This application note fully describes the working of a code hopping decoder implemented on a Microchip PIC16C56 microcontroller. Background is given on the various KEELOQ® code hopping encoders that can be used with the decoder, the decoder hardware described, and descriptions of the various software modules comprising the system. The software can be used to implement a stand-alone decoder or integrated with full function security systems. The decoder supports the Microchip HCS200, HCS201, HCS300, HCS301, and NTQ106 KEELOQ Code Hopping Encoders.

KEY FEATURES

- Stand-alone decoder
- Compatible with Microchip HCS200, HCS201, HCS300, HCS301, and NTQ106 encoders
- Automatic baud rate detection
- Automatic encoder type detection
- Four function outputs
- Six learnable transmitters
- RC Oscillator

INTRODUCTION TO KEELOQ ENCODERS

All KEELOQ encoders use the KEELOQ code hopping technology to make each transmission by an encoder unique. The encoder transmissions have two parts. The first part changes each time the encoder is activated and is called the hopping code part. The second part is the serial number of the encoder, identifying it to a decoder.

Hopping Code

The Hopping Code contains function information, a discrimination value, and a synchronization counter. This information is encrypted by an encryption algorithm before being transmitted. A 64-bit encryption key is used by the encryption algorithm. If one bit in the data that is encrypted changes, the result is that an average of half the bits in the output will change. As a result, the hopping code changes dramatically for each transmission and can not be predicted.

Function Information

The encoder transmits up to four bits of function information. Up to 15 different functions are available (0000 is related to the reset condition in all the current encoders, and can never be transmitted).

Discrimination Value

Stored in the encoder EEPROM, this information is used to check integrity of decryption operation in the decoder. If known information is inserted into the transmitted string before encryption, the same information can be used at the decoder to check whether the information has been decrypted correctly. In the NTQ106, 12 such bits are available, and 12 bits (including overflow bits) are available in the Microchip HCS encoders.

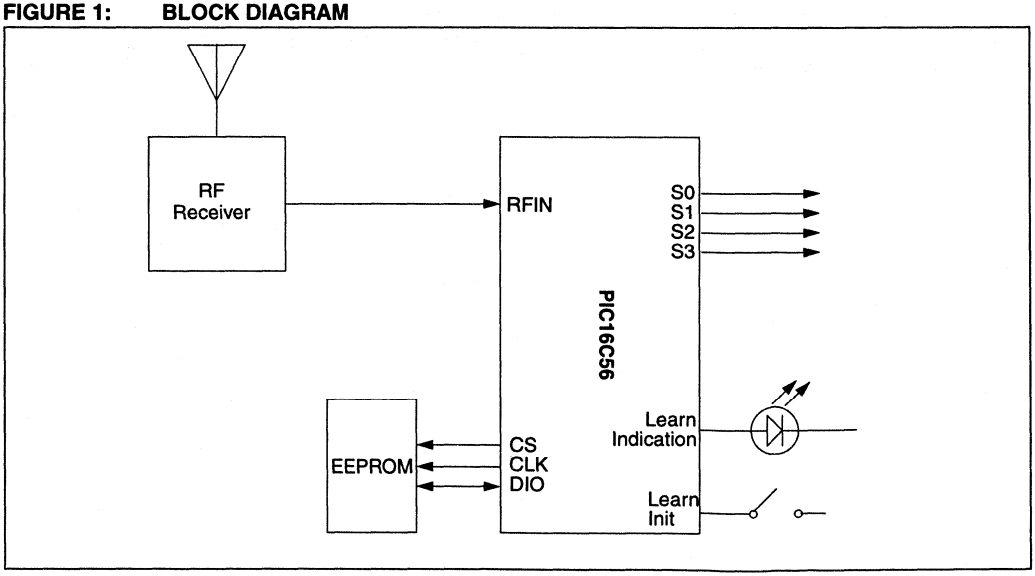
Synchronization Counters

The transmitted word contains a 16-bit synchronization counter. The synchronization information is used at the decoder to determine whether a transmission is valid, or a repetition of a previous transmission. Previous codes are rejected to safeguard against code grabbers. The HSC300/301 encoder transmits two overflow bits which may be used to extend the range of the synchronization counter from 65,536 to 196,608 button operations.

Fixed Code

Serial Number

The encoder's serial number is transmitted every time the button is pressed. The serial number is transmitted unencrypted as part of the transmission, and serves to identify the encoder to the decoder. The number can be used during learning operations to calculate the key to be used for decrypting the transmissions.



Other Status and Function Information

The HCS300/301 encoders include provision for four bits of function information and two status bits in the fixed code portion of its transmission. The two status bits indicate whether a repeated transmission is being sent, and whether the battery voltage is low. The HCS200/201 does not send repeated transmission information and the bit is permanently set to '0'.

Transmission Format

Table 1 contains a summary of the information contained in transmissions from each of the KEELOQ encoders that can be learned by the Microchip decoder.

TABLE 1: KEELOQ ENCODER TRANSMISSION SUMMARY

	NTQ106	HCS200/201*	HCS300/301
Total transmission length	56 bits	66 bits	66 bits
Hopping code portion (total length)	32 bits	32 bits	32 bits
Function bits	4 bits	3 bits (+1*)	4 bits
Discrimination bits	12 bits	12 bits	12 bits
Synchronization	16 bits	16 bits	16 bits
Fixed portion (total length)	24 bits	34 bits	34 bits
Serial number	24 bits	28 bits	28 bits
Function bits	—	3 bits (+1*)	4 bits
Status bits			
Low Voltage Indicator	—	1 bit	1 bit
Repeated Transmission Indicator	—	—	1 bit

*The HCS200/201 transmissions are padded to retain compatibility with the HCS300/301 encoders.

The code hopping portion is always transmitted first (LSB to MSB), followed by the fixed portion (LSB to MSB).

TABLE 2: HCS200/201* AND HCS300/301 TRANSMISSION FORMAT

Hop code	Serial number	Function	Status
LSB 32 bits MSB	LSB 28 bits MSB	4 bits	2 bits

*The HCS200/201 transmissions are padded to retain compatibility with the HCS300/301 encoders

TABLE 3: NTQ106 TRANSMISSION FORMAT

Hop code	Serial number
LSB 32 bits MSB	LSB 24 bits MSB

Bits are transmitted from left to right (i.e., the code hopping first).

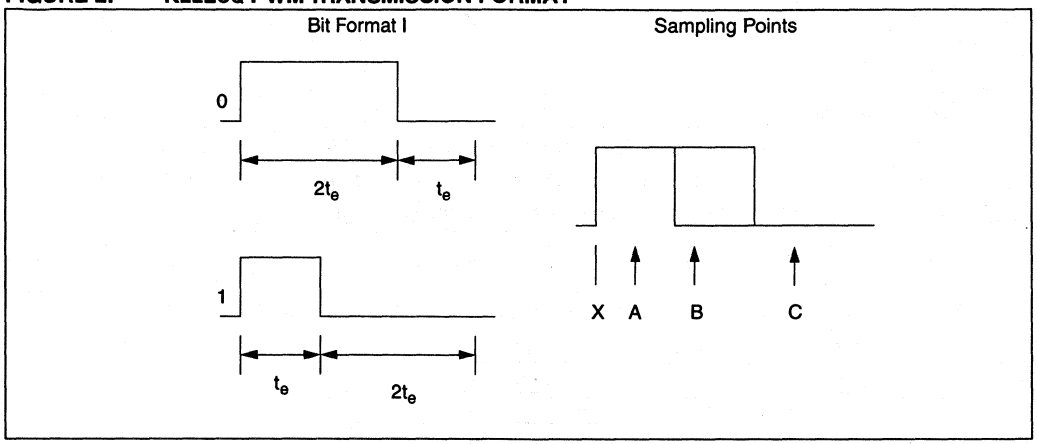
PWM Format

In general, all KEELOQ encoders share a common transmission format.

- A preamble to improve biasing of decision thresholds in super-regenerative receivers. The preamble consists of alternate on and off periods, each lasting as long as a single elemental period.
- A calibration header, consisting of a low period of 10 elemental periods. Calibration actions should be performed on the low period of the header to ensure correct operation with header chopping.
- A string of 56 or 66 pulse width modulated bits, each consisting of three elements. The first element is high, the second contains the data transmitted and is either high or low, the third element is always low.
- A guard period is usually left between the transmissions. During this period nothing is transmitted by the encoder.

Figure 2 shows the sampling points when sampling data. The first and last elements are used exclusively to verify the integrity of the received signal. The first element (sample point A) is always high, the second (sample point B) is the complement of the data bit being sent, and the final element (sample point C) is always low. Because the period between the low portion of a bit (sample point C) and the rising edge of the following bit (sample point X) can vary somewhat, the rising edge of the first element (sample point X) is used to resynchronize the receiving routine to each incoming bit.

If random noise is being received, the probability of a set of three samples producing a valid combination is only 2^{-2} = 1/4. For a string of 56 bits, the corresponding figure is $2^{-112} > 2 \times 10^{-34}$. For longer strings, the probability is considerably less.



Integrity checking on incoming signals is important. Code hopping signals require significant processing, as well as EEPROM access, to decrypt. Unnecessary processing can be avoided by not attempting to decrypt incoming codes that have bit errors.

TABLE 4: TRANSMISSION FORMATS

Encoder	Preamble	Header Chopping	Code Hopping Length	Fixed Code Length	Guard Period
NTQ106	—	—	32 bits	24 bits	3.4 ms
HCS200/201	•	•	32 bits	34 bits	6.4 ms
HCS300/301	•	•	32 bits	34 bits	6.4 ms

FIGURE 2: KEELOQ PWM TRANSMISSION FORMAT

IMPLEMENTATION

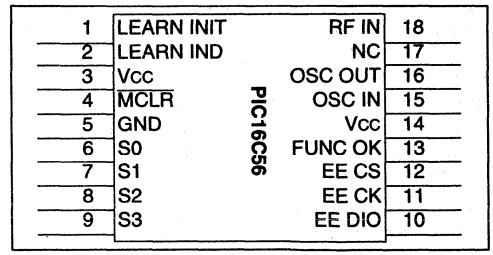
The Microchip decoder's primary hardware components are a PIC16C56 RISC microcontroller and a 93C46 EEPROM. However, this solution can be implemented in any PICmicro™ microcontroller with at least 1K words of programming. The operating frequency of the controller is 4 MHz. The microcontroller is used to capture transmissions from the various encoders, decrypt transmissions captured, and check the validity of the transmission based on the information in the decrypted transmission and information stored in the EEPROM. If a transmission from a valid encoder is received, the Microchip decoder activates the outputs dictated by the transmission.

Encoder information, such as serial number, synchronization information, and decryption key are stored externally in an EEPROM. The EEPROM used is a Microchip 93C46 CMOS serial EEPROM. The information stored in the EEPROM is encrypted to protect the decoders from cloning. The EEPROM encryption is less secure than the KEELOQ code hopping algorithm.

A more secure implementation of the decoder would be to modify the software in the application note and use a PIC16CXX with an internal EEPROM such as a PIC16C84. In this way communication between the PIC16C56 and EEPROM cannot be monitored.

As can be seen from the section on encoder transmissions there are differences in the transmission formats of the different encoders that are compatible with the system. The following section summarizes how the differences in transmitted data are dealt with by the decoder.

As the **serial number** information follows after the code hopping portion of the transmission, any number of serial number bits can be received and processed. For example, to maintain full compatibility between the Microchip NTQ106 and HCS encoders transmissions, a specific manufacturer might decide to disregard all but the first 24 serial number bits. In the Microchip decoder described the complete serial number is stored for both the NTQ106 encoders (24 bits) and the HCS range of encoders (28 bits).



The serial number is used to identify the memory block used to store the 64-bit decryption key for a particular encoder because of the relationship between serial number and decryption key. In other words, the serial number is stored with the key. When a transmission is received, the decoder finds the correct memory block by checking all blocks until a matching serial number is found. The key is then retrieved from that particular memory block. A serial number of 0000000_{16} is considered invalid.

© 1997 Microchip Technology Inc.

Validation of a received transmission consists of two parts. The first includes checking the integrity of the decryption operation. Here the decoder compares the 12-bit discrimination value received with the stored discrimination value. This includes the full 12-bit discrimination value of the NTQ106. The discrimination value stored for the HCS300/301 includes the overflow bits.

The second portion of validation involves checking **synchronization** information for that particular encoder. The synchronization counter transmitted by all encoders is 16 bits long. Two copies of the full synchronization counter are stored for all valid encoders. The storing of two copies of the synchronization information protects the decoder from loosing synchronization with an encoder if one of the counters is corrupted.

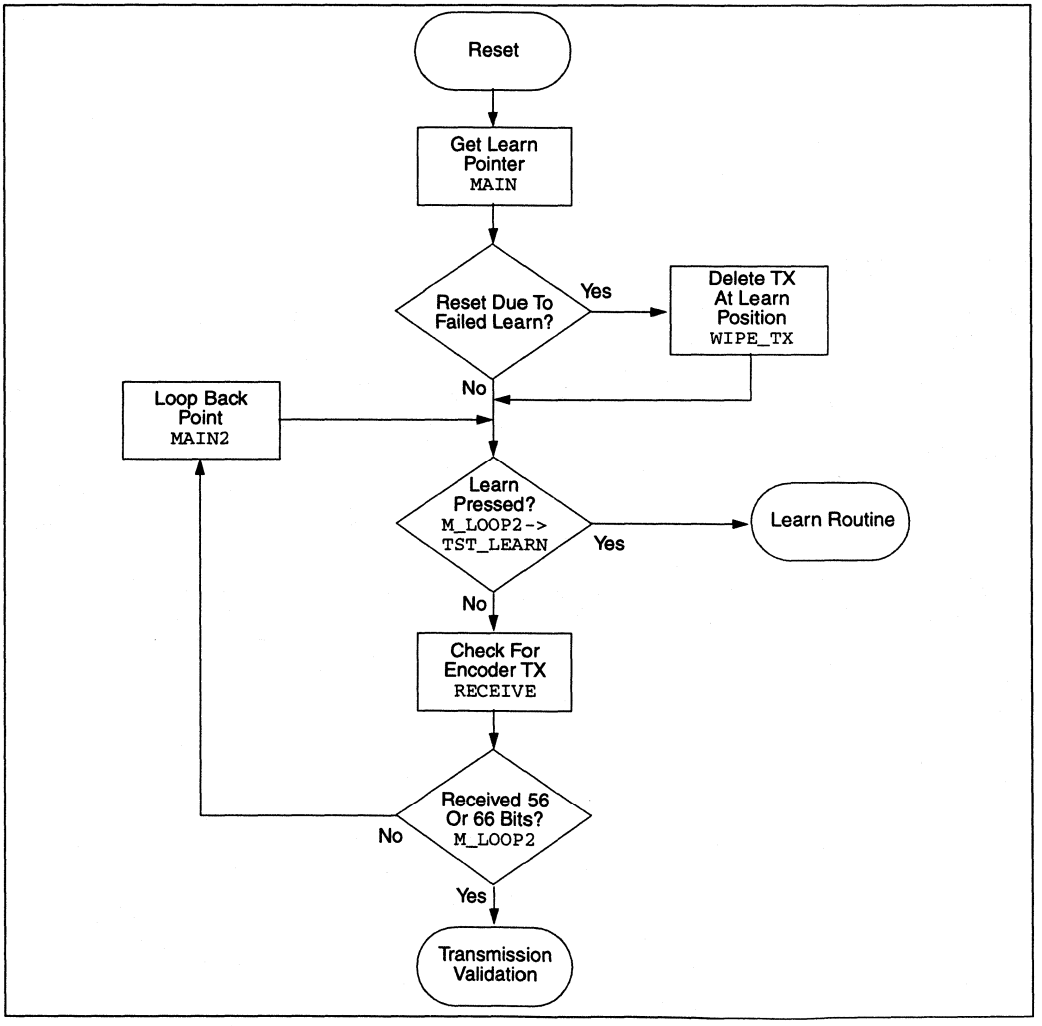
PROGRAM FLOW



The software for the Microchip decoder has been written for the PIC16C56 microcontroller. The compiler used is MPASM. The operating frequency of the PIC16C56 is 4 MHz. The clock speed is important as the reception routine (RECEIVE) has some critical timing specifications. Other decoder functions that rely on a 4 MHz clock speed are the hold times of the various outputs, time-outs, etc.

The main program flow is described here. More detailed descriptions of the modules can be found further in the application note. On power-up the decoder reads the learn pointer from the external EEPROM. The status flags are checked to see if a learn routine was interrupted when the microcontroller was reset. If so, it is assumed the learn cycle was not successfully completed and the encoder at the learn pointer subsequently deleted (WIPE_TX).

The encoder then enters the main loop where it spends most of its time. The main loop checks to see if the learn button is being activated (TST_LEARN). If so, the decoder enters the learn mode.

If learn has not been initiated, the microcontroller then checks for transmissions from encoders (RECEIVE). If either 56 bits (NTQ106) or 66 bits (HCS encoders) are received, the microcontroller validates the transmission received. If the transmission received is a valid transmission from an encoder learned into the system, the system sets the appropriate outputs (M_BUT).

FIGURE 4: MICROCHIP DECODER MAIN PROGRAM FLOW

FUNCTIONAL MODULES

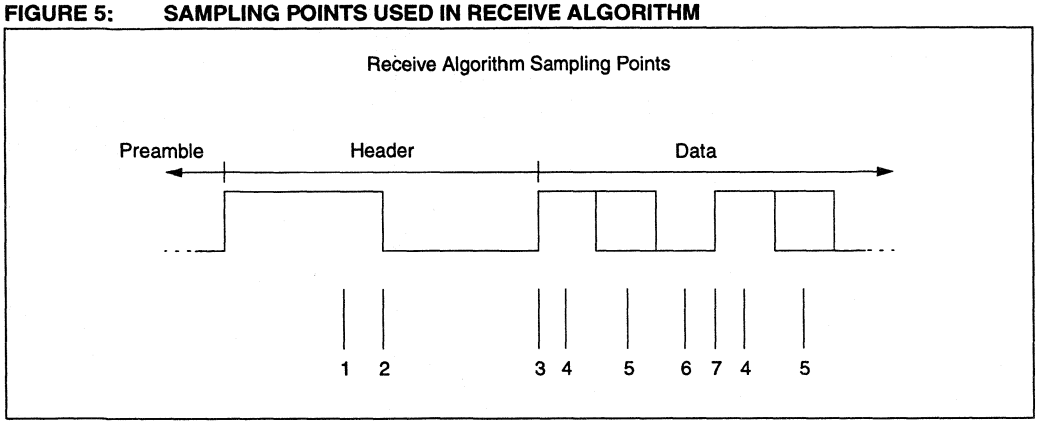
Reception

The reception routine (RECEIVE) is based on a reliable algorithm which has successfully been used in previous implementations of KEELOQ decoders. Automatic baud rate detection is used to compensate for variations in baud rate of different encoders of a specific type, as well as the difference in baud rate between different encoders (NTQ106, HCS200, and HCS300). The reception routine is able to handle 56- and 66-bit transmissions. The reception routine is able to determine the type of encoder by the number of bits in the transmission.

The reception algorithm performs the following functions when an output is detected from the receiver:

1. Calibrate on the header low period to determine the actual elemental period for the transmission being received. The required elemental period is 10% of the low header period. In the diagram below (Figure 5) the header calibration sample points are marked 1 through 3. The calibration flow chart (Figure 6) shows at what points in the source code samples 1, 2, and 3 are taken.
   Elemental periods outside the capture range of the algorithm (either too long or too short) should be rejected, since they would be due either to noise or to reception of an incomplete signal.
2. Using the determined elemental period, three samples after the first rising edge following the header are taken. The first sample is taken half an elemental period after the rising edge (Sample 4); the second, one elemental period later (Sample 5), and the third, another one elemental period later (Sample 6). The first sample must be high, the second could be either high or low, and the third sample must be low. If either the first or the third sample is not as expected, the attempt at capturing a transmission is abandoned. In the diagram below (Figure 5), the data sample points are points 4 through 6. The flow chart describing data reception (Figure 7) shows where in the code the samples are taken.
3. If all 56 or 66 bits have been captured, each with the correct first and third elements, the transmission can be assumed to be correct, and decryption can commence.

The receiving routine should be called often enough to ensure that the high portion in the header is not missed (Sample 1, Figure 5).



In systems where the receive routine is called to check if there is activity on the receiver input, the routine should poll the input for a valid transmission for at least the time taken to complete one transmission if activity is detected on the input line. This makes provision for the receive routine being called while a transmission is in progress. Having missed the first header, the first transmission will be invalid and be discarded. The decoder should continue sampling the input through the guard time in order to catch the next header and transmission (i.e., for a decoder designed to capture HCS300 transmissions the time spent polling for a valid transmission should be at least 100 ms if activity is detected in the input line).

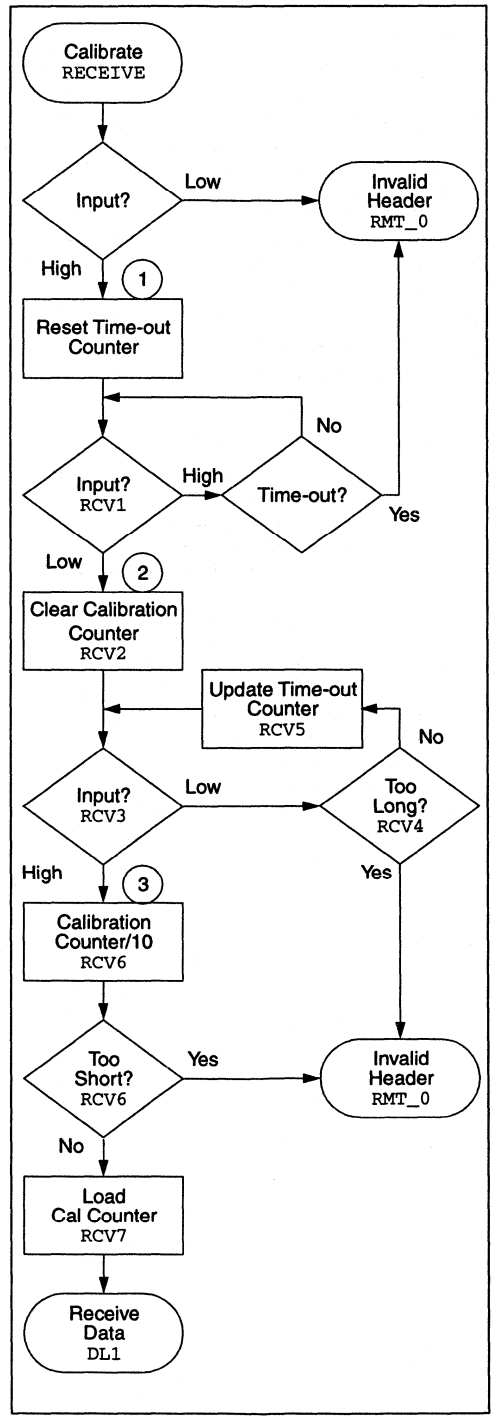
The diagram below (Figure 5) gives all the major sampling points in the receive algorithm.

Note: The sample points are labeled in the receive routine flow diagrams that follow.

6

FIGURE 5: SAMPLING POINTS USED IN RECEIVE ALGORITHM

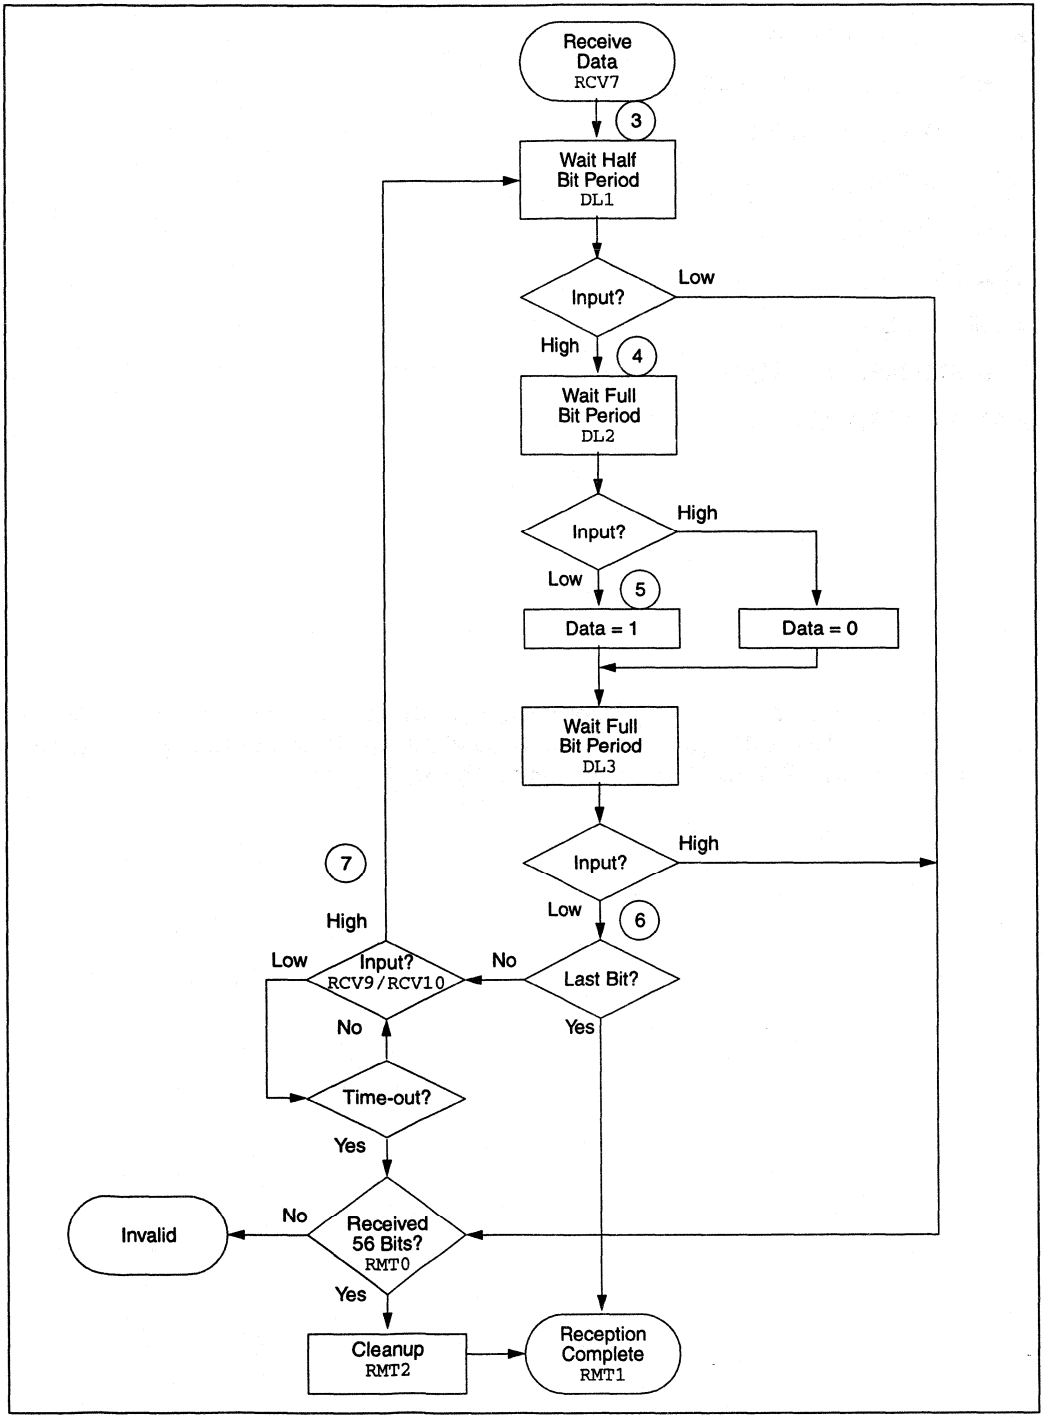
© 1997 Microchip Technology Inc.



Flow Diagrams

The first flow diagram (Figure 6) describes the calibration routine which is used to determine the actual transmission rate of the encoder so that the decoder can compensate for deviations from nominal timing. There are four different exit points, each of which should branch to a point in the program where housekeeping and input monitoring can be resumed. There is only one exit point for a valid calibration operation (RCV7). At this point, it is assumed that a valid header has been received and that a string of data bits will follow.

The second flow diagram (Figure 7) handles the reception of bits once the calibration routine has been successfully completed. The data bits are all sampled three times each to ensure that a noise free transmission has been received. The receive routine uses the calibrated elemental period, determined in the calibration routine, to ensure that the samples are spaced correctly. The routine resynchronizes itself on the rising flank of each bit. Provision for identification of the encoder type, based on the number of bits received, is included. A 56-bit transmission emanates from a NTQ106, while a 66-bit transmission comes from a Microchip HCSXXX encoder. The last two bits of the HCS300 transmission, VLOW and Repeat, are ignored by the Microchip decoder.



If all of the control samples in all of the bits are sampled correctly (i.e., the first element is high and the last element is low), the routine checks whether 56 bits have been received correctly (NTQ106 transmission). If not, the routine returns to the calling procedure.

