The magnitude of the measured analog voltage can be determined if the capacitance and the charging current are known. However, in practice, these values cannot be exactly determined. Therefore, a known reference voltage is used instead. This reference voltage is supplied by a very stable circuit known as a bandgap reference. The analog input voltage is determined ratiometrically by performing two successive A/D conversions, the first on the analog input voltage, and the second on the reference voltage. The analog voltage being measured can be calculated using the equation below.

EQUATION 3: VOLTAGE MEASURE

$$V_{IN} = \frac{N_{IN}}{N_{BG}} \times K_{BG}$$

N_{IN} = A/D count value for selected input.

N_{BG} = A/D count value for bandgap reference.

K_{BG} = Absolute voltage value of the bandgap reference voltage, stored in calibration space EPROM.

Equation 3 assumes that the starting voltage of the linear ramp (*V0*) in both the analog input and reference voltage conversions is zero. In practice, however, the capacitor cannot be discharged completely from the prior conversion and a few millivolts worth of charge,

© 1997 Microchip Technology Inc.

referred to as offset voltage, may remain on the capacitor. This effect is called capacitor dielectric absorption, and varies depending on the capacitor's dielectric material, the voltage to which it was charged during the last charge cycle, and the amount of time the capacitor has had to discharge. While teflon capacitors exhibit the lowest dielectric absorption, polystyrene and polyethylene are also very good. Ceramic, glass and mica are fair, and tantalum and electrolytic types are poor choices for A/D applications.

Additionally, the comparator (that compares the ramp voltage to the input voltage and stops the timer when the voltages are equal) usually has a few millivolts of offset error in its comparison. This comparator offset voltage adds (or subtracts) to the dielectric absorption offset. Finally, the counter that times the conversion may have a very small constant turn-on or turn-off delay that affects the measurement in the same manner as offset voltage.

In order to calculate an exact value for the analog input voltage, the various offset voltages must be factored into the equation. To do this, they are combined and measured.

The PIC14C000 provides two slope reference voltages for this purpose: upper and lower. The ratio of the magnitudes of these references is known and can be used to calculate the combined offset voltage.

This is done by performing conversions on both slope references, and using the supplied calibration constant for the ratio of their magnitudes, and calculating the offset voltage as an offset count. This offset count is then used in the other equations.

The equation used is that of calculating the x-intercept of a straight line when the slope of the line and two x coordinates are known.

EQUATION 4: OFFSET COUNT

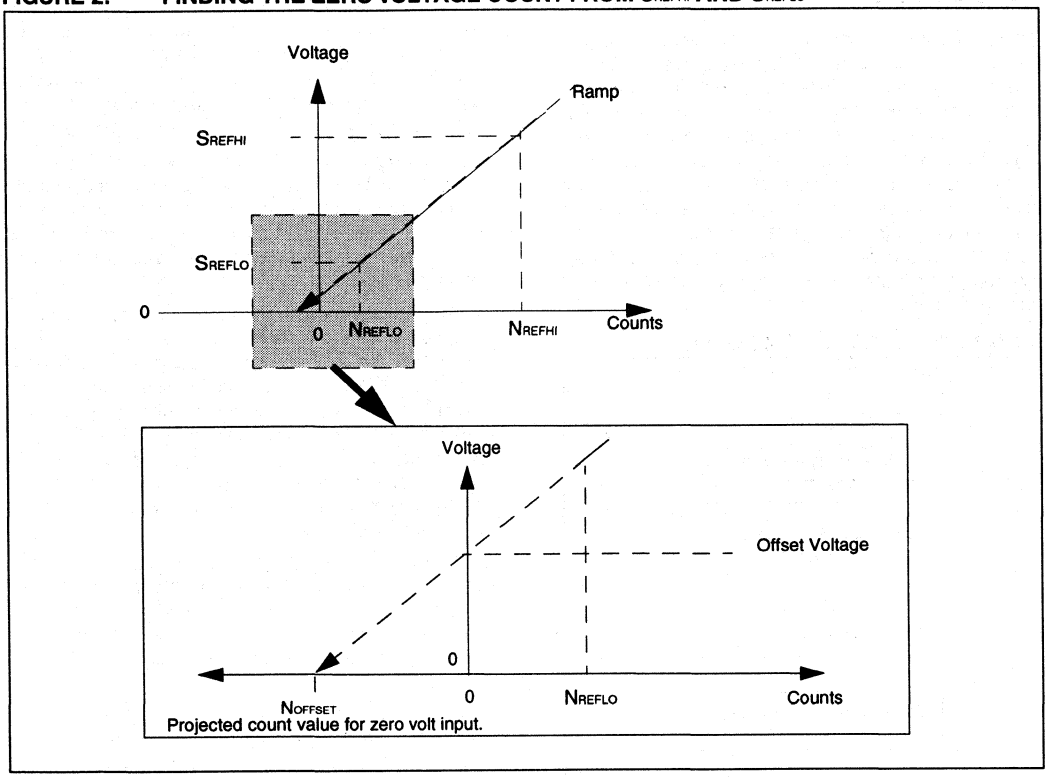
$$Noffset = Nreflo - Kref(Nrefhi - Nreflo)$$

Where:

N_{REFLO}	=	A/D count value low reference point.
N_{REFHI}	=	A/D count value high reference point
K_{REF}	=	S_{REFLO} / (S_{REFHI} - S_{REFLO}), stored in calibration space in EPROM.
S_{REFHI}	=	See PIC14C000 Data Sheet, section 8.
S_{REFLO}	=	See PIC14C000 Data Sheet, section 8.

This offset term and its measurement are illustrated graphically in Figure 2. Applying this offset term to the calculation of V_{IN} compensates the count obtained for both the input channel and the reference channel, to yield the counts as if each conversion did start from zero, instead of some offset voltage. Thus, the following equation may be used to determine the voltage at any input:

EQUATION 5: VOLTAGE AT ANY INPUT



$$V_{IN} = \frac{N_{IN} - N_{OFFSET}}{N_{BG} - N_{OFFSET}} \times K_{BG}$$

RA1/AN1 and RD5/AN5 Analog Input Pins

The AN1 and AN5 inputs pins have a special input offset feature that can allow these inputs to measure voltages that are either above or below device ground potential. This is accomplished with a summing junction that adds 0.5V to the signal at the pin before it reaches the A/D comparator. In order to determine the absolute voltage at the pin if the offset feature is turned on, two A/D conversions must be made. First, the input combined with the summing signal (0.5V) is converted. Then, a second conversion is performed with the AN1/AN5 side of the summing junction disconnected, resulting in just the 0.5V summing signal being converted. To compute the value of the voltage at the AN1/AN5 pin, the result from the second conversion is subtracted from the result of the first conversion.

IMPLEMENTATION

After initilization, the program continuously executes a 24 ms main loop. 16 ms is allocated for each A/D conversion, and 8 ms is allotted for calculations and other tasks. In order to conserve power and reduce noise in the A/D conversions, the CPU is put to sleep during each A/D conversion and during any unused portion of the 8 ms calculation time (Figure 3). This timing scheme allows both the charging time and the discharging time of the voltage ramp capacitor to be constant. This aids in achieving accurate A/D conversions by keeping the offset voltage due to capacitor dielectric absorption constant.

FIGURE 3: PROGRAM FLOW

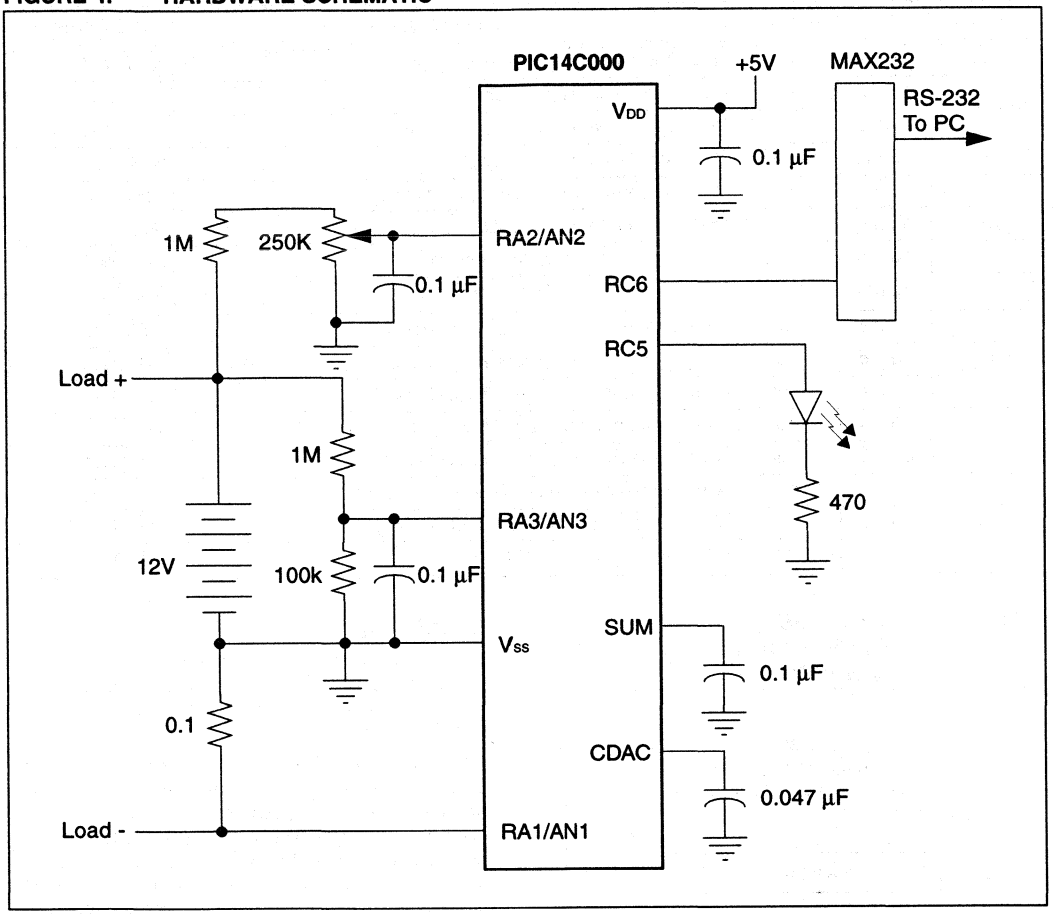
Hardware Allocation

For this application note, three external analog input channels are used. RA1/AN1, RA2/AN2, and RA3/AN3 are assigned to battery current measurement, battery voltage measurement, and external voltage measurement (in this case a potentiometer), respectively.

Since the A/D converter measures voltage, and not current, the battery current measurement is obtained by measuring the voltage drop across a low value resistor (in this case 0.1 ohm). Actual battery current is then calculated by the firmware using the value of the resistor and Ohms law.

Battery voltage measurement requires that an external resistive voltage divider be used to lower the voltage input into the A/D converter's range. A divider that results in an A/D input voltage that is as near as possible to the bandgap reference voltage is normally selected, since it reduces ratiometric errors during the calculation of the voltage. The firmware calculates the actual battery voltage from the voltage measured at the AN3 pin by multiplying the measured value by the external voltage divider ratio.

The external potentiometer voltage measurement is an auxiliary measurement, and could be used for measuring a thermistor, individual cell voltages, or other parameters. No scaling of this voltage is performed. The program simply reports the voltage sensed at the AN2 pin.



This program assumes that a 0.047 µF capacitor is connected between the CDAC pin of the device and ground. It is used for creating the ramp voltage for the A/D conversion process. Optionally, a 0.1 µF capacitor can be connected between the SUM pin and ground to allow for increased filtering of the battery current (AN1) input.

Port RC6 is used to transmit four parameters: battery current, battery voltage, internal temperature, and AN3 voltage. The format is 9600 baud (8,N,1) RS-232. Each parameter consists of four bytes and is in PICmicro™ 32-bit floating point format. Refer to AN575 for more information on floating point format.

For monitoring purposes, the program will toggle the RC5 output every ~384 ms. It will drive RC5 high just prior to starting the RS-232 data transmission, and drive it low after completing the transmission. If an LED and current limiting resistor are connected to RC5, a visible "heartbeat" indication will appear when the program is running in a normal manner.

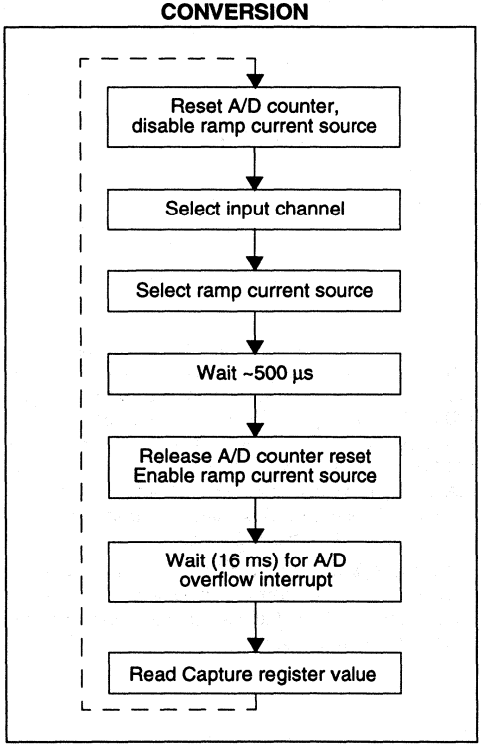
FIGURE 4: HARDWARE SCHEMATIC

A/D Conversion

The analog to digital conversion firmware modules control the operation of the analog to digital converter hardware. They convert the raw data received from the hardware into physical voltage values. This is accomplished by obtaining readings from the external inputs, the on-chip bandgap reference, and the on-chip A/D reference circuits. The physical voltages at the external inputs are computed based on these readings.

A/D Input Interleaving Sequence

Interleaving the selection of analog inputs scheduled for conversion maximizes the sampling rate for high priority signals such as the battery current, and reduces the sampling rate for low priority signals (that change at relatively slow rates), such as temperature inputs. The following interleaving scheme places the inputs in priority order from highest to lowest. Battery current is the highest priority with eight samples in 16 A/D cycles (~384 ms). Battery voltage is sampled two times in 16 A/D cycles. Battery temperature, via the external thermistor input and internal temperature, is sampled once each during 16 A/D cycles. Current network zero voltage, bandgap voltage, the A/D lower reference voltage, and the A/D upper reference voltage, are each sampled once for every 16 conversion cycles.



Conversions are scheduled at fixed intervals based upon the maximum conversion time to overflow (16 ms). This fixed scheduling method maintains determinism in the overall system.

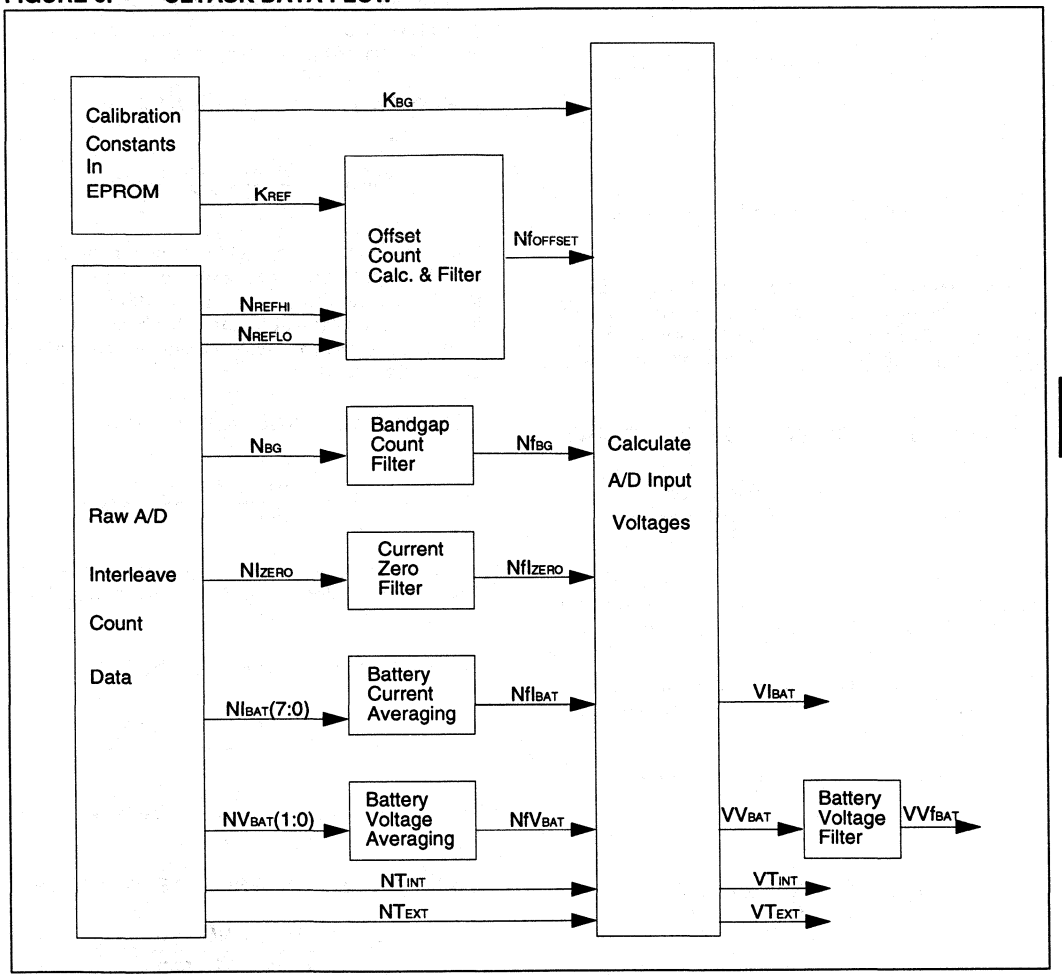
FIGURE 5: SEQUENCE FOR PERFORMING A SINGLE A/D CONVERSION

A/D Filtering



Due to the high resolution of the PIC14C000 A/D converter, digital filtering of the A/D count data is performed. This will reduce noise in the A/D readings, and enhance performance.

A/D count data is converted to PICmicro floating point format prior to being used in any calculation. All results are retained in floating point format as well. DC inputs such as bandgap reference voltage, slope reference high, slope reference low, and current zero offset voltage are filtered with long time-constant filters. Dynamic signals, such as battery voltage and current, are filtered less. Internal temperature and AN3 external voltage are not filtered at all. All calculated outputs are in voltage units. Figure 6 diagrams the data flow through the filtering and calculation task.

The formulas on the following page are used to filter the raw count data obtained from the A/D converter prior to calculating the actual voltage values for the A/D inputs. This filtering stabilizes the reference values to enhance A/D accuracy. The bandgap and offset reference are DC signals, so no information is lost by the filtering process.

© 1997 Microchip Technology Inc.

FIGURE 6: CLTASK DATA FLOW

The count value for the bandgap voltage reference is filtered by calculating the rolling average of the last 16 count values obtained. This filtered value of bandgap count is then used to calculate the input voltages. The subscript i denotes the interleave sequence number, not the conversion number within the interleave sequence.

The count offset value is filtered by calculating the rolling average of the last 16 count values obtained. The filtered value of the offset count is then used in Equation 6 to calculate the input voltages.

EQUATION 6: FILTERED BANDGAP COUNT

$$Nfbg = \frac{NBG_i + 15 \times Nbg_{i-1}}{16}$$

EQUATION 7: FILTERED OFFSET COUNT

$$Nfoffset = \frac{Noffset_i + 15 \times Noffset_{i-1}}{16}$$

where:

$$NOFFSET_i = NREFLO_i - KREF(NREFHI_i - NREFLO_i)$$

The current-input zero offset value is filtered by calculating the rolling average of the last 16 count values obtained. This filtered value of the current-input zero offset is used in the equation to calculate the input voltages.

EQUATION 8: FILTERED ZERO-CURRENT

$$NfIZERO = \frac{NIZERO_i + 15 \times NIZERO_{i-1}}{16}$$

The following formulas are used to filter the raw count data obtained from the battery voltage and current input channels. These filtered values are then used for communication and control functions.

The battery current value is filtered by taking the average of the eight samples of the input channel from the interleave sequence.

EQUATION 9: FILTERED CURRENT COUNT

$$NfIBAT = \left(\frac{1}{8}\right) \sum_{s=0}^{7} (NIBAT_S)$$

The count value for the battery voltage input is filtered by calculating the average of two samples of the input channel from the interleave sequence.

EQUATION 10: FILTERED VOLTAGE COUNT

$$NfVBAT = \left(\frac{1}{2}\right) \sum_{s=0}^{1} (NVBAT_S)$$

Calculation of Input Voltage Values

The following formulas are used to calculate the digital value for each of the input voltages.

EQUATION 11: VOLTAGE AT AN1

$$VIBAT = \frac{NIBAT - NfIZERO}{Nfbg - Nfoffset} \times KBG$$

VIBAT refers to the voltage at the battery current input, AN1. Note that there is no NfOFFSET term in the numerator. The NfOFFSET components of the NfIBAT and NfIZERO terms are canceled out by the subtraction. The equations for the remaining inputs all follow the general form given in Equation 5.

EQUATION 12: VOLTAGE AT AN0

$$VVBAT = \frac{NfVBAT - NfOFFSET}{NfbG - NfOFFSET} \times KBG$$

VVBAT refers to the voltage at the battery voltage input, AN0. Additional filtering is added to the computed VVBAT signal using the equation:

EQUATION 13: FILTERED VOLTAGE

$$VVfBAT = \frac{VVBAT_i + 7 \times VVbat_{i-1}}{8}$$

Temperature terms are calculated directly without any added filtering.

EQUATION 14: INTERNAL TEMPERATURE

$$VTINT = \frac{NTINT - NfOFFSET}{NfbG - NfOFFSET} \times KBG$$

VTINT refers to the voltage at the internal temperature sensor.

EQUATION 15: EXTERNAL TEMPERATURE

$$VTEXT = \frac{NText - NfOFFSET}{NfbG - NfOFFSET} \times KBG$$

VTEXT refers to the voltage at the external temperature sensor input.

© 1997 Microchip Technology Inc.

Conversion to Physical Units

The physical unit values (i.e., temperature, battery voltage, battery current) for the input voltages are computed prior to being transmitted via RS-232. To reduce data storage requirements, these values are not maintained in memory, but are destroyed after they are transmitted. Scaling constants read from EPROM are used to convert the voltage values measured at the pin into the appropriate physical value. The voltage at the AN2 pin is not scaled prior to transmission; the actual voltage at the pin is transmitted.

Current

$$I_{BAT} = \frac{V_{IBAT}}{R_{ISENSE}}$$

I_{BAT} = Battery current.

V_{IBAT} = measured voltage at RA1/AN1 pin.

R_{ISENSE} = External current sense resistor value (stored in user EPROM).

Voltage

$$V_{BAT} = VVf_{BAT}(V_{BAT}R_{DIV})$$

V_{BAT} = Battery voltage.

VVf_{BAT} = Filtered measured voltage at RA3/AN3 pin.

R_{DIV} = External resistor divider ratio for RA2/AN2 pin (stored in user EPROM).

Temperature

$$T_{EMPINT} = \frac{VT_{INT} - Vtherm}{Ktc} + 298.15$$

T_{EMPINT} = Temperature in degrees Kelvin.

VT_{INT} = measured temperature sensor voltage value.

V_{THERM} = Factory calibrated voltage value of the temperature sensor at 298 Kelvin (stored in calibration place in EPROM)

K_{TC} = Factory calibrated temperature constant of temperature sensor in volts per degrees Kelvin (stored in calibration space in EPROM).

RS-232 COMMUNICATION

The physical battery current, voltage, temperature, and RA3/AN3 voltage values are transmitted on the RC6 pin in 8,N,1 RS-232 format.

The transmit routine is designed to make use of the PIC14C000's calibrated internal (IN) oscillator. The oscillator frequency, stored in the factory calibration EPROM, is used as an index into a bit-delay lookup table. The bit-delay value controls the number of instructions executed during the software delay routine and is used to generate the time between bits being transmitted. The time resolution of this lookup table method results in a worst- case bit time error of less than two percent.

Several look up tables for baud rate are included as assembly time options. Normally the 9600 baud option is used.

ASSEMBLY FILES

The program code for this application note is available on the Microchip BBS as the AN624.ZIP file. Once the file is unzipped, the user should read the README file for further instructions.

Lead-Acid Battery Charger Implementation Using PIC14C000

Author: *Dan Butler*
Microchip Technology Inc.

INTRODUCTION

The PIC14C000 comes with several peripherals specifically aimed at the battery market. The programmable reference and onboard comparators are useful for creating charge control circuits, while the analog-to-digital (A/D) converter can monitor the charge state to prevent overcharge. The control software is written in "C" for maintainability and transportability. Where necessary, in line assembly is used.

This application note is intended to demonstrate the use of the PIC14C000 in an intelligent battery charger. The charger is designed to charge a sealed lead-acid battery (YUASA NP7-12 12V, 7AH); however, the charge parameters are easily modified to work with different lead-acid batteries.

The typical method of charging lead-acid batteries is with a constant voltage, current-limited source. That method allows a high initial charge current that tapers off until the battery reaches full charge.

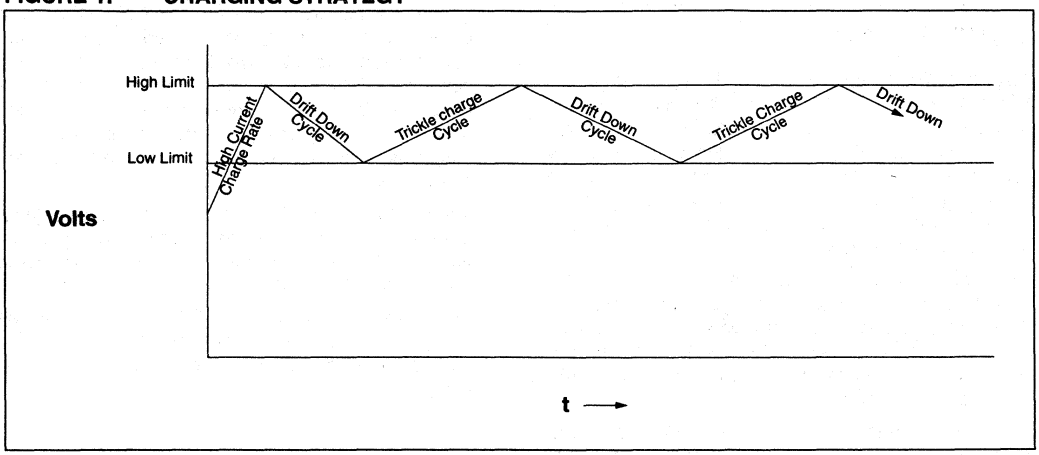
This design uses a constant current, allowing the voltage to rise until the battery voltage reaches a full charge. The charge current is then turned off to prevent overcharging. This allows a high initial charge to quickly bring the battery to a full charge and a low maintenance charge current as needed to maintain the full charge. The constant current design is also easily adaptable to NiCd batteries.

As voltage rises during the charge cycle of the lead-acid battery, it quickly passes 2.1 V/cell. As charging progresses, oxygen begins to be liberated at the positive plates at 2.2 V/cell. At 2.3 V/cell, hydrogen is liberated at the negative plates. This is considered a full charge, as any further current passed into the cell simply releases gasses rather than charging the battery. Hence, the upper voltage limit is set at 13.8V (2.3 V/cell), and the lower voltage is set at 12.6V (2.1 V/cell). As a practical consideration, the lower voltage limit is set slightly lower (12.5V) to lengthen the charge cycles. The battery voltage takes just minutes to decay from over 13.8V to 12.6V. It then takes several hours to decay from 12.6V to 12.5V.

THEORY OF OPERATION

Charge current is controlled by a comparator and programmable reference onboard the PIC14C000. The other side of the comparator is fed by the voltage across a sense resistor. The output of the comparator controls a FET (Q1), which switches the charge voltage on and off. The charge is interrupted once-per-second to read the battery voltage. When it reaches a maximum voltage, the charge current is shut off to prevent overcharge.

The PIC14C000 continues to monitor battery voltage. Over time, the battery voltage decays. When the voltage drops below the lower threshold, the trickle charge is activated to bring the battery back up to full charge.



The computing power of the PIC14C000 allows the charger to accurately control the charge cycles to quickly recharge the battery while preventing overcharge.

© 1997 Microchip Technology Inc.

CHARGING STRATEGY

First, charge at a high rate (1A for this battery) until the battery voltage is above the high limit (13.8V). The charge current is then cut off, allowing the battery voltage to decay until it descends past the low limit (12.5V). A low current charge (150 mA) is then applied to again bring the battery voltage up past the high limit. The drift-down/trickle charge cycle repeats (Figure 1).

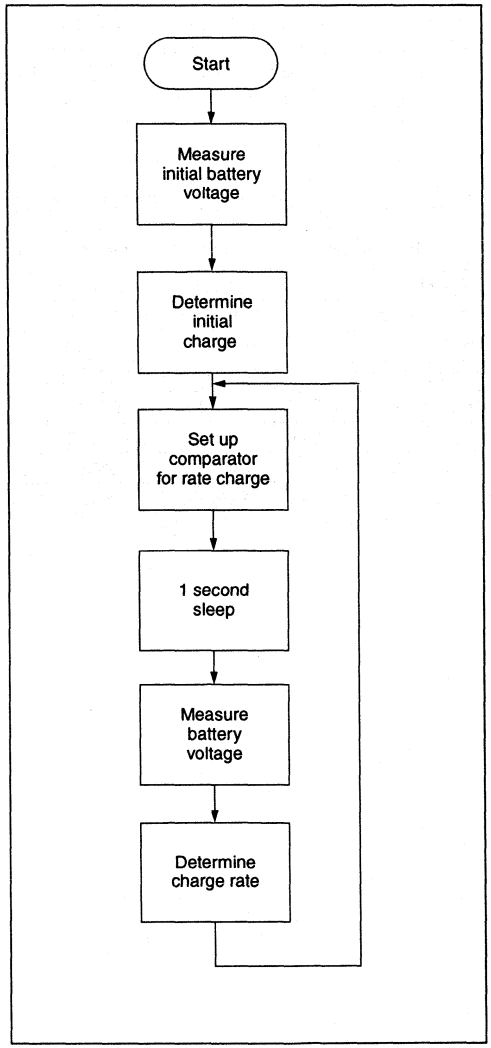
FIGURE 1: CHARGING STRATEGY

© 1997 Microchip Technology Inc.

ALGORITHM

The controller starts by measuring the voltage on the battery to determine the initial charge rate (high, low or off). Next, it sets up the comparator to control the constant current charge and then goes to sleep.

Note: The comparator continuously controls the current even while the controller sleeps.



After 1 second, the watchdog timer (WDT) wakes the controller, and the battery voltage is measured again. If any of the trip points are reached, the charge rate is adjusted. After the comparator is reset, the controller goes back to sleep, and the cycle repeats (Figure 2).

Once the measurement/decision cycle is complete, the controller goes to sleep for about 1.15 seconds (subject to the drift of the WDTs internal RC oscillator). Time-out of the WDT wakes up the controller and continues the cycle. The sleep cycle is used to save power and let the hardware do the work of counting the time rather than using timing loops.

Two LEDs are included to provide feedback on what the charger is doing. The red LED signifies a high current charge, and the green LED signifies a low current charge. While the charge is in progress, the active LED blinks at 1 Hz. This is the momentary suspension of charging while the battery voltage is measured.

As the battery ages, it may no longer be able to charge up past the high charge threshold. Time limits have been implemented to account for this. The high charge and low charge cycles have maximum time limits associated with them. The discharge cycle has a minimum time limit.

FIGURE 2: CONTROLLER FLOW CHART

Algorithm Parameters:

These parameters are #defines at the top of the code, meaning the code must be recompiled to change the parameters. The hardware could be modified to include dip or rotary switches to change some or all of these parameters.

TABLE 1: CONTROLLER PARAMETERS

Parameter	Units	Range†	Resolution†	Format	Description
V limit low	Volts	0-255.996	.00390625	Fixed point (16:8)	Minimum battery voltage
V limit high	Volts	0-255.996	.00390625	Fixed Point (16:8)	Maximum battery voltage
High current	Amperes	0-255.996	.00390625	Fixed point (16:8)	High charge current
Low current	Amperes	0-255.996	.00390625	Fixed Point (16:8)	Low charge current
High charge time limit	Minutes	0-65536	1	Unsigned long	Maximum time for high charge
Low charge time limit	Minutes	0-65536	1	Unsigned long	Maximum time for low charge
Charge rest time	Minutes	0-65536	1	Unsigned long	Minimum no charge time

† Range and Resolution are the mathematical precision that can be expressed with the parameter, not necessarily what the circuit is capable of.

© 1997 Microchip Technology Inc.

HARDWARE

The PIC14C000 provides two comparators and programmable references (Figure 3). One set is used to maintain the charge current on the battery. Once the comparator is set up, it controls the current without processor intervention. The other comparator is not used in this application; however, it could be used to control current on a second battery to implement parallel charging. Battery voltage is measured using the 16-bit A/D converter.

The board used assumes the existence of an external power supply. This supply needs to provide some headroom above the expected maximum battery voltage and supply enough current for the selected high charge current. In this example, a 16.7V, 2.6A power supply was used.

The charger current to the battery is controlled by the comparator/buck converter. When the comparator senses that the charge current is too high, it pulls the gate of the Q1 low, turning off the current from the power supply and allows current to flow through D2. The buck converter (L1, C2, and D2) takes over and modulates the current to the battery at a controlled rate. When the comparator senses the charge current is too low, it turns on, allowing current from the power supply to flow through Q1. The buck converter now increases current at a controlled rate.

The component values for L1 and C2 are chosen based on the operating parameters of the system. For this system, the buck converter frequency is 15 KHz. The inductor (L1) is calculated from the equation:

$$L = ((V_I - V_{SAT} - V_O)/I_{PK}) \bullet T_{ON}$$

where:

V_I	=	Input Voltage.
V_O	=	Output Voltage.
V_{SAT}	=	Saturation voltage of transistor.
I_{PK}	=	2 Io maximum.
$I_{O\ MAX}$	=	Maximum output current.
T_{ON}	=	"On Time" of duty cycle (output of comparator).

For this design, V_I = 16.7 V, V_{SAT} = 0.25V, V_O = 6.0V (minimum to support 6V battery) I_{PK} = 2A, T_{ON} = 54 µs (80% duty cycle for high current charge):

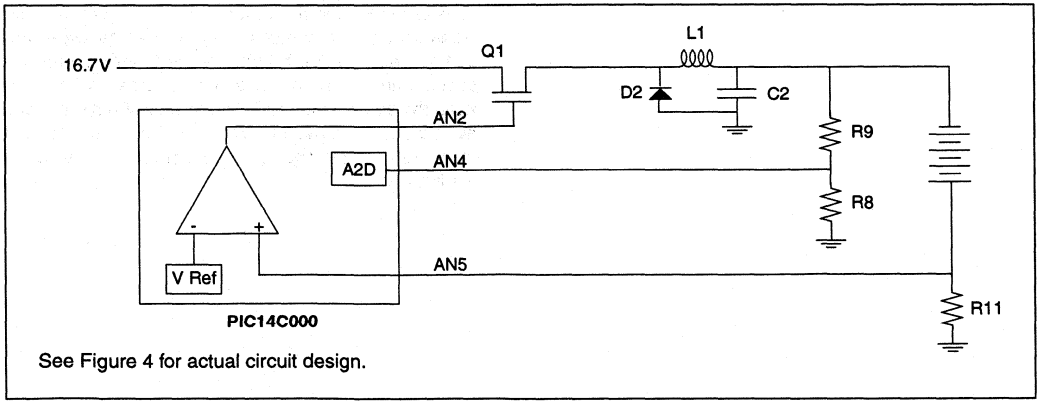
$$L = ((16.7 - 0.25 - 6.0)/2) \bullet 5\mu s = 282\mu H$$

The output capacitance is chosen such that:

$$C_O \geq I_{PK}T/(8V_{RIPPLE})$$

where:

I_{PK}	=	2 Io maximum
$I_{O\ MAX}$	=	Maximum output current
T	=	Total comparator cycle time
V_{RIPPLE}	=	Output voltage ripple



For this design:

$$I_{PK} = 2A, T = 66\mu s, V_{RIPPLE} = 400mV$$

$$C_O \geq (2 \bullet 66)/(8 \bullet 400mV) = 41\mu f$$

The diode (D2) needs to be sized large enough to handle I_{PK}.

FIGURE 3: SIMPLIFIED SCHEMATIC

See Figure 4 for actual circuit design.

DETAILS OF THE SOFTWARE IMPLEMENTATION

Constant Current Control

The comparator is used in conjunction with a programmable voltage reference to control the current into the battery. The voltage reference feeds one side of the comparator, while a sense resistor feeds the other. The output switches a FET to control the current. The voltage reference (PIC14C000 Data Sheet, Section 9 DS40122) is programmed as follows:

$$V = Current \bullet SenseResistor + LevelShift$$

where:

Current	=	The value we want the comparator to control to.
Sense Resistor	=	The value of the current resistor (0.2 Ohms).
Level Shift	=	The 0.5V shift performed on the voltage at the sense resistor (PIC14C000 Data Sheet, Section 9.2 – DS40122B).

This voltage is used in a lookup table which returns the coarse bits (PREFx<7:3>) for the programmable reference. The fine bits (PREFx<2:0>) are calculated as the difference between the voltage and coarse range, divided by the resolution of the table.

Analog-to-Digital Conversion

The battery voltage is measured via the A/D converter. The main program turns off the charger, then runs a conversion on the battery channel. Function AD_Counts performs 16 conversions on the channel, subtracts off the comparator/capacitor offset, and returns the average. The averaging is necessary to remove the noise from the system. The same A/D conversion is also performed on the internal bandgap reference. These values are then used in the following equation from AN624 to obtain the A/D converter voltage:

$$V_{IN} = ((N_{IN} - N_{OFFSET})/(N_{BG} - N_{OFFSET})) \bullet K_{BG}$$

The A/D converter operates most accurately with voltages near the bandgap reference. Therefore, the hardware runs the battery voltage through a voltage divider (R8 and R9) to drop the battery voltage (approximately 13V) down to 1.2V. The battery measurement calculation then multiplies the result from the A/D converter by the resistor ratio to get the original battery voltage:

$$BatteryVoltage = V_{IN} \bullet (R8 + R9)/(R8)$$

Recalibrating the A/D converter (Measuring NOFFSET and NBG) to compensate for component drift is done every cycle. Since the components do not drift very quickly, it's not necessary to recalibrate this frequently, however, it is more accurate and takes advantage of otherwise idle processor time. If processor time is a concern, recalibrating once per minute is sufficient.

Time Keeping

The program counts the seconds to limit the charge cycles on the battery. The WDT times out about every 1.15 seconds, and the rest of the measurement cycle takes about 0.1 seconds, giving have a total cycle time of 1.25 seconds. Each bump of the timer counts for 1 second, and every fourth second another is added to keep the count accurate. This method of timing is only accurate to a few percent. While not good enough for a clock, it's accurate enough to limit the charge cycles on the battery.

© 1997 Microchip Technology Inc.

Math

Fixed point math is used where resolutions of less than one are needed. This code can be updated to use floating point or 32-bit integers, which will allow a cleaner implementation of the calculations required. For this example, limited versions of basic Add/Subtract/Multiply/Divide functions operating on positive 32-bit integers are used. File "MATH32.C" implements 32-bit add, subtract, multiply, divide, and shift. The add, subtract, divide, and shift functions start with 32-bit values and give 32-bit results. The multiply starts with 32-bit multiplicands and gives a 64-bit result.

Charging Circuit Bench Results

When the programmable voltage reference was set to supply the fast charge current of 1A, the actual charge current was measured within 50 mA. However, when the programmable voltage reference was set to supply 150 mA trickle current, the actual output was measured to be as high as 275 mA. This higher trickle current is acceptable for this application since its purpose is to keep the battery topped off at full charge.

This delta is due to design limitations encountered when integrating analog components onto a digital substrate.

Converting the Charger to Work With Other Lead-Acid Batteries

This application note was specifically written to charge a YUASA 12V, 7AH battery, however other batteries may be charged with few modifications. Most of the charge algorithm parameters are in software. However, if the voltage is other than 12V, different resistors (R8 and R9) may be needed in the voltage divider leading to the A/D converter. For example, to charge a 6V, 2AH sealed lead-acid battery requires the necessary changes:

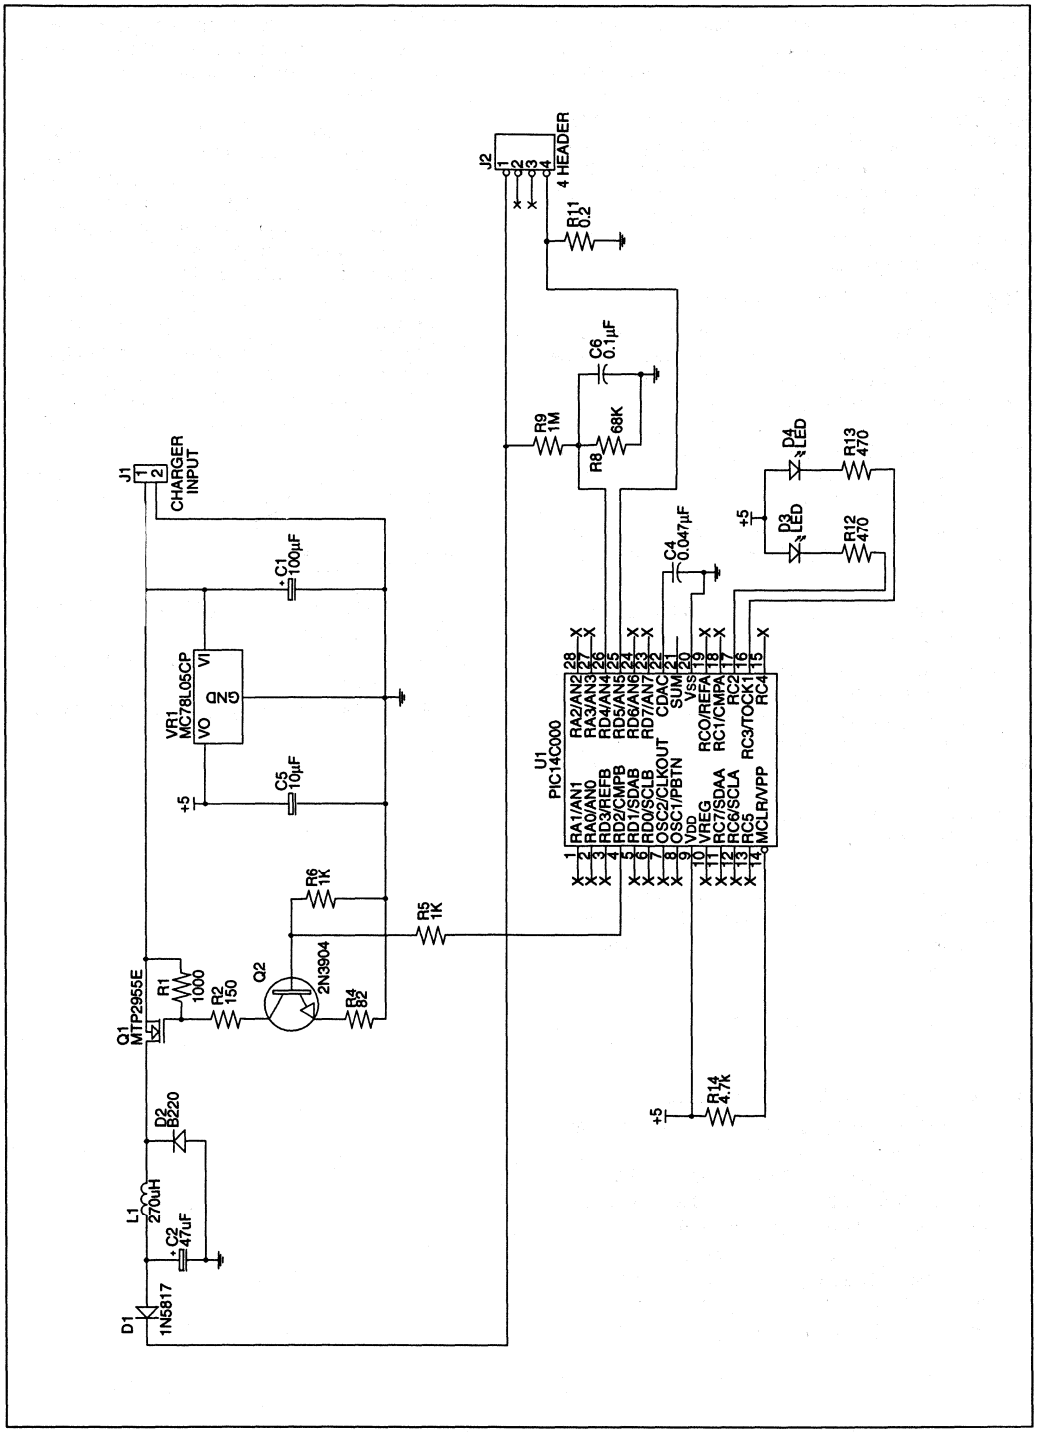
1. Swap R8 for a 137Ω, which will keep the voltage at the A/D converter around the 1.2V optimum.
2. Change the multiplier at the bottom of AN624, Equation 5 to:

$$\frac{(R9 + R8)}{R8} = \frac{(1M + 137K)}{137K} = 8.29927$$

3. Lower the power supply voltage (9V, 1A).
4. Change the charging parameters (#defines at the top of the code):
   a) V_LIMIT_HIGH 7.2V (0x0733 = 7.2 • 256)
   b) V_LIMIT_LOW 6.3V (0x064C = 6.3 • 256)
   c) HIGH_CURRENT (No change)
   d) LOW_CURRENT (No change)
   e) HIGH_CHARGE_TIME_LIMIT 120
   f) LOW_CHARGE_TIME_LIMIT 180
   g) CHARGE_REST_TIME 0

Conclusions

The PIC14C000 has several onboard peripherals that are specifically designed to simplify battery management applications. Further enhancements could be made such as:



1. Use an onboard temperature sensor to monitor battery temperature, which is another sign of overcharging. Once an over temperature condition is detected, the charge cycle would be terminated regardless off the battery voltage. This, however, would require the PIC14C000 to be physically attached to the battery. Alternatively, a remote temperature sensor could be mounted to the battery and read via the A/D converter.
2. The internal RC oscillator frequency drifts with temperature. This drift rate is known and stored in the calibration data (KTC), which would allow the timer to compensate with more accurate timing.
3. If better charge current accuracy is required, the charging circuitry should be implemented using external components.

/*************************************************************************
*       AN624Eq5
*              Takes the conversions previously done on the battery and the
*              Bandgap, along with the calibration data in memory, and
*              performs AN 624 Equation 5 to convert the battery counts
*              back to the original voltage.
*
*              An 624 Equation 5:
*                     V = (Nin - Noffset) / (Nbg - Noffset) * Kbg
*                     (Subtraction of Noffset is performed in ADC_Counts).
*              Actual Calculation performed here:
*                     V = AvgNin * Kbg / AvgNbg
*              This answer gives the voltage at the ADC, however the circuit
*              uses a resistive divider to take the ~12V at the battery down
*              to the ~1.2V for the ADC.  We need to multiply by the ratio
*              of the resistances to get actual battery voltage.
*                     Vbattery = V * (1Mohm + 68Kohm)/68Kohm
*                              = V * 15.70588  (Nominal values)
*              For best accuracy, use measured values on the resistors
*                              = V * 15.95981  (Actual values: 1072180 / 67180)
*
*              Input Variables:
*                     Nbattery unsigned int (16 bits)
*                     Nbg      unsigned int (16 bits)

/*************************************************************************
* Main Loop:  starts of by reading battery voltage and determining
* type of charge needed (HIGH CURRENT, LOW CURRENT, NO CURRENT).
* Then every second it takes a voltage reading on the battery.  If it's
* above the highest limit, it turns off the charge.  If it's drained
* down below the lower limit, it turns on the trickle charge.  Only
* way it can get set to fast charge is on startup.
*
* The processor is put to sleep for remainder of charging cycle (about 1S).
* WDT is setup to wake up the processor for the next cycle.
*
* state transition diagram:  HIGH -> OFF <---> LOW
* HIGH transitions to OFF when V_LIMIT_HIGH is exceeded.
* OFF transitions to LOW when battery voltage has drained below V_LIMIT_LOW
* LOW transitions to OFF when V_LIMIT_HIGH is exceeded.

Adaptive Differential Pulse Code Modulation using PICmicro™ Microcontrollers

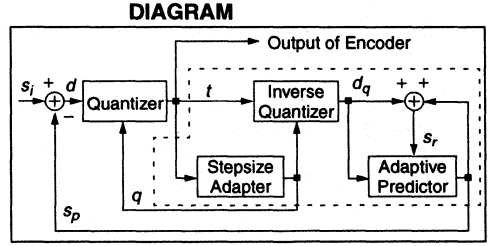
Author: *Rodger Richey*
Microchip Technology Inc.

INTRODUCTION

In the past, adding speech recording and playback capability to a product meant using a digital signal processor or a specialized audio chip. Now, using a simplified Adaptive Differential Pulse Code Modulation (ADPCM) algorithm, these audio capabilities can be added to any PICmicro device. This application note will cover the ADPCM compression and decompression algorithms, performance comparison of all PICmicro devices, and an application using a PIC16C72 microcontroller.

DEFINITION OF TERMS

step size - value of the step used for quantization of analog signals and inverse quantization of a number of steps.
quantization - the digital form of an analog input signal is represented by a finite number of steps.
adaptive quantization - the step size of a quantizer is dramatically changed with time in order to adapt to a changing input signal.
inverse quantizer - a finite number of steps is converted into a digital representation of an analog signal.



THEORY OF OPERATION

The ADPCM algorithm takes advantage of the high correlation between consecutive speech samples, which enables future sample values to be predicted. Instead of encoding the speech sample, ADPCM encodes the difference between a predicted sample and the speech sample. This method provides more efficient compression with a reduction in the number of bits per sample, yet preserves the overall quality of the speech signal. The implementation of the ADPCM algorithm provided in this application note is based on the Interactive Multimedia Association's (IMA) Recommended Practices for Enhancing Digital Audio Compatibility in Multimedia Systems revision 3.00. The ITU (formerly CCITT) G.721 ADPCM algorithm is well known and has been implemented on many digital signal processors such as the TMS320 family from Texas Instruments and the ADSP-2100 family from Analog Devices. ITU G.721 uses floating point arithmetic and logarithmic functions which are not easily implemented in the 8-bit microcontroller world. The IMA Reference algorithm significantly reduces the mathematical complexity of ITU G.721 by simplifying many of the operations and using table lookups where appropriate.

COMPRESSION

The input, s_i, to the encoder routine must be 16-bit two's complement speech data. The range of allowable values for s_i is 32767 to -32768. Figure 1 shows a block diagram for ADPCM compression and Appendix A has a listing of the function `ADPCMEncoder()`. The predicted sample, s_p, and the quantizer step size index are saved in a structure for the next iteration of the encoder. Initially, the quantizer step size index and the predicted sample (s_p) are set to zero. The encoder function takes a 16-bit two's complement speech sample and returns an 8-bit number containing the 4-bit sign-magnitude ADPCM code.

FIGURE 1: ADPCM ENCODER BLOCK DIAGRAM

The predicted sample, s_p, is subtracted from the linear input sample, s_i, to produce a difference, d. Adaptive quantization is performed on the difference, resulting in the 4-bit ADPCM value, t. The encoder and decoder both update their internal variables based on this ADPCM value. A full decoder is actually embedded within the encoder. This ensures that the encoder and decoder are synchronized without the need to send any additional data. The embedded decoder is shown within the dotted lines of Figure 1. The embedded decoder uses the ADPCM value to update the inverse quantizer, which produces a dequantized version, d_q, of the difference, d. The implementation of the ADPCM algorithm presented in this application note uses a fixed predictor instead of an adaptive predictor which reduces the amount of data memory and instruction cycles required.

© 1997 Microchip Technology Inc.

The adaptive predictor of ITU G.721 adjusts according to the value of each input sample using a weighted average of the last six dequantized difference values and the last two predicted values. So at this point, the dequantized difference, d_q, is added to the predicted sample, s_p, to produce a new predicted sample, s_r. Finally the new predicted sample, s_r, is saved into s_p.

The following (Table 1) is a step-by-step description of the **`ADPCMEncoder()`** function from Appendix A.

TABLE 1: `ADPCMEncoder()` STEP-BY-STEP FUNCTIONS

1. ADPCMEncoder takes a 16-bit signed number (speech sample, 32767 to -32768) and returns an 8-bit number containing the 4-bit ADPCM code (0-15)	`char ADPCMEncoder(long signed sample)`
2. Restore the previous values of predicted sample (s_p) and the quantizer step size index	`predsample = state.prevsample;` `index = state.previndex;`
3. Find the quantizer step size (q) from a table lookup using the quantizer step size index	`step = StepSizeTable[index];`
4. Compute the difference (d) between the actual sample (s_i) and the predicted sample (s_p)	`diff = sample - predsample;`

5. Set the sign bit of the ADPCM code (i) if necessary and find the absolute value of difference (d)	`if(diff >= 0)`
	`  code = 0;`
	`else`
	`{`
	`  code = 8;`
	`  diff = - diff;`
	`}`

6. Save quantizer step size (q) in a temporary variable	`tempstep = step;`

7. Quantize the difference (d) into the ADPCM code (i) using the quantizer step size (q)	`if(diff >= tempstep)`
	`{`
	`  code |= 4;`
	`  diff -= tempstep;`
	`}`
	`tempstep >>= 1;`
	`if(diff >= tempstep)`
	`{`
	`  code |= 2;`
	`  diff -= tempstep;`
	`}`
	`tempstep >>= 1;`
	`if(diff >= tempstep)`
	`  code |= 1;`

8. Inverse quantize the ADPCM code (i) into a predicted difference (d_q) using the quantizer step size (q)	`diffq = step >> 3;`
	`if(code & 4)`
	`  diffq += step;`
	`if(code & 2)`
	`  diffq += step >> 1;`
	`if(code & 1)`
	`  diffq += step >> 2;`

© 1997 Microchip Technology Inc.

TABLE 1: `ADPCMEncoder()` STEP-BY-STEP FUNCTIONS (CONTINUED)

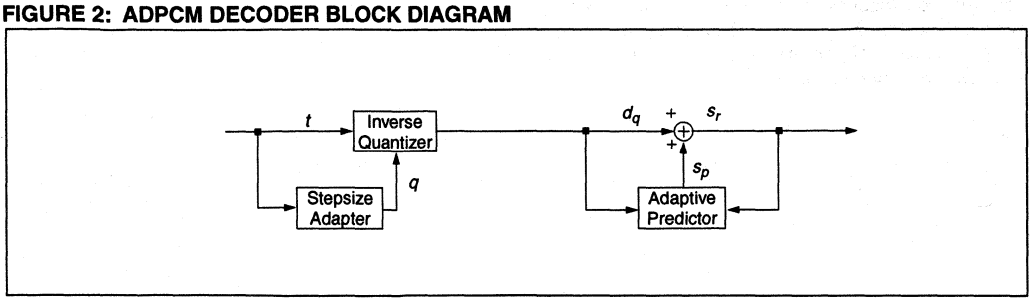
9. Fixed predictor computes new predicted sample (s_r) by adding the old predicted sample (s_p) to the predicted difference (d_q)	`if(code & 8)`
	`  predsample -= diffq;`
	`else`
	`  predsample += diffq;`

10. Check for overflow of the new predicted sample (s_r). s_n which is a signed 16-bit sample, must be in the range of 32767 to -32768	`if(predsample > 32767)`
	`  predsample = 32767;`
	`else if(predsample < -32768)`
	`  predsample = -32768;`

11. Find the new quantizer step size index (q) by adding the previous index and a table lookup using the ADPCM code (*t*)	`index += IndexTable[code];`

12. Check for overflow of the new quantizer step size index	`if(index < 0)`
	`  index = 0;`
	`if(index > 88)`
	`  index = 88;`

13. Save the new predicted sample (s_r) and quantizer step size index for next iteration	`state.prevsample = predsample;` `state.previndex = index;`
14. Return the ADPCM code (*t*)	`return (code & 0x0f);`



This function requires five 16-bit variables and two 8-bit variables. Some optimizations can be made to the code in Appendix A such as combining steps 7 and 8. Appendix C gives the output listing of the MPC compiler for a PIC16CXX device using the optimized encoder algorithm and the decoder algorithm from the next section.

DECOMPRESSION

The input into the decoder, *t*, must be an 8-bit number containing the 4-bit ADPCM data in sign-magnitude format. The range of allowable values for *t* is 0 to 15, where 7 = 0x07 and -7 = 0x0F. Figure 2 shows a block diagram for ADPCM decompression and Appendix B has a listing of the function **`ADPCMDecoder()`**. The predicted sample, s_p, and the quantizer step size index are saved in a structure for the next iteration of the decoder. Initially, the quantizer step size index and the predicted sample (s_p) are set to zero. This function takes a 4-bit sign-magnitude ADPCM code and returns the 16-bit two's complement speech sample.

This decoder is the same as the one used in the encoder routine. It uses the ADPCM value to update the inverse quantizer, which produces a difference, d_q. The difference, d_q, is added to the predicted sample, s_p, to produce the output sample, s_r. The output sample, s_r, is then saved into the predicted sample, s_p, for the next iteration of the decoder.

FIGURE 2: ADPCM DECODER BLOCK DIAGRAM

The following (Table 2) is a step-by-step description of the **ADPCMDecoder()** function from Appendix B.

TABLE 2: ADPCMDecoder() STEP-BY-STEP FUNCTIONS

1. ADPCMDecoder takes an 8-bit number containing the 4-bit ADPCM code (0-15) and returns a 16-bit signed number (speech sample, 32767 to -32768)	`signed long ADPCMDecoder( char code )`
2. Restore the previous values of predicted sample (s_p) and quantizer step size index	`predsample = state.prevsample;` `index = state.previndex;`
3. Find the quantizer step size (q) from a table lookup using the quantizer step size index	`step = StepSizeTable[index];`

4. Inverse quantize the ADPCM code (l) into a predicted difference (d_q) using the quantizer step size (q)	`diffq = step >> 3;`
	`if(code & 4)`
	`  diffq += step;`
	`if(code & 2)`
	`  diffq += step >> 1;`
	`if(code & 1)`
	`  diffq += step >> 2;`

5. Fixed predictor computes new predicted sample (s_r) by adding the old predicted sample (s_p) to the predicted difference (d_q)	`if(code & 8)`
	`  predsample -= diffq;`
	`else`
	`  predsample += diffq;`

6. Check for overflow of the new predicted sample (s_r). s_r, which is a signed 16-bit sample, must be in the range of 32767 to -32768	`if(predsample > 32767)`
	`  predsample = 32767;`
	`else if(predsample < -32768)`
	`  predsample = -32768;`

7. Find the new quantizer step size (q) by adding the previous index and a table lookup using the ADPCM code (l)	`index += IndexTable[code];`

8. Check for overflow of the new quantizer step size index	`if(index < 0)`
	`  index = 0;`
	`if(index > 88)`
	`  index = 88;`

9. Save the new predicted sample (s_r) and quantizer step size index for next iteration	`state.prevsample = predsample;` `state.previndex = index;`
10. Return the new sample (s_r)	`return ( predsample );`

This function requires three 16-bit variables and one 8-bit variable. Appendix C gives the listing output of the MP-C compiler of the decoder algorithm and the optimized encoder algorithm.

IMA ADPCM REFERENCE ALGORITHM

The IMA, specifically the Digital Audio Technical Working Group, is a trade association with representatives from companies such as Compaq®, Apple Computer®, Crystal Semiconductor®, DEC®, Hewlett-Packard®, Intel®, Microsoft®, Sony®, and Texas Instruments® to name a few. This group is working towards a standard that defines the exchange of high quality audio data between computing platforms. The algorithm from Intel/DVI® (Digital Video Interactive) has been selected as the standard due to it's audio dynamic range and low data rate. The recommended digital audio exchange formats are given in Table 3.

The algorithms that are implemented in this application note were derived from the IMA ADPCM Reference algorithm. The data format is 8.0 kHz, mono, 4-bit ADPCM. Essentially, the compression and decompression use an adaptive quantization with fixed prediction. The adaptive quantization are based on a table lookup first developed by Intel/DVI for the IMA. Appendix D gives the information about IMA and the supporting documentation for IMA ADPCM.

TABLE 3: DIGITAL AUDIO EXCHANGE FORMATS

Sampling Rate	Mono/Stereo	Data Format	Notes
8.0 kHz	mono	8-bit μ-Law PCM	CCITT G.711 Standard
	mono	8-bit A-Law PCM	CCITT G.711 Standard
	mono	4-bit ADPCM	DVI Algorithm
11.025 kHz	mono/stereo	8-bit Linear PCM	Macintosh® & MP-C Standard
	mono/stereo	4-bit ADPCM	DVI Algorithm
22.05 kHz	mono/stereo	8-bit Linear PCM	Macintosh & MPC Standard
	mono/stereo	4-bit ADPCM	DVI Algorithm
44.10 kHz	mono/stereo	16-bit Linear PCM	CD-DA Standard
	mono/stereo	4-bit ADPCM	DVI Algorithm

PERFORMANCE

Table 4 shows the performance comparison of the ADPCM compression and decompression routines for the PIC16C5X, PIC16CXXX, and PIC17CXXX family of devices assuming 80 additional instruction cycles for overhead. Any device without a PWM module will have to increase the operating frequency to generate a software PWM. Table 4 also provides the minimum external operating frequency required to run the routines. The C code from Appendix C was used. The input/output data rate of the speech samples is 8.0 kHz. The minimum operating frequency is calculated as follows:

8000 x # of Total Instruction Cycles x 4.

For example, the ADPCM encoding using the PIC16CXXX family would require an 8000 x (225 + 80) x 4 = 9.760 MHz external crystal.

TABLE 4: PERFORMANCE COMPARISON TABLE

Device	Encode/Decode	# of Instruction Cycles	Minimum External Operating Frequency
PIC16C5X	Encode	273	11.296 MHz
	Decode	208	9.216 MHz
PIC16CXXX	Encode	225	9.760 MHz
	Decode	168	7.936 MHz
PIC17CXXX	Encode	199	8.928 MHz
	Decode	161	7.712 MHz

Table 5 illustrates the amount of program and data memory that the ADPCM algorithms consume for the various PICmicro devices. The program memory numbers may change slightly depending on the specific device being used. The table memory column shows how much program memory is used to store the two lookup tables used by the ADPCM algorithm.

TABLE 5: DEVICE MEMORY CONSUMED

Device		Program Memory (words)	Data Memory (bytes)	Table Lookup (words)
PIC16C5X	Encode	273	13	196
	Decode	205	10	
PIC16CXXX	Encode	220	13	196
	Decode	162	10	
PIC17CXXX	Encode	203	13	97
	Decode	164	10	

APPLICATION

The hardware for this application note implements only the decompression algorithm, but the compression algorithm is also included in the firmware. A block diagram is shown in Figure 3 and the schematic is provided in Appendix E. The complete source code listing, including a block diagram, is given in Appendix F.

The board uses a PIC16C72, rated for 20 MHz operation, to control the speech decoding and output. The A/D (Analog-to-Digital) converter of the PIC16C72 is not used in this design. Two 27C512A EPROMs from Microchip Technology are used to store up to 32.768 seconds of ADPCM data. Each EPROM holds 65536 bytes. Each byte in the EPROM contains two ADPCM values. One second of speech requires 8000 ADPCM codes (8 kHz sample rate). Therefore, each EPROM holds (65536 x 2) / 8000 = 16.384 seconds of speech. A 16-bit up counter is used to clock data out of the EPROMs. This method uses only two I/O lines to control the counter and eleven I/O lines to read the EPROM data.

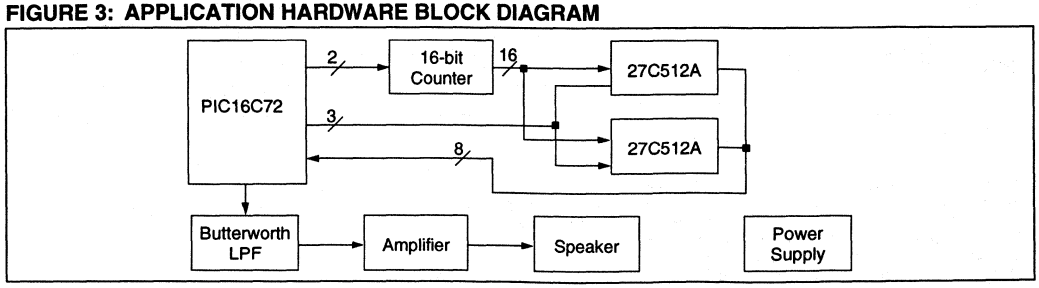
Speech regeneration is accomplished by using the Capture/Compare/PWM (CCP) module of the PIC16C72. The PWM module is configured for a period of 32 kHz. This allows each sample of the speech signal to be output for four PWM periods. The period is calculated by using the following equation from Section 10.3 of the PIC16C7X Data Sheet (DS30390). From the following calculation, PR2 is set to a value of 155.

$$\text{PWM period} = [\text{PR2} + 1] * 4 * \text{Tosc} * (\text{TMR2 prescale value})$$

$$1 / 32\ \text{kHz} = [\text{PR2} + 1] * 4 * (1 / 20\ \text{MHz}) * 1$$
$$31.25\ \mu\text{s} = [\text{PR2} + 1] * 4 * 50\ \text{ns} * 1$$
$$156.25 = \text{PR2} + 1$$
$$155.25 = \text{PR2}$$

The CCP module has the capability of up to 10-bit resolution for the PWM duty cycle. The maximum resolution of the duty cycle that can be achieved for a 32 kHz period can be calculated using the following equation from Section 10.3 of the PIC16C7X Data Sheet.

$$\text{PWM duty cycle} = \text{DC<10:0>} * \text{Tosc} * (\text{TMR2 prescale value})$$



where DC<10:0> = 2^x where x = bits of resolution

$$1 / 32\ \text{kHz} = 2^x * (1 / 20\ \text{MHz}) * 1$$
$$31.25\ \mu\text{s} = 2^x * 50\ \text{ns} * 1$$
$$625 = 2^x$$
$$\log(625) = \log(2^x)$$
$$\log(625) = x * \log(2)$$
$$9.3 = x$$

A PWM duty cycle with up to 9-bits of resolution may be used with a period of 32 kHz. The upper 9-bits of each speech sample are used to set the PWM duty cycle (CCPR1L = sample<15:9>, CCP1CON<5:4> = sample<8:7>). This PWM speech signal is passed through a 4th-order Butterworth low pass filter with a corner frequency of 4 kHz. The low pass filter converts the PWM into an analog voltage level. Finally, the analog voltage level is amplified by a National Semiconductor LM386N-3 before entering the speaker.

Every 125 μs (8 kHz) one ADPCM code must be converted into a speech sample for output to the PWM. This frame of 125 μs relates to 625 instruction cycles for an external crystal frequency of 20 MHz. The ADPCM decode routine, EPROM reads and writes to the PWM must be accomplished within 625 instruction cycles.

FIGURE 3: APPLICATION HARDWARE BLOCK DIAGRAM

© 1997 Microchip Technology Inc.

To implement audio recording, the following changes to the application hardware would have to be made:

- Replace the EPROMs with RAM and
- Add a microphone with input filtering and
- Use the on-board A/D converter of the PIC16C7X devices for 8-bit recording or
- Use an external 12- to 16-bit A/D converter for better quality recording

The following is the sequence of events to record and store speech data. A timer would be used to set the sample rate. When the timer overflowed an A/D conversion would be started.

1. Start an A/D conversion when the timer overflows.
2. Read the sample and call the routine `ADPCMEncoder()`.
3. Store the result in the upper 4-bits of a temporary variable.
4. Start an A/D conversion when the timer overflows.
5. Read the sample and call the routine `ADPCMEncoder()`.
6. Store the result in the lower 4-bits of the temporary variable.
7. Write the temporary variable to the SRAM.
8. GOTO 1.

Typical conversion times for the PIC16C7XX devices are 40 μs. Assuming that the external crystal frequency is 20 MHz and the sample rate is 8 kHz, the encoder routine takes approximately 45 μs (225 instruction cycles x 200 ns) to complete. This leaves approximately 40 μs or 200 instruction cycles to read the A/D converter, write to the SRAM and complete any other tasks. An external A/D converter that is faster could be used to increase the amount of time for processing other tasks.

COMPUTER PROGRAM

The IMA Reference ADPCM algorithm was written for a PC using Borland C++ version 3.1. This program uses the same routines that are used in Appendix C. A raw sound file is recorded on the PC using a 16-bit sound card. Speech is recorded at 8.0 kHz in 16-bit mono mode. This raw speech file is processed by the encoder part of the program which creates a file with the ADPCM values. This file can now be burned into EPROMs for use with the application hardware. The decoder part of the program can take this file and create a new 16-bit raw speech file. The 16-bit sound card on the PC can play this file to ensure that the ADPCM compression/decompression routines are working properly. The PC program is given in Appendix F. It is composed of three files: `pcspeech.c`, `pcadpcm.c`, and `pcadpcm.h`.

CONCLUSION

The final results of the application hardware using the PIC16C72 are:

- Compression and Decompression
  - 906 words of Program Memory used
  - 44% of total Program Memory
  - 24 bytes of Data Memory used
  - 19% of total Data Memory
- Decompression only
  - 686 words of Program Memory used
  - 33% of total Program Memory
  - 22 bytes of Data Memory used
  - 17% of total Data Memory
- ~250 Instruction cycles to decode one ADPCM code
  - 40% of frame (250/625)
- Hardware used
  - CCP1 configured for PWM (9-bit duty cycle, 32 kHz period speech output)
  - Timer2 to set the 8.0 kHz output sample rate
  - 13 I/O lines to read data from the EPROMs

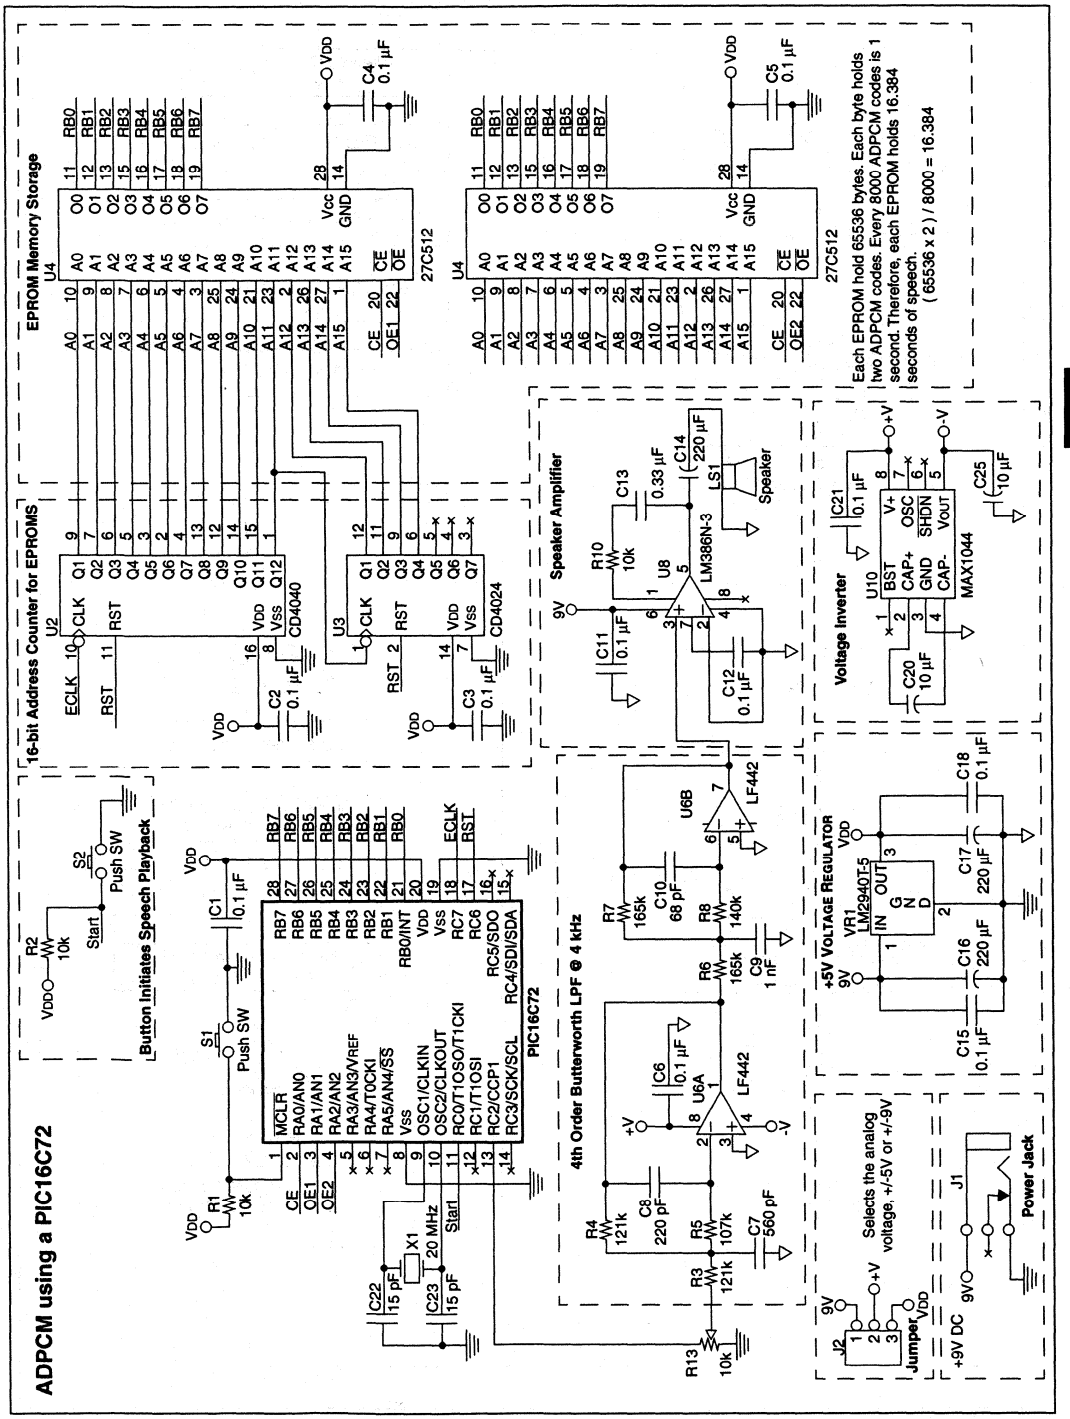
APPENDIX D: INTERACTIVE MULTIMEDIA ASSOCIATION INFORMATION

The IMA ADPCM Reference Algorithm is contained in the Digital Audio Doc-Pac. The Doc-Pac contains the following information:



- *About IMA Digital Audio* - describes the IMA's activities in digital audio
- IMA *Recommended Practices for Enhancing Digital Audio Compatability in Multimedia Systems* (version 3.0). This document contains the official technical recommendations including the ADPCM algorithm
- *IMA Digital Audio Special Edition Proceedings* This document contains a detailed notes of the evaluation process, code fragments and testing methodologies.
- Floppy disk with code fragments.
- Contact information for companies supporting IMA ADPCM.

