bond, and is shown to be a phenomenon of even broader occurrence and greater potential generality. For *cis,mer*-$RhMe_2ClL_3$ containing the bulkier ligand $PMePh_2$, variable temperature ^1H and ^{31}P NMR studies reveal the occurrence of two dynamic processes: hindered rotation about Rh—P and P—C bonds and also dissociation of the unique phosphine *trans* to one methyl group.

We report separately[1] that the reaction of (tripod)$CrCl_3$ (tripod = $MeC(CH_2PMe_2)_3$) with excess *n*-BuLi (6 mol/mol Cr), run under mild conditions to avoid decomposition of the chromium alkyl product, reveals a considerable selectivity to stop at the *di*alkylation stage: (tripod)Cr(*n*-Bu)$_2$Cl. We report here sufficient additional examples of this behaviour to qualify it as a consistent pattern and offer an explanation subject to further experimental test.

EXPERIMENTAL

All manipulations were carried out using standard Schlenk and glove-box techniques under purified nitrogen. Methyl lithium and methyl magnesium chloride solutions were purchased from Aldrich Chemicals, methyldiphenyl phosphine from Strem Chemicals, and chlorine gas from Matheson Gas Company. Benzene, pentane and tetrahydrofuran were dried and distilled prior to use from solutions containing sodium/potassium benzophenone ketyl. ^1H and ^{31}P NMR spectra were recorded on a Nicolet NT-360 spectrometer at 360 and 146 MHz, respectively.

* Author to whom correspondence should be addressed.

mer-$RhCl_3(PMe_2Ph)_3$

This was made according to a literature procedure.[2] ^1H NMR (360 MHz, C_6D_6, 25°C): 1.1 ppm (d, PMe, J = 11 Hz), 2.0 ppm (vt, PMe, line spacing = 4.2 Hz), 6.7–7.6 ppm (m, Ph). $^{31}P\{^1H\}$ NMR (146 MHz, C_6D_6, 25°C): 7.3 ppm (d of t, $J_{P—Rh}$ = 113 Hz; $J_{P—P'}$ = 25 Hz); −4.7 ppm (d of d, $J_{P'—Rh}$ = 85 Hz; $J_{P—P'}$ = 25 Hz).

mer-$RhCl_3(PMePh_2)_3$

Into an ethanol slurry of $RhCl_3 \cdot nH_2O$ (1.0 g, 3.8 mmol) was syringed $PMePh_2$ (2.28 g, 11.43 mmol). The solution was then stirred and refluxed for 1 h. Allowing this solution to cool to room temperature yielded large amounts of a yellow–orange precipitate.

This precipitate, a 50:50 mixture of $RhCl_3(PMePh_2)_3$ and $RhHCl_2(PMePh_2)_3$, was collected by filtration and dried *in vacuo*. This mixture was dissolved in CH_2Cl_2 and converted completely to *mer*-$RhCl_3(PMePh_2)_3$ by slow addition of Cl_2 (0.5 cm^3 portions) using a gas-tight syringe. Reaction progress is conveniently monitored by $^{31}P\{^1H\}$ NMR. After complete conversion, the volume of CH_2Cl_2 was reduced to 15 cm^3, the product was precipitated using pentane, and yellow–orange *mer*-$RhCl_3(PMePh_2)_3$ was collected by fil-

tration. $^{31}P\{^1H\}$ NMR (CH_2Cl_2): −3.5 ppm (d of t, $J_{P—Rh}$ = 114 Hz, J_{PP} = 24 Hz); −5.7 ppm (d of d, $J_{P—Rh}$ = 85 Hz).

Reaction of $RhCl_3(PMe_2Ph)_3$ *with* MeMgCl

To $RhCl_3(PMe_2Ph)_3$ (2.75 g) in 50 cm^3 of benzene was added 25 cm^3 of 2.7 M MeMgCl in Et_2O. The volume was reduced *in vacuo* to 50 cm^3 to remove most of the ether, and the solution was refluxed for 3 h. Excess Grignard was hydrolysed by the addition of 10 cm^3 of water and stirring. The benzene layer was separated from the aqueous layer and was retained. The aqueous layer and associated solids were extracted with 2 × 50 cm^3 of CH_2Cl_2. From the dried $(MgSO_4)CH_2Cl_2$ extracts was isolated 0.75 g of colourless $RhMe_3(PMe_2Ph)_3$. ^1H NMR (360 MHz, 25°C, CD_2Cl_2): −0.28 (m, 9H); 1.10 (d, $J_{Me—P}$ = 8 Hz, 18H); 7.0–7.5 (m, Ph—P). $^{31}P\{^1H\}$ NMR (146 MHz, 25°C, C_6D_6): −8.9 (d, $J_{P—Rh}$ = 80 Hz). From the dried benzene phase was isolated 1.25 g of yellow *cis,mer*-$RhMe_2Cl(PMe_2Ph)_3$. ^1H NMR (360 MHz, 25°C, CD_2Cl_2): −0.03 (m, 3H); 0.48 (q, 3H); 0.85 (d, PMe); 1.20 (t, PMe); 1.40 (t, PMe); 7.0–7.5 (m, Ph—P). $^{31}P\{^1H\}$ NMR (146 MHz, 25°C, C_6D_6): −0.1 (d of d, $J_{P—Rh}$ = 110 Hz), −18.0 (d of t, $J_{P—Rh}$ = 83 Hz, $J_{P—P'}$ = 25 Hz).

Reaction of $RhCl_3(PMePh_2)_3$ *with* MeLi

To a homogeneous THF solution of $RhCl_3(PMePh_2)_3$ (0.57 g, 0.7 mmol) was added a diethyl ether solution of MeLi (1.4 M, 12.6 mmol). The solution immediately turned deep red–brown and then gradually lightened over a period of 3 h. At this stage, the solution was cooled to 0°C and the unreacted MeLi was hydrolysed with THF–H_2O (60:40). The volatiles were removed *in vacuo* and the resulting off-white solid was extracted with 60 cm^3 of CH_2Cl_2 and filtered to yield a yellow homogeneous solution. The volume of CH_2Cl_2 was reduced to 15 cm^3 and pentane added to precipitate $RhMe_2Cl(PMePh_2)_3$ as a pale yellow powder. ^1H NMR (360 MHz, −30°C, CD_2Cl_2): −0.55 (m, 3H); 0.23 (br q, line spacing 10 Hz, 3H), 1.27 (d, $J_{P—CH_3}$ = 7 Hz, 3H); 1.9 (br. s, 6H); 7–7.8 (m, P—Ph). ^{31}P (146 MHz, −10°C, CH_2Cl_2): −12.8 (d or t, $J_{P—Rh}$ = 76 Hz, $J_{P—P}$ = 21 Hz); 11.5 (br d, $J_{P—Rh}$ = 110 Hz).

RESULTS

Polyalkylation of $RhCl_3L_3$

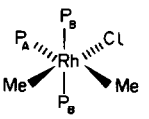
We find that reaction of *mer*-$RhCl_3(PMe_2Ph)_3$ with an excess (15 mol/mol Rh) of MeMgCl in benzene at 80°C gives only a low (28%) yield of the *per*-alkyl compound, $RhMe_3(PMe_2Ph)_3$. The major product is the compound *cis,mer*-$RhClMe_2(PMe_2Ph)_3$, which is easily separated from $RhMe_3(PMe_2Ph)_3$ by its higher solubility in benzene; the trimethyl compound may be dissolved in CH_2Cl_2.

A similar tendency to leave one chloride unreacted is demonstrated by *mer*-$RhCl_3(PMePh_2)_3$, which reacts with 18 mol MeLi/mol Rh in THF in the temperature range 0–25°C to give only *cis,mer*-$RhClMe_2(PMePh_2)_3$. Since $RhClMe_2(PMePh_2)_3$ readily dissociates phosphine in solution (see below), the resistance of the last chloride to alkylation cannot be due to the coordinatively saturated character of this compound. That is, the mechanism in eq. (1) (P = $PMePh_2$) remains available

$$\begin{aligned} RhClMe_2P_3 &\rightleftarrows RhClMe_2P_2 + P \\ RhClMe_2P_2 + MeLi &\rightarrow Li[RhClMe_3P_2] \\ Li[RhClMe_3P_2] &\rightarrow RhMe_3P_2 + LiCl \\ RhMe_3P_2 + P &\rightarrow RhMe_3P_3. \end{aligned} \qquad (1)$$

Solution dynamics of cis,mer-$RhClMe_2(PMePh_2)_3$

This molecule shows two P*Me* ^1H NMR signals at and below 25°C in CD_2Cl_2. At −30°C, there are two Rh/Me signals, one a pseudoquartet and the other an unresolved multiplet. At −25°C, however, each Rh/Me signal is very broad ($\Delta\nu_{1/2}$ = 68 Hz). The $^{31}P\{^1H\}$ NMR spectrum of $RhClMe_2(PMePh_2)_3$ shows two resonances (intensity, 2:1) at 25°C, the less intense one is a broad singlet (i.e. neither P—Rh nor P—P′ coupling is resolved) and the more intense one is a broad doublet ($J_{Rh—P}$ = 110 Hz). This behaviour we attribute to selective dissociation of P_A in eq. (2), due both to the steric bulk of diphenylmethyl phosphine and its location opposite the strong *trans*-directing methyl ligand. The importance of the *trans*-methyl group rests on the observation that *mer*-$RhCl_3(PMePh_2)_3$ shows no line broadening in the $^{31}P\{^1H\}$ NMR; a sharp AM_2X pattern is observed.



$$\rightleftharpoons \quad RhClMe_2(P_B)_2 + P_A \qquad (2)$$

$RhMe_2Cl(PMePh_2)_3$ reveals its crowded character in yet another way (Fig. 1). The P_A—Rh and P_A—P_B coupling which is absent in the P_A resonance at and above 25°C is restored at −10°C; a sharp doublet ($J(P_A—Rh)$ = 76 Hz) of triplets ($J(P_A—P_B)$ = 21 Hz) is observed. However, at

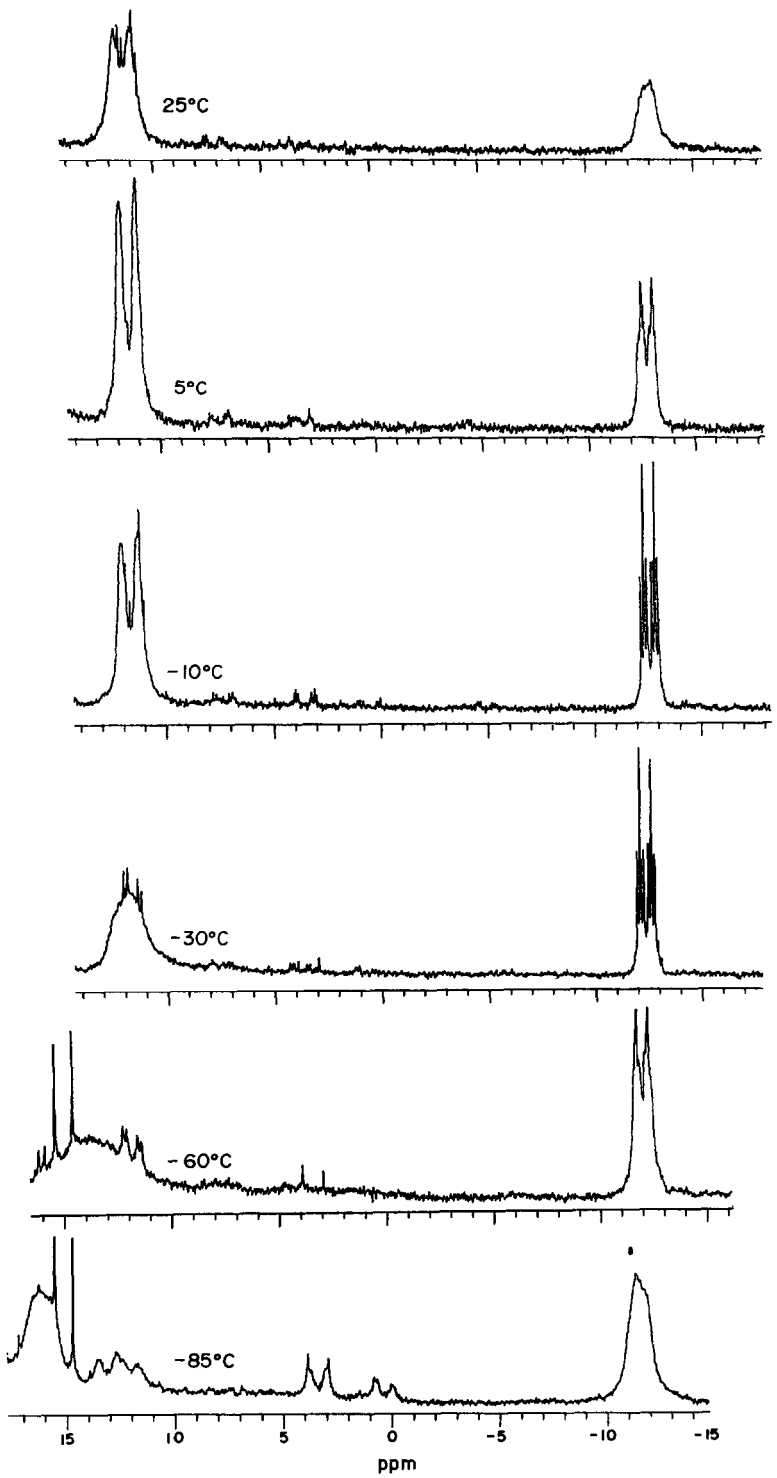


Fig. 1. Variable temperature $^{31}P\{^1H\}$ NMR spectra of $RhMe_2Cl(PMe_2Ph_2)_3$ in CD_2Cl_2. The consistently sharp peaks between 10 and 15 ppm are impurities.

$-10°C$, the P_B resonance is still a doublet of broad lines. At -25 and $-40°C$, the $^{31}P\{^1H\}$ NMR resonance of P_A remains a sharp doublet of triplets, but the P_B doublet becomes increasingly broad. Nevertheless, the sharp P_A—P_B coupling in the P_A resonances assures the lack of significant phosphine dissociation at these temperatures. Finally, at $-85°C$, the P_A resonance is one unresolved broad line and the P_B region now contains several broad lines (no J(P—Rh) observed) indicative of *several* closely spaced chemical shifts undergoing dynamic exchange at an intermediate rate. This we interpret as the freezing out of an ABCX spin system, where B and C are the axial phosphines in $RhMe_2Cl(PMePh_2)_3$, made inequivalent by the freezing out of distinct rotational conformations about the Rh—P and P—C bonds in the T-shaped $Rh(PMePh_2)_3$ substructure. Similar phenomena have been reported by Bushweller for $M(CO)Cl[P(^tBu)_2R]_2$ compounds.[3] Note that no ^{31}P NMR signal of free $PMePh_2$ is seen at (or above) $-85°C$.

DISCUSSION

We feel that the isolation of monohalopolyalkyl compounds during attempted *per*-alkylation of $(R_3P)_mMCl_n$ compounds *under mild conditions* of temperature is a kinetic effect due to the sequential strengthening of the M—Cl bonds (increased Cl→M π-donation) as the number of π-donor ligands decline. Thus, at the stage of $(R_3P)_mMR'_{n-1}Cl$, all π-donation is concentrated in the single remaining M—Cl bond (there being no other π-donor ligands present), and this bond is therefore uniquely resistant to replacement by alkyl. The effect is subtle; there is no evidence of Ir—Cl bond length shortening along the series $IrCl_{3-n}H_n(PMe_2Ph)_3$,[4] so it has only kinetic (not ground state) manifestations, but it may well occur in the unsaturated $RhMe_2ClP_2$ intermediate. Increasing alkylation also would be expected to increase steric suppression of the rate of alkylation.

Based on the above reasoning, we anticipate that this phenomenon would be of even greater importance in the alkylation of *unsaturated* metal halides, where ground-state bond shortening is evident (e.g. $TiCl_4$, where d(Ti—Cl) = 2.170 Å[5] and $TiCl_3(CH_3)$, where d(Ti—Cl) = 2.185 Å[6] vs Cp_2TiCl_2, where d(Ti—Cl) = 2.366 Å,[7] and $Ti(Me_2PC_2H_4PMe_2)Cl_3R$, where d(Ti—Cl) = 2.30–2.32 Å[8]) and thus kinetic effects should be magnified.* This effect should, of course, also be evident whenever π-donor ligands are replaced by purely σ-ligands (e.g. hydrides).

The special tendency of $PMePh_2$ to promote phosphine dissociation in $L_mM(PMePh_2)_n$ complexes ($n \geqslant 3$) is worthy of note, particularly in comparison to the (perhaps) more frequently used PMe_2Ph. The benefits of using this bulky phosphine to furnish 16-electron species are evident in, for example, the C/O multiple bond splitting reactions of Mayer and co-workers[9,10] using $WCl_2(PMePh_2)_4$ (but not the PMe_3 analogue). The close relationship between $PMePh_2$ and PPh_3 is also evident in that $RhMeI_2(PPh_3)_2$, analogous to the transient $RhMe_2Cl(PMePh_2)_2$ implicated above, is an isolable compound.[11]

BINARY AND TERNARY COMPLEXES OF 1,3-PHENYLENEDIAMINE-N,N′-DISUCCINIC ACID WITH DIVALENT CATIONS

J. FUENTES,* R. REBOSO and A. RODRIGUEZ

Departamento de Química Inorgánica, Universidad de La Laguna, Tenerife, Canary Islands, Spain

(*Received* 21 *May* 1989; *accepted* 26 *June* 1989)

Abstract—The formation equilibria involved in the novel binary and ternary systems, M^{II}–A and M^{II}–A–B, have been studied by potentiometric and conductimetric methods in an aqueous solution of 0.5 M NaCl at 25°C (where A is 1,3-phenylenediamine-N,N′-disuccinic acid (1,3-FDDS) and B is oxalic, malonic or succinic acid), where M is Co, Ni or Zn for the ternary systems and Co, Ni, Zn, Mg, Ca, Sr, Ba, Mn or Cd, for the binary systems. The results indicate that in the ternary systems, where the secondary ligand B forms five-membered chelate rings (oxalic acid), the MAB complexes are more stable than MABH, $MABH_2$ and $MABH_3$, while in those systems where B forms six- and seven-membered chelate rings (malonic and succinic acids) MAB complexes are not formed, the complexes arising being the acid ones MABH, $MABH_2$ and $MABH_3$. The negative values of $\Delta \log K$ for the MAB complexes in the case of oxalic acid indicate a greater tendency of this acid to bond to the aqueous ion than the MA or MAH species.

This work is a contribution to the systematic study of polyaminocarboxylic ligands derived from aromatic diamines, by reaction with bromosuccinic acid, which we began with the preparation of 1,4-phenylenediamine-N-succinic acid (1,4-FDS)[1] and 1,4-phenylenediamine-N,N′-disuccinic acid (1,4-FDDS).[2] We have also prepared the derivatives of 1,2-phenylenediamine (1,2-FDDS),[3] 2,5-toluenediamine (2,5-TDDS)[4] and 1,3-phenylenediamine (1,3-FDDS).[5] We reported only the preparation and determination of the dissociation constants of 1,3-FDDS at an ionic strength of 0.5 M NaCl and at 25°C.[5] This paper includes conductimetric and potentiometric studies of the complexation ability of 1,3-FDDS acid with the cations Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+} and Cd^{2+}, as well as the calculation of the stability constants of the binary complexes formed at the same ionic strength and temperature as used in the determination of the dissociation constants of the acid. A study of the equilibria of formation involved in the ternary systems M^{II}–1,3-FDDS–B in an aqueous solution of 0.5 M NaCl and at 25°C (where B is oxalic, malonic or succinic acid and M is Co, Ni or Zn, these being the most widely complexed by 1,3-FDDS acid of all the cations studied) is also presented.

Since the primary ligand, although it contains two coordination spheres (each of which is potentially tridentate), can only use one of them in mononuclear complexes, and the secondary ligand is normally bidentate, the anticipated species are ternary complex species with MAB stoichiometry or MABH, $MABH_2$ and $MABH_3$ protonated complex species. In fact, as was expected, these four species are found in the present work, but MA_2B or MAB_2 species were not detected, possibly due to steric factors associated with the very large primary ligand. The presence of oxalic, malonic or succinic acid as a secondary ligand permits the influence of the size of the chelate ring on the stability of the ternary complexes formed to be observed.

EXPERIMENTAL

The ligand 1,3-FDDS was prepared by us and described in an earlier paper.[5] The oxalic acid (Merck), malonic acid (BDH) and succinic acid

*Author to whom correspondence should be addressed.

(Riedel) were recrystallized from water. The remaining products used were from Merck and, as well as the aforementioned ones, were of p.a. quality. The experimental apparatus used in the potentiometric titrations has been described in ref. 2. The titrations were carried out in an aqueous solution of 0.5 M NaCl and at 25 ± 0.05°C, the initial concentration of the acid being of the order 10^{-3} M. The measurements were recorded with a Radiometer potentiometer (64pHM type) with an accuracy of approximately 0.1 mV, and by using glass and calomel electrodes, G202B and K401, respectively, from the same company. The cell used was: Glass electrode/System M^{II}–A, M^{II}–B or M^{II}–A–B ($I = 0.5$; $T = 25 \pm 0.05$°C)/Calomel electrode; whose standard potential and $[H^+]$ were determined by a similar procedure to that described in ref. 6. The conductimetric titrations of 1,3-FDDS alone and in the presence of the cations studied were performed, without adjusting the ionic strength, at 25°C and using the same experimental apparatus as employed in the potentiometric titrations. The metal–acid ratios were 1 : 1, 2 : 1 and 15 : 1 for all of the cations, and the initial concentration of the acid was of the order 10^{-3} M. The measurements were recorded in a Radiometer conductimeter, model CDM 83, equipped with a CDC 304 conductivity cell.

The solutions of the metal chlorides were prepared at a concentration of approx. 0.1 M and were calculated as indicated in ref. 6, as were those of EDTA, HCl and carbonate-free NaOH.

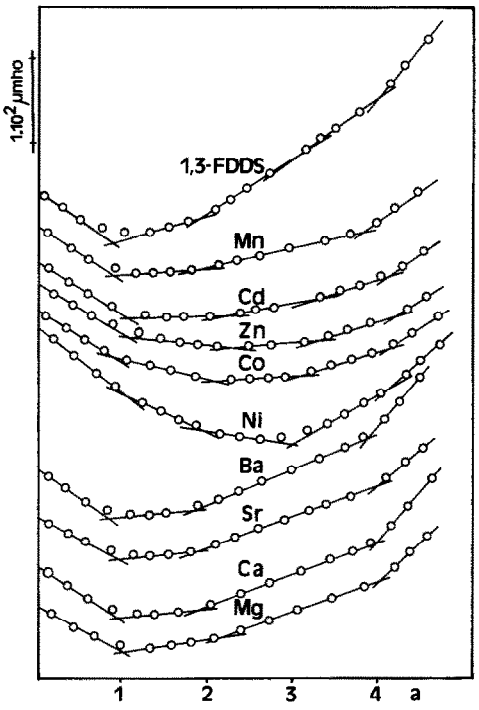

Fig. 1. Conductimetric curves of the free acid 1,3-FDDS and in the presence of different divalent cations in the ratio $[M^{II}]$–[1,3-FDDS] = 1 : 1.

RESULTS AND DISCUSSION

Binary complexes

The process of metal complex formation, in which the ligand is a weak organic acid, can be represented by the equation:

$$H_sA_q + pM^{z+} \rightleftharpoons M_pH_{s-n}A_q^{(pz-n)+} + nH^+. \quad (1)$$

In this type of reaction new species are formed in solution, which can be detected by conductimetric and/or potentiometric techniques.

The conductimetric titration curves of 1,3-FDDS acid in the presence of the divalent cations under study, for the ratio $[M^{II}]/[1,3\text{-FDDS}] = 1:1$, are plotted in Fig. 1. The curve corresponding to the titration of the free acid has been included for comparison purposes. For all the cations studied a decrease is observed in the slopes from $a = 1$, which can be interpreted by assuming that in addition to the acid dissociation equilibria, the following equilibria come about:

$$H_2A^{2-} + M^{2+} \overset{K''}{\rightleftharpoons} MH_2A \qquad 1 < a < 2$$

$$HA^{3-} + M^{2+} \overset{K'}{\rightleftharpoons} MHA^- \qquad 2 < a < 3$$

$$A^{4-} + M^{2+} \overset{K_c}{\rightleftharpoons} MA^{2-} \qquad 3 < a < 4,$$

where, K'', K' and K_c are the corresponding stability constants. The most significant feature to be pointed out is that between $a = 3$ and 4, where the slope of the curve of 1,3-FDDS decreases less, with any of the cations studied, than in the case of 1,4-FDDS[7] and 2,5-TDDS[4] acids. This is in agreement with the basicity sequence of the amine nitrogens: 1,3-FDDS < 2,5-TDDS < 1,4-FDDS,[8] which results in a decrease in the value of the stability constants of the neutral complexes of 1,3-FDDS with respect to the other two.

The potentiometric curves of $[M^{II}]/[1,3\text{-FDDS}]$ in the ratio 1 : 1 plotted in Fig. 2 are deformed with respect to that of the acid from $a = 1$. The observed decrease in pH is in agreement with the formation of the above-mentioned complex species by way of the following shift equilibria:

$$H_3A^- + M^{2+} \rightleftharpoons MH_2A + H^+ \qquad 1 < a < 2$$

$$H_2A^{2-} + M^{2+} \rightleftharpoons MHA^- + H^+ \qquad 2 < a < 3$$

$$HA^{3-} + M^{2+} \rightleftharpoons MA^{2-} + H^+ \qquad 3 < a < 4.$$

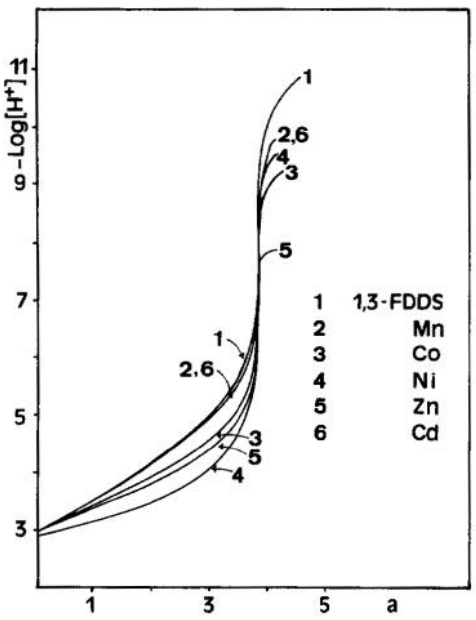

Fig. 2. Potentiometric curves of the free acid 1,3-FDDS and in the presence of different divalent cations in the ratio $[M^{II}]$–[1,3-FDDS] = 1 : 1.

In the case of the curves with an excess of metal a greater deformation is observed, both in the conductimetric and potentiometric curves, with respect to the ratio 1 : 1, due to the fact that the concentration of metal ion shifts the equilibria defined by eq. (1) towards the right. In the interval $3 < a < 4$, the deformation of the curve of the acid is even more marked as a consequence of the additional shift of protons by the metal cation:

$$MHA^- + M^{2+} \rightleftharpoons M_2A + H^+$$

and formation of the bimetallic particle M_2A:

$$MA^{2-} + M^{2+} \rightleftharpoons M_2A.$$

The formation of the bimetallic particle is possible in view of the type of structure presented by 1,3-FDDS acid,[5] analogous to those of 1,4-FDDS[2] and 2,5-TDDS[4] acids, which may act as a ligand with one or two coordination spheres.

The decrease in the pH and, therefore, the complexation strength increases in the series: $Mg^{2+} < Sr^{2+} \approx Ba^{2+} < Ca^{2+} < Mn^{2+} < Cd^{2+} < Co^{2+} < Zn^{2+} < Ni^{2+}$. This sequence coincides with that found for 1,4-FDDS[7] and 2,5-TDDS[4] acids and is in agreement with the Irving and Williams' scale.[9]

Determination of the stability constants

The potentiometric titrations of solutions of 1,3-FDDS in 0.5 M NaCl, in the presence of a divalent metal cation in the ratios $[M^{II}]/[1,3\text{-FDDS}] = 1:1$, 1 : 2, 2 : 1 and 15 : 1, allow the calculation of the

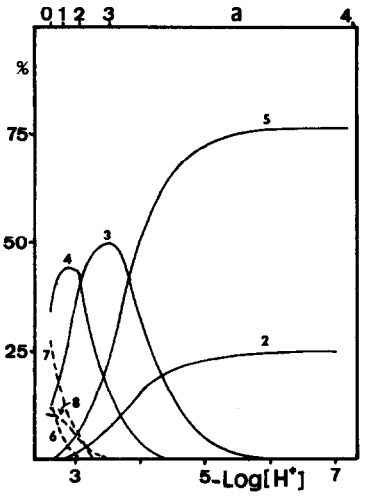

Fig. 4. Distribution diagram of the species as a function of $-\log[H^+]$ for the system $[Ni^{II}]$–[1,3-FDDS] = 15 : 1. (2) MA, (3) MAH, (4) MAH_2, (5) M_2A, (6) AH_5, (7) AH_4, (8) AH_3.

formation constants, β_{pqs}, of the binary complexes defined by means of the equilibrium:

$$pM + qA + sH \rightleftharpoons M_pA_qH_s.$$

The species detected and for which the stability constants were calculated (Table 1) are: pqs = 110, 111, 112 and 210. For the calculation the graphical criterion of Schwarzenbach *et al.*[10] was used, and the values obtained were refined by means of the MINIQUAD program.[11,12]

In Figs 3 and 4, and as an example, the species distribution diagrams are plotted as a function of the pH for the system $[Ni^{II}]$/[1,3-FDDS] = 1 : 1 and 15 : 1. In the diagram corresponding to the ratio 15 : 1 the M_2Y species appears, in agreement with the double coordination sphere mentioned for the 1,3-FDDS ligand. The species distribution curves for cobalt and zinc are analogous to those of nickel.

The dissociation constants of 1,3-FDDS acid are given in Table 2, together with those of oxalic, malonic and succinic acids, since they will be used in the study of the ternary complexes. It was necessary to calculate the above constants since none were reported in the literature at I = 0.5 M NaCl and at 25°C.

Although the dissociation constants of 1,3-FDDS acid were determined by us in an earlier paper,[5] we have recalculated them by considering, as in the cases of 1,4-FDDS[8] and 2,5-TDDS,[4] the possibility that in aqueous solution the species H_4A

might become self-dissociated according to the equilibrium:

$$2H_4A \rightleftharpoons H_5A^+ + H_3A^-.$$

Assuming the existence of the species H_5A^+, a new model was proposed in which, in addition to the species H_4A, H_3A^-, H_2A^{2-}, HA^{3-} and A^{4-}, there appeared a protonated species H_5A^+. Calculation by means of the MINIQUAD program, using as initial values those obtained in ref. 5, shows a better fit for this model, in agreement with the standard deviation values of the constants of R and U.

We have also not found any values for the stability constants of the binary complexes formed by oxalic, malonic and succinic acids with the cations Co^{2+}, Ni^{2+} and Zn^{2+} at 25°C and ionic strength 0.5 M NaCl in the literature. It was thus necessary to calculate these constants under such conditions. The values obtained by means of the MINIQUAD program are given in Table 3. The data for the determination of the stability constants of these binary complexes were obtained from potentiometric titrations of M^{II}–B in the ratios, 1 : 1 and 1 : 2, which are the same as those used for ternary complexes.

The values of the dissociation constants of the protonated ligands and of the stability constants of the binary complexes were taken as fixed in the model tested for the determination of the stability constants of the ternary complexes.

Ternary complexes

The formation of ternary complexes of the type M^{II}–A–B, where M is Co, Ni or Zn, A is the primary ligand 1,3-FDDS and B is oxalic, malonic or succinic acid, which acts as secondary ligand, will allow the influence of the number of members in the chelate ring of the secondary ligand on the stability of the ternary complexes formed to be seen. In order to evaluate quantitatively the stabilization of the ternary complexes, with respect to the binary ones, the parameter $\Delta\log K$ was used in accordance with the equilibria:

$$MA + MB \rightleftharpoons MAB + M$$
$$\Delta\log K_{MAB} = \log\beta_{MAB} - (\log\beta_{MA} + \log\beta_{MB})$$
$$MAH + MB \rightleftharpoons MABH + M$$
$$\Delta\log K_{MABH} = \log\beta_{MABH} - (\log\beta_{MAH} + \log\beta_{MB})$$
$$MAH_2 + MB \rightleftharpoons MABH_2 + M$$
$$\Delta\log K_{MABH_2} = \log\beta_{MABH_2} - (\log\beta_{MAH_2} + \log\beta_{MB})$$
$$MAH_2 + MBH \rightleftharpoons MABH_3 + M$$
$$\Delta\log K_{MABH_3} = \log\beta_{MABH_3} - (\log\beta_{MAH_2} + \log\beta_{MBH}),$$

where the charges are not included, in the interest of clarity. According to Sigel,[13,14] $\Delta\log K$ is used as a measure of stability instead of $\log\beta^{M}_{MAB}$ or $\log K^{MA}_{MAB}$ because it only depends indirectly on the basicity of the ligand.

According to the definition of $\Delta\log K$, it represents a measure of the tendency of ligand B to coordinate with the binary complex of A with respect to the aqueous ion. In general, positive values of $\Delta\log K$ indicate a marked stabilization of the ternary complexes with respect to the binary ones, or rather an important synergic effect on the formation of ternary complexes.[15] However, negative $\Delta\log K$ values do not indicate the absence of the ternary species but rather that the secondary ligand, B, presents a greater tendency to coordinate with the aqueous metal ion than with the binary complex of A.

The formation constants, β_{pqrs}, defined in accordance with the equation:

$$pM + qA + rB + sH \rightleftharpoons M_pA_qB_rH_s$$

were calculated with the MINIQUAD program[11] by treatment of the data obtained by potentiometric titrations with aqueous solutions of 0.1 M NaOH (0.5 M NaCl and at 25°C) containing M^{II}–A–B in the ratios 1 : 1 : 1, 2 : 1 : 1, 2 : 1 : 2 and 1 : 1 : 2.

The values of $\log\beta_{1110}$, $\log\beta_{1111}$, $\log\beta_{1112}$ and $\log\beta_{1113}$ are given in Table 4, together with the values of the parameter $\Delta\log K$ for each of them. Only neutral complexes, MAB, are formed with the cations studied if the secondary ligand is oxalic acid, with which little tendency is observed for the formation of protonated species. When the secondary ligand is malonic or succinic acid, the complexes formed are MABH, $MABH_2$ and $MABH_3$,

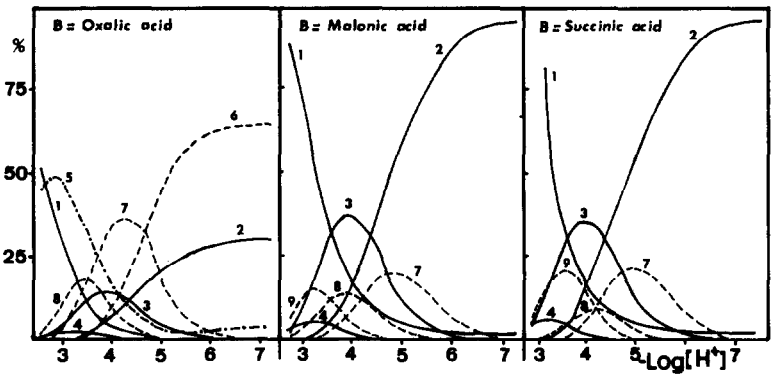

Fig. 5. Distribution diagrams for the ternary systems [M^{II}]–[1,3-FDDS]–[B] in the ratio 1 : 1 : 1. (1) M, (2) MA, (3) MAH, (4) MAH_2, (5) MB, (6) MAB, (7) MABH, (8) $MABH_2$ and (9) $MABH_3$.

for the three cations, but not the neutral complex MAB, as can be observed in the corresponding species distribution curves (Fig. 5). This seems to be in agreement with the greater tendency of the oxalate ion to form stable chelate rings with respect to the other secondary ligands,[16] and with a low basicity of the amino nitrogens in the *meta*-position[17] which facilitates the dissociation of the protons situated thereon, as deduced from the resonant forms in Fig. 6.

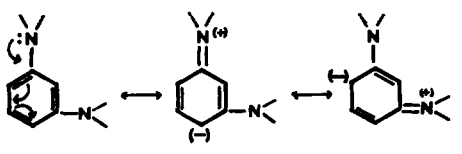

Fig. 6.

From the analysis of the values of $\Delta\log K$ a tendency is deduced for the formation of ternary complexes, following the sequence: *succinic acid* > *malonic acid* > *oxalic acid*, which corresponds to the reverse bonding sequence of the above ligands with the aqueous ion (Table 4). This was expected, in view of the capacity of oxalic acid to form highly stable five-membered chelate rings in comparison with the less stable six- and seven-membered ones which can be formed by malonic and succinic acids, respectively.[18,19] Negative $\Delta\log K$ values were found only when the secondary ligand was oxalic acid, reflecting its greater tendency to bond to the aqueous metal ion, $M^{II}_{aq.}$, than to the corresponding binary complex of A, in contrast with malonic and succinic acids which, on forming weaker binary complexes than oxalic acid, facilitate the formation of ($\Delta\log K$ positive) ternary complexes.

THE HYDROLYSIS OF THE NEODYMIUM(III) ION, Nd^{3+}, IN 3 m (Li)ClO_4 MEDIUM AT 60°C

LIBERATO CIAVATTA,† RAFFAELLA PORTO and ERMANNO VASCA

Dipartimento di Chimica dell'Università, Via Mezzocannone, 4, 80134 Napoli, Italy

(*Received* 8 *June* 1989; *accepted* 26 *June* 1989)

Abstract—The hydrolysis equilibria of the neodymium(III) ion have been studied in 3 m (Li)ClO_4 ionic medium at 60°C by electrometric measurements with a glass electrode. The neodymium(III) concentration ranged from 0.03 to 1 m, whereas the acidity was decreased, with coulometrically generated OH^- ions, down to the incipient precipitation of neodymium(III) hydroxide. This occurred when less than 2% of the metal ion was transformed into reaction products. The species $Nd(OH)^{2+}$, $Nd_2(OH)_2^{4+}$ and $Nd_6(OH)_{12}^{6+}$ were assumed in dilute solutions, $\leqslant 0.3$ m Nd^{III}. At higher concentrations the data were best explained by replacing $Nd_6(OH)_{12}^{6+}$ with $Nd_6(OH)_8^{10+}$. Formation constants in the inert 3 m $LiClO_4$ medium are reported.

The reaction of tripositive lanthanide ions, Ln^{3+}, with water has received much attention in this laboratory. In three preceding papers the hydrolysis equilibria at 60°C of the La^{3+} ion[1] and the Pr^{3+} ion,[3] as well as those of the Ce^{3+} ion at 50°C,[2] were studied by potentiometric procedures. In addition to minor complexes such as $Ln(OH)^{2+}$ and $Ln_2(OH)^{5+}$, the species $La_2(OH)_3^{3+}$, $Ce_3(OH)_5^{4+}$, $Pr_2(OH)_2^{4+}$ and $Pr_3(OH)_5^{4+}$ were proposed to explain the data. This result, on consideration of the nearly equal ionic radii and electronegativities, in addition to the identical charges, was unexpected. It seemed, therefore, essential for understanding the different behaviour of the lanthanides on hydrolysis to extend the investigation to the heavier elements of the series.

A temperature of 60°C was chosen, firstly, to render a more direct comparison with previous results and secondly, because temperatures higher than 25°C proved particularly suitable to obtain hydrolysed solutions of high purity by coulometry. As a matter of fact, at 25°C we have not been able to prepare clear hydrolysed solutions of appreciable buffer capacity even by electrolysis at very low current densities. Most likely, the local excess of base in the vicinity of the cathode causes the transient precipitation of neodymium(III) hydroxide which redissolves only slowly at room temperature.

† Author to whom correspondence should be addressed.

Previous work on the protolysis of the Nd^{3+} *ion*

The only real attempt to find the composition of the hydrolysis products and the equilibrium constants is that made by Burkov *et al.*[4] who titrated $Nd(ClO_4)_3$ with NaOH, using a glass electrode, at 25°C in 3 M (Na)ClO_4. In the small region of hydrolysis (less than 0.5% of the metal could be converted into reaction products before the precipitation of the hydroxide) the following equilibria were assumed

$$Nd^{3+} + H_2O \rightleftarrows Nd(OH)^{2+} + H^+ \qquad \log {}^*\beta_{11} = -9.4$$

$$2Nd^{3+} + 2H_2O \rightleftarrows Nd_2(OH)_2^{4+} + 2H^+ \qquad \log {}^*\beta_{22} = -13.93.$$

As it will appear below, the ${}^*\beta_{22}$ value is much greater than one would expect.

METHOD

The protolytic equilibria were investigated by measuring the EMF of cell (A)

$$\ominus \text{ Ag/AgCl/TS/GE } \oplus, \qquad \text{(A)}$$

where GE denotes the glass electrode and TS (test solution) had the general composition (molal units)

$$TS = Nd^{III}m_M,\ H^+m_H,\ Cl^-m_X,$$
$$Li^+(3-3m_M-m_H+m_X),\ ClO_4^-\ 3\text{ m}.$$

In TS, $m_H = 3 + m_X - 3m_M - [Li^+]$ is the analytical concentration excess of hydrogen ions and attained negative values in hydrolysed solutions. The chloride ions, in the range $5 \times 10^{-3} \leqslant m_X \leqslant 0.05$ m, had negligible influence on the hydrolytic equilibria, as shown by experiments carried out at different m_X but identical m_M. The EMF of cell (A) is written as eq. (1) at 60°C:

$$E = E_0 + 0.06610 \log \{[H^+][Cl^-] y_{HCl}^2\}, \quad (1)$$

in which E_0 is a constant during a series of measurements and y_{HCl} symbolizes the activity coefficient of hydrochloric acid. The standard states are so defined that activities tend to molalities as the composition of TS approaches 3 m $LiClO_4$. In each experiment, carried out at constant m_M, the composition of TS varies, but only slightly owing to the small extent of hydrolysis. Hence, within each experiment y_{HCl} remains essentially unchanged and the expression of the EMF can be simplified to give

$$E = E_0^* + 0.06610 \log \{[H^+][Cl^-]\}, \quad (2)$$

where $E_0^* = E_0 + 0.06610 \log y_{HCl}^2$ was determined before a run started by inserting in cell (A) solutions with $m_H > 10^{-4}$ m, where hydrolysis is suppressed, and consequently $[H^+] = m_H$.

In TS, m_M was varied between 0.03 and 1 m and m_H from 10^{-3}, where hydrolysis is negligible, to negative values, prior to the formation of solid hydroxides. This occurred when less than 2% of the metal was transformed into reaction products. It is easy to calculate that at the lowest m_M the concentration of the hydrolytic complexes does not exceed the 5×10^{-4} m level. Thus, it is obvious that severe demands are imposed for the accurate determination of m_H and particular care is required to avoid contamination by protolytic impurities, such as CO_2, Al^{III} and others usually present in strong base solutions. To meet these requirements the acidity of TS was lowered by coulometric procedures using the electrolysis cell (B)

$$\ominus \text{ Pt/TS/AgCl/Ag } \oplus, \quad \text{(B)}$$

which was connected to a constant-current source. Concerning the efficiency of OH^- ion generation using cell (B) the reader should refer to details in our previous papers.[1-3]

The experiments were carried out as titrations. From a known amount of TS of initial acidity m_H^*, large enough to hinder hydrolysis, protons were stepwise removed at the cathode of (B) up to the incipient precipitation of hydroxide. By ensuing each step of electrolysis a constant value of EMF of (A) was soon reached and kept constant for several hours within 0.03×10^{-3} V.

The data for the first part of the titration, where $[H^+] = m_H$, were used to calculate E_0^* from eq. (2) and an accurate value of m_H^* was determined by means of a Gran[5] plot. From measurements relevant to the region of hydrolysis $\bar{n}$, the average number of protons set free per neodymium atom, was evaluated as a function of $\log[H^+]$. In constructing the $\bar{n}(\log[H^+])$ function, which forms the basis of the following calculations, we had to account for the effect of small amounts of dissolved CO_2 that, as shown in a preceding publication,[6] are removed only with difficulty by prolonged scrubbing with nitrogen gas even from acidic solutions. After three days purging the protolytic contaminant level in TS could be reduced to about $(3 \pm 1) \times 10^{-6}$ m. On the basis of a study on the formation of carbonato complexes of the La^{3+} ion[7] we estimate that in our solutions with $[H^+] < 10^{-5}$ m CO_2, besides undergoing a small amount of protolysis to HCO_3^-, is to a large extent bound in species such as $Nd(CO_3)^+$, $Nd(HCO_3)^{2+}$ and $Nd_2(CO_3)^{4+}$. The average number of hydrogen ions set free per CO_2 is in the range 1.5–2. Thus a correction term of $(5 \pm 2) \times 10^{-6}$ m was assumed over the entire acidity interval and $\bar{n}$ was calculated by neglecting the $[OH^-]$ term according to eq. (3)

$$\bar{n} = ([H^+] - m_H - 5 \times 10^{-6})/m_M. \quad (3)$$

To ascertain that true equilibrium had been attained in the course of an experiment, back titrations were performed by adding acid solutions of equal m_M. The data, as shown in Fig. 1, are in good agreement with those from forward titrations.

EXPERIMENTAL

Neodymium perchlorate solutions

These were prepared from the freshly ignited oxide, Nd_2O_3 (99.9% purity, Fluka) and $HClO_4$ (Merck p.a.). The oxide was added in slight excess to hot 4 m $HClO_4$ and the solution, after standing for a week, which removed the heavy metal impurities as insoluble hydroxides, was filtered and re-acidified to about pH = 3. The neodymium concentration was established to within 0.1% by titration with EDTA, using xylenol orange as the visual indicator. The hydrogen ion concentration was determined by coulometric acid–base titration with a glass electrode. The perchlorate ion concentration was obtained from the sum: $m_H + 3m_M$.

Lithium perchlorate, perchloric acid and lithium chloride solutions

These were prepared and analysed as described previously.[1-3]

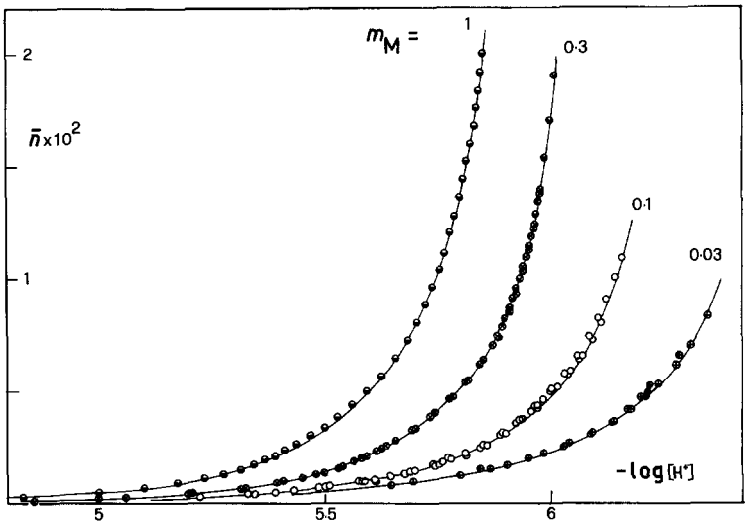

Fig. 1. $\bar{n}$, the average number of OH^- ions bound per neodymium atom, as a function of $\log[H^+]$. The curves have been calculated with the equilibrium constants and the interaction coefficients given in Table 3.

For experimental details on the EMF measurements and apparatus the reader should refer to a previous paper involving the hydrolysis of the Pr^{III} ion.[3]

RESULTS

The composition of the hydrolysis products

The primary $\bar{n}(\log[H^+], m_M)$ data, from which the composition of the hydrolysis products and the corresponding equilibrium constants were calculated, are collected in Table 1 and are graphically represented in Fig. 1.

By assuming the formation of a series of complexes of the general composition $Nd_q(OH)_p^{3q-p}$, the concentration of hydrogen ions set free per hydrolysis, $\bar{n}m_M$, can be expressed by eq. (4)

$$\bar{n}m_M = \sum\sum p[Nd_q(OH)_p^{3q-p}]$$

$$= \sum\sum p^*\beta_{pq}[Nd^{3+}]^q[H^+]^{-p}y_M^q y_H^{-p} y_{pq}^{-1} a_W^q, \quad (4)$$

where y_H, y_M, y_{pq} and a_W represent, respectively, the activity coefficients of H^+, Nd^{3+}, $Nd_q(OH)_p^{3q-p}$ and the water activity, and $^*\beta_{pq}$ is the equilibrium constant for

$$qNd^{3+} + pH_2O \leftrightarrows Nd_q(OH)_p^{3q-p} + pH^+. \quad (5)$$

At constant m_M, since only $\bar{n}$ values not exceeding 0.02 are available, the activity coefficients and water activity do not vary appreciably, hence the hydrolysis equilibria may be as well described by the concentration quotient, Q_{pq}, according to eq. (6)

$$\bar{n}m_M = \sum\sum pQ_{pq}[Nd^{3+}]^q[H^+]^{-p}, \quad (6)$$

where

$$Q_{pq} = {}^*\beta_{pq} y_M^q y_H^{-p} y_{pq}^{-1} a_W^q. \quad (7)$$

Clearly, a rigorous treatment involving no assumptions about the variation of activity coefficients caused by the substitution of Li^+ with Nd^{3+} ions is only possible for data at a given m_M by applying the "self-medium" principle.[8] This furnishes detailed information on the p values. On the contrary, since $[Nd^{3+}]$ changes but not sufficiently at constant m_M, it does not allow certain conclusions on q to be reached. Reasonable guesses of the number of metal ions bound in the prevailing complexes can be deduced from comparison of the results at different m_M by disregarding activity coefficient variations. At any rate, estimates of medium changes seem essential for conclusions concerning minor complexes as well as the refinement of the equilibrium constants. In the initial stage of the treatment, activity coefficients were evaluated by the specific interaction theory, SIT,[9] in its simplified form, which considers the interaction coefficients independent of the ionic strength.

In the course of the calculations, however, evidence showed that the more accurate formulation was necessary. Since no probable values of interaction coefficients between complex species and ClO_4^- ions were available, they were determined simultaneously with the $^*\beta_{pq}$ values. This approach precluded any information on minor complexes.

The most important p *and* q *values*

A preliminary graphical treatment, of comparing $\bar{n}(\log[H^+])m_M$ plots with normalized model func-

tions,[10] constructed by setting $[Nd^{3+}] \simeq m_M$, gave evidence for species with $p = 1$ and 2 and for at least one other complex with $p \geqslant 6$. The curve-fitting procedure also yielded values for the functions $K_p = K_p(m_M) = \sum Q_{pq} m_M^q$ whose analysis permitted us to infer the presence of $NdOH^{2+}$, $Nd_2(OH)_2^{4+}$ and a species with $q \geqslant 4$ and $p \geqslant 6$.

In order to check the validity of the conclusions reached by graphical methods based on some approximations, it seemed necessary to examine the data in a more rigorous way using the general minimizing program Letagrop.[11] To avoid the introduction of uncertainties in the evaluation of activity coefficients, the least-squares treatment separately considered data at constant m_M. The minimum of the sum $U = \sum((\bar{n}m_M)_{calc} - \bar{n}m_M)^2$, where $(\bar{n}m_M)_{calc}$ denotes a value calculated with a given set of assumed constants, was sought for by assuming three complexes: $Nd(OH)^{2+}$, $Nd_2(OH)_2^{4+}$ and $Nd_{q'}(OH)_{p'}^{3q'-p'}$ with the compositions $6 \leqslant p' \leqslant 13$ and $4 \leqslant q' \leqslant 7$. The values of E_0^* and m_M^* are considered as being known with sufficient accuracy to try to "adjust" them together with Q_{pq}-s.

The results for a series of hypotheses affording

comparable U values are listed in Table 2. For data at $m_M = 1$ the minimum agreement factor was obtained for $q' = 6$ and $p' = 8$ and a slightly poorer fit was found with $q' = 4$ and $p' = 8$. Both of these species yield significantly better fits than any other. The measurements in more dilute solutions are most consistent with $q' = 6$ and $p' = 12$ as a minor polynuclear complex, but are explained as well by $Nd_5(OH)_{11}^{4+}$. At any rate, the presence of $Nd_6(OH)_8^{10+}$ or $Nd_4(OH)_8^{4+}$ instead of $Nd_6(OH)_{12}^{6+}$ gives minima which are at least 10% higher. Calculations with both $Nd_6(OH)_8^{10+}$ and $Nd_6(OH)_{12}^{6+}$ yielded no significant improvement. We may thus infer that the data of the present accuracy can be explained by the formation of $Nd(OH)^{2+}$, $Nd_2(OH)_2^{4+}$ and $Nd_6(OH)_{12}^{6+}$, for $m_M \leqslant 0.3$, or $Nd_6(OH)_8^{10+}$ for $m_M = 1$. At first thought the proposal of $Nd_6(OH)_8^{10+}$ in 1 m $Nd(ClO_4)_3$ and $Nd_6(OH)_{12}^{6+}$ in more dilute solutions would imply a contradiction of the mass action law. Nevertheless, as shown in the next section, the complete replacement of Li^+ with Nd^{3+} ions produces medium changes in which $Nd_6(OH)_8^{10+}$ becomes strongly disfavoured at $m_M \leqslant 0.3$, but is the main hexanuclear species in 1 m $Nd(ClO_4)_3$.

Calculation of the $^*\beta_{pq}$ constants

To obtain the equilibrium constants, relevant to the inert 3 m $LiClO_4$ medium, from the Q_{pq} values one has to evaluate the variations of the activity coefficients caused by the substitution of Li^+ with Nd^{3+} ions. Medium effects were accounted for by SIT.[9] According to theory the activity coefficient y_i of a positively-charged species "i" of charge z_i is expressed on the medium scale, at the ionic strength I, by eq. (8)

$$\log y_i = -z_i^2\left[0.5452\left(\frac{I^{0.5}}{1+1.5I^{0.5}} - 0.4814\right)\right] + [b(i, ClO_4^-, I) - b(i, ClO_4^-, 3)]3 = -z_i^2 D + \Delta b(i)3, \quad (8)$$

in which $b(i, ClO_4^-, I)$ is the interaction coefficient of i with ClO_4^- at the ionic strength I. Most often $b(i, ClO_4^-, I)$ is nearly independent of I, at least in the I range from 0.5 and 3.5, thus $\Delta b(i) = 0$. During the calculations there was evidence that the more accurate formulation was necessary for the present case.

The $\Delta b(H^+)$ and $\Delta b(Nd^{3+})$ values given in Table 3, in addition to eq. (9) for the water activity, were found from the activity data listed by Pitzer[12]

$$\log a_W = 0.0199 m_M. \quad (9)$$

Since we were not able to estimate the probable values for the interaction coefficient between reac-

Table 3. Equilibrium constants and interaction coefficients

Species	$\Delta b(i)/(I-3)$	$-\log {}^*\beta_{pq}$
H^+	0.0048	
Nd^{3+}	$-0.028+0.0066(I-3)$	
$Nd(OH)^{2+}$	$0.12-0.06(I-3)$	8.96±0.15
$Nd_2(OH)_2^{4+}$	$-0.08+0.024(I-3)$	13.73±0.03
$Nd_6(OH)_{12}^{6+}$	$-0.39+0.15(I-3)$	72.9±0.2
$Nd_6(OH)_8^{10+}$		50.0±0.2

tion products and the ClO_4^- ion, we considered them as unknowns to be determined simultaneously with $^*\beta_{pq}$. As simplifying hypothesis, the variation of Δb(i) with I was approximated by a quadratic function. The procedure is illustrated by the calculation of $^*\beta_{22}$ and $\Delta b(Nd_2(OH)_2^{4+})$. From the definitions we have

$$-\log Q_{22}+2\log a_W-6[\Delta b(H^+)-\Delta b(Nd^{3+})] = 3\Delta b(Nd_2(OH)_2^{4+})-\log {}^*\beta_{22} = F. \quad (10)$$

By putting

$$\Delta b(Nd_2(OH)_2^{4+}) = c(I-3)+d(I-3)^2 \quad (11)$$

eq. (10) can be transformed into eq. (12):

$$\log F = \log(-\log {}^*\beta_{22}) + \log\left(1+\frac{3c(I-3)}{-\log {}^*\beta_{22}}+\frac{3d(I-3)^2}{-\log {}^*\beta_{22}}\right). \quad (12)$$

Values of $\log(-\log {}^*\beta_{22})$, c and d can be deduced by comparing the graph of $\log F[\log(I-3)]$ with the family of normalized functions,[10] $Y(\log u)_L$, where

$$Y = \log(1+Lu+u^2) \quad (13)$$

$$3d(I-3)^2/(-\log {}^*\beta_{22}) = u^2 \quad (14)$$

and

$$L = 3c/[3d(-\log {}^*\beta_{22})]^{1/2}. \quad (15)$$

From the position of best agreement, shown in Fig. 2, the $^*\beta_{22}$ and $\Delta b(Nd_2(OH)_2^{4+})$ values given in Table 3 were calculated.

Analogous procedures were adopted to find $^*\beta_{11}$, $^*\beta_{12,6}$ and the corresponding interaction coefficients. The results are summarized in Table 3. The $^*\beta_{86}$ value proposed in Table 3 has been derived by tentatively setting $\Delta b(Nd_6(OH)_8^{10+}) = \Delta b(Nd_6(OH)_{12}^{6+})$.

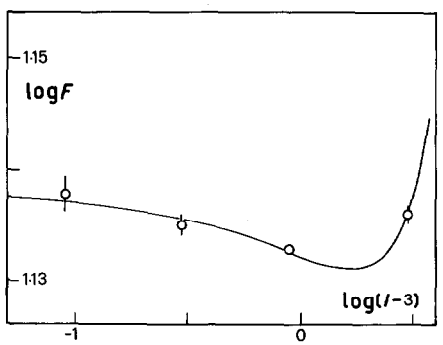

Fig. 2. Evaluation of $^*\beta_{22}$ and $\Delta b(Nd_2(OH)_2^{4+})$ by curve-fitting. Log F, eq. (10), as a function of $\log(I-3)$. The curve has been calculated with parameters of Table 3.

In order to support with convincing arguments the predominance of $Nd_6(OH)_8^{10+}$ instead of $Nd_6(OH)_{12}^{6+}$ in the most concentrated neodymium solutions, we present calculations of the ratio $[Nd_6(OH)_8^{10+}]/[Nd_6(OH)_{12}^{6+}]$ as a function of medium changes. From the above estimates we obtain $\log Q_{12,6} = -74.3_6$ at $m_M = 1$ and $\log Q_{86} = -49.2_2$ at $m_M = 0.3$ which on introduction into the expression

$$\log([Nd_6(OH)_8^{10+}]/[Nd_6(OH)_{12}^{6+}]) = \log(Q_{86}/Q_{12,6})+4\log[H^+]$$

yields

$$\log([Nd_6(OH)_8^{10+}]/[Nd_6(OH)_{12}^{6+}]) = 24.3_5+4\log[H^+] \text{ for } m_M = 1$$
$$= 23.4_9+4\log[H^+] \text{ for } m_M = 0.3.$$

This means that at the lowest determined values of $[H^+]$, when the hexanuclear complexes attain the highest concentration, the ratio $[Nd_6(OH)_8^{10+}]/[Nd_6(OH)_{12}^{6+}]$ is about 9 for $m_M = 1$ and decreases to 0.28 at $m_M = 0.3$. Thus, the concentration of $Nd_6(OH)_{12}^{6+}$ is no more than 10% of that of $Nd_6(OH)_8^{10+}$ at $m_M = 1$. On the other hand, at $m_M = 0.3$ $[Nd_6(OH)_8^{10+}]$ is less than 25% of $[Nd_6(OH)_{12}^{6+}]$ and only less than 10% of the global effect measured. The simultaneous detection of both of the hexanuclear species under these conditions would require data of much greater accuracy than the present data.

DISCUSSION

In dilute neodymium(III) solutions, e.g. $m_M \leqslant 0.3$, the main hydrolysis products are $Nd(OH)^{2+}$, $Nd_2(OH)_2^{4+}$ and $Nd_6(OH)_{12}^{6+}$. However, with increasing metal concentrations such large medium changes occur that at $m_M = 1$ the complex $Nd_6(OH)_8^{10+}$ becomes more important than $Nd_6(OH)_{12}^{6+}$. Hexanuclear species such as $Nd_6(OH)_8^{10+}$ (probably a Nd_6 octahedron with eight OH^- ions centred on the faces) and $Nd_6(OH)_{12}^{6+}$ (with 12 OH^- ions centred along edges of the octahedron) have never been detected in other lanthanide systems, but have been reliably identified in many others, e.g. $Be_6(OH)_8^{4+}$, $Pb_6(OH)_8^{4+}$ and $Bi_6(OH)_{12}^{6+}$.

A comparison with the results found for La^{3+}, Ce^{3+} and Pr^{3+} ions[1-3] indicates a different hydrolysis pattern and an irregular variation of $^*\beta_{11}$. This, when considering the monotonically increasing electronegativities and decreasing ionic radii with the atomic number of the Ln^{3+} ions, was expected

to be larger than the $10^{-8.7}$ value determined for Pr^{3+}, and is in fact almost identical to that of Ce^{3+}. It is not unlikely that the incomplete $4f$ and the empty $5d$, $6s$ and $6p$ orbitals play a determinant role in the trend of the $*\beta_{11}$ values.

The $Ln_2(OH)_2^{4+}$ species becomes more important in Nd^{III} with respect to preceding elements of the series. While it could not be detected in the La^{III} and Ce^{III} systems, its formation is more favoured in Nd^{III} than in Pr^{III} solutions. We calculate for $2Nd(OH)^{2+} \rightleftarrows Nd_2(OH)_2^{4+}$ an equilibrium constant of $10^{4.19}$ which is almost 10 times higher than that observed for $2Pr(OH)^{2+} \rightleftarrows Pr_2(OH)_2^{4+}$.

In conclusion, we would like to point out the small difference between the $\log *\beta_{22}$ value at 25°C, proposed by Burkov *et al.*,[4] and ours, whereas a difference of more than one log unit is predictable by temperature effects. The discrepancy was most probably due to the deleterious influence of small amounts of protolytic impurities, such as CO_2, which may have contaminated the NaOH solutions used by the Russian workers to titrate $Nd(ClO_4)_3$. It is worth emphasizing in this connection the superiority of coulometry when preparing pure hydrolysed solutions.

MÖSSBAUER AND ESR STUDIES OF THE THERMOCHEMISTRY OF ILLITE AND MONTMORILLONITE

PAUL J. MICHAEL and WILLIAM R. McWHINNIE*

Department of Chemical Engineering and Applied Chemistry, Aston University, Aston Triangle, Birmingham B4 7ET, U.K.

(*Received* 16 *June* 1989; *accepted* 30 *June* 1989)

Abstract—The thermal decomposition of two clay minerals, illite and montmorillonite, is followed by a combination of powder XRD, ^{57}Fe Mössbauer and ESR investigations. The changes in the resonance spectra reflect well the various phases of clay decomposition; thus the relocation of structural iron during dehydroxylation (also the oxidation of iron(II) present in the illite sample) is complete by 800°C. The breakdown of the clay structure and the recrystallization of new phases is also well reflected; indeed the bulk of the initial structural iron distributes itself between a spinel phase and haematite. In the case of illite, a homogeneous glass is formed at 1300°C; but for montmorillonite, crystalline phases, together with a glassy matrix are present at that temperature. The paper illustrates that the combined use of ESR and Mössbauer spectroscopies can offer a sensitive probe for the investigation of the thermolysis of iron-bearing clays.

Much sophisticated information may be obtained from studies of very crystalline materials by a combination of single crystal structure analysis with the results of a range of spectroscopic investigations. It is not surprising, therefore, that single crystal X-ray methods now assume such importance in molecular inorganic and organometallic chemistry. Yet the fact remains that microcrystalline, amorphous and glassy materials are of immense practical importance but are much more difficult to study. This paper reports on some investigations of the thermochemistry of representatives of two types of clay mineral—illite and montmorillonite.

Illite and montmorillonite are microcrystalline clay minerals. Illites may be assigned to the mica group; they are extremely common in nature. The isomorphous replacement of silicon by aluminium in the tetrahedral sheets is less pronounced than in the true mica and this results in a proportionate diminution in the alkali metal ions between the structural layers; a typical composition would be:

$$K_xAl_2(Si_{4-x}Al_x)O_{10}(OH)_2, \quad 0.5 < x < 0.75.$$

Illites generally have low ion-exchange capacity of between 10 and 40 m-equiv 100 g^{-1} of clay.[1]

Montmorillonites are also related structurally to the micas in that they contain an octahedral layer sandwiched between two tetrahedral layers. The ion exchange capacity is considerable (80–150 m-equiv 100 g^{-1}[1]) and the clays swell; montmorillonite is a member of the smectite group. A typical composition is:

$$Na_{0.33}(Al_{1.67}Mg_{0.33})Si_4O_{10}(OH)_2, \quad nH_2O.$$

Both naturally occurring illite and montmorillonite often contain appreciable quantities of structural iron, usually iron(III) replacing aluminium in the octahedral layer. Thus, this naturally occurring iron can provide a useful spectroscopic probe for following the thermal decomposition of the minerals using a combination of ^{57}Fe Mössbauer and ESR spectroscopy in conjunction with powder XRD.

Information on the thermolysis of clay minerals can be valuable in a number of contexts. For example, such minerals are often present as inorganic "impurities" in coal and they may have some influence on the coking of coal,[2–6] thus their behaviour at temperatures at which coal is coked will be of interest. In addition, such minerals are often components of ceramic ware—both body and glaze; again knowledge of how the individual mineral

species break down to new phases at temperatures relevant to the firing of ceramics can be valuable.

EXPERIMENTAL

Materials

The illite used was illite No. 36; the sample was light grey in colour and had been pre-washed, dried and crushed. The major impurity was quartz. Montmorillonite was supplied by Steetley Minerals Ltd and was termed Berkbond I (Woburn Fullers Earth). The sample was light brown–yellow in colour and had been washed, dried and pre-crushed. The main impurities were quartz and iron–aluminium oxyhydroxides.

Physical measurements

(a) ^{57}Fe *Mössbauer spectroscopy.* Mössbauer spectra were obtained using a constant acceleration spectrometer of standard design, counts being recorded on 512 channels of an Inotech 5200 multichannel analyser. Spectra were calibrated with iron foil. The source was ^{57}Co in a palladium matrix. The spectra, which were recorded at room temperature were computer fitted (ICL 1904S; HARRIS H800) to Lorentzians using the Gaussian non-linear regression method;[7] the X^2 criterion[8] was used as a measure of the acceptability of the fit.

(b) *Electron spin resonance (ESR) spectroscopy.* Spectra were recorded on a JEOL PE-1X type spectrometer operating in the X-band microwave region (~9.5 GHz). Spectra were calibrated and g-values determined from a manganese(II) standard.

(c) *X-ray diffraction (powder), XRD.* Finely-powdered samples were packed into standard aluminium XRD slides and analysed on either a JEOL X-ray diffractometer using Cu-K_α radiation (30 kV/30 mA) with a scan speed of 2° 2θ min^{-1}, or a Philips X-ray diffractometer using Co-K_α radiation (40 kV/40 mA) and an iron filter, with a scan speed of 1° 2θ min^{-1}. The d-spacings were calculated from the observed 2θ values using standard charts.[9]

(d) *Thermal treatment of clay minerals.* Powdered samples were heated in air to a given temperature (maximum 1300°C) in a Carbolite muffle furnace. Samples were allowed to soak for 3 h in the furnace, removed, then stored in a desiccator prior to recrushing for analysis.

(e) *X-ray fluorescence.* Major element analyses of clay minerals were obtained by fusion of dry, powdered minerals (15%) with a borax flux (85%) at 1100°C to discs which were analysed with a Philips PW1400 sequential X-ray spectrometer using a rhodium anode.

RESULTS

Major element analyses of the illite and montmorillonite samples are given in Table 1. Table 2 combines Mössbauer data for illite over a range of temperatures and also includes the more positive conclusions from the XRD study. Table 3 provides a similar collection of data for montmorillonite. Figures 1 and 2 attempt to display the major changes occurring on heating illite and montmorillonite in a more readily assimilated graphical form. Figures 3 and 4 show representative Mössbauer and ESR spectra. Table 4 (illite) and Table 5 (montmorillonite) summarize the ESR data in terms of apparent "g-values".

DISCUSSION

Mössbauer data—some general observations

^{57}Fe Mössbauer spectra of clay minerals are usually broad.[10] For montmorillonite, in particular, it is often possible to fit the observed spectrum to two iron(III) doublets with similar chemical isomer shifts, but with the more intense doublet having a quadrupole splitting approximately half that of the less intense doublet. Given that, in a dioctahedral

clay mineral such as montmorillonite, ions in the octahedral layer may occupy sites with either *cis*-dihydroxo- or *trans*-dihydroxo-environments, the so called M(1) and M(2) sites, it would follow from simple electrostatic reasoning[8] that the quadrupole splitting of the *trans* site should be twice that of the *cis* site; thus the implication is that the iron(III) is generally located predominantly in the M(2) sites. This conclusion is not supported by a recent careful electron diffraction study by Tsipursky and Drits[11] which concludes that the iron(III) locates almost entirely in the *trans*-M(1) sites. An important paper by Cardile and Johnston[12] suggested that the actual "best fit" of a Mössbauer spectrum of montmorillonite is often an artefact of the fitting procedure and that in reality the iron(III) ions, located in essentially M(1) sites, are subjected to differing degrees of distortion in those sites and hence are subject to a spectrum of electric field gradients at the nuclei. We concur with this view and believe it to be relevant also to illite.

In Tables 2 and 3 we have presented data for the simplest spectral fit consistent with a satisfactory X^2 value. Only when a two-doublet fit gave a significantly improved X^2 value was it preferred to a one-doublet fit. Attempts at multi-doublet fits of broad resonances have been resisted on the grounds that the results would have little chemical meaning. We therefore view the observed quadrupole splitting as an average value for a range of field gradients; the chemical isomer shift is a "better" parameter in that it is likely to be more sensitive to

phase changes when absolute changes in the electronic environment of the iron(III) ions should occur. Another important parameter is the full-width at half-height ($\Gamma_{1/2}$) which will give some measure of the range of field gradients operating. It is against this background that we interpret the observed Mössbauer data.

Illite

The analysis (XRF) of the sample of illite used is given in Table 1 and is in good agreement with literature data for natural illites.[1] XRD showed an α-quartz (SiO_2) impurity,[13] but was consistent with the trace expected for illite.[9] A representative basal spacing [$d(001)$] of 10.05 Å was seen, but weaker signals corresponding to $d(001)$ of 7.25 and 13.10 Å may imply the presence of some mixed-layer illite–montmorillonite and illite–chlorite. The elemental analysis suggests a little manganese to be present and this is confirmed by the ESR data (Table 4). The manganese(II) spectrum is superimposed on a broad component arising from iron(III); it consists of six lines with some evidence of forbidden electronic and nuclear transitions giving weaker signals between the individual lines. The g-value is approximately 2 and the hyperfine splitting parameter, A, is 81 G. The spectrum may indicate a trace of calcite with a manganese impurity. If so, within this system, following a calcite-to-aragonite phase transition, the carbonate should decompose above 800°C when, from past experience,[14] the signal should be lost on the formation of silicate phases. In this instance, even when illite is heated to 500°C, the signal is lost under a dominant iron(III) contribution. If calcite is present, it is not in sufficient quantity to be detectable by XRD. Thus, an alternative explanation that the manganese(II) is substitutional in the illite cannot be eliminated.

Ericsson *et al.*[15] have reported the Mössbauer spectrum of a similar illite (No. 36) which they have fitted to two iron(III) doublets ($\delta = 0.32$, $\Delta = 0.58$ mm s^{-1}; $\delta = 0.41$, $\Delta = 1.07$ mm s^{-1}) and one iron(II) doublet ($\delta = 1.18$, $\Delta = 2.88$ mm s^{-1}). The two iron(III) doublets were assigned to "*cis*" ($\Delta = 0.58$) and "*trans*" ($\Delta = 1.07$) [M(1) and M(2)] locations of iron(III) in the octahedral layer. For the reason stated above we feel that the assignment is simplistic and prefer the one-doublet fit of Table 4 which gives a measure of the average iron(III) environment. The danger of the M(1), M(2) assignment is further underlined by the XRD data which suggests the illite may not be monophasic. The Swedish workers comment on a small asymmetry of their iron(II) doublet; in this case we prefer a two-doublet fit (Table 2) and, interestingly, if the illite is washed with 0.5 M acetic acid the doublet, $\delta = 1.48$, $\Delta = 2.48$ mm s^{-1}, is removed, thus suggesting that it arises from one of the hydrates, $FeSO_4 \cdot nH_2O$,[3,16] e.g. szoinolnolcite ($n = 1$), rozenite ($n = 4$) or melanerite ($n = 7$). A trace of sulphur was detected by XRF analysis of illite (Table 1), but the amount was sufficiently small to make the assignment very tentative.

The ESR spectrum of natural illite is complex, although it agrees well with that presented previously in a study of illite containing shales.[17] The sharp isotropic resonance ($g = 2.010$) which vanishes on heating the illite to 500°C is attributed to organic radicals. The manganese components have been discussed and probably three iron(III) contributions can be observed: a broad resonance centred on $g \simeq 6$ (presumably with a counterpart at $g = 2.0$ hidden under the major broad feature). These spectra are difficult to interpret but it is probably reasonable to suggest that the $g \simeq 6$ resonance is a component arising from iron(III) in an axially-distorted environment.[18,19] The broad resonance at $g \simeq 2.0$ may be assigned with reasonable certainty to transitions within the super-exchange multiplet resulting from the coupling of two $S = 5/2$ ions in adjacent cation sites, i.e. Fe–OFe pairs either within the lattice or in an impurity phase.[18,20,21] The most probable such impurity phase would be Fe_2O_3 or perhaps FeO(OH)—no magnetic spectrum was observed in the Mössbauer study, but if the particle size were small superparamagnetic behaviour is possible. Since no specific iron oxide impurity phase was observed in the XRD, the balance of probability is that this ESR feature arises from adjacent iron(III) ions in structural cation sites. Many interpretations have been given for the origin of the $g = 4.15$ resonance in clays;[20–22] in the present case it is considered to arise from iron(III) sites of orthorhombic symmetry.[17,18] Thus the ESR data confirm a variety of iron(III) sites and environments and, to our mind, this justifies our reluctance to be more specific in our interpretation of the iron(III) Mössbauer data.

It is clear from Fig. 1 that the bulk of lattice water is lost from illite at 400°C and that the "structural" water is lost between 400 and 800°C. Clearly the iron ions will need to adapt to the loss of structural water; another change is the oxidation of iron(II) to iron(III), which is complete on heating to 500°C. The Mössbauer spectra of samples heated to 400°C show a much reduced iron(II) resonance and a more distorted range of iron(III) sites as indicated by the larger value of Δ and the large $\Gamma_{1/2}$ value (Table 2). The samples heated to 500, 600 and 700°C show two clear doublets, one with parameters comparable to the 400°C spectrum and a new doublet with a

greater quadrupole splitting. By 800°C, when the illite structure is about to undergo irreversible breakdown, the iron(III) ions have migrated to a range of similar sites. A reasonable chemical interpretation of these data is that between 400 and 700°C there are two ligand environments, i.e. FeO_6 and $FeO_{6-x}(OH)_x$ ($2 > x > 0$); within each of these ligand environments there will be a range of site micro-symmetries. Since the $FeO_{6-x}(OH)_x$ sites would be expected to dominate at 400°C, the doublet with $\delta = 0.30$–0.36 and $\Delta = 0.95$–1.14 mm s^{-1} can be assigned to those environments. The implication is, then, that the larger Δ (1.53–1.76 mm s^{-1}) corresponds to the FeO_6 sites which are, by implication, more distorted. The ESR spectra show a marked increase in the $g \simeq 2.0$ resonance on heating to 400°C, also at this level of heating, the $g \simeq 4.0$ resonance becomes complex and a hint of the $g \simeq 6$ resonance is to be seen. Samples heated to 500, 600 and 700°C show a progression to two broad isotropic resonances at 700°C (Table 4); a feature at $g = 2.35$ is present at 500 and 600°C (this may be the $g \simeq 2.0$ component expected with the $g \simeq 6$ component). At 800°C, the dominant feature of the spectrum is a very broad isotropic resonance centred on $g \simeq 2.01$, which together with a weak feature at $g = 4.25$ can now, following the Mössbauer deductions, be ascribed to the dehydroxo "FeO_6" environment, and the $g \simeq 6$, 2.35 features which are steadily lost on heating to 700 and 800°C can be tentatively assigned to the $FeO_{6-x}(OH)_x$ environment. Thus, there exists a satisfying degree of self consistency between the Mössbauer and ESR data.

Heating samples of illite beyond 800°C results in the irreversible breakdown of the silicate structure and new phases, some recognizable by XRD, crystallize. Thus the sample heated to 900°C shows a decrease in the SiO_2 impurity trace and clear evidence of a spinel phase. Between 900 and 1100°C the spinel phase grows, α-Fe_2O_3 is formed and the SiO_2 impurity diminishes further. Mullite is discernable as a new phase on heating to 1200°C and, at this temperature, the trace for α-Fe_2O_3 becomes weak. Heating to 1300°C gives a glass.

The ESR spectra are rather insensitive to these changes, being dominated by a very broad isotropic resonance with $g \simeq 2.01$–2.04 (Table 4). This may be attributed to species with Fe—O—Fe groupings; the resonance at $g = 4.25$ (1000°C) is weak but becomes a little more intense as the temperature to which the samples are heated is increased. This resonance may be attributed to iron(III) in a low-symmetry rhombically-distorted phase—thus supporting the Mössbauer observations (Table 2 see below) that the iron(III) is distributed between two phases. Indeed the Mössbauer data of Table 2 clearly support the deductions from the XRD data that α-Fe_2O_3 appears as an illite decomposition product on heating to 1000°C; this phase may be identified from the value of the magnetic hyperfine field.[8] A second iron(III) phase is present and is shown by a significant change in δ and Δ between 900 and 1000°C; the illite structure is lost and the iron(III) may be associated with the spinel phase, which is recognised by XRD. By 1200°C the α-Fe_2O_3 phase is not clearly discernable from the Mössbauer spectrum, nor is it detectable by XRD; mullite is detectable and the spinel phase persists, together with the iron(III) Mössbauer species with $\delta = 0.32$ mm s^{-1}. Most interestingly, a new iron phase is detectable by Mössbauer spectroscopy—one containing iron(II), and at 1300°C the iron(II) signal is about a third the intensity of the iron(III) signal. The origin of the iron(II) is problematic and we believe that it may be an artefact of our experimental conditions. The furnace we used was lined with silicon carbide and at temperatures beyond 1200°C the furnace atmosphere may be somewhat reducing (it is well known to Craft Potters that the addition of SiC to a glaze will give "reduced" effects in electric kilns[23]).

Combination of the ESR and Mössbauer data suggest that the spectrum of iron(III) sites may occur in the glass found when the decomposed illite fuses at 1300°C. The small clusters of Fe—O—Fe species (superparamagnetic) together with other iron(III) species located in appropriate holes within the glassy silica structure may give rise to a broad ($\Gamma_{1/2} = 0.77$ mm s^{-1}) Mössbauer spectrum and the two ESR features. Thus, these investigations, summarized in Fig. 1, give useful insight to the path of thermolysis of illite. Careful examination of the data reveal that there is good overall agreement between the results of the three techniques used.

Montmorillonite

Many ideas developed in the discussion of the illite data may be carried over to montmorillonite, hence this material can be dealt with more briefly.

The room temperature XRD trace was typical of that for montmorillonite,[9] but it also indicated a α-quartz impurity and the weak presence of iron oxhydroxide minerals.[13] The sample was poorly crystalline but the basal spacing, $d(001)$, of 15.24 Å is typical.[24] On heating the sample, the trace for the clay showed little change until 700°C, but by 900°C it had vanished totally. The X-ray crystallinity is not lost as a result of dehydroxylation (the major weight loss is complete at 700°C, Fig. 1).[25,26] At

900°C, low intensity reflections indicate the onset of crystallization of new phases, e.g. spinel ($MgAl_2O_4$), α-Fe_2O_3 and enstatite ($MgSiO_3$). Crystallinity increases in the sample heated to 1000°C and a strong cristobalite component is now seen; the spinel and enstatite components grow. At 1200°C the spinel and enstatite phases have decreased and mullite is apparent ($3Al_2O_3 \cdot 2SiO_2$) —thus it would seem that the phases have undergone a solid state reaction with cristobalite to afford the mullite; by 1300°C the only crystalline phases discernable are mullite, cristobalite and α-Fe_2O_3. The appearance of the material heated to 1300°C and cooled suggested some glass formation but not to the same degree as illite, a fact explained by the considerably smaller quantities of alkali metal oxides associated with montmorillonite than illite (Table 1).

The room temperature Mössbauer spectrum of the unheated clay may be fitted to a broad quadrupole doublet, which has been discussed above. Thus it is considered to arise from a spectrum of iron sites, including possibly some contribution from the small iron oxyhydroxide phase detected by XRD. The ESR spectrum is typical of that of an iron-rich poorly crystalline clay[27] and consists of two features: a broad resonance at $g = 2.06$ and a sharper signal at $g = 4.26$. The broad resonance reflects Fe—O—Fe groupings within the lattice and, possibly, also within impurity phases.[21,27] Following Cracium and Meghea,[27] the resonance at $g = 4.26$ is assigned to isolated iron(III) ions occupying distorted octahedral sites within the clay structure.

As dehydroxylation of the clay progresses between 150 and 700°C, a new iron phase is established. Thus, from the Mössbauer data the original average quadrupole splitting of 0.54 mm s^{-1} gives way by 700°C to a more distorted site with $\Delta = 1.46$ mm s^{-1}. The consolidation of this site coincides with a breakdown of the montmorillonite lattice and the appearance of a magnetic hyperfine spectrum characteristic of α-Fe_2O_3. The origin of the haematite will be a combination of the initial impurity phases and structural iron from the collapsed clay lattice. The ESR spectrum remains relatively invariant, except that there is some evidence of a sharper feature at $g \sim 2.0$ which becomes more established by 800–900°C (see Table 5)—no corresponding component at $g = 6$ is seen, but the feature may be too weak for detection. Possibly this new resonance may be correlated with a further change in the Mössbauer spectrum which occurs at 900°C ($\delta = 0.32$, $\Delta = 0.89$ mm s^{-1}), at which temperature a crystalline spinel phase is detected in the XRD trace, alternatively the $g = 4.26$ signal must be assigned to the non-magnetic iron site. Indeed, the Mössbauer parameters are comparable with those arising for illite at 1000°C, and it was speculated above that this resonance arose from iron(III) in a spinel phase. Indeed, one section of the iron(III) now enjoys a relatively constant environment, possibly within this spinel phase, or when heated to 1300°C, within a glassy phase derived from the melting of the spiral and other magnesium-containing phases. The ESR spectrum beyond 1000°C becomes increasingly dominated by the magnetic iron phase, although even when heated to 1200°C, the sample retains a signal at $g = 4.18$. It must be assumed that this signal may arise from the iron/spinel phase, in which case throughout the temperature range the ESR does little more than differentiate "magnetic" Fe—O—Fe and isolated iron(III) sites. The Mössbauer data clearly show the increase of the α-Fe_2O_3 phase at 1200°C, but as with illite, in the 1300°C spectrum, definite evidence of iron(II) is seen, this time with an increased quadrupole splitting of 1.90 mm s^{-1}. The same explanation is offered, that it is an artefact of the experimental procedure. In this instance, a further complication occurs. The six line spectrum is well-resolved (Fig. 4) and the hyperfine field may be quite accurately determined at 487 kG, a figure which is not in good agreement with that expected for α-Fe_2O_3 (516 kG[8]) but which is in better agreement with one of the components identified for Fe_3O_4, magnetite, (496 kG[8]). However, clear resolution of the iron(II) and iron(III) components, particularly to negative velocity, would have been expected. The situation is complicated further by the XRD evidence for α-Fe_2O_3, however, the XRD trace is poor; thus we can speculate the α-Fe_2O_3 trace is modified by an underlying contribution from magnetite or possibly from γ-Fe_2O_3.

CONCLUSIONS

We have attempted to show that a contribution of XRD, Mössbauer and ESR studies can throw much light on the thermolytic behaviour of iron-containing clay minerals. The clays in the spectroscopic parameters reflect, in a gratifying way, the major changes detected in XRD and pseudo-TGA studies. We have concluded, albeit tentatively, that at breakdown of the clay structure the bulk of the iron(III) distributes itself between oxide and spinel phases. We have also noted that at 1300°C the observed Mössbauer spectra reflect the prevailing atmosphere (oxidizing or reducing) within the furnace.

SYNTHESIS OF A BIMETALLIC CHROMIUM COMPLEX CONTAINING THE NOVEL PENTAOXAPENTAPHOSPHORINANE $[RPO]_5$ RING

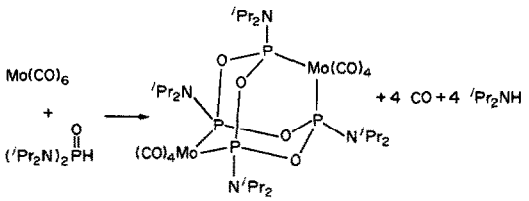
CAROLYN M. BANSE, MELISSA A. PRAY and MARK M. TURNBULL*

Department of Chemistry, Clark University, 950 Main Street, Worcester, MA 01610, U.S.A.

(*Received* 6 *June* 1989; *accepted* 4 *August* 1989)

Abstract—The reaction of $(^iPr_2N)_2P(O)H$ with $Cr(CO)_6$ in refluxing xylenes yields the complex $(CO)_4Cr[(^iPr_2N)PO]_5Cr(CO)_3$ (**2**) in 33% yield after chromatography. A novel pentaoxapentaphosphorinane ring is generated during the reaction. IR, ^1H, ^{13}C and ^{31}P NMR spectra are all consistent with a structure containing one *cis*-disubstituted chromium atom and one *fac*-trisubstituted chromium atom, bridged by the phosphorinane ligand.

Since the serendipitous preparation of the bimetallic cage complex **1**, from $(^iPr_2N)_2P(O)H$ and $Mo(CO)_6$, we have been investigating the mechanism and limits of the reaction.[1] In addition to studying the effects of the ancillary groups on the phosphine oxide, we have also studied the effect of varying the metal itself.



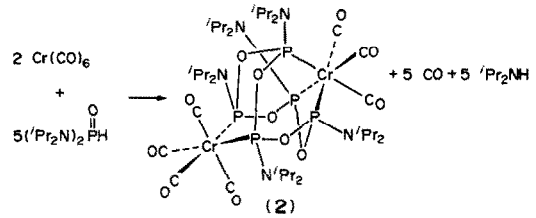
(1)

The 1,3,5,7-tetraoxa-2,4,6,8-tetraphosphorinane, $[RPO]_4$, ligand contained in complex **1** is unique. We have found no reports of such a compound in the uncoordinated state, although the dimeric $[RPO]_2$ and trimeric species $[RPO]_3$ have been prepared.[2]

We wish to report that the reaction of $(^iPr_2N)_2P(O)H$ with $Cr(CO)_6$ in refluxing xylenes yields the related cage complex $(CO)_4Cr[(^iPr_2N)PO]_5Cr(CO)_3$ (**2**), instead of the chromium analogue of **1**. Of note is that this complex contains the expanded 1,3,5,7,9-pentaoxa-2,4,6,8,10-pentaphosphorinane ring, bridging the chromium atoms. The compound is characterized by IR and NMR spectroscopy, as well as by elemental analysis.

RESULTS AND DISCUSSION

Reaction of $(^iPr_2N)_2P(O)H$ and $Cr(CO)_6$ in refluxing xylenes gave compound **2** as a yellow powder in 30% isolated yield after column chromatography: IR spectroscopy provided the first indication that the product was not the expected chromium analogue of **1**. The carbonyl region showed six strong bands, ranging from 2022 to 1874 cm^{-1}. In accord with its D_{2d} symmetry, **1** has only four absorptions in that region. We therefore assumed two inequivalent metal centres to be



(2)

Fig. 1.

present, one of which was *cis*-substituted (as indicated by the 2022 cm^{-1} band).*

$^{31}P(H)$ NMR spectroscopy revealed an A_2MX_2 spectrum (J_{AM} = 8.3 HZ, J_{MX} = 40.1 Hz, J_{AX} < 1.5 Hz) indicating a total of five phosphorus atoms in three inequivalent environments. The chemical shifts of the signals (δ 156–176 ppm) showed no phorphoryls to be present and suggested that all the phosphorus atoms were coordinated to chromium. The ^{1}H-coupled ^{31}P NMR spectrum further revealed that each phosphorus was coupled to two hydrogens (J = 12–14 Hz), in agreement with one attached diisopropylamino substituent. Based on these data, we tentatively assigned the structure of **2** as having the *cis*-substituted metal centre, previously noted, and a *fac*-substituted metal centre. A *fac*-$CrL_3(CO)_3$ complex is expected to have two CO stretching vibrations in the IR[4] and thus all six observed CO bands are accounted for. The *mer*-isomer, **3** (Fig. 1), with P_M in the centre, would also explain the IR spectrum, but was ruled out since AM coupling would not be expected in the ^{31}P NMR spectrum. More important perhaps, is the presence of two fused four-membered rings in compound **3**, making it extremely unlikely. The final assignment, namely which pairs of phosphorus atoms were A and X, was made based on the observed coupling constants. The larger coupling (40 Hz) was assigned as the through-metal coupling and the smaller coupling (8 Hz) was assigned as the P—O—P coupling. The apparent absence of coupling in the similar P—O—P linkage between P_A and P_X was surprising, but not without precedent based on related spectra from the oxidation products of **1** where these coupings are less than 2 Hz.[5] The final assignments are shown in Fig. 1.†

The ^{13}C NMR {H} spectrum of **2** shows four apparent triplets (δ 230, 225, 220, 217 ppm; J = 10–30 Hz) and an unresolved multiplet (228 ppm). These resonances are surprisingly far downfield relative to **1** (δ 206, 213 ppm). The shift may be due to steric congestion around the metals. The methyne region reveals two apparent triplets (δ 48.5, 48.0 ppm; J = 2–6 Hz) which are assigned to the methyne carbons of the amino groups attached to P_A and P_X, not necessarily in that order, and a doublet (δ 47.7 ppm; J = 13 Hz) which is assigned to the methyne carbons of the amino group attached to P_M. The apparent triplets are the same as is observed for **1**, and are in agreement with the predicted spectrum for an ABX spectrum (A, B = P, X = C) where $\delta_{AB} = 0$.[7] The methyl region shows six signals (δ 23.7–25.4 ppm), when symmetry would predict only five types of methyls. The resonances are too well separated (10–40 Hz) for P—C coupling to be a likely explanation. We suggest the idea that the extra signal is caused by restricted rotation about a P—N bond as a result of steric congestion.

Finally, the ^{1}H NMR spectrum shows a broad unresolved multiplet at 1.4 ppm from the methyl groups. Two more signals, an apparent heptet and an apparent nonet (δ 4.7 (1H) and 4.2 (4H), respectively) occur in the methyne region. We assign the downfield signal to the methyne protons attached to the unique P_M, based solely on their integrated values.

EXPERIMENTAL

All procedures were carried out using standard Schlenk techniques under an argon atmosphere. Xylenes (mixed isomers) were purified by distillation from sodium metal. Dichloromethane was distilled from CaH_2. Diisopropylamine was distilled from KOH. PCl_3 and $Cr(CO)_6$ were purchased from Alfa Products and used without further purification. Bis(N,N-diisopropylamino)phosphine oxide

* Empirical observations indicate that the position of the strong absorption above 2000 cm^{-1} in these complexes is a reliable indication of geometry about the metal (see ref. 3).

† We wish to acknowledge the independent synthesis of compound **2** by Wong and co-workers and thank them for providing us with their unpublished results. Single crystal X-ray analysis confirms our proposed structure for compound **2** (see ref. 6).

was prepared as previously described.[1a] IR spectra were recorded on a Perkin–Elmer 1330 spectrophotometer and were calibrated against polystyrene. NMR spectra were recorded on a Bruker AC-200 spectrometer (courtesy of the Worcester NMR Consortium) and calibrated against TMS (^{1}H) solvent (^{13}C) or external Ph_3P (^{31}P).