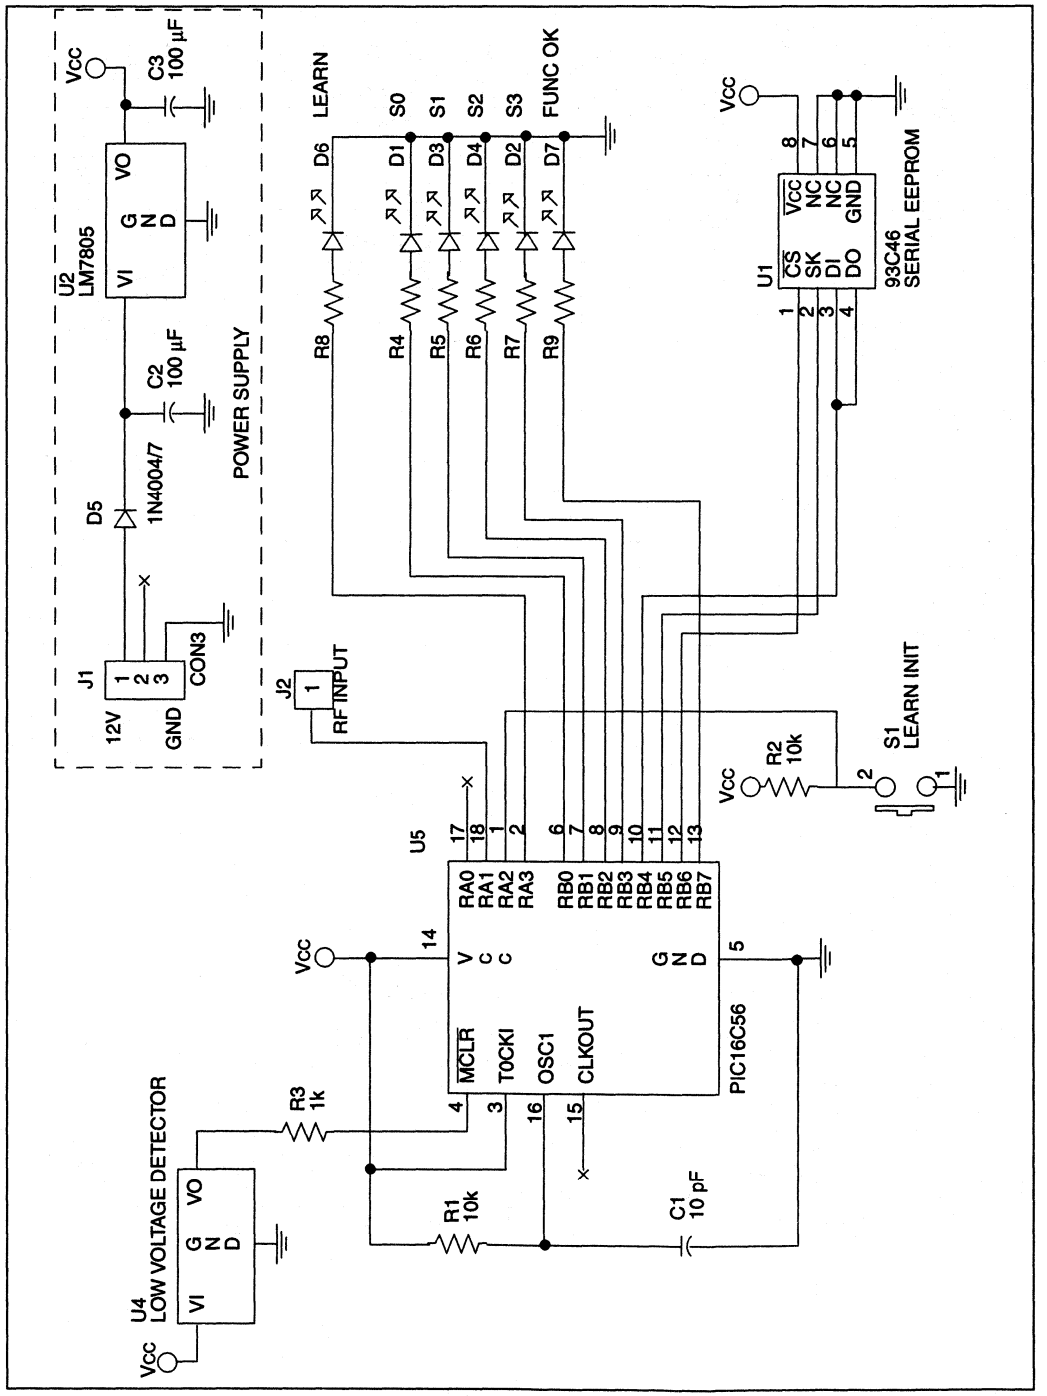
SOURCE CODE LISTING

A diskette is supplied containing source code for the Microchip decoder in the file `mcdec12.asm`. The code has been compiled using MPASM v01.30.01. Certain functions are dependent on the oscillator speed for correct functioning. Examples of time dependent functions include `RECEIVE` and `TST_RTCC`. The PIC16C56 Microcontroller should run at 4 MHz.



LIST OF IMPORTANT FUNCTIONS

Function Name	Description	Line Number	Function Length
CALC_KEY	Key generation routine.	1219	62
DECRYPT	Decryption routine for Code Hop.	469	61
EEREAD	The data in the EEPROM at ADDRESS is read and decrypted to TMP1 and TMP2. Note that TMP1, TMP2 and ADDRESS are user defined registers.	945	31
EEWRITE	The data in TMP1 and TMP2 is encrypted and written to the EEPROM at ADDRESS. Note that TMP1, TMP2 and ADDRESS are user defined registers.	860	48
M_DIS	Check discrimination value.	1605	19
M_CNT	Check synchronization (counter) values.	1633	69
RECEIVE	Start of the RF receive routine.	580	121
TST_LEARN1	Check for learn mode and entry to learn.	775	21
TST_RTCC	Check TIMER0 and do whatever real time tasks are required.	397	38

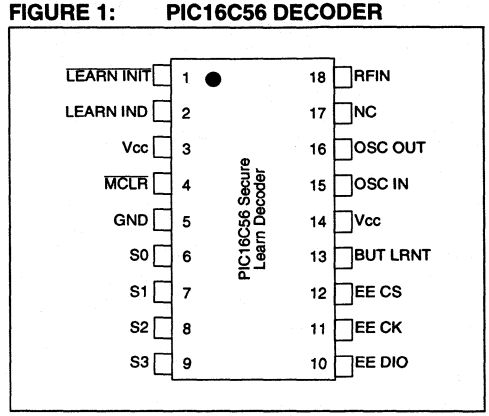
KEELOQ® Code Hopping Decoder Using Secure Learn

Author: Steven Dawson
Microchip Technology Inc.



OVERVIEW

This application note fully describes the working of a code hopping decoder implemented on a Microchip PIC16C56 microcontroller. This decoder uses the secure learn (seed-based) method of learning new transmitters. This application note describes the various KEELOQ code hopping encoders that can be used with the decoder, the decoder hardware, and the various software modules comprising the system. The software can be used to implement a stand alone decoder or integrate with full function security systems. The decoder supports the Microchip HCS200, HCS300, HCS301, HCS360, and HCS361 KEELOQ code hopping encoders.

KEY FEATURES

- Stand alone decoder
- Compatible with Microchip HCS200, HCS300, HCS301, HCS360, and HCS361 encoders
- Automatic bit rate detection
- Automatic encoder type detection
- Four function outputs
- Six learnable transmitters
- RC Oscillator

INTRODUCTION TO KEELOQ ENCODERS

All KEELOQ encoders use the KEELOQ code hopping technology to make each transmission by an encoder unique. The encoder transmissions have two parts. The first part changes each time the encoder is activated and is called the hopping code part and is encrypted. The second part is the unencrypted part of the transmission, principally containing the encoder's serial number identifying it to a decoder. Refer to DS91002, *Introduction to KEELOQ*.

Hopping Code

The hopping code contains function information, a discrimination value, and a synchronization counter. This information is encrypted by an encryption algorithm before being transmitted. A 64-bit encryption key is used by the encryption algorithm. If one bit in the data that is encrypted changes, the result is that an average of half the bits in the output will change. As a result, the hopping code changes dramatically for each transmission and can not be predicted.

Function Information

The encoder transmits up to four bits of function information. Up to 15 different functions are available.

Discrimination Value

Stored in the encoder EEPROM, this information can be used to check integrity of decryption operation by a decoder. If known information is inserted into the transmitted string before encryption, the same information can be used at the decoder to check whether the information has been decrypted correctly. 12 bits (including overflow bits) are available in the Microchip HCSXXX encoders.

Synchronization Counters

The transmitted word contains a 16-bit synchronization counter. The synchronization information is used at the decoder to determine whether a transmission is valid or is a repetition of a previous transmission. Previous codes are rejected to safeguard against code grabbers. The HSC300 and HCS301 encoders transmit two overflow bits which may be used to extend the range of the synchronization counter from 65,536 to 196,608 button operations. The HCS360 and HCS361 encoders transmit one overflow bit which can be used to extend the range of the synchronization counter from 65,536 to 131,071 button operations.

Unencrypted Code

Serial Number

The encoder's serial number is transmitted every time the button is pressed. The serial number is transmitted unencrypted as part of the transmission and serves to identify the encoder to the decoder.

Other Status and Function Information

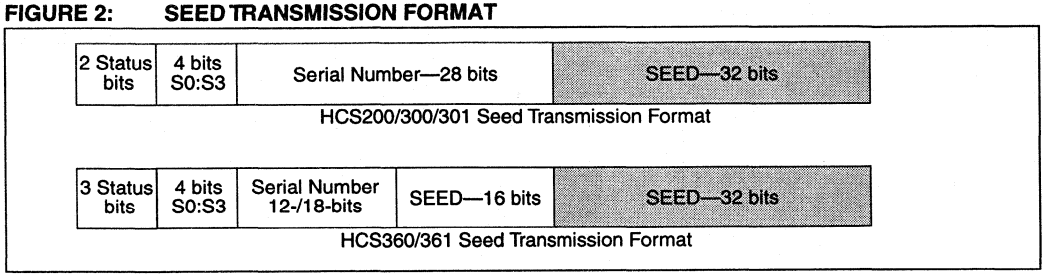
The HCS200, HCS300, and HCS301 encoders include provision for four bits of function information and two status bits in the fixed code portion of its transmission. The two status bits indicate whether a repeated transmission is being sent, and whether the battery voltage is low. The HCS200 does not send repeated transmission information, and the bit is permanently set to '0'.

The HCS360/361 encoders transmit two bits that are used as a Cyclic Redundancy check. These bits can be used to check the integrity of the reception. Additionally, the HCS360 and HCS361 encoders can extend the length of the serial number from 28 bits to 32 bits, replacing the unencrypted function code.

Seed Transmissions

The Microchip HCSXXX encoders all have the ability to transmit a fixed seed. The seed value is programmed into the encoder when the encoder is first initialized along with the counters, key, serial number, and other information. The seed length differs from encoder to encoder with the HCS200, HCS300, and HCS301 having a 32-bit seed. The HCS360 and HCS361 encoders have a 48-bit seed. The HCS200, HCS300, and HCS301 encoders transmit the seed if all the inputs are activated simultaneously (S0, S1, S2, and S3). The HCS360 and HCS361 encoders transmit the seed immediately if S0 and S3 are activated or delayed if S0 and S1 are activated for more than 3 seconds.

Table 1 summarizes seed transmissions in the Microchip HCSXXX encoders.



© 1997 Microchip Technology Inc.

TABLE 1: HCSXXX ENCODER SEED TRANSMISSION SUMMARY

Encoder	Seed Length	Seed Transmission Activation
HCS200	32 bits	Seed transmitted immediately if S0, S1, and S2 are activated.
HCS300	32 bits	Seed transmitted immediately if S0, S1, S2, and S3 are activated.
HCS301	32 bits	Seed transmitted immediately if S0, S1, S2, and S3 are activated.
HCS360	48 bits	Seed transmitted immediately if S0 and S3 are activated. Seed transmitted after 3 seconds if S0 and S1 are activated.
HCS361	48 bits	Seed transmitted immediately if S0 and S3 are activated. Seed transmitted after 3 seconds if S0 and S1 are activated.

The seed transmission is transmitted in place of the HOP transmission and is not encrypted. When the seed is transmitted, the transmitted word changes as shown in Figure 2 below.

PWM Format

In general, all KEELOQ encoders share a common transmission format:

A **preamble** to improve biasing of decision thresholds in super-regenerative receivers. The preamble consists of alternate on and off periods, each lasting as long as a single elemental period.

A **calibration** header consisting of a low period of 10 elemental periods. Calibration actions should be performed on the low period of the header to ensure correct operation with header chopping.

A **string** of 66 or 67 pulse-width modulated bits, each consisting of three elements. The first element is high, the second contains the data transmitted and is either high or low, the third element is always low.

A **guard** period is usually left between the transmissions. During this period nothing is transmitted by the encoder.

Figure 4 shows the sampling points when sampling the data bits. The first and last elements are used exclusively to verify the integrity of the received symbol. The first element (sample point A) is always high, the second (sample point B) is the complement of the data bit being sent, and the final element (sample point C) is always low. Because the period between the low portion of a bit (sample point C) and the rising edge of the following bit (sample point X) can vary, the rising edge of the first element (sample point X) is used to resynchronize the receiving routine to each incoming bit.

If random noise is being received, the probability of a set of three samples producing a valid combination is only $2^{-2} = 1/4$. For a string of 66 bits, the corresponding figure is $2^{-132} < 2 \times 10^{-40}$.

Integrity checking on incoming signals is important. Code hopping signals require significant processing, as well as EEPROM access, to decrypt. Unnecessary processing can be avoided by not attempting to decrypt incoming codes that have bit errors.

DECODER IMPLEMENTATION

The Microchip decoder's primary hardware components are a PIC16C56 RISC microcontroller and a 93C46 EEPROM as shown in the decoder schematic in Figure 11. However, this solution can be implemented in any PICmicro™ microcontroller with at least 1K words of program memory. The operating frequency of the controller is 4 MHz. The microcontroller is used to capture transmissions from the various encoders, decrypt transmissions captured, and check the validity of the transmission based on the information in the decrypted transmission and information stored in the EEPROM. If a transmission from a valid encoder is received, the decoder activates the outputs dictated by the transmission.

Encoder information, such as serial number, synchronization information, and decryption key is stored externally in an EEPROM. The EEPROM used is a Microchip 93C46 Microwire® Serial EEPROM. The information stored in the EEPROM is encrypted to protect the contents. The EEPROM encryption is less secure than the KEELOQ code hopping algorithm.

As can be seen from the section on encoder transmissions, there are differences in the transmission formats of the different encoders that can be used with the decoder. The following section summarizes how the differences in transmitted data are dealt with by the decoder.

As the serial number information follows after the code hopping portion of the transmission, any number of serial number bits can be received and processed. In the Microchip decoder described, the complete serial number (28 bits) is stored.

The serial number is used to identify the memory block used to store the 64-bit decryption key for a particular encoder because of the relationship between serial number, seed, and the decryption key. In other words, the serial number is stored with the key. When a transmission is received, the decoder finds the correct memory block by checking all blocks until a matching serial number is found. The key is then retrieved from that particular memory block. A serial number of 0000000_{16} is considered invalid and is ignored by the decoder.

After matching the received and stored serial number, validation of a received transmission consists of two steps. The first includes checking the integrity of the decryption operation. Here the decoder compares the 12-bit discrimination value received with the stored discrimination value. The discrimination value stored with the HCS300/301/360/361 includes overflow bits and user bits.

The second portion of validation involves checking synchronization information for that particular encoder. The synchronization counter transmitted by all encoders is 16 bits long. Two copies of the full synchronization counter are stored for all valid encoders. The storing of two copies of the synchronization information protects the decoder from loosing synchronization with an encoder if one of the counters is corrupted.

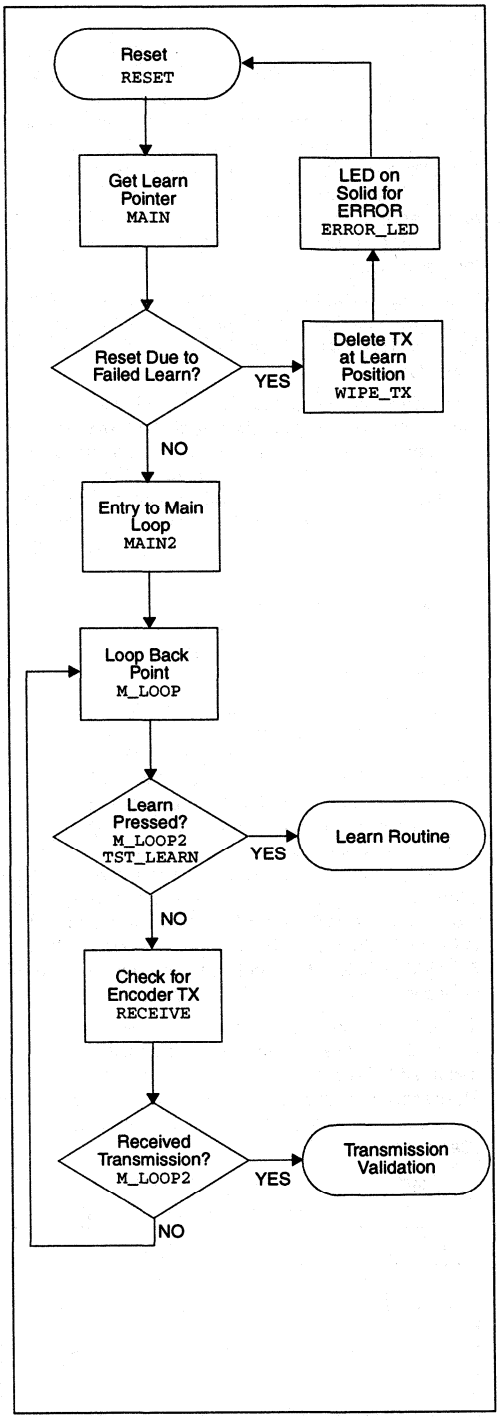
PROGRAM FLOW



The software for the Microchip decoder has been written for the PIC16C56 microcontroller. The compiler used is MPASM version 01.30.01. The operating frequency of the PIC16C56 is 4 MHz. The clock speed should be kept as close as possible to 4 MHz as the reception routine (RECEIVE) is dependent on the 4 MHz clock for correct functioning. Other decoder functions that rely on a 4 MHz clock speed are the hold times of the various outputs and time-outs. The main program flow is described here. Detailed descriptions of individual functions can be found further in the application note.

As can be seen from Figure 6, the decoder reads the learn pointer, which stores the next position to be overwritten when the decoder enters a learn sequence and decoder status flags, from the external EEPROM on power-up. The status flags are checked to see if a learn routine was interrupted when the microcontroller was reset. If so, it is assumed the learn cycle was not successfully completed, and the encoder at the learn pointer is subsequently deleted (WIPE_TX).

The encoder then enters the main loop where it spends most of its time. The main loop checks to see if the learn button is being activated (TST_LEARN). If so, the decoder enters the learn mode described in the "Learn" section in AN652.

If learn has not been initiated, the microcontroller then checks for transmissions from encoders (RECEIVE) as described on page 40. If a transmission from an encoder has successfully been received, the microcontroller validates the transmission received as described in the "Transmission Validation" in AN652. If the transmission received is a valid transmission from an encoder learned into the system, the system sets the appropriate outputs (M_BUT).

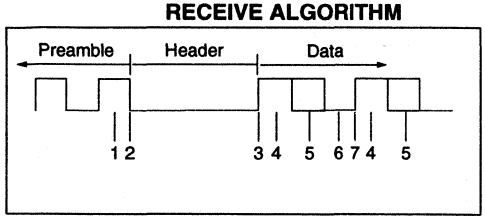
FUNCTIONAL MODULES

Reception

The reception routine (RECEIVE) is based on a reliable algorithm which has successfully been used in previous implementations of KEELOQ decoders. Automatic bit-rate detection is used to compensate for variations in bit rate of different encoders of a specific type, as well as the differences in bit rate between different encoders (HCS200, HCS300, and HCS360). The reception routine is able to receive 66-bit transmissions. The reception routine is able to determine the number of bits in the transmission.

The reception algorithm performs a number of functions when an output is detected from the receiver. Figure 7 gives all the major sampling points in the reception algorithm.



The reception algorithm calibrates on the low period of the header to determine the actual elemental period for the transmission being received. The required elemental period is 10% of the low header period. In Figure 7 the header calibration sample points are marked 1 through 3. The calibration flow chart (Figure 8) shows at what points in the program samples 1, 2, and 3 are taken.

Elemental periods outside the capture range of the algorithm (either too long or too short) are rejected, since they are due either to noise or to reception of an incomplete signal.

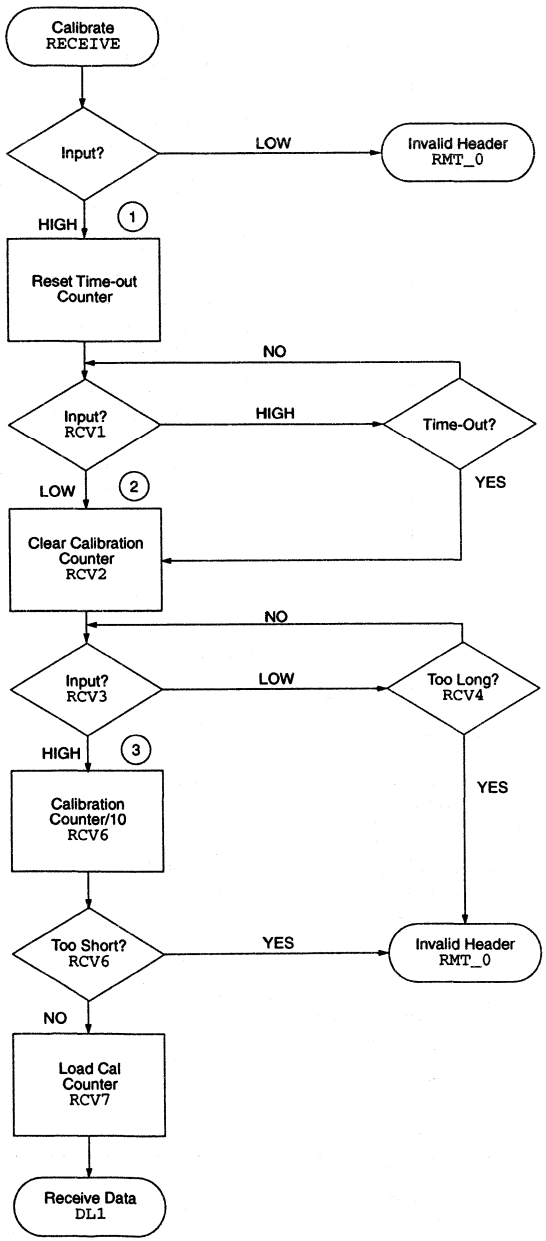
Using the determined elemental period, three samples after the first rising edge (Sample 3) following the header are taken. The first sample is taken half an elemental period after the rising edge (Sample 4); the second, one elemental period later (Sample 5), and the third, another one elemental period later (Sample 6). The first sample must be high, the second could be either high or low, and the third sample must be low. If either the first or the third sample is not as expected, the attempt at capturing a transmission is abandoned. In Figure 7, the data sample points are points 4 through 6. The flow chart describing data reception (Figure 9) shows where in the code the samples are taken.

If all 66 bits have been captured, each with the correct first and third elements, the transmission can be assumed to be correct, and decryption can commence. The receiving routine should be called often enough to ensure that the high portion in the header is not missed (Sample 1, Figure 7).

FIGURE 7: SAMPLING POINTS USED IN RECEIVE ALGORITHM

In systems where the reception routine is called to check if there is activity on the receiver input, the routine should poll the input for a valid transmission for at least the time taken to complete one transmission if activity is detected on the input line. This makes provision for the reception routine being called while a transmission is in progress. Having missed the first header, the first transmission will be invalid and be discarded. The decoder should continue sampling the input through the guard time in order to catch the next header and transmission (i.e., for a decoder designed to capture HCS300 transmissions the time spent polling for a valid transmission should be at least 100 ms if activity is detected in the input line).

Reception Algorithm Flow Chart



The first flow chart (Figure 8) describes the calibration routine which is used to determine the actual transmission rate of the encoder so that the decoder can compensate for deviations from nominal timing. There are four different exit points, each of which should branch to a point in the program where housekeeping and input monitoring can be resumed. There is only one exit point for a valid calibration operation (RCV7). At this point, it is assumed that a valid header has been received and that a string of data bits will follow.

The second flow chart (Figure 9) handles the reception of bits once the calibration routine has been successfully completed. The data bits are all sampled three times each to ensure that a noise free transmission has been received. The reception routine uses the calibrated elemental period, determined in the calibration routine, to ensure that the samples are correctly spaced. The routine resynchronizes itself on the rising flank of each bit. Only 60 bits of the data received are used by the Microchip decoder described, the decoder ignores the unencrypted function code and the status bits.

If the control samples in a given bit are sampled correctly (i.e., the first element is high and the last element is low), the routine checks whether more than 56 bits have been received correctly. If not, the routine returns to the calling procedure.

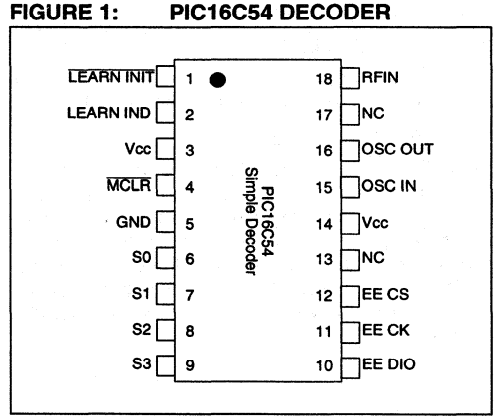
AN663

KEELOQ® Simple Code Hopping Decoder

Author: Steven Dawson
Microchip Technology Inc.



OVERVIEW

This application note fully describes the working of a code hopping decoder implemented on a Microchip PIC16C54 microcontroller. The PIC16C54 is smaller than the PIC16C56 used in the normal decoder (AN642) or the secure learn decoder (AN652). A simplified learning scheme with all encoders sharing a common key and a simplified counter synchronization scheme has been used to reduce the code space requirements. The use of a common key reduces the security of the system. The simple decoder can learn up to 15 encoders. This application note describes the various KEELOQ code hopping encoders that can be used with the decoder, the decoder hardware, and the various software modules comprising the system. The software can be used to implement a stand alone decoder or integrated with full function security systems. The decoder supports the Microchip HCS200, HCS300, HCS301, HCS360, and HCS361 KEELOQ Code Hopping Encoders.

KEY FEATURES

- PIC16C54
- Stand alone decoder
- Compatible with Microchip HCS200, HCS300, HCS301, HCS360, and HCS361 encoders
- Automatic bit rate detection
- Automatic encoder type detection
- Four function outputs
- Up to 15 learnable transmitters
- RC Oscillator
- Single press learn

INTRODUCTION TO KEELOQ ENCODERS

All KEELOQ encoders use the KEELOQ code hopping technology to make each transmission by an encoder unique. The encoder transmissions have two parts. The first part changes each time the encoder is activated and is called the hopping code part and is encrypted. The second part is the unencrypted part of the transmission, principally containing the encoder's serial number identifying it to a decoder. Refer to DS91002, Introduction to KEELOQ.

Hopping Code

The hopping code contains function information, a discrimination value, and a synchronization counter. This information is encrypted by an encryption algorithm before being transmitted. A 64-bit encryption key is used by the encryption algorithm. If one bit in the data that is encrypted changes, the result is that an average of half the bits in the output will change. As a result, the hopping code changes dramatically for each transmission and can not be predicted.

Function Information

The encoder transmits up to four bits of function information. Up to 15 different functions are available.

Discrimination Value

Stored in the encoder EEPROM, this information can be used to check integrity of decryption operation by a decoder. If known information is inserted into the transmitted string before encryption, the same information can be used at the decoder to check whether the information has been decrypted correctly. 12 bits (including overflow bits) are available in the Microchip HCSXXX encoders.

Synchronization Counters

The transmitted word contains a 16-bit synchronization counter. The synchronization information is used at the decoder to determine whether a transmission is valid or is a repetition of a previous transmission. Previous codes are rejected to safeguard against code grabbers. The HSC300 and HCS301 encoders transmit two overflow bits which may be used to extend the range of the synchronization counter from 65,536 to 196,608 button operations. The HCS360 and HCS361 encoders transmit one overflow bit which can be used to extend the range of the synchronization counter from 65,536 to 131,071 button operations.

Unencrypted Code

Serial Number

The encoder's serial number is transmitted every time the button is pressed. The serial number is transmitted unencrypted as part of the transmission and serves to identify the encoder to the decoder.

Other Status and Function Information

The HCS200, HCS300, and HCS301 encoders include provision for four bits of function information and two status bits in the fixed code portion of its transmission. The two status bits indicate whether a repeated transmission is being sent, and whether the battery voltage is low. The HCS200 does not send repeated transmission information, and the bit is permanently set to '0'.

The HCS360/361 encoders transmit two bits that are used as a Cyclic Redundancy check. These bits can be used to check the integrity of the reception. Additionally, the HCS360 and HCS361 encoders can extend the length of the serial number from 28 bits to 32 bits, replacing the unencrypted function code.

Transmission Format Summary

Table 1 contains a summary of the information contained in transmissions from each of the KEELOQ encoders that can be learned by the Microchip decoder.