The IMA can be reached at:

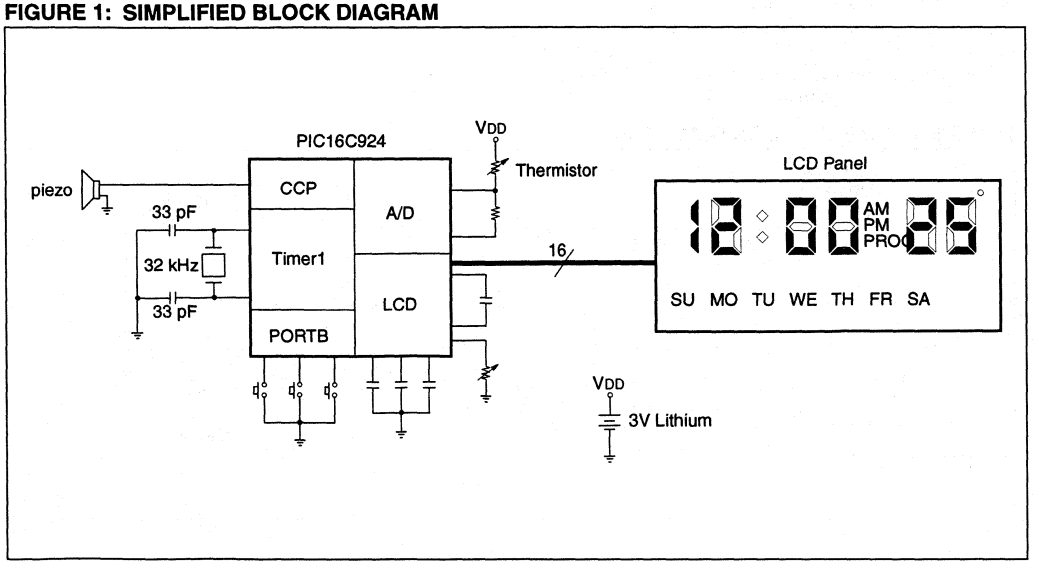
Yet Another Clock Featuring the PIC16C924

Author: Rodger Richey
Microchip Technology Inc.

INTRODUCTION

Once again, because of its universal familiarity and range of functionality, the clock is used to convey the use of the PIC16C92X microcontrollers. In this case we have added a twist to the clock with the addition of a thermometer. The LCD panel has a two digit temperature readout.



This application note will discuss the use of the following peripherals used to implement the clock: Timer1, PORTB, CCP, A/D converter, and the LCD Module. All source code and examples are written in C and compiled using Microchip's MPLAB-C compiler.

The features of the PIC16C924 are:

- 4K x 14 EPROM program memory
- 176 x 8 SRAM data memory
- DC - 8 MHz operating speed
- Timer0, Timer1, and Timer2
- One CCP pin
- SSP Module with SPI and I^2C capability
- 8-bit, 5 channel A/D converter
- LCD Module
  - Multiple LCD timing sources
  - LCD can be driven while in SLEEP
  - Static, 1/2, 1/3 and 1/4 multiplex modes
  - Static and 1/3 bias capability
  - Up to 32 segments, up to 4 commons
    - 1 COM x 32 SEGs = 32 pixels
    - 2 COMs x 31 SEGs = 62 pixels
    - 3 COMs x 30 SEGs = 90 pixels
    - 4 COMs x 29 SEGs = 116 pixels
- Available in DIE form, 68-pin PLCC, and 64-pin TQFP packages

3

FIGURE 1: SIMPLIFIED BLOCK DIAGRAM

LCD panels offer many advantages over LED type displays such as; lower cost, lower power consumption, and better display quality. Figure 2 shows typical examples of an LED and an LCD application. Table 1 further describes each application according to components, cost, power consumption, etc.

TABLE 1: LED vs. LCD

	LED	LCD
Cost (1000 units)	$7.05	$5.42
# Components	20	6
Power Consumption	~ 10 mA	~ 50 µA
Hardware	Timer, 12 I/O pins	LCD Module
Signal Generation	Firmware	LCD Module

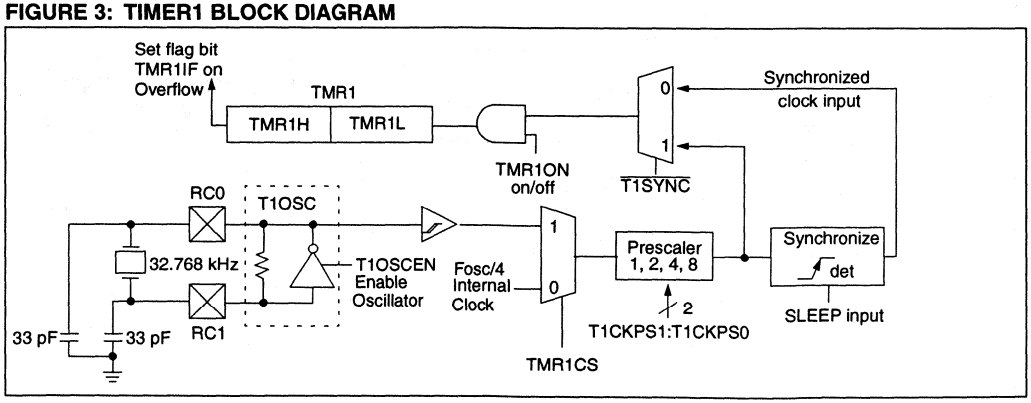

FIGURE 2: EXAMPLE LED AND LCD APPLICATIONS

TIMER1

Currently, the Timer1 module exists in all the PIC16CXXX devices with 28 or more pins. This module can be used to easily implement a real-time clock. Instead of an external real-time clock device, an inexpensive 32.768 kHz watch crystal and two 33 pF capacitors are used to complete the circuit. Figure 3 shows the block diagram for Timer1.

FIGURE 3: TIMER1 BLOCK DIAGRAM

© 1997 Microchip Technology Inc.

In this application, Timer1 is clocked by an external crystal connected across RC0 and RC1. The following is some sample code to initialize Timer1.

```
TMR1H = 0x80;
TMR1L = 0x00;
T1CON = 0b00001111;
PIR1.TMR1IF = 0;
PIE1.TMR1IE = 1;
```

The first step in initializing Timer1 is to preset TMR1H:TMR1L to 0x8000. Since Timer1 is a 16-bit timer, the 32.768 kHz crystal will cause Timer1 to overflow every two seconds or 65536 counts. For this reason, Timer1 is initialized to 0x8000 so that every overflow relates to one second. The second step is to configure Timer1. For this mode, the Timer1 oscillator must be enabled via T1CON<T1OSCEN>. This bit enables the internal oscillator, which is functionally equivalent to the LP oscillator of the microcontroller. The clock source for Timer1 is selected to be the external input using the T1CON<TMR1CS> bit. The prescaler is set to 1:1 using the T1CKPS1:T1CKPS0 bits of the T1CON register. Since the timer is to operate during SLEEP, it is not synchronized to the internal Fosc clock. Synchronization is controlled by the $\overline{\text{T1SYNC}}$ bit of the T1CON register. Finally, the clock source is enabled to clock TMR1H:TMR1L using the TMR1ON bit of T1CON.

In this mode of operation, Timer1 can operate during SLEEP while consuming a minimal amount of current (≈20 µA). The last two lines of code clear the Timer1 Overflow flag and enable the Timer1 Overflow interrupt. This interrupt will wake up the processor from SLEEP at a predetermined rate for updating the clock, in this case once each second. The following is a sample interrupt service routine for Timer1 Overflow:

```
if(PIR1.TMR1IF)
{
   Seconds++;              //Increment seconds
   if(Seconds > 59)        //60 seconds?
   {
      Seconds = 0;
      Minutes++;
   }
   if(Minutes > 59)        //60 minutes?
   {
      Minutes = 0;
      Hours++;
   }
   if(Hours > 12)          //Do not use 24hr
      Hours = 1;           //military time

   TMR1H |= 0x80;          //Reset timer1
   PIR1.TMR1IF = 0;        //Clear flag
}
```

First, register PIR1 is checked to verify that the Timer1 Overflow interrupt occurred. Next the variable `Seconds` is incremented every time a Timer1 overflow occurs. Once `Seconds` reaches 60, the `Minutes` variable is incremented and `Seconds` is cleared thus implementing 60 seconds per minute. If `Minutes` reaches 60, then the `Hours` variable is incremented and `Minutes` is cleared which implements 60 minutes per hour. For civilian time, if `Hours` is greater than 12, `Hours` is reset to 1. Military time uses 24 hours a day, so that when `Hours` reaches 24 it is reset to 1.

Since it takes a finite amount of time to enter the interrupt service routine and execute it, the program adds 0x80 to TMR1H so that the next Timer1 Overflow interrupt occurs exactly in one second. If the program simply cleared TMR1L and set TMR1H to 0x80, the real-time clock would now be off by the finite amount of time previously described. Finally, the Timer1 Overflow interrupt flag is reset.

PORTB

The wake-up on change feature of PORTB was specifically designed to interface keys or a keypad directly to the microcontroller. Internal weak pull-up resistors are provided to reduce external parts count, while adding only a small amount of current. This feature allows the microcontroller to remain in the low-power SLEEP mode until a key is pressed. The device will wake-up from SLEEP when the key is pressed. The interrupt service routine will process the key input. The following example routine shows how to initialize the PORTB wake-up on change interrupt.

```
OPTION.RBPU = 0;
Temp = PORTB;
INTCON.RBIF = 0;
INTCON.RBIE = 1;
```

Whenever the state of the RB7:RB4 pins change, a mismatch condition occurs inside the microcontroller. The only way to clear the mismatch condition is to read PORTB, which also allows the RBIF interrupt flag to be cleared. In the previous code, the first line enables the internal weak pull-up resistors. The second line of the code resets the mismatch condition. Then the following lines clear the interrupt flag and enable the interrupt. A sample interrupt service routine is given below.

```
if(INTCON.RBIF)
{
   Temp = PORTB;
   Delay_Ms_4MHz(16);  //key debounce
   if(Temp!=0xf0 && Temp==PORTB)
   {
      StartBEEP(); //key press starts
beep

      if(!Temp.SET)        //SET key
         Flags.SET = 1;
      if(!Temp.UP)         //UP key
         Flags.UP = 1;
      if(!Temp.SOUND)      //SOUND key
      {
         if(Flags.SOUND_STATE)
            Flags.SOUND_STATE = 0;
         else
            Flags.SOUND_STATE = 1;
      }
   }
   INTCON.RBIF = 0;        //clear flag
}
```

The first line of the above example is used to verify that a change on PORTB interrupt has occurred. The next line is a 5 ms delay followed by a read of PORTB. This resets the mismatch condition. The following 20 ms delay is used in conjunction with the previous 5 ms delay for switch debouncing. The value of `Temp` and PORTB are compared and if equal a key press has been detected. The if statement also checks to see if the mismatch condition is from a key press or when the key is released. The key inputs are processed only when a key is pressed. When a key is pressed, it grounds the respective input pin. The nested if statements check each of the individual keys to see which have been pressed. If the SOUND key has been pressed, it merely toggles whether the hourly beep is enabled. Finally, the RBIF interrupt flag is cleared.

This application takes advantage of the wake-up on change and internal pull-up resistors to implement the SET, ▲, and SOUND keys. The SET key puts the clock in program mode and the PROG icon appears on the LCD. Program mode allows the user to set the time, AM or PM, and day of the week (see LCD Module for details on the LCD). Once in program mode, the hours digits flash. Pressing the ▲ key increments `Hours` from 12 to 11 AM and then from 12 to 11 PM. At any point the SET key can be pressed to advance to the minutes digits. The minutes digits are incremented using the ▲ key. `Minutes` can be incremented from 0 to 59. Pressing the SET key again flashes the day of the week. Using the ▲ key increments the day of the week from SU to SA. Finally, pressing the SET key takes the user out of program mode. If no key presses are detected for five seconds the program exits program mode.

CCP

The CCP module is used in Pulse Width Modulation (PWM) mode. The PWM signal is used to drive a piezo alarm circuit. The operation of PWM mode will not be discussed since it has been explained in great depth in application notes AN531, AN538, AN539, AN564, and AN594.

An example of configuring the CCP as a PWM output is shown below.

```
CCP1CON = 0x0f;       //Set CCP to PWM
PR2 = 122;            //period of 2048 Hz
CCPR1L = 5;           //Duty Cycle very low
TRISC.RC2 = 0;        //PWM pin output
T2CON = 0b01111101;   //Enable timer2
PIR1.TMR2IF = 0;      //Clear flag
PIE1.TMR2IE = 1;      //Enable interrupt
```

The CCP1CON register is set to 0x0F which puts the CCP into PWM mode. The period or frequency of the PWM output is set using the PR2 register. The following formula is used to calculate the value in PR2.

$$\text{PWM period} = [\ (\text{PR2}) + 1\ ] \cdot 4 \cdot \text{Tosc} \cdot (\text{TMR2 prescale value})\ ]$$

Another step in configuring the CCP is to set the value of the T2CON register. In the case above, a value of 0x7D configures the Timer2 output postscaler to 1:16, enables Timer2, and sets the Timer2 clock prescaler to 4. Using PR2 = 122, Tosc = 250 ns, and TMR2 prescale = 4, the resultant PWM period is approximately 500 µs or 2 kHz. This is the resonant frequency of the piezo alarm. The duty cycle, or more specifically the time the PWM output stays high, of the PWM output is set by the value of CCPR1L and bits CCP1CON<5:4>. The following formula uses the 10-bit value of CCPR1L:CCP1CON<5:4> to calculate the duty cycle.

$$\text{PWM duty cycle} = [\ (\text{CCPR1L:CCP1CON<5:4>}) \cdot \text{Tosc} \cdot (\text{TMR2 prescale value})\ ]$$

Using 0x014 as the value of CCPR1L:CCP1CON<5:4>, Tosc = 250 ns, and a TMR2 prescale = 4, the PWM duty cycle is calculated to be 20 µs or 4% duty cycle. The TRISC register must also be configured such that the PWM pin is setup as an output.

The Timer2 Overflow interrupt is used to turn off the PWM output. This produces a "beep" when the keys are pressed or an hourly alarm. The Timer2 postscaler waits for 16 PWM periods before the interrupt occurs. The following interrupt service routine is an example of how to generate a "beep".

```
if(PIR1.TMR2IF)
{
   Count--;
   if(!Count)
   {
      CCP1CON = 0;       //Disable CCP, and
      T2CON = 0;         //Timer2 and TMR2
      PIE1.TMR2IE = 0;   //interrupts
      CCPR1L = 0;
   }
   PIR1.TMR2IF = 0;      //Clear flag
}
```

The first line of code detects if a Timer2 Overflow interrupt has occurred. The variable `Count` is used to vary the length of the beep. `Count` is set previous to enabling the PWM. If `Count` reaches zero the following occurs:

- The PWM is disabled by clearing the CCP1CON register
- Timer2 is disabled by clearing the T2CON register
- The Timer2 Overflow interrupt is disabled by clearing the TMR2IE bit of the register PIE1
- The duty cycle register is cleared

Before exiting the service routine, the TMR2IF interrupt flag is cleared.

© 1997 Microchip Technology Inc.

A/D CONVERTER

Since the PIC16C924 has a five channel, 8-bit A/D converter and the LCD has a ° (degree) symbol and two digits, the application circuit has a thermistor for measuring temperature. Thermistors typically take hundreds of milliseconds to stabilize at a particular temperature and therefore the A/D converter is ideal for temperature measurements. Another feature of the A/D converter is the on-chip RC oscillator that can be used as the conversion clock. This feature allows the A/D to operate in SLEEP. The following code segment is used to initialize the A/D converter.

```
ADCON0 = 0b11000001;   //Enable A/D
ADCON1 = 0b00000100;   //Configure D/A I/O
PIR1.ADIF = 0;         //Clear flag
PIE1.ADIE = 1;         //Enable interrupt
```

The first line enables the internal RC for conversion clock, channel 0, and enables the A/D converter. The second line makes PORTA<1:0> analog inputs and PORTA<5,3:2> as digital I/O. The following lines clear the A/D conversion complete interrupt flag and enable the interrupt. The application uses the Timer1 Overflow interrupt to start a conversion every second using the GO bit of the ADCON0 register. The A/D conversion complete interrupt then processes the result of the conversion. The following is an example of the service routine.

```
if(PIR1.ADIF)
{
   TempC = ThermTable[ADRES];
   PIR1.ADIF = 0;
}
```

The first line checks for the ADIF interrupt flag. A lookup table, `ThermTable`, is used to convert the A/D result into a temperature reading. This table was created using calibration data from the thermistor. Finally, the ADIF interrupt flag is cleared.

The following code was added to the Timer1 interrupt service routine to start the A/D conversion.

```
TRISA.THERM_GND = 0;
DELAY_10_µs_4MHz(4);
ADCON0.GO = 1
NOP();
NOP();
TRISA.THERM_GND = 1;
```

The first line of code grounds the I/O pin connected to resistor R1. The 40 µs delay is provided so the A/D converter can sample the input signal. The A/D converter is then instructed to convert by setting the GO bit. A two cycle delay is added so that the sampling capacitor is disconnected from the input. Finally the I/O pin connected to R1 is made an input. This scheme only powers the thermistor when sampling, to reduce power consumption.

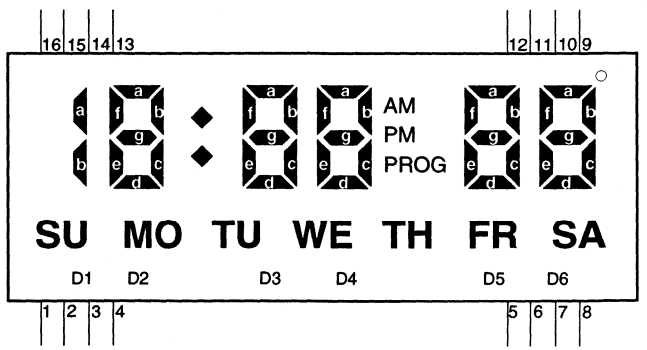
LCD MODULE



The LCD Module has a wealth of features typically found on more expensive dedicated LCD driver devices. The following is a detailed list of features:

- LCD Timing Sources
  - Fosc/256 (internal system clock)
  - Timer1 oscillator
  - Internal RC oscillator
- LCD Voltage Generation
  - Internal charge pump
  - External resistor ladder
- Bias
  - Static
  - 1/3
- Multiplex
  - Static
  - 1/2
  - 1/3
  - 1/4
- Operation during SLEEP
  - Only with internal RC or Timer1 clock sources
- Capable of up to 4 commons and 32 segments
  - 1 COM x 32 SEGs, total of 32 pixels
  - 2 COMs x 31 SEGs, total of 62 pixels
  - 3 COMs x 30 SEGs, total of 90 pixels
  - 4 COMs x 29 SEGs, total of 116 pixels
- 16 x 8 LCD data registers

The LCD Module is ideal for systems that use one controller board that has several applications with different displays. Microchip's OTP technology means that the controller board can be assembled with blank microcontrollers, and at final test the device can be programmed depending on the display type. This helps to reduce overhead and creates one board to track in inventory.

The particular LCD panel that was selected for this application is shown in Figure 2. It has four common electrodes and 12 segment electrodes. The panel provides 3 1/2 digits, colon, and AM/PM icons for time display. The panel also has day of the week icons (SU,MO,TU,WE,TH,FR,SA). This was the basis of another clock design using the PIC16C924.

© 1997 Microchip Technology Inc.

The LCD Module is initialized by the following code:

```
STATUS.RP1 = 1;          //Change to Bank 2
LCDPS = 6;               //Frame freq to 37Hz
LCDSE = 0xff;            //All LCD I/O as LCD
LCDCON = 0b00010111;     //1/4 MUX charge pump
LCDD00 = 0;              //Clear all LCD
LCDD01 = 0;              //data RAM
LCDD02 = 0;
LCDD03 = 0;
LCDD04 = 0;
LCDD05 = 0;
LCDD06 = 0;
LCDD07 = 0;
LCDD08 = 0;
LCDD09 = 0;
LCDD10 = 0;
LCDD11 = 0;
LCDD12 = 0;
LCDD13 = 0;
LCDD14 = 0;
LCDD15 = 0;
LCDCON.LCDEN = 1;        //Enable LCD module
STATUS.RP1 = 0;          //Back to Bank 0
PIR1.LCDIF = 0;          //Clear flag
PIE1.LCDIE = 1;          //Enable interrupt
```

Note: At the time when this application note was generated, four banks of data memory were not supported by the MPC or MPLAB-C compilers.

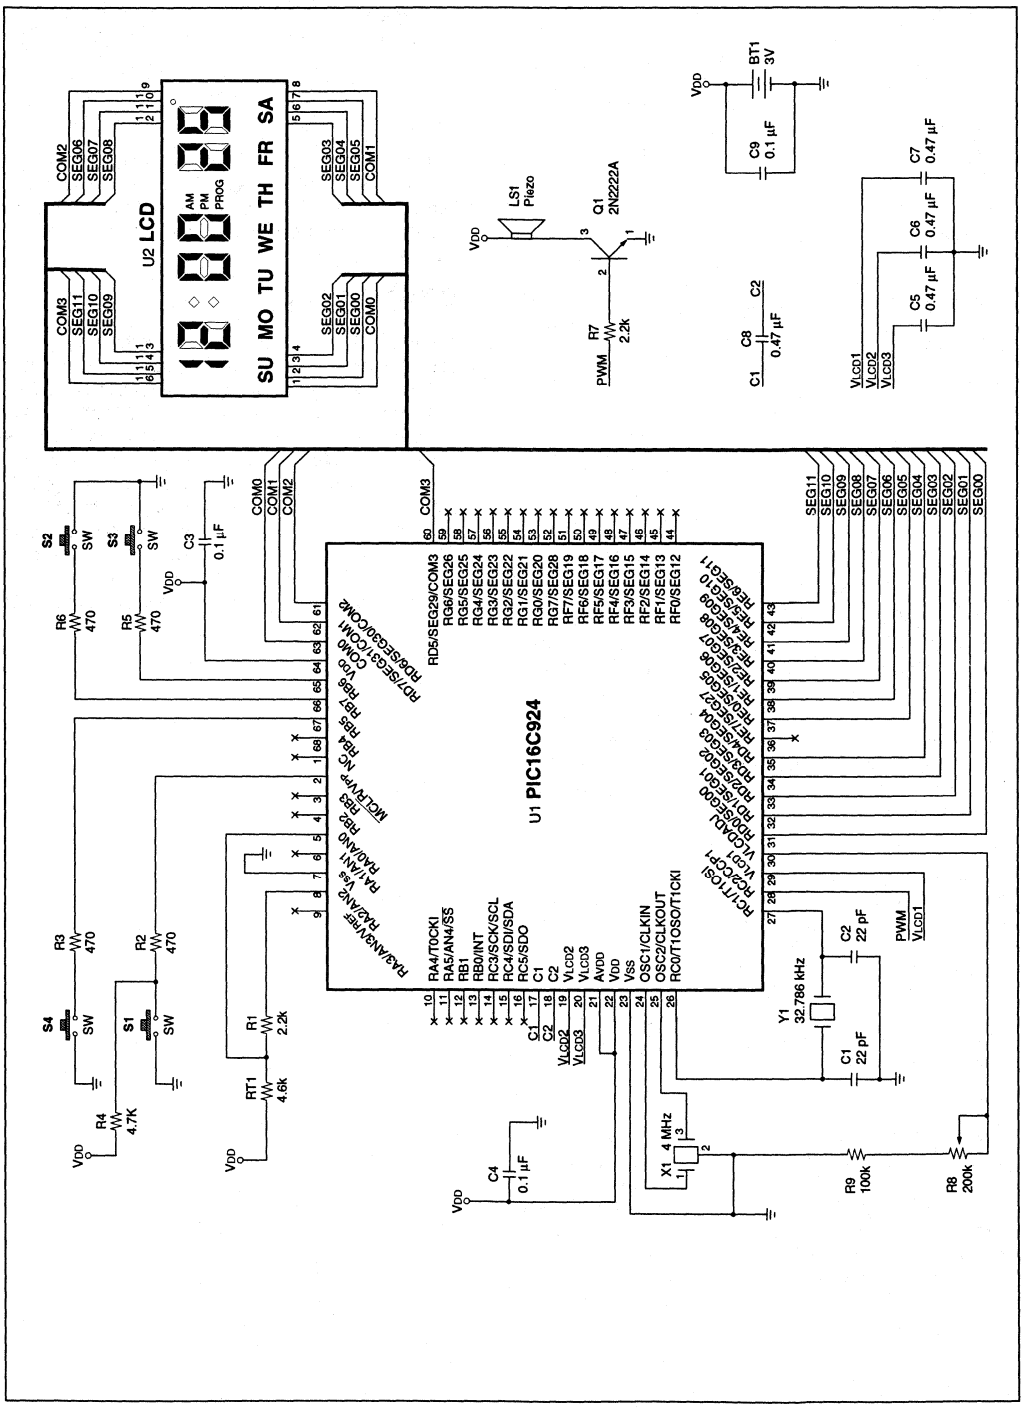
The PIC16C924 starts a new page in Microchip history with four banks of data memory for the PIC16CXXX mid-range products. The first line of code switches to the second set of banks. The second line of code sets a frame frequency of approximately 37 Hz using the Timer1 oscillator. This frequency can be calculated by using the following formula:

$$\text{Clock source} / (128 \bullet (\text{LP3:LP0} + 1))$$

Using 32.768 kHz as the clock source and LP3:LP0 = 6 the resultant frame frequency is 36.57 Hz. Setting LCDSE to 0xFF configures ports D,E,F, and G as LCD drivers. Setting LCDCON to 0x17 configures the LCD Module for 1/4 MUX, 1/3 Bias, Timer1 clock source, charge pump enabled, and the LCD module will continue to drive during SLEEP. The LCD data registers LCDD00 - LCDD15 are all cleared, which turns off all pixels on the LCD panel. Any unused bits in the LCD data registers can be used as general purpose RAM. The PIC16C924 Clock can use the upper 4-bits of registers LCDD01, LCDD05, LCDD09, LCDD13 and all of LCDD02, LCDD03, LCDD06, LCDD07, LCDD10, LCDD11, LCDD14, LCDD15. This is a result of not using segments 13 through 28. The LCD Module is then enabled by setting the LCDEN bit in the LCDCON register. Finally the LCD interrupt flag is cleared and the interrupt is enabled.

The following is an example of the LCD interrupt service routine.

```
if(PIR1.LCDIF)
{
   Flags.FRAME = 1;
   PIR1.LCDIF = 0;
}
```



In this application, the LCD interrupt is used to signal the main routine that the LCD data registers can be updated without causing any flicker on the panel. Finally, as in any interrupt service routine, the interrupt flag is cleared.

CONCLUSION

The PIC16C924 is ideally suited towards battery applications such as thermostats or meters. It can extend battery life while maintaining a rich feature set such as A/D converter, SPI/I^2C module, and CCP module. All of the peripherals that have been previously described can operate during SLEEP, thus lowering the average current consumption. If the 8-bit A/D converter is not sufficient or not used in your design, Microchip also offers the PIC16C923 which has all the features of the PIC16C924 without the A/D converter. This device can use an external higher resolution A/D converter that can be interfaced to the SSP module, specifically the SPI port.

                 *   LCD.C       Rev A1
                 *   TIME.C      Rev A1
                 *****************************************************************************
                 *   Peripheral Modules Used:
                 *     Timer0    : Used by the music generation program for timing notes
                 *                 and durations
                 *     Timer1    : Used as a real time clock using an external 32.768KHz
                 *                 crystal and (2) 33pF capacitors
                 *     Timer2    : Used in conjunction with the PWM
                 *     CCP       : Used in PWM mode, for driving the piezo alarm
                 *     PORTB     : Used to decode key presses
                 *     A/D       : Used to measure temperature via a thermistor on RA0
                 *     LCD       : Used to display time, temperature, day of week
                 *****************************************************************************
                 *   External Clock Frequency    : 4MHz
                 *   Timer1 OSC Frequency        : 32.768KHz
                 *   Configuration Bit Settings  : XT Oscillator
                 *                               : Watchdog Timer OFF
                 *                               : Code Protect OFF
                 *                               : Power-Up Timer ON
                 *   Program Memory Usage        : 1095 words
                 *   Data Memory Usage           : 19 bytes
                 *****************************************************************************
                 *   Revision History
                 *   A1 - First Release
                 *   A2 - Added code to clear CCPR1L after PWM has finished
                 *      - Set No sleep flag in StartMusic
                 *   A3 - Changed __INT interrupt service routine.
                 *   Added INTCON.T0IE to check for Timer0 interrupt
                 *****************************************************************************
                 *   Note: Make sure that the temporary variables in the 16c924.h file
                 *         have been changed to locations 0x7a to 0x7f
                 *****************************************************************************/

PWM, a Software Solution for the PIC16CXXX

Author: Ole Röpcke
Consultant, Europe

INTRODUCTION

The low cost, high performance features of a PIC16CXXX microcontroller make it a suitable device for automatic control technology applications. Sometimes, an additional PWM output is needed. For some devices, such as the PIC16C71, the addition of a software PWM adds the missing element. It is possible to use Timer0 (which also provides the system clock) and its corresponding interrupt to generate a PWM output with a duty cycle that can vary from nearly 10% to 90%. However, some applications require a greater duty cycle range.

This application note provides a software solution for a more accurate and flexible PWM output, which is characterized by the following:

1. PWM frequency up to 19.6 kHz (20 MHz crystal).
2. Variable duty cycle from 0% to 100%.
3. 8-bit resolution.
4. PWM step size of 1 TCY (Instruction Cycle Time).
5. Simultaneous generation of a system time clock.

METHODS

Before the solution is revealed, we must first examine the various software methods used to generate variable length pulses.

In the following explanations, the unit of time will be the length of an Instruction Cycle (TCY). We will use TCY because one instruction (if the program counter is not changed) executes in one TCY and Timer0 (without prescaling) increments every TCY. This provides us with a simple method to control a potentially complex timing sequence.

Making use of the time needed to execute an instruction provides a very simple method of generating an pulse. Example 1 (Method A) shows an instruction sequence, which will generate a high pulse of 99 TCY on pin 3 of PORTA. The pulse length is controlled by the value of register LENGTH in steps of 3 TCY. This is the computing time needed by one program loop.

The drawbacks of this method are an excessive use of computing time and a poor PWM resolution.

EXAMPLE 1: USING TCY AS A TIME BASE FOR PULSE GENERATION (METHOD A)

```
        .
        .
        .
        PORTA     equ  04h
        LENGTH    equ  0ch
        COUNTER   equ  0dh
        .
        .
        .
        movlw     34              ; value for pulse length of 99 Tcy
        movwf     LENGTH          ;
        .
        .
        .
        movf      LENGTH,W        ; write value to the loop counter
        movwf     COUNTER         ;
        bsf       PORTA,3         ; start high pulse
Loop
        decfsz    COUNTER,F       ; counting pulse length
        goto      Loop            ;
        bcf       PORTA,3         ; end high pulse
        .
        .
        .
```

© 1997 Microchip Technology Inc.

However, the architectural features of Microchip's midrange microcontrollers allow us to proceed in another direction. Example 2 shows an instruction sequence (Method B), which enables us to generate a high pulse with lengths varying from 1 to 5 TCY. The addition of any number to the file register PCL increases the program counter and skips a predetermined number of instructions (depending on the number added to PCL). The length of the high pulse is the same as the computing time consumed by the number of executed BSF instructions and is controlled by the value of file register LENGTH. If LENGTH is set to 4, 4 BSF instructions will be skipped and a high pulse of 1 TCY will be generated. If LENGTH is set to 0, no instructions will be skipped and the length of the pulse remains 5 TCY. A special effect takes place, when LENGTH is set to 5. All BSF instructions are skipped and therefore no high pulse occurs. This instruction sequence is able to generate pulses of various lengths including the length 0 TCY. Between each length the step size is only 1 TCY. This method will generate a long pulse if LENGTH is set to a small value, and a short pulse if LENGTH is set to a large value.

The drawback of this method is that it is suitable only for short pulses. Long pulses require an excessive amount of ROM and computing time.

EXAMPLE 2: PULSE GENERATION OPTIMIZED TO DEVICE ARCHITECTURE (METHOD B)

```
.
.
.
PORTA     equ  04h
LENGTH    equ  0ch
.
.
.
movlw     4              ; value for pulse length of 1 Tcy
movwf     LENGTH         ;
.
.
.
movf      LENGTH,W       ; This is an indirectly addressed relative jump
addwf     PCL,F          ;
bsf       PORTA,3        ; start high pulse 5 Tcy
bsf       PORTA,3        ; start high pulse 4 Tcy
bsf       PORTA,3        ; start high pulse 3 Tcy
bsf       PORTA,3        ; start high pulse 2 Tcy
bsf       PORTA,3        ; start high pulse 1 Tcy
bcf       PORTA,3        ; end high pulse
.
.
.
```

© 1997 Microchip Technology Inc.

A third method (Method C) uses the Timer0 Interrupt. After the port is set, the timer is loaded with an adjusted number corresponding to the desired pulse length. If the timer overflows, the interrupt service routine starts and resets the port. The number, which has to be loaded, is defined by the following factors:

- the counting direction of the timer (up/down)
- the time between loading the timer and setting the port
- the timer clock cycles needed to write to the timer
- the computing time between timer overflow and executing the first instruction of the interrupt service routine
- the computing time of the interrupt service routine until the port is reset
- the desired pulse length
- an additional correction number, which is related to the method of calculation

Method C is able to generate very different pulse lengths without wasting any computing time. This method is specifically useful to generate long pulses. When the prescaler is not used, the available step size is 1 TCY. But this procedure is unsuitable for generating very short pulses, because every interrupt service routine needs a minimum of computing time for execution, which defines the minimum pulse length.

Every PWM signal is a continuous succession of high and low pulses. The length of each pulse is defined by the desired duty cycle. Adding the length of a low and a high pulse gives us the PWM frequency, which should be kept constant.

Method C will only work if each of the pulses are longer than the minimum computing time of the interrupt service routine. The interrupt service routine has to find the required pulse and set or reset the port. In addition to that the interrupt service routine has to calculate the number required by the timer and write that value to the timer.

Whether it is feasible to use the timer interrupt depends on the desired pulse length and the known minimum computing time of the interrupt service routine. If Method C will not give the desired PWM signal, one has to fall back on methods A or B as described in Example 1 and Example 2.

Each method has its advantages and disadvantages. Because all three methods are software based, it is possible to change methods at any time. Therefore the microcontroller can determine, even during the interrupt service routine, which method is best suited to generate the next pulse. This is the underlying concept for this application.

The software PWM module uses methods B and C, which are shown in Table 1. If possible, both pulses are generated by the timer interrupt and two timer interrupts occur during one PWM period. If a very short pulse is needed, the interrupt service routine will generate this short pulse using method B. Afterwards it writes a new number corresponding to the next long pulse to the timer. Here, only one interrupt occurs during one PWM period. Knowing the computing time of each part of the interrupt service routine ensures that a change in methods will not visibly affect the PWM signal or vary the PWM frequency.

Now, let us have a look at a simple application of this PWM software module. The circuit diagram is shown in Figure 1.

Potentiometer R1 adjusts voltage from 0V to VDD. A PIC16C71 converts this voltage to an 8-bit value thirty times per second and sends it to PORTB. The eight LEDs connected to PORTB show the result. The PWM signal value, which is output on pin RA3, is shown by the intensity of the connected LED. If the value is equal to 0, a continuous low signal is generated. If the value is equal to 255 a continuous high signal is generated.

The method of operation of the program is the same as the described procedure, which is shown by Table 1.

The file register `COUNTER` is the file register of the system clock. It is incremented by the PWM module at the rising edge of the PWM signal. Bit 7 is toggled each 255 • 128 • TCY and is used as the system clock bit.

The file register `PWMDESIRED` contains the desired PWM value in the range of 0 to 255. Register `PWMMAX` and `PWMHELP` are needed by the PWM module. They must not be modified by any other part of the program except during initialization.

The constant `PWMADJUSTVAL` contains the previously described factors, which have to be taken into account while calculating the adjusted timer value. The constant `PWMMAXVAL` controls the maximum pulse length, which is generated by making use of the time needed to execute `BSF`/`BCF` instructions. If the interrupt service routine is modified, then both constants will also have to be modified.

The comments in the code explain each instruction sequence.

CONCLUSION

This software based PWM module is able to generate a PWM frequency of up to 19.6 kHz with a variable duty cycle of 0% to 100%. The consumption of RAM is 3 bytes, the consumption of ROM less than 10% (nearly 100 instructions) and the consumption of computing time, in the worst case, amounts to 57/266 = 22.4%. The remaining computing time is more than the total available computing time of a 8051 microcontroller with a 12 MHz crystal.

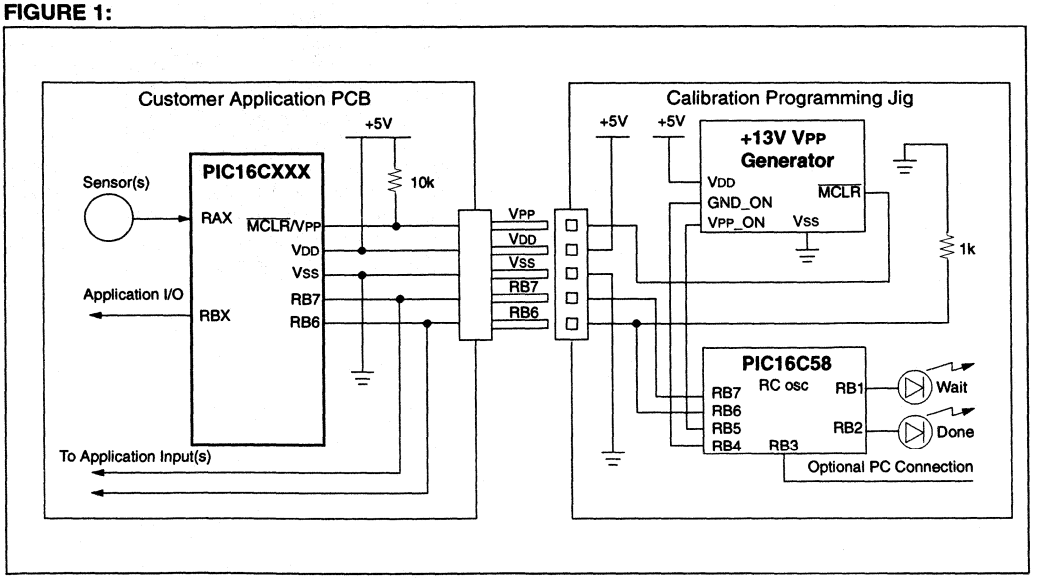
In-Circuit Serial Programming of Calibration Parameters Using a PICmicro™ Microcontroller

Author: John Day
Microchip Technology Inc.

INTRODUCTION



Many embedded control applications, where sensor offsets, slopes and configuration information are measured and stored, require a calibration step. Traditionally, potentiometers or serial EEPROM devices are used to set up and store this calibration information. This application note will show how to construct a programming jig that will receive calibration parameters from the application midrange PICmicro and program this information into the application baseline PICmicro using the In-Circuit Programming protocol. This method uses the PIC16CXXX In Circuit Serial Programming algorithm of the 14-bit core microcontrollers.

PROGRAMMING FIXTURE

A programming fixture is needed to assist with the self programming operation. This is typically a small re-usable module that plugs into the application PCB being calibrated. Only 5 pin connections are needed and this programming fixture can draw its power from the application PCB to simplify the connections.

3

FIGURE 1:

Electrical Interface

There are a total of five electrical connections needed between the application PIC16CXXX microcontroller and the programming jig:

- **$\overline{MCLR}$/VPP** - High voltage pin used to place application PIC16CXX into programming mode
- **VDD** - +5 volt power supply connection to the application PIC16CXXX
- **Vss** - Ground power supply connection to the application PIC16CXXX
- **RB6** - PORTB, bit6 connection to application PIC16CXX used to clock programming data
- **RB7** - PORTB, bit7 connection to application PIC16CXX used to send programming data

This programming jig is intended to grab power from the application power supply through the VDD connection. The programming jig will require 100 mA of peak current during programming. The application will need to set RB6 and RB7 as inputs, which means external devices cannot drive these lines. The calibration data will be sent to the programming jig by the application PIC16CXXX through RB6 and RB7. The programming jig will later use these lines to clock the calibration data into the application PIC16CXXX.

Programming Issues

The PIC16CXXX Programming specification suggests verification of program memory Specification at both Maximum and Minimum VDD for each device. This is done to ensure proper programming margins and to detect (and reject) any improperly programmed devices. All production quality programmers vary VDD from VDD min to VDD max after programming and verify the device under each of these conditions.

Since both the application voltage and it's tolerances are known, it is not necessary to verify the PIC16CXXX calibration parameters at the device VDD Max and VDD Min. It is only necessary to verify at the application power supply Max and Min voltages. This application note shows the nominal (+5V) verification routine and hardware. If the power supply is a regulated +5V, this is adequate and no additional hardware or software is needed. If the application power supply is not regulated (such as a battery powered or poorly regulated system) it is important to complete a VDD min and VDD Max verification cycle following the +5V verification cycle. See programming specifications for more details on VDD verification procedures.

- PIC16C5X Programming Specifications - DS30190
- PIC16C55X Programming Specifications - DS30261
- PIC16C6X/7X/9XX Programming Specifications - DS30228
- PIC16C84 Programming Specifications - DS30189

Note: The designer must consider environmental conditions, voltage ranges, and aging issues when determing VDD min/max verification levels. Please refer to the programming specification for the application device.

The calibration programming and initial verification MUST occur at +5V. If the application is intended to run at lower (or higher voltage), a second verification pass must be added where those voltages are applied to VDD and the device is verified.

Communication format (Application Microcontroller to Programming Jig)

Unused program memory, in the application PIC16CXXX, is left unprogrammed as all 1s; therefore the unprogrammed program memory for the calibration look-up table would contain 3FFF (hex). This is interpreted as a "ADDLW FF". The application microcontroller simply needs one "RETLW FF" instruction at the end of the space allocated in program memory for the calibration parameter look-up table. When the application microcontroller is powered up, it will receive a "FFh" for each calibration parameter that is looked up; therefore, it can detect that it is uncalibrated and jump to the calibration code.

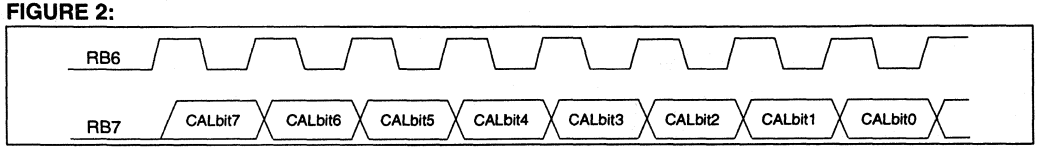
Once the calibration constants are calculated by the application PICmicro, they need to be communicated to the (PIC16C58A based) programming jig. This is accomplished through the RB6 and RB7 lines. The format is a simple synchronous clock and data format as shown in Figure 2.

A pulldown on the clock line is used to hold it low. The application microcontroller needs to send the high and low bytes of the target start address of the calibration constants to the calibration jig. Next, the data bytes are sent followed by a checksum of the entire data transfer as shown in Figure 3.

Once the data transfer is complete, the checksum is verified by the programming jig and the data printed at 9600 baud, 8-bits, no parity, 1 stop bit through RB3. A connection to this pin is optional. Next the programming jig applies +13V, programs and verifies the application PIC16CXXX calibration parameters.

3

FIGURE 2:



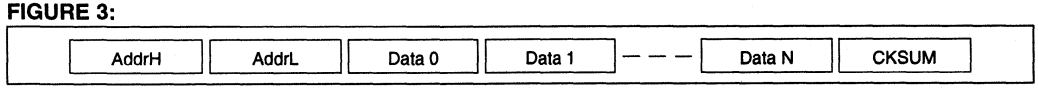


FIGURE 3:

LED Operation

When the programming jig is waiting for communication from the application PICmicro, both LEDs are OFF. Once a valid data stream is received (with at least one calibration byte and a correct checksum) the WORK LED is lit while the calibration parameters are printed through the optional RB3 port. Next, the DONE LED is lit to indicate that these parameters are being programmed and verified by the programming jig. Once the programming is finished, the WORK LED is extinguished and the DONE LED remains lit. If any parameters fail programming, the DONE LED is extinguished; therefore both LEDs would remain off.

FIGURE 4: ISP CALIBRATION JIG PROGRAMMER SCHEMATIC

Code Protection

Selection of the code protection configuration bit on PIC16CXXX microcontrollers prevents further programming of the program memory array. This would prevent writing self calibration parameters if the device is code protected prior to calibration. There are two ways to address this issue:

1. Do not code protect the device when programming it with the programmer. Add additional code (See the PIC16C6X/7X programming Spec) to the `ISPPRGM.ASM` to program the code protection bit after complete verification of the calibration parameters
2. Only code protect 1/2 or 3/4 of the program memory with the programmer. Place the calibration constants into the unprotected part of program memory.

Software Routines

There are two source code files needed for this application note:

1. `ISPTEST.ASM` (Appendix A) Contains the source code for the application PIC16CXXX, sets up the calibration look-up table and implements the communication protocol to the programming jig.

2. `ISPPRGM.ASM` (Appendix B) Source code for a PIC16C58A to implement the programming jig. This waits for and receives the calibration parameters from the application PIC16CXXX, places it into programming mode and programs/verifies each calibration word.

CONCLUSION

Typically, calibration information about a system is stored in EEPROM. For calibration data that does not change over time, the In-circuit Serial Programming capability of the PIC16CXXX devices provide a simple, cost effective solution to an external EEPROM. This method not only decreases the cost of a design, but also reduces the complexity and possible failure points of the application.

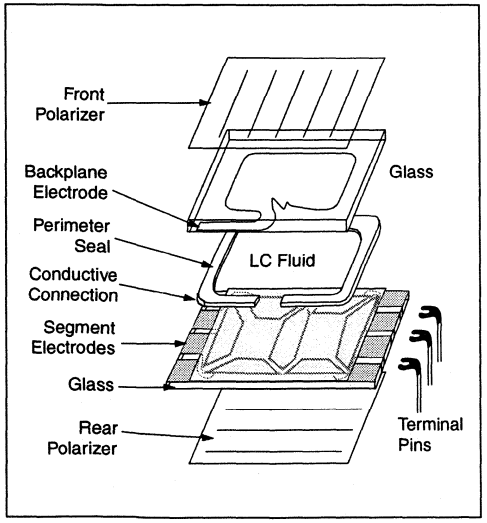
LCD Fundamentals Using PIC16C92X Microcontrollers

Author: *Rodger Richey*
Microchip Technology Inc.

INTRODUCTION

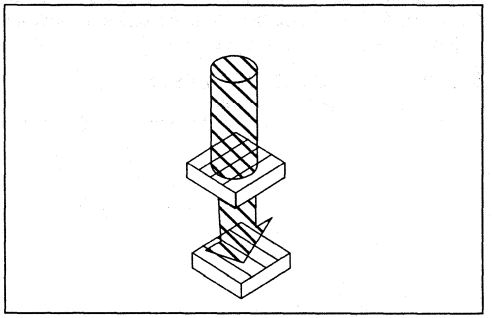
This Application Note provides a basic introduction to the features and uses of Liquid Crystal Displays (LCD).



At the end of this Application Note, you should be able to answer the following questions:

- What are the basic components in an LCD panel?
- How does an LCD work?
- What are the different types of LCD panels?
- How are LCD panels driven?

WHAT ARE THE BASIC COMPONENTS IN AN LCD PANEL?



An LCD panel, or more commonly known as a piece of "glass", is constructed of many layers. Figure 1 shows all the layers that are typically present in LCD panels. The first layer is called the **front polarizer**.

FIGURE 1: BASIC LCD COMPONENTS

Polarization is a process or state in which rays of light exhibit different properties in different directions, especially the state in which all the vibration takes place in one plane. Essentially, a polarizer passes light only in one plane. As shown in Figure 2, if light is polarized in one plane, by passing through a polarizer, it cannot pass through a second polarizer if its plane is 90° out of phase to the first.

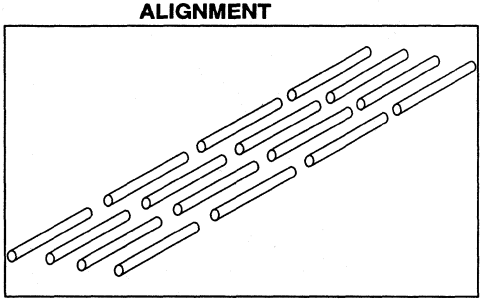
FIGURE 2: POLARIZERS OUT OF PHASE

The front polarizer is applied to the outside surface of the top piece of **glass**. The top piece of glass also provides structural support for the LCD panel.

On the bottom of the top glass, a transparent coating of Indium-Tin Oxide (ITO) is applied to the glass. ITO is conductive and forms the **backplane** or common electrodes of the LCD panel. The patterns of the backplane and segment ITO forms the numbers, letters, symbols, icons, etc.

After the ITO has been applied to the glass, a thin polyimide coating is applied to the ITO. The polyimide is "rubbed" in a single direction that matches the polarization plane of the front polarizer. The action of "rubbing" the polyimide causes the Liquid Crystal (LC) molecules in the outermost plane to align themselves in the same direction.

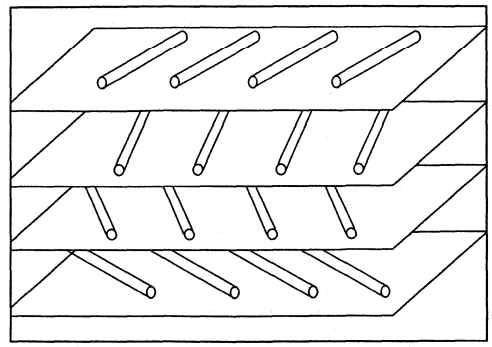
3



© 1997 Microchip Technology Inc.

The next layer is a reservoir of LC. The **LC fluid** has many planes of molecules.

The next layer is the polyimide coating on the bottom glass followed by the ITO **segment electrodes**. The bottom glass also supplies structural integrity for the LCD panel as well as mounting surface for the electrode connections. Applied to the external surface of the bottom glass is the rear polarizer. Depending on the type of viewing mode employed by the LCD panel, the axis of polarization is the same or 90° apart from the front polarizer.



LC molecules are long and cylindrical. On any plane within the LC fluid, the molecules align themselves such that the major axis of each molecule is parallel to all others, as shown in Figure 3. The outermost planes of LC molecules will align themselves on the same axis that the polyimide is "rubbed". The direction of "rubbing" of the polyimide on the bottom glass is 90° apart from that of the polyimide on the top glass. This orientation creates the twist in the LC fluid.

FIGURE 3: LC MOLECULES IN ALIGNMENT

A consequence of this alignment is that each intermediate plane of LC molecules will have a slightly different orientation from the plane above or below as seen in Figure 4.

FIGURE 4: LC MOLECULES PLANE ORIENTATION

The twisting of the planes causes the polarization of the light to twist as it passes through the LC fluid. The twisting of the LC planes is critical to the operation of the LCD panel as will be shown in the next section.

Now that the mystery of what the LCD panel is made of has been uncovered, how does an LCD work?

© 1997 Microchip Technology Inc.

HOW DOES AN LCD WORK?

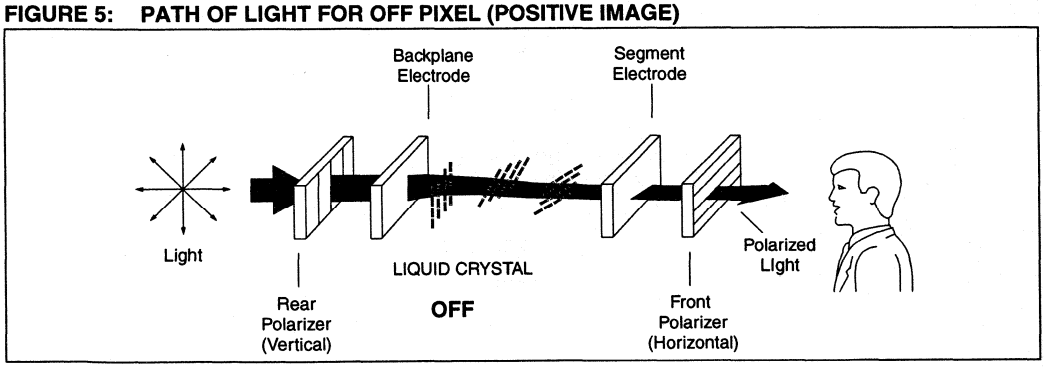
As explained before, the twist created in the LC fluid is the basis of how the panel operates. Figure 5 shows how an LCD panel creates a pixel that is OFF. For this example the LC fluid is not energized, i.e. there is 0 VRMS potential between the backplane and segment electrodes. The following is a step-by-step description of the path light takes through the LCD panel.

1. Light enters the panel through the rear polarizer. At this point the light becomes polarized to the vertical plane.
2. The polarized light passes unobstructed through the transparent backplane electrode.
3. As the polarized light passes through the LC fluid it gets twisted into the horizontal plane.
4. The polarized light passes unobstructed through the transparent segment electrode.
5. Since the light is now polarized in the horizontal plane, it passes unobstructed through the front polarizer which has a horizontal polarization.
6. The observer does not detect that the pixel is on because the light has not been obstructed.

If a potential is applied across the backplane and segment electrodes, the LC fluid becomes energized. The LC molecule planes will now align themselves such that they are parallel to the electrical field generated by the potential difference. This removes the twisting effect of the LC fluid. Figure 6 shows a pixel that is ON or, more specifically energized. The following is a step-by-step description of the path that the light takes through this LCD panel.

1. Light enters the panel through the rear polarizer. At this point the light becomes polarized to the vertical plane.
2. The polarized light passes unobstructed through the transparent backplane electrode.
3. As the polarized light passes through the LC fluid it does not twist and remains in the vertical plane.
4. The polarized light passes unobstructed through the transparent segment electrode.
5. Since the light is still polarized in the vertical plane, it is obstructed by the front polarizer which has a horizontal polarization.
6. The observer detects that the pixel is on because the light has been obstructed and creates a dark image on the panel.

FIGURE 5: PATH OF LIGHT FOR OFF PIXEL (POSITIVE IMAGE)



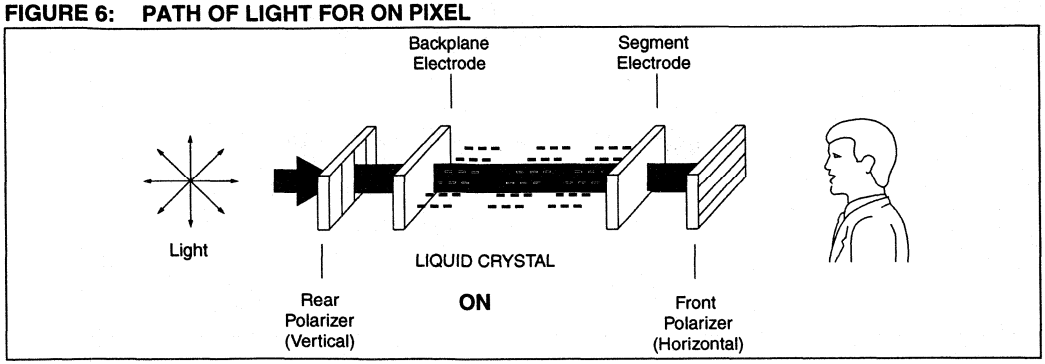


FIGURE 6: PATH OF LIGHT FOR ON PIXEL

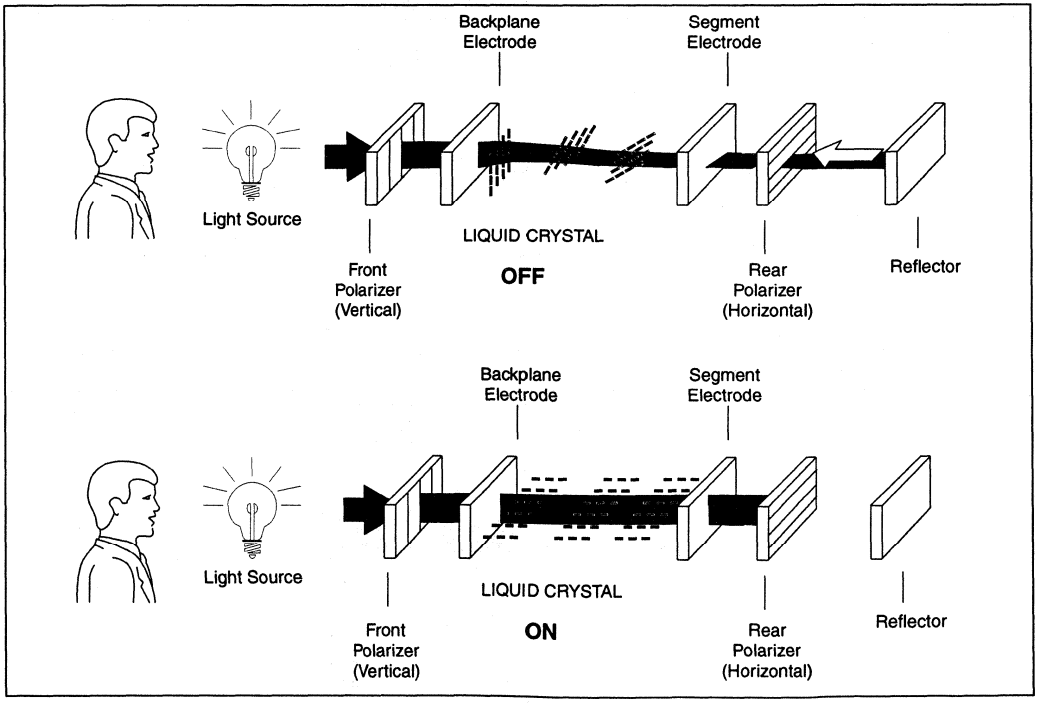
LCD IMAGES



LCDs have the capability to produce both positive and negative images. A **positive image** is defined to be a dark image on a light background. In a positive image display, the front and rear polarizers are perpendicular to each other. Unenergized pixels and the background area transmit the light and energized pixels obstruct the light creating dark images on the light background. A **negative image** is a light image on a dark background. In this type of display, the front and rear polarizers are aligned to each other. Unenergized pixels and the background inhibit light from passing through the display. Energized pixels allow the light to pass creating a light image on a dark background.

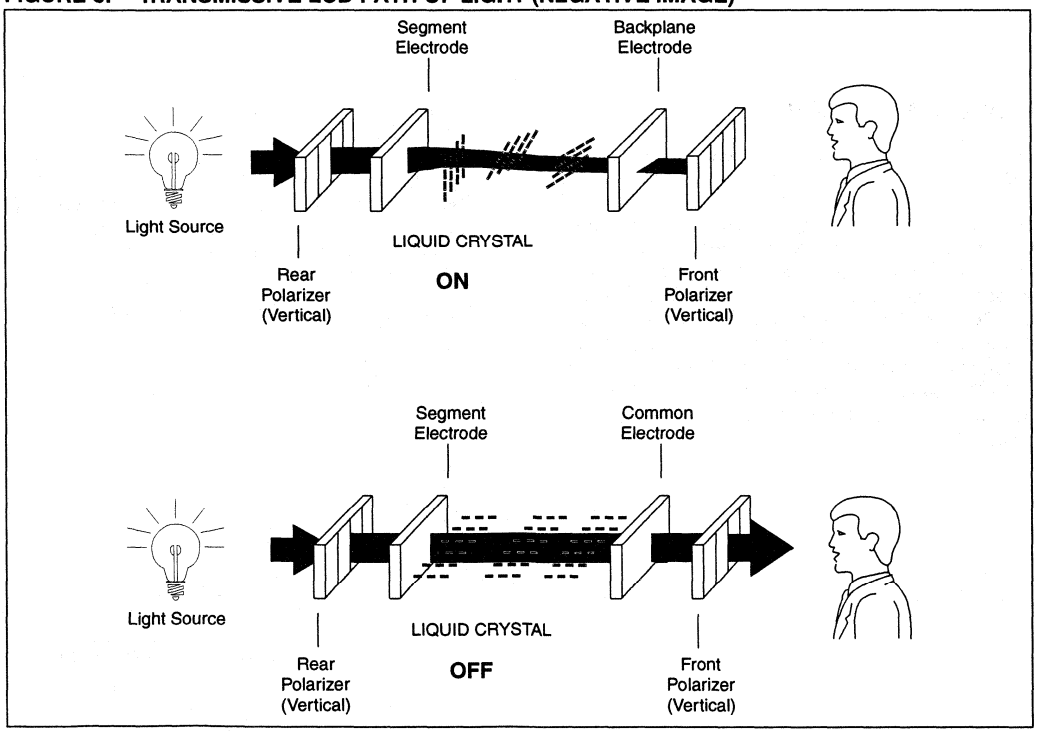
There are essentially three types of viewing modes for a LCD: reflective, transmissive, and transflective. Typically **Reflective displays** use only positive images. The front and rear polarizers are perpendicular to each other. The LCD panel will have an additional layer added to the bottom of the display, a reflector. Figure 7 shows the diagrams for pixels that are ON and OFF for reflective displays. Here again, the path that light takes is described in a step-by-step fashion for a pixel that is OFF in a positive image display.

1. Light enters the panel through the front polarizer. At this point the light becomes polarized to the vertical plane.
2. The polarized light passes unobstructed through the transparent backplane electrode.
3. As the polarized light passes through the LC fluid it gets twisted into the horizontal plane.
4. The polarized light passes unobstructed through the transparent segment electrode.
5. Since the light is now polarized in the horizontal plane, it passes unobstructed through the rear polarizer which has a horizontal polarization.
6. The reflector behind the rear polarizer reflects the incoming light back on the same path.
7. The observer does not detect that the pixel is ON because the light was reflected back.

A pixel that is ON follows the same basic steps except that the light never reaches the reflector and therefore does not return to the observer. Reflective displays lend themselves to battery powered applications because the images are created using ambient light sources. These displays are very bright under proper lighting conditions, with excellent contrast, and have a wide viewing angle.

FIGURE 7: REFLECTIVE LCD PATH OF LIGHT

© 1997 Microchip Technology Inc.



Transmissive displays do not reflect light back to the observer. Instead, they rely upon a light source behind the panel to create images. A transmissive display has front and rear polarizers that are in phase to each other. Figure 8 shows the OFF and ON diagrams for a transmissive display. The path of light is described below for the ON state only in a positive image display.

1. Light enters the panel through the rear polarizer. At this point the light becomes polarized to the vertical plane.
2. The polarized light passes unobstructed through the transparent segment electrode.
3. As the polarized light passes through the LC fluid it gets twisted into the horizontal plane.
4. The polarized light passes unobstructed through the transparent backplane electrode.
5. Since the light is now polarized in the horizontal plane, it is obstructed by the front polarizer which has a vertical polarization. Very little light passes through the front polarizer
6. The observer does not detect that the pixel is ON because the light was obstructed.

An OFF pixel would allow the light to pass through the display unobstructed because the polarization does not get twisted by the LC fluid. These displays are very good for very low light level conditions. They are very poor when used in direct sunlight because the sunlight swamps out the backlighting.

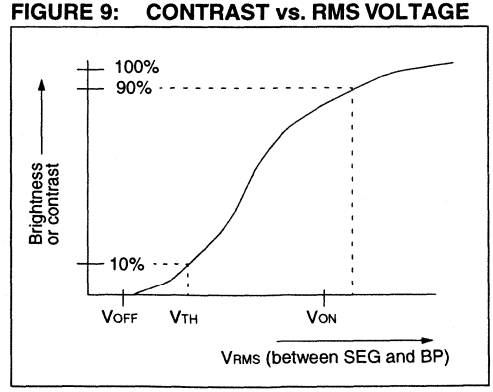
The third type of display is called **transflective**. As you can probably tell from the name, it is a combination of reflective and transmissive. A white or silver translucent material is applied to the rear of the display. It reflects some of the ambient light back to the observer while also allowing backlighting. Transflective displays are very good for applications which have varying light conditions such as gas pumps. They must operate during the day in bright sunlight, but must also operate at night. Transflective displays have lower contrast ratios than reflective displays because some of the light passes through the reflector.

FIGURE 8: TRANSMISSIVE LCD PATH OF LIGHT (NEGATIVE IMAGE)

© 1997 Microchip Technology Inc.

The type of LCD that an application requires is largely dependent on the ambient light available. Table 1 gives some guidelines for selecting a display according to the lighting conditions.

TABLE 1: LIGHTING CONDITION REFERENCE



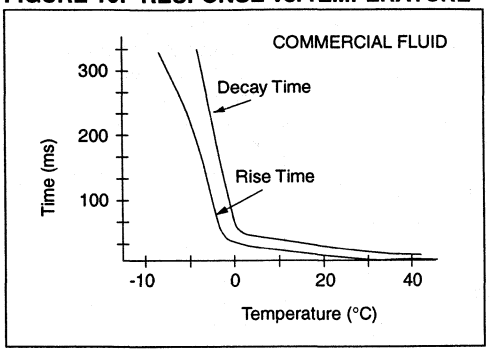
Viewing Mode	Display Description	Application Comments	Direct Sunlight	Office Light	Very Low Light
Reflective (Positive)	Dark images on light background	No backlighting. Gives best contrast and environmental stability	Excellent	Very Good	Unusable
Transflective (Positive)	Dark images on gray background	Can be viewed with both ambient light and backlighting	Excellent (no backlight)	Good (no backlight)	Very Good (backlight)
Transflective (Negative)	Light gray images on dark background	Requires high ambient light or backlighting.	Good (no backlight)	Fair (no backlight)	Very Good (backlight)
Transmissive (Negative)	Backlit images on dark background	Cannot be viewed by reflection	Poor (backlight)	Good (backlight)	Excellent (backlight)
Transmissive (Positive)	Dark images on a backlit background	Good for very low light conditions	Poor (backlight)	Good (backlight)	Excellent (backlight)

DRIVER VOLTAGES

The number one cause of LCD damage is having a DC voltage applied to it. A DC voltage will deteriorate the LC fluid such that it cannot be energized. The LCD driver waveforms are designed to create a 0 VDC potential across all pixels. The specifications for a LCD panel will include some RMS voltages such as **VOFF** and **VON**. A third voltage is **VTH** which is the RMS voltage across an LCD pixel when contrast reaches a 10% level. Often this voltage is used as VOFF. VON is defined as the RMS voltage applied by the LCD driver to the segment electrode that creates an ON pixel which is typically at the 90% contrast level. It is desirable that VON be much greater than VOFF.

Figure 9 graphically represents the voltage potential versus the contrast across a pixel. The final specification for an LCD panel is the discrimination ratio which is VON divided by VOFF (VON/VOFF). The **discrimination ratio** specifies what type of contrast levels the LCD panel will be able to achieve. Examples of discrimination ratio calculations will be given in the section "How are LCD Panels Driven?".

FIGURE 9: CONTRAST vs. RMS VOLTAGE



© 1997 Microchip Technology Inc.

RESPONSE TIME

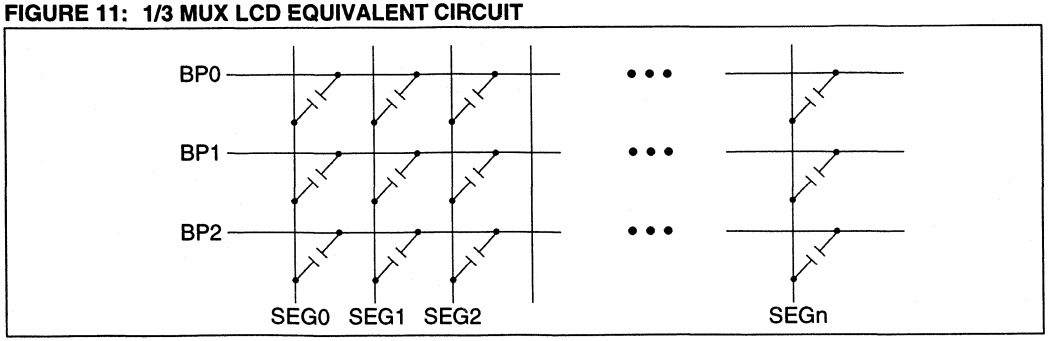
An LCD panel will have a typical ON and OFF response time. The **ON time** parameter refers to the time for an OFF pixel to become visible after the appropriate voltages have been applied. The **OFF time** parameter specifies the time for an ON segment to disappear. Sometimes these parameters are called rise and decay, respectively. Temperature plays a key role in the response time of an LCD panel. Figure 10 shows the response times versus temperature for commercial type LC fluid. For this reason, there are no LCD panels in gas pumps in Alaska without heaters. Displays with heaters can help to decrease response time even at temperatures as low as -55°C. The drawback of an LCD heater is that every square inch of surface on the back of the display requires 2 to 3 watts.

FIGURE 10: RESPONSE vs. TEMPERATURE

TEMPERATURE EFFECTS

As previously shown, temperature has a large impact on the performance of the LCD panel. Not only is the LC fluid affected, but the internal coatings begin to deteriorate. All LC fluids have well defined operating temperature limits. If an LCD is operated above its fluid limits, the LC molecules begin to assume random orientations. The pixels on a positive image display will become completely dark, while pixels on a negative image display will become completely transparent. An LCD can recover from these conditions if the exposure is kept short, however, temperatures above 110°C will cause the ITO and polyimide coatings to deteriorate.

On the low end of the temperature spectrum, response times increase because the viscosity of the LC fluid increases. At very low temperatures, typically -60°C, the LC fluid transitions into a crystalline state. Usually, the LC fluid can recover from the effects of low temperature. Many different types of LC fluid are available, which allows the LCD panel to be tailored to the expected operating conditions. As mentioned in the previous section, heaters can combat the effects of low temperature.



CAPACITANCE

The LCD panel can be modeled as a lossy, non-linear capacitor. The area of the pixel, and therefore the size of the LCD panel, has a direct impact on the value of the capacitance that a common or segment driver must be able to drive. Typical values of capacitance are in the range of 1000 - 1500 pF/cm^2. Figure 11 shows an example of a 1/3 MUX panel. As you can see the backplane driver must be capable of driving significantly higher capacitances than the segment driver.

Care must be taken when designing a system such that your LCD driver is capable of driving the capacitance on the segment and common. Otherwise the LCD panel may be damaged due to a DC offset voltage generated by overloaded segment and common drivers.

PIC16C92X microcontrollers are capable of driving backplanes up to 5000 pF and segments up to 500 pF.

FIGURE 11: 1/3 MUX LCD EQUIVALENT CIRCUIT

BACKLIGHTING

A variety of methods exist for backlighting LCD panels, such as, incandescent lamps, LEDs, and electroluminescent lamps. Incandescent lamps require some type of reflector to provide uniform lighting to all areas of the panel. LEDs require some type of lightguide or lightpipe to evenly distribute light. Electroluminescent lamps typically come in some type of a panel arrangement. Other lighting methods are available for specific applications, such as fluorescent. Table 2 provides a comparison of these methods of backlighting.

TABLE 2: BACKLIGHTING FEATURES COMPARISON

Feature	LED	Incandescent	Electroluminescent
Brightness	Medium	High	Low-Medium
Color	Limited	White	White
Size	Small	Small-Medium	Thin
Voltage	5V	1.5V - 28V	45V - 100V
Current @5V/sq. in	10-30 mA	20 mA	1 mA - 10 mA
Temperature	Warm	Hot	Cool
Cost/sq. in	$0.10 - $1.00	$0.10 - $0.80	$0.50 - $2.00
Shock Tolerance	Excellent	Fragile	Excellent
Life (hours)	100,000	150 - 10,000	500 - 15,000

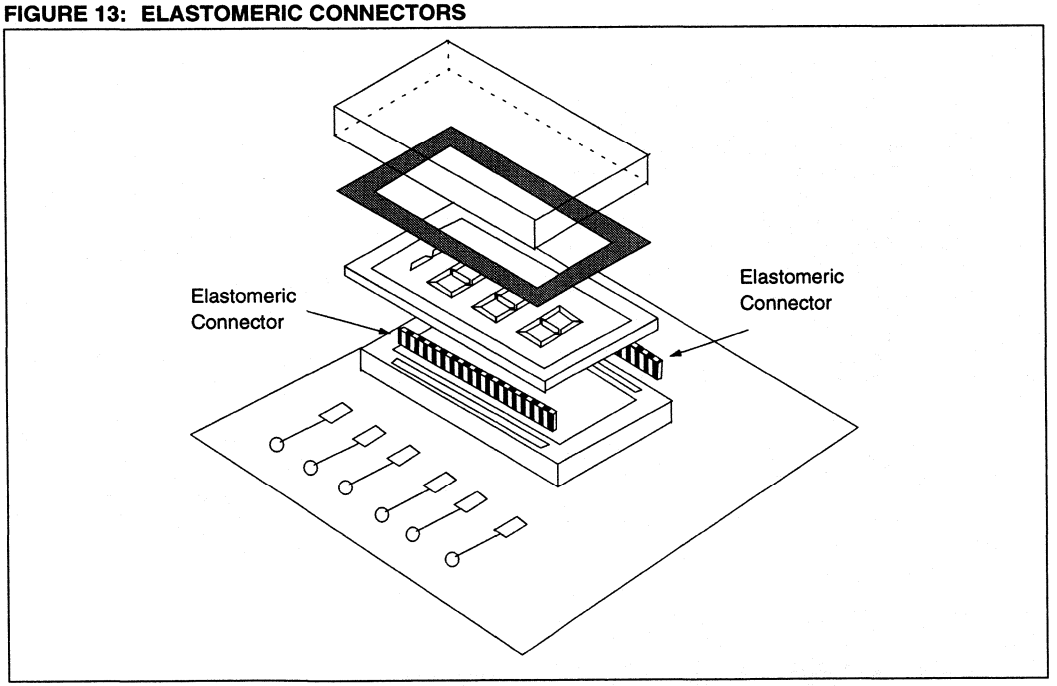
CONNECTION METHODS

The first method of connecting the LCD panel to the world was the dual-in-line pin shown in Figure 12.



These pins provide excellent protection for harsh environments, vibration or shock. The LCD panel is either soldered directly to the printed circuit board (PCB) or inserted into headers.

FIGURE 12: DUAL IN-LINE PINS

The second method is elastomeric connectors. This method allows fast assembly/disassembly without having to solder the LCD panel. Elastomeric connectors are used on small applications where space is a concern. These connectors are relatively resistant to shock and vibration, but special consideration must be used when the panel will be exposed to harsh environments. Figure 13 shows an assembly drawing of an elastomeric connector.