$Cr(CO)_4[(^iPr_2N)PO]_5Cr(CO)_3$ (**2**)

Bis(N,N-diisopropylamino)phosphine oxide (3.00 g, 12.1 mmol), $Cr(CO)_6$ (1.75 g, 7.95 mmol, 0.66 equiv.) and xylenes (50 cm^3) were combined in a round-bottomed Schlenk flask fitted with a magnetic stirrer and reflux condenser. The mixture was heated to reflux in an oil bath (bath temperature, 145°C) and stirred overnight (14–16 h). The xylenes were removed *in vacuo* from the now black reaction mixture, the residue was dissolved in a minimum volume of CH_2Cl_2 and chromatographed (silica gel, CH_2Cl_2) to yield a pale yellow powder, 0.82 g (33%). Compound **2** oxidizes slowly in air and is soluble in most organic solvents. IR (KBr): 2022, 1966, 1941, 1885, 1874 (C≡O) 985 (P—N) 900 (P—O—P) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 4.7 (app. h, 1H, $J_{app} \approx 7$ Hz), 4.2 (app. nonet, 4H, $J_{app} \approx 7.5$ Hz), 1.4 (broad m, 30H). ^{13}C NMR {H} ($CDCl_3$): δ 230 (m, C≡O), 224.8 (t, $J = 10$ Hz, C≡O), 219.9 (t, $J = 9$ Hz, C≡O), 217.1 (t, $J = 9$ Hz, C≡O), 49.0 (app. t, $J = 5.5$ Hz, N—C), 48.5 (app. t, $J \approx 2$ Hz, N—C), 47.7 (d, $J = 13$ Hz, N—C), 25.4, 24.8, 24.6, 24.3, 24.2, 23.7 (CH_3's). ^{31}P NMR {H} ($CDCl_3$): δ 176.2 (d, 2P, $J = 8.3$ Hz), 174.9 (t of t, 1P, $J = 8.3$, 40.1 Hz), 156.4 (d, 2P, $J = 40.1$ Hz). Found: C, 42.7; H, 6.9; N, 6.4. Calc. for $C_{37}H_{70}Cr_2N_5O_{12}P_5$: C, 42.9; H, 6.8; N, 6.8%.

SYNTHESIS AND CHARACTERIZATION OF COPPER(II) AND NICKEL(II) COMPLEXES OF 4-ALKYLDITHIOATE-5-HYDROXY-3-METHYL-1-PHENYLPYRAZOLES

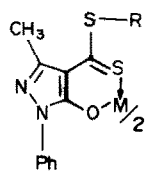
RENE MAURELIA,* GERARDO LEON and ALFONSO OLIVA

Institute of Chemistry, Catholic University of Valparaíso Casilla 4059, Valparaíso, Chile

(*Received* 24 *April* 1989; *accepted* 3 *August* 1989)

Abstract—Copper(II) and nickel(II) complexes of 4-alkyldithioate-5-hydroxy-3-methyl-1-phenylpyrazoles have been prepared and characterized by elemental analysis, UV–vis and IR spectroscopy. All compounds have a metal–ligand ratio of 1 : 2 and analytical or spectroscopic data agree with a square-planar structure.

4-Acyl derivatives of 2-pyrazoline-5-ones are known to be good chelating and extractant agents.[1–3] As a part of a programme to synthesize sulphur–metal complexing molecules, we have studied the introduction of the alkyldithioate moiety at the C-4 position of 3-methyl-1-phenyl-2-pyrazoline-5-one in order to obtain organosulphur chelating pyrazoles.[4] The reaction was achieved by condensation of the above pyrazoline-5-one with carbon disulphide and alkyl halides to afford 4-alkyldithioate-5-hydroxy-3-methyl-1-phenylpyrazoles. We now report the synthesis and characterization of the corresponding copper(II) and nickel(II) complexes, I.



(I)

M = Ni; R = *n*-C_6H_{13}, *n*-C_8H_{17}, *n*-$C_{10}H_{21}$, *n*-$C_{12}H_{25}$
M = Cu; R = C_2H_5, *n*-C_6H_{13}, *n*-$C_{12}H_{25}$

EXPERIMENTAL

Magnetic moment measurements were performed on a Gouy balance at room temperature, using $HgCo(SCN)_4$ as the reference substance. IR spectra were recorded in the 600–300 cm^{-1} range on a Perkin–Elmer 599 spectrophotometer, using polyethylene discs. ^1H NMR spectra were recorded on a Varian 360 A spectrometer. UV–vis spectra were measured on a Cary 219 spectrophotometer, with chloroform as solvent.

All the complexes were prepared by the same general method described below: a water solution of the metal acetate (0.5 mmol) was mixed with an alcoholic solution of the ligand (1 mmol) and heated on a water bath (50°C) for 1 h. The product was filtered off, dried and recrystallized from benezene or toluene.

RESULTS AND DISCUSSION

Analytical data of the copper(II) and nickel(II) complexes (Table 1) agree with the general formula I. The magnetic moment of the copper(II) complexes corresponds to one unpaired spin per copper atom.

IR spectra of the ligands exhibit a wide but weak band at 3250–2600 cm^{-1} due to the strongly associated hydroxy-thiocarbonyl group, and four bands in the 600–300 cm^{-1} region (355, 415, 515 and 555 cm^{-1}) assigned to the chelate ring vibration.[4–6] A comparative analysis in the IR spectra of the ligands and the complexes shows that the absorption at 3250–2600 cm^{-1} is absent, due to the replacement of the hydrogen by the metal ion. In the 600–300 cm^{-1} region, two additional bands are observed in

copper(II) complexes at 390 and 440 cm^{-1}. We have assigned these bands to Cu—S and Cu—O vibrations. In the nickel(II) complexes, the Ni—S and Ni—O vibrations are observed at 385 and 450 cm^{-1}.[7]

^1H NMR spectra of the ligands display a singlet at 13.7–13.8 ppm due to the hydroxyl proton.[4] This signal is absent in the spectra of the nickel(II) complexes because of coordination. The chemical shift of the other signals are very close to those of the ligands, and a slight displacement of 0.2–0.4 ppm is observed.

Three bands at *ca* 245, 313 and 365 nm are observed in the UV–vis spectra of the ligands.[4] These absorptions can be ascribed to the phenylpyrazole, pyrazole and chelate ring conjugations.[8,9] Copper(II) complexes exhibit five bands at 244, 329, 361, 470 and 595 nm, and the first three can be related to the ligands. However, the 329 nm transition can also be assigned as a charge-transfer band, $b_{1a} \rightarrow b_{3g}$, observed in related copper(II) complexes with acetylacetone, β-acetodithioesters and thiohydroxamic acids.[10–12] The shoulders at 470 and 595 nm are typical of $S \rightarrow Cu^{II}$ ligand-to-metal charge-transfer and *d–d* transitions observed in square-planar copper(II) complexes.[10–12]

The UV-vis spectra of nickel(II) complexes are characterized by seven bands. In the UV region, those at 255, 314 and 332 nm can be related to the ligands and the absorption at 290 nm must be a charge-transfer band. The visible region shows three bands at 400, 465 and 708 nm. We have identified these absorptions as the ν_1, ν_2 and ν_3 bands observed in square-planar complexes of nickel(II) with sulphur ligands.[13]

Acknowledgements—The authors wish to thank the Catholic University of Valparaíso, Chile, for financial support, and Dr F. Castañeda (University of Chile) for elemental analyses of carbon, hydrogen and nitrogen.

CHEMO- AND REGIOSELECTIVE HALOGENATION OF A CYCLOPALLADATED IMINE

JOAN ALBERT, JAUME GRANELL and JOAQUIM SALES*

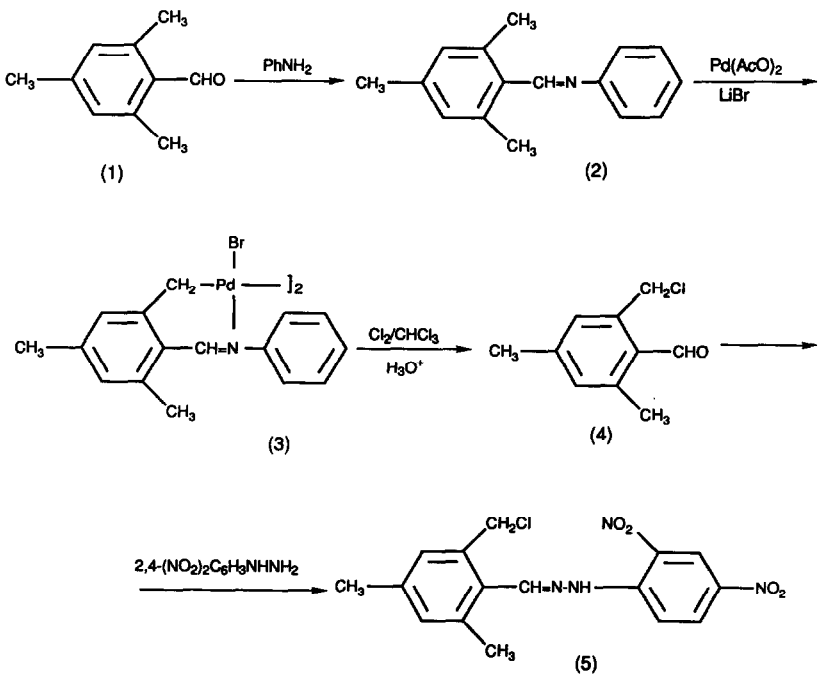
Departament de Química Inorgànica, Universitat de Barcelona, Diagonal 647, 08028 Barcelona, Spain

(*Received* 9 *June* 1989; *accepted* 15 *August* 1989)

Abstract—2-Chloromethyl-4,6-dimethylbenzaldehyde is obtained by chlorination of a cyclopalladated-imine derivative of mesitylenecarbaldehyde.

Cleavage of organometallic compounds with halogens has been widely studied,[1] but many of the reactions are complicated by radical processes, trihalide ion reactions, and oxidation of the metal prior to metal bond cleavage.

With halogens, competitive cleavage reactions and electrophilic substitution reactions of the aromatic ring can occur. For example, solutions of halogens almost completely cleave the cobalt–carbon bond in benzylcobaloximes. However, the *meta*- and 3,5-dimethylbenzylcobaloximes, in which the aromatic ring is activated by both the methyl



Scheme 1.

* Author to whom correspondence should be addressed.

groups and the —CH_2—$Co(dmgH)_2py$ group, undergo halogenation of the aromatic nucleus.[2]

Cyclometallated compounds are very useful reagents for organic syntheses, but up to now their applications have been almost restricted to aromatic systems.[3]

Recently we have described that the imine derivatives of mesitylenecarbaldehyde (**2**) react with $Pd(OAc)_2$ to give six-membered metallocycles possessing an aliphatic carbon–metal bond.[4] The metallocycle (**3**) contains two methyl substituents in positions 3 and 5, and the —CH_2—Pd— group which activates the electrophilic substitution on C(4), but the imine group can cancel out this effect. So, the halogenation should take place only on the palladium–carbon bond, opening a new way to the selective benzylic halogenation.

In order to prove this assumption we have studied the reaction between chlorine and the cyclometallated complex (**3**). The action of chlorine, at room temperature, on the cyclometallated compound (**3**) in chloroform, cleaves only the palladium–carbon bond, and after acid hydrolysis the chloromethylbenzaldehyde (**4**) is formed. The aldehyde obtained has been characterized as a 2,4-dinitrophenylhydrazone derivative (**5**) (~ 50%) (^{1}H NMR: δ(NH) 11.3(1H, s); δ(HC=N) 8.46(1H, s); $\delta(CH_2Cl)$ 4.87(2H, s); $\delta(CH_3)$ 2.51(3H, s) and 2.35(3H, s). *m/z* 362).

In summary, the present reaction allows the chemo- and regioselective halogenation of a methyl group in the *ortho*-position to an aldehyde function and represents a good illustration of the potential synthetic applications of cyclometallated complexes in the selective functionalization of organic compounds.

THE PREPARATION AND X-RAY CRYSTAL STRUCTURE OF [RhPh(OCOCF$_3$)(C$_{10}$H$_4$NO$_2$){P(*p*-FC$_6$H$_4$)$_3$}(H$_2$O)], AN OCTAHEDRAL COMPLEX CONTAINING A σ-RhPh BOND

(*Received* 9 *August* 1989; *accepted* 21 *August* 1989)

Abstract—New complexes containing a σ-RhPh bond have been obtained by elimination of Hg from the intermediate heterobimetallic complexes [Rh(OCOCF$_3$)(HgPh)(quin)(CO){P(*p*-RC$_6$H$_4$)$_3$}] (quin = 2-quinaldinate (C$_9$NH$_6$COO$^-$), R = Cl, F, CH$_3$ and CH$_3$O). The heterobimetallic complexes were prepared by reactions of [Rh(quin)(CO){P(*p*-RC$_6$H$_4$)$_3$}] with PhHg(OCOCF$_3$). The crystal structure of [RhPh(OCOCF$_3$)(quin){P(*p*-FC$_6$H$_4$)$_3$}(H$_2$O)] has been determined.

In a previous paper we have shown that complexes of the type [Rh(pyC)(CO){P(*p*-RC$_6$H$_4$)$_3$}] (pyC = 2-C$_5$NH$_4$COO$^-$) react with PhHgCl to give [RhCl(HgPh)(pyC)(CO){P(*p*-RC$_6$H$_4$)$_3$}].[1] Related reactions with PhHg(OCOCF$_3$) yield unstable heterobimetallic complexes, which after deposition of metallic mercury give new compounds with RhPh bonds. So, we propose the synthesis of σ-organometallic RhPh compounds using heterobimetallic Rh—Hg complexes as intermediates.

In this paper we describe the reactions of [Rh(quin)(CO){P(*p*-RC$_6$H$_4$)$_3$}] with PhHg(OCOCF$_3$) and the formation of new σ-organometallic compounds. The crystal structure of the complex [RhPh(OCOCF$_3$)(quin){P(*p*-FC$_6$H$_4$)$_3$}(H$_2$O)] has been determined and is shown in Fig. 1.†

The reactions of [Rh(quin)(CO){P(*p*-RC$_6$H$_4$)$_3$}] with PhHg(OCOCF$_3$) yielded the new products [Rh(OCOCF$_3$)(HgPh)(quin)(CO){P(*p*-RC$_6$H$_4$)$_3$}]. The addition of HgPh and OCOCF$_3$ groups to the rhodium atom is in agreement with the related reactions with PhHgCl.[1] The complexes were stable in the solid state, but when treated in acetone decarbonylated products were observed. The new decarbonylated complexes were characterized as [RhPh(OCOCF$_3$)(quin){P(*p*-RC$_6$H$_4$)$_3$}] on the basis of analytical and spectroscopic data.

We have solved the crystal structure for one

PHOTOREDOX REACTION OF TRIAZIDOMERCURATE(II). GENERATION OF STABLE MERCURY ATOMS UNDER AMBIENT CONDITIONS

HORST KUNKELY and ARND VOGLER†

Institut für Anorganische Chemie, Universität Regensburg, Universitätsstraße 31, D-8400 Regensburg, F.R.G.

(*Received* 19 *July* 1989; *accepted* 23 *August* 1989)

Abstract—Upon ligand-to-metal charge-transfer excitation the complex $[Hg(N_3)_3]^-$ in ethanol underwent a photoredox reaction ($\lambda_{irr} = 254$ nm; $\phi = 0.02$): $[Hg^{II}(N_3)_3]^- \rightarrow Hg^0 + 3N_2 + N_3^-$. Elemental mercury was released in the form of metal atoms which are stable under ambient conditions.

Upon ligand-to-metal charge-transfer (LMCT) excitation many transition metal azide complexes undergo a redox reaction which leads to the formation of the free metal as a colloid.[1] It is assumed that first free metal atoms are formed which agglomerate to smaller clusters, then to large clusters, and finally to colloidal particles. However, the metal atoms and clusters have not been detected since the agglomeration is apparently very rapid and does not stop at intermediate stages. In the present communication we report the direct observation of mercury atoms which are generated by the photolysis of $[Hg(N_3)_3]^-$ in ethanol under ambient conditions. This observation is facilitated by the relatively high stability of mercury atoms. Our study is also an interesting contribution to the photochemistry of mercury(II) complexes. While several organometallic mercury(II) compounds[2–5] are known to undergo a light-induced reductive elimination with the release of metallic mercury, the photochemistry of classical mercury(II) complexes seems to be rather complicated.[3,6] Finally, our observations may be also important with regard to the mechanism of the mercury-photosensitized dehydrodimerization of organic compounds in solution[7,8] and in the gas phase.

The absorption spectrum of $[Hg(N_3)_3]^-$ (Fig. 1) displays an intense band at $\lambda_{max} = 246$ nm ($\varepsilon = 5600$). This band has not been detected before since it was obscured by the absorption spectrum of $[As(C_6H_5)_4]^+$, which was used as counter-ion for the isolation of the complex anion.[9] Upon irradiation of $[Hg(N_3)_3]^-$ in ethanol with white or monochromatic light ($\lambda_{irr} = 254$ nm) nitrogen was evolved which was detected by gas chromatography. Free azide was also formed. It was identified as the red Fe^{3+} complex. Simultaneously the absorption band of $[Hg(N_3)_3]^-$ disappeared (Fig.

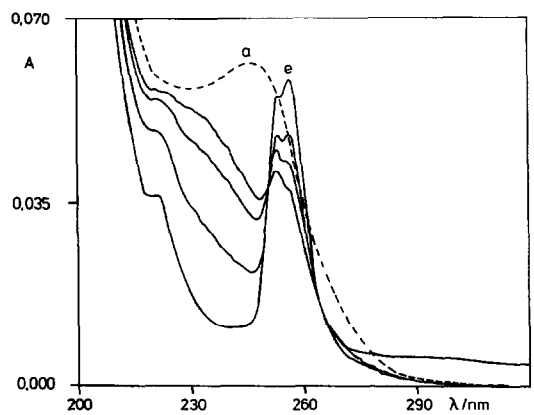

Fig. 1. Spectral changes during the photolysis of 1.04×10^{-5} M $[N(C_4H_9)_4][Hg(N_3)_3]$ in C_2H_5OH at (a) 0, 3, 6, 12 and (e) 18 min irradiation time, with white light irradiation (Osram HBO 100 W/2 lamp) and a 1-cm cell.

† Author to whom correspondence should be addressed.

1). The spectral changes which accompanied the photolysis are characterized by the appearance of a new narrow band with two maxima at $\lambda = 253$ and 256 nm. This absorption[8,10-12] indicated the formation of atomic mercury. Since the solubility of elemental mercury is rather low in all common solvents ($\sim 10^{-7}$ M),[12] the photochemical generation of the free metal did not only lead to the appearance of mercury atoms. The bulk metal was also formed. At later stages of the photolysis the release of colloidal metal can be recognized by an increase of the extinction coefficient over the entire absorption spectrum. This effect is apparently caused by light scattering of colloidal metal particles.[1]

The photolysis of $[Hg(N_3)_3]^-$ was monitored by measuring the decrease of the extinction coefficient at 246 nm, taking into account a residual absorption of the photolysis product of about 20% at this wavelength. The absorbed light intensity (1.4×10^{-10} E s^{-1}) was determined with a Polytec pyroelectric radiometer, calibrated and equipped with a RkP-345 detector. For quantum yield determinations the amount of photolysis was limited to less than 10%. At an irradiating wavelength of $\lambda = 254$ nm the quantum yield for the disappearance of $[Hg(N_3)_3]^-$ was $\phi = 0.02$.

The absorption band of $[Hg(N_3)_3]^-$ (Fig. 1) at $\lambda_{max} = 246$ nm is assigned to a LMCT transition involving the promotion of an electron from the reducing azide ligands to the empty 6*s* orbital of mercury(II). Analogous LMCT assignments were made for the mercury(II) halides, HgX_2,[13-15] and halide complex anions, $[HgX_4]^{2-}$,[15-17] with X = Cl, Br and I. Since Br^- and N_3^- have the same optical electronegativities (2.8)[19] the LMCT bands of $[HgBr_4]^{2-}$ ($\lambda_{max} = 253$ nm)[16,17] and $[Hg(N_3)_3]^-$ appear at comparable energies.

Upon LMCT excitation $[Hg(N_3)_3]^-$ undergoes a photoredox reaction according to the equation:

$$[Hg^{II}(N_3)_3]^- \rightarrow Hg^0 + 3N_2 + N_3^-.$$

The formation of metallic mercury is not surprising since organometallic mercury(II) complexes are well known to show this photoredox behaviour.[2-5] In some cases it has been demonstrated that this is initiated by CT excitation.[4,5] The most interesting aspect of the present work is the observation of stable mercury atoms which are formed upon LMCT excitation of $[Hg(N_3)_3]^-$ under ambient conditions. Mercury atoms in solution are characterized by an intense ($\varepsilon \sim 10^5$) narrow absorption near 250 nm which shows band splitting.[8,10-12] The absorption is assigned to the $^1S_0 \rightarrow {}^3P_1 sp$ transition of the mercury atoms which are perturbed by the solvent.[11,12] Due to the low solubility of mercury the photolysis of $[Hg(N_3)_3]^-$ leads not only to the appearance of atomic mercury but also colloidal mercury.

The photoredox reaction of metal azide complexes induced by LMCT excitation seems to be a rather general method for the generation of free metals which are released as colloids.[1] It has been suggested that this release is preceded by the generation of free metal atoms which undergo an aggregation to clusters. These clusters grow until they finally reach colloidal dimensions. It is certainly important to identify these intermediate stages under ambient conditions in order to learn more about these processes. The detection of mercury atoms as immediate photolysis product is thus an interesting contribution towards this goal.

The photochemical formation of mercury atoms may also play an important role in the mercury-photosensitized dehydrodimerization of organic compounds in solution and the gas phase.[7,8,18] It has been assumed to take place via the formation of some kind of exciplex:[18]

$$Hg^* + H{-}CR_3 \rightarrow Hg^* \cdots H{-}CR_3 \rightarrow [Hg^* \cdots H \cdots CR_3] \rightarrow Hg{-}H^* + {}^\bullet CR_3 \rightarrow Hg + H + {}^\bullet CR_3.$$

As an alternative it seems feasible that this reaction proceeds as a photochemical oxidative addition to excited mercury atoms and a subsequent reductive elimination:

$$Hg^* + H{-}CR_3 \rightarrow H{-}Hg^{II}{-}CR_3 \rightarrow Hg^0 + {}^\bullet H + {}^\bullet CR_3.$$

The latter step, which could take place photochemically or thermally, regenerates the mercury atoms. These are now available for a repetition of this process.

BOOK REVIEW

Journal of Organometallic Chemistry Library 20: Organometallic Chemistry Reviews. Edited by A. G. Davies, E. O. Fischer and O. A. Reutov. Elsevier, Amsterdam, 1988, ISBN 0-444-42950-6, 365 pp., approx. £81.50.

This addition to the *Journal of Organometallic Chemistry Library Series* contains five reviews. The chemistry of boron-substituted icosahedral *closo*-carboranes(12) (Grushin, Bregadze and Kalinin, Moscow; 204 refs to 1986) is covered systematically with sections on compounds containing boron bonded to: nitrogen; carbon; oxygen; sulphur, selenium or tellurium; halogens; non-transition metals; transition metals. A final short section discusses the electronic effects associated with different patterns of substitution. Given that 72% of the references are to Russian publications, this is a useful overview of this area of chemistry.

The second article, by Lukevics and Segal (Riga), reviews pyridine and quinoline derivatives containing Si, Ge, Sn, and Pb (423 refs to 1986). Preparation, physical properties, chemical properties, biological properties and applications of compounds containing E—C, E—N, or E—O(S) bonds (E = Si, Ge, Sn or Pb) are covered in separate sections with a final section devoted to intermolecular complexes. This lengthy review, dominated by Si chemistry with some Ge and Sn and few Pb derivatives, should be useful to anyone involved in the synthesis of pyridine and quinoline compounds.

Goldberg, Dirnens and Lukevics (Riga) review the use of phase-transfer catalysis in organosilicon chemistry (85 refs to 1986) in an interesting article which also mentions related Ge and Sn chemistry and describes nucleophilic substitution of X in R_3SiX, dichlorocarbene and nitrene reactions with organosilanes, hydrosilation, electrophilic substitution, and also contains sections on silacrowns and immobilized phase-transfer catalysts.

A compilation of structural details for rhenium carbonyl and organometallic complexes by Holloway (York, Canada) and Melnik (Bratislava) contains data from X-ray, neutron and electron diffraction studies (257 refs to 1987). Trends are highlighted and comparisons are made with analogous technetium compounds.

The final review by Klapötke and Köpf (Berlin) is in German and deals with metallocenedichalcogenolene complexes (59 refs to 1987). Dithiolenes, diolenes, diselenolenes and ditellurolenes are described for the Ti, V and Cr groups. There are also short sections on bonding, ring inversion and reactivity.

In general these articles are sufficiently well-presented to enable the reader, whether or not a specialist in any of the areas covered, easily to browse through this volume and pick out any features of interest.

ANNOUNCEMENT

33rd IUPAC CONGRESS
BUDAPEST, HUNGARY
17–22 AUGUST 1991

The 33rd International Congress of the International Union of Pure and Applied Chemistry is to be held from Saturday 17 to Thursday 22 August 1991, in Budapest, Hungary. Plenary and keynote lectures will be presented by invited prominent chemists from all over the world. Participants are encouraged to contribute papers, which will be presented as posters. A second circular, which will include instructions for authors, will be distributed in September 1990.

Further details can be obtained from:

E. Pungor, President of the 33rd IUPAC Congress

UV, IR, ^{71}Ga AND ^{17}O NMR SPECTROSCOPIC STUDIES OF THE 12-MOLYBDOGALLATE HETEROPOLYANION

L. P. TSIGANOK* and A. B. VISHNIKIN

State University, Dniepropetrovsk 320625, U.S.S.R.

and

R. I. MAKSIMOVSKAYA

Institute of Catalysis, Novosibirsk 630090, U.S.S.R.

(*Received* 2 *September* 1988; *accepted after revision* 27 *January* 1989)

Abstract—UV, IR, ^{71}Ga and ^{17}O NMR spectra clearly demonstrate the Keggin structure for the new heteropolyanion—12-molybdogallate (12-MGA). The UV spectrum of the 12-MGA solution has charge-transfer bands at 49,000, 40,000 and 32,500 cm^{-1}, which have been attributed to oxygen-to-molybdenum(VI) transitions. The IR spectra of the synthesized samples of 12-MGA contain the expected triplet of bands, which could be assigned to molybdenum–oxygen stretching vibrations. The data obtained from the ^{71}Ga and ^{17}O NMR spectroscopy confirmed the tetrahedral oxygen environment of the gallium atoms and the Keggin structure of 12-MGA. The ^{71}Ga NMR chemical shifts of crystalline $(TEBA)_5GaMo_{12}O_{40}$ (TEBA—triethylbenzyl ammonium) as well as of aqueous solutions of 12-MGA are situated in the range characteristic of a tetrahedral oxygen environment of gallium (223 ppm relative to $Ga(H_2O)_6^{3+}$). In these solutions $GaMo_6O_{24}H_6^{3-}$ polyanions can co-exist (52 ppm). The ^{17}O NMR spectrum of $Na_5GaMo_{12}O_{40}$ has three resonances with chemical shifts of 923, 575 and 568 ppm (relative to H_2O) and an intensity ratio 1 : 1 : 1, which is similar to the spectra of other Keggin heteropolyanions. The changes of the nature and length of the Mo—O bonds in the 12-molybdogallate relative to the parent 12-molybdophosphate are discussed.

Due to its electron-donor properties, the oxogallate ion forms 6-molybdogallate,[1,2] 12-tungstogallate,[3,4] the vacant 11-tungstogallate anion and its derivatives,[5] mixed molybdotungstic heteropolyanions (HPA)[6] with the Keggin structure.[7] Recently, we have observed the formation in aqueous solution and obtained in the solid state the 12-molybdogallate anion (12-MGA) with reversible redox properties.[8] The gallium(III) ion has a preference for octahedral coordination in acidic aqueous solution, and the ionic radius of gallium is large enough, so that the formation of the Keggin anion could be prevented. To check these possibilities, we have used ^{17}O and ^{71}Ga NMR methods and other spectroscopic techniques, which provide structural information about polycomplexes in solution.[9–15]

EXPERIMENTAL

Solid samples of $(TEBA)_5GaMo_{12}O_{40}$ (TEBA—triethylbenzyl ammonium) were prepared as described in refs 8 and 16. Found: Ga, 2.01; Mo, 32.4. Required for $(TEBA)_5GaMo_{12}O_{40}$: Ga, 1.97; Mo, 32.4%.

The solution of $Na_5GaMo_{12}O_{40}$ was prepared as follows. Sodium molybdate $Na_2MoO_4 \cdot 2H_2O$ (5.5 g, 22.7 mmol) was dissolved in a mixture of water (1.5 cm^3) enriched with ^{17}O ($\sim$ 1.5%) and HNO_3 (60%, 2.5 cm^3). Then gallium nitrate $(Ga(NO_3)_3 \cdot 8H_2O$ (0.721 g, 1.8 mmol) was added to this solution. The resulting solution was heated at 90°C for 1 h, the pH being kept at 1.5. On heating a yellow colour appeared.

The IR spectra were recorded on a Zeiss Specord M 80 with the samples dispersed in Nujol. UV spectral measurements of aqueous solutions of

12-MGA were obtained with a Zeiss Specord M 40 spectrophotometer.

NMR spectra were measured on a BRUKER CXP-300 spectrometer. The ^{71}Ga spectra were obtained at 91.53 MHz with a spectral width of 125 kHz, a pulse duration of 1 μs for solid samples and 10 μs for solutions. ^{71}Ga spectra of solid samples were measured using the magic angle spinning (MAS, 4 kHz) technique. The number of transients was about 20,000 and the pulse delay was 0.2 s. The chemical shifts are given relative to the aqua ion, $Ga(H_2O)_6^{3+}$.

The ^{17}O NMR spectra were obtained at 40.7 MHz with a spectral width of 62.5 kHz, a pulse duration of 10 μs and a pulse delay of 0.02 s. ^{17}O spectra were obtained using water with a natural abundance of ^{17}O and enriched with ^{17}O ($\sim$ 1.5%). The chemical shifts are given relative to solvent H_2O. The downfield shift is taken as positive.

RESULTS AND DISCUSSION

The formation of 12-molybdogallate is slow in aqueous solutions. This is explained by kinetic difficulties due to changes in the coordination of gallium from octahedral in aqua and hydroxo complexes to tetrahedral in 12-MGA. Heating accelerates the formation of 12-MGA and completion of the reaction requires about 1 h. The HPA is stable in the pH range 0–3.0.

UV absorption spectra of the $(TEBA)_5GaMo_{12}O_{40}$ solutions show three bands at 49,000, 40,000 and 32,500 cm^{-1} (Fig. 1). The last two bands appear as broad shoulders. The absorption band at 32,500 cm^{-1} is responsible for the yellow colour of 12-MGA. The maximal deflection of the absorption from the additivity of the solutions containing Ga^{3+} and MoO_4^{2-} ions at an atomic Ga–Mo ratio equal to 1:12 relative to the molybdate solution is observed at 40,000 cm^{-1}. These bands have been attributed to charge-transfer transitions of oxygen to molybdenum(VI) and are typical for Keggin HPA.[14] UV spectra do not change in the pH range 1–3, showing the absence of the protonation of HPA.

The IR spectra of $(TEBA)_5GaMo_{12}O_{40}$ closely

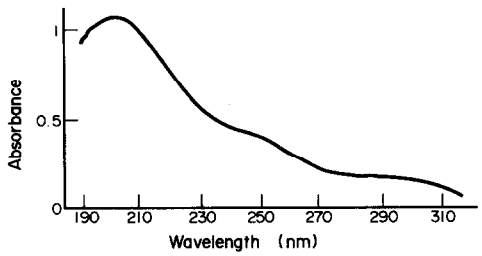

Fig. 1. UV absorption spectrum of the solution of $(TEBA)_5GaMo_{12}O_{40}$ ([HPA] = 10^{-5} M).

resemble those reported for 12-HPA.[15] Similarities of positions of the triplet of the most characteristic bands in the 1000–700 cm^{-1} region due to molybdenum–oxygen stretching vibrations strongly indicate that these complexes have identical structures. Selected IR frequencies are given in Table 1.

NMR spectroscopy can give reliable structural information about polycomplexes,[10–12] and we have used ^{17}O and ^{71}Ga NMR methods to prove the Keggin structure for the 12-molybdogallate.

The ^{71}Ga NMR spectrum of the solid sample of $(TEBA)_5GaMo_{12}O_{40}$ contains the isotropic signal (Fig. 2(a), Table 2), which is situated in the range of gallium chemical shifts characteristic of a tetrahedral oxygen environment.[11,17,18] The width of the signal became smaller but the value of the chemical shift remained constant when the sample was rotated at the magic angle (54°44′, 4 kHz) [Fig. 2(b)]. The same peak is observed in the yellow methylethylketone solution. In the ^{71}Ga NMR spectrum of the acidic solution (pH = 1.5) of 12-MGA (prepared as described above) two resonances are observed: firstly, a broad peak (width $\sim$ 2600 Hz) at 52 ppm arises from $GaMo_6O_{24}H_6^{3-}$-HPA containing an octahedral oxygen environment of gallium[18] and secondly, a narrow peak (width $\sim$ 50 Hz) at 223 ppm belongs to 12-MGA [Fig. 2(d)]. These polyanions co-exist in aqueous solution.

Besides the above mentioned signals there is also a weak narrow peak at 218 ppm. Nearness to the neighbouring signal at 223 ppm and the small linewidth show the tetrahedral oxygen arrangement of

the central atom in this HPA. The difference in chemical shifts of these two signals can be compared with the data for pairs, GaW_{12}–GaW_{11}, PW_{12}–PW_{11} and AlW_{12}–AlW_{11}.[19] The existence of the 11-molybdogallate HPA in the studied system is supposed.

Thus, the data obtained from the ^{71}Ga NMR spectra confirm the formation of gallium 12-HPA with the Keggin structure.[7] Good agreement between the spectra of the crystalline and dissolved polyanion demonstrates that the structure of the anion in solution is the same as that observed in the solid state. There are complex equilibria between at least three polyanions of gallium in solution.

Further support for these conclusions comes from the ^{17}O NMR spectra (Fig. 3, Table 2). In the ^{17}O NMR spectrum of the concentrated solutions containing Ga^{3+} and MoO_4^{2-} ions in the atomic

[a] MAS spectrum.
[b] From ref. 11.

Ga–Mo ratio equal to 1 : 12 at pH = 1.5, in addition to two signals from $GaMo_6O_{24}H_6^{3-}$, three signals belonging to $GaMo_{12}O_{40}^{5-}$ are observed. By analogy with other Keggin anions[10–12,20] these lines can be attributed to the following oxygen atoms: the peak at 923 ppm appears from the terminal Mo=O oxygen atoms and the peaks at 575 and 568 ppm arise from the bridging Mo—O—Mo oxygen atoms.

The chemical shifts, as well as the number and the integrated intensity of the resonances (1 : 1 : 1) of the oxygen atoms, conform well with the $GaMo_{12}O_{40}^{5-}$ structure. These facts together with the data of ^{71}Ga NMR spectra, prove the formation of 12-MGA in the investigated solutions. Similar ^{17}O NMR spectra were recorded for solutions of 12-MGA prepared using water with a natural ^{17}O content.

We did not observe any signal from the oxygen atoms of the Mo—O—Ga bridges. It is probable that it is situated near the signal of H_2O (38 ppm) or it is strongly broadened due to the closeness of the Ga^{3+} ion.

The difference in lengths of the bridging Mo—O—Mo bonds is very small ($\Delta\delta = 7$ ppm) and depends upon the electronic structure and the radius of the central atom. One can estimate the relative stability of the 12-molybdogallate using the ^{17}O NMR chemical shift scale of oxygen atoms and the bond length–^{17}O NMR O—Mo correlation.[10–12] The downfield shift in the ^{17}O NMR spectrum of $PMo_{12}O_{40}^{3-}$ (δ 940 ppm) relative to $GaMo_{12}O_{40}^{5-}$ (923 ppm) shows that the Mo=O bond is longer in 12-MGA and the extent of covalency is smaller. Consequently, this indicates a smaller stability of the gallium HPA due to the metallic properties and the large radius of the gallium atom.

Thus, using ^{17}O and ^{71}Ga NMR and other spectroscopic techniques, we have shown that gallium forms a sufficiently stable 12-heteropolymolybdate with the Keggin structure. This HPA compound exists in aqueous solutions, in organic solvents and in the solid state. Other heteropolyanions such as $GaMo_6O_{24}H_6^{3-}$ and probably $GaMo_{11}O_{39}^{9-}$ co-exist in acidic solutions.

Abstract—Complexes with the ligand 1,3-bis-(2-hydroxyphenyl)-1,3-propanedione ($bhppH_3$) of formula $M(bhppH_2)_2 \cdot 2$ solvent (M = Co, Ni, Zn) can be desolvated by controlled heating. These compounds contain the metal ion tetracoordinated in a square-planar fashion by the β-ketonic oxygen atoms of the ligand, and they behave as Lewis acids toward Lewis bases, like pyridine or pyridine derivatives. Two pyridine molecules complete the octahedral coordination of the metal. The pyridine coordination is weak, as evidenced by the Cd—N bond length (2.342 Å), compared to that of the Cd—O bond (mean value, 2.248 Å). In addition, the easy substitution reactions support this assumption. The new compounds are more soluble in common solvents than their parent compounds. The molecular structure of $Cd(bhppH_2)_2 \cdot 2$ pyridine is reported, being monoclinic, space group $P2_1/c$ with $a = 8.868(6)$, $b = 11.128(3)$, $c = 17.508(4)$ Å, $\beta = 100.84(5)°$, $V = 1697$ Å^3, $Z = 2$, $D_c = 1.53$ g cm^{-3} and $\mu = 8.79$ cm^{-1}.

The compound 1,3-bis-(2-hydroxyphenyl)-1,3-propanedione ($bhppH_3$) (Fig. 1) is an excellent ligand, affording mononuclear complexes with divalent transition metal ions of formula $M(bhppH_2)_2$.[1] In these complexes the metal ion is coordinated by the β-diketone moiety of two ligand molecules in a square-planar environment, except in the case of the lithium complex where the coordination is tetrahedral.[2] Usually, the metal achieves hexacoordination by the addition of solvent molecules. This molecule is also a potentially trinucleating ligand. With it we have prepared linear trinuclear complexes of the type UO_2—M—UO_2, M being a first-row divalent transition metal ion.[3] Consequently, it is a potential synthesis-director ligand which permits the formation of different positional isomers of the type: A–B–A or B–A–B, depending on the starting mononuclear complex. The synthesis of the trinuclear compounds becomes difficult due to the general insolubility of the mononuclear precursors in common solvents.

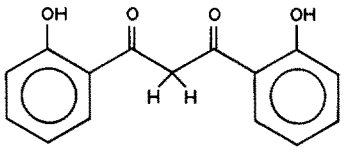

Fig. 1. 1,3-bis-(2-hydroxyphenyl)-1,3-propanedione.

† Author to whom correspondence should be addressed.

In order to improve the solubility of the mononuclear complexes, we have modified the original ligand, via substitution at the methine carbon atom. In doing so we expected that the synthesis of the trinuclear compounds would be easier. For this reason we synthesized the chromium(III) mononuclear complex, $Cr(bhppH_2)_3$,[4] a compound that shows useful solubilities in common organic solvents, hence permitting nucleophilic substitutions at the α-carbon of the β-diketone moiety, as is usual in β-diketonate metal complexes.

Always with the aim of increasing the solubility of the mononuclear complexes, we have also tried its reaction with different Lewis bases, like pyridine derivatives, expecting that the solvated compounds would be more soluble than the corresponding parent complexes. In this paper we report on the products of these reactions and their solubility properties, as well as the crystalline structure of $Cd(bhppH_2)_2 \cdot 2py$.

EXPERIMENTAL

All operations were carried out in the atmosphere. The bis(1,3-bis-(2-hydroxyphenyl)-1,3-propanedione)metal(II) complexes, solvated with two alcohol molecules, were prepared following a reported procedure.[1] Pyridines were reagent grade and were used as received, except 4-($COOCH_3$)py which was prepared from 4-COOH-py following Levine's procedure.[5] Tetrahydrofuran (THF) was partially dried with KOH. All other solvents were reagent grade and used as received. Microanalyses (C, H, N) were performed in our analytical laboratory using a Perkin–Elmer 240-B instrument. ^{1}H NMR spectra were obtained using a Brucker WP.80SY spectrophotometer. IR spectra were determined on a Beckman IR-20A as KBr pellets. Electronic spectra were run on a Shimadzu 240 spectrophotometer in solution.

Synthesis of $M(bhppH_2)_2$ ($M = Co^{II}$, Ni^{II}, Zn^{II}, Cd^{II})

The elimination of the alcohol molecules in $M(bhppH_2)_2 \cdot 2ROH$ was achieved by controlled heating of these solids in an oven at 120°C for 30 min.

Synthesis of $M(bhppH_2)_2 \cdot 2py'$ (py' = *pyridine, 3-hydroxypyridine, 4-methylpyridine, methylpyridine-4-carboxylate, 4-N,N-dimethylaminopyridine*; M = Co^{II}, Ni^{II}, Zn^{II}, Cd^{II})

In a typical experiment, $Co(bhppH_2)_2$ (0.2 g, 0.35 mmol) was dissolved in THF (20 cm^3). Pyridine (1 cm^3, 13 mmol) was added and the resulting solution was refluxed for $\frac{1}{2}$ h and then allowed to cool to room temperature. Solvent and volatiles were stripped off in a rotavapor and the oily solid was treated with benzene, which was later evaporated again in the rotavapor. The yellow solid, which is now manageable, was stirred in CCl_4 and dried with dry air.

Yields were in all cases very high: 90–100%. The amount of pyridine or substituted pyridines used for 0.2 g of $M(bhppH_2)_2$ complex was variable and depended on the state of the pyridine, 1–2 cm^3 of the appropriate chemical was used if this was a liquid, but a 10% excess if it was a solid.

X-ray structure determination

The colourless single crystals of $C_{30}H_{22}O_8Cd \cdot 2C_6H_5N$ are monoclinic, space group $P2_1/c$ with $a = 8.868(6)$, $b = 11.128(3)$, $c = 17.508(4)$ Å, $\beta = 100.84(5)°$, $V = 1697$ Å^3, $Z = 2$, $D_c = 1.53$ g cm^{-3}, $\mu = 8.79$ cm^{-1}.

X-ray diffraction data for $Cd(bhppH_2)_2 \cdot 2py$ at 294 K were collected with an Enraf–Nonius CAD4 four-circle diffractometer using graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) on a $0.15 \times 0.28 \times 0.34$ mm prismatic crystal. Reflections were measured at the azimuth position corresponding to a minimum absorption, using an imaginary crystal with finite but small thickness, having an infinitely large surface area (flat psi mode).

Using the ω–2θ scan technique, 3321 reflections with $2\theta < 50°$ ($-10 < h < 10$; $0 < k < 13$; $0 < l < 20$) were obtained. Intensities of two standard reflections were followed during data collection and no significant decay was observed. These non-unique data were averaged and the resulting 2954 intensities were corrected for Lorentz and polarization effects, and only 1159 were considered observed with $I > 5\sigma(I)$. The scattering factors and anomalous corrections were taken from the *International Tables for X-ray Crystallography*.[6]

The atomic coordinates of cadmium and part of the ligand were located by direct methods (MULTAN 11/84 system 1).[7] Subsequent difference Fourier syntheses combined with refinement of located atoms led to a complete model of the structure. This model was refined with Shelx76[8] using anisotropic thermal parameters for non-hydrogen atoms and a common isotropic temperature factor for hydrogen atoms, which were placed in geometrically calculated positions [except H(1) and H(15)], giving an R factor of 0.056 and $R_w = 0.047$ ($w = 1/\sigma^2(F) + 0.000304F^2$). On a final difference Fourier syn-

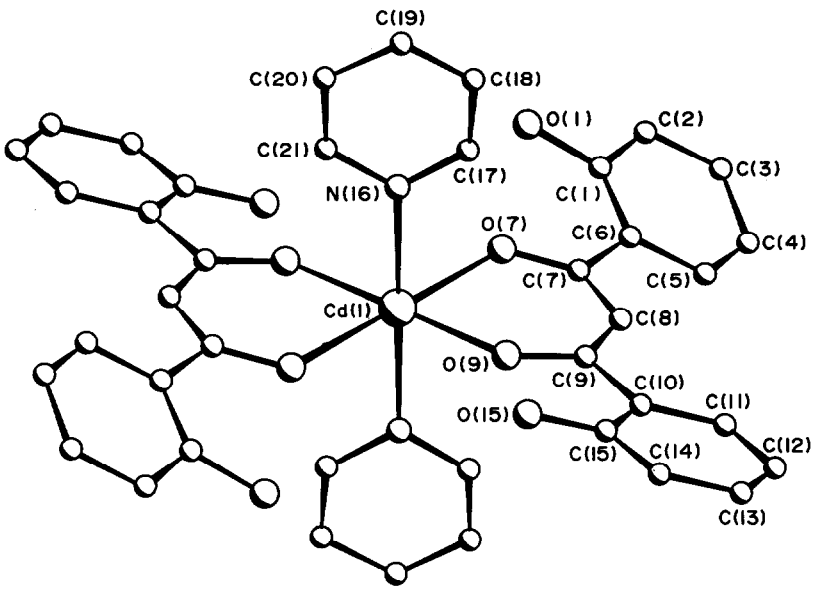

Fig. 2. Perspective view and atom numbering scheme for $Cd(bhppH_2)_2 \cdot 2py$.

thesis, the largest peaks were 0.68 e Å^3, located near to the cadmium atom, and -0.48 e Å^3.†

RESULTS AND DISCUSSION

Molecular structure of $Cd(bhppH_2)_2 \cdot 2py$

Figure 2 shows the molecular structure and numbering scheme of the title molecule. Table 1 reports selected bond lengths and angles.

The cadmium atom is located on a crystallographic symmetry centre, however, the whole unit cell contains two complete molecules. The metal ion is coordinated by two ligand and two pyridine molecules in a distorted octahedral fashion. The coordination polyhedron has a nearly rhombic distortion (angle O(7)—Cd(1)—O(9), 80.19°), with the axial distances (Cd—N, 2.342 Å) larger than the equatorial ones (Cd—O(7), 2.253 Å; Cd(1)—O(9), 2.243 Å). Atoms Cd(1), O(7), O(9), O(7*), O(9*) lie in a plane, Cd(1) being located on the symmetry centre of the rectangle defined by O(7), O(9), O(7*) and O(9*). Angles between mean planes, N(16)—Cd(1)—O(7) and N(16)—Cd(1)—O(9), with respect to the O(7)—Cd(1)—O(9) plane, are 91.47 and 89.02°, respectively.

Coordinated pyridine molecules are placed almost perpendicular to the O(7)—Cd(1)—O(9) plane (angle between mean planes 91.61°) and lie close to the octahedron symmetry plane bisecting the angle O(7)—Cd(1)—O(9) (angle between mean planes, N(16)—Cd(1)—O(7) and pyridine molecular plane, 42.32°). Bond lengths and angles for the pyridine molecules are typical for this compound.

The conformation of the ligand molecule is not

strictly planar as could be originally expected. The β-diketone moiety is not co-planar with the octahedron equatorial plane (angle between mean planes, O(7)—Cd(1)—O(9) and C(7)—C(8)—C(9), is 165.28°). Furthermore, the phenolic rings are not co-planar with the β-diketone moiety plane (angle between mean planes, C(7)—C(8)—C(9) and C(1)···C(6) phenolic ring plane, is 156.80°). Both phenolic rings are twisted in the same direction, in a butterfly-like fashion; so, the O(1) and O(15) atoms lie 0.6931 and 0.5612 Å, respectively, below the O(7)—Cd(1)—O(9) plane. A hydrogen bond is found between the hydroxyl phenolic group, O(1), O(15) and O(7), O(9), oxygen atoms, respectively.

General chemistry and physical properties

The reactions of cobalt(II), nickel(II) and zinc(II) complexes of 1,3-bis-(2-hydroxyphenyl)-1,3-propanedione ($bhppH_3$) (Fig. 1) with pyridine derivatives yield compounds with the general formula $M(bhppH_2)_2 \cdot 2py'$ [py′ = pyridine (py), 3-hydroxypyridine (3-(OH)-py), 4-methylpyridine (4-(CH_3)-py), methylpyridine-4-carboxylate (4-$(COOCH_3)$-py), 4-N,N-dimethylamino pyridine (4-$(CH_3)_2$N-py]. The similarity of the IR spectra of these complexes with those of $M(bhppH_2)_2 \cdot 2ROH$[1] seems to indicate a molecular structure for all of them, similar to that found in $Zn(bhppH_2)_2 \cdot 2EtOH$.[9] The general reaction to get these pyridine complexes is indicated in Scheme 1:

$$M(bhppH_2)_2 \cdot 2ROH \xrightarrow{\text{heat}} M(bhppH_2)_2 \xrightleftharpoons[py']{\text{heat}} M(bhppH_2)_2 \cdot 2py'$$

Scheme 1.

The pyridines, like the alcohols,[10] are weakly bonded and may be removed by heating the complexes in an oven at 125°C overnight. The thermogravimetric analysis (TG) for $Co(bhppH_2)_2 \cdot 2py$ shows two weight losses concurrent with two endothermic peaks. The first one corresponds to the elimination of pyridine in the complex, and the second one to a dehydration reaction taking place in the ligand $bhppH_3$, as is shown in Scheme 2:

$$Co(bhppH_2)_2 \cdot 2py \rightarrow Co(bhppH_2)_2 \rightarrow CoO + H_2O + \text{"flavona"}$$

Scheme 2.

The solubility of these pyridine complexes is markedly higher than the corresponding alcohol complexes. The most dramatic change is observed with 4-$(COOCH_3)$-py, where the complex $Zn(bhppH_2)_2 \cdot 2$(4-$(COOCH_3)$-py) is even soluble in benzene. This enhancement of the solubility has allowed all ^{1}H NMR spectra of the pyridine–zinc complexes to be run in d_1-chloroform, while the ^{1}H NMR spectra of the alcohol–zinc complexes[1] had to be run in d_6-dmso. As a conclusion, it has been possible to greatly enlarge the solubility range of the $M(bhppH_2)_2 \cdot 2ROH$ complexes, simply by replacing the axial alcohols by pyridine-substituted ligands.

^{1}H NMR spectra of the zinc complexes

The ^{1}H NMR spectra of $Zn(bhppH_2)_2 \cdot 2py'$ are very similar [py′ = (py), (3-(OH)-py), (4-(CH_3)-py), (4-$(COOCH_3)$-py), (4-$(CH_3)_2$N-py)]. The ^{1}H NMR spectrum of $Zn(bhppH_2)_2 \cdot 2$(4-(CH_3)-py) is discussed as a typical example. Mainly, three groups of signals are observed, one group near to $\delta = 12$ ppm due to the phenolic proton, another group occupying a larger region at $\delta = 6.5$–9 ppm due to the aromatics, and finally a third group (when appropriate) due to the pyridine substituent, e.g. 2.3 ppm in 4-(CH_3)-py, 2.9 ppm in 4-$(CH_3)_2$N-py, 4 ppm in 4-$(COOCH_3)$-py. In all cases integrations were in agreement with the proposed stoichiometry of the complex. On comparison with the ^{1}H NMR of non-coordinated $bhppH_3$ the methine signal is, as expected when chelation has occurred, in the aromatic region. However, due to the existence of several signals in this region, its exact position is difficult to be determined.

Spectroscopic properties

The $^3A_{2g} \rightarrow {}^3T_{1g}$ absorption band for the individual Ni—pyridine complexes are as follows, for: (py) 595 nm; (4-$(CH_3)_2$N-py) 595 nm; (4-(CH_3)-py) 585 nm; (3-(OH)-py) 580 nm; (4-$(COOCH_3)$-py) 580 nm, according to the position of the pyridine derivatives in the spectrochemical series. The cobalt complexes exhibit an intense charge-transfer band at 430 nm, considerably limiting the study of the *d–d* bands in the visible spectrum. Only one shoulder at 490 nm is observed for all of them.

All these complexes exhibit almost the same pattern in the IR spectra, evidencing their similar molecular structures. Several characteristic bands may be seen in these complexes: (4-$(CH_3)_2$N-py), ν(CH, aliphatic) at 2900 cm^{-1}; (4-(CH_3)-py), ν(CH, aliphatic) at 2900 cm^{-1}; (3-(OH)-py), ν(OH) at 3300 cm^{-1}; (4-$(COOCH_3)$-py), ν(CO) at 1725 cm^{-1}.

Abstract—The NSN-donor ligand 2,10-diaza-6-thiaundecane forms five coordinate complexes with copper(II). The preparation, crystal and molecular structures of $[CuLX_2]$ (L = 2,10-diaza-6-thiaundecane; X = Cl or Br) are reported.

The thermodynamic stability of transition metal complexes frequently follows that given in the Irving–Williams series, with copper(II) forming the most stable complexes with a given ligand or set of ligands.[2] This presents the fundamental problem in the design of reagents for the selective extraction of specific transition metal ions. Various approaches have been proposed in attempts to circumvent the dictates of the Irving–Williams series. In general, these rely on some dramatic change in the metal–ligand interaction on crossing the first row transition metals. Although ideal reagents would give complexes with the largest thermodynamic stability with the metal of interest, it has been demonstrated that satisfactory selectivity can be obtained by the design of reagents maximizing the stability differences.[3] The majority of the studies reported to date have utilized macrocyclic ligands, and have relied upon the mis-match between metal ion radius and ligand hole size to tune the metal–ligand interaction. We have been investigating the coordination chemistry of ligands incorporating both hard and soft donor atoms as an alternative methodology. Open-chain ligands offer some synthetic advantages, as entropically disfavoured ring closure reactions are not involved in their preparation. The balance between the donor properties of the ligand and the acceptor properties of the metal may be tuned by varying the donor atoms, the substituents on the donor atoms, and the chelate ring size. The bis(aminoalkyl)thioethers, $R_2N(CH_2)_nS(CH_2)_mNR_2$, have proved to be a particularly versatile series of ligands. The hardness and steric properties of the R_2N groups may be varied by the introduction of various alkyl groups, and the chelate ring size may be varied at will by changing the values of n and m. We recently reported[1] the crystal and molecular structure of the square-planar complex $[PdL^1Br]Br$ (L^1 = 2,10-diaza-6-thiaundecane), and wish to report herein, the preparation and structural characterization of copper(II) complexes with this ligand.

EXPERIMENTAL

Electronic spectra were recorded using a Pye–Unicam 8800 spectrophotometer; IR spectra were recorded using Perkin–Elmer 1710 FT or 983 spectrometers with the compound in compressed KBr pellets or in a suspension in Nujol. Fast-atom bombardment mass spectra were measured using a Kratos MS-50 spectrometer, and were loaded using

* For part I, see ref. 1.

† Author to whom correspondence should be addressed.

acetonitrile as solvent with 3-nitrobenzyl alcohol as supporting matrix. NMR spectra were recorded on a Bruker WM250 spectromter. Magnetic moments were measured at ambient temperature using a Johnson Matthey susceptibility balance. ESR spectra were determined on powdered solid samples or on glassy acetonitrile solutions at −196°C using a Varian E109 spectrometer calibrated with the diphenyl picryl hydrazyl radical. The compounds $OHCNH(CH_2)_3OH$ and $MeNH(CH_2)_3OH$ were prepared by the literature methods.[4] All preparations were conducted under an atmosphere of dry dinitrogen or argon; solutions containing the thiolate are particularly sensitive to oxidation.

Caution: the compound $Cl(CH_2)_3NHMe$ and its hydrochloride salt are nitrogen mustards, and highly toxic, carcinogenic vesicants. The thiol has a particularly offensive odour. The compounds should always be handled in an efficient fume hood.

Preparation of $[MeH_2N(CH_2)_3Cl]Cl$

$MeHN(CH_2)_3OH$ (12.4 g, 0.14 mol) was added over a period of 1 h to freshly distilled $SOCl_2$ (20.0 g, 0.17 mol) and the mixture was stirred at room temperature for 16 h. After this period, Et_2O (20 cm^3) was added and the solution cooled to −20°C, whereupon $[MeH_2N(CH_2)_3Cl]Cl$ was obtained as a white crystalline solid (16.0 g, 80%) (^1H NMR, CD_3OD, δ 2.02–2.38, m, 2H, $CH_2CH_2CH_2$; δ 2.77, s, 3H, NCH_3; δ 3.22, t, NCH_2; δ 3.74, t, $J = 6.2$ Hz, $ClCH_2$).

Preparation of $MeH_2N(CH_2)_3SH$

Thiourea (8.62 g, 0.08 mol) and $[MeH_2N(CH_2)_3Cl]Cl$ (11.3 g, 0.08 mol) were maintained at 95°C in $HOCH_2CH_2(OCH_2CH_2)_2OH$ (50 cm^3) for 24 h, after which period $H_2NCH_2CH_2(NHCH_2CH_2)_3NH_2$ (15.0 g, 0.08 mol) was added, and the solution heated to 130°C for a further 2 h. The resultant solution was vacuum distilled, and the fraction distilling at 47–49°C/11 mm Hg was collected as a colourless oil. Upon cooling to −20°C, the oil solidified to a white mass of $MeH_2N(CH_2)_3SH$ (5.5 g, 67%) (^1H NMR, $CDCl_3$, δ 1.35, s, 1H, NH; δ 1.59–1.95, m, 2H, $CH_2CH_2CH_2$; δ 2.38–2.82, m, 4H, SCH_2 and NCH_2; d 2.42, s, 3H, NCH_3; *m/z*, 105).

Preparation of 2,10-*diaza*-6-*thiaundecane*, L

$MeH_2N(CH_2)_3SH$ (1.70 g, 0.016 mol) was added to a solution of sodium methoxide prepared by the reaction of sodium (0.82 g, 0.036 mol) with methanol (20 cm^3). A solution of $[MeH_2N(CH_2)_3Cl]Cl$ (2.80 g, 0.019 mol) was added to the resultant solution over a period of 25 min, after which the mixture was stirred for 25 min at room temperature and then heated to reflux for 3 h. The cooled solution was diluted with Et_2O (30 cm^3), filtered to remove NaCl and the filtrate concentrated *in vacuo*. The resultant oil was vacuum distilled and 2,10-diaza-6-thiaundecane was collected as the colourless fraction distilling at 90–92°C/0.25 mm Hg (1.6 g, 54%) (IR: ν_{N-H} 3295 cm^{-1}, ν_{CH} 2792 cm^{-1}; ^1H NMR, $CDCl_3$, δ 1.40, s, 1H, NH; δ 1.67–1.78, m, 2H, $CH_2CH_2CH_2$; δ 2.38, s, 3H, NCH_3; δ 2.52, t, $J = 7.3$ Hz, 2H, SCH_2; δ 2.61, t, $J = 7.0$ Hz; 2H, NCH_2). Treatment of an ethanolic solution of the oil with gaseous HBr led to the deposition of the $[H_2L]Br_2$ as a white crystalline solid (Found: C, 28.7; H, 6.6; N, 8.1. Calc. for $C_8H_{22}N_2SBr_2$: C, 28.4; H, 6.6; N, 8.3%).

Preparation of $[CuLBr_2]$

A solution of L (0.05 g, 0.29 mmol) in EtOH (1 cm^3) was added dropwise to a solution of $CuBr_2$ (0.05 g, 0.22 mmol) in EtOH (3 cm^3). The mixture was stirred for 30 min at room temperature, after which period the green precipitate was collected by filtration, washed with EtOH (2 cm^3) and Et_2O (3×5 cm^3). Green crystals of the complex were obtained by the slow diffusion of Et_2O vapour into a Me_2CO solution of the complex (Found: C, 24.1; H, 5.1; N, 6.9. Calc. for $C_8H_{20}N_2SCuBr_2$: C, 24.0; H, 5.0; N, 7.9%).

Preparation of $[CuLCl_2]$

This was prepared in exactly the same manner as the bromo complex, substituting $CuCl_2$. Green crystals of the complex were obtained by the slow diffusion of Et_2O vapour into a Me_2CO solution of the complex (Found: C, 30.4; H, 6.4; N, 8.8. Calc. for $C_8H_{20}N_2SCuCl_2$: C, 30.9; H, 6.5; N, 9.0%).

Crystal structural determination of $[CuLCl_2]$ *and* $[CuLBr_2]$

Dark green blocks of the complexes were obtained by diffusion of Et_2O vapour into Me_2CO solutions of the complexes. Suitable green crystals were mounted on a glass fibre with epoxy resin.

Crystal data. $C_8Cl_2CuH_{20}N_2S$, green blocks, $M = 310.8$, orthorhombic, $a = 17.960(14)$, $b = 14.104(9)$, $c = 10.400(12)$ Å, $U = 2633.6$ Å^3, space group *Pbca* (No. 61), $Z = 8$, $D_c = 1.56$ g cm^{-3}, $D_m = 1.52$ g cm^{-3}, $F(000) = 1288$. Crystal dimensions $0.60 \times 0.20 \times 0.20$ mm, Mo-K_α radiation ($\lambda = 0.7107$ Å), μ(Mo-K_α) = 22.3 cm^{-1}.

Crystal data. $Br_2C_8CuH_{20}N_2S$, green blocks, $M = 399.7$, orthorhombic, $a = 18.440(15)$, $b = 14.214(9)$, $c = 10.587(12)$ Å, $U = 2774.9$ Å^3, space group *Pbca* (No. 61), $Z = 8$, $D_c = 1.93$ g cm^{-3}, $D_m = 1.95$ g cm^{-3}, $F(000) = 1576$. Crystal dimensions $0.50 \times 0.15 \times 0.15$ mm, Mo-K_α radiation ($\lambda = 0.7107$ Å), μ(Mo-K_α) = 79.3 cm^{-1}.

Data collection and processing

The two crystals were set up in turn to rotate about the *a* and *c* axes, respectively, on a Stoe Stadi2 diffractometer and data were collected via variable width ω scan. Background counts were for 20 s and a scan rate of 0.0333° s^{-1} was applied to a width of $(1.5 + \sin\mu/\tan\theta)$. For [$CuLCl_2$], 2047 and for [$CuLBr_2$], 2134 independent reflections with $2\theta_{max}$ of 50° were measured on a Stoe Stadi2 diffractometer, of which 1298 with $I > 3\sigma(I)$ for [$CuLCl_2$] and 1015 with $I > 2\sigma(I)$ for [$CuLBr_2$] were used in the calculations. An empirical absorption correction was applied to both sets of data.[5]

Structure analysis and refinement of [$CuLCl_2$]

The structure was solved by direct methods followed by Fourier difference techniques. Blocked full-matrix least-squares refinement with Cu, Cl, N, S and C atoms anisotropic. Hydrogen atoms were not located directly, but were placed in idealized positions and allowed to ride on the relevant carbon with C—H fixed at 0.95 Å; the methyl groups were refined as rigid groups. The structure was chemically reasonable, although there was a surprising disparity in the S(9)—C(10) and S(9)—C(8) bond lengths [1.921(13), 1.825(15)]. The weighting scheme, $w = 1/[\sigma^2(F) + 0.003|F|^2]$, gave satisfactory agreement analyses. Final converged R and R_w values were 0.058 and 0.065, respectively.

Structure analysis and refinement of [$CuLBr_2$]

The structure was solved by direct methods followed by Fourier difference techniques. Initial blocked full-matrix least-squares refinement with all atoms isotropic. Hydrogen atoms were not located directly, but were placed in idealized positions and allowed to ride on the relevant carbon with C—H fixed at 0.95 Å; the methyl groups were refined as rigid groups. The data for [$CuLBr_2$] was less good than for [$CuLCl_2$], and on initial isotropic refinement, the disparity in S—C bond lengths was 0.30 Å. In addition, there were some unusual dimensions around the chelate ring and C(10) had a large thermal parameter. When the sulphur atom was refined anisotropically, U_{11} was twice as large as U_{22} and U_{23}; this suggested the presence of disorder and several models based on two sulphur atom positions with different occupancies were tried unsuccessfully. In the final model, Cu, Br and S were refined anisotropically and C, N and H were refined isotropically, with the S(9)—C(10) and S(9)—C(8) distances constrained to be equivalent via DFIX with an allowed standard deviation of 0.05 Å. They refined to values of 1.965(28) and 1.822(39) Å. The weighting scheme, $w = 1/[\sigma^2(F) + 0.003|F|^2]$, gave satisfactory agreement analyses. Final converged R and R_w values were 0.083 and 0.096, respectively. A final electron density map showed a maximum electron density of 0.96 e Å^{-3} in a position close to S(9). Clearly there is some positional disorder in the ligand, although no obvious disordered model was found appropriate. For both compounds, complex neutral atom scattering factors were taken from ref. 6. Calculations were performed using SHELX 76 on the Amdahl V7 Computer at the University of Reading.[7] Selected bond lengths and bond angles are presented in Table 1.*

RESULTS AND DISCUSSION

The aminothioether ligand, $MeNH(CH_2)_3S(CH_2)_3NHMe$, is readily prepared in 54% yield by the nucleophilic attack of the thiolate anion,

Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

$MeNH(CH_2)_3S^-$, upon $MeNH(CH_2)_3Cl$. The compound is an oil, which is best stored as its hydrobromide salt. In general, the compound was prepared as required, and used immediately. The desired thiol is prepared in moderately good yield via the thiouronium salt, obtained from the reaction of thiourea with $MeNH(CH_2)_3Cl$. The key intermediate for the synthesis is thus $MeNH(CH_2)_3Cl$, which is prepared by the reaction of $MeNH(CH_2)_3OH$ with $SOCl_2$. The compound $MeNH(CH_2)_3Cl$ is a particularly irritating nitrogen mustard, and must be treated with due deference. The compound was always handled in a fume cupboard, and was generally used immediately it was prepared. The compound was always isolated as the hydrochloride salt, but even this relatively non-volatile compound was extremely irritant.

The reaction of L with CuX_2 (X = Br or Cl) led to the formation of the green, air-stable 1 : 1 adducts $[CuLX_2]$. The complexes are readily soluble in MeCN, Me_2CO and $MeNO_2$, but only sparingly soluble or insoluble in protic solvents such as EtOH or MeOH. The electronic spectra of the complexes $[CuLCl_2]$ and $[CuLBr_2]$ in MeCN solution exhibit maxima at 709 nm ($\varepsilon = 269$ mol^{-1} dm^3 cm^{-1}) and 707 nm ($\varepsilon = 515$ mol^{-1} dm^3 cm^{-1}), respectively. The spectra in nitromethane and CH_2Cl_2 were not significantly different, strongly suggesting that the solvent is not interacting directly with the metal centre. In addition to the *d–d* bands, charge-transfer absorptions were observed in the 340–450 nm region ($\varepsilon \sim 1000$ mol^{-1} dm^3 cm^{-1}). These observations are in accord with a five-coordinate structure.[8] The absorption around 400 nm has been assigned to a ligand-to-metal charge-transfer.[9] The vibrational spectra of $[CuLCl_2]$ and $[CuLBr_2]$ exhibit strong absorptions at 3211 and 3200 cm^{-1}, respectively, which may be assigned to N—H stretching modes in the complexes. Upon coordination, the C—H stretching modes of the N-methyl groups diminish in intensity.

Both of the complexes $[CuLCl_2]$ and $[CuLBr_2]$ behave as non-conductors in MeCN solution. In an attempt to further probe the solution structure of the complexes, the ESR spectra were measured. Surprisingly, both complexes gave isotropic spectra in MeCN glass at −196°C. The cyclic voltammograms of both complexes showed strong absorption processes associated with halide loss, but no reversible electron-transfer processes. The fast atom bombardment mass spectra of $[CuLCl_2]$ and $[CuLBr_2]$ exhibited fragmentation peaks, but no peaks corresponding to the molecular ions. The bulk of the evidence suggests that the two complexes, $[CuLCl_2]$ and $[CuLBr_2]$, are five-coordinate in both the solid and solution phases.

At room temperature, $[CuLCl_2]$ was found to have $\mu_{eff} = 1.8 \pm 0.1$ BM, whereas $[CuLBr_2]$ was found to have a considerably higher moment, $\mu_{eff} = 2.5 \pm 0.1$ BM. Typical values for five-coordinate copper(II) complexes are in the region 1.75–1.90 BM. The magnetic moment of $[CuLBr_2]$ is unusually high, but was shown to be a consistent value obtained from various samples. On the basis of the magnetic measurements, we considered that the two complexes might have different structures in the solid state, and we accordingly determined the crystal and molecular structures of the two complexes.

The crystal and molecular structure of $[CuLCl_2]$ is shown in Fig. 1. The dibromo compound is isomorphous and isostructural, the only difference in geometry being in the scale of the disorder, which is considerably greater in $[CuLBr_2]$. In both complexes, the copper is in a five-coordinate N_2SX_2 environment. In $[CuLCl_2]$ the geometry is close to trigonal prismatic, with the SCl_2 groups occupying the equatorial sites of the trigonal bipyramid [Cu—Cl(2), 2.374(3); Cu—Cl(3), 2.312(3); Cu—S(9), 2.493(3) Å] and the nitrogen atoms occupy the axial sites [Cu—N(5), 2.010(8); Cu—N(13), 1.985(8) Å; N(5)—Cu—N(13), 176.3(3)°]. The pattern of dimensions is similar in $CuLBr_2$ [Cu—Br(3), 2.461(4); Cu—Br(2), 2.541(4); Cu—S(9), 2.478(10); Cu—N(5), 2.038(23); Cu—N(13), 2.031(22) Å]. The reason for the disparity in the Cu—Cl (and Cu—Br) bond distances

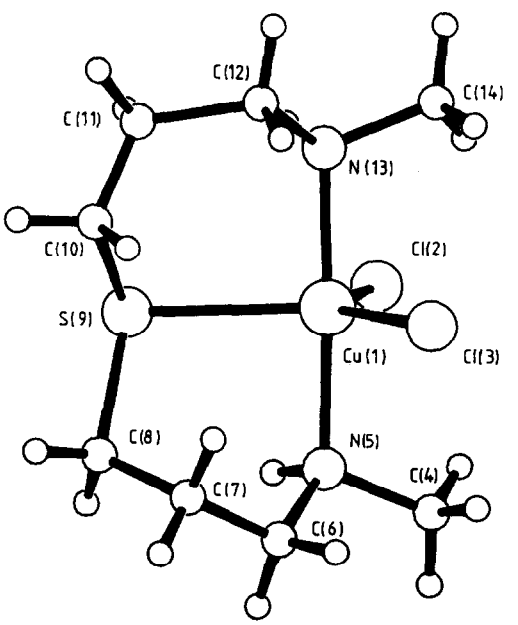

Fig. 1. The crystal and molecular structure of the $[CuLCl_2]$ complex showing the numbering scheme adopted. The $[CuLBr_2]$ complex is isostructural.

is not clear (particularly as both atoms are coplanar in the equatorial plane within experimental error). However, it is noticeable that the sulphur atom, S(9), is much closer to Cl(2) than Cl(3), the two S—Cu—Cl angles being 103.6(1) and 124.1(1)°, respectively. This disparity is presumably due to the asymmetric conformation of the ligand in [$CuLCl_2$]; the values in [$CuLBr_2$] are comparable.

The conformation of the ligand in the complexes [$CuLCl_2$] and [$CuLBr_2$] is significantly different from that in [PdLBr]Br.[1] In [PdLBr]Br, the cation has crystallographic mirror symmetry with torsion angles around the ring very different from those observed in [$CuLCl_2$] and [$CuLBr_2$]. In [$CuLCl_2$] and [$CuLBr_2$], one half of the ligand [from S(9) to N(13)] has similar torsion angles to those observed in [PdLBr]Br, but the other half [from S(9) to N(5)] is different, and judging from the torsion angles, considerably more strained. Torsion angles for [$CuLCl_2$], [$CuLBr_2$] and [PdLBr]Br are presented in Table 2. It is interesting to note that the Pd—S bond length of 2.285(4) Å is considerably shorter than the Cu—S distances, although the Cu—N and Pd—N distances are comparable. The disparity in the Cu—S distances in [$CuLBr_2$] is no doubt due to disorder. This finding strongly suggests that the smaller difference in these distances found in [$CuLCl_2$] is also due to a similar but smaller effect.

The packing of the molecules in the lattice is dictated by hydrogen bonding of the type N—H···Cl [N(5)—H···Cl(3) (symmetry element, $-x$, y, $+z$) and N(13)—H···Cl(2) (symmetry element, $-x$, $1-y$, $1-z$)]. Dimensions for N···Cl, H···Cl and ∠N—H···Cl are 3.29 Å, 2.52 Å, 138°, and 3.35 Å, 2.63 Å and 133°, respectively. Similar interactions are observed in [$CuLBr_2$], where the corresponding dimensions N···Br, H···Br and ∠N—H···Br are 3.48 Å, 2.65 Å, 146°, and 3.44 Å, 2.65 Å and 141°, respectively.

Although five-coordinate copper(II) is relatively common, only a single example of a [CuN_2SX_2] complex has been structurally characterized.[10] In the macrocyclic complex [Cu(9-ane-N_2S)Br_2] the copper is in a square-pyramidal environment, with the sulphur in the axial site. The Cu—S, Cu—N and Cu—Br distances in this complex are all significantly longer than those observed in the complexes described above.

Acknowledgements—We thank the SERC for providing funds for the diffractometer and support (P.J.S.). Also we thank ICI for support (P.J.S.) and Mr A. W. Johans for his help with the crystallographic investigation.

ORGANOTIN(IV) COMPLEXES WITH TRIDENTATE LIGANDS—I. DIMETHYLTIN(IV) COMPLEXES WITH N-SALICYLIDENE DERIVATIVES OF AROYLHYDRAZINES, S-METHYLHYDRAZINECARBODITHIOATE AND 4-SUBSTITUTED THIOSEMICARBAZIDES

M. F. ISKANDER,* L. LABIB, M. M. Z. NOUR EL-DIN and M. TAWFIK

(*Received* 16 *May* 1989; *accepted* 26 *June* 1989)

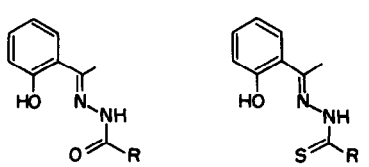
Abstract—Dimethyltin(IV) complexes with N-salicylidene derivatives of aroylhydrazines, S-methylhydrazinecarbodithioate and 4-substituted thiosemicarbazides have been prepared and their IR, NMR (^1H, ^{13}C) and mass spectra have been studied. A slightly distorted five-coordinate trigonal bipyramidal structure is proposed for these complexes. The two methyl carbons and the azomethine nitrogen occupy the trigonal plane, while the highly polar O—Sn—O and O—Sn—S are axial. The chemical shifts (δ) of the Sn—CH_3 carbon and the corresponding $^1J_{Sn-C}$ values show a dependence on the nature of the donor atoms in the axial position.

N-salicylidene aroylhydrazines and their copper(II) complexes are potent inhibitors for DNA synthesis and cell growth in a number of human and rodent cell-line grown cultures.[1] The cytotoxic action of some transition metal complexes of bidentate and tridentate Schiff bases derived from S-methylhydrazinecarbodithioate have also been reported.[2] In addition, there has been considerable interest in the antitumour activity of organotin(IV) complexes.[3–7] A number of organotin(IV) complexes with O-, S- and N-containing ligands have also been tested *in vivo* in p-388 leukaemic mice,[7] but the structural factors which affect the antitumour activity and cytotoxicity of organotin(IV) complexes are still uncertain.[7]

We considered that a systematic study of the coordination chemistry of organotin(IV) complexes with biologically or pharmacologically active ONO, NNS and ONS tridentate ligands might provide further information concerning the structural characteristics required for their antitumour and cytotoxic activity. In the present paper, the synthesis and structure of a series of dimethyltin(IV) complexes with N-salicylidene derivatives of aroylhydrazines (**1**) (R = C_6H_5, *p*-ClC_6H_4, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$), S-methylhydrazinecarbodithioate (**2**) (R = SCH_3) and four-substituted thiosemicarbazides (**2**) [R = $C_5H_{10}N$ (piperidyl) and C_4H_8NO (morpholyl)] are discussed.

RESULTS AND DISCUSSION

In methanol, the reactions of both **1** (R = C_6H_5, *p*-$CH_3OC_6H_4$, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4) and **2** (R = SCH_3, $C_5H_{10}N$, C_8H_8NO) with $(CH_3)_2SnCl_2$



1 **2**

in the presence of 2 equivalents of sodium methoxide, respectively, afford complexes of the general formulae $(CH_3)_2SnL$ and $(CH_3)_2SnL'$, where L and L′ refer to the dinegative anions of **1** and **2**, respectively. The dimethyltin(IV) complexes isolated, together with their elemental analyses, are listed in Table 1.

The IR spectra of $(CH_3)_2SnL$ complexes lack absorptions due to ν(OH), ν(NH) and ν(C=O)

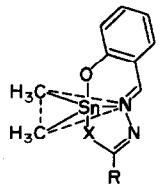
(amide I band) which are present in the spectra of uncoordinated aroylhydrazones.[8] The spectra, however, show a strong band at *ca* 1600 cm^{-1} due to ν(C=N—N=C), as well as two bands at *ca* 1520 and 1285 cm^{-1} attributed to C—O stretching and bending vibrations, respectively.[9] The spectra suggest that the aroylhydrazone moiety in $(CH_3)_2SnL$ complexes acts as a dinegative ONO tridentate ligand which is coordinated to the central tin(IV) via a phenolic oxygen, an azomethine nitrogen and an enolic oxygen. A similar coordination mode has been reported for many transition and non-transition metal complexes with N-salicylidene aroylhydrazines.[8–12] Furthermore, the IR spectra of **3**



3

(R = SCH_3, $C_5H_{10}N$, C_4H_8NO) show a broad band centred at 3350 cm^{-1} in addition to a strong band at *ca* 3200 cm^{-1} due to ν(OH) and ν(NH), respectively, which do not appear in the spectra of the corresponding $(CH_3)_2SnL'$ complexes. The doublet at *ca* 1600 cm^{-1} in the spectra of **2** (R = SCH_3, $C_5H_{10}N$, C_4H_8NO), which can be attributed to ν(C=N)+ν(C=C), undergoes a pronounced shift to lower frequencies ($\Delta\nu$ = 20 cm^{-1}) in the spectra of the corresponding $(CH_3)_2SnL'$ complexes. Complex formation also results in the disappearance of the band at *ca* 1100 cm^{-1} due to ρ(H—N)+ν(C=S), which was originally present in the spectra of **2** (R = SCH_3, $C_5H_{10}N$, C_4H_8NO). Here again, the IR spectral data suggest the tridentate nature of **2** in $(CH_3)_2SnL'$ where tin(IV) is coordinated to the deprotonated phenolic oxygen, the azomethine nitrogen and the thiol sulphur.[13,14] The IR spectra of both $(CH_3)_2SnL$ and $(CH_3)_2SnL'$ show new bands at *ca* 500±10 and 435±5 cm^{-1}, which are absent in the spectra of the uncoordinated hydrazones, which can be assigned to ν(Sn—O)[15] and ν(Sn—N),[16] respectively. The two new bands at *ca* 520±10 and 560±10 cm^{-1} appear in the spectra of both $(CH_3)_2SnL$ and $(CH_3)_2SnL'$ complexes, respectively, due to ν_{sym}(Sn—C) and ν_{asym}(Sn—C) vibration modes, suggesting that the C—Sn—C moiety is non-linear.[15,17,18]

Due to the extended conjugation, the dinegative tridentate anions of **1** and **2** impose a rigid planar configuration around the tin(IV) and a slightly distorted trigonal bipyramidal structure, **3**, can be proposed for both $(CH_3)_2SnL$ and $(CH_3)_2SnL'$ complexes. The two methyl carbons and the azomethine nitrogen occupy the trigonal plane, while the highly polar O—Sn—O or O—Sn—S groups are in axial positions.[15]

The ^1H NMR spectra of both $(CH_3)_2SnL$ and $(CH_3)_2SnL'$ complexes, Table 2, display the Sn—CH_3 protons as one sharp singlet within the ranges 0.82–0.84 and 0.82–0.90 ppm, respectively. The observed $^2J(^{119}Sn—CH_3)$, $^2J(^{117}Sn—CH_3)$ and $^3J(^{119}Sn—N=CH)$ values are within the ranges reported for other trigonal bipyramidal $(CH_3)_2Sn^{IV}$ chelate complexes with two methyl groups in the *cis*-configuration.[15,19,20] The data given in Table 2 show that both the $^2J(^{119}Sn—CH_3)$ and $^3J(^{119}Sn—N=CH)$ values depend on the nature of the donor atoms in the axial position. The ^2J values recorded for the $(CH_3)_2SnL$ complexes with ONO tridentate hydrazones (**3**, X = O) are higher than those of the $(CH_3)_2SnL'$ complexes with ONS ligands (**3**, X = S). This can be attributed to higher *s*-character of the tin orbital in the Sn—CH_3 bond. It is also observed from the ^{13}C NMR spectral data given in Table 3, that the chemical shifts (δ) of the Sn—CH_3 carbon, as well as the values of $^1J(^{119}Sn—^{13}C)$ and $^1J(^{117}Sn—^{13}C)$, show a dependence on the nature of the donor atoms in the

axial positions. The δ (Sn—CH_3) carbon of the $(CH_3)_2SnL$ complexes appears at *ca* 1.3 ppm, while that of the $(CH_3)_2SnL'$ series is shifted downfield and appears within the range 5.2–6.0 ppm. The observed dependence of the chemical shift of the (Sn—CH_3) carbon on the nature of the donor atoms in the axial positions can be related to the relative polarity of the Sn—CH_3 bonds in the equatorial plane. The polarity of such Sn—C bonds depends on the amount of residual positive charge located on the tin, as well as on the *s*-character of the tin orbitals in this bond.

In ^{119}Sn NMR studies on organotin(IV) chelate complexes, Otera[21] found that the $\delta(^{119}Sn)$ values reflect the nature of the donor atoms, and the coordination of tin(IV) to sulphur gives rise to increased shielding on tin relative to oxygen as the donor atom. It was deduced from these observations that sulphur is a more favourable donor towards tin than oxygen. Accordingly, more residual positive charge is localized on the central tin(IV) atom of the $(CH_3)_2SnL$ (3, X = O) complexes with two oxygens in the axial positions, as compared to that of the $(CH_3)_2SnL'$ (3, X = S) with sulphur and oxygen atoms. Consequently, more shielding is expected on the Sn—CH_3 carbon of the $(CH_3)_2SnL$ complexes. This is also in agreement with the high $^1J(^{119}Sn—^{13}C)$ values (647 ± 2 Hz) observed for $(CH_3)_2SnL$ complexes relative to the 597 ± 2 Hz values measured for the $(CH_3)_2SnL'$ series. Furthermore, the measured values of $^1J(^{119}Sn—^{13}C)$ and $^2J(^{119}Sn—^{13}C)$ for both $(CH_3)_2SnL$ and $(CH_3)_2SnL'$ complexes (Table 3) are within the range reported for five-coordinate diorganotin(IV) chelate complexes.[22,23]

The EI mass spectra of the $(CH_3)_2SnL$ and $(CH_3)_2SnL'$ complexes display prominent peaks corresponding to the mononuclear parent molecular ion ($P^{+\cdot}$). Fragments containing tin are easily recognized by their characteristic tin isotope pattern. The m/z values (based on ^{120}Sn) of these fragments, together with their relative intensities, are listed in Table 4. The mass spectra of these complexes may be discussed in terms of the valence change concept[24,25] for rationalizing the major fragmentation pathways. The mass spectral fragmentation of these complexes is shown in Scheme 1, where only fragments containing tin are given.

Fragmentation of these complexes starts with simple cleavage of an Sn—CH_3 bond with loss of a CH_3 radical from $P^{+\cdot}$, giving the even electron four-coordinate tin(IV) ion which changes to the odd electron ion (**II**) by a decrease of the oxidation state of tin from tin(IV) to tin(III). Organotin(III) rad-

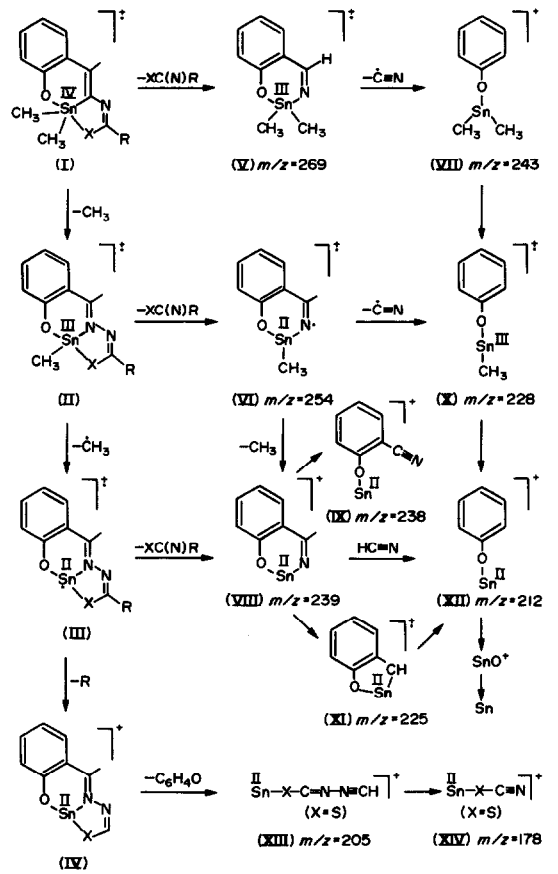

Scheme 1.

icals have been detected both in solution and the solid state by ESR spectroscopy.[26] Further elimination of a CH_3 radical from **II** similarly gives the odd electron tri-coordinate tin(II) ion (**III**).

The spectra are dominated by the elimination of XC(N)R radicals from both **II** and **III** giving, respectively, **VI** and **VIII**. Similar to other Schiff base complexes,[27] the expulsion of the CN radical from **VI** and **VII** gives **IX** and **X**, respectively. The spectra also show a peak at $m/z = 225$ (**XII**) resulting from the elimination of nitrogen from **VII**. It is worthwhile noting that the changes in the formal oxidation state of tin assumed for fragments **II**, **III**, **V** and **VI** allows further elimination of simple radical(s) from these fragments, since elimination of radicals from an even electron ion is quite unlikely.

The spectra of $(CH_3)_2SnL'$ (**3**, X = S) complexes show peaks at $m/z = 297$, 269, 242, 205 and 178 which are not present in the spectra of $(CH_3)_2SnL$ (**3**, X = O) complexes. The peak at $m/z = 297$ (**IV**) results from the expulsion of an R radical (R = SCH_3, $C_5H_{10}N$ or C_4H_8NO) from **III**. The presence of the peak at $m/z = 205$ (**XIII**) indicates the extra stability of the Sn—S relative to the Sn—O bond in **IV**. Furthermore, the peaks at $m/z = 269$ (**V**) and 242 (**VIII**) originate from the molecular ion **I** (X = S) by successive elimination of SC(N)R and C≡N radicals, respectively.

EXPERIMENTAL

Methanol (Merck) was distilled over magnesium metal just before use. Dimethyltin(IV) dichloride was prepared and crystallized (m.p. 107°C, literature value 108°C) as previously described.[27] The N-salicylidene derivatives of aroylhydrazines **1** (R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$, *p*-ClC_6H_4),[8–11] S-methylhydrazinecarbodithioate **2** (R = SCH_3)[13,14] and N-substituted thiosemicarbazide **2** (R = $C_5H_{10}N$, C_4H_8NO) were prepared, as previously described, by the condensation of distilled salicylaldehyde (Prolabo) with the corresponding hydrazine derivative in ethanol. The isolated hydrazones were crystallized from methanol and their purity was checked by melting point, TLC and IR spectra.

Elemental analyses (C, H and N) were carried out at the microanalytical laboratory of the Chemistry Department, Philipps Universität, Marburg (F.R.G.). The IR spectra were recorded on Perkin–Elmer 225 and or 457 spectrophotometers. The calibration of frequency readings was made with a polystyrene film and solid samples were examined as KBr discs. ^{1}H NMR spectra were measured using a Brucker WH 400 instrument using tetramethylsilane as the internal standard. ^{13}C NMR spectra were recorded on either Brucker WH 400 or Varian XL 100 spectrometers. The mass spectra were obtained using a Varian MAT 711 double focussing spectrometer equipped with a direct inlet system and operating at 70 eV electron beam energy. All the spectra were recorded at the lowest possible temperatures.

Preparation of dimethyltin(IV) *complexes* (**3**, X = O; R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$, *p*-ClC_6H_4. X = S; R = SCH_3, $C_5H_{10}N$, C_4H_8NO)

To a suspension of the appropriate N-salicylidene derivative (0.01 mol) in dry methanol (20 cm^3), a solution of sodium methoxide (0.02 mol) in dry methanol (10 cm^3) was added. The resulting solution was treated with a solution of $(CH_3)_2SnCl_2$ (0.01 mol) in dry methanol (20 cm^3) and was refluxed with constant stirring for 2 h. The solvent was then removed under reduced pressure and the residue was recrystallized from *n*-hexane or benzene–petroleum ether (40–60°C).

Acknowledgements—M.F.I. and L.L. thank Professor Dr J. Lorberth, Philipps Universität, Marburg (F.R.G.) for

a gift of dimethyltin dichloride, and the staff of the NMR and Mass Spectrometry Laboratories of Philipps Universität for recording the spectra.

(*Received* 5 *March* 1989; *accepted* 18 *July* 1989)

Abstract—The reaction between vanadocene and dithioacetic acid gave the novel product $[(\eta^5\text{-}C_5H_5)_4V_4(\mu_3\text{-}S)_4]$. The single-crystal X-ray structure of this low-valent vanadium cluster has been determined. The crystallographic data are: monoclinic space group $C2/c$, $a = 17.764(5)$, $b = 8.119(2)$, $c = 16.158(2)$ Å, $\beta = 116.65(2)°$, $V = 2083(2)$ Å^3, $Z = 4$. Refinement, using a data-to-parameter ratio of 12.0, converged with an unweighted discrepancy index of 4.99%. The molecule is located on a crystallographic two-fold rotation axis and consists of a central tetrahedron of vanadium atoms, each face of which is capped by a sulphur atom with vanadium–sulphur distances of 2.296(1) Å. There is a cyclopentadienyl ring coordinated to each vanadium atom with vanadium–carbon distances ranging from 2.281(9) to 2.319(7) Å. The vanadium–vanadium distance in $[V_4(\mu_3\text{-}S)_4(\eta^5\text{-}C_5H_5)_4]$ is 2.876(11) Å and corresponds to a metal–metal bond order of 2/3. The cluster is paramagnetic; $\mu_{eff} = 2.65\ \mu_B$.

Since the recognition by Cotton in the mid-1960s that metal atoms form direct bonds, the chemistry of transition metal compounds possessing metal–metal bonds has grown at an enormous rate.[1] Dinuclear complexes of early transition metals containing four carboxylato ligands of the type $[M_2(\mu\text{-}O_2CR)_4L_2]$ (M = Cr, Mo, W; R = alkyl or aryl groups; L = δ-donor ligands, e.g. H_2O, THF, etc.),[2] as well as dithio congeners such as $Mo_2(\mu\text{-}S_2CR)_4L_2$ (R = CH_3 or Ph; L = THF),[3] play a very important role in this development because such compounds have quadruple metal-to-metal bonds and serve as excellent starting materials for further preparative work. Several methods for synthesizing these tetracarboxylates have been developed including reactions of chromocene with various organic acids in which both cyclopentadienyl rings of the metallocene are displaced by the carboxylato ligands.[4,5] With regard to the group 5 (V) metals, however, such simple inorganic carboxylates are not reported, although the π-complexes $(\eta^5\text{-}C_5H_5)_2V$ and $(\eta^5\text{-}C_5Me_5)_2V$ readily react with benzoic acid to give $(\eta^5\text{-}C_5R_5)V(\mu\text{-}O_2CPh)_4V(\eta^5\text{-}C_5R_5)$, where R = H and Me, respectively.[6] The vanadium–vanadium distances of 3.636(1) Å for the cyclopentadienyl compound and 3.652(2) Å for the pentamethylcyclopentadienyl derivative suggest that little, if any, direct bonding exists between the two vanadium atoms.

In the course of our studies utilizing vanadocene and strong organic acidic ligands such as dithiocarboxylic acids—in the hope of removing both cyclopentadienyl groups—we discovered a new reaction between vanadocene and dithioacetic acid which leads to a V_4 compound possessing metal–metal bonds:

$$(\eta^5\text{-}C_5H_5)_2V + CH_3CSSH \rightarrow [(\eta^5\text{-}C_5H_5)_4V_4(\mu_3\text{-}S)_4].$$

In the present report we describe the new method of synthesis and characterization of the paramagnetic cluster $[(C_5H_5)_4V_4S_4]$. The results of a single-crystal X-ray diffraction study of $[(C_5H_5)_4V_4S_4]$ are also described.