FIGURE 2: DECODER BLOCK DIAGRAM

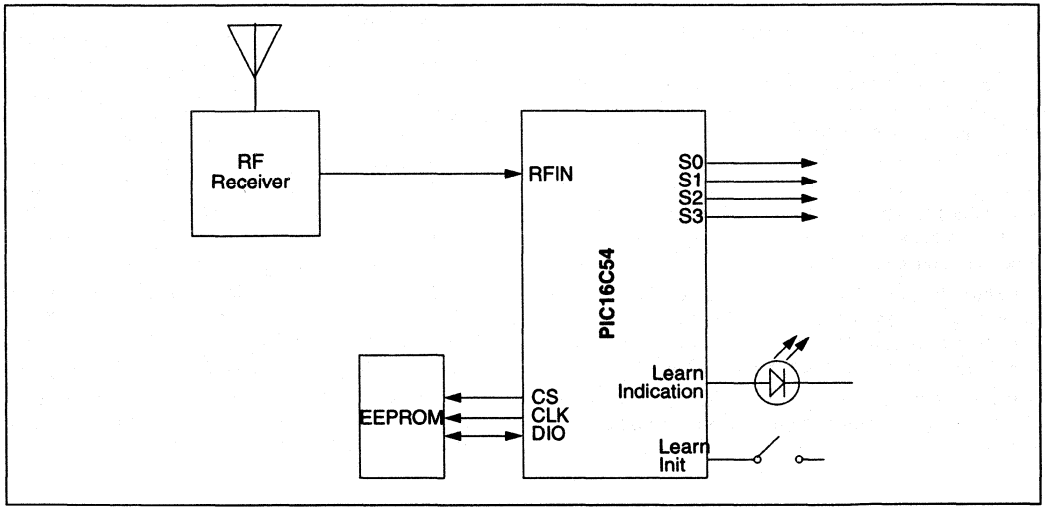

TABLE 1: KEELOQ ENCODER TRANSMISSION SUMMARY

	HCS200[1]	HCS300/301	HCS360/361
Total transmission length	66 bits	66 bits	67 bits
Hopping code portion (total length)	32 bits	32 bits	32 bits
Function bits	3 bits (+1[1])	4 bits	4 bits
Discrimination bits	12 bits	12 bits	12 bits
Synchronization	16 bits	16 bits	16 bits
Fixed portion (total length)	34 bits	34 bits	35 bits
Serial number	28 bits	28 bits	28/32 bits[2]
Function bits	3 bits (+1[1])	4 bits	4/0 bits[2]
Status bits			
VLOW	1 bit	1 bit	1 bit
RPT	0	1 bit	0
CRC	0	0	2 bits

[1]The HCS200 transmissions are padded to retain compatibility with the HCS300/301 encoders.
[2]User selectable with a 32-bit serial number or a 28-bit serial number, and 4 unencrypted function bits.

The code hopping portion is always transmitted first (LSB to MSB), followed by the fixed portion (LSB to MSB).

TABLE 2: HCS200† AND HCS300/301 TRANSMISSION FORMAT

Hop Code			Serial Number			Function	Status
LSB	32 bits	MSB	LSB	28 bits	MSB	4 bits	2 bits

†The HCS200 transmissions are padded to retain compatibility with the HCS300/301 encoders.

TABLE 3: HCS360/361 TRANSMISSION FORMAT

Hop Code			Serial Number			Function	Status
LSB	32 bits	MSB	LSB	28/32 bits	MSB	4/0 bits	3 bits

Bits are transmitted from left to right (i.e., the code hopping part first).

PWM Format

In general, all KEELOQ encoders share a common transmission format:

A **preamble** to improve biasing of decision thresholds in super-regenerative receivers. The preamble consists of alternate on and off periods, each lasting as long as a single elemental period.

A **calibration** header consisting of a low period of 10 elemental periods. Calibration actions should be performed on the low period of the header to ensure correct operation with header chopping.

A **string** of 66 or 67 pulse-width modulated bits, each consisting of three elements. The first element is high, the second contains the data transmitted and is either high or low, the third element is always low.

A **guard** period is usually left between the transmissions. During this period nothing is transmitted by the encoder.

Figure 3 shows the sampling points when sampling the data bits. The first and last elements are used exclusively to verify the integrity of the received symbol. The first element (sample point A) is always high, the second (sample point B) is the complement of the data bit being sent, and the final element (sample point C) is always low. Because the period between the low portion of a bit (sample point C) and the rising edge of the following bit (sample point X) can vary, the rising edge of the first element (sample point X) is used to resynchronize the receiving routine to each incoming bit.

If random noise is being received, the probability of a set of three samples producing a valid combination is only $2^{-2} = 1/4$. For a string of 66 bits, the corresponding figure is $2^{-132} < 2 \times 10^{-40}$.

Integrity checking on incoming signals is important. Code hopping signals require significant processing, as well as EEPROM access, to decrypt. Unnecessary processing can be avoided by not attempting to decrypt incoming codes that have bit errors.

FIGURE 3: KEELOQ PWM TRANSMISSION FORMAT

DECODER IMPLEMENTATION

The decoder is implemented on a PIC16C54 RISC microcontroller and a 93C46 EEPROM as shown in the decoder schematic in Figure 9. However, this solution can be implemented in any PICmicro™ microcontroller with at least 500 words of program memory. The operating frequency of the controller is 4 MHz. The microcontroller is used to capture transmissions from the various encoders, decrypt transmissions captured, and check the validity of the transmission based on the information in the decrypted transmission and information stored in the EEPROM. If a transmission from a valid encoder is received, the decoder activates the outputs dictated by the transmission.

Encoder information, such as serial number and synchronization information is stored externally in an EEPROM. The EEPROM used is a Microchip 93C46 Microwire® Serial EEPROM. The information stored in the EEPROM is encrypted to protect the contents. The EEPROM encryption is less secure than the KEELOQ code hopping algorithm.

As can be seen from the section on encoder transmissions there are differences in the transmission formats of the different encoders that can be used with the decoder. The following section summarizes how the differences in transmitted data are dealt with by the decoder.

As the serial number information follows after the code hopping portion of the transmission, any number of serial number bits can be received and processed. In the Microchip decoder described, the complete serial number (28 bits) is stored.

After matching the received and stored serial number, validation of a received transmission consists of two steps. The first includes checking the integrity of the decryption operation. Here the decoder compares the least significant 8-bits of the discrimination value received with the least significant 8-bits of the serial number. The discrimination value stored with the HCS300/301/360/361 includes overflow bits and user bits.

The second portion of validation involves checking synchronization information for that particular encoder. The synchronization counter transmitted by all encoders is 16 bits long. Two copies of the full synchronization counter are stored for all valid encoders. The storing of two copies of the synchronization information protects the decoder from loosing synchronization with an encoder if one of the counters is corrupted.

6

PROGRAM FLOW

The software for the Microchip decoder has been written for the PIC16C54 microcontroller. The compiler used is MPASM version 01.30.01. The operating frequency of the PIC16C54 is 4 MHz. The clock speed should be kept as close as possible to 4 MHz as the reception routine (RECEIVE) is dependent on the 4 MHz clock for correct functioning. Other decoder functions that rely on a 4 MHz clock speed are the hold times of the various outputs and time-outs. The main program flow is described here. Detailed descriptions of individual functions can be found further in the application note.

After startup, the encoder enters the main loop where it spends most of its time. The main loop checks to see if the learn button is being activated. If so, the decoder enters the learn mode described in the "Learn" in AN659.

If learn has not been initiated, the microcontroller checks for transmissions from encoders (RECEIVE) as described on page 55. If a transmission from an encoder has successfully been received, the microcontroller validates the transmission received as described in the "Transmission Validation" section in AN659. If the transmission received is a valid transmission from an encoder learned into the system, the system sets the appropriate outputs (M_OUTPUT).

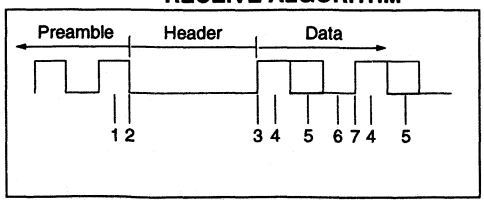
FUNCTIONAL MODULES

Reception

The reception routine (RECEIVE) is based on a reliable algorithm which has successfully been used in previous implementations of KEELOQ decoders. Automatic bit rate detection is used to compensate for variations in bit rate of different encoders of a specific type, as well as the differences in bit rate between different encoders (HCS200, HCS300, and HCS360). The reception routine is able to receive 64-bit transmissions. The decoder only uses the first 60 bits received. The remaining bits are ignored.

The reception algorithm performs a number of functions when an output is detected from the receiver. Figure 5 gives all the major sampling points in the reception algorithm.



The reception algorithm calibrates on the low period of the header to determine the actual elemental period for the transmission being received. The required elemental period is 10% of the low header period. In Figure 5 the header calibration sample points are marked 1 through 3. The calibration flow chart (Figure 6) shows at what points in the program samples 1, 2, and 3 are taken.

Elemental periods outside the capture range of the algorithm (either too long or too short) are rejected, since they are due either to noise or to reception of an incomplete signal.

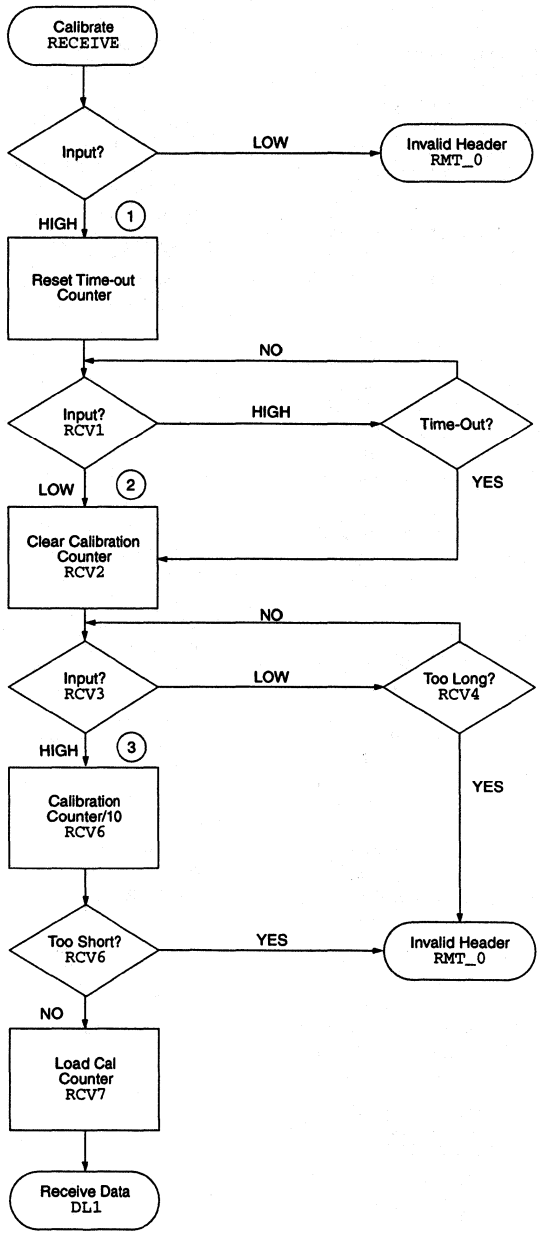
Using the determined elemental period, three samples after the first rising edge (sample 3) following the header are taken. The first sample is taken half an elemental period after the rising edge (Sample 4); the second, one elemental period later (Sample 5), and the third, another one elemental period later (Sample 6). The first sample must be high, the second could be either high or low, and the third sample must be low. If either the first or the third sample is not as expected, the attempt at capturing a transmission is abandoned. In Figure 5, the data sample points are points 4 through 6. The flow chart describing data reception (Figure 7) shows where in the code the samples are taken.

If all 64 bits have been captured, each with the correct first and third elements, the transmission can be assumed to be correct, and decryption can commence. The receiving routine should be called often enough to ensure that the high portion in the header is not missed (Sample 1, Figure 5).

FIGURE 5: SAMPLING POINTS USED IN RECEIVE ALGORITHM

In systems where the reception routine is called to check if there is activity on the receiver input, the routine should poll the input for a valid transmission for at least the time taken to complete one transmission if activity is detected on the input line. This makes provision for the reception routine being called while a transmission is in progress. Having missed the first header, the first transmission will be invalid and be discarded. The decoder should continue sampling the input through the guard time in order to catch the next header and transmission (i.e., for a decoder designed to capture HCS300 transmissions the time spent polling for a valid transmission should be at least 100 ms if activity is detected in the input line).

Reception Algorithm Flow Chart



The flow chart in Figure 6 describes the calibration routine which is used to determine the actual transmission rate of the encoder so that the decoder can compensate for deviations from nominal timing. There are four different exit points, each of which should branch to a point in the program where housekeeping and input monitoring can be resumed. There is only one exit point for a valid calibration operation (RCV7). At this point, it is assumed that a valid header has been received and that a string of data bits will follow.

The second flow chart (Figure 7) handles the reception of bits once the calibration routine has been successfully completed. The data bits are all sampled three times each to ensure that a noise free transmission has been received. The reception routine uses the calibrated elemental period, determined in the calibration routine, to ensure that the samples are correctly spaced. The routine resynchronizes itself on the rising flank of each bit. Only 60 bits of the data received are used by the decoder described, the decoder ignores the unencrypted function code and the status bits.

If the control samples in a given bit are sampled correctly (i.e., the first element is high and the last element is low), the routine checks whether 66 bits have been received correctly. If not, the routine returns to the calling procedure.

Using KEELOQ® to Generate Hopping Passwords

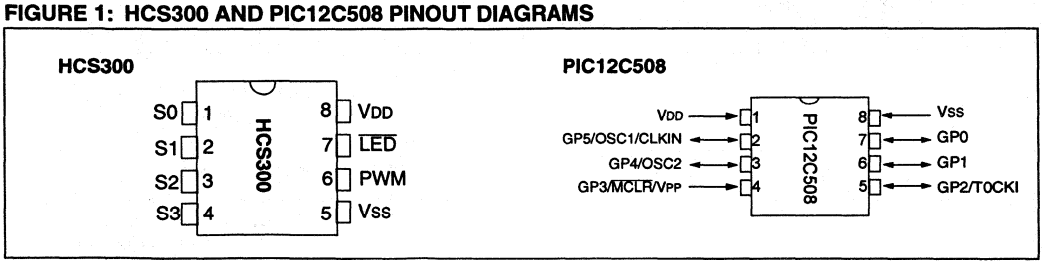
Author: *Lucio Di Jasio*
Arizona Microchip Technology, Italy

INTRODUCTION

The purpose of this application note is to demonstrate how KEELOQ code hopping technology can be conveniently employed to implement an automatic code hopping password generator/keypad. Using a PIC12C508, the hopping code produced by an HCS300 is converted to a string of 16 hex digits. This string is then transferred to the PC via the keyboard line, thereby emulating the actual pressure of a sequence of keys on a standard PC/AT® keyboard. Since this conversion process is transparent to any application, it appears as if the user is simply typing on a PC/AT-type keyboard.

An ideal situation for implementing this application would be in creating a "super password" for general, access-control secure logins when transmitting information onto the internet (i.e., through a browser) or a Java applet.

THE "HOPPING" ADVANTAGE



Password-based access control systems are very popular today, but the level of security they provide are often overestimated. Being basically a unidirectional transmission, a password-based system has two very important shortcomings which can lead to unauthorized access: the code is fixed, and the number of possible combinations is relatively low.

The growing speed of communication lines and the computing power of available systems increases the chance of a brute force attack or "code scanning." The use of unsecure means of transmission, where code "grabbing" is possible (i.e., a typical modem connection over phone lines), can make the use of a fixed code highly undesirable. Note that these are the same situation that led to the introduction of the "code hopping" concept in the remote control market.

The basic idea is to have the access code change each time it is used through a sequence where the new codes cannot be predicted even knowing a very large number of previously used ones. Producing such a sequence requires the use of a solid encryption engine. Microchip Technology is currently offering a broad range of encoders based on the proprietary KEELOQ code hopping technology. These encoders make producing a code hopping remote control easy, but as we will see, can also be conveniently used to add the hopping advantage to old password based access control systems in a transparent way.

INTRODUCTION TO KEELOQ ENCODERS

All KEELOQ encoders use the KEELOQ code hopping technology to make each transmission by an encoder unique. The encoder transmissions have two parts. The first part changes each time the encoder is activated and is called the code hopping part and is encrypted. The second part is the unencrypted part of the transmission, principally containing the encoder serial number identifying it to a decoder.

The code hopping contains function information, a discrimination value, and a synchronization counter. This information is encrypted by an encryption algorithm before being transmitted. A 64-bit encryption key is used by the encryption algorithm. If one bit in the data that is encrypted changes, the result is that an average of half the bits in the output will change. As a result, the code hopping changes dramatically for each transmission and can not be predicted.

The synchronization information is used at the decoder to determine whether a transmission is valid or is a repetition of a previous transmission. Previous codes are rejected to safeguard against code grabbers.

The HSC300 and HCS301 encoders transmit two overflow bits which may be used to extend the range of the synchronization counter from 65,536 to 196,608 button operations. The HCS300 and HCS301 encoders include provision for four bits of function information and two status bits in the fixed code portion of its transmission. The two status bits indicate whether a repeated transmission is being sent, and whether the battery voltage is low.

The Microchip HCSXXX encoders all have the ability to transmit a fixed seed. The seed value is programmed into the encoder when the encoder is first initialized along with the counters, key, serial number, and other information. The seed length differs from encoder to encoder, with the HCS300 and HCS301 having a 32-bit seed.

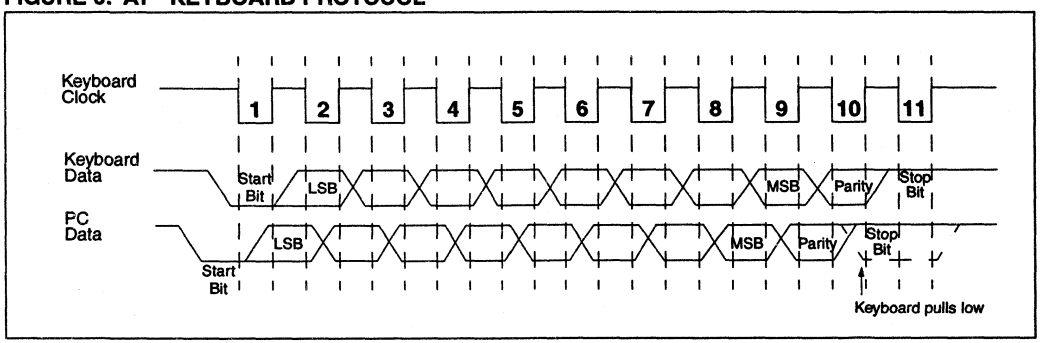
The IBM PC-AT® Keyboard Protocol

IBM® was the first to introduce the synchronous serial protocol most of today's PC-ATs use to communicate with a keyboard. This now-standard, 5-pole shielding connector (Figure 5) carries the clock line, data line, ground, and +5V power supply in order to transmit data bidirectionally from the keyboard to the PC.



Typically, data travelling from the keyboard to the PC is accomplished by either key pressure or release information. However, some configuration data (i.e., repeat, delay, and rate) can flow in the opposite direction – for example, during a system boot. The keyboard drives the clock line by using open collector drivers. To disable the keyboard, the PC can keep the clock line low. If the data line is held low by the PC while the clock line is high, the computer transmits a requests to send, and the keyboard goes into receive mode. The keyboard is only allowed to send data when both the clock line and data line are high.

Keyboard Transmission

The keyboard pulls the data line low (start bit) and starts the clock. The eight data bits (least significant bit first) are shifted out, followed by the parity (odd), and stop bit (high). Data is valid after the falling edge of the clock and changes after the rising edge of the clock. If no data is transmitted, both the clock line and data line are high. If the computer pulls the clock line low for at least 60 µs before the tenth bit is transmitted, the keyboard stops the transmission and stores the aborted data in a buffer for retransmission at a later time.

Keyboard Receiving

The computer pulls the data line low (start bit), after which the keyboard starts to shift out 11 clock pulses within 15 ms. Transmission has to be completed within 2 ms. Data from the computer changes after the falling edge of the clock line, and is valid before the rising edge of the clock. After the start bit, eight data bits (least significant bit first), followed by the parity bit (odd), and the stop bit (high) are shifted out by the computer with the clock signal provided by the keyboard. The keyboard pulls the stop bit low in order to acknowledge the receipt of the data. If a transmission error occurs (parity error or similar) the keyboard issues a "RESEND" command to the PC.

Key Pressure Release Encoding

Key pressure is communicated to the PC by sending a scan code. Table 1 lists the scan codes corresponding to keys '0'...'F'. Release is communicated by sending the break code (0F0), followed by the previous scan code.

TABLE 1 SCAN CODES

Codes	Key
45	'0'
16	'1'

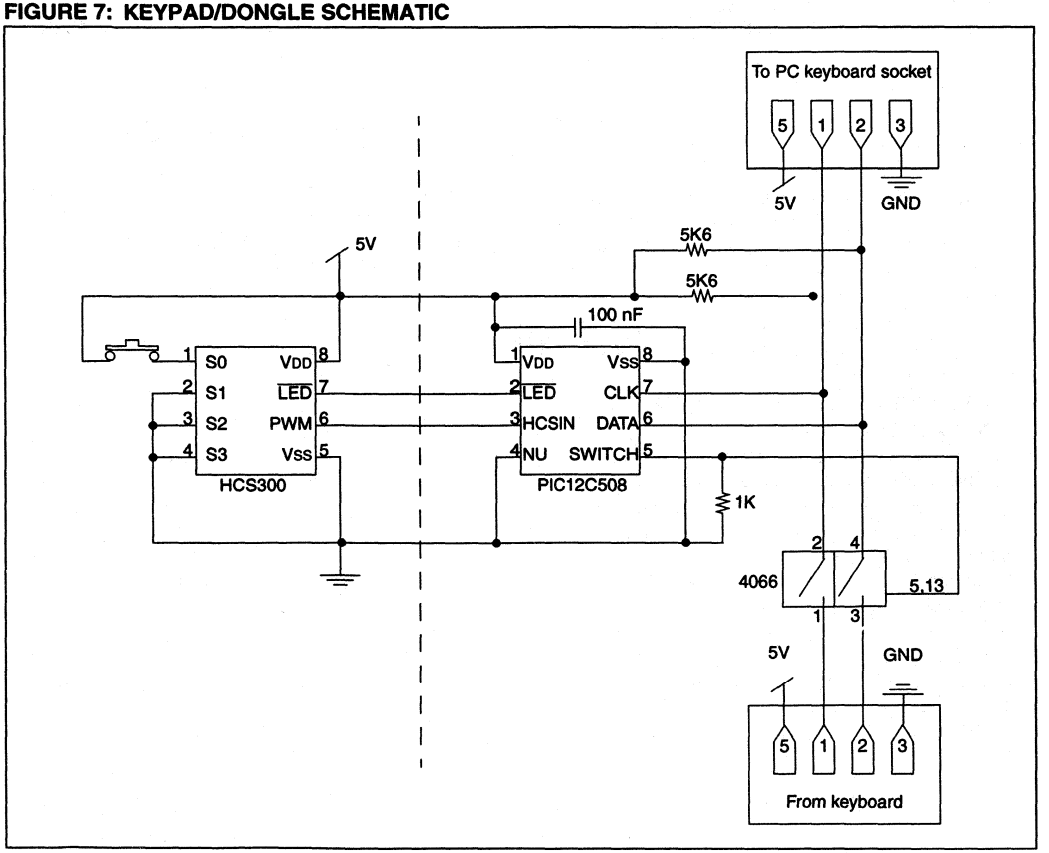
Proposing a Demo Keypad/Dongle Implementation



The password generator fits between the keyboard and the PC. A 5-pin plug connects to the PC, supplying power to our device, and the keyboard plugs into the 5-pin socket (Figure 7). The clock and data lines are passed between the PC and keyboard, allowing normal keyboard operations. When S1 is activated, the PIC12C508 receives the new message (16 hex digits) produced by the KEELOQ HCS300 Encoder. The PIC12C508 will then emulate the keyboard, sending the appropriate sequence of key press and key release messages to the PC. To prevent the keyboard from interpreting this transmission as a 'request to send' from the PC, it is necessary to isolate the keyboard from the clock line and data line during the transmission.

The KEELOQ HCS300 Encoder can be part of the dongle or can be removable, like a key, in order to allow different encoders with different encryption keys or serial numbers to be easily exchanged.

Power consumption has to be the lowest possible in order not to excessively load the line. Size and component count should also be kept to the possible minimum in order to allow for a very small package. Ideally, the whole circuit should fit into a small gap between the two connectors.

In the implementation we are proposing, an HCS300 KEELOQ code hopping encoder is used together with a PIC12C508 microcontroller.For simplicity, a standard CMOS quadruple switch (4066) is used to alternatively connect the dongle or the keyboard to the PC line. The HCS300 and the PIC12C508 (both available in 8-pin DIP or SOIC packages), draw extremely low currents as well as internally produce the clock required to operate the dongle. Beside a couple of pull-up resistors required for the clock line and data line, no other components are required to obtain a fully functional hopping password dongle (Figure 7).

Software Implementation

The software is composed of three short code segments:

- Receive routine for the KEELOQ HCS300 Encoder
- Keyboard Emulation Routines
- Main loop routine.

Receive Routine for the HCS300 Encoder (RECEIVE)

The RECEIVE routine gathers the first 64 bits transmitted by the HCS300, ignoring the last two bits (repeat and battery status) as they carry no useful information for this application, and packs them into a 8-bytes buffer (Buffer0...Buffer7).

Keyboard Emulation Routines (Sendbit, SendKey)

These implement the transmission of the key scan codes according to the IBM-PC/AT keyboard protocol.

Main Loop

While the CMOS switch connects the PC to the keyboard clock and data lines, the $\overline{\text{LED}}$ output line is continuously polled to detect the activation of the HCS300

Note: Any combination of its four input lines after debouncing activates the encoder.

When the $\overline{\text{LED}}$ line goes low, the CMOS switch is activated to isolate the clock and data lines from the keyboard. The RECEIVE routine is called.

Upon successfully receiving a transmission, a loop is entered where 16 hex digits from the receive buffer are transmitted as a sequence of key press and key release messages, separated by appropriate delays repetitively calling the SENDKEY subroutine.

The software has been developed in the simplest possible form and, therefore, is open to a number of optimizations. For example:

- The PIC12C508 could be put to "sleep" to further reduce power consumption.
- The encoder could be removable and its presence/activation should be properly detected.
- For simplicity, the presented RECEIVE routine requires a 400 µs transmission speed being configured in the encoder, while a more flexible multi-baud rate routine can be used as presented in various other application notes.
- A second code word could be compared with the first code word received to recognize transmission errors (although highly improbable when the encoder is wired to the PIC12508), since there is no decryption, there is no other means to tell that the transmission has not been corrupted.

Decoding Options

A code hopping password can be used to validate access to a wide variety of electronic services providing the recipient application (typically, it will be some software running on a server) is capable of following some simple decryption and verification steps. The fixed unencrypted part of the code (last 8 digits) can be used to identify the user (7 digits) and the function activated on the encoder (1 out of 15, corresponding to the last digit).

The hopping part has to be decrypted using the appropriate 64-bit decryption key. Depending on the desired level of security, many different key generation and management techniques can be adopted. For example, the key could be deduced by the User ID and a Manufacturer's Key, by the "seed" code of the encoder or could simply be a fixed 64-bit constant.

Learning techniques can also be applied so that the application actually autonomously acquires the required keys and builds a database of users, ID codes, and decryption keys. For a further analysis, consult the following literature:

Communicating with the I²C™ Bus Using the PIC16C5X

Author: Bruce Negley
Microchip Technology Inc.

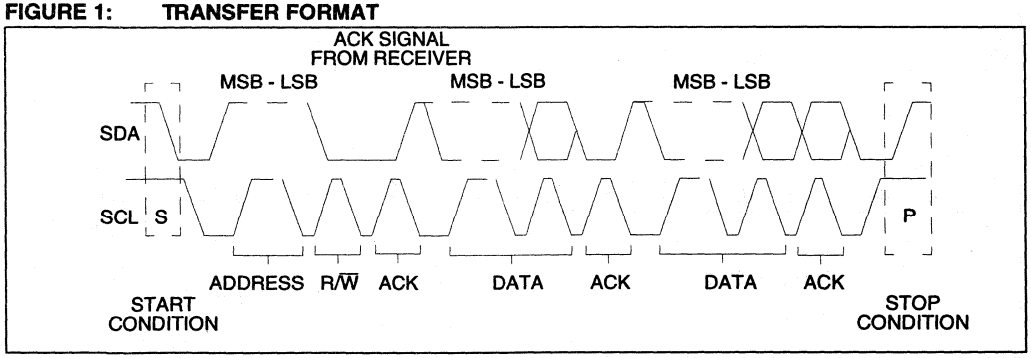
INTRODUCTION

The Microchip Technology Inc.'s 24CXX and 85CXX Serial EEPROMs feature a two wire serial interface bus. The bus protocol is I²C compatible. Interface to a serial port with I²C bus protocol in a microcontroller is trivial. This application note is intended for design engineers who want to develop their software programs to communicate a microcontroller with a 2-wire bus Serial EEPROM through a general purpose I/O port.