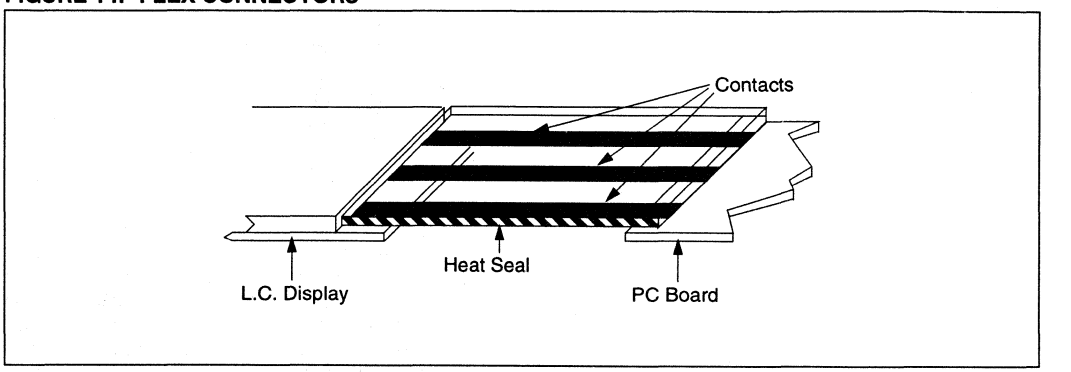


FIGURE 13: ELASTOMERIC CONNECTORS

© 1997 Microchip Technology Inc.

One of the newer methods is the flex connector. A PCB and the LCD panel are connected by a flexible cable using a heat seal process. The flexible cable is typically a anisotropic connective film that is applied to the PCB and LCD panel using heat and pressure. These connectors were designed for harsh environments where the connector must be flexible enough to prevent breakage during stress. These connectors are becoming more popular with large or remotely mounted LCD panels. Figure 14 shows a typical application.

FIGURE 14: FLEX CONNECTORS

WHAT ARE THE DIFFERENT TYPES OF LCD PANELS?

LCD panels come in many flavors depending on the application and the operating environment. LCDs can be classified in two ways. First of all, LCDs come in direct drive or multiplex drive variations. Direct drive, otherwise known as static, means that each pixel of the LCD panel has an independent driver. The LCD panel also has only one backplane. A static drive panel also has static bias. Bias is defined as the number of voltage levels the LCD driver uses to create images on the screen. The number of voltage levels is equivalent to the 1 + 1/bias. Static bias refers to two voltage levels which create a square wave, ground and V_{DD}. Static drive panels also have the best contrast ratios over the widest temperature range.

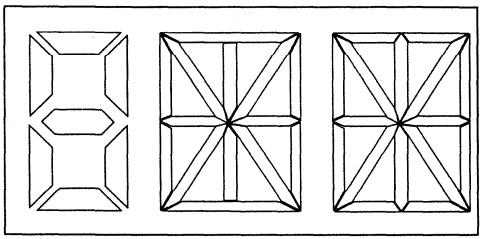
Multiplex drive panels reduce the overall amount of interconnections between the LCD and the driver. Put simply, multiplex panels have more than one backplane. A multiplex LCD driver produces an amplitude-varying, time synchronized waveform for both the segment and backplanes. These waveforms allow access to one pixel on each of the backplanes. This significantly increases the complexity of the driver. The number of backplanes a panel has is referred to the multiplexing ratio or "MUX" of the panel. MUX also refers to duty cycle. For instance, a 1/3 MUX panel has three backplanes. The bias for multiplex panels is at least 1/2 - 1/5 for segment type drivers and from 1/8 - 1/33 for dot matrix. Table 3 illustrates the advantage of multiplex panels.

TABLE 3: STATIC vs. MULTIPLEX PIN COUNT

LCD panel	Back planes	Segments	Total
3 - 1/2 digit	1	23	24
	2	12	14
8 digits	1	64	65
	4	16	20
2 x 16 character dot matrix, 5 x 7 characters	1	1280	1281
	8	160	168
	16	80	96
128 x 240 graphic display	1	30,720	30721
	64	480	544
	128	240	368

The last time Microchip investigated high pin count packages, 30,000+ was not an option.

© 1997 Microchip Technology Inc.



PIC16C92X microcontrollers have the following drive capabilities:

TABLE 4: PIC16C92X DRIVE CAPABILITY

MUX	Bias	Backplanes	Segments
Static	Static	1	32
1/2	1/3	2	31
1/3	1/3	3	30
1/4	1/3	4	29

The other method of classifying LCD panels is the type of display notation used, i.e. segment, dot matrix, or functional. Segment displays are usually the 7-segment, 14-segment, or 16-segment ("British Flag") types used to create numbers and letters. These type of displays are static drive which provides the best contrast and readability in sunlight. Figure 15 shows all three segment displays mentioned.

FIGURE 15: SEGMENT TYPE DISPLAY

Dot matrix displays are always multiplex type displays due to the large number of pixels required and pin limitations on the driver. Dot matrix displays can create more natural letters and numbers as well as custom graphic symbols. Figure 16 shows a typical 5x7 dot matrix character set.

The third type of display is most commonly used in conjunction with the previous types. A function indicator or icon provides status information about the system. They are only capable of being turned on or off. One example would be a digital multimeter. The meter has three 1/2 digits which are 7-segment type and also some icons for volts, amps, ohms and the ranges for m, µ, K, and M. Another example would be a cellular telephone. The LCD panel will have eight or more 5x7 dot matrix characters with icons for events such as in use, roam, no service, battery status, and signal strength. Figure 17 shows what a typical cellular phone panel might resemble.

3

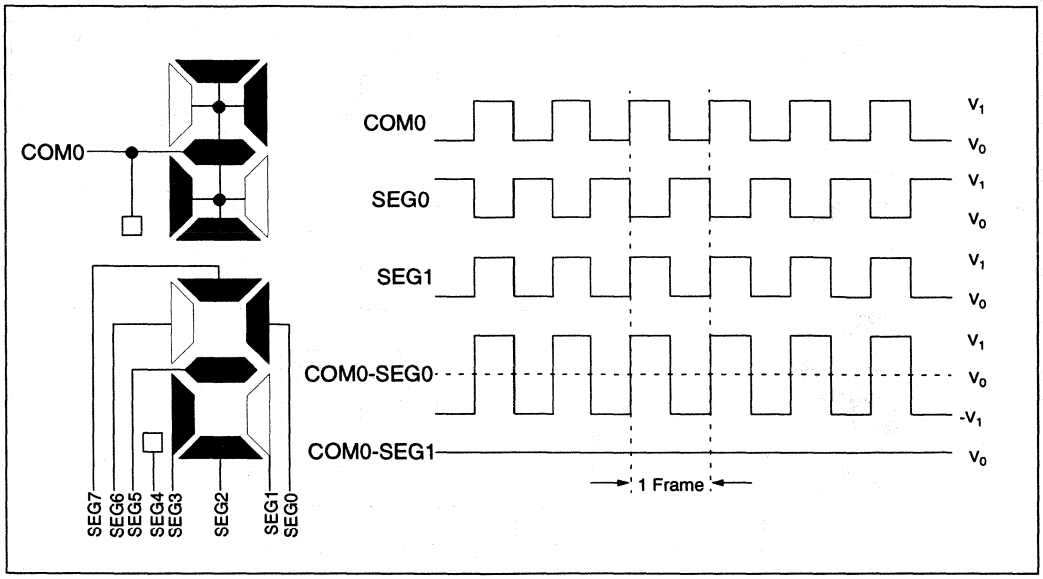
HOW ARE LCD PANELS DRIVEN?

So far, the mysteries of how an LCD is made, how it works, and what the different type of panels have been revealed. This section will demystify the LCD waveforms. An LCD can be characterized by the MUX ratio and bias, but one piece of information is still missing - Drive Waveforms. LCDs can be driven by two types of waveforms: Type A and Type B. Before the definitions of the two types are given, the term frame frequency must be defined. The LCD frame frequency is the rate at which the backplane and segment outputs change. The frame frequency is then calculated to be the LCD period / 2 • number of backplanes. The range of frame frequencies is from 25 to 250 Hz with the most common being between 50 and 150 Hz. Higher frequencies result in higher power consumption while lower frequencies cause flicker in the images on the LCD panel. An earlier section mentioned that a LCD driver must maintain a 0 VDC potential across each pixel. Type A waveforms maintain 0 VDC over a single frame whereas Type B takes two frames. Figure 18 shows both types of waveforms with 1/3 MUX and 1/3 Bias. PIC16C92X microcontrollers support only Type A waveforms.



The voltage applied across a particular pixel is the voltage on the COM pin minus the voltage on the SEG pin. If the resulting voltage is at or above the VON threshold then the pixel is visible. Otherwise the voltage will be at or below the VOFF threshold and the pixel will not be visible. This formula is used for all drive/bias methods. The following figures show each of the modes that are currently supported by the PIC16C92X devices. Since the PIC16C92X devices only support Type A waveforms, only Type A waveforms for each of the modes are shown. Each figure has the LCD period and the frame locations marked.

DISCRIMINATION RATIO

Now that the LCD waveforms have been presented, let's calculate the discrimination ratio for some of them. The first example is a static waveform from Figure 19. The voltages V_1 and V_0 will be assigned values of 1 and 0. The next step is to construct a matrix for one frame to help visualize the DC and RMS voltages present on an individual pixel when it is ON and when it is OFF. The rest of the following shows the calculation of the DC, RMS, and Discrimination Ratio.

EXAMPLE 1: DISCRIMINATION RATIO CALCULATION FOR STATIC MUX

BPx	0	1	
SEGx	1	0	ON
	0	1	OFF

BPx - SEGx [ON] = -1 + 1, $V_{DC} = 0$

BPx - SEGx [OFF] = 0 + 0, $V_{DC} = 0$

$$V_{RMS}\,[ON] = \Delta V\sqrt{\frac{(-1)^2 + (1)^2}{2}} = 1\Delta V$$

$$V_{RMS}\,[OFF] = \Delta V\sqrt{\frac{(0)^2 + (0)^2}{2}} = 0\Delta V$$

$$D = \frac{V_{RMS}\,[ON]}{V_{RMS}\,[OFF]} = \frac{1\Delta V}{0\Delta V} = \infty$$

The next example is for Figure 22 which is a 1/4 MUX, 1/3 BIAS waveform. For this example, the values 3, 2, 1 and 0 will be assigned to V_3, V_2, V_1, and V_0 respectively. The frame matrix, DC voltage, RMS voltage and discrimination ratio calculations are shown in Example 2:

EXAMPLE 2: DISCRIMINATION RATIO CALCULATION 1/4 MUX

BP0	0	3	2	1	2	1	2	1	
BP1	2	1	0	3	2	1	2	1	
BP2	2	1	2	1	0	3	2	1	
BP3	2	1	2	1	2	1	0	3	
SEGx	3	0	3	0	3	0	3	0	ON
	1	2	1	2	1	2	1	2	OFF

BP0 - SEGx [ON] = - 3 + 3 - 1 + 1 - 1 + 1 - 1 + 1 $V_{DC} = 0$

BP0 - SEGx [OFF] = - 1 + 1 - 1 + 1 - 1 + 1 - 1 + 1 $V_{DC} = 0$

$$V_{RMS}\,[ON] = \Delta V\sqrt{\frac{(-3)^2 + (3)^2 + (-1)^2 + (1)^2 + (-1)^2 + (1)^2 + (-1)^2 + (1)^2}{8}} = \sqrt{3}\,\Delta V$$

$$V_{RMS}\,[OFF] = \Delta V\sqrt{\frac{(-1)^2 + (1)^2 + (-1)^2 + (1)^2 + (-1)^2 + (1)^2 + (-1)^2 + (1)^2}{8}} = \Delta V$$

$$D = \frac{V_{RMS}\,[ON]}{V_{RMS}\,[OFF]} = \frac{\sqrt{3}\,\Delta V}{1\ \Delta V} = 1.732$$

As shown in these examples, static displays have excellent contrast. The higher the multiplex ratio of the LCD, the lower the discrimination ratio, and therefore, the lower the contrast of the display.

The following table shows the VOFF, VON and discrimination ratios of the various combinations of MUX and BIAS.

TABLE 5: DISCRIMINATION RATION vs. MUX AND BIAS

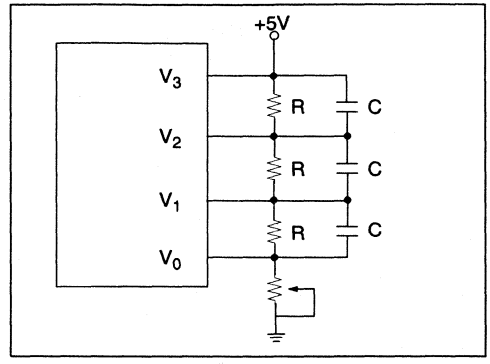
	1/3 BIAS		
	Voff	**Von**	**D**
STATIC	0	1	∞
1/2 MUX	0.333	0.745	2.236
1/3 MUX	0.333	0.638	1.915
1/4 MUX	0.333	0.577	1.732

Table 5 shows that as the multiplex of the LCD panel increases, the discrimination ratio decreases. The contrast of the panel will also decrease, so to provide better contrast the LCD voltages must be increased to provide greater separation between each level.

LCD VOLTAGE GENERATION

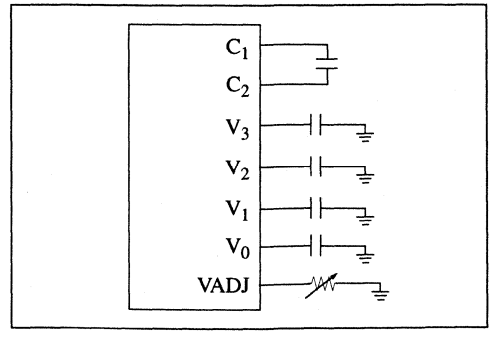
Among the many ways to generate LCD voltage, two methods stand out above the crowd: resistor ladder and charge pump.

FIGURE 23: RESISTOR LADDER



The resistor ladder methods, shown in Figure 23 is most commonly used for higher Vcc voltages. This method uses inexpensive resistors to create the multilevel LCD voltages. Regardless of the number of pixels that are energized the current remains constant. The voltage at point V3 is typically tied to Vcc, either internally or externally.

The resistance values are determined by two factors: display quality and power consumption. Display quality is a function of the LCD drive waveforms. Since the LCD panel is a capacitive load, the waveform is distorted due to the charging and discharging currents. This distortion can be reduced by decreasing the value of resistance. However this change increases the power consumption due to the increased current now flowing through the resistors. As the LCD panel increases in size, the resistance value must be decreased to maintain the image quality of the display.



Sometimes the addition of parallel capacitors to the resistance can reduce the distortion caused by charging/discharging currents. This effect is limited since at some point a large resistor and large capacitor cause a voltage level shift which negatively impacts the display quality. In general, R is 1 kΩ to 50 kΩ and the potentiometer is 5 kΩ to 200 kΩ.

FIGURE 24: RESISTOR LADDER WITH CAPACITORS

A charge pump is ideal for low voltage battery operation because the VDD voltage can be boosted up to drive the LCD panel. The charge pump requires a charging capacitor and filter capacitor for each of the LCD voltages as seen in Figure 25. These capacitors are typically polyester, polypropylene, or polystyrene material. Another feature that makes the charge pump ideal for battery applications is that the current consumption is proportional to the number of pixels that are energized.

FIGURE 25: CHARGE PUMP

© 1997 Microchip Technology Inc.

CONTRAST

Although contrast is heavily dependent on the light source available and the multiplex mode, it also varies with the LCD voltage levels. As previously seen, a potentiometer is used to control the contrast of the LCD panel. The potentiometer sets the separation between each of the LCD voltages. The larger the separation, the better the contrast achievable.

CONCLUSION:

Hopefully you can now answer the questions:

- What are the basic components in an LCD panel?
- How does an LCD work?
- What are the different types of LCD panels?
- How are LCD panels driven?

This application note has covered LCD fundamentals in great detail. Please refer to the PIC16C92X microcontroller data sheet for more information. Also application note AN649, "Yet Another Clock Featuring the PIC16C924" shows an example application using the PIC16C924.

Smart Battery Charger with SMBus Interface

Authors: *Laszlo Kiraly, Linear Technology*
Robert Schreiber, Microchip Technology

INTRODUCTION

This application note provides the schematics, software listings, and circuit board layout for a PIC16C73 based Smart Battery Charger. The Demo Board, DC101, is available to selected customers through Linear Technology Corp. product marketing.

The DC101 (Figure 1) is the Smart Battery Charger (SBC) portion of a Smart Battery System. A simplified block diagram of a Smart Battery System is shown in Figure 3 (refer to "The Smart Battery Charger Specification," Duracell).

The Smart Battery (SB) contains circuitry which provides charging information to the SBC. The SBC receives this information in terms of ChargingVoltage(), ChargingCurrent(), and AlarmWarning() commands from the SB. The SBC and SB communicate via the System Management Bus (SMB), which is an implementation of the I^2C bus (refer to "The Smart Management Bus Specification," Intel; and "The I^2C Bus and How to Use It," Philips Semiconductor). The SBC sets the charging current and voltage based on input from the SB. The SBC charger also has the intelligence to monitor the SB's thermistor. The thermistor provides temperature information for charge termination, and battery chemistry information.

3

FIGURE 3: BLOCK DIAGRAM

OPERATING THE BOARD

Input voltage. The nominal input voltage of the board is 24V DC (Refer to Appendix A for Performance Summary). The input voltage must be higher than the battery voltage by a minimum of 3V. The minimum input voltage is 16V, limited by the undervoltage lockout circuit in the LT1511 and set by resistors R16, R17 and R18. The highest input voltage is 27.4V, that is limited by the maximum input voltage of the LT1511. The input is protected against reverse polarity up to 30V.

Input current. The sum of the system current and the charger input current is limited by the LT1511 to 2A. When both the system current and the charger input current requirements are high, the charger reduces the charging current to meet the 2A current limit.

RED LED. It indicates SMBus activity. It lights-up for about 1 second when the charger recognizes its own address (12hex) on the SMBus.

Green LED. Flashing green LED indicates microprocessor activity and charger status.

Fast blinking (approximately 8 Hz) indicates normal microprocessor activity and either trickle charge or shut down charger status. After valid voltage and current data have been received the blinking speed of the LED slows down to about 2 Hz, indicating normal charging.

Battery removal, thermistor measurements. The charger periodically checks the thermistor in the battery through the T terminal. When the thermistor is out of normal operating temperature range, the charger switches to trickle charge mode and increases the flashing frequency of the green LED to indicate an abnormal charging condition. When the resistance of the thermistor is in the 500Ω < Rth < 1.5 kΩ range, the charger assumes Li Ion battery is at the output, and instead of trickle charging the battery it shuts-down the charger until a valid voltage and current request arrives from the battery.

An open thermistor forces the charger into trickle charge mode and the charger disregards data on the SMBus.

The schematics, parts list, and circuit layout are shown in Appendix A.

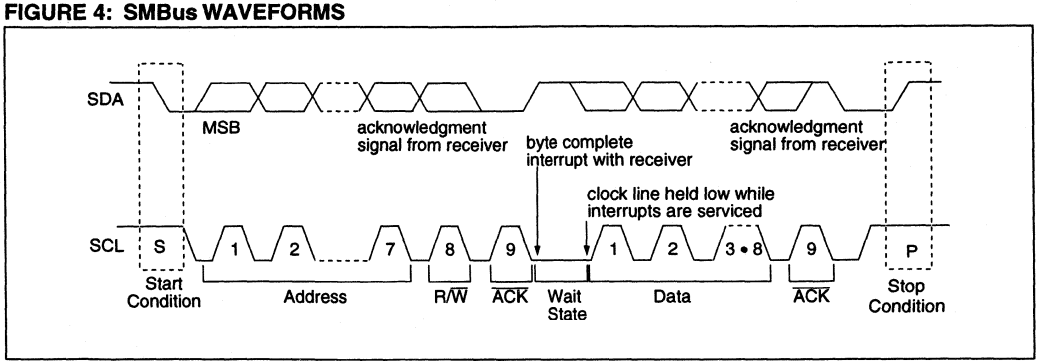
© 1997 Microchip Technology Inc.

SYSTEM MANAGEMENT BUS (SMBUS)

When charge in the Smart Battery (SB) drops below 85% of the nominal capacity, it initiates communication over the SMBus every 64 seconds. After sending a START sequence the battery addresses the Smart Battery charger and waits for acknowledgment (ACK) from it. If the charger fails to acknowledge the word, the battery terminates further communication by placing a STOP sequence onto the SMBus. If the charger acknowledges (ACK) the reception of first word, the battery continues the communication sequence and it sends six more words to the charger. The complete current and voltage request communication sequence is shown below:

```
START
address (12 hex)
ChargingCurrent() command code (14 hex),
current_LSB
current_MSB,
address (12 hex)
ChargingVoltage() command code (15 hex)
voltage_LSB
voltage_MSB
STOP
```

The idealized SMBus waveforms shown in Figure 4 illustrate SMBus communication between the battery and the charger. The first seven bits after the start sequence is the battery address. The R/$\overline{W}$ tells the charger that the battery attempts to write to the charger.



During the acknowledge period (ACK), the charger becomes active and it pulls the data line (SDA) low indicating reception of a data word. When reception of the data word is not acknowledged by the charger, the battery terminates the communication by sending a STOP sequence to the bus. The clock pulses for the communication are always generated by the battery (BUS MASTER).

CONCLUSION

The PIC16C73 contains the on-board peripherals necessary to easily implement an SMBus battery charger. The I^2C module allows for the SMBus communications and the PWM modules allow for voltage and current control. This high level of integration reduces the external components required and increases the flexibility of the design.

A complete software listing is shown in Appendix B.

/*-------------------------------------------------------------------------
                                                    April 16,1996
This program:
 Sets-up PWMs and I2C communication.
 It receives data from I2C (including its own address) and stores them
 in i2c_data[10] as they come in, including its own address (0x12).

               0 charger i2c address (always 0x12)
               1 ChargingCurrent() CMD (0x14)
               2 charging current data byte L
               3 charging current data byte H       (unsigned int, mA)
               4 charger i2c address (0x12)
               5 ChargingVoltage CMD (0x15)
               6 charging voltage data byte L
               7 charging voltage data byte H       (unsigned int, mV)

Revision changes:

- scales current word and loads value to IPWM (PWM2).
- scales voltage word and loads value to VPWM (PWM1).
- 16CC73.H bits for CCP1CON registers need to be specified.
- thermistor limits were changed   (2/21/96)
- using easy math (2/21/96)
//
- comments were added                                          (4/11/96)
- init() function was created                                  (4/11/96)
- AlarmWarning() function now checks b15:b12 bits.             (4/11/96)
* At LT1511 UV shutdown (DCOK-L) uP pulls its shut-down high.
- The uP enables the charger after valid data received from battery.(4/11/96)
- No broadcast from battery timeout (180 sec. nom.) now implemented.(4/11/96)
- SMBus reset function has been added.                         (4/15/96)
- GIE disable and enable was removed (__int handles them)      (4/16/96)

Servo Control of a DC-Brush Motor

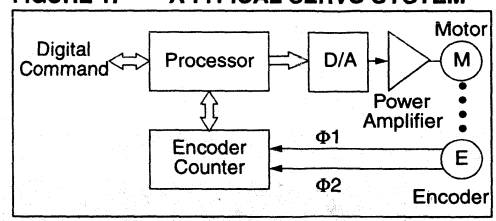
Author: Tim Bucella
Teknic, Inc.

INTRODUCTION

The PIC17C42 microcontroller is an excellent choice for cost-effective servo control in embedded applications. Due to its Harvard architecture and RISC features, the PIC17C42 offers excellent computation speed needed for real-time closed loop servo control. This application note examines the use of the PIC17C42 as a DC brush motor servo controller. It is shown that a PID (Proportional, Integral, Differential) control calculation can be performed in less than 200 µs (@16 MHz) allowing control loop sample times in the 2 kHz range. Encoder rates up to 3 MHz are easily handled by the PIC17C42's high speed peripherals. Further, the on-chip peripherals allow an absolute minimum cost system to be constructed.

Closed-loop servo motor control is usually handled by 16-bit, high-end microcontrollers and external logic. In an attempt to increase performance many applications are upgrading to DSPs (Digital Signal Processors). However, the very high performance of the PIC17C42 makes it possible to implement these servo control applications at a significant reduction in overall system cost.

The servo system discussed in this application note uses a PIC17C42 microcontroller, a programmable logic device (PLD), and a single-chip H-bridge driver. Such a system might be used as a positioning controller in a printer, plotter, or scanner. The low cost of implementing a servo control system using the PIC17C42 allows this system to compete favorably with stepper motor systems by offering a number of advantages:



- Increased Acceleration, Velocity
- Improved Efficiency
- Reduced Audible Noise
- True Disturbance Rejection

SYSTEM OVERVIEW

DC Servo Control

Modern digital servo systems are formed as shown in Figure 1. These systems control a motor with an incremental feedback device known as a sequential encoder. They consist of an encoder counter, a processor, some form of D/A (Digital-to-Analog) converter, and a power amplifier which delivers current or voltage to the motor.

FIGURE 1: A TYPICAL SERVO SYSTEM

The PIC17C42 implements both the servo compensator algorithm and the trajectory profile (trapezoidal) generation. A trajectory generation algorithm is necessary for optimum motion and its implementation is as important as the servo compensator itself. The servo compensator can be implemented as a traditional digital filter, a fuzzy logic algorithm, or a simple PID algorithm (as implemented in this application note). The combination of servo compensator and trajectory calculations can place significant demands on the processor.

The D/A conversion can be handled by a conventional DAC or by using the PIC17C42's pulse-width modulation (PWM). In either case the output signal is fed to a power stage which translates the analog signal(s) into usable voltages and currents to drive the motor.

PWM output can be a duty-cycle signal in combination with a direction signal or a single signal which carries both pieces of information. In the latter case a 50% duty cycle commands a null output, a 0% duty cycle commands maximum negative output, and 100% maximum positive output.

The amplifier can be configured to supply a controlled voltage or current to the motor. Most embedded systems use voltage output because its simpler and cheaper.

Sequential encoders produce quadrature pulse trains, from which position, speed, and direction of the motor rotation can be derived. The frequency is proportional to speed and each transition of F1 and F2 represents an increment of position. The phase of the signals is used to determine direction of rotation.

These encoder signals are usually decoded into Count Up and Count Down pulses, using a small state machine. These pulses are then routed to an N-bit, up/down counter whose value corresponds to the position of the motor shaft. The decoder/counter may be implemented in hardware, software, or a combination of the two.

The PIC17C42 Based Motor Control Board

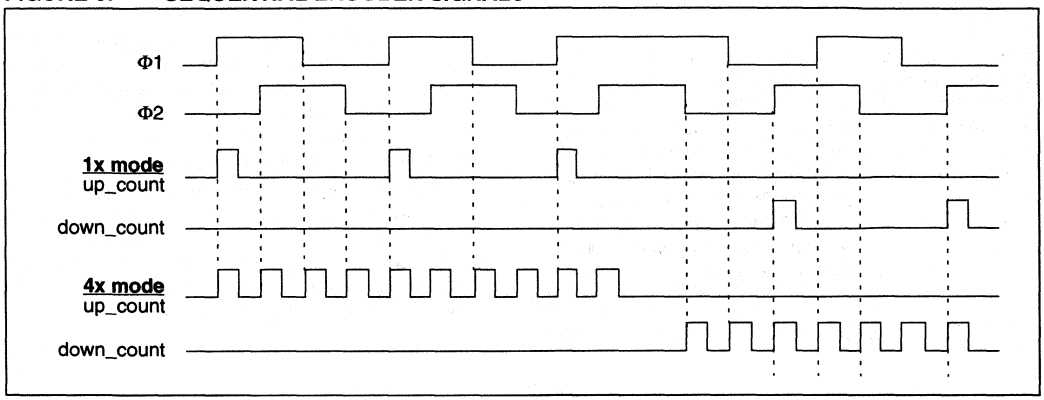
The PIC17C42 based servo system described here has a full RS-232 ASCII interface, on-board switching power supply, H-bridge motor drive, over-current protection, limit switch inputs and digital I/O. The entire system measures 5" x 3.5" and is shown in Figure 2. The system can be used to evaluate the PIC17C42 in servo applications. All unused PIC17C42 pins are available at an I/O connector for prototyping.

FIGURE 2: THE PIC17C42 BASED SERVO CONTROL BOARD

© 1997 Microchip Technology Inc.

A PID algorithm is used as a servo compensator and position trajectories are derived from linear velocity ramp segments. This system uses 50%-null PWM as the D/A conversion technique. The power stage is a high current output switching stage which steps-up the level of the PWM signal. Encoder signal decoding is accomplished using an external PLD. The up/down counter is implemented internally in the PIC17C42 as combination of hardware and software (Figure 3 and Figure 4).

FIGURE 3: SEQUENTIAL ENCODER SIGNALS



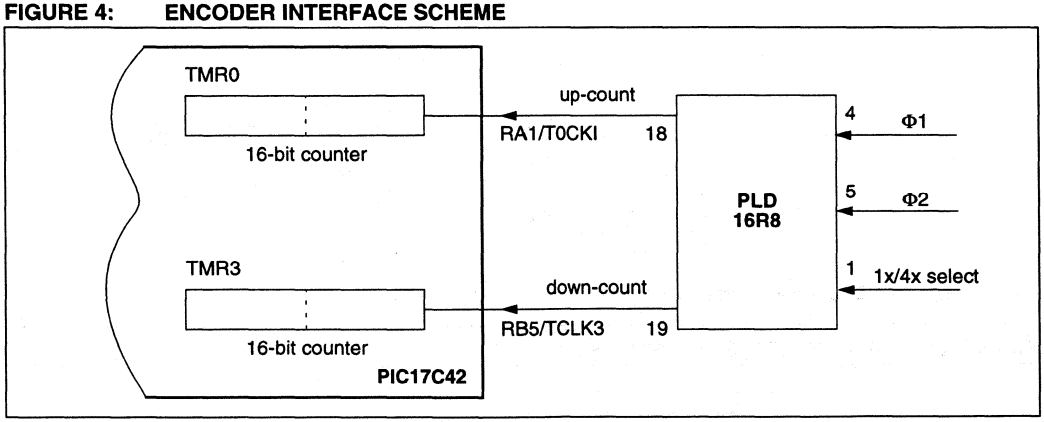


FIGURE 4: ENCODER INTERFACE SCHEME

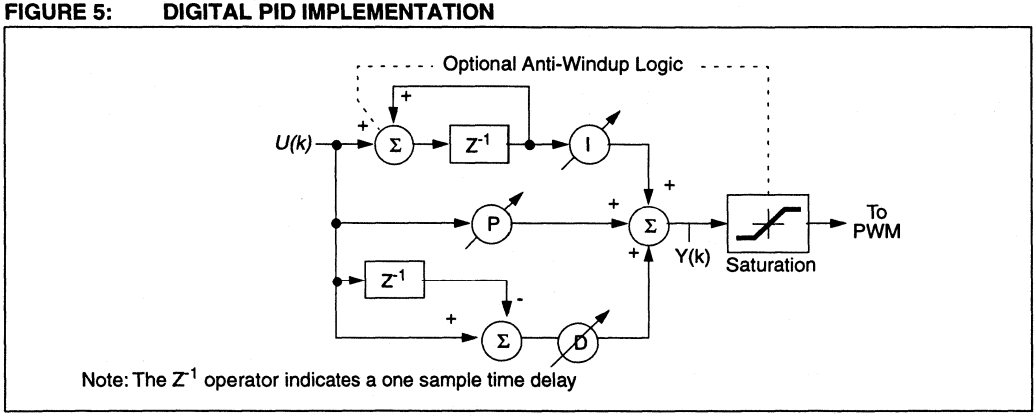
THE COMPENSATOR

A PID routine is the most widely used algorithm for servo motor control. Although it may not be the most optimum controller for all applications, it is easy to understand and tune.

The standard digital PID algorithm's form is shown in Figure 5. *U(k)* is the position or velocity error and *Y(k)* is the output.

This algorithm has been implemented using the PIC17C42's math library. Only 800 instruction cycles are required, resulting in a 0.2 ms PID execution time at 16 MHz.

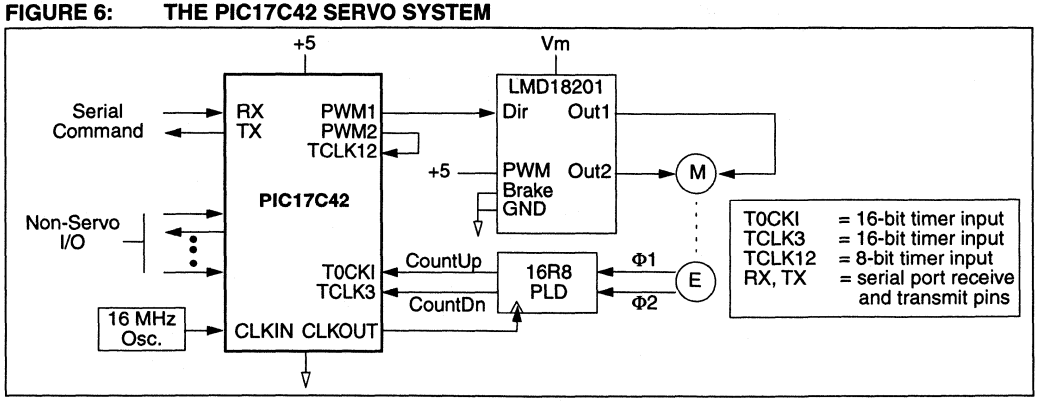
Integrator windup is a condition which occurs in PID controllers when a large following error is present in the system, for instance when a large step disturbance is encountered. The integrator continually builds up during this following error condition even though the output is saturated. The integrator then "unwinds" when the servo system reaches its final destination causing excessive oscillation. The PID implementation shown in Figure 5 avoids this problem by stopping the action of the integrator during output saturation.



MOTOR ACTUATION

The PIC17C42 contains a high-resolution pulse width modulation (PWM) subsystem. This forms a very efficient power D/A converter when coupled to a simple switching power stage. The resolution of the PIC17C42 PWM subsystem is 62.5 ns (at 16 MHz). This translates into 10-bit resolution at a 15.6 kHz rate or 1 part in 800 (9 1/2-bit) resolution at 20 kHz. This allows effective voltage control while still maintaining the modulation frequency at or above the limit of human hearing. This is especially relevant in office automation equipment where minimizing noise is a design goal.

The motor responds to a PWM output stage by time averaging the duty cycle of the output. Most motors react slowly, having an electrical time constant of 0.5 ms or more and a mechanical time constant of 20.0 ms or more. A 15 kHz PWM output is effectively equivalent to that of a linear amplifier.



In the system shown in Figure 6, the H-bridge's direction input is wired directly to the PIC17C42's PWM output. The H-bridge is powered by a DC supply voltage, V_m. In this configuration 0 volts is presented to the motor when the PWM signal is at a 50% duty cycle, $-V_m$ volts at 0% duty cycle and $+V_m$ volts at 100% duty cycle.

FIGURE 5: DIGITAL PID IMPLEMENTATION

Note: The Z^{-1} operator indicates a one sample time delay

ENCODER FEEDBACK

Position feedback for the example system is derived from a quadrature encoder mounted on the motor shaft. Both incremental position and direction can be derived from this inexpensive device. The quadrature encoder signals are processed by a 16R8-type PLD device as shown in Figure 6. The PLD converts the quadrature pulses into two pulse streams: Count Up and Count Down (Figure 3). These signals are then fed to two 16-bit timers of the PIC17C42 (Timer3 and Timer0). A logic description for the PLD decoder is shown in Appendix B.

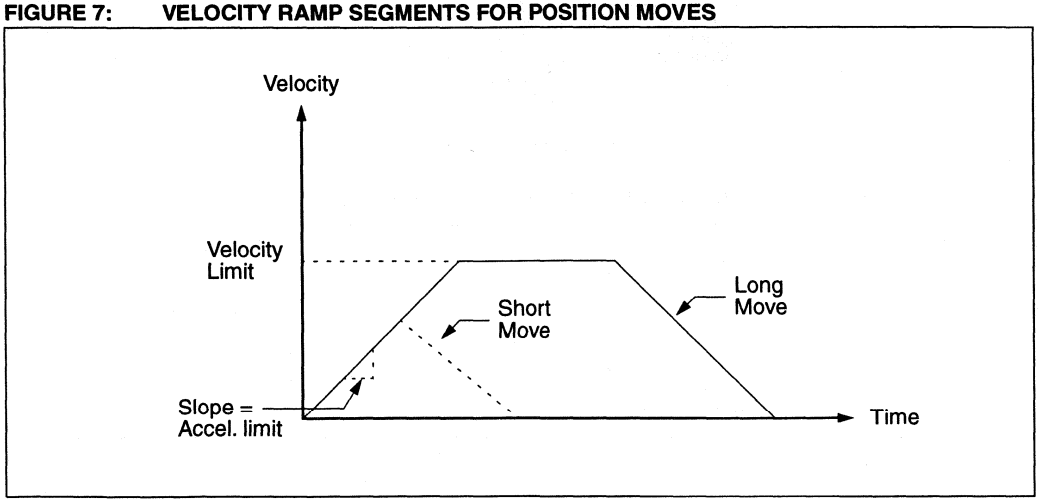
The PIC17C42 keeps track of the motor shaft's incremental position by differencing these two 16-bit timers. This operation is performed each servo sample time and the current position is calculated by adding the incremental position to the previous position. Since both timers are 16-bits, keeping track of the overflow is unnecessary, unless the encoder signals frequency is greater than 32767 times the sample frequency. **For example, at a servo sample time of 1 ms, the maximum encoder rate would be 3.2767 MHz.**

Counter wraparound is not a concern because only the difference between the two counters is used. Two's-complement subtraction takes care of this automatically. Position is maintained as a three-byte, 24-bit quantity in the example program shown in Appendix F. However, there is no limit to the size of the internal position register. By adding the 16-bit incremental position each sample time to an N-byte software register, an N-byte position may be maintained.

TRAJECTORY GENERATION

A trajectory generation algorithm is essential for optimum motion control. A linear piecewise velocity trajectory is implemented in this application. For a position move, the velocity is incremented by a constant acceleration value until a specified maximum velocity is reached. The maximum velocity is maintained for a required amount of time and then decremented by the same acceleration (deceleration) value until zero velocity is attained. The velocity trajectory is therefore trapezoidal for a long move and triangular for a short move where maximum velocity was not reached (Figure 7).

The `doPreMove` subroutine is invoked once at the beginning of a move to calculate the trajectory limits. The `doMove` routine is then invoked at every sample time to calculate new "desired" velocity and position values as follows:



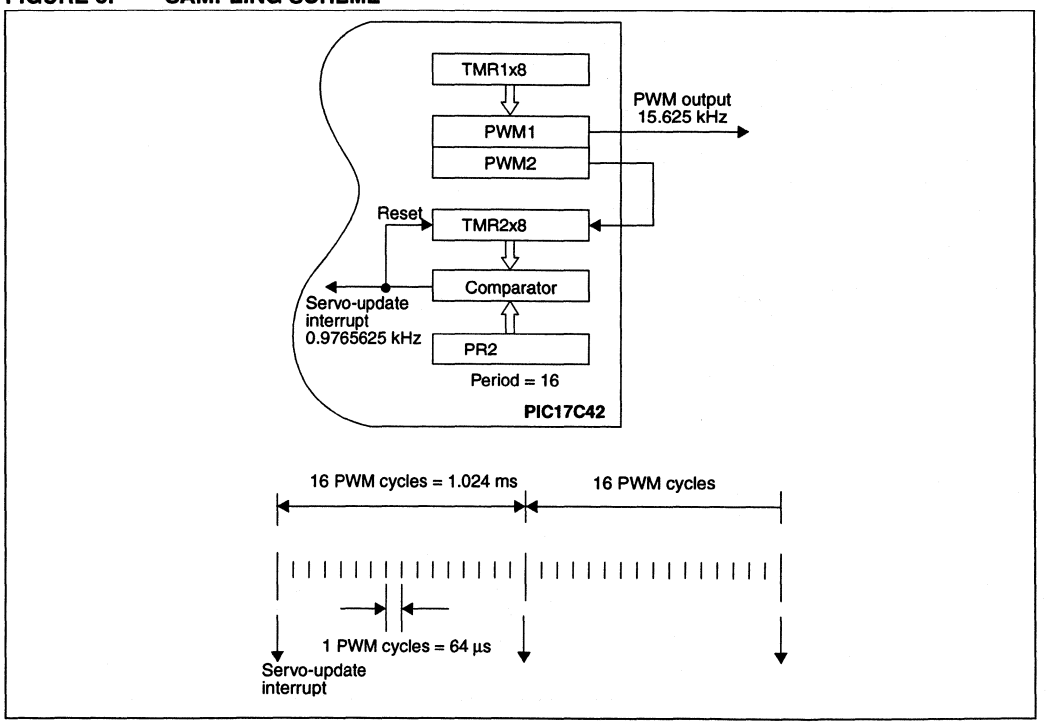
$$VK = VK\text{-}1 + A \quad (A = \text{Acceleration})$$

$$PK = PK\text{-}1 + VK\text{-}1 + A/2$$

For more details on trajectory generation, see Appendix E.

4

FIGURE 7: VELOCITY RAMP SEGMENTS FOR POSITION MOVES



IMPLEMENTATION DETAILS

The program structure is straightforward: An interrupt service routine (ISR) processes the servo control and trajectory generation calculations, and a foreground loop is used to implement the user interface, serial communication, and any exception processing (i.e., limit switches, watchdog timer, etc.).

The ISR has a simple structure. In order to effect servo control we need to read the encoder, calculate the new trajectory point and PID values, and set the output of the PWM, all at a constant, predefined rate. The ISR is initiated by a hardware timer (Timer2) on the PIC17C42. To make sure that the servo calculation always occurs synchronously with the PWM subsystem, the PWM2 output is wired to the input pin of TMR12 (TMR1 in internally-clocked, 8-bit timer mode; TMR2 in externally-clocked, 8-bit counter mode). N is loaded into the PR2 register. The sample rate then becomes the PWM rate divided by N. In this implementation N = 16 (Figure 8).

FIGURE 8: SAMPLING SCHEME

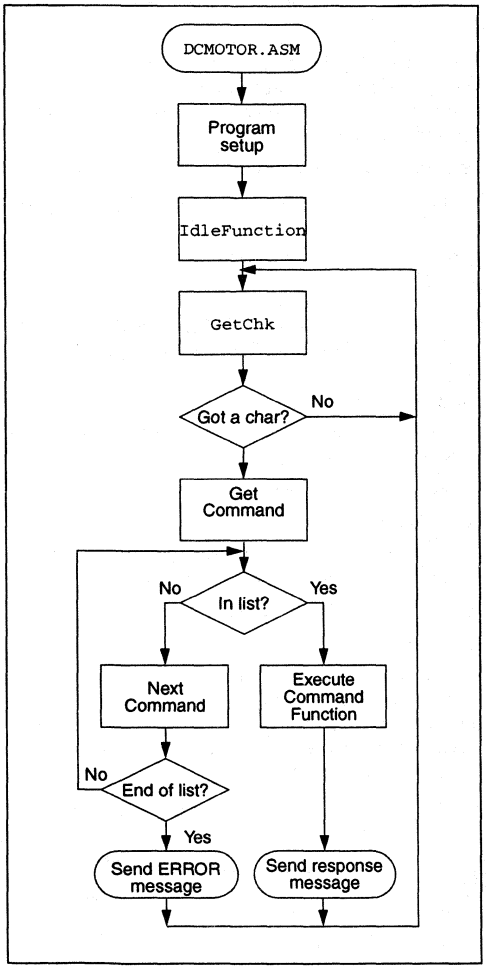
FIGURE 9: FLOWCHART FOR FOREGROUND PROCESSING



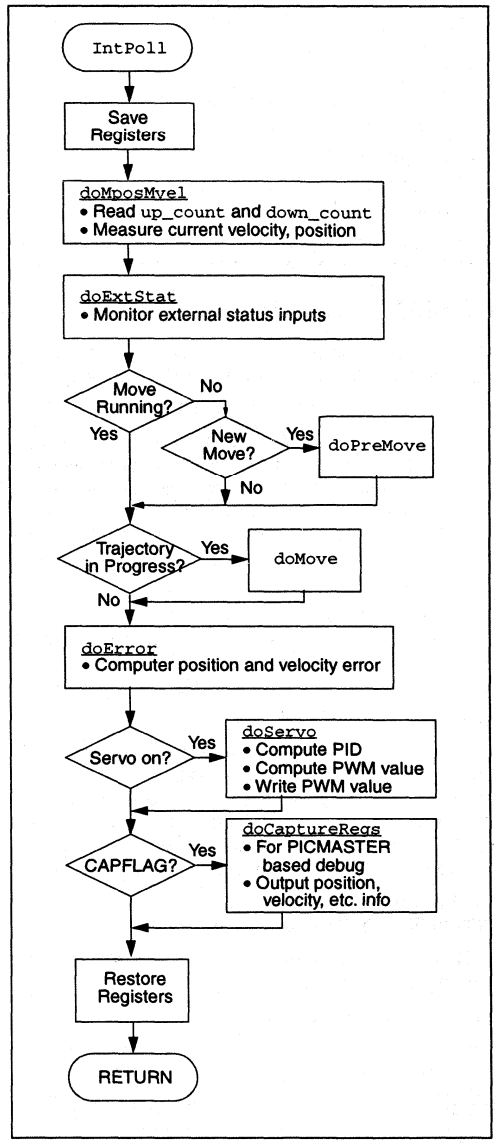


FIGURE 10: FLOWCHART FOR INTERRUPT SERVICE ROUTINE

4

The following events must occur in the interrupt service routine:

- Read Timers (TMR0 & TMR3)
- Calculate the new Reference Position using the Trajectory Generation Routine.
- Calculate Error:
  U(k) = Reference Position - Current Position
- Calculate Y(k) using PID
- Set PWM output
- Manage other housekeeping tasks
  (i.e. service serial characters)

The entire ISR requires only 0.250 ms to execute with 16 MHz processor clock frequency.

COMMAND INTERFACE

The following commands are implemented and recognized by the user interface in the foreground loop.

Move (Value): M, [$-8,388,608_{10}$ to $8,388,607_{10}$]

Commands the axis to move to a new position or velocity. Position data is relative, velocity data is absolute. Position data is in encoder counts. Velocity data is given in encoder counts per sample time multiplied by 256. All moves are performed by the controller such that velocity and acceleration limits set into parameter memory will not be violated.

All move commands are kept in a one deep FIFO buffer. The command in the buffer is executed as soon as the executing command is complete. If no move is currently executing the commanded move will start immediately.

Mode: O, (Type), [P,V, T]

An argument of "P" will cause all subsequent move commands to be incremental position moves. A "V" argument will cause all subsequent moves to be absolute velocity moves. A "T" argument sets a "Torque mode'" where all subsequent M commands directly write to the PWM. This is useful for debug purposes.

Set Parameter: S, (#,Value)
[00h to FFh, $-8,388,608_{10}$ to $8,388,607_{10}$]

Sets controller parameters to the value given. Parameters are shown in Table 1.

TABLE 1: PARAMETERS

Parameter	#	Range
Velocity Limit	00h	0 to $8,388,607_{10}$ *
Acceleration Limit	01h	0 to $8,388,607_{10}$ **
Kp: Proportional Gain	02h	-32768_{10} to 32767_{10}
Kd: Differential Gain	03h	-32768_{10} to 32767_{10}
Ki: Integral Gain	04h	-32768_{10} to 32767_{10}

* (counts per sample time multiplied by 256)
** (counts per sample time per sample time multiplied by 256)

Read Parameter: R, (#) [00h to FFh]

Returns the present value of a parameter.

Shutter: C

Returns the time (in sample time counts 0 to $65,536_{10}$) since the start of the present move and captures the commanded and actual values of position and velocity at the time of the command.

Read commanded position: P

Returns the commanded position count which was captured during the last Shutter command.

Range: $-8,388,608_{10}$ to $8,388,607_{10}$.

Read commanded velocity: V

Returns the commanded velocity multiplied by 256 which was captured during the last Shutter command. Range: $-8,388,608_{10}$ to $8,388,607_{10}$.

Read actual position: p

Returns the actual position count which was captured during the last Shutter command.

Range: $-8,388,608_{10}$ to $8,388,607_{10}$.

Read actual velocity: v

Returns the actual velocity multiplied by 256 which was captured during the last Shutter command.

Range: $-8,388,608_{10}$ to $8,388,607_{10}$.

External Status:

Returns a two digit hex number which defines the state of the bits in the external status register. Issuing this command will clear all the bits in the external status register unless the event which set the bit is still true. The bits are defined in Table 2.

TABLE 2: EXTERNAL STATUS REGISTER BITS

bit 7	index marker detected
bit 6	+limit reached
bit 5	-limit reached
bit 4	input true
bit 3-0	N/A

Move Status: Y

Returns a two-digit hex number which defines the state of the bits in the move status register. Issuing this command will clear all the bits in the move status register unless the event which set the bit is still true. The bits are defined in Table 3.

TABLE 3: MOVE STATUS REGISTER BITS

bit 7	move buffer empty
bit 6	move complete
bit 5-0	N/A

© 1997 Microchip Technology Inc.

Read Index position: I

Returns the last index position captured in position counts.

Set Position (Value): H, [-8,388,60810to8,388,60710]

Sets the actual and commanded positions to the value given. Should not be sent unless the move FIFO buffer is empty.

Reset: Z

Performs a software reset.

Capture Servo-Response: c (#Count)

The c command will set a flag inside indicating that starting with the next M (servo move) command, velocity and position information will be sent out (by invoking the `doCaptureRegs` procedure) during every servo-loop for #count times. At the end of the #count, the processor will halt (see `doCaptureRegs` procedure). This is useful for debug purposes.

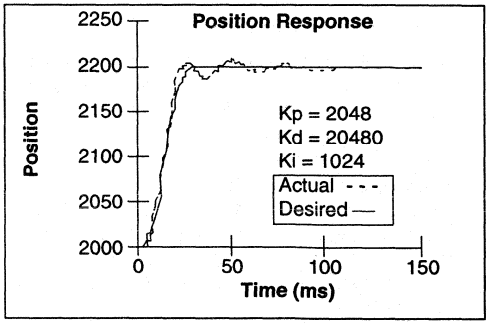
Disable Servo: s

This command disables servo actuation. The servo will activate again with the execution of the next M (move) command. This is useful for debug purposes.

Examples:

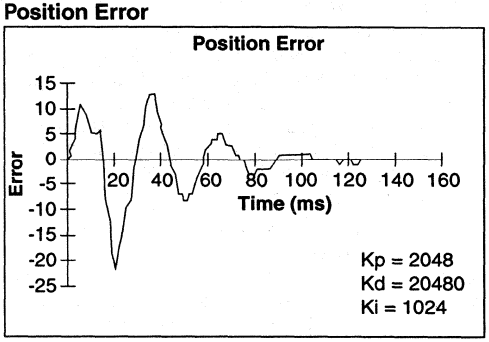
```
Z           ;Reset software (No <CR> required)
OV          ;Set velocity servo mode
            ;(No <CR> required)
M 1000<CR>  ;Set velocity to 1000
M-1000<CR>  ;Set velocity to 1000 in reverse
            ;direction
```

OPTIMIZING THE SYSTEM



Once the PID loop is successfully implemented, the next challenge is to tune it. This was made simple through extensive use of the PICMASTER™ In-Circuit Emulator for the PIC17C42.

The PICMASTER is a highly sophisticated real-time in-circuit emulator with unlimited break-point capability, an 8K deep trace buffer and external logic probes. Its user interface software runs under Windows® 3.1 with pull-down menus and on-line help. The PICMASTER software also supports dynamic data exchange (DDE). The DDE makes it possible to send its trace buffer information to a spreadsheet, such as EXCEL®, also running under Windows.



To tune the PID, first a small amount of diagnostics code is added in the servo routine (`doCaptureRegs`). This code simply outputs, at every sample point, the actual and desired position values, actual and desired velocity values, position error and velocity error by using a `TABLWT` instruction. These are captured in the trace buffer of the emulator. The 'trace' condition is set up to only trace the data cycles of the 2-cycle `TABLWT` instructions. Next, the trace buffer is transferred to EXCEL and the various parameters are plotted. The plots graphically show the amounts of overshoot, ripple and response time. By altering Kp, Ki and Kd, and plotting the results, the system can be fine tuned.

Under Windows multi-tasking environment, using a PICMASTER emulator, this can be done in real time as described below.

Three sessions are set up under Windows:

1. A terminal emulator session to send commands to the motor control board. The "terminal" program provided with Windows is used, although any communications software such as PROCOMM will work.
2. Second, a PICMASTER emulation session is invoked. The actual PIC17C42 is replaced in-circuit by the emulator probe. Within the emulator, trace points are setup to capture the actual and desired position and velocity values on appropriate bus cycles.
3. Third, a session of EXCEL is started and dynamically linked to the PICMASTER sessions such that whenever the trace buffer is full, the data is sent over to EXCEL. A few simple filtering commands in EXCEL are used to separate the various data types, i.e. actual position data from desired position from actual velocity etc. Next, various plot windows are set up within EXCEL to plot these information.

Once these setups have been done, for every servo move, the responses are automatically plotted. It is then a simple matter of varying the PID coefficients and observing the responses to achieve the desired system response. At any point, the responses can be stored in files and/or printed out.

Except for very long "move" commands, most position and velocity commands are executed (i.e. system settled) in less than 500 samples, making it possible to capture all variables (actual and desired position and velocity, and position errors and servo output) in PICMASTER's 8K trace buffer.

CONCLUSIONS

Using a high-performance 8-bit microcontroller as the heart of a servo control system is a cost-effective solution which requires very few external components. A comparison with a popular dedicated servo-control chip, is presented in Table 4.

TABLE 4: SERVO CONTROL CHIP COMPARISON

	LM629 @8 MHz	PIC17C42 @16 MHz	PIC17C42 @25 MHz
Max Encoder Rate	1 MHz	3.3 MHz	4.5 MHz
Servo Update Time	-	0.25 ms	0.16 ms
Max Sampling Frequency	4 kHz	2-3 kHz	4-5 kHz

Also apparent in the comparison table is the additional processing power available when using the microcontroller. This processing can be used to provide a user interface, handle other I/O, etc. Alternatively, the additional processing time might be used to improve the performance of compensator and trajectory generation algorithms. A further advantage is that for many embedded applications using motor control the microcontroller proves to be a complete, minimum cost solution.

APPENDIX E: IMPLEMENTATION DETAILS OF TRAJECTORY GENERATION

doPreMove

This routine is executed only once at the beginning of each move. First, various buffers and flags are initialized and a test for modetype is performed. In position mode, the minimum move is triangular and consists of two steps. Therefore, if abs (MOVVAL) > 2, an immediate move is performed. Otherwise, normal move generation is possible with the sign of the move in MOVSIGN and the appropriate signed velocity and acceleration limits in V and A, and MOVVAL/2 in HMOVVAL.

In velocity mode, the sign of the move is calculated in MOVSIGN and the appropriate signed velocity and acceleration limits are placed in V and A. Finally, at modeready, MOVVAL is sign extended for higher precision arithmetic and the servo is enabled.

In torque mode, MOVVAL is output directly to the PWM and the servo is disabled, and doMove is not executed.

doMove

Move generation is based on a piecewise constant acceleration model. During constant acceleration, this results in the standard equations for position and velocity given by:

$$x(t) = x0 + v0 \times t + a \times = (t \times 2)/2, v(t) = v0 + a \times t$$

With the units for t in sample times, the time increment between subsequent sample times is 1, yielding the iterative equations for updating position and velocity implemented in doPosVel and given by:

$$P(k) = P(k-1) + V(k-1) + A/2, V(k) = V(k-1) + A$$

where A is the signed acceleration limit calculated in doPreMove. The inverse equations of this iteration, necessary for undoing an unwanted step, are contained in undoPosVel and given by:

$$P(k-1) = P(k) - V(K-1) - A/2, V(K-1) = V(k) - A$$

In position mode, the actual shape of the velocity profile depends on the values of V, A, and the size of the move. Either the velocity limit is reached before half the move is completed, resulting in a trapezoidal velocity profile, or half the move is completed before the velocity limit is realized, resulting in a triangular velocity profile.

In the algorithm employed here, the velocity limit is treated as a bound on the actual velocity limit, thereby permitting exactly the same number of steps during the speedup and speed down sections of the move. Phase 1 is defined as the section of the move where the commanded position is less than half the move, and phase 2 is the remaining portion of the move. T1 is time when the actual velocity limit is reached and T2 is the time at the end of phase 1.

4

FIGURE 12:

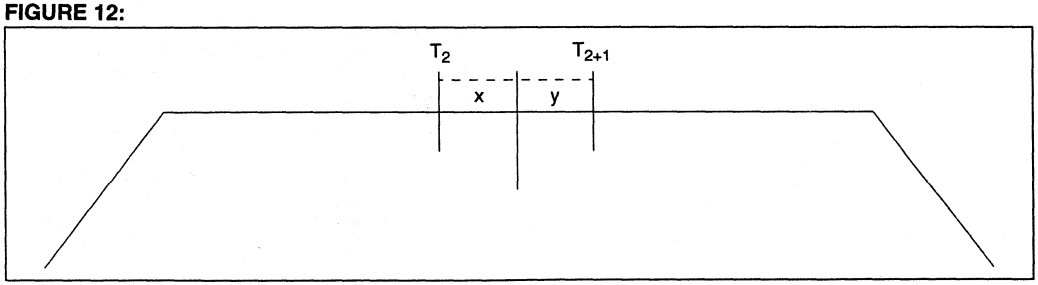

FIGURE 13:

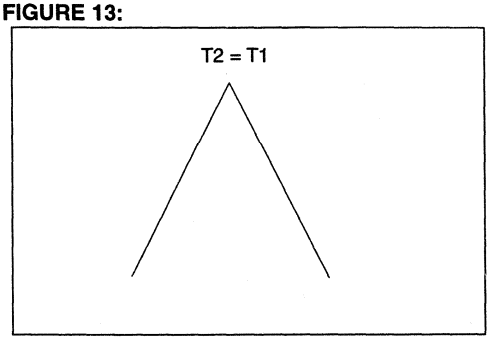

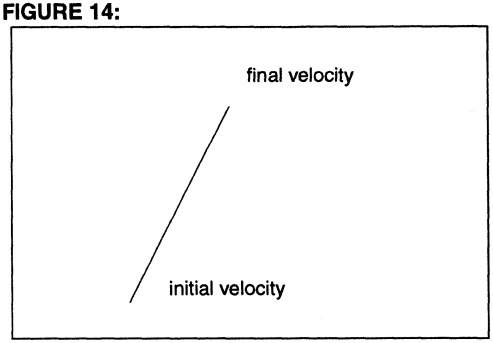

FIGURE 14:

Furthermore, let x be the amount of undershoot and y the amount of overshoot of half the move at T2. Discretization error is minimized by using the values of x and y whether one more step will reduce the size of the final immediate move during the last step of the move. For a triangular move, the discretization error is given by min. (2x, 2y), resulting in the condition that if 2x > 2y, then take one more speedup step. In the case of a trapezoidal move, the discretization error is given by min. (2x, y - x), yielding the condition that if 3x > y, take one more step during the flat section of phase2.

At the beginning of doMove, MOVTIME is incremented and doPosVel is called to evaluate the next proposed values of commanded position and velocity under the current value of A. In position mode, phase1, the original position plus half the move minus the new proposed commanded position is calculated and placed in MOVDEL, with the previous MOVDEL saved in MOVTMP. As half the move would be passed, MOVTMP = -x and MOVDEL = y, with y > 0 for the first time indicating that phase1 is about to be completed. Therefore, if y < 0, we continue in phase1, where if maximum velocity has not been reached, the new proposed commanded position is executed. On the other hand, if the proposed move would exceed the maximum velocity, we undo the proposed move, set the current acceleration to zero, reevaluate the iterative equations with the new acceleration, set T1 = MOVTIME - 1, and execute the move.

Since T1 is cleared in doPreMove, it is used as a flag to indicate if this corner in the velocity profile has been reached. Once we find that y > 0, we drop into code that is executed only one time, with phase2 beginning on the next step. If T1 = 0, maximum velocity has not yet been reached, so T1 = T2 and the velocity profile is triangular. In this case, A is negated for speed down, and if x>y, one more step is needed to minimize the discretization error. So A is negated, the proposed step undone, A is again negated for speed down and the step recalculated and executed, with T2 = T1=MOVTIME - 1.

If T1 is not zero, indicating that we are in the flat section of phase1, then go to t2net1, where T2 = MOVTIME - 1, and if 3x > y, then one more phase2 flat step is necessary to minimize the discretization error. PH2FLAT is defined as the number of steps in the flat section of phase2, and is used as a counter during its completion. If 3x > y, then PH2FLAT = T2-T1, otherwise PH2FLAT = T2-T1-1 and phase1 is finally complete. All subsequent steps will proceed through phase2, first deciding if the flat section is finished by checking if PH2FLAT has reached zero. If not, go to flat where PH2FLAT is decremented, and tested if zero. If so, the speed down section is begun by calculating the appropriate signed acceleration limit A, and executing the last of the flat section moves. For all following steps, PH2FLAT = 0, leaving only the final test for zero commanded velocity to indicate the end of the move. This will always occur since the actual maximum velocity, bounded above by the user supplied limit, is always an integer multiple of the user supplied acceleration limit, with exactly the same number of steps taken during speedup and speed down.

The velocity mode is much more straightforward, with the velocity profile in the form of a ramp. If the final velocity has not been reached, the move continues at maximum acceleration. If the final velocity has been reached, the acceleration is set to zero and the move generation of commanded position and velocity continued unless the final velocity is zero.

                   01770 ; NAME:          doMove
                   01771 ;
                   01772 ; DESCRIPTION:   In position mode, trapezoidal moves are performed. Phase1
                   01773 ;                and phase2 respectively, are the periods for the first and
                   01774 ;                second halves of the move. The move time is defined as zero
                   01775 ;                at the beginning of the move,T2 is the time at half the move, T1 is the time w
                   01776 ;                begins,(the region of constant velocity reduces to a point
                   01777 ;                in the case where maximum speed is not realized, and the
                   01778 ;                trapezoidal move degenerates into a trianglular move,
                   01779 ;                together with T1=T2), and TAU is the total time of the move.
                   01780 ;                The accelerations are +-AL or 0.
                   01781 ;
                   01782 ;
                   01783 ;                 triangle speed                 trapezoidal speed
                   01784 ;
                   01785 ;                                                  ____________
                   01786 ;                                                 /            \
                   01787 ;                   /\                           /              \
                   01788 ;                  /  \                         /                \
                   01789 ;                 /    \                       /                  \
                   01790 ;                /      \                     /                    \

Saving and Restoring Status on Interrupt (Implementing a Parameter Stack)

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

The PIC17C42 has a 16 level deep hardware stack. The program counter is pushed into this stack on interrupts and subroutine calls. However, other key registers are not saved to the stack. Registers such as WREG, ALUSTA (which has carry, zero and other flag bits) and the bank select register (BSR) must be saved in an interrupt service routine. The following macros, PUSH and POP implement a parameter stack in data memory to save these register values.

The indirect addressing register, FSR0, is used to implement this parameter stack. It is assumed that FSR0 and its control bits are not used or modified elsewhere. The stack pointer (FSR0) is initialized at the highest RAM location (FFh).

```
Main_prog           SETF    FSR0            ;Initialize and dedicate FSR0 as stack pointer
                    BCF     ALUSTA,FS0      ;
                    BCF     ALUSTA,FS1      ;Set-up FSR0 for auto-dec
                    •
                    •
                    •
PUSH                MACRO
                    BCF     ALUSTA,FS0      ;Set-up FSR0 for auto-dec
                    MOVFP   ALUSTA,IND0     ;Save ALUSTA first
                    MOVFP   BSR,IND0        ;
                    MOVFP   W,IND0          ;
                    MOVFP   RAM_x, IND0     ;Now save general
                    MOVFP   RAM_y, IND0     ;Purpose registers
                    ENDM
POP                 MACRO
                    BSF     ALUSTA,FS0      ;Set-up for auto-inc
                    INCF    FSR0            ;
                    MOVPF   IND0, RAM_y     ;
                    MOVPF   IND0, RAM_x     ;
                    MOVPF   IND0,W          ;
                    MOVPF   IND0,BSR        ;
                    MOVFP   IND0,ALUSTA     ;restore ALUSTA last
                    DECF    FSR0            ;Adjust stack pointer
                    ENDM
                    •
                    •
                    •
interrupt_routine
                    PUSH                    ;save registers
                    •
                    •
                    •

                    •
                    •
                    •
                    POP                     ;restore status
                    RETFIE                  ;return
```

© 1997 Microchip Technology Inc.

While the macros are quite self-explanatory, the user should note a few subtle points.

- `MOVFP` instruction does not affect status flags while `MOVPF` does.
- `MOVFP` and `MOVPF` are used such that any register can be saved and restored. Note that the register being saved or restored has address 'f' (which can be anywhere from 00h to FFh) and the other address, IND0 (indirect), therefore, can be any address.
- FSR auto-increments or auto-decrements after the operation ('post'). Therefore, in the POP macro pre-increment is simulated.
- All interrupts should be disabled when executing the PUSH and POP macros. While PUSH will have the GIE bit disabled, POP may not necessarily have the GIE bit disabled. The user should disable the GIE bit when executing the POP.

Using this scheme, interrupts and subroutine calls can be nested, since the stack will grow and shrink. The stack can be used to pass parameters to subroutines.

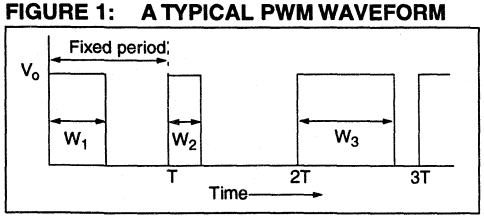
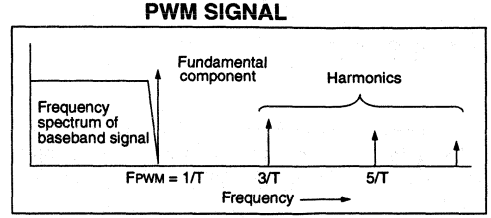
Using PWM to Generate Analog Output



Author: *Amar Palacherla*
Microchip Technology Inc.

Pulse Width Modulation (PWM) modules, which produce basically digital waveforms, can be used as cheap Digital-to-Analog (D/A) converters only a few external components. A wide variety of microcontroller applications exist that need analog output but do not require high resolution D/A converters. Some speech applications (talk back units, speech synthesis systems in toys, etc.) also do not require high resolution D/A converters. For these applications, Pulse Width Modulated outputs may be converted to analog outputs.

Conversion of PWM waveforms to analog signals involves the use of analog low-pass filters. This application note describes the design criteria of the analog filters necessary and the requirements of the PWM frequency. Later in this application note, a simple RC low-pass filter is designed to convert PWM speech signals of 4 kHz bandwidth.

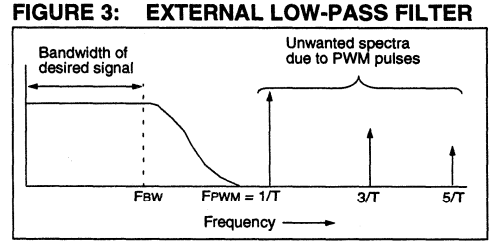


In a typical PWM signal, the base frequency is fixed, but the pulse width is a variable. The pulse width is directly proportional to the amplitude of the original unmodulated signal. In other words, in a PWM signal, the frequency of the waveform is a constant while the duty cycle varies (from 0% to 100%) according to the amplitude of the original signal. A typical PWM signal is shown in Figure 1.

FIGURE 1: A TYPICAL PWM WAVEFORM

A Fourier analysis of a typical PWM signal (such as the one depicted in Figure 1) shows that there is a strong peak at frequency $Fn = 1/T$. Other strong harmonics also exist at $F = K/T$, where K is an integer. These peaks are unwanted noise and should be eliminated. This requires that the PWM signal be low-pass filtered, thus eliminating these inherent noise components as shown in Figure 2.

FIGURE 2: FREQUENCY SPECTRUM OF A PWM SIGNAL



The band-width of the desired signal should be

$$F_{BW} <= (F_{PWM} = 1/T)$$

If FBW is selected such that FBW = FPWM, then the external low-pass filter should be a brick-wall type filter. Brick-wall type analog filters are very difficult and expensive to build. So, for practical purpose, the external low-pass filter should be as shown in Figure 3.

FIGURE 3: EXTERNAL LOW-PASS FILTER

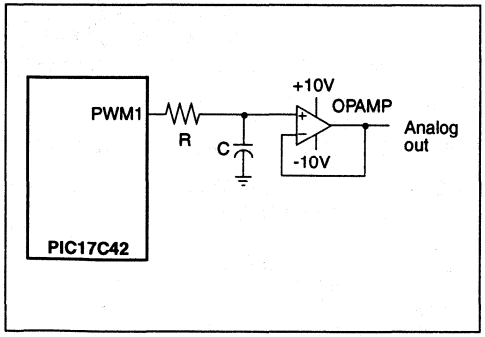
This means, $F_{BW} << F_{PWM}$

$$or\ F_{PWM} >> F_{BW}$$

$$=> F_{PWM} = K \bullet F_{BW} \qquad (1)$$

where, K is a constant such that $K >> 1$

The value of K should be chosen dependant upon the number dB the inherent fundamental noise component of PWM will be rejected. An example follows:



Example: It is required to design a simple RC low-pass filter to obtain an analog output from a pulse width modulated speech signal of bandwidth 4 kHz.

From *eqn (1)*, choosing arbitrarily K = 5,

$F_{PWM} = K \bullet f_{BW} = 5 \bullet 4\ kHz = 20\ kHz.$

© 1997 Microchip Technology Inc.

FIGURE 4: RC FILTER CONNECTED TO PWM1 OF PIC17C42

Choosing, the -3 dB point at 4 kHz, and using the relation RC = 1/(2 • π•f), we get R = 4 kΩ, if C is chosen as 0.01 µF:

R = 4.0 kΩ

C = 0.01 µF

Since the PWM frequency is selected as 20 kHz, the fundamental noise peak to be filtered is at 20 kHz. Now, lets calculate by how many dB the main peak of PWM signal is cut-off at 20 kHz:

$$(dB)\ 20\ kHz = -10 \bullet log[1 + (2\pi f.RC)2] = -14\ dB.$$

For many applications, this rejection of -14 dB will not suffice. Therefore instead of a simple RC low-pass filter, a higher order active low-pass filter may be necessary. Or, if the microcontroller is capable of modulating at higher PWM frequencies, the rejection of noise will be greater.

For example, using 8-bit resolution, the PIC17C42 can generate PWM frequency of 62.5 kHz.

At this frequency the attenuation of the PWM frequency is:

$$(dB)62.5\ kHz = -10 \bullet log[1 + (2\pi f.RC)2] = -24\ dB.$$

The higher frequency of the PIC17C42 PWM outputs makes it easier to generate analog output.

Frequency and Resolution Options for PWM Outputs

Authors: *Stan D'Souza and Sumit Mitra*
Microchip Technology Inc.

INTRODUCTION

The PIC17C42 is equipped with two high frequency Pulse Width Modulation (PWM) outputs. In a pulse width modulated signal the period of the signal is (usually) kept fixed, while the duty cycle is varied. In this application note, we will discuss options in selecting PWM frequency and resolution.

This application note assumes that the internal clock is used for the time-base, which is typically the preferred setup. Also, throughout this application note, PWM1 output is used in examples, Timer1 is assumed to be the time-base.

Definition of terms:

Period of a PWM output is the duration after which the PWM pattern will repeat itself.

Frequency of a PWM output is = 1/Period.

Resolution of a PWM output is the granularity with which the duty cycle can be modulated.

In the case of the PIC17C42, when using PWM1 with Timer1 as the time-base:

PWM1 period = [(PR1) + 1] x 4TOSC

PWM1 duty cycle = (DC1) x TOSC

where PR1 = period register for Timer1

DC1 = PW1DCH, PW2DCL concantenated (10-bit value)

TOSC = oscillator period

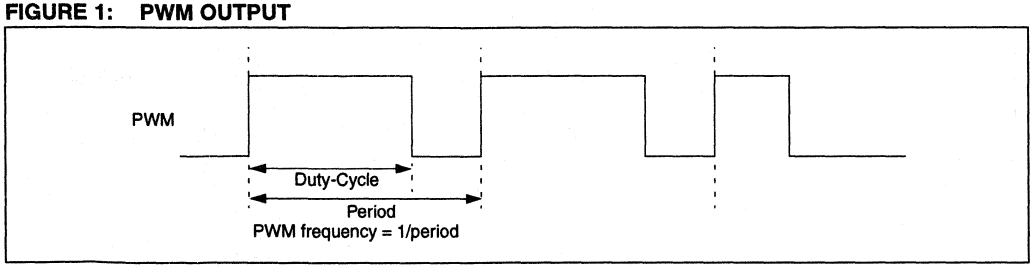
At 16 MHz oscillator frequency, TOSC = 62.5 ns. The user can control the frequency of the PWM output by altering the 'period' value of the time-base. For example, if the period is chosen to be 100 TOSC (PR1 = 18h), then PWM frequency is:

1/(100 x 62.5) ns = 160 kHz.

Note however that the duty cycle resolution is a little less than 7-bits.

Useful and Common PWM Modes

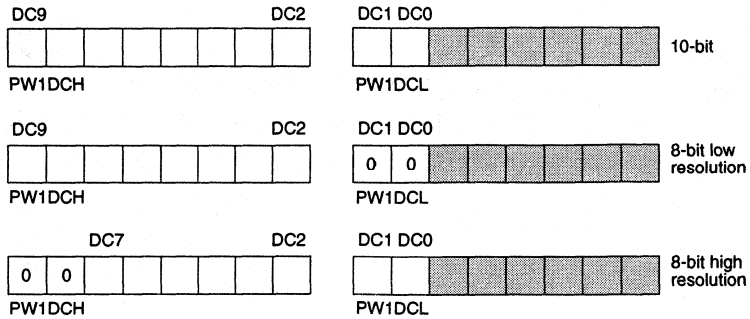
While a variety of period values can be selected, the following modes would be most commonly used:



10-bit Mode: In this mode PWM duty cycle has full 10-bit resolution (maximum offered by the PIC17C42). The period register PR1 is set at FFh. PWM period = 1024TOSC = 64 µs. PWM frequency is 15.625 kHz. The user must write both PW1DCH and PW1DCL to update PWM output. See Appendix A for an example of code that modulates 10-bit resolution PWM output (PWM10.LST).

8-bit Hi-Resolution Mode: In this mode, the user has only an 8-bit quantity to write to the duty-cycle register. Period register is set at 3Fh (63 decimal), such that PWM period is 256Tosc. To write the 8-bit duty-cycle value, first the 8th bit is right shifted two bits. The upper six bits are written to PW1DCH and the lower two bits are written to PW1DCL as follows:

```
;8-bit duty-cycle value is in WREG
CLRF   TEMP          ;
RRCF   WREG          ;
RRCF   TEMP          ;
RRCF   WREG          ;
RRCF   TEMP          ;Shift right twice
ANDLW  b'00111111    ;Mask off two-high bits
MOVPF  WREG,PW1DCH ;Write duty-cycle values
MOVFP  TEMP,PW1DCL ;
```



Note that in 8-bit, hi-resolution mode, maximum PWM frequency is attained. For example, at 16 MHz clock, PWM period = 256TOSC = 16 µs; PWM frequency = 62.5 kHz. See appendix B for an example code that generates 8-bit low high resolution PWM output (PWM8HI.LST).