EXPERIMENTAL

All operations of moisture- and air-sensitive materials were performed under an inert atmosphere employing standard Schlenk techniques and a double manifold vacuum-line. Solids were

* Author to whom correspondence should be addressed.

manipulated in a Vacuum Atmospheres Co. glove-box equipped with a HE-493 dri-train. Solvents were freshly distilled from benzophenone ketyl prior to use. Solutions were transferred via stainless steel cannulae and/or syringes. Vanadocene and dithioacetic acid were prepared according to literature methods.[7,8] Elemental analyses were performed by Galbraith Microanalytical Laboratories. The IR spectrum was measured on a Perkin–Elmer 599B spectrophotometer. The magnetic susceptibility was determined at room temperature on a MSB1 Johnson Matthey magnetic susceptibility balance. Corrections for diamagnetism were made with Pascal's constants.[9]

Preparation of $[cp_4V_4S_4]$

In a dry-box, a 250-cm^3 round-bottomed flask was charged with freshly sublimed vanadocene (0.6 g, 3.3 mmol). Under an inert atmosphere, the flask was connected to a double manifold vacuum-line through a U-shaped adapter with a septum. The starting material was dissolved in 100 cm^3 of THF–toluene mixture (v/v 75:25) and redistilled dithioacetic acid was added via syringe (0.5 cm^3, 6.7 mmol). The reaction mixture was stirred for 4 days, during which time the colour changed gradually from purple to brown. The volume was reduced in vacuum to about 15 cm^3 and the dark brown cluster was precipitated with 50 cm^3 of hexane. Recrystallization from toluene–hexane gave 0.231 g (47%) of $[(C_5H_5)_4V_4S_4]$. Single crystals with habits of rectangular blocks, suitable for X-ray diffraction studies, were grown by slow interdiffusion of hexane into a toluene solution of $[cpVS]_4$ in a Schlenk tube. Found: C, 38.72; H, 3.93. Calc. for $C_{20}H_{20}S_4V_4$: C, 40.55; H, 3.40%. IR (KBr, cm^{-1}): 3035(w), 1410(m), 1345(w), 1240(m), 1055(s, br), 995(s), 885(w), 825(sh), 785(s), 655(w), 540(w), 450(w, br), 405(w), 390(w), 375(w). Magnetic moment: $\chi_M = 2.92 \times 10^{-3}$ emu mol^{-1} at 298 K; $\mu_{eff} = 2.65\ \mu_B$.

X-ray crystallography

Single-crystal X-ray diffraction analyses were carried out by application of general procedures which were previously described.[10] The crystallographic parameters and basic information about data collection and structure refinement are summarized in Table 1. The data were corrected for Lorentz, polarization, crystal decay (17%) and absorption effects.

Systematic absences in the intensity data were indicative of the space groups *Cc* or *C2/c*. The structure was solved on the basis of a 3-D Patterson function, on the assumption of the space group being *C2/c*. All subsequent difference maps and least-square refinements revealed the rest of the cluster and justified the choice of this space group. All 14 atoms were refined anisotropically. The final difference Fourier map contained some residual electron density below 1 e/Å^3 in the immediate vicinity of the vanadium atoms; the largest peak was 0.75 e/Å^3.

Data collection and crystallographic calculations were carried out on a PDP-11/60 computer (at Cleveland State University), with software from the Enraf–Nonius SDP-PLUS package.

Tables of positional and isotropic equivalent displacement parameters, anisotropic displacement parameters, *B*'s, observed and calculated structure factors, as well as full lists of bond distances and angles for $[(C_5H_5)_4V_4S_4]$ have been deposited as supplementary material with the Editor.

RESULTS AND DISCUSSION

Synthesis

The reaction between vanadocene, $(C_5H_5)_2V$, and dithioacetic acid, CH_3CSSH, in THF and toluene at room temperature for 4 days affords a brown–black product proved by X-ray studies to contain $[(C_5H_5)_4V_4S_4]$ molecules. Additional support for the assigned formula is provided by elemental analyses, the IR spectrum and magnetic susceptibility data.

Our synthetic and X-ray studies contain several points of interest. The reaction shows a new pattern of reactivity for vanadocene. It represents a simple and direct route to a thio-capped tetranuclear vanadium(III) cluster which possesses short vanadium–vanadium distances (*vide infra*). Under mild conditions, desulphurization (or partial desulphurization) of the dithioacetic acid occurs. The parent unsubstituted cluster, $[(C_5H_5)_4V_4S_4]$, is crystallographically characterized for the first time.

Interestingly enough, cubane clusters of the type which we are describing in this report have been intensively studied for some time. This is perhaps because cubane cluster units are important in living systems and solid-state polymers.[11,12] Much attention was devoted to cubane compounds containing a larger number of electrons, for instance, $[(\eta^5\text{-}C_5H_5)_4Co_4(\mu_3\text{-}S)_4]$.[13] This cluster contains 72 electrons, and it possesses long non-bonding metal–metal distances (average value 3.298(2) Å). However, only recently, were electron-deficient cubane clusters, namely $[(MeC_5H_4)_4M_4S_4]$ where M = Ti[14] or V[14–16] and $[(C_5H_5)_4V_4S_4]$,[14,17] synthesized and their X-ray structures (for MeC_5H_4

^{a} $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$.
^{b} $R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(|F_o|)$.
^{c} Quality-of-fit $= [\Sigma w(|F_o|-|F_c|)^2/(N_{obs}-N_{parameters})]^{1/2}$.

derivatives) and bonding studied.[14] Two methods for the preparation of the vanadium compounds were reported. The Rauchfuss' group prepared $[(MeC_5H_4)_4V_4S_4]$ (45% yield) and $[(C_5H_5)_4V_4S_4]$ (27% yield) by desulphurization of $[(Mecp)_2V_2S_4]$ and $[cp_2V_2S_4]$, respectively, with PBu_3. The Russian workers obtained these cubanes by reacting $(Mecp)_2V$ or cp_2V with *t*-BuSH. The yield of 60% is reported only for the methyl derivative.

In this context, the synthetic reaction reported here, which involves cp_2V and CH_3CSSH, represents a new route to the $[(C_5H_5)_4V_4S_4]$ cluster in yields of *ca* 47%.

Molecular structure

The crystal structure of $[(\eta^5\text{-}C_5H_5)V_4(\mu_3\text{-}S)_4]$ is composed of discrete tetranuclear molecules. Important interatomic distances and angles are listed in Tables 2 and 3, respectively. Complete lists of distances and angles are included in the supplementary material. An ORTEP drawing of the molecular structure of the $[cp_4V_4S_4]$ cluster is shown in Fig. 1. The tetranuclear molecule is located on a crystallographic two-fold rotation axis and consists of two interpenetrating tetrahedra, V_4 within S_4, and therefore can be viewed as a distorted cube. Additionally, each vanadium atom coordinates to a cyclopentadienyl ligand. The averaged* values of important interatomic distances (in Å) are as follows: V—V, 2.876(11); V—S, 2.296(1); V(1)—Ccp, 2.293(3); V(2)—Ccp, 2.301(6); S—S, 3.548(13). The averaged values of V—S—V and S—V—S angles (in deg.) are 77.6(3) and 101.1(5), respectively. Additonally, the averaged values of V—V—V and S—S—S angles (in deg.) are 60.0(3) and 60.0(3), respectively and are nearly equal to the angles of an ideal tetrahedron.

The overall structure of our cluster is very similar to that of the $[(\eta^5\text{-}MeC_5H_4)_4V_4(\mu_3\text{-}S)_4]$ compound

* Chemically equivalent distances were averaged. $[\chi]$ is defined as $[\chi]^2 = \Sigma\Delta_i^2/n(n-1)$ for the deviations, Δ_i of n independent values.

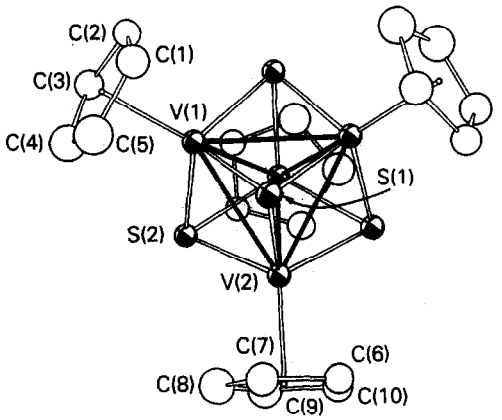

Fig. 1. An ORTEP drawing of the $[cp_4V_4S_4]$ molecule which also defines the labelling scheme. The thermal ellipsoids enclose 30% of electron density.

mentioned above.[14] The methyl derivative crystallizes in the cubic space group $P\bar{4}3n$ with $a = 16.551(3)$ Å. All important interatomic distances and angles for the methyl analogue are almost identical to those of the parent $[(C_5H_5)_4V_4S_4]$ cluster. Thus, the reported selected values of distances (in Å) and angles (in deg.) for the $[(MeC_5H_4)_4V_4S_4]$ cubane are:[14] V—V(av.), 2.873(3); V—S(av.), 2.295(3); V—Ccp(av.), 2.28(1); V—S—V(av.), 77.5(1); S—V—S(av.), 101.1(1).

Metal–metal bonding

The electronic structure of $[(C_5H_5)_4V_4S_4]$ was calculated by the SCF-scattered wave-X_α method to give the ground-state configuration for this cluster's metal bonding orbitals as $a_1^2e^4t_2^2$ (for ideal T_d symmetry).[14]

Because the total number of metal bonding electrons in $[(C_5H_5)_4V_4S_4]$ is eight, we calculate a vanadium–vanadium bond order of 2/3 for this 56-electron cluster. This is in excellent agreement with our crystallographically determined vanadium–vanadium distance of 2.876(11) Å. A very similar distance was found in the $[Nb_3O_2(O_2CMe_3)_6(THF)_3]BPh_4$ cluster, in which the niobium–niobium bond order is 2/3 (the distance: 2.842(3) Å),[18] whereas single and double vanadium–

vanadium bond distances of *ca* 2.61 and 2.41 Å in $(i\text{-PrC}_5H_4)_2V_2S_4$[19] and $V_2(\text{salophen})_2Na_2(THF)_6$,[20] respectively, are, of course, shorter as expected for higher bond orders. The $[(C_5H_5)_4V_4S_4]$ cluster is paramagnetic, and we find its magnetic moment to be equal to 2.65 μ_B at 298 K, which is in accord with literature values for $[(MeC_5H_4)_4V_4S_4]$, viz. 2.68[14] and 2.67 μ_B[15].

Further work is in progress to explore the reactivity of aromatic dithiocarboxylic acids. Additional preliminary data (e.g. elemental analyses) point out that dithiobenzoic acid reacts with vanadocene to give a different compound. More results in this new area will be reported in due course.

COMPLEXES OF PALLADIUM, PLATINUM AND RHODIUM WITH POTENTIALLY TETRADENTATE LIGANDS CONTAINING NITROGEN AND TELLURIUM DONOR ATOMS (N_2Te_2)

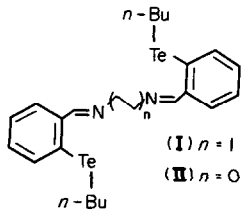
N. I. AL-SALIM and W. R. McWHINNIE*

Department of Chemical Engineering and Applied Chemistry, Aston University, Aston Triangle, Birmingham B4 7ET, U.K.

(*Received* 7 *February* 1989; *accepted* 20 *July* 1989)

Abstract—Complexes of the ligands 1,6-bis-2-butyltellurophenyl-2,5-diazahexa-1,5-diene (**I**) and 1,4-bis-2-butyltellurophenyl-2,3-diazabuta-1,3-diene (**II**) with palladium, platinum, and rhodium are described. [PdCl(**I**)(H_2O)]Cl is an electrolyte and has the chloro-ligand *trans* to water; the implications for the mode of coordination of **I** are discussed. For [$PdCl_2$(**II**)] evidence for both "*cis*" and "*trans*" isomers is obtained; since, as in the above case, no evidence for N-coordination is obtained, the nature of the "*trans*" isomer is debated. [PtCl(**I**)(H_2O)]Cl, an electrolyte, decomposes in polar solvents to give [$PtCl_2$(I^{2-})], where (I^{2-}) donotes ligand **I** which has lost two butyl groups, the complex being a platinum(IV) derivative. Ligand **I** coordinates only via tellurium in the platinum(II) complex, but some evidence of N-coordination to platinum(IV) is obtained. The early stages of the de-alkylation reaction are monitored by ^{125}Te and ^{195}Pt NMR spectroscopy. By contrast, [$PtCl_2$(**II**)]·H_2O is a *cis* complex in which **II** coordinates via tellurium only and does not undergo de-alkylation. Some complexes of both rhodium(III) and rhodium(I) are reported. The most interesting observation being that **I** may function as a terdentate ligand (Te, N, Te) in [RhCl(**I**)].

We have recently published papers describing the syntheses of potentially bidentate Te, Te ligands[1] of the type $RTe(CH_2)_nTeR$, and of ligands containing both tellurium and nitrogen as potential donor atoms, e.g. derivatives of tellurated 2-phenylpyridine[2] and 1,6-bis-2-butyltellurophenyl-2,5-diazahexa-1,5-diene (**I**),[3] together with 1,4-bis-2-butyltellurophenyl-2,3-diazabuta-1,3-diene (**II**).



(**I**) $n = 1$
(**II**) $n = 0$

Some investigations on the coordination chemistry of these materials have been reported. For example, the reactions of (p-EtO·C_6H_4)Te(CH_2)$_n$Te (C_6H_4OEt-p) (n = 5–10) with palladium(II), platinum(II) and mercury(II) have been described.[4] The complexes were poorly crystalline and tended to have a limited range of thermal stability which limited the information obtainable from multinuclear NMR studies. The crystal structure of compound **I** has been reported together with that of the complex with $HgCl_2$[5] in which only the two tellurium atoms coordinated mercury(II).

In this paper we attempt to extend studies of **I** in complexes with palladium, platinum and rhodium. The literature contains a paucity of reports on bi- and multidentate tellurium ligands, although many sulphur systems are known. Of relevance is the report by Bertini *et al.*[6] on Schiff base ligands having donor sets S, N and S_2N_2, including an analogue of **I** in which —SH replaces —TeBu. Blum *et al.*[7] have also produced a related sulphur ligand which forms square-planar complexes with a range

(III)

of divalent metals, e.g. ligand **III**. An interesting feature of the crystal structure of **I**[5] was a weak Te---N interaction. One objective of this paper is to ascertain to what extent this interaction limits the availability of the nitrogen for coordination to the added transition metal salt.

EXPERIMENTAL

The details of the preparations of **I** and **II** appear elsewhere.[3,5]

(a) *Palladium complexes*

With ligand **I**. Bis(benzonitrile)dichloropalladium(II)[8] (0.38 g, 0.001 mol) in acetonitrile (15 cm^3) was added to an acetonitrile (15 cm^3) solution of **I** (0.60 g, 0.001 mol), and the mixture was stirred at room temperature, under dinitrogen, for 2 h. The volume was reduced to 5 cm^3 in a stream of dinitrogen gas and benzene was added to precipitate a brown compound, which was filtered, washed with benzene and diethyl ether and dried *in vacuo*. The yield of the blackish-brown material was 0.67 g, m.p. 131–132°C (dec.).

With ligand **II**. Two methods were used: (i) Bis(benzonitrile)dichloropalladium(II) (0.38 g, 0.001 mol) in a 1:1 benzene–acetonitrile mixture (15 cm^3) was treated with a warm acetonitrile solution (15 cm^3) of **II** (0.58 g, 0.001 mol). The mixture was stirred at 50°C under dinitrogen for 5 h to give a brown precipitate which was collected by filtration and washed several times with benzene. Recrystallization from toluene gave a brownish-red compound, m.p. 183–185°C (dec.).

(ii) A solution of $[Ph_4As][PdCl_4]$ (prepared by metathesis of Ph_4AsCl and K_2PtCl_4) (0.20 g, 0.0002 mol) in dichloromethane (15 cm^3) was added slowly, with stirring, to a solution of **II** (0.115 g, 0.0002 mol) in dichloromethane (10 cm^3). On setting aside for 2 h the solution deposited an orange–brown compound which was separated, washed with dichloromethane and air-dried (yield: 0.136 g); m.p. 185°C (dec.).

(b) *Platinum complexes*

With ligand **I**. Two methods were used: (i) A solution of $[Ph_4As]_2[PtCl_4]$ (1.103 g, 0.001 mol) in dichloromethane (20 cm^3) was added to **I** (0.60 g, 0.001 mol) in dichloromethane (15 cm^3) and refluxed for 1 h, during which time a pale cream suspension formed. The compound was collected by filtration, washed with dichloromethane and air-dried. During the melting point determination the compound darkened at 80°C, became black, but failed to melt under 300°C.

(ii) The same experiment was carried out in refluxing acetonitrile. The cream suspension was visible for the first 15 min, but when reflux was continued beyond that point the product became brownish. After 2 h, a dark brown solution and solid were present, the solid was filtered, washed with acetonitrile and dried *in vacuo*. The material failed to melt under 300°C.

With ligand **II**. A solution of $[Ph_4As]_2[PtCl_4]$ (0.22 g, 0.0002 mol) in dichloromethane (15 cm^3) was added slowly, with stirring, to a solution of **II** (0.115 g, 0.002 mol) in dichloromethane (10 cm^3). The resulting solution was stirred and heated under reflux for 5 h. The orange precipitate so formed was filtered, washed with dichloromethane and air-dried (Yield: 0.10 g); m.p. 170°C (dec.).

(c) *Rhodium complexes*

With ligand **I**. (i) *Thodium*(III): Dipotassium pentachloroaquorhodate(III), $K_2[Rh(H_2O)Cl_5]$ (supplied) (0.38 g, 0.001 mol), in a mixture of methanol (20 cm^3) and DMSO (10 cm^3) was reacted with a warm solution of **I** (0.60 g, 0.001 mol) in methanol (10 cm^3). The mixture was stirred for 2 h under dinitrogen, after which the methanol was removed *in vacuo*; the remaining solution was allowed to evaporate slowly at room temperature. The resulting solid was dissolved in dichloromethane (20 cm^3) and filtered, the filtrate, after evaporation at room temperature, afforded a brown solid, m.p. 122°C.

(ii) *Rhodium*(I): Method A. Di-μ-chloro-bis(η^4-1,5-cyclooctadiene)dirhodium(I)[9] (0.15 g, 0.0003 mol) in dichloromethane (10 cm^3) was added to a solution of **I** (0.36 g, 0.0006 mol) in dichloromethane (15 cm^3). The colour changed immediately to brown. Following reflux (4 h) the colour of the solution became red–brown and some precipitate deposited. Filtration afforded a red–violet solid (product A) which was washed with dichloromethane and air-dried (yield: 0.02 g); m.p. 243°C (dec.). Dry diethyl ether was added to the filtrate to give a brown material which was redissolved in ethanol, filtered and recovered by evaporation at room temperature: product B, yield: 0.26 g, m.p. 185°C (dec.).

Method B. Di-μ-chloro-bis(η^4-1,5-cyclooctadiene)dirhodium(I) (0.15 g, 0.0003 mol) was dis-

solved in dichloromethane (10 cm^3) and added to **I** (0.54 g, 0.0009 mol) in dichloromethane (10 cm^3) at room temperature. The mixture was refrigerated at 4°C for 4 h, after which the solution was filtered to give a red–violet crystalline compound (product A) which was washed with dichloromethane (yield: 0.1 g); m.p. 243°C (dec.). The filtrate was treated with diethyl ether as described above to give a further quantity (0.28 g) of product B, m.p. 186°C (dec.). The elemental analytical data for A and B were independent of the method of preparation.

With ligand **II**. (i) *Rhodium*(III): $K_2[Rh(H_2O)Cl_5]$ (0.19 g, 0.0005 mol) was dissolved in ethanol–DMSO (1 : 1, 20 cm^3) and treated with a solution of **II** (0.29 g, 0.0005 mol) in ethanol (10 cm^3). The mixture was stirred at 80°C under dinitrogen for 2 h, during which time the colour changed from orange to dark brown. The solution was taken to 5 cm^3 *in vacuo* and left to evaporate at room temperature. The resulting solid was dissolved in chloroform, recovered by removal of solvent *in vacuo* and washed with methanol followed by diethyl ether, m.p. 160°C (dec.).

(ii) *Rhodium*(I): Di-μ-chloro-bis(η^4-1,5-cyclooctadiene)dirhodium(I) (0.25 g, 0.0005 mol) in dichloromethane (15 cm^3) was added slowly to a solution of **II** (0.58 g, 0.001 mol) and refluxed for 7 h under dinitrogen. The colour changed from orange to deep brown, the solution was cooled and treated with diethyl ether to give a brown compound which was filtered, washed with diethyl ether and air-dried (yield: 0.51 g); m.p. 220°C (dec.).

Physical measurements

Elemental analyses were carried out by the Analytical Services Unit, Aston University. NMR spectra (^1H, 90 MHz; ^{13}C, 22.5 MHz; ^{125}Te, 28.2 MHz; ^{195}Pt, 21.46 MHz) were obtained with a JEOL FX 90Q spectrometer. Conductivities were measured using a standard Mullard bridge and an immersion-type bright platinum electrode cell (E 7591/B). IR spectra were determined as KBr pellets or Nujol mulls with a Perkin–Elmer 599B instrument (range 4000–200 cm^{-1}). UV–vis spectra were recorded with a Unicam SP8-100 instrument.

DISCUSSION

Table 1 gives the stoichiometries of the complexes. Where the presence of water is involved, IR support for this is available. Although precautions were taken to exclude air from the preparations, no particular precautions were taken for the exclusion of moisture.

Of importance to this work is the complex of mercury(II) chloride and 1,6-bis-2-butyltellurophenyl-2,5-diazahexa-1,5-diene (**I**), the structure of which has been reported.[5] Only the tellurium atoms coordinate mercury, the weak but significant Te---N contact remains almost unaltered in the complex (Te---N, 2.773 Å—free ligand; 2.752, 2.786 Å—complex). Formally, the mercury(II) complex contains a 13-membered chelate ring, but if the Te---N interaction is taken as a bond then

Table 1. Analytical data for new complexes

[e] "Product A".
[f] "Product B".

the mercury(II) ion "sees" a seven-membered ring. The change in the ligand ν(C=N) frequency on complexing mercury(II) is $+5$ cm^{-1}, thus changes of this order are likely to imply that the Te---N interaction in the coordinated ligand remains intact and that the ligand functions as a Te, Te bidentate. It is not unreasonable to apply similar reasoning to ligand **II**. Thus, inspection of Table 2 suggests that only in the cases of complexes **9** and **10** need the question of nitrogen coordination be considered. Complex **5** comes into this category, but is clearly a complex of a derived ligand (*vide infra*).

Palladium(II) *complexes*

[$PdCl_2$(**I**)]·H_2O (compound **1**, Tables 1 and 2) is a 1 : 1 electrolyte in both DMSO and acetonitrile, thus the formulation [Pd(**I**)Cl(H_2O)]Cl is suggested. In the IR spectrum ν(OH) is noted at 3400 cm^{-1} and the position of ν(C=N) (Table 2) implies Te,Te coordination only; ν(PdCl) may be assigned at 345 cm^{-1}. It is known that ν(PdCl) for [PdClL′L_2]$^+$, where L′ = neutral ligand and L = phosphine, is a function of L′ in the *trans* isomer.[10] It is also known that the *trans* influence decreases in the order: C-donors (sp^3 > sp^2 > sp) > P-donors > As-donors > S-donors > N-donors > halide > O-donors; also Te-donors > Se-donors > S-donors.[11] Thus in the present complex the value of 345 cm^{-1} suggests that the chloro-ligand is *trans* to oxygen. We also note that for[12] *trans*-{Pd[Te(CH_2SiMe_3)$_2$]$_2$$Cl_2$}, ν(PdCl) = 348 cm^{-1} and for[13] *trans*-{Pd[Te(C_6H_4·OEt-*p*)$_2$]$_2$$Cl_2$}, ν(PdCl) = 351 cm^{-1}.

The above data suggest that the structure of the complex may be more complex than at first imagined. One model would have the ligand spanning *trans* coordination sites, however, given that the Te---N interaction is retained we feel that the ligand is too inflexible for this to be realistic (the TeĤgTe angle is 109.1°).[5] An alternative model is given in Fig. 1. This type of dimer has been suggested for complexes of RTe(CH_2)$_8$TeR.[4] The conductivities would now be 228 (MeCN) and 70 (DMSO) Ω^{-1} cm^2 mol^{-1}, values not inconsistent with 2 : 1 electrolytes. Geometric isomers are possible but the available data would make differentiation difficult. Unfortunately, limited solubility prevented a comprehensive NMR study.

[$PdCl_2$(**II**)] (compound **2**, Tables 1 and 2) is a non-electrolyte in benzonitrile and is insoluble in more polar solvents. We argue that the position of ν(C=N) suggests that the ligand is bidentate (Te,Te), in which case the metal "sees" a five-membered chelate ring if the Te---N interactions remain intact. Two ν(PdCl) frequencies are seen at 332 and 288 cm^{-1} suggestive of a *cis* complex, although the ν_{as}(PdCl) frequency at 332 cm^{-1} is rather higher than the range normally associated with this mode (305–312 cm^{-1}), however, ν_s(PdCl) is usually assigned between 285–292 cm^{-1}.[14,15] Attempts to recrystallize this complex from chloroform led to the recovery of material having the same

Table 2. Physical data for new complexes

Complex[a]	ν(C=N) (cm^{-1})	$\Delta\nu$(C=N)	ν(M—Cl) (cm^{-1})	UV–vis spectra maxima (nm)	Λ_M (Ω^{-1} cm^2 mol^{-1})

[a] See Table 1.

[b] Compound **2** after digestion in $CHCl_3$.

Note: the complex [$HgCl_2$(**I**)][5] gives ν(C=N) at 1642 cm^{-1}, i.e. $\Delta\nu$(C=N) = +5 cm^{-1}.

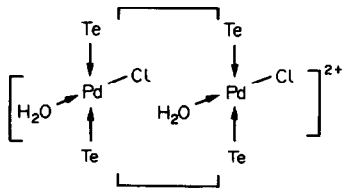

Fig. 1.

elemental analysis but with a new ν(PdCl) frequency at 345 cm^{-1}, in addition to those already noted. This appears to indicate the presence of a "*trans*" isomer which, for reasons given above, would have to be modelled on Fig. 1. Thus the available data suggest that either of the two equilibria (A) or (B) (see Scheme 1) could provide an explanation of the observations.

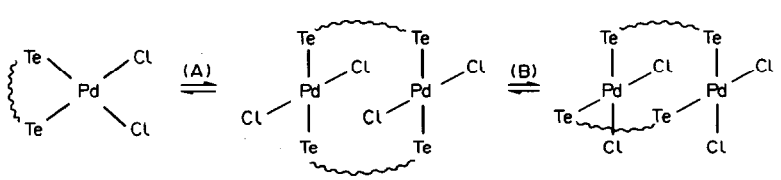
The UV–vis spectra (Table 2) of **1** and **2** are consistent with square-planar palladium; for example bands around 420 nm have been reported for other ditellurium complexes.[4]

Platinum complexes

Compounds **4** and **6** (Tables 1 and 2) have the stoichiometry $[PtCl_2(L)]\cdot(H_2O)$ (L = **I** or **II**). In neither case does the shift in ν(C=N) from the free ligand value seem large enough to invoke nitrogen coordination. Compound **4** has a Λ_M value consistent with that for a 1:1 electrolyte (but see below). The single ν(PtCl) frequency at 315 cm^{-1} suggests that the chloro-ligand is *trans* to groups with moderate *trans* influence;[11] of particular interest is a comparison with the complex $[Pt(bmsp)Cl]PF_6$,[16] where bmsp = $(MeSeCH_2CH_2)_2Se$, which has ν(PtCl) at 320 cm^{-1}. Thus the probability is that chlorine is *trans* to tellurium rather than to H_2O.

The ^{125}Te NMR of complex **4** was measured in DMSO, but not without gentle heating to obtain a clear solution of the appropriate concentration. It was noted that the colour of the solution had become slightly brown during the dissolution process. The observed spectrum (Fig. 2) shows two resonances centred at δ 469.5 and 512.2 ppm downfield from dimethyltelluride. Both resonances have associated satellites arising from spin–spin coupling to ^{195}Pt (δ 469.5 ppm J(PtTe) = 1014 Hz; δ 512.2 ppm J(PtTe) = 1035 Hz), thus demonstrating that both signals originate from tellurium bound to platinum. The observed coupling constants support the IR implication of *cis*-tellurium atoms, since for *trans*-TePtTe, J(PtTe) is generally of the order of 600 Hz.[4,15] Further, the ^{125}Te chemical shift of the resonance at 512.2 ppm also supports a *cis* configuration since $\Delta(\delta)$ (the coordination shift) for *trans* complexes is generally greater than the 47.8 ppm observed here.[4,15] The second tellurium resonance is, however, at 469.5 ppm, close to the free ligand value of 464.4 ppm, but it cannot arise from uncoordinated tellurium since J(PtTe) is clearly seen. No evidence for the coupling of inequivalent tellurium atoms is seen (however, J(TeTe) may be small or apparently zero due to multiple transmission paths), also the resonances are of unequal intensity; we believe this to imply that the resonances arise from different solution species. *Cis–trans* isomers are eliminated by the similar values of J(PtTe). A common phenomenon in group 16 ligand chemistry is the observation of *meso* and DL isomers which may arise due to inversion at the coordinated S, Se, or Te ligand atoms of the bidentate ligands.[16,17] It is anticipated that the barrier to inversion at tellurium will be greater than for selenium and sulphur,[18] thus distinct signals from the *meso* and DL invertomers may well be seen at ambient temperature. Although it had been suggested previously that chemical shift differences between *meso* and DL invertomers may be small,[4] a recent paper[19] demonstrates, for platinum(II) complexes of $[RTeCH_2CH_2CH_2CH_2TeR]$ (R = Me, Ph), that chemical shift differences of 63 ppm {for $[Pt(MeTe(CH_2)_3TeMe)Cl_2]$} and 26 ppm {for $[Pt(PhTe(CH_2)_3TePh)Cl_2]$} are possible for the invertomers; however both invertomers show large *coordination* shifts.[19] Thus we believe that the species observed may not be accounted for in terms of invertomers.

The reaction of $[Ph_4As]_2[PtCl_4]$ with **I** in refluxing acetonitrile gives complex **5** (Table 1), which analyses as a complex of de-butylated **I**. IR data



Scheme 1.

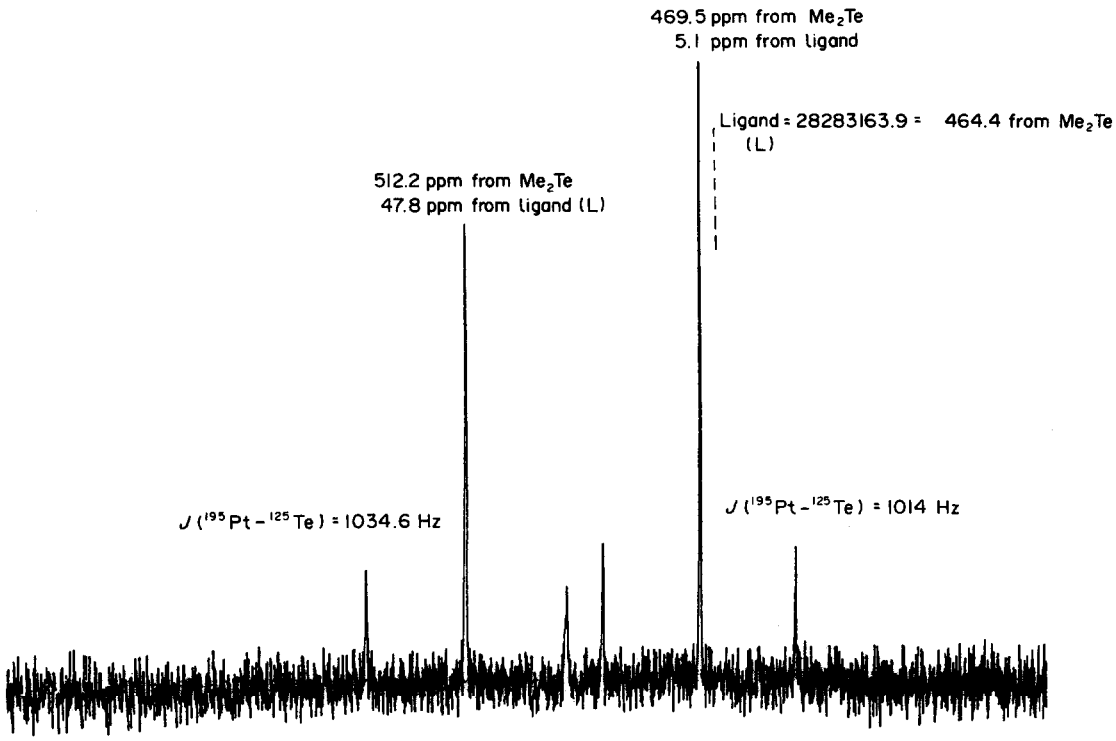


Fig. 2.

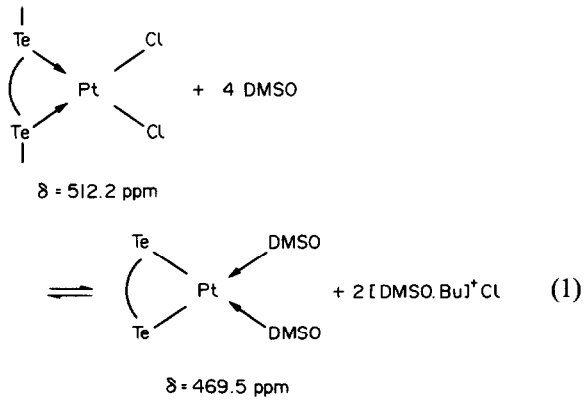
support the postulate of de-butylation and complex **5** is therefore, by implication, a complex of platinum(IV) (see Fig. 3).

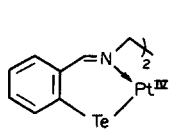
The shift of ν(C=N) for de-butylated **I** is also greater than for other palladium and platinum complexes in Table 1, and this must raise the possibility of $Pt^{IV} \leftarrow N$ coordination in complex **5**. The final formation of complex **5** does then raise the possibility that the species giving a chemical shift of δ 469.5 ppm in the ^{125}Te NMR spectrum is a complex of de-butylated **I**. It is improbable that the species seen is a complex of platinum(IV), since if similar platinum(II)–platinum(IV) complexes are compared $J_{PtX}(Pt^{IV}) \simeq 0.67\ J_{PtX}(Pt^{II})$[20] (where X = ligand atom), whereas J(PtTe) for the two species are virtually identical. Thus, if the species with $\delta(^{125}Te)$ at 469.5 ppm is a complex of the de-butylated ligand, the solvent DMSO must be implicated [eq. (1)]:



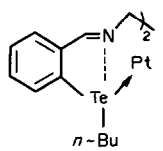
(1)

Rainville and Zingaro[21] have demonstrated that 10-methylphenoxatelluronium iodide will readily form $[(CD_3)_2SO(Me)]^+I^-$ in $(CD_3)_2SO$; since there is Mössbauer evidence that, electronically, tellurium experiences similar environments in R_3Te^+ and $R_2Te \rightarrow Pt$,[22,23] the postulate of facile de-butylation of coordinated **I** in DMSO is reasonable. The model of tellurium de-butylation mirrors a phenomenon well known for organosulphur[24] and organoselenium[25] ligands.

Further NMR and conductivity work was then carried out. Thus the ^{1}H NMR spectrum of a solu-



Aryl tellurate complex of Pt^{IV}.



Alkyl aryl telluride complex of Pt^{II}

Fig. 3.

tion of complex **4** in DMSO was determined. The most interesting feature was a doubling of the —CH=N— resonance ($\delta = 9.12$, 9.15 ppm vs TMS) one component of which shows J(PtH) = 92 Hz. This coupling constant is higher than some values of J(PtH) reported for various organoselenium complexes[17,26] (41 Hz); it seems improbable that the coupling should occur through five bonds, but if the nitrogen was coordinated in the de-butyl case, as implied by IR evidence, a more convincing explanation for the magnitude of this coupling becomes available.

The implication from compound **5** that the final de-butylated species must be a complex of platinum(IV) was explored by measurement of ^{195}Pt NMR spectrum in DMSO. These spectra were monitored over 15 h. After 1 h, three signals were seen at 5986, 5981 and 5975 ppm *downfield* from $Na_2[PtCl_6]$. After 15 h the 5986 ppm and 5975 ppm signals had become very weak leaving the 5981 ppm signal as the dominant feature of the spectrum. The ^{195}Pt resonance covers a wide range of chemical shifts[27-29] but usually platinum(II) resonates at a higher field than $Na_2[PtCl_6]$, thus the data here are consistent with platinum(IV). Thus, the initial platinum(II) complex, detectable but changing in the ^{125}Te NMR experiment, has been removed after 1 h in DMSO (the colour of the solution having changed to deep brown). A mixture of platinum(IV) species is initially formed, but after 15 h one species, presumably that which is insoluble in refluxing acetonitrile, is seen. Monitoring the conductivity over the same period of time shows a slow decline from a value of Λ_M consistent with a 1:1 electrolyte to a non-conducting solution. Thus the three platinum(IV) species are possibly different solvates.

The mechanism of the loss of the butyl group is not currently known. If the reasoning above is correct, the solvent may be implicated in the early stages but the mechanism of the redox reaction may not be inferred from current data.

By contrast with the above system, the complex of $PtCl_2$ with ligand **II** (compound **6**, Table 1) seems straightforward. Thus, the evidence (mainly IR) favours a *cis*-dichloro complex which, unlike the palladium(II) counterpart gives no evidence for the presence of a *trans* isomer under any circumstances.

Rhodium complexes

The rhodium complexes were less well-defined than their palladium and platinum counterparts. Thus the rhodium(III) species (compounds **7** and **8**, Table 1) are both hydrates (analysis, IR). The complex of **I** (compound **7**) gives values of Λ_M of 20 Ω^{-1} cm^2 mol^{-1} in DMSO and 65 Ω^{-1} cm^2 mol^{-1} in CH_3CN. These values are significant, but less than values usually associated with 1:1 electrolytes in these solvents; thus a dimeric formulation may be implied. At least one ν(RhCl) was assigned in the terminal region (322 cm^{-1}, Table 2) but no bridging rhodium–chlorine vibrations could be confidently assigned above 200 cm^{-1}. Based on arguments presented above, ligand **I** coordinates only via tellurium. The complex of ligand **II** is a non-electrolyte and gives two bands in the $\nu(RhCl)_{terminal}$ region (Table 2); here too, coordination of **II** via tellurium only, is implied. Solubility in non-polar solvents implies that a simple [$RhCl_3$(**II**)(H_2O)] formulation to give an octahedral complex (possibly *fac*) is likely.

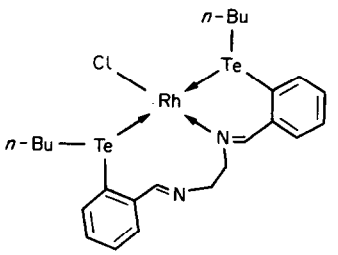


Fig. 4.

Rhodium(I) complexes were formed using [(COD)RhCl]$_2$ as precursor. In the case of ligand **I**, two products could be obtained reproducibly (compounds **9** and **10**, Table 2). However, **10** was non-stoichiometric. The ν(C=N) bands suggest that both nitrogen atoms of the ligand are involved, but unequally, in coordination but little more can be said about **10**. By contrast, **9** seems to have one coordinated and one non-coordinated nitrogen. The complex is non-ionic and soluble in non-polar and mildly polar solvents. It seems probable that a structure such as that in Fig. 4 may be valid. By contrast, the complex (compound **11**, Table 2) of ligand **II** gives no IR evidence for nitrogen coordinated to rhodium. The material fails to conduct and may therefore be dimeric and arise from the simple substitution of **II** for the COD ligands of the precursor. Thus, the extra flexibility of **I** arising from the presence of the dimethylene bridge between the nitrogen atoms would make the terdentate mode possible for **I** but not for **II**.

SYNTHESIS AND CHARACTERIZATION OF MONONUCLEAR COPPER(II) ASPIRINATE ADDUCTS WITH IMIDAZOLE AND ITS METHYL DERIVATIVES

A. LATIF ABU HIJLEH

Chemistry Department, Birzeit University, P.O. Box 14, West Bank–via Israel

(*Received* 10 *February* 1989; *accepted* 20 *July* 1989)

Abstract—A synthetic investigation of copper(II) aspirinate addition compounds with imidazoles has led to the isolation of monomers of the form $[Cu(asp)_2 \cdot L_n]$, where asp is the aspirinate anion and $n = 4$ when L is imidazole or N-methylimidazole and $n = 2$ when L is 1,2-dimethylimidazole. These compounds have been characterized by means of elemental analysis, magnetic moments, electronic, IR and ESR spectroscopic properties. The tetrakis-adducts of imidazole and N-methylimidazole showed physical properties which indicated a tetragonal six-coordinated configuration containing the (CuN_4+O_2) chromophore. For the bis-adduct of 1,2-dimethylimidazole, the proposed geometry is a tetragonal distorted octahedron, having essentially the CuN_2O_2 chromophore in a *trans* distorted square-planar environment. The adoption of monomeric rather than the more common dimeric structure is discussed in terms of the electronic and steric effects of these imidazole ligands.

Aspirin (acetyl salicylic acid) and its derivatives have been used as analgesic, antipyretic and anti-inflammatory drugs. It was suggested that copper(II) complexes of aspirin are more effective and desirable drugs than aspirin.[1,2] Other solvated copper(II) aspirinates, in addition to other copper(II) carboxylates, with pyridine and imidazole have been found to have a variety of pharmacological effects[3,4] including antitumour activity.[5]

Dimeric copper(II) carboxylates with several basic ligands are well documented and reviewed,[6,7] but few spectroscopic studies of copper(II) complexes of aspirin have been reported. X-ray analysis of copper aspirinate showed that it contains binuclear units with bridging carboxylate,[8] similar to the familiar copper acetate[9] and many other carboxylate dimers.[7,10] Solvated copper(II) aspirinate dimers are only known for weakly basic ligands such as DMF, DMSO, H_2O or CH_3OH.[11,12] In addition to dimers, few monomers for the non-halogenated carboxylates, including the aspirinate, are known.[13–17] The only known monomeric complex of copper(II) aspirinate is that with pyridine.[17] X-ray analysis showed that this complex exists as bis(aspirinate)bis(pyridine)copper(II), having essentially the CuN_2O_2 chromophore in a *trans* square-planar arrangement. This structure is similar to those known for the monomeric bis-adducts of copper(II) acetate with imidazole[15] and collidine.[16] This article reports the synthesis and characterization of monomeric tetrakis-adducts, as well as the bis-adduct of copper(II) aspirinate with imidazole and its methyl derivatives. The formation of these stable monomers rather than the more common copper(II) aspirinate dimers is discussed in terms of the basicity strength of imidazoles compared to the less basic ligands.

EXPERIMENTAL

Imidazole (Aldrich) was used without further purification. N-methylimidazole and 1,2-dimethylimidazole (Aldrich) were distilled under reduced pressure immediately prior to use. All solvents were spectral grade and used without further purification.

Synthesis

(1) *Tetrakis-μ-aspirinato-dicopper*(II), Cu_2asp_4 (asp = *aspirinato* = *acetylsalicylato*). This was prepared as described before.[1] Found: C, 51.1; H, 3.4; Cu, 15.1. Calc.: C, 51.2; H, 3.3; Cu, 15.1%.

(2) *Bis(aspirinato)tetrakis(imidazole)copper*(II), $Cu(asp)_2(imid)_4$. 3 g of imidazole in 15 cm^3 of *n*-butanol was added to *ca* 1.5 g of Cu_2asp_4. The mixture was magnetically stirred in a stoppered round-bottomed flask for 1 h in an ice-bath. The oily-blue mixture which formed was separated from the solvent by decantation, then stirred for a few minutes. Anhydrous diethyl ether was added to the blue mixture which was further stirred at room temperature until a faint sky-blue precipitate formed. The complex was filtered under reduced pressure in a closed apparatus, washed several times with anhydrous diethyl ether and dried *in vacuo*. Found: C, 51.8; H, 4.3; N, 16.3; Cu, 9.1. Calc.: C, 51.9; H, 4.3; N, 16.1; Cu, 9.2%.

(3) *Bis(aspirinato)tetrakis(N-methylimidazole) copper*(II), $Cu(asp)_2(N\text{-}Me \cdot imid)_4$. 10 cm^3 of freshly distilled N-methylimidazole was added to 1.5 g of Cu_2asp_4 in a round-bottomed flask. The mixture was magnetically stirred in an ice-bath for 1 h and set aside at room temperature. After 4 days the blue crystalline product was filtered under reduced pressure in a closed apparatus, washed with anhydrous diethyl ether, dried *in vacuo* and stored in a stoppered flask. Found: C, 54.5; H, 5.0; N, 14.6; Cu, 8.6. Calc.: C, 54.4; H, 5.1; N, 14.9; Cu, 8.5%.

(4) *Bis(aspirinato)bis*(1,2-*dimethylimidazole)copper* (II), $Cu(asp)_2(1,2\text{-}diMe \cdot imid)_2$. 10 cm^3 of freshly distilled 1,2-dimethylimidazole was added to about 1 g of Cu_2asp_4. The mixture was stirred at about 50°C for 30 min, filtered in a closed apparatus over anhydrous diethyl ether, then stirred overnight at room temperature. The sky-blue precipitate formed was filtered in a closed apparatus under reduced pressure, washed several times with anhydrous diethyl ether and dried *in vacuo*. Found: C, 54.5; H, 5.0; N, 9.1; Cu, 10.3. Calc.: C, 54.8; H, 4.9; N, 9.1; Cu, 10.3%. Elemental analyses for C, H and N were performed by Galbraith Laboratories, Knoxville, Tennessee. Copper was determined volumetrically.

Physical measurements

Room temperature (300 K) magnetic susceptibility measurements of powdered samples were determined by the Gouy method, with $HgCo(NCS)_4$ as calibrant, and corrected for diamagnetism with the appropriate Pascal constants. The effective magnetic moment was calculated from the expression: $\mu_{eff} = 2.84(\chi'_m \cdot T)^{1/2}$. The ESR spectra of powdered and methanol–toluene solution samples were taken at different temperatures, with a Varian E-4 X-band spectrometer equipped with a variable temperature unit and 100 KHz field modulation, using diphenyl picryhydrazyl (DPPH, $g = 2.0036$) as the calibrating field marker. Electronic spectra were obtained, using THF or chloroform solutions in matched 1-cm quartz cells, using Bauch and Lomb spectronic 2000. Nujol mulls and potassium bromide discs of complexes were employed to obtain IR spectra in the 4000–600 cm^{-1} region, with a Perkin–Elmer Model 298 spectrophotometer.

RESULTS AND DISCUSSION

The imidazole adduct dissolves in polar solvents (THF, DMSO, alcohols, etc.) but does not dissolve in less polar solvents (chloroform, methylene chloride). N-methylimidazole and 1,2-dimethylimidazole adducts dissolve in most organic solvents. All complexes are stable in air except the N-methylimidazole adduct which appears to be hygroscopic.

Electron spin resonance

The ESR spectrum obtained for a powdered sample of Cu_2asp_4 at room temperature exhibits three absorption bands typical of triplet-state binuclear copper(II) complexes with axial symmetry.[11] The values obtained for the spin-Hamiltonian parameters are: $g_\perp = 2.08$, $g_\parallel = 2.28$, $g_{av} = 2.15$ and $|D| = 0.36$ cm^{-1}. The values are comparable to those found in binuclear copper(II) carboxylates.[10] The crystal structure of copper(II) aspirinate has been reported,[8] and contains dimetallic units of $[Cu(asp)_2]_2$ interconnected by acetyl oxygens from neighbouring dimetallic units.

X-band ESR spectra of polycrystalline samples, for the tetrakis-adducts of imidazole and N-methylimidazole (Fig. 1(A) and (B), respectively) and for the bis-adduct of 1,2-dimethylimidazole [Fig. 2(A)], are anisotropic and contain $g_\perp$ and $g_\parallel$ components. In addition to the hyperfine structure of copper(II) in the $g_\parallel$ region, the bis-adduct of the 1,2-dimethylimidazole spectrum is partially resolved into its X and Y components in the $g_\perp$ region, Fig. 2(A). This may result from the non-equivalence of the Cu—O and Cu—N bonds formed by the carboxylate and by 1,2-dimethylimidazole ligands, respectively, in the XY plane. The ESR spectral parameters of the three complexes and some similar complexes, Table 1, are characteristic of tetragonal elongated monomeric copper(II) complexes having the $d_{x^2-y^2}$ ground state.[18]

ESR spectra of solution samples for the three adducts, at room temperature, are isotropic and consist of four equally-spaced lines, as expected for the copper(II) ion. In frozen solutions, the imidazole and N-methylimidazole adduts' spectra (Fig. 3(A) and 4(A), respectively) show substantial ^{14}N

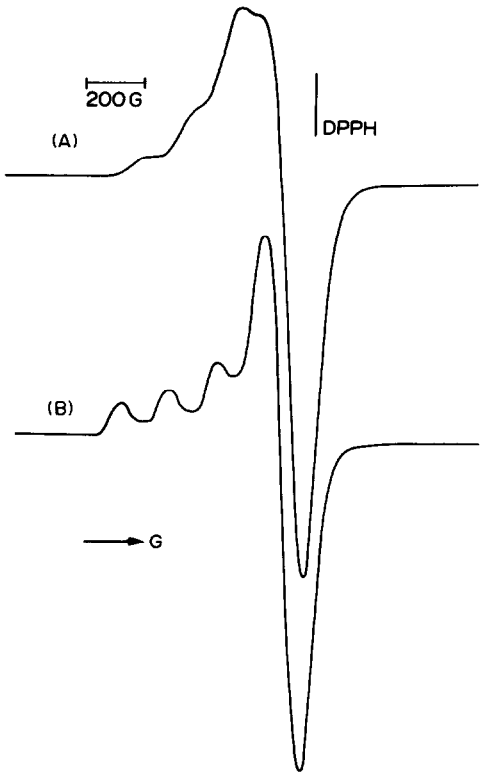

Fig. 1. X-band ESR powder spectra of $Cu(asp)_2(imid)_4$ (A) and $Cu(asp)_2(N\text{-}Me \cdot imid)_4$ (B) at 300 K.

super-hyperfine structure in the $g_\perp$ region. This resolved into nine equally-spaced peaks with $A_\perp(N)$ of 15 cm^{-1}, and expanded spectra of this region are shown in Fig. 3(B) and 4(B) for the imidazole and N-methylimidazole adducts, respectively. The resolution of the $g_\perp$ region is attributed to the presence of four equivalent nitrogen atoms in the copper(II) ion plane. These spectra are comparable to the ESR spectra of a bis(acetato) tetrakis(imidazole)copper(II) complex[13] having a CuN_4O_2 chromophore, and with those containing a CuN_4 chromophore.[19] The spectral parameters for the imidazole and N-methylimidazole are rather similar (Table 1) and comparable with those reported for CuN_4O_2 chromophores.[13,20,21] In these chromophores the copper(II) complexes have a tetragonal elongated structure and the equatorial positions are occupied by the four nitrogen atoms, while the axial positions are occupied by the oxygen atoms of the carboxylate groups. In the complexes $Cu(asp)_2(imid)_4$ and $Cu(asp)_2(N\text{-}Me \cdot imid)_4$, the four equatorial positions are occupied by four imidazole or N-methylimidazole molecules coordinated through their pyridine nitrogen, while each axial position is occupied by one carboxylate oxygen atom from each of two aspirinate anions.

The ESR spectrum of a frozen solution of the bis-adduct of 1,2-dimethylimidazole, is shown in Fig. 2(B). Although the ^{14}N superhyperfine splitting in the $g_\perp$ region is not resolved, ESR spectra parameters for this adduct are comparable with those of copper acetate bis-adducts with imidazole,[5] 1,2-dimethylimidazole[13] and with $Cu(asp)_2(Py)_2$,[17] and with previously reported complexes having essentially a *trans*-square-planar CuN_2O_2 chromophore,[10,18,20,22] In these complexes the copper(II) ion is bonded in a *trans* arrangement to two ligand nitrogen atoms and one oxygen atom from each of the two carboxylate anions. The second oxygen

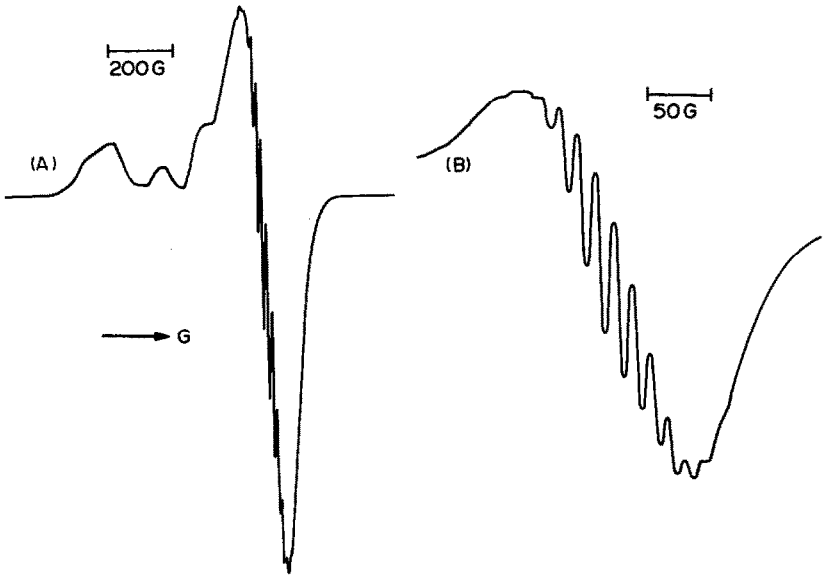

Fig. 4. X-band ESR spectra of $Cu(asp)_2(N\text{-}Me\cdot imid)_4$ (A) in frozen methanol–toluene solution at 120 K and an expanded spectrum of the $g_\perp$ region (B).

atom of the carboxylates are weakly bonded in the axial positions. The absence of the ^{14}N splittings may be attributed to the presence of a distorted square-planar CuN_2O_2 chromophore in this adduct, which weakens the interaction between the σ-orbitals of the nitrogen atoms and the copper(II) $d_{x^2-y^2}$ orbital. In addition, the partial resolution of $g_\perp$ in the powdered spectrum [Fig. 2(A)] into its X and Y components supports the proposed distorted square planar CuN_2O_2 chromophore in this adduct. This distortion is attributed to the presence of bulky aspirinate anions and sterically hindered methyl groups in 1,2-dimethylimidazole ligands.

Inspection of the ESR parameters (Table 1) shows that $A_\parallel$ for the tetrakis-adducts, $Cu(asp)_2(imid)_4$ and $Cu(asp)_2(N\text{-}Me\cdot imid)_4$, is greater than $A_\parallel$ for the bis-adduct, $Cu(asp)_2(1,2\text{-}diMe\cdot imid)_2$; while $g_\parallel$ values in the former complexes are

smaller. These results are consistent with the presence of a stronger equatorial ligand-field in the tetrakis-adducts, which have the CuN_4 chromophore in the plane, compared to the bis-adduct which is proposed to contain the CuN_2O_2 chromophore.

Magnetic moments

The results of the effective magnetic moments, as well as electronic and IR spectral measurements, are summarized in Table 2. The magnetic moment of $Cu_2(asp)_4$ at room temperature is 1.36 BM. This subnormal moment is indicative of spin–spin coupling and is in the range expected for dimeric copper(II) carboxylate complexes.[6,7,10] The exchange coupling constants, $-2J$, value determined[12] for this complex is 363 cm^{-1}. The magnetic moments, at room temperature, for the three imidazole complexes of copper(II) aspirinate are in the range 1.85–1.90 BM. These values correspond to the presence of one unpaired electron in monomeric copper(II) ion complexes.

Electronic spectra

The electronic spectra, in the visible region, of dimeric $Cu_2(asp)_4$ in a Nujol mull show the two bands characteristic of dimeric copper(II) carboxylates.[10,14] The electronic spectra for the three mononuclear adducts in THF or chloroform solutions exhibit one broad asymmetric band due to the copper *d–d* transitions. The position of the band and the value of its molar absorptivity are in the range expected for monomeric copper(II) carboxylate adducts.[10] The tetrakis-adducts, $Cu(asp)_2(imid)_4$ and $Cu(asp)_2$(N-Me·imid)$_4$, show absorption maxima which are comparable with that found for monomeric $Cu(CH_3COO)_2(imid)_4$ [band maximum around 635 nm ($\varepsilon_m = 60$)][13] and is in the range expected for complexes containing a CuN_4O_2 chromophore.[10,21] The bis-adduct, $Cu(asp)_2$(1,2-diMe·imid)$_2$, has an absorption maximum which is comparable with those found for structurally known Cu(aspirinate)$_2$(pyridine)$_2$ [band maximum in chloroform solution at 725 nm ($\varepsilon_m = 230$)][17] and other complexes having an essentially *trans*-CuN_2O_2 chromophore.[10,21]

Infrared spectra

The assignments of all the bands for the complexes have not been made, but the IR absorptions for the antisymmetric and symmetric carboxyl stretching frequencies are compared in Table 2. For $Cu_2(asp)_4$ the asymmetric ν_{as}(COO) and the symmetric ν_s(COO) frequencies are similar to those reported for dimeric copper(II) carboxylates,[10,23] in which the carboxylate acts as a "bridging" bidentate ligand. The IR spectra for the two tetrakis-adducts of imidazole and N-methylimidazole are very similar to one another in band shape and position, especially the antisymmetric and symmetric carboxylate bands. The positions of these bands and the separation between them, $\Delta\nu$, are comparable with those of structurally known monomeric copper(II) carboxylate complexes with imidazoles in which the carboxylate acts as monodentate ligand.[24] The $\Delta\nu$ value and ν_s(COO) position for the bis-adduct of 1,2-dimethylimidazole are comparable with those of structurally known monomeric copper(II) carboxylates containing an essentially CuN_2O_2 chromophore, in which $\Delta\nu$ is about 230–250 cm^{-1} and ν_s(COO) about 1370–1380 cm^{-1}. In these complexes the carboxylate group acts as an essentially monodentate or asymmetric bidentate ligand.[24,25] X-ray analysis of $Cu_2(asp)_4$ revealed two types of acetoxy carbonyl group.[8] One of these is weakly bonded to a copper(II) ion of a neighbouring copper(II) aspirin-

ate molecule, while the other is not. As a consequence, the IR spectrum of $Cu_2(asp)_4$ shows two different acetoxy carbonyl stretching frequencies at 1735 and 1758 cm^{-1}. The IR spectra for the three monomer complexes show only one acetoxy carbonyl frequency at about 1750 cm^{-1} and it is not coordinated. These IR results along with the above spectral results confirm the presence of the CuN_4O_2 chromophore in the tetrakis-adducts and the presence of an essentially CuN_2O_2 chromophore or tetragonally elongated CuN_2O_4 chromophore in the bis-adduct.

There have been many studies to investigate the factors which influence dimer formation over monomer formation in copper(II) carboxylate solvate complexes.[10,14,16,17] Halogenation of the alkyl group increases the tendency towards formation of a monomeric adduct which is related to the electronic effects on the acidity of the carboxylates. In addition, the electronic effects of the addend play a significant role in the adoption of one of the two structural types of copper(II) carboxylate adducts. The results of this study support the previous ones[13,17] in showing that there is a preference for monomer formation with basic ligands such as imidazoles (this work) and pyridines,[16,17] than with less basic ligands such as water, DMSO or DMF. Although steric effects of the addends play a less important role than the electronic effects in the adoption of one of the two structures,[14,16] the results of this study demonstrate the role of steric requirements of the addend in affecting the structural properties of monomeric copper(II) carboxylate adducts. The less sterically hindered ligands, imidazole and N-methylimidazole, formed the tetrakis-adducts with copper(II) aspirinate, whereas the more sterically hindered ligand, 1,2-dimethylimidazole, formed the bis-adduct.

Acknowledgements—I am grateful to Professor I. Y. Ahmed at the University of Mississippi for obtaining the ESR spectra and to Birzeit University for the support of this research under Grant No. 86/68/97/8.

(*Received* 7 *March* 1989; *accepted* 20 *July* 1989)

Abstract—It has been shown that a *d–p* π-conjugate interaction exists on the non-planar ring skeleton M_3X_3 and the structured energy levels for the isoelectron series have the same order in the core $M_3X_{4-n}Y_n$, containing both M_3X_3 and $M_3X_{4-n}Y_n$ in the incomplete metallic cubane-type cluster compounds. It has also been found that the abilities of the π-lone pair electron donation in the X atom and of the π-electron acception in the M atom are the key factors for the *d–p* π-conjugate interaction over the non-planar ring skeleton M_3X_3. The π-electronic delocalization for the S atom over M_3S_3 is larger than at the O atom over M_3O_3 (M = Mo, W), and the strengths of the *d–p* π-conjugate interaction are larger over M_3S_3 than M_3O_3, but the M—M transannular interactions are stronger in M_3O_3 than M_3S_3. The latter fact may be due to a contribution from the *d–d* π-interaction within the triangle of metal atoms, because the typical π-orbital interactions take place both between M—M and M—X in the non-planar ring skeleton M_3X_3.

Incomplete metallic cubane-type cluster compounds having a core of the general formula $M_3X_{4-n}Y_n$ (n = 1, 0) have been the subject not only of numerous experimental studies,[1–10] but also of various theoretical studies.[11–13] The theoretical attempts to understand the electronic structure and properties of these clusters have been from qualitative[14] and parameter-free[11] approximate molecular orbital (MO) treatments. Most of these theoretical treatments have employed a MO approach to describe the electronic structure of the various clusters. Particularly noteworthy among the MO descriptions of the clusters containing a $M_3X_{4-n}Y_n$ core is the work of Dahl and co-workers.[14] This group developed a qualitative molecular orbital picture by considering the symmetry of the metal skeleton orbitals. However, most of the theoretical investigations have paid less attention to the discussion of the *d–p* π-conjugate interaction over the non-planar ring skeleton M_3X_3, although Curtis and Butler[15] have pointed out that the S---Mo π-donation to cause both M—M and M—S bond contraction is postulated to be a more important bonding feature in $Mo_3S_4Cp_3^+$. We will describe the *d–p* π-conjugate interaction over the non-planar ring skeleton M_3X_3 and its influence upon the bonding and physicochemical properties in the incomplete metallic cubane-type cluster compounds, and give an eigenvalue spectrum for the isoelectron series $M_3X_{4-n}Y_n$ (M = Mo, W; X = O, S, Cl, Br; Y = O, S; n = 0, 1).

RESULTS AND DISCUSSION

Eigenvalue spectrum and orbital components

Molecular orbital calculations were carried out on 10 cores with the triangle pyramidal structure shown in Fig. 1. The energy level diagrams for each of the six cores are given in Fig. 2, the orbital compositions are also tabulated in Table 1. The isoelectron series, $M_3X_{4-n}Y_n^{4+}$, has 19 occupied MO's, in which 6*e* or its splitting *a'*(6*e*) orbital is HOMO, and $Mo_3X_3O^{5+}$ (X = Cl, Br) has 20 occupied MO's, in which $7a_1$ is the HOMO, if we only consider the valence electrons.

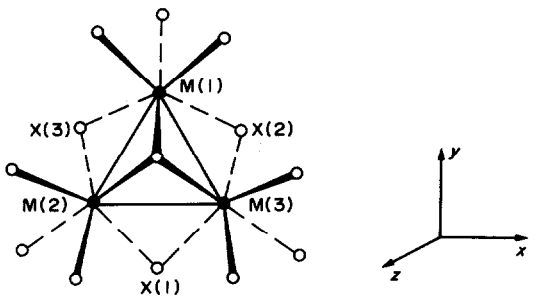

Fig. 1. The configuration of the $M_3X_{4-n}Y_nL_9$ cluster and the definition of coordinate orientation.

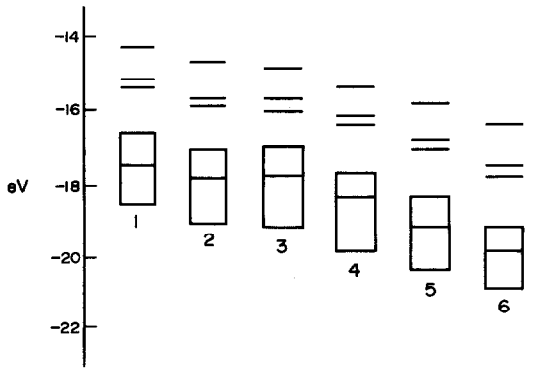

Fig. 2. The eigenvalue spectrum for 38 valence electrons. The core numbers 1 ($Mo_3S_4^{4+}$), 2 ($Mo_3OS_3^{4+}$), 5 ($Mo_3SO_3^{4+}$) and 6 ($Mo_3O_4^{4+}$) have C_{3v} symmetry and the energy levels are $7e$ (LUMO), $6e$ (HOMO), $6a_1$, $5e$, $5a$ and $1a_1$. The core numbers 3 [$Mo_3(\mu_3\text{-}S)(\mu\text{-}S_2)(\mu\text{-}O)^{4+}$] and 4 [$Mo_3(\mu_3\text{-}S)(\mu\text{-}S)(\mu\text{-}O)_2^{4+}$] have C_s symmetry and the energy levels are $a'(7e)$, $a'(6e)$, $a'(6a_1)$, $a'(5e)$, $a'(5a_1)$ and $a'(1a_1)$.

The high-lying occupied $6e$ and $6a_1$ MO's for $M_3X_{4-n}Y_n^{4+}$ are considered as M—M bonding orbitals. As shown in Table 1, the metal atom *d*-orbital character for $6e$ (HOMO) contributes about 53–72%, and $6a_1$ MO's contribute about 30–54% in a 38-valence electron series. In 40-valence electron series, $7a_1$ (HOMO) consists of about 58% and $6a_1$ consists of about 47% *d*-orbital character. It seems that there is generally a trend in the values of Table 1. The contributions of the metal atom *d*-orbital character decrease and the bridging atoms X and Y *p* orbital characters increase, while the MO energy level tends towards stabilization. The $1a_1$, $1e$ and $2a_1$ orbitals are not shown in Fig. 2 and Table 1. Each of them is nearly an entire orbital of the filled low-lying *s*-orbital of the bridging atoms. The calculated results on the $Mo_3O_4^{4+}$ using the Fenske–Hall method by Bursten *et al.*[11] are in agreement with our results in a general trend.

It is suggested from Fig. 2 and Table 1, as well as from the results of the calculations, that the diagram of the structured energy levels is generally divided into five blocks in this type of core series. The first block is virtually non-bonding combinations of the filled orbital of four X atoms, and will accommodate eight electrons. The next block is the bonding interactions between the metal atom *d*-orbitals (containing smaller metal atom *s*-orbital) and the X atom *p*-orbitals, and will accommodate 24 electrons. The third block consists of metal atom *d*-orbitals, which includes bonding and antibonding interactions between the *d*-orbitals, and the remainder of the core valence electrons will accommodate this block. The fourth block is the counterpart of the second block and contains antibonding interactions between the M atom *d*-orbital and X atom *p*-orbital, and is vacant. The highest non-occupied block consisting of the M atom *p*-orbitals is the fifth one. This

[a] The HOMO is $7a_1$ and the $6e$ molecular orbital is not shown.

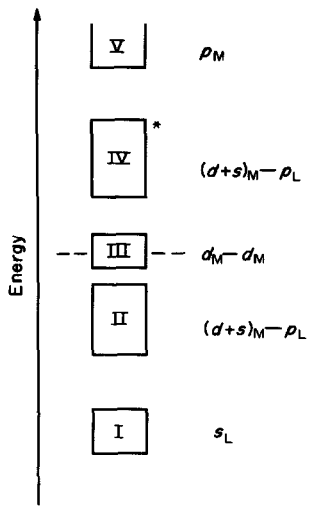

Fig. 3. The general structural energy levels of the core.

scheme has been drawn in Fig. 3. It is noteworthy that the scheme is only qualitatively correct. It is seen from Table 1 that HOMO $7a_1$ in the third block for $Mo_3X_3O^{5+}$ is about 58% *d*-orbital character of the Mo atoms and 42% *p*-orbital character of the bridging ligand atoms, and this HOMO is believed to be the antibonding orbital for the interaction between the metal atomic skeleton *d*-orbitals and edge-bridging ligand atom *p*-orbitals.

Bonding properties of M_3X_3

There are three types of bond that need to be considered in these incomplete metallic cubane-type clusters. These are the bonds between the metal atom and the terminal ligand atom, the metal atom and the edge- or face-bridging ligand atom, as well as between two metal atoms.

Generally, the interactions between the metal atom and both the terminal and bridging ligand atoms are stronger than the interactions between the two metal atoms. However, if the interactions of *d–p* π-bonding exist and the *d–p* π-bonding strength is comparable to the *d–d* interactions in the non-planar ring skeleton M_3X_3, all the interactions between metal atoms and terminal ligands should be viewed separately from the interactions within the M_3X_4 core. Bursten *et al.*[11] have indicated that the electronic structure of the pyramidal fragment $Mo_3O_4^{4+}$ is dominated by the influence of the three-bridging μ_2-O groups. Thus, the discussion in this section will be focused on the bonding within the M_3X_3 ring skeleton itself, with special attention paid to the effect of the *d–p* π-conjugate interactions upon the cluster bonding and physicochemical properties.

Table 3 lists several overlap populations for d_M–d_M and *d–p* π-interactions of M—X in the $M_3X_4^{4+}$ or $M_3X_3Y^{5+}$ core, as well as in the cluster ion compounds. The interactions between the d_z^2, d_{xz}, d_{yz} orbitals on the M(2) and M(3) atoms, or the d_z^2, d_{yz} orbitals on the M(1) atom and the p_y orbital on the X(1) atom, or p_y, p_x orbitals on the X(2) and X(3) atoms are called *d–p* π-interactions in view of the molecular coordinate system, as shown in Fig. 1. This assignment is only an approximation because the molecular orbitals are not localized in the present studies. It is seen from Table 3 that the *d–p* π-overlap populations are larger than those of d_M–d_M in either the $Mo_3S_4^{4+}$, $Mo_3S_3O^{4+}$ and $W_3S_4^{4+}$ cores or the $Mo_3S_4Cp_3^+$, $Mo_3S_4(CN)_9^{5-}$ and model $Mo_3S_4(H_2PS_2^-)_4OH_2$, cluster compounds, however, the *d–p* π-overlap populations are not larger than those of d_M–d_M in either the $Mo_3O_4^{4+}$, $Mo_3O_3S^{4+}$ and $W_3O_4^{4+}$ cores or the $Mo_3O_4F_9^{5-}$ cluster ion compound. In other words, the *d–p* π-bonding strengths are stronger in the Mo_3S_3 non-planar ring skeleton than in that of Mo_3O_3,

while the overlap population is considered as an index for the strength of the bonding interaction.[16] These are the reasons why the electrons are attracted more by the oxygen atomic nucleus than by the sulphur atomic nucleus, and the π-electrons delocalized over Mo_3O_3 are less than those over Mo_3S_3. Moreover, it appears from experiments that the average lengths of Mo—S in Mo_3S_3 and Mo—O in Mo_3O_3 are different; the Mo—S bond length falls between single and double bonds,[1] while the Mo—O length falls in the single bond range.[2] However, the stability of $Mo_3O_4(OH_2)_9^{4+}$ is greater than that of $Mo_3S_4(dtp)_4OH_2$, as proved by the oxidation of $Mo_3S_4(dtp)_4OH_2$ in hydrotropic solution over a period of time.[1] Now, the question arising at this stage is: how is it possible to explain this stability of $Mo_3O_4(OH_2)_9^{4+}$? The answer is provided by the calculational results of quantum chemistry: the d_M–d_M interactions are stronger in the $Mo_3O_4^{4+}$ and $Mo_3O_4(OH_2)_9^{4+}$ species than in $Mo_3S_4^{4+}$ and $Mo_3S_4(H_2PS_2^-)_4OH_2$ in terms of the population analyses shown in Table 3. Perking[17] and Faucher[18] have shown that strong transannular interactions exist between endocyclic P atoms for which the strength of the transannular P—P bonding is about 10% of that of a P—N bond in the $(NPCl_2)_3$ trimer, and this provides an important contribution to the stability in $(NPCl_2)_3$. We consider that the transannular bonding interactions between M—M in the non-planar ring skeleton M_3X_3 should be more important contributions to the stability in the incomplete metallic cubane-type cluster compounds. The strength of the Mo—Mo bond is about 18% of the Mo—S bond strength of the Mo_3S_3 core contained in $Mo_3S_4(H_2PS_2^-)_4OH_2$, and the strength of the Mo—Mo bond is about 24% of the strength of the Mo—O bond in the Mo_3O_3 core contained in $Mo_3O_4F_9^{5-}$, according to the energy partitions[19,20] based on our calculated results. It is seen that the transannular Mo—Mo bond gives more contribution to the stability of the clusters containing Mo_3O_3 than to the clusters containing Mo_3S_3. It is possible to explain why the stability of $Mo_3O_4(OH_2)_9^{4+}$ is greater than that of $Mo_3S_4(dtp)_4OH_2$.

There are other types of non-planar ring skeleton Mo_3X_3 (X = Cl, Br) in $Mo_3X_3O(OAc)_3Cl_3^-$,[8] in which the formal molybdenum oxidation state is $3\frac{1}{3}$ and the trimolybdenum has eight valence electrons. Comparing the compounds which contain the non-planar ring skeleton Mo_3X_3 (X = O, S) with those containing Mo_3X_3 (X = Cl, Br), there are two additional electrons in the latter cluster compounds. Which kind of orbital (M—M or M—X interaction) are the additional electrons occupying? This question has been discussed in several papers.[11,21] We consider that the two additional electrons will occupy a d–p π-antibonding orbital in Mo_3X_3 (X = Cl, Br). The Mo—Mo bond would be weakly bonding, and one would not expect a shortening of the Mo—Mo bond (2.577 Å) in $Mo_3Cl_3O(OAc)_3Cl_3^-$,[8] if the two additional electrons occupy the Mo—Mo antibonding orbital. By comparing it with the Mo—Mo bond (2.65 Å) in $Mo_3S_3O(S_2P(OEt)_2)_4(C_3H_3N_2)$,[4] the short Mo—Mo bond in $Mo_3Cl_3O(OAc)_3Cl_3^-$ will not be influenced by the geometric factors of atomic size, on account of the fact that the reduction of the effective metal charge from 4 to $3\frac{1}{3}$ should be accompanied by an increase in the effective atomic radius of the molybdenum atom for the eight-electron system, and the difference between the covalent

radii of the sulphur and chlorine atoms is only 0.03 Å. Moreover, the calculated results on the $Mo_3Cl_3O^{5+}$ core have shown that the HOMO is $7a_1$ and consists of 38% d π-character on the tri-metal and 21% p π-character on the tri-edge-ligand in terms of the orbital analysis based on the calculation results.

It is also seen from Table 3 that substitution of molybdenum by tungsten induces a large overlap population of d_M–d_M and d–p π-interactions in the non-planar ring skeleton W_3X_3 (X = O, S), although the distances of both the W—W and W—X are not less than those of both the Mo—Mo and Mo—X separately. This means that the W_3X_3 stabilization is more than that for Mo_3X_3 (X = O, S) for an exact homologue.

COMPUTATIONAL DETAILS

The calculations were based on the SCCC–EH method with weighted H_{ij}'s developed by Hoffmann *et al.*[19,22] There are nine VSIT(Q) functions for d-orbitals and three VSIE(Q) functions for s- and p-orbitals in the transition metal atom. The standard of convergence is 0.002 in iterative procedure.

All atomic and charge iteration parameters used in the calculations were taken from the default values of the ICON8 program,[22] except those of molybdenum, tungsten and bromine, and all geometric parameters, except for the model compound $Mo_3S_4(H_2PS_2^-)_4OH_2$, were taken from the crystal structural data[1-10] and are idealized to C_{3v} symmetry, excluding $Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_2(\mu\text{-}O)^{4+}$ and $Mo_3(\mu_3\text{-}S)(\mu\text{-}S)(\mu\text{-}O)_2^{4+}$ which have C_s symmetry. The structural data of the model compound $Mo_3S_4(H_2PS_2^-)_4OH_2$ are the same as those of $Mo_3S_4(dtp)_4OH_2$ (dtp = $(EtO)_2PS_2^-$),[3] in which the EtO group was replaced by a hydrogen atom and the P—H distance is 1.42 Å. All core $M_3X_{4-n}Y_n$ conformations in the calculations are the same as those for the $M_3X_{4-n}Y_n$ core in the cluster compounds $M_3X_{4-n}Y_nL_9$[1-10] (M = Mo, W; X = O, S, Cl, Br; Y = O, S; L = terminal ligand; n = 1, 0). The atomic parameters for molybdenum and tungsten were taken from ref. 23. The charge iteration parameters for tungsten were the same as for molybdenum, and were taken from ref. 24. The parameters for 4s and 4p valence orbitals of the bromine atom are as follows: both orbital exponents are 2.257 and the Coulomb integrals are −24.1 and −12.5 eV, the iterative parameters A, B, C are, respectively, 0.0, 9.86, 23.79 for the 4s orbital and 0.0, 9.86 and 11.84 for the 4p orbital.

THE MECHANISM OF OXIDATION OF CUBOIDAL $[Mo_4S_4(edta)_2]^{4-}$ AND $[Mo_4S_4(edta)_2]^{3-}$ BY *cis*-$[V(O)_2(H_2O)_4]^+$ AND BrO_3^-

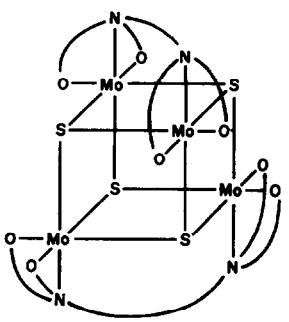
PAUL W. DIMMOCK, BEE-LEAN OOI and A. GEOFFREY SYKES*

Department of Chemistry, The University, Newcastle upon Tyne NE1 7RU, U.K.

(*Received* 30 *March* 1989; *accepted* 20 *July* 1989)

Abstract—The air-sensitive cuboidal Mo_4^{III} complex $[Mo_4S_4(edta)_2]^{4-}$ (edta = N,N,N′,N′-ethylenediaminetetraacetate), reduction potential −0.046 V for one-equivalent oxidation, is rapidly oxidized by $V(O)_2^+$ (1.0 V for $V(O)_2^+/VO^{2+}$) and BrO_3^- (1.15 V for BrO_3^-/BrO_2) to $[Mo_4S_4(edta)_2]^{3-}$ at pH < 3. The slower, further oxidation to $[Mo_4S_4(edta)_2]^{2-}$ (0.65 V) has been studied independently by stopped-flow (for $V(O)_2^+$), and conventional time range spectrophotometry (for BrO_3^-). In the case of the $V(O)_2^+$ reaction (25°C) the rate law is $(k_1+k_2[H^+])[Mo_4S_4(edta)_2^{3-}][V(O)_2^+]$, $k_1 = 83\ M^{-1}\ s^{-1}$ and $k_2 = 4.6\times10^3\ M^{-2}\ s^{-1}$ over the $[H^+]$ range, 0.025–0.200 M, studied, $I = 1.00$ ($LiClO_4$). Studies on the BrO_3^- reaction under similar conditions indicated a more complicated reaction sequence, which is faster the higher the $[H^+]$. The initial induction phase exhibits an $[H^+]^2$-dependence. The $[H^+]$-dependences observed are consistent with the need to decrease the extent of hydrolysis as rate-determining steps $V(O)_2^+ \rightarrow VO^{2+}$ and $BrO_3^- \rightarrow BrO_2$ occur. No evidence was obtained for single stage two-equivalent steps. Reactions are most likely of the outer-sphere type.

The existence of cuboidal Mo_4S_4 complexes in three adjacent average molybdenum states, 3.0, 3.25 and 3.50, has been established in recent work.[1–4] Redox reactions of the aqua ions $[Mo_4S_4(H_2O)_{12}]^{n+}$ ($n = 4$, 5 and 6),[5,6] and the corresponding $[Mo_4S_4(edta)_2]^{m-}$ ($m = 4$, 3 and 2) states,[7] have been reported previously and illustrate the readiness with which interconversion of these ions can occur.



$[Mo_4S_4(edta)_2]^{m+}$

Self-exchange rate constants for the reactions $[Mo_4S_4(edta)_2]^{4-/3-}$ ($1.5\times10^7\ M^{-1}\ s^{-1}$), and $[Mo_4S_4(edta)_2]^{3-/2-}$ ($7.7\times10^5\ M^{-1}\ s^{-1}$) have been obtained.[7] In this study we explore the reactivity of the oxo-containing oxidants, *cis*-$[V(O)_2(H_2O)_4]^+$ (hereafter referred to as $V(O)_2^+$) and BrO_3^-. In the case of BrO_3^- at least, the possibility of a single two-equivalent rate-determining step, $BrO_3^- \rightarrow BrO_2^-$, exists as BrO_3^- is converted through to Br^-. Such changes have been reported (with I^-, Br^-, Cl^-, H_2O_2, HN_3 and HSO_3^-),[8–12] although the one-equivalent change $BrO_3^- \rightarrow BrO_2$ is observed with other reductants ($[Fe(CN)_6]^{4-}$, VO^{2+}, Hg^0 etc).[13–16] There are as yet no examples of two-equivalent reduction of the $V(O)_2^+$ ion, the $V(O)_2^+ \rightarrow V^{3+}$ conversion representing too drastic a change in hydrolysis for reaction to occur in a single rate-determining step. Reduction potentials[7] and colours of the $[Mo_4S_4(edta)_2]^{m-}$ ions are as indicated in eq. (1):

$$\underset{\text{Orange}}{[Mo_4S_4(edta)_2]^{4-}} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} \underset{-0.046\,V}{} \underset{\text{Green}}{[Mo_4S_4(edta)_2]^{3-}} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} \underset{0.65\,V}{} \underset{\text{Red}}{[Mo_4S_4(edta)_2]^{2-}}. \quad (1)$$

EXPERIMENTAL

Preparation of $[Mo_4S_4(edta)_2]^{3-}$

The di-μ-sulphido molybdenum(V) dimer $Na_2[Mo_2O_2S_2(edta)]\cdot 2H_2O$ was prepared,[17] and conversion of cyclic Mo_2S_2 to cuboidal Mo_4S_4 achieved by $NaBH_4$ (1 g) reduction of the dimer (2 g) in 0.03 M HCl (200 cm^3), all under N_2.[1,4] The resultant solution was left to stand overnight at ~ 4°C, after which it was heated in air to ~ 90°C on a steam bath for ~ 24 h. Column purification of $[Mo_4S_4(edta)_2]^{3-}$ was as described previously,[7] to give a UV–vis–near-IR spectrum in 0.5 M $LiClO_4$ at neutral pH, with peaks λ (nm) (ε/M^{-1} cm^{-1} per cube) at 636 (635) and 1145 (280), and shoulders at 300 (7500) and 450 (750), Fig. 1. Stock solutions up to 6 mM in 0.5 M $LiClO_4$ were stable in air. Solutions were standardized for $[Li^+]$ by loading onto an Amberlite 1R(H)120 cation-exchange column and titrating the $[H^+]$ released.

Preparation of $[Mo_4S_4(edta)_2]^{4-}$

Solutions of $[Mo_4S_4(edta)_2]^{3-}$ in 0.5 M $LiClO_4$ as prepared above, were reduced under N_2 at a high surface area carbon–cloth electrode (RVG 100 cloth from Le Carbonne, Brighton, U.K.) as already described,[5] using a constant potential of 0.50 V (vs SCE) for ~ 2 h. After reduction was complete the orange $[Mo_4S_4(edta)_2]^{4-}$ was millipore filtered (8 μm pore size) to remove any carbon particles. This operation was performed under N_2 in a glove bag. Spectrophotometric standardization was carried out at the 390 nm peak (ε = 2445 M^{-1} cm^{-1} per cube), Fig. 1, and checked by allowing the complex to air-oxidize to $[Mo_4S_4(edta)_2]^{3-}$. Stock solutions were stored under N_2 at 0°C and used the same day for kinetic runs.

Preparation of $[V(O)_2(H_2O)_4]^+$

The yellow *cis*-di-oxo aqua ion of vanadium(V) was prepared by first dissolving ammonium vanadate, NH_4VO_3 (BDH, Analar), in hot water. An equal volume of 4 M $HClO_4$ was then added with stirring to give a 0.05 M solution of vanadium(V) in 2 M acid. After cooling to room temperature the solution was filtered (removal of any solid V_2O_5) and standardized by titration with freshly prepared iron(II) ammonium sulphate in 2 M H_2SO_4 using ferroin as indicator. *Cis*-di-oxo $V(O)_2^+$ is known to be the sole vanadium(V) form present at $[H^+] > 0.05$ M.[18]

Other reagents

Sodium bromate (BDH Reagent Grade), was used. Lithium perchlorate (Aldrich) was recrystallized three times. Perchloric acid (BDH) was of Analar grade purity.

Kinetics

Relevant spectra are compared in Fig. 1. Details for $[Mo_4S_4(edta)_2]^{2-}$ are peaks λ (nm) (ε/M^{-1} cm^{-1} per cube) at 570 (820) and 945 (670). All studies were at 25.0 ± 0.1°C, and in aqueous perchloric acid solution with ionic strength *I* adjusted

to 1.00 M with $LiClO_4$. Stopped-flow studies were on a Dionex D-110 spectrophotometer, and rate constants were obtained using OLIS programs (Jefferson, Georgia, U.S.A.). Conventional time range spectrophotometry was carried out on a Perkin–Elmer Lambda 9 instrument.

Treatment of data

Second-order rate constants for the $V(O)_2^+$ reaction, eq. (3) and Fig. 2, were evaluated using a linear least-squares treatment with weighting to pass through the origin.

RESULTS

Oxidation of $[Mo_4S_4(edta)_2]^{4-}$

Both the $V(O)_2^+$ and BrO_3^- oxidants give $[Mo_4S_4(edta)_2]^{3-}$ in a fast process at pH < 3. At 25°C, $[H^+] = 0.025$ M, for example the 1 : 1 reaction with $V(O)_2^+$ is too fast to follow $k > 10^6$ M^{-1} s^{-1}. With excess oxidant the slower further oxidation to $[Mo_4S_4(edta)_2]^{2-}$ is observed. In the case of BrO_3^- it was possible to study the effect of further increases in pH without any structural changes occurring on the oxidant. At neutral pH in 0.5 M $LiClO_4$ the reaction is significantly slower, and with both reactants $[Mo_4S_4(edta)_2]^{4-}$ and BrO_3^- at 0.3 mM, the half-life is 10 min. The rate constant for the $[Mo_4S_4(edta)_2]^{4-}$ reaction with H^+ at 1 M total $[ClO_4^-]$ has been determined previously and is 76 M^{-1} s^{-1}, precluding studies at high $[H^+]$.[19]

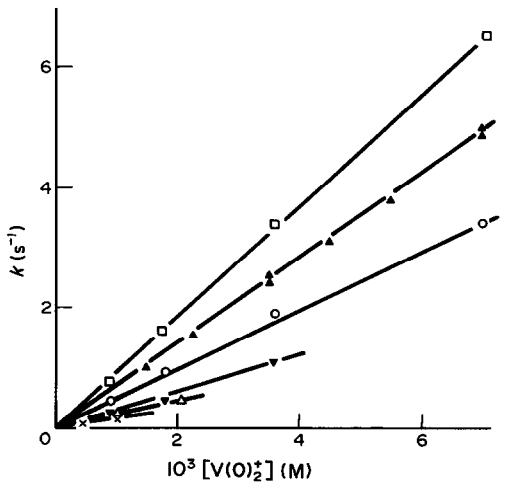

Fig. 2. The dependence of first-order rate constants k_{obs} (25°C) for the $V(O)_2^+$ oxidation of $[Mo_4S_4(edta)_2]^{3-}$ on oxidant concentration, and the effect of $[H^+]$/M: □, 0.2 M; ▲, 0.15 M; ○, 0.10 M; ▼, 0.050 M; △, 0.030 M; and ×, 0.025 M, $I = 1.00$ M ($LiClO_4$).

$V(O)_2^+$ oxidation of $[Mo_4S_4(edta)_2]^{3-}$

The reaction conforms to eq. (2):

$$[Mo_4S_4(edta)_2]^{3-} + V(O)_2^+ + 2H^+ \longrightarrow [Mo_4S_4(edta)_2]^{2-} + VO^{2+} + H_2O. \quad (2)$$

No further oxidation of $[Mo_4S_4(edta)_2]^{2-}$ is observed as in the corresponding oxidation of $[Mo_4S_4(H_2O)_{12}]^{5+}$, when the reaction of $[Mo_4S_4(H_2O)_{12}]^{6+}$ with excess $V(O)_2^+$ results in a break-up of the cube.[6]

Absorbance changes were monitored at 850 nm with $V(O)_2^+$ in more than a 10-fold excess. Good first-order behaviour was observed, yielding rate constants, k_{obs}, Table 1. From the dependence on $[V(O)_2^+]$, Fig. 2, second-order rate constants at each $[H^+]$ were obtained, Table 2. The $[H^+]$ dependence, Fig. 3, can be expressed as in eq. (3):

$$k = k_1 + k_2[H^+], \quad (3)$$

where $k_1 = 83 \pm 7$ M^{-1} s^{-1} and $k_2 = (4.6 \pm 0.4) \times 10^3$ M^{-2} s^{-1}. In the case of k_1, contributions from spurious effects due to the medium (validity of interchanging Li^+ and H^+)[20] cannot be ruled out, and

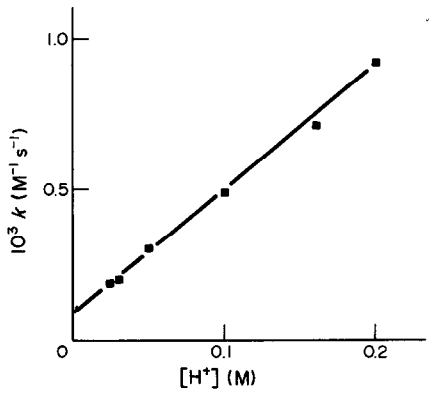

Fig. 3. The dependence of second-order rate constants k (25°C) for the $V(O)_2^+$ oxidation of $[Mo_4S_4(edta)_2]^{3-}$ on $[H^+]$, $I = 1.00$ M ($LiClO_4$).

for the $[H^+]$ range 0.025–0.200 M, k_2 is to be regarded as the principal rate law term.

BrO_3^- *oxidation of* $[Mo_4S_4(edta)_2]^{3-}$

The formation of $[Mo_4S_4(edta)_2]^{2-}$ was monitored at 945 nm with BrO_3^- in greater than 10-fold excess. The conversion $BrO_3^- \rightarrow Br^-$ was assumed to occur. Absorbance changes were more complicated as illustrated in Fig. 4. A slower second stage corresponding to further reaction (absorbance decrease) of the $[Mo_4S_4(edta)_2]^{2-}$ product was also observed. From initial slopes for the induction stage in Fig. 4, an $[H^+]^2$ dependence is observed, Fig. 5. Within experimental error the line passes through the origin. No reaction was obtained in neutral solutions indicating the need for H^+ for the reaction to proceed.

DISCUSSION

Two separate stages are observed in the reactions of excess $V(O)_2^+$ or BrO_3^- with $[Mo_4S_4(edta)_2]^{4-}$.

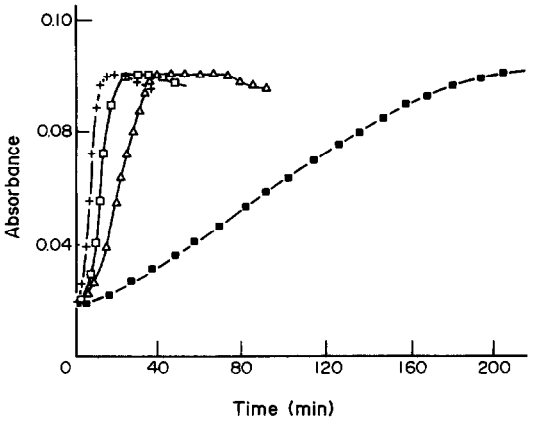

Fig. 4. Absorbance changes at 945 nm for the BrO_3^- oxidation of $[Mo_4S_4(edta)]^{3-}$ (both 1.5×10^{-4} M) at 25°C, at different $[H^+]$/M: +, 0.50; □, 0.38; △, 0.25; ■, 0.10.

At the end of the first stage the product is $[Mo_4S_4(edta)_2]^{3-}$. Whether reaction has occurred in a single redox step, or by a more circuitous route involving two-equivalent change to $[Mo_4S_4(edta)_2]^{2-}$ followed by comproportionation of the 4− and 2− states is not immediately clear. Elsewhere,[7] from studies on cross reactions, the self-exchange rate constants for $[Mo_4S_4(edta)_2]^{4-/3-}$ and $[Mo_4S_4(edta)_2]^{3-/2-}$ are very favourable (order of magnitude 10^6–10^7 $M^{-1}\,s^{-1}$) and give a comproportionation rate constant of 2.4×10^{10} $M^{-1}\,s^{-1}$. In these studies no initial rapid formation of $[Mo_4S_4(edta)_2]^{2-}$ as a product of a two-equivalent process was detected, but in view of the rapid comproportionation this is hardly a definitive test. For

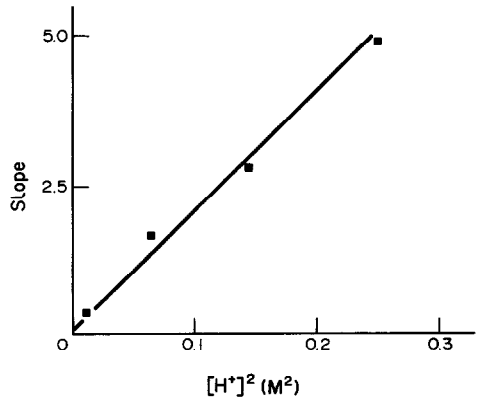

Fig. 5. Dependence of the initial slopes from Fig. 4 (arbitrary units) on $[H^+]$ for the BrO_3^- oxidation of $[Mo_4S_4(edta)_2]^{3-}$ at 25°C, $I = 1.00$ M ($LiClO_4$).

other reasons, namely the need for two-equivalent reactions to be inner-sphere, and the obvious difficulty of such a process occurring in the present case, one-equivalent changes seem most likely. Certainly we have no evidence for edta dechelation, and the molybdenums are expected to remain at least six-coordinate. There are in special cases examples of higher coordination numbers to molybdenum (e.g. with CN^-),[21,22] and in the case of edta complexes of d^5-ions, iron(III) and manganese(II).[23,24] However, an increase in coordination number involving the use of high energy orbitals may be more difficult for cuboidal Mo_4S_4, and at present there are no examples of this occurring.