Unlike the 3-wire bus Serial EEPROMs, the 24CXX/85CXX communicate with any microcontroller only by a serial data I/O line (SDA) and a serial clock (SCL). Chip select is not required. Data transfer may be initiated only when the bus is not busy. During such transfer, the data line (SDA) must remain stable whenever the clock line (SCL) is high. Changes in the data line while the clock line is high are interpreted as a START or STOP. A typical transfer format is shown in Figure 1.

After the START, a slave address is sent. This address is 7-bits long, the eighth bit is a data direction bit. R/$\overline{W}$ - a logical '0' indicates a transmission WRITE, a logical '1' represents a request for data READ. A data transfer is always terminated by a STOP generated by the master controller. However, if a master still wishes to communicate on the bus, it can generate another START and address another slave without first generating a STOP. Various combinations of read/write formats are then possible within such transfer.

FIGURE 1: TRANSFER FORMAT



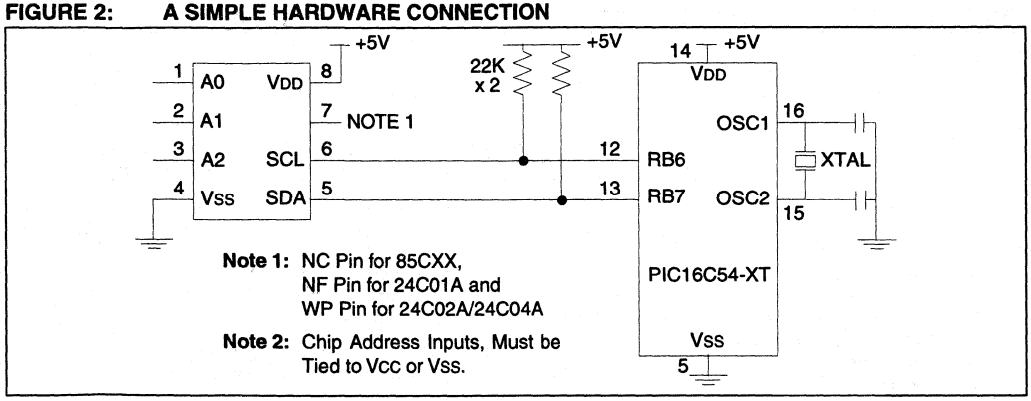


FIGURE 2: A SIMPLE HARDWARE CONNECTION

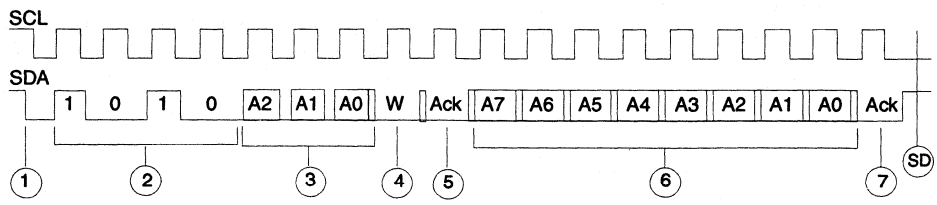
7



© 1997 Microchip Technology Inc.

An example program has been provided in Appendix A containing all PIC16C54 routines needed to exercise a 24CXX or 85CXX device. A simple hardware connection is illustrated in Figure 2. A maximum of eight 24C01A/24C02A/85C72/85C82's, or four 24C04A/85C92's can be addressed by a microcontroller on the same two wire bus without additional interfaces. Each device is identified by its Chip Address and will only respond to the correct slave address. A detailed bus flow is shown in Figure 3, Figure 4 and Figure 5.

These three figures, as shown below describes how the bit stream is set up for READ and WRITE mode in the microcomputer programming software prior to sending it on the two wire serial bus.

The stop condition, after the write sequence, starts the internal self-timed write cycle which may last up to 6 milliseconds (0.7 ms per byte). Acknowledge signal should be monitored during this period.

FIGURE 3: SETTING THE INTERNAL WORD ADDRESS OF THE 24CXX/85CXX

1. Start Condition
2. 4-Bit Device Code 1010 For 24CXX/85CXX
3. Device Address A0=PA, High Order Address Bit A8 For 24C04A/85C92
4. 0=Write to Address Register
5. EEPROM Drives Bus Low with Acknowledgement (Timeout if No Response)
6. Address for Data, A7-A0 (MSB-LSB)
7. Bus Low for Acknowledgement

24C01A Compatibility Issue and Its Mobility for Memory Upgrade

Author: *Bruce Negley*
Microchip Technology Inc.

INTRODUCTION

The 24C01A is a 1K (128 x 8) Serial EEPROM which is currently offered by Microchip and Xicor. There are several important differences between the two devices which are discussed in this report. This report refers to the Microchip part as the 24C01A and the Xicor part as the X24C01. It is intended to assist in designing a memory subsystem which is compatible with either device.

COMPATIBILITY ISSUES

There are three major differences between Microchip's 24C01A and Xicor's X24C01 as detailed below.

PAGE MODE DIFFERENCES

The 24C01A was originally designed to work in the same socket as the PCD8572 which has a two-byte page mode. Therefore, its page buffer is two bytes deep. The X24C01 has a page mode of four bytes depth.

If more than two bytes are transmitted to the 24C01A during a page programming cycle, the 24C01A will terminate the write cycle.

In many applications where serial EEPROMs are used and speed is not a key issue, the byte write mode can be used without any loss of system performance. If only the byte write mode is used, there is no compatibility problem (other than slave address software differences discussed in the Software Differences section).

If the page write feature must be used, two different page mode algorithms can be transmitted by the master depending upon whose device is being used. The master will have to first do a polling routine to determine if it is interfacing with a 24C01A or X24C01. This polling technique is discussed in the Software Difference section.

Interestingly, the 24C01A actually updates faster in the page mode even though it has one-half the page depth of the X24C01. This is due to the faster write cycle time of the 24C01A. The two devices are compared in Figure 1.

SOFTWARE DIFFERENCES

Microchip's 24C01A is designed to share a 2-wire bus on which it resides with other devices. To support this, the first byte of each command sequence from the master to the 24C01A must be a slave address. The 24C01A monitors the 2-wire bus for its slave address and "wake-up" from standby mode if the address transmitted matches its address as defined by the voltage level (Vss or Vcc) on pins 1, 2 and 3. X24C01 does not support a multiple device bus and will always "wake-up" if a start condition is detected.

A slave address must be transmitted to the 24C01A at certain points during reading and writing. This slave address is not required by the X24C01. Transmitting a slave address to X24C01 will result in erroneous operation. This problem can be solved by having the master transmit the proper serial bit pattern to the slave, but first the master has to ascertain with which 24C01A it is communicating.

7

FIGURE 1: PAGE MODE DIFFERENCES

	Microchip	Xicor
Max byte program time	1 ms	10 ms
Max page program time	2 ms (2 bytes)	10 ms (4 bytes)
Max time to program 4 bytes	4 ms	10 ms
Max time to rewrite device	128 ms	320 ms

© 1997 Microchip Technology Inc.

The polling consists of the pattern like the one shown below:

| SDA LINE: | START BIT | 00000001 | ACKNOWLEDGE BIT | DATA 7...0 |

The master can do a simple polling routine before beginning serial communication with 24C01A or X24C01 to determine with which device it is working. The proper serial protocol for both devices must be contained in the master controller's firmware. Once the master knows which 24C01A is on the bus, it can execute the proper serial commands.

If an X24C01 is used on the 2-wire bus, an acknowledge bit and eight data bits will be returned whereas 24C01A will issue no response and will ignore the command.

HARDWARE DIFFERENCES

Unlike the X24C01, the 24C01A is designed to share a 2-wire bus with other devices. Chip address bits are included in the slave address for the 24C01A, and are incorporated into pins 1, 2 and 3 of the device. They must be connected to VCC or VSS for proper operation. Since pins 1, 2 and 3 of the Xicor part are NC (no connect) pins and they are not internally connected, they can be tied high or low.

Another hardware difference involves pin 7 which MUST be connected to VSS on the X24C01. The 24C01A can have pin 7 connected to VSS or VCC.

If only one device is planned for the 2-wire bus, the board can be made compatible for either device by connecting pins 1, 2 and 3 to either VSS or VCC and tying pin 7 to VSS.

Mobility For Memory Upgrade And Expansion

In system applications where the master device needs to address more than one serial EEPROM on a 2-wire bus, the Microchip 24C01A offers the flexibility. Up to eight 24C01A's can be connected to the 2-wire bus. More than one Xicor X24C01 connected to the bus may result in bus contention.

If memory upgrade is required, the Microchip 24C01A can be upgraded to the 24C02A (256 x 8) or the 24C04A (512 x 8) in the same IC socket with NO change in hardware. Using the Xicor X24C01, both software and hardware would have to be reconfigured to accommodate the changes.

Interfacing 93CX6 Serial EEPROMs to PIC16C5X Microcontrollers

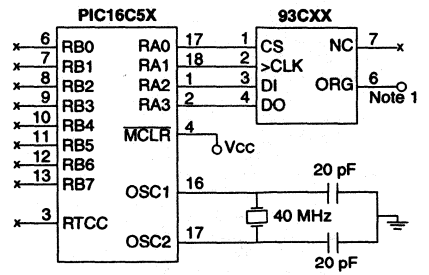
Authors: Stan D'Souza
Microchip Technology Inc.
Bob Ward
Microchip Technology Inc.

INTRODUCTION

Microchip Technology Inc.'s popular 93C46/56/66 and 93LC46/56/66 Serial EEPROMs feature a three/four wire serial interface bus. The attractive price and simple interface make it the ideal device for additional memory space. This application note is intended for design engineers who wish to incorporate a pre-packaged serial EEPROM interface driver into their application.

THE HARDWARE CONNECTION

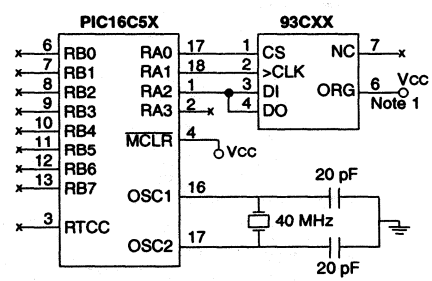
A typical 4-wire hardware connection is illustrated in Figure 1 and a typical 3-wire connection is illustrated in Figure 2. Since all I/O ports on the PIC16C5X are configurable as input and/or output, a 3-wire interface makes optimum utilization of the I/O pins by having a common connection for the DI and DO lines of the Serial EEPROM. The port pin on the PIC16C5X connected to these pins, has a default setting as an output and is configured, when needed, as an input during program execution.



THE SOFTWARE CONNECTION

An example interface driver is listed in Appendix A. A flow diagram is given in Figure 2. The interface driver is written to minimize both overhead to the calling program as well as the program space necessary for its inclusion into the user's code. The driver has been written as a generic driver to service all 93 Series Serial EEPROMs made by Microchip. Processor resources which must be made available to the driver prior to being called are:

1. Two levels of processor stack.
2. Six register locations (four for command/data passing and two for software counters).
3. The File Select Register (FSR), which is used to pass a command/data string pointer to the driver.



Note: The four command/data passing registers have to be defined consecutively in order for the FSR to access them successfully in the program execution.

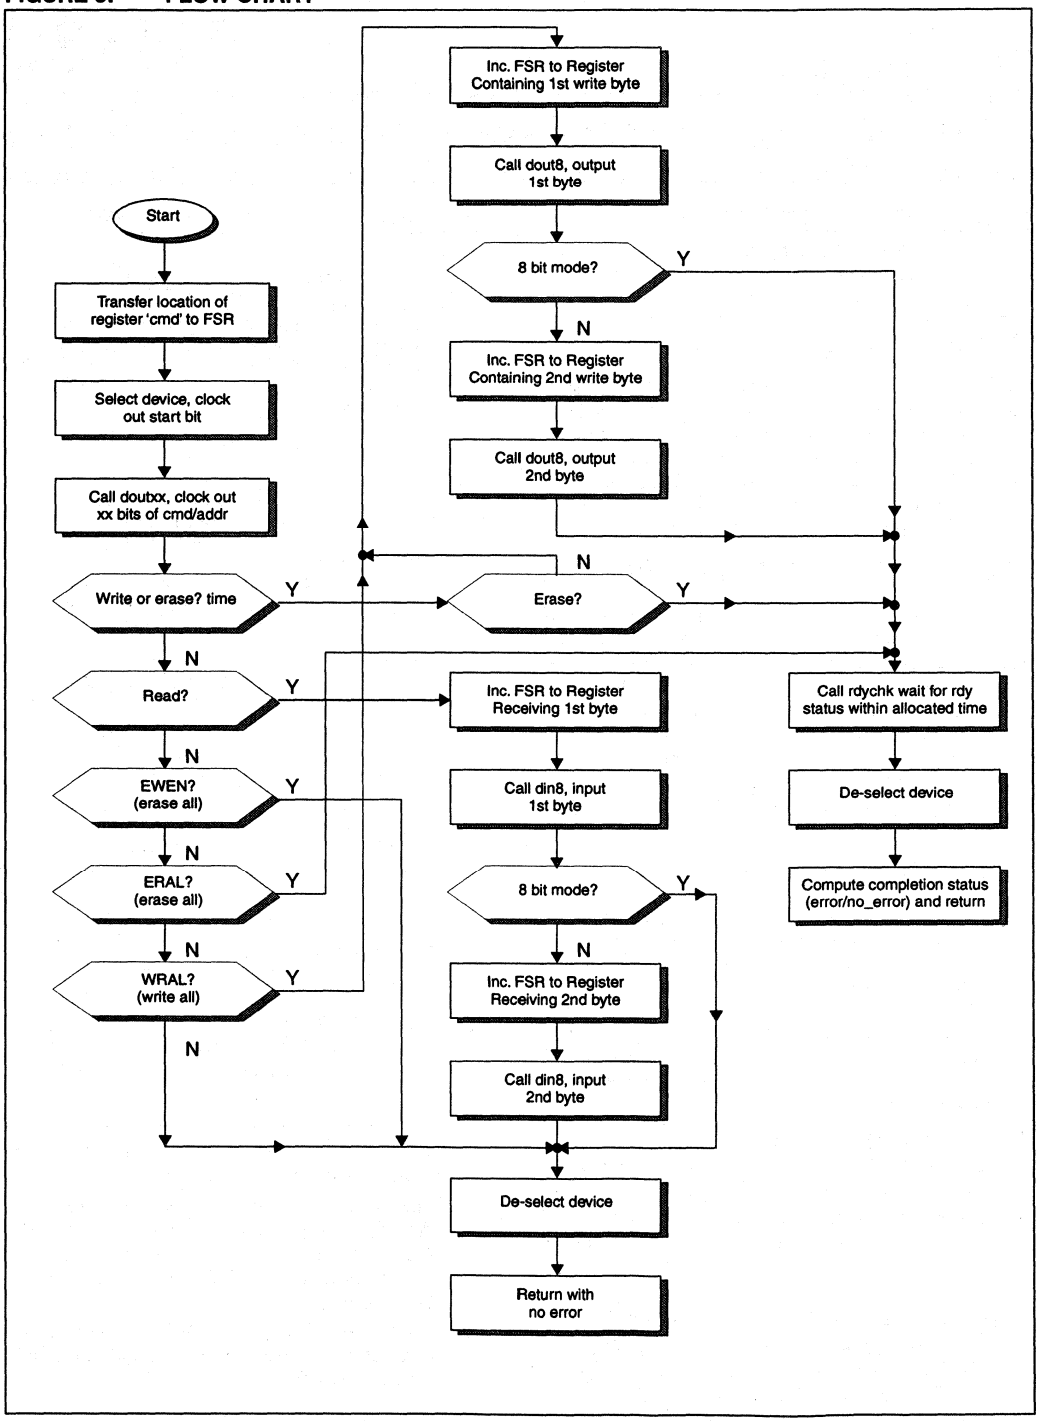
FIGURE 1: 4-WIRE CONNECTION

Note 1: FOR 93LCXX
For 16-bit data word connect to Vcc
For 8-bit data word connect to GND

FIGURE 2: 3-WIRE CONNECTION

Note 1: FOR 93LCXX
For 16-bit data word connect to Vcc
For 8-bit data word connect to GND

The user should take the following steps when using the routines provided in Appendix A.



A) Specify and define a 3-/4-wire interface by defining the common connection to the DI/DO lines and setting the equate 'wire3' TRUE or FALSE (4-wire is automatically assumed if 3-wire is false).

B) Specify and define if 16-bit or 8-bit data organization is used, by setting equate 'org8' TRUE or FALSE.

7

FIGURE 3: FLOW CHART

© 1997 Microchip Technology Inc.

C) The user should assemble the source file by specifying which type of serial EEPROM is being used. This is done by defining the equate S93C46, S93LC46, etc., as TRUE. Only one device can be TRUE, the rest have to be defined FALSE.

D) The user would invoke the driver as follows:

1. Load the register defined as 'cmd' with the 93CX6 Command Opcode (only the four upper bits are used in this register; see Figure 3).
2. If necessary, load the register defined 'addr' with the lower 8/7/6 bit address of the location.
3. If necessary, load the 9th bit of the address as bit 3 of the register defined as 'cmd' (Figure 3).

Note: READ, WRITE and ERASE commands need to have an address associated with the command and the 9th bit of the address is only required when using the 93C56/66 or 93LC56/66 devices in the 8 bit mode (ORG tied to GND).

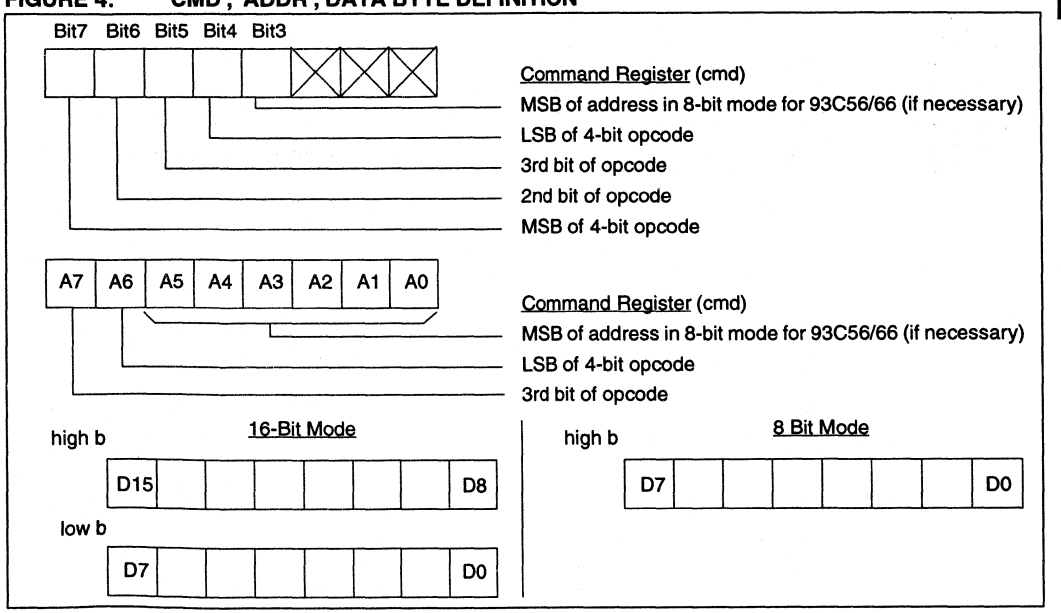
4. If necessary, load the register defined as 'highb' and 'lowb' with the 16 bits of data, the most significant byte loaded in 'highb'. In 8 bit mode, 'highb' should be loaded with the 8 bit data.

Note: Only the WRITE and WRAL commands require data to be loaded in the 'highb', 'lowb' locations.

5. Call the driver sub-routine 'see'.
6. Upon completion, the driver will return a completion status in the W register (error/no error). Only commands requiring a status check are capable of returning a valid error/no error status, in all other cases a no error is returned.
7. If the READ command is executed, the 16/8 bit data will be loaded in the 'highb' and 'lowb' registers, where 'highb' contains the MSB in the 16 bit mode and 8 bit data in the 8-bit mode.
   The Example interface assumes a 4 MHz oscillator clock which gives us a 1 µS instruction cycle. If a higher clock speed is used, additional NOPs have to be included in the code in order to meet the minimum clock speed requirements of the 93 Series Serial EEPROMs (see data sheet for further details).

Listing in Appendix B is for an interface to 93C46 Serial EEPROM only.

SUMMARY



The 93 Series Serial EEPROMs are a simple and versatile method of increasing read/write memory capability in a PIC16C5X application. The 'generic' code in Appendix A makes it easy to incorporate in any PIC16C5X application. Any of the 93 Series Serial EEPROMs can be applied, while at the same time using a minimal amount of I/O, code and RAM resources.

Code size: 6 bytes of RAM.

Appendix A listing:	127 bytes program code (max.) 100 bytes program code (min.)
Appendix B listing:	86 bytes program code

Logic Powered Serial EEPROMs

Authore: *Richard J. Fisher*
Microchip Technology Inc.
Bruce Negley
Microchip Technolgy Inc.

Embedded applications increasingly want more integration and power, in less space for less cost. Using low power Serial EEPROMs (SEE) for application firmware, lookup tables, and microcode coupled with small footprints makes for permanent storage at respectable savings. One additional method of saving on the power budget is selectively powering off components when not needed, a basic for embedded power management. The low-power SEEs offered by Microchip Technology Inc., offer an additional benefit, powering the SEE from a microcontroller port. This allows the host controller to not only manipulate the Serial EEPROM Reads and Write, but also the periods when it is powered off or on. Satellite communications use this technique to save power and total dose accumulation. We call this technique POWER PORT™. The microcontroller port must have sufficient Ioh (source current) to sustain the voltage and current for all memory functions, READ, ERASE, and WRITE. Obviously, not all memory or peripheral devices could be powered thusly, but Microchip's SEE devices will function in this environment.

The microcontroller, using its internal software and hardware decision functions, determines when it needs to communicate with the memory device, then acts accordingly. Any standard wake-up sequence will accomplish this task. The wake-up code needs only power up the memory and wait for the power to become stable before doing a read or write by driving the POWER PORT high. Then all serial communication executes normally. The SEEs are powered off for additional power savings and the data or code is utilized from RAM. Obviously, the port output must be allowed to settle, but normal operation of the output structures would guarantee that this would be met. The I/O port Tpd for the Microchip PIC16C5X, is specified at 40ns maximum.

The 24LCXX and 93LCXX CMOS SEE series parts from Microchip were designed to achieve low current consumption across all ranges of operation.

The four primary ICC parameters for these products are:

Parameter	Conditions
ICC STANDBY	Not in an active operation while VCC is supplied.
ICC READ	The part is in a READ operation.
ICC PEAK WRITE	The BYTE / PAGE WRITE and ERASE operations have self timed cycles of 10 ms. A typical of 4 ms is the actual time of the operation. This is the amount of time when the ICC requires the most current (PEAK WRITE). The part is drawing STANDBY ICC during the remaining 6ms of the cycle.
ICC AVG WRITE	The avg of the PEAK WRITE ICC and STANDBY ICC during the self-timed 10ms write cycle.

The attached characteristic curves (Figure 1 and Figure 2) indicate that ICC PEAK WRITE current consumes the most current. The worst case condition is at 6.0V and –40°C. The 24LCXX series parts draw a typical 3.2 mA and the 93LCXX series parts draw a typical of 2.0 mA. These low ICC characteristics offer a unique current saving benefit for battery applications. Figure 3 and Figure 4 illustrate the sink and source current capabilities of the PIC16C5X family of microcontrollers. It is clear from these characterization curves that the microcontroller can deliver sufficient current across all temperature ranges to power a SEE using the POWER PORT technique.

Figure 5 shows the connection scheme for the Microchip PIC16C54. It should be noted that not all versions of competitive microcontrollers are capable of powering a device in this manner and the specific data sheets for the microcontroller being considered must be consulted for maximum source current. The microcontroller port must be capable of sourcing sufficient current for the duration of the write cycle or 10ms, worse case. The peak write requirement for the 24LCXX product family is 3.2 mA at 5.5 Vdc (–40°C).

Listing A demonstrates the appropriate code sequences when using the PIC16C54 microcontroller. The sequences included are power control, start bit, stop bit, send and receive bit, Tx and Rx, and a general addressing routine.

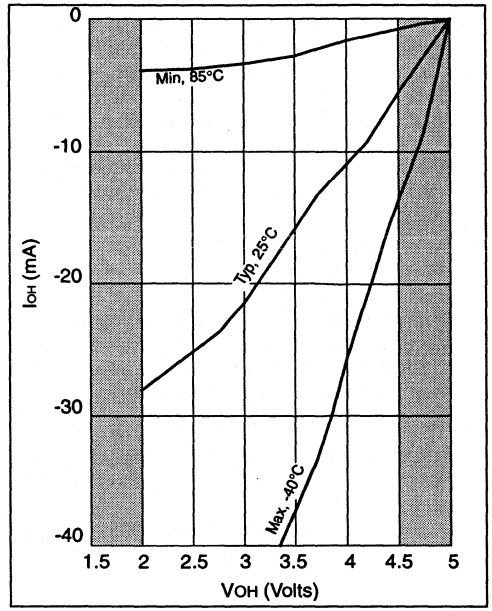

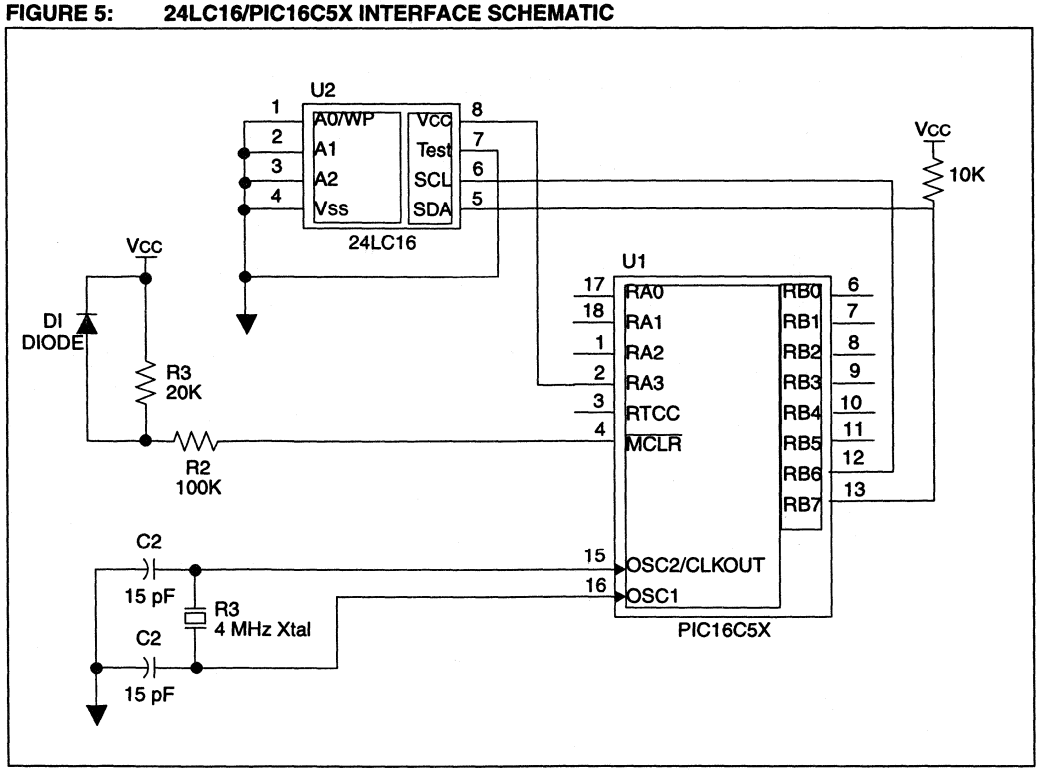

FIGURE 5: 24LC16/PIC16C5X INTERFACE SCHEMATIC

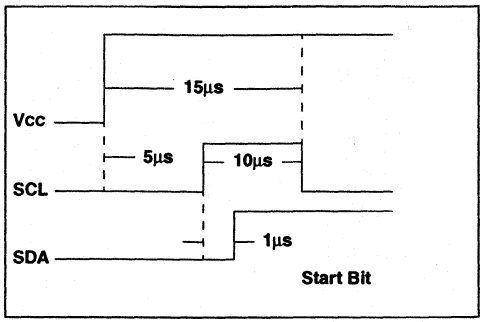
7

The primary benefits of this application are:



- The SEE is completely powered down to save power when the SEE is not executing an operation. This will directly effect the total system power consumption. This means that the SEE is in a total quiescent state and even the standby current savings are realized, greatly increasing usable battery life, and consequently allowing for a more sophisticated design on the same power budget.
- The very fast 5 µs power-up time minimizes power-up delay.
- Since the serial operation is gated by a stable microcontroller V_{OH}, risk of data being corrupted by a glitch is minimized. This, in effect, is a regulated V_{CC} supply and provides a reliable power source to ensure data integrity.

Several cautions need to be noted:

1. *Gang powering multiple devices must not exceed the I/O port I_{OH} or capacitive load specifications.*
2. *The total power requirements vs. power budget must be considered, including the extra drain on the microcontroller.*
3. *The microcontroller I_{CC} max must not be exceeded.*
4. *Normal decoupling methods must be employed.*
5. *The microcontroller I_{OH} for the port in use must not be exceeded.*

Figure 6 shows a typical power on to start bit sequence. Notice that the device is available to receive a clock at 5 µs after V_{CC} has become stable.