FIGURE 2: VARIOUS PWM MODES

Note: DC registers suited for 16-bit computation, using 10 MSb only.

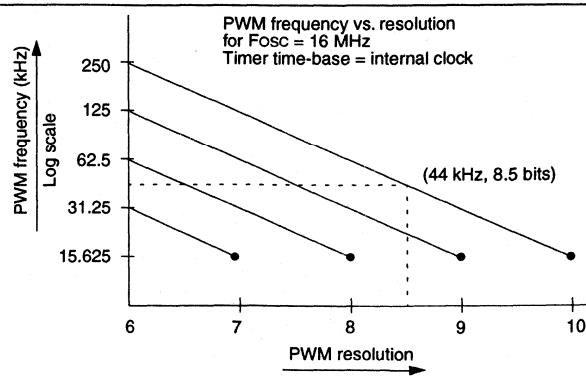
8-bit Low Resolution Mode

In this mode, the user still has only an 8-bit quantity to write to the duty cycle register. However, the desired frequency of the PWM output is less, due to the nature of the application. For example, if the PWM output is being used to drive a motor through a power stage, the power transistors, (or devices) due to their switching time, will prefer PWM frequency not to exceed a certain frequency. In the previous section, we derived an 8-bit resolution PWM output at 62.5 kHz.

To attain a low-resolution PWM output, PW1DCL is always kept at zero. The 8-bit value is written to PW1DCH. The period (PR1) is set at FFh (i.e., 256 TCY equals 1024TOSC [15.625 kHz]). See Appendix C for an example code that produces 8-bit low resolution PWM output (`PWM8LO.LST`).

Choosing Resolution and Frequency of PWM Output

Actually, the resolution and the frequency of the PWM output is selectable within certain limits. The user will need to first define the requirements based on the application. There may be an upper limit to the frequency if the PWM is being used to drive motors. On the other hand, if the PWM is being filtered to generate an analog signal, higher frequency may be desirable. In any case, the lowest frequency achievable (using internal clock for the timer) is (FOSC/1024). At 16 MHz oscillator input, the lowest PWM frequency possible is 15.625 kHz. At resolutions less than 10-bit, higher frequencies are possible (Figure 3). For example, if 7-bit resolution is chosen, then the PWM frequencies can be 15.625 kHz, 31.25 kHz, 62.5 kHz or 125 kHz. The reader will note that it's how the 7-bits are placed within the 10-bit possible duty cycle value.



Conversely, if a certain frequency is desired, such as 44 kHz, then referring to Figure 1, resolution can be 8.5-bit or 7.5-bit or 6.5-bit etc.

Summary

The frequency and resolution of the PWM outputs of the PIC17C42 can be traded off against each other to best suit the application. The oscillator frequency can also be varied to adjust PWM frequency, if necessary. External clock should be used as timer time-base to generate very low frequency PWM output.

FIGURE 3: PWM FREQUENCY vs. RESOLUTION

At a given oscillator frequency (16 MHz in this figure), a family of curves represents the PWM freq/resolution combinations possible.

  00000022           00009 TEMP    equ     0x22
                     00010 ;
  00000001           00011 F       equ     1
                     00012 ;
                     00013 ;The user would generate a 16 bit value which is saved in ram
                     00014 ;locations PWM_HI and PWM_LO byte. In 8 bit hi-res mode, the program
                     00015 ;transfers the 8 bit values to the lo Duty Cycle (DC) registers, to
                     00016 ;generate the required 8 bit hi-res PWM.
                     00028         LIST
                     00029 ;
                     00030 ;
                     00031 ;This is a short program to demonstrate how to generate PWM outputs with
                     00032 ;8 bit resolution. Since a 10Mhz crystal was used in the test system.
                     00033 ;The max. period = 256x100nS = 25.6uS or 39KHz. This program
                     00034 ;keeps the period constant and varies the duty cycle (which corresponds
                     00035 ;to the most significant 10 bits of the 16 bit value PWM_LO&PWM_HI).
                     00036 ;This program is interrupt driven, i.e. the update to the Duty cycle
                     00037 ;is done in the TMR0 interrupt, which then enables the pwm interrupt.
                     00038 ;The period update is done during the pwm interrupt. The pwm output
                     00039 ;ramps up from 0% to 100% duty cycle and then repeats. The full
                     00040 ;sweep takes approx. 13.3 secs.
                     00041 ;

Implementing IIR Digital Filters

Author: *Amar Palacherla*
Microchip Technology Inc.

INTRODUCTION

This application note describes the implementation of various digital filters using the PIC17C42, the first member of Microchip's 2nd generation of 8-bit microcontrollers. The PIC17C42 is a very high speed 8-bit microcontroller with an instruction cycle time of 250 ns (@ 16 MHz input clock). Even though the PIC17C42 is an 8-bit device, it's high speed and efficient instruction set allows implementation of digital filters for practical applications. Traditionally digital filters have been implemented using expensive Digital Signal Processors (DSPs). In a system the DSP is normally a slave processor being controlled by either an 8-bit or 16-bit microcontroller. Where sampling rates are not high (especially in mechanical control systems), a single chip solution is possible using the PIC17C42.

This application note provides a few examples of implementing digital filters. Example code for 2nd order Infinite Impulse Response (IIR) filters is given. The following type of filters are implemented:

- Low Pass
- High Pass
- Band Pass
- Band Stop (notch) filter

This application note does not explain how to design a filter. Filter design theory is well established and is beyond the scope of this application note. It is assumed that a filter is designed according to the desired specifications. The desired digital filters may be designed using either standard techniques or using commonly available digital filter design software packages.

Finite Impulse Response (FIR) filters have many advantages over IIR filters, but are much more resource intensive (both in terms of execution time and RAM). On the other hand, IIR filters are quite attractive for implementing with the PIC17C42 resources. Especially where phase information is not so important, IIR filters are a good choice (FIR filters have a linear phase response). Of the various forms used for realizing digital filters (like, Direct form, Direct II form, Cascade form, Parallel, Lattice structure, etc.) the Direct II form is used in this application note. It is easy to understand and simple macros can be built using these structures.

THEORY OF OPERATION

Digital filters in most cases assume the following form of relationship between the output and input sequences.

$$y(n) = \sum_{i=o}^{M} a_i y(n-i) + \sum_{j=o}^{N} b_j x(n-j)$$

The above equation basically states that the present output is a weighted sum of the past inputs and past outputs. In case of FIR filters, the weighted constants $ai = 0$ and in case of IIR filters, at least one of the ai constants is non zero. In case of IIR, the above formula may be rewritten in terms of Z transform as:

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\sum_{k=o}^{M} b_k Z^{-k}}{1 + \sum_{k=1}^{N} a_k Z^{-k}}$$

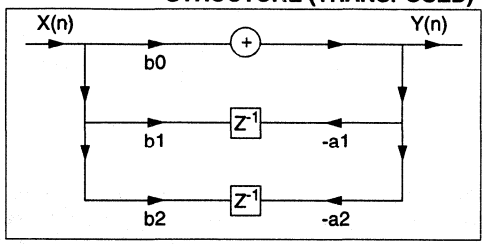
The above equation can further be rewritten in difference equation format as follows:

$$y(n) = \sum_{i=1}^{M} a_i y(n-i) + \sum_{j=o}^{N} b_j x(n-j)$$

© 1997 Microchip Technology Inc.

Realization of the above equation is called the Direct Form II structure. For example, in case of a second order structure, $M = N = 2$, gives the following difference equations:

EQUATION 1:



$$d(n) = x(n) + a_1 d(n-1) + a_2 d(n-2)$$

EQUATION 2:

$$y(n) = b_0 d(n) + b_1 d(n-1) + b_2 (d(n-2))$$

The above difference equations may be represented as shown in Figure 1.

FIGURE 1: 2ND ORDER DIRECT FORM II STRUCTURE (TRANSPOSED)

The structure as shown in Figure 1 may be cascaded to attain a higher order filter. For example, if two stages are cascaded together, a 4th Order IIR Filter is obtained. This way, the output of the 1st stage becomes the input to the second stage. Multiple order filters are thus implemented by cascading a 2nd order filter structure as shown in Figure 1.

IMPLEMENTATION

A 4th order IIR Filter is implemented by cascading two of the structures shown in Figure 1. The output Y (output of each filter stage) is computed by direct implementation of Equation 1 and Equation 2. Since each stage is similar algorithmically, it is implemented as a macro using Microchip's, Assembler/Linker for PIC17C42. This Macro (labelled `BIQUAD`) is called twice for implementing a 4th order filter. The output of the 1st stage is directly fed to the input of the second stage without any scaling.

Scaling may be required depending on the particular application. The user can modify the code very easily without any penalty on speed. Also, saturation arithmetic is not used. Overflows can be avoided by limiting the input sequence amplitude. All numbers are assumed to be 16 bits in Q15 format (15 decimal points, MSb is sign bit). Thus the user must scale and sign extend the input sequence accordingly. For example, if the input is from a 12-bit A/D converter, the user must sign extend the 12-bit input if bit 11 is a one.

The `BIQUAD` macro is a generic macro and can be used for all IIR filters whether it is Low Pass, High Pass, Band Pass or Band Stop. A general purpose 16x16 multiplier routine is also provided. This routine is implemented as a straight line code for speed considerations.

The 4th order IIR filter implemented is a Low Pass Filter with the specifications shown in Table 1.

TABLE 1: FILTER CONSTANTS

	BAND1	BAND2
Lower Band Edge	0.0	600 Hz
Upper Band Edge	500 Hz	1 kHz
Nominal Gain	1.0	0.0
Nominal Ripple	0.01	0.05
Maximum Ripple	0.00906	0.04601
Ripple in dB	0.07830	-26.75
Sampling Frequency = 2 kHz		

The Low Pass Filter is designed using a digital filter design package (DFDP™ by Atlanta Signal Processors Inc.). The filter package produces filter constants of the structure shown in Table 1. Table 2 shows the filter co-efficients that are obtained for the above Low Pass filter specification.

TABLE 2: FILTER CO-EFFICIENTS

Stage	Co-efficients				
	a1	a2	b0	b1	b2
1	-0.133331	0.167145	0.285431	0.462921	0.285431
2	0.147827	0.765900	0.698273	0.499908	0.698273

The above filter co-efficients (5 per stage) are quantized to Q15 format (i.e they are multiplied by 32768) and saved in program memory (starting at label `_coeff_lpass`). The constants for both the stages are read into data memory using `TLRD` and `TABLRD` instructions in the Initialization Routine (labelled `initFilter`). The user may read the coefficients of only one stage at a time and save some RAM at the expense of speed.

The sample 4th order Low Pass IIR Filter is tested by analyzing the impulse response of the filter. An impulse signal is fed as input to the filter. This is simulated by forcing the input to the filter by a large quantity (say 7F00h) on the first input sample, and the all zeros from the 2nd sample onwards. The output sequence is the filter's impulse response and is captured into the PICMASTER's (Microchip's Universal In-Circuit Emulator) real-time trace buffer. This captured data from PICMASTER is saved to file and analyzed. Analysis was done using MathCad™ for Windows® and a DSP Analysis program from Burr-Brown (DSPLAY™). The Fourier Transform of this impulse response of the filter should display the filter's frequency response, in this case being a Low Pass type. The plots of the impulse response and the frequency response are shown in Figure 2, Figure 3 and Figure 4.

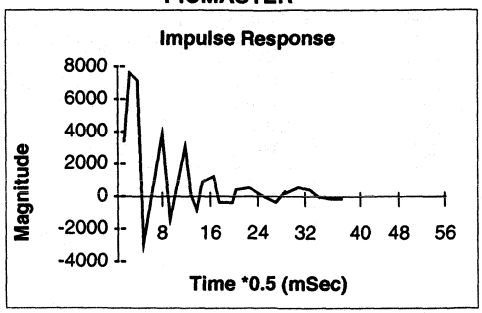

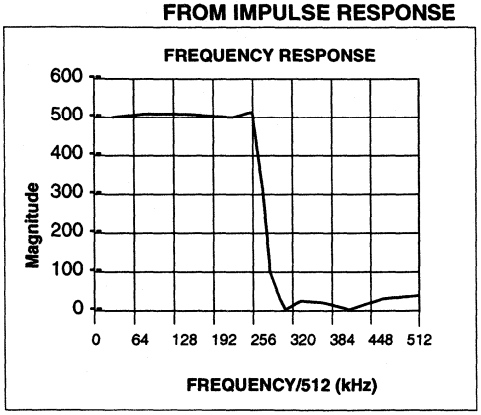

FIGURE 3: SPECTRUM COMPUTED FROM IMPULSE RESPONSE

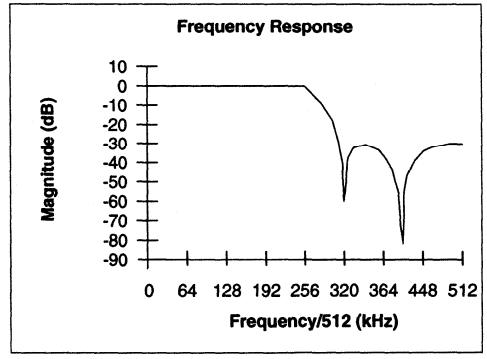
PERFORMANCE

The resource requirements for filter implementations using a PIC17C42 is given in Table 3. These numbers can be used to determine whether a higher order filter can be executed in real-time. The same information may be used to determine the highest sampling rate possible.

FILTER APPLICATIONS



Digital filters find applications in many areas especially those involving processing of real world signals. In some applications like ABS systems in an automobile, digital filtering becomes a must. In this case elimination of noise (especially glitches and false readings of sensors) is very critical and thus becomes a requirement of digital signal processing.

TABLE 3: RESOURCE REQUIREMENTS

Timing (Cycles)(1)	#of Filter Stages*775 + 16
Program Memory (locations)(1)	#of Filter Stages*68 + 290
RAM (File Registers)	#of Filter Stages*16 + 16

Note 1: The above numbers do not include the initialization routine.

FIGURE 4: LOG MAGNITUDE SPECTRUM OF IMPULSE RESPONSE

Digital filters are also needed in Process Control where notch filters and low pass filters are desired because the signals from sensors are transmitted over long lines, especially in a very noisy environment. In these cases, typically a notch filter (centering 50 Hz or 60 Hz) is used. In cases of eliminating background noise, a band stop filter (e.g., 40 Hz to 120 Hz) is used. The sample code given in this application note can be used to design a feedback control system's digital compensator. For example, a typical DC Motor's digital compensator (like a dead-beat compensator) is of second order and has the same filter structure that is implemented in this application note.

Implementation of Fast Fourier Transforms

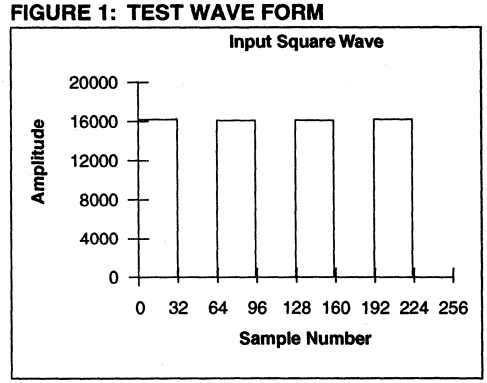
Author: *Amar Palacherla*
Microchip Technology Inc.

INTRODUCTION

Fourier transforms are one of the fundamental operations in signal processing. In digital computations, Discrete Fourier Transforms (DFT) are used to describe, represent, and analyze discrete-time signals. However, direct implementation of DFT is computationally very inefficient. Of the various available high speed algorithms to compute DFT, the Cooley-Tukey algorithm is the simplest and most commonly used. These efficient algorithms, used to compute DFTs, are called Fast Fourier Transforms (FFTs).

This application note provides the source code to compute FFTs using a PIC17C42. The theory behind the FFT algorithms is well established and described in literature and hence not described in this application note. A Radix-2 Cooley-Tukey FFT is implemented with no limits on the length of the FFT. The length is only limited by the amount of available program memory space. All computations are performed using double precision arithmetic.

IMPLEMENTATION



Since the PIC17C42 has only 232 x 8 general purpose RAM (equivalent of 116 x 16), at most a 32-point FFT (16-bit REAL & IMAGINARY data) can be implemented using on-chip RAM. To compute higher point FFTs, the data can be stored in the program memory space of the PIC17C42. The PIC17C42 has instructions (`TABLRD` & `TABLWT`) to transfer data between program memory space and on-chip file registers. In extended microcontroller mode, the PIC17C42 has 2K x 16 (0000h:07FFh) on-chip program memory space and is capable of addressing 62K x 16 (0800h:0FFFFh) of external program memory space. In this mode, the code (in this case, the FFT code) may reside on the on-chip EPROM and the data to be analyzed may be stored in external RAM (up to 62K). A suggested method of connecting external RAM (appropriate EEPROMs may also be used) is shown in Figure 3.

If the PIC17C42 is used in extended microcontroller mode and if all the code resides on-chip, then the cost may further be reduced by using only one external SRAM instead of two. The block diagram is shown in Figure 4. The 16-bit data stored in the external RAM is organized as low byte followed by high byte. To achieve this, the code presented in this application note needs minor modifications, especially where `TABLRD` and `TABLWT` instructions are used. Address indexing must be incremented by two since two reads/writes must be performed to access a 16-bit data.

The FFT is implemented with Decimation In Frequency. Thus the input data, before calling the FFT routine (`R2FFT`), should be in normal order and the transformed data should be in scrambled order. The original data is overwritten by the transformed data to conserve memory. This is achieved by use of in-place calculations. These in-place calculations cause the order of the DFT terms to be permuted. So at the end of the transform, all of the data needs to be unscrambled to get the right order of the DFT terms. In some applications the order of terms is not necessary. Keeping this in mind, the unscrambling code is written as a separate subroutine (`Unscramble`) and may be called if necessary.

Before implementing the FFT using a PIC17C42, a C program was written and tested. This high level programming helps in writing the assembly code and the results of both programs can be compared while debugging the assembly code. The C source code for the Radix-2 FFT is shown in Appendix A. The assembly code source file of the FFT program is shown in Appendix B. For a listing of the header file `17C42.h` and the macro definition file `17C42.mac` please refer to Appendices C and D respectively of application note AN540.

FIGURE 1: TEST WAVE FORM

TESTING

The assembly code was developed and debugged using Microchip's PICMASTER In-Circuit Emulator System. A main program generates a test pattern (like a square wave) and calls FFT routines `R2FFT` and `Unscramble`. After the DFT terms are computed, the results are captured into PICMASTER's real-time trace buffer by putting a trace point on a dummy `TABLRD` instruction and capturing only the 2nd cycle (data cycle of `TABLRD`) of the instruction. The data from the trace buffer was hot linked to a Microsoft Excel spread sheet using DDE and then the graphs were plotted and analyzed.

The code was tested on various waveforms (a rectangular pulse, a triangular wave, square wave and a sine wave) using FFT lengths of 64, 256 and 1024. The results of a 256 point FFT on a square wave is shown below. The test waveform is shown in Figure 1 and it's frequency spectrum computed by the PIC17C42 is shown in Figure 2. As expected, the spectra appears at the odd harmonics of the input waveform's fundamental frequency (At N*256/64, N = 0,1,3,5,..).

PERFORMANCE

The performance of FFTs using a PIC17C42 is quite impressive for an 8-bit machine with no hardware multiplier. Also note that all computations are performed using double precision arithmetic (16- and 32-bit) which is the case for most of the low end DSPs. Table 1 provides the real-time performance in total number of Instruction cycles for both the `R2FFT` and `Unscramble` routines using 64, 256 and 1024 point FFTs. Note that the timings are in a worst case situation and in general will be a lot better than shown in the table. The worst case situation arises because the 16 x 16 software multiplier (`DblMult`) does not have uniform timing and depends on the input data. The worst case timing of the multiplier is used in computing it's performance.

FIGURE 2: FFT (MAGNITUDE SPECTRUM) OF FIGURE 1 COMPUTED BY A PIC17C42

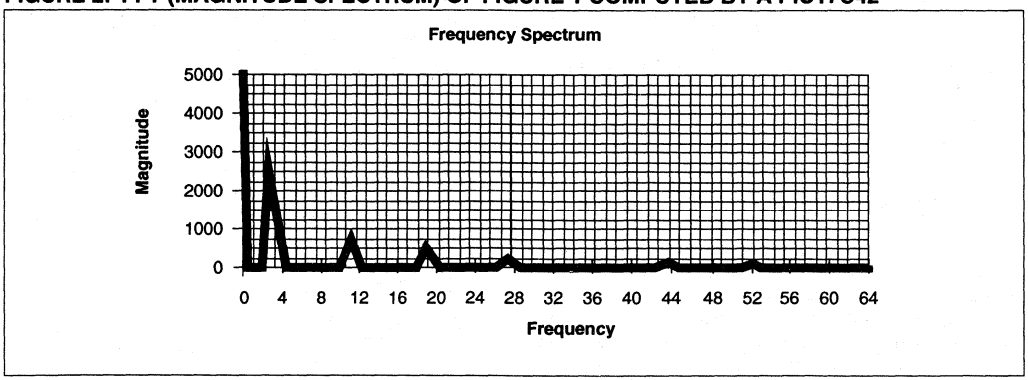

TABLE 1: WORST CASE PERFORMANCE OF FFT IN INSTRUCTION CYCLES AND REAL-TIME @ 25 MHz

N (FFT Length)	64 Point	256 Point	1024 Point
R2FFT	34116 + 768* Mult = 171588	178024 + 4096* Mult = 911208	878752 + 20480* Mult = 4544672
Unscramble	5143	22495	93525
Total	176731 (28.28 ms)	933703 (149.39 ms)	4638197 (742.11 ms)

© 1997 Microchip Technology Inc.

Table 2 shows the Program Memory and Data RAM requirements for an N Point FFT. The multiplier routine and other general purpose macro requirements are included in the memory requirements. The speed performance for the square wave test differs from Table 1, since "worst case timings" is not used and reflects a more reasonable data.

FFT APPLICATIONS

Although the FFT does not find a place in many microcontroller applications, it is very useful in providing a benchmark of the processor. As can be seen from Table 2, the performance is very satisfactory, considering the fact that the PIC17C42 is a Microcontroller and not a DSP. Also it should be borne in mind that all computations are performed in 16/32 bit arithmetic and that the PIC17C42 is a low-cost 8-bit device unlike DSPs which are relatively expensive.

In applications such as Instrumentation, where real-time FFT computation is not required, a PIC17C42 can be used as a single chip solution instead of a microcontroller and a Digital Signal Processor.

Tone Generation

Author: *Amar Palacherla*
Microchip Technology Inc.

INTRODUCTION

A general purpose resonator routine is implemented using a PIC17C42. This routine is used to generate multiple tones. A tone signal is normally generated using extensive table lookup schemes. When a multiple tone signal is desired, each tone must have its own lookup table, thus requiring a large amount of storage space, especially when various frequencies are to be generated. This application note implements tone generation using recursive techniques. The algorithm for a resonator is developed and implemented using PIC17C42.

THEORY

Generation of a single tone basically implies generating samples of a sine/cosine wave. The Z-Transform of a sine wave is given as follows:

$$Z\{sin(wt)\} = \frac{Y(z)}{X(z)} = \frac{z^{*}sin(wT)}{z^{2} - 2^{*}z^{*}cos(wT) + 1}$$

The impulse response of the above transform (i.e., for X(z) = 1) will generate a sine wave of frequency w sampled at a rate of T (= 1/fs). Thus the above equation is translated to:

$$Y(z) = \frac{z^{-1^{*}}sin(wT)}{1 - 2^{*}z^{-1^{*}}cos(wT) + z^{2}}$$

The above equation can be rewritten in a difference equation form as follows:

$$y(n) - 2y(n-1)\cos(wT) + y(n-2) = x(n-1)sin(wT)$$

Rearranging the above equation and setting, x(n) as an impulse sequence, the following recursive equations are obtained.

$$y(n) = 2^{*}K1^{*}y(n-1) - y(n-2)$$
$$y(n-2) = y(n-1)$$
$$y(n-1) = y(n)$$

with the following conditions:

$$K1 = cos(wT)$$
$$K2 = initial\ y(n-1) = sin(wT)$$
$$K3 = initial\ y(n-2) = 0$$

IMPLEMENTATION

The above developed algorithm is implemented as a subroutine using a PIC17C42. All computations are performed using double precision arithmetic (16/32-bits). The recursive tone generation algorithm is implemented as a subroutine (labeled as `Resonator`). This subroutine generates samples of a single tone. To generate multiple frequencies, simply call this resonator routine for the desired frequencies and sum the outputs. The three tone co-efficients are stored in program memory and are read into the data memory using `TABLRD` instructions.

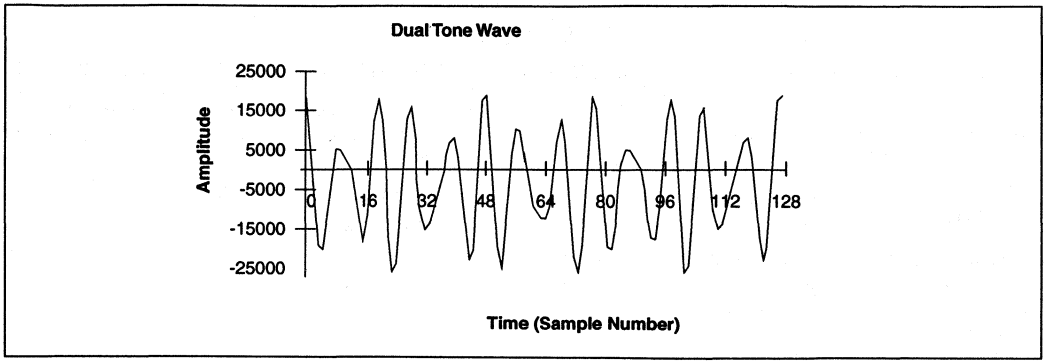
The fully commented code is listed in Appendix A. The timing and memory requirements are included in the comment sections of the code. For a listing of the header file `17C42.h` and the macro definition file `17C42.mac` please refer to Appendices C and D respectively of the application note DS00540. This code can be easily modified and used in various applications like DTMF generation, sound generation, etc. The tones generated can easily be output to an on-chip PWM channel which in turn can drive a speaker for producing various sounds. If using a PWM channel, set the PWM frequency much higher than the sampling frequency used (in the example code, for 8 kHz sampling frequency, use at least 20 kHz PWM frequency).

As an example, a dual tone is generated and the resulting digital wave form is analyzed. The main program calls the function `Resonator` twice for generating the two desired tones and the two outputs are summed. A sampling frequency of 8 kHz was used to generate a dual tone of 800 Hz and 1.10 kHz. The resulting wave form is shown in Figure 1. The spectrum of the signal shown in Figure 2 shows two peaks corresponding to the two desired tones (800 Hz and 1.10 kHz). The assembly code was tested using PICMASTER® (Microchip's Universal In-Circuit Emulator System).

© 1997 Microchip Technology Inc.

The generated tones were captured into the PICMASTER's trace buffer and then transferred to Microsoft® Excel® using Dynamic Data Exchange (DDE). Once the data is in Excel it is analyzed using Excel's FFT utility.

FIGURE 1: DUAL TONE WAVE FORM CAPTURED BY PICMASTER



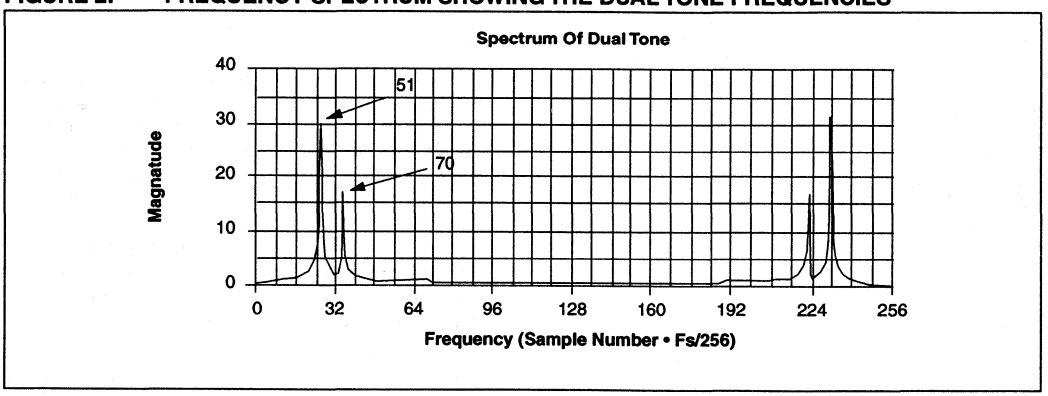


FIGURE 2: FREQUENCY SPECTRUM SHOWING THE DUAL TONE FREQUENCIES

PERFORMANCE

Table 1 below provides the performance of the resonator (labeled in the source code as `Resonator`) in terms of both timing and memory requirements. Since a double precision multiplier is used (software implementation), the multiplier timing is not always constant. Therefore the timings are given for the worst case. Note that irrespective of the frequency and the sampling (resolution) of the tone, program memory requirements is only 54 locations which in case of table lookup could be very large.

TABLE 0-1:

Cycles	235 Cycles
Time @ 16 MHz	58.75 µs
Time @ 25 MHz	47 µs
Data Memory	9 + 9* (# of tones to be generated)
Program memory	54 locations

APPLICATIONS

Tone generation is required in many applications. The code provided in this application note may be used as a general purpose routine to generate desired tones. It can be used in applications involving secure off-site control, where commands/data in the format of tones are transmitted over a telephone line. The tone generation finds applications involving signal modulations as well. The routine can be used to generate audible tones and output to a speaker connected to an I/O Port or a PWM channel.

Math Utility Routines

Author: *Amar Palacherla*
Microchip Technology Inc.

INTRODUCTION

PLEASE NOTE: *This application note uses the old Microchip Math Routine format. It is intended for reference purposes only and is being provided for those of you still implementing Binary Coded Decimal(BCD) routines. For any new designs, please refer to application notes contained in Microchip's Embedded Control Handbook Volume II - Math Library*

This application note provides some utility math routines for Microchip's second generation of high performance 8-bit microcontroller, the PIC17C42. Three assembly language modules are provided, namely ARITH.ASM, BCD.ASM and FXP–DIV.ASM. Currently in each file the following subroutines are implemented:

ARITH.ASM

- Single precision 8 x 8 unsigned multiply
- 16 x 16 double precision multiply (signed or unsigned)
- 16 / 16 double precision divide (signed or unsigned)
- 16 x 16 double precision addition
- 16 x 16 double precision subtraction
- double precision square root
- double precision numerical differentiation
- double precision numerical integration
- Pseudo Random number generation
- Gaussian distributed random number generation

BCD.ASM

- 8-bit binary to 2 digit BCD conversion
- 16-bit binary to 5 digit BCD conversion
- 5-bit BCD to 16-bit binary conversion
- 2 digit BCD addition

FXP–DIV.ASM.

The routines that are implementing in this source file are shown in Table 3.

As more routines are available, they will be added to the library. The latest routines may be obtained either through Microchip's bulletin board or by contacting your nearest Microchip sales office for a copy on a MS-DOS® floppy.

These routines have been optimized wherever possible with a compromise between speed, RAM utilization, and code size. Some routines (multiplication and division) are provided in two forms, one optimized for speed and the other optimized for code size.

All the routines have been implemented as callable subroutines and the usage of each routine is explained below. At the end of the application note, the listing files of the above programs are given.

4

SINGLE PRECISION UNSIGNED MULTIPLICATION (8 x 8)

This routine computes the product of two unsigned 8-bit numbers and produces a 16-bit result. Two routines are provided: one routine is optimized for speed (a straight line code) and the other one has been optimized for code size (a looped code version). These subroutines are located in ARITH.ASM and printed in the listing file ARITH.LST. The performance specs are shown in Table 1.

DOUBLE PRECISION MULTIPLICATION

This routine computes the product of 16- bit numbers and produces a 32-bit result. Both signed and unsigned arithmetic is provided (2's complement arithmetic). Whether to use signed or unsigned is decided at assembly time depending on whether "SIGNED" is set to true or false (refer to the source code). These routines are extremely useful for high precision computation and are used extensively in the other programs provided in this application note (for example, the square root, integrator, differentiator call these routines). Two routines are provided. One routine is optimized for speed (a straight line code) and the other one has been optimized for code size (a looped code version). These subroutines are located in ARITH.ASM and printed in the listing file ARITH.LST. The performance specs are shown in Table 2.

TABLE 1: SINGLE PRECISION MULTIPLICATION

Name	Comments	Program Memory	Instruction Cycles	Scratch RAM	W Register
mpy8x8_F	speed efficient	36	36	0	used
MPY8X8_s	code efficient	13	69	1	used

MS-DOS is a registered trademark of Microsoft Corporation.

© 1997 Microchip Technology Inc.

The listing file shown is assembled with "SIGNED equ TRUE". If unsigned arithmetic is needed, the source code should be changed to "SIGNED equ FALSE". Conditional assembly and the advanced macro features of the assembler are used.

The data memory organization is explained in the comment section of the code. Faster execution and code space saving can be achieved by setting "MODE_FAST equ TRUE". However, setting MODE_FAST variable to TRUE restricts that operands and the 32-bit result be in data RAM locations 0x18 and 0x1F (in this mode, MOVFP and MOVPF instructions may be used to transfer data to/from any RAM location to addresses less than 0x1F). If MODE_FAST is set to FALSE, there will be no restriction on the location of the data RAM values used in this subroutine. However, the code will be slightly slower and occupies more program memory.

The listing file shown is assembled with "SIGNED equ TRUE". If unsigned arithmetic is needed, the source code should be changed to "SIGNED equ FALSE". Conditional assembly and the advanced macro features of the assembler are used.

DOUBLE PRECISION DIVISION

This routine performs a 2's complement division of two 16-bit numbers and produces a 16-bit quotient with a 16-bit remainder. Both signed and unsigned arithmetic is provided (2's complement arithmetic). Whether to use signed or unsigned is decided at assembly time depending on whether "SIGNED" is set to true or false (refer to the source code).

These routines are extremely useful for high precision computation and are used extensively in the other programs provided in this application note (for example, the square root, integrator, differentiator call these routines). Two routines are provided. One routine is optimized for speed (a straight line code) and the other one has been optimized for code size (a looped code version). These subroutines are located in Appendix C. The performance specs are shown in Table 3.

TABLE 2: DOUBLE PRECISION MULTIPLICATION

Name	Comments	Program Memory	Instruction Cycles	Scratch RAM	W Register
D_myfF	Speed Efficient, Signed Arithmetic	204	183	1	used
D_mpyF	Speed Efficient, Unsigned Arithmetic	179	176	0	used
D_mpyS	Code Efficient, Signed Arithmetic	52	254	4	used
D_mpyS	Code Efficient, Unsigned Arithmetic	21	242	3	used

TABLE 3: FIXED POINT DIVIDE PERFORMANCE DATA

Routine	Max. Cycles	Min. Cycles	Program Memory	Data Memory
16 / 8 Signed	146	135	146	5
16 / 8 Unsigned	196	156	195	4
16 / 7 Unsigned	130	130	129	4
15 / 7 Unsigned	125	125	124	4
16 / 16 Unsigned	214	187	241	7
16 / 16 Unsigned	244	180	243	6
16 / 15 Unsigned	197	182	216	6

32 / 16 Unsigned	414	363	476	9
32 / 16 Unsigned	485	459	608	9
32 / 15 Unsigned	390	359	451	8
31 / 15 Unsigned	383	353	442	8

© 1997 Microchip Technology Inc.

DOUBLE PRECISION ADDITION AND SUBTRACTION

Two routines are provided. One performs a 2's complement addition and the other one performs a 2's complement subtraction of two 16-bit binary numbers. These subroutines are located in ARITH.ASM and printed in the listing file ARITH.LST. The performance specs are shown in Table 4.

NEGATE A DOUBLE PRECISION NUMBER

These routines negate a double precision number (16-bit and 32-bit). Two routines and two macros are provided to negate a 16-bit number. The subroutines use indirect addressing mode and the macros use a direct addressing scheme. A macro is provided to negate a 32- bit number.

DOUBLE PRECISION SQUARE ROOT

Often in many applications, one needs to find the square root of a number. Of the many numerical methods available to compute the square root of a number, the Newton-Raphson method is one of the most attractive because of its fast convergence rate. In this method, the square root of number, N, is obtained as an approximate solution of

$$f(Y) = Y^2 - N = 0$$

The function f(Y) can be expanded about Y_0 using the first order Taylor polynomial expansion as:

EQUATION 1:

$$f(Y) = f(Y_0) + (Y - Y_0)f'(Y_0) + \frac{(Y - Y_0)2f''f(Y_0)}{2!} + \ldots$$

If X is a root of f(Y), then f(X) = 0: Therefore,

If Y0 is an approximate root of f(Y), then the higher order terms in the above equation are negligible.

Therefore, $f(Y_0) + (X - Y_0)f(Y_0) = 0$

i.e., $X = Y_0 + \frac{f(Y_0)}{f'(Y_0)}$

Thus X is a better approximation for Y_0. From the previous equation, the sequence {Xn} can be generated:

EQUATION 2: $$X_n = X_{n-1} - \frac{f(X_{n-1})}{f'(X_{n-1})}, n \geq 1$$

For our case, equation 2, reduces to:

EQUATION 3: $$\frac{X_{n-1} + \frac{N}{X_{n-1}}}{2}$$

The routine "Sqrt" in ARITH.ASM implements the above equation. Equation 3 requires that at first an initial approximation for the root is known. The better the initial approximation, the faster the convergence rate would be. In the "Sqrt" routine, the initial approximation root is set as N/2. This routine calls the double precision division routine (D_divS).

In the code size, the Division routine (Ddiv_S) size is not included.

BCD ROUTINES

Three routines are provided for general purpose BCD arithmetic:

a) BCD to binary conversion
b) Binary to BCD conversion
c) BCD addition

The BCD to binary conversion routine converts a 5-digit BCD code to a 16-bit binary number. The BCD addition routine adds two BCD digits directly without converting them at first to binary. Note the usage of the **"DAW"** instruction. The other two routines convert a binary number to a BCD code. The performance specs for the BCD routines is given in the Table 7 below.

NUMERICAL DIFFERENTIATION

This routine performs numerical differentiation of a sequence of data if the input sequence is assumed to be piecewise linear with no discontinuances (this is the case in most real world signals). Although this routine is provided as a tool to implement a PID algorithm for motor control, it can be used as a general purpose subroutine. This routine uses the so called 3-Point formula to compute the differential of a sequence of numbers.

Given an equation f(t), its derivative is given by

$$f'(t) = \frac{df(t)}{dt}$$

The above equation can be approximated using the 3-Point formula as given below:

EQUATION 4: 3-POINT FORMULA:

$$f'(t) = \frac{df(t)}{dt} = \frac{1}{2h}[f(t_0 - 2h) - 4f(T_0 - h) + 3f(t_0)]$$

where t_0 is the point at which the numerical derivative is desired and "h" is the step size. The smaller the value of the step size (h), the better the approximation. In case of say, PID motor control, the step size is proportional to the time intervals at which the new sample value of the position (or speed) is obtained. Using the above equation to compute the differential, three samples are necessary (present value and the last two past values). The subroutine "Diff" is implemented so that 1/2h factor is stored already in a RAM location (location DiffK) as 1/2h and not as "h" because it is more efficient to multiply than divide.

After computation, the routine does not move the present value to the past value. So the user must update the past values before calling this routine again. This way, if necessary, differentiation may be performed without disturbing the present and past values. Also, when this routine is called for the first time, it is user's responsibility to set the initial values of the past data points (may be set to zero). This routine called "Diff" is located in "ARITH.ASM".

In the code size, the double precision multiplication routine (Dmpy_S) used is not included.

NUMERICAL INTEGRATION

This routine performs numerical integration using Simpson's Three-Eighths Rule. This is a third order approximation for the function, whose integral is to be computed at a given point. Although this routine is provided as a tool to implement a PID algorithm for motor control, it can be used as a general purpose subroutine. Given a function f(t), its integral over a range t_0 to t_3 is represented as:

t3

$\int$f(t)dt. This function is approximated as follows:

t0

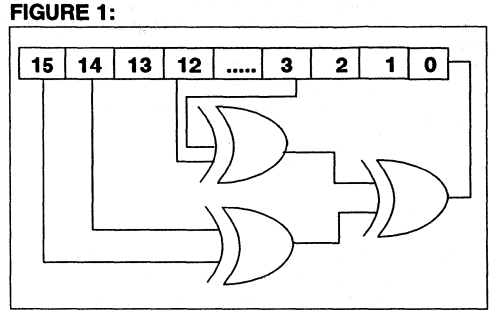
Simpson's Three-Eighths Rule:

t3

$$\int f(t)dt = \frac{3h}{8}[f(t_0) + 3f(t1) + 3f(t2) + f(t3)]$$

(t_0)

The constant 3h/8 can be computed before hand and stored in a RAM location (in location IntgKLo and IntgKHi as a 16-bit number). After computation, the routine does not move the present value to the past value. So the user must update the past values before calling this routine again. This way, if necessary, integration may be performed without disturbing the present and past values. Also, when this routine is called for the first time, it is user's responsibility to set the initial values of the past data points (may be set to zero). This routine called "Integrate" is located in "ARITH.ASM".



In the code size, the double precision multiplication routine (Dmpy_S) used is not included.

PSEUDO RANDOM NUMBER GENERATOR

This routine (subroutine "Random 16" provided in ARITH.ASM) generates a pseudo random number sequence. The random points are generated using a 16-bit register and left shifting the contents with the LSB set as shown by the following schematic.

As a test, the random points are generated by calling the subroutine from an infinite loop, and the data points are continuously captured into the real time trace buffer using the PICMASTER (the Universal In-Circuit Emulator for the PICmicro™ series). The autocorrelation of the captured data is computed using a stand alone program and is shown in Figure 2. From this figure, it can be seen that the data has a strong autocorrelation only at the origin and sharply approaches to zero within a few points. This demonstrates the randomness of the data captured.

Gauss	Gaussian Random Number Generator	21	452	4	used

PN (pseudo noise) sequences are widely used in digital communication systems for synchronization. These code words can also be used for data scrambling because of their good correlation properties. An interesting application of these sequences is system integrity. For example, these sequences can be regularly transmitted to a processor whose watchdog timer will time out if, say, two consecutive PN sequences do not match.

FIGURE 3: HISTOGRAM OF THE DATA GENERATED BY THE GAUSSIAN GENERATOR

GAUSSIAN DISTRIBUTED RANDOM NUMBER GENERATOR

This routine (subroutine "Gauss" provided in ARITH.ASM) generates a sequence of random numbers with a characteristic of a normal distribution (Gaussian distributed points). This routine calls the pseudo random number generator ("random16") to obtain a near uniformly distributed random points and from these points, the Gaussian distributed points are generated. The method of generating Gaussian points is based on the "Central Limit Theorem", which states that an ensemble of average weighted sum of a sequence of uncorrelated samples tends to have a Gaussian distribution.

As a test, the Gaussian points are generated by calling the subroutine from an infinite loop, and the data points are continuously captured into the real time trace buffer using the PICMASTER (the Universal In-Circuit Emulator for the PICmicro series). A plot of the points captured is shown in Figure 3, which shows that the random points generated have the characteristics of a Gaussian distribution.

                00794 ;*****************************************************************
                00795 ;
                00796 ;             Square Root By Newton Raphson Method
                00797 ;
                00798 ;    This routine computes the square root of a 16 bit number(with
                00799 ;  low byte in NumLo & high byte in NumHi ). After loading NumLo &
                00800 ;  NumHi with the desired number whose square root is to be computed,
                00801 ;  branch to location Sqrt ( by "GOTO  Sqrt" ). " CALL  Sqrt" cannot
                00802 ;  be issued because the Sqrt function makes calls to Math routines
                00803 ;  and the stack is completely used up.
                00804 ;       The result = sqrt(NumHi,NumLo) is returned in location SqrtLo.
                00805 ;  The total number of iterations is set to ten. If more iterations
                00806 ;  are desired, change "LupCnt equ .10" to the desired value. Also,
                00807 ;  the initial guess value of the square root is given set as
                00808 ;  input/2 ( in subroutine "init" ). The user may modify this scheme
                00809 ;  if a better initial approximation value is known. A good initial
                00810 ;  guess will help the algorithm converge at a faster rate and thus
                00811 ;  less number of iterations required.
                00812 ;       Two utility math routines are used by this program : D_divS
                00813 ;  and D_add. These two routines are listed as seperate routines
                00814 ;  under double precision Division and double precision addition
                00815 ;  respectively.
                00816 ;
                00817 ;  Note : If square root of an 8 bit number is desired, it is probably
                00818 ;         better to have a table look scheme rather than using numerical
                00819 ;         methods.
                00820 ;              This method is computationally quite intensive and
                00821 ;         slow, but very accurate and the convergence rate is high
                00822 ;

                00971 ; differenciate a sequence of points (uniformly sampled).
                00972 ;       The eqn implemented is :
                00973 ;             f'(Xn) = [ f(Xn - 2h) - 4*f(Xn - h) + 3*f(Xn)]*0.5/h
                00974 ;    where Xn is the present sample and 'h' is the step size.
                00975 ;
                00976 ;       The above formula may be rewritten as :
                00977 ;
                00978 ;         f'(Xn) = [ 0.5*f(Xn -2) - 2*f(Xn - 1) + 0.5*3*f(Xn)]*1/DiffK
                00979 ;  where DiffK = h = Step Size
                00980 ;
                00981 ;   This differenciation routine can be used very effectively
                00982 ; in the computation of the differential component part in
                00983 ; a PID Loop calculation in Motor Control Applications
                00984 ;
                00985 ;       Double precision arithmetic is used throught
                00986 ;  The present sample value is assumed to be in locations
                00987 ; (XnHi, XnLo). The past two values are assumed to be in locations
                00988 ; (Xn_1_Hi, Xn_1_Lo) & (Xn_2_Hi, Xn_2_Lo).
                00989 ;       The output value is located in DiffHi & DiffLo. No overflow
                00990 ; checking mechanism is implemented. If the values are limited
                00991 ; to 12 bits, then the user need not worry about overflows

              01170 ;                        Gaussian Noise Generator
              01171 ;
              01172 ; This routine generates a 16 Bit Gaussian distributed random
              01173 ; points. This routine calls the routine "Random16", which
              01174 ; generates a psuedo random noise sequence. Gaussian noise
              01175 ; is computed using the CENTRAL LIMIT THEOREM.
              01176 ;       The Central Limit Theorem states that the average weighted
              01177 ; sum of uncorelated samples tends to have a Gaussian distribution
              01178 ; For practical purposes, the sum could be over a sample size
              01179 ; of 32 Random numbers. Better results could result if a larger
              01180 ; sample size is desired. For faster results, a sum over 16 samples
              01181 ; would also be adequate ( say, for applications like Speech synthesis,
              01182 ; channel simulations, etc).
              01183 ;
              01184 ;       The 16 bit Gaussian distributed point is in locations
              01185 ; GaussHi & GaussLo
              01186 ;
              01187 ;       Before calling this routine, the initial seed of Random
              01188 ; number should be NON ZERO ( refer to notes on "Random16" routine
              01189 ;

Using the Capture Module

Author: *Mark Palmer*
Microchip Technology Inc.

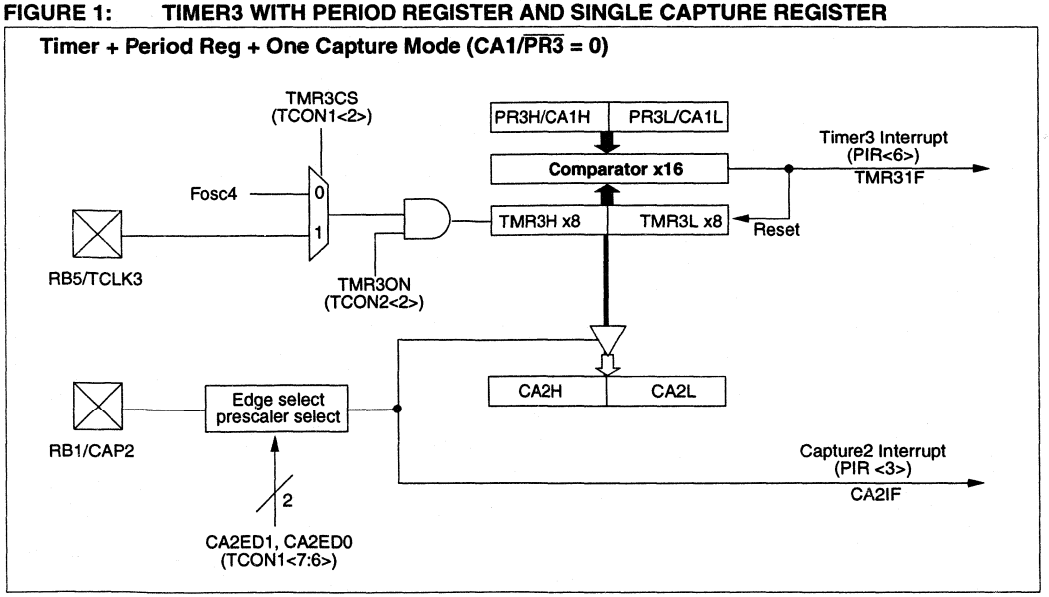
INTRODUCTION

The PICmicro™ family of RISC microcontrollers has been designed to provide advanced performance and a cost-effective solution for a variety of applications. This application note provides examples which illustrate the uses of input capture using the PIC17C42 Timer3 module. These examples may be modified to suit the specific needs of an application.

This application note has 4 examples that use the Timer3 input capture. They are:

- Frequency Counter (Period Measurement)
- Frequency Counter (Period Measurement) using a Free Running Timer
- Pulse Width Measurement
- Frequency Counter (Period Measurement) with Input Prescaler

TIMER3 DESCRIPTION



Timer3 is a 16-bit timer/counter that has two modes of operation which are software selected. The CA1/$\overline{PR3}$ bit (TCON2<3>) selects the mode of operation. The two modes are:

- Timer3 with Period Register and Single Capture Register (Figure 1).
- Timer3 and Dual Capture Registers (Figure 2).

Timer3 is the time-base for capture operations.

FIGURE 2: TIMER3 AND DUAL CAPTURE REGISTERS

The period register allows the time base of Timer3 to be something other than the 2^{16} counter overflow value, which corresponds to FFFFh (65536) cycles. This is accomplished by loading the desired period value into the PR3H/CA1H:PR3L/CA1L register pair. The overflow time can be calculated by this equation:

TOFL = TCLK • (value in PR3H/CA1H:PR3L/CA1L register pair + 1).

Where TCLK is either the internal system clock (TCY) or the external clock cycle time. Table 1 the shows time-out periods for different period values at different frequencies. The values in the register are the closest approximation for the period value. All examples in this application note uses a Timer3 overflow value of FFFFh.

The uses of an input capture are all for time based measurements. These include:

- Frequency measurement
- Duty cycle and pulse width measurements

The PIC17C42 has two pins (RB0/CAP1 and RB1/CAP2) which can be used for capturing the Timer3 value, when a specified edge occurs. The input capture can be specified to occur on one of the following four events:

- Falling Edge
- Rising Edge
- 4th Rising Edge
- 16th Rising Edge

These are specified bits 7:6 for CAP2 and 5:4 for CAP2 by the register TCON1<7:4>.

This flexibility allows an interface without the need of additional hardware to change polarity or specify an input prescaler.

© 1997 Microchip Technology Inc.

The control registers that are used for by Timer3 are shown in Table 2. Shaded Boxes are control bits that are not used by the Timer3 module, the Peripheral Interrupt enable and flag bits, and the Global Interrupt enable bit.

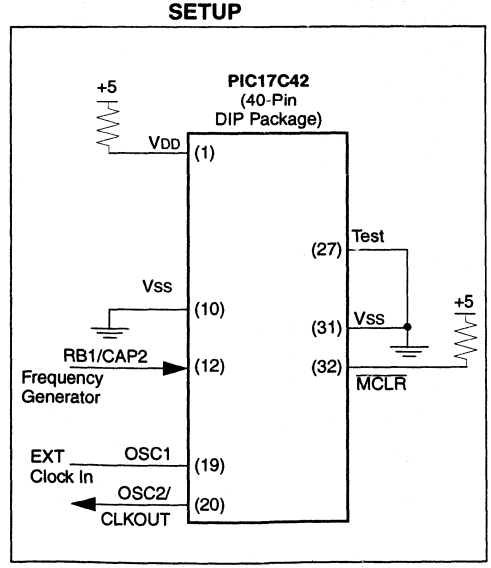
Legend: x = unknown, u = unchanged, - = unimplemented read as a '0', q - value depends on condition, shaded cells are not used by Timer1 or Timer2.



Note 1: Other (non power-up) resets include: external reset through $\overline{MCLR}$ and WDT Timer Reset.

This Application Note has 4 examples that USE the Timer3 input capture. They are:

- Frequency Counter (Period Measurement)
- Frequency Counter (Period Measurement) using a Free Running Timer
- Pulse Width Measurement
- Frequency Counter (Period Measurement) with Input Prescaler

All these examples can be run from a simple setup, this is shown in Figure 3.

FIGURE 3: APPLICATION HARDWARE SETUP

A discussion of each application with the operation of the software and application issues. The source listings for these are in appendices A-D.

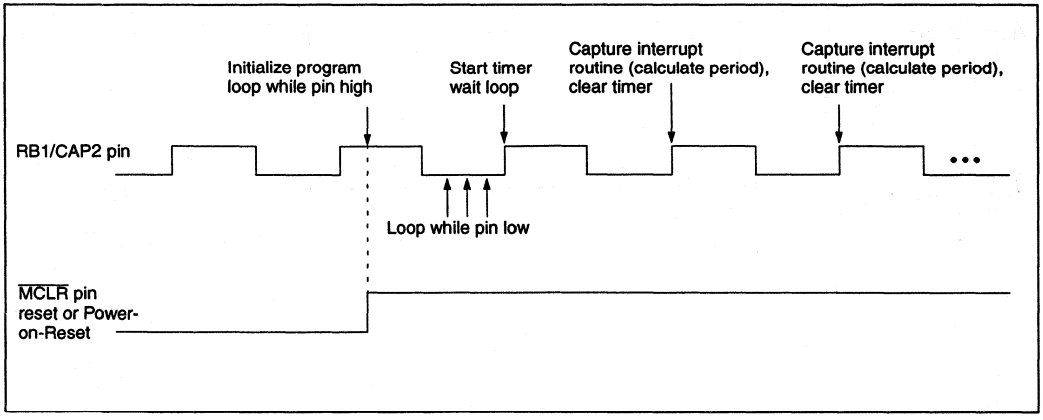
PERIOD MEASUREMENT (FREQUENCY COUNTER)

Period measurement is simply done by clearing the counter to 0000h, then starting the counter on the 1st rising edge. On the following rising edge, the capture2 register is loaded with the Timer3 value and the TMR3 register CA2H:CA2L is cleared. If the period is greater than the overflow rate of TMR3, the register overflows, causing an interrupt. With a TMR3 overflow, an interrupt occurs and the overflow counter may need to be incremented. The overflow counter should be incremented if:

- The TMR3 overflow is the only interrupt source.
- Both the TMR3 overflow and capture2 interrupts occurred at near the same time, but the TMR3 overflow occurred first, Most Significant Byte of the Capture2 register is cleared (CA24-00h)).



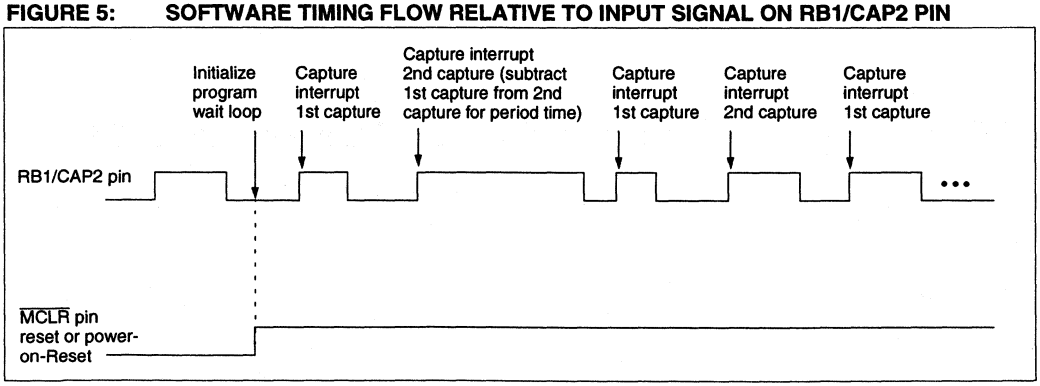
Once a capture has occurred, the capture registers are moved to data RAM, the capture2 interrupt flag is cleared and the TMR3 register is loaded with an offset value. This offset value is the number of cycles from the time the interrupt routine is entered to when the TMR3 register is reloaded. In this example a data RAM location is used as an overflow counter. This gives in effect a 24-bit timer. The software flow for this routine is shown in Figure 4.

The program listing in Appendix A implements this, assuming only TMR3 overflow and capture2 interrupt sources. This example may be modified to suit the particular needs of your application. The following is a performance summary for this program (@ 16 MHz):

Code size:	30 Words
RAM used:	4 Bytes
Maximum frequency that can be measured:	130 kHz
Minimum frequency that can be measured:	0.25 Hz
Measurement Accuracy:	± TCY (± 250 ns)

4

FIGURE 4: SOFTWARE TIMING FLOW RELATIVE TO INPUT SIGNAL ON RB1/CAP2 PIN



PERIOD MEASUREMENT (FREQUENCY COUNTER) USING A FREE RUNNING TIMER

In many applications the timer would need to be used for multiple tasks, and is required not to be reset (modified) by any one of these tasks. This is called a free running timer. To do period measurement in an application with a free-running timer, the program needs to store each capture in a data RAM location pair (word). The 1st capture in data RAM locations input capture2A (IC2AH:IC2AL) and the 2nd capture in data RAM locations input capture2B (IC2BH:IC2BL). Once the two captures have occurred, the values in these two words are subtracted. Since this is a free running timer, the value in input capture2B may be less than the value in input capture2A. This is if the 1st capture occurs, then the TMR3 overflows, and then the 2nd capture occurs. So an overflow counter should only be incremented if the TMR3 overflow occurs after a capture1 but before the capture2 occurs. With the use of an overflow counter this becomes an effective 24-bit period counter. The software flow for this routine is shown in Figure 5.

The program listing in Appendix B implements this, assuming only TMR3 overflow and capture2 interrupt sources. This example may be modified to suit the particular needs of your application. The following is a performance summary for this program (@ 16 MHz):

Code size:	41 Words
RAM used:	7 Bytes
Maximum frequency that can be measured:	71 kHz
Minimum frequency that can be measured:	0.25 Hz
Measurement Accuracy:	± TCY (± 250 ns)

FIGURE 5: SOFTWARE TIMING FLOW RELATIVE TO INPUT SIGNAL ON RB1/CAP2 PIN

PULSE WIDTH MEASUREMENT USING A FREE RUNNING TIMER

Applications that require the measurement of a pulse width can also be easily handled. The PIC17C42 can be programmed to measure either the low or the high pulse time. The software example in Appendix C measures the high pulse time. The program is initialized to capture on the rising edge of the RB1/CAP2 pin. After this event occurs, the capture mode is switched to the falling edge of the RB1/CAP2 pin. When the capture edge is modified (rising to falling, or falling to rising) a capture interrupt is generated. This "false" interrupt request must be cleared before leaving the interrupt service routine, or the program will immediately re-enter the interrupt service routine due to this "false" request. When the falling edge of the RB1/CAP2 pin occurs, the difference of the two capture values is calculated. The flow for this is shown in Figure 6.

Due to the software overhead of the peripheral interrupt routine the following are the limitations on the input signal on the RB1/CAP2 pin. This does not include any software overhead that may be required in the main routine, or if additional peripheral interrupt features need to be included. This is shown in Table 3. If you assume that the input is a square wave (high time = low time), one needs to take the worst case time of the two minimum pulse times (11 µs) times two, to determine the period. The maximum continuous input frequency would then be approximately 45.5 kHz. For a single pulse measurement, minimum pulse width is 4.5 µs.

The program listing in Appendix C implements this, assuming only TMR3 overflow and capture2 interrupt sources. This example may be modified to suit the particular needs of your application. The following is a performance summary for this program (@ 16 MHz):

Code size:	51 Words
RAM used:	7 Bytes
Maximum frequency that can be measured:	71 kHz
Minimum frequency that can be measured:	0.25 Hz
Measurement Accuracy:	± TCY (± 250 ns)

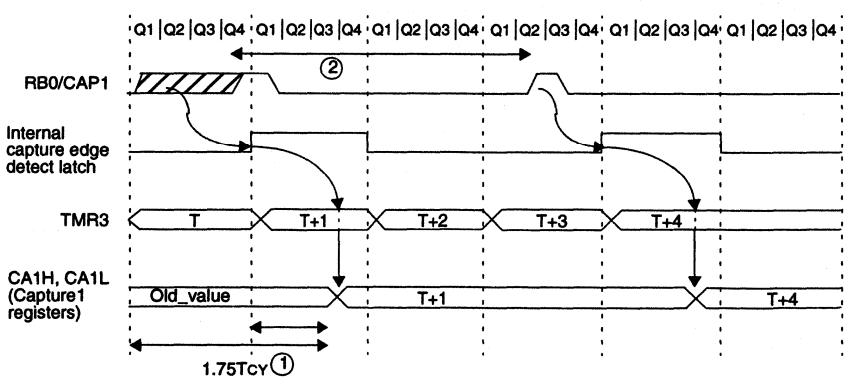
PERIOD MEASUREMENT (FREE RUNNING TIMER) WITH A PRESCALER

Occasionally the application may require a prescaler on the input signal. This may be due to application requirements, such as:

- Require higher resolution measurement of the input signal
- Reduce interrupt service overhead
- The input frequency is higher than interrupt service routine

The software selectable prescaler of the PIC17C42 allows the designer to easily implement this in their system without the cost of additional hardware. Care must be taken in determining if this option is appropriate. For example, if the input frequency is not stable (excessive frequency change per period) then the prescaler will give a less accurate capture value than the individual measurements.



In cases where the resolution of the input frequency is important, the prescaler can be used to reduce the input capture error. There are two components to input capture:

- Resolution Error
- Input Synchronization Error

These two errors combine to form the total capture error. Resolution error is dependent on the rate at which the timer is incremented. Remember the timer may be based on an external clock (must be slower than TCY). The input synchronization error is dependent on the system clock speed (TCY), and will be less than TCY.

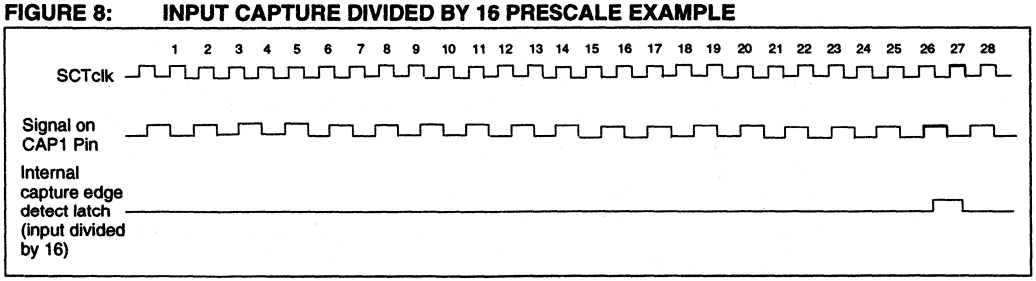
It is easy to see that when a capture occurs the synchronization error (TESYSC) can be up to 1 TCY (Figure 7). This error is constant regardless of the number of edges that occur before the capture is taken. So a capture on the 1st edge gives a synchronization error per sample up to TCY. While a capture taken on the 16th edge gives a synchronization error per sample only up to TCY / 16, by achieving a smaller percentage of error, the captured value becomes more accurate.

FIGURE 7: SYNCHRONIZATION ERROR WITH NO CAPTURE PRESCALER

Note 1: Capture edge to actual register update latency is 1.75 TCY maximum, 0.75 TCY minimum. This implies that when measuring a pulse or a period, the measurement error is ± TCY.

Note 2: With no prescaler on the input capture, two consecutive capturing edges must be apart by at least TCY. This allows the internal "capture edge detect latch" to reset.

© 1997 Microchip Technology Inc.



Another scenario is when the signal on the input capture pin is different than the system cycle time (TCY), for example 1.6TCY. If you tried to capture this you would have a capture value of 1. If you set the prescaler to actually capture on the 16th edge you would have 16 * 1.6 TCY = 25.6TCY, which would be latched on the 26th TCY (Figure 8). This 0.4 TCY error is over 16 samples, which therefore gives an effective error/sample of 0.025TCY.

The program listing in Appendix D implements this, assuming only TMR3 overflow and Capture2 interrupt sources. This example may be modified to suit the particular needs of your application. The following is a performance summary for this program (@ 16 MHz):

Code size:	41 Words
RAM used:	7 Bytes
Maximum frequency that can be measured:	80 kHz
Minimum frequency that can be measured:	0.25 Hz
Measurement Accuracy:	± TCY (± 16.625 ns)

                     00004 ;
                     00005 ; This is the basic outline for a program that can determine the
                     00006 ; frequency of an input, via input capture. The input capture has
                     00007 ; been selected to capture on the 16th rising edge. This is useful
                     00008 ; for high frequency inputs, where an interrupt on each rising edge
                     00009 ; would not be able to be serviced (at that rate). This particular
                     00010 ; example can support an input signal with a period of approximatly
                     00011 ; 625 nS. Without the divide by 16 selected, this is approximatly
                     00012 ; 10 us. This period time increases (frequency decreases) as the
                     00013 ; overhead in the main routine increases.
                     00014 ;
                     00015 ; This routine uses an 8-bit register to count the times that timer3
                     00016 ; overflowed. At the Max crystal frequency of 16 MHz, this gives an
                     00017 ; overflow time of (16)(2**8 + 1)(2**16)(250 nS) > 67.37 sec. If
                     00018 ; measurement of longer time intervals is required, the overflow
                     00019 ; counter could be extended to 16 (or more) bits.
                     00020 ;
                     00021 ; Timer 3 in this example is a free running timer. The input
                     00022 ; capture is generated on the RB1/CAP2 pin. There is a flag
                     00023 ; that specifies if this is the 1st or 2nd capture.
                     00024 ; The first capture is the start of the period measurement. The
                     00025 ; second capture value gives the end of the period. In this type
                     00026 ; of measurement If the 2nd capture value < the 1st captue value
                     00027 ; then the overflow counter should be decremented.

  VALUE

                     00001         LIST    P = 17C42, n = 66
                     00002 ;
                     00003 ;*****************************************************
                     00004 ;
                     00005 ; This is the basic outline for a program that can determine the
                     00006 ; frequency of an input, via input capture. This routine uses an
                     00007 ; 8-bit register to count the times that timer3 overflowed. At the
                     00008 ; Max crystal frequency of 16 MHz, this gives an overflow time of
                     00009 ; (2**16)(256 + 1)(250 nS) > 4.21 sec or a frequncy < 0.25 Hz. If
                     00010 ; measurement of longer time intervals is required, the overflow
                     00011 ; counter could be extended to 16 (or more) bits.
                     00012 ;
                     00013 ; Timer 3 in this example is a free running timer. The input
                     00014 ; capture is generated on the RB1/CAP2 pin. There is a flag
                     00015 ; that specifies if this is the 1st or 2nd capture.
                     00016 ; The first capture is the start of the period measurement. The
                     00017 ; second capture value gives the end of the period. In this type
                     00018 ; of measurement If the 2nd capture value < the 1st captue value
                     00019 ; then the overflow counter should be decremented.
                     00020 ;

                     00005 ; This is the basic outline for a program that can determine the
                     00006 ; Pulse Width of an input, via input capture. This routine uses an
                     00007 ; 8-bit register to count the times that timer3 overflowed. At the
                     00008 ; Max crystal frequency of 16 MHz, this gives an overflow time of
                     00009 ; (2**16)(256 + 1)(250 nS) > 4.21 sec or a frequency < 0.25 Hz. If
                     00010 ; measurement of longer time intervals is required, the overflow
                     00011 ; counter could be extended to 16 (or more) bits.

Serial Port Utilities

Author: *Amar Palacherla*
Microchip Technology Inc.

INTRODUCTION

The PIC17C42 has an on-chip high speed Universal Synchronous Asynchronous Receiver Transmitter (USART). The serial port can be configured to operate either in full-duplex asynchronous mode or half duplex synchronous mode. The serial port has a dedicated 8-bit baud rate generator. Either 8- or 9-bits can be transmitted/received.

This application note provides information on using the serial port, parity generation, serial port expansion, RS-232 interface, I/O port expansion using the serial port in synchronous mode.

SERIAL PORT USAGE

A brief code to setup the serial port, and receive and transmit data is given in Example 1. Small sections of code for both asynchronous and synchronous mode are given.