The slower $V(O)_2^+$ and BrO_3^- oxidation of $[Mo_4S_4(edta)_2]^{3-}$ to $[Mo_4S_4(edta)_2]^{2-}$ was studied in separate experiments. A feature of the kinetics is the need for $[H^+]$ involvement in the rate laws. There are ambiguities with regard to interpretation, since although protonation of the oxidant might seem more obvious, the carboxylates of edta might also be involved. Such a protonation is not favourable however unless dissociation, i.e. aquation, of the carboxylate arm in question is occurring, and there is no evidence for this. Therefore the $[H^+]$ terms most likely originate from the oxidant, and are related to the need for protonation to facilitate the redox changes $V(O)_2^+ \rightarrow VO^{2+}$ and $BrO_3^- \rightarrow BrO_2$. The kinetics in the case of the $V(O)_2^+$ oxidation are relatively straightforward, and a rate law first-order in oxidant and reductant is observed. For the $[H^+]$-dependent k_2 term it is likely that $V(O)_2^+$ brings a proton into the activated complex. Similar $[H^+]$-dependences have been observed previously.[25,26] At high $[H^+]$ values an $[H^+]^2$ term might be expected to contribute.

The BrO_3^- oxidation is more complex, as Fig. 4 clearly illustrates, and an induction period is observed. From the initial slopes an $[H^+]^2$-dependence is apparent, Fig. 5. The propagation step, exhibiting at least a first-order $[H^+]$-dependence, is followed by an abrupt termination of reaction. An induction phase has been observed previously in BrO_3^- reactions, and interpretations have been summarized in the review by Thompson.[16] There are two possible explanations for the initial stage. This can be due to a rate law term $[H^+]^2[BrO_3^-][Br^-]$ giving autocatalytic behaviour, as is observed with reductants such as $[Fe(CN)_6]^{4-}$. Alternatively, with less strong reductants such as cerium(III), manganese(II) or neptunium(V), a poorly defined induction period is followed by a rate law dependence $[H^+]^2[BrO_3^-]^2$.[27,28] For the reduction potential applying in this instance (0.69 V),[7] the first of these explanations is the more likely.

(*Received* 31 *March* 1989; *accepted* 20 *July* 1989)

Abstract—A systematic study of the factors affecting the extraction of strontium, as an ion-pair formed between the positively charged cryptate of strontium with cryptand 2.2.2 and the eosinate anion, into chloroform has been carried out. The pK_1 and pK_2 values of the ligand, the stability constant of the cryptate inclusion complex, as well as the partition coefficient and the extraction constant of the ion-pair, were measured as a function of the ionic strength of the solution. The pK_a and K_s values remained reasonably constant at ionic strength $\leqslant 0.1$ M. Nevertheless, the partition coefficient values, and consequently the extraction constant values, decrease as the ionic strength increases.

Recently, a large number of papers dealing with the extraction constants of crown- and cryptand–ether complexes of alkali and alkaline-earth ions associated with coloured or fluorescent anions have been published. Much less work has been carried out on analogous systems involving transition metals as well as lanthanide and actinide ions. The overall extraction equilibrium formulated by Frensdorff[1] can be rewritten as

$$M^{n+} + L + A^{n-} \overset{K_{ex}}{\rightleftharpoons} (MLA)_o, \qquad (1)$$

where M^{n+}, L, A^{n-} and $(MLA)_o$ are the metal cation, the cyclic polyether, the counter-ion and the ion-pair, respectively. The subscript o and the absence of a subscript denote the organic and the aqueous phase, respectively. The equilibrium constant of eq. (1) was designated as the extraction constant, K_{ex}:

$$K_{ex} = [MLA]_o/[M^{n+}][L][A^{n-}],$$

where the brackets denote equilibrium activities. This extraction equilibrium may be analysed in terms of two constituent equilibria which, when added to each other, give eq. (1):

$$M^{n+} + L \overset{K_s}{\rightleftharpoons} ML^{n+}$$

$$ML^{n+} + A^{n-} \overset{P_{CT}}{\rightleftharpoons} (MLA)_o.$$

The two equilibrium constants are K_s, the aqueous stability constant of the binary complex, and P_{CT}, the partition coefficient of the complex from separate ions in the aqueous phase into ion-pairs in the organic phase. Thus the overall extraction equilibrium constant is given by

$$K_{ex} = K_s P_{CT}.$$

If the ligand is a diamine or cryptand the following acid–base equilibria take place:

$$LH_2^{2+} \overset{K_1}{\rightleftharpoons} LH^+ + H^+$$

$$LH^+ \overset{K_2}{\rightleftharpoons} L + H^+.$$

Addition of a metal cation, M^{n+}, will thus affect the basicity of a solution of the free ligand. The role of these equilibria will be considered in detail in the Experimental.

However, in more recent publications the extraction constants have been reported using concentrations (K_{ex}^{conc}) instead of activities, and the extraction method has been applied at appreciable

ionic strengths, e.g. for the determination of K^+ in blood serum[2,3] or Pb^{2+} in tap water[4] and soft drinks,[5] where K_{ex}^{conc} differs considerably from K_{ex}.

In our earlier studies we have observed a critical influence of ionic strength on the extraction of some metal ions, e.g. K^+, Sr^{2+}, Ca^{2+} or Pb^{2+}, with crown– and cryptand–ethers. Thus, while the extraction of potassium with 18-crown-6[3] or lead with 18-crown-6[4] or cryptand 2.2.2[5] is not affected by this parameter (probably due to the formation of polymeric species in the organic phase), an increase in the ionic strength promotes a sharp decrease in the extraction of lead with cryptand 2.2.1[6] or strontium with cryptand 2.2.2,[7] using eosin as the counter-ion, and consequently a decrease in the fluorescence intensity of the organic phase. This factor could be a problem in the analytical application of these extraction systems. For this, we are at present engaged in a detailed study of various factors which affect the extraction constants of potassium, strontium and lead, including extraction of polymeric species and effects of counter-ion and solvents for the extraction.

In the present study we report the effect of ionic strength on the extraction of strontium using cryptand 2.2.2 (L) as the ligand, eosinate (A) as the counter-ion and chloroform as the extractant. On this account, we have studied the effect that the variation of the ionic strength causes on the different constants involved in the extraction process: the dissociation constants of the ligand, the stability constant of the cryptate inclusion complex, the partition coefficient and the extraction constant of the ion-pair, and the partition coefficient of the complex.

EXPERIMENTAL

Reagents and equipment

All reagents were of analytical grade and doubly distilled and demineralized water was used throughout.

Cryptand 2.2.2. The commercial product (Kryptofix 2.2.2 from Merck) was used as received. An aqueous stock solution (1.689×10^{-4} M) of the cryptand was stored in a PVC container and was diluted as required before use.

Strontium(II) *stock solution* (0.0114 M). Prepared by dissolving 1.2063 g of strontium nitrate in water, diluting to 500 cm^3 and standardizing by complexometric titration. All working standard solutions (5.772×10^{-5} M) were freshly prepared by appropriate dilution of the stock solution.

Eosin acid aqueous solution (8.970×10^{-3} M). Prepared by dissolving 0.1453 g of eosin in 25 cm^3 of basic water. Eosin was synthesized by reaction of Br^-/BrO_3^- with fluorescein in an acidic water–acetone mixture as described elsewhere.[8]

Tetramethylammonium hydroxide (4.388×10^{-2} M). The $(CH_3)_4N^+$ cation would be large enough so as not to enter the intramolecular cavity of the ligand. The basic solutions were made from commercial Fluka AG reagent. Preliminary titration showed about 3% of the latter to be carbonated. In order to avoid carbonation of these basic solutions argon was bubbled through them and they were stored in PVC containers.

The instrumentation included a UV–vis spectrophotometer (Perkin–Elmer, model 124) with quartz cells (10 mm path), an LS-5 Perkin–Elmer spectrofluorimeter equipped with a Model 3600 data-station, an inductively coupled plasma Perkin–Elmer spectrometer model 5000, a Crison-501 potentiometer and a Dosimat automatic microburet. A thermostatted shaker (Grant) with a time switch was used for horizontal shaking of the stoppered tubes.

Potentiometric titrations

To determine the protonation and the stability constants (K_1, K_2 and K_s), solutions of the protonated ligands (0.02 M) alone and in the presence of Sr^{2+} (0.01 M) were titrated with a strong base, $(CH_3)_4NOH$ (0.073 M). Variable concentrations of supporting electrolyte, $(CH_3)_4NBr$, in order to maintain the ionic strength (0.01, 0.05 and 0.10 M) in the test solution and in the titrant, were used. Calibration of the cell was achieved with HNO_3 solutions at different ionic strengths by titration with tetramethylammonium hydroxide. The potential of the solutions was measured with the following cell: glass electrode/test solution (I = 0.01–0.10 M, $(CH_3)_4NBr$)/0.01–0.10 M $(CH_3)_4NBr$, SCE, in order to avoid diffusion phenomena of potassium from the calomel electrode.

All measurements were performed in a glass cell maintained at 25 ± 0.1°C. Portions of 0.01 cm^3 of

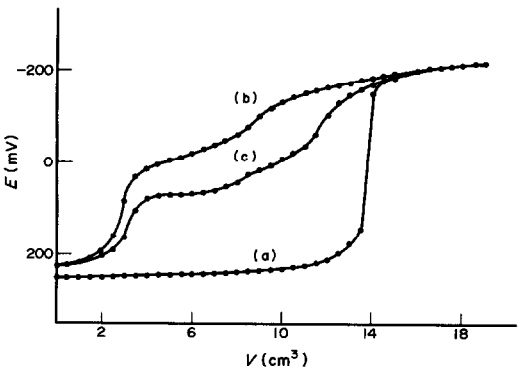

Fig. 1. Potential measurements (E) as a function of the volume of alkali added (V) to solutions containing: (a) strong acid (HNO_3); (b) strong acid and ligand (cryptand 2.2.2); (c) strong acid, ligand and metal ion (Sr^{2+}); $I = 0.01$ M.

titrant were added from an automatic microburet. The titration cell was purged with argon which had previously been saturated with water at 25°C. A typical titration curve is shown in Fig. 1. The results were analysed using a general equilibrium-solving program, MINIPOT,[9] to calculate the protonation and the formation constants.

Extraction procedure

An aliquot (5 cm^3) of an aqueous solution containing the metal ion (1.154×10^{-5} M), the cryptand solution (5.067×10^{-5} M), the $(CH_3)_4NOH$ solution (4.388×10^{-3} M, pH = 11.5), the eosinate anion for the formation of the ion-pair (9.440×10^{-6}–1.4×10^{-4} M; this concentration range allows extraction yields ranging from 15 to 85% to be obtained), and variable concentrations of $(CH_3)_4NBr$ solution in order to keep the ionic strength at 0.01, 0.05 or 0.10 M, was placed in a glass cylindrical tube with a PVC stopper. After the addition of 5 cm^3 of chloroform, the mixture was shaken for 60 min at 25 ± 0.1°C. The solvents were saturated with each other before use to prevent volume changes in the phases during extraction. The mixture was centrifuged for 5 min to separate the phases, the pH of the aqueous phase was checked and the concentration of the metal ion was measured by ICP emission photometry at 407.77 nm. Eosin equilibrium concentrations in the aqueous layer were measured spectrophotometrically at 516 nm. Strontium concentrations in the organic phases were determined as follows: 4 cm^3 of the chloroform phase were allowed to evaporate, the residue was dissolved in 10% nitric acid solution and determined by ICP emission photometry.

Partition coefficient of cryptand 2.2.2

Partition coefficients, $P(L)$, at different ionic strengths were determined by equilibration of equal volumes of the cryptand solution in water and in chloroform, followed by spectrofluorimetric determination of the amount of cryptand remaining in the aqueous phase. The determination was carried out by addition of eosin and strontium to the aqueous phase and extraction of the cryptand–strontium–eosinate complex into chloroform, following the general extraction procedure described elsewhere.[7] The concentration found in this way in the aqueous phase was subtracted from the initial total concentration of cryptand to deduce the concentration in the organic phase.

RESULTS AND DISCUSSION

Table 1 shows the results obtained for the concentration equilibrium constants, K_s, of complexes of cryptand 2.2.2 with Sr^{2+} at different ionic strengths, as well as the pK_1, pK_2 and $P(L)$ values of the ligand. As can be seen, in the ionic strength range 0.01–0.10 M, the concentration formation constant remains reasonably constant and close to values from the literature.[10,11] In a similar manner, the pK_a and $P(L)$ values of the ligand present a similar behaviour.

Distribution coefficient

When a divalent metal ion M^{2+}, such as Sr^{2+}, forms a complex with a cryptand, L, such as cryptand 2.2.2 and the complex is extractable as an ion-pair with large anions, A^{2-}, such as the eosinate ion, the distribution coefficient (D) for the extraction system

$$pM^{2+} + qL + rA^{2-} \rightleftharpoons (M_pL_qE_r)_o$$

may be written as

$$D = \sum[M^{2+}]_o / \sum[M^{2+}]$$

$$= \sum_{1}^{p,q,r} p[M_pL_qE_r]_o / [M^{2+}] + [ML^{2+}] + \sum_{1}^{i,j} [M_j(OH)_i^{2j-i}], \quad (2)$$

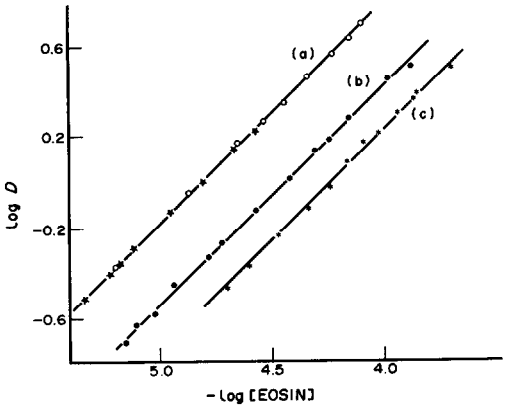

Fig. 2. Dependence of the distribution ratio for strontium on the eosin concentration in the aqueous phase at different ionic strengths: (a) $I = 0.01$ M, [2.2.2] = 5.07×10^{-5} M; ○ $[Sr^{2+}] = 1.14 \times 10^{-5}$ M, [eosin] = $(1.07\text{–}8.75) \times 10^{-5}$ M; ★ $[Sr^{2+}] = 5.71 \times 10^{-6}$ M, [eosin] = $(0.72\text{–}3.87) \times 10^{-5}$ M. (b) $I = 0.05$ M, [2.2.2] = 5.07×10^{-5} M, $[Sr^{2+}] = 1.14 \times 10^{-5}$ M, [eosin] = $(1.1\text{–}14.0) \times 10^{-5}$ M. (c) $I = 0.10$ M, [2.2.2] = 5.07×10^{-5} M, $[Sr^{2+}] = 1.14 \times 10^{-5}$ M, [eosin] = $(2.9\text{–}25.1) \times 10^{-5}$ M.

assuming that the association between ML^{2+} and A^{2-} in the aqueous phase and the dissociation of the ion-pair in the organic phase are negligible.

The strontium–cryptand ratio was described as 1 : 1, with strontium occupying a central position in the cavity of the macrobicyclic ligand.[10] The dissociation constants of eosin[12] and the pH value of 11.5 used suggest that only a neutral complex (1 : 1 : 1, strontium–cryptand–eosin) should be extracted.

If we suppose that non-polimeric species are formed in the organic phase and that under the experimental conditions used one may assume that $[ML^{2+}] \gg [M^{2+}]$ and that the hydroxylation of the metal cation is negligible, eq. (2) can be rewritten by using the partition coefficient of the complex, P_{CT},

$$\log D = \log P_{CT} + \log [A^{2-}].$$

The experimental results are shown in Fig. 2. The slope of the $\log D$ vs $\log [A^{2-}]$ plot is unity for the same strontium concentration and different ionic strengths tested, which clearly indicates the 1 : 1 : 1 metal–ligand–counter-ion stoichiometry. On the other hand, the superposition of the extraction curves (A) for different strontium concentrations at the same ionic strength indicates the non-existence of polymerization reactions.

Table 2. P_{CT} and K_{ex} values for the strontium–cryptand 2.2.2–eosin system in chloroform at different ionic strengths

I	$\log P_{CT}$	$\log K_{ex}$
0.01	4.86±0.05	13.11±0.03
0.05	4.42±0.01	12.53±0.02
0.10	4.17±0.04	12.13±0.06

The data obtained from these experiments have been refined by the LETAGROP program version DISTR[13] which provides the partition coefficients and extraction constants at different ionic strengths. The results are shown in Table 2 and Fig. 3. As can be seen, the value of the concentration formation constant remains reasonably constant as long as the partition coefficients and obviously the extraction constants decrease appreciably as the ionic strength increases. These results clearly explain the decrease of fluorescence intensity of the ion-pair (λ_{ex} = 536

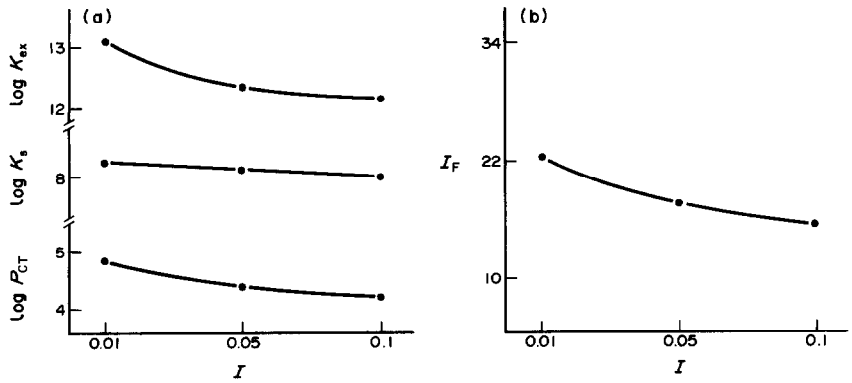

Fig. 3. Influence of ionic strength on: (a) The partition coefficients (P_{CT}), the concentration formation constants (K_s) and the extraction constants (K_{ex}). (b) The fluorescence intensity of the ion-pair in the organic phase.

nm, $\lambda_{em} = 552$ nm) in the organic phase with increasing ionic strength as it can be deduced from the same figure.

CONCLUSIONS

Our results on stability constants are in accordance with the studies of Lehn and Sauvage,[10] and Smetana and Popov.[14] They reported a change in $\log K_s$ of less than 0.3 for a variation of ionic strength from 0.005 to 0.3 M.

In a recent study on the effects of ionic strength on the extraction of potassium complexed with 18-crown-6, Kolthoff[15] reported the salting-out effect on the partition coefficient of the crown-ether, an effect which is not observed by us in the present study. The partition coefficients of cryptand 2.2.2 are the same for the different ionic strengths tested. From these results, it can be concluded that the ionic strength critically affects the association of ion-pairs in the aqueous phase and its extraction into the organic phase. This trend and the absence of secondary reactions, such as polymerization, observed in other systems,[6] promotes the fluorescence decrease observed.

Abstract—The two-electron reduction of dinuclear ruthenium complexes $[RuCl_2(\eta^6\text{-}p\text{-cymene})]_2$ (p-cymene = p-$CH_3C_6H_4CH(CH_3)_2$] give the corresponding relatively stable ruthenium(I) dimer derivative. The same species can also be obtained by electrochemical reduction of the cationic complexes $[(\eta^6\text{-}p\text{-cymene})Ru(\mu\text{-}Cl)_3Ru(\eta^6\text{-}p\text{-cymene})]PF_6$. A redox mechanism is proposed.

Dinuclear ruthenium(II) complexes of the type $[RuCl_2(arene)]_2$, [arene = C_6H_6; 1,4-$CH_3C_6H_4CH(CH_3)_2$] have been used as starting materials in a variety of reactions.[1] In particular, ruthenium(0) arene complexes have been prepared by chemical reduction of these ruthenium(II) complexes.[2] We are interested in exploring the potential utility of arene compounds of the type $[RuCl_2(arene)]_2$ as starting materials for the preparation of relatively uncommon[3] ruthenium(I) complexes. We report here the electrochemical behaviour of $[RuCl_2(\eta^6\text{-}p\text{-cymene})]_2$ (**1**) and the related cationic complex $[(\eta^6\text{-}p\text{-cymene})Ru(\mu\text{-}Cl)_3Ru(\eta^6\text{-}p\text{-cymene})]PF_6$ (**2**).

RESULTS

Compound **1** in THF exhibits, by linear sweep voltammetry (Pt electrode at 0.1 V s^{-1}), three reduction peaks B, −0.74; A_1, −0.98; and A_2, −2.08 V (Fig. 1). A small shoulder at −1.8 V is also always present. If the sweep is reversed after peak A_1, two oxidation peaks A'_1, −0.86 V and A'_3, −0.08 V are detected. The couple A_1/A'_1 is not totally reversible ($i_p(A'_1)/i_p(A_1) = 0.75$ and $\Delta E_p = E_p(A_1) - E_p(A'_1) = 0.12$ V at 0.1 V s^{-1}). The relative intensity of these two oxidation peaks depends

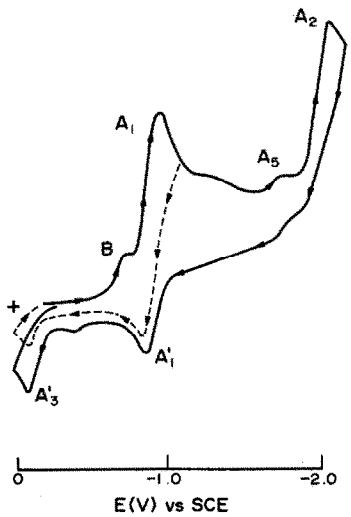

Fig. 1.

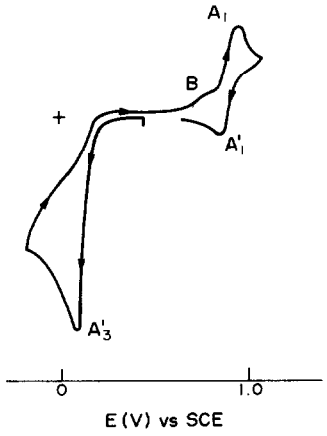

Fig. 2.

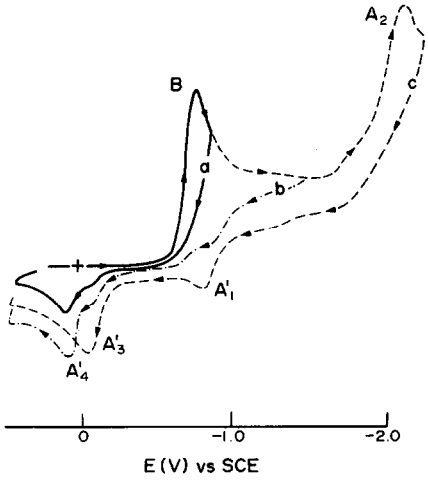

Fig. 3.

on the sweep rates used; at 0.01 V s^{-1} only A'_3 can be observed in the reverse anodic sweep.

After exhaustive electrolysis of $[RuCl_2(\eta^6\text{-}p\text{-cymene})]_2$ on the plateau of peak A_1 (−1.30 V) using a platinum electrode, 2F/mol of dimer are consumed. The voltammogram at a rotating disc electrode (r.d.e.) of the resulting solution, exhibits the waves A'_3 and A_2. By cyclic voltammetry, after oxidation at the A'_3 peak, the system A_1/A'_1 and peak B are clearly detected (Fig. 2). After electrolysis no EPR signal can be detected in the resulting solution.

Some evolution can be observed in the voltammogram when this reduced solution is left to stand at room temperature in the cell; A'_3 decreases in intensity and at the same time A_1 appears again. After 2 h A'_3 has practically disappeared and the voltammogram shows mainly A_1 as well as some unidentified peaks in the range 1.3–2.0 V. The electrolysis on the plateau of the A_2 peak gives a total charge consumption of nearly 4F/mol.

Compound **1** in dichloromethane also shows two reduction peaks, by linear sweep voltammetry (at Pt electrode at 0.1 V s^{-1}), B, −0.78 and A_1, −1.30 V. The narrower electrochemical range of dichloromethane prevents the observation of any reduction peaks at higher potential values. In this case only one oxidation peak A'_3, −0.20 V can be detected in the reversed anodic sweep; the A'_1 peak, observed working in the same experimental conditions but using THF as solvent, can only be detected in dichloromethane solution if an excess of NEt_4Cl is added, with a simultaneous decrease in temperature to 0°C and increase of the sweep rate to 1 V s^{-1}.

We have also studied the electrochemical behaviour of the cationic complex **2**. By cyclic voltammetry in THF, peaks B and A_2 are detected in the cathodic sweep. If the sweep is reversed immediately after peak B, we observe two oxidation peaks, A'_3 and A'_4 [Fig. 3(a)], but if the sweep range is increased towards more negative values the oxidation peak A'_1 appears with low intensity in addition to A'_3 and A'_4 [Fig. 3(b)]. Finally, if the sweep range includes the A'_2 peak, A'_1 and A'_3 are the only important oxidation peaks observed in the anodic sweep [Fig. 3(c)]. If potential controlled electrolysis is performed at the potential value of B, a variable charge consumption is found (more than 1F/mol) and the r.d.e. voltammogram shows the oxidation wave A'_3 and the reduction wave A_1. No EPR signal is detected for the resulting solution.

DISCUSSION

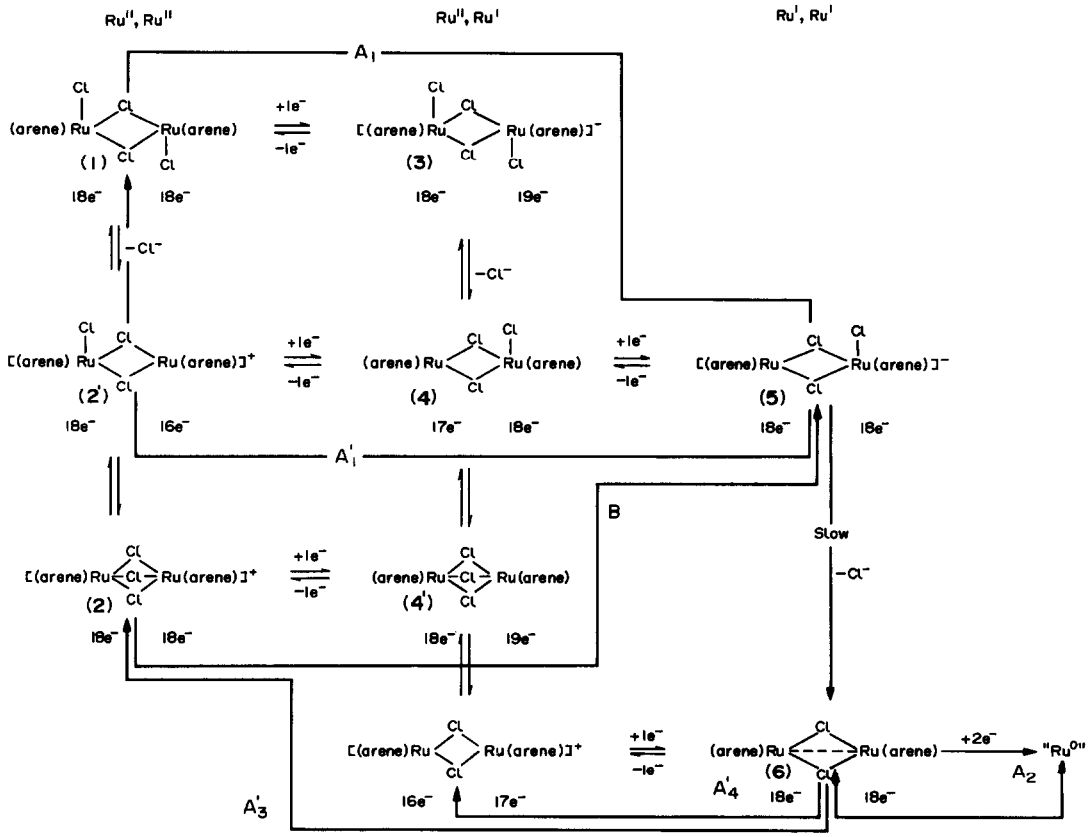
The previous results can be interpreted most consistently according to Scheme 1.

The first small reduction peak, B, always observed in the voltammogram of compound **1** corresponds to the reduction of the cationic species $[(\eta^6\text{-}p\text{-cymene})Ru(\mu\text{-}Cl)_3(Ru(\eta^6\text{-}p\text{-cymene})]^+$ existing in equilibrium with **1** in the experimental conditions according to:

$$[RuCl_2(\eta^6\text{-}p\text{-cymene})]_2 \overset{NBu_4PF_6/THF}{\rightleftharpoons} [(\eta^6\text{-}p\text{-cymene})Ru(\mu\text{-}Cl)_3Ru(\eta^6\text{-}p\text{-cymene})]^+ + Cl^-.$$

This transformation probably occurs via the unsaturated intermediate species (16–18e$^-$), **2'**. After the two-electron reduction of **1** at the potential value of peak A_1, an oxidizable species, A'_1, must be obtained firstly.

A mechanism EE for the electrochemical reduction of **1** is unlikely. An ECE mechanism seems to be more likely according to $\Delta E_p = E_p(A_1) - E_p(A'_1) = 120$ mV higher than that found for the reversible system Cp_2Co^+/Cp_2Co (65–70



Scheme 1.

mV) in similar experimental conditions. The observation that an excess of NEt_4Cl in CH_2Cl_2 solution at low temperature increases the intensity of A'_1 suggest that the chemical reaction associated with the electrochemical process must be the rapid dissociation chloride ion. The intermediate species **4** with 17–18 electrons reduces in the same range as the initial product **1**, yielding the 18–18-electron anionic species **5** (see Scheme 1). The two-electron reduction of **5** (A_5 peak), yields a very unstable ruthenium(0) species.

A similar pattern has been proposed for the electrochemical reduction of dinuclear arene complexes of bis(tricarbonylchromium). In this case the chemical reaction changes the type of coordination of the arene ligands.[4]

The oxidation of species **5**, can occur by two different methods: (a) **5–4–3–1** and (b) **5–4–2–1**. There is not enough data available to decide which one of these reaction pathways is the correct one. In the first pathway (**5–4–3–1**) we should obtain an $\Delta E_p = E_p(A_1) - E_p(A'_1)$ value of approximately 30 mV if the equilibrium **3** → **4** is rapidly established.

Species **5** (18–18e$^-$) cannot be obtained by electrolysis because it undergoes chemical evolution to complex **6**, which oxidizes to A'_3 and reduces to A_2. This intermediate ruthenium(I) species can be formulated either as a dinuclear compound with two bridging chlorine atoms and a ruthenium–ruthenium bond or as a paramagnetic mononuclear compound. Some evidence supporting a dimeric formulation can be obtained from the electrochemical behaviour of several mono- and dinuclear ruthenium(II) arene complexes (see Table 1). The observed ΔE_p^* $[\Delta E_p^* = E_p(A_1) - E_p(A_2)]$ values are only significant in dinuclear compounds containing bridging ligands between the ruthenium atoms. These data indicate that the intermediate oxidation state is only stabilized in dinuclear compounds where a metal–metal bond can be formed. Thus we can propose that the product of a two-electron reduction of **1** will be a dimer. The lack of an EPR signal also supports the proposed formation of a compound with a metal–metal bond.

The ruthenium(I)–ruthenium(I) species are not stable enough to allow their isolation. Considering the high value of ΔE_p^* these species should be stable against a disproportionation reaction:

$$2Ru^I—Ru^I \longrightarrow Ru^{II}—Ru^{II} + 2Ru^0.$$

As A'_3 disappears with the formation of the starting material **1**, which is identified by the reduction peak A_1, we assume that a dissociation of the dimeric ruthenium(I) compound is the cause of its limited

Table 1.

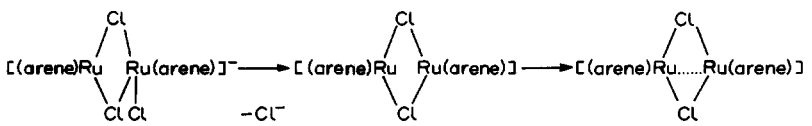
stability. Similar behaviour has been observed for the electrogenerated cyclopentadienyl niobium(III) complexes[6] in which very unstable bridging Nb—Cl—Nb bonds have been found. In this case Cp_2NbCl_2 and "Cp_2Nb" are obtained in a 1 : 1 ratio.

The presence of peak A_2 with high intensity indicates the existence of **6** by cyclic voltammetry. However, the transformation of **5** to **6** is slow, in good agreement with the fact that the A'_1 peak is clearly detected. In order to interpret these results, we can assume that the reduction of **5** takes place by means of a CE mechanism. The chemical reaction is the transformation of **5** into **6**.

The assignment of peak A_5 is complicated. This peak must be associated with the reduction of a very unstable intermediate species, only observed by cyclic voltammetry and with low intensity. The transformation of **5** into **6** implies initially the loss of a chloride ion yielding complex **5'**, according to the following reaction:



(5) (5') (6)

This intermediate complex **5'** (17–17e$^-$) should reduce more easily than complex **6**. Compound **1** is formed by electrochemical oxidation of **6**, at the potential value of A'_3, in the presence of free chloride ions.

The proposed mechanism is also in good agreement with the experimental results obtained for the cationic compound **2**. By cyclic voltammetry we have confirmed that the two-electron reduction of **2** gives the intermediate **5**. The reduction of **2** takes place according to an ECE mechanism. The chemical step consists of a fast cleavage of the ruthenium–chloride bridging bond to give **4** (17–18e$^-$) which reduces more easily than **2**.

By cyclic voltammetry for compound **2**, in the reversed sweep (if A_2 is not scanned) the A'_1 peak is not detected [Fig. 3(a)] or is only detected with low intensity [Fig. 3(b)]. This observation can be explained by a rapid cation–anion reaction of the electrogenerated species **5** with **2** present in solution according to:

$$5+2 \rightarrow 6+1.$$

If the sweep is extended to more negative values [Fig. 3(b) and 3(c)], complex **5** is electrogenerated in higher amounts and the chemical reaction **5**+**2** → **6**+**1** can not be completed because of insufficient diffusion of compound **2** from the bulk solution to the electrode. Due to this peak, A'_1, corresponding to the oxidation of **5**, is observed with increasing intensity. This is in agreement with the values of the charge consumptions obtained by PCE and also with the resulting products.

Peak A'_4 is assigned to the oxidation of **6** in the absence of free chloride ions. In the presence of free chloride ions, generated as a consequence of the reduction of the starting compound, the oxidation takes place at the potential value of A'_3. According to this, two different pathways can be proposed for the oxidation of **6**, depending on the amount of chloride ions on the electrode surface (see Scheme 1).

EXPERIMENTAL

$[RuCl_2(arene)]_2$ and $[(arene)Ru(\mu_3\text{-}Cl)_3Ru(arene)]BPh_4$, where arene = *p*-cymene, were prepared by literature procedures.[7,8]

The electrochemical studies were conducted in tetrahydrofuran and dichloromethane with tetrabutylammonium hexafluorophosphate (0.2 M) as supporting electrolyte. Cyclic voltammograms were obtained with a programming function generator, A 305 HQ instruments, connected to a 552 Amel potentiostat. Voltammograms were recorded with a Riken–Denshi Co. Ltd F-35 *X–Y* recorder.

The working electrode was a platinum disc with a saturated calomel reference electrode separated from the test solution via a salt bridge containing the solvent/supporting electrolyte. The auxiliary electrode was a platinum wire.

Tetrahydrofuran was dried with sodium benzophenone. Dichloromethane was dried with P205. Both solvents were freshly distilled before each experiment. The electrochemical cell used for potential controlled electrolysis was a conventional H-type design with an isolation compartment separated from the reference and other compartments by fine porosity frits.

All experiments were carried out under an argon atmosphere.

Acknowledgements—We thank the Comisión Asesora de Investigación Científica y Técnica (CAICYT) for financial support and Professor C. Moise for helpful discussions.

(*Received* 28 *April* 1989; *accepted* 24 *July* 1989)

Abstract—As the first step in the investigation of tin and technetium complexes of 2,3-dimercaptosuccinic acid (DMSA), the thermodynamic values of the DMSA ligand—dissociation constants, free energy, enthalpy and entropy have been determined. Dissociation constants have been determined by potentiometric titration. The following logarithmic values for the four thermodynamic constants were obtained: 2.5 ± 0.07, 3.9 ± 0.08, 10.1 ± 0.1 and 11.4 ± 0.1 at 293 K; 2.5 ± 0.05, 3.9 ± 0.06, 9.7 ± 0.07 and 10.8 ± 0.1 at 303 K; and 2.5 ± 0.05, 3.8 ± 0.04, 9.7 ± 0.09 and 10.7 ± 0.1 at 310 K. At 303 K the following thermodynamic parameters of the dissociation were calculated: changes in free energy, in free entropy and in free enthalpy.

Complexes of 2,3-dimercaptosuccinic acid (DMSA) with Tc-99m have been well known for many years and very widely used in nuclear medical diagnosis.[1–6] The complexes of Tc-99m and DMSA form in presence of tin(II). The first step in the examination of Tc–DMSA complexes is the examination of tin(II) complexes, which in turn requires exact data about dissociation constants of DMSA.

Ionization constants of DMSA were previously determined by several authors[7–10] and can be also found in certain reviews.[11,12] The dissociation constants reported are given at only two temperatures (293 and 298 K), and at one ionic strength, $\mu = 0.1$ M.

The aim of this work was to determine the ionization constants of DMSA at various temperatures and ionic strengths of the medium.

EXPERIMENTAL

Reagents and solutions

Meso-2,3-dimercaptosuccinic acid was purchased from Fluka (Buchs, Switzerland), pure (higher than 98%, m.p. 210°C). The chemical purity of the substance was checked by IR spectrometry and by determination of the melting point (softening started at 196–198 K, followed by decomposition at 210 K, which was in accordance with literature data[8]). Standardization was performed by potentiometric titration, showing the high purity of the ligand.

The ionic strengths were adjusted by addition of hydrated sodium perchlorate (Merck, Darmstadt, F.R.G.). Sodium hydroxide solution, standardized by potassium phthalate, was used as a titration agent. For calibration of the electrode system, phosphate buffer pH $= 7.0 \pm 0.02$ and phthalate buffer

* Author to whom correspondence should be addressed.

pH = 4.01 ± 0.01 (at 293 K) (product of Beckman Instruments) were used.

For preparation of the solutions, double-distilled and degassed water (cooled in a stream of nitrogen) was used.

A stock solution of DMSA (1×10^{-3} mol dm^{-3}) was prepared every day and dissolution was accelerated only by magnetic stirring at room temperature for 1 h. The heating was avoided in order to preserve chemical stability. The concentrations mentioned have been chosen as optimum, depending on the solubility of DMSA in water (4.09 mol dm^{-3} at 25°C).[17] The working solutions of DMSA (concentration of 5×10^{-4} mol dm^{-3}) were made by dilution of the stock solution and addition of $NaClO_4$ and water until the volume reached 25 cm^3. The working solution was purged with nitrogen in the titration cell, the temperature was equilibrated to a definite constant value and titration carried out by continual addition of 0.1 M NaOH as a titrant, with continual stirring.

Instrumentation

All potentiometric measurements were performed on a fully automated titration system ETS-822 (Radiometer, Copenhagen, Denmark). The glass electrode G2040C was used as the indicator electrode, while a saturated calomel electrode K 4040 was used as the reference electrode (both "Radiometer"). Titrations were performed in a closed system with a continual flow of purified nitrogen. The gas was purified by passing through two washing bottles: the first one containing Fieser's solution (for elimination of CO_2 and/or O_2) and the second one containing water for absorption of possible traces of alkaline vapours from the first bottle.

Titrations were performed at temperatures of 293, 303 and 310 K. A constant temperature in the range ±0.2 K was maintained by using the thermostat VEB Mechanik Prüfgeräte, Medingen, F.R.G.

Procedure

In calculations related to strongly alkaline regions of titrations curves (for pH values higher than 9), the correction for sodium ion concentration was made according to Linnet.[13]

Activity coefficients, necessary for the assessment of hydrogen ion concentrations, were calculated according to Debye–Hückel using the values for the effective radii of the hydrated ion published by Kielland.[14]

A combined algebraic–graphical method by Schwarzenbach[15,16] was used for calculation of ionization constants. The DMSA ligand has two ionization constants in the acidic region between pH 3 and 5 (due to dissociation of two carboxyl groups), and two dissociations in the alkaline region between pH 8 and 10 (due to ionization of thiolate groups). All four constants were calculated by the algebraic method, while K_2, K_3 and K_4 were also determined by a geometric method.

Thermodynamic parameters

The change in free energy, ΔG, for all four dissociation constants has been calculated by use of the Van't Hoff equation, change in entropy, ΔS, according to the Gibbs–Helmholz relationship, and

Table 1. Ionization constants of *meso*-2,3-dimercaptosuccinic acid

0.05	303	2.6±0.07	3.8±0.04	9.6±0.05	10.8±0.1
	310	2.6±0.06	3.7±0.04	9.5±0.03	10.6±0.2
	293	2.5±0.08	3.8±0.06	9.9±0.03	11.3±0.2
0.01	303	2.6±0.07	3.8±0.03	9.6±0.05	10.8±0.1
	310	2.5±0.08	3.8±0.05	9.6±0.03	10.7±0.2
	293	2.5±0.07	3.9±0.08	10.1±0.1	11.4±0.1
0	303	2.5±0.05	3.9±0.06	9.7±0.07	10.8±0.1
	310	2.5±0.05	3.8±0.04	9.7±0.09	10.7±0.1

the change in enthalpy, ΔH, according to the Arrhenius equation (from the slope of the line $\ln K$ vs $1/T$).

RESULTS

All four concentration constants of DMSA dissociation have been calculated using the results obtained by performing a series of six titrations for every working temperature (293, 303 and 310 K) and for every ionic strength (0.1, 0.05 and 0.01 M). The exact concentration of DMSA was determined from the equivalence point. The recorded titration curves have been read at a pitch of 0.004 cm^3 and correlated with the corresponding pH. The values obtained for the ionization constants at temperatures of 293, 303 and 310 K, as well as at ionic strengths 0.1, 0.05 and 0.01 M are presented in Table 1 with the corresponding standard deviations. Thermodynamic dissociation constants at zero ionic strength at 293, 303 and 310 K have been determined by a graphical method, by extrapolation of the straight line $\log K_n$ vs $\sqrt{\mu}$ and they are also given in Table 1. Thermodynamic parameters of the DMSA dissociation are presented in Table 2.

DISCUSSION

The results obtained for an ionic strength equal to 0.1 M are in close agreement with the majority of literature values (Table 3), especially for the pK_2, pK_3 and pK_4 values, whereas for pK_1 the differences are more pronounced. In our opinion, the differences are due to the degree of purity of the starting substance. The exact concentration of the stock solution of DMSA was checked by determination of the equivalence point, as mentioned in the Experimental.

The previously published data have been here confirmed and completed with other relevant and significant data and physicochemical parameters.

COMPLEXES OF RUTHENIUM(III) DERIVED FROM O,O-DONOR LIGANDS

AHMED M. EL-HENDAWY† and MOHAMED S. EL-SHAHAWI

Chemistry Department, Faculty of Science, Damietta, Egypt

(*Received* 28 *April* 1989; *accepted* 24 *July* 1989)

Abstract—The complexes $[Ru^{III}Cl_2(PPh_3)_2L]$ (L = monoanions of maltol, kojic acid, tropolone and acetylacetone) were prepared and characterized by spectroscopic and electrochemical measurements. The catalytic oxidation of alcohols in the presence of excess N-methylmorpholine-N-oxide by $[Ru^{III}Cl_2(PPh_3)_2(acac)]$ has also been reported.

It has been recently noted[1] that reaction of $RuCl_2(Ph_3P)_3$ with Schiff bases ($OC_6H_4CH{=}N{-}R$, where R = Ph, *o*- or *p*-ClC_6H_4), in warm benzene under aerobic conditions, gives the green paramagnetic ruthenium(III) products *trans*-$[RuCl_2(OC_6H_4CH{=}NR)(Ph_3P)_2]$, which in turn form $[Ru^{II}(OC_6H_4CH{=}NR)_2(Ph_3P)_2]$ in the presence of triethylamine under anaerobic conditions.[2] The brown complexes $[RuX_2(EPh_3)_2(3\text{-bromotropolonato})]$ (E = P or As; X = Cl or Br) have been synthesized by refluxing $[Ru^{III}X_3(EPh_3)_3]$ and 3-bromotropolone in benzene.[3]

We now report the preparation of the new complexes $[Ru^{III}Cl_2(PPh_3)_2L]$ [L = monoanions of maltol (malt), 3-hydroxy-2-methyl-4-pyrone; kojic acid (koj), 5-hydroxy-2-(hydroxymethyl)-4-H-pyran-4-one; tropolone (trop), 2-hydroxy-2,4,6-cycloheptatrienone, acetylacetone (acac)], starting with $[Ru^{II}(PPh_3)_3Cl_2]$. We also discuss their spectroscopic and electrochemical behaviour, together with the application of $[Ru^{III}Cl_2(PPh_3)_2(acac)]$ to the catalytic oxidations of alcohols in the presence of N-methylmorpholine N-oxide (NMO) as co-oxidant, since the $Ru^{II}Cl_2(PPh_3)_2$/NMO system has been reported before.[4,5]

RESULTS AND DISCUSSION

Elemental analyses indicate that the complexes have the formula $[RuCl_2(PPh_3)_2L]$ (L = koj, **I**; malt, **II**; trop, **III**; or acac, **IV**). Most of the complexes are only soluble in CH_2Cl_2 and their molar conductivities are very low.

The IR spectra of the complexes showed all the bands due to triphenylphosphine and coordinated L. The band at 1555 cm^{-1}, observed in both kojato and maltolato complexes, is tentatively assigned to the ν(C=O) vibration. The largest bathochromic shift (75–105 cm^{-1}) for the carbonyl group upon coordination is expected.[6] Tropolonato and acetylacetonato complexes showed strong bands near 1360 and 1375 cm^{-1}, respectively, arising from ν(C—O) vibrations, as observed for $W_2O_5(trop)_2$[7] at 1360 cm^{-1}; also, distinct bands were found at 1510 and 1520 cm^{-1} similar to those reported for $[RuCl_2(PPh_3)_2L']$[3] (L′ = 3-bromotropolonate), and these are characteristic of coordinated diketones.[8] The *trans*-arrangement of chloro ligands in $[RuCl_2(PPh_3)_2L]$ is suggested by the appearance of only one band near 335 cm^{-1} which is due to (Ru—Cl) vibrations.[9,10] Some of these IR bands are also observed in the Raman spectra (see Table 1).

The magnetic moments of the complexes at room temperature (in Table 1) are near the spin-only value corresponding to one unpaired electron, suggesting the low spin d^5 $(t_{2g})^5$ configuration for the ruthenium(III) ion in an octahedral environment.

Electronic spectra and electron spin resonance

The electronic spectra of complexes **II**, **III** and **IV** in CH_2Cl_2 show a broad intense band around 600 nm which could be assigned to a *d–d* electronic transition, whereas the intense band near 375 nm is tentatively assigned to a M → L π^*-transition.[3] The bands near or below 300 nm may arise from either an intraligand or from M → L charge-transfer

bands. Similar but shifted bands are assigned for complex **I** which is soluble only in DMF.

The spin Hamiltonian parameters for complexes **II** and **IV** were sufficiently resolved to allow more than the facile deduction that the unpaired electron is delocalized onto the ligand. The observed lines were similar to each other. The $g_{\|}$ values were 1.88 and 1.92, while $g_{\perp}$ values were 2.30 and 2.38 for complexes **II** and **IV**, respectively, with respect to DPPH. These values are in good agreement with the g values reported for analogous ruthenium(III) species.[3] The spectra are typical of a large axial distortion of an elongated octahedral ruthenium(III) ion environment[3,11] (a representative example is given in Fig. 1).

Cyclic voltammetric studies

The cyclic voltammogram (CV) of the complexes for $\sim 10^{-3}$ M concentration in CH_2Cl_2 using

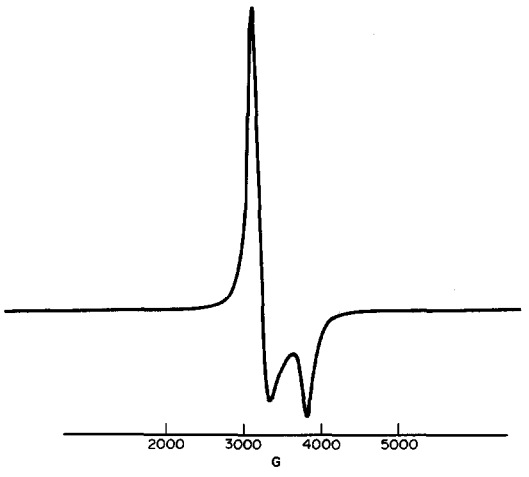

Fig. 1. ESR spectra of *trans*-$[RuCl_2(PPh_3)_2(acac)]$.

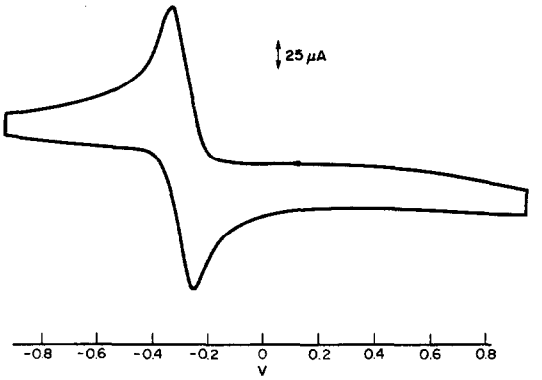

Fig. 2. Cyclic voltammogram of *trans*-$[RuCl_2(PPh_3)_2(acac)]$ (10^{-3} M) in CH_2Cl_2 with 0.1 M $(Bu^n_4N)PF_6$ as supporting electrolyte; scan rate 50 mV s^{-1}; volts vs Ag/AgCl electrode.

0.1 M $Bu^n_4NPF_6$ as the supporting electrolyte, shows only one reversible (or quasi-reversible, ΔE = 70–80 mV) reduction wave at a negative potential (data in Table 1 and Fig. 2 as a typical example). This corresponds to Ru^{III}/Ru^{II} reduction vs Ag/AgCl electrode. We also prepared $Ru(acac)_3$[12] and found that its CV was the same as that previously reported,[13] for both reversible redox reduction and oxidation waves at $E_{1/2}$ = −0.71 and +1.13 V corresponding to $Ru^{III/II}$ and $Ru^{III/IV}$, respectively. The redox potential values for our complexes compared with those for $Ru(acac)_3$ (for the couple Ru^{III}–Ru^{II}) reflect the order of increasing electron-donating nature, i.e. compound **IV** < **III** < **II** < $Ru(acac)_3$. This decrease of electron donating character in our complexes could explain why they only display one reduction wave.

Table 2. Catalytic oxidations of alcohols by *trans*-$[RuCl_2(PPh_3)_2acac]$/NMO

Alcohol	Product[a]	Yield	Time (h)	Turnover[b]
Benzyl	A	99	2	77
p-Methoxybenzyl	A	98	1.5	75
Cinnamyl	A	60	2	50
Benzohydrol	K	94	2	50
Benzoin	K	55	3	50
Cyclohexanol	K	74	3	50

[a] A = corresponding aldehyde, K = corresponding ketone.

[b] Turnover = moles of product/moles of catalyst.

Catalytic oxidation of alcohols

$Ru^{II}Cl_2(PPh_3)_3$ has been used in the presence of excess NMO, for catalytic oxidation of alcohols to give the corresponding aldehydes or ketones.[4,5] Thus $[RuCl_2(PPh_3)_2(acac)]$ was found to give such catalytic oxidations in the presence of excess NMO. Primary alcohols are oxidized to the corresponding aldehydes, and secondary alcohols to ketones (Table 2). There is no oxidation by NMO in the absence of the catalyst and no reaction between $[RuCl_2(PPh_3)_2(acac)]$ (**IV**) and the alcohols in the absence of NMO as shown by electronic spectroscopy. On mixing **IV** (10^{-3} M) and NMO (0.15 M) in CH_2Cl_2 and shaking, the green colour changes to yellowish and the bands at 605 and 388 nm for compound **IV** are replaced by bands at 525 and 375 nm. The intensity of the former band was found to increase with time: at 1, 2, 4 and 5 h, the corresponding absorbances were 0.37, 0.43, 0.54 and 0.75, respectively, whereas the intensity of the band at 375 nm remained nearly constant. The appearance of these two bands is similar to those observed for high oxidation state ruthenium complexes.[5,10] This could explain the continuation of the catalytic cycle of oxidation.

EXPERIMENTAL

Preparation of complexes

All preparations use $RuCl_2(PPh_3)_3$ which was synthesized by the literature method.[14]

trans-$[RuCl_2(PPh_3)_2L]$ (L = koj *or* malt) (**I, II**). To kojic acid (0.21 g, 1.5 mmol) dissolved in hot methanol (10 cm^3) was added $RuCl_2(PPh_3)_3$ (0.48 g, 0.5 mmol). The mixture gave a green solution on reflux, and after 1 h a yellow precipitate formed, which was filtered off, washed with hot methanol and then ether, and dried *in vacuo* (Found: C, 60.1; H, 4.2; Cl, 8.4. $[RuCl_2(PPh_3)_2(koj)]$ (**I**) requires: C, 60.2; H, 4.2; Cl, 8.5%).

Similar procedures were used in which maltol replaced kojic acid and a green precipitate was obtained (Found: C, 61.4; H, 4.3; Cl, 8.8. $[Ru(PPh_3)_2Cl_2(malt)]$ (**II**) requires: C, 61.4; H, 4.3; Cl, 8.6%).

trans-$[RuCl_2(PPh_3)_2(trop)]$ (**III**). Tropolone (0.18 g, 1.5 mmol) was dissolved in benzene (25 cm^3) and $RuCl_2(PPh_3)_3$ (0.96 g, 1 mmol) added. After refluxing the mixture for 0.5 h, a reddish-brown solution resulted. A yellow precipitate formed on continued heating; this was filtered off, washed with methanol and then ether, and dried *in vacuo* (Found: C, 63.1; H, 4.2; Cl, 9.0. $[RuCl_2(PPh_3)_2(trop)]$ requires: C, 63.2; H, 4.3; Cl, 8.7%).

trans-$[RuCl_2(PPh_3)_2(acac)]$ (**IV**). To $RuCl_2(PPh_3)_3$ (0.24 g, 0.25 mmol) was added excess acetylacetate (10 cm^3) and the mixture was refluxed on a steam bath for 2 h. Green microcrystals were isolated, filtered off and washed with ether and dried *in vacuo* (Found: C, 62.1; H, 4.6; Cl, 8.9. $[RuCl_2(PPh_3)_2(acac)]$ requires: C, 61.9; H, 4.7; Cl, 8.9%). Yields of 60–75% of the above complexes were obtained.

Catalytic oxidations by trans-$[RuCl_2(PPh_3)_2(acac)]$ (**IV**)

The oxidation of benzohydrol is typical. To benzohydrol (1 mmol) was added NMO (3 mmol) in 25 cm^3 of CH_2Cl_2 and 2×10^{-2} mmol of compound **IV**. The solution was stirred for 2 h during which time the colour changed from green to brown. The mixture was evaporated to dryness and extracted with ether (2×25 cm^3); the combined ethereal extracts were filtered and evaporated to give benzophenone which was characterized as its 2,4-dinitrophenylhydrazone derivative.

IR spectra were measured on a Perkin–Elmer 683 spectrophotometer as liquid paraffin mulls between CsI plates and as KBr discs. Raman spectra were measured on a Spex Ramalog 5 instrument with a CRL Innova Krypton ion laser with excitation at 6471 or 5682 Å as KBr discs. ESR spectra were recorded with a Varian E-12 spectrometer equipped with 100 kHz modulation. Cyclic voltammetric studies were carried out on a potentiostat/wave generator (Oxford Electrodes) using platinum working electrode. Magnetic measurements were made on a Johnson Matthey magnetic susceptibility balance.

Acknowledgements—We thank Zahar Hussein for carrying out the ESR spectra, Dr W. P. Griffith for helpful advice and also Johnson Matthey Ltd for the loan of ruthenium trichloride.

THE SYNTHESIS OF SOME NEW THIOPHENE DERIVATIVES

M. J. EARLE, A. G. MASSEY,* A.-R. AL-SOUDANI and T. ZAIDI

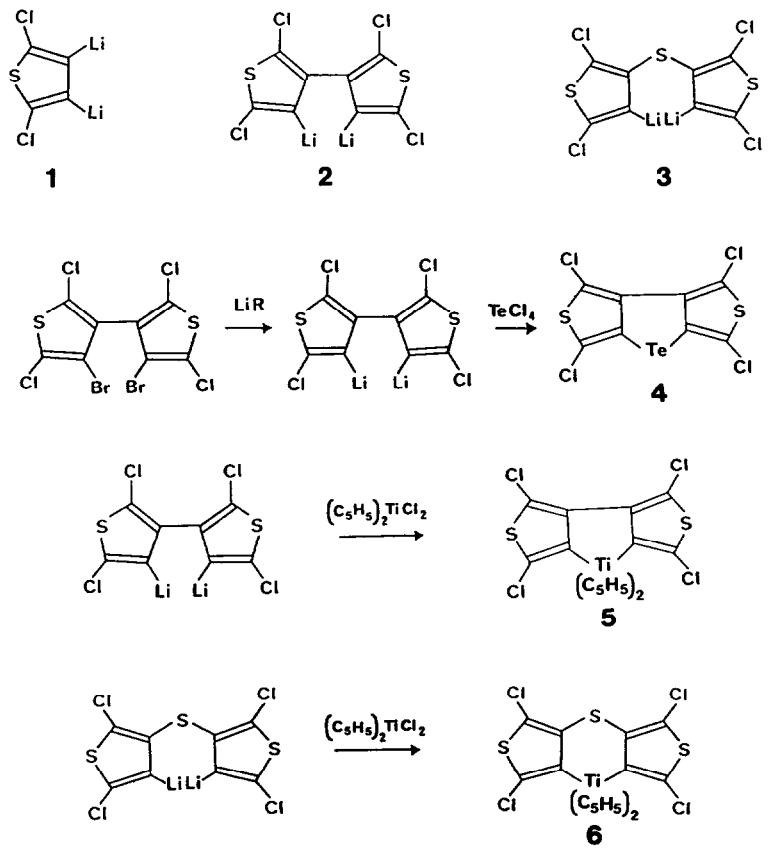
Department of Chemistry, University of Technology, Loughborough, Leicestershire LE11 3TU, U.K.

(*Received* 19 *July* 1989; *accepted* 31 *July* 1989)

Abstract—Several sulphur, selenium, tellurium and titanium heterocycles have been synthesized in which the 2,5-dichlorothiophene unit is the structure former. Tetrachlorotetrafluorodibenzothiophene may be made via a benzyne-insertion reaction.

Due to their possible use in electrically-conducting complexes there is currently an active interest in the preparation of substituted thiophenes. The ready availability of the dilithio-reagents **1**, **2**, and **3** has allowed the isolation of a wide variety of heterocycles containing the thiophene ring as a structure-forming unit.[1] We now report further synthetic possibilities using these versatile lithium derivatives.

Addition of $TeCl_4$ or $(C_5H_5)_2TiCl_2$ to **2** or **3** in a ether–hexane solution at low temperature, followed by slow warm up to ambient temperature, gives the expected heterocycles:



* Author to whom correspondence should be addressed.

The unusual titanium heterocycle, **5**, gave well-formed, but thin, red crystals on crystallization from toluene. Its mass spectrum showed a parent ion cluster of about 15% relative intensity around 480, and P^{2+} was among the several doubly-charged peaks which could easily be distinguished. Most of the metastable peaks represent loss of chlorine atoms from the parent ion and its fragments:

$$(C_5H_5)_2Ti(C_4Cl_2S)_2^+ \xrightarrow{-Cl} C_{18}H_{10}S_2TiCl_3^+$$

$$C_{18}H_{10}S_2TiCl_3^+ \xrightarrow{-Cl} C_{18}H_{10}S_2TiCl_2^+$$

$$C_{18}H_{10}S_2TiCl_2^+ \xrightarrow{-Cl} C_{18}H_{10}S_2TiCl^+$$

$$C_{18}H_{10}S_2Cl^+ \xrightarrow{-Cl} C_{18}H_{10}S_2^+$$

$$C_{13}H_5S_2Cl_2^+ \xrightarrow{-Cl} C_{13}H_5S_2Cl^+$$

$$C_{18}H_{10}S_2Cl^+ \xrightarrow{-C_5H_5} C_{13}H_5S_2Cl^+$$

$$C_{13}H_5S_2Cl^+ \xrightarrow{-Cl} C_{13}H_5S_2^+.$$

Treatment of **1** with disulphur dichloride, S_2Cl_2, gave a complex mixture of products, **7**–**12**, some of which were obtained in only very low yield.

and reacted almost instantaneously with metallic mercury on shaking. The solid also decomposed when inserted into a mass spectrometer. These are not the properties associated with compounds having thiophene rings linked by —S—S— bridges; hence from its method of preparation, its analysis and its initial solubility in several cold solvents we are led to the only possible conclusion that this solid is dithietane (**12**). No identifiable material could be isolated from the reaction of **12** with mercury in toluene; during some unsuccessful recrystallization attempts a few crystals of decomposition products arising from **12** were obtained.

The asymmetrically-bridged species **9** was not isolated but could be detected in some samples of $(C_4Cl_2S)_2S_4$ (**8**). (Although $(C_4Cl_2S)_2S_3^+$ occurs as a fragment ion in the mass spectrum of pure **8** it gives only a relatively weak peak.) The identity of **9** was confirmed by high resolution mass spectral studies *m/z*: 395.738 (calc. for $C_{12}^{35}Cl_4S_5$: 395.736); 397.734 (calc. for $C_{12}^{35}Cl_3^{37}ClS_5$: 397.733); 399.729 (calc. for $C_{12}^{35}Cl_2^{37}Cl_2S_5$: 399.730).

At about −30°C the dilithium reagent **1** reacts smoothly with elemental sulphur to give the dithiolate $(C_4Cl_2S)(SLi)_2$ (**13**); this latter compound gives three major products, **14**, **15** and **16**, when treated with sulphur dichloride.

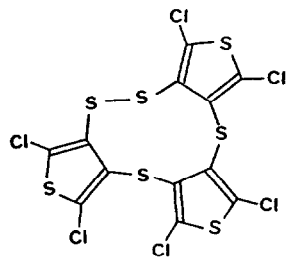
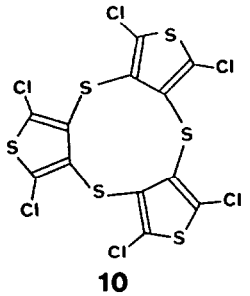
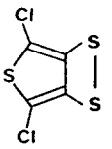
9



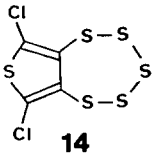
11



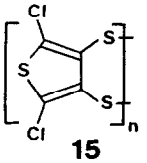
10



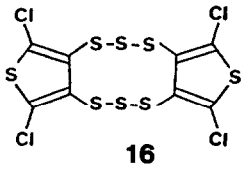
12



14



15



16

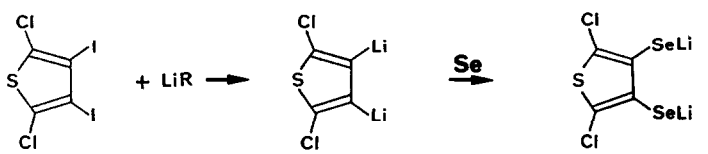
The major product of this reaction was a beige powder analysing, after washing with pentane and methanol followed by drying under high vacuum, as "$(C_4Cl_2S)S_2$". Due to its thermal fragility all attempts at recrystallizing this compound from a variety of solvents failed; when in solution at room temperature it rapidly turned nickel spatulas black

The pentathiole, $(C_4Cl_2S)S_5$, which forms very pale yellow needles, was identified by both elemental analysis and accurate mass measurements on the $C_4^{35}Cl_2^{32}S_6^+$ ion (found: 309.770; calc.: 309.770). The base peak in its mass spectrum is due to the ion $(C_4Cl_2S)S_3^+$; ions representing the loss of one, two and three sulphur atoms from this base-

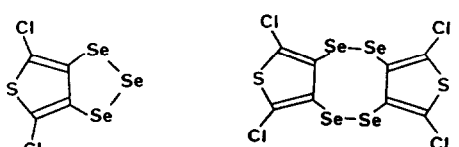
ion were present in about 4–6% abundance. Prominent low-mass, fragment ions present in this and other thiophene spectra were $C_3S_2Cl^+$ (134.911; calc. for $C_3^{32}S^{35}Cl^+$: 134.913); $C_2S_2Cl^+$ (122.914, calc. for $C_2^{32}S^{35}Cl^+$: 122.913); C_4SCl^+ (114.941, calc. for $C_4^{32}S^{35}Cl^+$: 114.941); C_3SCl^+ (102.941, calc. for $C_3^{32}S^{35}Cl^+$: 102.941); C_3S^+ (99.943, calc. for $C_3^{32}S_2$: 99.944); $C_2S_2^+$ (87.945, calc. for $C_2^{32}S_2^+$: 87.944); $CSCl^+$ (78.942, calc. for $C^{32}S^{35}Cl$: 78.941) and S_2^+ (63.947, calc. for $^{32}S_2$: 63.944).

The polymeric material **15** analysing as $[(C_4Cl_2S)S_2]_x$ is insoluble in boiling dimethylformamide; in boiling nitrobenzene depolymerization appears to take place giving **8**. Judging from models, this tetrathiocane can conceivably exist in both a rigid "chair" and a flexible "boat" form. The needle crystals of $(C_4Cl_2S)_2S_4$ arising from the lithium reaction melt at 171°C, whereas the product from the nitrobenzene decomposition of polymer **15** melts at 256°C; both species have the parent ion $(C_4Cl_2S)_2S_4^+$ in their mass spectra. Whether these compounds represent the two tetrathiocane isomers remains to be decided by X-ray crystallography.

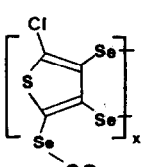
Treatment of **1** with selenium readily forms the diselenolate **17** which, on reaction with $SeCl_4$, gives three major products, **18**, **19**, and **20**.



17



18 19



20

The red triselenole (**18**), which can be recrystallized from dimethylformamide, was identified by high resolution mass spectral studies: Found: 385.665; calc. for $C_4^{35}Cl^{37}Cl^{80}Se_3S$: 385.661. Found: 387.660; calc. for $C_4^{35}Cl_2^{78}Se^{80}Se_2S$: 387.660. Found: 389.659; calc. for $C_4^{35}Cl_2^{80}Se_3S$: 389.659. Found: 391.655; calc. for $C_4^{35}Cl^{37}Cl^{80}Se_3S$: 391.656.

High resolution mass measurements on the bright yellow tetraselenocane **19** similarly gave excellent correlations with the calculated masses; a selection of the data is given below:

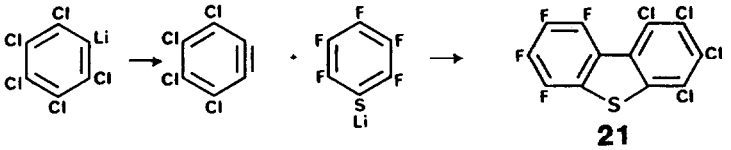
Found: 615.487; calc. for $C_8^{35}Cl_4S_2^{80}Se_2^{78}Se_2$: 615.491. Found: 617.489; calc. for $C_8^{35}Cl_4S_2^{80}Se_3^{78}Se$: 617.489. Found: 619.487; calc. for $C_8^{35}Cl_3^{37}ClS_2^{80}Se_3^{78}Se$: 619.487. Found: 618.485; calc. for $C_8^{35}Cl_2^{37}Cl_2S_2^{80}Se_2^{78}Se_2$: 618.485. Found: 621.486; calc. for $C_8^{35}Cl_2^{37}Cl_2S_2^{80}Se_3^{78}Se$: 621.484. Found: 623.485; calc. for $C_8^{35}Cl_2^{37}Cl_2S_2^{80}Se_4$: 623.484.

The pale green, polymeric material **20** was found to be deficient in chlorine, the formula approximating to $[(C_4ClS)Se_3]_x$, where an average of one chlorine atom per thiophene ring remains. It appears likely that the lithium reagent **17** attacked some of the C—Cl bonds in neighbouring molecules to give this polymer; such reactions are relatively common when RXLi compounds (X = chalcogen) are used in the presence of organohalides. Unexpectedly, when this polymer is refluxed with nitrobenzene, orange crystals are produced which give a $(C_4Cl_2S)_2Se_4^+$ parent ion in their mass spectrum and a typical fragmentation pattern for **19**. The simplest route to **19** is to oxidize the dilithium reagent **17** with an equivalent amount of iodine in ether–hexane.

The IR spectra of the sulphur heterocycles are very similar, which sometimes makes deductions about levels of purity using this technique almost impossible; elemental analysis, thin-layer chromatography and mass spectroscopy proved to be much more reliable. Two ring-stretching vibrations[2] at 1540–1510 and 1450–1400 cm^{-1} gave some of the more intense peaks, with a medium intensity band around 890 cm^{-1} representing the ring-breathing mode; the strongest band was always at about 1060 cm^{-1} and this may arise from

a chlorine-sensitive vibration. Their selenium analogues showed similar spectral features in the IR but the corresponding bands occurred at somewhat lower wave numbers.

When two molecules of butyllithium are added to a 1 : 1 mixture of pentachlorobenzene and pentafluorothiophenol, and the whole mixture stirred at room temperature, tetrachlorotetrafluorodibenzothiophene (**21**) is formed in 55% yield. The reaction probably occurs via the initial formation of tetrachlorobenzyne, followed by addition of C_6F_5SLi and ring-closure as LiF is eliminated.



21

The parent ion $C_{12}Cl_4F_4S^+$ gave rise to the base peak in the mass spectrum of **21** with the doubly-charged parent ion having an intensity of 14%. Very little fragmentation occurred, the only peaks of intensity greater than 15% were $C_{12}Cl_2F_4S^+$ and $C_{12}Cl_2F_4S^{2+}$. There appears to be no reason why this reaction should not become a general method for making dibenzothiophenes, -selenophenes and -tellurophenes if lithium reagents halogenated in the correct positions are treated with *half* a mole of elemental chalcogen at room temperature or below.

EXPERIMENTAL

All reactions were carried out under a dry nitrogen atmosphere using 100 cm^3 of sodium-dried ether as solvent; 4.85 g of 2,5-dichloro-3,4-diiodothiophene (0.012 mol) were used in each experiment, together with 0.024 mol of butyllithium added at −95°C as a 1.6 M hexane solution.

Reaction of **1** *with* S_2Cl_2

To 0.012 mol of 3,4-dilithio-2,5-dichlorothiophene was added an equivalent quantity of disulphur dichloride at −95°C and the mixture allowed to warm up slowly to room temperature; after 15 min, water (50 cm^3) was added to quench the reaction. Many unsuccessful attempts were made to recrystallize the beige-coloured ether-insoluble product **12** from all the common organic solvents including dimethylformamide (DMF); the solvent was stripped from the ether-soluble material and the solid crystallized from toluene. Chromatography on alumina or fractional crystallization from toluene gave **7**, **8** and **11**; compounds **9** and **10** were detected by mass spectrometry but could not be isolated.

Compound **7**: needle-shaped, colourless crystals, m.p. 283°C (Found: C, 26.5; S, 36.9. Calc. for $C_8Cl_4S_4$: C, 26.2; S, 35.0%).

Compound **8**: dendritic, colourless crystals, m.p. 171°C (Found: C, 22.2; S, 42.2. Calc. for $C_8Cl_4S_6$: C, 22.3: S, 44.7%).

Compound **11**: cube-shaped, colourless crystals, m.p. 224°C (d) (Found: C, 24.9. Calc. for $C_{12}Cl_6S_7$: 24.8%). The identity of **11** was confirmed by high resolution mass spectrometry *m/z*: Found: 577.613; calc. for $C_{12}^{35}Cl_6S_7$: 577.618. Found: 579.609; calc. for $C_{12}^{35}Cl_5^{37}ClS_7$: 579.615. Found: 581.607; calc. for $C_{12}^{35}Cl_4^{37}Cl_2S_7$: 581.612.

Compound **12**: the methanol-washed, vacuum-dried product (*ca* 90% yield) was analysed without further purification (Found: C, 22.25; S, 44.4. Calc. for $C_4Cl_2S_3$: C, 22.3; S, 44.7%). The compound decomposes above *ca* 80°C.

Compound **9**: detected by mass spectrometry (see text).

Compound **10**: high resolution mass spectrometry on a tiny sample showed a mass cut-off at an ion cluster around *m/z* = 548. The identity of the species was confirmed by the following data *m/z*: Found: 551.631; calc. for $C_{12}^{35}Cl_3^{37}Cl_3S_6$: 551.637. Found: 549.636; calc. for $C_{12}^{35}Cl_4^{37}Cl_2S_6$: 549.640. Found: 547.638; calc. for $C_{12}^{35}Cl_5^{37}ClS_6$: 547.643. Found: 545.642; calc. for $C_{12}^{35}Cl_6S_6$: 545.646.

Reaction of **13** *with* SCl_2

Compound **1** (1 mol) was treated with 2 mol of elemental sulphur at −95°C; on warming, a reaction between the two components to give **13** was observed to occur at about −20°C. SCl_2 (1 mol) was added slowly, with stirring, at room temperature; after 15 min, water (50 cm^3) was added to quench the reaction. The products were worked up as described above to give **8**, **14** and **15**.

Compound **8**: colourless, dendritic crystals, m.p. 171°C (Found: C, 22.2; S, 42.3. Calc. for $C_8Cl_4S_6$: C, 22.3; S, 44.7%). The molecular formula was confirmed by high resolution mass spectrometry.

Compound **14**: large, very pale yellow needles, m.p. 126°C (Found for two different preparations: C, 15.6, 15.7; S, 60.5, 63.4. Calc. for $C_4Cl_2S_6$: C, 15.4; S, 61.8%). The molecular formula was con-

firmed by high resolution mass spectrometry (see text).

Compound **15**: pale yellow powder, insoluble in boiling DMF, m.p. 241°C (d) (Found: C, 22.2; S, 42.3. Calc. for $(C_4Cl_2S_3)_x$: C, 22.3; S, 44.7%). The compound gave $[(C_4Cl_2S)S_2]_2^+$ as the highest ion in the mass spectrum, with the doubly-charged parent ion also detectable: Found: 215.351, Calc. for P^{2+}: 215.354. This suggests that either all the dimer had not been removed or that decomposition of the polymer occurred in the spectrometer.

Compound **9** was confirmed by high resolution mass spectrometry to be an impurity in some samples of **11**; see text.

Compound **16**: yellow rosettes from toluene, m.p. 228°C (Found: C, 20.6. Calc. for $C_8Cl_4S_8$: 19.4%. MW 491.652; $C_8^{35}Cl_4^{32}S_8$ 491.652); base peak in mass spectrum due to $C_4Cl_2S_3^+$. In a mass spectrum of the neat reaction product before work-up, a weak cluster of peaks around mass 732 suggested the presence of $(C_4Cl_2S)_4S_4$, but this "tetramer" was not isolated during recrystallizations.

Reactions of **17** *with* $SeCl_4$

Selenium powder (2 mol) was added to **1** at −95°C and the mixture warmed slowly to room temperature. When the black colour of selenium disappeared, $SeCl_4$ (1 mol) was added and, after 15 min, the reaction was quenched by the addition of 50 cm^3 of water. The products were worked up as before to yield **18**, **19** and **20**.

Compound **18**: red solid, decomposes slowly at 100°C; identified by high resolution mass spectrometry (see text).

Compound **19**: bright yellow, microcrystals, m.p. 252°C (d) (Found: C, 17.3; S, 10.1; Se, 49.3. Calc. for $C_{12}Cl_4S_2Se_4$: C, 15.5; S, 10.4; Se, 51.1%). The molecular formula was confirmed by high resolution mass spectrometry m/z: Found: 615.487; calc. for $C_8^{35}Cl_4S_2^{80}Se_2^{78}Se_2$: 615.491. Found: 617.490; calc. for $C_8^{35}Cl_4S_2^{80}Se_3^{78}Se$: 617.489. Found: 619.487; calc. for $C_8^{35}Cl_3^{37}ClS_2^{80}Se_3^{78}Se$: 619.487.

Compound **20**: yellow–green powder, insoluble in boiling DMF, m.p. 198°C (d) (Found for two different preparations: C, 13.0, 13.3; S, 8.5, 8.95; Se, 66.9, 66.5. Calc. for "$[C_4ClS)Se_3]_x$": C, 13.6; S, 9.1; Se, 67.2%).

Reaction between C_6Cl_5Li *and* C_6F_5SLi

Molar equivalents of C_6Cl_5H and C_6F_5SH were dissolved in 100 cm^3 of dry ether at −95°C under dry nitrogen; after 2 mol of butyllithium had been added, the mixture was slowly warmed to room temperature and stirred for 2 h. The ether solvent was filtered, stripped and the remaining solid recrystallized twice from toluene to give tetrachlorotetrafluorodibenzothiophene (**21**). (Found: C, 36.3; F, 19.0. Calc. for $C_{12}Cl_4F_4S$: C, 36.6; F, 19.3%).

Reactions of **2** *or* **3** *with* $TeCl_4$ *and* $(C_5H_5)_2TiCl_2$

These reactions were carried out as described in ref. 1.

$(C_4Cl_2S)_2Te$ (**4**): yellow–green needles, m.p. 200–201°C (Found: C, 22.2; S, 14.7. Calc. for $C_8Cl_4S_2Te$: C, 22.3; Se, 14.9%); 90% yield.

$(C_4Cl_2S)_2Ti(C_5H_5)_2$ (**5**): orange–red, thin plates, m.p. 230–231°C (Found: C, 45.4; H, 2.1; S, 13.2. Calc. for $C_{18}H_{10}Cl_4S_2Ti$: C, 45.0; H, 2.1; S, 13.3%); 85% yield.

$(C_4Cl_2S)_2STi(C_5H_5)_2$ (**6**): red needle crystals, m.p. 292–293°C; the molecular formula was confirmed by mass spectrometry, the parent ion cluster appearing around m/z 512; 60% yield.

Main IR absorptions

Samples were prepared in KBr discs unless stated otherwise; peaks are given in cm^{-1}. Many of the compounds have very similar IR spectra, the peaks differing by only a few wave numbers.

$(C_4Cl_2S)_2Te$ (**4**): Nujol mull: 1530 w; 1405 m; 1360 s; 1230 m; 1070 s; 1115 s; 960 vw; 955 vw; 915 m; 725 msh; 720 mb; 630 w; 575 m; 470 w. $(C_4Cl_2S)_2Ti(C_5H_5)_2$ (**5**): Nujol mull: 3070 w; 1500 vw; 1485 sh; 1375 sh; 1350 s; 1180 vw; 1170 vw; 1055 w; 1030 s; 995 m; 985 m; 900 m; 810 vs; 765 w; 705 m; 620 m; 615 m; 490 m; 430 w. $(C_4Cl_2S)_2STi(C_5H_5)_2$ (**6**): Nujol mull: 3070 w; 1470 w; 1415 sh; 1400 m; 1355 m; 1330 m; 1170 m; 1010 s; 970 m; 915 w; 820 s; 810 s; 705 m; 485 m; 410 m. $(C_4Cl_2S)_2S_4$ (**8**): 1460 s; 1405 s; 1060 vs; 894 m; 693 w; 642 w; 529 m; 440 m. $(C_4Cl_2S)S_2$ (**12**): 1473 m; 1408 s; 1059 vs; 891 m; 640 w; 447 w. $(C_4Cl_2S)S_5$ (**14**): 1460 m; 1405 s; 1056 vs; 888 m; 640 w; 530 w; 465 w. $[(C_4Cl_2S)S_2]_x$ (**15**): 1460 m; 1405 s; 1060 s; 894 m; 643 vw; 530 w. $(C_4Cl_2S)Se_3$ (**18**): 1450 m; 1396 s; 1039 s; 849 m; 514 w; 408 w. $(C_4Cl_2S)_2Se_4$ (**19**): 1451 m; 1396 s; 1040 s; 850 w; 514 w. SYNTHESIS AND SPECTROSCOPIC STUDIES OF GOLD(I) THIOCYANATE WITH IMIDAZOLIDINE-2-THIONE AND ITS DERIVATIVES

ANVARHUSEIN A. ISAB

Chemistry Department, King Fahd University of Petroleum and Minerals, Dhahran 31261, Saudi Arabia

(*Received* 23 *January* 1989; *accepted* 31 *July* 1989)

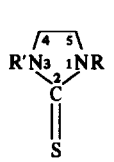
Abstract—The reaction of ammonium gold(III) thiocyanate with imidazolidine-2-thione (Imt) and its N- and N,N′-disubstituted derivatives yields complexes of stoichiometry L—Au^{I}—SCN (where L = Imt and its derivatives). However, a six-membered heterocyclic ligand, 1,3-diazinane-2-thione (Diaz), and its N-substituted derivative yields complexes of the type L'_2—Au^{I}—SCN (where L′ = Diaz and its derivative). These complexes are characterized by elemental analysis, IR and ^{13}C NMR spectroscopy.

The current interest in the coordination chemistry of thione derivatives of various heterocycles arises from the application of heterocyclic S,N-containing ligands in medicine[1–3] and the binding characteristics towards different metal ions.[4–8] Our interest in these ligands is because the thione donor group forms stable complexes with gold(I).[9–13] The gold(I) thiolates (AuSR), in which SR is a thiomalate or a substituted thioglucose group, are the most commonly used anti-arthritic gold complexes.[14–16]

It has recently been reported that chrysotherapy patients who are tobacco smokers accumulate gold from injectable gold drugs into their red blood cells while non-smokers do not.[17,18] Hydrogen cyanide is present in tobacco smokers at a concentration of 1600 ppm and is absorbed into the blood.[19] In the absence of gold, it undergoes two reactions: reversible binding to met-haemoglobin and irreversible oxidation to thiocyanate.[20]

Once the thiocyanate is generated *in vivo*, the gold(I) will react to form AuSCN or $Au(SCN)_2^-$ which will then further react with thiols (e.g. haemoglobin, glutathione) or thione (e.g. ergothionine). To understand the nature of these complexes, the present work was devoted to complexes originating from ammonium gold(III) thiocyanate with Imt, Diaz and their derivatives.

The complexes obtained have been characterized by means of elemental analysis, IR and ^{13}C NMR spectroscopy.



Imt (**a–f**)

EXPERIMENTAL

Chemicals

All chemicals and deuterated solvents were obtained from ICN K and K Laboratories, Plainview, New York and were used without any purification.

Preparation of complexes

The ligands were prepared by the procedures described in the literature.[21,22] Ammonium gold (III) thiocyanate, which is a reddish colour, was suspended in methanol and an excess of ligand was added. The solution of these suspensions was stirred until all the solid dissolved completely and the solution became colourless. The solvent was evaporated at room temperature and the crystals or powders were collected but some solvent still remained.

Spectroscopic measurements

IR spectra of the pure ligands and their gold(I) complexes were obtained on a Perkin–Elmer IR 180 or on a Beckman Microlab IR spectrophotometer using KBr pellets. ^{13}C NMR spectra were obtained on a Varian XL-200 NMR spectrometer operating at 50.3 MHz frequency. The ligands and gold(I) complexes were dissolved in a 50 : 50 (v/v) DMSO–acetone-d_6 solvent. The chemical shifts were measured relative to 1,4-dioxane as internal reference having a resonance at +67.4 ppm from TMS.

RESULTS AND DISCUSSION

The analytical data for complexes (**a–j**) are given in Table 1. These data show that Imt and its derivative (**a–f**) form 1 : 1 L–AuSCN complexes, whereas the analogous six-membered ring Diaz and its derivative (**g–j**) form bis-complexes. The reduction of gold(III) to gold(I) is similar to that described for copper(II) to copper(I) complexes for the ligands under investigation.[4–8]

IR studies

The IR data for the free ligands and their thiocyanate gold(I) complexes are given in Table 2.

$NH_4Au(SCN)_4$ shows a ν(NH) absorption at 3175 and 3080 cm^{-1}. There is also a ν(CN) absorption at 2130 cm^{-1}. All the [(L)AuSCN] complexes show two absorptions in the CN region. The smaller but sharp absorption at 2130 cm^{-1} and the more intense absorption at 2045 cm^{-1}.

In all the complexes reported here, the ν(S—C≡N) was shifted from 2130 to 2045 cm^{-1}, which indicates that —SCN is bonded to gold(I).[12]

Lorenzotti *et al.*[23] have prepared various [(Az)HgSCN] and [$(AZR)_nHg(SCN)_2$] complexes, where, Az = diazole, AZR = triazole and n = 1, 1.5 and 2. The IR absorptions of these complexes indicate that when [(Az)HgSCN]-type linear complexes are formed, they give a ν(CN) absorption at 2055–2078 cm^{-1}. For [$(AZR)_nHg(SCN)_2$]-type complexes, the ν(CN) was observed around 2120–2130 cm^{-1}. These results indicate that when the

isoelectronic mercury(II) binds to the monothiocyanate group, the range for ν(CN) is 2055–2078 cm^{-1}, whereas dithiocyanate gives an absorption at 2120–2130 cm^{-1}.

Similarly, a band at 2130 cm^{-1} was observed for $[NH_4Au(SCN)_4]$ in which it can be concluded that gold(III) is bonded to SCN via sulphur.[24] The results presented in Table 2 for [(Imt)AuSCN] and $[(Diaz)_2AuSCN]$ and their complexes show a sharp absorption at 2040–2045 cm^{-1} which also indicates that gold(I) is bonded to the thiocyanate group via sulphur. These results further indicate that [(L)Au SCN] may form linear complexes which are most favoured for gold(I), and $[(L'_2)AuSCN]$ may have three-coordinate bonds around gold(I). However, from the present IR results reported here, it is not possible to differentiate between the linear and three-coordinated gold(I) complexes.

The absorption at 321–350 cm^{-1} can be assigned to the Au—S vibration.[11] A low-field shift of the ν(C=S) absorption by about 30 cm^{-1} indicates that gold(I) is bonded to the ligands via the thione group. Similar results were obtained in our previous studies.[9–13]

^{13}C *NMR studies*

The ^{13}C NMR chemical shifts of Imt and its derivatives along with their thiocyanate gold(I) complexes are given in Table 3. For the analogous six-membered Diaz complexes, NMR chemical shifts are given in Table 4.

As reported in our previous studies,[9–13] the C(2) resonance of all the ligands was shifted the most after complexing with gold(I). This high-field shift of the C(2) resonance is due to back donation of electrons from thione to gold(I), which is shielded after complexing with gold(I).

The ^{13}C resonance of SCN^- for any [(Imt)Au SCN] or $[(Diaz)_2AuSCN]$ complexes and their derivatives was not observed. This is in contrast to [(Imt)AuCN] and its analogous complexes where the $^{13}CN^-$ resonance was observed.[12] This may be due to either the T_1 for the thiocyanate complexes

[a] ^{13}C NMR resonances are assigned as given in R. Faure, E. J. Vincent, G. Assef, J. Kister and J. Metzger, *Org. Magn. Res.* 1977, **9**, 688. The numbers in parentheses indicate shifts with respect to the free ligands. A positive value indicates a high-field shift whereas a negative value represents a low-field shift.

[b] This resonance could not be detected in the spectrum.

being long or the thiocyanate undergoing slow exchange with the *trans* ligand under study. Also there is no proton directly bonded to the carbon of the thiocyanate and, therefore, there is no Overhauser effect.

For the [(Imt)AuSCN] system, the chemical shift difference between the free and bound C(2) resonance is 9.57 ppm, whereas, for the $[(Diaz)_2Au$ SCN] system it is 8.95 ppm. For their N-ethyl analogous systems [(EtImt)AuSCN], this difference is found to be 8.62 ppm, and 7.97 ppm for $[(EtDiaz)_2$ AuSCN]. This observation indicates some back donation of electrons from the thione to the 6*s* and 6*p* orbitals of gold(I). The shielding of the C(2)

[a] ^{13}C NMR resonance are assigned as given in R. Faure, E. J. Vincent, G. Assef, J. Kister and J. Metzger, *Org. Magn. Res.* 1977, **9**, 688. The numbers in parentheses indicate shifts with respect to the free ligands. A positive value indicates a high-field shift whereas a negative value represents a low-field shift.

[b] This resonance could not be detected in the spectrum.

resonance is greater for the linear system than for the three-coordinated system. Similar observations were made for the isoelectronic copper(I) system in which it was found that for the three-coordinated copper(I) complexes the C(2) resonance was shifted upfield by 3–4 ppm. However, for the two-coordinated (linear) complex system the shift was found to be 6–7 ppm[25].

It should be noted here, however, that six-membered ring systems always form three coordinated complexes with ammonium thiocyanate–gold(I), $AuCl_2^-$ and $AuBr_2^-$. When $AuCl_4^-$ was reduced to $AuCl_2^-$ with SO_2,[26] followed by the addition of Imt type ligands, it resulted in the formation of linear complexes of the type [L—Au—X]. However, addition of Diaz to $AuCl_2^-$ afforded a $[L'_2Au_3X_2]$-type multinuclear complex (where X = halides) instead of the [(Diaz)AuX]-type complex.

The most plausible explanation is that a six-membered ring (Diaz) has a more favourable steric environment in the neighbourhood of the thione group than the five-membered Imt ring. The Diaz ligand can form a boat or chair conformation to relieve any steric congestion which may not be relieved in the Imt system. This in turn allows Diaz to form the three-coordinated complex and Imt to form a linear complex.

The results presented here indicate that gold(I) thiocyanate forms stable complexes with thiones. Further studies are in progress to identify the nature of interaction of gold(I) thiocyanate with thiols such as cysteine, glutathione, haemoglobin and a thione such as ergothionine which are present in the red blood cells.

CONCLUSIONS

On the basis of elemental analysis, IR and ^{13}C NMR spectral data, the following conclusions can be drawn:

(1) Imt and its derivatives form stable complexes of the type [(L)Au^{I}SCN] which may be linear in nature.
(2) Diaz and its derivatives also form stable complexes of the type [(L'_2)Au^{I}SCN] which favours three-coordinated complexes.
(3) The upfield shift of the C(2) resonance in the ^{13}C NMR spectra is greater for linear complexes such as the [(Imt)AuSCN] system compared to three-coordinated [$(Diaz)_2$Au SCN] complexes.

Abstract—In the presence of cysteine, ferrihydrite transforms into haematite, goethite or lepidocrocite at pH 6–8. Which compound forms depends on the cysteine–iron ratio and the nature of the buffering medium. In the absence of bicarbonate ions (which suppress lepidocrocite formation), the transformation product changed from haematite and lepidocrocite, to lepidocrocite and goethite and finally to goethite as the cysteine–iron ratio rose from $0.1 \rightarrow 0.4$. Interaction of cysteine with ferrihydrite leads to partial reduction of the interfacial ferric sites. Goethite and lepidocrocite formed from the partly reduced ferrihydrite by a dissolution/reprecipitation process, whereas haematite formed by a solid-state mechanism at a cysteine–iron ratio which was too low to permit extensive dissolution of partly reduced ferrihydrite to take place. Conversion of ferrihydrite to lepidocrocite under the influence of cysteine represents a new transformation route for the system. Transmission electron microscopy showed that the lepidocrocite thus formed consisted of well-developed laths or plates. Reducing organic ligands such as cysteamine, glutathione and penicillamine did not induce the formation of lepidocrocite.

The numerous interconversions between iron oxides and iron oxyhydroxides reflect the diversity and complexity of reactions in this system. These interconversions find application in industrial processes, for example, the conversion of goethite [α-FeO(OH)] or lepidocrocite [γ-FeO(OH)] into maghaemite (γ-Fe_2O_3) for use in magnetic tapes. They are also responsible for the mixtures of iron oxides–oxyhydroxides which exist in natural systems.