FIGURE 6:

Many applications, especially remote or handheld data acquisition applications, where power consumption is at a premium or battery life is critical can use the POWER PORT technique with the PICmicro™ microcontrollers and possibly other microcontrollers. Remote metering applications where the microcontroller must wake up and report previously stored data or periodically sample inputs, such as gas, electrical, or water monitoring systems are good examples where POWER PORT would be beneficial. Underground monitoring equipment for fuel storage and environmental monitoring systems are also suitable applications.

Basic Serial EEPROM Operation

Author: Steve Drehobl
Microchip Technology Inc.

Looking for the optimum non-volatile memory product for your system that requires a small footprint, byte level flexibility, low power, and is highly cost effective? Serial EEPROM technology is one of the non-volatile memory technologies that has emerged as a leading embedded control solution. Unfortunately, most system designers are not aware of the serial EEPROM benefits. Also, the supporting documentation in databooks is most often not adequate due to incomplete or ambiguous information. As a result, the system designer often selects a non-volatile solution that does not meet his requirements, or, the designer must face a more complicated design-in with a serial EEPROM.

This article addresses two issues that exist today for designers considering serial EEPROM products:

First, to provide awareness of the application benefits.

Secondly, to provide a primer on the operating principles and instructions. These items are often buried in databook text or not adequately addressed. Also included are common default conditions to significantly reduce the system designer's learning curve.

SERIAL EEPROM APPLICATIONS

Serial EEPROMS are ideal non-volatile cost effective memory solutions in applications that require:

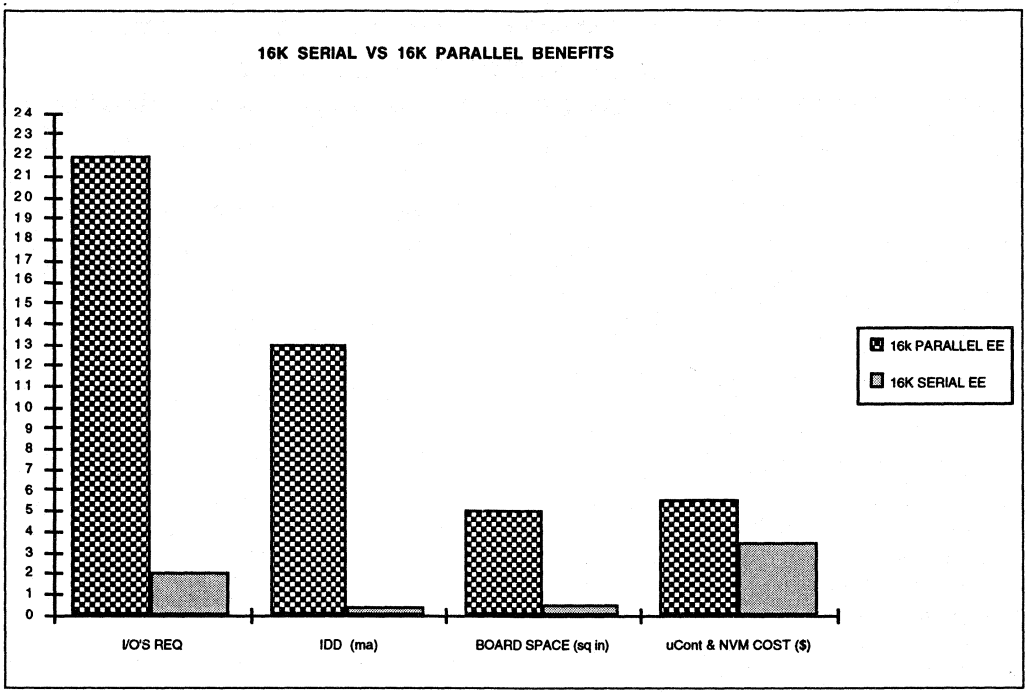
- Small footprint and board space as in cellular phone applications
- BYTE level ERASE, WRITE, and READ of data as in a TV tuner
- Low voltage and current for handheld battery applications as in a keyless entry transmitter
- Multiple non-volatile functions in the same application such as a VCR
- Low availability of microcontroller I/O lines

The common applications for Serial EEPROMS are shown below:

Market	Common Applications
Consumer	TV tuners, VCRs, CD players, cameras, radios, and remote controls
Automotive	Airbags, anti-lock brakes, odometers, radios, and keyless entry
Office Automation	Printers, copiers, PCs, and portable PCs
Telecom	Cellular, cordless and full feature phones, faxes, modems, pagers, and satellite receivers
Industrial	Bar code readers, point-of-sale terminals, smart cards, lock boxes, garage door openers, and test measurement equipment

The typical functions that serial EEPROMs are utilized for are:

- Memory storage of channel selectors or analog controls (volume, tone, etc.) in consumer electronics products
- Power down storage and retrieval of events such as fault detection or error diagnostics in automotive products
- Electronic real time event or maintenance logs such as page counting in office automation products. Also, configuration or DIP switch storage in office automation products
- Last number redial storage and speed dial number storage in telecom products
- User in-circuit reprogrammable look up tables such as bar code readers, point-of-sale terminals, environmental controls and other industrial products



Other application examples include:

- Data storage from a learn function as in a remote control transmitter
- ID number storage for security or remote access for electronic keys and entry databases
- Reprogrammable calibration data for test equipment or analog interface products

7

© 1997 Microchip Technology Inc.

As a result of density and architectural evolution, Serial EEPROMs offer significant benefits in some applications that previously could only utilize Parallel EEPROM products. The diagram below illustrates the footprint and board space differences

The Serial EEPROM requires only 10% of the board space that a Parallel EEPROM requires. Also, the Serial EEPROM requires fewer I/O lines from the microcontroller which significantly reduces the overall system cost and board space.

A very fast READ speed is the only significant limitation of a Serial EEPROM for a decision between a serial and a Parallel EEPROM. It is very interesting to note that the Serial EEPROM READ speed is restricted more by the protocol than the process technology. The 2-wire I^2C (Inter-Integrated Circuit) products must add large internal delays to slow down the part to meet the 100KHz protocol requirements, which will be reviewed later. Characterization of 3-wire bus Serial EEPROMs have indicated clock frequencies in excess of 6MHz.

OVERVIEW OF THE PRIMARY PROTOCOL BENEFITS

After a designer decides to use a serial EEPROM solution, the next step is to select one of the two primary serial EEPROM protocols. Unfortunately, most system designers select the type of serial EEPROM (2- or 3-wire) that they are most familiar with, regardless of the benefits associated with each type.

© 1997 Microchip Technology Inc.

The benefits of each protocol are shown below:

3-Wire Bus Serial EEPROMS	2-Wire Bus Serial EEPROMS
Single VDD supply of <2V to 5.5V	Single VDD supply of <2V to 5.5V
Very low current consumption	Very low current consumption
Reduced overall component cost	Reduced overall component cost
Four pins (other than VCC & GND) are required for operation	Two pins (other than VCC & GND) are required for operation
x16 bit and x8 bit data widths	x8 data bit width
Software WRITE Protection	Hardware WRITE Protection
Edge triggered clocks and signals	Level triggered clocks and signals and input glitch filters for high noise immunity
2MHz+ operation	I^2C standard 100KHz and 400KHz protocols with a 1MHz option
Ready/Busy data polling	Page WRITE capability to 16 bytes
Security options available	Software and hardware compatible from 2K to 16K densities
Less complex protocol	

A 2- wire product is utilized in applications that require an I^2C bus, noise immunity, limited microcontroller I/O pin availability, or a WRITE buffer for multiple bytes to be stored with one instruction. A 3-wire product is utilized in applications that have limited protocol requirements, an SPI protocol, higher clock frequency requirements, or x16 data width applications.

The next two sections describe the basic operation and Microchip's default conditions for the 3-wire and 2-wire Serial EEPROMs to allow the system designer to utilize the benefits of Serial EEPROMs.

3-WIRE BUS OPERATION PRIMER

Many serial EEPROM data sheets are written in a conventional memory data sheet format which emphasizes the features of the part more than the basic operating principles. The operating principles are unfortunately either vaguely embedded in the data sheet text or not included. Serial EEPROMs are not conventional memories due to the Serial communication protocols involved. This section is a PRIMER for the data sheet to familiarize the system designer with the basic principles of the 3-wire bus operation.

Basic Principles

Common device nomenclature is 93XXXX.

The 93XX06 is a 256 bit product.

The 93XX46 is a 1K bit product.

The 93XX56 is a 2K bit product.

The 93XX66 is a 4K bit product.

Four pins are required:

CS (Chip Select)	DI (data in)
CLK (Clock)	DO (data out)

All 93XXXX parts are hardware compatible for these four pins. However, there may be compatibility issues for the other pins.

Even though there is hardware compatibility on the four pins, there can be differences from a software standpoint. Subtle differences between each manufacturer's products, referred to as default conditions, can prevent plug compatibility. These issues are addressed later in the attached 3-Wire Timing Diagram. There is no industry standardized upgrade path for density migration. Please review density upgrades for Microchip's products on a case-by-case basis.

Data is available in x8 or x16 organizations. This selection is determined either by the ORG pin or by purchasing a standard x16 organization.

Units will power-up in a EWDS (ERASE/WRITE Disable State). All ERASE and WRITE functions are disabled until the EWEN (ERASE/WRITE Enable) instruction is performed. This is to prevent accidental data corruption.

An Auto-ERASE (logical "1") cycle is performed during each WRITE Cycle.

The seven instructions are shown in the attached instruction set table. These instructions are for Microchip's 93LCXX family products.

After an instruction is loaded, the CLK and DI pins are in a DON'T CARE state until the next START bit.

© 1997 Microchip Technology Inc.

The following is required for each instruction set (all input bits are triggered by the positive clock edges):

Start Bit	The first Data-in high signal clocked in after CS is high.
Opcode	Two Bits to identify the instruction
Address	Refer to the Instruction Set table for the number of bits required.
Data	Separate data-in and data-out pins. However, these two pins may be tied together for true 3-wire operation. Please refer to the attached 3-wire Bus READ timing diagram example.

READ, WRITE, and ERASE

The attached 93LC66 timing diagrams illustrate the key concepts and timing parameters for each of these operations. Please refer to the instruction set tables and the AC parameters in the databook for supplemental information.

ERASE ALL (ERAL)

An ERASE ALL (ERAL) operation is identified by a "00" opcode. The ERAL instruction requires the next two bits to be clocked in as "10" in the address block of the instruction set. All bits in the array will be set to a logic "1" state by one command in typically less than 10ms.

WRITE ALL (WRAL)

A WRITE ALL (WRAL) operation is also identified by a "00" opcode. The WRAL requires the next two bits to be clocked in as "01" in the address block of the instruction set. The data-in block will contain the data for a SINGLE BYTE which is to be repeated throughout the entire array. For example, if a 4F5A is loaded in the 16 data-in bits of the instruction set, a 4F5A will be written into every word in the array.

EWEN and EWDS

As stated before, all units will power up in to an ERASE/WRITE DISABLE (EWDS) state to prevent data corruption. All future ERASE/WRITE operations must execute an ERASE/WRITE ENABLE (EWEN) opcode until the next power down is detected or until other EWDS opcodes are executed. Please refer to the instruction set table.

2-WIRE BUS OPERATION PRIMER

As indicated in the 3-wire bus section, many serial EEPROM data sheets are written in a conventional memory data sheet format which emphasizes the features of the part more than the basic operating principles. The operating principles are, unfortunately, either vaguely embedded in the data sheet text or not included. This section is a PRIMER for the data sheet to familiarize the system designer with the basic 2-wire serial EEPROM operation principles.

Basic Principles

The common device nomenclature is 24XXXX and 85XXXX.

Only the SCL and SDA pins are essential for bus operation. The other pins are supplementary:

SCL (Serial clock)

SDA (Serial Data)

WP (Active High WRITE Protection)

A0, V A1, and A2 (Chip or block select)

SDA's open-drain requires a pull-up resistor to V_{DD}.

The data is organized as x8.

Signals are level triggered, not edge triggered. Also, there are filters on the inputs that will filter noise glitches <100ns wide.

An Auto-ERASE (logical "1") cycle is performed during each WRITE cycle.

The I^2C protocol utilizes master/slave bi-directional communication. A device that sends data onto the bus is defined as the transmitter, and a device that is receiving data is the receiver. Both the master and the slave can operate as the transmitter or receiver. The bus must be controlled by a master device (most often a microcontroller), which generates the serial clock (SCL), controls the bus direction, and generates the START and the STOP conditions.

The serial EEPROM is the slave. The serial EEPROM will be the bus transmitter during READ operations and when the serial EEPROM must acknowledge data transmitted by the master.

START and STOP bits control the bus activity. Operations must begin with a START bit and end with a STOP bit.

A START bit is when SDA transitions LOW while SCL is HIGH while observing the START set-up and hold time specifications.

A STOP bit is when SDA transitions HIGH while SCL is HIGH while observing the STOP set-up and hold time specifications.

Data is recognized as valid while SCL is high. The data on SDA must observe data in set-up and hold specifications before and after SCL is pulsed. There is only one bit of data for each SCL pulse.

Control Byte Requirements

After a START bit, each command begins with an 8 bit control byte sent by the master. This control byte has the following three primary functions before the data and/or word address information is loaded for all commands:

Identify the serial EEPROM as the slave addressed on the bus.

Select the specific serial EEPROM or the internal memory block on the bus. There may be up to 8 serial EEPROMs on the bus)

Select the READ or WRITE function for the next command transmitted by the master.

The diagram of a control byte (not including the START bit) is shown below:

1	0	1	0	A2	A1	A0	X
I^2C Slave Address				Chip or Block Select			Read or W rite bit

Control Bits 1-4 are the Slave Address Bits (Must be 1010 for Memory)

Since there is not a chip select pin, the part is selected by a four bit code in the control byte to identify the type of product. The four bit code was established by Philips for the I^2C protocol. A 1010 code identifies the slave device as a Serial EEPROM. The Serial EEPROM will remain in stand-by until the 1010 code is transmitted on the bus. Other non Serial EEPROM slave devices will not respond to the 1010 code on the bus.

Control Bits 5-7 are the 1 of 8 Chip or Block Address Select Bits

The next three control bits are utilized for the chip selection or internal block selection. The standard I^2C protocol was developed to allow up to 16K bits of memory to be selected. This could be accomplished by accessing a combination of devices or blocks within a device, as shown in the table on the following page:

© 1997 Microchip Technology Inc.

Device	K bits Density	Internal Blocks	A0	A1	A2	Bus Access Devices
24LC01B, 24C01,85C72	1	1	H or L	H or L	H or L	Up to 8 devices
24LC02B, 24C02,85C82	2	1	H or L	H or L	H or L	Up to 8 devices
24LC04B, 24C04,85C92	4	2	X	H or L	H or L	Up to 4 devices
24LC08B	8	4	X	X	H or L	Up to 2 devices
24LC16B	16	8	X	X	X	Only 1 device

X= NOT USED. This pin must be tied to VSS or VDD. It is not recommended to FLOAT these pins since there may be test modes accessed to these pins via a high voltage signal.

These three bits for this select must match the hardware conditions (IF ANY ARE USED) of the external A0, A1, and A2 pins or the internal block selects.

With this selection scheme, devices from 2K to 16K are software compatible. For example, four 2K devices or one 8K device could be connected to the bus with the same software.

The A0, A1, and A2 signals are the same for the 1K and 2K products. The A7 bit for the 1K product is a DON'T CARE.

The A0, A1, and A2 pins are not commonly used today in the industry with the advent of the density evolution up to the I^2C protocol limit of 16K bits.

Control Bit 8 Operation Code

If this bit is a "1" then the operation will be a READ

If this bit is a "0" then the operation will be a WRITE

After the control byte acknowledge bit is generated by the serial EEPROM, the master will send the appropriate word address and data information.

Acknowledge Requirements

The serial EEPROM must generate an acknowledge bit after receiving each byte segment in a command. The serial EEPROM will generate the acknowledge bit automatically after the master has transmitted all of the data for the segment.

To acknowledge the master, the serial EEPROM must pull the SDA line LOW during the entire HIGH period of the next clock generated by the master. During the READ operations, the master must acknowledge each data byte or the serial EEPROM will abort the READ operation and return to a stand-by mode waiting for the next START bit.

The attached 24LC16 timing diagrams illustrate the READ and WRITE operations.

MICROCHIP 2-WIRE DEFAULT CONDITIONS

As stated before, data sheets do not provide adequate information on basic operation. This lack of information forces each reader of the databook to make interpretations about the operating conditions. These readers have included other semiconductor circuit designers, which unfortunately leads to subtle compatibility problems. The part is designed to operate to the default of the circuit designer's interpretation. This next section details Microchip's default conditions to help the system engineer minimize "Trial and Error" prototyping and to increase the awareness of these default conditions.

Also, to improve corporate-wide compatibility, Microchip is standardizing their circuits on various product versions. Unless indicated otherwise, all references to default conditions are for the 24LCXX products, not the 24CXXXX products.

Power Up

READ, WRITE, and ERASE operations are valid 5 µS after VDD has ramped to the specified operating range.

PAGE WRITE by Product for Multiple BYTE WRITE Operation

The 24C01 and 24C02 have a 2-byte buffer.

The 24C04 has an 8-byte buffer.

The 24LC01 and 24LC02 have an 8 byte page.

The 24LC04, 24LC08, and 24LC16 have a 16 byte page.

The buffer will load bytes identically as the page loads bytes. The difference in the two modes is that the buffer will execute a WRITE of one byte per WRITE cycle in sequence. The page mode will execute all bytes loaded in one WRITE cycle in parallel.

© 1997 Microchip Technology Inc.

There are pages within blocks. For a 16 byte page product, the most significant 4 bits of the word address point to the page address and the least significant 4 bits point to the byte address within a page. For an 8 byte page product, the most significant 5 bits of the word address point to the page address and the least significant 3 bits point to the byte address within a page.

The number of bytes loaded in to the page is from one byte up to the page size. For example, three bytes can be loaded into the 16 byte page of the 24LC16. If during the loading of the fourth byte a STOP bit is received, the page will WRITE three bytes. The fourth byte will not be written since loading the fourth byte was not complete.

Note: New versions released in March 1993 will default to ABORTING the entire operation if a STOP bit is received in the middle of a byte while loading a page.

If more than 16 bytes are loaded in the page of a 16 byte page product, then the 17th byte will override the data loaded into the original first byte (the page data will wrap around WITHIN a page). Therefore, the system designer must take precautions to not WRITE over a page boundary during a multiple byte WRITE operation.

Bytes not changed in the page will NOT result in data corruption in the array. For example, If two bytes are loaded in to the 24LC16 page with the least significant word address bits of 0000 and then a STOP bit is transmitted. Bytes 1 and 2 in the array will have the data changed to the new page contents. Bytes 3 through 16 WILL NOT change.

The WRITE operation will not be executed until a STOP bit is transmitted.

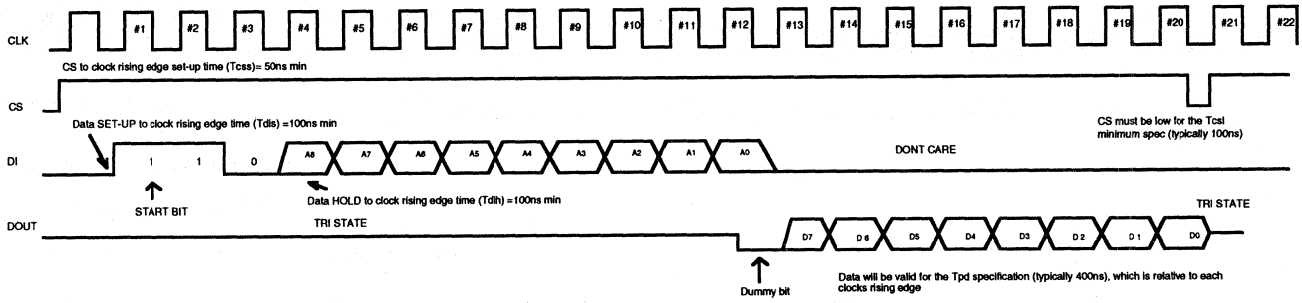
At this point, the serial EEPROM is free from the bus since the actual WRITE function is self-timed. Therefore, the microcontroller interfacing to the serial EEPROM may perform other functions not associated to communication with the serial EEPROM during the self-timed WRITE operations.

Once the part is in the auto-ERASE mode, it will complete the ERASE/WRITE operation unless power is removed. STOP and START bits will be ignored.

READ

Once the Serial EEPROM is in a RANDOM READ operation, it can be placed into the sequential READ operation. If the master issues an acknowledge bit instead of a STOP bit, the Serial EEPROM will READ the next sequential 8 bits. The Serial will wait for the next bit command from the master. The sequential READ will continue as long as the master issues an acknowledge bit on the next clock cycle after the last bit is READ. The READ will continue from block to block and will wrap around if the last bit in the array is addressed. Again, this will continue until the master issues a STOP bit instead of an acknowledge bit.

While reading zeroes the master cannot pull SDA high to generate a STOP bit, since the serial EEPROM SDA pin is outputting a low. To recover from a fault during a READ, repeat 9 clocks with data floating high. Therefore, the acknowledge bit will not occur and the part will reset and return to stand-by.



A START bit during an operation will cease the current operation and begin the next operation.

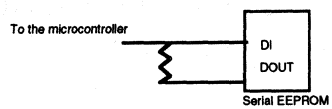
3 WIRE BUS EXAMPLE

MICROCHIP 93LC66 READ CYCLE TIMING DIAGRAM

NOTE: THIS EXAMPLE IS FOR X8 OPERATION OF MICROCHIP'S 93LC66. INSTRUCTION LENGHTS MAY VARY WITH ARRAY SIZE AND DATA WIDTHS

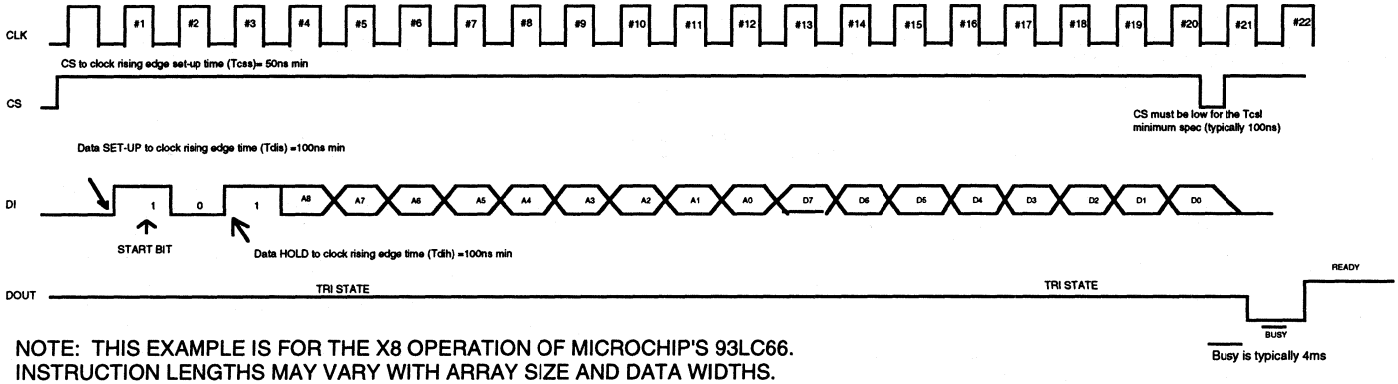
Data must conform to specified set-up and hold times (Tdis and Tdih) relative to the RISING clock edge. Each parameter is typically 100ns.



A Read operation is identified by the "1 0 " op-code following the start bit.

Next, the address location bits are loaded.

Then the address contents are clocked out on the rising clock pulse edge. Data will become valid on the DOUT pin per the specified Tpd time (typically 400ns) relative to the rising edge of the clock on the DOUT pin. Note, the first bit output will be a "dummy bit" with a logical zero state. This event is triggered by the clock rising edge of the last address bit for a duration of one clock pulse.



If the data from the current address is complete and the clock pulses continue, the data from the next address will be READ automatically as long as CS remains high. This is the SEQUENTIAL READ FUNCTION. READ operations will continue while clock pulses continue or until CS is brought low.

It is possible to tie the DOUT pin and the DI pin together to save on I/O requirements from the microcontroller. Caution must be exercised to avoid bus contention for an A0 high condition, because of the dummy bit. It recommended that a resistor between the microcontroller port connected to the DI pin and DOUT pin be added for isolation. This example is shown below:

3 WIRE BUS EXAMPLE

MICROCHIP'S 93LC66 WRITE CYCLE TIMING DIAGRAM

NOTE: THIS EXAMPLE IS FOR THE X8 OPERATION OF MICROCHIP'S 93LC66.
INSTRUCTION LENGTHS MAY VARY WITH ARRAY SIZE AND DATA WIDTHS.

Data must conform to specific set-up and hold times (Tdis and Tdih) relative to the clock edge. Each parameter is typically 100ns.

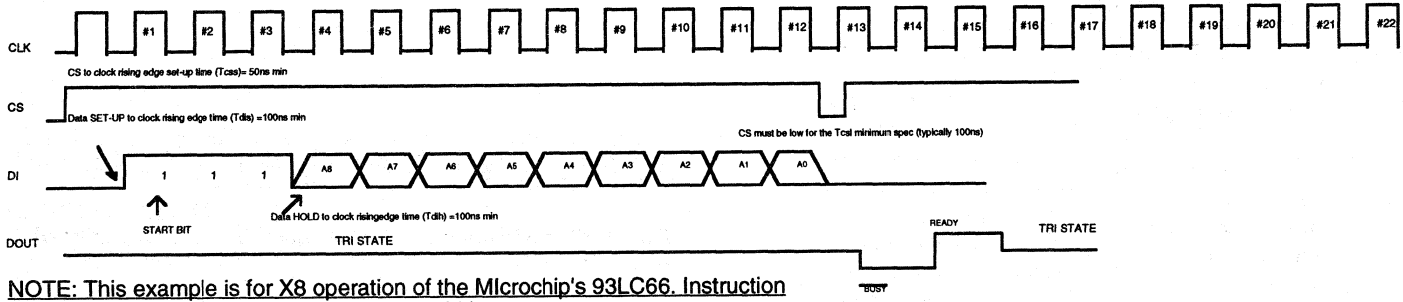
A WRITE operation is identified by a the "0 1 " op code following the start bit

Next, the address location bits are loaded on the DI pin.

Then, the data bits to be written are loaded on the DI pin.

CS must be brought low after the last DI bit is loaded. When CS is brought low for the Tcsl period, a self timed WRITE is executed. If too many bits are loaded during ERASE and WRITE instructions prior to CS being brought low at the end of an instruction set, then the extra bits will be ignored. Only the first bits loaded will be executed.

The DOUT pins only function during a WRITE is to indicate the status of the write with the READY/$\overline{\text{BUSY}}$ function. While DOUT is low, the Serial EEPROM is indicating that programming is not complete (the part is BUSY). When DOUT is high,the Serial EEPROM is indicating that programming is complete and it is READY for another instruction. Note CS must be brought high after completing the Tcsl time is complete to initiate the READY/ BUSY function. Microchip's 93LCXX products can be polled multiple times for the same cycle.



Up through clock pulse 20, data for the instruction is being LOADED. When the CS goes low, the instruction is being EXECUTED. If there are not enough bits loaded during ERASE and WRITE instructions prior to CS being brought low, then the operation WILL NOT BE EXECUTED and the Serial EEPROM will return to stand-by.

3 WIRE BUS EXAMPLE

MICROCHIP 93LC66 ERASE CYCLE TIMING DIAGRAM

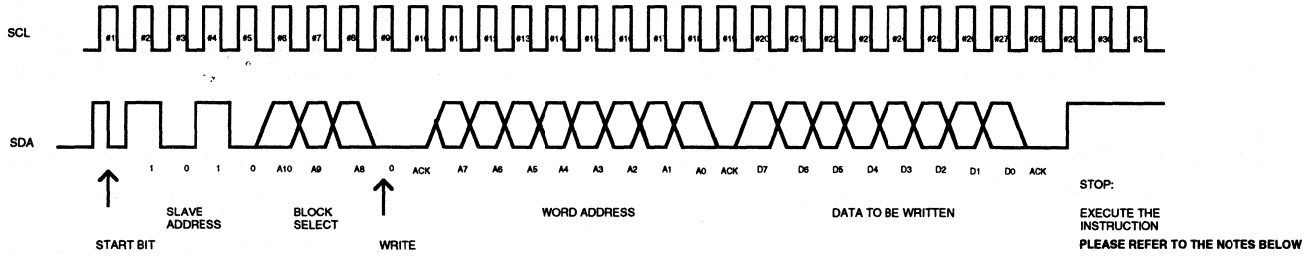
NOTE: This example is for X8 operation of the MIcrochip's 93LC66. Instruction lengths may vary with array size and data widths.

Data must conform to specified set-up and hold times (Tdis and Tdih) relative to the clock edge. Each parameter is typically 100ns.

AN ERASE operation is identified by a "11 " two bit code that follows the start bit

Next, the address location bits are loaded on the DI pin.

THERE ARE NO DATA BITS TO LOAD. THE ADDRESS LOCATION LOADED WILL BE SET TO AN ERASE STATE OF "1".



CS must be brought low after the last DI bit is loaded. When CS is brought low for the Tcsl period, a self timed ERASE is executed. If too many bits are loaded during the ERASE and WRITE instructions prior to CS being brought low at the end of an instruction set, then the extra bits will be ignored. Only the first bits loaded will be executed.