Asynchronous Mode Setup

Asynchronous mode setup requires selection of 8/9-bits of data transfer, baud rate, setting the baud rate generator, and configuring the TXSTA and RCSTA control registers. The baud rate generator is configured by writing the appropriate value to SPBRG register (bank0, file 17h). The value to be written to SPBRG is given by:

$$SPBRG = \frac{Input_Clk_Freq}{64 \bullet Baud_Rate} - 1$$

For example, to select a baud rate of 9600 bits/sec with input clock frequency of 16 MHz, SPBRG is computed from the above equation to be 25. Once the Baud Rate Generator is set up, it is necessary to configure the TXSTA and RCSTA control registers as shown in Example 1 (refer to the data sheet):

4

EXAMPLE 1: INITIALIZATION EXAMPLE

```
SPBRG   :   25                  :   9600 baud @ 16 MHz input clock
TXSTA   :   00100000    (20h)   :   8-bit transmission, async mode
RCSTA   :   10010000    (90h)   :   8-bit reception, enable serial port, enable reception

Synchronous Mode Setup

Synchronous mode setup requires selection of 8/9-bits of data transfer, bit rate, setting the baud rate generator, and configuring the TXSTA and RCSTA control registers. The baud rate generator is configured by writing the appropriate value to SPBRG register (bank0, file 17h). The value to be written to SPBRG is given by:

$$SPBRG = \frac{Input_Clk_Freq}{4 \bullet Baud_Rate} - 1$$

For example, to select a bit rate of 1 Mbits/sec with input clock frequency of 16 MHz, SPBRG is computed from the above equation to be 3. Once the Baud Rate Generator is set up, it is necessary to configure the TXSTA and RCSTA control registers as follows (please refer to the data sheet) :

EXAMPLE 2: CONFIGURING TXSTA AND RCSTA CONTROL REGISTORS

```
SPBRG   :   3                   :   1 Mbits/sec @ 16 Mhz input clock
TXSTA   :   10110000    (B0h)   :   8-bit transmission, Sync mode (MASTER)
RCSTA   :   10010000    (90h)   :   8-bit reception, enable serial port, continuous
                                    reception

;**********************************************************************
;          Sample Code For Synchronous Mode (MASTER) Serial Port Setup
;**********************************************************************

#define ClkFreq         16000000                ; input clock frequency = 16 Mhz
#define baud(X)         ((10*ClkFreq/(4*X))+5)/10 - 1
#define TXSTA_INIT      0xB0
#define RCTSA_INIT      0x90

        #include                "17C42.h"           ; file containing the Register Definitions

Setup_Sync_Master_Mode
                movlb   0                       ; SPBRG, TXSTA & RCSTA are in bank 0
                movlw   baud(1000000)           ; equals 3 for 1 Mbits/sec
                movwf   SPBRG                   ; baud rate generator is reset & initialized
                movlw   TXSTA_INIT
                movwf   TXSTA                   ; 8-bit transmission, async mode
                movlw   RCSTA_INIT
                movwf   RCSTA                   ; 8-bit reception, enable serial port,
                                                ; enable reception
                return
;**********************************************************************
```

Receiving Data (Software Polling)

The sample code in Example 3 provides a way to read the received serial data by software polling (with no serial port interrupts). This applies to both asynchronous and synchronous mode. Software polling is done by checking the RCIF bit (PIR<0>). If this bit is set it means that a word has been received (8 bits are in RCREG and the 9th bit in RCSTA<0>).

EXAMPLE 3: POLLING FOR RECEIVE DATA

```
;*********************************************************************
;          Return The 8-bit received Data By Software Polling
;       The received data is returned in location SerInData
;*********************************************************************
Get_Serial_Data_Poll
               movlb   1                ; PIR is in bank 1
PollRcv        btfss   PIR,0            ; check the RBIF bit
               goto    PollRcv          ; loop until char received, assume WDT is off
               movlb   0                ; RCREG is in bank 0
               movpf   RCREG,SerInData
               return                   ; Received 8-bits are in SerInData
;*********************************************************************
```

Transmitting Data (Software Polling)

The sample code in Example 4 provides a way to transmit serial data by software polling (no serial port interrupts). Software polling is done by checking the bit (PIR<1> in bank 1) to be one, indicating the transfer of TXIF to the serial shift register.

EXAMPLE 4: POLLING FOR TRANSMIT DATA

```
;*********************************************************************
;          Transmit 8-bit  Data By Software Polling
;       The data to be transmitted is in location SerOutData
;*********************************************************************
Send_Serial_Data_Poll
               movlb   1                ; PIR is in bank 1
PollTXIFbtfss  PIR,1                    ; check the TXIF bit of PIR register in bank1
               goto    PollTXIF         ; loop until char received, assume WDT is off
               movlb   0                ; RCREG is in bank 0
               movfp   SerOutData,TXREG
               return                   ; Received 8-bits are in SerInData
;*********************************************************************
```

Transmitting & Receiving A Block Of Data (Interrupt Driven)

A general purpose routine which is interrupt driven, that transmits and receives a block of data is provided in Example 5. The reception or transmission of the block is ended when an end of block character is detected. As an example, the end of block is identified by a 0. The block of data to be transmitted is stored in the program memory and the TABLRD instruction is used to transfer this example data to the file registers and serial port. The user may modify this code to a more general purpose routine that suits the application.

Please check the Microchip BBS for the latest version of the source code. Microchip's Worldwide Web Address: www.microchip.com; Bulletin Board Support: MCHIPBBS using CompuServe® (CompuServe membership not required).

PARITY GENERATION

Since the serial port of the PIC17C42 does not have an on-chip parity generator, parity is generated using software. It takes only 10 program memory words and executes in 10 instruction cycles to generate parity. Since the serial port of the PIC17C42 can operate in a 9-bit mode, the parity bit can be generated in software and transmitted as the 9th bit or it can be compared with the received 9th bit.

In case of transmission, set TX9 to 1 (TXSTA < 6>) to enable 9-bit transmission and write the computed parity bit to TX9D (TXSTA<0>). The 9th bit (parity bit) must be written prior to writing the 8 data bits to TXREG.

In case of a reception, first of all enable 9-bit reception by setting RX9 to 1 (RCSTA<6>). Upon successful reception, the 9th bit is received in RX9D (RCSTA<0>). Parity of the 8 bits of received data is computed using the routine listed below and compared with the 9-bit received.

SERIAL PORT EXPANSION

The PIC17C42 has only one serial port. For applications that require the PIC17C42 to communicate with multiple serial ports, a scheme that multiplexes and demultiplexes the RX and TX pins is provided below. This method is suitable only if no more than one USART is needed at any one time. This is the case in many applications where the microcontroller drives several output devices serially. Figure 1, shown below suggests a way to expand the on-chip serial port to four serial ports. To use the scheme shown in Figure 1, The PIC17C42 must select the desired serial port by appropriately setting the two pins of PORTB. The same scheme may be used to further expand the serial ports by using more I/O Ports.

FIGURE 1: MULTIPLEXING THE ON-CHIP USART

RS-232 INTERFACE

Two circuits are provided to interface the CMOS levels of a PIC17C42 to the RS-232 levels. Figure 2 provides an interface to MAX232 (MAXIM's RS-232 Driver/Receiver) with a single +5V power supply. Figure 3 provides a low cost two-chip solution for the RS-232 level translation using a single +5V supply (Note that V- of MC14C88 is connected to DTR of RS-232 Interface. By asserting DTR to low, V- gets the negative voltage from the RS-232 line). An alternative single chip low cost solution is provided in Figure 4. However, 3V sources (+5, +12, -12) are necessary.

FIGURE 2: RS-232 INTERFACE TO MAX232

Table 1 provides the summary of RS-232 and V.28 Electrical Specifications.

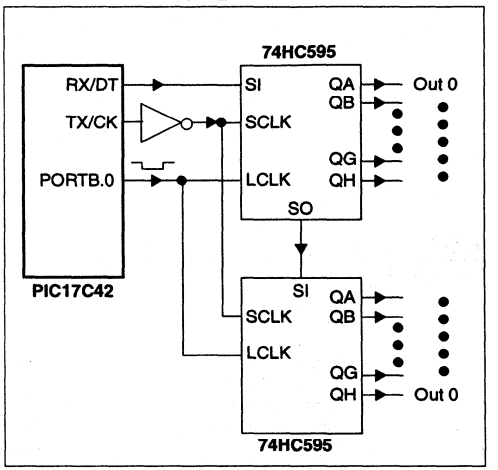

TABLE 1: SUMMARY OF RS-232C AND V.28 ELECTRICAL SPECIFICATIONS

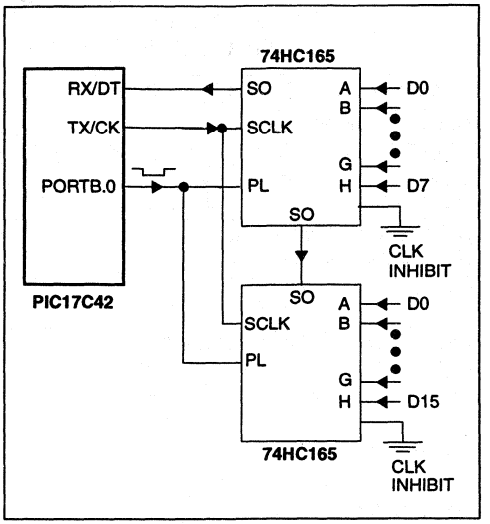
Parameter	Specification	Comments
Driver Output Voltage		
0 level 1 level Max. output	+5V to +15V -5V to -15V ±25V	With 3-7 kΩ load With 3-7 kΩ load No load
Receiver Input Thresholds (Data and clock signals)		
0 level 1 level	+3V to +125V -3V to -25V	
Receiver Thresholds RTS, DSR, DTR		
On level Off level	+3V to +25V Open circuit or -3V to -25V	Detects power Off condition at driver
Receiver Input resistance		
	3 kΩ to 7 kΩ	
Driver Output resistance		
Power off condition Driver slew rate	300Ω Min. 30V/µs max.	VOUT < ±2V 3 kΩ < RL < 7k 0pF < CL < 2500 pF
Signalling rate		
	Up to 20K bits/sec.	
Cable length		
	50'/15m. Recommended max. length.	Longer cables permissible, if CLOAD ≤ 2500 pF

I/O PORT EXPANSION USING SYNCHRONOUS MODE

Although the PIC17C42 has 33 I/O pins, most of these are multiplexed with other peripheral functions. In cases where more I/O ports are needed, the scheme below expands the I/O port using the synchronous mode of serial port by serially shifting the data. Figure 5 shows a scheme to expand the output ports to 16 bits using two standard logic chips (74HC595). The PIC17C42's serial port is configured in synchronous mode and set to be the MASTER. Thus serial data is available on DT (pin 22) and the clock is available on CK (pin 21). The following code will transmit 16 bits serially and clock all the 16 bits at the same time.

FIGURE 5: OUTPUT PORT EXPANSION USING SYNCHRONOUS MODE



EXAMPLE 7: PORT IMPORT EXPANSION

```
InitSerialPortTxmt
        movlb   0
        clrf    SPBRG                   ; set to highest baud rate = CLKOUT = CLKIN/4
        movlw   0x80
        movwf   RCSTA                   ; enable serial port
        movlw   0xB0
        movwf   TXSTA                   ; 8 bit synchronous master mode
        bcf     DDRB,0                  ; set bit 0 of PortB as output, to be used as Latch Clk
        return
SendSerialData                          ; shift out DataLo & DataHi serially
        movlb   0
        movfp   DataLo,TXREG
        nop                             ; wait for TXREG transfer : if slower baud rate is
                                        ; used check for TBMT reset
        movfp   DataHi,TXREG
wait    btfss   TXSTA,TRMT              ; wait until all 16 bits shifted out
        goto    wait
        bcf     PortB,0
        bsf     PortB,0                 ; clock in the serial data to parallel output of HC595
        return
```

© 1997 Microchip Technology Inc.

A similar scheme as shown above may be implemented in a reverse manner to expand the input ports. This requires a Parallel In and Serial Out device. Using a standard logic chip (74HC165), the scheme is shown in Figure 6. In order to read the 16-bit input data, the serial port of the PIC17C42 is configured for Synchronous Mode Reception (MASTER mode). An I/O port (PORTB<0>) is used to parallel load the 16 inputs for reading serially. A sample code to read the 16 inputs is shown below.

FIGURE 6: INPUT PORT EXPANSION USING SYNCHRONOUS MODE

EXAMPLE 8:

```
InitSerialPortRcv
            movlb   0
            clrf    SPBRG               ; set to highest baud rate = CLKOUT = CLKIN/4
            movlw   0x80
            movwf   RCSTA               ; enable serial port
            movlw   0x90
            movwf   TXSTA               ; 8-bit synchronous master mode
            bcf     DDRB,0              ; bit 0 of PortB is output, to be used as Parallel
                                        ; Load
            bsf     PortB,0             ; disable parallel Load
            return
ReadSerialData                          ; shift out DataLo & DataHi serially
            movlb   0

Implementing Table Read and Table Write

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

This application note discusses how to retrieve data from program memory to data memory and write data from data memory to program memory.

RETLW K Instruction

As in all PIC17CXXX family parts, the simplest method used to retrieve data from program memory to data memory is to use the RETLW K instruction. For example:

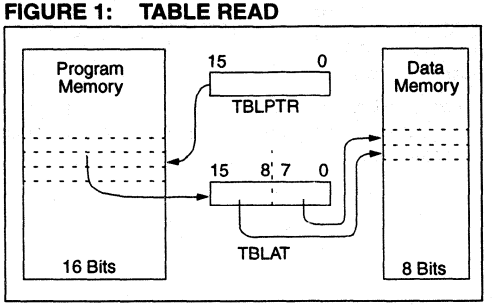
```
; simple program to transfer
; table values to PortB
Main
        movlw   5,W         ;load offset
        call    SimpleTableRead
        movwf   PortB       ;output to PortB
        •
        •
        •
SimpleTableRead
        addwf   PC          ;add offset to PC
Table   retlw   0           ;return a known
                            ;table value based
                            ;on the OFFSET.
        •
        •
        •
        retlw   10
```

In the example above, OFFSET is loaded with the required offset to the Table and the subroutine SimpleTableRead is called. The table value is returned in the W register. In this manner program memory can be transferred to data memory.

Table Read Instruction

The PIC17C42 has an expanded instruction set which includes the TABLRD and TLRD instructions. These instructions are specifically constructed to transfer data from program memory to data memory.

If the instruction syntax is: TABLRD t,i,f, the sequence in which this instruction is executed is as follows:



a) if t = 1 then the high byte of the table latch (TBLATH) is loaded in the file register f.
b) else (if t = 0) the low byte of the table latch (TBLATL) is loaded in the file register f.
c) next, the 16 bit data pointed to by the table pointer (TBLPTR) is loaded into the table latch.
d) lastly, if i = 1 the table pointer (TBLPTR) is incremented.

Note: The first time this instruction is executed in a sequence, the table latch will not be initialized, hence an unknown value will be loaded in the file register. This is not a problem if the user overwrites the same f register in the next subsequent instruction.

If the instruction syntax is: TLRD t,f, the sequence in which this instruction is executed is as follows:

a) if t = 1 then the high byte of the table latch (TBLATH) is loaded in the file register f.
b) else (if t = 0) the low byte of the table latch (TBLATH) is loaded in the file register f.

FIGURE 1: TABLE READ

4

Read In-Line

A simple method of transferring data from program memory to data memory is to use the TABLRD and TLRD instructions in sequence as shown in the example below:

```
;transfer 6 bytes of data from program memory
;at 0x500, to data memory at 0x80
ReadInLine
   movlw   05          ;load table pointer
                       ; with 0x500
   movwf   TBLPTRH     ;       /
   clrf    TBLPTRL     ;       /
   tablrd  0,1,0x80    ;get 16 bit value in
                       ;table latch.
   tlrd    0,0x80      ;low byte (1st) @ 80
   tablrd  1,1,0x81    ;high byte (2nd) @ 81
   tlrd    0,0x82      ;3rd byte @ 82
   tablrd  1,1,0x83    ;4th byte @ 83
   tlrd    0,0x84      ;5th byte @ 84
   tablrd  1,1,0x85    ;6th byte @ 85
```

Reading a Block of Data

In instances where a block of N bytes needs to be transferred from program memory to data memory, the TABLRD and TLRD instruction need to be included in a loop which checks for N transfers.

```
;transfer 'COUNT' bytes (even values only) of
;data at program memory 'MESSAGE' to data
;memory at: 'RAM_BUFFER'
ReadBlock
   movlw   high MESSAGE    ;load table pointer
   movpf   W,TBLPTRH       ;       /
   movlw   low MESSAGE     ;       /
   movpf   W,TBLPTRL       ;       /
   bcf     ALUSTA,5        ;enable post auto
                           ;increment of FSR0
   movlw   RAM_BUFFER      ;initialize FSR0
                           ;to RAM_BUFFER
   movfp   W,FSR0          ;       /
   movlw   COUNT/2         ;initialize count
   tablrd  1,1,RAM_BUFFER  ;initialize table
                           ;latch
ReadBlockLoop
   tlrd    1,0x00          ;do indirect read
                           ;of high byte
   tablrd  0,1,0x00        ;do indirect read
                           ;of low byte
   decfsz  W               ;check if count=0
   goto    ReadBlockLoop   ;no then do next
   return                  ;else end of
                           ;transfer.
```

Program	Code Size	Transfer Rate
Simple Table Read (using RETLW)	N + 3	6 cycles/byte
Read In-Line	4 + N + N/2	1.5 cycles/byte
Read Block (using loop)	14 + N/2	3 cycles/byte

N = Number of bytes to transfer

	Code Size		
	Simple Table Read	Read In-Line	Read Block
N = 10	13	19	19
N = 20	23	34	24

Conclusion:

In cases where the number of bytes to be transferred is small, the Read In-Line offers small code size for fast transfer rate. However, as the number of bytes to be transferred increases, the Read Block offers optimum code size for a decent transfer rate.

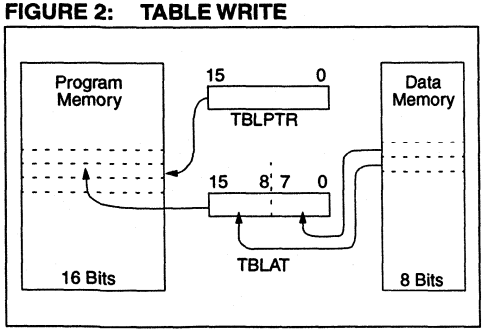
Table Write Instruction

The PIC17C42 has a TABLWT and a TLWT instruction which transfer data from data memory to program memory. Note in cases where the table pointer points to internal EPROM, the table write instruction will try to program the EPROM, hence the programming voltage must be present on the VPP line to successfully program the part.

The instruction syntax is: TABLWT t,i,f.

The sequence in which this instruction is executed is as follows:



a) if t = 1 then the file register f is loaded to the high byte of the table latch (TBLATH).
b) else (if t = 0) the file register f is loaded to the low byte of the table latch (TBLATL).
c) next, the 16-bit data in the table latch is transferred to the program memory pointed to by the table pointer (TBLPTR).
d) lastly, if i = 1 the table pointer (TBLPTR) is incremented.

The instruction syntax is: TLWT t,f

The sequence in which this instruction is executed is as follows:

a) if t = 1 then the file register f is loaded to the high byte of the table latch (TBLATH).
b) else (if t = 0) the file register f is loaded to the low byte of the table latch (TBLATL).

FIGURE 2: TABLE WRITE

Write In-Line

A simple method of transferring data from data memory to program memory is to use the TABLWT and TLWT instruction in sequence as shown in the example below:

```
;transfer 6 bytes of data in data memory at
;0x80, to program memory at 0x5000:
ReadInLine
   movlw   50          ;load table pointer
                       ;with 0x5000
   movwf   TBLPTRH     ;       /
   clrf    TBLPTRL     ;       /
   tlwt    1,0x80      ;high byte @ table latch.
   tablwt  0,1,0x81    ;low byte @ table latch
                       ;latch  @ prog. mem.
   tlwt    1,0x82      ;3rd and 4th byte
                       ;@ prog. mem.
   tablwt  0,1,0x83    ;       /
   tlwt    1,0x84      ;5th and 6th byte
                       ;@ prog. mem.
   tablwt  0,1,0x85    ;       /
```

Writing a Block of Data

In instances where a block of N bytes needs to be transferred from data memory to program memory, the tablwt and tlwt instructions need to be included in a loop which checks for N transfers.

```
;transfer 'COUNT' bytes (even values only) of
;data at program memory at 'RAM_BUFFER' to
;program memory at 'MESSAGE'
WriteBlock
   movlw   high MESSAGE    ;load table pointer
   movpf   W,TBLPTRH       ;       /
   movlw   low MESSAGE     ;       /
   movpf   W,TBLPTRL       ;       /
   bcf     ALUSTA,5        ;enable post auto
                           ;increment of FSR0
   movlw   RAM_BUFFER      ;initialize FSR0
                           ;to RAM_BUFFER
   movfp   W,FSR0          ;       /
   movlw   COUNT/2         ;initialize count
WriteBlockLoop
   tlwt    1,0x00          ;high byte
                           ;@ table latch
   tablwt  0,1,0x00        ;low byte @ table
                           ;latch;
                           ;table latch
                           ;@ prog. mem.
   decfsz  W               ;check if count = 0
   goto    WriteBlockLoop  ;no then do next
   return                  ;else end of transfer
```

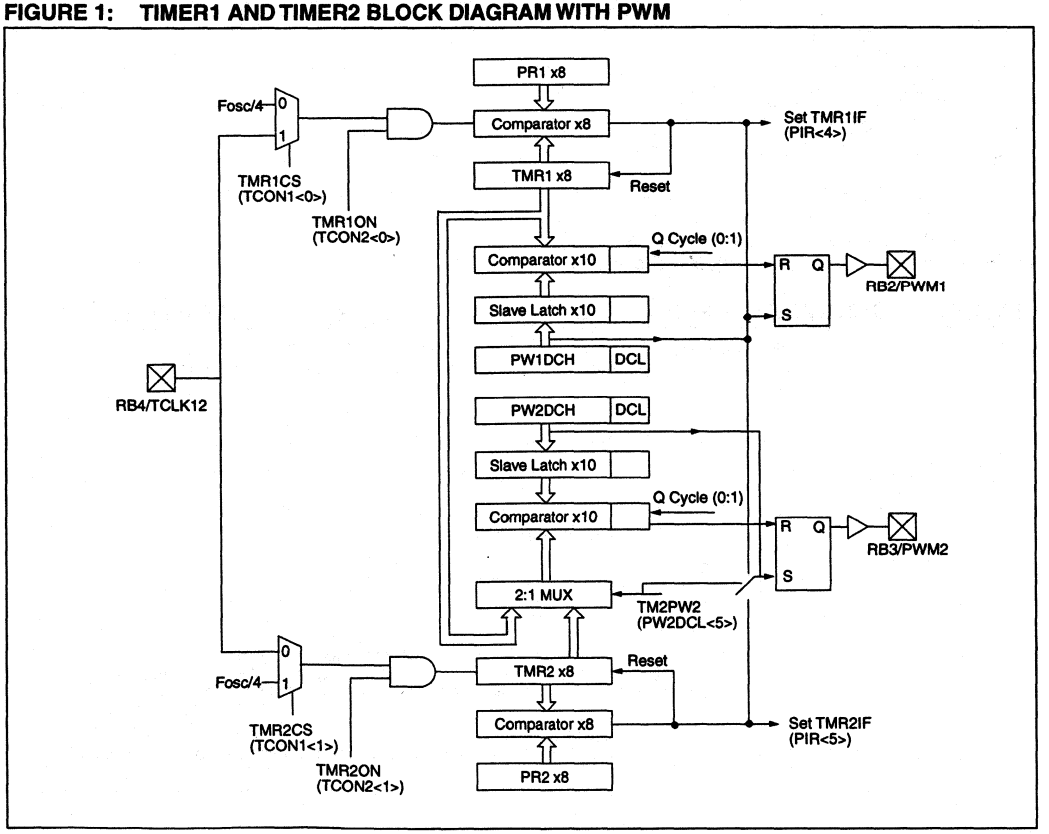
Using the PWM

Author: *Mark Palmer*
Microchip Technology Inc.

INTRODUCTION



The PICmico™ family of RISC microcontrollers hax been designed to provide advanced performance and a cost-effective solution for a variety of applications. This application note provides examples which illustrate some uses of Pulse Width Modulation (PWM) using the PIC17C42's Timer1 or Timer2 module. These examples may be modified to suit the specific needs of your application.

This Application Note describes the operation of the PWM. They include the following topics:

1. Simple PWM Operation
2. Variable Period / Variable Duty Cycle PWM
3. External Clock for Timer Time-base (ramifications/issues)

The listing file for the Variable Period / Variable Duty Cycle example can be found in Appendix A. The source files can be found on the Microchip BBS. On directions on how to access the Microchip BBS please refer to DS30128, which can also be found in the Microchip Embedded Control Handbook (Literature Number DS00092).

FIGURE 1: TIMER1 AND TIMER2 BLOCK DIAGRAM WITH PWM

14h, Bank 3	CA2L	Capture2 low byte								xxxx xxxx	uuuu uuuu
15h, Bank 3	CA2H	Capture2 high byte								xxxx xxxx	uuuu uuuu

Legend: x = unknown, u = unchanged, - = unimplemented, reads as '0'. ? - Value depends on condition.
Note 1: Shaded cells are not used by TMR1, TMR2,TMR3 or Capture.

Care must be taken when loading values into the PWM registers. These registers are the duty cycle registers (PWxDCH:PWxDCL) and the period register (PRx). Figure 2 shows proper update timing of these values.

FIGURE 2: TIMING FOR UPDATING THE DUTY CYCLE REGISTERS AND PERIOD REGISTER

Note: When updating the period register, the value loaded must be greater than the timer value. If the period value is less than the timer value, the duty cycle value is not latched and the timer is not reset to 00h until the next Timer = Period match. This causes the current cycle to not output as expected and cause a "glitch".

Note: It is generally good practice to load the new period value into the PRx register as soon as possible after Point A.

© 1997 Microchip Technology Inc.

SIMPLE PWM OPERATION

Simple PWM operation is where the period of the PWM output remains constant, and only the duty cycle is modified. The PWM can operate in either of two modes:

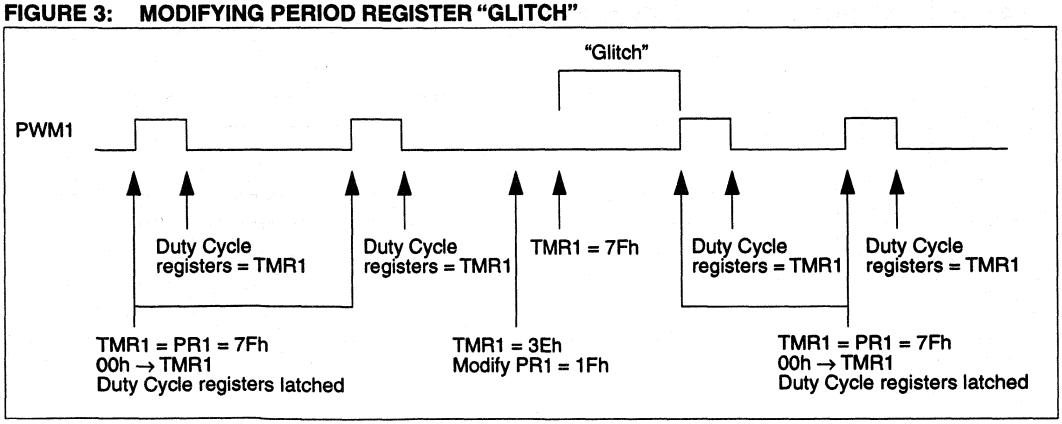
- Hi-resolution mode: the PWxDCL register is modified
- Standard resolution mode: the PWxDCL register is not modified

When operating in the standard-resolution mode, only the PWDCH register is ever modified. Since the modification takes only a single cycle and can be done at any time. Also since the period is remaining constant this may be done without any PWM interrupt software overhead.

When operating in the high-resolution mode both the PWxDCH:PWxDCL register pair is modified. Since this is a multicycle update, care needs to be taken that the "new" PWM duty cycle value is not latched until the update is complete. If the duty cycle is latched before this update is complete, the duty cycle will display a "glitch". If the PWxDCH is written first, the maximum error is 3 Q-cycles (187.5 ns @ 16 MHz). If the PWxDCL is written first, the maximum error is also 3 Q-cycles (187.5 ns @ 16 MHz), with the PWxDCH delayed by one PWM period. This may be acceptable for some applications. If this is not acceptable for your application then a subroutine can be written to ensure that these duty cycle writes are not done when the timer will equal the period. One implementation of this subroutine (`PWM_UD`) is used in the Variable Period / Variable Duty Cycle PWM example. This is discussed in the following section, with the listing in Appendix A.

Additional code examples can be found in application note AN539 in the Embedded Control Handbook.

VARIABLE PERIOD / VARIABLE DUTY CYCLE PWM



In a variable period / variable duty cycle PWM both the duty cycle of the PWM as well as the frequency (period) of the PWM are modified.

The PIC17C42's hardware double buffers the duty cycle registers, but the period registers are not double buffered. What this means is that you can modify the duty cycle registers, but the value will only be latched when the timer register equals the period register. Since the period register is not buffered, as the period register is modified this becomes the "new" period. This means that care must be taken when modifying the period register. The most common problem would be to modify the period register resulting in a "glitch." This "glitch" occurs when the period register is modified with a value that is less than the present timer value. The timer does not have a match with the old period value, and continues to count until the timer register equals the period register.

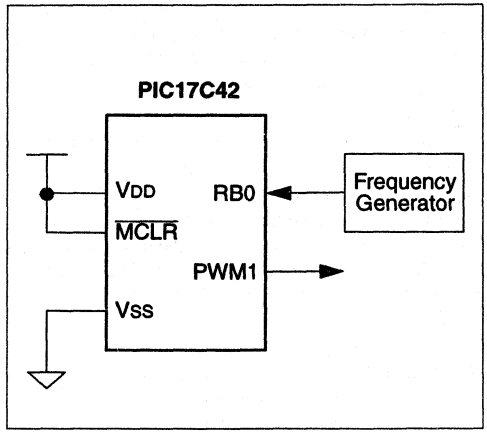
Figure 3, shows an example where PR1 the register period = 7Fh. Then the period is modified to a smaller value (PR1 = 1Fh) without checking that the value in Timer1 (TMR1) register = 3Eh. Since the new period (PR1) value is less then the present timer (TMR1) value, a glitch has occurred.

4

FIGURE 3: MODIFYING PERIOD REGISTER "GLITCH"

© 1997 Microchip Technology Inc.

Care must be taken when writing a 10-bit duty cycle value. Since this requires two register writes, the "Timer Equals Period" could occur between these two writes, which would give a duty cycle that was not as expected. The cases are as follows:



a) If the duty cycle low register (DCL) is written, and then the Timer equals period. The old DCH register and the new DCL register becomes the duty cycle.

b) If the duty cycle high register (DCH) is written, and then the Timer equals period. The new DCH register and the old DCL register becomes the duty cycle

At the following occurrence of the timer equaling the period, the second register written would be updated. The subroutine `PWM_UD` (Appendix A) ensures that these duty cycle writes are not done when the timer will equal the period.

A software example of a variable period / variable duty cycle is shown in Appendix A. In this example the period is double buffered in software, and the new period value is loaded in the timer overflow interrupt service routine. When the new duty cycle needs to be loaded. The device connections are shown in Figure 4. This program has two PWM settings (period / duty cycle combinations) that are switched between depending on the level on pin RB0. A frequency generator was used to give a low frequency signal on the RB0 pin. Figure 5 shows an example of the input and output waveforms.

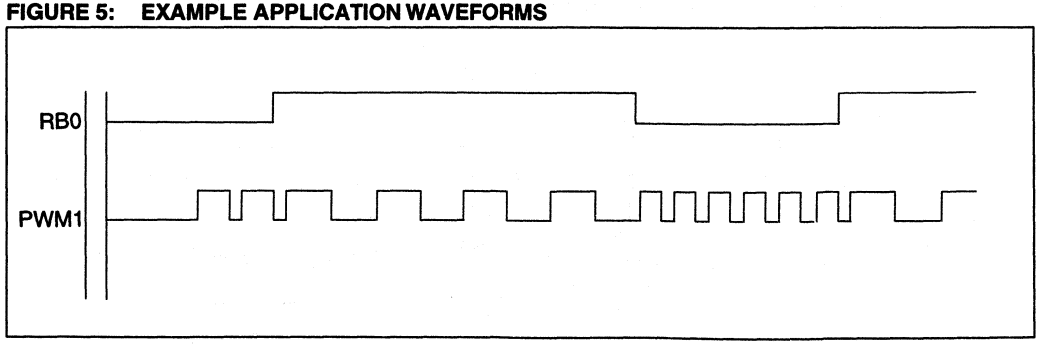


FIGURE 4: APPLICATION HARDWARE SETUP

The program listing in Appendix A implements this example, Figure 8 is the hardware function. This example may be modified to suit the particular needs of your application. The following table is a summary of the requirements for this program (@ 16 MHz):

Code Size:	52 Words
RAM used:	11 Bytes
Interrupt Service Routine time	3.0 µs
Subroutine time	4.5 µs 6.0 µs
Maximum PWM frequency:	200 kHz
PWM Accuracy:	62.5 µs

FIGURE 5: EXAMPLE APPLICATION WAVEFORMS

© 1997 Microchip Technology Inc.

EXTERNAL CLOCK FOR TIMER TIMEBASE

The counters used for the time-base of the PWM outputs can be software selected to operate from an external clock source. This allows a lower frequency PWM to be achieved. This brings up new issues that must be understood for the application.

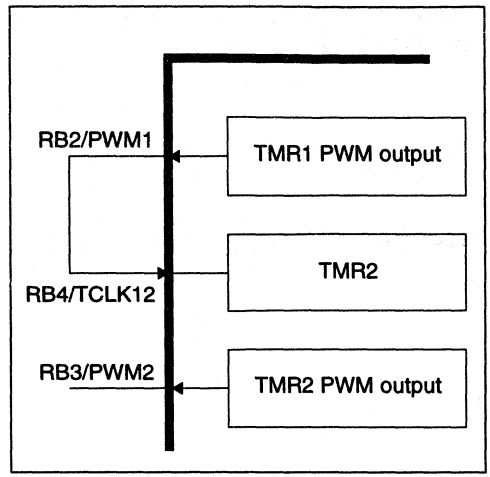
One of these issues is clock synchronization. All external clocks must be synchronized to the internal operating speed of the microcontroller, as shown in Figure 6. When this synchronization occurs the PWM output is not truly operating from the external clock, but actually the internal synchronized clock. This leads to a "jitter" of the output to the clock. This jitter is caused from the delta time between the external clock and the synchronized clock not being constant. The synchronization errors are:

Duty cycle error = ± TCY

Period error = ± TCY

If you needed to run the PWM at a low frequency, and also want to reduce the "jitter" from the use of an external asynchronous clock, a PWM output could be used as the synchronous clock source. When the clock is synchronized to the device the clock error is always constant, so there is no jitter. Figure 7 shows this example.

FIGURE 7: PWM OUTPUT TO GENERATE A SYNCHRONOUS CLOCK



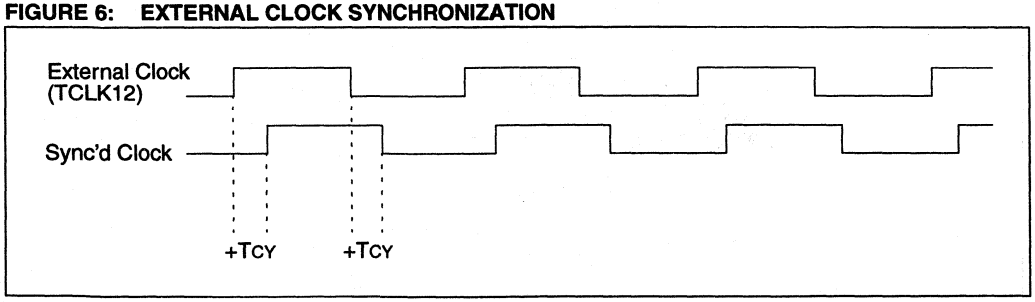


FIGURE 6: EXTERNAL CLOCK SYNCHRONIZATION

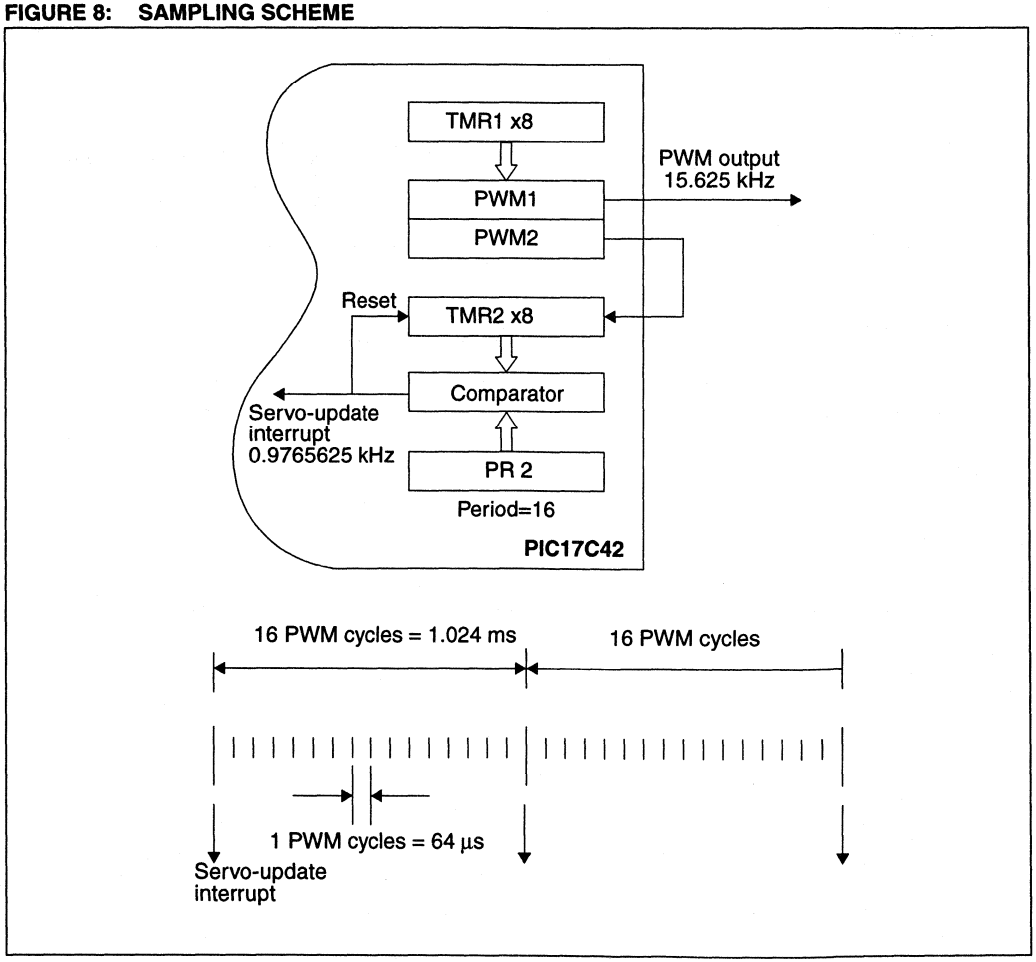
© 1997 Microchip Technology Inc.

Another use is where precise timing of updates need to be done, but not at the frequency of the PWM output. In this discussion, TMR1 is used as the time-base of a constant frequency PWM output. TMR1 uses the internal clock of the device and TMR2 uses the external clock input. TMR2 will get the clock input from the PWM2 output.



The PWM output is a constant frequency variable duty cycle output. The PW1DCH:PW1DCL register pair contain the variable duty cycle value of PWM1 output. The PW2DCH:PW2DCL register pair is set for a fixed duty cycle (50%) for the PWM2 output.

The PWM outputs could be programmed to have a frequency of 20 kHz, so to reduce audible noise. The PWM2 signal is connected to the RB4/TCLK12, as shown in Figure 8. The PR2 register could be loaded with 14h (20), to give an interrupt every 1 kHz. This interrupt can then trigger tasks, such as updating the duty cycle of PWM1. This is useful in motor control as well as other applications where the update rate is less then the PWM frequency.

CONCLUSION

The PIC17C42's PWM features offer a high performance solution at a lower system cost than previously available. The versatility of PWMs make the PIC17C42 ideal for motor control applications (ses AN532) and many industrial control applications.

                     00010 ;
                     00011
                     00012 ; This is the basic outline for a program that generates a
                     00013 ; variable PWM output. The PWM's period and duty cycle can
                     00014 ; be varied. The new period (NEW_PR1) and the new duty cycle
                     00015 ; (NEW_DC1 and NEW_DC1Q) are loaded by the user program.
                     00016 ; The peripheral interrupt routine loads the new period value
                     00017 ; (frequency) into the PR1 register. A subroutine (PWM_UD)
                     00018 ; is also used to ensure that the 10-bit duty cycle registers
                     00019 ; are updated in the same PWM cycle, i.e. the timer match does not
                     00020 ; occur between two duty cycle register writes.
                     00021 ;
                     00022 ; The duty cycle value gets latched on the overflow (Period match)
                     00023 ; of the timer. The period value gets modified as soon as the period
                     00024 ; register is changed. Therefore care must be taken in updating
                     00025 ; the period register. In cases where the period value is modified
                     00026 ; to a smaller value, we must ensure that the Timer counter is less
                     00027 ; then this value when the period register is updated (TMR1 < new PR1).
                     00028 ; If TMR1 is greater then PR1, the counter will count to FFh, rollover
                     00029 ; to 00H, and only cause the overflow interrupt when it then reaches
                     00030 ; the period value. This would give a wrong PWM output.
                     00031 ;
                     00032 ; In this example the event which cause the PWM to be updated
                     00033 ; is an asynchronous event. A low frequency signal was placed on
                     00034 ; port pin RB0.
                     00035 ; For a high level the PWM registers are updated as follows:
                     00036 ;    PR1 = 7Fh, PW1DCH = 3Fh, and PW1DCL = 40h
                     00037 ; For a low level the PWM registers are updated as follows:
                     00038 ;    PR1 = 1Fh, PW1DCH = 07h, and PW1DCL = 80h
                     00039 ;
                     00040 ; Do the EQUate table
                     00041 ;
00000020             00042 NEW_DC1          EQU  0x20 ; New PWM1 duty cycle value
00000021             00043 NEW_DC1Q         EQU  0x21 ;

Implementation of the Data Encryption Standard Using PIC17C42

Authors: *Al Lovrich*
Mark Palmer
Microchip Technology Inc.

INTRODUCTION

In January 1977, The United States government adopted a product cipher developed by IBM as its official encryption standard [1]. This algorithm, called the Data Encryption Standard (DES), has been adopted as a worldwide standard for data encryption by ISO (International Standards Organization) [2, 3]. This application note describes the implementation of the DES algorithm on PIC17C42.

THE DATA ENCRYPTION STANDARD

The DES algorithm is a substitution cipher which takes a block of 64 bits of input (plaintext) into a unique block of 64 bits of output (ciphertext), under the control of a 64-bit key, which is known only to the people intended to read the message. In this system, plaintext information is divided into several blocks which are then operated upon independently to generate a sequence of ciphertext blocks. The basic idea behind DES is to build a strong system out of simple, individually weak, components. The DES encryption system is based on a system of transpositions and permutations. The permutation box or P-box, is used to transpose, or map a sequence of input values to another sequence of values of the same length. Substitutions are performed by what are called S-boxes. A combination of the S-boxes and P-boxes can be viewed as a decoder/coder operation, where the output is simply a linear mapping of the input values. Each combination of the S-box and P-box comprises a single weak component of the algorithm. By including a sufficiently large number of stages in the product cipher, the output can be made to be a nonlinear function of the input.

The mapping of input to output is one-to-one and invertible, since the encrypted messages can be decrypted. The DES has three distinct components: key schedule, cipher function, and invertibility.

KEY SCHEDULE

The DES uses a 64-bit key for encryption and decryption process. Initially, the original 64-bit key is reduced to 56-bit by ignoring every eighth bit. In general these bits are used as parity bits to make sure that there were no errors when entering the key or during key transmission. After the 56-bit key is extracted a different 48-bit key, referred to as subkey, is generated for each of the 16 rounds of the DES. These keys, K_i, are determined as shown in Figure 1. The 56-bit key is divided into two 28-bit halves C_i and D_i which are then shifted left by either 1 or 2 digits, depending on the round. Table 1 shows the number of circular left shifts for C_i and D_i halves. After the shifting operation, 48 out of the 56 bits are selected. Since this operation permutes the order of the bits as well as selecting a subset of the original bits, it is called compression permutation or permuted choice. The permuted choice 1 and permuted choice 2 matrices are shown in Figure 2 and Figure 3 respectively.

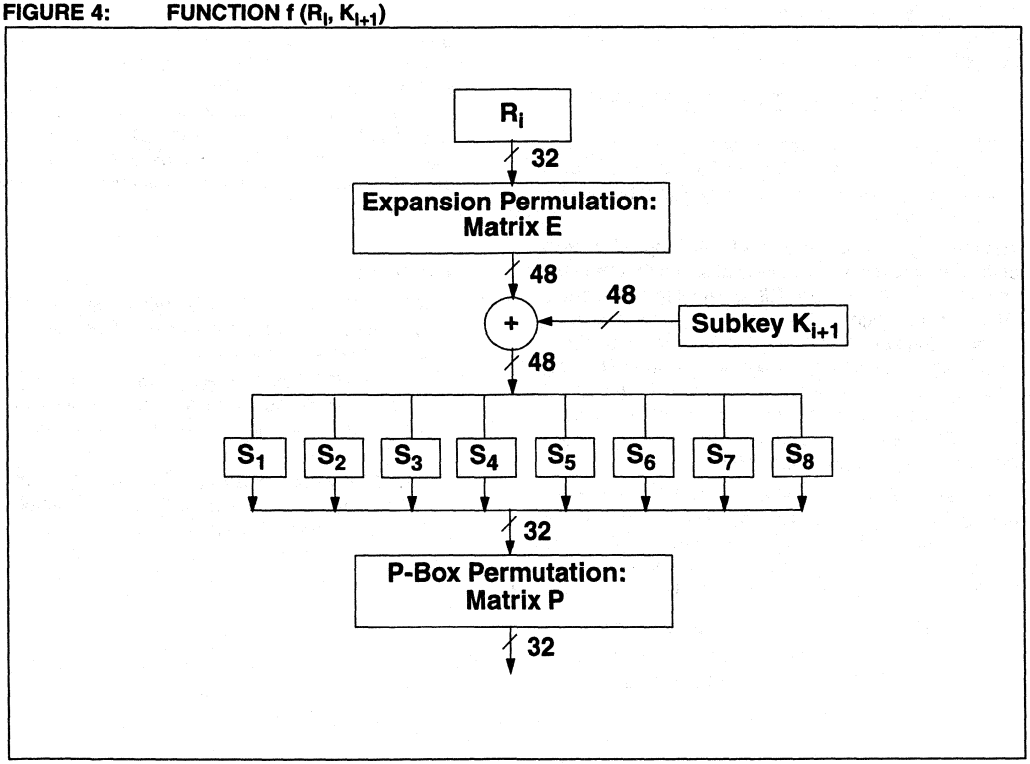
CIPHER FUNCTION

The strength of the DES is based on the cipher function component. This is a fixed, highly nonlinear function which guarantees that each bit of the ciphertext depend on every bit of the plaintext and every bit of the key.

After an initial permutation, the 64-bit block of plaintext is broken into a right half and left half, each 32 bits long. This step is followed by 16 identical rounds of operation, called function *f*, that combines the data with a 48-bit key, K_i. At each stage *i*, the inputs are the left block L_{i-1} and the right block R_{i-1} of the previous stage, and the outputs are the left shift block L_i and right block R_i of this stage. The outputs of L_i and R_i of each stage are computed from L_{i-1} and R_{i-1}, and a subkey K_i that is generated from the encryption key. In other words a round of the DES can be shown as:

$$L_i = R_i$$



$$R_i = L_{i-1} \; XOR \; f(R_{i-1}, K_i)$$

All the complexity of the DES algorithm lies in the function f, as shown in Figure 4. The function has four steps that are carried out in sequence. First a 48-bit number, *E*, is constructed by expanding the 32-bit previous right value, R_{i-1}, according to a fixed transposition and duplication rule. Then, K_i and R_{i-1} are XORed together, generating a 48-bit result. This output is then partitioned into eight groups of 6-bits each, each of which is fed into a different S-box or substitution box. The S-boxes generate four instead of six outputs. In other words, the 64-bit input is mapped into a 32-bit output. Each S-box is a table of 4 rows and 16 columns. Each entry in the box is a 4-bit number. The six input bits of the S-box specify under which row and column number to look for the output. Figure 7 shows the 8 S-boxes.

The six input bits specify an entry in the Sbox in a particular fashion as follows: the first and last bits of the sequence, taken together, represent a number between 0 and 3 (row entry), while the middle 4-bits represent a number between 0 and 15 (column entry). The output is simply the entry that corresponds to the (row, column) entry. For example, that the input to the first S-box is the binary sequence `110010`. The first and last bits combine to form 10 which corresponds to the third row of the S-box. The middle 4-bits are combined to form `1001` which corresponds to the ninth column of the for `110010`. The substitution boxes are the most critical step in the DES algorithm and more than anything else give DES its security.

4

FIGURE 4: FUNCTION f (R_i, K_{i+1})

© 1997 Microchip Technology Inc.

Finally, the last stage consists of a permutation stage that generates a 32-bit output. After the 16 rounds, the left and right halves are joined, and a final permutation generates the ciphertext. The final permutation is the inverse of the initial permutation. Figure 10 shows a block diagram of the enciphering portion of the algorithm. The reverse process of deciphering is shown in Figure 11. The initial permutation and inverse initial permutation matrices in Figure 10 are shown in Figure 8 and Figure 9. Where the algorithm requires bit manipulation of a stream of data according to a matrix, the matrix is read from left to right, top to bottom, and interpreted as the bit position in the output block. For example, the initial permutation matrix transposes bit1 to bit58, bit2 to bit50, bit3 to bit42, etc.

INVERTIBILITY

The DES cipher function is not necessarily invertible, meaning to decode a message, it is not necessary to recover the input to the cipher function from its output and a knowledge of the key. In fact the cipher function must be highly nonlinear to be resistant to plaintext attack (a method used for breaking a given algorithm). Invertibility of the DES is that one half-word of the output is precisely the bit configuration which was used to encode the other half, with the aid of the particular stage subkey. Therefore, by using the subkeys in reverse order, the encryption process can be reversed. This is really the reason that one half-word is always passed through unchanged - to provide the means of decrypting the other half-word.

PIC17C42 IMPLEMENTATION OF DES

CPU processing is required to generate the encryption key into the DES subkeys. The 64-bit encryption key is reduced to 56-bits, by ignoring every eighth bit, usually used as parity bit.

The majority of the DES code is for the Implementation of the permutation of the block of bits. The 56-bits of the key, stored in K1 through K8, scrambled-bit output is stored in the eight bytes D0-D7. The scrambling is accomplished by constructing D0-D7, one bit at a time. This is accomplished by initializing the D0 to D7 locations to a known state (cleared). Then the 64-bits of plain text are processed through the Initial Permutation Matrix (IP), which permutes the plain text and divides the information into two 32-bit blocks.

The use of Indirect addressing and the PICmicro™ single word instructions allows tight efficient coding of the DES algorithm. These bit testing capabilities allows the same code structure to generate the different subkey blocks. This permutation macro looks like:

```
Permute   Macro     KEY,TEST,BIT
          BTFS C    KEY,TEST,BIT
          BSF       INDOF0,BIT
          endm
```

Where KEY is the DES key and TEST is the bit is the KEY being tested. If the KEY<TEST> bit is set, then the bit position (BIT) in the data location pointed to by INDF0 is set.

The main algorithm requires that the 16 subkeys, each 48-bits long, be generated. These 16 subkeys are then used at the 16 stages of the algorithm.

Using the generated subkeys, the incoming stream of bits can be encrypted or decrypted. Table 2 shows the requirements of the DES algorithm.

TABLE 2: DES ALGORITHM REQUIREMENTS

		Execution time	
Function	Program Memory words	Instruction cycles	ms
Key management and subkey generation	382	2729	0.436
Encryption	789	7714	1.234

A bit rate of about 51 Kbps baud can be achieved, with a device utilization of 100%. This makes the PIC17C42 a price/performance leader for DES algorithms.

CONCLUSION

We have demonstrated the implementation of the DES algorithm on the PIC17C42 microcontroller. The 160 ns cycle time of the PIC17C42 makes possible a half-duplex rate of 51 Kbps for the DES. This rate is as good or superior to other implementations of the algorithm. The high performance of the PIC17C42 provides a low-cost alternative to many dedicated solutions resulting in minimum system cost because of the programmability of the device.

PIC16C5X / PIC16CXXX Math Utility Routines

Author: *Amar Palacherla*
Microchip Technology Inc.

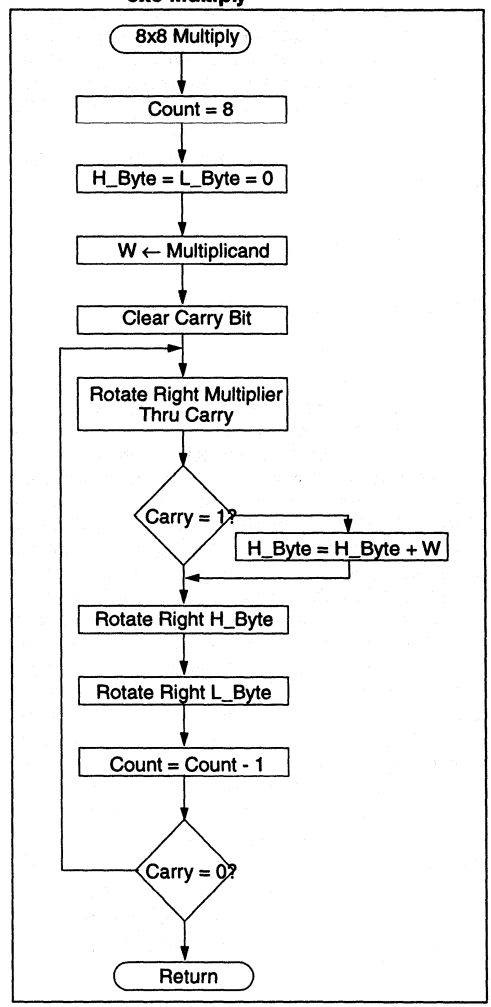
PLEASE NOTE: *This application note uses the old Microchip Math Routine format. It is intended for reference purposes only and is being provided for those of you still implementing Binary Coded Decimal(BCD) routines. For any new designs, please refer to application notes contained in Microchip's Embedded Control Handbook Volume II - Math Library.*

INTRODUCTION

This application note provides some utility math routines for Microchip's PIC16C5X and PIC16CXXX series of 8-bit microcontrollers. The following math outlines are provided:

- 8x8 unsigned multiply
- 16x16 double precision multiply
- Fixed Point Division (Table 3)
- 16x16 double precision addition
- 16x16 double precision subtraction
- BCD (Binary Coded Decimal) to binary conversion routines
- Binary to BCD conversion routines
- BCD addition
- BCD subtraction
- Square root

These are written in native assembly language and the listing files are provided. They are also available on a disk (MS-DOS®). All the routines provided can be called as subroutines. Most of the routines have two different versions: one optimized for speed and the other optimized for code size. The calling sequence of each routine is explained at the beginning of each listing file.



SINGLE PRECISION UNSIGNED MULTIPLICATION (8x8)

This routine computes the product of two 8-bit unsigned numbers and produces a 16-bit result. Two routines are provided: one routine is optimized for speed (by writing a straight line code) and the other routine has been written to reduce the code size (a looped code). The listing of these routines are given in Appendices A and B. The performance specs for the routines are shown in Table 1.

TABLE 1: PERFORMANCE SPECS

Spec	Program Memory	Instruction Cycles
Speed Efficient	35	37
Code Efficient	16	71

DOUBLE PRECISION MULTIPLY

This routine computes the product of two 16-bit numbers and produces a 32-bit result. Both signed and unsigned arithmetic are supported. Two routines are provided: one routine is optimized for speed (by writing a straight line code) the other routine has been written to reduce code size (a looped code). The listing of these routines are given in Appendices C and D. The performance specs for routines are shown in Table 2.

TABLE 2: PERFORMANCE SPECS

Spec	Program Memory	Instruction Cycles
Speed Efficient	240	233
Code Efficient	33	333

The code in Appendices C and D has been setup for unsigned arithmetic and the performance specs in the table above is for unsigned arithmetic. If signed arithmetic is desired, edit the line with "`SIGNED equ FALSE`" to "`SIGNED equ TRUE`" then re-assemble the code.

In case of signed multiply, both operands are assumed to be 16-bit 2's complement numbers.

Conditional assembly is supported by MPASM. If you have an older version, please contact the Microchip Technology sales office nearest you.

DOUBLE PRECISION DIVISION

Fixed Point Divide Routines

Fixed point division is fundamentally a conditional shift and subtract operation, resulting in a quotient and a remainder, with standard methods related to simple binary long division by hand calculation. Typically, a processor with n-bit operands uses a fixed accumulator of 2n bits containing the dividend. In standard restoring division, the dividend is left shifted by one bit and the divisor is subtracted from the high half of the accumulator, referred to as the partial remainder. If the result is positive, the divisor was less than or equal to the partial remainder and the corresponding quotient bit in the LSb of the accumulator is set to one. If the result is negative, the divisor was greater than the partial remainder and the dividend is restored by adding back the divisor to the high half of the accumulator and setting the LSb to zero. This process is repeated for each of the n bits in the divisor, resulting in an n-bit quotient in the low half of the accumulator and the n-bit remainder in the high half, and requiring n subtractions and on average n/2 additions [1].

Nonrestoring division, requiring a total of at most n+1 subtractions and additions, offers potential for speed improvement by allowing a negative partial remainder during the calculation with a final addition of the divisor if the final remainder is negative. After the first left shift of the dividend, the divisor is subtracted and the corresponding quotient bit as well as the next add or subtract operation is determined by the carry bit [1].

Unfortunately, no simple method exists for performing two's complement binary division, thereby requiring negate operations during a preprocessing phase. It is important to note that with the dividend initially loaded into the accumulator, an overflow of the final quotient will result if the high half of the dividend is greater than or equal to the divisor [1], indicating that the n-bit range of the quotient will be exceeded.

Because of the inherent byte structure of the PICmicro™ family of microcontrollers, a more creative and efficient implementation of the above algorithms is possible. In what follows, partial remainder is initialized at zero and is separated from the dividend, thereby avoiding any alignment logic overhead and yielding a quotient with the same number of bits as the dividend and a remainder with the same number as the divisor. Furthermore, routines are named in format FXDxxyyz, where xx is the number of bits in the dividend, yy is the number of bits in the divisor, and z indicates a signed or unsigned routine. Macros are used for core sections of each routine, thereby permitting simple switching between restoring and nonrestoring methods. The signed macros are exclusively a variation of the nonrestoring method, taking advantage of the zero MSb of the arguments after the preprocessing negation. Both restoring and nonrestoring macros are included for the unsigned case, with selection based on best worst case or best average performance as desired. For example, the unsigned macros exhibit the following performance data:

		# of Cycles (TCY)		
		32/16	16/16	16/8
restore	max.	561	240	193
	ave.	481	208	173
nonrestore	max.	481	240	190
	ave.	466	233	183

This demonstrates that while the nonrestoring algorithm is preferred for the 32/16 case, the restoring method is preferred for the 16/16 case, with the choice for the 16/8 case a function of user requirements. These optimization complications are a result of trade-offs between the number of instructions required for the restore operations verses the added logic requirements. Finally, additional routines with tacit MSb equal to zero in each argument are included, yielding significant speed improvement. These routines can also be called in the signed case when the arguments are known to be positive for a small benefit.

Routines

It is useful to note that the additional routines FXD3115U, FXD1515U, and FXD1507U can be called in a signed divide application in the special case where AARG > 0 and BARG > 0, thereby offering some improvement in performance.

Data RAM Requirements

The following contiguous data RAM locations are used by the fixed point divide routines:

ACC+B0	=	AARG+B0	AARG and ACC
ACC+B1	=	AARG+B1	
ACC+B2	=	AARG+B2	
ACC+B3	=	AARG+B3	
ACC+B4	=	REM+B0	remainder
ACC+B5	=	REM+B1	
SIGN			sign in MSb
BARG+B0			BARG
BARG+B1			
TEMP+B0			temporary storage
TEMP+B1			

where Bx = x.

DOUBLE PRECISION ADDITION & SUBTRACTION

This routine adds or subtracts two 16-bit numbers and produces a 16-bit result. This routine is used by other double precision routines. The listing of these routines is given in Appendix E. The performance specs for the routines are shown below:

TABLE 5: PERFORMANCE SPECS

Spec	Program Memory	Instruction Cycles
Addition	7	8
Subtraction	14	17

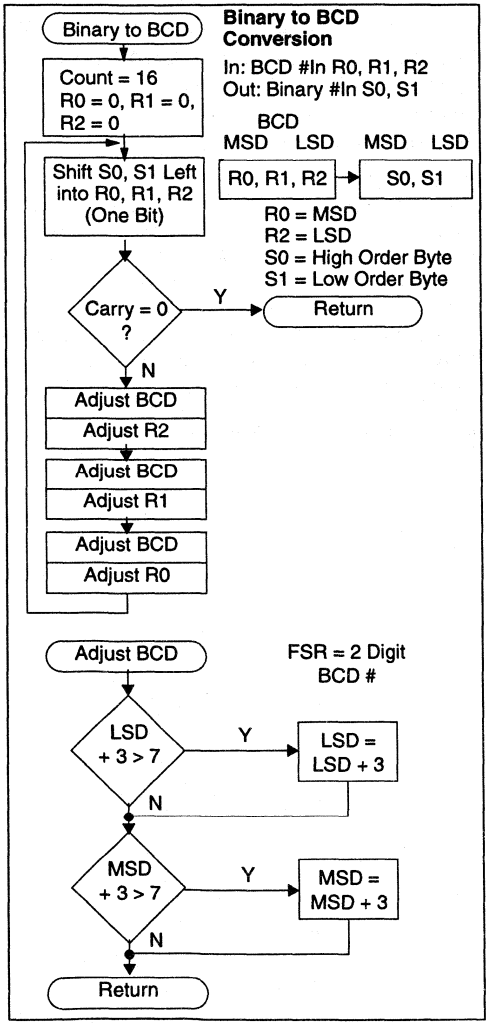
BCD TO BINARY CONVERSION

This routine converts a five digit BCD number to a 16-bit binary number. The listing of this routine is given in Appendix F. The performance spec for the routine is shown below:

TABLE 6: PERFORMANCE SPECS

Spec	Program Memory	Instruction Cycles
BCD to Binary	30	121

© 1997 Microchip Technology Inc.



BINARY TO BCD CONVERSION

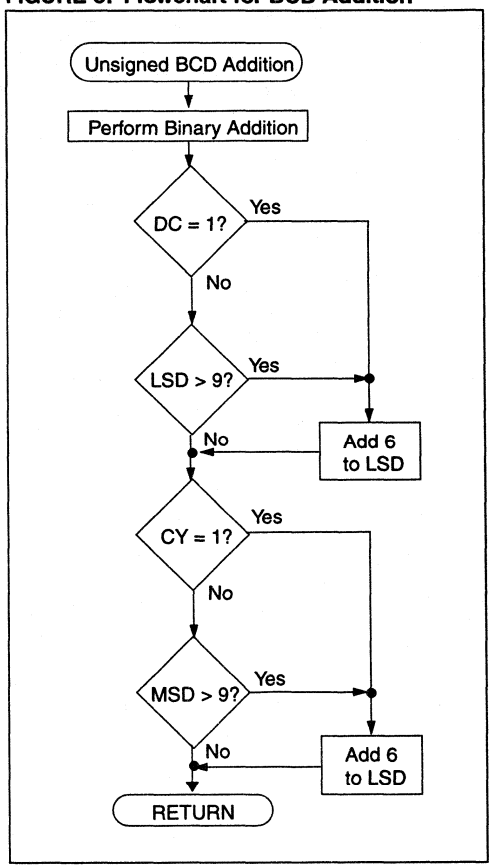
Two routines are provided: one routine converts a 16-bit binary number to a five-digit BCD number and the other routine converts an 8-bit binary number to a two-digit BCD number. The listing of these routines are given in Appendices G and H. The performance specs for the routines are shown below:

TABLE 7: PERFORMANCE SPECS

Spec	Program Memory	Instruction Cycles
Binary (8-Bit) to BCD	10	81 (Worst Case)
Binary (16-Bit) to BCD	30	719

FIGURE 2: Flowchart for Binary to BCD Conversion

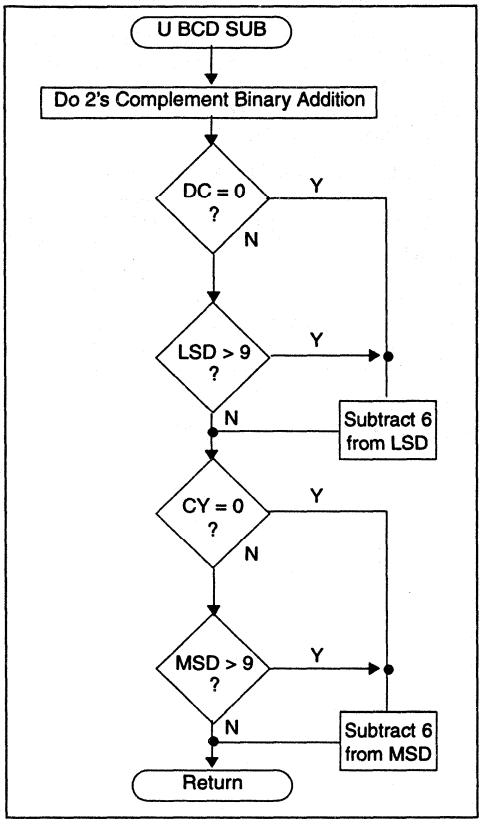
BCD ADDITION & SUBTRACTION



These two routines perform a two-digit unsigned BCD addition and subtraction. The results are the sum (or difference) in one file register and with a overflow carry-bit in another file register. The performance specs for the routines are shown below:

TABLE 8: PERFORMANCE SPECS

Spec	Program Memory	Instruction Cycles
BCD Addition	29	23 (Worst Case)
BCD Subtraction	31	21 (Worst Case)



The listing files for the above two routines are given in Appendices J and K. The flow charts for BCD addition and BCD subtraction are given in Figure 3 and Figure 4, respectively.

FIGURE 4: Flowchart for BCD Subtraction

SQUARE ROOT

Often in many applications one needs to find the square root of a number. Of many numerical methods to find the square root of a number, the Newton-Raphson method is very attractive because of its fast convergence rate. In this method the square root of a number, "N", is obtained from the approximate solution of:

$$f(Y) = Y^2 - N = 0$$

The function "f(Y)" can be expanded about Y_0 using first order Taylor polynomial expansion as:

Equation 1: $f(Y)=f(Y0)+(Y-Y0)f'(Y0)+(Y-Y0)2f''(Y0)/2!+....$

If X is a root of f(Y), then f(X) = 0:

$f(X) = f(Y0) + (x - Y0)\ f'(Y0) + (X - Y0)\ 2f''(Y0) / 2! + ... = 0$

If Y0 is an approximate root of f(Y), then higher order terms are negligible. Therefore:

Equation 2: $f(Y_0) + (X - Y_0)\ f'(Y_0)$ [i.e., $X = Y0 - f(Y0) / f'(Y0)$]

Thus, X is a better approximation for Y0. From this, the sequence {Xn} can be generated:

Equation 3: $Xn = Xn - 1 - f(Xn - 1) / f'(Xn - 1),\ n \geq 1$

From equation 1 and equation 3 we get,

Equation 4: $Xn = 0.5^* \{Xn - 1 + N/Xn - 1\}$

The initial approximate root of N is taken to be N/2. If the approximate range of N is known a priori, then the total number of iterations may be cut down by starting with a better approximate root than N/2.

This program, as listed in Appendix K, computes the square root of a 16-bit number. This routine uses double precision math routines (division and addition) as described in the previous pages of this application note. The divide routines are integrated into the source listing. For fixed point divide routines, see Appendices L - O.

APPENDIX J:SQUARE ROOT METHOD

```
MPASM 01.40 Released              SQRT.ASM   1-16-1997  12:55:13          PAGE  1

LOC  OBJECT CODE     LINE SOURCE TEXT
  VALUE

                     00001         LIST    P = 16C54, n = 66
                     00002 ;
                     00003 ;*****************************************************************
                     00004 ;
                     00005 ;             Square Root By Newton Raphson Method
                     00006 ;
                     00007 ;  This routine computes the square root of a 16 bit number(with
                     00008 ;  low byte in NumLo & high byte in NumHi ). After loading NumLo &
                     00009 ;  NumHi with the desired number whose square root is to be computed,
                     00010 ;  branch to location Sqrt ( by "GOTO  Sqrt" ). " CALL  Sqrt" cannot
                     00011 ;  be issued because the Sqrt function makes calls to Math routines
                     00012 ;  and the stack is completely used up.
                     00013 ;  The result = sqrt(NumHi,NumLo) is returned in location SqrtLo.
                     00014 ;  The total number of iterations is set to ten. If more iterations
                     00015 ;  are desired, change "LupCnt equ .10" to the desired value. Also,
                     00016 ;  the initial guess value of the square root is given set as
                     00017 ;  input/2 ( in subroutine "init" ). The user may modify this scheme
                     00018 ;  if a better initial approximation value is known. A good initial
                     00019 ;  guess will help the algorithm converge at a faster rate and thus
                     00020 ;  less number of iterations required.
                     00021 ;  Two utility math routines are used by this program : D_divS
                     00022 ;  and D_add. These two routines are listed as seperate routines
                     00023 ;  under double precision Division and double precision addtion
                     00024 ;  respectively.
                     00025 ;
                     00026 ;  Note : If square root of an 8 bit number is desired, it is probably
                     00027 ;         better to have a table look scheme rather than using numerical
                     00028 ;         methods.
                     00029 ;
                     00030 ;
                     00031 ;
                     00032 ;   Performance :
                     00033 ;                Program Memory  :       27  (excluding Math Routines
                     00034 ;                                            D_divS & D_add )
                     00035 ;                Clock Cycles    :       3600 ( approximately )
                     00036 ;
                     00037 ;
                     00038 ;        Program:          SQRT.ASM
                     00039 ;        Revision Date:
                     00040 ;                          1-13-97      Compatibility with MPASMWIN 1.40
                     00041 ;
                     00042 ;        To assemble this program, two routines, namely "D_add" &
                     00043 ;        "D_divS" must be included into this program. These two routines
                     00044 ;        are listed as separate programs in files "DBL_ADD.ASM" &
                     00045 ;        "DBL_DIVS.ASM" respectively.

APPENDIX M:

```
    LIST
; P16C5X.INC  Standard Header File, Version 3.30    Microchip Technology, Inc.
    NOLIST

; This header file defines configurations, registers, and other useful bits of
; information for the 16C5X microcontrollers.  These names are taken to match
; the data sheets as closely as possible.  The microcontrollers included
; in this file are:

;    16C52
;    16C54
;    16CR54
;    16C54A
;    16CR54A
;    16C55
;    16C56
;    16C57
;    16CR57A
;    16CR57B
;    16C58A
;    16CR58A

; There is one group of symbols that is valid for all microcontrollers.
; Each microcontroller in this family also has its own section of special
; symbols.  Note that the processor must be selected before this file is
; included.  The processor may be selected the following ways:

;       1. Command line switch:
;               C:\ MPASM MYFILE.ASM /P16C54A
;       2. LIST directive in the source file
;               LIST   P=16C54A
;       3. Processor Type entry in the MPASM full-screen interface

;==========================================================================
;
;      Revision History
;
;==========================================================================

;Rev:    Date:    Reason:

;3.30   07/16/96 Aligned processors with MPASM v1.40
;3.2004/09/96 Added 16C54B, 16CR56B, 16C58B
;3.10   12/14/95 Added 16C52
;3.01   11/29/95 Removed 16CR55
;3.00   10/16/95 Added new processors for MPASM v1.30
;2.04   07/26/95 Reformatted for readability
;2.03   06/21/95 Removed leading spaces

APPENDIX O:

```
;       16/8 PIC16 FIXED POINT DIVIDE ROUTINES  VERSION 1.5

;       Input:  fixed point arguments in AARG and BARG

;       Output: quotient AARG/BARG followed by remainder in REM

;       All timings are worst case cycle counts

;       It is useful to note that the additional routine FXD1507U
;       can be called in a signed divide application in the special case
;       where AARG > 0 and BARG > 0, thereby offering some improvement in
;       performance.

;         Routine             Clocks     Function

;       FXD1608S    188 16 bit/8 bit -> 16.08 signed fixed point divide

;       FXD1608U    294 16 bit/8 bit -> 16.08 unsigned fixed point divide

;       FXD1607U    174 16 bit/7 bit -> 16.07 unsigned fixed point divide

;       FXD1507U    166 15 bit/7 bit -> 15.07 unsigned fixed point divide

;       The above timings are based on the looped macros. If space permits,
;       approximately 41-50 clocks can be saved by using the unrolled macros.

                list    r=dec,x=on,t=off,p=16C71

APPENDIX P:16/16 FIXED POINT DIVIDE ROUTINES

```
;       16/16 PIC16 FIXED POINT DIVIDE ROUTINES VERSION 1.5

;       Input:  fixed point arguments in AARG and BARG

;       Output: quotient AARG/BARG followed by remainder in REM

;       All timings are worst case cycle counts

;       It is useful to note that the additional routine FXD1515U
;       can be called in a signed divide application in the special case
;       where AARG > 0 and BARG > 0, thereby offering some improvement in
;       performance.

;         Routine             Clocks     Function

;       FXD1616S    319 16 bit/16 bit -> 16.16 signed fixed point divide

;       FXD1616U    373 16 bit/16 bit -> 16.16 unsigned fixed point divide

;       FXD1515U    294 15 bit/15 bit -> 15.15 unsigned fixed point divide

;       The above timings are based on the looped macros. If space permits,
;       approximately 65-69 clocks can be saved by using the unrolled macros.

                list    r=dec,x=on,t=off,p=16C71

                include <PIC16.INC>

;*****************************************************************************************
;*****************************************************************************************

;       Define divide register variables

ACC             equ     0x0D    ; most significant byte of contiguous 4 byte accumulator

SIGN            equ     0x13    ; save location for sign in MSB

TEMP            equ     0x19    ; temporary storage

;       Define binary operation arguments

AARG            equ     0x0D    ; most significant byte of argument A

BARG            equ     0x16    ; most significant byte of argument B

REM             equ     0x11    ; most significant byte of remainder

APPENDIX Q:32/16 FIXED POINT DIVIDE ROUTINES

```
;       32/16 PIC16 FIXED POINT DIVIDE ROUTINES VERSION 1.5

;       Input:  fixed point arguments in AARG and BARG

;       Output: quotient AARG/BARG followed by remainder in REM

;       All timings are worst case cycle counts

;       It is useful to note that the additional routine FXD3115U
;       can be called in a signed divide application in the special case
;       where AARG > 0 and BARG > 0, thereby offering some improvement in
;       performance.

;         Routine             Clocks     Function

;       FXD3216S    578 32 bit/16 bit -> 32.16 signed fixed point divide

;       FXD3216U    702 32 bit/16 bit -> 32.16 unsigned fixed point divide

;       FXD3115U    541 31 bit/15 bit -> 31.15 unsigned fixed point divide

Implementing a Table Read

Author: *Stan D'Souza*
Microchip Technology Inc.

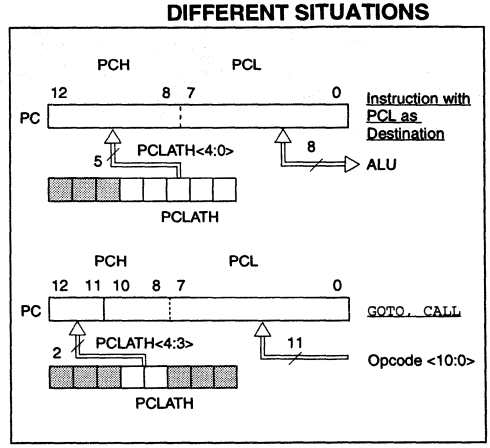
INTRODUCTION

This application note shows how to implement a table look-up for all PICmicro™ products. The examples shown are for the PIC16CXXX family. An explanation of differences between the PIC16C5X family and the PIC17C42 is at the end of this application note.

To access data in program memory, a table read operation must be performed. The table consists of a series of `retlw K` instructions where, the 8-bit table constants are assigned to the literal K. The first instruction in the table computes the offset to the table by using `addwf pcl`, and consequently the program branches to the appropriate `retlw K` instruction (Example 1).

EXAMPLE 1:

```
    .
    .
    movlw   offset  ;load offset in w reg
    call    Table
    .
    .
    .
Table:
    addwf   pcl     ;add offset to pc to
                    ;generate a computed goto
    retlw   'A'     ;return the ASCII char A
    retlw   'B'     ;return the ASCII char B
    retlw   'C'     ;return the ASCII char C
    .
    .
    .
```



The method is straight forward, however certain precautions have to be exercised when doing a table read in the PIC16CXXX.

IMPLEMENTATION

Program Counter Loading

The Program Counter (PC) in the PIC16CXXX is 13-bits wide. The low 8-bits (PCL) are mapped in RAM at location 02h and are directly readable and writable. The high 5-bits are not accessible directly and can only by written through the PCLATH register (Figure 1). The PCLATH register is a R/W register with only five of its bits implemented <4:0>, all other bits read as '0'.

FIGURE 1: LOADING OF PC IN DIFFERENT SITUATIONS

5

SECTION 1

CALL and GOTO Instructions

When executing a CALL or GOTO, the low 11-bits are loaded directly from the instruction opcode. The high 2-bits are loaded from bits 3 and 4 of the PCLATH register. It is a good practice to pre-load PCLATH with the high byte of the location of the routine before executing the routine. This can be done as follows:

EXAMPLE 2:

```
    .
    .
movlw   HIGH Table  ;load high 8-bit
                    ;address of Table
movwf   PCLATH      ;into PCLATH
call    Routine     ;execute Call
                    ;instruction
    .
    .
```

Note: If the program memory size is less than 2K-words, then the above precaution is not necessary.

Computed GOTO Instruction

Any instruction with PCL as the destination, will load the PCH with the 5 low bits from the PCLATH (Figure 1). In Program 3, if the address where the CALL was made, was on page 0 and the address of the actual table was on page 3, then when executing the computed GOTO, the program will go to a location in page 0 instead of a location on page 3. To avoid the program from branching "erratically" when doing a table read, the PCLATH register should be pre-loaded with the high byte of the "Table" address. Example 3 shows how this can be done.

EXAMPLE 3:

```
    .
    org     0x80    ;code location in page 0
    movlw   offset  ;load offset in w reg
    call    Table
    .
    .
    org     0x0320  ;Table located in page 3
Table:
    addwf   pcl     ;add offset to pc to
                    ;generate a computed goto
    retlw   'A'     ;return the ASCII char A
    retlw   'B'     ;return the ASCII char B
    retlw   'C'     ;return the ASCII char C
    .
    .
    .
```

© 1997 Microchip Technology Inc.

When doing a computed GOTO for a table read, care should taken about page boundaries. The ADDWF PCL instruction will not compute a value greater than 8-bits. In Example 4, the result of the computed GOTO will result in a branch to an unintended portion of the code. The user either has to be cautious as to where in a page the Table is resident or will have to monitor page roll-over and add it to the PCLATH ahead of the computed GOTO.

EXAMPLE 4:

```
    .
    org     0x80        ;code location in
                        ; page 0
    movlw   HIGH Table  ;load PCLATH with hi
                        ; address
    movwf   PCLATH      ;   /
    movlw   offset      ;load offset in w reg
    call    Table
    .
    .
    org     0x02ff      ;Table located end of
                        ; page 2
Table:
    addwf   pcl         ;value in pc will not
                        ; roll over to page 3
    retlw   'A'         ;return the ASCII
                        ; char A
    retlw   'B'         ;return the ASCII
                        ; char B
    retlw   'C'         ;return the ASCII
                        ; char C
    .
    .
    .
```

To take care of both table location and page boundary crossing, it is necessary to do a 13-bit computed GOTO operation as shown in Example 5.

The code in Example 5 will allow the user to place and access a table anywhere in program memory.

EXAMPLE 5:

```
    movlw   LOW Table   ;get low 8 bits of
                        ; address
    addwf   offset      ;do an 8-bit add
                        ; operation
    movlw   HIGH Table  ;get high 5 bits of
                        ; address
    btfsc   status,c    ;page crossed?
    addlw   1           ;yes then increment
                        ; high address
    movwf   PCLATH      ;load high address in
                        ; latch
    movf    offset,w    ;load computed offset
                        ; in w reg
    call    Table
    .
    .
Table:
    movwf   pcl         ;load computed offset
                        ; in PCL
    retlw   'A'         ;return the ASCII
                        ; char A
    retlw   'B'         ;return the ASCII
                        ; char B
    retlw   'C'         ;return the ASCII
                        ; char C
    .
    .
    .
```

5

SECTION 2

Implementation for the PIC16C5X Family

The PIC16C5X has no PCH or PCLATH register, so the user has to take into consideration all the precautions mentioned in Section 1. In the PIC16C5X, the location of the Table has to be in the top-half of a 512 word page. This restriction is not valid for the PIC16CXXX family. To convert a table read operation from PIC16C5X code to the PIC16CXXX code, the following should be done:

- Remove any program memory page select instructions (PIC16C56/57), if present.
- Do a 13-bit computed GOTO operation (as shown in Example 5), when doing a table read operation.

Implementation for the PIC17C42

Unlike the PIC16CXXX family, the PIC17C42 loads the PCLATH register with the PCH value during a CALL or GOTO operation, however a computed GOTO, does not take care of page boundary crossing. A 16-bit computed jump address should be calculated before the table read is executed. Example 6 shows how this is done.

Example 6 allows the user to locate the Table at any program memory location, however, for large tables or tables which cross page boundaries, it is recommended that the tablrd/tlrd instructions be used, these instructions are specific for table read operations and are very code efficient.

EXAMPLE 6:

```
    .
    movlw   LOW Table    ;get low 8 bits of

Techniques to Disable Global Interrupts

Author: *Mark Palmer*
Microchip Technology Inc.
Contributions by Martin Burghardt
Manager Applications (Central Europe)

INTRODUCTION

This application note discusses four methods for disabling global interrupts. The method best suited for the application may then be used. All discussion will be specific to the PIC16CXXX family of products, but these concepts are also applicable to the PIC17C42, and are shown in the even numbered examples. Note that the PIC17C42's global interrupt bit is called GLINTD and has an inverse sense compared to the GIE bit of the PIC16CXXX family.