The behaviour of ferrihydrite ($5Fe_2O_3 \cdot 9H_2O$) illustrates the ability of an iron oxyhydroxide to transform into a variety of other iron compounds according to the reaction conditions. Ferrihydrite is a poorly ordered, thermodynamically unstable compound that gradually changes into goethite and/or haematite (α-Fe_2O_3).[1,2] The presence of foreign ions in the system can alter the kinetics of the competing mechanisms by which these compounds form and hence also the proportions of goethite and haematite in the reaction product.[3] Ferrihydrite may also transform to a spinel phase as a result of interaction with divalent cations.[4,5]

In an earlier publication[6] we reported that the presence of an organic reducing ligand, L-cysteine ($HSCH_2CH(NH_2)COOH$), induced the rapid conversion of ferrihydrite to goethite at a pH (8) at which, in the absence of the ligand, haematite was the predominant reaction product. This investigation has since been extended to consider the effect of cysteine on the transformation of ferrihydrite in slightly acid media. It was found that under these conditions, yet another transformation product, lepidocrocite, could be obtained from ferrihydrite. Lepidocrocite is used industrially as a pigment, a catalyst and in the production of photochemicals; it is widespread in soils and is a com-

* Author to whom correspondence should be addressed.

ponent of rust. Although it can precipitate from acid (pH 2) ferric solutions,[1,7] lepidocrocite is invariably synthesized by oxidation of ferrous systems at pHs of between 5 and 7.[8] The formation of lepidocrocite from ferrihydrite represents a novel extension of the interconversions between ferrihydrite and other iron oxides.

The present investigation considers the effect of L-cysteine on the products and kinetics of the transformation of ferrihydrite in the pH range 6–8.5. Particular attention was given to the formation of lepidocrocite. One question of interest was whether lepidocrocite could form from a ferrihydrite/cysteine suspension under slightly alkaline conditions (i.e. pH 8); earlier studies[6] showed that when the system was buffered with bicarbonate ions, only goethite formed. In the present work in alkaline media, the bicarbonate buffer was, therefore, replaced by a NH_4Cl/NH_3 buffer.

Transmission electron microscopy (TEM) was used to follow the progress of the transformation reaction and to establish the stage at which the different products nucleated. TEM was also used to determine whether lepidocrocite grown from ferrihydrite differed morphologically from that produced by oxidation of a ferrous system.

EXPERIMENTAL

Ferrihydrite was precipitated from ferric nitrate solution with 1 M KOH and the pH adjusted to either 6–6.5 with imidazole buffer solution or to 7.5–8.5 with NH_4Cl/NH_3 buffer. In a number of experiments bicarbonate buffer replaced NH_4Cl/NH_3 buffer. Enough L-cysteine to give a final concentration of between 10^{-3}–4×10^{-3} M (L : Fe ratio = 0.1–0.4) was then added to the ferrihydrite. The suspensions (1 g ferrihydrate/dm^3) were held in closed polypropylene bottles and aged in the dark at 70°C for up to 72 h. In some experiments L-cysteine was replaced by DL-cysteine (which gave identical results), cysteamine, D-penicillamine or glutathione (reduced form). All chemicals were AR (Fluka).

The kinetics of the transformation were followed by taking subsamples during the reaction and dissolving the unconverted ferrihydrite using a 30 min extraction with 0.4 M HCl (25°C).[6] Preliminary tests indicated that neither goethite, haematite nor lepidocrocite dissolved to any extent under these conditions. The extent of the transformation was expressed as the ratio, Fe_A/Fe_T, where Fe_A is the acid soluble material (i.e. unconverted ferrihydrite) and Fe_T is the total iron in the system. Analysis for iron was carried out using atomic absorption spectroscopy.

The crystalline product of the transformation was washed, dried at 50°C and X-ray powder diffraction (XRD) patterns obtained using a Guinier–Enraf camera (Mk IV) with Fe-$K_{\alpha 1}$ radiation. Where the reaction product consisted of a mixture of goethite and lepidocrocite or haematite and lepidocrocite, the proportion of each component was estimated by comparison with a series of standards. These standards were made by mixing known amounts of synthetic lepidocrocite with synthetic goethite or haematite. The 110 and 111 XRD lines of goethite, the 102 peak of haematite and the 020 peak of lepidocrocite were used for comparison.

Transmission electron micrographs were obtained with a Hitachi H-600-2 (100 kV) electron microscope equipped with a tracor TN 5400 energy dispersive X-ray spectrometer. For TEM examination the samples were dispersed in doubly distilled water using an ultrasonic treatment and a drop of suspension was dried on a carbon-coated bronze grid. Some samples were shadowed with chromium at an angle of 15°. Selected area electron diffraction (SAD) patterns were obtained using gold as an internal standard. For EDSX spectra the sample was dried on a graphitized nylon grid. Elemental analysis for C, H, N and S was carried out by the microanalytical department.

The interaction between L-cysteine and ferrihydrite was followed using differential pulse polarography (Polaroid E 506 metrohm polarograph with Ag/AgCl reference electrode). Suspensions of L-cysteine and ferrihydrite (0.1 g/100 cm^3, pH 8 or pH 6) were equilibrated for 1, 5 or 10 min or 2 h at 25°C, centrifuged and the level of L-cysteine in the supernatant liquid found by polarographic measurement. Fresh, standard solutions of L-cysteine at pH 8 (NH_4Cl/NH_3 buffer or bicarbonate buffer) or pH 6 (imidazole buffer) were also prepared for calibration purposes. The cysteine peak was observed at −0.51 V (pH 8) or at −0.39 V (pH 6).

RESULTS AND DISCUSSION

Reaction products

These depended mainly on the ratio of L-cysteine–iron (L : Fe) in the system together with the suspension pH and the nature of the buffering ions (Table 1).

In the absence of L-cysteine, ferrihydrite transformed into a mixture of haematite and goethite in both imidazole (pH 6) and NH_4Cl/NH_3 (pH 8) buffered systems: the proportion of goethite in the product decreased with rising pH (Table 1). On addition of 10^{-3} M L-cysteine (L : Fe = 0.1) ferri-

Table 1. Effect of cysteine concentration, pH and the nature of the buffer ions on the transformation products of ferrihydrite; 70°C, 48 h

Cysteine–iron	Products at pH 6 (Imidazole)	Products at pH 8 (NH_4Cl/NH_3)	Products at pH 8 ($NaHCO_3$)
0	Goethite + haematite (50%)	Haematite + goethite (10%)	Haematite + trace goethite
0.1	Haematite + lepidocrocite (45%)	Haematite + lepidocrocite (30%)	Haematite
0.2	Lepidocrocite + goethite (5%)	Lepidocrocite + goethite (55%)	Goethite
0.4	Goethite	Goethite	Goethite

hydrite transformed into a mixture of haematite and lepidocrocite. With increasing L : Fe ratio, haematite was replaced by lepidocrocite, which in turn, was replaced by goethite (Table 1); at L : Fe = 0.4, goethite was the sole reaction product.

Lepidocrocite was always associated with at least a few per cent of either haematite (L : Fe < 0.2) or goethite (L : Fe > 0.2). Under optimum conditions for lepidocrocite formation (L : Fe = 0.2, pH 6), there was still around 5% goethite in the product.

Addition of 6% seed crystals of lepidocrocite to a system with L : Fe = 0.1 increased the amount of lepidocrocite formed (from around 45 to 75%) at the expense of the haematite. Lepidocrocite seeding of systems with L : Fe $\geqslant$ 0.2 did not, however, eliminate or even reduce the proportion of goethite in the product.

Lepidocrocite did not form in the presence of organic reducing ligands related to L-cysteine, namely, cysteamine ($NH_2CH_2CH_2SH$), D-penicillamine [$(CH_3)_2C(SH)CH(NH_2)COOH$] or glutathione [$COOHCH(NH_2)(CH_2)_2CONHCH(CH_2SH)CONHCH_2COOH$] (L : Fe = 0.1–1.0).

Effect of bicarbonate buffer medium

No lepidocrocite formed at any L-cysteine–iron ratio when the system was buffered with bicarbonate ions. As the L : Fe ratio increased, the reaction product simply changed from haematite to 100% goethite.

Addition of bicarbonate buffer (0.05 M) to a suspension buffered with the same concentration of NH_4Cl/NH_3 60 min after addition of L-cysteine, also completely suppressed lepidocrocite in favour of either haematite (at L : Fe = 0.1) or goethite (at L : Fe = 0.2). If a bicarbonate solution was added to the system after the induction period (during which nucleation of the crystalline product occurs)[9] had been passed, however, formation of lepidocrocite was not suppressed. These observations suggest that the bicarbonate ion interferes with nucleation of lepidocrocite.

Interactions of L-cysteine with ferrihydrite

In a previous investigation,[6] polarography measurements showed that the presence of ferrihydrite promoted the rapid oxidation of L-cysteine to the disulphide (cystine) at pH 8 in bicarbonate buffer. The formation of cystine was shown by the appearance of polarography peaks at −0.63 and −0.94 V in the supernatant liquid.[10]

In the present work the same effect was observed when bicarbonate buffer was replaced by NH_4Cl/NH_3 buffer. After a few minutes contact with ferrihydrite (25°C) in this buffer system, polarographic peaks at −0.51 V (due to L-cysteine) and at −0.63 and −0.94 V were observed. In both buffers, oxidation of L-cysteine was around 85% complete after a few minutes contact with ferrihydrite.

The polarographic peaks of L-cysteine and cystine were observed at −0.39, −0.47 and −0.83 V, respectively, in imidazole buffer. This shift in peak position with decreasing pH is in line with that reported earlier by Kolthoff *et al.*[11] Oxidation of L-cysteine to cystine at the ferrihydrite interface was slower at pH 6 than at pH 8. After the first 10 min of contact little cystine formation was detected. During the following 2 h around 70% oxidation gradually took place.

Oxidation of L-cysteine is accompanied by simultaneous reduction of a proportion of the ferric ions in the system.[6,12] The interaction can be summarized by the following equation:

$$\equiv Fe^{III} + RSH \longrightarrow \equiv Fe^{II} + 1/2RSSR + 1/2H^+,$$

hence with an initial L : Fe ratio of 0.2, a maximum

of 20% of the total iron(III) in the ferrihydrite could be reduced.

The oxidation/reduction reaction is preceded by adsorption of L-cysteine on ferrihydrite through the sulphydral group.[6] As the pK of this group is 8.3, adsorption at pH 6 would be expected to proceed less readily than at pH 8 and this would account for the slower reaction at low pH.

Addition of L-cysteine to ferrihydrite at pH 8 was accompanied by an almost immediate darkening of the suspension, which can be attributed to the formation of mixed valence iron(II)–iron(III) hydroxide domains in the ferrihydrite. At pH 6 and with L : Fe = 0.2, the ferrihydrite was a much lighter brown immediately after addition of the organic ligand; the lighter colour is consistent with a slower rate of oxidation/reduction. Considerably higher levels of L-cysteine (L : Fe = 1.0) were needed to produce a noticeable darkening of the suspension at this pH.

Kinetics

The kinetic curves for the system both with and without L-cysteine consisted of an initial induction period followed by a faster transformation stage.

Comparison of the transformation curves at L : Fe = 0.2 in different buffers (Fig. 1) shows that conversion was fastest in bicarbonate buffer (product 100% goethite) and slowest at pH 6 (product 95% lepidocrocite). These differences can be attributed to differences in the rate of interaction of L-cysteine with ferrihydrite at the two pHs.

At pH 8, the overall transformation was slower in the system buffered with NH_4Cl/NH_3 than in that buffered with bicarbonate solution although there was no difference in the rate and extent of oxidation of L-cysteine in either system. The difference in transformation rates suggests that the chloride ion stabilizes ferrihydrite or, alternatively, that the combination of bicarbonate ion and a reducing ligand directly promotes goethite formation.

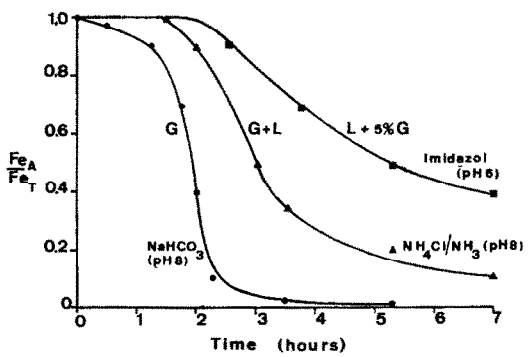

Fig. 1. Fe_A/Fe_T as a measure of the degree of transformation of ferrihydrite into crystalline oxides vs time, for systems with different buffers. Cysteine–iron = 0.2, 70°C. G = goethite, L = lepidocrocite.

Electron microscopy

Lepidocrocite grew from ferrihydrite as comparatively large laths or plates depending on the pH of the system. At pH 6, laths up to 150 nm in width formed [Fig. 2(a)], whereas at pH 8, the crystals grew as plates up to 800 nm in length and 500 nm across [Fig. 2(b)]. Measurements on micrographs of shadowed samples indicated that the crystal thickness was between 20 and 80 nm. SAD measurements showed that these crystals usually lie with the (010) plane parallel to the electron microscope grid as do lepidocrocite crystals grown from ferrous systems: occasionally, thick crystals lie on the (100) face.

Both the laths and the plates usually terminated in serrated ends and the surfaces of the platey crystals often displayed thin cracks or deep serrations [Fig. 2(a) and 2(b)]. These imperfections are probably due to interference during growth by temporarily adsorbed ligands. EDSX spectra (Fig. 3) indicated that sulphur was associated with lepidocrocite grown in the presence of L-cysteine and chemical microanalysis confirmed the presence of 1–2% of organic ligand in the sample. The large sizes of both the cysteine and the cystine molecules make it more probable that the organic ligand would be adsorbed on the surfaces of the crystals rather than incorporated into the crystal lattice.

The crystallinity of lepidocrocite grown from a *ferrous* precursor depends strongly on the rate of crystal growth: the crystals usually form as thin narrow laths.[8] Only with careful control of pH and rate of oxidation are well-developed crystals similar to those obtained here from ferrihydrite produced.

Haematite grew as irregular platelets less than 100 nm across, both with and without the presence of L-cysteine at pH 8 [Fig. 2(c)] and as a mixture of platelets and rhombohedra at pH 6 in imidazole buffered systems. However, in the presence of L-cysteine, haematite grew as granular, rod-like, or, in some cases, ellipsoidal crystals at pH 6 [Fig. 2(d)]. This morphology is reminiscent of that of haematite grown at the same pH in the presence of oxalic acid.[13]

Goethite grew as poorly developed acicular crystals around 300 nm in length in the presence of L-cysteine (pH 6–8) [Fig. 2(e)]. Twinned crystals were not observed.

The transformation of ferrihydrite at pH 6 and at L : Fe = 0.2 into lepidocrocite and some goethite

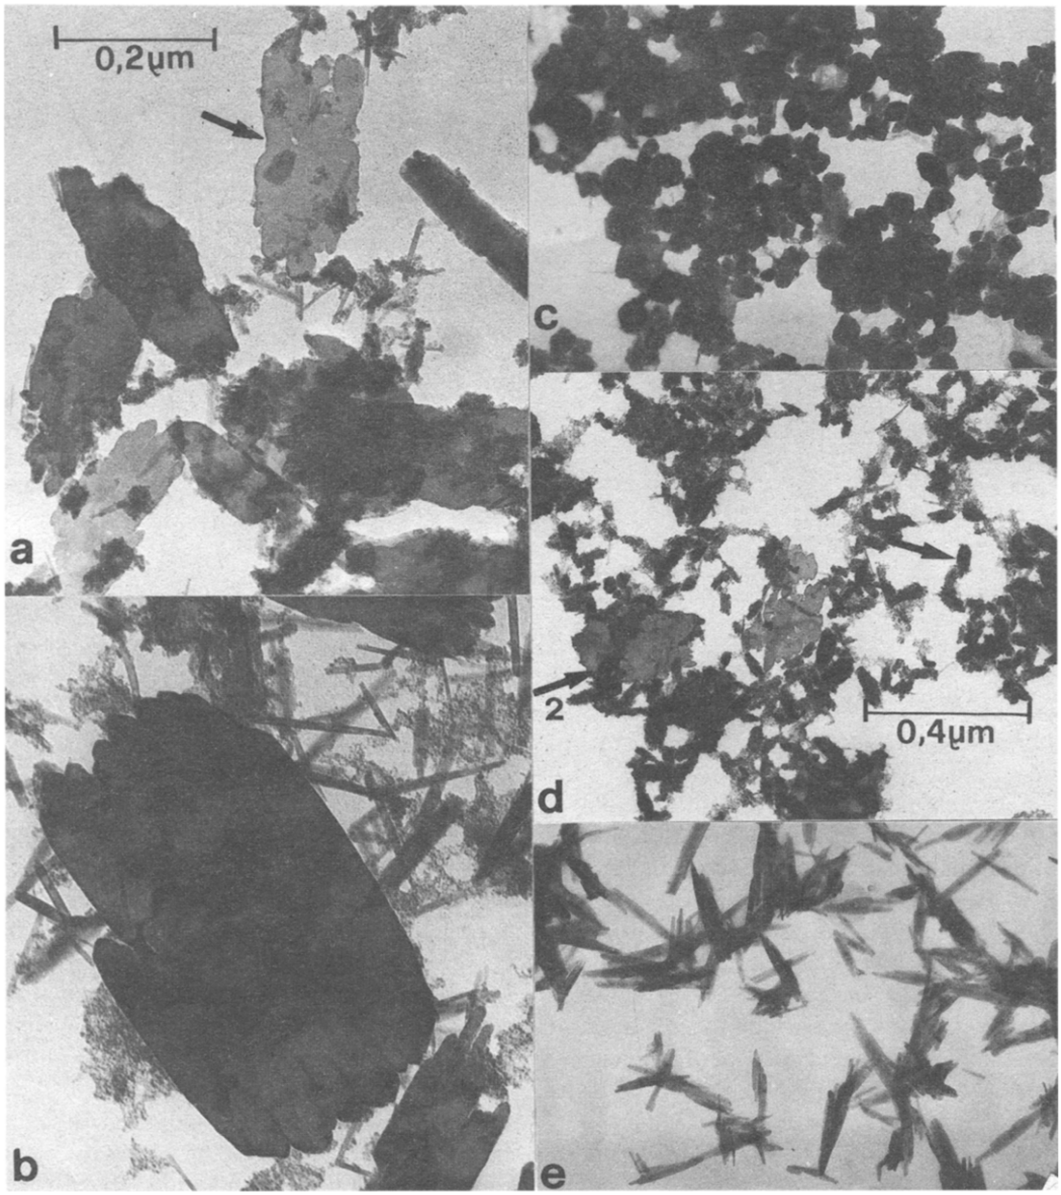

Fig. 2. Transmission electron micrographs of oxides formed from ferrihydrite in the presence of cysteine, 70°C. (a) Lath-like crystals of lepidocrocite (arrow), small acicular crystals of goethite and a trace of ferrihydrite (pH 6, cysteine–iron = 0.1). (b) Large platey crystal of lepidocrocite together with acicular goethite crystals. The amorphous background material is ferrihydrite (pH 8, NH_4Cl/NH_3 buffer, cysteine–iron = 0.2). (c) Haematite platelets (pH 8, $NaHCO_3$ buffer, cysteine–iron = 0.1). (d) Rod-like haematite (arrowed) together with some plates of lepidocrocite (arrow 2) (pH 6, cysteine–iron = 0.1). (e) Acicular crystals of goethite (pH 6–8, cysteine–iron = 0.3).

was followed by TEM examination of subsamples taken during the course of the reaction. After the initial 2–3% transformation, TEM showed an amorphous looking mass of ferrihydrite together with a few laths of lepidocrocite and the occasional needles of goethite [Fig. 4(a)]. These laths were initially very thin and thickened as the reaction proceeded. After 20% reaction the lepidocrocite product consisted of a mixture of very thin laths and much thicker crystals [Fig. 4(b)]. This mixture of crystals suggests that nucleation and growth had occurred simultaneously. The proportion of very thin crystals decreased as the reaction proceeded further, indicating that in the later stages of the transformation growth predominated over nucleation [Fig. 4(c) and 4(d)]. The lepidocrocite crystals reached their maximum widths and lengths in the early stages (first 20%) of the conversion

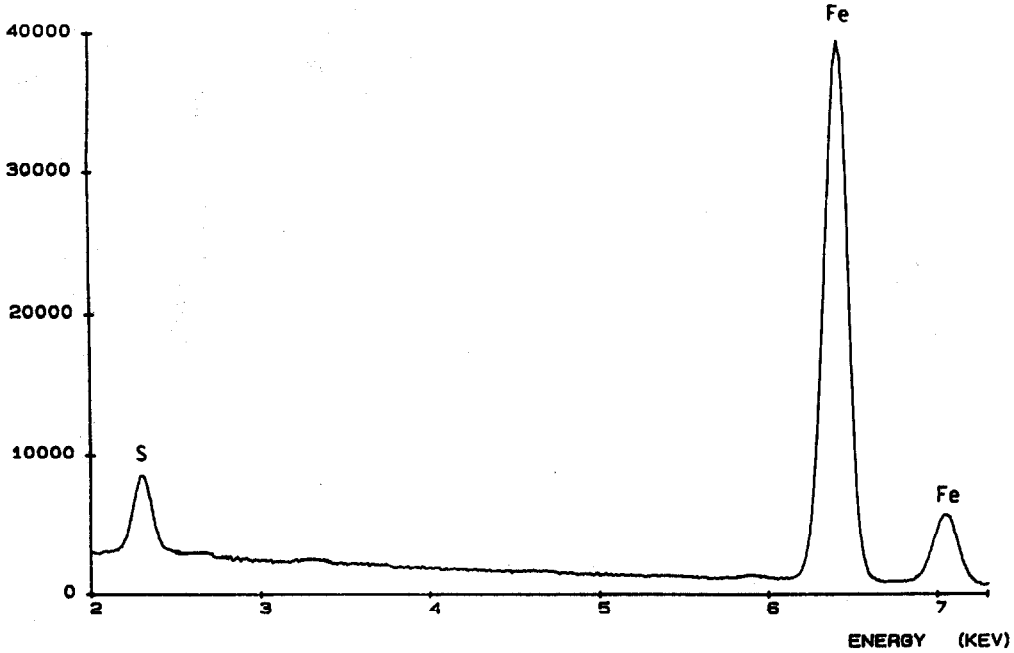

Fig. 3. Energy dispersive X-ray spectrum of lepidocrocite showing the presence of S.

process and subsequent growth took place mainly in the [010] direction, i.e. the crystals became thicker.

TEM examination of a series of subsamples taken during a transformation at pH 8 (L : Fe = 0.2, NH_4Cl/NH_3 buffer) showed similar features to those observed at pH 6. At pH 8, however, the lepidocrocite crystals increased in width as well as thickness over the main part of the reaction. In both systems, lepidocrocite and goethite nucleated simultaneously at the beginning of the transformation.

Formation of crystalline compounds from ferrihydrite

At L : Fe ratios > 0.2, L-cysteine had a strong goethite promoting effect in imidazole and NH_4Cl/NH_3 as well as in bicarbonate systems. As shown earlier,[6] partial reduction of interfacial ferric ions during interaction with L-cysteine converted ferrihydrite into a mixed valence iron(II)–iron(III) compound which dissolved more readily than the original material. As goethite forms in solution from soluble ferric species released by dissolution of ferrihydrite, whereas haematite forms within the particles of ferrihydrite by a solid-state transformation,[1,2] any factor that enhances the solubility of ferrihydrite causes the formation of goethite to become increasingly competitive with that of haematite.

Although lepidocrocite can precipitate directly from acidic ferric solutions, it is commonly synthesized from green rust obtained by oxidation of ferrous solutions.[8] How green rust transforms to lepidocrocite has not been established; both a topotactic transformation and a dissolution/reprecipitation mechanism have been proposed.[14,15]

The present work is the first report of the formation of lepidocrocite by interaction of *ferrihydrite* with a ligand. Although the modified ferrihydrite that develops in systems with L : Fe = 0.1–0.2 is a mixed valence compound, it cannot be termed a green rust. Green rusts are crystalline, greenish-blue compounds and have a ratio of $Fe^{2+} : Fe^{3+} = 3$–4, whereas the partly reduced ferrihydrite was amorphous, light to dark brown and had an estimated $Fe^{2+} : Fe^{3+}$ ratio of 0.1–0.2.

Evidence from both TEM and seeding experiments suggests that lepidocrocite forms from partly reduced ferrihydrite by a dissolution/reprecipitation mechanism. The very thin plates of lepidocrocite that develop initially and the marked difference between the morphology of ferrihydrite (particles 3–5 nm in diameter) and that of lepidocrocite (well-developed laths or plates) are indicative of a transformation involving dissolution of the solid precursor. Structural considerations also support this mechanism. A solid-state transformation which involves structural changes from the hexagonally close-packed anion array of ferrihydrite to the cubic close-packed anion array of the lepidocrocite lattice would be expected to be less

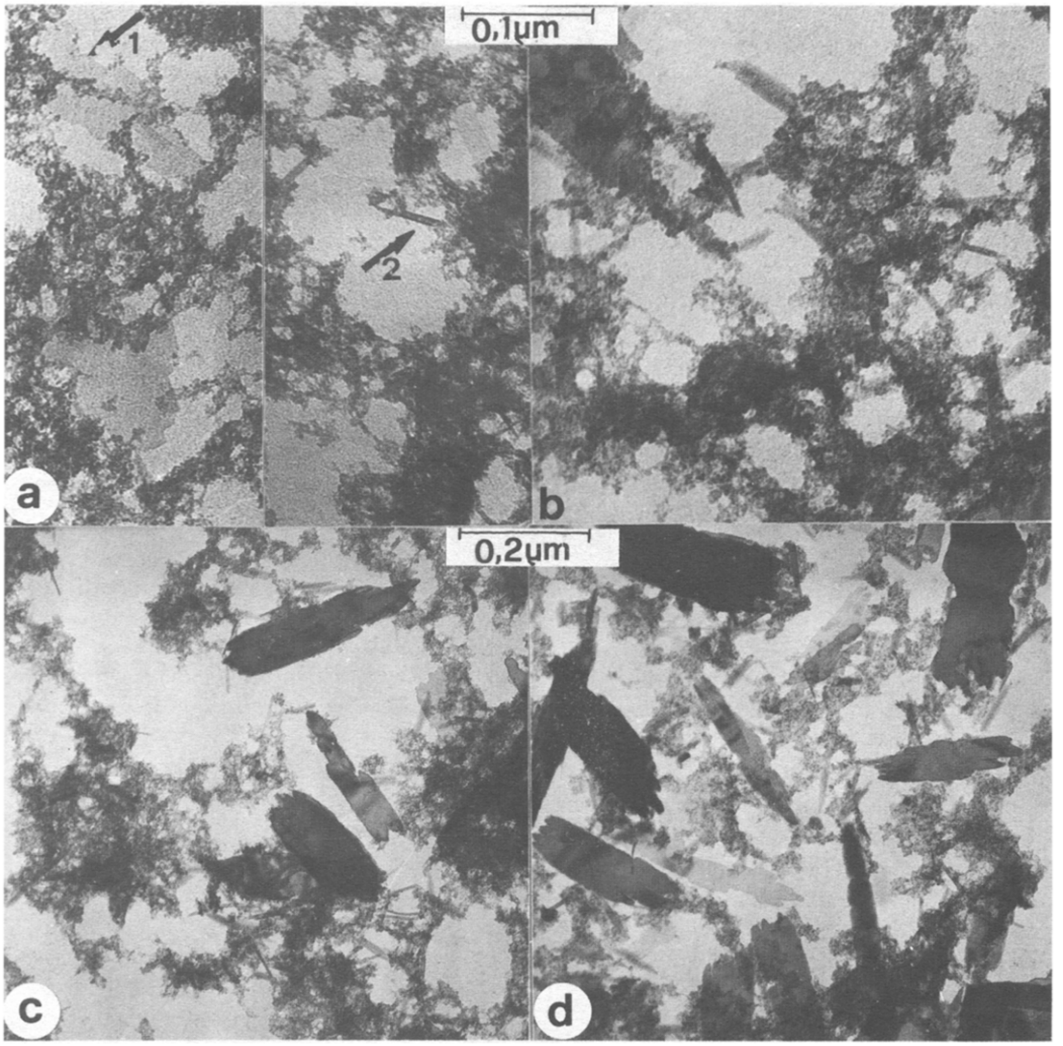

Fig. 4. Transmission electron micrographs of the stages in the transformation of ferrihydrite to lepidocrocite and goethite at pH 6, cysteine–iron = 0.2. (a) 2–3% transformation; arrow 1 indicates lepidocrocite and arrow 2 shows goethite. (b) 20% transformation. (c) 45% transformation. (d) 60% transformation.

favourable energetically than dissolution of partly reduced ferrihydrite. Growth of lepidocrocite from soluble ferric species has been observed previously in alkaline media.[16] At pH 12–13, lepidocrocite is gradually converted into goethite by a dissolution/reprecipitation process: when goethite nucleation was inhibited by the presence of silicate species, the soluble ferric species produced by dissolution of lepidocrocite reprecipitated on the remaining crystals of lepidocrocite causing a change in their morphology from laths to cubes.[16]

A feature of the L-cysteine/ferrihydrite system is the successive appearance of three different transformation products as the L : Fe ratio varies over a narrow range. This characteristic reflects the operation of different transformation mechanisms in the system. At the lowest L : Fe ratio (0.1), haematite and lepidocrocite formed together because the extent of partial reduction was not sufficient for dissolution of ferrihydrite to outweigh completely the internal rearrangement process by which haematite forms. Increasing the transformation temperature of this system from 70 to 90°C enhanced the amount of haematite in the product, presumably because a higher temperature accelerates the dehydration process which precedes haematite formation. The present work provides the first example of lepidocrocite and haematite co-existing in a product: haematite does not form from green rust.

Both goethite and lepidocrocite formed from partly reduced ferrihydrite by a dissolution/reprecipitation process. It is not clear why lepidocrocite forms when the extent of reduction is low, whereas goethite forms as the extent of reduc-

tion (and the rate of dissolution) increases. Differences in solubility products do not appear to influence the order of precipitation. Goethite has a lower solubility product than lepidocrocite ($\log K_{so} = -44$ and -39.8, respectively)[17] and so might be expected to precipitate preferentially in systems with the lowest L:Fe ratios, instead of vice versa. The transformation of the thermodynamically less stable lepidocrocite into goethite can also be excluded, because under the conditions of these experiments, the process is too slow to make any contribution to the formation of goethite.

Murphy *et al.*[7] found that lepidocrocite precipitated from dilute, acidic ferric solutions consisting of monomeric ferric species, whereas goethite could be obtained from ferric solutions containing polynuclear as well as low molecular weight species. In the present work it was observed that at pH 6 and L:Fe = 0.2, increasing either the suspension concentration (five-fold) or the ionic strength (10-fold with KNO_3) completely suppressed lepidocrocite in favour of goethite. These observations suggest that the reaction product in these systems depends mainly on the size and/or charge of the soluble species. Both properties can govern the way in which the soluble ferric species link up to form nuclei[18] and hence could determine the structure of the crystalline precipitate.

In *ferrous* systems the presence of carbonate or bicarbonate ions reduces formation of lepidocrocite in favour of that of goethite.[19] A similar effect with bicarbonate has been observed here in the L-cysteine/ferrihydrite system and has been attributed to interference by the bicarbonate ion in nucleation of lepidocrocite. The lepidocrocite lattice consists of sheets of $Fe(O,OH)_6$ octahedra linked by hydrogen bonds, and TEM showed that an important feature of crystal growth was an increase in crystal thickness, i.e. formation of new sheets of octahedra. These considerations suggest that bicarbonate ions may suppress lepidocrocite by interfering in the formation of new sheets of octahedra, particularly in the earliest stages of nucleation.

Acknowledgements—We are indebted to Miss E. Ettinger for carrying out the electron microscopy and to Mr M. Faller for the X-ray powder diffraction measurements. Financial support was provided by ETH-Kredite für Unterricht und Forschung (Inter-institutional project 1987) and by Robert Ghehm Fonds.

(*Received* 26 *April* 1989; *accepted* 31 *July* 1989)

Abstract—Nickel(II) and copper(II) chlorides react with an excess of cystamine in ethanol to give the bis(cystamine)nickel(II) and copper(II) chlorides which appear to have distorted octahedral and tetragonal symmetry, respectively, on the basis of the IR, Raman and reflectance spectra. In aqueous solution, the metal–S(disulphide) interaction promotes the nucleophilic scission of the sulphur–sulphur bond. In the case of the copper-catalysed reaction, partial reduction of the metal centre occurs. With nickel(II), the reaction leads to the formation of *trans*-[Ni(SCH$_2$CH$_2$CH$_2$)$_2$] which has been characterized by single-crystal X-ray diffraction.

The chemistry of coordinated sulphur is of current interest because of its relevance to biological systems.[1] A salient feature is the redox equilibrium between organic disulphides, RSSR, and mercaptides, RS$^-$, in aqueous solution, which can be shifted by complexation to metal ions. While the existence of disulphide coordination has been postulated for a long time, only recently has it been proved to occur. But, although a number of crystallographic papers are now available which describe the role of the ligand structure on the stereochemistry of the ligated disulphide moiety,[2,3] and although the aminomercaptan chemistry has been widely studied, some aspects of the coordination chemistry of the cysteamine–cystamine couple ($H_2NCH_2CH_2SH-H_2NCH_2CH_2SSCH_2CH_2NH_2$) are still not clear:

(i) neither copper(II) nor nickel(II) cystamine complexes have been reported until now;

(ii) the nature of the deep violet complex formed during the reactions of copper(II) with cysteamine and copper(I) with cystamine has been much debated;[4,5]

(iii) conflicting *cis*[6] and *trans*[7] structures have been assigned to bis(β-mercaptoethylamine)nickel (II) on the basis of vibrational studies.

We report here the synthesis and the characterization of copper(II) and nickel(II) cystamine complexes and their reactivity in aqueous solution. While this work was being completed the X-ray crystal structure of *trans*-bis(β-mercaptoethylamine) nickel(II) has been reported.[8] Some data in this paper are wrong because of a typing error,[9] therefore we will briefly comment on this structure.

EXPERIMENTAL

Materials

Cysteamine hydrochloride and cystamine dihydrochloride (Fluka, purum) were used without

* Author to whom correspondence should be addressed.

further purification. All other chemicals and solvents were of reagent grade quality.

Preparations

Bis(cystamine)nickel(II) *chloride.* A solution of KOH (0.01 mol) in deaerated ethanol (50 cm^3) was added to a stirred suspension of cystamine dihydrochloride (0.05 mol) in ethanol (50 cm^3). The mixture was ice-cooled and KCl was filtered off. The filtrate was then added dropwise under nitrogen to a vigorously stirred solution of $NiCl_2 \cdot 6H_2O$ (5 mmol) in ethanol (50 cm^3). A light green precipitate formed immediately. It was filtered off under nitrogen, washed with ethanol and with diethyl ether, and kept in a refrigerator. Yield 95%. Found: C, 22.6; H, 5.6; N, 12.8; Cl, 16.8; Ni, 13.3; S, 29.2. Calc. for $C_8H_{24}N_4Cl_2NiS_4$: C, 22.1; H, 5.6; N, 12.9; Cl, 16.3; Ni, 13.5; S, 29.5%.

Bis(cystamine)copper(II) *chloride.* A light blue copper complex was prepared by the same method $CuCl_2 \cdot 2H_2O$. Yield 90%. Found; C, 22.1; H, 5.4; N, 12.9; Cl, 16.2; Cu, 14.1; S, 28.7. Calc. for $C_8H_{24}N_4Cl_2CuS_4$: C, 21.9; H, 5.5; N, 12.8; Cl, 16.1; Cu, 14.5; S, 29.2%.

Bis(cystamine)copper(II) *perchlorate.* $[Cu(cystam)_2](ClO_4)_2$ was obtained similarly from $Cu(ClO_4)_2 \cdot 6H_2O$.

Crystals of bis(β-mercaptoethylamine)nickel(II). Bis(cystamine)nickel(II) chloride (0.3 g) was dissolved in water (50 cm^3). The pH was decreased to *ca* 7 and after standing at room temperature for 3 days, the solution yielded dark red rectangular prisms of $[Ni(NH_2CH_2CH_2S)_2]$. A small amount of $Ni(OH)_2$ slurry was separated; crystals were then filtered and washed with water, ethanol and diethyl ether. Yield 15%.

Spectroscopic measurements

IR spectra (KBr pellets) were obtained on a Perkin-Elmer 597 spectrophotometer. Solution UV–vis spectra were recorded with a Beckman 5240 spectrophotometer. A Beckman 5270 spectrophotometer was used for measuring the diffuse-reflectance spectra (reference compound $BaSO_4$). Raman spectra were measured with a Coderg PHO spectrometer by using the 5145 Å line of a Spectra Physics Ar^+ laser. Spectra of cystamine dihydrochloride and $[Ni(cystam)_2]Cl_2$ were obtained from solid pellets mounted on a spinning sample holder. Attempts to measure the Raman spectrum of the copper complex were unsuccessful. The crystallographic study used the standard methods of the laboratory.[10]

RESULTS AND DISCUSSION

Cystamine complexes

The addition of a large excess of cystamine to nickel(II) or copper(II) chlorides or perchlorates in ethanol results in the precipitation of the bis(cystamine)nickel(II) or bis(cystamine)copper(II) complexes. They have not been previously reported although a lot of work has been carried out on the coordination chemistry of cystamine and its methyl derivatives.[4,11,12] The isolation of the copper complexes is also particularly noteworthy since it was reported[12] that all attempts to prepare such complexes by mixing copper(II) perchlorate and cystamine in a variety of solvents failed because of the reduction of copper(II). Disulphide copper(II) complexes are scarce: representative examples are those of cystine,[13] D-penicillamine disulphide[14] and glutathione.[15] The complexes $[Cu(Me_4\text{-cystam})X](ClO_4)_2$ (X = H_2O or CH_3CN; Me_4-cystam = bis[(2-amino-1,1-dimethyl)ethyl]disulphide) have been described in solution.[12]

Analytical data indicate that $[Ni(cystam)_2]Cl_2$ and $[Cu(cystam)_2]Cl_2$ were obtained in a reasonably pure state despite their relative instability and the lack of any suitable organic solvent for recrystallization. They dissolve in water with decomposition (see below). The solids slowly decompose in moisture.

Three ν(N—H) bands at *ca* 3110, 3200 and 3260 cm^{-1} are observed in the IR spectra of $[Cu(cystam)_2]Cl_2$ and $[Cu(cystam)_2](ClO_4)_2$, and at *ca* 3160, 3240 and 3310 in the IR spectrum of $[Ni(cystam)_2]Cl_2$. This supports coordination to the metal atom through both nitrogen atoms of each ligand.

The reflectance spectrum of $[Ni(cystam)_2]Cl_2$ shows several bands at 8000, 11,365, 16,130, 26,100, 37,000 cm^{-1} and somewhat less-resolved features at 12,800, 15,850 and 20,400 cm^{-1}. The two low-energy well-resolved bands indicate an octahedral coordination. Nickel is likely to be surrounded by two tridentate cystamine ligands: each ligand would coordinate by both nitrogen atoms and by one sulphur atom. However, this nickel–sulphur interaction would not significantly alter the disulphide bond since the S—S Raman stretch frequency (502 cm^{-1}) is only slightly lowered compared to that of the free ligand (511 cm^{-1}). A similar situation has been found in chloro- and bromo(bis{2-[(2-pyridylmethyl)amino]ethyl}disulphide)nickel(II) perchlorates.[2,16] Another possibility would be a polymeric structure with nickel(II) ions bridged by cystamine ligands.

The reflectance spectrum of $[Cu(cystam)_2]Cl_2$ shows two broad bands centred at 12,500 and

37,000 cm^{-1}, consistent with tetragonal symmetry. The 12,500 cm^{-1} band is assigned to a *d–d* transition. The 37,000 cm^{-1} band may be assigned to a $N(\sigma) \rightarrow Cu^{II}$ charge-transfer transition and/or to the $n_a \rightarrow \sigma^*$ transition that occurs in aliphatic disulphides.[17] The absence of any intense band at *ca* 20,000 cm^{-1}, where the $S(\sigma) \rightarrow Cu^{II}$ charge-transfer band is expected,[12] indicates that the sulphur–copper(II) interaction is at best weak. Coordination of chloride can be excluded since the IR spectrum of $[Cu(cystam)_2](ClO_4)_2$ is essentially identical to that of the chloride compound, except for the perchlorate absorption at 1120, 1085 and 625 cm^{-1}.[18]

Disulphide bond cleavage

Bis(cystamine)nickel(II) and -copper(II) complexes are unstable in the presence of water.

The nickel(II) complex aqueous solution becomes turbid on standing due to the precipitation of nickel hydroxide. Then the mixture turns to red–brown and dark red crystals of a good size (1 mm) deposit within a few days. This crystalline material was proved by IR and X-ray powder diffraction studies to be identical to samples of the bis(β-mercaptoethylamine)nickel(II) complex obtained from nickel(II) and cysteamine[19] and from the trinuclear $[Ni\{Ni(SCH_2CH_2NH_2)_2\}_2]^{2+}$ complex.[19]

When the $[Cu(cystam)_2]Cl_2$ complex is dissolved in water, a red–brown solution is formed. The absorbance reaches its maximum (450 nm; $\varepsilon \simeq 600$ mol^{-1} dm^3 cm^{-1} per Cu) after *ca* 30 min and then slowly decreases. A purple–grey solid precipitates when excess chloride is added to the solution. This observation may be compared to the fact that chloride is essential for the formation of the purple mixed-valence copper(I)–copper(II)–penicillamine[5] and –dimethylcysteamine complexes[20] and of some other mixed-valence copper compounds.[21] The red–brown species is clearly distinct from the violet transient species formed during the reaction of Cu^{2+} and cysteamine.[4] But, whatever its true nature is, its formation almost certainly implies that part of the copper(II) is reduced to copper(I) by the cysteamine formed by cleavage of the cystamine. This is in agreement with previous observations.[12]

The above facts clearly point out the faster cleavage of cystamine in aqueous solutions containing nickel(II) or copper(I) ions. It is well known that heterolytic bond cleavage of disulphides is facilitated by concomitant electrophilic and nucleophilic attack.[22] Although most effective catalysts in the sulphur–sulphur bond scission are silver(I), mercury(II) and palladium(II), the reaction is now well documented with copper(II)[12,23,24] and with cobalt(III).[25,26] The reaction is supposed to occur via initial electrophilic attack on the sulphur–sulphur bond by the metal ion and subsequent nucleophilic attack by water to form the thiol and the unstable sulphenic acid (RSOH).

To our knowledge, no case of catalysis of the disulphide bond scission by nickel(II) has been previously reported, although extensive studies of nickel(II) complexes with thiols and disulphides have been made.[2,16,27,28] By comparison, the half-life of cystamine disulphide cleavage in 1.0 M NaOH in 80% ethanol solution at 37°C is 84 h.[29]

Crystal structure of bis(β-mercaptoethylamine) nickel(II)

The *trans*-$[Ni(SCH_2CH_2NH_2)_2]$ complex forms monoclinic crystals of space group $P2_1/c$ with two molecules per unit cell; $a = 4.847(3)$, $b = 10.255(5)$, $c = 7.892(4)$ Å and $\beta = 94.35(5)°$. Using the alternative $P2_1/a$ space group, Font-Altaba and coworkers quoted $a = 7.298$ Å, their correct value being 7.928 Å,[9] unfortunately all computations and discussions were based upon $a = 7.298$ Å.[8]

The structure was refined by full-matrix least-squares techniques to $R = 0.044$ for 61 parameters and 525 observed reflections with $\theta \leqslant 25°$ [$I \geqslant 3\sigma(I)$].[30] The structure is in agreement with ref. 8. However, the actual dimensions of the NiN_2S_2 skeleton deserve some comments. The value of the NNiS angle (87.9(2)°) is exactly the same as in bis(N,N-dimethyl-β-mercaptoethylamine)nickel (II).[31] Also the Ni—S bond length (2.193(2) Å) is nearly identical with that of the dimethyl derivative (2.198(3) Å).[31] Both values are in agreement with literature data[32–34] although significantly longer than the mean value of 2.155(3) Å found in the *cis*-$[Ni(SCH_2CH_2NH_2)_2]$ units of the $[Ni\{Ni(SCH_2CH_2NH_2)_2\}_2]^{2+}$ complex.[32] The Ni—N distance (1.904(7) Å) is in the range normally found for planar nickel(II) chelates,[31] so that the N—H···S bond does not seem to affect the chelate ring geometry.

Tables of atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

ANNOUNCEMENT

THE ROYAL SOCIETY OF CHEMISTRY
IXth INTERNATIONAL SYMPOSIUM ON
ORGANOSILICON CHEMISTRY
UNIVERSITY OF EDINBURGH
16-20 JULY 1990

The Organisers have pleasure in inviting all interested persons to attend the **IXth International Symposium on Organosilicon Chemistry** to be held at the University of Edinburgh from Monday 16 July to Friday 20 July 1990, with participants foregathering on Sunday 15 July. A reception will be held on Sunday evening for all participants. The afternoon and evening of Wednesday 18 July will be set aside for organised excursions, with the Symposium Dinner on Thursday 19 July. The meeting concludes after lunch on Friday 20 July.

SCIENTIFIC PROGRAMME

The plenary lectures will be held in single sessions whereas the invited and contributed papers will be in parallel sessions. Time will also be set aside in the programme for posters and discussion sessions.

Contributed papers are invited for oral or poster presentation. Anyone wishing to contribute a paper should submit a title and synopsis (*ca* 100 words) **not later than 8 January 1990** to Dr John F. Gibson at the address below, indicating the type of presentation preferred.

FURTHER INFORMATION

Further information, including details of the programme, submission of papers, plus fees and other charges are available from:

Dr John F. Gibson

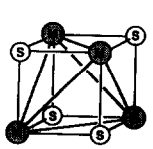
5. SUMMARY 2879

1. INTRODUCTION

Homometallic M_4S_4 cubane-type clusters have been known for some 20 years. They all contain the core **1**, which is characterized by two interpenetrating tetrahedra made up of four metal atoms and four triply-bridging sulphur atoms, respectively. (Although the core in **1** is drawn as a cube to

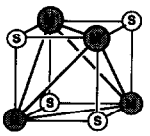


(1)

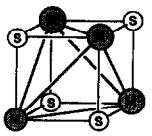
emphasize the cubane-type structure, the M_4 tetrahedron is usually smaller than the surrounding S_4 tetrahedron.) Each metal atom is also coordinated by one to three other ligands (L). Although this general structure is observed in all the cubanes, various distortions are observed in the two

tetrahedra. The number and type of distortions are determined both by the direct metal–metal bonding and by the metal–sulphur and metal–ligand bonding. These in turn are influenced by several factors, two of the most important being the number of metal *d*-electrons and the coordination geometry around each metal atom. The M_4S_4 clusters not only form an intriguing class of inorganic and organometallic clusters, but also, in the case of many of the Fe_4S_4 clusters, have served as important synthetic analogues for the redox sites of iron–sulphur proteins.[1-3] The theoretical attempts to understand the electronic structure and properties of these clusters have ranged from qualitative and approximate molecular orbital (MO) treatments[4-12] to more exact spin- and space-unrestricted X_α calculations.[13-16] Notable among the theoretical treatments of these clusters is the development of qualitative MO bonding schemes by Dahl and co-workers.[4,8,17,18] Based initially upon the T_d symmetry of the clusters, and later augmented by approximate MO calculations, these schemes make it possible to understand the metal–metal bonding and to predict the structures of many of the M_4S_4 clusters.

Within the last 10 years a number of heterometallic $M_2M'_2S_4$ and MM'_3S_4 clusters containing the cores **2** and **3**, respectively, have been synthesized and characterized. The motivation for the



(2)



(3)

synthesis and study of the clusters having an $MoFe_3S_4$ core has come primarily from their relation to a mixed-metal–sulphide cluster present in nitrogenase,[19,20] but the combinations of metals, ligands and ligand coordination geometry observed in the heterometallic clusters extend far beyond those found in the $MoFe_3S_4$ clusters. In spite of the proliferation of these heterometallic clusters, the theoretical treatments of these systems have been few.[12,21,22] Unfortunately, the qualitative MO schemes of Dahl and co-workers are not easily extended to these lower symmetry heterometallic clusters. A recent set of calculations on several $M_2M'_2S_4$ clusters showed that it was useful to view the metal–metal bonding in these clusters in terms of available orbitals on the MS_3L_x ($x = 1, 2, 3$) fragments within the clusters.[22] An examination of the structures, electron counts and available MO calculations for a wide range of both homo- and heterometallic cubane-type clusters suggests that this same approach can be used to derive qualitative cluster MO bonding schemes for a large number of both homo- and heterometallic cubanes.

The cubane-type clusters can be divided into various groups based upon the coordination geometry around each metal atom in the cluster. Many of the homometallic clusters fall into the classification where all of the metals in the cluster lie in a pseudo-octahedral environment. In a number of other clusters the coordination around the metal atoms may be pseudo-tetrahedral, square pyramidal, or trigonal bipyramidal. In most of the homometallic clusters, the coordination geometry around each metal is identical, and there are only a few clusters in which the metal atoms exhibit two different coordination geometries. In the heterometallic $M_2M'_2S_4$ and MM'_3S_4 clusters, on the other hand, the different metals usually exhibit different coordination geometries, and only a few heterometallic clusters are known in which the coordination geometry around all the metals is the same.

This report groups the clusters into classes according to metal coordination geometry and considers the relation between structure, bonding and electron counts in each group. A qualitative metal cluster bonding scheme is presented for each class. In several of the homometallic groups the metal cluster bonding is described in terms of both the qualitative Dahl model, which is most applicable to homometallic clusters in which the ligand coordination around all four metals is the same, and a "metal fragment orbital" model, which becomes particularly useful for clusters having two different kinds of metal coordination and/or two different metals. It is important to recognize that in the systems where both of these models can be applied, the Dahl model and the fragment model provide consistent pictures of the metal cluster bonding. It should be pointed out that the bonding schemes described in this report are *qualitative* and are subject to the limitations inherent in such schemes. In several cases these limitations are pointed out and the need for further electronic structure calculations is discussed. Electronic structure calculations have already provided a more

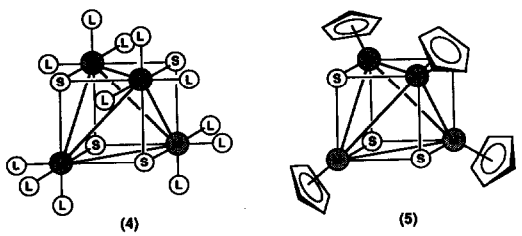
detailed picture of the bonding in some of these clusters, and the results of these calculations provide both a basis and a check for the qualitative schemes.

The discussion in this report is limited to clusters having metal–sulphur cores of structures type **1**, **2** or **3**. A number of clusters incorporating other cubane-type cores are known,[23] and the metal cluster bonding schemes described in this report should be useful in describing the cluster bonding in many of these other cubane-type clusters. Since the discussion is also limited to "single" cubane clusters, the "double" cubane clusters containing two MFe_3S_4 cores are not explicitly considered. The bonding schemes described here should also be applicable to the individual cubane units within these larger clusters.

2. HOMOMETALLIC CLUSTERS HAVING AN M_4S_4 CORE

2.1. *All four metals octahedrally coordinated*

The clusters in this class are characterized by the general formula $M_4S_4L_{12}$ (**4**) or $M_4S_4Cp_4$ (**5**). If the metal–metal bonds are ignored, each M atom is six-coordinate (Cp is considered to occupy



three coordination sites) and can be viewed as part of a pseudo-octahedral fragment within the cluster. A number of the clusters making up this group are listed in Table 1. Also included in the table are the number of "metal" electrons (this number is calculated from the formal oxidation states of the four metals in the clusters) and the metal–metal distances found in each cluster. It should be noted that all 12 of the ligands in the $M_4S_4L_{12}$ clusters are not always identical. In $[Mo_4S_4(NO)_4(CN)_8]^{8-}$, for example, each molybdenum atom is coordinated by two cyanide ligands and one nitrosyl ligand.[24] In some clusters multidentate ligands occupy more than one coordination site and may actually span two metal atoms. The structure of $Mo_4S_4(S_2CNEt_2)_6$ is shown in Fig. 1. Here, four of the bidentate Et_2dtc ligands each bind to a single molybdenum atom, while each of

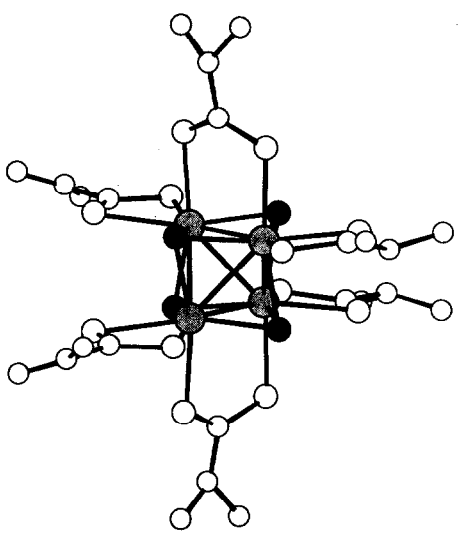


Fig. 1. Structure of $Mo_4S_4(S_2CNEt_2)_6$ (refs 25 and 26). Only the first C in each Et group is shown. One bidentate Et_2dtc ligand is bound to each Mo, and the remaining two Et_2dtc ligands each span two Mo atoms. Neglecting the Mo—Mo bonds, each Mo is bound to six S atoms and is approximately octahedral.

Table 1. Homometallic clusters having structure type **4** or **5**: all four metals octahedrally coordinated

Cluster	Number of metal electrons	M—M distances	Reference
$Ti_4S_4(MeCp)_4$	4	2.927, 2.932 3.006(2), 3008(2)[a]	16

[a] Numbers in parentheses indicate number of averaged distances.

the two remaining Et_2dtc ligands span two molybdenum atoms.[25,26] The $M_4S_4L_{12}$ and $M_4S_4Cp_4$ designations are meant to indicate that in these clusters six coordination sites are occupied around each metal atom resulting in approximately octahedral coordination of all four metals.

In all the cubane-type clusters there are three sets of bonds which have to be considered when describing the electronic structure. These are the metal–metal bonds, the metal–ligand bonds, and the bonds between the metals and the sulphurs which are part of the M_4S_4 core. The metal–ligand and metal–sulphur interactions are both stronger than the metal–metal interactions, and the qualitative bonding schemes described here assume that the stronger metal–ligand and metal–sulphur interactions can be separated from the weaker metal–metal interactions. (From now on the stronger M—L and M—S interactions will be grouped together and described collectively as "metal–ligand interactions".)

The Dahl group synthesized and characterized several $M_4S_4Cp_4$ clusters.[4,17,40,42] The structure of $Co_4S_4Cp_4$ is illustrated in Fig. 2. In this cluster the long non-bonding cobalt–cobalt distances result in a Co_4S_4 core which closely resembles a true cube. Making use of the T_d symmetry of the clusters, the Dahl group developed a qualitative cluster bonding scheme that makes it possible to understand and predict the changes in metal–metal bonding which accompany changes in the number of cluster electrons. Assuming that the metal–metal interactions can be separated from the metal–ligand interactions, the metal *nd*, $(n+1)s$ and $(n+1)p$ orbitals of the four metals making up the metal tetrahedron can be combined to form 36 symmetry adapted combinations. The 20 symmetry combinations involving the 20 *nd* orbitals (five from each metal) prove to be most important to the description of the tetrametal cluster bonding, since it is these combinations which are bonding, non-bonding or antibonding with respect to metal–metal interactions. The ligand orbitals

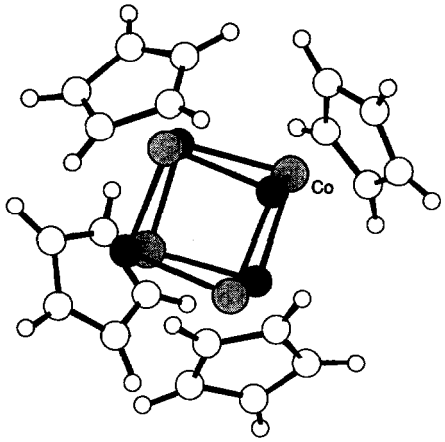

Fig. 2. Structure of $Co_4S_4Cp_4$ (ref. 17). Each octahedral Co is bound to three core S atoms and a Cp ring. Since there are no Co—Co bonds, the Co_4S_4 core closely resembles a cube.

can also be combined into symmetry orbitals, their number and symmetry properties depending on the number and nature of the ligands. The metal and ligand symmetry orbitals can then be combined to form cluster molecular orbitals.

The qualitative MO scheme derived in this manner for the T_d $M_4S_4Cp_4$ complexes[4] is shown in Fig. 3. The M_4 symmetry orbitals are shown on the left. The 20 orbitals resulting from the metal *d* orbitals are divided into three groups—six M_4 bonding orbitals (a_1+e+t_2), six M_4 antibonding orbitals (t_1+t_2), and eight orbitals which are essentially non-bonding between the metal atoms ($e+t_1+t_2$). The symmetry orbitals resulting from combinations of the various S atomic and Cp molecular orbitals are indicated on the right side of the diagram. The cluster orbitals which arise from the interactions of the metal and ligand combinations are indicated in the centre. The lower

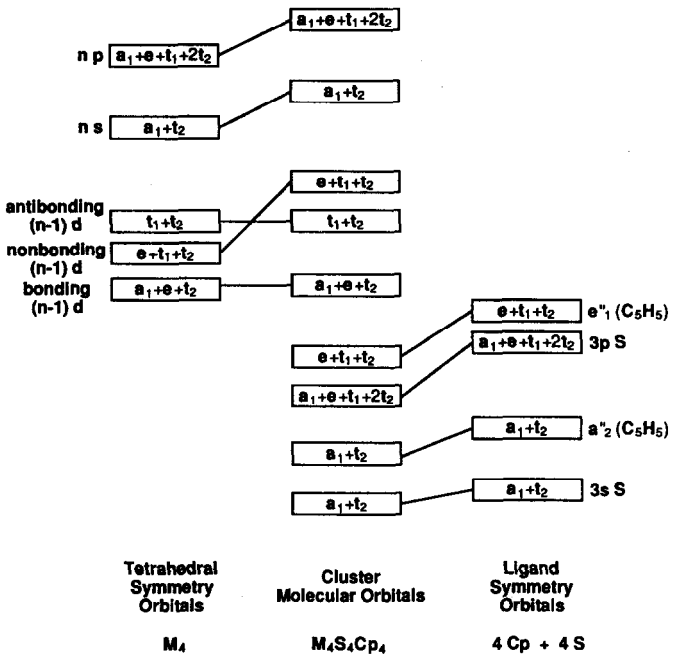

Fig. 3. Qualitative MO energy level scheme derived by the Dahl group (ref. 4) for $M_4S_4Cp_4$ clusters. The scheme is based on cubic T_d symmetry. The symmetry orbitals for the M_4 tetrahedron are shown on the left, while the symmetry combinations of the S and Cp orbitals are shown on the right. The cluster orbitals resulting from interactions between the M_4, S and Cp orbitals are shown in the middle.

energy cluster orbitals are centred primarily on the ligands and are either ligand or M—L bonding orbitals. These levels are completely occupied. The higher energy orbitals are primarily metal in character and are M—L antibonding. The number of electrons occupying these orbitals will depend on both the total electron count of the cluster and the relative energies of the three sets of levels. The relative energies of the metal based cluster orbitals—particularly those which are non-bonding between the metals—are influenced by the metal–ligand interactions. In the $M_4S_4Cp_4$ clusters the interaction between the M_4 non-bonding combinations ($e+t_1+t_2$) and the ligand orbitals of appropriate symmetry are strong enough to destabilize the M_4 non-bonding combinations to energies above the M_4 bonding and antibonding sets of orbitals.

In the cluster valence electron (CVE) scheme of Lauher,[44] an electron count of 60 should result in a completely bonded (six M—M bonds) tetrahedron of metals. In the $M_4S_4Cp_4$ clusters, the lower energy metal–ligand bonding orbitals are occupied by 48 of these electrons. (The four low energy MOs corresponding to the sulphur 3*s* orbitals are not involved in the M—L bonding and are not included in the cluster electron count.) A 60-electron cluster would therefore have 12 metal electrons available to occupy the M_4 cluster orbitals, in this case the set of six M–M bonding orbitals. This should result in a completely bonding tetrahedron of metals, in accordance with the CVE scheme. The $M_4S_4Cp_4$ clusters considered by the Dahl group ($Co_4S_4Cp_4$, with a 72 CVE count and $[Fe_4S_4Cp_4]^{0,1+,2+}$, with 68, 67 and 66 CVE counts, respectively) all have electron counts in excess of 60 and thus have more than 12 metal electrons. These extra metal electrons will occupy M—M antibonding orbitals. In $Co_4S_4Cp_4$, the 24 metal electrons should occupy all six M—M bonding orbitals and all six M—M antibonding orbitals, leading to a completely non-bonding tetrahedron of metals. This is consistent with the non-bonding M—M distance of 3.295 observed in $Co_4S_4Cp_4$. In $[Fe_4S_4Cp_4]^{0,1+,2+}$, where there are 20, 19 and 18 metals electrons, respectively, the M—M antibonding orbitals are partially occupied by 8, 7 and 6 electrons. This should lead to distortions of the M_4 unit away from T_d symmetry, and the Dahl group successfully correlated the experimentally observed differences in M—M bond lengths with the symmetry of the M_4 antibonding orbitals expected to be occupied. They also noted that the larger changes in M—M distances in comparison to the relatively small changes in M—S and M—L distances tend to confirm that these orbitals are primarily metal in character.

This qualitative scheme can be applied to both the $M_4S_4Cp_4$ and $M_4S_4L_{12}$ clusters, and the M—M distances in the clusters listed in Table 1 are consistent with the bonding scheme. The 60-electron clusters, those having 12 metal electrons and a completely filled set of M—M bonding orbitals, all contain a completely bonding metal tetrahedron. The presence of more than 12 metal electrons results in the occupation of M—M antibonding orbitals and leads to a corresponding decrease in the degree of M—M bonding. The M—M non-bonding orbitals are sufficiently high in energy in these clusters that they are never occupied. Clusters containing less than 12 metal electrons will have an incompletely filled set of M—M bonding orbitals, and differences in the M—M distances are again expected. This is certainly true in the clusters containing four metal electrons, where only two short M—M distances, or two M—M bonds, are observed. Interestingly, the structures of clusters such as $[Mo_4S_4(i\text{-PrCp})_4]^+$ and $[Mo_4S_4(i\text{-PrCp})_4]^{2+}$, which contain 11 and 10 metal electrons, respectively, show only small deviations from the structure of $Mo_4S_4(i\text{-PrCp})_4$, which contains 12 metal electrons. According to the bonding scheme in Fig. 3, the occupied M—M bonding orbitals have a_1, e and t_2 symmetry. The relative peak intensities and energies in the valence photoelectron spectrum of $Mo_4S_4(i\text{-PrCp})_4$ indicate that the highest occupied set of orbitals has t_2 symmetry and that the energy ordering of the three highest energy sets of orbitals is $t_2 > e > a_1$.[33] It was suggested by Bandy *et al.*[33] and Davies *et al.*[45] that the highest energy t_2 orbitals are only weakly M—M bonding or nearly non-bonding. This would explain the very small changes in structure in the series $[Mo_4S_4(i\text{-PrCp})_4]^{0,1+,2+}$, where the metal electron count goes from 12 to 11 to 10. Molecular orbital calculations for $Mo_4S_4Cp_4$ and $Cr_4S_4Cp_4$,[11] $V_4S_4(MeCp)_4$ and $[V_4S_4(MeCp)_4]^+$[16] and $[Mo_4S_4(CN)_{12}]^{8-}$,[9] confirm that the t_2 set of orbitals lies highest in energy and that, in general, the order of the levels is $t_2 > e > a_1$. (Results of an earlier calculation for $Cr_4O_4Cp_4$ indicated that a different ordering of levels was appropriate for the $M_4X_4Cp_4$ clusters.[7] This different ordering is inconsistent, however, with both the observed structures of many of the clusters and all other reported calculations.) In a recent study of the magnetic susceptibility of $[Mo_4S_4(edta)_2]^{2-}$, Shibahara and co-workers found that $[Mo_4S_4(edta)_2]^{2-}$ (10 metal electrons) is diamagnetic.[46] They concluded that the HOMO in $[Mo_4S_4(edta)_2]^{4-}$ (12 metal electrons) must be the a_1 orbital, since removal of

two electrons from this singly degenerate orbital would lead to a diamagnetic cluster. They argued that if the electrons were initially removed from the set of t_2 orbitals, the distortions from T_d symmetry are not sufficient to ultimately yield a diamagnetic cluster. Once again, these conclusions are inconsistent with the numerous calculations which repeatedly find that the a_1 orbital is the most stable of the M_4 cluster bonding orbitals. Since $[Mo_4S_4(i\text{-}PrCp)_4]^{2+}$ (10 metal electrons), where it seems certain that two electrons have been removed from the t_2-orbitals, is also diamagnetic,[45] it is more likely that the HOMO in $[Mo_4S_4(edta)_2]^{4-}$ is also of t_2 symmetry. Using overlap population analyses, Williams and Curtis found that for $Mo_4S_4Cp_4$ and $Cr_4S_4Cp_4$ only the a_1 orbital is strongly M—M bonding.[11] The e orbitals are weakly M—M bonding, while the t_2 orbitals are nearly M—M non-bonding in character. They commented that the number of clusters with fewer than 12 metal electrons but short M—M distances is, therefore, not surprising, since even in these clusters the more strongly M—M bonding orbitals are occupied, and partial occupation of the nearly non-bonding t_2 orbitals should lead to only weak first-order Jahn–Teller distortions. It should be noted that a number of the clusters having fewer than 12 metal electrons contain several multidentate ligands which span two metals. Although distinct patterns of short and long M—M distances are more pronounced in these clusters, comparisons of the M—M distances in these clusters should be made with care, since the shorter M—M distances may be dictated by these spanning ligands.

The qualitative bonding scheme developed by the Dahl group is thus seen to be generally applicable to a large number of $M_4S_4Cp_4$ and $M_4S_4L_{12}$ clusters. As discussed above, the development of this scheme depends on the separability of the stronger metal–ligand interactions from the weaker metal–metal interactions. The scheme drawn in Fig. 3 first considers the metal–metal interactions and then adds on the metal–ligand interactions. Alternatively, it is possible to first consider the metal–ligand interactions and then add on the metal–metal interactions. That is, we can first consider a fragment within the cluster composed of a metal and its surrounding ligands. We determine how the metal–ligand interactions within this fragment affect the energies of the metal-based orbitals and *then* combine the metal orbitals to form the tetrametal cluster orbitals. As will be seen below, treating the interactions in this order becomes extremely useful for the less symmetric clusters considered later in the report. We will call this a "metal fragment orbital" approach. Fragment orbital approaches have proved extremely useful in describing the bonding in many organometallic clusters (particularly metal carbonyl clusters)[47,48] where the stronger metal–ligand interactions and the weaker metal–metal interactions can be viewed separately. In metal carbonyl clusters, for example, it is possible to separate a cluster into several $M(CO)_x$ fragments. The M—M bonds in the cluster can then be described in terms of metal-based fragment orbitals. The number, nature and relative energy of these fragment orbitals is determined largely by the number and geometry of the ligands in the $M(CO)_x$ fragment. Each fragment can often be viewed as some part of an octahedron, and the fragment metal orbitals which are available for cluster formation can be related to the t_{2g} and e_g orbitals in an octahedral complex. Upon formation of the cluster, the lower energy t_{2g}-like orbitals remain non-bonding between the metals, while the high energy e_g-like orbitals on each fragment are utilized for the formation of M—M bonds. The spatial orientation of the e_g-like fragment orbitals is such that formation of the M—M bonds tends to complete the octahedral coordination about each metal.

When the M—M bonds are neglected, each of the metal atoms in an $M_4S_4Cp_4$ or $M_4S_4L_{12}$ cluster lies in a pseudo-octahedral environment and can be viewed as part of an MS_3Cp or MS_3L_3 fragment. From the point of view of the metals, there are four such fragments in each cluster. Since the strongest interactions in the cluster occur within these fragments, the numerous lower energy molecular orbitals in each fragment or in the overall cluster are associated with L and M—L bonds. Once these bonds have been separated off, the formation of M—M bonds can be considered. Within each fragment, the energies and orderings of the five metal-based d orbitals are determined by the metal–ligand interactions and the formation of M—L bonds. (These "metal-based" orbitals do contain some ligand character because they are in fact generally M—L antibonding in character. Since they are primarily metal d orbital in character, however, we will refer to them as metal-based.) The actual number of electrons occupying these d orbitals will be determined by the formal oxidation state of the metal.

In a cluster where each metal is approximately octahedrally coordinated, the d orbitals will be split into the familiar pattern for near octahedral coordination, i.e. a set of two e_g orbitals lying higher in energy than a set of three t_{2g} orbitals. This is illustrated in the left side of Fig. 4. Although

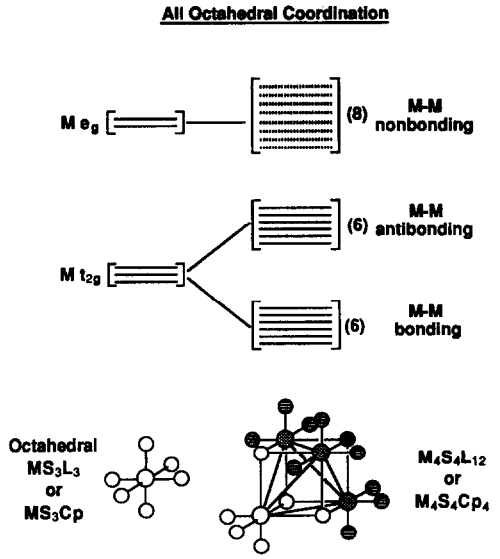

Fig. 4. Qualitative MO energy level scheme (based on the "fragment metal orbital" approach) for the metal-based cluster orbitals in an $M_4S_4L_{12}$ or $M_4S_4Cp_4$ cluster, where each metal is octahedrally coordinated. The splitting of the metal *d* orbitals in an octahedral environment is shown on the left and the resulting groups of cluster orbitals are shown on the right. The lower energy M—L and L bonding orbitals are not shown.

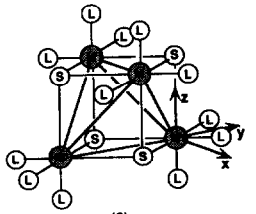
these are not really degenerate sets of orbitals as they would be for perfect O_h symmetry, it is useful to designate them as "e_g" and "t_{2g}" because they are still distinguishable as sets of two and three orbitals. When the local coordinate system on each metal is defined as in **6**, the two sets are $(d_{z^2}, d_{xy})e_g$



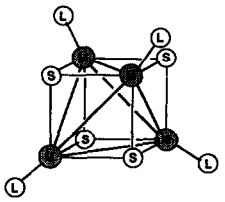
(6)

and $(d_{xz}, d_{yz}, d_{x^2-y^2})t_{2g}$. These are the orbitals which are available for the formation of M—M bonds. The e_g orbitals, which point directly at the six ligands, are not oriented properly for M—M bonding and thus remain non-bonding between the metals. The t_{2g} orbitals *are* oriented properly for M—M bonding and combine in the cluster to form sets of M—M bonding and M—M antibonding orbitals. (This is in contrast to the metal–carbonyl clusters discussed above, where the e_g orbitals are oriented properly to form M—M bonds and the t_g orbitals remain non-bonding between the metals in the cluster.) As illustrated schematically in Fig. 4, the t_{2g} orbitals from the four metal atoms combine to form sets of six bonding and six antibonding levels. The splitting of the metal e_g and t_{2g} orbitals resulting from the metal–ligand interactions is sufficiently large, however, that both sets of cluster orbitals derived from the metal t_{2g} orbitals lie below the set of non-bonding levels derived from the metal e_g orbitals. These sets of bonding, antibonding and non-bonding levels are of course the same sets of levels illustrated in Fig. 3, although the symmetry labels have been omitted in Fig. 4. The main difference between the two approaches is that because the metal fragment orbital approach first takes the *stronger* metal–ligand interactions into account, it is possible to identify the sets of M_4 cluster orbitals with specific sets of metal fragment orbitals. This approach also makes it clear that the energy of the non-bonding M_4 cluster orbitals relative to the M_4 cluster bonding and antibonding orbitals is determined by the relative energies of the e_g and t_{2g} sets of orbitals within each MS_3Cp or MS_3L_3 fragment. Although these non-bonding orbitals are high in energy and not occupied in this group of clusters, this is not the case for many of the other groups described below,

and it becomes useful to understand how and why the energy of the non-bonding levels changes in the different groups of clusters.

2.2. *All four metals tetrahedrally coordinated*

The clusters in this class are characterized by the general formula $M_4S_4L_4$ (7). Neglecting the M—M bonds, each M atom is four-coordinate and can be viewed as part of a pseudo-tetrahedral



(7)

MS_3L fragment within the cluster. A number of clusters which fall into this group are listed in Table 2. These clusters can be further divided into those where L is a π-acceptor ligand and those where L is a π-donor ligand. The acceptor or donor properties of the ligands have a significant impact on the energetic ordering of the M_4 cluster orbitals.

Table 2. Homometallic clusters having structure type 7: all four metals tetrahedrally coordinated

Cluster	Number of metal electrons	M—M distances	Reference
(L = *π-acceptor ligand*)

[a] Et_4N^+ salt.

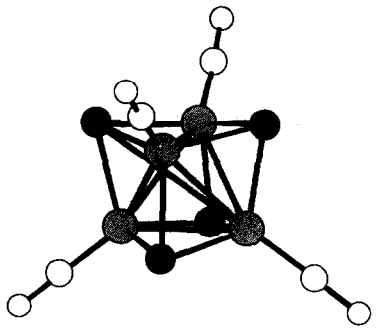

Fig. 5. Structure of $Fe_4S_4(NO)_4$ (ref. 8). Each Fe is bound to three core S atoms and a π-acceptor NO ligand. Neglecting the Fe—Fe bonds, the geometry around each Fe atom is approximately tetrahedral.

2.2.1. *π-Acceptor ligands.* The Dahl group synthesized and characterized both $Fe_4S_4(NO)_4$ and $[Fe_4S_4(NO)_4]^-$.[8,49] (The structure of $Fe_4S_4(NO)_4$ is illustrated in Fig. 5.) Using the same approach applied earlier to the $M_4S_4Cp_4$ clusters, they developed a qualitative bonding scheme appropriate for this type of cluster. Once again, making use of the T_d symmetry of the cluster, the metal orbitals are first combined separately from the ligand orbitals, and the metal and ligand symmetry orbitals are then combined to form cluster molecular orbitals. This scheme is illustrated in Fig. 6. The M_4 symmetry orbitals shown on the left are identical to those in Fig. 3. The symmetry orbitals arising from the S atomic and NO molecular orbitals are shown on the right. The cluster orbitals resulting from the mixing of the metal and ligand orbitals are indicated in the centre. Once again, the lower energy orbitals are either L or M—L bonding orbitals and are fully occupied. The higher energy orbitals are primarily metal centred and fall into the same M—M bonding, antibonding and non-bonding groups found in the clusters where all the metals are octahedrally coordinated. A comparison of the diagrams in Figs 3 and 6 shows, however, that the relative ordering of these groups

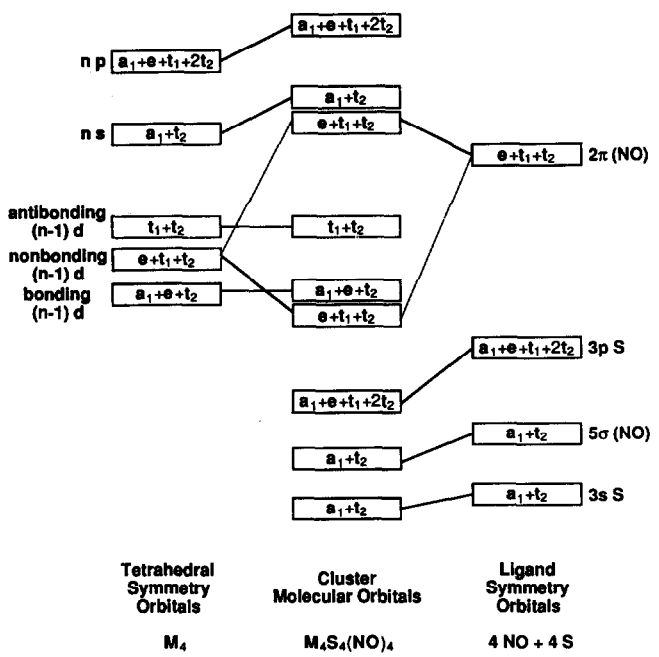

Fig. 6. Qualitative MO energy level scheme derived by the Dahl group (ref. 8) for $M_4S_4(NO)_4$ clusters. The scheme is based on cubic T_d symmetry. The symmetry orbitals for the M_4 tetrahedron are shown on the left, while the symmetry combinations of the S and NO orbitals are shown on the right. The cluster orbitals resulting from interactions between the M_4, S and NO orbitals are shown in the middle.

is different in the two types of clusters. In the clusters containing all octahedral metals the non-bonding M_4 cluster orbitals are destabilized by metal–ligand interactions and lie *above* the M—M bonding and antibonding orbitals. In $Fe_4S_4(NO)_4$ the eight non-bonding cluster orbitals are strongly stabilized by interactions with the π-acceptor NO ligands and lie *below* the M—M bonding and antibonding levels.

Within the CVE counting scheme, the 60-electron $Fe_4S_4(NO)_4$ should contain a completely bonding M_4 tetrahedron. When the 16 lower energy L and M—L bonding orbitals have been occupied by 32 of these electrons, 28 excess metal electrons remain to occupy the M_4 cluster orbitals. (These 28 electrons can also be associated with the presence in the cluster of four Fe^+ (d^7) centres.) These 28 metal electrons will occupy all eight of the non-bonding orbitals and all six of the M—M bonding orbitals. The occupation of the six M—M bonding orbitals is consistent with the six bonding M—M distances of 2.65 Å found in $Fe_4S_4(NO)_4$. Although a CVE count of 60 once again corresponds to a completely bonded M_4 tetrahedron, the actual number of metal electrons and the ordering and occupations of the metal-based cluster orbitals are quite different in this $M_4S_4L_4$ (L = π-acceptor) cluster than in the $M_4S_4Cp_4$ or $M_4S_4L_{12}$ clusters. In the clusters containing octahedral metals, 12 metal electrons are necessary to completely fill the M—M bonding orbitals, and electrons in excess of the required 12 will occupy M—M antibonding orbitals. In the clusters containing tetrahedral π-acceptor ligands, 28 metal electrons are necessary to completely fill the M—M bonding set of orbitals, and only electrons in excess of the required 28 will occupy M—M antibonding orbitals. This qualitative bonding model is confirmed by the fact that when $Fe_4S_4(NO)_4$ is reduced to give $[Fe_4S_4(NO)_4]^-$, all of the M—M distances increase slightly, suggesting that the additional electron occupies an M—M antibonding orbital. Smaller changes in the M—S distances once again confirm that the antibonding cluster orbitals are primarily metal in character. Although no clusters with less than 28 metal electrons have been synthesized, a loss of one or two electrons from the M—M bonding orbitals is expected to have little effect on the M—M distances, since it is probable that just as in the $M_4S_4Cp_4$ or $M_4S_4L_{12}$ clusters the higher energy orbitals belonging to the M—M bonding set are quite delocalized and close to non-bonding. A recent Extended Hückel calculation for $Fe_4S_4(NO)_4$ confirms the occupation of both the non-bonding and bonding cluster orbitals and finds that the t_2 HOMO is essentially non-bonding.[10]

The orbital scheme shown in Fig. 6 is once again derived by first considering the metal–metal interactions and then adding on the metal–ligand interactions. This orbital scheme can also be derived using the metal fragment orbital approach, that is by first considering the stronger metal–ligand interactions and then adding on the metal–metal interactions (Fig. 7). Each metal in the

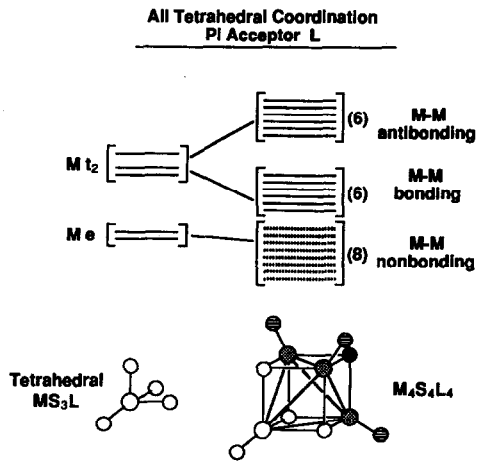

Fig. 7. Qualitative energy level scheme (based on the "metal fragment orbital" approach) for the metal-based cluster orbitals in an $M_4S_4L_4$ cluster, where each metal is tetrahedrally coordinated and L is a π-acceptor ligand. The splitting of the metal *d* orbitals in a tetrahedral environment is shown on the left and the resulting cluster orbitals are shown on the right. The relatively large separation between the "*e*" and "t_2" orbitals in the tetrahedral MS_3L fragment is expected when L is a π-acceptor ligand.

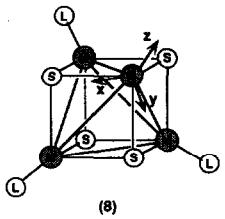
$M_4S_4L_4$ cluster is first viewed as a part of a tetrahedral MS_3L fragment. Within each fragment, the metal *d*-orbitals are split by the metal–ligand interactions into two sets of levels, *e* and t_2. In the tetrahedral environment the *e* orbitals now lie at lower energies than the t_2 orbitals. This is shown on the left side of Fig. 7. Once again, because the MS_3L fragment does not actually have T_d symmetry, these groups of two and three orbitals are not degenerate but do lie close enough in energy to be grouped together. When the local metal coordinate system is defined as in **8** these



(8)

groups of orbitals correspond to $(d_{xz}, d_{yz})e$, and $(d_{xy}, d_{x^2-y^2}, d_{z^2})t_2$. (Because the MS_3L fragment actually has near C_{3v} symmetry, groupings of two, two and one metal orbitals will be apparent. Under C_{3v} symmetry these correspond to *e*, *e* and a_1 sets, where the higher energy a_1 orbital is d_{z^2}. For consistency, however, it is useful to view these as tetrahedral fragments and to classify the two sets of metal orbitals as t_2 and *e*.) In clusters containing octahedrally-coordinated metals the t_{2g} orbitals are used to form M—M bonds while the e_g orbitals remain non-bonding. In clusters containing tetrahedral metals the t_2 orbitals are used for the formation of M—M bonds, while the *e* orbitals can be viewed as non-bonding. The resulting cluster bonding scheme is shown on the right side of Fig. 7. The t_2 orbitals from the four metal "fragments" combine as before to form six bonding and six antibonding cluster orbitals. The bonding orbitals are not the lowest energy M_4 cluster orbitals, however, because the metal *e* levels are sufficiently stabilized by the presence of the π-acceptor ligands that even though they remain non-bonding in the cluster they lie below the bonding levels. The qualitative cluster bonding scheme is entirely equivalent to the scheme in Fig. 6, except that it makes clear why the non-bonding levels lie below the M_4 cluster bonding orbitals. It should be noted that although the non-bonding and bonding orbitals are shown as derived exclusively from the *e* and t_2 metal fragment orbitals this separation is not as clean cut as in the clusters with octahedrally coordinated metals. In those clusters the separation is exact. Here, because the MS_3L fragment is closer to C_{3v} than to T_d symmetry, there will be some mixing of the two sets of metal fragment *e* orbitals upon formation of the cluster orbitals. This does not change the fact, however, that in general the energetic ordering of the M_4 cluster orbitals is non-bonding < bonding < antibonding.

2.2.2. *π-Donor ligands.* All of the known $M_4S_4L_4$ clusters containing π-donor ligands have Fe_4S_4 cores and generally have metal electron counts of 22 or 23. The structure of one of these clusters, $[Fe_4S_4(SPh)_4]^{2-}$, is shown in Fig. 8. While a qualitative cluster bonding scheme can be derived for these clusters, an accurate description of the electronic structure becomes more complicated. Although the Dahl group did not characterize any clusters of this class, they did discuss how the qualitative bonding picture would be altered by the presence of π-donor ligands.[8] They noted that the cluster non-bonding orbitals $(e+t_1+t_2)$ are now expected to be energetically situated between the M_4 bonding orbitals (a_1+e+t_2) and the M_4 antibonding orbitals (t_1+t_2). This ordering comes about because the cluster non-bonding orbitals are somewhat destabilized (relative to the corresponding non-bonding orbitals in the clusters containing π-acceptor ligands) by the presence of π-donor ligands.

A qualitative energy level diagram for an $M_4S_4L_4$ cluster where L is a π-donor ligand can be derived via the metal fragment orbital approach. This diagram is shown in Fig. 9. Once again, the metal *d* orbitals within each MS_3L fragment are split by the metal–ligand interactions into t_2 and *e* sets. In the presence of π-donor ligands the *e* orbitals are destabilized by metal–ligand interactions (or conversely, they are not stabilized as they are in the presence of π-acceptor ligands), so that the separation between the *e* and t_2 orbitals is smaller than in the presence of π-acceptor ligands. As a result, when the t_2 orbitals combine to form bonding and antibonding combinations the energy of the non-bonding cluster orbitals (the metal *e* orbitals) is intermediate between the energies of the bonding and antibonding orbitals.

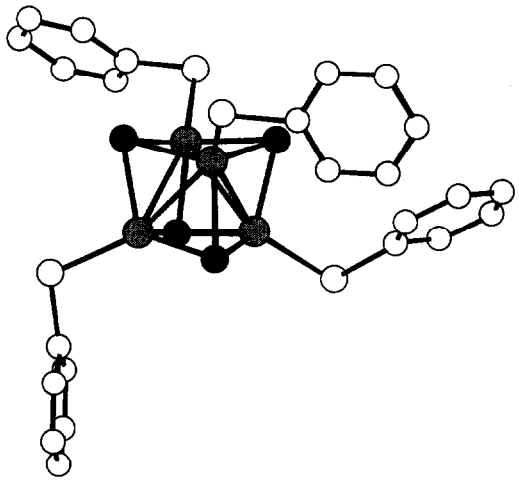


Fig. 8. Structure of $[Fe_4S_4(SPh)_4]^{2-}$ (ref. 57). Each Fe atom is bound to three core S atoms and the S atom of a π-donor thiolate ligand. Neglecting the Fe—Fe bonds, the geometry around each Fe atom is approximately tetrahedral.

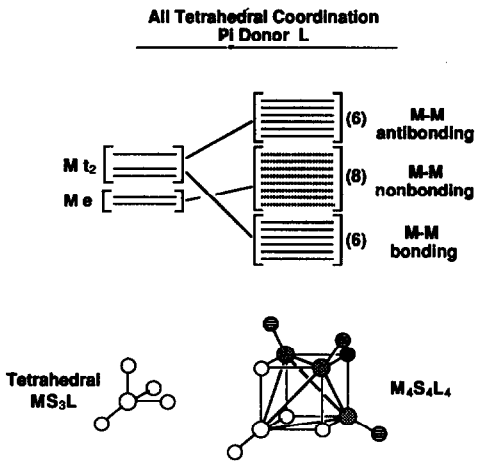

Fig. 9. Qualitative energy level scheme for the metal-based cluster orbitals in an $M_4S_4L_4$ cluster, where each metal is tetrahedrally coordinated and L is a π-donor ligand. The splitting of the metal d orbitals in a tetrahedral environment is shown on the left and the resulting cluster orbitals are shown on the right. The relatively small separation between the "e" and "t_2" orbitals in the tetrahedral MS_3L fragment reflects the presence of the π-donor ligand.

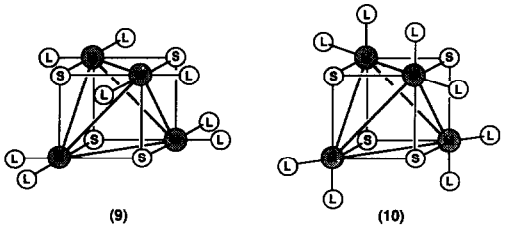
Using the CVE counting scheme, any of the $[Fe_4S_4(SR)_4]^{2-}$ clusters is a 54-electron cluster. When 32 electrons are used for M—L bonding, 22 metal electrons remain to occupy the M_4 cluster orbitals. Alternatively, the 22 "metal" electrons can be associated with two Fe^{2+} (d^6) and two Fe^{3+} (d^5) centres. After 12 of these metal electrons occupy the bonding levels, the 10 remaining metal electrons partially occupy the eight non-bonding levels. The complete occupation of the M_4 bonding levels is consistent with the completely bonded tetrahedron of metals observed in the clusters having 22 metal electrons. That this simple description gives a generally correct picture of the bonding is confirmed by the structural changes which accompany the addition of a metal electron to the core. The most significant changes occur in the M—S bond distances, while the M—M distances remain essentially constant. This suggests that the extra electron enters an orbital which is non-bonding between the metals but is M—S antibonding. Similar changes in the core structure are observed when one electron is removed from the core, also suggesting that the electron is removed from a non-bonding cluster orbital. The similarities and differences in the structures of many of the $Fe_4S_4L_4$ clusters have been discussed in detail in a number of the references in Table 2.

It is interesting to note that a cluster having anywhere from 44 to 60 cluster valence electrons is expected to contain a completely bonded M_4 tetrahedron, since any of the 16 electrons in excess of 44 should occupy a non-bonding cluster orbital. Only an electron count in excess of 60 will result in the occupation of M—M antibonding orbitals. (This assumes that the non-bonding orbitals *all* lie between the bonding and antibonding levels. In fact the energy ranges of the groups of orbitals may well overlap, so that an electron could occupy an antibonding level before all the non-bonding levels were occupied.) This apparent inconsistency with the general rule that a 60-electron count is required for a completely bonding tetrahedron appears to arise from the fact that the original CVE scheme was derived for metal–carbonyl clusters where the bonding schemes are somewhat different.[44] It is not really surprising that the rules derived for those clusters are not always obeyed here.

The bonding scheme in Fig. 9 makes it possible to determine the number of bonding and non-bonding electrons and is consistent with the observed molecular structures for these clusters. It does not, however, provide a description of the various spin states which can occur in these clusters. Eight closely spaced non-bonding metal orbitals are partially occupied by a large number of electrons (in the $[Fe_4S_4(SR)_4]^{2-}$ clusters, 10 electrons occupy eight closely spaced non-bonding levels). Various spin configurations lie close in energy, and it is difficult to calculate an accurate description of the ground-state spin configuration. From a simple viewpoint, we can think of such a cluster as containing four high-spin irons. The t_2 orbitals combine to form completely filled bonding molecular orbitals, leaving a number of electrons in non-bonding orbitals on each iron centre. The spins of these electrons can be weakly coupled together, and a complete description of the electronic structure of these systems requires a calculational technique which can treat this coupling. The $[Fe_4S_4(SR)_4]^{2-}$ clusters have been the subject of several sets of calculations,[5,6,13–15,69] many of which have been aimed at understanding the spin interactions. These calculations confirm that the delocalized MO bonding scheme illustrated in Fig. 9 presents a bonding picture which is qualitatively correct. It is also clear, however, particularly from the work of Aizman and Case[14] and Noodleman *et al.*[15] that an accurate description of the electronic structure of these clusters requires a computational technique which can take into account both the delocalized nature of the interactions and the weak coupling of the spins on the four metal centres.

2.3. *All four metals five-coordinate*

A cluster in this class is characterized by the general formula $M_4S_4L_8$ and ideally may exhibit either of two structures, **9** or **10**. In **9**, each metal atom is five-coordinate (neglecting M—M bonds)



(9) (10)

and can be viewed as part of a nearly square pyramidal MS_3L_2 fragment within the cluster. In **10**, each metal is again five-coordinate but can be viewed as part of a trigonal bipyramidal MS_3L_2 fragment. Clusters having these structures are listed in Table 3. As will become apparent, both in this discussion of clusters in which all of the metals are five-coordinate and in the later discussions

Table 3. Homometallic clusters having structure type **9** or **10**: all metals five-coordinate

Cluster	Number of metal electrons	M—M distances	Reference
$[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$	18	2.730(4), 3.224(2)	70, 71
$[Fe_4S_4(S_2CNEt_2)_4]^{-}$	21	2.845(4), 3.070(2)	72

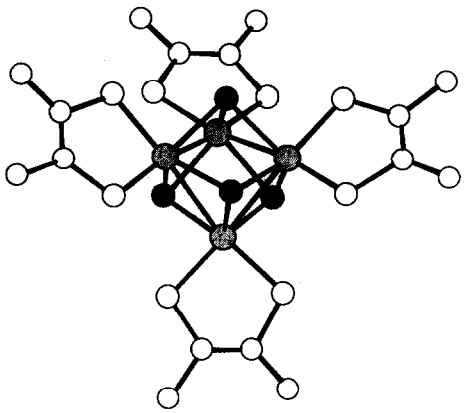


Fig. 10. Structure of $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$ (refs 70 and 71). The F atoms are not shown. Each five-coordinate Fe is bound to three core S atoms and two S atoms of a bidentate dithiolene ligand. Neglecting the Fe—Fe bonds, the geometry around each Fe atom is approximately square pyramidal. Two long Fe—Fe distances indicate that there are only four Fe—Fe bonds in the cluster.

of clusters in which only one or two of the metals are five-coordinate, the distinction between square pyramidal and trigonal bipyramidal coordination is not always clear cut.