The DOUT pin's only function during a ERASE is to indicate the status of the write with the READY/$\overline{\text{BUSY}}$ function. While DOUT islow, the Serial EEPROM is indicating that programming is not complete (the part is BUSY). When Do is high, the Serial EEPROM is indicating that programming is complete and it is READY for another instruction. Note CS must be brought high after completing the Tcsl time is complete to initiate the READY/$\overline{\text{BUSY}}$ function.

Up through clock pulse 12, the address for the instruction is being LOADED. When CS goes low, the instruction is being EXECUTED.If there are not enough bits loaded during the ERASE and WRITE instructions prior to CS being brought low, then the operation WILL NOT BE EXECUTED and the serial EEPROM will return to stand-by.

Serial EEPROM Endurance

Author: *Steve Drehobl*
Microchip Technology Inc.

INTRODUCTION

The term "endurance" has become a confusing parameter for both users and manufacturers of EEPROM products. This is largely because many semiconductor vendors treat this important application-dependent reliability parameter as a vague specmanship topic. As a result, the system engineer often designs without proper reliability information or under-utilizes the EEPROM as an effective solution.

Endurance (the number of times an EEPROM cell can be erased and rewritten without corrupting data) is a measure of the device's reliability, not its parametric performance. As such, endurance is not achieved by somehow making EEPROM devices more durable or robust to extend the life of the intrinsic erase/write cycle, but rather by reducing their defect-density failure rates. This has a direct impact on the design engineer characterizing EEPROM memory needs for an application and evaluating components from various manufacturers. The system design engineer needs to understand not only the relationship between the application, expected use and failure mechanisms, but also how the manufacturer has arrived at published endurance data for its components.

This tutorial volume is intended to clarify some of the issues in the industry and provide a tool for the system design engineer, the system reliability engineer, and the component engineer to determine EEPROM reliability and understanding how to apply it to actual application requirements. It will examine four main areas:

- CMOS floating gate memory cell operation and characteristics
- Significant process and design interactions and endurance characterization variables
- Common misinterpretations of endurance
- Determining some real world application reliability requirements

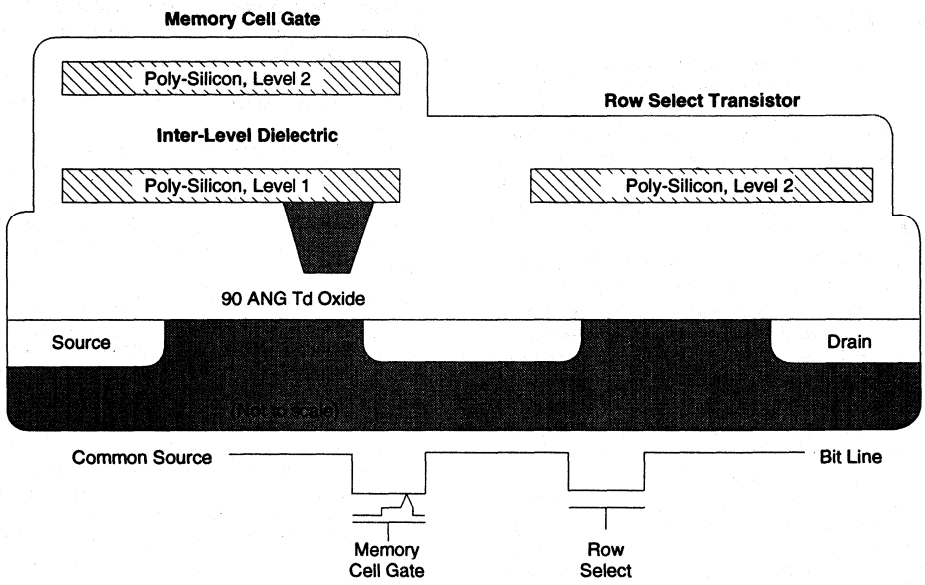
EEPROM MEMORY CELL OPERATION AND CHARACTERISTICS

In discussing endurance characteristics of EEPROMs, it's important to review how these components operate, and why and how they fail. Figure 1 illustrates a CMOS floating gate EEPROM cell, including voltage conditions for READ, ERASE, and WRITE operations. To erase or write, the row select transistor must have the relatively high potential of 20V. This voltage is internally generated on chip by a charge pump, with the only external voltage required being VDD. The only difference between an ERASE and a WRITE is the direction of the applied field potential relative to the polysilicon floating gate.

When 20V is applied to the polysilicon memory cell gate and 0V is applied to the bit line drain (column), electrons tunnel from the substrate through the 90-angstrom Tunnel Dielectric (TD) oxide to the polysilicon floating gate until the polysilicon floating gate is saturated with charge. The cell is now at an ERASE state of "1". When 0V is applied to the polysilicon memory cell gate and 20V is applied to the bit line drain (column), electrons tunnel from the polysilicon floating gate through the TD oxide to the substrate. The cell then is at a WRITE state of "0". This sequence of the transfer of charge onto the floating gate (ERASE) and the electrical removal of that charge from the floating gate (WRITE) is one ERASE/ WRITE cycle, or "E/W cycle."

The field (applied voltage to an oxide thickness) across the tunneling path created by the 20V potential is extremely high in order to transfer the electrons. Over the cell's "application time," as measured by E/W cycles, the EEPROM cell begins to wear out due to the field stress. The EEPROM cell wears out as the number of cycles increase resulting in the voltage margin between the ERASE and WRITE states decreasing until finally there is not enough margin for the EEPROM sense amp to detect a difference in the two states during a READ. Failure is defined as when the sense amp can no longer reliably differentiate logic state changes.

Figure 2 (single cell EEPROM endurance characteristics) illustrates that the intrinsic wear out point for a normal cell with specified dimensions and electrical characteristics is very acceptable, in excess of 2 million E/W cycles. Failures at lower cycles are due mostly to very small defects or imperfections in the oxide or silicon-to-oxide interface.



© 1997 Microchip Technology Inc.

A key point to remember is that most failures occurring at less than 2 million E/W cycles are due to the number of defects per a given area (defect density dependent.) Thus high EEPROM endurance reliability is achieved by reducing the defect density failure rates, not by increasing the number of intrinsic cycles in the cell's operational design.

Error correction circuits are design techniques commonly used by EEPROM manufacturers to increase endurance by reducing the failure rate caused by single bit failures. These circuits are transparent to the user. One typical scheme is using 4 bits of error correction for every 8 "real" bits (one byte). In this scheme, one bit failure in the byte is correctable, while if two bits within the byte fail, the byte is not correctable.

Another error correction scheme is to use one "parity" bit for every "cell." Here both EEPROM cells must fail to result in a bit fail.

FIGURE 2: SINGLE EEPROM CELL ENDURANCE CHARACTERISTICS

PROCESS AND DESIGN VARIABLES AFFECTING ENDURANCE

There are many subtle process and design variables that have a strong impact on endurance. These interacting variables will play very different roles depending on the different process technologies of various semiconductor manufacturers.

The primary interaction is the amount of TIME at the HIGH VOLTAGES that is ultimately applied to the cell. A finite amount of time at finite voltages are required to achieve "optimal" ERASE and WRITE thresholds. If the time is too short and the voltage is too low, the EEPROM will not program to the proper threshold. Also, if the programming ramp time is too fast and the voltage is too high, the EEPROMs endurance will be reduced. Unfortunately, there is most often a trade-off between fast reliable programming performance or high endurance reliability. Some of the significant process and design variables are shown below and their impact on programming performance and endurance performance.

PARAMETER	PROGRAMMING	ENDURANCE
Internal High Voltages	HIGHER = Faster Programming	LOWER = Increased Endurance
Internal High Voltage Ramp Rate	FASTER = Faster Programming	SLOWER = Increased Endurance
Programming Time	LONGER = Improved Voltage Margin on the Cell	SHORTER = Less Oxide Stress for Increased Reliability
TD Oxide Thickness	THICKER = Slower Programming	THINNER = Reduced Endurance
Temperature	LOWER = Faster Programming	LOWER = Increased Endurance

COMMON MISINTERPRETATIONS

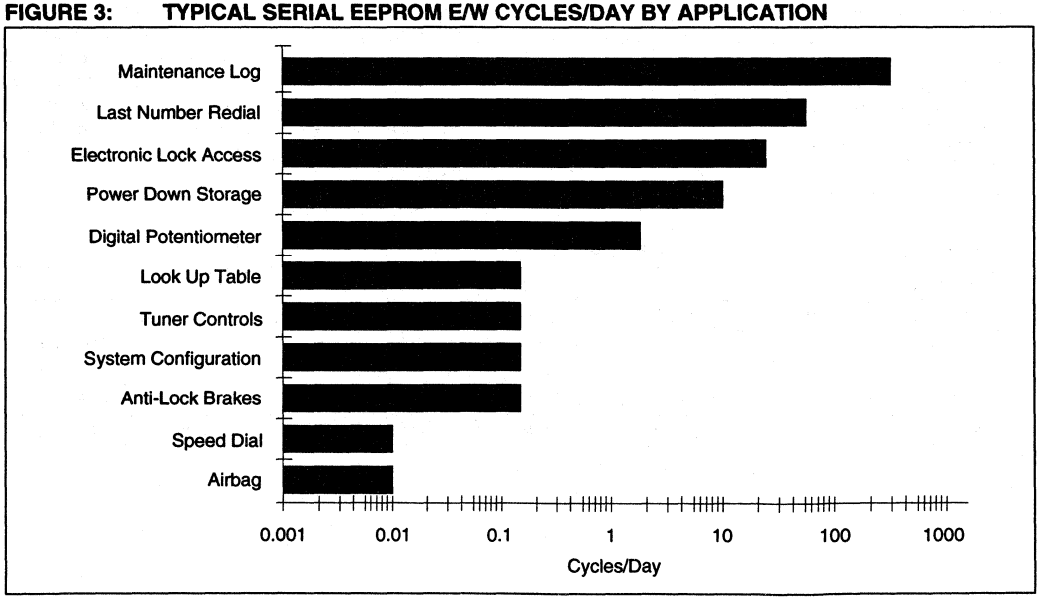
In examining industry EEPROM literature on the topic of endurance, it's easy to misunderstand or misinterpret endurance concepts due to incomplete databook statements. The following are clarifications to some of the common misinterpretations:

Endurance and Read Cycles

READ operations are unlimited since they impose virtually no stress on the cell. Endurance data apply only to E/W cycles.

Erase/Write Ratings

E/W ratings are based on each byte in the application, not on the number of opcodes or control byte commands utilized. For example, if a part is rated to 100K E/W cycles, then each individual byte can be erased and written 100K times. The part is NOT limited to only a total of 100K E/W opcodes or control bytes. This is probably the most common misinterpretation made by system designers. Endurance is thus an interactive application-specific reliability parameter. It is not a typical data sheet specification, such as a parametric AC/DC specification with benchmark standards for measurement.



Cycles/Day

In many cases, a serial EEPROM is used for widely varying functions in an application. These functions have different E/W usage requirements (cycles/day), resulting in different endurance requirements and, usually, different reliability results for each function.

For example, assume a given end-product application will have a 10-year life. For each function within that application, an assumption must be made for the expected E/W cycles per day for a given segment of bytes. If a function has a segment of bytes cycled 1 time per day, then this segment of bytes will have 3,650 cycles in its lifetime (365 days per year for 10 years at 1 cycle per day and 7 days per week operation). Any given segment of bytes would have to cycle 274 times per day everyday to reach 1,000,000 E/W cycles in its 10-year application lifetime. Such a frequency is, of course, very rare in actual applications.

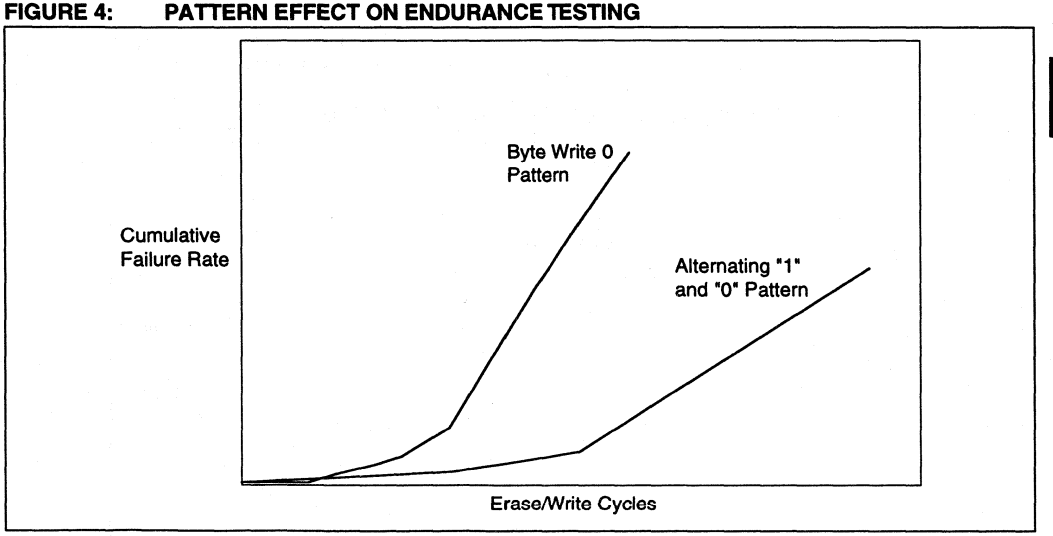
For reference purposes, Figure 3 indicates typical cycles per day for some common applications. Although many manufacturers routinely discuss very high numbers of E/W cycles, the amount of applications actually utilizing 1 million cycles is very small.

FIGURE 3: TYPICAL SERIAL EEPROM E/W CYCLES/DAY BY APPLICATION

© 1997 Microchip Technology Inc.

A further and very important incorrect assumption often made is that ALL bits in an application need the same number of cycles and endurance ratings. In most applications, however, functions that require a high number of E/W cycles per day require only a small number of bits. Last number redial in a telephone, for example, consumes many E/W cycles per day, but utilizes only a few bytes for this function. By contrast, speed dial storage in that same telephone consumes only a fraction of E/W cycles per day, but requires a relatively large segment of bits to accommodate the many speed dial options. In such an application, the same serial EEPROM normally performs both functions at different address locations.

ENDURANCE DATA FROM THE CUSTOMER'S PERSPECTIVE



Unfortunately, an industry standard for an endurance test method has yet to be adopted. Since endurance data is not baselined, the process of evaluating endurance becomes that much more complicated for the system designer and reliability engineer.

It is not uncommon for customers to request endurance data from many semiconductor vendors. All vendors would be expected to comment that they experience a low failure rate through 100K E/W cycles. While this can be a true statement, it can also be a very incomplete statement. It is extremely doubtful that all vendors test their components to the same conditions. Yet the variables within endurance testing are extremely significant. Small differences in text protocol can have enormous differences. Pattern, cycling mode, temperature and array size, for example, are the most significant testing variables.

First, memory cell failure rates are defect density driven up to the intrinsic wear out point. Existing defects in a cell, while not causing failure initially, are stressed during every transfer of electrons through the TD oxide until they eventually cause cell failure. Worst case testing would be to erase and write each bit, which is what a write all "0"s pattern with an auto-erase of "1" routine will perform. Indeed, this write all "0"s test pattern will produce very different results than a checkerboard test pattern of alternating "1"s and "0"s within a byte, since cells are changed more often writing all "0"s than in an alternating "1" and "0" write pattern. The resultant failure rate differences are indicated on the pattern effect graph in Figure 4.

In actual use, however, a system will experience a random pattern much more like the alternating "1"s and "0"s pattern than the more stressful all "0"s pattern. The key point for system designers is to determine how accurate a test routine has been used to determine a particular manufacturer's endurance data, and make the appropriate judgement on that part's expected endurance in the application.

FIGURE 4: PATTERN EFFECT ON ENDURANCE TESTING

7

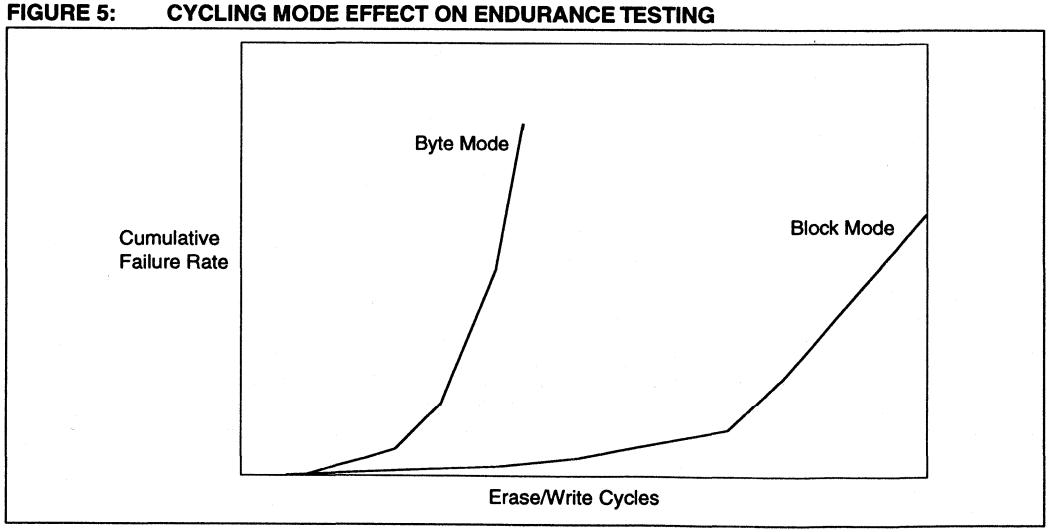
Second, the cycling mode graph in Figure 5 indicates that significantly different results can be achieved in endurance testing using a block cycle mode than using a byte cycle mode. The block mode is commonly used by manufacturers to "speed up" the endurance characterization process. However, endurance results usually will appear much better for the block mode than the byte mode, due to the high voltage variables discussed earlier. The reason is that the voltage ramp rate is significantly SLOWER, the high voltages are slightly lower, thus less stressful for block cycling since the capacitive load of the entire array is on the high voltage charge pump. The capacitive load is much lower with a single row or byte, which thus has a significantly faster ramp rate. Also, there is not a polysilicon to polysilicon stress for adjacent cells since all cells are at the same potential. Most often, these factors combine to yield lower failure rates for block cycling than for byte cycling. Again, the test conditions must match the system conditions.

Finally, increasing temperature also increases stress on the cell. Microchip's endurance characterization data indicates that increasing temperature adds an activation energy (Ea) of 0.12eV on the cell. From a 25°C to 85°C ambient the acceleration factor is approximately 2.1. Therefore, the higher the temperature, the higher the stress. These results will vary significantly with each EEPROM manufacturer.

RECOMMENDED EEPROM ENDURANCE TESTING

Microchip believes that EEPROM components should be endurance tested to reflect system conditions. Therefore, units are cycled to an alternating ONE and ZERO pattern (checkerboard), then to an alternating ZERO and ONE pattern (inverse checkerboard).

Again, since endurance characterization data indicates that a random single bit fail is the primary first order failure mode, endurance is defect density (def/cm2 or segment of bit size) dependent. Therefore an expected failure rate range by density can be established.



DETERMINING THE RELIABILITY CALCULATIONS

There are three primary components for the system design engineers to use in determining the endurance reliability required for a defect density limited application. These three components are:

- Erase/write cycles/day estimated for the function.
- The number of bits in the function (or segment size).
- Case operating temperature of the Serial EEPROM.

Let's look at three typical examples utilizing the above information to predict a cumulative failure rate at different points in a system lifetime. Please note that Industry endurance perceptions have improved from a very high (> 2%) failure rate expectation to a very low actual PPM level failure rate in the past few years.

FIGURE 5: CYCLING MODE EFFECT ON ENDURANCE TESTING

EXAMPLE #1 - AUTOMOBILE ELECTRONIC COMPASS

A 16-byte (128-bits) segment from a 2K array stores data every time the power is turned off in an automobile electronic compass. The design engineers expect the system to power down an average of 5 times/day over a 10-year life in an 85°C case temperature environment. The projected Microchip cumulative failure rate under these conditions at the 10 year point is less than 8 PPM or 0.0008% failures in 10 years. The cumulative PPM failure rate graph is referenced on Figure 6.

EXAMPLE #2 FULL-FEATURED TELEPHONE

An 8-byte (64-bit) segment is used to store the last number redial on a stationary full feature phone operating in a room temperature environment. A 12K bit (12,288-bits) segment is used for storage of speed dial numbers on the same phone. This application has two major functions and therefore it will have two separate failure rate calculations.

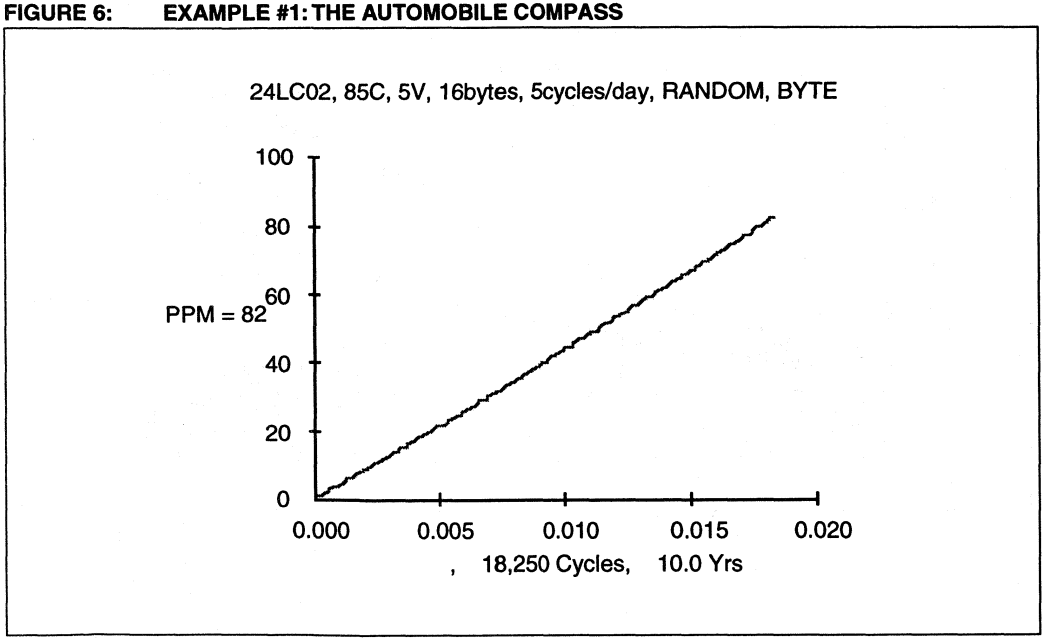
The last number redial function is expected to be utilized an average of 20 times/day over a 10 year life. Each speed dial is expected to be updated an average of 0.1 times/day over a 10 year life.

Figure 7, the cumulative failure rate graph for these two conditions indicates an extremely low failure rate in the projected 10 year lifetime. The failure rate begins beyond 20 years as shown on the attached cumulative PPM failure rate graph.

EXAMPLE #3 - LASER PRINTER

A serial EEPROM could have many functions in a laser printer. A function that would likely require the most cycles/day is the maintenance log storage of the pages printed (estimated to be 100 cycles/day). Three bytes are utilized to store this number. The case temperature environment is estimated to be between 55°C and 85°C

The high number of cycles at an extreme temperature of 85°C indicate a failure rate of less than 1200 PPM through the first 5 years and 2600 PPM through the first 10 years.



This failure rate can be dramatically reduced if the operating temperature is reduced to 55°C. The same 5 and 10 year PPM levels are reduced to 450 PPM and 1600 PPM at 55°C.

These failure rates are illustrated on Figure 8.

SUMMARY

Microchip Technology Inc. has recognized that increasing reliability in serial EEPROMs through increased endurance is not a function of extending the life of the intrinsic erase/write cycle, but depends on reducing defect-density failure rates. Design engineers characterizing EEPROM memory needs for an application and evaluating EEPROM components from various manufacturers need to understand not only the relationship between the application and expected use and failure mechanisms, but also how the manufacturer has arrived at published endurance data for its components.

FIGURE 6: EXAMPLE #1: THE AUTOMOBILE COMPASS

Microchip has developed a program to calculate the cumulative PPM failure rates for specific system conditions, as shown on the previous pages. This program is being transferred onto menu driven DOS floppy disks. These disks will be available in December 1992 to the system designers, reliability engineers, and component engineers to project endurance failure rates for specific system conditions. These disks will be periodically updated to reflect Microchip's most recent endurance data.

1.8 Volt Technology – Benefits

Author: *Tom Tyson*
Microchip Technology Inc.

Portability is and will continue to be one of the key features driving the design and development of new electronic equipment. Existing products such as palmtop computers, cellular phones and data acquisition devices are becoming increasingly smaller and more powerful. Handheld markets will demand that product feature sets be enhanced and that battery operating life be increased. These market requirements, in turn, will put more demands on battery and integrated circuit technology.

In order to optimize battery technology ICs must be able to operate at voltages well below the 5V range that most ICs operate at today. In fact, even integrated circuits operating at 3 volts do not make the most of the available battery technology. Thus the need for devices that operate below 3 volts.

BATTERY TECHNOLOGY OVERVIEW

Primary versus Secondary

In portable or handheld equipment there are two major battery types employed; primary and secondary. Primary cells are disposable, and alkaline and lithium cells are the main primary batteries in use today. Alkaline batteries are extremely common in consumer applications such as electronic games, cordless phones and palmtop computers. While lithium batteries are used as a primary power source in other consumer products such as cameras and as a back-up supply in palmtops.

Secondary cells are rechargeable batteries. Among the many secondary cells available, lead-acid, Ni-cad and Nickel Metal Hydride (NMH) are the most popular.

Voltage Ratings

Batteries for portable applications, whether primary or secondary, have three different voltage ratings; Rated or nominal, Operating, and End-of-life. The rated voltage is usually the open circuit voltage, which in the case of alkaline "AA" cells is 1.5V. Under normal load the "operating voltage" is realized and in all cases is less than the nominal voltage. The final battery voltage rating is the end-of-life voltage, which is defined as the voltage at which 100% of the usable power of the battery is consumed, or as 75% of the operating voltage. In the case of the same alkaline battery the end-of-life voltage is 0.9 volts. Table 1 lists the operating and end-of-life voltages for a single "AA" or equivalent cell of the five battery types mentioned above.

TABLE 1: BATTERY VOLTAGE SUMMARY

Battery Type	Operating Voltage	End-of-Life Voltage
ALKALINE	1.2V	0.9V
LITHIUM	2.7V	2.0V
LEAD-ACID	2.0V	1.75V
NI-CAD	1.2V	0.9V
NMH	1.2V	1.0V

With applications employing primary cells this means that batteries are replaced less often, thus reducing operating cost as well as having a positive effect on the environment due to the use and disposal of fewer batteries. In systems with secondary cells time between recharging increased, thus enhancing the performance of the product.

LOW VOLTAGE APPLICATIONS

As mentioned previously, the need for increased portability will drive the employment of low voltage technology. Portable and handheld applications requiring low voltage (sub 3V) technology will be numerous and will in many cases be high volume. These include a variety of personal communications devices such as cellular and cordless phones, computing devices like palmtops and portable PCs, and a number of data acquisition devices for a variety of medical, industrial and commercial applications.

© 1997 Microchip Technology Inc.

MICROCHIP'S LOW VOLTAGE PRODUCT POSITION

Prior to the announcement of a family of 1.8V Serial EEPROMs in November of 1992, Microchip had already established itself as a leader in low voltage semiconductor products. Microchip's current product portfolio consists of: (1) Serial EEPROMs that operate, both READ and WRITE, down to the following voltage levels: 1.8V, 2.0V, 2.5V and 5V; (2) ROM based microcontrollers that operate down to 2V; and (3) 3V One Time Programmable EPROMs.

The 1.8V Serial EEPROM family operates down to 1.8V without the relaxation of any specification. This includes all AC, DC retention and endurance parameters. Currently the 1.8V family consists of three 3-wire devices, in densities ranging from 1K to 4K bits. Packaging options include 8 pin SOIC and 8 pin PDIP devices. Typical operating currents for these devices, at 1.8V, are in the 70uA range, resulting in power consumption levels of less than 150uW. This compares to 1 to 5 mW for comparable devices operating at 5V. In the near future, the 1.8V family of Serial EEPROMs will be expanded to include all 2-wire devices.

SUMMARY

With the introduction of 1.8V Serial EEPROMs, Microchip has made available silicon technology that optimizes existing battery technology. This over time will result in the development, production, marketing and application of more portable and higher performance handheld and portable computing, telecommunications, and data acquisition products.

Serial EEPROM Solutions vs. Parallel Solutions

Author: *Tom Tyson*
Microchip Technology Inc.

In searching for solutions to their system non-volatile memory requirements, equipment, systems and product designers are faced with a plethora of design related issues and trade-offs. The non-volatile memory options available to them offer a variety of different device features including performance, ease of design, power consumption, operating voltage, programmability, density, and physical size. For the most part these non-volatile memory options can be grouped into two major categories: serial solutions and parallel solutions. This paper discusses the attributes of each, conducts a comparative analysis and in the process identifies the benefits and advantages of Serial EEPROMs.