To disable all interrupts, either the Global Interrupt Enable (GIE) bit must be cleared or all the individual interrupt enable bits must be cleared. An issue arises when an instruction clears the GIE bit and an interrupt occurs "simultaneously". For example, when a program executes the instruction `BCF INTCON, GIE` (at address PC), there is a possibility that an interrupt will occur during this instruction. If an interrupt occurs during this instruction, the program would complete execution of this instruction, and then immediately branch to the user's interrupt service routine. This occurs because the GIE bit was not clear (disabled) when the interrupt occurred. Normally at the end of the interrupt service routine is the `RETFIE` instruction. This instruction causes the program to return to the instruction at PC + 1, but also sets the GIE bit (enabled). Therefore the GIE bit is not cleared as expected, and unintended program execution may occur.

One method to ensure that the GIE bit is cleared is shown in Example 1 and Example 2, as well as in the PIC16CXXX data sheets. This method tests the state of the GIE bit, after clearing, to ensure that it was not accidentally set in the user's interrupt service routine by the `RETFIE` instruction. If the GIE bit was accidentally set, the program branches back to the instruction that clears the GIE bit.

In this method, the time to ensure that the GIE bit is cleared is indeterminate. Depending on the frequency of the enabled interrupts during this code segment, unexpected delays into the following code segment may occur. For some applications, this may be undesirable. The following three methods address this issue.

5

EXAMPLE 1: CLEARING THE GIE BIT (DISABLING INTERRUPTS, METHOD 1, PIC16CXXX)

```
LOOP    BCF     INTCON, GIE     ; Disable Global Interrupt
        BTFSC   INTCON, GIE     ; Global Interrupt Disabled?
        GOTO    LOOP            ; NO, try again
        :                       ; YES, continue with program flow
        :
        BSF     INTCON, GIE     ; Re-enable Global Interrupt
```

EXAMPLE 2: SETTING THE GLINTD BIT (DISABLING INTERRUPTS, METHOD 1, PIC17C42)

```
        :
LOOP    BSF     CPUSTA, GLINTD ; Disable Global Interrupt
        BTFSS   CPUSTA, GLINTD ; Global Interrupt Disabled?
        GOTO    LOOP           ; NO, try again
        :                      ; YES, continue with program flow
        :
        BCF     CPUSTA, GLINTD ; Re-enable Global Interrupt
```

© 1997 Microchip Technology Inc.

The second method is to disable the individual interrupt enable bits. If it is known which bits are enabled at this point, it can easily be done. Example 3 and Example 4 show the disabling of interrupts, where it is known which sources are enabled (some peripheral interrupts and the T0CKI pin interrupt).

This method also requires the same number of instructions for the disabling/enabling of interrupts, as method 1, but requires a knowledge of which individual interrupt enable bits need to be disabled and (more importantly) re-enabled. The major advantage of this method is that it can minimize the time delay entering the code segment which follows the point where interrupts are disabled.

EXAMPLE 3: CLEARING KNOWN INDIVIDUAL INTERRUPT ENABLE BITS (METHOD 2, PIC16CXXX)

```
:
MOVLW   b'10011111'     ; Disable  Peripheral and T0CKI pin interrupts,
ANDWF   INTCON, F       ; All other bits unchanged
:
:
:
MOVLW   b'01100000'     ; Re-enable Peripheral and T0CKI pin interrupts,
IORWF   INTCON, F       ; All other bits unchanged
:
```

EXAMPLE 4: CLEARING KNOWN INDIVIDUAL INTERRUPT ENABLE BITS (METHOD 2, PIC17C42)

```
:
MOVLW   b'11110011'     ; Disable Peripheral and T0CKI pin interrupts,
ANDWF   INTSTA, F       ; All other bits unchanged
:
:
:
MOVLW   b'00001100'     ; Re-enable Peripheral and T0CKI pin interrupts,
IORWF   INTSTA, F       ; All other bits unchanged
:
```

© 1997 Microchip Technology Inc.

Method 3 can be used if the states of the individual interrupt enable bits are unknown. A temporary byte of data RAM is required to store the value of the INTCON register. This method is shown in Example 5 and Example 6.

This method also requires more instructions for the disabling/enabling of interrupts than in method 1 or method 2, and also a byte of data RAM to temporarily store the value of the INTCON register. The major advantage of this method is that it minimizes the time delay into the code segment which follows the point where interrupts are disabled.

EXAMPLE 5: CLEARING THE INDIVIDUAL INTERRUPT ENABLE BITS (METHOD 3, PIC16CXXX)

```
    :
    MOVF    INTCON, W           ; Move the value in INTCON to
    MOVWF   S_INTCON            ; a shadow register
    MOVLW   b'10000111'         ; Disable all individual interrupts,
    ANDWF   INTCON, F           ; All other bits unchanged
    :
    :
    :
    MOVF    S_INTCON, W         ; Restore the INTCON register
    IORWF   INTCON, F           ;
    :
```

EXAMPLE 6: CLEARING THE INDIVIDUAL INTERRUPT ENABLE BITS (METHOD 3, PIC17C42)

```
    :
    MOVPF   INTSTA, S_INTSTA    ; Move the value in INTSTA to a shadow register
    MOVLW   b'11110000'         ; Disable all individual interrupts,
    ANDWF   INTSTA, F           ; All other bits unchanged
    :
    :
    :
    MOVFP   S_INTSTA, W         ; Restore the INTSTA register
    IORWF   INTSTA, F           ;
    :
```

© 1997 Microchip Technology Inc.

The final method is to use a RAM location to "shadow" the value of the GIE bit. This shadow bit can then be used in the interrupt service routine to determine which return instruction to use. That is, either the RETURN or the RETFIE (which enables the GIE bit) instruction. Example 7 and Example 8 show this implementation, which require that a general purpose bit be available to hold the "shadow" GIE value. In these examples, the shadow GIE (S_GIE) bit is contained in the register FLAG_REG. If an interrupt occurs during the clearing of the shadow GIE, the interrupt is responded to. At the end of the interrupt service routine, the shadow GIE bit is cleared so the RETURN instruction is executed. The GIE bit remains disabled and program execution returns to the instruction which tries to clear the GIE bit (disable). No interrupts can occur during this instruction since the GIE bit was not re-enabled after the interrupt service routine.

This method also requires more instructions for the disabling/enabling of interrupts than in method 1 or method 2, and a single bit of data RAM to temporarily store the value of the desired GIE value, and increases the interrupt service routine execution time by one instruction cycle, for most occurrences of interrupts (two cycles worst case). The major advantage of this method is that it minimizes the time delay into the code segment which follows the point where interrupts are disabled. Also, the individual interrupt enable bits need not be modified.

EXAMPLE 7: THE "SHADOW" GIE BIT (METHOD 4, PIC16CXXX)

```
    :
            org     0x004
INT_SERVICE_ROUTINE
    :
    :
    BTFSC   FLAG_REG, S_GIE         ; Is the S_GIE bit enabled?
    RETFIE                          ; YES, the GIE should be enabled
    RETURN                          ; NO, the GIE should be disabled
END_INT_SERVICE_ROUTINE
;
MAIN:
    :
    :
    BCF     FLAG_REG, S_GIE         ; Clear the shadow GIE bit
    BCF     INTCON, GIE             ; Disable interrupts by clearing the GIE bit
    :
    :
    :
    BSF     FLAG_REG, S_GIE         ; Set the shadow GIE bit
    BSF     INTCON, GIE             ; Enable interrupts by setting the GIE bit
    :
    :
    END
```

EXAMPLE 8: THE "SHADOW" GLINTD BIT (METHOD 4, PIC17C42)

```
    :
            org     0x004
INT_SERVICE_ROUTINE
    :
    :
    BTFSS   FLAG_REG, S_GLINTD      ; Is the S_GLINTD bit enabled?
    RETFIE                          ; YES, the GLINTD should be enabled
    RETURN                          ; NO, the GLINTD should be disabled
END_INT_SERVICE_ROUTINE
;
MAIN:
    :
    :
    BSF     FLAG_REG, S_GLINTD      ; Set the shadow GLINTD bit
    BSF     CPUSTA, GLINTD          ; Disable interrupts by setting the GLINTD bit
    :
    :
    :
    BCF     FLAG_REG, S_GLINTD      ; Clear the shadow GLINTD bit
    BCF     CPUSTA, GLINTD          ; Enable interrupts by clearing the GLINTD bit
    :
    :
    END
```

CONCLUSIION

In conclusion, different methods exist to ensure that all interrupts are disabled. The requirement(s) of the application determines which of the methods is the best fit. A comparison of the different methods is shown in Table 1.

TABLE 1: COMPARISON OF DIFFERENT METHODS

	Program Memory	Data Memory	Cycle Delay (TCY)	
			Best Case	Worst Case
Method 1	2 words * N	—	2	Indeterminate
Method 2	2 words * N	—	1	1 + TISR
Method 3 - PIC16CXXX	4 words * N	1 byte	3	3 + TISR
- PIC17C42	3 words * N	1 byte	2	2 + TISR
Method 4	2 words * N + 2 words	1 bit	1†	1 + (TISR + 2)

Legend: N - Number of occurrences to disable / re-enable interrupts.
TISR - Time to execute the interrupt service routine.
† This method increases the interrupt service routine time (TISR) by 1 cycle for most occurrences (2 cycles worst case).

A Real-Time Operating System for PICmicro™ Microcontrollers

Author: *Jerry Farmer*
Myriad Development Company

INTRODUCTION

Ever dream of having a Real-Time Kernel for the PIC16CXXX family of microcontrollers? Or ever wonder what Multitasking or Threads are all about? Then this article is for you. We will explore how to implement all of the features of a large Real-Time Multitasking Kernel in much less space, with more control, and without the large overhead of existing kernels. By planning ahead, and using the techniques outlined here, you can build your own fast, light, powerful, flexible real-time kernel with just the features needed to get the job done.

Included in this article are two large examples: one on the PIC16C54, and the other on the more powerful PIC16C64. A "Remote Alarm" is implemented on the PIC16C54 as an example of a Non-Preemptive Kernel, with two asynchronous serial input sources capable of running up to 19,200 Baud along with seven sensors needing to be debounced as inputs. One more input line is monitored and causes an internal software recount. For output, this example has an LED that shows eight different internal states of the "Remote Alarm", blinking at different rates and different sequences. Last but not least, is an asynchronous serial output capable of running at 38,400 Baud, passing the inputs to the next remote alarm station. Several short and long timers are included to round out the nine cooperating tasks in this example. Please refer to Figure 2 and Appendix B.

The second example is implemented on an PIC16C64 featuring an interrupt driven Semi-Preemptive Kernel. This example has the serial input and output routines of the first example moved into Interrupt Service Routines (ISR) for more speed and accuracy. The interrupt capabilities of the PIC16C64 will be explored, and a Real-Time Multitasking Kernel framework will be developed. Please refer to Figure 5 and Appendix C.

Why do I Need a Real-Time Kernel?

Real-time design techniques allow the engineer/designer to break-up large, complicated problems into smaller simpler tasks or threads. These more manageable units of code allow faster response to important events, while prioritizing the jobs to be done in a structured well-tested format. The kernel does the job of keeping the time, the peace between tasks, and keeping all the tasks' communication flowing. More activities can be performed in the same amount of time by allowing other tasks to work while other tasks are waiting for some event to occur. Smaller code is also the result of using State-Driven techniques because much information is condensed into the state variables and code structure. If you need an example, look at the PIC16C54's "Remote Alarm" code.

What is Multitasking Anyway?

This is the appearance of several tasks working at the same time. Each task thinks that it owns the CPU, but this appearance is controlled by the kernel. Only one task can be running at a time, but there is undone work that can be done by other tasks not blocked. Multitasking is the orchestration of interrupts, events, communication, shared data, and timing to get a job done. Real-Time Programming is just a bunch of ideas, concepts, and techniques that allow us to divide problems into units of code that are based on units of time, or events that drive a task from one state to another.

5

CONCEPTS

We will cover the basic concepts of kernels here so that we are using the same definitions when talking about this difficult topic. This article is a very quick survey on Real-Time Kernel concepts. I hope to get you thinking, reading more, and hopefully writing RT Operating Systems for your current and future projects. Many great books have been written about this very broad and interesting subject. We will refer to some of these books which have a different point of view other than those expressed in this paper.

Critical Section

A critical section is a shared data structure, or a shared resource, or a critical time section of code, or a non-reentrant section of code that can have only one owner that is allowed to view/change/use that section at any one time. These sections must not be interrupted during the update process. They must be protected so that other tasks can not get in and change the pointers/data or modify the hardware at the same time. Remember that if two tasks can get into a critical section, at the same time, then data WILL be corrupted. Make sure that critical sections are small, with time for pending interrupts to get serviced. Not understanding critical sections is where the beginning RT programmers get into the most trouble. Even without interrupts, you must protect variables that are changing over time, such as the byte sized variable `xmt_byte` used in the PIC16C54 example. This variable changes each time the STATE changes for the Serial Out Task. Semaphores, and Disabling Interrupts are two of the techniques used to coordinate between different tasks wanting to control a critical section. Task #4 is devoted to the proper feeding of the shared Serial Out Resource in the PIC16C54 example. Note the use of the binary semaphore "OState_B" to control Task #4, Task #1, and the variable `xmt_byte`. There are several more examples of critical sections in the PIC16C64 example due to the use of interrupts. We disable interrupts for very short time periods to protect these areas. Also in the PIC16C64 example, all critical sections are finished before checking to see if the kernel wants another task to start running instead of the current task. We will discuss in more detail how to protect critical sections later in this article.

FIGURE 1: TASK / PROCESS STATE TRANSITION DIAGRAM

Shared Resources

Data structures, displays, I/O hardware, and non-reentrant routines are a few resource examples. If two or more tasks use these resources, then they are called Shared Resources and you must protect them from being corrupted. They must have only one owner, a way of telling others to wait, and possibly a waiting list for future users of that resource. A rare example of a shared resource is when there exists a critical timing sequence of input and output operations to control some hardware. You must disable interrupts before starting this sequence, and re-enable them upon finishing. Note that Task #1 in the PIC16C64 example is an example of an "non-reentrant" routine that must be finished by the current owner before another task can use it.

Context Switch/Task Switch

When one task takes over from another, the current values of the CPU registers for this running task are saved and the old saved registers for the new task are restored. The new task continues where it left off. This is all done by the Context Switch part of the Real-Time Kernel. Each task usually has a "context switch storage area". Each task's SP (Stack Pointer pointing into its own stack) is stored there along with all the other important saved registers. The "Remote Alarm" example does not need to use a context switch because all the important registers are properly freed-up before each task is finished. The PIC16C64 example uses a similar concept, thus keeping the number of saved registers per task way down. We use an old concept called "where I came from". The variable "FROM" is used to direct the dispatcher to start up the task where it left off. This is because you cannot manipulate the stack in the PIC16CXXX family. This same reason is why we have a "Semi-Preemptive" kernel on the PIC16C64 as an example. By the way, the faster the context switch is done, the better.

Scheduler

The scheduler is that part of the kernel that decides which task will run next. We will talk about several common types in this section. This is where a lot of thinking should be done before starting your new project. By understanding the different kinds of schedulers and what features and problems each type has, you can match your problem to a creatively styled scheduler that meets your needs. For example, the PIC16C54 example shows the recalling of Tasks #1-3 just before a long sequence of code is executed. More creative ways can also be implemented, but be careful to allow all tasks to execute in a timely fashion.

Please see Figure 1. Each task must be in "Ready State" or the "Executing State" to be considered by the scheduler to get temporary control of the CPU next.

© 1997 Microchip Technology Inc.

Non-Preemptive Kernel

The Non-Preemptive Kernel is also called a "Cooperative Kernel" because the tasks only give-up control when they want/need to in coordination with other tasks, and events. The "Remote Alarm" example uses a Non-Preemptive Kernel type, showing that despite its reputation as being a simple kernel type, a lot can be done with it. The Non-Preemptive Kernel type is well suited for the non-interrupt type PIC16C5Xs. The heart beat of the PIC16C54 example is the internal TMR0 counter crossing over from a high value to a low value of the counter. Use the prescaler to adjust the time units. The very fast tasks continually read the TMR0 directly comparing the delta of time to see if it should fire.

Preemptive Kernel

In a Preemptive Kernel, a running task can be swapped out for a higher priority task when it becomes ready. The Preemptive Kernel relies much more on interrupts as its driving force. The context switch is at the heart of this type of kernel. To implement a true Preemptive Kernel, you must be able to manipulate the stack. This is why we implemented a "Semi-Preemptive" kernel on the PIC16C64, with some of the best features of both types of kernels. We moved some of the tasks in the PIC16C54 example into ISRs to handle the I/Os. This works very well as the ISRs are very short and do most of the real work in this example. The TIMER0 interrupt is the heart beat for the PIC16C64 example. You must have a clock interrupt in order to make a true Preemptive kernel.

Round Robin Scheduler

When the scheduler finds tasks on the ready queue that have the same priorities, the scheduler often uses a technique called Round Robin scheduling to make sure each task gets its day in the sun. This means more housekeeping to get it right. This is part of the creative ways you can tailor the scheduler to fit your needs. In the PIC16C54 example, all tasks will get to run shortly after their appointed time. This means that no task will dominate all others in this simple approach. In the "olden" days of the first Real-Time Operating Systems the term was used to mean the same as "time slicing". The Preemptive Kernels of today are a major step forward, with their priority schemes, and intertask communication capabilities.

Preemptive vs. Non-Preemptive

The Preemptive Kernel is harder to develop, but is easier to use, and is sometimes used incorrectly. You must spend more upfront time with the Non-Preemptive Kernel but it is better for more cramped microcontrollers. You get much better response time between a cause/event and the response/action for that event with a Non-Preemptive Kernel. The Preemptive Kernel is more predictable in the response times, and can be calculated as to the maximum time to complete a given job. Often the Preemptive Kernel is more expensive.

Reentrancy

In a Preemptive Kernel, two or more tasks may want to use the same subroutine. The problem is that you can not control when a task is swapped out and when another takes its place. Thus, if a subroutine uses only local or passed variables that are stored only in each tasks' stack, then it is call reentrant or a pure routine. No global variables or hardware may be used in such a pure routine. A way around this reentrancy requirement is to treat the whole subroutine as a critical section.

Appendix D is an example of reentrant code segment as might have been used in the PIC16C54 code example.

Task Priority

Some tasks are not created equal. Some jobs must be done on time or data will be lost. Make the tasks that must get done the highest priority and go down the scale from there. Some kernels make you have a different priority for each task. This is a good idea and requires some thought before coding to make the design work.

Static vs. Dynamic Priorities and Priority Inversions

For most embedded Real-Time Kernels, both static priorities and static tasks are used. Dynamic priorities are sometimes used to solve deadlock and other complex situations that arise from not understanding the problem and not understanding Real-Time Techniques. If the need for dynamic priorities seem to occur, you should relook at how you divided the problem, and divide less so as to include the resources in question under one semaphore. You could divide the problem more to have more tasks not needing two or more resources to complete its job, and have the new tasks talk more together.

© 1997 Microchip Technology Inc.

As for Dynamic tasks, you should define the problem so as to know, ahead of coding, the continuous use of all tasks. You will need more upfront time in the planning stage to get all tasks talking, but it is well worth it to keep Dynamic Priorities and Dynamic Tasking out of the kernel design.

Priority Inversions is a trick used to get past a poorly designed system by inverting the priorities to allow lower tasks to run that were previously blocked. This is a cheap trick, and is best kept out of a Real-Time Kernel. Use the other techniques outlined in this section to solve this kind of problem.

Semaphores

There are basically two types: binary and counting semaphores. The binary semaphore allows only one owner, and all other tasks wanting access are made to wait. The counting semaphore keeps a list of users that need access. Semaphores can be used in many ways. We will illustrate most of them in the following paragraphs. Note that you can implement counting semaphores using binary semaphores.

Mutual Exclusion

We have touched on the subject of Mutual Exclusion earlier (a method to exclude other tasks from gaining access to critical sections). Mutual Exclusion is the process of excluding others from access to the shared resources. To make a semaphore is a very complicated process. The semaphore's construction must be atomic. That means that once the process has started, it can not be interrupted until it has saved the name of the new owner. From there on, it knows that no one else can break-in and change owners. We have implemented a binary semaphore using bits and kernel functions to mutually exclude access in the PIC16C54 example.

In the PIC16C64 example, we also disable interrupts to get the same effect. There are at least two good ways of implementing a binary semaphore. The first and oldest way was discovered by a Dutch mathematician named Dekker. We will refer you to a book that talks more about this algorithm. The second method of implementing a binary semaphore was also discovered by another Dutchman named Dijkstra. This method uses the "testandset" type instruction and is much more important to us. We used the `dec & jump if not zero` instruction (see PIC16C64 example).

Deadlock

Deadlock is a condition where two or more tasks own resources that other tasks need to complete there assignment but will not release their own resources until the other tasks release theirs. Talk about cooperation. Please read section, "Static vs. Dynamic Priorities and Priority Inversions" for a discussion about such problems and ways to solve them. The root of such problems is not understanding the original problem.

Synchronization

Semaphores can be used to synchronize tasks so that messages can be passed between them. Also tasks can be started up by semaphores, stopped by semaphores, or started together. They are the foundation blocks for Real-Time Programming. Once you have built a binary semaphore for your kernel, you can build very complex semaphores to synchronize anything. In the PIC16C54 example, data from several sources are passed out the Serial Port Resource. Task #4 synchronizes the other tasks trying to send data out and synchronizes with task #1 to get it done. When task #1 is running, then task #4 can not run until task #1 is ready for more data to send out.

Intertask Communication

We have touched on this topic already, but for large kernels, one can include more complex communication methods to pass data/messages between tasks. Much of the handshaking is done for you inside the kernel. This takes a lot more space and execution speed to implement them in a kernel.

Event Flags

We implemented Event Flags as simple bits having two states (on and off). More info can be stored per Event Flag such as time it was recorded, by who, and who the event belongs to, and whether data was lost.

Message Mailboxes

This is a nice feature to have if you have the ram space. Mailboxes allow the designer to pass messages between tasks, and allows messages to be looked at when the task is ready, and to reply telling the sender that the message was received. One message can be sent to many tasks at the same time.

Message Queues

This again is a very nice feature if you have the execution time, and the ram to implement them. This feature is related to Mailboxes, in that you can store several messages even after reading, to be processed later. If you want to only operate on the highest prioritized messages before handling the rest, this is allowed. You can be very fancy with the Mailboxes and Queues. If you have them, use them.

© 1997 Microchip Technology Inc.

Interrupts

Interrupts are one of the best inventions to come along for solving Real-Time problems. You can get very quick response to the need, and then go back to what you were doing. The only problem is that they can and do happen at the worst times. That means that you must learn how to turn them on and off to protect your critical sections. Note that before an interrupt can be handled, you must save all important registers so that you can restore them so that the kernel can restart the task where it left off. This is much like the context switch issue, but for interrupts, you must always save and restore. In the PIC16C64 example, the Status, W, and FSR registers are saved in RAM because of the interrupt. The PC register is saved onto the stack by hardware.

Interrupt Latency, Response and Recovery

Interrupt Latency is defined as the largest time period that interrupts are disabled, plus the time it takes for the ISR to start to execute.

The Interrupt Response Time is defined for a Non-Preemptive system as Interrupt Latency plus the "context saving time." For a Preemptive system, add the execution time for the kernel to record the interrupt.

Interrupt Recovery Time for a Non-Preemptive system is defined as the time to restore the saved context and for the restarting of the task that was interrupted. Interrupt Recovery Time for a Preemptive system is the same as for the Non-Preemptive system plus the time the kernel takes in the scheduler deciding which task to run next. These measurements are how most kernels are compared with each other. The PIC16C64 example does very well in these measurements. That is because of the PIC16CXXX processor and that they are mostly a Non-Preemptive system. You must keep the time you disable interrupts to a minimum in any kernel you write or any task that you write. You should break-up long sequences of instructions to allow for interrupts that are already waiting to execute.

ISR Processing Time

ISR (Interrupt Service Routine) Processing Time is defined as the time an ISR keeps control of the CPU. This amount of time should be short, and if a lot of processing needs to be done in a ISR, then break up the ISR. The new ISR should now just store the new data and return. Next, create a new task and move the extra code from the old ISR into the new task. Remember that the longer you are in one interrupt, the longer you can not answer another pressing interrupt.

Nesting interrupts are where the interrupt with a higher priority can interrupt a lower priority interrupt. Care must be used, as different interrupts may have critical sections too, and disabling interrupts must be used here too to protect critical sections. Nesting of interrupts may not exist on all microcontrollers, such as the PIC16CXXX family.

Non-Maskable Interrupts

On some microprocessors, you can enable/disable selected interrupts, such as on the PICmicro family. This is a great tool to control the flow of data into the system and out. Some systems have what is called Non-Maskable Interrupts. Here you can not turn them off by software masking. These NMIs as they are call for short, are used as clock Ticks, because you do not want problems with complex critical sections on a interrupt that you can not turn off. The PIC16CXXX family does not have any NMIs. NMIs are not as useful as maskable interrupts.

Clock Tick

The Clock Tick, is the heart beat of the system. This is how the kernel keeps time (relative & absolute). This is how the kernel is restarted to see if there is a delay that has finished, so that the task can be moved into the ready state. In the PIC16C54 example, the Timer0 clock is used. In the PIC16C64 example, Timer0 is used. You must have a clock interrupt in order to make a true Preemptive kernel. This is the other reason why we implemented a Non-Preemptive Kernel on the PIC16C54 - no clock interrupt.

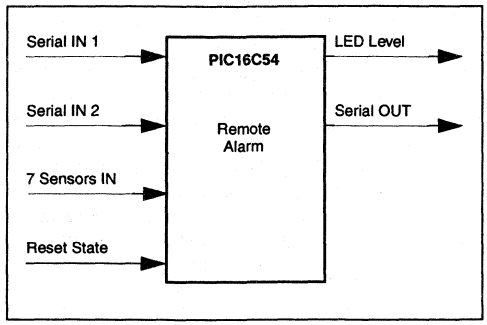
© 1997 Microchip Technology Inc.

ANALYSIS OF CODE EXAMPLES

These sections are the real meat of this article. In these sections we will explain how the concepts are put to practical use line by line in each of the two main examples - PIC16C54 (Appendix C) and PIC16C64 (Appendix D).

We will also examine a short reentrant code example in Appendix B. We will give some ideas on how to expand the examples and how far and how fast the examples can be pushed. Be sure to read both sections on the two examples.

The "Remote Alarm" application has many interesting features. The concept is to have as many tiers of units like a tree feeding into the lower level units the status of each of the larger branches to one central point. Each unit can detect any changes in status before the intruder shuts that unit down, or tampers with it. If any unit's power or wires connecting it down the tree are cut, the lack of the flow of status and passwords would be noticed in five seconds and reported down the line. The two Serial Input lines per unit receive the status and passwords from it's two larger branches, checking the data and passing the info down the line by its own Serial Output line. The seven input status lines are debounced in these examples, showing the technique.



The LED on each unit reports the status at that node as to the importance of its own seven input status lines and the status flowing down the line. The level indication outputted on the LED continues at the last highest level until either a reset is received on the "Reset State" line or five minutes of no new activity on the seven input status lines are received. When either of these two events occur, the level of the LED output is adjusted to the current level of input. Some of the features are changed for this article (Figure 2 and Figure 5).

Another Embedded System use of this type of "Remote Alarm" application is that of placing the unit on the outside of a safe. Hopefully the intruder would be detected before arriving at the unit itself. The continuous stream of status and passwords to the larger unit inside would slow down any simple theft.

PIC16C54 - "Remote Alarm" Example

This example is a cross between a true application and an attempt to show new concepts and some extra features for show. Some of the application specific code has been removed to show more clearly the possibilities of a Real-time Operating System on the PICmicro family. We chose the Baud rate for the Serial output to be twice the speed of the two Serial inputs because it is harder to accurately output a precise Serial Output than it is to monitor Serial inputs.

FIGURE 2: REMOTE ALARM-PIC16C54 EXAMPLE

This example operates at 4 Mhz. By simply increasing the crystal speed to 8 MHz, the two Asynchronous input Serial Baud rates increase from 4800 Baud to 9600 Baud. The Serial Output Baud rate increases from 9600 Baud to 19,200 Baud. By increasing the crystal speed to 16 MHz, it will increase the Baud rates to 19,200 Baud for the two independent Asynchronous inputs, and increase the baud rate for the Asynchronous Serial output to 38,400 Baud. By adjusting the constants in the code for the Serial routines, other Baud rates can be achieved at other crystal speeds. Note that you must use a very stable crystal setup and NOT an RC combination to run these examples.

We will now give a quick outline of the PIC16C54 code example. Lines 1-85 are the equates for this program. Lines 88-95 are simple jump tables so as to save some of the precious "first 256 bytes" of each page. The Serial Output Routines - Task #1 are in lines 97-159. Task #7's subroutines start at line 160 and continue to line 277. In this section, the LED output is controlled. The subroutine QCheck_T123, lines 278-301, is used to allow the checking of Tasks #1-3 to see if they are ready to execute before a long section of code in a slower Task is about to be executed. This is a creative way for the Kernel's Scheduler to makes sure that the highest Prioritized Tasks get serviced before the less important tasks get executed. Task #2 starts at line 302. This task reads the Serial Input #1 for Asynchronous data. Task #2 can be described as a State Machine for outputting a byte Serially. Task #3 interrupts the code of Task #2 at line 333 and continues until line 362. Task #3 also reads the Serial Input but on input #2. Task #2's subroutines continue at line 363 and continue until line 423. Task #3's subroutines continue at line 424 and continue until line 484 is reached. The main or starting code is started at line 485. From that line to line 515, all variables are initialized, and all tasks are initialized at this time also. The Main Loop is started at line 516 and ends at line 665. This is where the real action is done. Each task checks the time to see if the conditions are correct for it to run. The tasks that are not Blocked, and have a job to do now are in a Ready State. In the Main Loop, we check the current state of each task in order of Priority (1-9). If ready, we do a very simple Task

© 1997 Microchip Technology Inc.

Switch and place that task in the Executing State/Running State. Several time unit changes take place in the Main Loop. Tasks #1-4 use 2 µs as a time base by reading the TMR0 directly. A time unit change takes place at lines 562-575 to 512 µs per unit for Tasks #5-6. Another time unit change takes place for Tasks #7-9, to 131072 µs per unit. For Tasks #5-9, each task counts the time units and compares them to their standard for activation or activity. Task #4 starts at line 538 and finishes at line 561. Task #4 controls the feeding of Task #1 from several other tasks that want data to be outputted. It uses several Semaphores to make sure that Task #1 is not bothered until it is ready for another byte. Task #5 monitors the Level Reset Line, and is always running. It simply resets the status of the LED, to be recalculated in Task #6. Task #5 runs through lines 576-581, and is very short. Lines 582-611 represent Task #6. Here we debounce the seven sensor input lines, leaving the current standard in the variable "Old_RB". Task #6 asks/Signals Task #4 to output the current standard out the Serial pin. Task #7's main code is lines 621-628. Task #8 is a five second lack of activity timer, and exists in lines 629-645. If no data comes from either of the two input Serial lines, then Task #8 Signals Task #4 to send a special byte to be outputted by Task #1. This Signals the next "Remote Alarm" of the lack of communication between units. The last task is Task #9. This is a five minute lack of Severe Errors the from Sensor Reset Timer. Lines 646-663 compose Task #9. Subroutine `Do_D_H_E_L` starts at line 667 and continues through to line 692. This routine determines the Highest Error Level, and passes Task #7, the current state, to output on the LED. Lines 693-703, clear the registers #7-1Fh. The "jump at Power-On" code is the last lines 705-706.

The following sections describe in more detail how and what each part of the code does and why. The code segment lines 1-87 are explained in this paragraph. Line 4 tells the MPASM assembler which PICmicro you are using. The include file `PICREG.H` follows with the equates and assignments to make the code more readable and changeable. You should use equates that relate symbols to each other. The Constants — lines 10-12 are the values to change for different Baud rates. They represent the Bit Times for the Baud rates divided by 2 minus some latency factor. You might have to adjust the "Fudge Factor" and other values to fine tune the performance. The value used for the "Fudge Factor" is related to the longest path of code. Lines 21-24 are an experiment that allows a simple name to be associated to a single bit. This allows for easily changeable assignments. Lines 30-54 are the variable assignments. Variables (lines 35-39) are used as time counters. They count the number of units of time, and are compared to literals to see if an Event has just happened. The bits defined in lines 57-64 are used as Binary Semaphores. They keep Critical Sections of data protected. We will see them in action later in the code. The bits defined in lines 67-73 are error flags. They define the current or last error states of the Serial routines, and whether data was lost coming in or out.

The section of equates in lines 76-85 are used to define the different LED activity. They are used by Task #7 to keep the LED blinking. In lines 89-94, we try to save the all important first 256 bytes of any page.

Task #1 outputs a byte Asynchronously over the Serial Output pin. Task #1 is started at line 98. The time units used for Tasks #1-4 are 2µS. We first sample the TMR0 and store the count. When Tasks #1-4 are then allowed to run, they check the difference between the first sample and the current time. If the delta is greater than or equal to the delay, then that Event has just happened. We first check if the state of the Serial Output is zero. We then jump to OStateS to start the outputting of the "Start Bit". Because any Serial Output timings must be rock solid, we use a trick in lines 101-116 that helps greatly. We check if we are within a certain amount of time BEFORE the deadline and then wait for the time to output another bit. This trick allows us to be within a certain ± amount of time within the expected time to output that bit. With this code, we are about <±8% accurate for the Serial Output. You can only use this trick on the most critical tasks, and only on one. In this section of code, we are constantly checking the delta of time from the "FIRST_TMR0_O" reading and the current reading of TMR0. When we are very close to the output time, we jump to line 117. If we are not even close to the proper time, we exit back to the main loop, so we can check the other timers and tasks. Now look at Figure 4 for a description of the Output Pulses, the "Bit units of Time", and the associated state numbers. Note that the activities are spread out over time.

The timer Events help to define the different states and their associated output activities. Each Event is handled in a very short, well-defined set of code as Task #1. Lines 117-131, are a quick state jump table. You need to break all Real-Time code into very short segments — in and then out. Each segment is just a few lines long. You do your activity, save status, and increment to the next state. Notice that OState0_7 code is used several times to output all 8 bits. The state variable is used also to count the number of bits already outputted. The time to the next outputting of a bit is calculated and is adjusted to take out the accumulation of errors in lines 151-152. We make sure of a full "Stop Bit" length in the OStateE code. In the OStateL code, we reset the OState variable to zero, and tell the world that we are not outputting now in line 157. This is important because we use that bit (OState_B) to Signal that we need to protect the variable xmt_byte that changes over several states. We also use it to Signal that we are ready for another byte to output. Look at Task #4. See how it uses this Semaphore to full advantage. We have just explained a Critical Segment variable as outlined in the theory sections of this article.

© 1997 Microchip Technology Inc.

Task #2 reads the Serial Input line 1, running at 4800 Baud. The code structure is very similar to that of Task #1 (Figure 3). Notice that there are more states than the Serial Output Task #1. Once the "Start Bit" is detected, we half step into the "Start Bit" to see if it was a "False Start" or not. We then sample and store the incoming bits to form an 8-bit byte just like Task #1. We sample the "Stop Bit" to see if it is a "Frame Error". We delay another 1/2 bit to get to the end of the "Stop Bit" if there was an "Frame Error" before resetting Task #1's state to 0. Otherwise, we reset Task #1's state to 0, and Signal that we are ready for another "Start Bit". The just received byte is stored in variable "RCV_Storage". A check is made to see if we already sent out the last received byte before clobbering the old byte with the new byte.

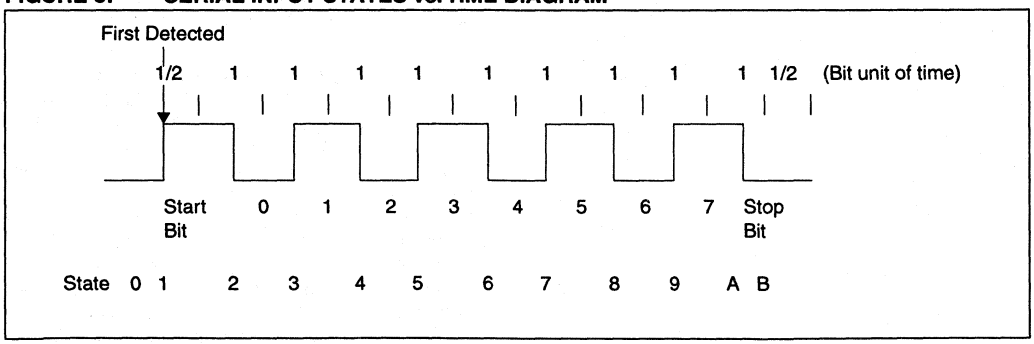
Task #3 reads the Serial Input line 2, running at 4800 Baud. The code structure is the same as Task #2 Figure 3). The received byte is also put into the same storage variable as Task #2 - "RCV_Storage". When either Task #2 or Task #3 receives a valid byte, Task #8's counter is reset. You can up the Baud rate of Task #2 and 3 if you lower the output Baud rate of Task #1. Note that for reading the Serial Input Lines, you can be off by ±15% for each sampling, but not accumulatively.

Task #4 finds the next buffered byte to send out through Task #1. Task #4 also controls the order of which byte goes first over another less important byte of data. It can be said that Task #1 Blocks Task #4 from running. You can think of the Serial Output Line as a Shared Resource. The use of Semaphores here allow the Synchronization of data and actions.

Task #5 monitors the Level Reset Input Line and will reset the LED state variable if the line ever goes low. This task is always in the Ready State. This task is said to simply "pole the input line" when ever it can.

Task #6 debounces the seven sensor input lines, running every 20 ms. The variable "T_20_mS_CO" is incremented every 512 µs (Clock Tick) and is compared to the count needed to equal 20 ms. If it is time, the subroutine QCheck_T123 is called to see if Tasks #1-3 are in the Ready State. If any of the Tasks #1-3 are ready, they are ran and we then continue with Task #6. We compare the current value of the input Port_B to see if it stayed the same from the last reading 20 ms back. If the two readings are the same, then Port_B is considered to be stable and the possibly new value is placed in the variable "Old_RB" to be outputted by Task #1. The subroutine D_H_E_L is called to determine the new LED state. We then check if Task #1 was too busy to output the last sensor status byte, if so then that error is recorded.

FIGURE 3: SERIAL INPUT STATES vs. TIME DIAGRAM



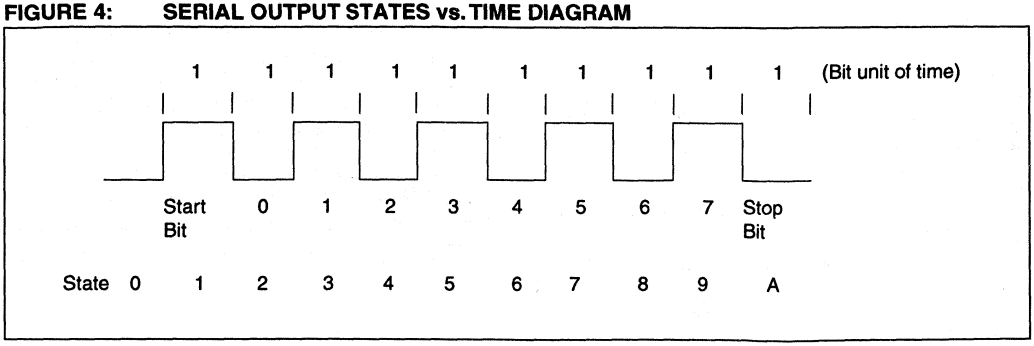


FIGURE 4: SERIAL OUTPUT STATES vs. TIME DIAGRAM

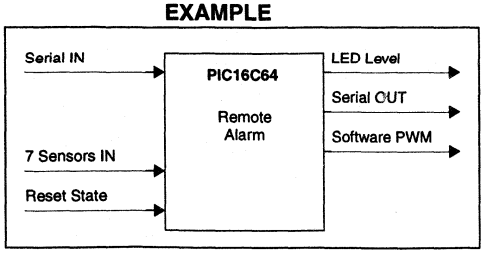
© 1997 Microchip Technology Inc.

Task #7 outputs the Highest Severity Level Indication on the LED. Do_LED starts at line 161, and continues to 276. This task is also broken into small time units of code. It is constantly checking to see if it is time to switch the on/off condition of the LED. The time units for Task #7 are regulated by the code in lines 613-619. 131072 µS = time unit for Tasks #7-9. Task #7 has many state jump tables so it is included in the first 256 bytes of the first page. Lines 168-175 explain the on and off sequences and offs that represent levels of severity of the input status lines. The variable "LED_Mode" has both Task #7's current state number and the sub-state-number for that state's output sequence.

Task #8 is a 5 second lack of input from either of the two Serial input timers. Tasks #2 and #3 will reset the time counter for Task #8, when either receives a full byte. If the time counter "T_5_S_CO" equals 5 secs, then the LED's state is bumped to the highest, and a special byte is sent down the line to the next "Remote Alarm" unit. The counter variable is reset, and count starts all over. We then check if Task #1 was too busy to output the last special status byte, if so then that error is recorded.

Task #9 measures 5 minutes of calm on the 7 sensor lines and then resets the LED's state. Task #9 needs 16 bits of counter power to record 5 minutes of time. The counter variables are reset after being triggered.



`Do_D_H_E_L` determines the LED's next state based on the 7 sensor input status. This subroutine checks each bit to see if it is active and then checks if a change in the LED's current state needs changing.

`Do_Clear_Regs` clears registers 7-1Fh. It leaves the FSR register zeroed out. This is very important for the PIC16C57 chip.

PIC16C64 - "Remote Alarm64" Example

This example is the same as the PIC16C54 example with a few changes to take advantage of the three timers on the PIC16C64 and interrupts. The second Serial input routine was replaced by an example of a software PWM (Pulse Width Modulation) example. The same code as the PIC16C54 example will run on the PIC16C64 with very few changes using only the TMR0 (TMR0). Be sure to read about the PIC16C54 example, as the comments will not be repeated, except to make a strong point.

FIGURE 5: REMOTE ALARM - PIC16C64 EXAMPLE

This example operates at 4 Mhz. By simply increasing the crystal speeds, you can change the input and output Baud rates just as outlined in the section on the PIC16C54 example's crystal selection. By adjusting the constants in the code for the Serial routines, other Baud rates can be achieved at other crystal speeds.

Note: You must use a very stable crystal setup and NOT an RC combination to run these examples.

We will now give a quick outline of the PIC16C64 code example. Lines 1-78 are the equates for this program. Notice that there is no need for jump tables for subroutines to be in the "first 256 bytes" of each page as there was in the PIC16C54 example. Note that the "Reset Vector" is now at code address 0, and the "Interrupt Vector" is at code address 4. Task #1 and 2 have been simplified greatly by using interrupts and timers. For Task #1, we no longer need to use the "trick" any more. It is time to execute once the routines for Task #1 and others are called. The section of code that handles the "Start Bit" (OStateS) lines 106-122 has been changed to setting up TMR2 with its interrupt to trigger the next call to this subroutine. The initial `CALL` to this subroutine was by Task #4, but later calls are due to Timer 2's interrupts. The amount of time until the next interrupt is set by each state's code. This amount is based on the "Bit Unit of Time" which is based on Baud rate and crystal speed. An easy change to the code is to add a software selectable and "changeable on the fly" Baud rate. This is done by having a variable that selects the new Baud rate from the two data tables. One table gets you the Bit Delay value - see line 110. The other data table gets the value to be put into T2CON - see line 107, which selects the Post and Pre-scalers. You may need to adjust the Bit Delay value to take in account the Interrupt Latency. The OStateL state code shuts down Timer2 and its interrupt. See lines 647-676 to understand how we get here by interrupt. Once Timer 2's count equals the count we put into register PR2, we get an interrupt if the following three conditions are true:

1. Not already in an interrupt. When the current interrupt is done, our interrupt will be executed.
2. GIE and PEIE bits are set.
3. TMR2IE bit is set.

Remember to clear the Flag bit as in line 114 before returning from an interrupt. Return from this subroutine will return you back to Task #4 or back to the ISR handle lines 647-676 depending on who called this routine. The Task #7's subroutines are the same as in the PIC16C54 example, lines 151-268. Task #2 is different from the previous example, lines 288-380. First Task #2 uses two interrupts. The INT interrupt on pin RB0/INT is used to detect the "Start Bit". It is very accurate. It is turned off after the detection in I1StateS code. The second interrupt TMR1 is then Enabled in the I1StateS code. Timer1 is then used to cause an interrupt for all the other states for Task #2. Notice that Timer1 has a

© 1997 Microchip Technology Inc.

16-bit counter and we calculate the amount of Clock Ticks until overflow in lines 329-333. In the state code I1StateL, TMR1 is shut down, and the INT interrupt is now Enabled so as to detect the next input byte. The initializing of the PIC16C64 variable takes place in lines 383-426. The initializing of the tasks take place in lines 427-451. Notice that the last bit to be set is the GIE bit in line 451 after ALL is setup. There are several ways to execute the Task #3-9 code: by Timer0 overflow interrupt, by having the code be in the background as in this example. The trade-offs are many, and too deep for this article. Notice that the subroutine QCheck_T123 is not needed in this method. Timer0 overflow interrupt sets the flag: Time_Bit. The code in lines 454-457 can be considered the "IDLE Task" on some systems. It waits for a Clock Tick from TMR0's overflow. Task #3 is new, and is a simple 8-bit software PWM. Lines 459-478 show how to have 8 bits of ON, and 8 bits of OFF. This task has two states, on and off. You may add to the code by allowing the Real-Time changing of the 8-bit values under software control. When you change the values in the variables PWM_Out and PWM_In, disable all interrupts by using the following line: `BCF INTCON,GIE`, and enable all interrupts by using the following line: `BSF INTCON,GIE`. The new values will be used at the next transition, thus allowing a smooth change. This task could easily be used in the PIC16C54 example type Kernel. Task #4 is the same except that it calls Task #1's subroutine to initiate the outputting of a byte. See line 503. Tasks #5-9 are the same as in the PIC16C54 example. The subroutines: `D_H_E_L` and `Clear_Regs` are the same in both examples. The TMR0 (Timer0) Overflow interrupt ISR (Interrupt Service Routine) is lines 641-645. This ISR will set the Time_Bit bit and clear the Flag that caused the interrupt. The Interrupt code lines 647-676 handles the saving of the Context Registers and the restoring of the Context Registers (W, Status, FSR) and by checking the order which interrupts are to be handled first - see lines 656-669. A very important line is 654. You must set the memory page pointers here for the ISR routines! Line 676 is the only place that an interrupt is allowed to return and set the GIE bit (`RETFIE`).

Reentrant example

See Appendix E for the short code segment. This code corresponds to lines 302-332 in the PIC16C54 example. The purpose of reentrant code is to allow two or more tasks to use the same code at the "same time". See the section about reentrant in the theory section of this article. Notice how the registers 18h-1Bh match the registers 1Ch-1Fh, both starting with the state variable for the two tasks using this routine. Note how Task #2 and Task #3 load a pointer to the state variable for their task before calling DO_I State code. By using the FSR register as a pointer, and incrementing or decrementing the FSR register, you can keep the variables in the two tasks straight even if the two tasks are using different code in the subroutine at any one time. This method is not easy to implement, as can be seen, so use two copies for readability instead, like the PIC16C54 example.

SUMMARY

Now that the PICmicro family of microcontrollers have a way of executing Real-Time Programs, using the techniques outlined in this article, there is very little that PICmicros cannot do! Much more than was ever dreamed before. Many of you will quickly understand and start modifying these examples. Great. That means that we have done our job at Myriad. A few of you may want more help. Great. At Myriad Development Co., we LOVE the PICmicro family.

APPENDIX A:

A Real-Time Vocabulary

ASYNCHRONOUS - An activity that can happen at any moment, at any time.

BLOCKING - The act of wanting to waiting for an EVENT before continuing.

CLOCK TICK - The heart beat that all time is based on.

CONTEXT/TASK SWITCH - Module that saves and restores the states of a task.

CRITICAL SECTION - Section of code or hardware - only one user at a time.

DEADLOCK - That is where two TASKs are waiting for each others resources.

DISPATCHING - The act of starting up a TASK to run from an RT Kernel.

DYNAMIC PRIORITIES - The ability for TASKs to have there PRIORITIES changed.

DYNAMIC TASKING - The creation and the killing of TASKs.

EMBEDDED SYSTEM - An internal system that operates all by itself.

ENABLING/DISABLING INTERRUPTS - Controlling the interrupting processing.

EVENT - Timer, communication, handshaking, interrupts, data, external events.

EVENT FLAGS - The storage of current states or info on what has happened.

INTERRUPT - A hardware event (external/internal) that triggers a jump to the ISR routines to handle that event.

INTERRUPT LATENCY - How long it takes once signaled to start an ISR.

INTERRUPT RECOVERY - How long it takes once interrupted to return back to code.

KERNEL - Module that controls TASKs, INTERRUPTs, and intertask communications.

MAILBOXES - Away to pass data from one TASK to another.

MASKABLE INTERRUPTS - The ability to control whether an ISR is called or not.

MULTITASKING - The act of several TASKs thinking they own the CPU.

MUTUAL EXCLUSION - The act of allowing only ONE owner to a RESOURCE.

NMI - NON-MASKABLE INTERRUPT - Can not be turned off by software.

READY STATE - Referring to a list of TASKs ready (having work to do NOW).

REENTRANT - Code that can be used by several TASKs at the same time.

RESOURCE - Data structures, display, I/O hardware, non-reentrant routines.

RUNNING STATE - Referring to the ONE task owning/using the CPU currently .

SCHEDULER - That part of a kernel that decides which TASK to run next.

SEMAPHORES - A protocol to control RESOURCES, SIGNAL EVENTS, synchronize tasks.

SIGNAL - The act of one task signaling another that something has happened.

STATE MACHINE - An important concept in dividing a job into TASKs & ISRs.

SYNCHRONIZATION - Were TASKs synchronize over data or at a special time.

TASK PRIORITY - Each TASK is ranked as to its importance to getting done.

TASK/THREAD - Code that is defined by a small coherent job/work to be done.

TIME SLICING - The act of giving the same amount of "time" to each TASK to run.

TRAP - A software caused interrupt, useful for system access.

WAITING STATE - Referring to a list of TASKs waiting for an EVENT(s).

PICmicro™ Microcontroller Oscillator Design Guide

Author: *Kim Peck*
Consultant

Designing a clock oscillator without some knowledge of the fundamental principals of acoustic resonators is possible but fraught with the uncertainty of "cut and try" methods. While the oscillator may be made to run with the chosen resonator, it is quite likely that the unit will be slightly off the intended frequency, be grossly off frequency because it is operating on an unintended mode, or have unacceptable temperature characteristics because the wrong resonator was chosen for the application.

This application note is primarily for informational purposes. It is intended to help the designer of clock oscillators understand the parameters of crystal resonators and the terminology of the crystal resonator industry, both of which tend to be somewhat mysterious and arcane to the uninitiated. Details of crystal cuts and rotations, for instance, are of no use to the oscillator designer, only the designer of crystals. The oscillator designer still needs to understand and be able to predict the performance and trade-offs associated with these parameters. This is not an in-depth or rigorous treatment of acoustic resonators, but a practical guide, which should allow the designer to gain a basic understanding, and to help in choosing and specifying resonators.

INTRODUCTION

The main purpose of the oscillator in PICmicro microcontrollers, or almost any other microcontroller, is to provide a reliable clock for the controller processes. At the most basic level, the clock provides a timing interval to account for circuit rise times and to allow data to stabilize before that data is processed. This is a "synchronous" process. The clock also provides an opportunity for the programmer to perform time keeping of several types. In the PICmicro, the clock also drives hardware dedicated to timekeeping. The applications may include keeping "real time", or timing sensitive processes such as serial data communication. The accuracy of these timing applications is dependent upon the accuracy of the clock oscillator.

Design Challenges

The PICmicro microcontrollers offer unique design challenges because they are uniquely flexible. Flexibility usually demands difficult decisions on the part of the designer, but offers otherwise unattainable performance. The multiple oscillator options and wide range of operating voltages require awareness of advantages and trade-offs of various configurations. The PICmicro designer must be able to accurately predict stability performance of various configuration and then obtain that performance from the PICmicro clock in order to successfully implement these functions.

Wide Voltage Range

The PICmicro operates over such a wide voltage range that the oscillator parameters may be the limiting factor in the operation of the controller. If low power operation at low voltages is desired, the loop gain must be raised in order to insure reliable clock operation. If a nominal supply voltage is available, the loop gain must be reduced in order to prevent excessive power dissipation in the crystal. If battery operation is intended, then a careful balance must be struck between reliable operation at the low voltage, and damaging delicate resonators, or spurious oscillations at the high voltage when the battery is fresh.

Low Power

The outstanding performance of the Low Power option places a burden on the designer who would take advantage of this feature. The frequency chosen must be the lowest practical. Attention must be paid to the reactances associated with the crystal so as not to excessively load the oscillator output and cause excessive power consumption.

Low Cost

The low cost of the PICmicro series presents a challenge in finding commensurately low-cost components to complete the design. The relationship between cost and performance when various types of resonators are considered, is far from linear. The low cost of PICmicro microcontrollers, may remove them from the position of being the cost driver in some designs, challenging the designer to aggressively seek cost reductions in components which were previously not considered. The second challenge offered by such economical parts is that of new applications which were not considered practical before the advent of PICmicro processors.

THEORY OF OSCILLATORS

Conditions necessary for oscillation

An oscillator is a device which operates in a closed loop. This condition can be difficult to analyze, but the techniques for analysis are as valid for motor speed controls as it is for phase lock loops and oscillators. Oscillators are somewhat unique in that they are intentionally unstable, but in a controlled manner. In order for oscillation to occur in any feedback system, two primary requirements must be met. The total phase shift must be zero or 360° at the desired frequency and the system gain must be unity or greater at that frequency.

The Ideal Oscillator

The ideal oscillator has a perfectly flat temperature coefficient, is 100% power efficient, has no limits on operating frequency, has no spurious modes, has a perfect output wave shape, and is available in the high degrees of miniaturization which exists in semiconductors. This oscillator of course, does not exist. The primary limiting factor for most oscillator parameters is the resonator. The following is a discussion of the trade-off, potential advantages and primary disadvantages of several popular types of resonators, and how they will behave in a PICmicro oscillator design.

RESONATOR BASICS

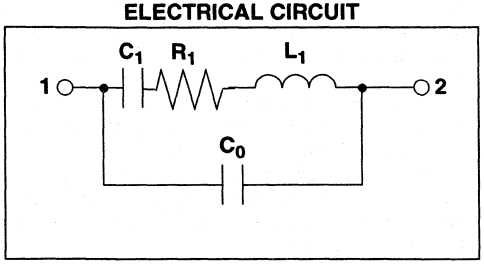
There are several types of resonators available to the designer of microprocessor clocks. They all provide trade-offs between performance, size, frequency range and cost. Resonators for clock oscillators usually fall into two basic groups. These are quartz and ceramic resonators. Historically, ceramic resonators came into use in oscillators much later than quartz crystals and derive all of their terminology and conventions from the longer history of quartz crystals. A third type of clock oscillator is the RC (resistor / capacitor). This oscillator is a relaxation type, and employs no resonator as such. While this type requires the same basic conditions for oscillation to occur it is better described using different techniques and analogies.

Quartz Resonators

Quartz is the crystalline form of silicon dioxide. This same material, in amorphous form, is commonly found as beach sand and window glass. As a crystal, it exhibits piezoelectric effects as well as desirable mechanical characteristics. A quartz crystal resonator is an acoustical device which operates into the hundreds of MHz. Its resonance and high Q are mechanical in nature, and its piezoelectric effects create an alternating electrical potential which mirrors that of the mechanical vibration. Although it is one of the most common of naturally occurring crystals, natural quartz of sufficient size and purity to be used in the manufacturing suitable resonators, is unusual and expensive. Almost all modern resonators are manufactured using cultured quartz, grown in large autoclaves at high temperatures and pressures.

Whether naturally occurring or cultured, quartz crystals occur as six-sided prisms with pyramids at each end. This raw crystal is called a "boule". In an arbitrary coordinate system the Z, or optical axis, runs the length of the crystal, connecting the points of the pyramids at each end. If one views this hexagonal bar on end, three lines may be drawn between each of the six opposing corners. These are called X axes. Perpendicular to each X axis is a Y axis, which connects opposite pairs of faces. When the boule is cut into thin plates or bars called blanks, the cut of the saw is carefully oriented either along, or rotated relative to one of these axes. Orientation of the saw is chosen based on the mode of vibration for which the plate is intended, and the desired temperature profile. Plates are usually rounded into discs. Types of crystal cuts are named for the axis which the cutting angle is referenced when the blanks are cut from the boule. After being cut and rounded, the blanks are lapped to frequency and any surface finishing or polishing is done at this time. Electrodes are deposited on the blanks by evaporation plating, and the blank is mounted in the lower half of the holder. It is finished to the final frequency by fine adjustments in the mass of the electrode plating, either by evaporation or electroplating. The top cover is then hermetically sealed by one of several methods, which include cold welding and solder sealing.

Most crystals made today are A-T cut, which employ a thickness mode. This mode provides the highest frequency for a given thickness of the plate, and the best possible frequency stability over most temperature ranges. Many other modes of vibration are possible. Flexure modes are usually bar shaped, and are used for low frequency (near 100 kHz) resonators. Tuning fork crystals are a special case of this type.



© 1997 Microchip Technology Inc.

Ceramic Resonators

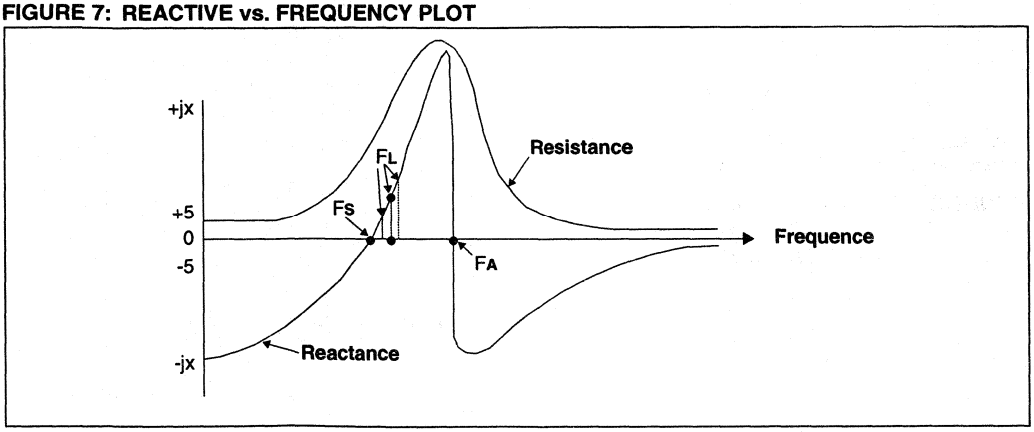
Unlike quartz resonators, which are cut from a single crystal, a ceramic resonator is molded to a desired shape instead of grown. The material is polycrystalline form of barium titanate, or some similar material. The electrical model is almost identical, with the addition of one resistor, as the material is intrinsically conductive. The material is artificially made to exhibit piezoelectrically active by allowing it to cool very slowly, as in growing a quartz crystal (not nearly as long a time), but in the presence of a strong electric field. The molecular electric dipoles align themselves with the applied electric field. When the material has cooled, the alignment of the electric dipoles is retained, which is equivalent to piezoelectricity.

These materials have elastic properties that are not as desirable as quartz, and so their performance is not equal to that of quartz resonators. Specifically, ceramic resonators have far lower Qs and frequency deviations due to temperature on the order of 1000 to 10000 times greater than that of an A-T cut quartz crystal. The cost of ceramic resonators is much lower however, because the material is not grown under the extreme and expensive conditions that are necessary for quartz. They are also much smaller than A-T cut quartz resonators, particularly at frequencies under 2 MHz.

FIGURE 6: RESONATOR EQUIVALENT ELECTRICAL CIRCUIT

Since the "Q" of ceramic resonators is generally lower than quartz, they are more easily pulled off frequency by variations in circuit or parasitic reactances. This is desirable if a circuit is designed with a variable element, as greater tuning range is realized. It is not desirable if the highest possible stability is the design goal, because the resonator will be more susceptible to variation in parasitic reactances, such as capacitors formed by circuit board etch, and temperature variations of intended circuit reactances. These variances will add to the already substantial deviation over temperature of the resonator itself. If your stability needs are modest however, ceramic resonators do provide a good cost / performance trade-off.

Equivalent electrical circuit



The circuit shown in Figure 6 is a close approximation of a quartz or ceramic resonator. It is valid for frequencies of interest to the PICmicro designer. Not all of the parasitic elements are shown as they are not important to this discussion. In this circuit, L_1 and C_1 are the reactances which primarily determine the resonator frequency, while a series resistor represents circuit losses. A shunt capacitor, C_1 represents the holder and electrode capacitance.

Because L_1 and C_1 are associated with mechanical vibration of the crystal, these are commonly referred to as motional parameters, while C_1 is called the static capacitance. The reactance of L_1 and C_1 are equal and opposite at the series resonant frequency, and their magnitude is very large as compared to R_1. The phase shift at the series resonant frequency is zero, because the reactances cancel. The series resonant frequency is calculated as shown in Equation 1.

EQUATION 1: SERIES RESONANT FREQUENCY

$$F_s = \frac{1}{2\pi\sqrt{L_1 C_1}}$$

FIGURE 7: REACTIVE vs. FREQUENCY PLOT

The actual series resonant frequency as determined by the zero phase point is slightly lower than this calculation because of the effects of C_0, and for practical purposes can be considered identical. This fact may be useful to those designing tunable crystal oscillators. These resonator parameters are generally considered to be constant in the region of the main resonance, with the exception of R_1. A plot of reactance over frequency is shown in Figure 7. The point labeled F_S is the series frequency, while F_L, is the frequency where the crystal is resonant with an external load capacitor. Operation at this point is sometimes called parallel resonance. F_A is the frequency where the crystal is anti-resonant with its own electrode capacitance. Only the region below F_A is useful as an oscillator. Notice that the resistive component begins to rise, before F_S and continues steeply above F_S. This makes operation with small load capacitors (large reactances) difficult. One must be sure that if the resonator is specified to operate at a load capacity that the maximum value of R_1 is specified at that operating point. The zero phase shift point is the most common method of identifying the exact series resonant frequency. When the series frequency is known, operation at a load reactance is easily calculated as follows:

EQUATION 2: OPERATION AT A LOAD REACTANCE

$$\frac{\Delta F}{F_S} = \frac{C_1}{2(C_0 + C_L)}$$

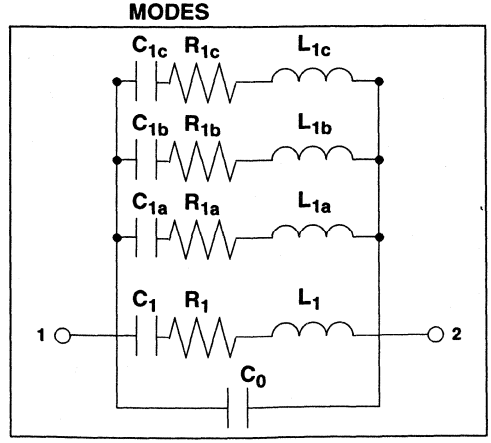
where ΔF is the deviation from F_S to F_L, F_L is the operating frequency when in series with a load capacitor, F_S is the series resonant frequency (without any load capacitor), and C_L is the load capacitor.

The value of R_1 at the frequency F_L can be approximated by:

EQUATION 3: VALUE OF R_1 AT THE FREQUENCY F_L

$$R_1 = R_L\left(\frac{C_L}{C_0 + C_L}\right)2$$

The reactance slope in the region of the series resonance can be approximated by:



EQUATION 4: REACTANCE SLOPE IN REGION OF SERIES RESONANCE

$$\frac{\Delta X}{\left(\frac{\Delta F}{F}\right)} \approx \frac{10^6}{\pi F C_1}$$

where ΔX is the reactance difference, in Ω, from series, at which of course the reactance is zero. $\Delta F/F$ is the fractional frequency deviation from series resonance. F is the frequency of interest in MHz, and C_1 is the crystal static capacitance of Figure 6. This is only accurate in the region of series resonance and the accuracy declines as frequencies further away from series are considered. This parameter is useful in determining the optimum C_1, which the designer might specify in order to have the correct tuning sensitivity for any frequency adjustments, or given a crystal C_1, what tuning sensitivity will result from various reactive components.

The ratio of the reactance of L_1 or C_1 to R_1 is arbitrarily designated as Q. This is also known as quality factor, and applies to any reactive component. The series resonant frequency of the crystal is the sum of the total series reactances. Quartz A-T cut crystals exhibit spurious modes which are always found at frequencies just above the main response. These are always present and are not associated with activity dips. There are also odd ordered mechanical overtone modes. Any of these modes (spurious or overtone) can be modeled as duplicates of the primary RLC electrical model, and placed in parallel with it (Figure 8). Notice however, that there is only one C_0. Near the resonance of each series circuit, the effects of the other resonances may be considered negligible. Each resonance of course, has its own motional properties, the one of primary interest here is the R_1 of each resonance. The R_1 usually increases with increasing overtones, making higher overtones more lossy. The PICmicro designer must take care to specify the crystal spurious to always be of higher resistance than the desired response. This can be achieved in a well designed resonator. A heavy metal such as gold, as an electrode, will discourage higher overtones, by virtue of its higher mass. Crystals designed for high frequencies, almost always use a lighter material, such as aluminum. Electrode size also plays an important role.

FIGURE 8: EQUIVALENT CIRCUIT FOR SPURIOUS AND OVERTONE MODES

OSCILLATORS

Phase and Gain

As stated earlier, two conditions must be met for oscillation to occur. The phase shift must be zero or 360° at the desired frequency, and the total system gain must be one greater or at that frequency. Logic gates or inverters are convenient for this purpose. They have large amounts of gain, limit cleanly, produce square waves, and their output is appropriate for directly driving their respective logic families. Most oscillators in this family use an inverting amplifier, as shown in Figure 13. The phase shift is 180° through the gate, and the two reactances at either end of the crystal are chosen to provide an additional 90° each, bringing the total to the required 360°. The primary effect of changes in phase is to shift the operating frequency (to tune the crystal). The primary effect of changes in gain is to cause the oscillator to cease functioning when reduced, or cause spurious modes and excess power to be dissipated in the crystal when increased.

Oscillation will occur at the frequency for which the total phase shift is 360°. This is true for any frequency (or resonator response) for which the gain is greater than unity (including unwanted responses). The series resistor (R_S) is used to adjust the loop gain, and to provide some isolation from reactive loads for the amplifier. The lower limit of loop gain is determined primarily by the need for sufficient excess gain to account for all variations, such as those caused by temperature and voltage (not just in the amplifier, the crystal resistance may change as a function of temperature). The upper limit of loop gain should be that where it becomes possible (or at least likely) for the oscillator to operate on a spurious mode. In some resonators damage to the resonator is the overriding concern regarding drive level. If the stability requirement is rather "loose" the stability problems may not be the first indications of trouble. Excessive drive levels in tuning fork types for instance, may cause damage to the point that the crystal unit fails. It is important to estimate drive levels before operation begins, include and adjust a series resistance appropriately, and by measurement, verify the results.

Estimating Drive Levels

The drive levels may be estimated with the following steps. First find load impedance presented by crystal network, including phase shift capacitors and amplifier input impedance. This is found by the following:

EQUATION 5: LOAD IMPEDANCE

$$R_n \cong \frac{X_c^{\,2}}{R_S + R_{OSC1}}$$

where R_N is the network impedance. X_C is the reactance of one phase shift capacitor (assuming they are the same). R_{OSC1} is the input impedance of the OSC1 pin (should include reactance). R_S is reactance + resistance at operating frequency ($R_S + X_S$).

The current delivered into this impedance is found by:

EQUATION 6: CURRENT DELIVERED

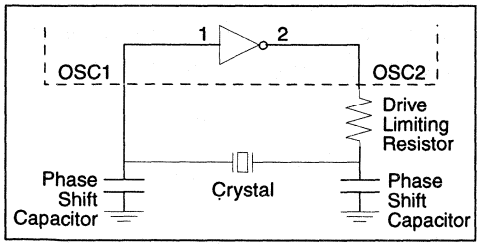
$$I_n \cong \frac{V_{OUT}}{R_S + R_N}$$

where I_N is the RMS current drawn by the network. V_{OUT} is the OSC2 output RMS voltage. R_N is calculated above. R_S is described above. The current which passes through the crystal then is found by:

EQUATION 7: CURRENT THROUGH CRYSTAL

$$I_S \cong \frac{V_C}{R_S + R_{OSC1}}$$

The power dissipated by the crystal is then found by I_S squared times the crystal R_1.



Controlling Drive Levels

When designing any oscillator, one should take care not to lower the loaded Q of the resonator by inserting any resistive components between the phase shift capacitors (or any other reactive components) and the crystal. If It is necessary to reduce the drive level to the crystal, or lower overall loop gain, resistance should be inserted between the amplifier output, and the crystal (Figure 9). This method is much better than changing load reactances, which will have no significant effect on gain until the frequency has been pulled well away from the design center. This will also have the more significant effect of raising operating current, because if no series resistor is present, larger reactance of the phase shift capacitor will load the OSC2 output directly. If a very low drive level is required, such as with tuning fork type crystals, the series resistor is the best method. The resistor should be adjusted until the unit just runs with a typical crystal at the lowest operating voltage, and resulting drive measured at the highest operating voltage. The actual resistor value is best determined experimentally with a representative sample of crystals, and a broad range of values should be satisfactory. In general, the point where oscillation stops for any crystal unit (within specified parameters), is the resistor's upper limit. The lower limit may be 0 Ω, for a less fragile crystal type, depending on the operating frequency. If no spurious or overtone modes are encountered, it is likely that the oscillator may have relatively little excess

© 1997 Microchip Technology Inc.

gain at that operating frequency. If resulting drive level at higher voltage is still unacceptable, then supply voltage variations must be reduced.

FIGURE 9: PICMICRO OSCILLATOR CIRCUIT

Measuring Drive Levels

Drive levels cannot be easily measured with any certainty by reading voltages at each end of the crystal. This is because of the phase shift which is present in varying degrees, depending on how close to series resonance of the crystal, the oscillator is operating. It is much more reliable and accurate to measure the crystal current with a clip-on type oscilloscope current probe. This probe may require an outboard amplifier in order to measure very low drive levels. It is also important to accurately know the series resistance of the crystal under the same operating conditions of frequency and drive level. This information is easily obtained with a network analyzer or a modern crystal impedance meter. While the oscillator designer may not be equipped with such a meter, the manufacturer of the crystal most certainly should be, and resistance data should be provided for at least one, and perhaps several possible drive levels, if variations in drive are expected.

UNDESIRED MODES

Mechanical resonators are not perfect devices. They exhibit many spurious responses, either continuously or over narrow temperature ranges. If a quartz resonator is swept with a R.F. network analyzer, several smaller responses will be seen just above the main response. These are always present in mechanical plate resonators. For oscillator applications, they must be specified to have a lower response than desired mode. The crystal designer can control these to some extent by varying plate geometry and electrode size. These spurious modes are usually similar in nature to the main response, and do not vary in relation to it to any important degree. Other spurious are caused by completely different modes of vibration, and have radically different temperature curves. These may lay unnoticed until a temperature is reached where the two temperature curves intersect. At this one temperature, the spurious mode traps some of the mechanical energy created by the main mode. This causes a rise in the series resistance, usually accompanied by an unacceptable change in frequency. With a very small change in temperature, the effect will disappear. This is know as an "activity dip", activity being a dimensionless mechanical property which is inversely proportional to resistance. These can also be successfully specified away in most resonators. Any response of the resonator, be it from spurious, or mechanical overtones, may control the oscillator output frequency if phase and gain criteria are met. In some unusual circumstances, the oscillator may run simultaneously on two or more modes. In general, the fundamental response of any mechanical resonator is usually the largest (lowest loss), and the oscillator will run on this response if no other circuit elements are introduced which favor higher frequencies. If the desired frequency is such that the third overtone, begin the first available (mechanical overtones are always odd ordered), is below 15 or 20 MHz, the oscillator may occasionally run at around three times the desired frequency. This may only happen every third or fifth time the unit is activated. The unit may start correctly, but jump to higher overtone when the unit is exposed to a very narrow temperature range, but remain there after the temperature has changed. The best fix for this problem is usually a reduction in overall loop gain. Occasionally a crystal may have a very low resistance at overtone modes as well as the fundamental. In this case it may be useful to specify overtone modes, as spurious and guarantee at least a -3dB difference between the overtone and the fundamental responses. This condition will already exist for 99% of the resonator designs, and is not usually specified.