The structure of $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$ is illustrated in Fig. 10. One bidentate dithiolene ligand is bound to each iron atom. Since the coordination geometry around each metal is clearly square pyramidal, the cluster corresponds to structure **9**. When the Dahl group structurally characterized this cluster,[71] they noted that the pattern of M—M distances (four shorter plus two long) combined with the presence of 18 "metal" electrons (corresponding formally to four $Fe^{3.5+}$ atoms) suggests that the cluster bonding scheme in $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$ is probably similar to the scheme in $[Fe_4S_4Cp_4]^{2+}$. In that cluster, which contains octahedrally-coordinated metals and 18 metal electrons, 12 metal electrons completely occupy the M—M cluster bonding orbitals and the remaining six metal electrons partially occupy the M—M antibonding orbitals.

A qualitative orbital scheme for a cluster in which each metal is square pyramidal is shown in Fig. 11. The splitting of the metal orbitals brought about by the metal–ligand interactions in each of the square pyramidal MS_3L_2 fragments is illustrated on the left hand side of the figure. A square pyramid is easily derived from an octahedron by removing one of the six ligands surrounding the

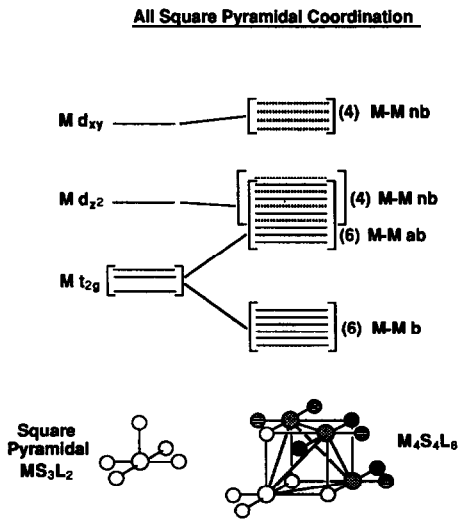

Fig. 11. Qualitative energy level scheme for the metal-based cluster orbitals in an $M_4S_4L_8$ cluster, where each metal is square pyramidal. The splitting of the metal *d* orbitals in a square pyramidal environment is shown on the left and the resulting cluster orbitals are shown on the right.

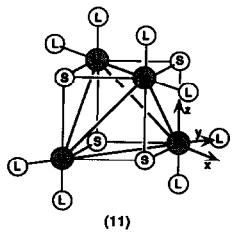
metal. The removal of this ligand (here it is assumed to be a ligand lying on the z-axis in the local coordinate system illustrated in **6**) affects primarily the energy of the metal d_{z^2} orbital, so the degeneracy of the "e_g" orbitals is lost in square pyramidal coordination. Although the d_{xy} orbital remains high in energy, the d_{z^2} orbital is stabilized by the loss of the sixth ligand. The size of this stabilization will depend on the nature of the ligands and the actual geometry of the fragment, but it is clear that the energy of the d_{z^2} orbital will be well separated from the energy of the d_{xy} orbital. Three orbitals corresponding to the t_{2g} orbitals in an octahedral environment lie close together and lowest in energy. (As indicated in Fig. 6, these orbitals actually break up into two sets, because in most examples of square pyramidal coordination, the metal atom lies above the plane defined by the four basal plane ligands. In this geometry, the metal d_{xz} and d_{yz} orbitals lie somewhat higher in energy than the $d_{x^2-y^2}$ orbital.) In the cluster, the t_{2g} orbitals combine to form sets of six bonding and six antibonding M_4 cluster orbitals. The d_{xy} and d_{z^2} orbitals remain M—M non-bonding, but now they will occur as two separate groups of non-bonding cluster orbitals. The non-bonding orbitals derived from the metal d_{xy} orbitals lie highest in energy, while those derived from the metal d_{z^2} orbitals lie lower in energy. As indicated by the qualitative scheme in Fig. 11, non-bonding orbitals derived from these d_{z^2} orbitals are expected to lie within the same energy range as the M—M antibonding orbitals. In the 18-electron $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$ complex, 12 of the metal electrons occupy the M—M bonding orbitals, leaving six electrons to occupy the higher energy cluster orbitals. As discussed above, the similarities in the structures of $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$ and $[Fe_4S_4Cp_4]^{2+}$ suggest that in $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$ these six electrons occupy M—M antibonding orbitals very similar in character to those occupied by six electrons in $[Fe_4S_4Cp_4]^{2+}$. That is, in $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$ the non-bonding metal d_{z^2} orbitals do not lie low enough in energy to be occupied. (This analysis is based on the presence of 18 metal electrons in $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$. Due to the presence of the dithiolene ligands the actual number of "metal" electrons may be somewhat uncertain. If there are actually more than 18 "metal" electrons present in the cluster, then the structure of the cluster suggests that the non-bonding cluster orbitals derived from the metal d_{z^2} orbitals lie at low enough energies to be at least partially occupied.)

The main difference between the bonding schemes for a cluster containing all octahedral or all square pyramidal metals is seen to occur in the relative energies of the non-bonding cluster orbitals. For all octahedral coordination, the non-bonding cluster orbitals lie at sufficiently high energies to always remain unoccupied. For all square pyramidal coordination, the set of non-bonding cluster orbitals derived from the metal d_{z^2} orbitals lie at lower energies and may become occupied in clusters having higher metal electron counts.

The other idealized metal coordination geometry in an $M_4S_4L_8$ cluster is trigonal bipyramidal. As seen in **10**, each metal can be viewed as part of a trigonal bipyramidal MS_3L_2 fragment. In comparison to a square pyramid this coordination geometry alters the energy ordering of the d orbitals within the MS_3L_2 fragment and will therefore also have an effect on the energies of the cluster orbitals. A qualitative energy level scheme for a cluster in which all the metals are trigonal bipyramidal is shown in Fig. 12. The splitting of the metal orbitals within the MS_3L_2 fragment is illustrated on the left. Under the D_{3h} symmetry of a trigonal bipyramid the metal d orbitals are split into three sets—e'', e' and a_1'. When the local coordinate system on each metal in the cluster is defined as shown in **11**, the three sets are $(d_{xz}, d_{yz})e''$, $(d_{x^2-y^2}, d_{xy})e'$ and $(d_{z^2})a_1'$. The d_{xz} and d_{yz} orbitals



(11)

lie lowest in energy, while the d_{z^2} orbital is most destabilized by the metal–ligand interactions and lies highest in energy. The $d_{x^2-y^2}$ and d_{xy} orbitals lie at intermediate energies. Although the orbital splittings are different in a trigonal bipyramid than in a square pyramid, the same metal orbitals (the "t_{2g}" $d_{x^2-y^2}$, d_{xz} and d_{yz}) are used to form M—M bonds. The qualitative cluster orbital scheme

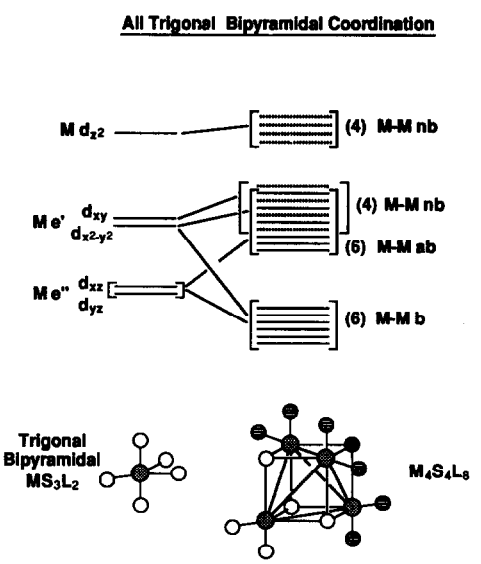


Fig. 12. Qualitative energy level scheme for the metal-based cluster orbitals in an $M_4S_4L_8$ cluster, where each metal is trigonal bipyramidal. The splitting of the metal *d* orbitals in a trigonal bipyramidal environment is shown on the left and the resulting cluster orbitals are shown on the right.

is shown on the right hand side of Fig. 12. The d_{xz}, d_{yz} and $d_{x^2-y^2}$ orbitals from each metal centre, combine to form sets of six bonding and six antibonding cluster orbitals. The metal d_{z^2} and d_{xy} orbitals form two groups of non-bonding cluster orbitals, but the relative energies of these groups are different here than in a cluster where the metals are square pyramidal. Now the non-bonding cluster orbitals derived from the metal d_{z^2} orbitals lie highest in energy, while the non-bonding cluster orbitals derived from the metal d_{xy} orbital lie lower in energy. Once again, the lower energy non-bonding orbitals lie within the same energy range as the M—M antibonding orbitals. In general, simple bonding arguments[48] suggest that the metal d_{xy} orbital in a trigonal bipyramid lies lower in energy than the d_{z^2} orbital in a square pyramid. This suggests that in a cluster containing trigonal bipyramidal metals, the group of non-bonding cluster orbitals derived from the metal d_{xy} orbitals may lie lower in energy, relative to the M—M antibonding orbitals, than the corresponding set of cluster non-bonding orbitals derived from the metal d_{z^2} orbitals in a cluster containing square pyramidal metals. Such generalizations must be made with great caution, however, since the stabilization of the d_{z^2} orbital in a square pyramid is extremely sensitive to both the geometry of the pyramid and the nature of the ligands.

The diagrams in Figs 11 and 12 show that in a cluster with either of the five-coordinate geometries a count of 12 metal electrons will result in the occupation of all six M—M bonding orbitals. Electrons in excess of 12 will first occupy M—M antibonding orbitals, and then at higher electron counts will occupy cluster non-bonding orbitals. It is not clear what forces favour square pyramidal or trigonal bipyramidal coordination in these clusters. This is not surprising, since even in mononuclear complexes the forces favouring one or the other of these coordination geometries are not completely understood.[73] Since the energy barriers to interconversion tend to be small, many complexes are known whose coordination geometries lies somewhere between square pyramidal and trigonal bipyramidal.[74] This "intermediate" coordinate geometry, which can be described either as a distorted square pyramid or as a distorted trigonal bipyramid, is also found in several of the cubane-type clusters containing five-coordinate metals. Although this will further complicate the cluster bonding, the qualitative bonding schemes outlined here for the idealized geometries enable us to recognize that when a cluster contains five-coordinate metals an important feature of the cluster bonding scheme is the presence of a group of cluster non-bonding orbitals at relatively low energies. These orbitals may be occupied *before* all of the M—M antibonding orbitals are occupied, so that in comparison to a cluster with all octahedral metals, a cluster with all five-coordinate metals should be able to accommodate a relatively high metal electron count without as substantial a loss of M—M bonding.

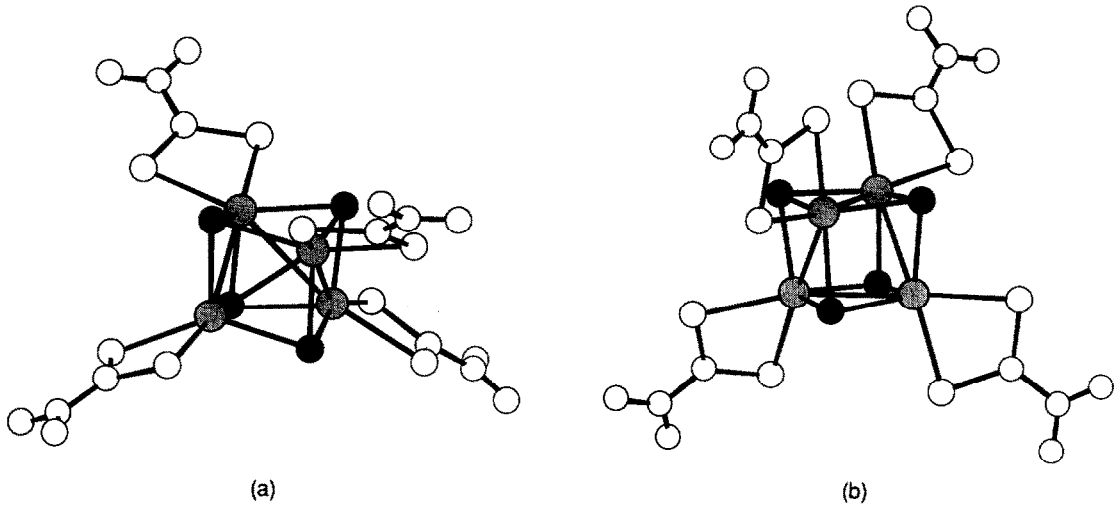

Fig. 13. Two views of the structure of $[Fe_4S_4(S_2CNEt_2)_4]^-$ (ref. 72). Only the first C in each Et group is shown. One Et_2dtc ligand is bound to each Fe atom and, neglecting the Fe—Fe bonds, each Fe is five-coordinate. The view in (a) shows that the geometry around each Fe can be described as distorted square pyramidal, while the view in (b) shows that the geometry around each Fe can also be described as distorted trigonal bipyramidal.

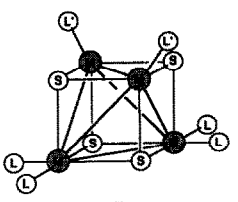
The structure of $[Fe_4S_4(S_2CNEt_2)_4]^-$ illustrates several of these points. In this cluster one bidentate Et_2dtc ligand is coordinated to each metal. Although Liu *et al.* describe the coordination of the metals in this cluster as distorted trigonal bipyramidal,[72] the two views of this cluster shown in Fig. 13 demonstrate that the local coordination about each metal might also be described as distorted square pyramidal. Clearly, the actual coordination geometry lies somewhere in between. Although the cluster contains 21 metal electrons, the M—M distances (four shorter plus two long) are similar to those found in $[Fe_4S_4Cp_4]^{2+}$ and $[Fe_4S_4(S_2C_2(CF_3)_2)_4]^{2-}$, which contain only 18 metal electrons. After 12 metal electrons occupy the six M—M bonding orbitals in $[Fe_4S_4(S_2CNEt_2)_4]^-$, nine electrons remain to occupy higher energy orbitals. If all nine of these electrons occupied M—M antibonding orbitals, we would expect to see longer M—M distances (cf. clusters in Table 1 with metal electron counts of 19 and 20). The similarities in structure with the 18-electron clusters suggest that in $[Fe_4S_4(S_2CNEt_2)_4]^-$ some of these nine electrons occupy non-bonding cluster orbitals. This in turn suggests that in this cluster the lower energy non-bonding orbitals shown in Fig. 11 or 12 lie low enough in energy to become at least partially occupied.

2.4. *Two tetrahedral metals—two five-coordinate metals*

Homometallic cubane-type clusters exhibiting two different metal coordination geometries are relatively rare. One type of cluster falling into this classification can be represented by the general formula $M_4S_4L_4L'_2$ (**12**). Two of the metals are four-coordinate and can be viewed as part of a



(12)

tetrahedral MS_3L' fragment, while the other two metals are five-coordinate and can be viewed as part of a square pyramidal MS_3L_2 fragment. Clusters having this framework are listed in Table 4. The structure of $[Fe_4S_4(Et_2dtc)_2(SPh)_2]^{2-}$ is shown in Fig. 14. In this cluster, the coordination geometry around each five-coordinate iron can be clearly identified as square pyramidal. In

Table 4. Homometallic clusters having structure type **12**: two tetrahedral metals—two five-coordinate metals

Cluster	Number of metal electrons	M—M distances	Reference
$[Fe_4S_4(S_2CNEt_2)_2X_2]^{2-}$			75
(X = Cl^-)	22	2.733, 2.780(4), 3.053	
(X = SPh^-)	22	2.766, 2.816(4), 3.045	

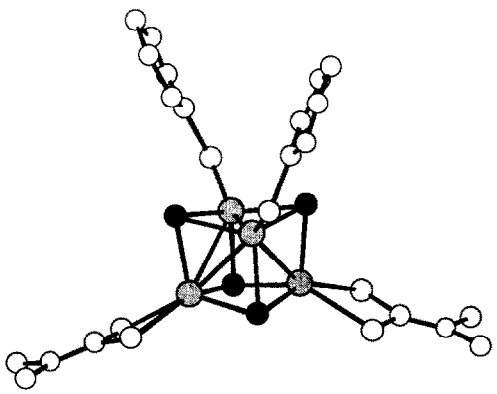


Fig. 14. Structure of $[Fe_4S_4(S_2CNEt_2)_2(SPh)_2]^{2-}$ (ref. 75). Only the first C atom in each Et group is shown. Two of the Fe atoms are bound to three core S atoms and the S atom of a π-donor thiolate ligand. The geometry around these Fe atoms is approximately tetrahedral. Each of the other two Fe atoms is bound to three core S atoms and the two S atoms of a bidentate Et_2dtc ligand. The geometry around each of these five-coordinate Fe atoms is approximately square pyramidal.

$[Fe_4S_4(Et_2dtc)_2Cl_2]^{2-}$, on the other hand, the sulphurs in the dtc ligand are twisted somewhat so that the geometry around the five-coordinate iron is a distorted square pyramid.

A qualitative energy level scheme for clusters having two tetrahedral metals and two square pyramidal metals is derived in Fig. 15. Viewing the M_4 cluster orbitals in terms of metal fragment orbitals becomes extremely useful when the metals in the cluster have different coordination geometries. The splittings of the metal *d* orbitals within the square pyramidal MS_3L_2 and tetrahedral MS_3L' fragments are shown on the left and right of the figure, respectively. The orderings of the metal *d* orbitals are similar to those shown in Figs 11 and 9 for square pyramidal and tetrahedral metal fragments. Since the ligand L′ in the tetrahedral MS_3L' fragment is a π-donor, the separation between the "t_2" and "e" orbitals of the tetrahedral metal is expected to be small. A qualitative scheme for the M_4 cluster orbitals is shown in the centre of Fig. 15. As in the clusters described previously, the square pyramidal "t_{2g}" and tetrahedral "t_2" orbitals are used for M—M bonding. These 12 orbitals from the four metal centres will combine to form sets of six bonding and six antibonding cluster orbitals. The major effect of the two different coordination geometries is the appearance of *three* sets of non-bonding cluster orbitals. These arise from the square pyramidal metal d_{z^2} and d_{xy} orbitals and the tetrahedral metal "e" orbitals. The highest energy set of two non-bonding orbitals is derived from the square pyramidal metal d_{xy} orbitals. Next highest in energy is the set of two non-bonding orbitals derived from the square pyramidal metal d_{z^2} orbitals. This set is expected to lie within the same energy range as the cluster antibonding orbitals. Finally, the lowest energy set of four non-bonding orbitals is derived from the tetrahedral metal "e" orbitals. The energy range of this set is expected to lie between the M—M bonding and antibonding sets. This orbital scheme is consistent both with the schemes appropriate for the clusters described earlier and with the established structures of the $M_4S_4L_2L'_4$ clusters.

The scheme shown in Fig. 15 indicates that after 12 metal electrons occupy the six M—M

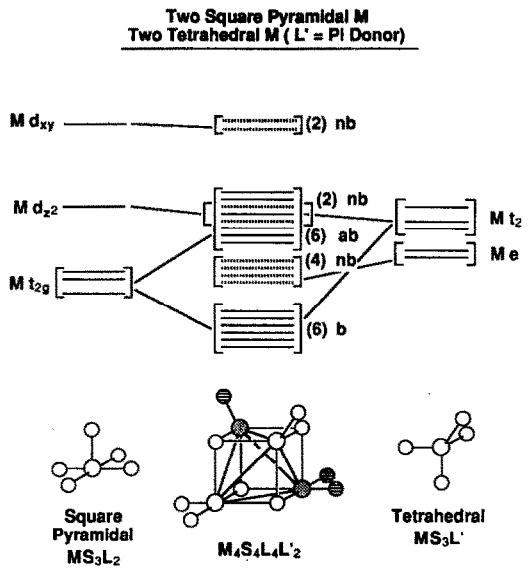

Fig. 15. Qualitative energy level scheme for the metal-based cluster orbitals in an $M_4S_4L_4L'_2$ cluster containing two square pyramidal metals and two tetrahedral metals. The splittings of the metal d orbitals in square pyramidal and tetrahedral environments are shown on the left and right sides of the diagram, respectively. The resulting cluster orbitals are shown in the middle. The relatively small separation between the "e" and "t_2" orbitals in the tetrahedral MS_3L' fragment reflects the presence of a π-donor ligand.

bonding orbitals, up to eight additional metal electrons could be added to the cluster before M—M antibonding orbitals have to be occupied. These eight additional electrons would occupy the cluster non-bonding orbitals derived from the tetrahedral metal "e" orbitals. Thus clusters, having anywhere from 12 to 20 metal electrons, are expected to have a fully bonded metal tetrahedron. Metal electron counts in excess of 20 will result in the occupation of M—M antibonding orbitals. (The upper limit of 20 is not really definite, because the energy range of this set of non-bonding orbitals may well overlap with the energy range of the M—M antibonding levels. If this occurs, antibonding orbitals will become occupied before all of the non-bonding orbitals are filled, i.e. at metal electron counts $\leqslant 20$.) Both $[Fe_4S_4(Et_2dtc)_2X_2]^{2-}$ clusters contain 22 metal electrons and both have similar structures. The distinctive structural feature of each cluster is a long distance (> 3 Å) between the two square pyramidal iron atoms. The other M—M distances are all within bonding range. The cluster bonding scheme in Fig. 15 provides a simple explanation for this structure. Of the 22 metal electrons, if 12 electrons occupy M—M bonding orbitals and eight electrons occupy the lower energy set of non-bonding orbitals, two electrons will have to occupy an M—M antibonding orbital. The one long Fe—Fe distance is consistent with the occupation of an antibonding orbital localized between the two five-coordinate iron atoms.

Although it is satisfying to arrive at this simple description of the bonding in these clusters, further examination of both this bonding picture and the properties of these clusters suggests that this simple description is incorrect. First, although the two clusters are found to be paramagnetic,[75] the orbital occupations just outlined would lead to a diamagnetic cluster. Second, the complete occupation of the "e" non-bonding orbitals would correspond to two tetrahedral Fe^{+} centres and two square pyramidal Fe^{4+} centres. This combination of oxidation states is highly unlikely; a combination of two Fe^{2+} and two Fe^{3+} centres is much more plausible. Oxidation states of 2+ or 3+ for the tetrahedral irons would result in only partial occupation of the "e" non-bonding orbitals. Since the structures of the clusters indicate that only one antibonding orbital is occupied, however, eight electrons *must* occupy non-bonding orbitals. If the "e" non-bonding levels are not completely occupied, some of these eight electrons must therefore occupy the non-bonding orbitals derived from the square pyramidal metal d_{z^2} orbitals. In terms of the diagram in Fig. 15, this means that several of the "e" non-bonding levels, the lower energy antibonding levels, and the "d_{z^2}" non-bonding levels must lie very close in energy. Furthermore, the square pyramidal metal d_{z^2} orbital must be sufficiently

stabilized to become occupied after only one M—M antibonding orbital is occupied. This picture is consistent with high-spin square pyramidal and tetrahedral Fe^{2+} and Fe^{3+} centres combining to form a paramagnetic cluster having one long Fe—Fe bond. Although a detailed description of the electronic structure of these clusters will require calculations capable of treating the spin couplings, the combination of the qualitative bonding scheme and the known properties and structure of the complexes make it possible to understand the general features of the cluster bonding.

This discussion introduces an important element which must be included in any description of the electronic structure of these cubane-type clusters—the electronic configurations of the individual metal centres. The descriptions in this report focus primarily on the total number of metal electrons occupying the M_4 cluster orbitals and generally do not stress the electron configurations or formal oxidation states of the individual metals in the cluster. As we have just seen, however, concentration only on the total electron count can lead to incorrect descriptions of the electronic structure of the cluster. In order to correctly describe the electronic structure it is important to take into account *both* the total number of metal electrons and the number of electrons associated with each metal centre.

2.5. *Three tetrahedral metals—one five-coordinate metal*

Another type of cluster exhibiting two different metal coordination geometries has the general formula $M_4S_4L_2L'_3$. Three of the metals are four-coordinate and can be viewed as part of a tetrahedral MS_3L' fragment, while the fourth metal is five-coordinate and can be viewed as part of an MS_3L_2 fragment. This fragment may be either square pyramidal (**13**) or trigonal bipyramidal (**14**). Clusters having these structures are listed in Table 5. In $[Fe_4S_4(Et_2dtc)Cl_3]^{2-}$, illustrated in

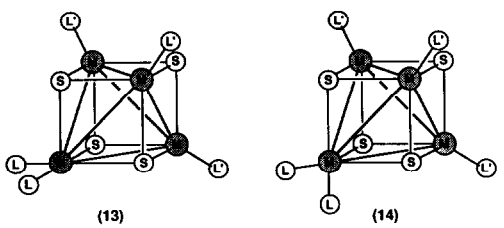

Fig. 16(a), three irons are part of the tetrahedral FeS_3Cl fragments while the third iron is bound to an Et_2dtc ligand and is part of a square pyramidal fragment. In $[Fe_4S_4(SC_6H_4\text{-}o\text{-}OH)_4]^{2-}$, [Fig. 16(b)] three irons are part of tetrahedral fragments, while the fourth iron is bound to both the sulphur and oxygen atoms in the $(SC_6H_4\text{-}o\text{-}OH)^-$ ligand and is best viewed as part of a trigonal bipyramidal fragment.

A qualitative bonding scheme for a cluster having structure **13** is illustrated in Fig. 17. The ordering of the metal orbitals within the square pyramidal and tetrahedral fragments are shown on the left and right hand side of the figure, respectively. These orderings are the same as the orderings shown in Fig. 15. The narrow separation of the tetrahedral "e" and "t_2" orbitals reflects the π-donor ligands in the tetrahedral fragments. The cluster orbitals are shown in the centre of the figure, and the overall groupings of orbitals are similar to the groups shown in Fig. 15. The square pyramidal "t_{2g}" and tetrahedral "t_2" orbitals combine to form sets of M—M bonding and antibonding orbitals. The two different coordination geometries once again result in three sets of cluster non-bonding

Table 5. Homometallic clusters having structure type **13** or **14**: three tetrahedral metals—one five-coordinate metal

Cluster	Number of metal electrons	M—M distances	Reference
$[Fe_4S_4(S_2CNEt_2)Cl_3]^{2-}$	22	2.76(3), 2.850(2), 2.936	75
$[Fe_4S_4(SC_6H_4\text{-}o\text{-}OH)_4]^{2-}$	22	2.725(4), 2.839, 2.868	76

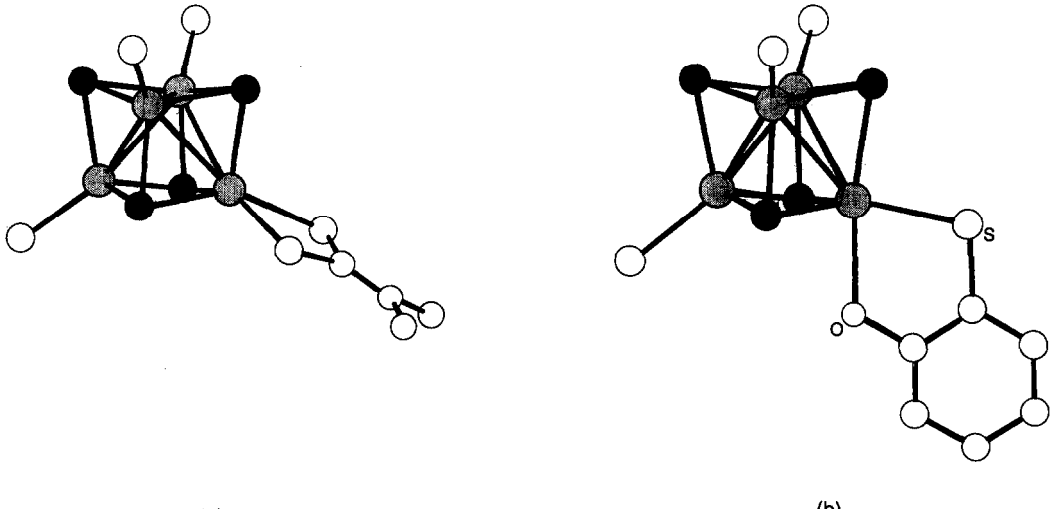

Fig. 16. Structures of (a) $[Fe_4S_4(S_2CNEt_2)Cl_3]^{2-}$ (ref. 75) and (b) $[Fe_4S_4(SC_6H_4\text{-}o\text{-}OH)_4]^{2-}$ (ref. 76). In (a) only the first C atom in each Et group is shown, and in (b) only the S atoms of the three monodentate $(SC_6H_4\text{-}o\text{-}OH)^-$ ligands bound to the tetrahedral Fe atoms are shown. In both clusters the geometry around three of the Fe atoms is approximately tetrahedral, while the fourth Fe atom is five-coordinate. In $[Fe_4S_4(S_2CNEt_2)Cl_3]^{2-}$ (a) the fourth Fe is bound to the two S atoms of the Et_2dtc ligand, and the geometry around this five-coordinate Fe is approximately square pyramidal. In $[Fe_4S_4(SC_6H_4\text{-}o\text{-}OH)_4]^{2-}$ (b) the fourth Fe is bound to both the S and O atoms of the $(SC_6H_4\text{-}o\text{-}OH)^-$ ligand, and the geometry around this five-coordinate metal is better described as trigonal bipyramidal.

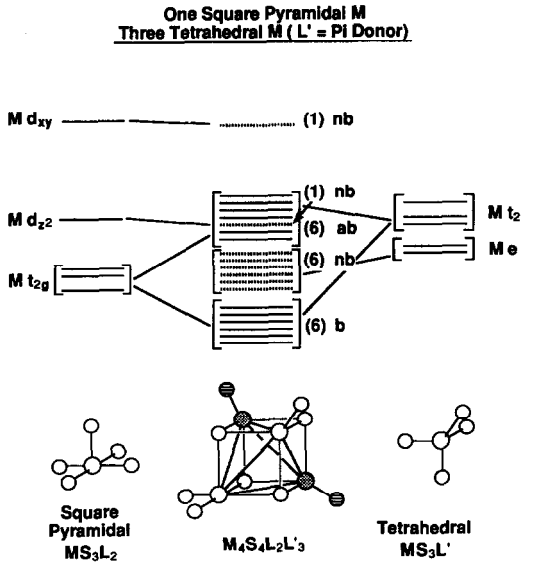

Fig. 17. Qualitative energy level scheme for the metal-based cluster orbitals in an $M_4S_4L_2L'_3$ cluster containing one square pyramidal metal and three tetrahedral metals. The splittings of the metal *d* orbitals in square pyramidal and tetrahedral environments are shown on the left and right sides of the diagram, respectively. The resulting cluster orbitals are shown in the middle. The relatively small separation between the "*e*" and "t_2" orbitals in the tetrahedral MS_3L' fragment reflects the presence of a π-donor ligand.

orbitals, but now the number of orbitals in each set is different from the number shown in Fig. 15. Because there is only one square pyramidal metal, there are only two non-bonding levels associated with the square pyramidal metal orbitals. One non-bonding orbital derived from the square pyramidal metal d_{xy} orbital lies at high energy, and one non-bonding level derived from the square pyramidal metal d_{z^2} orbital lies at lower energy. Since there are now three tetrahedral metals, a group of six non-bonding orbitals derived from the tetrahedral metal "*e*" orbitals falls between the M—M bonding and antibonding sets of orbitals. Although the bonding scheme indicates that all six of these non-bonding orbitals lie between the bonding and antibonding levels, it is very likely that the energy ranges of the non-bonding and antibonding orbitals overlap. If this overlap actually occurs, some of the antibonding orbitals could become occupied before all six of the non-bonding orbitals are occupied. The scheme shown in Fig. 17 indicates that after 12 metal electrons occupy the six M—M bonding orbitals, 12 more metal electrons can be added to the cluster without occupying antibonding orbitals. Thus clusters having anywhere from 12 to 24 metal electrons are expected to have a fully bonded metal tetrahedron. It is only when the electron count exceeds 24 that M—M antibonding orbitals must be occupied. As noted above, however, some of the six non-bonding orbitals may actually lie above the lower energy antibonding orbitals, and if this is the case antibonding orbitals could become occupied at metal electron counts $\leqslant 24$.

The bonding scheme in Fig. 17 can be used to describe the bonding in $[Fe_4S_4(Etdtc)Cl_3]^{2-}$ [Fig. 16(a)]. This cluster has 22 metal electrons, so after 12 metal electrons occupy the six M—M bonding orbitals, the 10 remaining metal electrons could occupy non-bonding orbitals. Based on this analysis, $[Fe_4S_4(Etdtc)Cl_3]^{2-}$ should contain a completely bonded tetrahedron of metal atoms. The actual structure of $[Fe_4S_4(Etdtc)Cl_3]^{2-}$ suggests, however, that an antibonding orbital is occupied, since at least one Fe—Fe distance is somewhat longer than might be expected for Fe—Fe bonding. This indicates that the energy ranges of the group of six non-bonding "*e*" orbitals and the group of six M—M antibonding orbitals do overlap, resulting in the occupation of an antibonding orbital before all of the non-bonding orbitals are occupied. An orbital occupation scheme where only eight electrons occupy the "*e*" cluster non-bonding orbitals and two electrons occupy an antibonding orbital is consistent with the molecular structure of the cluster and also corresponds to reasonable oxidation states for all of the metals (three high-spin tetrahedral iron centres, two Fe^{2-} and one Fe^{3+}, and one square pyramidal Fe^{3+} centre). Alternatively, an orbital occupation scheme in which only seven electrons occupy the "*e*" cluster non-bonding orbitals, two electrons occupy an antibonding orbital, and one electron occupies the non-bonding orbital derived from the square pyramidal metal d_{z^2} orbital is also possible. This scheme is also consistent with the structure of the cluster and corresponds to three high-spin tetrahedral iron centres, one Fe^{2+} and two Fe^{3+}, and one high-spin square pyramidal Fe^{2+} centre. Either one of these descriptions is reasonable.

The other cluster which fits into this class is $[Fe_4S_4(SC_6H_4\text{-}o\text{-}OH)_4]^{2-}$ [Fig. 16(b)], where the five-coordinate iron atom is best viewed as trigonal bipyramidal.[76] This cluster also contains 22 electrons, and the qualitative scheme in Fig. 17 can also be used to describe the cluster bonding in the cluster, since the major effect of a change from square pyramidal to trigonal bipyramidal geometry is the interchange of the non-bonding orbitals associated with the five-coordinate metal (cf. Figs 11 and 12). The bonding scheme in Fig. 17 indicates that $[Fe_4S_4(SC_6H_4\text{-}o\text{-}OH)_4]^{2-}$ should also have a completely bonded metal tetrahedron, but once again a relatively long Fe—Fe distance suggests that an antibonding orbital is occupied. This would again indicate an overlap in the energies of the "*e*" non-bonding and M—M antibonding cluster orbitals. An orbital occupation scheme in which eight electrons partially occupy the "*e*" non-bonding orbitals and two electrons occupy an antibonding orbital once again is consistent with the structure of the cluster and corresponds to reasonable oxidation states for all of the iron centres. The bonding picture will be further complicated if the d_{xy} non-bonding orbital associated with the five-coordinate iron is sufficiently stabilized to be occupied. Several occupation schemes are possible, depending on how the electrons are apportioned to the different metal centres. It is important to recognize, however, that a bonding scheme which assigns more than eight electrons to the non-bonding "*e*" orbitals is unlikely, since it leads to an unreasonable combination of metal oxidation states. It is also quite clear that a better understanding of the electronic structure of these clusters incorporating five-coordinate metals will require detailed calculations.

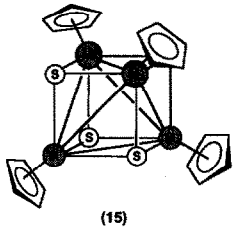
One important outcome of an overview of the bonding schemes expected for the different types of M_4S_4 clusters is the observation that although the same metal electron counts may be found in

a number of clusters, the actual electronic structure of the M_4S_4 cores may differ. For example, the relation between clusters having 22 metal electron $[Fe_4S_4]^{2+}$ cores and the iron–sulphur proteins makes this group of clusters especially interesting. Although most of the interest has concentrated on clusters listed in Table 2, the mixed coordination clusters listed in Tables 4 and 5 also have 22-electron $[Fe_4S_4]^{2+}$ cores. Comparison of the bonding schemes in Figs 9, 16 and 17 makes it clear, however, that even though these clusters all contain 22-electron $[Fe_4S_4]^{2+}$ cores, the cores are not equivalent electronically.

3. HETEROMETALLIC CLUSTERS HAVING AN $M_2M'_2S_4$ CORE

3.1. *All four metals octahedrally coordinated*

Unlike the homometallic clusters, heterometallic clusters in which all four metals have the same coordination geometry are relatively rare. The clusters listed in Table 6 are the only examples of $M_2M'_2S_4$ clusters in which all four metals have similar coordination geometries—in this case octahedral. Although the $M_2M'_2S_4(Me_5Cp)_2(Cp)_2$ clusters listed in Table 6 have not been structurally characterized, spectroscopic evidence indicates that they have the cubane-type structure $M_2M'_2S_4Cp_4$ (**15**). These clusters are therefore expected to be similar to the homometallic $M_4S_4Cp_4$ clusters **5**,

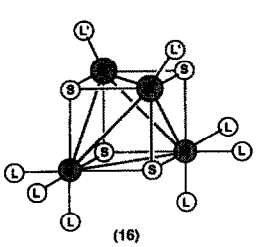


(15)

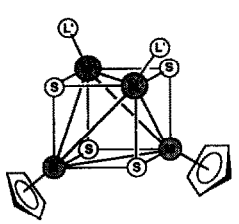
both in molecular and electronic structure. Since all four of the metals are octahedrally coordinated, the cluster bonding orbital scheme should be very similar to the scheme in Fig. 4. The *d* orbitals on each metal will split into "t_{2g}" and "e_g" groups, and although larger splittings are expected for the 4*d* orbitals, the 3*d* and 4*d* orbitals will combine to form the same groups of bonding, antibonding and non-bonding cluster orbitals shown in Fig. 4. Since both of these clusters have metal electron counts of 12, the cluster bonding orbitals should be completely occupied and a fully bonding metal tetrahedron is expected. Because of the two different metals, the metal "tetrahedron" will of course be less symmetric than the metal tetrahedron observed in an $M_4S_4Cp_4$ cluster.

3.2. *Two octahedral metals—two tetrahedral metals*

A cluster in this class is characterized by the general formula $M_2M'_2S_4L_6L'_2$ (**16**) or $M_2M'_2S_4Cp_2L'_2$ (**17**). A number of clusters belonging to this class are listed in Table 7. In each cluster, two of the



(16)



(17)

metals are six-coordinate and can be viewed as part of an octahedral MS_3L_3 or MS_3Cp fragment, while the other two metals are four-coordinate and can be viewed as part of a tetrahedral $M'S_3L'$ fragment. The structure of $Mo_2Co_2S_4(Et_2dtc)_2(CH_3CN)_2(CO)_2$ is shown in Fig. 18. In this cluster, each octahedral molybdenum atom is bound to an acetonitrile ligand and an Et_2dtc ligand, while each tetrahedral cobalt atom is bound to one π-acceptor CO ligand.

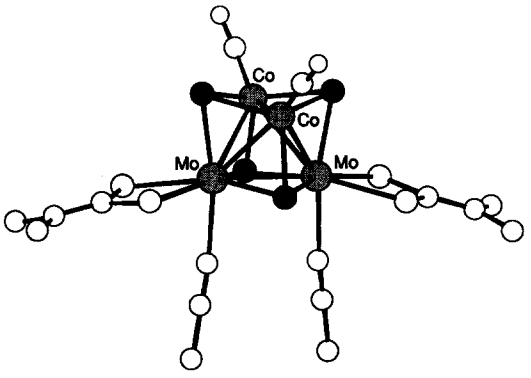

Fig. 18. Structure of $Mo_2Co_2S_4(S_2CNEt_2)_2(CH_3CN)_2(CO)_2$ (ref. 79). Only the first C atom in each Et group is shown. Each octahedral Mo atom is bound to three core S atoms, an acetonitrile ligand and a bidentate Et_2dtc ligand. Each tetrahedral Co atom is bound to three core S atoms and a π-acceptor CO ligand.

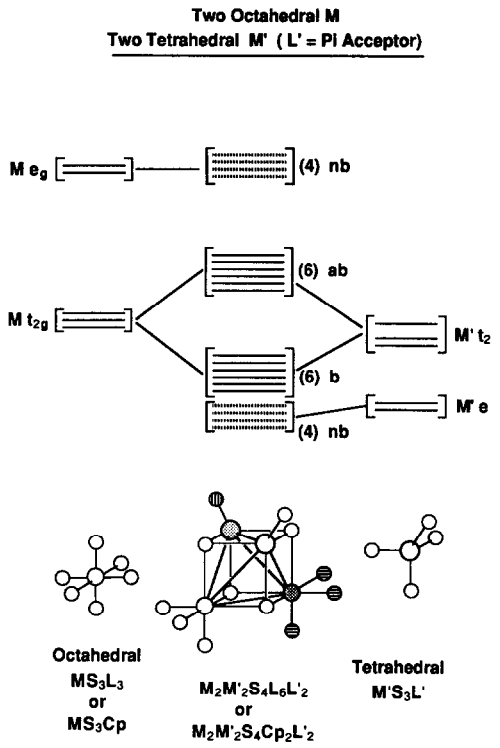

Fig. 19. Qualitative energy level scheme for the metal-based cluster orbitals in a heterometallic $M_2M'_2S_4L_6L'_2$ or $M_2M'_2S_4Cp_2L'_2$ cluster containing two octahedral metals and two tetrahedral metals. The splittings of the metal *d* orbitals in octahedral and tetrahedral environments are shown on the left and right sides of the diagram, respectively. The resulting cluster orbitals are shown in the middle. The relatively large separation between the "*e*" and "t_2" orbitals in the tetrahedral $M'S_3L'$ fragment reflects the presence of a π-acceptor ligand.

A qualitative bonding scheme for these clusters is shown in Fig. 19. The ordering of the metal *d* orbitals within each octahedral fragment is shown on the left hand side of the diagram, while the order of the metal *d* orbitals within each tetrahedral fragment is shown on the right. These fragment diagrams take into account two features of the clusters listed in Table 7. First, since the tetrahedral metal generally lies to the right of the octahedral metal in the periodic table, the tetrahedral metal *d* orbitals are expected to lie lower in energy than the octahedral metal *d* orbitals. Also, since in each cluster the ligand L′ associated with the tetrahedral metal is a π-acceptor, the tetrahedral "*e*" orbitals will be stabilized and the separation between the tetrahedral "*e*" and "t_2" orbitals will be relatively large. In the cluster, the "t_{2g}" and "t_2" orbitals combine to form sets of six bonding and six antibonding orbitals, while the metal "e_g" and "*e*" orbitals remain non-bonding. These non-bonding orbitals will occur in two groups, the octahedral "e_g" orbitals at high energy and the tetrahedral "*e*" orbitals at low energy. The stabilization of the tetrahedral metal "*e*" orbitals by the π-acceptor ligands is expected to result in the set of four cluster non-bonding orbitals lying below the cluster bonding orbitals.

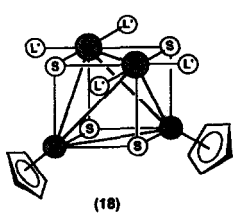
A cluster metal electron count of 20 is expected to be necessary for a completely bonding metal tetrahedron. Of these 20 electrons, eight will occupy the low energy non-bonding orbitals, leaving 12 to occupy the M—M bonding orbitals. Metal electrons in excess of 20 are expected to occupy antibonding orbitals. This scheme is consistent with the structures of $Mo_2Co_2S_4(Et_2dtc)_2(CH_3CN)_2$,[79] (20 metal electrons) and $Mo_2Ni_2S_4(MeCp)_2(CO)_2$[80,81] (22 metal electrons). All of the M—M distances in the 20-electron cluster correspond to M—M bonds, while in the 22-electron $Mo_2Ni_2S_4(MeCp)_2(CO)_2$ cluster the two nickel atoms are separated by a long non-bonding distance, indicating the occupation of an antibonding orbital. Recent molecular orbital calculations for $Mo_2Co_2S_4(dtc)_2(CH_3CN)_2(CO)_2$ and $Mo_2Ni_2S_4(Cp)_2(CO)_2$ confirm the qualitative energy level scheme shown in Fig. 19.[22] The four distinct groups of non-bonding, bonding, antibonding, and non-bonding cluster orbitals are all observed in the calculated energy levels of these

clusters, confirming that 20 metal electrons should result in a completely bonded metal tetrahedron. These calculations also show that just as in the homometallic clusters only the lower energy M—M bonding cluster orbitals are strongly bonding. The higher energy "bonding" orbitals are quite delocalized and nearly non-bonding, suggesting that clusters with electron counts short of 20 can be expected to have relatively short M—M distances. The lowest energy antibonding orbital, however, is localized between the two tetrahedral metals. It is this orbital which is occupied by the two extra electrons in $Mo_2Ni_2S_4(MeCp)_2(CO)_2$, resulting in the long Ni—Ni distance. The strongest M—M interactions in these clusters occur between the two 4*d* metals, and the M—M bonding interactions decrease in the order 4*d*–4*d* > 4*d*–3*d* > 3*d*–3*d*. The weaker overlap between the smaller 3*d* orbitals results in relatively weak M—M bonding interactions between the 3*d* metals. Several other $M_2Co_2S_4Cp_2L'_2$ (M = Cr, Mo) clusters[78,82] are also assumed to have cubane-type structures, and the bonding scheme in Fig. 19 should also apply to these clusters. The 20-electron clusters are expected to contain a completely bonding metal tetrahedron, while a long Co—Co distance is expected in the clusters containing 22 metal electrons.

Another series of clusters, $V_2M_2S_4(MeCp)_2(NO)_2$ (M = Fe, Co, Ni),[83,84] provides a further test of the qualitative scheme in Fig. 19. Based on this scheme and the previous discussion, the 20 metal electrons in $V_2Co_2S_4(MeCp)_2(NO)_2$ would occupy both the low energy non-bonding orbitals and the six M—M bonding orbitals, resulting in a completely bonded metal tetrahedron. The structure of the 18-electron $V_2Fe_2S_4(MeCp)_2(NO)_2$ cluster should be similar to the structure of $V_2Co_2S_4(MeCp)_2(NO)_2$, since any unoccupied high energy bonding orbital is expected to be at most weakly M—M bonding. The extra two electrons in the 22-electron $V_2Ni_2S_4(MeCp)_2(NO)_2$ cluster would occupy an antibonding orbital—probably one localized between the two tetrahedral nickel atoms, leading to a long Ni—Ni distance. The structure of the 22-electron $V_2Ni_2S_4(MeCp)_2(NO)_2$ cluster is consistent with this description of the bonding, since the long Ni—Ni distance can be considered non-bonding. An examination of the M—M distances in the three clusters, however, shows that in the set of three clusters, the M′—M′ distances increase in the order Fe—Fe < Co—Co < Ni—Ni. As Racuchfuss and co-workers have noted, the Co—Co distance in $V_2Co_2S_4(MeCp)_2(NO)_2$ is longer than expected for a Co—Co bond, suggesting that the 20-electron $V_2Co_2S_4(MeCp)_2(NO)_2$ cluster is not "electron precise".[84] (In the CVE counting scheme this is a 60-electron cluster and is also expected to contain a completely bonding metal tetrahedron.) This relatively long Co—Co distance, as well as the paramagnetism of the cluster, implies that in $V_2Co_2S_4(MeCp)_2(NO)_2$ the antibonding Co—Co orbital is occupied by one electron. An orbital occupation scheme for the three clusters which is consistent with their structures is $V_2Fe_2S_4(nb)^8(b)^{10}(ab)^0$, $V_2Co_2S_4(nb)^8(b)^{11}(ab)^1$, $V_2Ni_2S_4(nb)^8(b)^{12}(ab)^2$, where nb = non-bonding orbitals, b = bonding orbitals and ab = antibonding orbitals. Such a scheme would require the bonding and antibonding orbitals to be separated by only a small gap. In these clusters the relatively large energy separation between the V and M′ 3*d* orbitals and the weak bonding interactions between the small 3*d* orbitals could well result in the bonding orbitals spanning a large energy range, thus leading to such a narrow separation of the bonding and antibonding orbitals. Clearly, a more complete description of the electronic structure of these clusters is highly desirable. The apparent antiferromagnetic character of $V_2Fe_2S_4(MeCp)_2(NO)_2$ and the paramagnetism of $V_2Co_2S_4(MeCp)_2(NO)_2$ indicate that such a description will require spin unrestricted calculations.

3.3. *Two octahedral metals—two five-coordinate metals*

Another combination of coordination geometries occurs in a cluster which has the general formula $M_2M'_2S_4(Cp)_2L'_4$ (**18**). Here, two metals are six-coordinate and can be viewed as part of an



(18)

Table 8. Heterometallic clusters having structure type **18**: two octahedral metals—two square pyramidal metals

Cluster	Number of metal electrons	M—M distances M—M[a]	M′—M′[b]	M—M′	Reference
$Mo_2Fe_2S_4(Me_5Cp)_2(CO)_4$	18	2.761	3.334	2.813(4)	85

[a] M = octahedral metal.
[b] M′ = tetrahedral metal.

octahedral MS_3Cp fragment, while the other two metals are five-coordinate and can be viewed as part of a square pyramidal $M'S_3L'_2$ fragment. The one cluster having this geometry, $Mo_2Fe_2S_4(Me_5Cp)_2(CO)_4$, is listed in Table 8 and illustrated in Fig. 20. In this cluster there is no ambiguity concerning the square pyramidal configuration about the five-coordinate metals. Two C and two S atoms lie in the same plane to form the base of the pyramid, and the Fe atom lies about 0.5 Å above this plane.

A qualitative energy level scheme for this cluster is shown in Fig. 21. The octahedral metal *d* orbitals shown on the left are divided into the familiar "t_{2g}" and "e_g" groups. The square pyramidal metal *d* orbitals are shown on the right. As in the previous diagrams involving square pyramidal metals, the lowest energy orbitals are the "t_{2g}" set, while the highest energy orbital is d_{xy}. Intermediate in energy is the d_{z^2} orbital. In Fig. 21, the d_{z^2} orbital is shown to be at lower energy than in the previous diagrams for square pyramidal metals. This large stabilization of the d_{z^2} orbital is expected for a square pyramidal $M'S_3L'_2$ fragment only when (1) L′ is a π-acceptor ligand, and (2) the metal atom lies well out of the plane of the base of the pyramid. Under these conditions the d_{z^2} orbital is further stabilized by interactions with the ligand π-acceptor orbitals. In the cluster orbital scheme shown in the centre of Fig. 21 the metal "t_{2g}" orbitals combine to form sets of six bonding and six antibonding orbitals, while three sets of cluster non-bonding orbitals occur. These are derived from the octahedral metal "e_g" orbitals and the square pyramidal metal d_{xy} and d_{z^2} orbitals. The non-bonding "e_g" and d_{xy} orbitals lie above the antibonding orbitals, while the non-bonding set derived from the square pyramidal d_{z^2} orbitals lies *between* the bonding and antibonding orbitals. This ordering of both the metal fragment orbitals and the cluster orbitals is confirmed by a recent set of MO calculations on $Mo_2Fe_2S_4(Cp)_2(CO)_4$.[22]

Using the bonding scheme in Fig. 21, we would expect that a cluster metal electron count anywhere between 12 and 16 should lead to a completely bonding metal tetrahedron, since after 12 electrons occupy the bonding orbitals up to four more electrons can be added to the cluster before an antibonding orbital must be occupied. Since $Mo_2Fe_2S_4(Me_5Cp)_2(CO)_4$ contains 18 metal electrons, two electrons will occupy an antibonding orbital. The long Fe—Fe distance indicates that

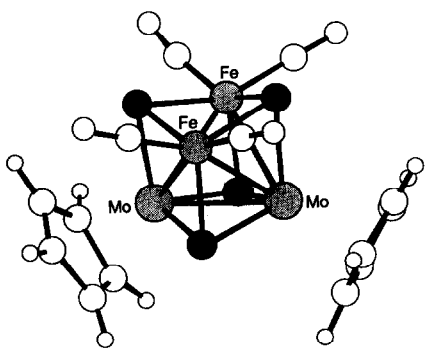


Fig. 20. Structure of $Mo_2Fe_2S_4(Me_5Cp)_2(CO)_4$ (ref. 85). The Me groups on the Cp ligands are not shown. Each octahedral Mo is bound to three core S atoms and a Cp ligand, while each five-coordinate Fe is bound to three core S atoms and two π-acceptor CO ligands. The geometry around each five-coordinate Fe atom is approximately square pyramidal.

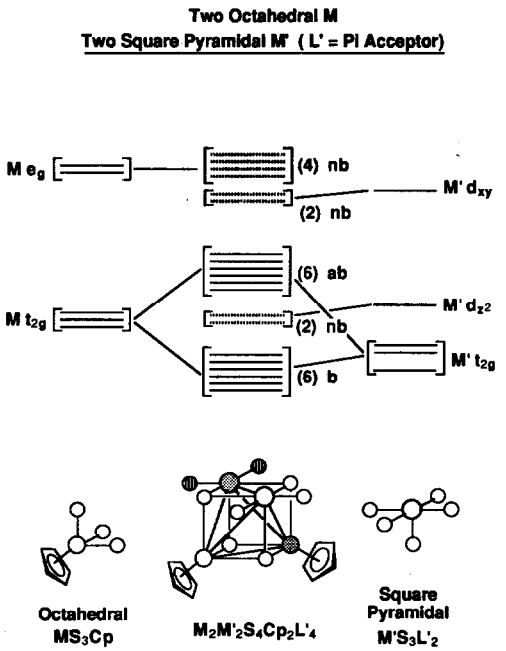

Fig. 21. Qualitative energy level scheme for the metal-based cluster orbitals in a heterometallic $M_2M'_2S_4Cp_2L'_4$ cluster containing two octahedral metals and two square pyramidal metals. The splittings of the metal *d* orbitals in octahedral and square pyramidal environments are shown on the left and right sides of the diagram, respectively. The resulting cluster orbitals are shown in the middle. The relatively large stabilization of the d_{z^2} orbital in the square pyramidal $MS_3L'_2$ fragment reflects the presence of two π-acceptor ligands.

these electrons occupy a localized Fe—Fe antibonding orbital, and the MO calculations confirm the occupation of six bonding, two non-bonding and one antibonding orbital localized between the two Fe atoms. It is important to recognize that the very low energy non-bonding orbitals are a consequence of the π-acceptor ligands coordinated to the square pyramidal metal. In the presence of π-donor ligands the metal d_{z^2} orbitals would lie at higher energies, antibonding orbitals would be occupied before non-bonding orbitals, and a smaller metal electron count would lead to a decrease in the degree of M—M bonding. The consequences of π-donor vs π-acceptor ligands on the ordering of the cluster orbitals was apparent in the earlier discussions of the $M_4S_4L_4$ clusters incorporating four-coordinate tetrahedral metals. The bonding scheme in Fig. 21 makes it clear that the presence of π-donor vs π-acceptor ligands will also have an effect on the ordering of the cluster orbitals in clusters incorporating five-coordinate square pyramidal metals.

4. HETEROMETALLIC CLUSTERS HAVING AN MM'_3S_4 CORE

4.1. *All four metals octahedrally coordinated*

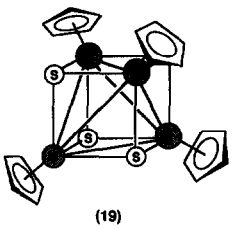
The clusters listed in Table 9 are the only examples of MM'_3S_4 clusters in which all four metal atoms have similar coordination geometries. Although the clusters $Cr_3MS_4(Cp)_4$ (M = V, Nb)[86]

Table 9. Heterometallic clusters having structure type **19**: all metals octahedrally coordinated

Cluster	Number of metal electrons	Reference
$Cr_3MS_4(Cp)_4$ (M = V, Nb)[a]	11	86

[a] Spectroscopic evidence suggests a cubane-type structure.

have not been structurally characterized, spectroscopic evidence indicates that they have the cubane-type structure $MM'_3S_4Cp_4$ (**19**). Each metal can be viewed as part of an octahedral MS_3Cp or

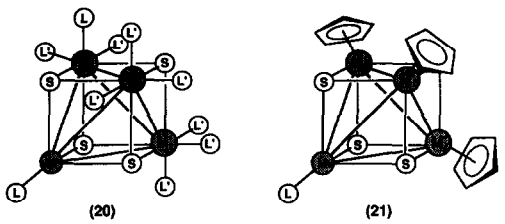


(19)

$M'S_3Cp$ fragment, and the clusters are expected to be similar in both molecular and electronic structure to the homometallic $M_4S_4Cp_4$ clusters (**5**). Making use of the cluster bonding scheme in Fig. 4, a cluster metal electron count of 12 is expected to lead to a fully bonding metal tetrahedron. Both $Cr_3MS_4(Cp)_4$ clusters are paramagnetic with a metal electron count of 11, and the M—M distances are expected to be within the range expected for M—M bonds.

4.2. *Three octahedral metals—one tetrahedral metal*

A number of clusters characterized by the general formula $MM'_3S_4LL'_9$ (**20**) or $MM'_3S_4LCp_3$ (**21**) are listed in Table 10. In each case three metals can be viewed as part of an octahedral $M'S_3L'_3$



or $M'S_3Cp$ fragment and one metal can be viewed as part of a tetrahedral MS_3L fragment. The structure of one of these clusters, $[Mo_3FeS_4(NH_3)_9(H_2O)]^{4+}$, is shown in Fig. 22. Here, each Mo is coordinated by three NH_3 ligands, while the Fe atom is bound to the O of the single H_2O molecule. In several of the clusters, such as $Mo_3CuS_4(S_2P(OCH_3)_2)_3(\mu\text{-}OOCCCl_3)(CH_3N)(I)$,[87] the octahedral metals are coordinated to monodentate, bidentate and spanning bidentate ligands. The metal electron counts in the clusters range from 14 to 16, and in all cases the M—M distances are indicative of M—M bonds.

A qualitative bonding scheme for these clusters is shown in Fig. 23. The groups of metal *d* orbitals within the tetrahedral and octahedral fragments are shown on the left and right side of the

Table 10. Heterometallic clusters having structure type **20** or **21**: three octahedral metals—one tetrahedral metal

[a] M′ = octahedral metal, M = tetrahedral metal.

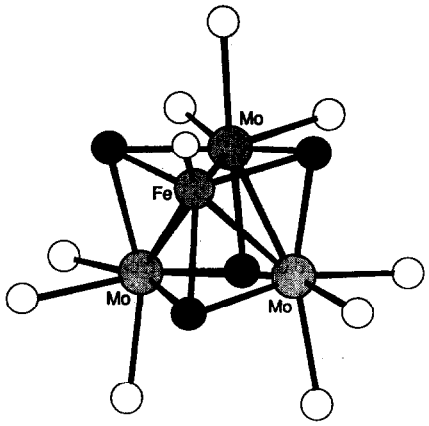

Fig. 22. Structure of $[Mo_3FeS_4(NH_3)_9(H_2O)]^{4+}$ (ref. 89). All of the H atoms have been omitted. Each octahedral Mo is bound to three core S atoms and three NH_3 ligands, while the tetrahedral Fe is bound to three core S atoms and an H_2O molecule.

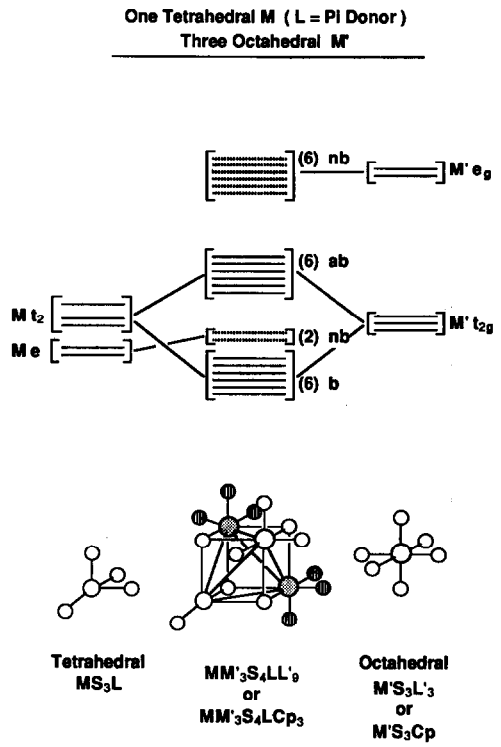

Fig. 23. Qualitative energy level scheme for the metal-based cluster orbitals in a heterometallic $MM'_3S_4LL'_9$ or $MM'_3S_4LCp_3$ cluster containing one tetrahedral metal and three octahedral metals. The splittings of the metal *d* orbitals in tetrahedral and octahedral environments are shown on the left and right sides of the diagram, respectively. The resulting cluster orbitals are shown in the middle. The relatively small separation between the "*e*" and "t_2" orbitals in the MS_3L fragment reflects the presence of a π-donor ligand.

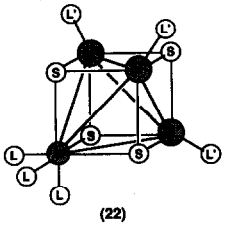
diagram, respectively. Because the octahedrally coordinated metals lie to the left of the periodic table, the energy of the octahedral metal orbitals is expected to be higher than the energy of the tetrahedral metal orbitals. Also, because in most of the clusters the ligand L coordinated to the tetrahedral metal is a π-donor, the separation between the tetrahedral "*e*" and "t_2" orbitals is expected to be small. The cluster orbitals are shown in the centre of the diagram. The octahedral

"t_{2g}" and tetrahedral "t_2" orbitals combine to form six bonding and six antibonding cluster orbitals. Six non-bonding orbitals derived from the octahedral "e_g" orbitals should lie high in energy, while two cluster non-bonding orbitals derived from tetrahedral "e" orbitals are expected to lie *between* the sets of cluster bonding and antibonding orbitals. Although no calculations have been carried out which can confirm this cluster bonding scheme, the scheme is consistent with the observed structures of the clusters, since occupation of antibonding orbitals would require metal electron counts greater than 16. In the clusters having electron counts of 14 and 16, 12 metal electrons will occupy the cluster bonding orbitals and two or four electrons will partially or fully occupy the low energy non-bonding orbitals. The presence of two unpaired electrons in $Cr_3FeS_4(Cp)_3(OOCCMe_3)$[88] (14 metal electrons) suggests that in this cluster one electron occupies each of the non-bonding orbitals derived from the Fe "e" orbitals. In $Cr_3CoS_4(Cp)_3(CO)$ the non-bonding cluster orbitals derived from the Co "e" orbitals will be stabilized by the π-acceptor CO ligand and are expected to lie below the cluster bonding orbitals. The 16 metal electrons will still fully occupy the non-bonding and bonding orbitals.

4.3. *One octahedral metal—three tetrahedral metals*

Structurally characterized clusters belonging to this class are listed in Table 11. They can all be represented by the general formula $MM'_3S_4L_3L'_3$ (**22**). One metal can be viewed as part of an



(22)

octahedral MS_3L_3 fragment, while the other three metals can be viewed as parts of tetrahedral $M'S_3L'$ fragments. Except for $[MoFe_3S_4(SEt)_3(CO_3)]^{3-}$,[93] all of the clusters listed in Table 11 contain 19-electron $[MoFe_3S_4]^{3+}$ or $[VFe_3S_4]^{+}$ cores. The structural, chemical and electronic properties of the $MoFe_3S_4$ clusters have been studied extensively by the Holm group.[20,94,95] (See also the references in Table 11. These studies have been motivated primarily by the similarities between these clusters and the Mo cofactor in nitrogenase. The structure of one of these clusters, $[MoFe_3S_4(SEt)_3(Cl_4cat)(CN)]^{3-}$, is illustrated in Fig. 24. The octahedral Mo atom is coordinated by the two O atoms of the cathecholate ligand and by the cyanide ligand, while each tetrahedral Fe atom is bound to one thiolate ligand. Recently a series of VFe_3S_4 clusters has also been studied by the Holm

The octahedral Mo atom is bound to three core S atoms, a cyanide ligand, and the two O atoms of the bidentate catecholate ligand.

group,[95–98] and the electronic and structural properties of these clusters are found to be very similar to the properties of the $MoFe_3S_4$ clusters. As in the $[Fe_4S_4(SR)_4]^{2-}$ clusters, a detailed understanding of the electronic structure of these heterometallic clusters is complicated by the weak coupling between high-spin transition metal ions. The results of spin-unrestricted Xα calculations on the model cluster, $[MoFe_3S_4(SH)_6]^{3-}$, provide an analysis of the electronic structure which is consistent with the experimentally observed electronic properties of the clusters having $[MoFe_3S_4]^{3+}$ cores.[21]

A qualitative cluster bonding scheme for this class of clusters can be derived from the metal fragment orbitals. This scheme is shown in Fig. 25. The groups of metal *d* orbitals within the octahedral and tetrahedral fragments are shown on the left and right of the diagram, respectively.

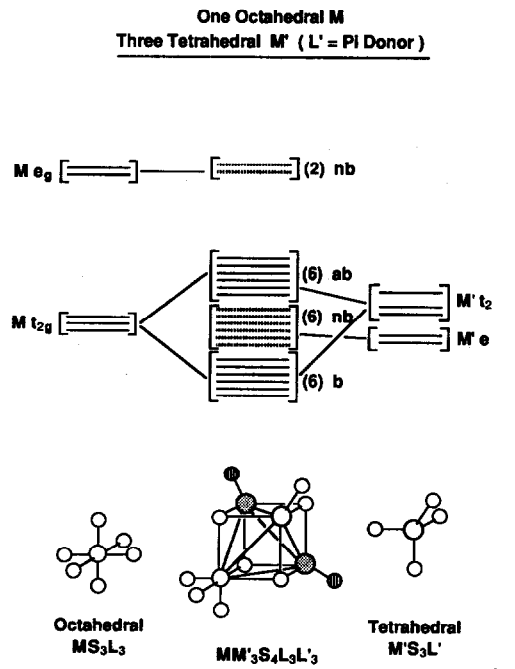

Fig. 25. Qualitative energy level scheme for the metal-based cluster orbitals in a heterometallic $MM'_3S_4L_3L'_3$ cluster containing one octahedral metal and three tetrahedral metals. The splittings of the metal *d* orbitals in octahedral and tetrahedral environments are shown on the left and right sides of the diagram, respectively. The resulting cluster orbitals are shown in the middle. The relatively small separation between the "*e*" and "t_2" orbitals in the $M'S_3L'$ fragment reflects the presence of a π-donor ligand.

Because the L′ ligand associated with each tetrahedral metal is a π-donor, the separation between the tetrahedral metal "e" and "t_2" orbitals is expected to be small. The cluster orbitals are shown in the centre of the diagram. Once again, the metal "t_{2g}" and "t_2" orbitals combine to form six bonding and six antibonding cluster orbitals. Two non-bonding cluster orbitals derived from the octahedral metal "e_g" orbitals lie high in energy, while six non-bonding cluster orbitals derived from the tetrahedral metal "e" orbitals are expected to lie *between* the sets of cluster bonding and antibonding orbitals. The intermediate energy of these six non-bonding orbitals is a result of the π-donor ligands. Based upon this simple bonding scheme, metal electron counts between 12 and 24 should result in a completely bonding metal tetrahedron, since after the bonding orbitals are occupied by 12 electrons, the six-nonbonding orbitals can accommodate up to 12 additional electrons before an antibonding orbital must be occupied. (As in several of the previously described classes of clusters, the energy ranges of the non-bonding and antibonding orbitals probably overlap. If they do, antibonding orbitals will be occupied for electron counts $\leqslant 24$.) The M—M distances (Table 11) in all of the clusters which have $[MoFe_3S_4]^{3+}$ and $[VFe_3S_4]^{2+}$ cores are indicative of M—M bonds. Since all of these clusters have 19 metal electrons, the bonding scheme in Fig. 25 indicates that in each cluster seven electrons will occupy non-bonding orbitals. Just as in the Fe_4S_4 clusters, it is the presence of these seven non-bonding electrons associated with the Fe atoms which leads to the observed complex electron-spin couplings.

The structure of the remaining cluster in Table 11, $[MoFe_3S_4(SEt)_3(CO)_3]^{3-}$, is markedly different from the structure of the other $MoFe_3S_4$ and VFe_3S_4 clusters in this class. This cluster, which contains 22 metal electrons, is characterized by long non-bonding Mo—Fe distances (*ca* 3.25 Å), as well as relatively long Mo—S distances (*ca* 2.63 Å compared to Mo—S distances of *ca* 2.35–2.40 Å in the other clusters listed in Table 11), and Coucouvanis *et al.* suggested that this cluster is best described as a weak complex of the $Mo(CO)_3$ unit and the $[Fe_3S_4(SR)_3]^{3-}$ cluster.[93] The different structure of this cluster once again calls attention to the need for considering the individual oxidation states of the metals in the cluster as well as the total metal electron count. For example, the $MoFe_3S_4$ clusters discussed in the preceding paragraph have a total of 19 metal electrons. This results in 12 metal electrons occupying the cluster M—M bonding orbitals and seven electrons occupying cluster non-bonding orbitals associated *only* with the Fe atoms. These cluster orbital occupations can be associated with one Mo^{3+}, one Fe^{2+} and two Fe^{3+} centres. In contrast, $[MoFe_3S_4(SEt)_3(CO)_3]^{3-}$ has three extra metal electrons, or a total of 22 metal electrons. Although the bonding scheme in Fig. 25 indicates that the cubane structure should be able to accommodate these three additional electrons, it also suggests that at least some of these extra electrons would have to occupy non-bonding orbitals associated with the Fe atoms. That is, even though the extra three electrons are introduced by the $Mo(CO)_3$ unit, formation of a true cubane-type cluster would require formal oxidation of the Mo and reduction of one or more of the three Fe atoms. The exact degree of oxidation and reduction would depend on the relative energies of the non-bonding "e" orbitals and the M—M antibonding orbitals. The fact that a true cubane-type cluster is not formed suggests that the required oxidation and reduction is unfavourable. We should recognize that even though the cluster bonding diagrams described in this report indicate that a range of total metal electron counts is possible for a cluster having a particular structure, there may not be any reasonable combinations of individual metal oxidation states which lead to some of these total metal electron counts.

4.4. *Two octahedral metals—two five-coordinate metals*

The last group of heterometallic clusters can be characterized by the general formula $MM'_3S_4L_3L'_7$, where two metals, one M and one M′, can be viewed as part of octahedral MS_3L_3 and $M'S_3L'_3$ fragments and two metals are part of five-coordinate $M'S_3L'_2$ fragments. Several clusters having this structure are listed in Table 12. These clusters can be viewed as having one of the ideal structures **23** or **24**. In **23**, each five-coordinate metal is square pyramidal, whereas in **24** each five-coordinate metal is trigonal pyramidal. In the $[MoFe_3S_4(S_2CNR_2)_5]^{0,-1}$ clusters listed in Table 12, each metal is coordinated by a bidentate dtc ligand, while the fifth dtc ligand spans an Fe and Mo atom. As in many of the homometallic clusters containing five-coordinate metals, the actual geometry about the five-coordinate metals lies somewhere in between the two geometries shown in **23** or **24** and can be described as either distorted square pyramidal or distorted trigonal bipyramidal. The two views of $MoFe_3S_4(S_2CNEt_2)_5$ shown in Fig. 26 demonstrate that either description might apply,

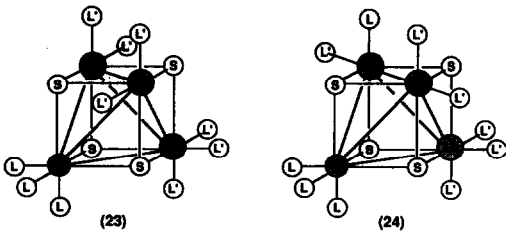

Table 12. Heterometallic clusters having structure type **23** or **24**: two octahedral metals—two five-coordinate metals

Cluster	Number of metal electrons	M—M[a]	M—M distances M—M'[b]	M'—M'	Reference

[a] M = octahedral metal.
[b] M' = five-coordinate metal.

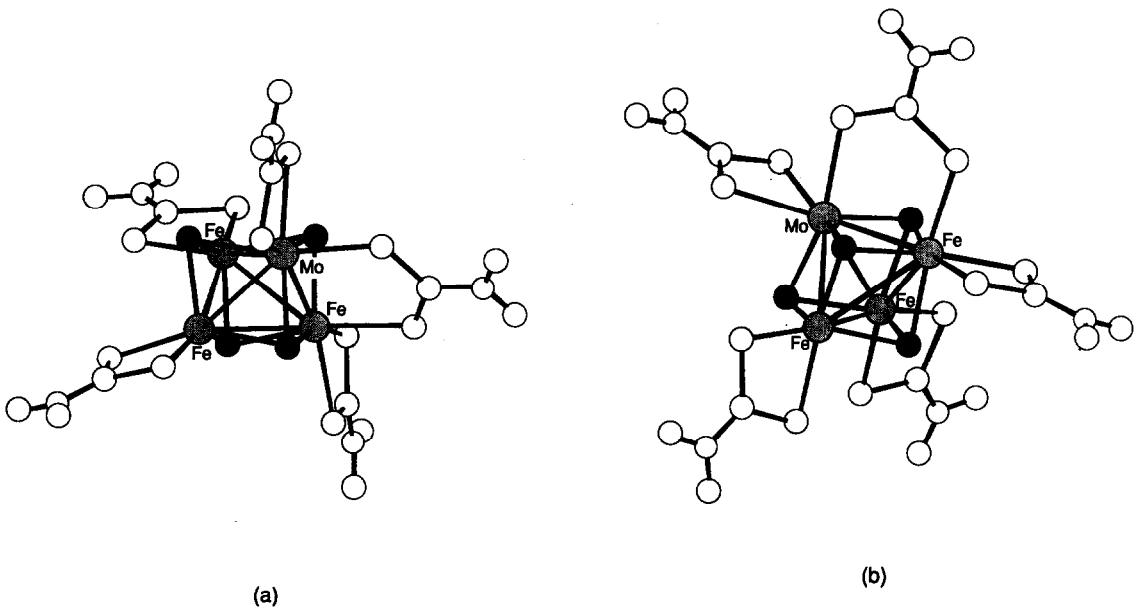

Fig. 26. Two views of the structure of $MoFe_3S_4(S_2CNEt_2)_5$ (ref. 105). Only the first C in each Et group is shown. Four of the bidentate Et_2dtc ligands each bind to a single metal atom, while the fifth Et_2dtc ligand spans an Mo atom and an Fe atom. The Mo atom and one of the Fe atoms are therefore six-coordinate and have approximately octahedral coordination geometry, while the two remaining Fe atoms are five-coordinate. The two views of the structure show that the geometry around the five-coordinate Fe atoms can be viewed as either (a) distorted square pyramidal or (b) distorted trigonal bipyramidal.

although in this cluster a designation of distorted square pyramidal may be more appropriate. The distortions are not the same in all of the clusters listed in Table 12, however, so as a group the five-coordinate metals are best described as having a geometry intermediate between that shown in **23** or **24**.

A qualitative energy scheme for a cluster having geometry **23** (two five-coordinate square pyramidal metals) is shown in Fig. 27. The ordering of the metal *d* orbitals within the octahedral and square pyramidal fragments are shown on the left and right side, respectively, of the diagram. The diagram has been simplified somewhat in that only one set of metal octahedral orbitals are shown. Because two different metals, in this case Fe and Mo, are octahedrally coordinated, there are actually two different sets of octahedral metal orbitals. Since the presence of these two sets should not greatly alter the general scheme derived in the centre of Fig. 16, the second set has been omitted. The "t_{2g}" sets of orbitals from all four metal atoms combine to form the sets of cluster bonding and antibonding orbitals. Three groups of cluster non-bonding orbitals are expected, four high energy orbitals derived from the octahedral metal "e_g" orbitals, two high energy orbitals derived from the square pyramidal metal d_{xy} orbitals and two lower energy orbitals derived from the square pyramidal metal d_{z^2} orbitals. The lower energy non-bonding orbitals are expected to lie within the same energy range as the antibonding orbitals. Just as in the homometallic clusters containing five-coordinate metals, the bonding in the $MM'_3S_4L_3L'_7$ clusters considered here is expected to be similar to the bonding in clusters containing all octahedral metals—*except* for higher electron counts.

All of the clusters in Table 12 contain 17 or 18 electrons. Using the diagram in Fig. 27, 12 of these electrons should fully occupy the cluster bonding orbitals, while the remaining five or six electrons are expected to occupy cluster antibonding orbitals. An examination of the M—M distances listed in Table 11 shows that in general the distances between the octahedral Mo and Fe atoms (the two atoms spanned by the dtc ligand) and between the two five-coordinate Fe atoms are indicative of Mo—Fe and Fe—Fe bonds. The other four M—M distances are less regular and are generally longer (in some cases long enough to be non-bonding). These distances are consistent with partial occupation of the cluster antibonding orbitals. An understanding of the actual deformations of the

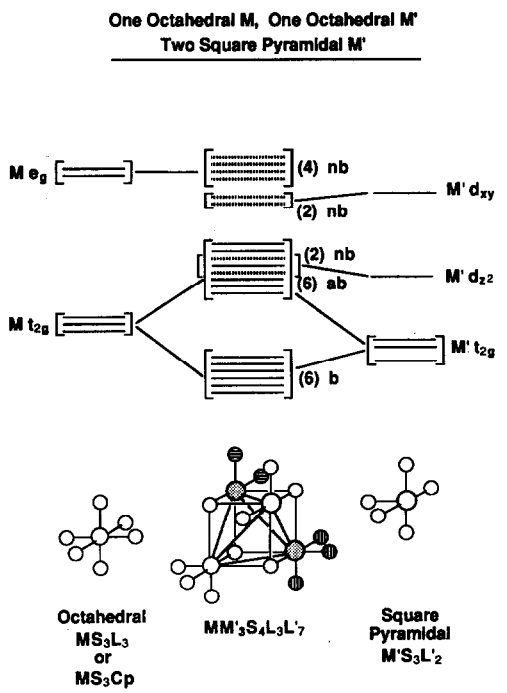

Fig. 27. Qualitative energy level scheme for the metal-based cluster orbitals in a heterometallic $MM'_3S_4L_3L'_7$ cluster containing two octahedral metals and two square pyramidal metals. The splittings of the metal *d* orbitals in octahedral and square pyramidal environments are shown on the left and right sides of the diagram, respectively. The resulting cluster orbitals are shown in the middle.

M—M bonds would require an understanding of the character of the antibonding orbitals, but the M—M distances do suggest that antibonding orbitals localized between either the two octahedral metals or the two five-coordinate metals lie high enough in energy to remain unoccupied, while the lower energy occupied antibonding orbitals involve interactions *between* the octahedral and five-coordinate metals. The lower energy non-bonding orbitals may be sufficiently stabilized to be at least partially occupied, but the long distances between the five- and six-coordinate metals indicate that these non-bonding orbitals are high enough in energy that at least the majority of the extra five or six electrons occupy antibonding orbitals.

A comparison of the energy level diagrams in Figs 25 and 27 shows that the bonding schemes are markedly different in the $MoFe_3S_4$ clusters having the two different structure types **22** and **23**. The tetrahedral coordination of the three Fe atoms in the $MM'_3S_4L_3L'_3$ (**22**) clusters introduces a large number of low energy non-bonding cluster orbitals. In the $MM'_3S_4L_3L'_7$ clusters (**23**), on the other hand, the non-bonding cluster orbitals are destabilized by the octahedral and square pyramidal or trigonal bipyramidal coordination of the Fe atoms. Even with equivalent metal electron counts the electronic structures of these two types of clusters would not be equivalent.

5. SUMMARY

When the cubane-type clusters are grouped into classes based on metal coordination geometry it is possible to develop a qualitative M_4 cluster bonding scheme for each class. These schemes make it possible to understand, at least qualitatively, the M—M bonding in a large number of both homo- and heterometallic clusters. The M—M bonding in these clusters is strongly influenced by the ligand environment of each metal in the cluster. When we view each metal as part of an MS_3L_x fragment within the cluster, we can see that M—M bonds are formed between $t_{2g}(t_2)$ type orbitals, while $e_g(e)$ type orbitals do not take part in the M—M bonding. Since the ligand environment (both the ligand geometry and the nature of the ligands) of each metal has a strong effect on the relative energies of these "t_{2g}" and "e_g" orbitals, it ultimately has an effect on the energies of the bonding, antibonding and non-bonding M_4 cluster orbitals. Specifically, changing the ligand geometry around the metals and/or the type of ligands bound to the metals changes the relative energy of the non-bonding cluster orbitals. This effect is closely related to the structure of a cluster, since the position of the non-bonding cluster orbitals determines how many "metal" electrons the cluster can accommodate without the loss of M—M bonding.

The Dahl group recognized the importance of these non-bonding cluster orbitals when they developed qualitative bonding schemes which could be applied to a number of the homometallic clusters. Their schemes assumed that the stronger metal–ligand (or metal–sulphur) interactions could be separated from the weaker metal–metal interactions, and in deriving these schemes they first considered the metal–metal interactions and then added on the metal–ligand interactions. Although these schemes are extremely useful for many of the homometallic clusters, this approach is not easily extended to the lower symmetry heterometallic clusters having more than one kind of coordination geometry. Alternatively, it is possible to first consider the stronger metal–ligand interactions and then add on the weaker metal–metal interactions. Using this approach each metal is viewed as part of an MS_3L_x fragment, and the cluster bonding, antibonding and most importantly non-bonding orbitals can be associated with specific sets of metal orbitals within these fragments. This approach makes it possible to derive qualitative cluster bonding schemes for even the low symmetry hetero-metallic clusters. Detailed descriptions of the electronic structure of many of these clusters must await accurate electronic structure calculations, but it is useful in the meantime to have these qualitative bonding descriptions.

KINETICS AND MECHANISMS OF THE REDOX REACTION OF HEXAAQUOTITANIUM(III) AND THE ETHYLENEDIAMINE TETRAACETATO TITANIUM(III) COMPLEX BY AQUEOUS SOLUTIONS OF BROMINE

J. FEMI IYUN† and ADE ADEGITE‡

Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

(*Received* 2 *June* 1988; *accepted after revision* 31 *May* 1989)

Abstract—At 25°C, $I = 1.0$ M ($CF_3SO_3^-Li^+ + CF_3SO_3H$), $[H^+] = 0.034$–0.274 M and $\lambda = 453$ nm, the rate equation for the oxidation of $Ti(H_2O)_6^{3+}$ by bromine was found to be:

$$\frac{-d[Br_2]_T}{dt} = \frac{kK[Br_2][Ti^{III}]}{[H^+]+K} + \frac{kK[Br_3^-][Ti^{III}]}{[H^+]+K},$$

where $k = 9.2 \times 10^{-3}$ M^{-1} s^{-1} and $K = 4.5 \times 10^{-3}$ M. At $[H^+] = 1.0$ M, $[Br^-] = 0.05$–0.4 M, the apparent second-order rate constant decreases as $[Br^-]$ increases.

The pH-dependence of the oxidation of Ti^{III}–edta by bromine is interpreted in terms of the change in identity of the Ti^{III}–edta species as the pH of the reaction medium changes. The second-order rate constants were fitted using a non-linear least-square computer program with $(1/k_0^{edta})^2$ weighting into an equation of the form:

$$k_0^{edta} = \frac{k_1 + k_2K_1[H^+]^{-1} + k_3K_1K_2[H^+]^{-2}}{1 + K_1[H^+]^{-1} + K_1K_2[H^+]^{-2}},$$

with K_1 and K_2 fixed as earlier determined at 9.55×10^{-3} and 2.29×10^{-9} M, respectively, for the oxidation of bromine.

$$k_1 = k_2 = (3.1 \pm 0.32) \times 10^3 M^{-1} s^{-1}$$

$$k_3 = (2.3 \pm 0.45) \times 10^6 M^{-1} s^{-1}.$$

It is proposed that these electron transfer reactions proceed by univalent changes with the production of $Br_2^{\bullet -}$ as a transient intermediate. An outer-sphere mechanism is proposed for these reactions. The homonuclear exchange rate for Ti^{III}–edta + Ti^{IV}–edta is estimated at 32 M^{-1} s^{-1}.

The kinetic investigations of the reactions[1–3] between $[Ti(H_2O)_6]^{3+}$ and Cl_2(aq), $[Co(NH_3)_5SCN]^{2+}$ and I_2(aq) have been reported. Such studies have also been extended to the oxidation of Ti^{III}–cdta by I_2(aq),[3] some cobalt(III) ammine complexes[4] and O_2.[5] This paper reports our results of the kinetic studies of the oxidation of Ti^{3+}(aq) and Ti^{III}–edta by aqueous acidic bromine solutions.

EXPERIMENTAL

Solutions of $CF_3SO_3^-Li^+$ were prepared by neutralizing Li_2CO_3 with doubly-distilled CF_3SO_3H. The solution was freed from dissolved carbon dioxide by bubbling pure nitrogen through. Solutions of hexaaquotitanium(III) ions in trifluoromethanesulphonic acid were prepared and analysed as previously reported.[1–3] Aqueous bromine solutions were prepared by shaking liquid bromine (BDH, Analar Grade) with water. The concentrations of the bromine solutions were determined by iodometry. Sodium acetate, HCl and LiCl

(all BDH, Analar Grade) were used without further purification. Ti^{III}–edta solutions were prepared by adding predetermined amounts of $[Ti(H_2O)_6]^{3+}$ solutions to a reaction medium containing the desired amount of LiCl, sodium acetate, HCl and recrystallized Na_2H_2edta in slight excess of what is required for a 1:1 Ti^{III}–edta complex.

Kinetics

We conducted our rate studies in a trifluoromethanesulphonate medium which has been shown to be an "innocent" medium for titanium(III) reactions.[6] We worked in the acid range $0.034 \leqslant [H^+] \leqslant 0.274$ M, in which the tendency to form polymeric oxobridged titanium(IV) species does not affect our rate measurements.[7]

Rate measurements were made on the Durrum–Gibson stopped-flow spectrophotometer by monitoring absorbance changes due to bromine at $\lambda = 453$ nm, the isobestic point for Br_2 and Br_3^-.

The kinetic runs, except where stated, were conducted under pseudo-first-order conditions with $[Ti^{III}] > 20[Br_2]_{total}$. The temperature was maintained constant at 25.0 ± 0.1°C.

In the Ti^{III}–edta + Br_2 reaction, the pH of the solution was kept constant by using a formate buffer for the pH range 2.5–3.8 and an acetate buffer for the pH range 3.7–6.0. Preliminary investigations showed that the rate of the bromine + formate reaction is negligible compared with that for the reaction of interest. Also for the same pH, rate constants obtained by varying the buffer concentration from 0.05 to 0.20 M agreed within 5%, confirming that the rate of reaction is unaffected by either formate or acetate ion. At pH = 3.7, the rate constant obtained was essentially the same whether the medium was formate or acetate. We also confirmed spectrally in the range 300–600 nm and at pH = 1.0 that there was no complex formation between Ti^{III}–edta and CH_3COOO^- and $HCOO^-$. To prevent extensive hydrolysis of Br_2 to HOBr, particularly at high pH, bromine solutions were unbuffered and were prepared to contain the calculated amounts of acid needed to attain the desired pH when the reactants are mixed in the reaction chamber. Each reaction medium was set at 1.0 M ionic strength using $CF_3SO_3^-Li^+$.

RESULTS AND DISCUSSION

The stoichiometries of the $Ti^{III}(aq) + Br_2$ and Ti^{III}–edta + Br_2 reactions were determined by spectrophotometric titrations at $\lambda = 453$ nm to be of the ratio 2:1. The pseudo-first-order plots were linear for more than 90% of the reaction, confirming an order of one with respect to bromine concentration. The pseudo-first-order rate constants in the range $1.9 \times 10^{-2} \leqslant [Ti^{III}] \leqslant 5.5 \times 10^{-2}$ M increased as $[Ti^{III}]$ increased. A plot of log k_{obs} vs log $[Ti^{III}]$ was linear with a slope of 0.96 ± 0.02. This confirms that the order with respect to $[Ti^{III}]$ is one. The computed second-order rate constants are reported in Table 1.

The acid dependence observed in the range $0.034 \leqslant [H^+] \leqslant 0.274$ M is similar to those reported earlier.[3] A plot of k^{-1} vs $[H^+]$ is linear with a finite intercept. For the $Ti^{3+} + Br_2$ reaction the following reaction scheme is proposed:

$$Ti(H_2O)_6^{3+} \overset{K_a}{\rightleftharpoons} [(H_2O)_5TiOH]^{2+} + H^+ \text{(fast)} \quad (1)$$

$$[Ti(H_2O)_5OH]^{2+} + Br_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [(H_2O)_5TiO]^{2+} + Br_2^{\bullet -} + H^+ \quad (2)$$

Table 1. Rate constants for the reaction of $[Ti(H_2O)_6]^{3+}$ with bromine; $[Br_2] = (5.0–8.0) \times 10^{-4}$ M, $I = 1.0$ M ($CF_3SO_3^-Li^+$)

$$[(H_2O)_5TiOH]^{2+} + Br_2^{\cdot-} \xrightarrow{k_2} [(H_2O)_5TiO]^{2+} + 2Br^- + H^+ \quad (3)$$

By applying the steady-state approximation to $[Br_2^{\cdot-}]$ in the above scheme and making the following assumptions,

(i) that $k_2K_a[Ti^{3+}][H^+] \gg k_{-1}[TiO^{2+}][H^+]$ and
(ii) $[Ti^{III}] = [Ti(H_2O)_6]^{3+} + [Ti(OH)^{2+}]$

then the following rate equation is derived:

$$\text{rate} = \frac{k_1K_a[H^+]^{-1}}{1 + K_a[H^+]^{-1}}[Ti^{III}][Br_2] \quad (4)$$

or

$$k_0[Ti^{III}][Br_2]$$

with

$$k_0 = \frac{k_1K_a[H^+]^{-1}}{1 + K_a[H^+]^{-1}}. \quad (5)$$

Least mean square analysis of the linear plot of k_0^{-1} vs $[H^+]$ gave

$$k_1 = 9.2 \times 10^3\,M^{-1}s^{-1}$$

$$K_a = 4.5 \times 10^{-3}\,M.$$

The value of $K_a = 4.5 \times 10^{-3}$ M, the kinetically determined value of the acid dissociation constant obtained for the $Ti^{III} + Br_2$ reaction, is in good agreement with the value of $K_a = 3.2 \times 10^{-3}$ M obtained for the $Ti^{III} + I_2$ system[3] and the value of 3.1×10^{-3} M earlier obtained by Orhanovic for some outer-sphere reactions of the aquotitanium(III) ion with the cobalt(III) complex.[8] Some other data on the outer-sphere reactions involving aquotitanium(III) as reductant have been fitted with K_a values of 1.6×10^{-3} and 4.6×10^{-3} M, respectively.[6,9] These values are at least an order of magnitude less than similar equilibrium constants derived for some complex hydrolytic pathways in the reactions of the Ti^{3+}(aq) ion. The latter reactions were also found to proceed by the inner-sphere mechanism.

† The data for the Ti^{III}–edta + Br_2 reaction was fitted into an equation of the form:

$$k_0^{edta} = \frac{k_1 + k_2K_1[H^+]^{-1} + k_3K_1K_2[H^+]^{-2}}{1 + K_1[H^+]^{-1} + K_1K_2[H^+]^{-2}},$$

where ($k_1 = k_2$), by using a non-linear least-square computer analysis with $(1/k_0^{edta})^2$, weighting and the values of K_1 and K_2 fixed as reported.[13]

An iterative procedure was used until there was convergence. A correlation coefficient of 99.5% between k_0^{edta}(expt.) and k_0^{edta}(calc.) was obtained. We are grateful to Mr L. Fulkerson of the Ahmadu Bello University Computer Centre for writing the program for this analysis.