SERIAL EEPROMS

The main feature that makes a device a "Serial" and sets it apart from parallel devices is, as its name implies, the ability to communicate through a serial interface. This ability has numerous benefits. First, serial communication is accomplished with a minimum number of I/O's. Serial EEPROMs require only two to four lines (depending on the hardware and software protocol) for complete communication; memory addressing, data input and output, and device control. Thus, the hardware interface requirements for Serial EEPROMs are kept at a minimum. The most common Serial EEPROMs in use today are devices that utilize a 2-wire protocol.

Another benefit of serial communication is package size. Ranging from densities of 256 to 16K bits, most Serial EEPROMs today are available in space-saving 8 pin PDIP and 150mil wide SOIC packaging. This obviously is very beneficial for applications where product size and weight is a key design factor. The final benefit is low current consumption. Due to a limited number of I/O ports and therefore on-chip support requirements, operating currents for Serial EEPROMs are usually well below 3 milliamperes.

Other features of Serial EEPROMs include:

1. Byte programmability—The ability to erase and program one byte at a time without affecting the contents of the other memory locations in the array.
2. Clock rates of up to 6MHz—2-wire devices are rated at 100KHz and 400KHz per the standard I^2C protocol, while 3-wire devices can be operated at 6M Hz rates.
3. Low voltage operation—Microchip has introduced a family of devices that operate, both read and write, down to 1.8V. This family complements other 2V and 2.5V low voltage Serial EEPROM families available.

PARALLEL NON-VOLATILE MEMORIES

There are a number of memory devices that fall into this category. The major ones include Parallel EEPROMs, Flash memory products, EPROMs, and SRAMs with battery back-up.

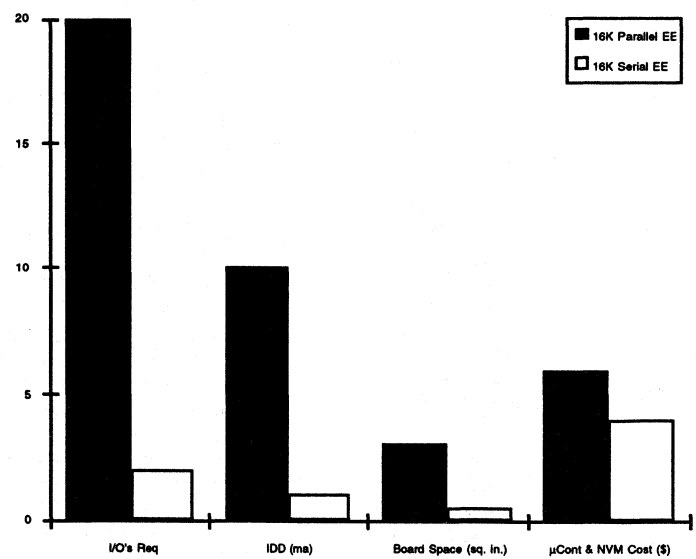
The main common feature of all of these devices is that communication with the device is done through a parallel interface, which results in a high system clock rate. Each type of device has separate data, address and control lines. Thus pin counts are in the 24 to 40 pin range. This also results in relatively large and costly packages and large footprints, even with the most advanced surface mount packages like TSOP. SRAMs with on-board batteries require DIP package heights that are significantly higher than those of standard DIP packages, adding to its package size and cost disadvantage.

Parallel EEPROM and battery backed-up SRAMs are the only two of the four major types of parallel non-volatile memories that have the capability to erase and program one byte at a time. EPROM and Flash devices require the whole array or at least large sectors to be erased prior to reprogramming.

SERIAL VERSUS PARALLEL

Serial EEPROMs have five major advantages over parallel non-volatile memories.

1. Lower Current Consumption - The maximum operating current (at 5 volts operating voltage) of a 16K serial EEPROM device is approximately an order of magnitude less than that of an equivalent density parallel EEPROM. Operating currents for 16K Serials are specified at 3mA, while 16K parallel devices are specified at 30mA and above. This relationship will continue as 64K serial devices are introduced. Since power consumption is directly proportional to current consumption, the lower the current the lower the power consumption.



© 1997 Microchip Technology Inc.

2. Lower Voltage - Serial EEPROMs have been available in single supply low voltage options for some time. As mentioned above, Microchip has low voltage Serial EEPROMs that operate down to 1.8V, as well as other low voltage Serials that function down to 2.0V or 2.5V volts. 3V EPROMs and parallel EEPROMs and single voltage 5V flash devices are just being introduced to the market. (Most flash devices on the market today require 12V for programming in addition to the 5 volts required for normal operation). Low voltage operation also has a positive effect on power consumption. A reduction in the operating voltage from 5 volts to 1.8 volts will result in a power consumption reduction of almost 90% and almost a 65% reduction in power if the operating voltage is reduced from 3V to 1.8V.
3. Programmability - Neither currently available Flash devices nor EPROMs have the ability to program one byte at a time. Erasing is an array or sector function. Therefore, whenever one byte needs to be reprogrammed the entire array or sector must be reprogrammed. This procedure takes a relatively long amount of time to complete, time which may not be available, as is the case when storing critical parameters or data during inadvertent and unexpected system power loss. This procedure also requires software overhead to manage the retrieval and reprogramming operation.
4. Physical Size - Again, when comparing a 16K Serial EEPROM to a 16K parallel device the serial has a significant advantage. The area of the 150mil 8 pin SOIC footprint is less than 50K square mils. This compares to an area of more than 250K square mils for a 24 pin SOIC and almost 800K square mils for a 24 pin 500mil DIP package footprint.
5. I/O Requirements - Serials only require 2 to 4 input or output lines for complete communications. Most parallel devices require at least 22 lines, depending on the memory density. This results in increased microcontroller/microprocessor overhead and additional real estate to accommodate the numerous hardware lines.

The advantages that parallel devices currently have over serial EEPROMs is memory density and AC performance. However, in most microcontroller based applications for which Serial EEPROMs are intended, high density and AC are not the most critical design issues or most needed product features.

The key benefits of Serial EEPROM solutions as a result of the advantages outlined above, are reduced system costs, enhanced feature sets, and improved system performance. System size and weight is reduced and power sourcing requirements are kept at a minimum. The following graph compares some of the main attributes of a 16K Serial EEPROM device to a 16K Parallel device.

16K Serial vs. 16K Parallel Benefits

USES AND APPLICATIONS OF SERIAL EEPROMS

Uses of Serial EEPROMs

The days of simply being a DIP switch replacement for Serial EEPROMs is over. Here is a list of the functions that Serial EEPROMs perform in a variety of computer, industrial, telecommunication, automotive and consumer applications:

1. Memory storage of channel selectors or analog controls (volume, tone, etc.)
2. Power down storage and retrieval of events such as fault detection or error diagnostics
3. Electronic real time event or maintenance log such as page counting
4. Configuration storage
5. Last number redial and speed dial storage
6. User in-circuit look-up tables

Serial EEPROM Applications

Serial EEPROMs have found homes in hundreds of embedded control applications in all major application markets. The following list demonstrates the number and variety of applications for serial EEPROMs.

Market	Applications
CONSUMER	TV tuners, VCRs, CD players, cameras, radios, and remote controls
COMPUTER/OA	Printers, copiers, PCs, palmtop and portable computers, disk drives and organizers
INDUSTRIAL	Bar code readers, point-of-sale terminals, smart cards, lock boxes, garage door openers, test measurement equipment and medical equipment
TELECOMM	Cellular, cordless and full feature phones, faxes, modems, pagers, and satellite receivers
AUTOMOTIVE	Air bags, anti-lock brakes, odometers, radios and keyless entry

Using Serial EEPROMs for critical data and configuration storage has only recently become a reality. The current offerings of 2- and 3-wire serial devices offers the systems designer interesting alternatives to the standard parallel EEPROM devices. The Serial EEPROM is basically a standard EEPROM array without the normal parallel data and address I/O. These functions are handled via serial I/O ports coupled with internal self-timed state machines. Not only will the serial device save power, board space, and cost, but they also offer the advantage of fewer I/O and consequently power in the embedded microcontroller because less I/O are needed to control the same functions. A typical embedded application is shown in Figure 1-A, depicting a controller and several functions used in a personal communications device, such as a mobile or portable phone. The EEPROM stores speed dial and last number redial numbers, credit card numbers, ID numbers, and configuration parameters.

Figure 1-B shows these same functions using a controller with fewer I/O and a Serial EEPROM. There is no loss of functionality but a significant savings in current, board space, I/O pads, and cost. The serial solution employs 8 to 16 less I/O on the microcontroller, freeing up much needed functionality, and possibly allowing for a much smaller device package and downsized circuit boards.

FIGURE A FIGURE B

SUMMARY

Serial EEPROMs are ideal cost effective solutions to all non-volatile memory embedded control applications that require: 1) A small footprint space saving format; 2) The ability and ease of programming one byte at a time; 3) Low current consumption and low operating voltage; 4) Low microcontroller overhead and support; and, 5) The best price performance non-volatile memory solution available.

Their size, ease of programmability, low power consumption, and low cost make Serial EEPROMs extremely suitable for all the fast growing handheld and portable battery powered computer, personal communications, medical and industrial markets.

MICROCHIP

AN558

Using the 24xx65 and 25xx32 with Stand-alone PIC16C54 Code

Authors: Dick Fisher and Bruce Negley
Microchip Technology Inc.

USING THE SMART SERIAL™ SERIES

With the advent of CMOS silicon devices came the battery powered application. The battery powered application required more functionality and thus more power from the microcontroller which required more power from the batteries which cost more. Just as nature has a definite cycle, so it seems, does the portable application. Nowhere has this been more evident than in the areas of personal communication and data acquisition. Never before in the history of the industrial revolution have the type of applications seen emerging today been possible. Every man-made object that requires human or machine interface, has the potential to be controlled by embedded circuits and to be powered by the advanced technology batteries available today. Along with this increased functionality comes the requirement for MORE MEMORY. More in a smaller package, at a better price requiring less power. The majority of the hand-held embedded applications either use what little non-volatile memory that is available on the controllers or they use external devices. Parallel EEPROMs require too many I/O connects, which is the major source of device active current. Serial EEPROMs are typically the answer for these applications and the industry standard I²CTM is the industry leader (>70% worldwide). The I²C standard specifies a maximum 16K bit address space. How does the personal communications system designer, who requires more memory, solve this problem?

THE I²C DILEMMA

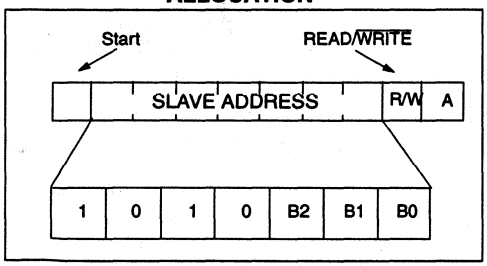
The I²C serial bus has many advantages over other common serial interfaces for serial embedded devices. The I²C bus with level-triggered inputs offers better noise immunity over edge triggered technology. Opcodes are not needed to communicate with storage devices because all interfaces are intuitive and comparable to parallel devices. The I²C protocol assigns a slave address for each unique device or device family. Microchip Technology, and most non-volatile suppliers, use the slave address of 1010 for serial electrical erasable programmable read only memory (Serial EEPROM). The protocol also facilitates up to a maximum of 16K bytes of memory on the bus via the 8-bit address and the three device or memory block select pins A0, A1, and A2. Herein lies the dilemma: with the advent of the more sophisticated personal communication devices such as cellular and full featured phones, personal digital assistants and palm-top computers, 16K bytes is not enough!

Smart Serial Products

The Smart Serial concept grew from the industry need for increased memory requirements in I²C embedded applications, smarter endurance performance, security needs, and the need for more functionality at lower power demands. Currently, Microchip Technology Inc. has the 24XX65 and 24xx32 devices available. All comments in this application note pertain primarily to the 24XX65 but the routines and general architectural comments apply to the 24xx32 as well.

The user should reference the individual data sheets for specific differences.

The Microchip 24xx65 is a serial memory device with 64K bits (8Kx8) capacity and additional patent pending unique features not found any where else. First let's look at the current I²C addressing scheme, the cascadable solution, and finally the Microchip total embedded systems solution.



I²C Addressing

The I²C protocol utilizes a master/slave bi-directional communication bus. The master, usually a microcontroller, which controls the bus, generates the serial clock (SCL) and originates the start and stop conditions. A Serial EEPROM is considered a slave device and is defined as a transmitter during read operations and generates acknowledges when receiving data from the master. The start and stop bits are utilized to control the bus. Normal operation begins with a start bit and ends with a stop bit. Following a start, commands begin with an 8 bit 'control' byte originated by the master. The control byte identifies the slave device to be addressed and defines the operation to take place. A typical control byte for a Serial EEPROM (slave address = 1010) is shown in Figure 1. The control byte, therefore, consists of a start bit, a four-bit slave address, a read/write bit and an acknowledge. The slave address consists of the 1010 identifying address plus the three block or chip select bits.

7

FIGURE 1: CONTROL BYTE ALLOCATION

All memory and peripheral devices on the I^2C bus conform to this sequence for identification and selection. There are 128 assigned slave addresses in the standard protocol. There is a 10-bit extension to the protocol for 1024 additional slave addresses.

THE CASCADABLE SOLUTION

Cascading is an addressing scheme used in the 24164 (2Kx8 SEEPROM) to enable using more than the 16K limit set forth by the standard. In this method the A0, A1, and A2 pins are mapped into bits 2, 3, and 4 of the 8-bit slave address. This approach allows the system designer to use the non-standard 24164 to increase the total memory of a given memory subsystem. This solution is definitely workable, but does not offer the user the system design flexibility needed for the newer and more complex systems. Most system architects would prefer to have a linear address space for program and data memory. Programmers also find the linear solution more attractive. The overhead required for bank switching and chip selection usually requires additional overhead and hardware.

THE ULTIMATE SOLUTION BY MICROCHIP

Microchip Technology has designed an addressing scheme based on the standard I^2C protocol and device addresses but incorporating an additional address byte for enabling the designer to use up to 256K bits per device and add from 1 to 8 devices on the system bus. This flexibility allows for future memory expansion and more advanced features in a smaller, more cost effective, design. This enhanced addressing combined with the many advanced and patent pending features of the 24xx65 make the 24xx65 an exciting and innovative device. It is the first in a family of sophisticated Smart Serial EEPROMs from Microchip Technology Inc.

24xx65 Features

The 24xx65 has an advanced architecture with the following features:

- 15-bit, 2-byte address field (14 bit for the 24xx32)
- 4K-bit High Endurance Block - 1 Million E/W cycles typical (Fixed at the last 4k bit block in the array)
- Programmable write protect security features with up to a 15 blocks of 4K bits
- 8 byte by 8 line input write cache for I^2C Fast Mode, burst mode capability, and use as a capture buffer

24xx65 Addressing

For the first byte or control byte, the 24xx65 adheres to the I^2C protocol (reference Figure 2). This is the first byte received following the start condition from the master device. The control byte consists of a four-bit control code for the 24xx65 (this is assigned as 1010 binary for read and write operations). The next three bits of the control byte are the device select bits (A2, A1, A0). They are used by the master device to select which of the eight devices are to be accessed. These bits are in effect the three most significant bits of the word address. The last bit of the control byte defines the operation to be performed. When set to a "1" a read operation is selected, when set to a "0" a write operation is selected. The least significant 13 bits of the next 2 bytes define the address of the first byte within the 8K block. The most significant byte is transferred first. Following the start condition, the 24xx65 monitors the SDA bus, checking the device type identifier being transmitted, upon receiving a 1010 code and appropriate device select bits, the slave device outputs an acknowledge signal on the SDA line. Depending on the state of the R/W bit, the 24xx65 will select a read or write operation.

The addressing scheme uses the standard first byte slave address format of the I^2C standard with the Microchip Technology-assigned 1010 slave address. The internal bus controller scans the next byte for bit 7 to be asserted indicating that a security operation is to take place. This will be further explained later. The remainder of the byte is composed of the most significant address bits. The next byte is the least significant address byte. See Figure 2 for graphical representation of this sequence. After receiving a valid 2 byte address and a stop bit, the 24xx65 will process this address according to bit "0" of the control byte and either wait for data to be written, if in a write sequence, or present the requested data if in a read sequence.

ADVANCED FEATURES

Programmable security

The 24xx65 has a sophisticated security mechanism by which selected blocks of memory may be write protected by the user. The write sequence includes a bit for enabling the security protection scheme, bit 7 of the first address byte. When this bit is set to a one, the first byte following the address during a write sequence defines the security block. This includes a pointer to the starting 4K block to be protected (the write address), a write/erase flag, and a non-zero four bit code for determining the number of 4K blocks to protect up to the maximum of 15 (60K). The 4K blocks must be contiguous. The high endurance block cannot be protected. In a normal application the security block or blocks would be set after all code or look-up table data has been finalized. THIS OPERATION CAN ONLY BE PERFORMED ONCE. (See Figures 2 and 3.)

Total Endurance™

When defining endurance, we need to look at a few common definitions and possible misconceptions. Endurance with respect to EEPROMs is defined in number of Erase/Write (E/W) Cycles and is the most common rating referred to when discussing or specifying endurance. E/W ratings are based on the environmental and operating conditions of voltage, temperature, cycling mode and rate, for each byte in the application, not on the number of opcodes or control byte commands, and is never based on any read functions whether they be a data read or configuration read. If a part is rated at 100K E/W cycles, then each individual byte can be erased and written 100,000 times. This is probably the most common misinterpretation made by system designers. Endurance is thus an interactive application-specific reliability parameter. It is not a typical data sheet specification, such as a parametric AC/DC specification with benchmark standards for measurement. Microchip has done extensive predictive laboratory studies on Microchip 2- and 3-wire Serial EEPROMs. Applying the predictive data from the 24LC04B, which has similar characteristics, to the 4K high endurance block and assuming the following:

- A five-year life for a personal communication device
- An expected E/W cycles of 10 times per day
- A last number redial function of 11 bytes

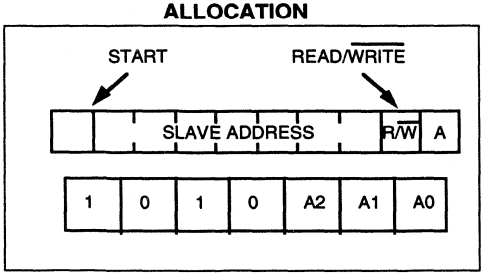
Operational specifications:

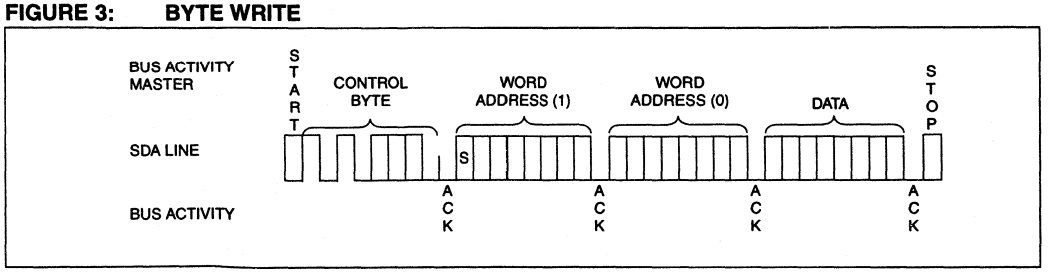
Device	24xx65
Voltage	5
Temperature	25 C
Bytes/Cycle	11
E/W/Day	10
App. Life (Yr.)	5
Cycling Mode	BYTE
Data Pattern	RANDOM

The 4K HE block with 1 M E/W cycles typical, in this application, should yield the following results:

FIT	1.0
PPM	6
Time	5.0
Write cycles	18,250

FIGURE 2: CONTROL BYTE ALLOCATION





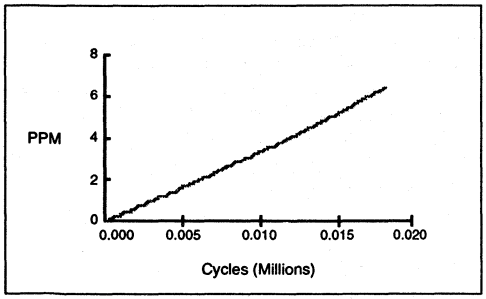


FIGURE 3: BYTE WRITE

FIGURE 4: PPM RATE IN MILLIONS OF CYCLES

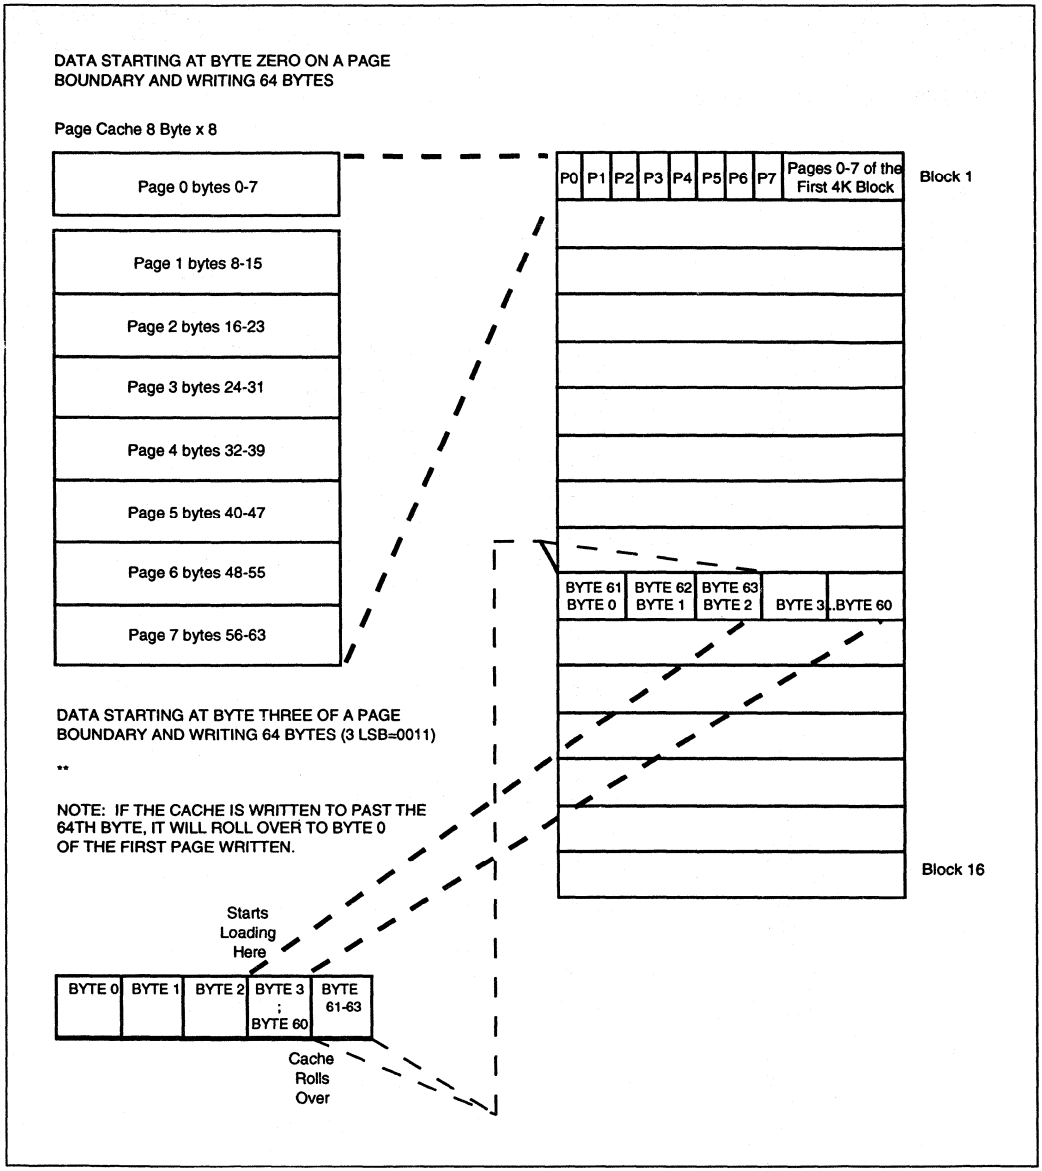
The results shown are predictive in nature and should reflect an accurate representation of the expected results. For a more detailed description of endurance see the related application notes AN537 and AN562 contained in this volume. (Figure 4.)

64 Byte Write Cache

The cache is arranged in 8-byte pages by 8 lines each. This yields a total of 64 bytes. The interface to the 24xx65 supports both the standard 100KHz mode and FAST mode at 400KHz. The input cache can therefore support a burst write option of up to 64 bytes. When using the I^2C protocol, an end of a page is defined by the transmission of a stop bit by the master. This sequence in the 24xx65 could be used to define pages from 8 to 64 bytes in length. The 8 byte by 8 line cache will roll over if a write is attempted past byte 8 of line 8, thus it can be used as a 64 byte capture or snapshot buffer. Each line is over written during a subsequent write to the same line. Faster memory and controller interfaces will become increasingly important in applications incorporating the ACCESS.bus™ interface standard.

Power Management

Increasingly, power management is becoming a predominant requirement for hand-held devices where a limited amount of power is available from the total power budget for a particular function. The 24xx65 has built-in power saving features such that the entire device is put into standby mode upon receiving a stop bit or an abort when in a read sequence, and after the completion of writing the data in the cache lines to the array when in an erase/write sequence. When the device is in standby mode, the only active circuit is the input circuit for the I^2C clock. This yields a standby current that is the current consumption of this lone input and the normal leakage current of the silicon and typically will be less than 2 μA.



The 24xx65 is the first device available in the Smart Serial product line. The features and capabilities initiated with this device will become standard on all future Microchip Technology Inc. serials and some features will be enhanced, such as the security options.

Appendix A of this application note contains the required PIC16C54 assembly routines for setting the security function, addressing the Smart Serial devices and using the most common addressing, read, write, and data polling functions for the I^2C bus.

All of the list programs are complete stand-alone programs.