It is also best not to insert any large reactances which would compete with the Q of the crystal for control of the oscillator output frequency. If this is done (say, for the purpose of adjusting the oscillator frequency), the tuning reactance (usually a variable capacitor) must be accompanied by an equal reactance of the opposite sign in order to bring the total loop reactance back to zero (unless the crystal is designed to operate with that large series reactance, which could cause other problems). If the oscillator is pulled far enough from the series frequency, the rising crystal resistance will lower the loaded Q of the crystal until the reactance slope of these components competes with that of the crystal. This will cause the oscillator to "run" on these components instead of the crystal, the loop being completed by the C_0 of the crystal. The component with the steepest reactance slope will control the frequency of the oscillator. The tuning sensitivity of these components will also be directly proportional to the magnitude of their reactances. Any unwanted variation of these components will have increased consequences for the stability of the oscillator. Another source of spurious is a relaxation mode which is caused by the amplifier bias circuits and the phase shift capacitors. The loop is completed through the crystal C_0. Again, a series resistor will usually solve this problem, although in some cases the amplifier bias values may need to be changed.

© 1997 Microchip Technology Inc.

Load Capacitors

In gate or logic type oscillators, the crystal is usually manufactured to be slightly inductive at the desired frequency, and this inductance is canceled by the two phase shift capacitors. The primary purpose of these capacitors is to provide the phase shift necessary for the oscillator to run. Their actual value is relatively unimportant except, as a load to the crystal, and as they load the output when no series resistor is used. These reactances are the sum total of selected fixed capacitors, any trimmer capacitors which may be desired, and circuit strays. If a loop is considered from one crystal terminal through one phase shift capacitor through ground and the second phase shift capacitor, to the second crystal terminal, all the reactances including the crystal motional parameters must add up to zero, at the desired operating frequency.

As a crystal load, all circuit reactances external to the crystal should be thought of as a series equivalent. In order to know the total load reactance seen by the crystal, the total shunt reactances on either terminal are summed, and the series equivalent is calculated. This should include the OSC1 and OSC2 terminal reactances, but these are negligible if they are sufficiently small when compared to the phase shift capacitors. The value of these capacitors, is then chosen to be twice the specified load capacity of the crystal. It some adjustment of the frequency is necessary, one of the phase shift capacitors can be chosen at a smaller value, and the difference made up by a variable capacitor placed across it. An alterative method is to place a larger value trimmer capacitor in series with the crystal. The value of the trimmer capacitor must be chosen along with the phase shift capacitors, all in series, to give the correct load capacity. Frequency should not be adjusted by shunting the crystal with a capacitor. If it is desired to use a crystal which is finished at series resonance, an inductor of equivalent reactance to half of the phase shift capacitor, must be placed in series with the crystal.

STABILITY

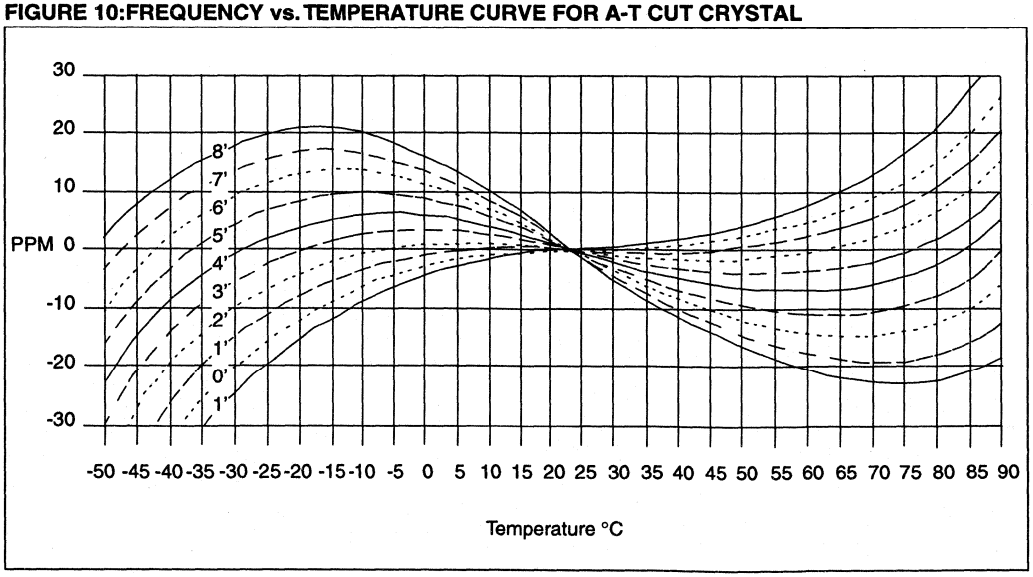
General

Frequency stability is the tendency of the oscillator to remain at the desired operating frequency. Its deviation from that frequency is most conveniently expressed as a dimensionless fraction, either in parts per million (PPM) or a percentage. Absolute deviations in Hz must always be referenced to the operating frequency, which is less convenient and not universal. In the following discussion of temperature characteristics, one can see that the fractional deviations are universal without any direct effect of operating frequency. In order to calculate a total frequency stability, various separate elements must be identified and quantified. Not all parameters of frequency stability are important to each design. The various items which effect the frequency of an oscillator are: the temperature profile of the resonator, the resonator's room temperature frequency tolerance (also known as "make tolerance"), its long term frequency drift which is normally know as ageing, and its sensitivity to other circuit reactances. Is it possible to adjust it to the exact desired frequency? If not, how big is the error due to other component tolerances. Due to the complexity of this combination, most crystal manufacturers will offer a standard crystal which is guaranteed to be ±100 PPM over -20°C to +70° C, or ±30 PPM over -0°C to +60°C. Note that the temperature coefficients of some of the curves in Figure 7 are much smaller than this over the same temperature range. Large portions of these tolerances are devoted to make tolerances and circuit component tolerances. The room temperature items can be relatively simple to specify in the resonator design. If careful attention is paid to specifying the crystal, or designing the oscillator to accommodate a standard crystal, more of the total stability requirement can be devoted to the temperature profile, or the overall stability requirement can be reduced. The temperature profile, however, is subject to other circuit influences external to the resonator. These may be somewhat more difficult to perceive and control. If, for example, the chosen resonator is an A-T cut or tuning fork type, possessed of a nominal temperature profile of less than 50 PPM over the desired temperature range, external influences, such as capacitor temperature coefficients, may play an important part in the overall stability of the oscillator. If however, a ceramic resonator is chosen, it's temperature profile of 40 to 80 PPM/C will dominate the oscillator stability, and 5 or 10 PPM shift from changes in amplifier impedance or capacitor temperature coefficients will not be important. The designer may choose a crystal even when the overall stability specification (of the oscillator) does not require it, giving large design margins. If any amount of testing or adjustment of the oscillator frequency is needed with the lower cost resonator, the crystal may be more cost effective. When designing any resonator as part of a simple logic type oscillator circuit (Figure 9), some attention should be given to swapping the amplifier reactances (that is to make them a very small part of the sum total circuit reactance) with the phase shift capacitors, and any other circuit reactances. This is at least, a good design practice. The largest reactance has the most effect on the operating frequency. It follows then that the motional parameters, which have very large reactances, dominate the equation for the total reactance, and so the operating frequency of the oscillator.

Another good design practice, is to specify only as much pullability as is required to accommodate the make tolerance and ageing of the resonator, and tolerance of other circuit elements. Pullability is a function of the ratio of C_1 to C_0. As the reactance of the crystal C_1 increases it becomes more stable in relation to outside reactive influences. It also becomes more difficult to intentionally adjust its operating frequency. If too high a C_1 is specified, the resonator will be sensitive to external influences, and the effect of these influences may be as large or larger than the temperature profile. If the

© 1997 Microchip Technology Inc.

C_1 is to small, it may not be possible to adjust the unit exactly to the desired operating frequency. The small electrode size needed to realize a low C_1 may also concentrate the mechanical energy in a very small percentage of the blank, causing unpredictable behavior. In order to quantify pullability in terms of C_1 to C_0 ratio and load capacitance (refer to the Equivalent Electrical Circuit section).



A-T Cuts

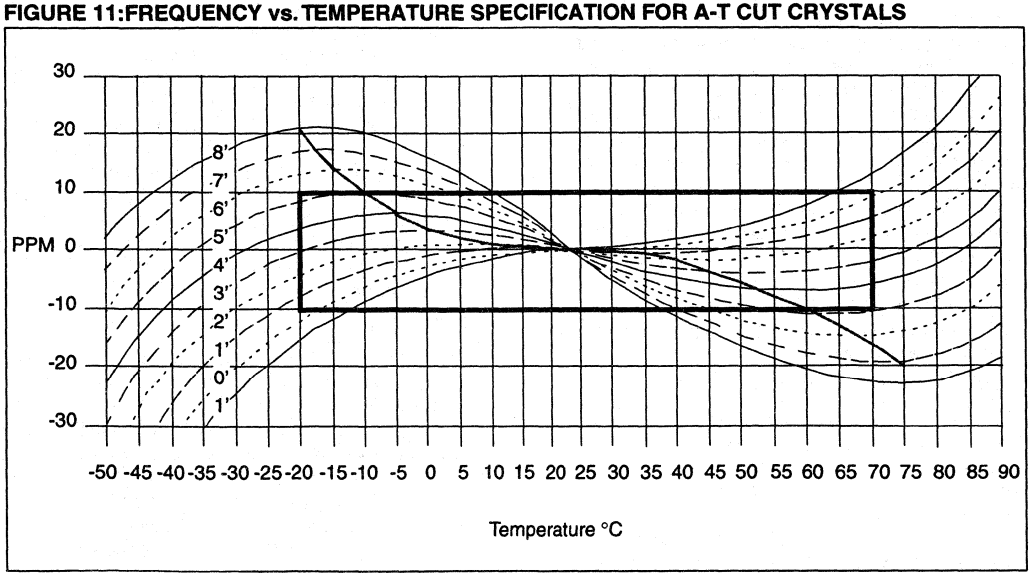
The A-T cut crystal and its variations, is by far the most popular resonator in the world today. A-T cut crystals are popular because the "S" shaped temperature curve is centered very near room temperature, typically around 27°C. This temperature profile is compact, symmetrical, and most manufacturers are able to provide good control of the cut angle.

Because most of the crystals manufactured in the last 40 years have been A-T cuts, they are very well understood and documented. This is important because while temperature coefficients can be calculated from the mechanical properties, such as elastic constants, they can (and have been) measured with much more accuracy. When the temperature coefficients are accurately known, the temperature profile can be calculated for an individual set of conditions. Figure 10 is a family of temperature curves of A-T cut crystals used for this purpose. Each curve represents a possible crystal at incremental changes in the cut angle. The practical limit for accuracy of the cut is about ± 1 minute of angle, and in any lot of crystals there will be variations of about ± 1 minute. The designer will create a box around these curves using the desired temperature limits as the vertical sides, and the desired frequency tolerance for the horizontal lines, as shown in Figure 10. If the curves are spaced at intervals of one minute of angle, then the specification is a practical one if three of these curves (± 1 minute) fit within the outlined area. It is possible to purchase crystals with a closer tolerance, but this is mostly a matter of yields, rather than a better process. The steeply increasing cost will reflect the higher reject rate.

When purchasing a crystal, do not attempt to specify a specific angle, rather specify a frequency deviation between turning points, with tolerances. The mathematics of these curves, is represented by a linear term between two turnover points, whose inflection point is at or near 27°C. The temperature above the high turnover and below the lower turnover, are characterized by cubed terms (very steep). This was described by Bechman in the late 1950s as a third order polynomial. This can be seen in Appendix A. Notice that as the linear portion of the curves between turnover points approaches zero slope, the turnover points move closer together. This tends to limit the temperature range over which very small stabilities can be realized. If the required operating temperature range is inside of the range of the turnover points, a low angle is desirable. If so specified, most manufacturers will provide a crystal with temperature profiles on the order of ±5 to ±10 PPM over modest temperature ranges for a reasonable cost. If the desired operating temperature range is outside of the range of turnover points, a higher angle is desirable in order to keep the frequency at extreme temperatures within the same realm as deviation between turnover points. This may approach ±60 PPM for large temperature ranges, but is still far less than the smallest deviations achievable with other resonators over the same temperature range.

FIGURE 10:FREQUENCY vs. TEMPERATURE CURVE FOR A-T CUT CRYSTAL

© 1997 Microchip Technology Inc.



What is not immediately obvious is that if a linear frequency shift with temperature is applied to a frequency curve the result is a rotation of the curve which will eventually match another member of the curve family. There is no other distortion of the temperature curve if the frequency shift is linear, such as from a temperature compensating capacitor. This fact also gives a convenient graphical technique to estimate the effect of temperature coefficients of other components. There exist several flaws in this picture of the A-T cut temperature profile, which may prevent the PICmicro designer from completely realizing the stability suggested by the curves in Figure 10.

The first problem which may arise when choosing a crystal angle based upon these curves, is that there may occur some rotation of the crystal angle due to external circuit influences. The most common influences are that of reactive components (inductors and capacitors). Most inductors have a slight positive temperature coefficient, while capacitors are available in both positive and negative temperature compensating types. Non-compensating type capacitors vary greatly depending on the dielectric from which they are manufactured. The best capacitors for frequency determining elements, are ceramic types with NP0 (flat) temperature coefficients. Avoid at all cost, capacitors made from Z5U material. These have a large temperature coefficient and are unsuitable even for supply line decoupling or D.C. blocking capacitors. This is because a slight change in the R.F. impedance which shunts the VCC and VDD pins, will have an effect on the output impedance of the amplifier, and so an effect on frequency. The effect will be on the order of a few PPM, and may well be of secondary importance, depending on the stability requirement. A word about D.C. voltages and crystals. It is permissible to place a D.C. voltage across the terminals of the crystal. This does cause a small change in frequency, but that change is not significant for stabilities of ±5 PPM or greater.

The second problem is one of dynamic temperature performance. When the unit has stabilized at any temperature on the curve, the frequency will agree with the curve. While the temperature is slowing however, the frequency may be in error as much as 5 to 15 PPM depending on the temperature change. This effect is caused by mechanical stresses placed on the blank by temperature gradients. These can be minimized by thermally integrating the crystal, and joining it to a larger thermal mass. One oscillator engineer has been known to attach a block of alumina (ceramic) to both of the crystal pins in order to join them thermally. Any other mechanical stresses placed upon the pins or leads of an A-T cut crystal unit will also result in a dramatic frequency shift (if the unit is not damaged first). This is to be avoided.

5

FIGURE 11:FREQUENCY vs. TEMPERATURE SPECIFICATION FOR A-T CUT CRYSTALS

© 1997 Microchip Technology Inc.

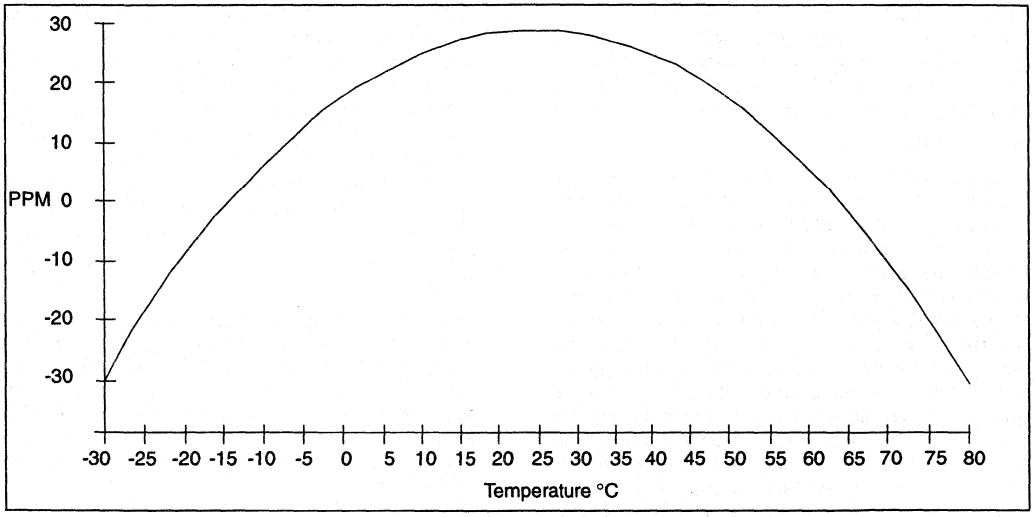
The third item which will cause a deviation from the curves of Figure 10, is spurious response. This is known in the crystal industry as an activity dip. This name originates from a time when the series resistance was referred to as crystal activity, and the frequency change is accompanied by a marked rise in series resistance. This phenomenon occurs when mechanical energy is coupled from the normal thickness shear mode into another undesired mode of vibration. Several other modes are possible for finite plate resonators, and they will usually resonant at frequencies well away from the design frequency. These modes will often have radically different temperature profiles, and may intersect with the profile of the desired mode at only one very narrow range of temperatures (much less than 1°C). This makes an activity dip difficult to spot in normal testing. Those which are discovered are often around room temperature where temperature changes are more gradual. This coupling between modes is greatly effected by drive level, and the best crystal may exhibit a dip if grossly overdriven. Fortunately, most manufacturers today can produce a crystal which is free of significant dips if so specified. As the accompanying rise in resistance is occasionally large enough to cause oscillation to halt, the PICmicro designer should always specify activity dips to be less than 1 PPM, even if the overall stability requirement is much larger than this. In the interest of low cost and flexibility, the designer may also specify activity dip in terms of a maximum change in resistance.

The other important effect on frequency stability of A-T cut crystals, is ageing. This is the long term frequency shift caused by several mechanisms, the most notable being mass loading of the resonator, causing the frequency to shift ever downward. Because this is the primary mechanism, the cleanliness of the interior of the unit is of prime importance. This is in turn greatly effected by the method used to seal the unit, and the type of holder chosen. If the unit is subjected to excessive drive levels, the frequency may age upwards, indicating electrode material is being etched off of the blank. A good general purpose high frequency crystal using a solder seal holder may be expected to age about 10 to 20 PPM / year maximum. Resistance weld holders will average 5 to 10 PPM / year, and for high stability applications, cold weld crystals are available at ageing rates of 1 to 2 PPM / year. The ageing rates of most crystals will decay exponentially, the most change being in the first year. Ageing rates are different if the unit is operated continuously, but aging will continue even if the unit is not operated.

32 kHz Watch Crystals

The typical 32 kHz watch crystal is a tuning fork type. This is a special case of a flexure mode (N -T cut). The unusual nature of this flexure type is that it is indeed shaped like a tuning fork. This shape gives the crystal a very small size for its low frequency of operation and is almost always manufactured in the NC 38 holder. This is a tube 3 mm x 8 mm. This type is available at frequencies from 10 to 200 kHz, although 32.768 kHz is by far the most popular frequency. The frequency is of course 215, which is ideal for time keeping applications, and being so low is ideal for low-power applications. This type is generally less stable than higher frequency A-T types, but is much better than ceramic resonators, the primary attraction being the possibility of very low operating power drains. The PICmicro LP option was designed with this crystal in mind. It has a parabolic temperature profile of about .04 PPM / (°C) 2. The turnover point of the temperature profile is near 25°C. In order to calculate the change in frequency it is only necessary to square the difference in temperature from 25°C and multiply by .04. The temperature profile is shown in Figure 12. The C_1 is on the order of .002 pF, which will make design for frequency adjustment possible but not trivial. The make tolerance is usually about 20 PPM at best, making some adjustment necessary for most applications. The series resistance of this type is very high, on the order of 30,000Ω. It is imperative that care be taken to limit the drive to the crystal. Only a fraction of a mA of crystal current will damage this unit, possibly causing it to cease oscillation. This is best done with a series resistor between the OSC2 pin and the junction of the crystal lead and phase shift capacitor (Figure 12). If the frequency is moving upward in a continuous manner, the drive level is probably too high. A portion of this change will be quite permanent.

Ceramic Resonators



Ceramic resonators are the least stable type available other than the Resistor/Capacitor networks. The temperature profile is a much distorted parabolic function, somewhat resembling that of some capacitors. Temperature coefficient is on the order of 40 to 80 PPM /°C. Typical specified stability for -20°C to +80°C is ± 0.3% (3000 PPM). The C_1 can be as high as 40 pF, making the oscillator extremely vulnerable to circuit influences external to the resonator. The Rs however is on a par with A-T type crystals, at around 40Ω. The positive features of this type are the small size, low cost, and relative simplicity of designing it into a PICmicro part. Because these have a very low Q, the start-up time can be very good, although with the large phase shift capacitors necessary at low frequencies where this would be an advantage, the bias stabilization time will probably dominate the start-up characteristics. If the stability requirements are very modest, this will be a good choice.

R/C Oscillators

The PICmicro parts can be configured to operate with only a resistor and a capacitor as frequency determining elements. This is a very low cost method of clocking the PICmicro. The stability achieved this way is at best only adequate if the only thing required of the oscillator is to keep the PICmicro marching along to the next instruction. The main effects on stability are that of the switching threshold of the OSC1 input, and the temperature coefficient of the resistor and capacitor.

© 1997 Microchip Technology Inc.

FIGURE 12:FREQUENCY vs. TEMPERATURE FOR NC38 TIMING FORK TYPE CRYSTAL

HOW TO CHOOSE A RESONATOR

Type Trade-offs

The primary trade-offs for a designer when choosing a resonator are frequency, size, stability and cost. The lowest cost oscillator is the RC type. This also has the worst stability. The components however tend to be reliable and small, where as resonators are in general larger and have limitations on the amount of physical punishment they can absorb.

A-T cut crystals have the best overall stability and are available in frequencies from 1 MHz to the upper limit of the PIC16C5X part, and in a roughly 0.5 "square package". T-05s and 0.3 "square packages" are available at higher costs, down to a frequency of around 5 MHz A-T cut crystals also have a smaller overall temperature profile which the designer has the best chance of specifying and controlling. Temperature stabilities on the order of ±10 PPM are possible over modest temperature ranges. The A-T cut can be sufficiently reluctant to move off frequency, in response to parasitic reactance changes, that it can fully realize these small deviations over temperature. Such is not always the case with other resonator types or incorrectly specified crystals.

Ceramic resonators offer smaller size and slightly lower cost, although in large quantities, microprocessor grade crystals (±100 PPM) can be competitive. Ceramic resonators will, however, suffer from temperature stabilities in the 0.3% to 0.5% region. This is a significant step down from quartz crystals of any kind.

A designer must choose a resonator which is available in the desired frequency range, has acceptable temperature characteristics, has the lowest cost package which is appropriate for that resonator and is suitable for the mechanical packaging of the oscillator chosen. A-T STRIP resonators are normal A-T cut resonators in which the resonator blank is cut in a long strip rather than a disc, and the electrodes cover a much higher percentage of the quartz blank. A standard A-T cut crystal is a thickness mode resonator, and is usually cut in the form of a disk. The electrodes usually cover only a small portion of the blank. The remainder of the blank, not covered by the electrodes, can be thought of as support structure. By removing this support structure, the size of an A-T cut resonator can be greatly reduced. This type of construction violates several rules having to do with thickness to diameter ratios and greatly reduces the overall mass of the blank. This results in reduced performance in the form of slightly less predictable temperature stability, and dramatically reduced power handling capabilities. The A-T STRIPs are generally available up to 20 MHz, depending on the manufacturer.

Tuning Fork type resonators are a type of flexure mode resonators. They are made from quartz, are very small and available at a cost which is competitive with microprocessor grade A-T cut crystals. Tuning forks have a predictable parabolic temperature coefficient, but any drive power in excess of their very low specified level will deteriorate this quickly.

If stability requirements are beyond what is achievable with a good, A-T cut crystal, the next option is to drive the OSC1 pin with an external oscillator. A good Temperature Compensated crystal(X) Oscillator (TCXO) is expensive when compared to crystal resonators. Stabilities of ±1.0 PPM over large temperature ranges are common.

© 1997 Microchip Technology Inc.

Price discounts for volume quantities do not always occur, because each unit must be individually compensated. This varies greatly with the stability and temperature range, and so of course does the price, which in any case will be much higher than any resonator, which the PICmicro designer might consider.

Size and Performance

It is generally true that as a designer considers resonators of smaller size, he or she is faced with decreasing overall performance. Even the A-T cut crystal, which has the best stability discussed here, will become less stable as size is reduced, especially when plate area is reduced in relation to the spot as in a STRIP A-T. One important factor is the thermal inertia represented by the mass of the blank. The bigger the blank, the slower it is to follow the changes in temperature. When the blank changes temperature too quickly, it will deviate from the temperature profiles. The frequency will return to this point once the blank has stabilized at the new temperature, but may be well off the profile during a temperature slew. This problem becomes greater as the size of the blank is decreased. Some stability issues are due to the unusual motional parameters associated with certain miniature resonators. Some low frequency types have a C_1 which is larger than the holder capacitance (C_0), making it extremely easy to tune and vulnerable to external influences. Most miniature types have parabolic temperature coefficients which are large enough to make them inferior to A-T cut crystals as well as A-T STRIP cuts, and not only suffer from temperature transient problems as mentioned above, but it is also difficult to control their cut angle and finish frequency. Tuning forks have a somewhat more predictable if larger temperature profile. Almost all miniature types will not perform well (or sometimes at all) with excessive drive levels. The drive power to the resonator must be controlled, and usually one resistor is sufficient.

Cost and Performance

The lowest cost timing system, of course, is the RC type. This rugged, low cost and small timing system is useful only for the most forgiving timing applications. If all you need is something to keep the PICmicro moving, this is a good choice. The next step in cost is most likely the ceramic resonator. Its size is smaller than most A-T cut crystals, but its frequency stability is measured in percent, rather than PPM. A high C_1 also makes it vulnerable to external influences.

Tuning fork types, like all others, vary in price. They may cost less than the ceramic resonator, if a standard frequency is acceptable, or may cost more than an A-T cut if a nonstandard frequency is ordered. Tuning forks usually have a very low C_1 contributing to overall stability. This may actually make it difficult to trim to frequency. Tuning forks have a relatively controllable parabolic temperature curve. A-T cuts have the best overall stability but their cost varies greatly. A-T cuts have an additional advantage in that their temperature profile is the most easily controlled. This offers some flexibility in specifying the angle of cut. A low angle may be order for minimum deviation near room temperature, or a high angle may be ordered to give minimum deviation at extreme temperatures. Standard frequencies and loose specifications for motional parameters will yield cost and delivery competitive with ceramic resonators. Any nonstandard parameters will raise the cost quickly and almost certainly rule out any "off the shelf" part. It will be necessary to specify a nonstandard crystal, if the greatest possible stability is to be "wrung out" of an A-T cut crystal.

Packages

Quartz crystals have a large and mostly obsolete stable of resonator holders to choose from. This is because of the much longer history of quartz crystals. Most of the nomenclature used to describe them, and the technology used to develop them, comes from the MIL-STD system. These include the H/C 6, which is about .750" square, and is only necessary to accommodate the lowest frequency A-T cut. The H/C 43 is only about .500" square, and probably accounts for most of the crystal production in the world today. The H/C 45 is still smaller at about .350" square. There are many other standard part numbers which are variations of these, with pins or wire leads, thin version and short versions, and several different methods of sealing the package. Most manufacturers offer their own nonstandard variations of these, as well as clever ways to surface mount them. Most of these variations however, have their origins in the standard H/C parts. The method used to seal the package will have the greatest impact on price and ageing. Solder sealed crystals are usually the least expensive owing to the modest equipment requirements, and simplicity. Resistance weld is slightly more costly, and cold weld is a distant third. This may be changing as more large volume production is implemented with resistance welded packages. Because more exotic (expensive) materials are involved in the cold weld and resistance weld packages before any crystal is mounted in it, is doubtful that this order of cost will change very much. Both solder sealed and resistance welds leave some residue, which over long periods of time contaminate the blank. This causes long term frequency shifts, known as ageing. Cold welded crystals cost more because of more expensive materials which must be used, and expensive tooling (dies) which eventually ware out. Cold weld packages, if assembled in a clean environment, have the potential for the lowest ageing rates. Glass crystal holders have in the past held a slight advantage in ageing over cold weld types, but in the last several years, cold weld techniques have matured to where they have surpassed the glass holder in performance. Some manufacturers, because of the processes in place, may offer glass at a competitive cost. There is nothing wrong with glass holders, but these have no particular advantage over a modern cold weld package. In any case, the differences in ageing rates will not be important to all but a few PICmicro designers. Most ceramic resonators are only available in two or three packages, depending on the

© 1997 Microchip Technology Inc.

manufacturer. The most popular is the dip molded, ranging from 0.3" to 04" square, with some higher frequencies available in lower profiles. Their major size advantage over crystals, if any, will be in height rather than footprint size.

Design Examples

A communications device that is designed around the PIC16C5X part and requires that connecting units have a close timing relationship. Size is not a primary factor, but cost and stability are. A high clock frequency is desired in order to obtain a good sampling rate of the input signal. The PIC16C5X-HS part is selected for a clock frequency of 8 MHz. An X-T Cut crystal is chosen and specified for a maximum frequency deviation of ±40 PPM over -20° to +70°C. The frequency is too high for a tuning fork type, and the stability is out of the question for a ceramic resonator. An examination of A-T cut frequency deviation / temperature curves show that a ±1 minute angle tolerance gives ±30 PPM frequency deviation over temperature. This leaves 10 PPM for ageing over the products five-year life. An A-T STRIP is a choice but at this quantity, the A-T cut in an H/C 43 cold weld type holder, comes in at a lower bid. Since there is space in the assembly, it is chosen.

HOW TO SPECIFY A CRYSTAL

When the PICmicro designer chooses a resonator, whether it is a standard or a custom part, a specification, while not essential, is an extremely good idea. A clear specification covering all items of form, fit and function, will eliminate any possibility of confusion on the part of the manufacturer, and insure the part will be suitable for the application. The specification should communicate your requirements to the manufacturer and be an instrument by which questionable parts may be measured. Time for discussion with the manufacturer of the resonator is when the specification is being written, not after. The designer must have or gain knowledge of what parameters raise the difficulty level of manufacturing the resonator, and so the cost. Items which effect cost and levels at which these items become an issue, may vary between manufacturers. A typical crystal design sheet is shown in Figure 13. The A-T cut crystal is likely to have the most detailed specification. Other types of resonators will follow this general form with differences being mostly that of omitting many items. This data sheet is likely to become a document in a drawing package for design of a larger assembly, so the sheet begins and ends with blocks for a drawing number, sign-offs, and revisions. The title informs the manufacturer that the crystal is intended for use in an oscillator, as opposed to filters, or other applications.

Motional Parameters

The first item in crystal design is frequency and the operating load. This might include series resonance (no load), but the PICmicro designer will almost certainly use a value of about 1/2 of the phase shift capacitors, plus any trimmer capacitors which may be added. It is customary to use a standard value here such as 20 or 32 pF, but a nonstandard value is not very difficult given modern manufacturing equipment. The frequencies possible with the PICmicro oscillator should not strain the capabilities of most manufacturers.

The second Item is the "Make Tolerance". This the accuracy to which the crystal is manufactured at room temperature. This should be at least as small as the temperature deviation, and a ± 20 PPM should not effect the cost significantly. Avoid tightly specifying this value. Tolerances of ± 10 PPM and less are quite practical but more difficult and will impact cost. If the stability budget does not allow this for at least ± 20 PPM for tolerance of the crystal and associated components, then an adjustable component may be necessary. The added cost of parts and labor to adjust them must be weighed against the cost of tighter make tolerances on the crystal. This decision must be made on an individual basis.

The third item in the design parameters is the mode of vibration. This will be the fundamental mode for almost all PICmicro designers. Other possibilities include the third overtone operation, but many other parts must be added in order to insure operation on only the desired overtone. While there are some advantages to overtone operation, almost all PICmicro designers will specify the fundamental mode. Still, what may be obvious to the PICmicro designer must be conveyed to the crystal designer, and so this item should not be omitted, or minimized. Series resistance is usually a "not to exceed" value. A good fundamental mode crystal in the PICmicro operating frequency range will not be above 10 or 15Ω, although the oscillator may run with a higher value. This depends on the frequency and excess gain available from the particular model of the PICmicro part, at that frequency. The higher resistance will mean more power dissipated in the crystal, and for this reason a nominally lower value should be adhered to. The load capacity will have an effect on this value. The practically achievable series resistance will rise as the load moves the operating point away from series resonance and towards anti-resonance (Figure 12).

The motional capacitance, or C_1, may be the most troublesome item for the PICmicro designer to specify. This item will have the single largest effect on the tuning sensitivity (intended or unintended) of the oscillator. Additionally, if the C_1 is specified to be too small, the crystal designer, who controls *C1* by adjusting the electrode size, will use a very small electrode. This will result in the drive power being dissipated by a small portion of the crystal blank, making drive related areas, such as activity dips and other spurious, more critical. If a large C_1 is specified, the unit may be unnecessarily less stable. The static capacitance or C_0, is usually a "not to exceed" value, and it is not of much interest the PICmicro designer unless a large and specific degree of adjustability is required from the oscillator. This may be important if an electrically tunable oscillator is desired. In this case, a specific ratio of C_1 to C_0 could

5

© 1997 Microchip Technology Inc.

be specified. This would not be a low-cost item. It is customary to leave this blank if a specific value is not desired, or the words "as required" can be placed in that location.

Other alternative methods of specifying C_1 and C_0 might include a fractional frequency deviation between series and load capacity operation. The drive level should indicate the highest drive level which the PICmicro designer estimates the crystal will experience in operation. The crystal designer would like this value to be very low, rendering it a nonissue. The PICmicro designer must specify a practical maximum value and take steps to insure that it is not exceeded. Operation at spurious modes and activity dips are just two of the possible consequences of excessive drive levels. Activity dips are not to be tolerated if reliable operation is expected. To quantify this, a maximum allowable value is placed on the frequency deviation. This should be less than 1 PPM and must be less than 5 PPM at reasonable drive levels (i.e., less than 1 mW). The maximum permissible drive level is determined somewhat by the size of the blank, the electrode, and therefore the size of the holder chosen. The crystal manufacturer should offer a realistic value.

Temperature Characteristics

The crystal manufacturer must know the temperature range over which operation is intended, and this is the first item under the heading of temperature characteristics. The temperature profile of an A-T cut crystal is controlled by the angle of cut. The desired profile is also chosen in terms of angle. When purchasing a crystal however, do not attempt to specify an angle. These angles are referenced to the crystal's atomic lattice, and are calibrated using an X-ray diffraction technique. There is little direct correlation between manufacturers. Once again the measured results, in the form of measured temperature profiles, are much more accurate, and are the final word in any process control. The PICmicro designer should specify a fractional frequency deviation with tolerances between the turning points of the temperature profile. This is the accepted industry standard for specifying temperature performance, and any crystal manufacturer will readily accept it if the tolerances are realistic. A typical temperature profile might read; "turn-to-turn 5.5 PPM, + 5.0, - 3.5".

Packages

The type of package and the method of sealing it should be specified, although it may be useful on occasion to leave this item blank. Some manufacturers are equipped especially well for a particular type of holder or sealing process, and may offer a better package than required, at a competitive price. In general however, it is best to specify this at the outset. Package types (holders) greatly effect the price of a crystal. The primary performance effect is that of ageing, though other factors, such as thermal characteristics may also be effected.

Other Resonators

Specification of the NC-38 type crystal is limited to motional parameters, as it is not a "rotated" cut. There is little the crystal designer can do to alter the temperature profile. Specifying a ceramic resonator is mostly a matter of custom frequencies, but some control of motional parameters and package variations are possible, though not common. The large temperature profile tends to dominate all other considerations.

Crystal Example

The following is a specification for a 10 MHz A-T cut crystal which the PICmicro designer is likely to choose for a high stability application. The frequency tolerance is ± 20 PPM. A rather modest C_1 of .028 pF ± 20% is specified and the C_0, though not specified, will be around 5 to 7 pF. It is required to operate on frequency with a 32 pF load. The maximum drive level is 1 mW, and no activity dips greater than 3 PPM will be accepted. The crystal will operate over the temperature range of - 20°C to + 70°C. The frequency deviation between turnover points, is 5.3 + 4.5, - 3.2 PPM. Notice that the turning points do not necessarily fall within the operating temperature range (Figure 10). These deviations between turning points correspond to 1, 2 and 3 minutes of angle relative to the zero coefficient angle. Although the 1 minute curve displays a smaller deviation between the turn points, if it were the center of the angle range the lower end of 0 minutes would be unacceptable due to the rapid changes at the ends of the operating range, where cubed terms are in effect. The exact deviations were computer generated for each crystal angle. These offer more detail and accuracy than is possible with graphical techniques. An alternate method of specifying this is to set a total deviation over the entire operating temperature range of about ± 8 PPM. This is not as exact, and leaves the manufacturer more freedom to interpret requirements. If the PICmicro designer is not comfortable with these concepts, this may be the best approach. One may notice a small dissymmetry in the turning deviations. This is because the chosen operating temperature range is symmetrical at about 25°C, and the inflection temperature of the A-T cut is closer to 27°C or 28°C (Figure 10). In some cases the center of the operating temperature range may be very different from the inflection point of the crystal, and in order to realize the benefit of the best angle, a frequency offset at 25°C would be needed to center the temperature profile (this would not be part of the design sheet). The package is chosen to be an H/C 49 type which has a resistance weld seal. A maximum ageing rate of 2 PPM / year is required. No unusual shock or vibration is expected for this unit. Under the area of testing, temperature testing is required only on a sample of the lot. All units will be exposed to a thermal shock, and 10 days of ageing at 85°C. Ageing is of concern, so gross leakage is specified to be tested on all the units, and a fine leak test is to be performed on a 13% sample. Any notes about the application or special concerns would complete the crystal design sheet.

THE PICMICRO ON BOARD OSCILLATOR(S)

PICmicro devices actually contains four complete oscillators which can be selected during the programming process. The selected oscillator is connected to the OSC1 and OSC2 pins, as well as the chip clock drivers by CMOS switches. In the windowed parts, these are all available to the programmer, while the OTP and QTP parts are pre-configured at the factory, and must be ordered as the desired type. The four types of oscillator available in the PIC16C5X/16CXXX series are:

RC (resistor capacitor)
LP (low power)
XT (crystal < 4 MHz)
HS (High speed)

The four types of oscillator available in the PIC17CXXX series are:

RC (resistor capacitor)
LF (low power)
XT (crystal < 4 MHz)
EC (External Clock)

The four circuits are shown in Figure 8. This unique arrangement gives the designer the ability to optimize the performance of the PICmicro in terms of clock speed, type of resonator, and power consumption.

The RC Oscillator

The RC oscillator is a relaxation type similar to the popular 555 timer. The OSC1 pin is the input to a Schmitt Trigger.

The LP oscillator

The LP, or low power oscillator, is designed to trade speed for low power operation. Although this circuit shares the same topology (schematic) as the XT oscillator, the transistors used in the LP oscillator have a higher Rdss value and draw considerably less current. This configuration is optimum for low frequency operation, because it trades the away unnecessary high frequency responses for dramatically reduced operating currents.

The XT oscillator

The XT oscillator is designed to give a compromise between high frequency performance and modest power consumption. The gain of this oscillator is as much as 15 times higher than the LP oscillator. This middle range will be used for frequencies up to 4 MHz.

The HS oscillator

The HS oscillator is designed to give the maximum gain and frequency response. The current consumption is accordingly higher. The gain is roughly five times higher than that of the XT oscillator. This gives the PICmicro the ability to operate at frequencies up to 20 MHz.

APPENDIX A

The curves of Figure 10 are calculated using a general form developed by Bechmand in 1955. For any temperature *T*, a factional deviation from the frequency at the reference temperature T_0, is given in the form:

$$\frac{\Delta F}{F} = a(T - T_0) + b(T - T_0) + (T - T_0)^3$$

where:

a = $-5.15 \times 10^{-6} * °(\theta - \theta_0)$

b = $0.39 \times 10^{-9} - 4.7 \times 10^{-9} * °(\theta - \theta_0)$

c = $109.5 \times 10^{-12} - 2 \times 10^{-12} * °(\theta - \theta_0)$

$(\theta - \theta_0)$ = the difference between the intended angle and the zero temperature coefficient angle, in degrees of arc.

T0 is the reference temperature and is usually taken as 25°C. The zero temperature coefficient angle is approximately - 35.25° relative to the Y-axis. The exact angle which produces a zero temperature coefficient and the exact inflection temperature are both strongly dependent on several factors, including overtone and resonator geometry. A degree as a unit of angle is too coarse for sufficient resolution. The following coefficients are divided by 60 for units of minutes of arc.

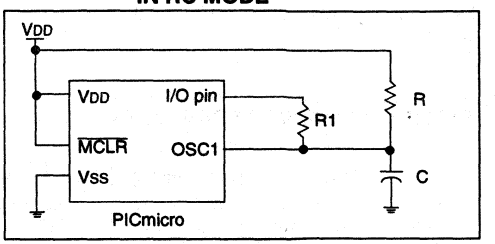
Low Power Design Using PICmicro™ Microcontrollers

Author: *Rodger Richey*
Microchip Technology Inc.

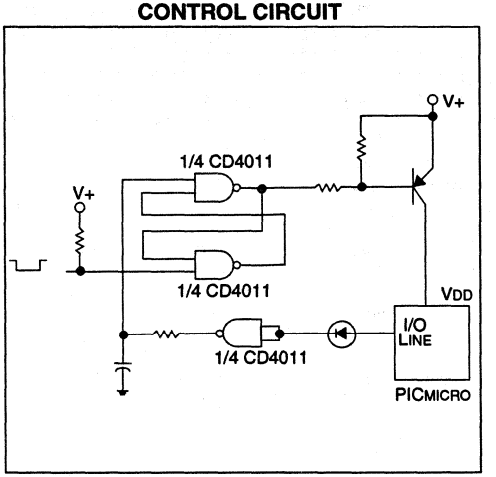
INTRODUCTION



Power consumption is an important element in designing a system, particularly in today's battery powered world. The PICmicro family of devices has been designed to give the user a low-cost, low-power, and high-performance solution to this problem. For the application to operate at the lowest possible power, the designer must ensure that the PICmicro devices are properly configured. This application note describes some design techniques to lower current consumption, some battery design considerations, and suggestions to assist the designer in resolving power consumption problems.

DESIGN TECHNIQUES

Many techniques are used to reduce power consumption in the PICmicro devices. The most commonly used methods are SLEEP Mode and external events. These modes are the best way to reduce IPD in a system. The PICmicro device can periodically wake-up from Sleep using the Watchdog Timer or external interrupt, execute code and then go back into SLEEP Mode. In SLEEP Mode the oscillator is shut off, which causes the PICmicro device to consume very little current. Typical IPD current in most PICmicro devices is on the order of a few microamps.



In cases where the PICmicro uses an RC oscillator but cannot use SLEEP Mode, another technique is used to lower power consumption. An I/O pin can remove a parallel resistance from the oscillator resistor while waiting for an event to occur. This would slow down the internal clock frequency, by increasing the resistance, and thus reduce Ipd. Once an event occurs the resistor can be switched in and the PICmicro device can process the event at full speed. Figure 1 shows how to implement this technique. The resistor **R1** would be used to increase the clock frequency by making the I/O pin an output and setting it to VDD.

FIGURE 1: USING AN EXTERNAL RESISTOR TO LOWER POWER IN RC MODE

External events can be used to control the power to PICmicro devices. For these cases, the Watchdog Timer can be disabled to further reduce current consumption. Figure 2 shows an example circuit that uses an external event to latch power on for the PICmicro device. Once the device has finished executing code, it disables power by resetting the latch. The latching circuit uses a low-power 4000 series CMOS quad chip which consumes a typical of 10 µA of current. The measured value of current consumption for the complete circuit with the PICmicro powered-down was 1 nA. Current consumption for a PICmicro in SLEEP Mode is typically 1 µA.

FIGURE 2: EXTERNAL EVENT POWER CONTROL CIRCUIT

5

© 1997 Microchip Technology Inc.

Power consumption is dependent on the oscillator frequency of the system. The device must operate fast enough to interface with external circuitry, yet slow enough to conserve power. The designer must account for oscillator start-up time, external circuitry initialization, and code execution time when calculating device power consumption. Table 1 shows various frequency oscillators, oscillator modes and the average current consumption of each mode. A PIC16C54 was used to collect data for Table 1 and the code is shown in Example 1. A current profile for a PIC16C54 in RC oscillator mode running at 261 kHz is shown in Figure 3. Figure 4 shows a current profile for a PIC16C54 in XT mode running at 1 MHz. The current profile includes three regions: power-up, active, and sleep. The power-up region is defined as the time the PICmicro device is in Power-on Reset and/or Oscillator Start-up Time. The active region is the time that the PICmicro device is executing code and the sleep region is the time the device is in SLEEP Mode. When using a 32.768 kHz crystal in LP oscillator mode, the designer must check that the oscillator has stabilized during the Power-on Reset. Otherwise, the device may not come out of reset properly.

TABLE 1: OSCILLATOR MODES

Osc. Type	Frequency	Osc. Mode	Power-up Region Current, Time	Active Region Current, Time	Sleep Region Current, Time
Resistor / Capacitor	261 kHz	RC	51.2 µA, 17.5 ms	396 µA , 12.8 ms	0.32 µA, 140 ms

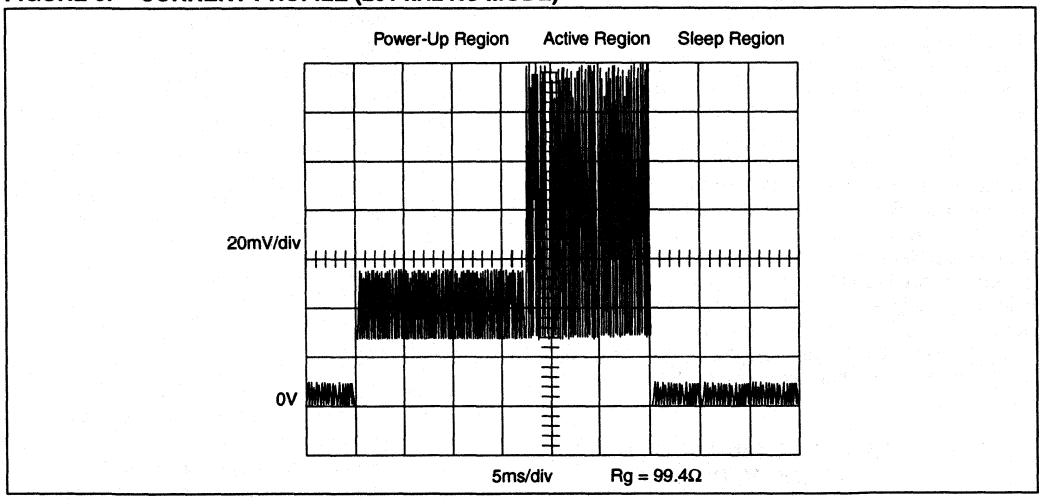
FIGURE 3: CURRENT PROFILE (261 kHz RC MODE)



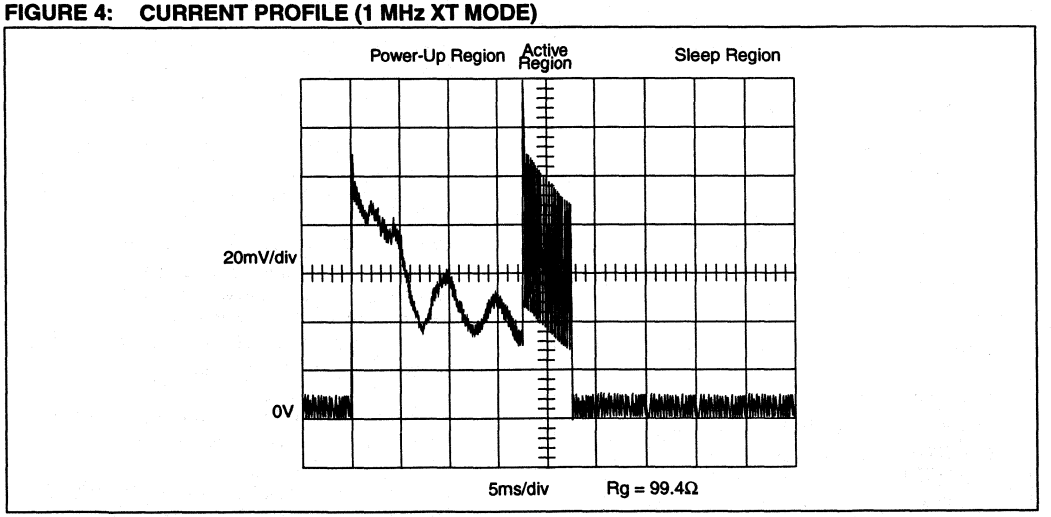


FIGURE 4: CURRENT PROFILE (1 MHz XT MODE)

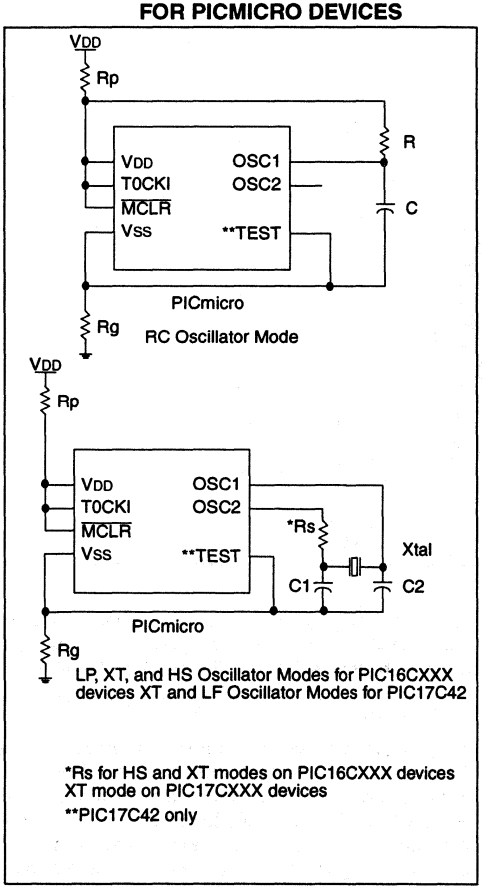
Designing a system for lower supply voltages, typically 3V, is another method to reduce IPD. This type of design is best utilized in a battery powered system where current consumption is very low. A wide range of devices from op-amps and Analog-to-Digital (A/D) converters to CMOS logic products are being manufactured for low voltage operation. This gives the designer the flexibility to design a low voltage system with the same type of components that are available for a 5V design. Refer to the PICmicro device data sheets for IPD vs. VDD data.

Since any I/O pin can source or sink up to 20 mA, the PICmicro devices can provide power to other components. Simply connect the VDD pin of an external component to an I/O pin. Currently, most of the op-amps, A/D converters, and other devices manufactured today are low-power and can be powered by this technique. This provides the ability to turn off power to sections of the system during periods of inactivity.



Temperature will effect the current consumption of the PICmicro devices in different ways. Typically devices will consume more current at extreme temperatures and batteries will have less available current at those same temperatures. PICmicro devices will exhibit higher IPD currents at high temperatures. Refer to the PICmicro device data sheets for IPD vs. Temperature data.

© 1997 Microchip Technology Inc.

TROUBLESHOOTING IPD

The first step in troubleshooting IPD problems is to measure the IPD that the circuit is consuming. Circuits to measure IPD for all oscillator modes are shown in Figure 5 for PICmicro devices. The resistor Rp is used to measure the amount of current entering the VDD pin when resistor Rg is shorted. The resistor Rg is used to measure the amount of current leaving the VSS pin when resistor Rp is shorted. The value of Rp and Rg should be approximately 100Ω for all oscillator modes. The two values of current should be approximately the same when the PICmicro is operating at the lowest possible power. If you find that the values of IPD measured from both configurations are not equivalent or are higher than the specifications, the following suggestions should help to find the source of extra current.

FIGURE 5: CIRCUITS TO MEASURE IPD FOR PICMICRO DEVICES

Basically, if Ip is not equal to Ig, then an I/O pin is either sourcing (IP>IG) current or sinking (IP<IG) current.

- Is the $\overline{MCLR}$ pin tied to VDD? Is the rate of rise of VDD slower than 0.05 V/ms? Does VDD start at VSS then rise? These conditions will not guarantee that the chip will come out of reset and function properly. Some of the circuits on PICmicro devices will start operating at lower voltage levels than other circuits. See Application Note AN522 "Power-Up Considerations" in the Microchip *Embedded Control Handbook*.
- Are all inputs being driven to VSS or VDD? If any input is not driven to either VSS or VDD, it will cause switching currents in the digital (i.e., flashing) input buffers. The exceptions are the oscillator pins and any pin configured as an analog input. During Power-on Reset or Oscillator Start-up time, pins that are floating may cause increased current consumption.
- All unused I/O pins should be configured as outputs and set high or low. This ensures that switching currents will not occur due to a floating input.
- Is the TMR0 (T0CKI) pin pulled to VSS or VDD? The TMR0 pin of PIC16C5X devices should be tied to VSS or VDD for the lowest possible current consumption.
- If an analog voltage is present at a pin, is that pin configured as an analog input? If an analog voltage is present at a pin configured as a digital input, the digital input buffers devices will consume more current due to switching currents.
- Are all on-chip peripherals turned off? Any on-chip peripheral that can operate with an external clock source, such as the A/D converter or asynchronous timers, will consume extra current.
- Are you using the PORTB internal pull-up resistors? If so and if any PORTB I/O pin is driving or receiving a zero, the additional current from these resistors must be considered in the overall current consumption.
- Is the Power-Up Timer being used? This will add additional current drain during power-up.
- If the currents measured at the Rp and Rg resistors are not the same, then current is being sourced or sunk by an I/O pin. Make sure that all I/O pins that are driving external circuitry are switched to a low power state. For instance, an I/O pin that is driving an LED should be switched to a state where the LED is off.
- Is the window of a JW package device covered? Light will affect the current consumption of a JW package device with the window left uncovered.

IPD Analysis Using A Random Sample

The Microchip *1994 Microchip Data Book* specifies the typical IPD current for a PIC16C5X part at 4 µA and the maximum IPD current at 12 µA. These values are valid at a VDD voltage of 3V and a temperature range of 0°C to 70°C with the Watchdog Timer enabled. A control group of fifty PIC16C54's were randomly selected with pre-production and production samples. IPD tests were run on the group for a voltage range of 2.5V to 6.5V and for a temperature range of 0°C to 70°C. Table 2 compares the median and maximum values obtained by the IPD tests to the typical and maximum values in the data book. The IPD test data and the data book values are based on VDD = 3.0V, Watchdog Timer Enabled, and a temperature range of 0°C to 70°C.

The values in the data book are obtained from devices in which the manufacturing process has been skewed to various extremes. This should produce devices which function close to the minimum and maximum operating ranges for each parameter shown in the data book. The typical values obtained in the data book are actually the mean value of characterization data at a temperature of 25°C. The minimum and maximum values shown in the data book are the mean value of the characterization data at the worst case temperature, plus or minus three times the standard deviation. Statistically this means that 99.5% of all devices will operate at or below the typical value and much less than the maximum value.

TABLE 2: IPD COMPARISON OF CONTROL GROUP vs. DATA BOOK VALUES

Source	Typical or Median IPD	Maximum
Control Group	2.349 µA	3.048 µA
1994 Microchip Data Book	4 µA	12 µA

BATTERY DESIGN

When designing a system to use batteries, the designer must consider the maximum current consumption, operating voltage range, size and weight constraints, operating temperature range, and the frequency of operation. Once the system design is finished, the designer must again ask some questions that will define what type of battery to use. What is the operating voltage range? What is the current drain rate? What are the size constraints? How long will the system be used? What type of battery costs can be tolerated? What range of temperatures will the system be operated?

It is difficult to state a rule of thumb for selecting batteries because there are many variables to consider. For example, operating voltages vary from one battery type to another. Lithium cells typically provide 3.0V while Nickel-Cadmium cells provide 1.2V. On the other hand, Lithium cells can withstand minimal discharge rates while Nickel-Cadmium can provide up to 30A of current. A designer must consider all characteristics of each battery type when making a selection. Appendix B contains a simple explanation of batteries, a characteristic table for some common battery types, and discharge curves for the common batteries.

It is very important when doing a low power design to correctly estimate the required capacity of the power source. At this point, the designer should be able to estimate the operating voltage, current drain rates and how long the system is supposed to operate. To explain how to estimate the required capacity of a system, we will use the first entry from Table 1 using an RC oscillator set at 261 kHz. Figure 3 shows the current profile for this entry. It can be seen that the profile has a period of 170.3 ms with a 17.5 ms power-up region, a 12.8 ms active region, and a 140 ms sleep region. Assuming that the system will be required to operate for six months, we can now calculate the capacity required to power this system. Example 2 will illustrate the procedure. If a system does not have a periodic current profile, then the percentages obtained in step 1 of Example 2 will have to be estimated.

EXAMPLE 2: CAPACITY CALCULATION

1. Calculate the percentage of time spent in power-up, active, and sleep regions.

   power-up
   (17.5 ms / 170.3 ms) x 100 = 10.3%

   active
   (12.8 ms / 170.3 ms) x 100 = 7.5%

   sleep
   (140 ms / 170.3 ms) x 100 = 82.2%

2. Calculate the number of hours in 6 months.

   6 months
   x (30 days / month)
   x (24 hours / day) = 4320 hours

3. Using the number of hours, percentages, and currents calculate the capacity for each period of time

   power-up
   4320 hours x 10.3% x 51.2 µA = 22.8 mAh

   active
   4320 hours x 7.5% x 396 µA = 128.3 mAh

   sleep
   4320 hours x 82.2% x 0.32 µA = 1.14 mAh

4. Sum the capacities of each period

   22.8 mAh + 128.3 mAh + 1.14 mAh = 152.2 mAh

The capacity required to operate the circuit for six months is 152.2 mAh. Example 2 does not take into consideration temperature effects or leakage currents that are associated with batteries. The load resistance of a battery is affected by temperature which in turn changes the available voltage and current; however, the self discharge rate is higher.

EXAMPLE DESIGN

A PIC16C54 with an LP oscillator of 32.768 kHz is used in this design. A Linear Technology low-power 12-bit A/D converter samples a temperature sensor. This data is transmitted via an LED at 300 baud to a receiver. The A/D converter, op-amp, and temperature sensor are powered from an I/O pin on the PIC16C54. The Watchdog Timer is enabled to periodically wake the system up from Sleep and take a sample. Figure 6 shows the schematic for the example design and Appendix A contains the source code.

This circuit has two operating modes, active and sleep. There was not a distinct power-up region in this design. In the circuit with the peripheral chips powered directly from the battery, the example design consumed 8 mA of current in the active mode and 6.5 mA in SLEEP Mode. With the peripheral chips powered from an I/O pin of the PIC16C54, the example design consumed 4 mA of current in the active mode and 0.5 µA in SLEEP Mode. The advantage of using an I/O pin to provide power to peripherals can be seen in a calculation of the capacity required to operate the circuit for one month. Example 3 details the two capacity calculations.

EXAMPLE 3: CAPACITY CALCULATION FOR THE EXAMPLE DESIGN

1. Calculate the percentage of time spent in the active and SLEEP Modes.

   active - battery power
   (210 ms / 2.61 s) x 100 = 8%

   sleep - battery power
   (2.4 s / 2.61 s) x 100 = 92%

   active - I/O power
   (188 ms / 2.638 s) x 100 = 7.1%

   sleep - I/O power
   (2.45 s / 2.638 s) x 100 = 92.9%

2. Calculate the number of hours in 1 month.

   1 month
   x (30 days / month)
   x (24 hours / day)
   = 720 hours

3. Using the number of hours, percentages and currents calculate the capacity for each period of time.

   active - battery power
   720 hours x 8% x 8 mA = 461 mAh

   sleep - battery power
   720 hours x 92% x 6.5 mA = 4306 mAh

   active - I/O power
   720 hours x 7.1% x 4 mA = 205 mAh

   sleep - I/O power
   720 hours x 92.9% x 0.5 µA = 0.4 mAh

4. Sum the capacities of each period.

   battery power
   461 mAh + 4306 mAh = 4767 mAh

   I/O power
   205 mAh + 0.4 mAh = 206 mAh

The capacity required to operate this circuit for one month can be reduced by a factor of twenty just by powering the peripheral components from an I/O pin. The example design will use two Panasonic® BR2325 Lithium batteries in series to provide power to the circuit. This results in a Vbatt of 6V and a capacity of 165 mAh. Using the estimation process, the circuit should function for approximately 24 days. The actual time of operation was 24.2 days with the system running in an ambient temperature of 22°C.

FIGURE 6: EXAMPLE DESIGN SCHEMATIC

SUMMARY

This application note has described some of the methods used to lower IPD and reduce overall system current consumption. Some obvious methods such as SLEEP Mode and low voltage design were given. Techniques such as powering components from I/O pins and oscillator mode and frequency selection can also be important in reducing IPD and overall system current. Some suggestions for troubleshooting IPD problems were presented. Finally, some considerations for designing a battery powered system were offered.

APPENDIX B: BATTERY DESCRIPTIONS

Presently there are two types of batteries that are manufactured, primary and secondary. Primary batteries are those that must be thrown away once their energy has been expended. Low current drain, short duty cycles, and remote operation favor primary batteries such as Carbon Zinc and Alkaline. Secondary batteries can be recharged once they have exhausted their energy. High current drain or extended usage favors secondary batteries especially when the cost of replacement of disposable batteries is not feasible. Secondary batteries include Nickel-Cadmium and Nickel Metal Hydride.

A battery may be discharged by different means depending on the type of load. The type of load will have a significant effect on the life of the battery. The typical modes of discharge are constant resistance, constant current, and constant power. Constant resistance is when the load maintains a constant resistance throughout the discharge cycle. Constant current is the mode where the load draws the same current during discharge. Finally, constant power is defined as the current during a discharge increases as the battery voltage decreases.

The constant resistance mode results in the capacity of the battery being drained at a rapid and excessive rate, resulting in a short life. This is caused by the current during discharge following the drop in battery voltage. As a result, the levels of current and power during discharge are in excess of the minimum required.

The constant current mode has lower current and power throughout the discharge cycle than the constant resistance mode. The average current drain on the battery is lower and the discharge time to the end-voltage is longer.

The constant power discharge mode has the lowest average current drain and therefore has the longest life. During discharge, the current is lowest at the beginning of the cycle and increases as the battery voltage drops. Under this mode the battery can be discharged below its end voltage, because the current is increased as the voltage drops. The constant power mode provides the most uniform performance throughout the life of the battery and has the most efficient use of the energy in the battery.

The nominal voltage is the no-load voltage of the battery, the operating voltage is the battery voltage with a load, and the end-of-life voltage is the voltage when the battery has expended its energy. Energy Density is used to describe the amount of energy per unit of volume or mass (Wh/kg or Wh/l). Generally, energy density decreases with decreasing battery size within a particular type of battery. Most batteries are rated by an amp-hour (Ah) or milliamp-hour (mAh) rating. This rating is based on a unit of charge, not energy. A 1-amp current corresponds to the movement of 1 coulomb (C) of charge past a given point in 1 second (s). Table B-1 lists some typical characteristics of the most common types of batteries.

TABLE B-1: TYPICAL BATTERY CHARACTERISTICS

	Carbon Zinc	Alkaline	Nickel Cadmium	Lithium	Nickel Metal Hydride	Zinc Air	Silver Oxide
Cell Voltage							
Nominal	1.5	1.5	1.2	3.0	1.2	1.4	1.6
Operating	1.25-1.15	1.25-1.15	1.25-1.00	2.5-3.0	1.25-1.0	1.35-1.1	1.5
End of life	0.8	0.9	0.9	1.75	0.9	0.9	0.9
Operating Temperature	-5°C to 45°C	-20°C to 55°C	-40°C to 70°C	-30°C to 70°C	-20°C to 50°C	0°C to 45°C	-20°C to 50°C
Energy Density (Wh/kg)	70	85	30	300	55	300	100
Capacity	60mAh to 18Ah	30mAh to 45Ah	150mAh to 4Ah	35mAh to 4Ah	500mAh to 5Ah	50mAh to 520mAh	15mAh to 210mAh
Advantages		High capacity, good low temp	good low temp, good high rate discharge	good low and high temp, good high rate discharge, long shelf life	better capacity than Nicad for same size	high energy density, good shelf life	good low temp, good shelf life
Limitations	Low energy density, poor low temp, poor high rate discharge		poor low rate discharge, disposal hazards	Violent reaction to water		Cannot stop reaction once started	poor high rate discharge
Relative Cost	low	low	medium	high	high	high	high
Type	**Primary**	**Primary**	**Secondary**	**Primary**	**Secondary**	**Primary**	**Primary**

Typical discharge curves for alkaline, carbon zinc, lithium, nickel cadmium, nickel metal hydride, silver oxide, and zinc air are shown in Figure B-1 through Figure B-7. These curves are only typical representations of each battery type and are not specific to any battery manufacturer. Also the load and current drain are different for each type of battery.

INTRODUCTION

For any application to begin proper operation, the application must power-up properly. Many criteria must be taken into account to ensure this. The PICmicro™ devices integrate several features to simplify the design for the power-up sequence. These integrated features also reduce the total system cost.

This application note describes the requirements for the device to properly power-up, common pitfalls that designers encounter, and methods to assist in solving power-up problems.

THE POWER-UP SEQUENCE

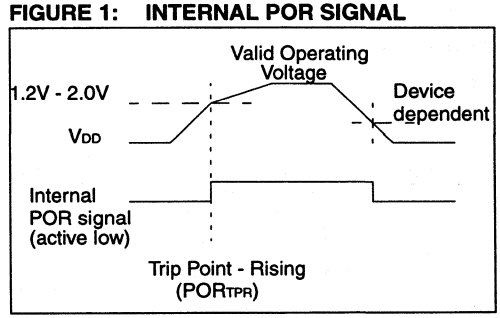
There are several factors that determine the actual power-up sequence that a device will go through. These factors are:

- The Processor Family
  - PIC16C5X (Baseline)
  - PIC16CXXX (Midrange)
  - PIC17CXXX (High-end)
- Oscillator Configuration
- Device Configuration
- $\overline{MCLR}$ pin

Note: The PIC16CXXX family refers to devices with a 14-bit instruction word. This does not include the PIC16C5X family.

The Power-on Reset (POR) signal generation is discussed, followed by the power-up sequence for the specific device families.

Power-on Reset (POR) signal



The data sheets show a Power-on Reset (POR) pulse, as in Figure 1. The POR signal is a level triggered signal. This representation may help in the understanding of future devices, which may have a brown-out reset capability.

The power-up sequence begins by increasing the voltage on the V_{DD} pin (from 0V). If the slope of the V_{DD} rise time is faster than 0.05 V/ms, the internal circuitry is capable of generating an internal reset signal. Depending on the device family, different power-up sequences will occur after this POR signal.

If the slope is less then 0.05 V/ms, the $\overline{MCLR}$ pin should be held low, by external circuitry, until a valid operating V_{DD} level is reached.

The V_{DD} rise time specification needs to be met, until the POR signal is generated. After the POR signal is generated the slope of the V_{DD} rise can change (to a faster or slower rise). This may have other ramifications, see the "Power-up Consideration" section. In general, the POR signal will trip (POR_{TP}) somewhere between 1.2V to 2.0V (Figure 1).

FIGURE 1: INTERNAL POR SIGNAL

When V_{DD} is falling, the voltage at which the internal POR signal returns to a low level is processor/device dependent. To ensure that a device will have a POR, the device voltage must return to V_{SS} before power is re-applied.

Note: Some devices (with EPROM program memory) have a newer POR circuit that does not require V_{DD} to return to V_{SS}. See the device data sheet for the complete specification on the POR operation.

The POR will be generated regardless of the level of the $\overline{MCLR}$ pin. The PICmicro device families are different on what triggers the power-up sequence. Table 1 describes the events that cause the POR sequence to occur.

After reaching the POR trip point (POR_{TPR}), the POR sequence holds the device in reset for a given time. Once this time has elapsed, the device voltage must be valid or the $\overline{MCLR}$ pin must be low. The time from the POR rising edge to the time that V_{DD} must be valid level is the $T_{POR2VDDV}$ time.

© 1997 Microchip Technology Inc.

TABLE 1: EVENTS THAT TRIGGER POR SEQUENCE

Device	Events
PIC16C5X	Both the POR signal rising edge and any $\overline{MCLR}$ rising edge(1)
PIC16CXXX	The POR signal rising edge
PIC17CXXX	Either the POR signal rising edge or the first $\overline{MCLR}$ rising edge (if $\overline{MCLR}$ is low when the POR occurs). After this event, all following $\overline{MCLR}$ rising edges(1) cause the device to start program execution immediately.

Note 1: The POR low-to-high transition onfigures Special Function Register (SFR) bits/registers to a specified value. The SFR bits/register are not identically affected by the $\overline{MCLR}$ signal. Refer to the device data sheet to see how the bits are affected by these two conditions.

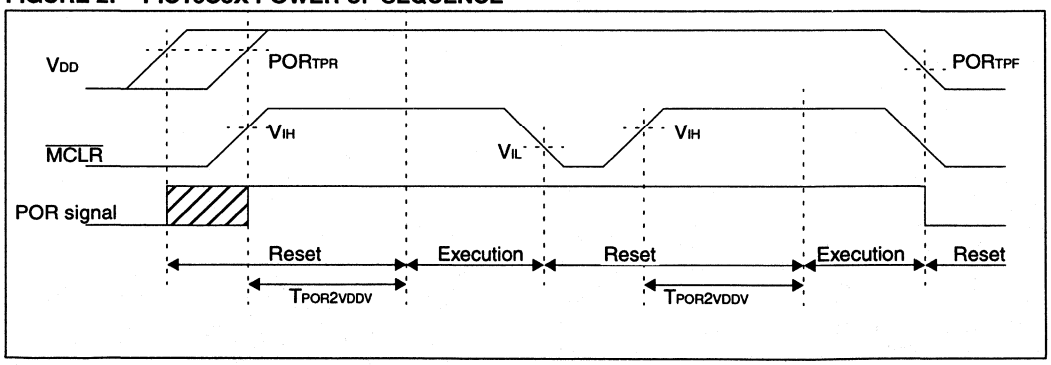
The POR sequence for each of the PICmicro families is described in the following three sections:

PIC16C5X Family

PIC16CXXX Family

PIC17CXXX Family

PIC16C5X Family



After the $\overline{MCLR}$ pin has reached a high level, the device is held in reset for typically 18 ms. This time is determined by an on-chip RC oscillator and 8-bit ripple counter. This Device Reset Timer (DRT), allows most crystals (except low frequency crystals) to start-up and stabilize. Due to the characteristics of resistors and capacitors, this time is extremely variable over temperature and voltage. There is also a device to device variation. See the data sheet for the range of this time-out.

TABLE 2: TIME-OUT IN VARIOUS SITUATIONS (TYPICAL)

Oscillator Configuration	Power-up	Wake-up from SLEEP
XT, HS, LP(1)	18 ms	18 ms
RC	18 ms	18 ms

Note 1: 32 kHz crystals have a typical start-up time of 1-2 seconds. Crystals >100 kHz have a typical start-up time of 10-20 ms. Resonators are typically <1 ms. All these times are voltage dependent.

FIGURE 2: PIC16C5X POWER-UP SEQUENCE

© 1997 Microchip Technology Inc.

PIC16CXXX Family

After the POR rising edge has occurred, the device can have up to 2 time-out sequences that occur in series. The first being the Power-up Timer (PWRT), the second being the Oscillator Start-up Timer (OST).

The Power-up Timer time-out will occur if enable bit PWRTE is read as a '1'. The PWRT uses a 10-bit counter, with the clock from an internal RC. Due to the characteristics of resistors and capacitors, this time is extremely variable over temperature and voltage. There is also a device to device variation. See the data sheet for the range of this time-out.

Note: Future devices will change the polarity of the PWRTE configuration bit. Refer to the specific data sheet for the polarity of this bit.

The OST will occur on power-up/wake-up when the device has oscillator mode selected. This allows the oscillator to stabilize before program execution begins. The OST uses a 10-bit counter, with the clock from the OSC pin. The time is dependent on the frequency of the input clock. This timer is disabled if the oscillator is configured as RC.

Figure 3 shows how the two timers work in the power-up sequence. V_{DD} must be valid when program execution starts. The T_{PWRT} + T_{OST} times can be thought of as the time that the device gives for the V_{DD} to become valid ($T_{POR2VDDV}$). Figure 4 shows when device execution begins for the case of the $\overline{MCLR}$ pin going high before $T_{POR2VDDV}$ times out. Figure 5 shows when the $\overline{MCLR}$ pin is held low longer than the $T_{POR2VDDV}$ time. The device starts execution immediately when $\overline{MCLR}$ goes high. Table 3 gives typical reset times.

TABLE 3: TIME-OUT IN VARIOUS SITUATIONS (TYPICAL)

Oscillator Configuration	Power-up		Wake-up from SLEEP
	PWRTE = 1 (2)	PWRTE = 0 (2)	
XT, HS, LP(1)	72 ms + 1024 Tosc	1024 Tosc	1024 Tosc
RC	72 ms	—	—

Note 1: 32 kHz crystals have a typical start-up time of 1-2 seconds. Crystals >100 kHz have a typical start-up time of 10-20 ms. Resonators are typically <1 ms. All these times are voltage dependent.

2: Future devices will change the polarity of this configuration bit. Refer to the specific data sheet for the polarity of the PWRT Configuration Bit.