K_a values as high as 0.01–0.16 M were reported for some inner-sphere reactions involving Ti^{3+}(aq).[10] The experimental value of K_a, as determined by independent workers[11] although not under identical conditions, places its value in the range $(1.6–6.9) \times 10^{-3}$ M. The proposition of the outer-sphere mechanism for the $Ti^{III} + Br_2$ reaction is supported by the comparison of the rate of electron transfer ($9.2 \times 10^3\ M^{-1}\ s^{-1}$) with the rate of substitution of NCS^- and $HC_2O_4^-$ into the Ti^{3+} aqua ion, (8×10^3 and $4 \times 10^5\ M^{-1}\ s^{-1}$, respectively).[12] The substitution mechanism is also assumed to be associative. Both NCS^- and $HC_2O_4^-$ are definitely more nucleophilic than Br_2. Hence, in order for the substitution of bromine into the inner coordination sphere of Ti^{3+} to preceed electron transfer, its rate must be less than the value of $9.2 \times 10^3\ M^{-1}\ s^{-1}$ obtained for the $TiOH^{2+} + Br_2$ reaction. The data obtained seem to rule out the inner-sphere mechanism. Tables 2–4 present the results of investigations involving the Ti^{III}–edta–bromine reaction. The pH-dependence of the rate of reaction of Ti^{III}–edta with an aqueous bromine solution has two mechanistic components. This reaction is pH-dependent below pH = 3 but shows an increase in rate as the pH increases above 3. Such complex dependence on pH has been observed in the reaction of Ti^{III}–edta with $[Co(NH_3)_6]^{3+}$ and $[Co(NH_3)_5NCS]^{2+}$.[4] As in earlier investigations this dependence on pH can be attributed to differing reactivities of Ti^{III}–edta, $Ti(H_2O)edta^-$ and $Ti(OH)edta^{2-}$.[13] The principal activation paths for this reaction can be proposed as follows:

$$TiY \rightleftharpoons^{K_1} TiY^- + H^+ \quad (6)$$

$$TiY^- \rightleftharpoons^{K_2} TiY^{2-} + H^+ \quad (7)$$

$$TiY + Br_2 \xrightarrow{k_1} (\text{activated complex})^* \quad (8)$$

$$TiY^- + Br_2 \xrightarrow{k_2} (\text{activated complex})^* \quad (9)$$

$$TiY^{2-} + Br_2 \xrightarrow{k_3} (\text{activated complex})^* \quad (10)$$

where Y = edta. From the above scheme, we obtain

$$k_0^{edta} = \frac{k_1 + k_2K_1[H^+]^{-1} + k_3K_1K_2[H^+]^{-2}}{1 + K_1[H^+]^{-1} + K_1K_2[H^+]^{-2}}. \quad (11)$$

From the titration studies of the Ti^{III}–edta solution at varying pH by Podlahova and Podlaha the first two species above exist at pH = 3. Our results suggest that these species react at the same rate, i.e. $k_1 = k_2$. This is also supported by the results of previous investigations.[4,14] Using a non-linear least-square computer program† to fit the experi-

reasonable agreement between the calculated rate constants and the experimental values. This implies that the model proposed is reasonably adequate to account for the complex hydrogen ion dependence in the Ti^{III}–edta system.

Generally, however, the lack of a systematic trend in the differences between the calculated and observed rate constants might result from:

(i) the uncertainty in the nature of the Ti–edta species present in solution, especially the less identifiable polymerized species whose kinetic significance has not been qualified in this work;
(ii) the limitation in the computer program employed.

The Marcus equation for the cross reaction[15] is:

$$\log k_{12} = \tfrac{1}{2}\log k_{11} + \tfrac{1}{2}\log k_{22} + \tfrac{1}{2}\log K_{12} + \tfrac{1}{2}\log f \quad (12)$$

$$\log f = \frac{(\log K_{12})^2}{4\log k_{11}k_{22}Z^{-2}}, \quad (13)$$

where k_{11} and k_{22} are the homonuclear electron exchange rate constants for the reducing and oxidizing complexes, respectively. k_{12} and K_{12} are, respectively, the rate and equilibrium constants for the cross reaction and $Z = 10^{11}$ is the collision frequency for the uncharged reactant molecules. In making this correlation we assumed k_{22} for $I_2 + I_2^-$ to be the same (8.5×10^4 M^{-1} s^{-1}, the value reported by Woodruff and Margerum[16]) as k_{22} for $I_3^- + I_3^{2-}(I_2^- + I^-)$. A similar assumption also holds for $Br_2 + Br_2^-$ and $Br_3 + Br_3^{2-}(Br_2^- + Br^-)$, $k_{22} = 29$ M^{-1} s^{-1}. K_{12} was calculated from the redox potentials for $X_2 + e \rightarrow X_2^-$ (X = Br, 0.5 V; X = I, 0.11 V), for $X_3^- + e \rightarrow X_2^- + X^-$ (X = Br, 0.44 V; X = I, 0.06 V) and for Ti–edta + e → Ti–edta$^-$, $E^0 = 0.03$ V, the value obtained from the polarographic studies of Pecsok and Maverick.[17] The exchange rate constant for Ti–edta + Ti–edta$^-$, k_{11}, is unknown. However, we made the initial estimates from the data of the Ti^{III}–edta + I_2 reaction on the assumption that "f" in eq. (12) is equal to one.

The initial value of k_{11} so obtained was 38 M^{-1} s^{-1}. This was then plugged into eq. (13) to calculate "f" for each reaction. From eq. (12) a plot of $\log k_{12} + \frac{1}{2}\log k_{22} - \frac{1}{2}\log f$ vs $\log K_{12}$ should be linear with a slope of 0.5 and an intercept of $\frac{1}{2}\log k_{11}$. With this improved value of $\log k_{11}$, the process was repeated until the initial value of k_{11} and that estimated from the intercept agreed within 5%. The final result is a good linear plot (correlation coefficient 99.52% shown in Fig. 1). From the slope of 0.45 and the intercept, the rate constant $k_{11} = 32.9$ M^{-1} s^{-1} was obtained. A slope of nearly half (0.48) has also been reported for such a correlation in the reactions of $Ti(OH)^{2+}$ with some ruthenium(III) ammine complexes.[18,19]

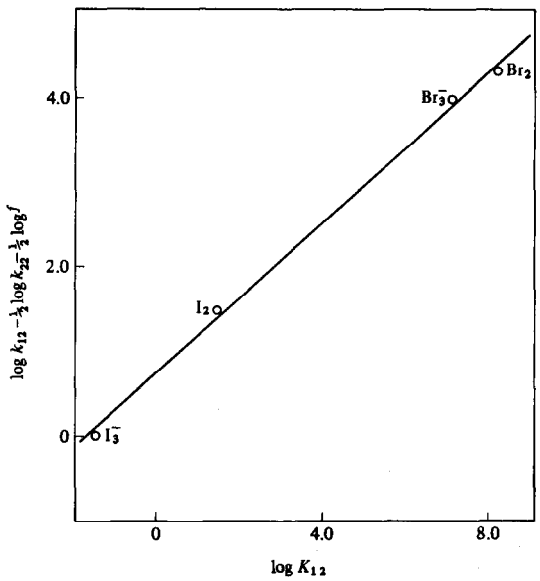

Fig. 1. Marcus plot for the Ti^{3+}(aq)–X_2, X_3^- (X = Br, I) reactions.

The kinetically derived value of k_{11} for $Ti(OH)^{2+}$ is 0.11 M^{-1} s^{-1} and the redox potential for the couple $Ti(OH)^{3+} + e \rightarrow Ti(OH)^{2+}$ is reported as 0.08 V. The corresponding values for the Ti–edta + Ti–edta$^-$ couple are 32 M^{-1} s^{-1} and 0.03 V, respectively.

As to the mechanism by which the Ti^{III}–edta + Br_2 reaction occurs, the only convincing evidence for the outer-sphere mechanism is in the magnitude of the rate constant for the oxidation of Ti^{III}–edta at pH = 3. The rate constant obtained for this reaction is much higher than the substitution-controlled electron-transfer rates in the inner-sphere reaction[10] of Ti–edta$^-$ with $[(NH_3)_5Ru(OAc)]^{2+}$, $[Co(NH_3)_5N_3]^{2+}$ and $[Co(NH_3)_5SCN]^{2+}$.

On comparative analysis with available results on the choice of the mechanism by aquotitanium(III) ion, three less convincing pieces of evidence seem to support the outer-sphere mechanism for the reaction reported in this work. These are:

(i) the fact that inner-sphere reactions of Ti^{3+}(aq) with metal complexes are accompanied by more complex acid dependence behaviour than can be explained by merely invoking the hydrolysis of aquotitanium(III) ion;
(ii) that inner-sphere reactions of Ti^{3+}(aq) have only been established for complexes where the "lead-in" ligands are typically Pearson's hard bases, whereas complexes with relatively soft

bases like iodide react by the outer-sphere mechanism;[20]

(iii) the excellent correlation obtained when the rate constant for the oxidation of Ti^{III}–edta by Br_2, Br_3^- and I_2 and I_3^- at pH = 2.5 are subjected to the Marcus equation for cross-reactions,[15] which suggests that the reactions occur by the same mechanism and this we believe to be the outer-sphere mechanism.

Kristine *et al.*[5] have reported that the measured rate constant for the generation of $[Ti(O_2)(edta)]^-$ by the addition of O_2 to $[Ti(edta)(H_2O)]^-$ is 200 times faster than the substitution of peroxo- for oxo- on $[TiO(edta)]^{2-}$ at pH = 5.0. They therefore suggested that an outer-sphere reduction of O_2 to H_2O_2, followed by substitution on a generated titanium(IV) species is not a possible mechanism for $O/[Ti(O_2)(edta)]^{2-}$ forming $[Ti(O_2)(edta)]^{2-}$. An inner-sphere mechanism was therefore suggested. However, steric considerations arising from the larger size of Br_2 compared to O_2, the relative affinity of the titanium(III) centre for Br_2 and O_2 and the relative stability of the eventual intermediate are possible factors that may have made the Ti^{III}–edta + Br_2 reaction prefer an outer-sphere pathway.

Acknowledgement—We thank Dr G. A. Ayoko for useful comments.

COBALT(III) COMPLEXES OF ETHYLENEDIAMINE-N,N′-DI-S-ISOBUTYLACETIC ACID

MOO-JIN JUN,* JIN WOO CHEON, SUNG SIL LEE and SUNG RACK CHOI

Department of Chemistry, Yonsei University, Seoul, Korea

(*Received* 8 *November* 1988; *accepted* 31 *May* 1989)

Abstract—A new optically active ONNO-type tetradentate ligand, ethylenediamine-N,N′-di-S-isobutylacetate (SS-eniba), has been synthesized. During the preparation of diaqua cobalt(III) complexes of SS-eniba, $[Co(SS\text{-}eniba)(H_2O)_2]^+$, the title ligand has coordinated stereospecifically to the cobalt(III) ion to give three isomers, Δ-s-*cis*, Δ-uns-*cis* and Λ-uns-*cis*, which have been isolated and characterized via electronic absorption, circular dichroism (CD), and ^1H NMR spectroscopy, along with elemental analysis data. The preparation of Δ-s-*cis*-$[Co(SS\text{-}eniba)Cl_2]^+$ and Δ-s-*cis*-$[Co(SS\text{-}eniba)CO_3]^+$ are also reported.

Although a large number of ONNO-type tetradentate ligands such as ethylenediamine-N,N′-diacetate (edda) are known,[1,2] only a few of them are optically active ligands which coordinate stereospecifically to metal ions. The ethylenediamine-di-S-α-propionate (SS-eddp)[3] has yielded Δ-s-*cis*, Λ-s-*cis* and Δ-uns-*cis* isomers of $[Co(SS\text{-}eddp)en]^+$ out of the four possible isomers (Fig. 1). In the case of ethylenediamine-N,N′-di-S-α-isovalerate (ven),[4] only the Δ-s-*cis* isomer has been produced for the $[Co(ven)H_2ONO_3]$ complex, while both Δ-s-*cis* and Δ-uns-*cis* isomers have been obtained for the $[Co(ven)(H_2O)_2]^+$ and $[Co(ven)en]^+$ complexes. The 2S,2′S-1,1′-(ethane-1,2-diyl)bis(pyrrolidine-2-carboxylate)(pren)[5] compound is shown to yield both Δ-s- and Δ-uns-*cis* isomers for $[Co(pren)(H_2O)_2]^+$. The L-stilbenediamine-N,N′-diacetate (L-sdda) compound has also been prepared but only the Δ-s-*cis*-$[Co(L\text{-}sdda)en]^+$ complex has been isolated.[6]

In the present work a new optically active ONNO-type ligand, ethylenediamine-N,N′-di-S-isobutylacetate (SS-eniba), has been prepared. It is of interest to see how the stereospecificity of this ligand is exhibited upon coordination to the cobalt(III) ion.

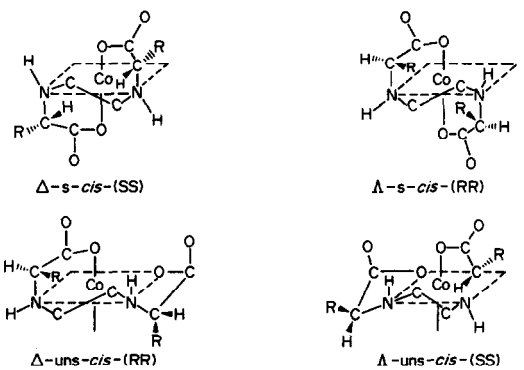

Fig. 1. Possible isomers of $[Co(eddp)X_2]^{n+}$ or $[Co(eniba)X_2]^{n+}$ complexes.

EXPERIMENTAL

Ethylenediamine-N,N′-*di*-S-*isobutylacetic acid* (SS-eniba)

NaOH (8.0 g) in 20 cm^3 of water was added to s-leucine (26.2 g) in 100 cm^3 of water. 1,2-Dibromoethane (17.4 g) and Na_2CO_3 (10.6 g) were added in portions to this solution while maintaining the system at 70°C. The reaction mixture was stirred for 30 h at 70°C. The solution was cooled and acidified to pH 6 with conc. HCl. The precipitated

* Author to whom correspondence should be addressed.

white product was collected on a filter, washed with water and petroleum ether, and dried in vacuum. Yield: 11.0 g. Found: C, 58.5; H, 9.8; N, 9.6. Calc. for $C_{14}H_{28}N_2O_4$: C, 58.3; H, 9.8; N, 9.7%. $[\alpha]_D = -14.2$ ($c = 4.1 \times 10^{-3}$ g cm^{-3} of water).

*Isomers of diaqua(ethylenediamine-N,N′-di-*S*-isobutylacetate)cobalt*(III) *perchlorate*, [Co(SS-eniba)$(H_2O)_2$]ClO_4

To a suspension of SS-eniba (8.64 g) in 100 cm^3 of water was added a solution of $CoCl_2 \cdot 6H_2O$ (0.13 g) in 50 cm^3 of water and 2.0 g of activated carbon. The reaction mixture was heated to 60°C for 10 h. Upon cooling, the activated carbon and unreacted PbO_2 were filtered off. Addition of a saturated Na_2SO_4 solution to the filtrate yielded the white $PbSO_4$ precipitate, which was filtered off. The solution was evaporated to 15 cm^3. This violet solution was admitted to a column packed with Dowex 50X4-400 (200–400 mesh) cation exchange resin in the H^+ cycle. The violet solution was sorbed at the top of the column and washed with water. Three fractions were obtained by elution with 0.3 M $NaClO_4$. Each fraction was concentrated, freed from excess $NaClO_4$ by extraction into absolute ethanol, and evaporated to dryness on a water bath. Yield: Δ-s-*cis*: 1.1 g, Δ-uns-*cis*: 0.4 g, Λ-uns-*cis*: 0.3 g. Found: Δ-s-*cis*: C, 33.4; H, 6.5; N, 5.6. Δ-uns-*cis*: C, 33.9; H, 6.5; N, 5.6. Calc. for [Co($C_{14}H_{26}N_2O_4$)$(H_2O)_2$]$ClO_4 \cdot H_2O$: C, 33.7; H, 6.4; N, 5.6%.

Δ-s-*cis*-H[Co(SS-eniba)Cl_2]

This complex was obtained by passing a solution of the diaqua complex through a cation exchange column using 0.4 M NaCl as eluent. Three fractions were obtained. The first fraction was concentrated, freed from excess NaCl by extraction into ethanol and evaporated to dryness on a water bath. Found: C, 40.1; H, 6.6; N, 6.7. Calc. for H[Co($C_{14}H_{26}N_2O_4$)Cl_2]: C, 40.3; H, 6.5; N, 6.7%.

Δ-s-*cis*-H[Co(SS-eniba)CO_3]

A suspension containing Δ-s-*cis*-H [Co(SS-eniba)Cl_2] (0.34 g) in 10 cm^3 of water was heated at 60°C until the colour of the solution changed from green to violet by aquation. Na_2CO_3 (0.34 g) was added to this solution, which was stirred for 5 h at 60°C and then concentrated to 5 cm^3 on a rotary evaporator. The addition of 20 cm^3 of acetone yielded a white precipitate, which was filtered off. An excess of acetone was added to the filtrate and the solution was stored in a refrigerator. The purple–violet crystals which formed were collected on a filter.

RESULTS AND DISCUSSION

The ligand has been prepared from optically active leucine of known configuration and contains two asymmetric carbon atoms of s-absolute configuration. The configuration of the ligands is shown in Fig. 2 along with its ^{1}H NMR spectrum. The methyl protons are shown at 0.9 ppm as a doublet and the α-carbon protons at 3.1 ppm as a triplet. The two methylene protons between two nitrogen atoms resonate at 2.6 ppm as a singlet.

Three isomers, Δ-s-*cis*, Δ-uns-*cis* and Λ-uns-*cis*, have eventually been isolated from the preparation of the diaqua cobalt(III) complex of SS-eniba, [Co(SS-eniba)$(H_2O)_2]^+$, which was prepared by oxidation of cobalt(II) in the presence of the desired ligand. The Δ-s-*cis*-[Co(SS-eniba)$Cl_2]^-$ and Δ-s-*cis*-[Co(SS-eniba)$CO_3]^-$ complexes have been obtained from the substitution reactions of Δ-s-*cis*-[Co(SS-eniba)$(H_2O)_2]^+$ and Δ-s-*cis*-[Co(SS-eniba)$Cl_2]^-$, respectively.

The electronic absorption spectrum of the s-*cis* isomer (Fig. 3) shows a symmetrical first band with λ_{max} at *ca* 550 nm, whereas more broad bands are observed in the absorption spectra of uns-*cis* isomers (λ_{max}: 515 nm for Δ-uns-*cis* and 520 nm for Λ-uns-*cis*). These *cis* isomers have also been differenciated from their ^{1}H NMR spectra. The ^{1}H NMR spectrum of the s-*cis* isomer has shown a sharp methyl doublet at 1.0 ppm, while the uns-*cis* isomers have shown two methyl doublets at about 1.0 ppm due to the overlapping of the non-equivalent methyl peaks.

The CD spectrum of the s-*cis* isomer (Fig. 3)

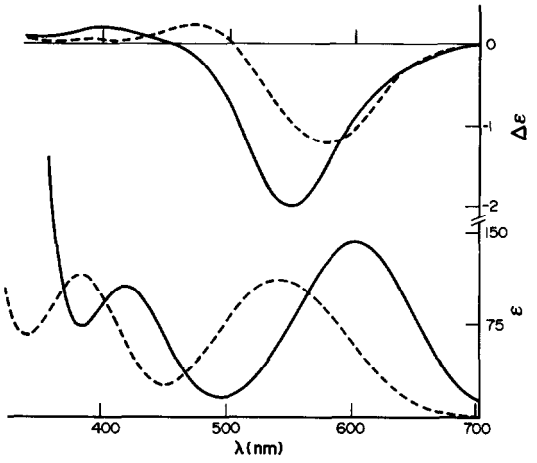

Fig. 4. Circular dichroism and electronic absorption spectra of Δ-s-*cis*-H[Co(SS-eniba)Cl_2] (———) and Δ-s-*cis*-H[Co(SS-eniba)CO_3] (– – – –).

shows a dominant negative band of the $Eg(D_{4h})$ component at 540 nm, which indicates a Δ absolute configuration.[1,3,7] The absolute configuration of the uns-*cis* isomers can also be assigned on the basis of their CD spectra. In the case of the Δ-uns-*cis* isomer a large negative peak at 550 nm and a smaller positive peak at 470 nm are observed, while a large positive peak at 550 nm and a small negative peak at 480 nm are shown for the Λ-uns-*cis* isomer.

The absorption maxima of the electronic absorption spectra of the Δ-s-*cis*-[Co(SS-eniba)$Cl_2]^-$ and Δ-s-*cis*-[Co(SS-eniba)$CO_3]^-$ shown in Fig. 4 are consistent with the spectrochemical series. Dominant negative CD bands are observed in these complexes since they are derived from Δ-s-*cis*-[Co(SS-eniba)$(H_2O)_2]^+$.

It is of interest to note that uns-*cis* isomers (Δ and Λ) have been obtained in addition to the Δ-s-*cis* isomer during the preparation of the [Co(SS-eniba)$(H_2O)_2]^+$ complex, while only the Δ-s-*cis* isomer has been observed in the diaqua cobalt(III) complex of the SS-ven ligand,[4] [Co(SS-ven)$(H_2O)_2]^+$. The yield of the Δ-s-*cis* isomer is twice as large as that of the Δ-uns-*cis* or Λ-uns-*cis* isomers. Such an observation may be attributed to the pronounced ring strain and intraligand steric hindrance of the uns-*cis* configuration. In addition, the non-existence of the Λ-s-*cis* isomer can be envisaged from the Dreiding molecular model, which shows non-bonding interactions not only between the isobutyl group and the en backbone, but also between the isobutyl groups.

THE PREPARATION OF BIS(ISOPROPOXY)THIOLATO COMPLEXES OF TITANIUM(IV) AND THEIR LEWIS BASE ADDUCTS

J. JONES* and J. A. DOUEK

Department of Physical Science, Polytechnic of the South Bank, London, U.K.

(*Received* 24 *April* 1989; *accepted* 5 *June* 1989)

Abstract—Reactions of titanium tetraisopropoxide with various thiols are reported. In the absence of other donating atoms, appreciable product formation is observed only with 1,2-dithiols. Monothiols and 1,3-dithiols react in the presence of nitrogen donors and 2-aminobenzene thiol reacts spontaneously. Complexes with 1,2-dithiols and bidentate nitrogen donors adopt the *cis* configuration in solution. Compounds were characterized by NMR, IR, molecular weights (in solution) and elemental analysis.

Numerous dithiolato complexes of titanium have been prepared, but in the absence of the cyclopentadienyl group they were generally found to be rather insoluble solids which did not lend themselves to study in solution.[1,2] A few soluble alkoxy dithiolates have been isolated and the purpose of this work was to extend the range of this type of compound, to investigate their reactivity towards Lewis bases and to study the structure in solution of the parent dithiolates and their adducts.

EXPERIMENTAL

Reactions and manipulations were performed in a dry nitrogen atmosphere using standard techniques and dried purified reagents. Compounds **1**, **2** and **21** were prepared by mixing stoichiometric quantities of $(i\text{-PrO})_4\text{Ti}$ and dithiol in dry benzene followed by azeotropic distillation of the isopropanol formed. Volatiles were removed at reduced pressure, the oily solids triturated with light petroleum, filtered and dried *in vacuo*. An attempt to prepare **3** by this method gave evidence of reaction as judged by the appearance of an orange coloration upon mixing of the reagents, but no product was isolated even after prolonged fractionation. Neither p1,4dt nor tpt showed evidence of reaction.

Compound **3** was eventually prepared from its pyridine adduct by stirring a suspension of **13** in petrol, elimination of the volatiles at reduced pressure and addition of more petrol followed by filtration. Compound **4** was prepared by mixing alkoxide and tdtH_2 in benzene at room temperature, elimination of the volatiles at reduced pressure, followed by dissolution of the deep purple solid in petrol and its subsequent evaporation at reduced pressure. The latter process, repeated twice, was sufficient to remove traces of benzene from the product. With the exception of pyridine complexes, **7**, **10** and **13**, compounds **5–18** were prepared by mixing stoichiometric quantities of alkoxide, thiol and nitrogen ligand in petrol (bipy and py) or benzene (phen). Complexes precipitated immediately and were filtered and dried. Compounds **7**, **10** and **13** were prepared using pyridine itself as solvent. Crystallization was induced by cooling at −15°C overnight, the products filtered on a frit surrounded by a cardice jacket, washed with small portions of cooled petrol and dried *in vacuo* at ambient temperature. Compound **19** was prepared by mixing stoichiometric quantities of alkoxide (7 mmol) and abt in benzene (total volume, 30 cm^3). An equal volume of petrol was added and the mixture cooled at 5°C overnight. The mass of yellow crystals was filtered, the product washed with cold petrol and dried. Compounds **20** and **21** were prepared by reaction of tetrabenzyltitanium(IV) with dithiol at ambient temperature (attempts using alkoxide failed to yield pure products). The brown solids

precipitated immediately from the petroleum solution and were filtered and dried.

All compounds had satisfactory elemental analyses which are listed in Table 1.

DISCUSSION

Syntheses

The influence of chelation on the reactivity of thiols with titanium tetraisopropoxide is evident and follows expected patterns. Thus, five-membered rings form more or less easily (compounds **1**, **2** and **4**), with tdtH_2 apparently of greater reactivity. Six-membered rings are not particularly favoured though colour changes indicate slight reaction (p1,3dtH_2), whilst seven-membered rings appear not to form at all (p1,4dtH_2). Neither aliphatic monothiols[3,4] nor simple aromatic thiols react (tpt). The presence of a second coordinating atom, introducing the possibility of chelation, renders the thiol reactive and the product is isolated under extremely mild conditions,**19**. That this is entirely due to chelation of the thiol ligand is, however, not certain as the preparation of **13**, **17** and **18** demonstrates.

^{1}H *NMR spectra*

All compounds examined showed signals at expected δ-values and integrations were in accord with proposed structures. In line with molecular weight determinations in solution showing the presence of oligomers, compounds **1**, **2** and **3** gave broad, unresolved signals with little improvement in resolution at higher temperatures. The spectrum of **4** was sharp with a single isopropoxy methyl doublet at δ 1.21. The spectra of **5** and **6** are of interest, and that of **5** was examined at various temperatures. The presence of two, well-resolved, isopropyl methyl doublets of equal intensity at δ 1.08 (A) and 1.38 (B) (J = 6 Hz for both A and B) and two thiol methylene signals at δ 3.66 and 3.85 indicates a *cis*

structure. This inference is strengthened by the low temperature spectra which show splitting of the two methyl doublets (at different rates) and the isopropyl methine septet (δ 5.23, $J = 6$ Hz in the room temperature spectrum). As the temperature is lowered, A splits into A1 and A2 and B splits into B1 and B2, so that in the spectrum at -50°C three sets of methyl doublets are observed at δ 1.6 (6H, A1 and B1 superimposed), δ 1.2 (3H, A2), δ 0.4 (3H, B2), and two, broad, unresolved methine signals appear at δ 5.6 and 4.8. The spectrum at -50°C thus corresponds to what one might predict for a *cis* isomer in the absence of configurational changes. Given the relatively large splitting observed for signal B, it is probable that this signal is due to the isopropyl group coordinated at the position perpendicular to the plane of the nitrogen ligand where it would experience the shielding effect of the ligand's ring currents. With increasing temperature, signals A and B gradually coalesce as do the thiol methylene signals, until at 100°C a single doublet (δ 1.23) and a sharp singlet (δ 3.72) are observed. These changes are consistent with dissociation of one end of the nitrogen ligand, complete dissociation is unlikely, at least up to the boiling point of chloroform, given the ebulliometry results. The spectra of similar complexes of **2** and **4** show multiplet signals in the methyl region and are not so readily analysed. However, the very complexity is, at least, indicative of *cis* geometry.

Pyridine complexes gave sharp, well-resolved signals and showed a single methyl doublet in all cases. That this should be so for **7**, **10** and **13** is to be expected given the ease of dissociation of the pyridine in these complexes. For **16**, in which pyridine is more strongly coordinated (m.p. ebulliometry), the spectrum is a reflection of the configurational instability of the complex rather than an indication of the adoption of the *trans* form with respect to the isopropoxy groups.

IR spectra

In all the compounds containing a bidentate nitrogen ligand, as well as the Ti—O stretching vibration observed in the region 600–620 cm^{-1}, a second band of variable intensity is present in the region 590–600 cm^{-1}. This band, absent in the pyridine complexes, may represent the Ti—O assymetric stretch expected for *cis* geometry.

In the region 330–400 cm^{-1}, to which Ti—S vibrations are generally assigned,[2,4] several bands are present in most cases. Although it has been proposed[5] that metal–nitrogen stretching bands with ligands such as bipy occur between 300 and 390 cm^{-1}, within the region 370–390 cm^{-1} in the majority of compounds examined in this work, including compounds **20**, **21** and **22** which do not contain a nitrogen ligand, there is at least one band which might be assigned to a Ti—S vibrational mode.

REDUCTIVE NITROSYLATION OF TETRAOXOMETALLATES—XVII. MOLYBDATE–HYDROXYLAMINE–CYANIDE REACTION, AND SYNTHESIS AND CHARACTERIZATION OF $K_2[Mo(NO)(CN)_5]$ AND $(NMe_4)_2[Mo(NO)(CN)_4]$

RAMGOPAL BHATTACHARYYA,* NABANITA GHOSH and ALOK MOHAN SAHA

Department of Chemistry, Jadavpur University, Calcutta 700 032, India

(*Received* 10 *February* 1989; *accepted* 20 *July* 1989)

Abstract—A reaction condition is established which determines the nature of the products in the molybdate–hydroxylamine–cyanide reaction. With hydroxylamine always used in excess, it is the hydroxyl ion concentration of the reaction mixture which plays a vital role in determining whether $K_4[Mo(NO)(CN)_5]$ or $K_2[Mo(NO)(CN)_5]$ is obtained exclusively. The latter product is hereby reported for the first time. Its powder diffractogram being typical of a cubic system, a gross structural characterization has been made possible. The former under aqueous, aerobic conditions yields a new product, $(NMe_4)_2[Mo(NO)(CN)_4]$.

The reaction between MoO_4^{2-} and hydroxylamine in the presence of CN^- ions in alkaline medium has been studied many times.[1–11]

Hoffman and Von der Heide's[1] red–violet product, formulated as $MoO_2 \cdot 4KCN \cdot NH_2OH \cdot H_2O$ was recognized about 50 years later by Hieber *et al.*[2] as a molybdenum nitrosyl compound, viz. $K_4[Mo(NO)(CN)_5] \cdot 2H_2O$. After a further 20 years the complex was structurally characterized by three-dimensional X-ray diffraction studies by Svedung and Vannerberg.[12]

The earlier workers[1–3,5,13] used a rather meagre amount of $NH_2OH \cdot HCl$ which was much less than that required stoichiometrically,[14] to carry out the nitrosylation reaction. In this paper we report an investigation on the reaction of MoO_4^{2-} with an excess of $NH_2OH \cdot HCl$, in an alkaline medium in the presence of excess of CN^-. The present work not only results in a generous yield of the $K_4[Mo(NO)(CN)_5]$ (**1**) but paves the way for synthesizing $K_2[Mo(NO)(CN)_5]$ (**2**), representing a molybdenum cyanonitrosyl compound containing the $Mo(NO)^{3+}$ moiety, considered to be a missing link in molybdenum cyanonitrosyls possessing the moiety $Mo(NO)^{n+}$ ($n = 1$–3). In addition, a hitherto unknown species, $[Mo(NO)(CN)_4]^{2-}$ (**3**), was obtained in the present investigation. This work also reports a gross structural characterization of **2** using the powder diffraction data only.

EXPERIMENTAL

Materials and methods

All reagents were of reagent grade and used without further purification. For physicochemical measurements, the solvents were further purified using literature methods.[15] IR spectra were recorded as KBr discs on a Perkin–Elmer 597 spectrophotometer, calibrated with polystyrene. Solution conductances were measured with a Systronics (India) Model 304 conductivity bridge and the electronic spectra (800–200 nm) were taken using a Pye Unicam SP8-150 UV–vis spectrophotometer. Magnetic susceptibilities were measured with a Gouy balance using $Hg[Co(NCS)_4]$ as calibrant. The elements carbon, hydrogen and nitrogen were analysed on a Perkin–Elmer 240C elemental analyser and molybdenum by a gravimetric method.[16]

Preparation of the complexes

Potassium pentacyanonitrosyl molybdate(0), $K_4[Mo(NO)(CN)_5]$ (**1**). MoO_3 (2.5 g, 0.017 mol)

* Author to whom correspondence should be addressed.

was dissolved in 10 cm^3 of cold saturated (5 g) KOH solution with stirring. Then KCN (10 g, 0.153 mol) dissolved in 15 cm^3 of water (filtered if necessary) was added. The mixture was stirred at room temperature until the solution became clear (a little more water needs to be added dropwise if the solution becomes turbid). Then $NH_2OH \cdot HCl$ (9.0 g, 0.130 mol) was added dropwise, when the colour of the solution changed from orange to blackish-red. On stirring for 5 min the red colour faded to yellow. Then, more KOH (2 g) was added and the solution was heated with stirring. Occasionally, further amounts (1–2 g) of KOH were added portionwise (a total of *ca* 8–10 g of KOH was added). After heating and stirring for a further 30 min a red–violet solution resulted and a violet crystalline compound started precipitating out. The solution was then allowed to cool to room temperature and the crystalline violet product was filtered off, washed quickly with EtOH (90%) and finally with ether, and then dried over fused $CaCl_2$ under vacuum. The compound was crystallized quickly from a H_2O–EtOH mixture. Yield: 6.9 g (90%). Found: C, 13.8; N, 19.3; K, 37.5; Mo, 22.6. $C_5N_6OK_4Mo$ requires: C, 13.9; N, 19.5; K, 37.9; Mo, 22.3%. IR: ν(CN) 2120 (sh), 2060 (s); ν(NO) 1455 (s), ν(Mo—N)(NO) 610 (w) cm^{-1}. λ_{max} 546 (208) nm. $\Lambda_M = 398\ \Omega^{-1}\ cm^2\ mol^{-1}$ in H_2O (measured instantaneously). [*d* spacings, *d* in Å = 6.60 (w), 5.27 (s), 4.98 (m), 4.23 (m), 4.04 (m), 3.63 (s), 3.53 (m), 3.16 (s), 3.09 (m), 3.02 (m), 2.87 (m), 2.78 (s), 2.65 (w), 2.25 (m), 2.15 (m), 2.12 (m), 2.05 (w), 2.03 (w).]

Potassium pentacyanonitrosyl molybdate(II), $K_2[Mo(NO)(CN)_5]$ (**2**). MoO_3 (2.5 g) was dissolved in a saturated aqueous (5 cm^3) solution of KOH (2.5 g). KCN (10 g, 0.153 mol) dissolved in 15 cm^3 of H_2O was filtered, and then added to the above solution with stirring. The mixture was stirred further at room temperature until the solution became clear (a few cm^3 of H_2O needs to be added if the solution still remains turbid). Then 9.0 g of $NH_2OH \cdot HCl$ (0.130 mol) was added portionwise when colour of the solution changed from orange to blackish-red. At this stage the solution has a pH value of 9. On stirring for another 5 min the deep-red colour faded to yellow. This solution was then heated at 80°C, with stirring, and a vigorous reaction set in, with a consequent colour change of the solution from orange–yellow to red–orange. The solution was then allowed to cool to room temperature. The orange, crystalline precipitate which separated was filtered off, washed with ethanol and ether, and finally dried over fused $CaCl_2$ *in vacuo*. The compound was crystallized from a H_2O–isopropanol mixture. Yield: 5.2 g (85%). Found: C, 16.6; N, 23.5; K, 23.7; Mo. 27.5%. $C_5N_6OK_2Mo$ requires: C, 17.1; N, 23.8; K, 23.4; Mo. 27.3%. IR: ν(CN) 2140 (sh), 2120 (s); ν(NO) 1640 (s) and ν(Mo—N) 600 (w) cm^{-1}. λ_{max} 632 (70), 392 (170) and 216 (7500) nm. $\Lambda_M = 210\ \Omega^{-1}\ cm^2\ mol^{-1}$ in H_2O.

Tetramethylammonium tetracyanonitrosyl molybdate(I), $(NMe_4)_2[Mo(NO)(CN)_4]$ (**3**). The complex $K_4[Mo(NO)(CN)_5]$ (1 g, 2.4 mmol) was dissolved in H_2O (10 cm^3), and to this solution 0.53 g of $(CH_3)_4NCl$ (4.8 mmol; dissolved in a minimum volume of H_2O) was added. The mixture was stirred at room temperature and within a few minutes a yellowish-green precipitate separated out. This was filtered off and washed with EtOH, ether and finally dried over fused $CaCl_2$ *in vacuo*. The product was further crystallized from a H_2O–EtOH mixture. Yield: 0.55 g (62.5%). Found: C, 37.9; H, 6.6; N, 25.9; Mo, 25.6. $C_{12}H_{24}N_7OMo$ requires: C, 38.1; H, 6.3; N, 25.9; Mo. 25.3%. IR: ν(CN) 2100 (sh), 2080 (s); ν(NO) 1580; ν(Mo—N)(NO) 575 cm^{-1}. λ_{max} 418 (50), 294 (620) nm. $\mu_{eff} = 1.9$ BM. $\Lambda_M = 226\ \Omega^{-1}\ cm^2\ mol^{-1}$ in H_2O. [*d* spacings, *d* in Å = 7.31 (s), 6.33 (s), 4.44 (s), 3.80 (s), 3.62 (w), 3.14 (s), 2.51 (s), 2.56 (m), 2.42 (m), 2.22 (s), 2.12 (m), 2.09 (s), 1.98 (m), 1.82 (w), 1.75 (w), 1.73 (w), 1.67 (m), 1.61 (m), 1.52 (w).]

RESULTS AND DISCUSSION

It is quite apparent from the experimental section that an excess of $NH_2OH \cdot HCl$ is necessary, both, to bring the MoO_4^{2-}—NH_2OH—CN^- reaction to completion, and to understand the reaction pathways. A reaction mixture containing MoO_4^{2-} and an excess of $NH_2OH \cdot HCl$, if cooked in a rather weakly alkaline condition (pH ~ 9) an orange potassium salt of bivalent molybdenum, viz. $K_2[Mo(NO)(CN)_5]$ (a product not obtained by earlier workers using 3–4 mol of NH_2OH per mol of MoO_4^{2-}; the PPh_4 salt of the anion, however, has been obtained otherwise, recently) is the only product obtained in reasonably high yield. On the other hand, if the reaction is conducted between pH 10 and 12, firstly $K_2[Mo(NO)(CN)_5]$ separates out, and from the filtrate $K_4[Mo(NO)(CN)_5]$ is obtained. However, using a large excess of KOH in the reaction medium, $K_4[Mo(NO)(CN)_5]$ becomes the exclusive product. The amount of NH_2OH and KOH thus play a crucial role in determining the selectivity and yield of the products. Hence, it becomes apparent that conversion of MoO_4^{2-} to the $Mo(NO)^+$ moiety using NH_2OH only occurs at very high alkalinity, and the reaction possibly proceeds via an intermediate $Mo(NO)^{3+}$ stage. At low alkalinity, the reaction only goes to the $Mo(NO)^{3+}$ stage.

Interestingly, an attempted cation metathesis of

Table 1. Powder diffraction data and derived parameters of $K_2[Mo(CN)_5NO]$

3.15	0.0593	0.0598	100	600
2.23	0.1190	0.1196	110	660
1.80	0.1793	0.1794	111	666
1.57	0.2395	0.2392	200	1200
1.41	0.2990	0.2990	210	1260

$K_4[Mo(NO)(CN)_5]$ (an air-unstable species) using NMe_4Cl, under aqueous, aerobic conditions, yields a hitherto unknown yellow–green air-stable product, $(NMe_4)_2[Mo(NO)(CN)_4]$, which obviously contains the $Mo(NO)^{2+}$ [3] [hence $\{Mo(NO)\}^5$]* moiety. As expected, the compound is paramagnetic ($\mu_{eff} = 1.9$ BM) and ESR-sensitive $[(e)^4(b_2)^1]$ with $\langle g\rangle_{av} = 2.00$ in the crystalline state. The cation metathesis does not occur in a dinitrogen atmosphere where also the above, formally molybdenum(I) nitrosyl product, results. It may be recalled that the $Mo(NO)^{2+}$ moiety has previously been introduced by Sarkar and Müller[5] when synthesizing $K_3[Mo(NO)(CN)_5]$ (and also the corresponding PPh_4 salt by cation metathesis) by the passage of dioxygen through an aquous solution of the formally zero-valent red–violet product.

The red–violet compound behaves as a 4 : 1 electrolyte, while compounds **2** and **3** show a 2 : 1 electrolytic behaviour in aqueous solution. The molybdenum(0) product shows ν(NO) at 1455 cm^{-1} (i.e. the same position as obtained by earlier workers), while the monovalent, **3**, and bivalent, **2**, compounds exhibit the above vibrational mode at 1580 and 1640 cm^{-1}, respectively, which is in accordance with molybdenum $d_\pi \rightarrow \pi^*$(NO) back-bonding efficiency.

Considering M—N—O to be linear (there is no exception to this behaviour in the structurally confirmed cases containing $\{M(NO)\}^n$ moieties where $n = 4$–6), all the complexes should possess C_{4v} symmetry and, accordingly, compounds **1**, **2** and **3** will have the MO configurations $(e)^4(b_2)^2$, $(e)^4$ and $(e)^4(b_2)^1$, respectively.[17] Being fully occupied by electrons, the b_2 level in **1** will be the most stabilized, being a LUMO in **2** the said orbital will have a reasonably high energy and being a SOMO, the latter will be at an intermediate energy region. Hence a single electronic spectral band observed (see Experimental) in **1** may originate from the $b_2 \rightarrow b_1$ transition, whilst in **2** three bands result from the $e \rightarrow b_2$, $e \rightarrow e_1$ and $e \rightarrow b_1$ transitions, in the order of increasing energy. Since **3** is a five-coordinate species, two electronic transitions are predicted in the C_{4v} case and it is highly satisfying that two bands are actually observed, which are due to $b_2 \rightarrow a_1$ and $b_2 \rightarrow b_1$ transitions.

X-ray powder diffraction studies

The X-ray powder diffraction data of **1** and **3** are given in the Experimental. The data reported here for **1** resemble that reported by Reiley and Ho.[13] The compound $K_2[Mo(NO)(CN)_5]$ (**2**) has an interesting diffractogram showing only five distinct and well separated peaks in the 2θ range 0–70° (Table 1).

The powder diffraction pattern may be indexed assuming a cubic cell with $a = 3.15$ Å (obtained by a graphical method). But considering the formula weight (334) and the measured density (1.5 g cm^{-3}), it is evident that the unit cell is much larger, with $a = 3.15n$, where n is an integer. Then

$$\frac{Z \times 334}{(3.15n)^3 \times 0.6023} = 1.5,$$

where Z = number of formula units per unit cell whence, $Z/n^3 = 0.083$. By trial, it is found that for $n = 6$, Z is closest to the integer value 18. Thus, the cubic cell has $a = 18.9$ Å, with $Z = 18$.

This leads to an interesting conclusion. The minimum rank of the general equipoint is 12 ($P23$ and $P2,3$) for cubic symmetry. So, at least half of the molybdenum complexes in the unit cell must lie on two-fold axes. The space group is, thus, most probably $P23$. Furthermore, this is a definite pointer to the fact that the CN—Mo—NO sequence lies strictly on a straight line. The four remaining CN groups must lie in a plane normal to this axis, arranged in two pairs of symmetry related groups.

SOME FEATURES OF 2- AND 4-AMINOPYRIDINES ANCHORED ON SILICA GEL: PROPERTIES AND CHEMISORPTION OF METAL(II) CHLORIDES IN NON-AQUEOUS SOLUTIONS

AFONSO S. GONÇALVES* and CLAUDIO AIROLDI†

(*Received* 11 *April* 1989; *accepted* 24 *July* 1989)

Abstract—Silica gel surfaces modified with 2- or 4-aminopyridine groups were used to adsorb MCl_2 (M = Co, Ni, Cu, Zn) from ethanol and acetone solutions at 298 K. The chemisorption isotherms fitted a modified Langmuir equation very well and are similar for all cations. The capacity of anchored 4-aminopyridine (SIL4) in adsorbing the metallic ion is larger than that of the immobilized 2-aminopyridine (SIL2). The maximum retention capacity has the sequence Cu > Co > Zn in acetone for both surfaces, and Zn > Co > Cu > Ni for SIL2, and Zn > Cu > Co > Ni for SIL4 in ethanol. For a given cation, the variation in enthalpy of solvent–solute exchange on the surface is always larger in ethanol. This process seems to be related to the enthalpy of solvation of the cation involved in the exchange.

Silica gel is one of the most widely used inorganic supports, with numerous kinds of chelating reagents immobilized on its surface.[1,2] For this, the application of 3-chloropropyltrialkoxysilane is one of the most popular approaches for modification of the silica gel surface through chemical bonding.[3] A great number of known chemical reactions, starting from this precursor, lead to a desired organic function. Surfaces containing specific functional groups, after being well characterized, have increased the application in a large variety of technological activities.[2,3]

The covalent immobilized groups attached to the support, through the formation of Si—C,[4,5] Si—N[6] or Si—O[7] bonds, can adsorb metal ions from non-aqueous solutions,[8–10] for preconcentration[11] or separation of metal ions,[12] as well as behave as bonded phases for liquid chromatography.[13]

The availability of a basic centre to coordinate cations in solution and, in particular, the availability of a heterocyclic nitrogen, is the main focus here. Some sorbents containing simple or very complex molecules have been reviewed,[2] with quinoline derivatives[14] and imidazole[9,15] showing an effective participation of cyclic nitrogen in adsorbing metallic ions from non-aqueous solvents.

An efficient chelation capacity was observed with immobilized 3-aminopyridine[10] on such surface-modified silica supports for extracting some bivalent cations from ethanol or acetone solutions. The solvent–solute exchange equilibria in this heterogeneous system enable the ordering of the maximum retention capacity of cations in both solvents and some thermodynamic data on these equilibria were obtained. We report here the results of adsorption studies of MCl_2 (M = Co, Ni, Cu, Zn) in ethanol and acetone by 2- and 4-aminopyridine groups bonded on silica gel surfaces. These data are also compared with the aforementioned modified surface.

EXPERIMENTAL

All chemicals used were reagent grade. The silica substrate used in the preparations was a commercial silica gel (Merck 60) which had its surface activated by heating for several hours in a stream of nitrogen

at 420 K or *in vacuo* at 400 K.[16] The specific area of 560 $m^2\ g^{-1}$ was determined using the BET method.[17]

Solutions of metal(II) ions for the adsorption processes were prepared from anhydrous salts. Hydrated cobalt, nickel and copper chlorides were dried *in vacuo* at 420 K.[10] Anhydrous zinc chloride was prepared by reacting the pure metal with hydrochloric acid in ether.[10] The solvents were stored over appropriate dehydrating agents overnight, distilled through an efficient column and kept over molecular sieves. 2- and 4-Aminopyridines (Carlo Erba) were recrystallized from ether before use.

The compound 3-chloropropyltrichlorosilane was obtained by slowly adding drops of trichlorosilane (0.52 mol) onto freshly distilled allylchloride (0.50 mol) in the presence of a H_2PtCl_6 catalyst.[18] After 4 h of reaction the product was distilled *in vacuo*, giving a yield of 65%. An excess of dry methanol was slowly added with stirring to 0.30 mol of this product. The mixture was refluxed for 4 h, then dry gaseous nitrogen was bubbled into the solution to eliminate part of the hydrogen chloride that was formed. Hydrogen chloride was completely eliminated by simple distillation *in vacuo* of the 3-chloropropyltrimethoxysilane, obtained in quantitative yield.

To a stirred suspension of activated silica gel (50 g) in dry xylene (300 cm^3), 3-chloropropyltrichlorotrimethoxysilane (0.10 mol) was slowly added. This suspension was stirred mechanically for 8 h at xylene reflux temperature. Then, the solid product was filtered, washed with water, ethanol and acetone. This material was transferred to a Soxhlet extractor and washed with ethanol for 48 h. Finally, the solid was dried *in vacuo* for 6 h at 393 K. The control of functionalization was followed by digesting approximately 0.1 g of this material with a large excess of pyridine for 5 h at 380 K. The resulting mixture was diluted and the amount of chlorine (5.4×10^{-4} mol g^{-1}) was determined by titration with standard silver nitrate solution.[10]

An identical procedure was used to functionalize the silica surface with 2- and 4-aminopyridine. In both cases, to an aliquot of the precursor halogen-functionalized silica gel (15.0 g) suspended in dry xylene (80.0 cm^3), aminopyridine (7.4×10^{-2} mol) was added and the mixture was refluxed for 5 h. After cooling, the solid was filtered, washed with cold water and acetone, followed by an efficient washing with ethanol in a Soxhlet extractor for 48 h. To eliminate the remaining aminopyridine bonded to the surface, the solid was transferred to a hydrochloric acid solution at pH 5.0. The suspension was stirred, filtered and washed. This material was immersed in water (500 cm^3), then the liquid was changed several times until a negative test for chloride in the supernatant (silver nitrate) was obtained. The preceding procedure was repeated with sodium hydroxide solution at pH 8.5. The control of this functionalization was checked by determination of the amount of nitrogen in the sample through the Kjeldhal method. To digest the material, mercury oxide was used as a catalyst to free the pyridine nitrogen, followed by treatment with sodium thiosulphate to destroy the amino-mercury complexes formed.[10]

The process of adsorption was followed batchwise in non-aqueous solvents or by using a calorimetric method in the same solvents system. In the first process, samples (5.0×10^{-2} g) of the functionalized material were suspended in metal chloride solution (50 cm^3), having concentrations in the range $(1.0\text{–}0.1) \times 10^{-3}$ $dm^3\ mol^{-1}$. Solutions of cobalt(II), nickel(II), copper(II) and zinc(II) dissolved in ethanol or acetone were equilibrated with the anchored material with vigorous stirring at 298.2 ± 0.2 K for 2 h. The suspension was left standing for a further 2 h, when the amount of metal ions in the supernatant was analysed by means of conventional EDTA complexiometric titrations.[10] This procedure was also repeated with untreated silica gel and no adsorption was detected. For each sample analysed, at least one duplicate run was titrated to check the reproducibility. The anchored material did not show any alteration in its loss of exchange capacity throughout the period of investigation.

The heat evolved in the above reaction was followed by means of an isoperibolic precision calorimeter system LKB 8700-2.[8,10] A sample of functionalized silica gel (0.1–0.2 g) was suspended in the calorimetric solvent (90.0 cm^{-3}), with vigorous stirring at 298.15 ± 0.02 K. To this suspension a thermostatted solution of the cation (~ 0.01 $dm^3\ mol^{-1}$) in the same calorimetric solvent, protected from humidity, was incrementally added into the calorimetric vessel and the heat of the reaction (Q_1) recorded. An identical titration of the metal solution in the same calorimetric solvent produced the heat of dilution (Q_2). Then, the net heat of reaction (Q_{obs}) is given by: $Q_{obs} = Q_1 - Q_2$. The variation of the enthalpy of reaction (ΔH) can be obtained by the expression $Q = n\Delta H$, where n is the number of moles of the solute adsorbed on the functionalized surface.

RESULTS AND DISCUSSION

Based on the chlorine elemental analysis (0.9%), 5.4×10^{-4} mol of γ-chloropropyl groups are bonded

to the silica surface. These groups are available for the next step of the reaction with aminopyridine derivatives. To quantify the amount of this new group anchored to the surface, nitrogen elemental analysis was performed. For nitrogen organic groups, 1.4 and 4.3×10^{-4} mol g^{-1}, were found for 2-aminopyridine (SIL2) and 4-aminopyridine (SIL4) silica gel surfaces, respectively. Considering the reaction of aminopyridines with trichloride bound to the surface has a 1 : 1 stoichiometry, these figures show a different behaviour in the functionalization, the last one reacting almost quantitatively, while for SIL2 only one fourth of the free γ-chloropropyl groups reacted. These results may be associated with electronic and steric features presented by the two pyridine derivatives.

The functionalization causes a change in the surface area, which increased (40 m^2 g^{-1}) for SIL2, while it showed a significant decrease (95 m^2 g^{-1}) for SIL4. These nitrogenated groups cover the total area of the surface, i.e. 1.4 and 4.3×10^{-4} mol g^{-1} for SIL2 and SIL4, respectively, which correspond to a molecular density of 1.4 and 5.5×10^{17} nitrogenated groups per square meter, giving them an area of 7.0 and 1.8 nm^2 for a pendant group in each functionalized surface.[10] Assuming that each group is centred in this square area, the distance to its next neighbour group is 2.7 and 1.3 nm for SIL2 and SIL4, respectively. These results indicate a high population in the last surface, reflected in the mean distance between the pendant groups.[10,19]

The pulverized material was compressed in discs with the purpose of obtaining the IR spectra of the surfaces. Matrix absorptions in the high frequency range completely mask the CH and NH stretching vibrations.[20] For SIL2 two distinct bands at 1590 and 1537 cm^{-1} can be visualized as relating to the anchored ligand. These medium bands may be attributed to CC/CN stretching frequencies of the pyridine ring. However, for SIL4 only one band at 1535 cm^{-1} was observed for the heterocyclic ring. On the other hand, the bonded metal ions on the surface showed that the spectra did not change, in comparison with the uncomplexed surface, as observed before.[10]

Sorption of metallic ions from solutions onto the modified silica gel occurs as a result of complexing with immobilized ligands on the surface. SIL2 and SIL4 adsorb cobalt(II), nickel(II), copper(II) and zinc(II) chlorides from ethanol, and cobalt(II), copper(II) and zinc(II) from acetone solutions. The adsorption of nickel(II) chloride from acetone failed due to its low solubility in this solvent. Profiles of the adsorption isotherms for all metal ions are very similar in shape, but vary in capacity.[21] Copper(II) ions are the most adsorbed from solution, with the adsorption being more efficient in acetone. With the exception of zinc(II) ions in ethanol, all other adsorptions are higher in acetone than in ethanol solutions.

The adsorption phenomena at the solid–liquid interface demand a competition between the solvent bonded to the anchored surface (AS), which is displaced gradually by the solute in solution to reach the equilibrium, as outlined by the reaction:[22]

$$AS(solvent) + MCl_2(solvent) \rightleftharpoons AS \cdot MCl_2(solvent) + solvent.$$

When the adsorption remains constant, a monolayer is assumed to have been formed. The chemical interaction, metallic ion–surface, may be accompanied by applying the transformed Langmuir adsorption isotherms:

$$\frac{C_2}{n_2^s} = \frac{1}{n^s b} + \frac{C_2}{n^s},$$

where C_2 is the residual concentration (mol dm^{-3}), of metallic ion in equilibrium with the solid. A plot of C_2^s/n_2^s vs C_2 permits the calculation of the constant b and n^s, where this last parameter is the maximum adsorption capacity, given by mole of solute per gram of adsorbent.

The results of adsorption can be represented by the isotherms n_2^s vs C_2, and the linearization of the adsorption results for metal(II) ions in ethanol are shown in Fig. 1. From this plot n_2^s and b values were obtained from the angular and linear coefficients, and are listed in Table 1.

The maximum adsorption capacity of both modified surfaces (n^s) is at least twice as large in acetone than in ethanol for cobalt(II) and copper(II), the adsorption being more efficient for this last metallic ion. However, for SIL2 the adsorption of zinc(II) ion in ethanol superimposes that of acetone, a behaviour opposite to that which occurred with the other surface, where an increase of 50% adsorption was observed in acetone. This greater tendency for adsorption has been interpreted as due to the lower polarity of acetone, which causes a weaker solvation of cations, and consequently, favouring the complexation of metallic ions on the anchored surface.

The capacity of SIL4 for adsorbing a given metallic ion from a solvent is considerably larger than for SIL2. For example, copper(II) ions have n^s values of 4.89 and 2.04×10^4 mol g^{-1} for SIL4 compared with 1.17 and 0.35×10^4 mol g^{-1} for SIL2, in acetone and ethanol, respectively. The sequence Cu > Co > Zn obtained in acetone for the maximum retention capacity with both surfaces, changes to Zn > Cu > Co > Ni for SIL2 and Zn > Cu > Co > Ni for SIL4 in ethanol. In com-

paring these results with those of 3-aminopyridine immobilized on silica gel (SIL3),[10] the sequence in retaining cations is SIL4 > SIL3 > SIL2, which is the same order as the degree of functionalization of these surfaces.

The "bond-term" values, b, listed in Table 1 follow the same sequence of n^s values,[23] as observed for the SIL3 surface.[10] For a low concentration of solute, as in the experimental conditions used here, the activity coefficient of the solvent is practically unity. Then, the equilibrium constant involving solvent–solute exchange on the surface should give values of the order of b. These values, which vary from 1.0 to 20×10^{-4} dm^3 mol^{-1} (Table 1) for both surfaces, are in fact very high in all equilibria studied, suggesting that the adsorption occurs with the metal ions directly coordinated with the pendant groups anchored on the surface, which have basic centres to bond them. This process gives an indication of the thermodynamic stability of the complexes formed on the surfaces.[24]

In an attempt to gain more information about the interactions of the basic centres on the surface with the cations in solution, this process was fol-

lowed by calorimetric titration. The enthalpy of adsorption and the concentration of the metallic ion in equilibrium can be given by the following equation:[25–27]

$$\frac{N}{H} = \frac{1}{(K-1)Hm} + \frac{N}{Hm},$$

where N is the mole fraction of the cation in solution, H is the integral enthalpy of adsorption (J g^{-1}), K is a proportionality factor which includes the equilibrium constant and Hm is the integral heat of adsorption for the saturated monolayer of unitary mass of anchored material. Taking into account the preceding equilibrium measurements, the N value could be obtained for each increment of solute on the surface in suspension.[10]

The thermodynamic values obtained for the interactions of metallic ions on surfaces are listed in Table 2 and were determined from the above equation.

A plot of N/H against N provides Hm from the angular coefficient, as shown in Fig. 2. This integral heat of adsorption (Hm) is related to the respective number of moles determined previously and gives the enthalpy change (ΔH) of the interactive process. In spite of great difficulty in obtaining ΔH for the SIL2 surface with all cations, cobalt(II) in both solvents and zinc(II) in ethanol showed a very exothermic adsorption, in comparison with SIL4, where only copper(II) in ethanol gave a high ΔH value (see Table 2). This thermodynamic parameter is always exothermic in ethanol, which superimposes in magnitude, for a given cation, the corresponding ΔH value in acetone. This same behaviour was also observed for the other anchored surface, whose results seem to be affected by the

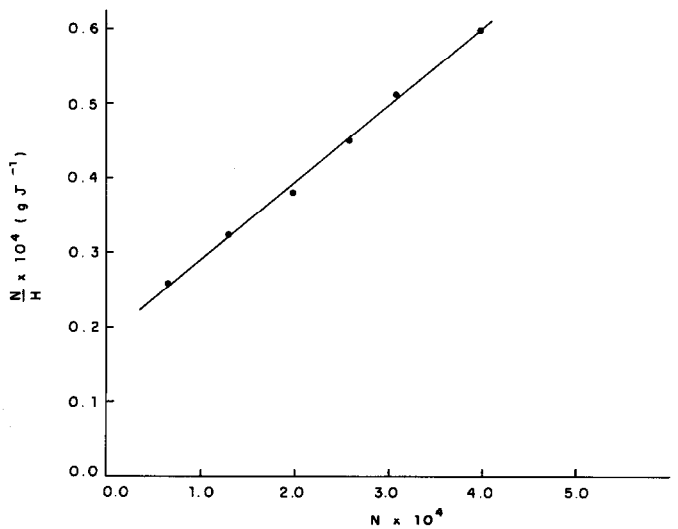

Fig. 2. The linear plot of calorimetric results for $CuCl_2$ adsorbed on SIL4 in ethanol solution at 298.15±0.02 K.

solvation properties of cations, being smaller in acetone than in ethanol.[10] The larger exothermicity displayed during the interactive process involving the cation–base centre on the SIL2 surface, even though the molecular density of the pendant groups is nearly one fourth of that of SIL4, may be attributed to the fact that both nitrogen basic centres are available to coordinate the cations, whilst for the anchored ligand on the SIL4 surface, only the heterocyclic nitrogen is available. Furthermore, the solvated cation releases solvent molecules into the solution on bonding to the anchored molecules. Consequently, the cation desolvation disturbs the structured solvent around it, causing an entropic enhancement. The data in Table 2 illustrates this behaviour, showing all ΔS values to be more favourable in acetone than in the more polar ethanol, for the same cation. The most favourable ΔH was obtained for the complexation of copper(II) with the SIL4 surface in ethanol (-50.5 ± 1.0 kJ mol^{-1}), which contrasts with its value in acetone ($+7.54 \pm 0.2$ kJ mol^{-1}). However, a reversal occurs with the ΔS values, which indicate that the reaction is entropically unfavourable in the more polar ethanol.

^{31}P NMR STUDIES ON THE *MER–FAC* ISOMERIZATION OF $Pt(S_4N_4)Cl_2(PMe_2Ph)$

PAUL F. KELLY and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London SW7 2AY, U.K.

(*Received* 30 *May* 1989; *accepted* 3 *August* 1989)

Abstract—When heated in chloroform the meridional $S_4N_4^{2-}$ complex, $Pt(S_4N_4)Cl_2(PMe_2Ph)$, readily isomerizes, giving a product which has, on the basis of ^{15}N-labelling studies, been identified as the facial isomer.

Previously we have reported on the preparation of $Pt(S_4N_4)Cl_2(PMe_2Ph)$ (**1**), from the reaction of S_4N_4 with $[PtCl_2(PMe_2Ph)]_2$.[1] The product is only the second example of a complex of $S_4N_4^{2-}$, and the first to display a meridional coordination geometry i.e. with the coordinating atoms (two sulphurs and one nitrogen) in the same plane.

Here, we report on investigations into the isomerization of **1**. Although we have as yet been unable to grow crystals of the isomeric species, **2**, suitable for X-ray crystallographic confirmation, we have assigned a facial conformation on the basis of the ^{31}P NMR spectra of 99% ^{15}N-labelled samples of **1** and **2**, which show greatly contrasting magnitudes of ^{15}N–^{31}P coupling constants.

EXPERIMENTAL

General reaction conditions were as described previously; $[PtCl_2(PMe_2Ph)]_2$ was prepared by reaction of *cis*-$PtCl_2(PMe_2Ph)_2$ with $PtCl_2$ in xylene at $\approx$ 160°C.[2]

IR spectra were obtained using a PE 1720X instrument. ^{31}P NMR spectra were obtained (in $CDCl_3$) using a JEOL FX90Q operating at 36.21 MHz and are referred to 85% H_3PO_4. Microanalyses were performed by the Imperial College Service.

In a typical reaction a sample of *mer*-$Pt(S_4N_4)Cl_2(PMe_2Ph)$ (**1**) was prepared, as described previously, by reaction of S_4N_4 (70 mg, 0.38 mmol) with $[PtCl_2(PMe_2Ph)]_2$ (150 mg, 0.19 mmol) in CH_2Cl_2. Precipitation with hexane yielded the crude product (197 mg, 88%); it did not prove necessary to purify the compound before use (which can be done by elution on a Bio-beads gel-permeation column) since identical results were obtained using crude and purified samples. Compound **1** was dissolved in $CHCl_3$ ($\approx$ 25 cm^3) and the red solution heated to 75–80°C (under a nitrogen pressure of *ca* 5 psi); at intervals, ^{31}P NMR was used to assess the degree of isomerization by measuring the ratio of **1** (δ 5.2 ppm) to the isomer **2** (δ −9.4 ppm, $^1J(^{195}Pt–^{31}P)$ 2453 Hz). After 20 min the ratio of **1**:**2** was $\approx$ 3:1; after 40 min 1:1, after 90 min 1:4 and after 3 h the reaction had effectively gone to completion. Also present in the ^{31}P NMR of the product was a singlet at δ −21 ppm ($^1J(^{195}Pt–^{31}P)$ 3411 Hz), indicative of $Pt(S_2N_2H)Cl(PMe_2Ph)$[3] [Fig. 1(b)], and a compound revealed by a singlet at δ −18.0, ^1J 1995 Hz. The ratio of the complex at δ −9.4 to the combined amounts of the other two species was approximately 4:1.

The $CHCl_3$ was removed *in vacuo* and the product redissolved in CH_2Cl_2 (10 cm^3) then placed on a Bio-beads gel-permeation column and eluted with CH_2Cl_2. The sample separated into a number of bands; a fast moving brown band followed by a green and a red–orange fraction. The latter was collected, reduced in volume and a brown–red solid was obtained by addition of hexane (yield, 80 mg). The ^{31}P NMR spectrum of the product revealed the presence of the species at δ −9.4, together with a small amount of δ −21 and a trace of the species at δ −18. Slow diffusion of hexane into a CH_2Cl_2 solution yielded a crop of small clustered red crystals interspersed with white needles. The red crystals were separated by hand and redissolved in CH_2Cl_2.

* Author to whom correspondence should be addressed.

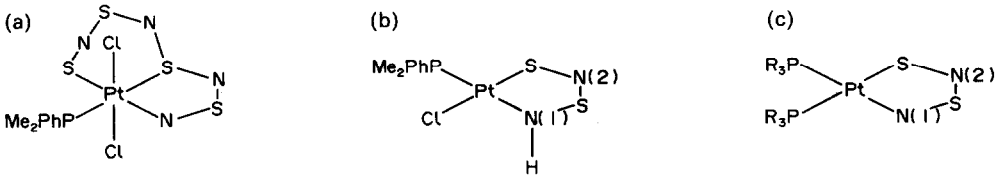

Fig. 1. Structures and numbering schemes of **1** and related compounds.

Slow hexane diffusion yielded poorly formed red crystals which were free of the white impurity. The ^{31}P NMR spectrum of these crystals revealed that they were the species responsible for the peak at δ −9.4 ppm, and they analysed correctly for $PtCl_2(S_4N_4)(PMe_2Ph)$; Found: C, 16.4; H, 1.6; N, 9.5. Calc.: C, 16.3; H, 1.9; N, 9.5%.

The reaction of $S_4^{15}N_4$ (19 mg, 0.1 mmol) with $[PtCl_2(PMe_2Ph)]_2$ (40 mg, 0.05 mmol) was performed as above and, after measurement of the ^{31}P NMR spectrum of the initial products, the chloroform solution was heated to 95°C for 3 h and the spectrum of the isomer recorded. No attempt was made to purify a sample of the ^{15}N-labelled species.

RESULTS AND DISCUSSION

The dimeric, chloro-bridged species $[PtCl_2(PMe_2Ph)]_2$ reacts with S_4N_4 at room temperature, in CH_2Cl_2, to give the platinum(IV) species $PtCl_2(S_4N_4)(PMe_2Ph)$ (**1**)[1] which contains a meridionally-coordinated tridentate $S_4N_4^{2-}$ ligand. This bonding mode is substantially different to that observed in $Ir(CO)Cl(S_4N_4)(PPh_3)$,[4] the only other $S_4N_4^{2-}$ complex known, in which the ligand adopts a facial geometry. In the light of this contrast in geometries we have attempted to assess the potential for isomerization within **1**. We have found that upon standing in solution for a number of days, or refluxing in chloroform for a few hours, **1** does indeed isomerize to a species which we believe contains a facial $S_4N_4^{2-}$ ligand.

If the chloroform solution of **1** is heated to $\approx$ 90°C, and the nature of the species in solution assessed by ^{31}P NMR, the amount of **1** present is seen to decrease and a new species, **2**, revealed by a singlet at δ −9.4 ($^1J(^{195}Pt–^{31}P)$ 2453 Hz), appears. After 3 h at this temperature there is complete conversion of **1** to **2**, together with small amounts of $Pt(S_2N_2H)Cl(PMe_2Ph)$ (**3**) (Fig. 1) and a complex at δ −18.0 (^1J 1995 Hz). Purification using a Biobeads gel-permeation column with CH_2Cl_2 as eluent, allows isolation of **2** along with traces of a colourless impurity. We have yet to fully characterize this impurity; its mass spectrum contains peaks at m/z 154 ($[\{PMe_2Ph\}NH_2]^+$), 293 ($[\{PMe_2Ph\}_2NH_3]^+$) and 307 ($[\{PMe_2Ph\}_2N_2H_3]^+$) with no evidence of the presence of sulphur.

We have not been able to grow crystals of **2** of sufficient quality to allow X-ray study, although they analyse correctly for $PtCl_2(S_4N_4)(PMe_2Ph)$, confirming that **2** is indeed an isomer of **1**. Furthermore, attempts to prepare crystalline samples of analogues of **1** and **2** ($PR_3 = PPh_2Me$, PEt_3) have been unsuccessful, the products (which by ^{31}P NMR are of the same type as **1** and **2**) being obtained as oils.

The large difference in the chemical shifts of the phosphine groups in **1** and **2**, 5.2 and −9.4 ppm, respectively, is indicative of a substantial change in geometry within the complexes, as is the fact that the IR spectrum of **2** contains strong peaks at 794 and 812 cm^{-1}, which are absent from the spectrum of **1**. Figure 2 illustrates some of the structures which **2** could, conceivably, adopt.

Insight into the structure of **2** can be obtained from the ^{31}P NMR spectrum of the ^{15}N-labelled complex. Figure 3 compares the ^{31}P spectrum of ^{15}N-labelled **1** with that of the isomer, **2**. As there is only one phosphine group present in **1** or **2**, the ^{31}P NMR of the unlabelled complexes are singlets, with appropriate ^{195}Pt satellites (for **1** and **2**,

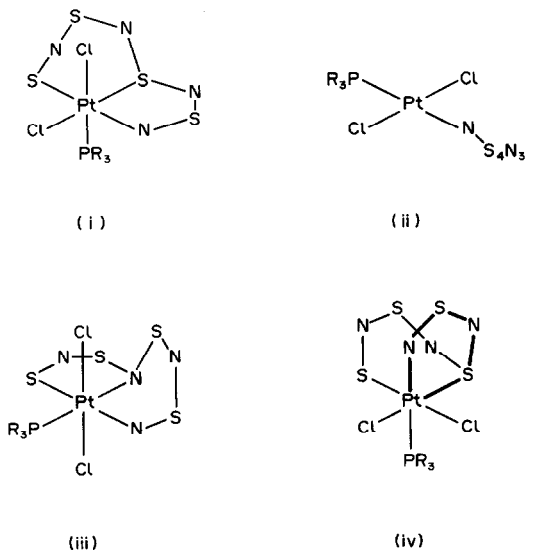

Fig. 2. Possible structures of **2**.

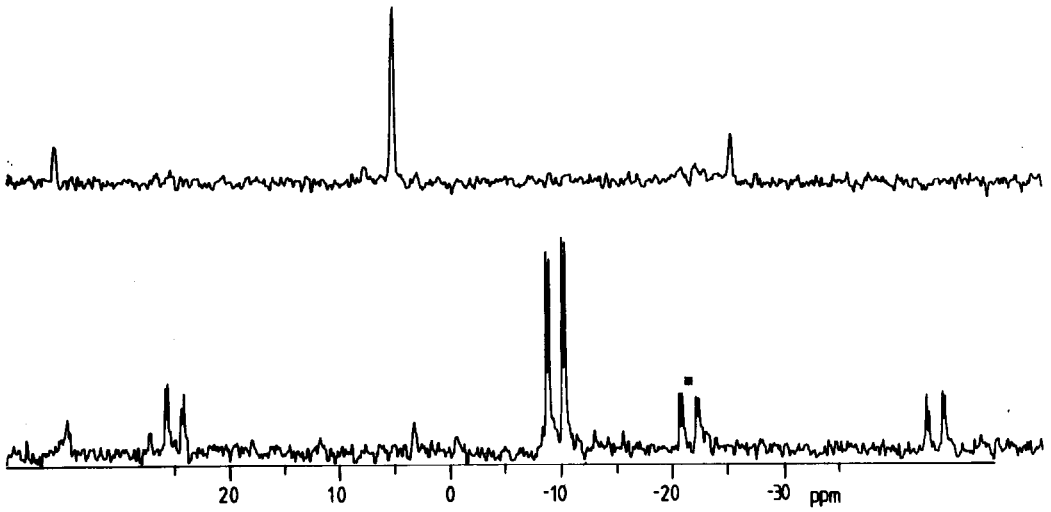

Fig. 3. 36.21 MHz ^{31}P-{^1H} NMR spectrum (in $CDCl_3$) of ^{15}N-labelled **1** (upper) and **2** (lower). The asterisk marks the peaks due to ^{15}N-labelled $PtCl(S_2N_2H)(PMe_2Ph)$.

^1J = 2170 and 2453 Hz, respectively). In the case of **1** [Fig. 3(a)] the only effect that introducing ^{15}N into the system appears to have is a slight broadening of this singlet, suggesting that none of the ^{15}N nuclei present couple to the phosphorus to any great degree. Results obtained previously for labelled complexes of the type $Pt(S_2^{15}N_2)(PR_3)_2$ (**4**)[5] (Fig. 1) show that the phosphorus *trans* to sulphur couples only to N(1), and that this coupling is small (5 Hz). Comparison of the structure of **1** with that of the aforementioned $S_2N_2^{2-}$ complexes suggests that the only ^{15}N–^{31}P coupling one would expect to see in ^{15}N-labelled **1** would be from N(1), and that this too would be weak. Hence it is this coupling that manifests itself as the slight broadening of the main peak.

In contrast, the ^{31}P NMR spectrum of ^{15}N-labelled **2** [Fig. 3(b)] shows much more fine structure; the original singlet is split into a pair of doublets. This is consistent with the presence of two ^{15}N–^{31}P couplings, of magnitude $\approx$ 57 and 8 Hz, and is almost identical to the pattern observed for $Pt(S_2^{15}N_2H)Cl(PMe_2Ph)$ [as seen in the small amount of impurity in the spectrum in Fig. 3(b)] in which the couplings are 54 and 7 Hz.[3] Therefore, we propose that the phosphine group in **2** must be in a similar environment to that in $Pt(S_2N_2H)Cl(PMe_2Ph)$, since, on the basis of our previous results, a ^{15}N–^{31}P interaction as large as 54 Hz could only be the result of a ^2J (^{31}P–^{15}N) coupling from a ^{15}N *trans* to phosphorus.[5] On this basis we can rule out structure (i) since this would require phosphorus *trans* to chlorine. The conversion of **1** to structure (ii) would require the oxidation of the $S_4N_4^{2-}$ ligand to neutral S_4N_4 and corresponding reduction of the platinum to platinum(II); this is somewhat unlikely in itself since any reduction at platinum would lead to species such as **3** or **4** and, although the value of the $^1J(^{195}Pt$–$^{31}P)$ coupling constant (2453 Hz) could be indicative of platinum(II), past results show such a small coupling is only observed for phosphorus *trans* to sulphur. Of the two remaining potential structures (iii) is unlikely since the presence of a nitrogen *cis* to the phosphorus would result in, at the least, a broadening of the lines, as seen in Fig. 3(a) (previously we have observed ^2J *cis* couplings of *ca* 5 Hz in **4**). Hence the only reasonable structure for **2** would appear to be (iv), that is a facial coordination, analogous to that seen in $Ir(CO)Cl(S_4N_4)(PPh_3)$. The use of ^{31}P–^{15}N coupling constants to identify the structure of **2** is clearly inferior to single crystal X-ray studies since other isomers could be possible. However, on the basis of the data that we have been able to obtain we believe structure (iv) to be the most likely.

We have yet to determine the mechanism of the *mer–fac* isomerization. Dissociation of the phosphine (*trans* to sulphur), rotation of the chlorides and nitrogen in a five-coordinate intermediate, followed by reassociation of the phosphine (*trans* to nitrogen) appears to be the most reasonable route. For comparison, it is interesting to note that in the isomerization of *trans*-$[PtBr_2(S_2N_2H)(PMe_2Ph)_2]^+$ to the *cis* form it is the phosphine *trans* to sulphur which is rotated.[6] We have yet to ascertain the nature of the species with δ −18.0, which is formed as a minor product during the isomerization of **1**. It is present in the green band which separates on Bio-beads; concentrated $CDCl_3$ solutions of this fraction deposit an insoluble red microcrystalline

product which can be shown by IR to contain PMe_2Ph, and which analyses as $[Pt(S_2N_2)(PMe_2Ph)]_2 \cdot 2CDCl_3$ (Found: C, 19.4; H, 2.1; N, 5.4. Calc.: C, 19.8; H, 2.0; N, 5.1%), suggesting that the red solid may be the PMe_2Ph analogue of $[Pt(S_2N_2)(PPh_3)]_2 \cdot CH_2Cl_2$, which we have previously reported.[7]

NOVEL IODOAMMONIUM CATIONS: SYNTHESIS AND CHARACTERIZATION OF *o*-$C_6H_4(NH_2)_2I^+X^-$ ($X^- = I^-$, AsF_6^-, AlI_4^-)

I. TORNIEPORTH-OETTING and TH. M. KLAPÖTKE*

Institut für Anorganische und Analytische Chemie, Technische Universität Berlin, Straße des 17. Juni 135, D-1000 Berlin 12, F.R.G.

(*Received* 20 *July* 1989; *accepted* 3 *August* 1989)

Abstract—The new iodoammonium salts *o*-$C_6H_4(NH_2)_2I^+I^-$ (**1**) and *o*-$C_6H_4(NH_2)_2I^+AsF_6^-$ (**2**) were prepared by reaction of *o*-phenylene diamine with I_2 or $I_3^+AsF_6^-$, respectively. Compound **1** reacts with AlI_3 yielding quantitatively the corresponding tetraiodoaluminate *o*-$C_6H_4(NH_2)_2I^+AlI_4^-$ (**3**). The species were characterized by chemical analysis, vibrational (IR and Raman) and temperature-dependent ^1H NMR spectropscopy. Direct evidence for a N—I bond was found in the Raman spectra of **1**, **2** and **3** (ν(NI) = 599–600 cm^{-1}).

Compounds containing the free monoatomic cation, I^+, in the condensed phase are still unknown.[1] However, the I^+ cation can be stabilized by coordination and both 1:1 and 1:2 adducts of pyridine[2–4] and nitriles[5] are known and may be prepared, via the disproportionation of iodine with nitriles or pyridine, respectively [eq. (1)]:[6]

$$n\text{R—CN} + I_3^+AsF_6^- \longrightarrow (\text{R—CN})_nI^+AsF_6^- + I_2 \qquad n = 1, 2. \tag{1}$$

On the other hand, the reaction of ammonia with $I_3^+AsF_6^-$ leads to the formation of NI_3, $NH_4^+AsF_6^-$ and I_2.[6] As far as we are aware no iodoammonium salt has been prepared prior to this work.

The reaction behaviour of I^+ toward chalcogens and chalcogen-containing compounds is well known. However, the reactivity of "I^+" towards compounds of group 15 is not very well established. For instance, $I_3^+AsF_6^-$ reacts with elemental selenium yielding $SeI_3^+AsF_6^-$.[7] It also reacts with $(CH_3)_2S$ giving $(CH_3)_2SI^+AsF_6^-$.[8] Quite recently the oxidation of iodine by MoF_6 and UF_6 in acetonitrile affording $I(CH_3CN)_2^+MF_6^-$ (M = Mo, U) was reported.[5,9]

We were particularly interested in the reaction behaviour of I_3^+ (and other "I^+" sources) towards organic amines, especially with respect to the synthesis of novel iodoammonium salts. These are unknown as far as we are aware. *o*-Phenylene diamine was used as the primary amine due to its ability to form chelate complexes.

On the basis of a simple Born–Haber cycle (see below) we estimated that a reaction according to eq. (2) should be thermodynamically favourable ($\Delta H = -59$ kcal mol^{-1})

$$o\text{-}C_6H_4(NH_2)_2(s) + I_3^+AsF_6^-(s) \longrightarrow I_2(s) + o\text{-}C_6H_4(NH_2)_2I^+AsF_6^-(s). \tag{2}$$

EXPERIMENTAL

Iodine (Merck) and AlI_3 (Aldrich) were used as commercially avaiable. *o*-Phenylene diamine (Merck) was recrystallized twice from acetonitrile. The preparation of $I_3^+AsF_6^-$ was carried out as described in the literature.[7] The solvent (SO_2(l), Messer–Griesheim) was purified by distillation and dried over CaH_2. All manipulations were carried out in an inert gas atmosphere (dry box).

Preparation of *o*-$C_6H_4(NH_2)_2I^+I^-$ (1)

A solution of 0.2129 g (1.97 mmol) of *o*-phenylene diamine in 5 cm^3 of SO_2 was added to a suspension of 0.500 g of I_2 (1.97 mmol) in 5 cm^3 SO_2 and stirred for 1 h at room temperature. The sulphur dioxide was pumped off *in vacuo*. The remaining black product was recrystallized from SO_2. Yield: 0.7126 g (100%). Found: C, 19.5; H, 2.1; N, 7.7. Calc. for $C_6H_8I_2N_2$ (361.953) C, 19.9; H, 2.2; N,

*Author to whom correspondence should be addressed.

Preparation of o-$C_6H_4(NH_2)_2I^+AsF_6^-$ **(2)**

A solution of 0.3147 g (2.91 mmol) of o-phenylene diamine in 5 cm^3 of SO_2 was reacted with 1.6576 g (2.91 mmol) of $I_3^+AsF_6^-$ in 5 cm^3 of SO_2 at room temperature. The reaction mixture was stirred for 1 h and the precipitated iodine was filtered off (D3). The remaining solution was evaporated and traces of dissolved iodine were removed by pumping in a dynamic vacuum. The remaining microcrystalline, deep red product was isolated nearly quantitatively. Yield: 1.2253 g (99%). Compound **2** was recrystallized twice from SO_2. Found: C, 17.4; H, 2.1; N, 6.8. Calc. for $C_6H_8AsF_6IN_2$ (423.952) C, 17.0; H, 1.9; N, 6.6%. RESULTS AND DISCUSSION

Preparative aspects

Reaction of o-phenylene diamine with elemental iodine led to the preparation of the new cationic iodoammonium salt **1** according to eq. (3):

$$o\text{-}C_6H_4(NH_2)_2 + I_2 \xrightarrow{SO_2} \underset{\textbf{(1)}}{o\text{-}C_6H_4(NH_2)_2I^+I^-}. \quad (3)$$

The hexafluoroarsenate species, **2**, was obtained by reaction of the amine with $I_3^+AsF_6^-$ [eq. (2)]. Complex **1** was converted into the tetraiodoaluminate salt, **3**, by reaction with one equivalent of AlI_3 according to eq. (4):

$$\mathbf{1} + AlI_3 \xrightarrow{SO_2} \underset{\textbf{(3)}}{o\text{-}C_6H_4(NH_2)_2I^+AlI_4^-}. \quad (4)$$

Complexes **1**, **2** and **3** were identified by chemical analysis (C, H, N), ^{1}H NMR, IR, Raman and mass spectroscopy. The quality of the elemental analyses varies and only freshly prepared samples give satisfying results; dependent on technique, too low C/H/N values (especially for the AlI_4^- salt) were often observed (probably due to carbide or nitride formation).

Thermodynamic aspects

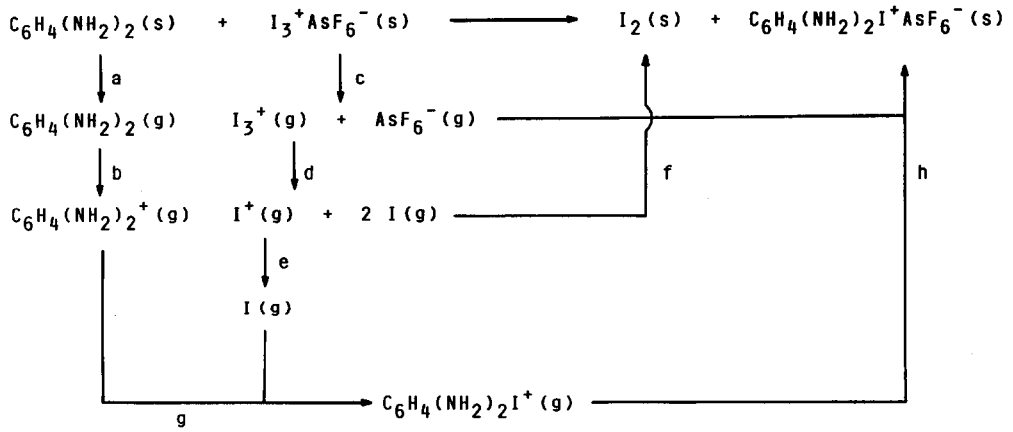
On the basis of a simple Born–Haber cycle (Scheme 1) (using a similar approach to that described in ref. 10) we estimated that a reaction according to eq. (2) should be thermodynamically favourable ($\Delta H = -59$ kcal mol^{-1}). The Born–Haber cycle estimate for ΔH^0 for the reaction indicates that nitrogen is a better base towards I^+ than I^-. Therefore the cationic N—I species should be thermodynamically more stable than neutral compounds. This is in good agreement with the experimental results described above.

Vibrational spectroscopy

Direct evidence for N—I bonds was found in the Raman spectra of all compounds. The most intense peak at 599–600 cm^{-1} can be attributed to a N—I stretching mode (Fig. 1). Both, the shift to higher wavenumbers compared with the neutral tetracoordinated $NI_3 \cdot NH_3$ ($\nu_1 = 378$ cm^{-1})[14] due to the stronger N—I bond in the cationic species and the similarity to the isoelectronic carbon derivative (CH_3I, ν(CI) = 523 cm^{-1})[15] are in good agreement with the formulated N—I bond.

^{1}H *NMR spectroscopy*

In the room temperature ^{1}H NMR spectrum of **1** and **3** two resonances appear, one due to the CH, the other due to the NH protons. (N.B. ^{1}H NMR of o-$C_6H_4(NH_2)_2$ in SO_2: δ(ppm) 6.68s, 3.97s.)[6]



Scheme 1. Energy cycle for the formation of *o*-$C_6H_4(NH_2)_2I^+AsF_6^-$ (**2**) from *o*-phenylene diamine and $I_3^+AsF_6^-$ according to eq. (2). (a) $\Delta H_{Subl.}(C_6H_8N_2)$ was taken to be equal to 20 kcal mol^{-1} (cf. $\Delta H_{Subl.}$(salicylic acid) = 22.8 kcal mol^{-1}).[10] (b) $I_P(C_6H_8N_2) = 172$ kcal mol^{-1}.[11] (c) $U_L(I_3^+AsF_6^-) = 128$ kcal mol^{-1}.[12] (d) $\Delta H(I_3^+, g \rightarrow I^+, g+2I, g) = 72.4$ kcal mol^{-1}.[12] (e) ΔHI, $g \rightarrow I^+$, g) = 242.5 kcal mol^{-1}.[12] (f) $\Delta H_f^0(I, g) = 25.6$ kcal mol^{-1}.[12] (g) Bond energy (N—I) = 48 kcal mol^{-1}.[13] (h) $U_L(C_6H_8N_2I^+AsF_6^-) = 110$ kcal mol^{-1}. Estimated as demonstrated in ref. 12 using the linear relationship: U_L(kcal mol^{-1}) = 556.3 $V_M(Å^3)^{-0.33}+26.3$;[12] $V_M(AsF_6^-) = 105$ $Å^3$,[12] assuming that $V_M(C_6H_8N_2I^+)$ is equal to $V_M(C_6H_8N_2)+V_M(I^+)$, using $V_M(C_6H_8N_2) = 148$ $Å^3$ and $V_M(I^+) = 34$ $Å^3$.[10,12] This gives: a+b+c+d−e−2f−g−h = −59.3 kcal mol^{-1}.

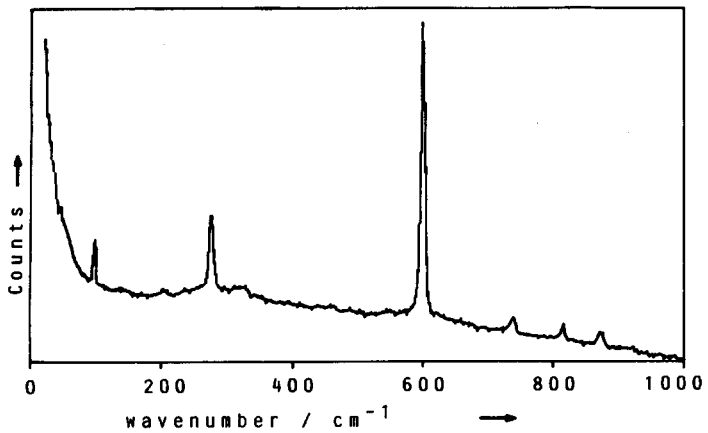


Fig. 1. Raman spectrum of *o*-$C_6H_4(NH_2)_2I^+I^-$ (**1**) (excitation line 647 nm, 100 mW, 20°C).

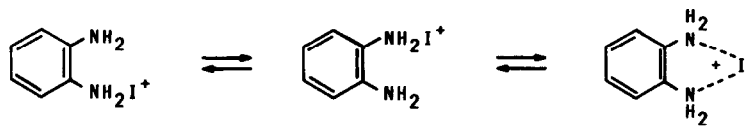
The room temperature spectrum of **2** shows one resonance in the aromatic CH region (7.42 ppm), which can be explained by intermolecular NH proton exchange (Fig. 2). As **2** is the only example with an iodine-free anion it may have the most ionic character, which probably favours the intermolecular exchange reactions. Moreover, the ^1H NMR spectrum of **2** (Fig. 2) shows a reversible temperature dependence. At low temperature resonances appear due to both the NH protons ("singlet") and the aromatic protons (multiplet, AA'XX' pattern).

The equivalence of the NH protons in all three compounds can be easily explained by the equilibrium of the cations according to eq. (5) and rapid exchange reactions:



(5)

(*Received* 22 *May* 1989; *accepted* 3 *August* 1989)

Abstract—$[(C_4H_9)_4N]_2[Mo_2O_7]$ reacts with a variety of organic species containing α-diketone groups to give tetranuclear complexes of general composition $[RMo_4O_{15}X]^{3-}$. The complexes $[(C_4H_9)_4N]_3[(C_9H_4O)Mo_4O_{15}(OCH_3)]$ (**I**), $[(C_4H_9)_4N]_3[(C_{14}H_{10})Mo_4O_{15}(C_6H_5CO_2)]$ (**II**) and $[(C_4H_9)_4N]_3[(C_{14}H_8)Mo_4O_{15}(OH)]$ (**III**) were synthesized from the reactions of dimolybdate with ninhydrin, benzil and phenanthraquinone, respectively. Complex **II** may also be prepared from dimolybdate and benzoin in acetonitrile–methanol solution, from which it co-crystallizes with the binuclear species $[(C_4H_9)_4N]_2[Mo_2O_5(C_6H_5C(O)C(O)C_6H_5)_2]\cdot CH_3CN\cdot CH_3OH$ (**IV**). Complexes **I–III** exhibit the tetranuclear core, previously described for the α-glyoxal derivatives $[(C_4H_9)_4N]_3[(HCCH)Mo_4O_{15}X]$, where $X = F^-$ or HCO_2^-. The ligands may be formally described as diketals, formed by insertion of ligand carbonyl subunits into molybdenum–oxygen bonds. The structures **I–III** differ most dramatically in the identity and coordination mode of the anionic ligand X^- which occupies a position opposite the diketal moiety relative to the $[Mo_4O_{11}]^{2+}$ central cage. Thus, **I** exhibits a doubly bridging methoxy group in this position, while **II** possesses a benzoate ligand with an unusual μ_3-O,O′ coordination mode. Complex **III** presents a hydroxy-group unsymmetrically bonded to three of the molybdenum centres. The stereochemical consequences of the various coordination modes are discussed. Crystal data: Compound **I**, monoclinic space group *Pc*, $a = 24.888(2)$, $b = 12.897(3)$, $c = 24.900(3)$ Å, $\beta = 101.94(2)°$, $D_{calc} = 1.28$ g cm^{-3} for $Z = 4$. Structure solution and refinement based on 8695 reflections with $F_o \geqslant 6\sigma(F_o)$ (Mo-K_α, $\lambda = 0.71073$ Å) converged at a conventional discrepancy factor of 0.060. Compound **II**, orthorhombic space group *Pbca*, $a = 20.426(6)$, $b = 26.916(6)$, $c = 32.147(7)$ Å, $V = 17673.2(20)$ Å^3, $D_{calc} = 1.33$ g cm^{-3} for $Z = 8$; 5224 reflections, $R = 0.076$. Compound **III**, tetragonal space group $I4_1/a$, $a = b = 48.129(6)$, $c = 13.057(2)$ Å, $V = 30246.2(12)$ Å^3, $D_{calc} = 1.35$ g cm^{3-} for $Z = 16$; 5554 reflections, $R = 0.053$. Compound **IV**, orthorhombic space group *Pnca*, $a = 16.097(4)$, $b = 16.755(4)$, $c = 25.986(7)$ Å, $V = 7008.1(13)$ Å^3, $Z = 4$, $D_{calc} = 1.18$ g cm^{-3}; 2944 reflections, $R = 0.061$.

Molybdenum oxides are remarkably versatile heterogeneous catalysts for numerous organic transformations as diverse as methanol oxidation,[1] propylene oxidation[2] and olefin metathesis.[3] As a consequence of the difficulty of characterizing these catalysts at a molecular level, coordination compounds of polyoxomolybdates with simple organic substrate molecules have received considerable attention.[4] Structurally characterized examples of polyoxomolybdate complexes incorporating relevant organic subunits include the formate derivative $[Mo_8O_{26}(HCO_2)_2]^{6-}$,[5] the alkoxy derivatives $[Mo_8O_{24}(OCH_3)_4]^{4-}$,[6] $[Mo_4O_8(OC_2H_5)_2\{CH_3C(CH_2O)_3\}_2]$,[7] $[Mo_4O_{10}(OCH_3)_6]^{2-}$,[8] and $[Mo_3O_6$

$(OCH_3)\{CH_3C(CH_2O)_3\}_2]^-$[9] and the siloxy derivatives of $[MoO_3(P_3O_9)]^{2-}$[10] and of the niobotungstate $[Nb_2W_4O_{19}]^{4-}$.[11] In the specific case of polyoxomolybdate–carbonyl interactions, the acetal derivatives $[(H_2CO_2)(Mo_4O_{12})(OH)]^{3-}$,[12] the diacetal species $[(H_2C_2O_4)(Mo_4O_{11})X]^{3-}$ (X = —F and HCO_2),[13] and the diketal $[(C_{14}H_8O_4)(Mo_4O_{11})(OCH_3)]^{3-}$[14] have been described. A common feature of these latter complexes is the insertion of the reactant carbonyl groups into Mo—O bonds. The product carbomolybdate clusters of general structural formula $[RMo_4O_{15}X]^{3-}$ contain an oxo-bridged tetranuclear core of sufficient structural flexibility to accommodate anions, X^-, of various sizes and with different bonding requirements.