FIGURE 3: PIC16CXX POWER-UP SEQUENCE

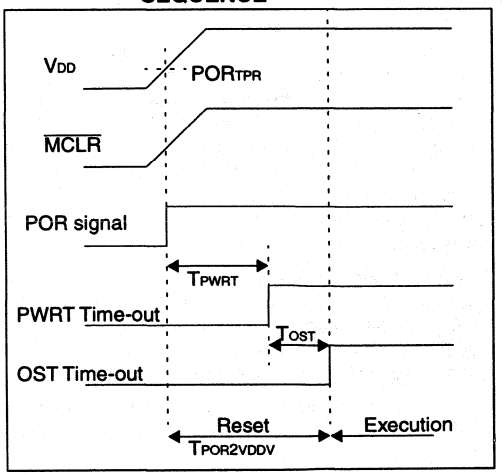


FIGURE 4: START OF DEVICE OPERATION ($\overline{MCLR}$ < $T_{POR2VDDV}$)

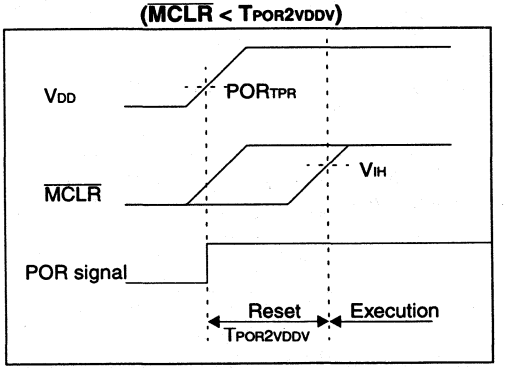

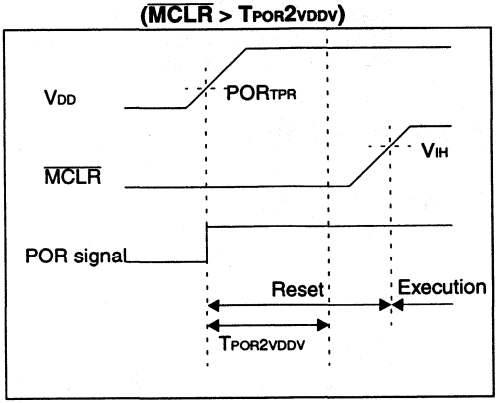

FIGURE 5: START OF DEVICE OPERATION ($\overline{MCLR}$ > $T_{POR2VDDV}$)

PIC17CXXX Family

When the $\overline{MCLR}$ pin comes to a high level, after the POR rising edge, the device has 2 time-out sequences that occur in parallel. One is the Power-up Timer (PWRT), the other is the Oscillator Start-up Timer (OST). The timer with the greater time holds the device in reset. Figure 6 shows the sequence with $\overline{MCLR}$ tied to V_{DD}. Figure 7 show the time-out when $\overline{MCLR}$ is independent of V_{DD}. The PWRT time is generally longer, except for low frequency crystals/resonators. The OST time does not include the start-up time of the oscillator/resonator.

The PWRT uses a 10-bit counter, with the clock from an internal RC. The characteristics of the RC vary from device to device and over temperature and voltage. The specification for the time-out range can be found in the electrical specification of the data sheet.

The OST uses a 10-bit counter, with the clock from the OSC pin. The time is dependent on the frequency of the input clock.

Until $\overline{MCLR}$ has reached a high level, the POR sequence will not start. While the POR signal remains high, all following $\overline{MCLR}$ pulses will not cause the POR sequences to occur (Figure 8).

TABLE 4: TIME-OUT IN VARIOUS SITUATIONS (TYPICAL)

Oscillator Configuration	Power-up	Wake-up from Sleep
RC, EC	Greater of 80 ms and 1024 Tosc	—
XT, LF(1)	Greater of 80 ms and 1024 Tosc	1024 Tosc

Note 1: 32 kHz crystals have a typical start-up time of 1-2 seconds. Crystals >100 kHz have a typical start-up time of 10-20 ms. Resonators are typically <1 ms. All these times are voltage dependent.

FIGURE 6: PIC17CXX POWER-UP SEQUENCE ($\overline{MCLR}$ TIED TO V_{DD})

POWER-UP CONSIDERATIONS

The device must be at a valid operating voltage when the device exits reset. This can be done by ensuring that the power supply rise time is fast enough to guarantee an operating V_{DD} level, or by using an external reset circuit which will hold $\overline{MCLR}$ low until the operating V_{DD} level is reached.

When the rise time of V_{DD} is very fast, there will be a time delay before the Power-on Reset (POR) signal will rise to a logic high ($T_{TP2PORH}$). This delay is in the 1-5 µs range, as shown in Figure 9.

Figure 10, Figure 11, and Figure 12 show the maximum time from the POR sequence beginning to the device having a valid operating voltage. Table 5 gives the $T_{POR2VDDV}$ times. When determining the time at which V_{DD} must be valid, the POR trip point must be assumed to be at the minimum POR voltage trip point.

How Crystal Frequencies affect Start-up time

Both the PIC16CXXX and PIC17CXXX families may have start-up times that include the contributions of the oscillator. Table 5 shows how the oscillator can affect each mode of operation, with Table 6 giving the reset time that an oscillator generates. This time can be used in the equation to calculate the total reset time, at the given frequency. This time may vary slightly due to the initial start-up characteristics of the crystal/oscillator circuit.

Note 1: The rise time specification does not ensure that a valid V_{DD} operating voltage will be reached before the device exits reset. The device's V_{DD} must be within the specified operating range for proper device operation.

Note 2: The start-up characteristics of the crystal/oscillator must also be taken into account when determining the time that the device must be held in reset.

TABLE 5: MAXIMUM TIME FROM POR RISING EDGE TO VALID V_{DD} VOLTAGE

	Osc Mode	Maximum Time	Conditions
PIC16C5X	LP, XT, HS, and RC	9 ms	
PIC16CXXX	RC	28 ms	
	LP, XT, and HS	28 ms + 1024 Tosc	PWRTE = 1
	LP, XT, and HS	1024 Tosc	PWRTE = 0
PIC17CXXX	LF, XT, EC, and RC	Greater of (40 ms or 1024 Tosc)	

FIGURE 9: POR DELAY FOR FAST V_{DD} RISE TIME

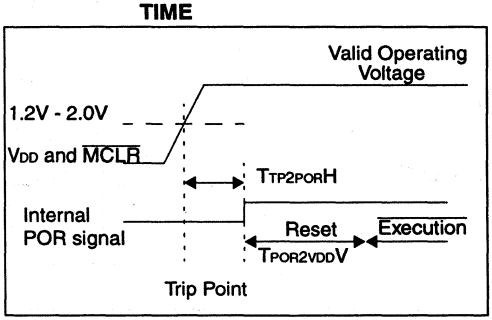

TABLE 6: RESET TIME DUE TO OSCILLATOR

	Clock Frequency								
	32 kHz	1 MHz	2 MHz	4 MHz	8 MHz	10 MHz	16 MHz	20 MHz	25 MHz
1024 Tosc	32 ms	1.0 ms	512 µs	256 µs	128 µs	102.4 µs	64 µs	51.2 µs	41 µs

Oscillator and Resonator Considerations

Oscillators and resonators from different manufacturers may have different characteristics. The recommended capacitor selection can be found in each device's data sheet. When we do the capacitor selection, during the oscillator/resonator characterization, we are currently using devices from one of several manufacturers. Generally we use oscillators from either ECS, CTS, FOX or Epson, and ceramic resonators from either Murata Erie or Panasonic. Other manufacturers may be used in the future, depending on availability and other factors.

Other manufacturers devices may have significantly different characteristics. To ensure proper oscillator operation, the circuit should be verified at the lowest temperature/highest V_{DD} (to ensure that the crystal is not overdriven), and with the highest temperature/lowest V_{DD} (to ensure the device still starts up) that the device will be subjected to while in the application. This ensures a stable start-up and frequency for this device, at the extreme conditions of the application.

For production purposes, the above testing should be done with many different samples of the components selected. This is so the part to part variation of the capacitors, resistors, crystals/resonators, and PICmicro devices are taken into account. All PICmicro final data sheets supply the characterization information on the transconductance of the oscillator (measurement of gain). This information can be used to check part to part variations of the PICmicro.

When selecting the crystal, the designer must ensure that it is a parallel cut type. Failure to use a parallel cut crystal may cause:

- Frequency operation out of the specified range of the crystal.
- Unreliable oscillator start-up.
- Device or crystal damage.

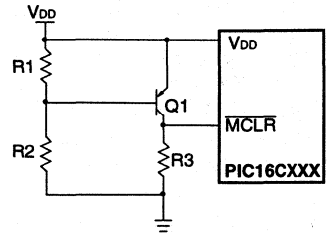
RAM and Special Function Register Initialization

After a successful Power-up Reset, the device will begin to execute the firmware program. To have expected operation, ALL RAM should be initialized by the program. This includes the Special Function Registers (SFR) and the general purpose data memory. The use (read) of an uninitialized RAM location will cause the program to do exactly what you told it, with the unexpected RAM value. It should not be expected that all devices will power-up with the same uninitialized device values.

There are many factors that contribute to how a RAM cell powers up, but the most common "gotcha" is between the Windowed and OTP device types. Many times a user forgets to cover the window after erasing the Windowed device. When the device is powering up, and the light is able to shine onto the device die, the transistor characteristics will shift. This can cause the device RAM to have a different power-up value than a device where no light can shine onto the die (OTP or covered).

Note:	RAM locations should be initialized before they are used. Use of an uninitialized location will cause proper device operation with the improper values. That is, it will do what you told it to do, not what you wanted it to do.

Valid Operating Voltage Levels



When the device is operating, the device voltage must be within the specified Min/Max limits. Operation of the device outside these limits may cause unexpected device operation.

One of the primary functional failure modes of a device is when the applied voltage is lower than the specified minimum requirement. This functional failure is called Brown-out. Brown-out causes the program memory not to be read correctly. For example, the program counter may be pointing to a `MOVE` instruction, but the device reads it as a `GOTO` instruction (with a random destination). This can have disastrous affects to the operation of the application. If brown-out conditions are possible, the application needs to be protected by using a brown-out circuit. A brown-out circuit works with the $\overline{MCLR}$ pin to put the device in RESET before the device's actual voltage violates the minimum limit.

Figure 13 shows a low cost external brown-out protection circuit. The voltage at which the circuit causes a reset is dependent upon the tolerances of the components. Figure 14 shows the use of a Dallas Semiconductor EconoReset. This device monitors the status of the power supply, and generates a reset when an out-of-tolerance condition is detected. Motorola also makes some 3-terminal devices to monitor the power supply, such as the MC34164, MC34064, MC33064. Their data sheets should be reviewed to ensure that the device is suitable for your application.

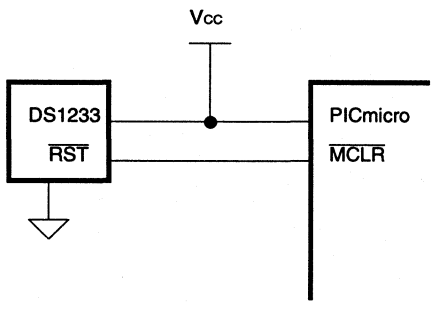

FIGURE 13: LOW COST EXTERNAL BROWN-OUT PROTECTION CIRCUIT

Note: This brown-out circuit is less expensive, albeit less accurate. Transistor Q1 turns off when VDD is below a certain level such that:

$$V_{DD} \bullet \frac{R1}{R1 + R2} = 0.7V$$

FIGURE 14: VOLTAGE SUPERVISORY CHIP

Brown-out and the WDT

The recommended solution for brown-out conditions is the use of a brown-out circuit. The brown-out circuit will keep the device in reset until a valid operating voltage is present. In some applications the additional cost of the external brown-out circuit, can be traded-off with system recovery from brown-out. Use of the Watchdog Timer (WDT) can enhance the probability of system recovery from a brown-out condition.

Note: If I/O drive conflicts can cause critical problems, this technique should not be used. This is due to the indeterminate time before a device reset could occur, which would reset all pins to inputs to eliminate any I/O conflict.

When using the WDT in brown-out conditions, care must be taken. Brown-outs may cause an unrecoverable condition, but with good design practice the probability of this can be significantly reduced.

During a brown-out, improper program execution can occur due to an EPROM read failure. This program execution can also corrupt data memory locations, which include the Special Function Registers (SFRs). Corrupting the control registers may cause hardware conflicts. For example, an input may become an output. Other conflicts are possible, but the situation will be application dependent.

As the device voltage gets lower, internal logic can become corrupted. This can include the Program Counter (PC) value, Stack Pointer and contents, State machines, Data Memory, etc.

When a valid voltage is returned, the device may be at an unexpected program location, possibly using corrupted values. In this situation, the device would not be expected to operate as intended and could get into a state that appears locked-up.

For the PIC17C42 in code protected microcontroller mode, once the Program Counter (PC) exceeds the 32K-word boundary, the device will become locked-up. The PC can exceed the 32K-word boundary from the execution of incorrect instructions (due to failure reading the EPROM) or by the PC becoming corrupted.

If the WDT is to be used to reset the device, care must be used in structuring the program. Optimally, only one CLRWDT instruction should be used. This minimizes the possibility of program execution returning to a loop which clears the WDT. This loop could then lock-up the device, since other control registers are corrupted and the device is not configured as expected. An example is; if the loop was waiting for an interrupt, but the bit that enables global interrupts was disabled, the device would no longer respond to the interrupts and would appear locked-up.

Example 1 shows a simple implementation of using the WDT reset for system recovery. The program loops, waiting for a WDT time-out (which clears the $\overline{TO}$ bit). After the WDT reset, the $\overline{TO}$ bit needs to be set (by executing a CLRWDT instruction). The program should then initialize the device. Then application code can start executing. There is a possibility of the $\overline{TO}$ bit being corrupted by low voltage, and the device not being in a reset state when the software initializes the device.

The WDT example in Appendix B: uses a different method, independent of the $\overline{TO}$ bit. This uses RAM locations which get loaded with a value. A WDT time-out (or other reset) needs to occur. The RAM locations are verified to contain the same values. Once the RAM is verified, it is cleared, and the device should be initialized. These RAM locations can be used by the application program.

EXAMPLE 1: USING WDT RESET

```
org     Reset_Address
        GOTO    TO_TEST     ;At any reset,
                            ;test the TO bit
org     TO_TEST
        BTFSC   STATUS, TO  ;WDT Time-Out?
HERE    GOTO    HERE        ;NO, Wait for TO
Time_Out                    ;YES, Good Reset
        CLRWDT              ;Start here
        :                   ;Initialize Device
        :                   ;Application Code
```

False Power-down

In applications where power is removed from the device's supply lines, but voltage is still applied to an I/O pin, unexpected operation may occur. Power is able to be supplied to the device through this I/O pin. Since the device is still partially powered, the internal logic is never completely powered down. Figure 15 shows the general structure of an I/O pin. Figure 16 depicts the internal voltage level that is actually applied to some device logic, versus what is seen at the pin.

To guarantee a Power-on Reset (POR) rising edge, the device voltage (V_{DD}) must start from Vss. When the device is inadvertently powered from an I/O pin, the voltage at the V_{DD} pin may appear to be near ground but may actually be higher in the device. With some of the internal logic powered, the characteristics of the device can be similar to a brown-out situation. Similar design practices to brown-out should be implemented.

A method for protecting the device from being powered from an I/O pin is shown in Figure 17.

FIGURE 15: TYPICAL ELECTRICAL STRUCTURE OF I/O PIN

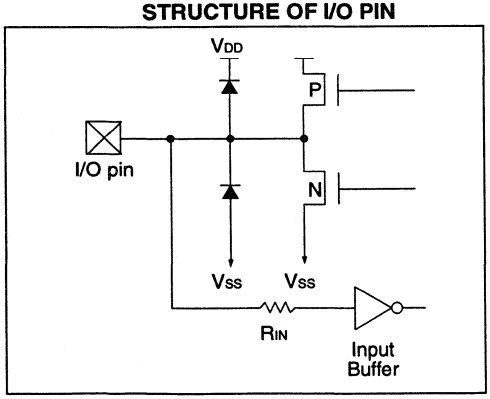

FIGURE 16: FALSE POWER-DOWN

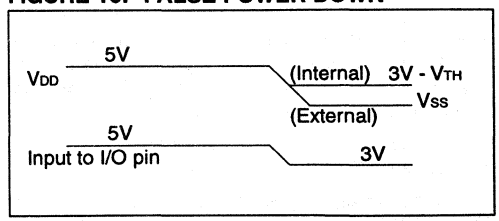

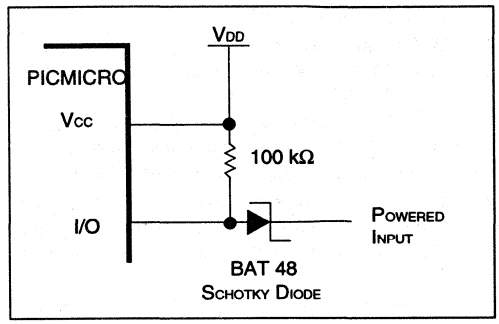

FIGURE 17: POWERED INPUT PROTECTION

In general, a brown-out detect circuit should cause the PICmicro to RESET ($\overline{MCLR}$ forced low). This ensures that the internal logic is in a known state until a valid device voltage level is reached. The actual brown-out circuit depends on the voltage range of the device and the application requirements. A comprehensive brown-out circuit would use a dedicated device to monitor the voltage and force the $\overline{MCLR}$ pin low when the voltage becomes lower than specified.

Another case of false power-down situations is when the power is removed from the system, but the capacitor loading keeps a non-zero voltage on the V_{DD} pin. When power is reapplied, the device never powered down so no Power-on-Reset will occur. A simple brown-out circuit should fix this.

5

TROUBLESHOOTING

There are several techniques that can be used to troubleshoot problems related to powering up. First it is important to try to locate the source of the problem. These sources could be:

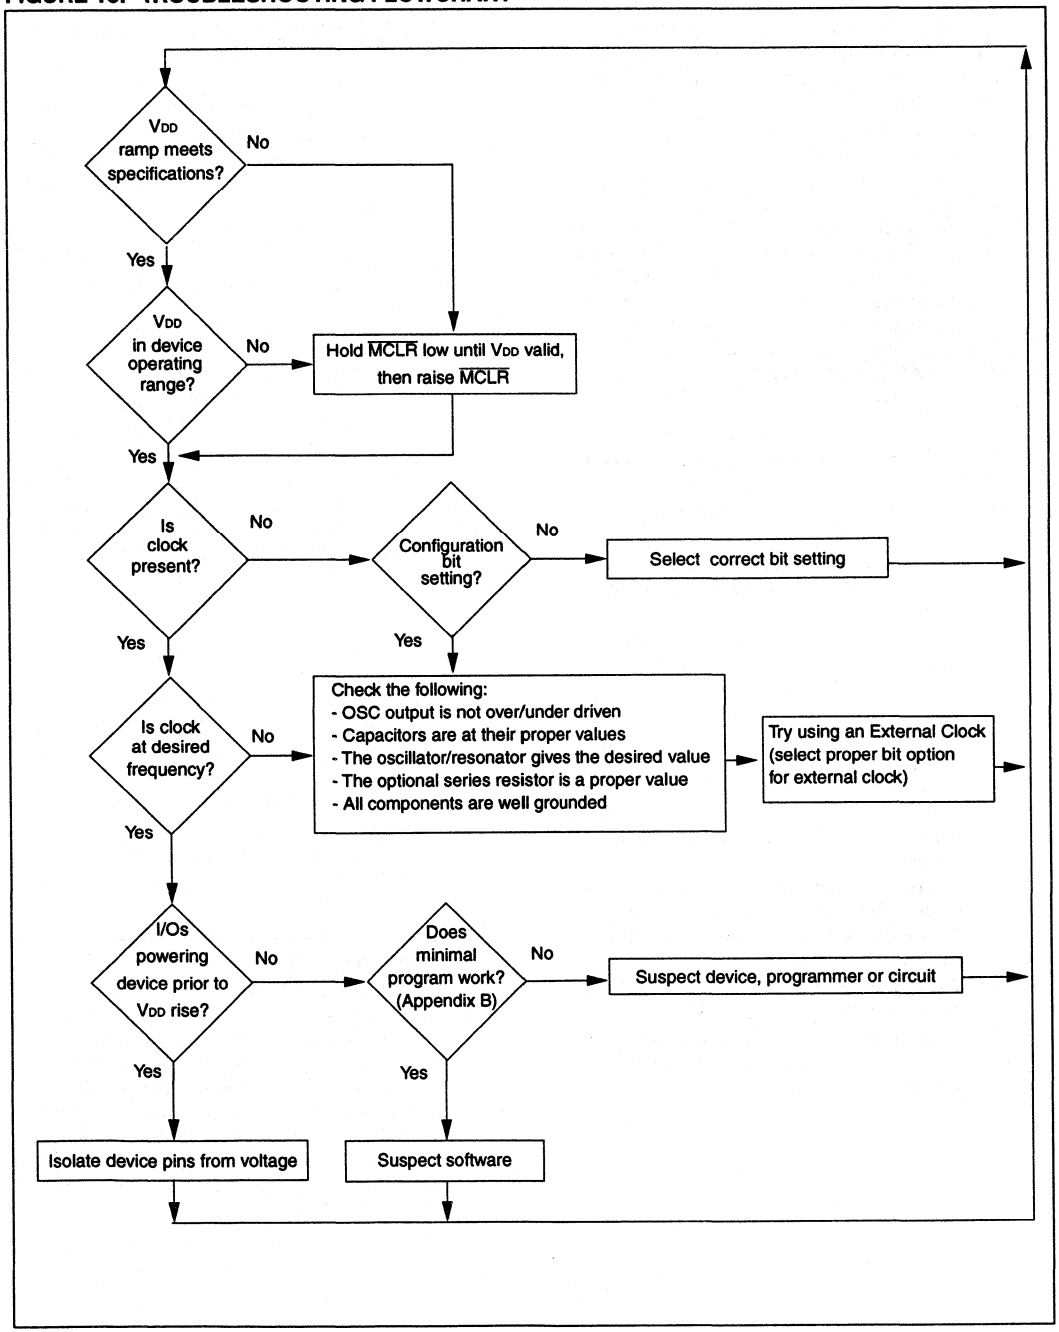
- No oscillation on OSC1/OSC2 pins
- Improper/no Program Execution

In cases where there is no oscillation on the OSC1/OSC2 pins, some of the following should be tried:

a) Verify that there are good connections/the components are good.
b) Verify that the crystal/resonator manufacturer is one that has been tested, if not try other capacitor values.
c) See if an external clock (from a function generator) causes device operation to begin.
d) Verify that all components are well grounded.
e) If a scope probe is connected to the oscillator output, it must be a low capacitance/high impedance probe. If it is not, the oscillator may stop.

In cases where program execution is not as expected:

a) Use a minimal program with external clock input.
b) Tie $\overline{MCLR}$ to ground until solid power is applied to the device then release $\overline{MCLR}$ (bring high).
c) Measure V_{DD} rise time to determine if an external reset circuit is needed, and, if so, what type of reset circuit should be used.
d) Verify that the device program memory and configuration bits are programmed to their expected states.



The flowchart shown in Figure 18 can be used to troubleshoot power-up problems. This flowchart is only intended to be the first level diagnostic in trying to solve a power-up problem. Many other flowcharts can be used, depending on the characteristics of the problem and the set-up of the application.

CONCLUSION

Understanding the criteria for the powering up of a device will allow you to make better design choices. If device power-up problems are still encountered, many techniques can be used to solve the problem. Appendix B contains example code which can be used to verify that a device is operating (powered-up correctly). This eliminates the possibility of the program as the cause, and allows debug on the hardware.

FIGURE 18: TROUBLESHOOTING FLOWCHART

5

APPENDIX A: Q & As

Q. ***When I use a windowed device (JW), my application works as expected. When I program an OTP device, it no longer works as expected. Why is this?***

A. The silicon is the same between the OTP and windowed devices. If the windowed device's window is not covered (with black tape), light shines onto the silicon. The light causes the potential levels of gates to shift. This in turn can cause RAM to be initialized to an unknown state, which could be different than in the OTP device. If RAM is not initialized by the program before it is used, these different power-up states of the RAM could be the cause of the problem. Ensure that all RAM is initialized in the device. This includes the SFRs.

Q. ***My oscillator is not oscillating, what could be wrong?***

A. There are several possibilities, some which include:

1. The wrong oscillator bit setting is selected. The erased (default) state is RC oscillator mode.
2. The wrong capacitor values are installed. Refer to the most current data sheet for recommended values.
3. The characteristics of your manufacturers crystal are different than those that are characterized by Microchip. Generally our tests have been done with one of the following manufacturers' crystals/ resonators: ECS, FOX, Murata Erie, or Panasonic.
4. The external connections to the device are wrong. Verify that all connections to the device are correct and that good signals / levels are being applied.
5. The cut of the crystal is a series type, as opposed to the specified parallel type.
6. No bypassing capacitors were used on the device. The noise on V_{DD} could be affecting the oscillator circuitry.

Q. ***The device was powered-down and then powered back up, but the device does not operate. What could be wrong.***

A. Possibilities include:

1. If power was applied to an I/O pin when the device was "powered-down", the device would be powered through the I/O pin. The internal logic is not actually powered-down, and Power-on Reset (POR) will not occur.
2. When V_{DD} was powered-down, V_{DD} was not given enough time to settle to 0V.
3. The V_{DD} ramp rate is too slow.

Q. ***My oscillator is oscillating, but the device is not working. What could be wrong?***

A. There are several possibilities, some which include:

1. Slow V_{DD} rise time, which was too slow to cause a Power-on Reset (POR). The rise time should not exceed the minimum device specification. For most devices this is 0.05 V/ms. Also the device must be at the minimum operating V_{DD} of the processor when reset is exited.
2. Ensure that the $\overline{MCLR}$ pin is not low. This holds the device in RESET.
3. A brown-out has occurred, and has corrupted the internal state machines (including the WDT). An external brown-out circuit is recommended to hold the device in RESET during the brown-out condition.
4. The `CLRWDT` instruction is not being used (often enough) when the WDT is enabled.

Q. ***When I power-up the device, it does not operate and it gets hot.***

A. Your design is probably permitting fast high voltage signals (spike) onto one of the device pins. This sudden high voltage (and associated current) is in excess of the protection diode limit. The device must be powered-down (to V_{SS}) to release this condition. This condition may cause a functional failure or affect device reliability. All Microchip devices meet or exceed the Human Body Model (HBM) and Machine Model (MM) for ESD and latch-up.

© 1997 Microchip Technology Inc.

Q. ***My oscillator is oscillating, but not at the expected frequency. What could be wrong.***

A. For many designers, working with oscillators and their related issues are a "black magic", since the characteristics can vary widely between manufacturers. I suggest that you read all the application notes that we have available on oscillators. Some quick possibilities are:

1. The cut of the crystal is a series type, as opposed to the specified parallel type.
2. No bypassing capacitors were used on the device. The noise on V_{DD} could affect the oscillator circuitry.
3. The capacitor values used are causing the oscillator to operate in one of the harmonic frequencies.

Note: This is not an all inclusive list. You may need to investigate other design aspects.

Q. ***The device seems to never exit reset, or is continually resetting.***

A. The CLRWDT instruction is not being used (often enough) when the WDT is enabled.

Q. ***The device was powered-down and back up again, but it does not reset. It just starts operating immediately.***

A. Possibilities include:

1. If power was applied to an I/O pin when the device was "powered-down", the device would be powered through the I/O pin. The internal logic is not actually powered-down, and a Power-on Reset (POR) will not occur.
2. When V_{DD} was powered down, V_{DD} was not given enough time to settle to 0V.

Q. ***The oscillator is operating (I check it with a scope), yet when I look at other pins the program is not executing. Why?***

A. One possible reason is that when the oscilloscope probe is placed on the OSC2 pin, the additional capacitance is enough to cause oscillation to start. Removing the capacitive load of the probe causes the oscillation to stop.

```

Note: Special Function Register data memory locations, in Bank 1, are specified by their true address in the file PIC16CXXX.INC. The use of the MPASM assembler will generate a warning message, when those labels are used with direct addressing. Warning messages can be turned off with an assembler option.

WDT RESET WITH RAM VERIFY

```
MPASM 01.20 Released          BO_RAMT.ASM   6-30-1995  16:04:36         PAGE  1

LOC  OBJECT CODE     LINE SOURCE TEXT
  VALUE

                     00001         LIST    P = 17C44,  F = INHX32, n = 66
                     00002 ;
                     00003 ;*****************************************************************************
                     00004 ;
                     00005 ; This program is a minimum program to recover from a brown-out condition thru
                     00006 ; the use of the WDT. The method is to load RAM locations with a known value
                     00007 ; and compare these locations after any RESET. If the RAM location matches the
                     00008 ; expected value then program flow can continue. The longer this RAM string
                     00009 ; is, the greater the probability that the RAM would NOT power up in that state.
                     00010 ;
                     00011 ;
                     00012 ; NOTE: This does not Guarantee device recovery, due to the random start-up
                     00013 ;       point after brown-out. This point could be a loop with a CLRWDT
                     00014 ;       instruction. The recommended solution is to always use a brown-out
                     00015 ;       circuit.
                     00016 ;

Clock Design Using Low Power/Cost Techniques

Author: *John Day*
Sr., Field Application Engineer, Boston

INTRODUCTION

Typical embedded control applications place demands such as low power consumption, small size, low cost and reduced component count onto the microcontroller. This application note implements a 24-hour digital clock, alarm and 99 minute 59 second count down timer, yet operates on two "AA" batteries. The PIC16C54A is perfect for this application, due to it's small size, high current I/Os with direct LED drive, low cost, fast instruction throughput and low frequency/current operation.

System cost

The objective of this design was to implement the maximum number of features with the least expensive and smallest device. The PIC16C54A is Microchip's lowest cost microcontroller and it has 12 I/O lines, each capable of sinking 25 mA and sourcing 20 mA. High efficiency common cathode LED displays were chosen for their 3.5 mA current requirement, eliminating the need for any external transistors for display drive. A low impedance direct drive piezo buzzer was chosen and it's tone is generated by the software of the PIC16C54A to further reduce system cost.

Operating power

In battery powered applications, the operating current determines the lifetime of the batteries. There are many ways to reduce the operating current of any application, including low frequency operation and the use of sleep mode. Since the clock has to keep track of time, SLEEP mode could not be used and the processor must be kept running all of the time. The PIC16C54A supports the 32.768 kHz "watch" crystal and typically consumes less than 15 µA of current in this configuration. Since the PIC16C54A executes instructions in one cycle and it's instruction set is very efficient, this application was able to be implemented using a low frequency crystal. Another solution to this problem comes with the PIC16C74/73/65/63 in it's Timer1 module. Timer1 will run when the device is asleep, so it could have been used to keep track of time, simplifying the software.

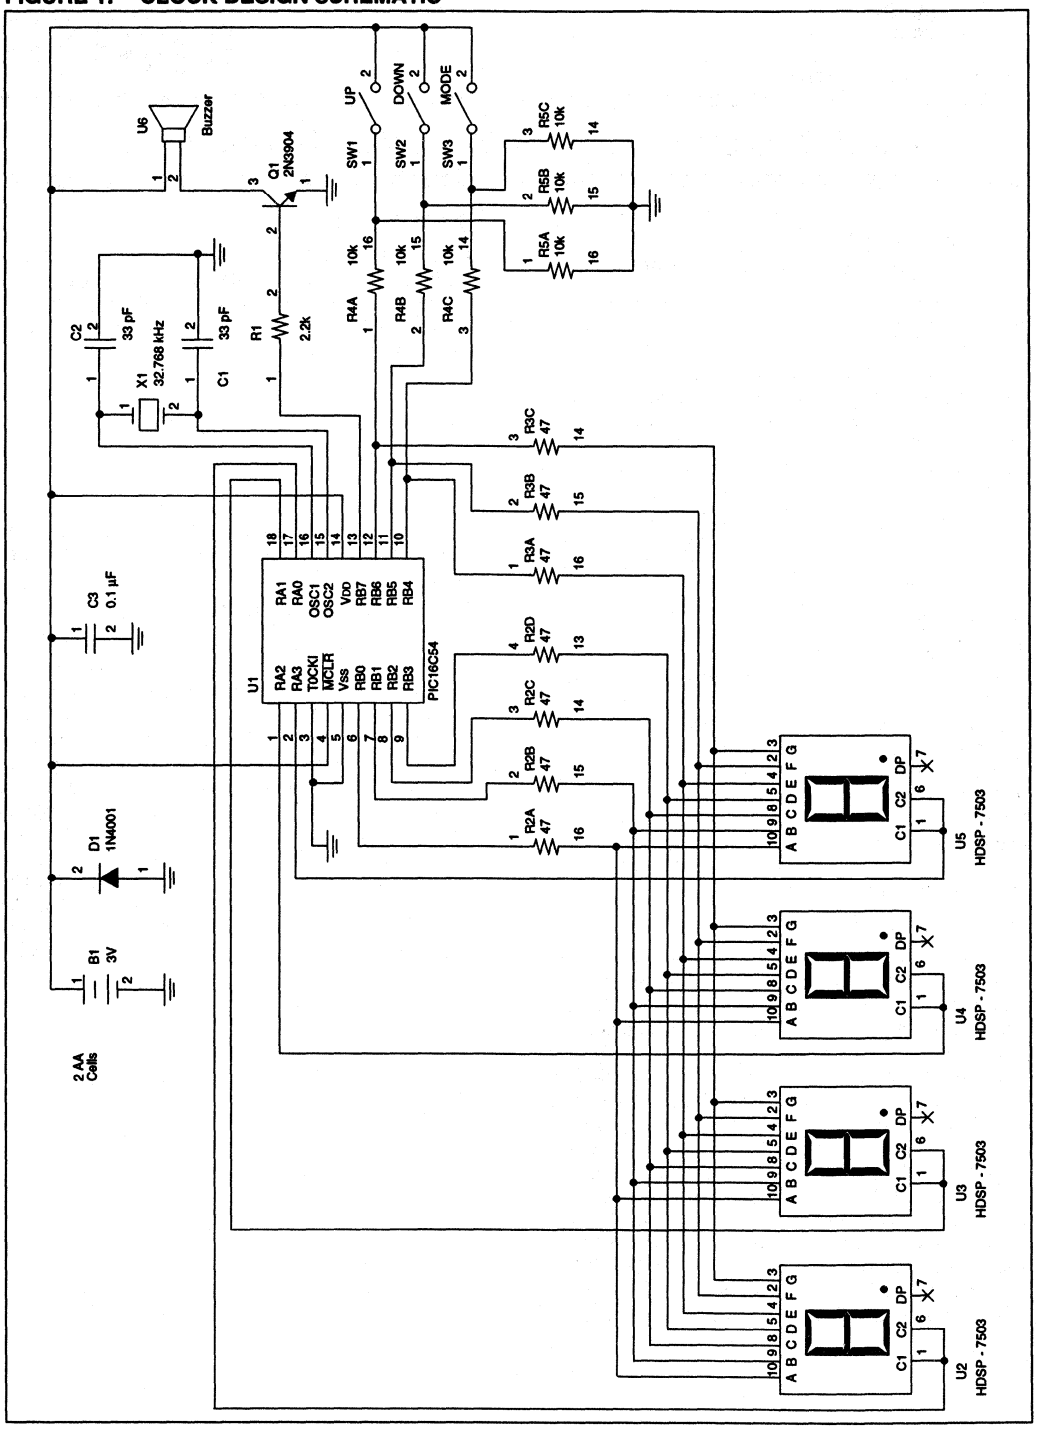
Clock system

A 32.768 kHz crystal was chosen for the clock due to the low power and cost requirements of this design. The four internal phases of this input clock create an internal instruction cycle. Therefore, the instruction time is calculated as follows:

$$\text{Instruction rate} = \frac{1}{(\text{CLKIN}/4)} = \frac{1}{32{,}768/4} = \frac{1}{8{,}192}$$

Instruction cycle = 122.07 µs

This means that every instruction executes in 122.07 µs or we execute exactly 8,192 instructions per second.



Display and keypad multiplexing

The display contains four digits with seven segments each; therefore a multiplexing scheme was used to reduce the number of I/O lines needed to drive the displays. There are 4 common cathode display connections (one for each display digit and connected to PORTA for convenience so that rotates and moves can be used) and 7 segments (connected to PORTB for convenience so that moves can be used) for a total of 11 I/O lines needed for the display. Common Cathode displays were chosen, since the PIC16C54A can sink 5 mA more current than it can source. The last I/O line (RB7) was used to drive the buzzer. The three keys for setting the time are multiplexed onto the LED display segments to eliminate the need for additional I/O lines.

SOFTWARE IMPLEMENTATION

The main loop of the software must perform the following tasks to implement the clock's functionality:

1. Determine when one second has passed (when bit7 on the TMR0 register changes state 4 times), increment the current time and (if enabled) decrement the countdown timer.
2. Determine if any of the alarms (countdown timer or the alarm time) are currently alarming or should be alarming. If so, the buzzer is buzzed.
3. Check for any keys that are pressed. If MODE is pressed, the current mode is incremented and if UP or DOWN is pressed, the time displayed is modified.
4. Automatically turn the displays on/off for power management.
5. Multiplex the displays every 3.9 ms (32 instruction cycles).

General purpose registers are defined and used for the following purposes:

- **DISPSEGS_A** through **DISPSEGS_D** store the bit pattern that is to be displayed on each of the four 7-segment displays.
- **CLK_SEC** stores the second counter for the current clock time (values from 0-59 decimal are stored).
- **CLK_MIN_LD, CLK_MIN_HD** store the upper and lower minute digit of the current time.
- **CLK_HOUR_LD, CLK_HOUR_HD** store the upper and lower hour digit of the current time.
- **ALM_MIN_LD, ALM_MIN_HD** store the upper and lower minute digit of the alarm time.
- **ALM_HOUR_LD, ALM_HOUR_HD** store the upper and lower hour digit of the alarm time.
- **TMR_SEC_LD, TMR_SEC_HD** store the upper and lower second digit of the countdown timer.
- **TMR_MIN_LD, TMR_MIN_HD** store the upper and lower minute digit of the countdown timer.
- **KEYPAT** stores a pattern showing the currently pressed keys:
  - UP = bit6
  - DOWN = bit5
  - MODE = bit4
- **FLAGS** stores key flag bits such as the current mode, display on, alarm on, etc.
- **PREVTMR0** stores previous TMR0 values so that the differences can be detected the next time the TMR0 is polled.
- **TEMP** is a temporary register used for various routines.
- **DISPONCNT** stores the remaining number of seconds the displays should be on.
- **MODE_COUNT** stores the number of 1/2 seconds the MODE and UP or DOWN buttons are pressed. Used to switch from setting minutes to hours.
- **ALARMCNT** stores the number of beeps remaining to be driven into the buzzer.

FLAGS Register

Most designs require flag or state bits to indicate current modes or the state of a software routines. In this design, the FLAGS register is defined as follows:

Bits 0,1 -indicates the current operating mode (changed by pressing and releasing the MODE button):

00 - Display OFF

01 - Display/Set countdown timer

10 - Display/Set alarm time

11 - Display/Set clock (current time)

Bit 3 - indicates if (alarm time) = (current clock time)

Bit 4 - indicates if (count down timer) = 0

Bits 5,6,7 -Used as a divide by four counter to keep track of seconds

The software is broken up into the following routines for modularity:

buzz_now routine - *Output buzzing tone during alarm for 156 ms.*

Buzzers are available in self-oscillating and direct drive models. To save cost, a low impedance, direct drive model was selected. The buzz_now routine is called by the main_loop and it chirps the buzzer for 156 ms at a 1638 Hz frequency. This routine first turns off the LEDs (by clearing PORTB) and then uses TEMP to count for 256 pulses. The pulse is sent to the buzzer by the `BSF BUZZEROUT` and `BCF BUZZEROUT` instructions. This routine returns once 256 pulses are sent to the buzzer. This is necessary, since the controller cannot buzz the buzzer and keep track of time at the same time (running at such a low frequency), so these two functions are multiplexed.

5

task_scan routine - *multiplex LEDs to display the next digit, only one digit is lit at a time).*

The PIC16C5X family is designed for polled I/O applications and does not contain a hardware interrupt structure. To achieve the lowest cost design, the PIC16C54A was selected and all modules are written to CALL this task_scan routine within the multiplexing time frame of 3.9 ms or 32 instruction cycles. This routine first synchronizes itself with the TMR0 register, bit0 to ensure that the scanning occurs at the same point in time, regardless of when the routine is called. Next, PREVSCAN is rotated, setting up the CARRY bit correctly. The bit pattern for the next digit to be displayed is then moved into the W. register. The display is blanked, PORTA is rotated (to select the next digit) and the next display bit pattern is moved to PORTB to display it. For ESD integrity, PORTA is later restored from the PREVSCAN register. This routine takes a total of 21 cycles (including the CALL and RETLW instructions) to execute and the displays are scanned every 3.9 ms (32 instruction cycles); therefore, this routine needs to be called after every 11 instruction cycles from every routine to maintain proper display multiplexing.

disp_value routine - *Update the display registers with the bitmap of what digits are to be displayed next.*

Indirect addressing is used here to reduce the amount of code needed and to simplify the routine. Since the clock, alarm or countdown time could each be displayed, the W register contains the base address (in the register file) of the four digits that are to currently be displayed. The W register is first moved to the FSR register so that the indirect address register contains the first digit to be displayed. The first digit is first converted into the segment bit pattern by calling the led_lookup table and then the bit pattern is moved to DISPSEGS_A. The FSR register is incremented (moving to the next digit) and the process is repeated for the remaining 3 digits. To maintain proper multiplexing, task_scan is called throughout this routine.

turnon_scan routine - *Turns on the LEDs and restores a legal scan position.*

To save battery power, the displays are automatically shut off after 8 seconds when no buttons are pressed. The DISPON bit is used to preset the remaining display on time to 8 seconds. This routine sets this flag (to later turn on the displays) and then checks to see if the PREVSCAN register contains a legal value (an illegal value of "FFh" is used to turn off all of the displays) and it restores a legal value if the displays were off.

scan_keys routine - *Turns off LEDs for a moment and scans the push-button inputs.*

To reduce the number of I/Os needed by this application, the three user input keys are multiplexed onto the LED display segments through PORTB. First, the PORTB is cleared and PORTA is set to '0Fh', turning off the LED displays. Next, PORTB is set up with bits 4,5 and 6 as inputs to read the keys. TEMP is then loaded with the keys that have changed state (to detect the falling edge of a key press) and KEYPAT is loaded with a pattern ('0' = not pressed, '1' = pressed) for the keys that are pressed. Lastly, PORTB is restored to all outputs and the current multiplex scan is restored to PORTA.

check_time routine - *Checks for alarm or countdown timer expiration.*

Each second, alarm conditions must be detected and the buzzer sounded if an alarm condition is true. ALARMNOW and EGGNOW are flag bits that are used by the main program to sound the buzzer if they are set. This routine starts by setting both ALARMNOW and EGGNOW. Next, the current time hours and minutes are compared (through a subtraction and a test of the STATUS register Z bit) with the alarm time. If there is any miscompare, the ALARMNOW bit is cleared. To finish, the countdown timer time minutes and seconds digits are each compared with zero. If there is any miscompare, the EGGNOW bit is cleared. To maintain proper multiplexing, the task_scan routine is regularly called throughout this routine.

inc_time routine - *Adds one second, minute or hour to the clock, alarm or timer.*

Every second, inc_time is called by main_loop to increment the seconds count for the clock. This routine is also called when the "UP" key is pressed and "MODE" key is held down to adjust the current time, alarm time or set the countdown timer. This routine uses indirect addressing to reduce the amount of code and simplify it's operation. Before this routine is called, the W register is loaded with the address of the clock second register and the routine is called. The FSR register is loaded with this value and the indirect address register is incremented (effectively incrementing the seconds counter).

Once the second counter is incremented, this register is checked for overflow (greater than 59 seconds) and if no overflow occurred, the routine returns. If an overflow happened, the second counter is cleared and the minute low digit is incremented. This register is then checked for an overflow (greater than 9 minutes) and so on until the all digits are updated.

This routine can also be called from multiple points. If called with the label inc_min_ld, only the minutes (and hours if an overflow occurs) will be incremented. Additionally, calling inc_hour_ld will increment only the hour digits. These features are used when setting the clock or alarm function. The FLAGS register (bits 0 and 1) is used to determine the current mode (clock, alarm or countdown timer) and ensure proper overflow calculations. To maintain proper multiplexing, the task_scan routine is regularly called throughout this routine.

© 1997 Microchip Technology Inc.

dec_time routine - *Subtracts one second, minute or hour from the clock, alarm or timer.*

If the countdown timer is enabled, dec_time is called by the main loop to decrement the seconds count for the countdown timer. This routine is also called by the main loop when the "DOWN" key is pressed and "MODE" key is held down to adjust the current time, alarm time or set the countdown timer. This routine uses indirect addressing to reduce the amount of code and simplify it's operation. Before this routine is called, the W register is loaded with the address of the countdown timer's second register and the routine is called. The FSR register is loaded with this value and the indirect address register is incremented (effectively incrementing the seconds counter).

Once the second counter LSD is decremented, this register is checked for underflow (less than 0 seconds) and if no underflow occurred, the routine returns. If an underflow happened, the second counter LSD is set to 9 and the second MSD is decremented. This register is then checked for an underflow (less than 0 seconds) and so on until all digits are updated.

This routine also can be called from multiple points. If called with the label dec_hour_ld_vec, only the hour digits (or minutes if it is the countdown timer) will be decremented. This feature is used when setting the clock or alarm function. The FLAGS register (bits 0 and 1) is used to determine the current mode (clock, alarm or countdown timer) and ensure proper underflow calculations. To maintain proper multiplexing, the task_scan routine is regularly called throughout this routine.

main_loop routine - *Calls the above routines as needed and keeps track of when to increment the clock or decrement the countdown timer.*

The main_loop calls all of the previous routines as necessary to maintain time, LED multiplexing, alarming and setting each function. The OPTION register is loaded with a 03h value to set up a Divide by 16 prescaler for the TMR0 register and internal instruction cycle increment. The instruction cycle is 122.07 µs; therefore, bit0 changes every (122 µs • 16) = 1.953 ms and bit7 changes every (122.07 µs • 16 • 128) = 250 ms. Bits 5 and 6 of the FLAGS register are used to divide this 250 ms event by 4 to call inc_time every second.

The check_time routine is called after calling inc_time (every second), setting the EGGNOW or ALARMNOW flag bits. If the alarm is enabled, the buzzer is buzzed by calling buzz_now; however, the main timer updates need to occur in between buzzer beeps to keep track of time.

Every 500 ms, the keys are scanned and the edges on the MODE key are detected. Pressing the UP or DOWN key will shut off the buzzer (clearing the enable bits) and pressing the MODE key will advance the current mode. The mode is a 4-state state machine, revolving between the following states:

1. Display OFF - saves battery power - defaults to this mode if no keys are pressed for 8 seconds.
2. Display or Set countdown timer (holding MODE key allows setting).
3. Display or Set Alarm time (holding MODE key allows setting).
4. Display or Set Clock time (holding MODE key allows setting).

Next, the UP and DOWN keyscan values are tested and if the MODE and UP are both pressed, the currently displayed mode time is incremented or decremented. If MODE is not pressed and UP or DOWN is pressed, the displays are turned on, but the displayed time is not altered.

DISPONCNT is used to keep track of how long the displays have been on once all buttons are released. After 8 seconds, the displays are automatically turned off to save power. MODE_COUNT is used to switch from setting the right hand displays (minutes or seconds) to the left hand displays (hours or minutes). When the UP or DOWN button is held with mode for more than 4 seconds consecutively, MODE_COUNT reaches zero, switching from the right to left hand displays.

Finally, the main_loop finishes by updating the display registers by calling disp_value and if DISPONCNT has decreased to zero, the displays are turned off.

Lookup Tables - *Convert a number into a bit pattern or RAM address.*

There are three lookup tables used in this design for BCD to 7-Segment decoding, manufacturing diagnostics and looking up the address of the currently displayed mode.

- **mode_timer** - look-up the address of the clock, Alarm or Timer data storage RAM.
- **led_lookup** - look-up table contains the bitmap display pattern for displaying digits 0-9.
- **mfg_led_lookup** - look-up table contains the bitmap display pattern used for manufacturing mode. Only one segment is lit at a time.

Miscellaneous routines used for initialization and manufacturing test:

- **init** - Initializes all of RAM to zero, sets up the I/O ports and sets default time values.
- **mfg_selftest** - Used in manufacturing mode only - tests each LED segment, push-button, buzzer and display separately to expose bad keys, connections, buzzer or displays.

CONCLUSION

The implementation of this application highlights the PIC16C54's highly efficient instruction set, low power and frequency operation, high current direct LED drive capability and high performance instruction execution. Many of the routines used in this application note apply to a variety embedded control applications.

Ram Used: 25 Bytes

Code Space Used: 444 Words (without manufacturing diagnostics)

510 Words (including manufacturing diagnostics)

Converting NTQ104/105/106 Designs to HCS200/300s

Author: Kobus Marneweck
Microchip Technology Inc.

INTRODUCTION

NTQ104/105/106 encoders have been used in many designs requiring the high security offered by the KEELOQ® code hopping system. With the introduction of Microchip's encoders, the HCS200/300 and the high-voltage HCS301, designers can do seamless conversions of their NTQ104/105/106 encoders to the new Microchip HCS200/300 devices. In addition, designers can convert their NTQ104/105/106 encoders to the new Microchip devices and take advantage of the extra features and lower cost of the new devices with minimal changes. This application note will help designers to do these conversion and take advantage of the features on the HCSXXX series to reduce the required component count.

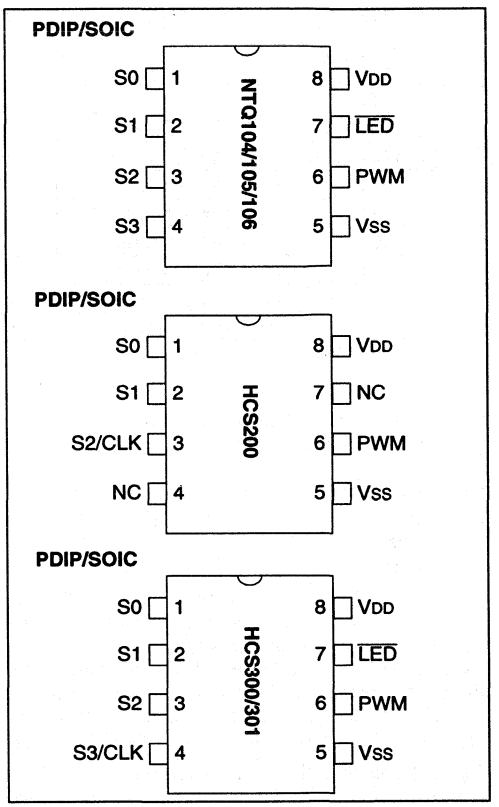

TABLE 1: SUMMARY OF FEATURES

Encoder	Function Codes	Operating Voltage	Programming Lines	Transmission Length
HCS300	15	2.0 to 6.3V	Clock + Data	66
HCS301	15	4.5 to 12.5V	Clock + Data	66

Note: The NTQ devices used a single bi-directional PWM line for programming, but required S3 to be pulled high to select programming mode. The NTQ and HCS devices, therefore, both require a 4-pin connection to program, but no external diodes are used.

1111	Not supported	Not supported	Not supported	1111 (Note)

Note: Seed transmission mode.

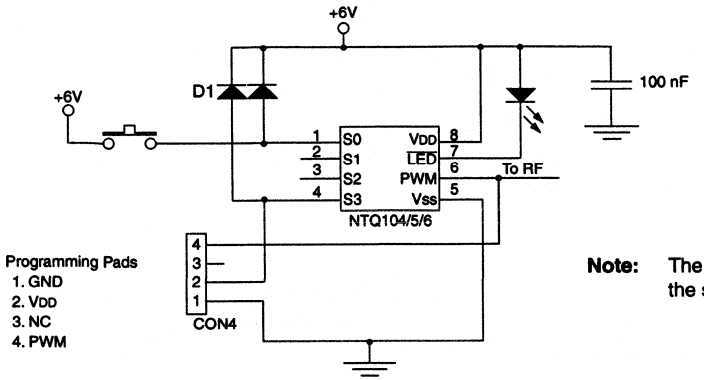
CONVERTING LOW VOLTAGE (3.0V TO 6.0V) DESIGNS

Low voltage designs do not require changes to the board layout since the NTQ and HCS devices are pin compatible. The HCS300 will support all the function codes available on the NTQ104/105/106.

The HCS200 can be used to replace the NTQ104/106, except where function X111 was used. Most designs, however, do not use function X111 and, therefore, can benefit from the extra functionality — in the HCS200, this button combination is used for the Secure Learning mode. The circuit diagram (Figure 1) shows the replacement of the NTQ devices with the HCS devices.

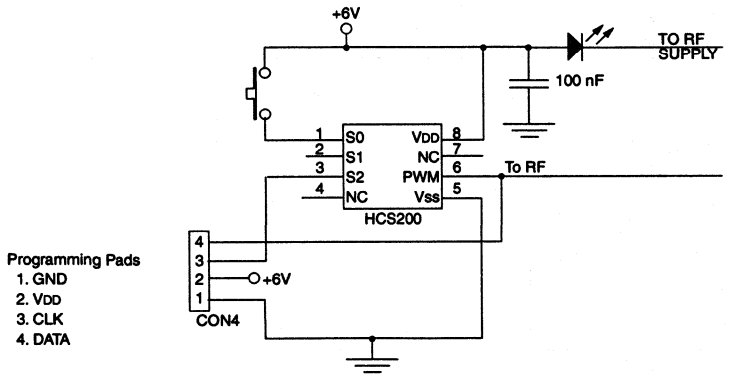
Figure 1 shows a NTQ transmitter design where two diodes were used to allow programming with a 3-pin probe. This is not an optimum implementation since the diodes are only used during programming. The HCS300 circuit shows how the design can be simplified. The HCS200 does not have an $\overline{\text{LED}}$ output but $\overline{\text{LED}}$ power indication can be implemented by connecting the $\overline{\text{LED}}$ in line with the RF power or in-line with the HCS200 power. The clock pin for the HCS200 is on pin three. Interchangeability between the HCS200 and HCS300 can be achieved by using pin three for the clock in the HCS300 circuit.

Figure 2 shows a typical multi-button transmitter design using the NTQ104/105/106. In this case no changes are required for the HCS300. The HCS200 will require the $\overline{\text{LED}}$ connected in-line of power indication and the clock line connected to pin three.

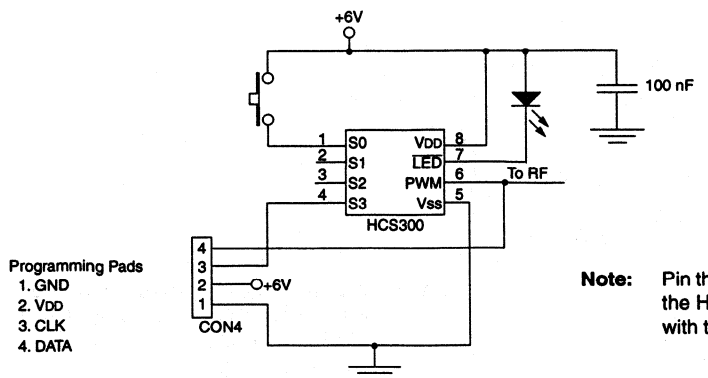


CONVERTING HIGH VOLTAGE (6.0V TO 12.0V) DESIGNS

The HCS301 has an on-board regulator that enables the device to operate with a 12V supply. This allows a significant reduction in external components. The steering diodes, protection resistors and zener diode are no longer required. Resistor R1 can be used to reduce the operating current. The PWM output voltage will swing between ground and V_{DD}. The circuit diagram (Figure 3) shows the simplified circuit.



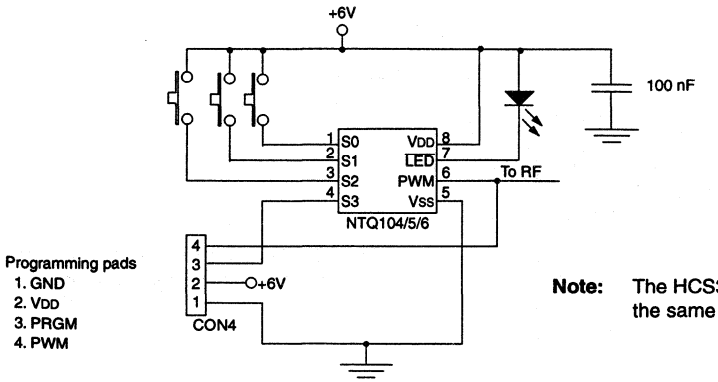
The HCS300/301 can also be used in the same circuit without changes.

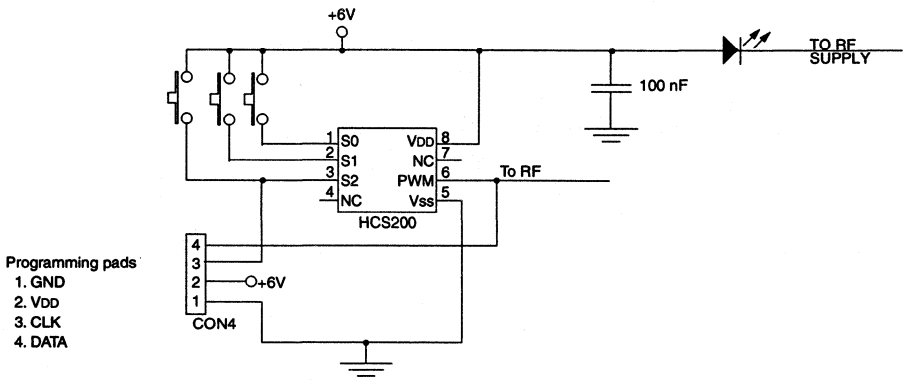


© 1997 Microchip Technology Inc.

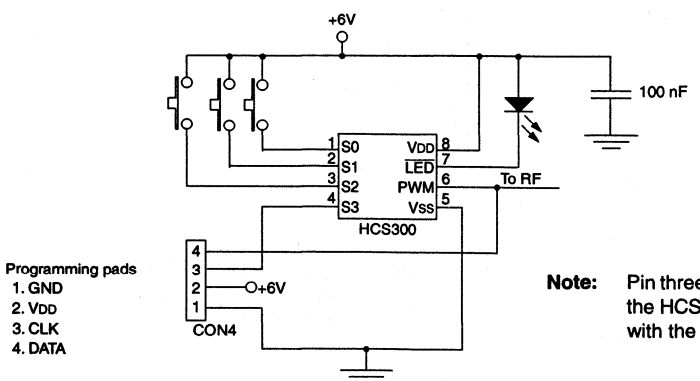
FIGURE 1: CONVERTING NTQ104/105/106 TO HCS200/300

Note: The HCS300/301 can also be used in the same circuit with D1 removed.





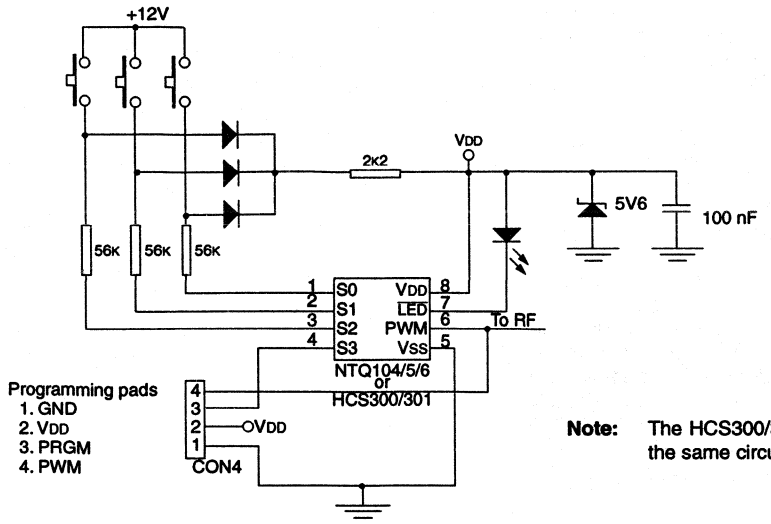
Note: Pin three can also be used as a clock on the HCS300 to provide pin compatibility with the HCS200.

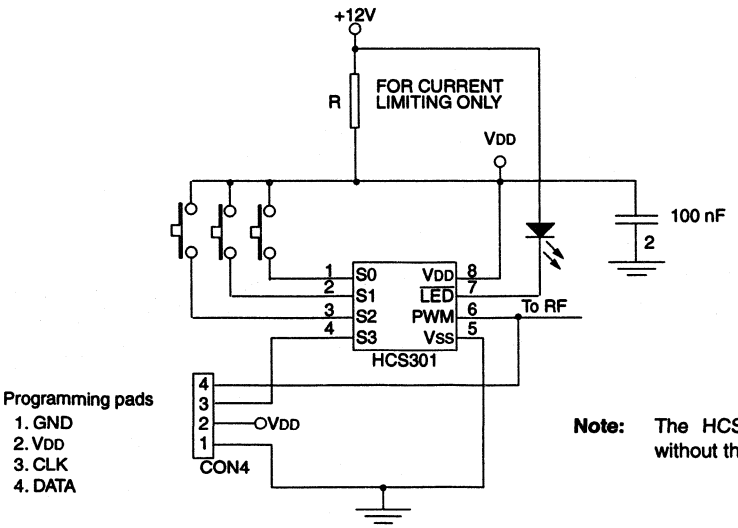


6

FIGURE 2: CONVERTING NTQ104/105/106 TO HCS200/300

Note: The HCS300/301 can also be used in the same circuit.





Note: Pin three can also be used as a clock on the HCS300 to provide pin compatibility with the HCS200.

© 1997 Microchip Technology Inc.

FIGURE 3: CONVERTING NTQ104/105/106 TO HCS301

Note: The HCS300/301 can also be used in the same circuit.

R = 1.5k for 12V battery.
R = 0R for 9V battery.

Note: The HCS301 must be programmed without the battery connected.

6

PROGRAMMING

It is suggested that programming be done without the battery connected. The programming probe supplies 5V during programming and damage to the probe may occur if for instance the transmitter is powered with a 12V battery.

COMPATIBILITY WITH DECODERS

NTQ109/NTQ110 Decoders

These decoders only receive 56-bit codes. Transmissions from HCS200/300 transmitters are, therefore, truncated to 56 bits. With the NTQ109/110 option selected in the programming software supplied with the PG306001 programmer, HCS200/300 transmitters will be programmed with a 24-bit serial number meaning the higher than 24 bits will all be zero. The 24-bit serial number will be used for key generation. An HCS200/300 transmitter is fully compatible with NTQ109/110 decoders if programmed correctly.

PIC16C56 and EEPROM Based Decoders, and HCS509 Decoder

PIC16C56 based HCS509 decoders automatically distinguish between NTQ104/105/106 56-bit transmissions and HCS200/300 66-bit transmissions. The decoder will generate the key from the longer 28-bit serial number if a 66-bit transmission is detected.

MICROCHIP

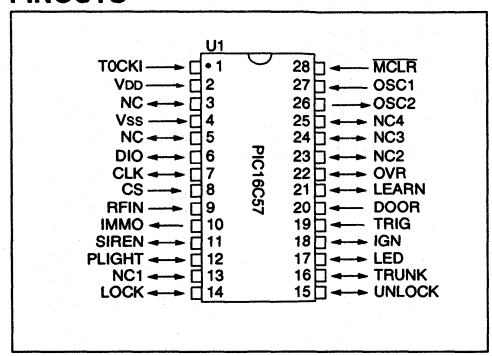
AN645

PIC16C57 Based Code Hopping Security System

Author: *Kobus Marneweck*
Microchip Technology Inc.

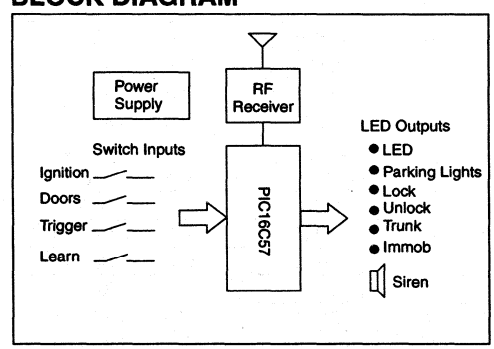
OVERVIEW

This document describes a PIC16C57 based code hopping automotive security system. The security system implements all the basic features found on security systems and can be changed to modify or add features as required. The code can also be moved to a higher functionality PICmicro™ microcontroller for more I/O or code space.



FEATURES

- Code hopping alarm system
- System can handle up to six transmitters
- Learning of new transmitters
- Arm/Disarm
- Trunk release
- Car finder
- Panic
- Locking/unlocking of doors
- Door and shock sensor trigger inputs



RECOMMENDED READING

If the reader is unfamiliar with KEELOQ Code Hopping it would be helpful to read *Introduction to KEELOQ* (DS91002). This and other KEELOQ literature can be found on Microchip's BBS, Web site or from a Microchip field application engineer. The software described in this application note is available on a diskette from Microchip by ordering DS40149. A complete list of KEELOQ literature can be found at the end of the application note.

FIGURE 1: ALARM STATE DIAGRAM

© 1997 Microchip Technology Inc.

OPERATION

Reset

Reset initializes the I/O ports, variables, and flags. The system status is read from EEPROM and the status is restored.

Armed

When the system enters armed state, the doors are locked (activate LOCK) and the SIREN and PLIGHT are activated for 50 ms. The LED changes to a slow flash rate. If a trigger is detected (IGN, DOOR or TRIGGER) the system changes to the alarm state.

Actions upon entry:

1. Flash parking lights for 50 ms.
2. Chirp siren for 50 ms.
3. Lock doors for 500 ms.
4. Update system status.
5. LED flash.
6. Disable start.

TABLE 1: STATE CHANGE TABLE

Condition	Next State
IGN high	Alarm
TRIG high	Alarm
DOOR high	Alarm
Panic (any button activated for 2 seconds)	Alarm
Remote function 1	Drive
Remote function 2 (trunk release)	Armed
Remote function 3 (car finder)	Armed
LEARN high	Learn

Alarm

Alarm state is entered whenever a trigger is detected in armed state. SIREN is activated and PLIGHT is turned on and off at a 1 Hz rate. If a remote is detected in this state, the system changes to drive state. After a 30-second delay, SIREN and PLIGHT will be deactivated and the system returned to armed state.

Actions upon entry:

1. Flash parking lights.
2. Siren on.
3. LED flash.
4. Update system status.
5. Disable start.

TABLE 2: STATE CHANGE TABLE

Condition	Next state
Panic (any button activated for 2 seconds)	Alarm
Remote function 1	Drive
Remote function 2 (trunk release)	Armed
30-second timeout	Drive

Drive

When the system enters drive state, the doors are unlocked (activate UNLOCK), and the SIREN and PLIGHT are activated twice for 50 ms.The IMMOB output is activated to enable the starting of the vehicle and LED is turned off. A remote signal will return the system to armed state.

Actions upon entry:

1. Flash parking lights for 50 ms.
2. Chirp siren for 50 ms.
3. Unlock doors for 500 ms.
4. Flash parking lights for 50 ms.
5. Chirp siren for 50 ms.
6. Update system status.
7. LED off.
8. Enable start.

TABLE 3: STATE CHANGE TABLE

Condition	Next State
Panic (any button activated for 2 seconds)	Alarm
Remote function 1 & IGN low	Armed
Remote function 1 & IGN high	Drive
Remote function 2 (trunk release)	Drive
Remote function 3 (car finder)	Drive
30-second timeout & IGN off	Immob
LEARN high	Learn

Immob

If the IGN is turned off for more than 30 seconds, the system will immobilize. The IMMOB output is turned off, and the LED is turned on. A remote signal only will change the state to armed, and a remote signal with the IGN on will return to drive state.

Actions upon entry:

1. Update system status.
2. LED off.
3. Disable start.

TABLE 4: STATE CHANGE TABLE

Condition	Next State
Panic (any button activated for 2 seconds)	Alarm
Remote function 1 & IGN low	Armed
Remote function 1 & IGN high	Drive
Remote function 2 (trunk release)	Immob
Remote function 3 (car finder)	Immob
LEARN high	Learn

© 1997 Microchip Technology Inc.

Learn

A LEARN input in any state will put the system in learn mode. After learn is completed or timed out the system returns to the previous state.

Actions upon entry:

1. Update system status—set PASS1.
2. LED on.

After first transmission:

1. Update system status—et PASS2.
2. LED off.

After second transmission:

1. Update system status—set NORMAL.
2. LED on for 1 second.
3. Return to previous state.

TABLE 5: STATE CHANGE TABLE

Condition	Next State
Remote first operation	Pass2
Remote second operation	Return to previous state
LEARN high for 8 seconds	Erase all transmitters

FUNCTIONAL MODULES

Reception

The reception routine is based on reliable algorithms used in previous implementations of KEELOQ decoders. Automatic baud rate detection is used to compensate for variations in baud rate from different encoders of a specific type as well as the difference in baud rate between different encoders (HCS200, HCS300, HCS301, HCS360, HCS361, and NTQ106). The reception routine will be able to handle 56- and 66-bit transmissions. The reception routine will determine the type of transmission by the number of bits in the transmission. This routine will be the same for all implementations.

Key Generation and Decryption

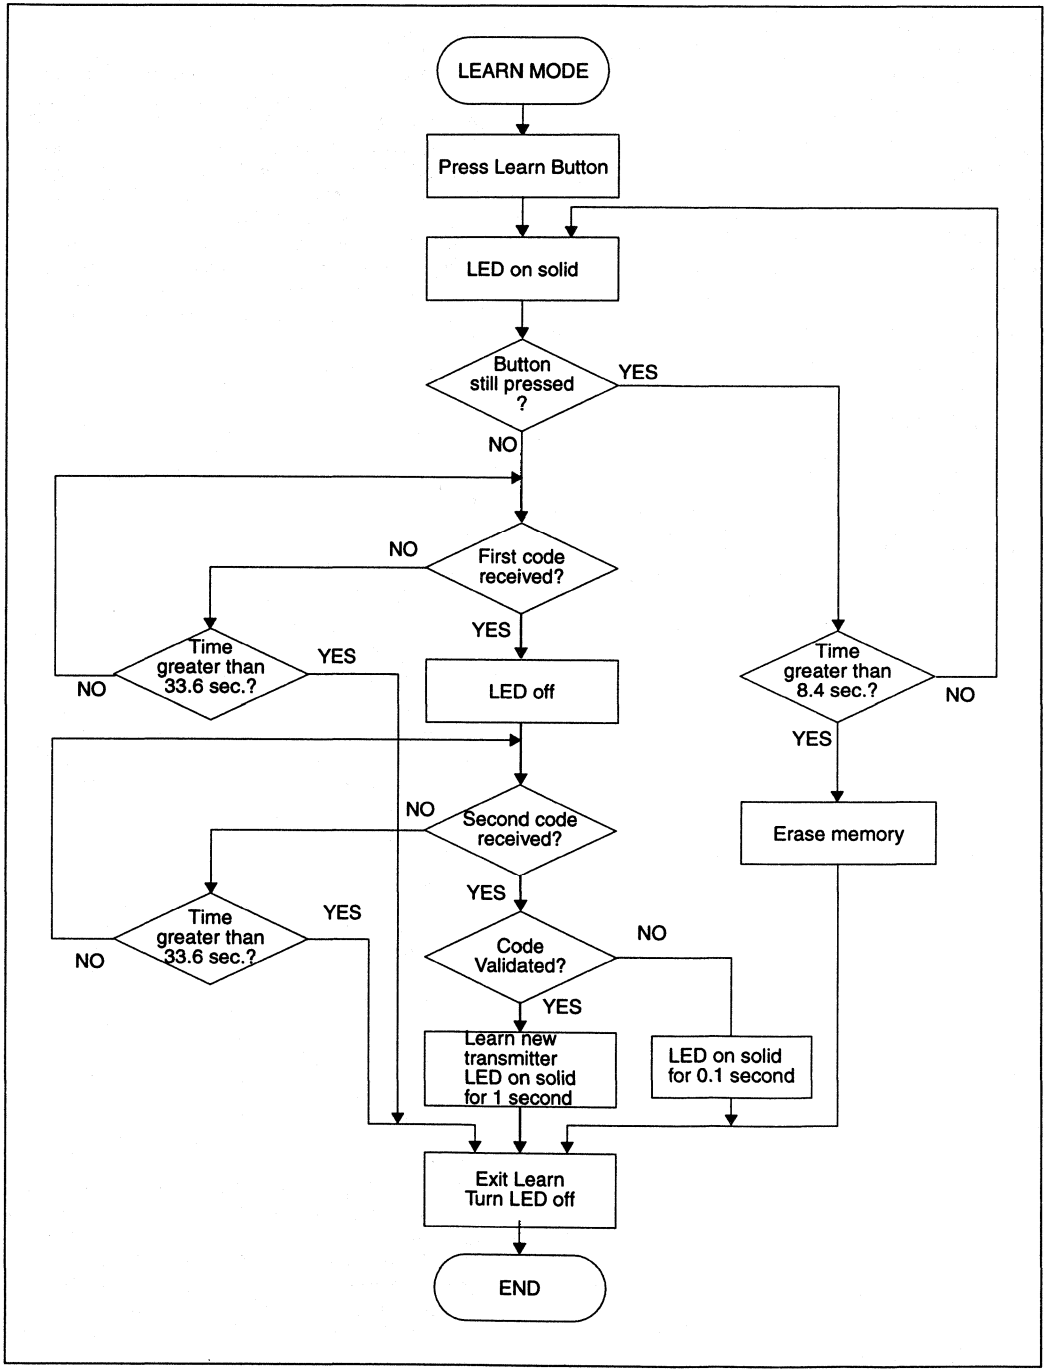
Decryption is done in software in the implementation. The decryption and key generation algorithms is implemented in software. The manufacturer's key is stored in program memory and code protected to securely store the key.

Validation

Validation consists of the following steps:

1. Checking the serial number (24 or 28 bits) against the stored transmitters.
2. Comparing the discrimination value (12 bits) against the stored discrimination value.
3. Checking that the synchronization counter falls within the first synchronization window.
4. Checking if the synchronization counter falls within the second synchronization window.
5. If found to be correct, updating the synchronization counter.

TABLE 6: Function Interpretation



Transmitter Button	Function Code	System Function
1	0001	Arm/Disarm
2	0010	Trunk release
3	0011	Car finder
1, 2 or 3 for 2 seconds	00XX	Panic

Learn

The LEARN input is active high. Learning is initiated by momentarily pressing the LEARN button. The decoder uses the current learning position as a scratch pad area. This means that an unsuccessful learn will delete the information stored at that learn position. The learn pointer will not be incremented if the learn was unsuccessful. The flow chart (Figure 2) shows the learning operation.

© 1997 Microchip Technology Inc.

FIGURE 2: LEARN OPERATION

© 1997 Microchip Technology Inc.

The following checks will be performed on the received codes to determine if the transmitter is valid:

1. The first code that is received is checked for bit integrity.
2. The stored serial numbers are searched to check if a transmitter is relearned. If a relearn is taking place, that position is used. Otherwise, the position pointed to by the learn pointer will be used.
3. The serial number is stored in the current learn position and used to generate a key.
4. The hop code is decrypted and the result stored temporarily.
5. The serial number of the second code that is received will be compared to the first received serial number.
6. The second hop code is decrypted and the discrimination values compared.
7. The synchronization counters of the decrypted codes will be compared to check that they are sequential codes.
8. If all the checks pass the learn were successful, the learn pointer is incremented. Otherwise, the position is erased.

Operation

1. Press and release the LEARN button. Indicator LED will turn on to indicate learn mode.
2. Press transmitter button. The LED will turn off.
3. Press transmitter a second time. The LED will turn on for 1 second to indicate that the transmitter was learned successfully.
4. Repeat steps 1-3 to learn up to six transmitters. The seventh transmitter will overwrite the first transmitter that was learned.
5. Learn will be terminated if two nonsequential codes were received or if two acceptable codes were not decoded within 33.6 seconds. A valid learn will be indicated by the LED turning on solid for 1 second.
6. Erasing all the transmitters is accomplished by pressing and holding the LEARN button for 8.4 seconds. The LED will turn off at the end of the 8.4 seconds to indicate that the transmitters were erased. The learn pointer will be reset to the first position.