As part of our investigations of the coordination chemistry of polyoxomolybdates with organic ligands containing α-dicarbonyl subunits, we have synthesized and structurally characterized a series of tetranuclear oxomolybdate–diketal complexes $[RMo_4O_{15}X]^{3-}$ (R = —C_9H_4O, X = —OCH_3, **I**; R = —$C_{14}H_{10}$, X = —$C_7H_5O_2$, **II**; R = —$C_{14}H_8$, X = —OH, **III**). Herein, we compare the structures of **I**–**III** with those of the related diacetal species $[(CH_2)Mo_4O_{15}H]^{3-}$[12] and $[(H_2C_2)Mo_4O_{15}X]^{3-}$ (X = —F and HCO_2)[13] and describe structural features related to the conformational flexibility of these polyoxomolybdate anions. The structure of the binuclear complex $[(C_4H_9)_4N]_2[Mo_2O_5(C_6H_5COCOC_6H_5)_2]$ (**IV**), which co-crystallizes in the synthesis of **II** from benzoin, is also described.

RESULTS AND DISCUSSION

Synthetic and spectroscopic properties

The reaction of the α-dialdehyde glyoxal, OHCCHO, with polyoxomolybdates was shown to yield the formylated methylenedioxymolybdate $[(OHCCH)Mo_4O_{15}H]^{3-}$,[13] a species structurally analogous to the acetal derivative $[CH_2Mo_4O_{15}H]^{3-}$.[12] The subsequent reaction of $[(OHCCH)Mo_4O_{15}H]^{3-}$ with acids, HX, resulted in the displacement of the reactant OH^- ligand by the X^- group and insertion of the pendant formyl–carbonyl group into a Mo—O bond. The unanticipated product of this reaction contains formally a diacetal unit, $(O_2HCCHO_2)^{4-}$, and a monoanionic ligand, X^-, coordinated to the $[Mo_4O_{11}]^{2+}$ core:

$$[(OHCCH)Mo_4O_{15}H]^{3-} + HX \longrightarrow [(HCCH)Mo_4O_{15}X]^{3-} + H_2O.$$

In contrast, the reactions of organic substrates containing the α-diketone subunit with dimolybdate proceed directly to the diketal products of the type $[RMo_4O_{15}X]^{3-}$. Thus, the reactions of dimolybdate, $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$, with 1,2,3-indantrione (ninhydrin), benzil and phenanthraquinone in methanol yielded the products $[(n\text{-}C_4H_9)_4N]_3[(C_9H_4O)Mo_4O_{15}(OCH_3)]$ (**I**), $[(n\text{-}C_4H_9)_4N]_3[(C_{14}H_{10})Mo_4O_{15}(C_7H_5O)]$ (**II**) and $[(n\text{-}C_4H_9)_4N]_3[(C_{14}H_8)Mo_4O_{15}(OH)]$ (**III**), respectively. In all cases, the α-diketone subunit of the organic ligand is incorporated into the $[RMo_4O_{15}X]^{3-}$ structure by insertion into the Mo—O bonds of adjacent metal centres, to give species which may be alternatively formulated as diketals $[(O_2RO_2)Mo_4O_{11}X]^{3-}$, in an analogous fashion to the previously reported diacetal species, $[(O_2HCCHO_2)Mo_4O_{11}X]^{3-}$.[12]

An unanticipated feature of the chemistry is the incorporation of a variety of anions, X^-, into the various complexes. Thus, complexes **I**, **II** and **III** are isolated directly from methanol as the methoxy, benzoate and hydroxy derivatives, respectively. The tetranuclear core associated with these complexes has been demonstrated to possess sufficient conformational flexibility to accommodate a variety of anions.[13] Thus, compound **III** reacts with a variety of reagents to replace the OH^- groups, yielding $[(C_{14}H_8)Mo_4O_{15}X]^{3-}$, where X^- = —F (**IIIa**), CH_3CO_2 (**IIIb**) and —OC_2H_5 (**IIIc**). The presence of a benzoate group $C_6H_5CO_2$ in **II** implies that a degree of C—C bond cleavage results as a consequence of carbonyl insertion into the Mo—O bonds. Although the details of the mechanism of benzoate formation have not been elucidated, C—C bond cleavage in combination with carbonyl insertion is a feature of the chemistry of multicentre molybdenum clusters with organic substrates.[15]

Complex **II** was synthesized from the reaction of $[Mo_2O_7]^{2-}$ with either benzil, $C_6H_5COCOC_6H_5$, or benzoin, $C_6H_5COCHOHC_6H_5$. However, the benzoin reaction yielded a mixture of products, the tetranuclear species **II** and the binuclear complex $[(C_4H_9)_4N]_2[Mo_2O_5(C_6H_5COCOC_6H_5)_2]$ (**IV**), which contains the dienolate form of the ligand, rather than the diketal insertion product.

The IR spectra of the complexes of this study exhibit several common features: two C—O absorptions in the 990–1100 cm^{-1} region and a similar pattern of Mo—O absorptions in the 500–950 cm^{-1} region. In addition, **I** exhibits a medium intensity sharp band at 3050 cm^{-1} assigned to ν(C—H) of the methoxy group and a strong band at 1630 cm^{-1} assigned to the uncoordinated carbonyl group of the organic ligand. The medium intensity band at 1565 cm^{-1} in the spectrum of **II** is assigned to the benzoate carbonyl group. The C—O absorp-

tions of the coordinated diketal subunit of **I** were shifted *ca* 15 cm^{-1} upon ^{18}O enrichment from 1082 and 1003 cm^{-1} to 1068 and 987 cm^{-1}, respectively.

Structural studies

The structures of complexes **I**, **II** and **III** are illustrated in Figs 1–3, respectively. Table 1 compares relevant bond lengths for the structures, while Table 2 lists selected bond angles.

The structures consist of discrete $[RMo_4O_{15}X]^{3-}$ anions which are structurally similar to the $[(HCCH)Mo_4O_{15}X]^{3-}$ anion.[13] As a consequence of two carbonyl residues inserting into the cluster core, complex **I** may be described as a diketal derivative with the $(C_9H_4O_5)^{4-}$ unit capping the $[Mo_4O_{11}(OCH_3)]^{+}$ framework, providing terminal [O(12) and O(13)] and bridging [O(14) and O(15)] oxygen donor interactions. Thus, the central $[Mo_4O_{11}]^{2+}$ tetramolybdate unit is bonded to the $(C_9H_4O_5)^{4-}$ and $(OCH_3)^{-}$ groups occupying the opposite poles. The gross structural details of complexes **II** and **III** are similar to those of **I**, with the exception of the identities of the diketal subunits and the anionic group X^{-}.

The structural variations exhibited by complexes **I**–**III** are consequences of the coordination requirements of the various X^{-} groups. As illustrated by the schematics in Fig. 4, $[\{(CH_3)_2As\}Mo_4O_{15}H]^{2-}$ [16] and $[(H_2C)Mo_4O_{15}H]^{3-}$ [12] provide the structural

prototypes for this structural class. Thus, structure **2** may be described in terms of a $[Mo_4O_{12}]^{2+}$ ring connected to a $(H_2CO_2)^{2-}$ moiety and an OH^- unit on opposite faces. Since the hydroxy group functions so as to bridge the four molybdenum centres, the coordination geometry about the molybdenum atoms is pseudo-octahedral. However, the introduction of the diacetal moiety in **3** results in the incorporation of one of the bridging oxo groups of the Mo_4O_4 heterocycle, present in both **1** and **2**, into the diacetal linkage with a concomitant increase in the Mo(1)···Mo(4) distance. The

$[Mo_4O_{12}]^{2+}$ core associated with **1** and **2** is transformed into the more flexible $[Mo_4O_{11}]^{4+}$ core. Since the bridging fluoride group (X^-) in **3** bridges the Mo(2) and Mo(3) sites only, the structure exhibits non-equivalent molybdenum centres; Mo(1) and Mo(4) are pentacoordinate with distorted trigonal bipyramidal geometry, while Mo(2) and Mo(3) display the usual pseudo-octahedral geometry. Replacement of F^- in **3** by formate in **4** produces an analogous structure with the bridging bidentate formate group coordinating to Mo(2) and Mo(3).

The methoxy derivative of this study, $[(C_9H_4O)Mo_4O_{15}(OCH_3)]^{3-}$ (**I**), which exhibits two independent molecules in the asymmetric unit, is structurally analogous to **3** with fluoride replaced by $-OCH_3$. In contrast, structures **II** and **III** demonstrate the remarkable flexibility of this structural type. The bridging benzoate group of $[(C_{14}H_{10})Mo_4O_{15}(C_6H_5CO_2)]^{3-}$ (**II**) does not adopt the symmetrical bidentate bridging mode of the formate group of **4**, but rather bridges the Mo(2) and Mo(3) centres through one carboxylate oxygen donor while bonding to Mo(1) through the other carboxylate oxygen in a weak interaction (2.62 Å). As a result of this unusual bridging mode, there are three chemically and crystallographically distinct molybdenum sites in **II**: the hexacoordinate Mo(1) centre, the carboxylate-bridged Mo(2) and Mo(3) sites, and the pentacoordinate Mo(4) centre. The hydroxy derivative, **III**, exhibits a similar pattern of molybdenum sites as a consequence of the triply-bridging OH^- group.

The data summarized in Table 3 show how the geometry of the $[RMo_4O_{15}X]^{3-}$ unit adjusts to accommodate various X^- groups. As the Mo(2)···Mo(3) separation increases, the Mo(2)—O(10)—Mo(3) angle also expands. Further adjustment in the anion geometry is provided by variation in the Mo(1)···Mo(4) distance coupled to rotation about the C—C bond of the (O_2CCO_2) unit of the diketal ligand.

The structure of the binuclear complex anion of **IV** is illustrated in Fig. 5 and is seen to consist of the $[Mo_2O_5]^{2+}$ core coordinated to two dienolate ligands functioning as bidentate chelating and bridging units. The molybdenum centres adopt $[MoO_6]$ pseudo-octahedral geometry via coordination to two terminal oxo groups, a bridging oxo group, the chelating enolate oxygen donors, O(4) and O(5), of the ligand, and the weakly coordinating bridging alkoxy group, O(4). The geometry of the molybdenum centres may be described alternatively as square-pyramidal with a weak axial interaction to the bridging oxygen donor. Thus, the oxygen donors occupying the basal plane, O(1), O(2), O(4) and O(5), are displaced away from the apical O(3) toward the Mo(1)—O(4a) vector, as demonstrated by the O(3)—Mo(1)—O(basal) angles in the range 102.3(2)–105.3(3)°.

The metrical parameters associated with the $[Mo_2O_5]^{2+}$ core are unexceptional as shown in Table 4. The lengthening of the Mo(1)—O(4) bond relative to the Mo(1)—O(5) distance (2.119(5) vs 1.972(5) Å) may be attributed to the strong *trans* influence of the terminal oxo group, O(2), compared to the negligible *trans* influence of the bridging O(1) group upon O(5) and to the adoption of a weakly-bridging coordination mode by O(4).

Since the ligand may be considered to be in the dienolate form, a double bond interaction between C(7)—C(8) is anticipated. The C(7)—C(8) bond distance of 1.343(11) Å is consistent with this description of the ligand structure and may be compared

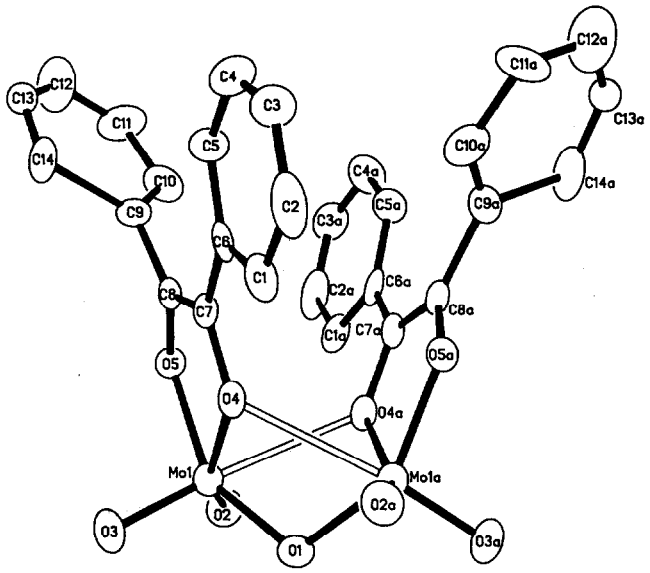

Fig. 5. ORTEP view of the structure of $[Mo_2O_5(C_6H_5COCOC_6H_5)_2]^{2-}$ (IV).

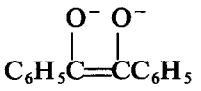

to the corresponding C(1)—C(2) distance of 1.62(2) Å for II, where these carbon centres are assumed to be sp^3-hybridized. A further consequence of this coordination mode is the planarity of the [C(6)—C(7)—O(4)—Mo(1)—O(5)—C(8)—C(9)] moiety.

EXPERIMENTAL

Materials and methods

All reactions were performed in freshly dried and distilled solvents. Dichloromethane was technical grade and was redistilled from $CoCl_2$ and P_4O_{10}. All other solvents were reagent grade. All other reagents were obtained from standard commercial sources without further purification $[(n\text{-}C_4H_9)_4N]_2$

[e] $R = \Sigma[|F_o| - |F_c|/\Sigma|F_o|]$; $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $w = 1/\delta^2(F_o) + g^*(F_o)$, $g = 0.005$.

[f] G-O-F $= [\Sigma w(|F_o| - |F_c|)^2/(NO - NV)]^{1/2}$, where NO is the number of observations and NV is the number of variables.

reported. Tables of bond lengths and angles, anisotropic thermal parameters and calculated and observed structure factors for all complexes are available.* Full details of the crystallographic methodologies may be found in ref. 18.

In no instance was an extinction correction applied to the data. Idealized hydrogen atom positions were used throughout the analysis, with the C—H distances set at 0.96 Å. The $(C_4H_9)_4N^+$ cations of structures **I–III** displayed some degree of orientational disorder, as evidenced by some large temperature factors and several unrealistic bond lengths. Since no major excursions of electron density (> 1.5 Å^3) were observed in the cation regions of the final Fourier maps, the problem was not pursued. Such disorder is not uncommon in tetraalkylammonium salts, and satisfactory disorder models are often not found.[19] The most appropriate cut-off for unobserved data in these structures was a value of $6\sigma(F_o)$. Although this is somewhat high, the structures did exhibit a large number of very weak data, presumably due to the cation disorder.

The final refinement stages of **IV** revealed the presence of two solvate molecules, MeCN and MeOH. The MeOH molecule is disordered about the mirror plane, and the geometry could not be corrected by the application of observational constraints to the bond length.

Since complex **I** crystallizes in the polar space group *Pc*, both enantiomorphs were refined. The atomic coordinates reported are for the proper enantiomorph based on the residuals for both settings. There are two independent molecules in the asymmetric unit of **I**, identified as **A** and **B** in the tables.

VARIABLE TEMPERATURE SOLUTION AND CP–MAS ^{13}C NMR OF [Mo(CO)$_3$(DIGLYME)]. DISPLACEMENT OF DIGLYME BY SOLVENTS AT SUBAMBIENT TEMPERATURES

GEORGE W. WAGNER and BRIAN E. HANSON*

Chemistry Department, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061, U.S.A.

(*Received* 13 *February* 1989; *accepted* 7 *August* 1989)

Abstract—Variable temperature solution ^{13}C NMR of [Mo(CO)$_3$(diglyme)] shows that the chelating diglyme ligand is displaced by the monodentate solvents acetone, methanol and ethanol at low temperature. Free and coordinated solvent are observed at low temperature while at ambient temperature rapid exchange prevents the observation of coordinated solvent.

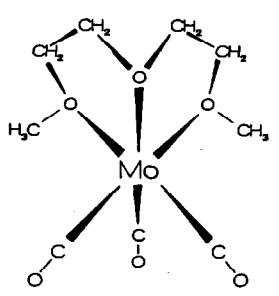
The [Mo(CO)$_3$(diglyme)] complex (**1**) was initially isolated by Werner and Coffield in 1960.[1] Although the structure of the compound has not been crystallographically determined, its IR stretching frequencies suggest the structure shown in Fig. 1. The tridentate diglyme ligand was observed to be easily displaced by other ligands and thus **1** was recognized as a valuable intermediate in the synthesis of molybdenum tricarbonyl complexes. Ligand substitution reactions involving [Mo(CO)$_3$L$_3$] complexes in solution have been well characterized and a large body of thermodynamic data now exists for these reactions.[2,3]

Although ^{13}C NMR spectra have been reported for many metal carbonyl complexes,[4] no data is available for [Mo(CO)$_3$(diglyme)]. The characterization of this particular complex by ^{13}C NMR is of interest to us because it is a good model compound for δ-alumina-supported [Mo(CO)$_3$(ads)] which is stabilized by OH^- and O^{2-} groups on the δ-alumina surface.[5,7] The δ-alumina-supported molybdenum sub-carbonyls have recently been the subject of many solid state ^{13}C NMR studies.[8–10]

Our initial interest in **1** was to determine its solid-state properties by variable temperature CP–MAS ^{13}C NMR. In the absence of any previous NMR data, variable temperature solution ^{13}C NMR was used to initially characterize the complex. These results indicated that substitution reactions were occurring between the complex and solvent molecules at subambient temperatures. This was surprising since thermodynamic data suggest that the solvents should not displace diglyme.

A similar effect has been previously noted for the [Mo(CO)$_3$(η^6-C$_6$H$_5$CH$_3$)]/THF system using ^1H NMR.[2] In this case, THF solvent molecules readily displace the toluene ligand at ambient temperatures because of a favourable ΔH for this reaction. However, at elevated temperatures the reaction reverses to yield the toluene complex as a result of the positive ΔS for this process. This term dominates at high temperatures causing a shift of the equilibrium in favour of the toluene complex.

In this study, variable temperature solution ^{13}C NMR results are presented demonstrating the



1

Fig. 1. Schematic representation of [Mo(CO)$_3$(diglyme)].

reversible displacement of the diglyme ligand in $[Mo(CO)_3(diglyme)]$ by solvent molecules at subambient temperatures when the complex is dissolved in acetone-d_6, methanol-d and ethanol-d. Also, variable temperature CP–MAS ^{13}C NMR spectra of solid $[Mo(CO)_3(diglyme)]$ are shown which indicate that the complex is static in the solid state.

EXPERIMENTAL

The diglyme complex, **1**, was synthesized by refluxing $[Mo(CO)_3(\eta^6\text{-}C_6H_5CH_3)]$ in 25% (v/v) diglyme (Aldrich 99%, anhydrous)/pentane solution, resulting in a light yellow precipitate which was filtered and washed with pentane. The toluene complex, $[Mo(CO)_3(\eta^6\text{-}C_6H_5CH_3)]$, was synthesized by refluxing $Mo(CO)_6$ in toluene. Both products gave satisfactory elemental analyses. Further characterization by IR spectroscopy showed stretching frequencies at 1951 and 1752 cm^{-1} (br) (KBr) for **1** and 1983 and 1913 cm^{-1} (pentane) for $[Mo(CO)_3(\eta^6\text{-}C_6H_5CH_3)]$.[11] The bands for the diglyme complex differ from those reported by Werner and Coffield [1905 and 1835 cm^{-1} (KBr)].[1]

The ^{13}CO enriched $[Mo(CO)_3(diglyme)]$ was prepared from the enriched toluene complex. Enriched $[Mo(CO)_3(\eta^6\text{-}C_6H_5CH_3)]$ was prepared by stirring the complex under a ^{13}CO atmosphere for 2 days. The $Mo(CO)_6$ which was formed during this process was reconverted to the toluene complex by additional reflux to yield ^{13}CO-enriched $[Mo(CO)_3(\eta^6\text{-}C_6H_5CH_3)]$.

Deuterated solvents, acetone-d_6 (99% D) (Cambridge Isotopes), ethanol-d (99.5% D) and methanol-d (99.5% D) (Aldrich Chemical Company) were degassed by purging with dry nitrogen before use.

Solutions for NMR samples were prepared under inert atmospheres using degassed NMR solvents. The solutions were then filtered through a glass frit and syringed into an outgassed 10-mm o.d. NMR tube. This procedure avoided exposure of the solution to air.

Variable temperature ^{13}C NMR spectra were recorded on a Bruker WP200 NMR spectrometer. The observation frequency for carbon was 50.323 MHz. The spectrometer was equipped with a Bruker variable temperature controller which was capable of maintaining temperatures to $\pm 1°C$. Samples were allowed to equilibrate at a given temperature for at least 5 min before data aquisition was initiated.

Variable temperature CP–MAS ^{13}C NMR spectra were obtained form a ^{13}CO-enriched sample of the diglyme complex using a Bruker MSL300 spectrometer. The observation frequency for carbon was 75.5 MHz. The sample was packed in a standard Bruker aluminium oxide rotor. The hole in the boron nitride endcap was sealed with rubber cement to prevent exposure of the sample to air. Nitrogen gas (from liquid nitrogen boil-off) was used as the drive and bearing gas. The solid-state spectrometer was equipped with a Bruker variable temperature controller which maintained temperatures to $\pm 1°C$. The sample was allowed to equilibrate for at least 10 min at each temperature before scanning.

RESULTS

The variable temperature ^{13}C NMR spectra for $[Mo(CO)_3(diglyme)]$ in acetone-d_6 are shown in Fig. 2. The solvent peaks are present at 206 and 29.8 ppm (TMS). The acetone-d_6 methyl peak at 29.8 ppm was used as the chemical shift reference. Where indicated, the solvent peaks have been truncated to allow amplification of the complex signals. There

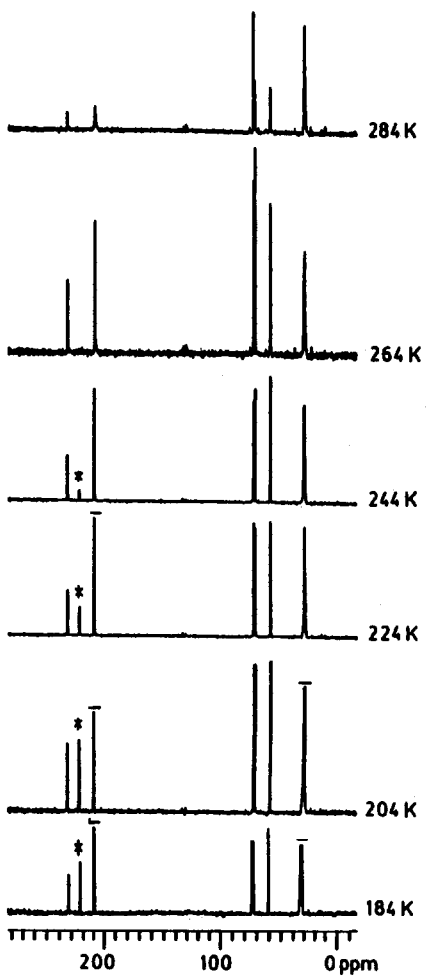

Fig. 2. Variable temperature 50.3 MHz ^{13}C NMR spectra of $[Mo(CO)_3(diglyme)]$ in acetone-d_6. The asterisked peak is due to coordinated acetone-d_6.

is only a single resonance in the carbonyl region at 230.7 ppm. Signals can also be observed for the diglyme ligand at 72.6, 71.5 and 59.2 ppm, which are barely shifted from the values obtained for the uncomplexed diglyme molecule in acetone-d_6 (72.7, 71.3 and 58.8). Two of the diglyme ligand resonances are broadened in this spectrum which seems to be due to a concentration effect, since dilute samples demonstrated less severe broadening. These signals are not broadened in the spectra of the uncomplexed diglyme ligand. The assignment of the diglyme ligands are not clear. However, it is reasonable to assume that the peak at 59.2 ppm is due to the pair of methyl carbons and the peaks at 72.7 and 72.3 ppm are due to the two pairs of methylene carbons.

A simple "ball-and-stick" model of the $[Mo(CO)_3(diglyme)]$ complex using an octahedral molybdenum centre and tetrahedral angles for all of the carbon atoms in the diglyme ligand indicates that the structure shown in Fig. 1 is less sterically hindered than a structure in which the methyl groups are directed towards each other. This structure possesses mirror plane symmetry and, thus a total of three resonances are expected for the coordinated diglyme ligand. The presence of a single carbonyl resonance is not predicted by the structure in Fig. 1 or by any other configuration possible for the diglyme ligand. The single carbonyl peak may imply either an accidental degeneracy of the chemical shifts or a motional process in which the carbonyls are rapidly exchanging positions. Many precedents exist for tricarbonyl group rotation in $[(arene)M(CO)_3]$ complexes in solution.[11-15]. However, the bonds between the metal atom and the arene ring are not directional (which may account for the low rotational barriers observed in these complexes), whereas in the diglyme molecule, the directional nature of the molybdenum–oxygen bonds may present a high barrier for rotation of the tricarbonyl group.

The carbonyl groups have a longer T_1 than the diglyme ligand carbons as evidenced by the relative enhancement of the carbonyl resonance by either increasing the delay time between pulses or by the addition of the relaxation agent, $Cr(acac)_3$. These treatments have little effect on the diglyme ligand signals.

At 284 K, the peaks due to the methyl groups and one pair of methylene groups have sharpened considerably and by 264 K they have attained approximately the same intensity and line width of the signal of the other pair of methylene carbons. This again suggests that the methyl groups adopt positions which allow mirror plane symmetry for the diglyme ligand.

At about 244 K, a new signal appears in the carbonyl region at 220.0 ppm and increases in intensity relative to the carbonyl resonance as the temperature is lowered. However, in the low temperature spectra of ^{13}CO-enriched $[Mo(CO)_3(diglyme)]$ in acetone-d_6 shown in Fig. 3, the new peak is very weak compared to the carbonyl ligand signal suggesting that the new peak originates from the acetone-d_6 solvent rather than the carbonyl groups. Thus, it appears that acetone molecules are able to coordinate to the molybdenum atom in the diglyme complex causing a downfield shift of the acetone carbonyl carbon. The chemical shift of the acetone methyl groups appears not to be greatly affected upon coordinated of the molecule to molybdenum, since their signal is not resolved from the solvent peak. In the lower temperature spectra, the area of the coordinated acetone-d_6 solvent molecules is approximately equal to the area of the carbonyl ligands, which indicates that the acetone molecules have completely displaced the diglyme ligand at the lower temperatures. The peaks due to complexed and uncomplexed diglyme ligand are not resolved in the spectra. This might be expected since the respective chemical shifts differ by less than 0.4 ppm. At 184 K, all of the line widths of the signals begin to broaden slightly. This temperature is near the freezing point of acetone, thus the line broadening is most likely due to freezing solvent or crystallization of the tricarbonyl complex.

The subambient temperature ^{13}C NMR spectra of $[Mo(CO)_3(diglyme)]$ in ethanol-d are shown in Fig. 4. The peaks at 56.8 and 17.2 ppm are due to the solvent and the 56.8 ppm signal was used as the chemical shift reference. The ambient temperature spectrum (top spectrum) is virtually identical to the corresponding spectrum obtained in acetone-d_6. The carbonyl resonance is at 228.8 ppm and the signals for the diglyme ligand are at 71.4, 69.8 and 52.7 ppm. Lowering the temperature of the sample again causes the signals at 69.8 and 52.7 ppm to sharpen in the lower temperature spectra. However, at 254 K, a new peak at 62.0 ppm begins to grow and attains the same relative intensity of the other methyl and methylene carbons in the diglyme ligand at 234 K. At the lower temperatures, the area of this new peak approaches a value which is 1.5 times the areas of the individual diglyme ligand signals, which suggest that the peak represents three molecules. This new peak is assigned to the methylene groups of coordinated ethanol-d molecules which displace the diglyme ligand at the lower temperatures in a manner analogous to acetone. However, the signals for the methyl groups of the coordinated ethanol-d molecules is not resolved from the solvent peak. Again, the signal due to com-

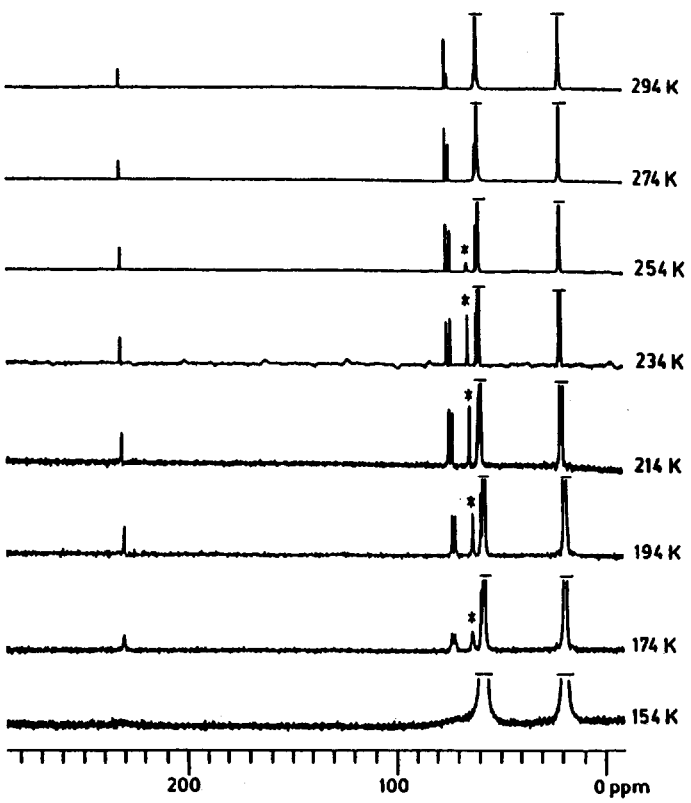

Fig. 4. Variable temperature 50.3 MHz ^{13}C NMR spectra of [$Mo(CO)_3$(diglyme)] in ethanol-d. The asterisked peak is due to coordinated ethanol-d.

plexed and uncomplexed diglyme ligand are not resolved. As the temperature is lowered further, the resonances due to the carbonyl ligands, diglyme molecule and the methylene signal of the coordinated ethanol-d molecule and the methylene signal of the coordinated ethanol-d molecules broaden considerably. It should be noted that the peak due to the methyl groups in the diglyme molecule broadens at a slower rate than the other signals. At 154 K, the peaks are so severely broadened that they are barely discernable in the spectrum. However, this temperature is very near the freezing point of ethanol which may account for the broadening. The solvent peaks at this temperature are also clearly broadened. The signal due to the methyl groups of the diglyme molecules would broaden at a slower rate since they would have greater mobility than the other carbons in the sample. Therefore, lower temperatures would have to be achieved in order to determine the dynamics of the carbonyl ligands in the substituted complex. In order to further substantiate the assignment of the peak at 62.0 ppm to coordinated ethanol-d molecules, the variable temperature spectra of the diglyme complex in methanol-d were also recorded.

A series of variable temperature solution ^{13}C NMR spectra of $[Mo(CO)_3(diglyme)]$ in methanol-d is shown in Fig. 5. In the 293 K spectrum, the peaks are at 229.6 ppm (carbonyl ligands), 72.0 and 70.4 ppm (methylene groups of the diglyme ligand) and 58.2 ppm (methyl groups of the diglyme ligand). The methanol-d solvent peak is at 49.0 ppm and was used as the chemical shift reference. At 293 K, the signals at 70.4 and 58.2 ppm are not as severely broadened as in the corresponding spectra in the other solvents, since this sample was very dilute. Again, lowering the temperature of the sample causes the signals of all three pairs of carbon atoms in the diglyme ligand to attain nearly equal intensities. In the 253 K spectrum, a new peak begins to appear at 58.7 ppm. In the lower temperature spectra, the ratio of the area of the new peak to the area of the diglyme methyl group approaches a value of 1.5. This indicates that three methanol-d molecules are coordinated per molybdenum complex which causes the observed shift of the coordinated methanol-d methyl groups from 49.0 to 53.8 ppm. Thus, as in the previous solvents, methanol-d is displacing the diglyme ligand in the complex at the lower temperatures. Again, the complexed and

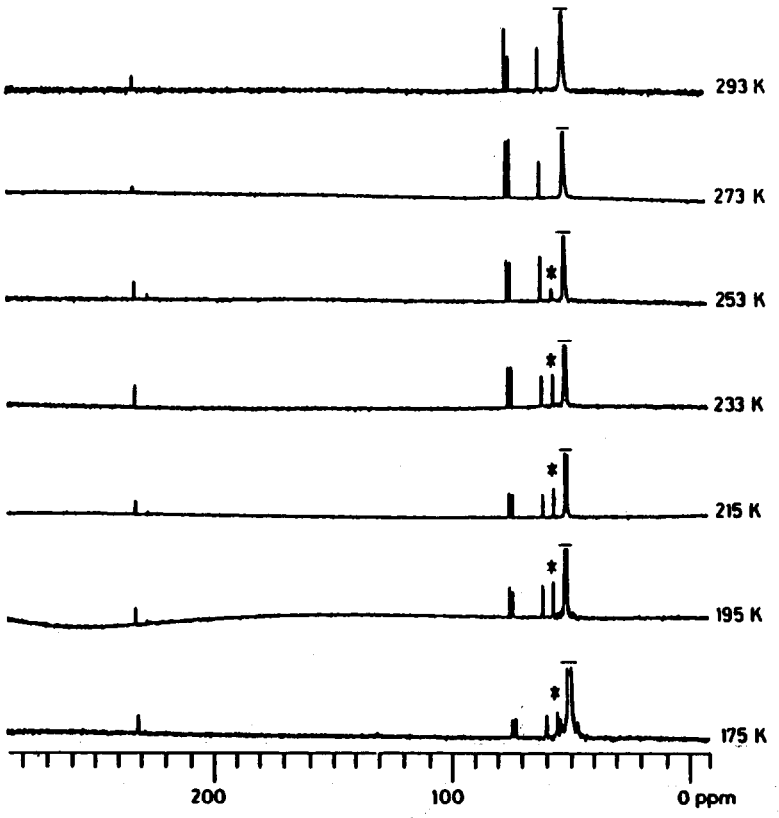

Fig. 5. Variable temperature 50.3 MHz ^{13}C NMR spectra of $[Mo(CO)_3(diglyme)]$ in methanol-d. The asterisked peak is due to coordinated methanol-d.

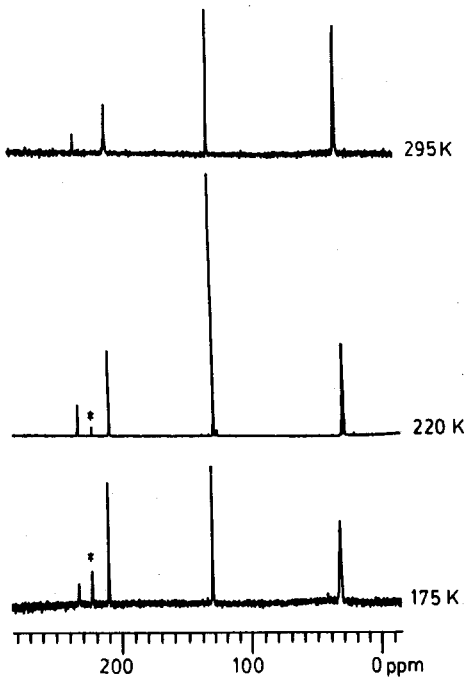

Fig. 6. Variable temperature 50.3 MHz ^{13}C NMR spectra of $[Mo(CO)_3(acetone)_3]$ generated *in situ* from $[Mo(CO)_3(\eta^6\text{-}C_6H_6)]$. The asterisked peak is due to coordinated acetone-d_6.

uncomplexed diglyme ligand signals are not resolvable. In the solution ^{13}C NMR spectra of this dilute sample of $[Mo(CO)_3(diglyme)]$ in methanol-d, no significant broadening of the signals was observed at the lower temperatures.

It should be noted that when $[Mo(CO)_3^-(\eta^6\text{-}C_6H_6)]$ is dissolved in acetone, the coordinated acetone ligands are again seen only at low temperature. Thus, there must be rapid exchange between free and coordinated acetone in $[(acetone)_3Mo(CO)_3]$ (Fig. 6).

The variable temperature 75.5 MHz CP–MAS ^{13}C NMR spectras of ^{13}CO-enriched $[Mo(CO)_3(diglyme)]$ are shown in Fig. 7. In the 299 K spectrum, a single, sharp carbonyl peak is present at 230.7 ppm and is very close to the solution value. The diglyme ligand resonances are at 74.1, 72.8 and 67.3 ppm. The peak due to the diglyme methyl groups at 67.3 ppm is slightly enhanced relative to the diglyme methylene groups. The other peaks present in the spectrum are due to spinning sidebands of the carbonyl peak. The spectrum obtained at 260 K is virtually unchanged except that the sidebands have moved toward the carbonyl peak at 230.5 ppm as a result of the slower spin rate. The spinning rates were about 4600 and 4300 Hz in the 299 and 260 K spectra, respectively.

The presence of only a single, sharp resonance for each pair of methyl and methylene groups indicates that the ligand probably has mirror plane symmetry in the solid state as previously suggested by the model shown in Fig. 1. The presence of a single, sharp resonance for the carbonyl ligands at both temperatures with nearly identical linewidths, suggests that the complex is static in the solid state and that the chemical shifts of the carbonyl ligands are degenerate. Furthermore, an inspection[16,17] of the intense array of spinning sidebands indicates a very large chemical shift anisotropy of about 400 ± 50 ppm for the carbonyl ligands which is close to the

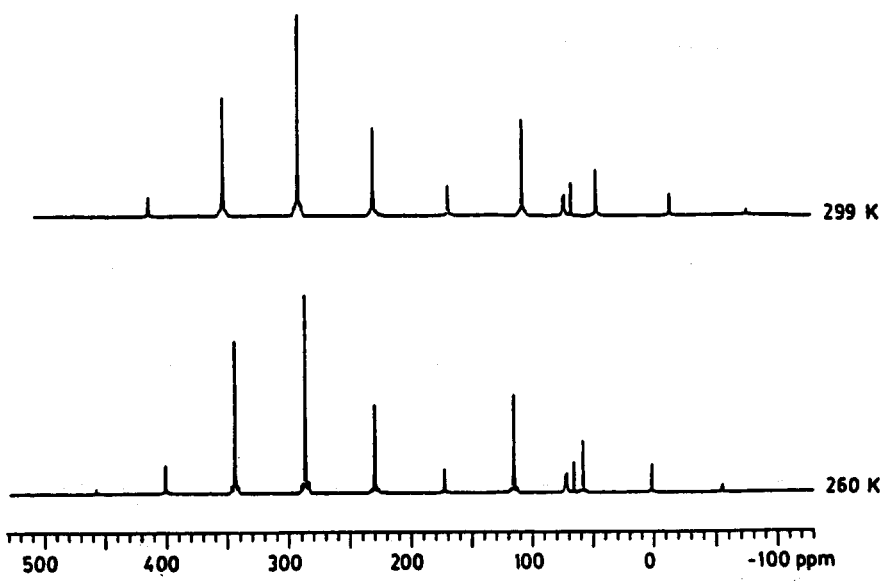

Fig. 7. Variable temperature 75.5 MHz ^{13}C CO–MAS spectra of ^{13}CO-enriched $[Mo(CO)_3(diglyme)]$.

value expected for a static metal carbonyl.[18] Therefore, the [Mo(CO)$_3$(diglyme)] molecule appears to be static in the solid state.

DISCUSSION

The coordination of acetone, methanol and ethanol to [Mo(CO)$_3$(diglyme)] at low temperature is clearly suggested by the variable temperature NMR data for **1**. This is contrary to what is expected based on the thermodynamic data of Hoff and co-workers[3] for ligand displacement reactions of [(arene)Mo(CO)$_3$]. The data in ref. 3 clearly shows that the bond enthalpy for diglyme coordinated to molybdenum is larger than the enthalpy for acetone to molybdenum. Thus, one predicts that diglyme would always displace acetone. However, the present data suggest that diglyme is rapidly displaced by weak oxygen donor ligands and that at low temperatures, up to three acetone, methanol or ethanol ligands may bond to the molybdenum tricarbonyl group.

The following equilibrium may be suggested for the Mo(CO)$_3$ group in acetone or other similar solvents.

$$[(\eta^3\text{-diglyme})\text{Mo(CO)}_3] + \text{acetone} \rightleftharpoons [(\eta^2\text{-diglyme})(\text{acetone})\text{Mo(CO)}_3]$$

$$[(\eta^2\text{-diglyme})(\text{acetone})\text{Mo(CO)}_3] + \text{acetone} \rightleftharpoons [(\eta^1\text{-diglyme})(\text{acetone})_2\text{Mo(CO)}_3]$$

$$[(\eta^1\text{-diglyme})(\text{acetone})_2\text{Mo(CO)}_3] \rightleftharpoons [(\text{acetone})_3\text{Mo(CO)}_3] + \text{diglyme}.$$

Furthermore, exchange of free and coordinated acetone appears fast at room temperature. At low temperatures for acetone, methanol and ethanol, the equilibrium clearly goes in favour of complete displacement of diglyme. At room temperature, however, it is impossible to determine the extent of reaction since ^{13}C NMR cannot distinguish between free and coordinated solvent and free and coordinated diglyme.

The apparent discrepancy between this work and that of Hoff's for the displacement of diglyme by acetone is most likely due to solvation energies, since the NMR work was done in neat acetone, methanol or ethanol and the calorimetric work was done in dilute methylene chloride. Solvation of free diglyme may be anticipated to be greater in the more polar solvents used in the NMR work.

SYNTHESIS AND STRUCTURAL CHARACTERIZATION OF $[Sn(1,2\text{-}O_2C_6H_3NO_2\text{-}4)(C_4H_8O)]_n$—A TIN(II) CATECHOL COMPLEX†

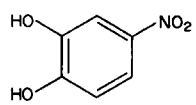
JONATHAN C. MACHELL, D. MICHAEL P. MINGOS‡ and TONIE L. STOLBERG

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 30 *August* 1989; *accepted* 18 *September* 1989)

Abstract—$[Sn(1,2\text{-}O_2C_6H_3NO_2\text{-}4)(C_4H_8O)]_n$ has a chain polymeric solid-state structure based on very distorted square-pyramidal SnO_5 moieties linked by oxygen bridges from the catechol ligands. It is, however, monomeric in dimethyl sulphoxide and soluble in many organic solvents.

Zuckerman and his co-workers[1] synthesized a large number of catechol and related complexes of tin(II), but their insolubility in common organic solvents precluded the development of their chemistries[2] and the isolation of single crystals suitable for definitive structural studies, which would have established the nature of the intermolecular interactions linking the tin(II) catechol units. In this paper we describe the synthesis and structural characterization of a 4-nitrocatechol (**1**) complex which has a polymeric structure in the solid state, but dissociates readily in donor solvents.



(1)

The reaction of **1** with $Sn(OMe)_2$ in tetrahydrofuran at room temperature results in the isolation of a yellow crystalline solid which analyses correctly for $[Sn(1,2\text{-}O_2C_6H_3NO_2\text{-}4)(C_4H_8O)]_n$ (**2**). Compound **2** is soluble in acetone, methanol, ethanol, acetonitrile and dimethyl sulphoxide. Its ^{119}Sn NMR spectrum in methanol consists of a single line at 131 ppm with respect to $SnMe_4$, and a cryoscopic molecular weight determination in dimethyl sulphoxide has established that it is monomeric in this solvent (Mol. $wt_{calc} = 272$ for $Sn(1,2\text{-}O_2C_6H_3\text{-}NO_2\text{-}4)$; Mol. $wt_{meas} = 298$).

Single crystals of compound **2** were obtained from tetrahydrofuran/hexane and an X-ray crystallographic determination has established the polymeric structure illustrated in Fig. 1.§ Structural details are included in Table 1. The coordination environment about each tin(II) atom can be described as very distorted square-pyramidal. The Sn—O bonds to the catechol ligand, 2.208(4) and

† Dedicated to the memory of Professor Jerold J. Zuckerman (1936–1987).

§ Crystal data: $C_{10}H_{11}NO_5Sn$, $M = 343.89$, triclinic, $P\bar{1}$, $a = 6.121(3)$, $b = 9.295(3)$, $c = 11.073(2)$ Å, $\alpha = 107.39(2)$, $\beta = 98.28(3)$, $\gamma = 98.28(4)°$, $U = 583$ Å^3, $D_c = 1.96$ g cm^{-3}, $Z = 2$, $F(000) = 336$, μ(Mo-K_α) = 22.06 cm^{-1}. 2458 reflections were measured on an Enraf–Nonius CAD4F diffractometer in the range $2.0 \leqslant 2\theta \leqslant 50°$. The structure was solved by a combination of direct methods, Patterson and Fourier methods and refined by block-matrix least-squares [Sn, N, C(1)—(10), O(1)—(5), H(31) anisotropic; H(41), H(61) isotropic] to $R = 0.0375$ for 1621 unique observed reflections [$I \geqslant 3\sigma(I)$].

The atomic coordinates for this structure are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K. Any request should be accompanied by the full literature citation for this communication.

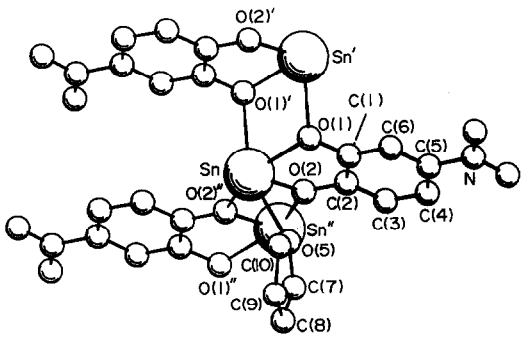

Fig. 1. Section of polymeric chain $[Sn(1,2\text{-}O_2C_6H_3NO_2\text{-}4)(C_4H_8O)]_n$ (**2**). For reasons of clarity, hydrogen atoms have been omitted. Important bond lengths include: Sn—O(1) 2.208(4), Sn—O(2) 2.112(4), Sn—O(5) 2.535(6), Sn—O(1′) 2.430(5), Sn—O(2″) 2.607(4) Å. Important angles include: O(1)—Sn—O(1′) 74.7(2), O(1)—Sn—O(2) 75.6(2), O(1)—Sn—O(2″) 138.1(2), O(1)—Sn—O(5) 78.7(2), O(1′)—Sn—O(2) 93.5(2), O(1′)—Sn—O(2″) 94.4(2), O(1′)—Sn—O(5) 153.3(2), O(2)—Sn—O(2″) 64.5(2), O(2)—Sn—O(5) 78.3(2), O(2″)—Sn—O(5) 104.5(2)°.

2.112(4) Å, are significantly shorter than that to the tetrahydrofuran oxygen, O(5) (2.535(4) Å). Interestingly, the Sn—O bond *para* to the NO_2 group is shorter than the other Sn—O catechol bond. In $[Sn(O_2C_6H_4)_3][Et_3NH]_2$[3] the corresponding average Sn—O distance is 2.05(2) Å. The $[Sn(1,2\text{-}O_2C_6H_3NO_2\text{-}4)(C_4H_8O)]$ moieties are linked by long Sn—O bonds, Sn—O(1′) (2.430(4) Å) and Sn—O(2″) (2.607(4) Å) to generate infinite polymeric chains. The square-pyramid is severely distorted as a result of the small bite angle of the catechol ligand (75.6(2)°), cf. 82.7(4)° in $[Sn(O_2C_6H_4)_3][Et_3NH]_2$, and the stereochemical consequences of the lone pair of electrons at the tin(II) atom. The basal plane of this distorted square-pyramid defined by O(1), O(1′), O(2″) and O(5) consequently has two angles which deviate a large amount from the ideal 180° (O(1)—Sn—O(2″) = 138.1(2)° and O(1′)—Sn—O(5) = 153.3(2)°). The apex of the square-pyramid is defined by O(2) and the remaining angles which ideally should be 90° vary from 64.5(2) to 104.5(2)°. A less distorted square-pyramidal geometry has been reported recently in the pyrazolylboratotin(II) complex, $[HB(pz^*)_3]_2Sn$[4] (pz^* = 3,5-dimethyl-1-pyrazolyl).

(3)

The manner in which the square-pyramidal units are linked to form the polymeric chains is represented in an idealized fashion in **3**. Pairs of square-pyramids are linked by basal oxygen atoms in a centrosymmetric fashion about a crystallographically imposed centre of symmetry at the midpoint of the common edge. These pairs are further linked by apical–basal bridges about a second centre of symmetry. Since each tin atom is in a chiral environment, this packing mode requires an alternation of enantiomeric forms of the asymmetric unit along the chain. The presence of the tetrahydrofuran ligands makes this polymer geometry quite different to that reported previously for $[Sn(O_2C_2H_4)]_n$,[5] which crystallizes in a rhombohedral point group and has a cross-linked arrangement of Sn—O rings about a three-fold symmetry axis.

The long intermolecular Sn—O(1′) and Sn—O(2″) bonds which must result in part from electronic effects associated with the NO_2 group, must contribute to the ease of dissociation of the

polymeric chains in donor solvents. These solubility properties have resulted in the isolation of adducts of the type $[Sn(1,2\text{-}O_2C_6H_3NO_2\text{-}4)(C_4H_8O)L]$ (L = 1,2-diaminopropane or 2,2′-dipyridyl) and some interesting transition metal tin(II) catechol complexes which will be described in subsequent publications.

The ^{119}Sn Mössbauer spectrum of **2** shows an isomer shift of 3.49 mm s^{-1} confirming a tin(II) oxidation state,[6] and is in accordance with Harrison's observation that tin(II)–oxygen bonded compounds with an isomer shift in excess of 3.15 mm s^{-1} are composed of molecules held together by only weak intermolecular interactions.[7] The size of the quadrupole splitting (2.33 mm s^{-1}), again, is indicative of the large departure of **2** from cubic symmetry.

Acknowledgements—The SERC and the International Tin Research Institute are thanked for financial support. We should also like to thank Professor F. Glockling for stimulating our interest in this area, and for many useful discussions.

COMMUNICATION

OPTICAL METAL-TO-LIGAND CHARGE-TRANSFER OF 2,2′-BIPYRIDYL COMPLEXES OF ANTIMONY(III) AND BISMUTH(III)

HORST KUNKELY, ALOIS PAUKNER and ARND VOGLER†

Institut für Anorganische Chemie der Universität Regensburg Universitätsstraße 31, D-8400 Regensburg, F.R.G.

(*Received* 20 *July* 1989; *accepted* 18 *September* 1989)

Abstract—The complexes [M(2,2′-bipyridyl)X_3], with M = Sb, Bi and X = Cl, Br, I, are characterized by long-wavelength metal-to-ligand charge-transfer (MLCT) bands which determine the colours of these compounds in the solid state. The energy of the MLCT bands depends on the reducing strength of the metal and the extent of *sp* mixing of the lone electron pair at the metal.

Coordination compounds of main group metals with a s^2 electron configuration at the metal show a large variety of different structures. Complexes of antimony(III) are good examples of this behaviour.[1,2] This structural diversity depends—at least partially—on *sp* orbital mixing. If this mixing occurs the lone electron pair gains *p*-character and becomes stereochemically active. In octahedral complexes such as $[TeBr_6]^{2-}$ and $[SbCl_6]^{3-}$, *sp* mixing does not take place and the lone pair preserves its *s*-character. The electronic spectra of $[TeBr_6]^{2-}$[3-5] and $[SBCl_6]^{3-}$[6-8] are relatively simple. They display long-wavelength absorptions in the UV. These bands belong to $s \rightarrow p$ transitions. On the contrary, there is not much known about the electronic spectra of complexes with a stereochemically active lone pair at the metal. In this case spectra assignments are certainly complicated due to the *sp* orbital mixing and molecular structures of lower symmetry as imposed by the lone pair. However, an identification and characterization of the lone pair is feasible by electronic spectroscopy if a 1,2-diimine ligand such as 2,2′-bipyridyl (bipy) or 1,10-phenanthroline (*o*-phen) is attached to the s^2 metal. Since these metals are reducing due to the presence of the lone pair, optical low-energy metal-to-ligand MLCT transitions should appear in analogy to diimine complexes of reducing transition metals such as iron(II), ruthenium(II), or copper(I).[9] With the exception of the organometallic cation $[Sn^{II}(C_5Me_5)bipy]^{+}$[10,11] such optical MLCT transitions of s^2 metal complexes are virtually unknown to our knowledge. In searching for simple examples our attention was drawn to the complexes [M(1,2-diimine)X_3], with M = Sb, Bi, X = Cl, Br, I, and 1,2-diimine = bipy[12] and *o*-phen.[13,14] These compounds exhibit remarkable colours. We suspected that these colours are due to low-energy MLCT absorptions. In the present communication we report the first results on the electronic spectra and the spectral assignments of the complexes [M(bipy)X_3].

Reliable absorption spectra of the complexes [M(bipy)X_3] in solution cannot be obtained since these compounds are either insoluble or undergo extensive dissociation in all common solvents, as indicated by the presence of free bipy which was identified by its absorption (λ_{max} = 280 nm, ε = 11230 and λ_{max} = 235 nm, ε = 9160) and fluorescence (λ_{max} = 325 nm) spectra. The spectra of the complexes were measured by scattered transmission spectroscopy of suspensions of the powdered materials in hexane or paraffin and recorded in absorbance vs wavelength on a Uvikon 860 spectrometer equipped with an end-on photomultiplier. The spectra are characterized by long-wavelength bands in the visible region which determine the colour of the complexes (Fig. 1, Table 1). In

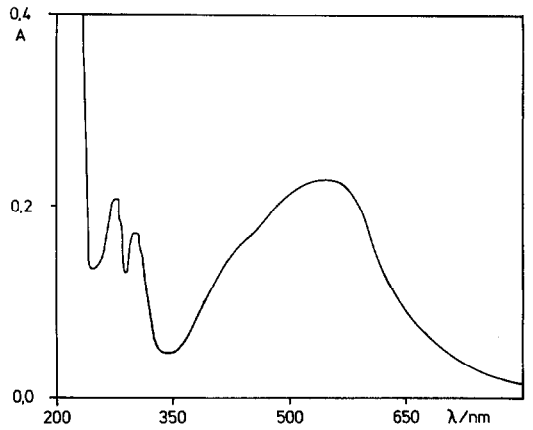

Fig. 1. Electronic absorption spectrum of $[Sb(bipy)I_3]$ at room temperature; absorbance in arbitrary units.

addition, absorptions also appear at shorter wavelength in the UV (Fig. 1).

The absorption spectra of the $[M(bipy)X_3]$ complexes all contain a maximum slightly above 300 nm which is assigned to the lowest-energy $\pi \rightarrow \pi^*$ intraligand transition of the bipy ligand. These bands also appear in the spectra of bipy complexes of transition metals such as rhodium[15,16] or platinum[17] and are indicative of coordinated bipy. Ligand-to-metal charge-transfer transitions involving the promotion of a halide electron to the *p* orbitals of M^{III} are not expected to occur at low energies. For example, $[SbCl_6]^{3-}$ does not show LMCT absorptions at wavelengths above 200 nm.[6-8] The long-wavelength absorptions of $[M(bipy)X_3]$ (Fig. 1, Table 1) are then logically assigned to MLCT transitions involving the promotion of an electron from the lone pair of the metal to the π^* orbital of the bipy ligand. This assignment is supported by the blue shift of this band which takes place when antimony(III) is replaced by bismuth(III) (Table 1). Bismuth(III) is generally less reducing ($Bi^{III/V}$: $E^0 \sim 1.7$ V) than antimony(III) ($Sb^{III/V}$: $E^0 \sim 0.6$ V).[18] The MLCT assignment of the low-energy absorptions of $[M(bipy)X_3]$ is thus quite obvious. However, the blue shift of the MLCT bands in the series X = I, Br, and Cl requires some further explanations.

It has been concluded from the Mössbauer spectra that the *p* character of the lone pair of $[M(diimine)X_3]$ increases from X = I to Br and Cl.[13] The *sp* orbital mixing which is achieved by a configuration interaction leads then to a stabilization of the lone pair.[19] Accordingly, the MLCT transition of $[M(bipy)I_3]$ occurs at rather low energies since the lone pair has less *p* contribution. On the contrary, the larger *p* character of the lone pair of $[M(bipy)Cl_3]$ shifts the MLCT transition to higher energies.

The origin of this difference in *sp* mixing does not seem to be clear. It may be related to the spatial demand of the ligand X. The configuration interaction which leads to the *sp* mixing requires a distortion from a more symmetrical structure.[19] Simultaneously, space opens for the lone pair which becomes stereochemically active. This steric flexibility is provided by the smaller Cl^- ligand rather than by the I^- ligand. Unfortunately, the structures of these complexes are not to our knowledge known. On the basis of IR measurements it has been suggested that the complexes $[M(diimine)X_3]$ consist of bridged dimers or chain polymers.[13,14,20]

COMMUNICATION

PREPARATION OF DIBROMOACETIC ANHYDRIDE AND ITS REACTIONS WITH Bi_2O_3 AND CrO_3 TO FORM METAL DIBROMOACETATES

RAM PARKASH,* SUKHJINDER SINGH and MEENA

Department of Chemistry, Panjab University, Chandigarh-160014, India

(*Received* 4 *August* 1989; *accepted* 18 *September* 1989)

Abstract—Dibromoacetic anhydride was prepared by reacting dibromoacetic acid with phosphorus(V) oxide in carbon tetrachloride at ~85°C for 11 h. It reacts with Bi_2O_3 and CrO_3 in CCl_4 on prolonged refluxing forming $Bi(CHBr_2COO)_3$ and $Cr(CHBr_2COO)_3$, respectively. These new compounds were characterized by elemental analyses, IR, ^1H NMR and mass spectroscopy.

Several halogen-substituted acetic anhydrides are known.[1–3] However, dibromoacetic anhydride has not been reported so far. In this communication, the preparation of $(CHBr_2CO)_2O$ and its reactions with Bi_2O_3 and CrO_3 are being discussed.

RESULTS AND DISCUSSION

Reaction of dibromoacetic acid with phosphorus(V) oxide and subsequent distillation of the anhydride produced, even under reduced pressure, lead to partial decomposition of the product. However, dibromoacetic acid reacts with phosphorus(V) oxide in CCl_4 at ~85°C producing dibromoacetic anhydride in good yield. The progress of the reaction is monitored by ^1H NMR spectroscopy. The reaction is considered to be complete when ^1H NMR of the test solution does not show any resonance relating to δ(OH) of the $CHBr_2COOH$. The reaction is complete in 11 h as observed in the repeated experiments:

$$2CHBr_2COOH \xrightarrow[11\,h,\ \sim 85°C]{P_4O_{10},CCl_4} (CHBr_2CO)_2O.$$

Dibromoacetic anhydride is a shiny white solid, stable indefinitely at ambient temperatures in a dry atmosphere. It is soluble in common organic solvents and reacts readily with water to give dibromoacetic acid. Attempts to record IR spectra of neat $(CHBr_2CO)_2O$ lead to the formation of some $CHBr_2COOH$ due to its hydrolysis by traces of moisture. The clean IR spectra have been recorded in Nujol as well as in CCl_4. A parent or molecular ion peak is not observed in the EI mass spectra of $(CHBr_2CO)_2O$ by a direct insertion method, however, strong peaks relating to $CHBr_2COO^+$, $CHBr_2CO^+$ and $CHBr_2^+$ fragment ions are observed.

The reaction between bismuth(III) oxide and a slight excess of dibromoacetic anhydride in CCl_4 at ~85°C for 90 h results in the formation of bismuth(III) dibromoacetate. However, quantitative yields are not realized because some of the product is always left behind in the filtration unit. Bismuth(III) dibromoacetate, $Bi(CHBr_2COO)_3$, is a creamy white solid insoluble in CCl_4, $CHCl_3$, CH_2Cl_2, $C_2H_5OC_2H_5$, CH_3NO_2 and $C_6H_5NO_2$.

Prolonged reaction between CrO_3 and excess $(CHBr_2CO)_2O$ in CCl_4 at ~85°C produces chromium(III) dibromoacetate, $Cr(CHBr_2COO)_3$. A yellowish-brown solution is obtained in the initial stages of the reaction, from which a greenish solid starts to separate on further refluxing. The yellowish-brown solution is probably due to the formation of chromyl species, which are subsequently reduced with excess $(CHBr_2CO)_2O$ under the experimental conditions:

$$2CrO_3 + 2(CHBr_2CO)_2O \xrightarrow[85°C]{CCl_4}$$

"$2CrO_2(CHBr_2COO)_2$"
Yellowish-brown solution

$$\xrightarrow[\sim 85°C]{(CHBr_2CO)_2O,\ CCl_4}$$

$$2Cr(CHBr_2COO)_3 + 3/2\,O_2$$
Greenish solid.

* Author to whom correspondence should be addressed.

This reaction is similar to those reported between CrO_3 and excess $(CHCl_2CO)_2O$, $(CF_3CO)_2O$ or $(CF_3SO_2)_2O$, which give the green solids $Cr(CHCl_2COO)_3$, $Cr(CF_3COO)_3$ and $Cr(CF_3SO_3)_3$, respectively.[4-6] $Cr(CHBr_2COO)_3$ is a fine, green, hygroscopic powdery material, soluble in diethyl ether and alcohols but insoluble in CCl_4, with no oxidizing power towards KI.

EXPERIMENTAL

Materials and methods

Dibromoacetic acid (Fluka) was used as such. Bismuth(III) oxide (Riedel) and chromium(VI) oxide (BDH) were dried *in vacuo* at 110–120°C for 4 h. The solvents were dried and distilled before use.

IR spectra were recorded as Nujol/hexachlorobutadiene/CCl_4 smears between AgCl or KBr plates on a Perkin–Elmer 1430 IR spectrophotometer. ^1H NMR spectra were taken on an EM-390 spectrometer using TMS as internal standard. Mass spectra (EI) were obtained on a Vg Micromass 7070F at 70 eV. Melting points are uncorrected. All manipulations were carried out in a dry box filled with nitrogen.

Metals and halogens were analysed by standard methods.[7] Carbon and hydrogen were determined microanalytically.

Preparation of dibromoacetic anhydride

Dibromoacetic acid (13.95 g, 64 mmol) was transferred onto 15.0 g of phosphorus(V) oxide in a 100 cm^3 Pyrex reactor in a dry box, and 50 cm^3 of CCl_4 were added to it. The contents were refluxed at ~85°C for 11 h and the reaction mixture was filtered in a specially designed filtration unit under positive pressure of dry nitrogen, and the residual portion was repeatedly washed with CCl_4 (6×10 cm^3). Dibromoacetic anhydride (10.87 g, 26 mmol) was obtained as a white solid (m.p. 54–57°C) after removing excess solvent from the filtrate *in vacuo*. The product was checked for the absence of phosphorus and then recrystallized from CCl_4 as a shiny white solid in >70% yield. $(CHBr_2CO)_2O$ (recrystallized): m.p. 56–57°C; b.p. 115°C/10 torr (decomp.). Found: C, 11.4; H, 0.46; Br, 76.0. Calc. for $C_4H_2Br_4O_3$; C, 11.5; H, 0.48; Br, 76.5%. IR* (CCl_4): 3022 w, 1830 sb, 1765 ms, 1420 w, 1240 mw, 1175 mw, 1152 w, 1125 m, 1053 m, 1030 ssh, 970 vw, 922 m, 870 w, 660 w, 600 m, 592 sh, 538 mw. IR (Nujol): 1830 sb, 1760 m, 1422 sh, 1265 mw, 1240, sh, 1170 w, 1150 sh, 1125 ms, 1050 m, 1030 sh, 972 vw, 922 ms, 880 w, 780 sh, 755 sh, 600 w, 525 ms cm^{-1}. ^1H NMR (CCl_4): 5.97 ppm (singlet, $CHBr_2$).

*S, strong; m, medium; w, weak; b, broad; sh, shoulder; v, very.

Preparation of bismuth(III) *dibromoacetate*

A slight excess of dibromoacetic anhydride (2.34 g, 5.6 mmol) dissolved in 30 cm^3 of CCl_4 was added to Bi_2O_3 (0.7 g, 1.5 mmol) in a 100 cm^3 Pyrex reactor in a dry box. The reaction mixture was refluxed for 90 h at ~85°C. The white solid formed was filtered under a positive pressure of nitrogen, repeatedly washed with CCl_4 and finally dried *in vacuo*. $Bi(CHBr_2COO)_3$ (2.49 g, 2.9 mmol) was obtained as a creamish-white solid in >96% yield. $Bi(CHBr_2COO)_3$: m.p. 183–185°C (decomp.). Found: C, 8.2; H, 0.34; Br, 55.2; Bi, 23.7. Calc. for $C_6H_3BiBr_6O_6$: C, 8.4; H, 0.35; Br, 55.8; Bi, 24.3%. IR: 3032 w, 3000 m, 1728 m, 1555 sh, 1525 s, 1425 m, 1370 s, 1255 sh, 1200 ms, 1134 m, 969 w, 948 w, 795 m, 735 s, 708 s, 695 ms, 603 m, 530 w cm^{-1}.

Preparation of chromium(III) *dibromoacetate*

A similar procedure as that used to prepare $Bi(CHBr_2COO)_3$ was used. A five-fold excess of dibromoacetic anhydride was used and refluxing (~85°C) was carried out for 10 days. $Cr(CHBr_2COO)_3$ was obtained as a green solid which was insoluble in CCl_4. More than 70% yields were realized. $Cr(CHBr_2COO)_3$: Found: C, 10.1; H, 0.42; Br, 67.1; Cr, 7.1. Calc. for $C_6H_3Br_6CrO_6$: C, 10.2; H, 0.43; Br, 68.3; Cr, 7.4%. IR: 1656 s, 1595 s, 1430 ms, 1263 w, 1197 m, 1146 mw, 1090 vw, 966 vw, 795 m, 705 s, 642 w, 606 m, 515 w cm^{-1}.

Acknowledgement—The authors are thankful to D. Niyogi for help during the experimental work.

A NEW ROUTE TO FLUOROCARBON-STABILIZED ORGANOAMIDOPLATINUM(II) COMPOUNDS— SYNTHESIS OF A NEW ISOMER OF [Pt(RNCH$_2$CH$_2$NMe$_2$)X(L)] (R = *p*-HC$_6$F$_4$ OR C$_6$F$_5$; X = Cl OR I; L = UNIDENTATE LIGAND) COMPLEXES

D. P. BUXTON, G. B. DEACON,* A. M. JAMES, S. J. KNOWLES and T. L. WILLIAMS

Chemistry Department, Monash University, Clayton, Victoria 3168, Australia

(*Received* 15 *August* 1989; *accepted* 20 *September* 1989)

Abstract—Reaction of the complexes PtX$_2$(RNHCH$_2$CH$_2$NMe$_2$) (X = Cl or I; R = *p*-HC$_6$F$_4$ or C$_6$F$_5$) with TlOR′ (R′ = Et or Bu^t) co-precipitates TlX and the organoamides [Pt(RNCH$_2$CH$_2$NMe$_2$)X]$_2$; these react with L (pyridine (py) or Me$_2$SO) to give [Pt(NRCH$_2$CH$_2$NMe$_2$)X(L)] complexes, which, in three cases (R = *p*-HC$_6$F$_4$ or C$_6$F$_5$, L = Me$_2$SO, X = Cl; R = *p*-HC$_6$F$_4$, L = py, X = I), were obtained as the isomer with L *trans* to the NR group.

The scope of platinum(II) organoamide chemistry[1–3] has been greatly increased by the preparation of polyfluorophenyl(R)-substituted complexes [Pt(RNCH$_2$)$_2$L$_2$] and [Pt(RNCH$_2$CH$_2$NMe$_2$)X(L)] (e.g. R = *p*-HC$_6$F$_4$ or C$_6$F$_5$; L = py; X = Cl or I)[4–8] where the fluorocarbon substitution provides stabilization against hydrolysis (cf. moisture-sensitive [Pt(RNCH$_2$)$_2$bpy] (R = H or Me; bpy = 2,2′-bipyridyl[9]). Their preparation by decarboxylation reactions in pyridine solution, e.g. eq. (1) (dmen = N,N-dimethylethane-1,2-diamine),[4–8] is unprecedented in organoamidometallic chemistry. However, the method has limitations. It is essentially restricted to complexes where L = pyridine or substituted pyridine (but see ref. 8) and to formation of [Pt(RNCH$_2$CH$_2$NMe$_2$)X(L)] complexes with structure **1** but *not* **2**.

$$PtI_2(dmen) + TlO_2CC_6F_4H\text{-}p + C_6F_5H + 2py \longrightarrow$$
$$[Pt(p\text{-}HC_6F_4NCH_2CH_2NMe_2)I(py)]$$
(1a)
$$+ p\text{-}H_2C_6F_4 + TlI + CO_2 + pyHF. \quad (1)$$

We now report a new synthetic route to [Pt(RNCH$_2$CH$_2$NMe$_2$)X(L)] complexes and the first preparation of compounds with structure **2**.

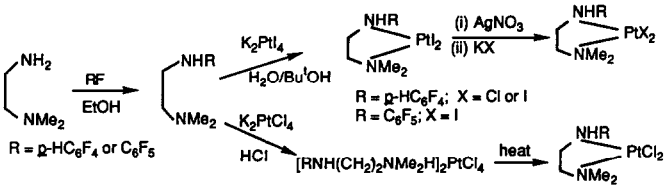
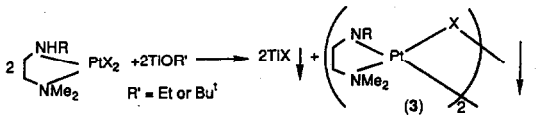
† Isomer **1** may be termed *trans* and isomer **2** *cis*, since donor atoms of similar charge are *trans* and *cis*, respectively.

‡ All new compounds were characterized by microanalysis, ^{1}H and ^{19}F NMR spectra, and, where volatile, by mass spectrometry.



Scheme 1.

platinum(II) complex, which was identified primarily by observation of the dimer parent ion in the mass spectrum (and appropriate fragment ions).



(**3a**) R = *p*-HC_6F_4, X = I;
(**3b**) R = *p*-HC_6F_4, X = Cl;
(**3c**) R = C_6F_5, X = Cl;
(**3d**) R = C_6F_5, X = I.

Treatment of the TlI/**3a** mixture with slightly less than the stoichiometric amount of py required for dimer cleavage in THF yielded [Pt(*p*-$HC_6F_4NCH_2CH_2NMe_2$)I(py)] with the previously unknown structure **2a**, which was obtained analytically and isomerically pure (81% yield) on recrystallization from ether–petrol. By contrast, cleavage with a large excess (> 500 : 1) of neat pyridine gave **1a** (90%). The two isomers were readily distinguished by values of ^3J[PtH(Me)] (**1a** 31, **2a** 45 Hz), ^3J[PtH2,6(py)] (**1a** 40, **2a** 24 Hz), and δF2,6 (**1a** −150.4, **2a** −146.5 ppm). The relative magnitudes of the coupling constants are consistent with the *trans* influence order, py > Cl[10] and N(amido) > N(amine).[7] Dissolution of the new isomer, **2a**, in a large excess of pyridine gave **1a** and [Pt(*p*-$HC_6F_4NCH_2CH_2NMe_2$)$(py)_2$]$^+I^-$ (**4**). The latter gave two, equal intensity, H2,6(py) resonances [^3J(PtH) 40 Hz, py *trans* to —NMe_2; ^3J(PtH)27Hz, py *trans* to —N(*p*-HC_6F_4)] downfield from that of **1a**, and a F2,6 resonance well displaced from that of **2a**. A plausible isomerization path is:

$$\mathbf{2a} + \text{py} \longrightarrow \mathbf{4} \longrightarrow \mathbf{1a} + \text{py}.$$

Substitution by iodide *trans* to the amido nitrogen rather than *trans* to the amine nitrogen is as expected from their *trans* effects.[7,11] Reaction of dimers **3b–3d** with a limited amount of pyridine gave mixtures of isomers **1** and **2**.

Treatment of **3d** or **3c**/TlCl mixtures with dimethyl sulphoxide for 2 h followed by filtration and addition of water gave [Pt($RNCH_2CH_2NMe_2$)Cl(Me_2SO)] (R = *p*-HC_6F_4 or C_6F_5) with structures **2b** or **2c**, respectively. Observation of δ(Me) of Me_2SO at 3.3–3.4 ppm is indicative[12] of S-bonding, as is observation of platinum–hydrogen (SMe_2) coupling [^3J(PtH) *ca* 20 Hz] (see refs 12 and 13). Identification as isomer **2** is based on the magnitude of ^3J[PtH(NMe_2)] (40–45 Hz) which is consistent with —NMe_2 *trans* to halogen (see, for example **2a**) and far too large for —NMe_2 *trans* to sulphur (see, for example **1a** for —NMe_2 *trans* to py which has a *trans* influence less than S-bonded Me_2SO– cf. ν(PtCl) of *cis*-$PtCl_2(py)_2$[14] and *cis*-$PtCl_2(Me_2SO)_2$[15]). When a solution of **2b** in Me_2SO was stirred for 7 days, only slight conversion into **1b** occurred (**2b** : **1b** = 3 : 1).

The outcome of the cleavage reactions indicates that isomer **2** is the kinetically favoured product. Thermodynamic control favours isomer **1**, thus accounting for the earlier isolation of this isomer from decarboxylation reactions in boiling pyridines.[5,7]

Studies are continuing on the cleavage of the dimers **3** and of the factors influencing the structure, **1** or **2**, and isomerization of the product. Preliminary results indicate that $RNH(CH_2)_2NEt_2$ (R = *p*-HC_6F_4 or C_6F_5) ligands and their platinum dihalide complexes can also be prepared, opening a possible route to [Pt($RNCH_2CH_2NEt_2$)X(L)] complexes.

IMIDO COMPLEXES OF MOLYBDENUM AND TUNGSTEN(VI); X-RAY CRYSTAL STRUCTURE OF *cis*-(η^1-CF_3SO_3)$_2$ $W(NBu^t)_2(NH_2Bu^t)_2$

ANDREAS A. DANOPOULOS and GEOFFREY WILKINSON*

(*Received* 15 *September* 1989; *accepted* 28 *September* 1989)

Abstract—The synthesis of the homoleptic molybdenum imido compound $Li_2Mo(NBu^t)_4$ is reported. The complexes $M(NBu^t)_2(NHBu^t)_2$ (M = Mo, W) can be protonated with various strong acids giving neutral species. The X-ray crystal structure of the tungsten complex $W(NBu^t)_2(NH_2Bu^t)_2(SO_3CF_3)_2$ confirms the presence of O-coordinated *cis*-CF_3SO_3 groups.

The deprotonation of the imido amido compounds $W(NBu^t)_2(NHBu^t)_2$[1] and $Re(NBu^t)_3(NHBu^t)$[1,2] by methyllithium in diethyl ether gives rise to the homoleptic imido compounds $Li_2W(NBu^t)_4$ and $[Li(tmed)]Re(NBu^t)_4$, respectively, that are analogues of tungstate and perrhenate. The crystal structures of these first homoleptic transition metal imido compounds were also reported.[1] We have now synthesized the tetraimido molybdate, $Li_2Mo(NBu^t)_4$, by a similar procedure, i.e. interaction of MeLi in Et_2O on $Mo(NBu^t)_2(NHBu^t)_2$. The latter was obtained by interaction of $LiNHBu^t$ on $Mo(NBu^t)_2Cl_2$,[3] which in turn is obtained by the reaction of MoO_2Cl_2 and Bu^tNCO in refluxing acetonitrile.

Although we have been unable to obtain X-ray quality crystals of $Li_2Mo(NBu^t)_4$, the IR and NMR spectra are virtually identical to those of $Li_2W(NBu^t)_4$; thus in the ^1H NMR spectra there are two NBu^t resonances in a 1:3 ratio at 1.66(9) and 1.47(27) ppm—corresponding, respectively, to the terminal linear and bent bridging MNC groups as found[1] in the structure $[(Bu^tN)W(NBu^t)_3\mu\text{-}Li_2]_2$. The chemistry of $Li_2Mo(NBu^t)_4$ seems to be similar to that of the tungsten analogue, e.g. in forming $X_2Al(\mu\text{-}Bu^tN)_2W(\mu\text{-}NBu^t)_2AlX_2$ (X = CH_3, Cl) on interaction with AlX_3 in toluene.

The converse of deprotonation of $M(NBu^t)_2(NHBu^t)_2$, i.e. protonation, gives rise to electrically non-conducting amine complexes by protonation of the *t*-butylamido group using strong acids such as CF_3SO_3H, CF_3CO_2H, HBF_4 and HCl. The first two give similar species, e.g. $M(NBu^t)_2(NH_2Bu^t)_2(\eta^1\text{-}O_2CCF_3)_2$, that have, from IR and NMR spectra, *cis*-O-bonded acid groups. The structure of $W(NBu^t)_2(NH_2Bu^t)_2(CF_3SO_3)_2$ is shown in Fig. 1 and selected bond lengths and angles are given in Table 1. The molecule has octahedral geometry with the pairs of imido and unidentate triflate ligands each mutually *cis*, and the coordinated amines mutually *trans*.

Protonation by tetrafluoroboric acid gives a species which has only one coordinate anion and whose NMR spectra show that it is $W(NBu^t)_2(NHBu^t)$

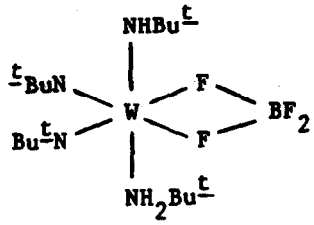
$(NH_2Bu^t)BF_4$. Thus the ^1H NMR spectra confirm the (NBu^t), $(NHBu^t)$ and (NH_2Bu^t) groups in a 2:1:1 ratio. The ^{19}F NMR spectra show two groups of magnetically inequivalent fluorine nuclei suggesting coordination of two fluorine atoms as in **1**.



1

Crystal data. $C_{18}H_{36}F_6N_4O_6S_2W$, $M_r = 766.53$. monoclinic, $a = 19.010(2)$, $b = 16.533(8)$, $c = 9.860(1)$ Å, $\beta = 102.64(7)°$, $V = 3038.3$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 1.674$, μ(Mo-K_α) = 40.85 cm^{-1}, $F(000) = 1520$, λ(Mo-K_α) = 0.71069. 4689 data measured ($-21 \leqslant h \leqslant 21$, $0 \leqslant k \leqslant 18$, $0 \leqslant l \leqslant 10$), $1.5 \leqslant \theta \leqslant 23°$ giving 4215 unique and 3351 observed [$F_o > 3\sigma(F_o)$]. The structure was solved by the heavy-atom method, refined by least-squares giving $R = 0.039$, $R_w = 0.043$ for 334 parameters, weights = $[\sigma^2(F_o)+0.00076F_o^2]^{-1}$. Tables of final atomic positional parameters and displacement factor coefficients, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Although complexing of the type M—F—BF_3 is most common,[4] more complex behaviour including triple bridging has been observed for $Mn(BF_4)_2$,[5] while the double fluorine bridge as in **1** has been considered as a possibility for $Cp''UF(BF_4)$ in solution [$Cp'' = \eta\text{-}C_5H_3(SiMe_2)_2$] although in the dimeric solid there is a U-μ-[FB(F_2)F]U bridge.[6]

Protonation of $W(NBu^t)_2(NBu^t)_2$ with HCl in Et_2O gives $[(Bu^tN)_2(Bu^tNH_2)_2ClW(\mu\text{-}Cl)]_2$, whose structure has been confirmed by X-ray study. A compound of similar stoichiometry obtained by interaction of WCl_6 and *t*-butyltrimethylsilylamine, was suggested on spectroscopic grounds to have bridging imido groups with *cis*-chlorine atoms on each tungsten.[7]

The new amine complexes are useful starting materials for synthesis of other complexes, as the NH_2Bu^t groups can be readily replaced by other ligands, e.g. pyridine. Studies on the reduction and other substitution reactions are in progress.

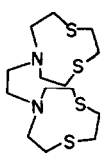
(*Received* 12 *September* 1989; *accepted* 4 *October* 1989)

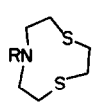
Abstract—During the course of studies directed towards the synthesis of kinetically stable silver(I) complexes, we have prepared a hexadentate bis-[9]-NS_2 ligand (**1**) which may be expected to form a series of stable octahedral complexes with many transition metal ions. The silver(I) complex has been characterized spectroscopically and crystallographically.

There are many examples of transition metal complexes in which two aza-coronands are N,N′-linked to form either mononuclear or dinuclear complexes depending upon the chain length separating each ring. Most have involved either [9]-N_3[1] or [12]-NX_3 (X = O, N or S)[2,3] coronands.

Reaction of N-(*p*-toluenesulphonyl)-3-aza-pentan-1,5-dithiol with 1,2-dibromoethane in DMF in the presence of Cs_2CO_3 afforded **2a** (43%, m.p. 123–124°C). Detosylation (HBr–AcOH–PhOH) yielded the amine **2b** (73%, m.p. 71-72°C) and further reaction with ethylene glycol ditosylate (0.5 equiv.) in MeCN gave the bis-coronand, **1** (53%,



I



2 (a) R = Ts
(b) R = H

m.p. 105–106°C). Admixture of **1** with silver nitrate in methanol followed by addition of NH_4PF_6 led to isolation of the colourless silver complex (*m/z* (FAB in 3-nitrobenzylalcohol) 461, 459 [M^+]). Analysis of pH-metric titration curves in the presence and absence of silver yielded $pK_1 = 6.53$, $pK_2 = 6.00$; $\log K_s$ [**1**·Ag]$^+$ = 7.00 (298 K, H_2O, $I = 0.1$ M NMe_4NO_3).

The crystal structure of [**1**·Ag]$^+$‡ (Fig. 1) revealed the silver to be bound by the ligand nitrogen and sulphur atoms in a very distorted octahedral coordination. Both the cation (and the PF_6

† Author to whom correspondence should be addressed.

‡ Crystals of [**1**·Ag]$^+PF_6^-$ are tetragonal, $a = 10.128(3)$, $c = 21.711(4)$ Å, $V = 2227(2)$ Å^3, $Z = 4$, $D_c = 1.81$ g cm^{-3}, $F(000) = 1224$, μ(Mo-K_α) = 13.8 cm^{-1}. The space group is either $P4(1)2(1)2$ or $P4(3)2(1)2$ from the systematic absence; $P4(1)2(1)2$ was established for the crystal used for the analysis by anomalous dispersion calculations. 1946 reflections were measured on a CAD4 diffractometer ($2 < 2\theta < 50°$). After corrections for Lorentz, polarization and absorption effects, 1050 unique reflections with $I > 3\sigma(I)$ were labelled observed and used in the structure solution and refinement. The structure was solved by the heavy-atom method and refined by full-matrix least-squares calculations. All hydrogen atoms were located and included as riding atoms in the calculations. At convergence, $R = 0.030$, $R_w = 0.035$. Full details of atomic coordinates and ion dimensions are available from the Director of the Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

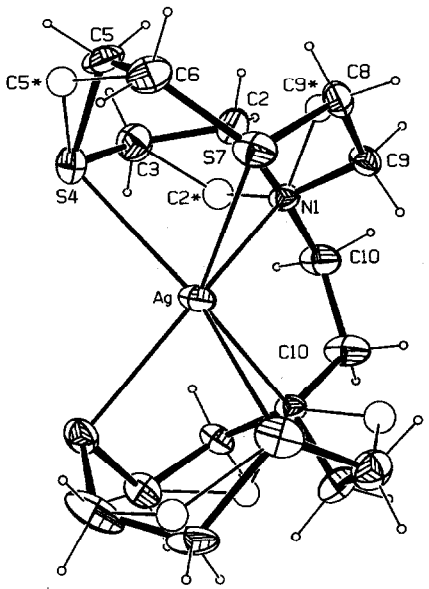


Fig. 1. The structure of $[1 \cdot Ag]^+$ in the crystal. Three of the carbon atoms in each nine-membered ring were found to be disordered over two sites (0.84:0.16 occupancies). The atoms of the minor component are shown by the open circles in the diagram. Selected bond lengths (Å) and bond angles (°): Ag—S(4) 2.802(2), Ag—S(7) 2.611(2), Ag—N(1) 2.586(3); S(4)—Ag—S(7) 80.90(7), S(4)—Ag—N(1) 74.0(1), S(4)—Ag—S(7)′ 93.04(6), S(7)—Ag—S(7)′ 149.62(6), N(1)—Ag—N(1)′ 73.7(1).

anion) have two-fold crystallographic symmetry, and there is one short (Ag—S(7) = 2.611(2) Å) and one longer silver–sulphur bond (Ag—S(4) = 2.802(2) Å). Although the structure resembles that of the 2:1-[9]-S_3 silver complex reported recently,[4] the planes through the S(4), S(7) and N(1) atoms in the two rings are not parallel but are inclined at an angle of 17° (enforced by the short —CH_2CH_2— link). The resultant coordination at silver is distorted octahedral in which the Ag—S(4)—S(7) and Ag—S(7)*—S(4)* moieties are twisted by 15° with respect to one another.

The synthesis of **2b**—the last of the [9]-X_3 series to be reported[5]—and of **1** (and its congeners) will permit the study of many more mono- and dinuclear transition metal complexes based on the [9]-NS_2 sub-unit. It may be expected that the presence of the sulphur donors will lead to the stabilization of further unusual oxidation states and geometries as described for homoleptic sulphur[4] macrocyclic complexes and some complexes of mixed aza-thia macrocycles.[6]

isopolymolybdate, 2605
lead(IV) phenyl vanadium complex, 2039
lithium alkylamide ether zirconium complex, 2515
lithium diamine diolate oxo manganese(III) complex, 2001
lithium molybdenum(II) alkylamide, 399
manganese(I) allyl carbonyl phosphido phosphite molybdenum(II) complexes, 987
manganese(III) methyl oxo lithium complex, 2001
mercury chloride thiolate complex, 2509
mercury nitrate pyrrolidinone silver complex, 1299
mercury pyrrolidinone thorium nitrate complex, 1807
molybdenum alkoxide alkyne cyclometallated imine nitrile complexes, 919
molybdenum alkylamido amine halide nitrosyl pyrazolyl-borate complexes, 1931
molybdenum carbonyl cyclopentadienyl dibismuth complex, 2239
molybdenum(0) carbonyl ethene isocyanide phosphine complexes, 1831
molybdenum(I) carbonyl cyclopentadienyl diphosphine complex, 1793
molybdenum(II) acetate chloride phosphinopyridine complex, 2201
molybdenum(II) acetate nitrosyl phenylamide pyrazolylborate complex, 103
molybdenum(II) allyl carbonyl cyclopentadienyl phosphido manganese(I) complexes, 987
molybdenum(II) arene carbonyl chloride complex, 2027
molybdenum(II) chloride diphosphine complexes, 463
molybdenum(II) chloride diphosphine nitrile thiophenoxide complexes, 2615
molybdenum(V) amidophenoxide diazenide methoxide oxo complex, 401

molybdenum(V) chloride complex, 2027
molybdenum(VI) diphenylcarbazone oxo complex, 401
molybdenum(VI) oxo tropolonate complex, 1129
neodymium proline water complex, 2495
nickel(II) chloride hydrazine complex, 1147
nickel(II) phenoxide pyridine Schiff base complex, 2641
nickel(II) thiolate, 1397
niobium(I) diene diphosphine hydride complex, 1819
niobium(V) chloride oxo phosphine complex, 2221
osmium acyl alkene carbonyl hydride complex, 1891
osmium alkyne carbonyl chloride mercury complex, 2159
osmium carbonyl chloride phosphide complex, 1759
osmium carbonyl isocyanide ketene complex, 791
osmium(II) benzotriazole carbonyl hydride phosphine complex, 1781
osmium(VI) aryl oxo complex, 1079
palladium(II) azobenzene sulphur - nitrogen complex, 647
palladium(II) carboxylates, 615
palladium(IV) bromide complex, 2611
peroxodiphosphates, 1305
platinum(0) alkene phosphine complex, 1349
platinum(II) chloride phosphido phosphine complex, 505
platinum(II) creatinine complex, 1273
platinum(II) diene diphosphine disulphurdinitride iron(II) complexes, 1925
platinum(II) porphyrin, 57
platinum(IV) hexasulphide complex, 1801
platinum(IV) methyl phosphonate cobalt(III) complexes, 2095
rhenium(I) amine carbonyl chloride hydride complex, 2543
rhenium(I) carbonyl chloride tetrahydrofuran complex, 1363
rhenium(I) carbonyl mercaptopyridine complex, 1401
rhenium(III) alkoxide chloride complexes, 1363
rhenium(III) chloride thioether complex, 1207
rhenium(III) iodide complex, 1667
rhenium(V) acetonitrile ammine chloride diazenide dimethylformamide hydrazide phosphine pyridine complexes, 171
rhenium(V) amine arylimide chloride complexes, 117
rhenium(V) polysulphide thio complex, 83
rhenium(VI) aryl oxo complex, 1079
rhenium(VII) alkylimido chloro aryl complexes, 1079
rhodium alkenyl arene cyclopentadienyl complex, 859
rhodium carbonyl diene hydride phosphine thio trinuclear complexes, 561
rhodium(I) carbonyl phosphine thiolate heteronuclear complexes, 2441
rhodium(III) chloride cyanide phosphine gold(I) complex, 651
rhodium(III) chloride hydrazine phosphine complex, 2087
ruthenium alkyne carbonyl thio cluster complex, 1071
ruthenium allylazaallyl carbonyl complexes, 2521
ruthenium(I) amine carbonyl triazenide complex, 1919
ruthenium(I,III) alkene alkenyl alkyl carbonyl cyclopentadienyl compound, 837
ruthenium(II) chloride cymene oxopyridinate complexes, 1311
samarium alkoxide azole cyclopentadienyl ether iodide isocyanide oxo complexes, 1693
selenium heteropolyborane anions, 17,187
silver cryptate Schiff base complex, 2229
silver pyrrolidinone mercury complex, 1299
tantalum(V) alkyl aryl phenoxide cyclometallated complexes, 753
tellurium(IV) dithiocarbamate perchlorate complex, 1267
titanium(III),tin(IV) chloride ether complexes, 2655
tungsten(II) acetonitrile carbonyl iodide complex, 245
tungsten(III) alkyl silylamide, 2049
tungsten(III) alkylamide carboxylate cyclopentadienyl complexes, 1991
tungsten(V) alkylamine alkylimido chloride complex, 297
tungsten(V) arylimido fluoride complexes, 2015
tungsten(VI) alkylimide arylimide chloride dipyridyl complexes, 117
uranium(IV) cyclopentadienyl vinyl complex, 1517
vanadium(-I) carbonyl lead complex, 2039
vanadium(II) bromide ether binuclear complexes, 737
vanadium(II) diphosphine isocyanide nitrile complexes, 2615
ytterbium diketonate pyrazolylborate, 79
zirconium alkylamide lithium complexes, 2515
zirconium chloride

cyclopentadienyl diazenyl methyl phosphido complexes, 2083
zirconium cyclopentadienyl diphosphine rhodium(I) complex, 2441
X-ray diffraction
iron(III) oxides, 385
nickel(II) phenanthroline complex hydrates, 1175
platinum(IV) hexasulphide complex, 1801
tin(IV) molybdate, 585
Xylyls
osmium(VI), 1079
rhenium(V),(VI),(VII), 1079
2,6-Xylylimido complexes
rhenium(VII), 1841
2,6-Xylylmethylidyne complexes
iron, ruthenium, 443

Y

Ytterbium
diacetylpyridinedihydrazone nitrate water complexes, 439
diketonate dipyridyl pyridine complexes, 155
diketonate pyrazolyborate, 79
Yttrium
diketonate pyrazolyborate, 79

Z

Zinc
acetate bromide diketonate pyridine complexes, 43
amine water complex, 2575
azole pyridine Schiff base complexes, 695
azole thioether water complex, 2591
benzoylhydrazone iron(II) complexes, 393
biuret halide complexes, 1869
chloride complexes, 2473
dithiocarboxylate mesogenic complexes, 1861
halide complexes, 2129,2473
halide hydrazone complexes, 1147
halide thione complexes, 2503
hydroxynaphthoate picolinate complexes, 1335
nitrite complexes, 213
peptide complexes, 1089
picolinate complexes, 689
polysalicylaldimine complexes, 1881
pyridine Schiff base thiolate complex, 2183
Zirconium(IV)
alkoxide amido carbonyl chloride cyanide hydride hydrosulphide hydroxide methyl phosphido silyl complexes, 1625
alkyl chloride cyclopentadienyl complexes, 2375
alkylamide lithium complexes, 2515
allyl cyclopentadienyl diene oxycarbene heteronuclear complexes, 2451
carbonyl cyclopentadienyl hydride ruthenium complex, 759
chloride cyclopentadienyl diazenyl methyl phosphido complexes, 2083
cyclopentadienyl diphosphine rhodium(I) complex, 2441
perchlorate, 345
Zirconoxy complexes
ruthenium, 759