                     00001          LIST P=16C54
                     00002 ;*****************************************************************
                     00003 ;       64K Byte Write Program (127 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to the 24LC65 Serial E≤ device
                     00007 ;       and perform a byte write operation on 8 consecutive
                     00008 ;       addresses.
                     00009 ;
                     00010 ;       After each byte is written, time must be given to the
                     00011 ;       device for it to complete the write cycle before
                     00012 ;       the next command can be sent.  The easiest solution
                     00013 ;       is to consult the data book for the maximum write
                     00014 ;       cycle time and just wait that long before the next
                     00015 ;       command is sent(10ms for this device).  This program
                     00016 ;       demonstrates that solution.
                     00017 ;
                     00018 ;       Another, more efficient method of determining when the
                     00019 ;       write cycle is complete is called 'data polling.'  This
                     00020 ;       method is demonstrated in the program "64kdpoll."
                     00021 ;
                     00022 ;       As an option, the user may connect a LED to pin 18
                     00023 ;       on the PIC (use about a 1K resistor in series) as an
                     00024 ;       acknowledge fail indicator.  This LED will come on if
                     00025 ;       the serial EE fails to acknowledge correctly.
                     00026 ;
                     00027 ;       Timing is based on using the PIC in 'XT' mode
                     00028 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00029 ;       will be approximately 60 Khz for this setup.
                     00030 ;
                     00031 ;        PIC to Serial EE Connections:
                     00032 ;
                     00033 ;           PIC          Serial EE
                     00034 ;       ------------    ------------
                     00035 ;       Pin 12 (RB6) -->  SCLK

                     00006 ;       Microchip PIC 16C54 to a 24LC65 Serial E≤ device.
                     00007 ;       This program performs a byte write operation on 8
                     00008 ;       consecutive addresses using the data polling method
                     00009 ;       to determine when the write cycle is complete.
                     00010 ;
                     00011 ;       When writing to a serial E≤ device, there are 2
                     00012 ;       ways to handle the internal timed write cycle
                     00013 ;       time of the device.  The simplest method is
                     00014 ;       simply to wait until the maximum cycle time
                     00015 ;       is exceeded before attempting another command.
                     00016 ;       The other, more efficient method is known as "data
                     00017 ;       polling."  Data polling is done by sending a start
                     00018 ;       bit and control byte to the part after the write
                     00019 ;       cycle has been initiated by a stop bit.  If the ack bit
                     00020 ;       is low, then the device is through writing, otherwise
                     00021 ;       the the sequence is repeated.  If no low acknowledge
                     00022 ;       is found within 40 attempts (about 10 milliseconds)
                     00023 ;       then the routine times out and sets the timeout
                     00024 ;       LED (pin 1) high.
                     00025 ;
                     00026 ;       As an option, the user can connect a LED to pin 1
                     00027 ;       on the PIC (use about a 1K resistor in series) as a
                     00028 ;       timeout indicator.  This LED will come on if the
                     00029 ;       data polling is unsuccessful and the device being
                     00030 ;       programmed does not respond.  This can be tested by
                     00031 ;       simply running the program with no part in the socket.
                     00032 ;
                     00033 ;       Timing is based on using the PIC in 'XT' mode
                     00034 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00035 ;       will be approximately 40 Khz for this setup.
                     00036 ;
                     00037 ;        PIC to Serial EE Connections:
                     00038 ;
                     00039 ;           PIC          Serial EE
                     00040 ;       ------------    ------------

                     00001          LIST P=16C54
                     00002 ;*****************************************************************
                     00003 ;       64K Page Write Program (126 bytes)
                     00004 ;
                     00005 ;       The 24LC65 has a page length of 8 bytes.  This page
                     00006 ;       can be used to write up to 8 bytes of data into the
                     00007 ;       part before initiating the write cycle.  Since the
                     00008 ;       write cycle is timed the same for 1 byte or 8 bytes
                     00009 ;       it is more efficient to use the page mode when
                     00010 ;       consecutive addresses are being written to.
                     00011 ;
                     00012 ;       When using page mode, the control byte, upper and lower
                     00013 ;       addresses are sent for the first address only. After the
                     00014 ;       data byte for the first address is sent, the data for the
                     00015 ;       next consecutive address is clocked in.  This is
                     00016 ;       repeated as many times as needed (as long as the page
                     00017 ;       length is not exceeded) and then a stop bit is sent.
                     00018 ;       The device will still acknowledge between every byte of
                     00019 ;       data.  After the stop bit is sent, the part will
                     00020 ;       initiate the self timed write cycle.
                     00021 ;
                     00022 ;       This routine waits approximately 10mS for the write
                     00023 ;       cycle to complete for each page.  A more efficient
                     00024 ;       method of determining when the write cycle is complete
                     00025 ;       is called "data polling."  The data polling method is
                     00026 ;       explained in the program "64kdpoll.asm."  That
                     00027 ;       particular program uses data polling in a byte write
                     00028 ;       mode but it can be used in exactly the same way for
                     00029 ;       a page mode write.
                     00030 ;
                     00031 ;       As an option, the user can connect a LED to pin 18
                     00032 ;       on the PIC (use about a 1K resistor in series) as a
                     00033 ;       acknowledge fail indicator.  This LED will come on
                     00034 ;       if the device being programmed does not send a low
                     00035 ;       acknowledge bit at the proper times.  This can be
                     00036 ;       tested by simply running the program with no part
                     00037 ;       in the socket.
                     00038 ;
                     00039 ;       Timing is based on using the PIC in 'XT' mode
                     00040 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00041 ;       will be approximately 40 Khz for this setup.
                     00042 ;

  VALUE

                     00001          LIST P=16C54
                     00002 ;*****************************************************************
                     00003 ;       64K Sequential Read Program (142 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 24LC65 Serial E≤ device
                     00007 ;       and perform a sequential read operation. This program
                     00008 ;       will read 8 consecutive addresses in the 'sequential
                     00009 ;       read' mode.  This entails setting the address pointer
                     00010 ;       for the first address only and then clocking out as many
                     00011 ;       bytes of data as needed.  The device will automatically
                     00012 ;       increment the address.
                     00013 ;
                     00014 ;       Timing is based on using the PIC in 'XT' mode
                     00015 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00016 ;       will be approximately 60 Khz for this setup.
                     00017 ;
                     00018 ;       As an option, the user may connect a LED to pin 18
                     00019 ;       on the PIC (use about a 1K resistor in series) as an
                     00020 ;       acknowledge fail indicator.  This LED will come on if
                     00021 ;       the serial EE fails to acknowledge correctly.
                     00022 ;
                     00023 ;        PIC to Serial EE Connections:
                     00024 ;
                     00025 ;           PIC          Serial EE

```

7

```
                    00253 ;       This routine reads 8 consecutive addresses of the
                    00254 ;       serial EE device starting at address 00 in the
                    00255 ;       sequential read mode. Reading in this mode is more
                    00256 ;       efficient than the random read mode as the control byte
                    00257 ;       and address have to be sent only once at the beginning
                    00258 ;       of the sequence.  As many consecutive addresses as
                    00259 ;       needed can then be read from the part until a stop bit is
                    00260 ;       sent.  In the read mode, the PIC must send the acknowledge
                    00261 ;       bit after every 8 data bits from the device.  When the
                    00262 ;       last byte needed has been read, then the controller will
                    00263 ;       send a high acknowledge bit and then a stop bit to halt
                    00264 ;       transmission from the device.

                     00001          LIST P=16C54
                     00002 ;*****************************************************************
                     00003 ;       Program to set the high endurance block on the 64K
                     00004 ;       device (24LC65).      (122 bytes)
                     00005 ;
                     00006 ;       The 24LC65 is a 64K device, 4K of which is error
                     00007 ;       corrected to increase the endurance of that portion
                     00008 ;       of the array.  The location of this high endurance
                     00009 ;       'block' can be set by the user.  When the device
                     00010 ;       comes from the factory, the high endurance block
                     00011 ;       will be set as the uppermost block in the array.
                     00012 ;
                     00013 ;       This program sets the high endurance block as the
                     00014 ;       first block in the array (address range 00h to 1FFh).
                     00015 ;
                     00016 ;       The high endurance block is set by sending the following
                     00017 ;       sequence to the device:
                     00018 ;
                     00019 ;       SB 10100000 1XXAAAAX XXXXXXXX 00XX0000 STB
                     00020 ;
                     00021 ;       Where SB=start bit
                     00022 ;              1=data high
                     00023 ;              0=data low
                     00024 ;              X=don't care
                     00025 ;           AAAA=4 bit high endurance block address
                     00026 ;            STB=stop bit
                     00027 ;
                     00028 ;       As an option, the user may connect a LED to pin 18
                     00029 ;       on the PIC (use about a 1K resistor in series) as an
                     00030 ;       acknowledge fail indicator.  This LED will come on if
                     00031 ;       the serial EE fails to acknowledge correctly.
                     00032 ;
                     00033 ;       Timing is based on using the PIC in 'XT' mode
                     00034 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00035 ;       will be approximately 60 Khz for this setup.
                     00036 ;
                     00037 ;        PIC to Serial EE Connections:
                     00038 ;

Optimizing Serial Bus Operations with Proper Write Cycle Times

Author: *Lenny French*
Microchip Technology Inc.

SERIAL EEPROM WRITE TIME REQUIREMENTS

Elements of the Write Cycle Time

The total write operation time for a Serial EEPROM is determined by three main elements:

- Number of bytes to load for each write operation
- Bus clock speed at which the write operation is loaded
- Fixed internal write cycle timer required for the programming operation

The load component of the write command consists of the control byte, address, and the data of up to 16 bytes. The time required to load the operation depends on the number of bytes to load at one time and the bus clock speed. After this load is complete, the part commences the internally controlled write cycle and the bus and system are free to perform other tasks. The internal write cycle timer is a fixed time delay which is required to program the EEPROM memory cells. Table 1 gives examples of total write time for 1 and 16 bytes for various parts at fast and normal clock speeds.

- **Load time (time at bus free)** is the time the part is being loaded with the instruction, address, and data. The bus is free after this time interval, and the part commences the internally controlled write cycle sequence.
- **Write timer (worse case)** indicates the time the part is in the internally controlled write cycle allowing for the maximum specified datasheet requirements.
- **Write timer (typical)** indicates the time the part is in the internally controlled write cycle assuming nominal conditions and utilizing write cycle polling.
- **Total write** time is the combined load time and typical internal write cycle time.

MINIMIZING SERIAL BUS COMMUNICATION TIME IN A SYSTEM

Utilizing the Page Write Option

The original Microchip Serial EEPROM products, though utilizing a page buffer, only write bytes sequentially. This means the time required to write 8 bytes is 8 ms, worse case. The new 24LCXX products incorporate a page mode that allows simultaneous writes of up to 16 bytes. This allows the programming of up to 16 bytes in one write cycle (10 ms) compared to 16 write cycles (16 ms) for the original 24CXX products. Microchip uses an 8 byte page in the 24LC01 and 24LC02, and a 16 byte page in the 24LC04 and higher densities. What this means to a system designer is a write of 8 bytes in a 24LC01 or 24LC02 would take 10 ms, worse

7

TABLE 1: WRITE OPERATION TIME COMPARISON

Product	Page Width	# Bytes to load	Speed (KHz)	Load time (ms) time at bus free	Write timer (ms) Worse case	Write timer (ms) Typical (25C)	Typical total write time (ms)
24C01A	2	1	100	0.28	1	0.4	0.68
		8 (4 x 2)	100	1.12	1	0.4	4.32
24LC01	8	1	100	0.28	10	3	3.28
		8	100	0.91	10	3	3.91
		1	400	0.07	10	3	3.07
		8	400	0.23	10	3	3.23
24C04A	8	1	100	0.28	1	0.4	0.68
		16 (2 x 8)	100	1.82	1	0.4	8.22
24LC04	16	1	100	0.28	10	3	3.28
		16	100	1.63	10	3	4.63
		1	400	0.07	10	3	3.07
		16	400	0.41	10	3	3.41

© 1997 Microchip Technology Inc.

case, versus 8 ms, worse case, in either a 24C01A or 24C02A. Loading the entire memory of an original 24C04A takes 512 ms, but the same operation on a new 24LC04 is reduced to only 320 ms, assuming worse case. As Table 1 shows, the difference is even greater using typical numbers.

The 93LCXX products do not utilize a page mode. However, in 16 bit mode, all 16 bits are written simultaneously. The original 93CXX products write the 16 bits in 2 write cycles, so the write cycle time increase of the new products is only 5 X (3.5 X typical).

Utilizing Write Cycle Polling

One powerful method of increasing programming efficiency is by periodically polling the part to determine if the write cycle has completed. To poll the 24LCXX series products, a control byte is sent and the acknowledge bit from the part is read. If the part acknowledges (pulls SDA low), it is ready to accept a new command. The part will not acknowledge while in the internally timed write cycle.

To poll the 93LCXX series products, the chip select is pulled high after the write cycle commences, and the data out line is read for the ready/busy status. If the part is still busy, it will pull the data line low. When the internally timed write cycle is complete, the part will pull the data line high, indicating it is ready for a new command.

Serial EEPROM System Optimization

Serial EEPROMs are used in systems for two purposes: storing data and reading back data. Read operations are at full clock speed, so the only methods for optimization are to run the clock at maximum frequency and to utilize sequential read whenever possible. Sequential read allows a continuous output data stream on one command.

The write operation, with its internal write timer component, needs special consideration when designing the control software. Efficient operation can be accomplished using both the page mode and write cycle polling. The following example shows a typical fetch-store operation in a system and how optimization can be incorporated. In the example system, the microcontroller must fetch bytes of data from a sensor and send the bytes to a EEPROM for storage. Two cases are shown in Figure 2: case 1 uses a 24C01A with no optimization; case 2 uses a 24LC01B with the available page mode and write cycle polling.

By utilizing the available page write mode and by polling for the write cycle completion, nearly four times as many bytes can be initially loaded to the serial EEPROM in the same time interval. Continuous operation for the optimized case 2 takes only 0.49 ms per byte compared to 1.28 ms per byte for the non-optimized case 1.

Using the 93LC56 and 93LC66

Author: *Bruce Negley*
Microchip Technology Inc.

INTRODUCTION

The Microchip Technology Inc. 93LC56/66 are low-power 3-wire non-volatile memories and are suitable for many embedded system code and data storage applications. These devices are easily interfaced to most microcontrollers in today's market place, but Microchip's 8-bit RISC series PIC16CXXX offers the best code density of any microcontroller on the market today. Using the PIC16C54, the assembly programs contained in this application note have been fully tested and provide the correct timing and 3-wire sequences to fully operate the 93LC56/66 in a PIC16CXXX-based embedded application. The PIC16C54 was clocked at a 10MHz frequency. This application note is intended to provide the engineer with readily available stand-alone code modules to accomplish all of the necessary functions to utilize these devices in a low power application using the efficient PIC16C54 microcontroller.

The 93 series of devices have essentially four I/O pins:

CS	Chip Select
CLK	Clock
DI	Data In
DO	Data Out

This series of devices use a series of commands to accomplish the normal memory functions. These are READ, WRITE, EWEN, ERASE, ERAL, WRAL, EWDS. For a more detailed discussion of the function of these devices reference the appropriate data sheet and AN536, also published by Microchip Technology.

The following programs are included in this application note and are fully functional stand-alone modules. They are intended for use by those who are not already familiar with interfacing a PIC16CXXX microcontroller to a 93 series device. For those with more experience, please refer to application note AN530.

                     00001          LIST P=16C54
                     00002 ;*****************************************************************
                     00003 ;       3-Wire Byte Read Program (80 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 93LC56 or 93LC66 Serial EE
                     00007 ;       device.  This program will read 8 consecutive addresses
                     00008 ;       in the 'random read' mode.  This means that the opcode
                     00009 ;       and address for each byte will be sent to the device.
                     00010 ;       This program will repeat forever.
                     00011 ;
                     00012 ;       Another, more efficient method of reading consecutive
                     00013 ;       addresses is called the 'sequential read' mode.  This
                     00014 ;       involves sending the opcode and address for the first
                     00015 ;       byte to read, then continuing to provide clocks for the
                     00016 ;       next addresses. The device will automatically increment
                     00017 ;       the address.  An example of the seqential read mode is
                     00018 ;       provided in the '3wseqr.asm' file.
                     00019 ;
                     00020 ;       This program communicates to the serial EE in the
                     00021 ;       x16 mode, and ASSUMES THE USER HAS SET THE ORG PIN
                     00022 ;       ON THE DEVICE TO Vcc.
                     00023 ;
                     00024 ;       Timing is based on using the PIC in 'XT' mode
                     00025 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00026 ;       will be approximately 50 Khz for this setup.
                     00027 ;
                     00028 ;        PIC to Serial EE Connections:
                     00029 ;
                     00030 ;          PIC            Serial EE
                     00031 ;       ------------     ------------
                     00032 ;       Pin 10 (RB4) --> Chip Select
                     00033 ;       Pin 11 (RB5) --> Clock
                     00034 ;       Pin 12 (RB6) --> Data In
                     00035 ;       Pin 13 (RB7) --> Data Out

  VALUE

                     00001          LIST P=16C54
                     00002 ;*****************************************************************
                     00003 ;       3-Wire Byte Write Program (106 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 93LC56 or 93LC66 Serial EE
                     00007 ;       device. This program will execute the erase/write enable
                     00008 ;       command, write to 8 consecutive addresses, and then
                     00009 ;       execute the erase/write disable command.  This
                     00010 ;       sequence will repeat forever.
                     00011 ;
                     00012 ;       After each byte is written, time must be given to the
                     00013 ;       device for it to complete the write cycle before
                     00014 ;       the next command can be sent.  The easiest solution
                     00015 ;       is to consult the data book for the maximum write
                     00016 ;       cycle time and just wait that long before the next
                     00017 ;       command is sent.  This program demonstrates that
                     00018 ;       solution.
                     00019 ;
                     00020 ;       Another, more efficient method of determining when the
                     00021 ;       write cycle is complete is called 'data polling.'  This
                     00022 ;       method is demonstrated in the program "3wdpoll."
                     00023 ;
                     00024 ;       This program communicates to the serial EE in the
                     00025 ;       x16 mode, and ASSUMES THE USER HAS SET THE ORG PIN
                     00026 ;       ON THE DEVICE TO Vcc.
                     00027 ;
                     00028 ;       Timing is based on using the PIC in 'XT' mode
                     00029 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00030 ;       will be approximately 40 Khz for this setup.
                     00031 ;
                     00032 ;        PIC to Serial EE Connections:
                     00033 ;
                     00034 ;          PIC            Serial EE
                     00035 ;       ------------     ------------
                     00036 ;       Pin 10 (RB4) --> Chip Select

                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 93LC56 or 93LC66 Serial EE
                     00007 ;       device. This program will execute the erase/write enable
                     00008 ;       command, write to 8 consecutive addresses, and then
                     00009 ;       use the 'data polling' method to determine when the
                     00010 ;       write cycle is complete.  The program then executes
                     00011 ;       the erase/write disable command.  This sequence will
                     00012 ;       repeat forever.
                     00013 ;
                     00014 ;       When writing to a 3-wire serial EE device, the
                     00015 ;       internally timed write cycle will begin after
                     00016 ;       the opcode, address and data are sent to the
                     00017 ;       device.  There are two ways to make sure that the
                     00018 ;       cycle is complete before you send it another command.
                     00019 ;       The simplest method is to simply wait for the maximum
                     00020 ;       write cycle time, which can be obtained from the data book.
                     00021 ;       A more efficient method is "Data polling."  This is
                     00022 ;       done by toggling the chip select line low and then
                     00023 ;       back high after the opcode, address and data are sent.
                     00024 ;       The chip select line must be low for at least 250ns
                     00025 ;       before bringing it high again.  The device will pull
                     00026 ;       the data out line low at that point, and set it high
                     00027 ;       when the write cycle is complete.  The user can then check
                     00028 ;       or "poll" the dataout line until it goes high before
                     00029 ;       sending the next command.
                     00030 ;
                     00031 ;       As an option, the user can connect a LED to pin 18
                     00032 ;       on the PIC (use about a 1K resistor in series) as a
                     00033 ;       timeout indicator.  This LED will come on if the
                     00034 ;       data polling is unsuccessful and the device being
                     00035 ;       programmed does not respond.  This can be tested by
                     00036 ;       simply running the program with no part in the socket.
                     00037 ;
                     00038 ;       This program communicates to the serial EE in the
                     00039 ;       x16 mode, and ASSUMES THE USER HAS SET THE ORG PIN
                     00040 ;       ON THE DEVICE TO Vcc.
                     00041 ;
                     00042 ;       Timing is based on using the PIC in 'XT' mode
                     00043 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00044 ;       will be approximately 50 Khz for this setup.
                     00045 ;
                     00046 ;        PIC to Serial EE Connections:
                     00047 ;
                     00048 ;           PIC             Serial EE
                     00049 ;       ------------     ------------
                     00050 ;       Pin 10 (RB4) --> Chip Select
                     00051 ;       Pin 11 (RB5) --> Clock
                     00052 ;       Pin 12 (RB6) --> Data In

                     00001          LIST P=16C54
                     00002 ;*****************************************************************
                     00003 ;       3-Wire Sequential Read Program (93 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 93LC56 or 93LC66 Serial EE
                     00007 ;       device.  This program will read 8 consecutive addresses
                     00008 ;       in the 'sequential read' mode.  This means that the opcode
                     00009 ;       and address are sent for the first address only.  After
                     00010 ;       the first address is read, the Chip Select line is left
                     00011 ;       high and clocks for the remaining 7 bytes are sent to the
                     00012 ;       device. The device will automatically increment the address
                     00013 ;       pointer in this mode, allowing the user to read as many
                     00014 ;       consecutive addresses as needed. This program will repeat
                     00015 ;       forever.
                     00016 ;;
                     00017 ;       This program communicates to the serial EE in the
                     00018 ;       x16 mode, and ASSUMES THE USER HAS SET THE ORG PIN
                     00019 ;       ON THE DEVICE TO Vcc.
                     00020 ;
                     00021 ;       Timing is based on using the PIC in 'XT' mode
                     00022 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00023 ;       will be approximately 50 Khz for this setup.
                     00024 ;
                     00025 ;        PIC to Serial EE Connections:

MICROCHIP

AN562

Using the Microchip Endurance Predictive Software

Authors: *Peter Sorrells*
Richard J. Fisher
David Wilkie
Microchip Technology Inc.

INTRODUCTION

Endurance, as it applies to nonvolatile EEPROM memory, refers to the number of times an individual memory cell can be erased and written. In this discussion, the term "ENDURANCE" will be used to describe the collective endurance of all memory cells in the EEPROM device (for a more detailed review of what EEPROM endurance is, refer to Microchip Technology Incorporated application notes AN536 in Serial EEPROM Tutorial Series Volume I, and AN537 in this tutorial series). Recent advances in process technology have made it possible to increase these limits and for Microchip to offer new concepts - Total Endurance™ and a split architectural design for variable endurance. These concepts lead to more reliable products with more bits per dice, such as the 24C32 and 24C65. It should be noted that this predictive model applies only to Microchip nonvolatile devices.

TOTAL ENDURANCE

When defining endurance, we need to look at a few common definitions and possible misconceptions. Endurance with respect to EEPROMs is defined in number of Erase/Write (E/W) Cycles and is the most common rating referred to when discussing or specifying endurance. E/W ratings are based on the environmental and operating conditions of voltage, temperature, cycling mode and rate (for each byte in the application not on the number of opcodes or control byte commands) and is never based on any read functions whether they be a data read or configuration read. If a part is rated at 100K E/W cycles, then each individual byte can be erased and written 100,000 times. This is probably the most common misinterpretation made by system designers. Endurance is thus an E/W application-specific reliability parameter. It is not a typical data sheet specification, such as a parametric AC/DC specification with benchmark standards for measurement. Microchip has done extensive predictive laboratory studies on its 2- and 3-wire Serial EEPROMs. These studies led to the concept of using the computer to predict the theoretical wear-out of the memory cell and ultimately to project the point in time of a product's life cycle when the first nonvolatile memory bit or periphery failure should occur. After many years of data collecting, predicting, and verifying the results, Microchip feels confident in publishing and offering for the general technical community this predictive model in the form of Windows®-based, IBM® PC-compatible software. Microchip has a patent pending on this predictive mathematical model.

TOTAL ENDURANCE PREDICTIVE SOFTWARE DESCRIPTION

The predictive software described here was originally developed as a tool for determining endurance levels of Microchip nonvolatile devices. Upon seeing the potential of the software as a design aid, it was decided to make a version that could be purchased by the engineering community. The benefit gained from this software is the ability to predict endurance capability of Microchip's EEPROM devices under various operating conditions. Prior to this tool becoming available, the only way to assemble this type of data would be to do extensive life testing in the target system.

The program uses an iterative statistical model developed by Microchip's physicists. The model was first used in a DOS-based text program as a proof of concept and for developing the database needed for such a tool (included on the program disk as enddos.exe). This model was then imported to a Windows-based software package with all the normal cut, paste, print, and viewing properties. The model actually operates as a mathematical function which is called from within the Windows Visual Basic shell and is passed all of the pertinent user application specific information. The model then, after calculating the essential data points, returns this information to the main program to be formatted and displayed both in a text and graph format.

7

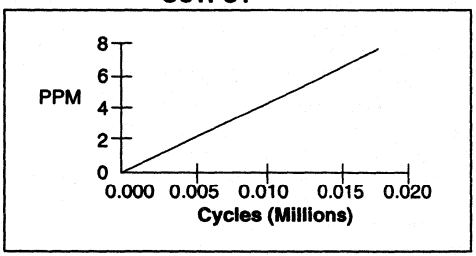
Example Application

Applying the predictive data to the high endurance (HE) block of the 24C65, using the 24LC04 which has similar characteristics, and assuming the following:

- a five-year life
- an expected E/W cycles of 10 times per day
- a function of 11 bytes



Operational specifications:

Device Data:	Input Parameter
Device	24C65 (24LC04B)
Voltage	5
Temperature	25°C
Bytes/Cycle	11
E/W/Day	10
App. Life (Yr.)	5
Cycling Mode	BYTE
Data Pattern	RANDOM

The 4K High Endurance block with 1 Million E/W cycles typical, in this application, should yield the following results:

FIT	1.0 PPM	8
Time	5.0 Write cycles	18,250

FIGURE 1: EXAMPLE OF GRAPHICAL OUTPUT

The results shown are predictive in nature and should reflect an accurate representation of the expected results. All operation parameters, along with the process technology, affect the effective endurance of a nonvolatile device. The voltage, temperature, cycles per, bytes per cycle, and even the number of times written per day (time between write cycles) all have an effect on the oxide breakdown or periphery failure rate of a particular nonvolatile process.

Endurance is not a well-defined concept within the semiconductor industry. The number of erase/write cycles which a particular EEPROM can endure is dependent not only upon the design of the device but also upon the application environment in which it is used. Therefore, blanket claims such as '1 million erase/write cycles typical' can only be validated based upon the specific parameters of each application. Yet until now, there has been no tool available for predicting the endurance of a particular EEPROM device within a set of application parameters. The trade-off analysis, previously required, can be painfully time-consuming and only marginally accurate without specific knowledge of the behavior of the device under different conditions of use.

The Microchip Total Endurance Software allows the designer to trade off voltage, temperature, write cycles, number of bytes written, number of writes per day, PPM and FIT rates, and years of use in order to optimize the system and accurately predict product lifetime and reliability.

The following is an example using the Endurance Software to aid in the design of an electronic phone book/ auto-dialer.

The auto-dialer may have new numbers added or changed several times per day; but how can the manufacturer specify the life of the unit, and at what rate of update of the phone numbers? First, the designer must make some assumptions. If we assume that the average user will change or add 50 phone numbers per day, and the manufacturer is willing to live with a 0.1% failure rate (1,000 PPM) after 10 years of use, then we have almost enough information to verify whether we are in the ball park given the physics of the EEPROM device which will store the numbers. We also need to know the operating voltage and temperature of the application; we will say that a 3.3V lithium button battery is powering the unit and the temperature range is limited to that for which the LCD display will function: 0°C to 70°C. End-of-life voltage for the battery is approximately 2.0V; assuming that the ASIC or microcontroller in the application will operate down to 2.5V, the EEPROM also has a 2.5V requirement. The designer would like to be able to store 100 phone numbers of 16 bytes each, which results in a 1.6K byte requirement for the Serial EEPROM. Because 1.6K bytes is equal to 12.8K bits, a 16K bit 2-wire Serial EEPROM will more than suffice. Specifically, Microchip's 24LC16B will operate down to 2.5V and even includes a write-protect feature which can be used to block inadvertent writes in a noisy environment.

Here is a summary of the application:

Device Data:	Input Parameters
Device	24LC16B
Voltage	2.5V - 3.3V
Temperature	0°C to 70°C (55°C typical)
Cycles per day	50
Bytes per cycle	16
Application life	10 years

© 1997 Microchip Technology Inc.

Once these values are entered into the Total Endurance program, it outputs the following:

Device Data:	Input Parameters
Device	24LC16B
Voltage	3.3
Temperature	55°C
Bytes/Cycle	16
E/W	50
App. Life (Yrs)	10
Cycling Mode	BYTE
Pulse Width (Ms)	N/A
Data Pattern	RANDOM

Device Data:	Output Parameters
FIT	19.1
PPM	1,670
Time	10.0
Write cycles	82,500

Both of the lists above were copied directly from the Total Endurance program output to the Microsoft Windows® clipboard and pasted into this document (the Total Endurance program has a handy menu click to make this easy).

Unfortunately for our designer, the desired 0.1% failure rate has almost doubled to 0.17% (1,670 PPM). But fortunately for the designer, the Total Endurance program makes trade-off analysis very simple and fast. At this point there are at least three options: (1) live with almost 2,000 PPM, or (2) look at the endurance plot and check whether there is a reasonable number of E/W cycles which will provide a 1,000 PPM failure rate, or (3) specify a PPM rate to the Total Endurance program and let it crank out the number of cycles it will take.

Below is the endurance plot, again pasted directly from the Total Endurance program:

You can see that by reducing the number of cycles from the 182,500 which resulted from our first trial to about 100,000, we can achieve a PPM rate of about 1,000 (0.1%). But how does 100,000 cycles translate into application life or cycles per day?

By switching the Total Endurance program mode to a PPM request mode instead of application life mode, we can query the program for this information. Let's ask it for the application life of the product given a 1,000 PPM failure rate. Here are the results:

Device Data:	Input Parameters
Device	24LC16B
Voltage	3.3
Temperature	55°C
Bytes/Cycle	16
E/W	50
PPM Level (Yrs)	1,000
Cycling Mode	BYTE
Pulse Width (Ms)	N/A
Data Pattern	RANDOM

Device Data:	Output Parameters
PPM	1,000
Time	6.52
Write cycles	119,000

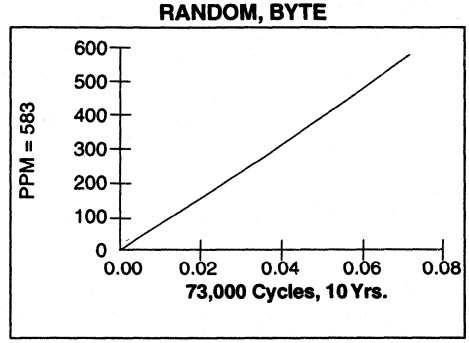
Now we have some more options: (1) specify the product life at 5 years or (2) trade-off other parameters of the application such as voltage or temperature, or (3) decide which is more important a 10-year product lifetime, or the ability to change 50 numbers every single day. Maybe this analysis has caused our designer to reevaluate the 50 cycle-per-day requirement. Will the user really change or add that many numbers per day - half of the unit's total capacity? Maybe 20 or even 10 is a more practical figure. Realistically, a user may enter or change quite a few numbers the first week or two of the application, and after that the unit will be used mostly for reading and dialing numbers.

Changing the number of erase/write cycles to 20 per day gives us the following results:

Device Data:	Input Parameters
Device	24LC16B
Voltage	3.3
Temperature	55°C
Bytes/Cycle	16
E/W	20
PPM Level (Yrs)	1,000
Cycling Mode	BYTE
Pulse Width (Ms)	N/A
Data Pattern	RANDOM

Device Data:	Output Parameters
PPM	1,000
Time	16.3
Write cycles	109,000

© 1997 Microchip Technology Inc.



By reducing the number of cycles per day not only brought us back to a 10-year life, it gave us some reserve on that, too. Keeping all the other parameters the same and forcing a 10-year lifetime gives us the following final results:

Device Data:	Output Parameters
FIT	6.7
PPM	583
Time	10.0
Write cycles	73,000

The new PPM rate of 583 gives our triumphant designer more than 40% reserve on his PPM target of 1,000.

This example shows the significant reduction in time for design trade-off analysis and time-to-market which can be achieved with a useful tool like the Microchip Total Endurance Disk. In addition, it demonstrates the increase in robustness of the system design by providing known quantities and readily accessible handles to modify those quantities in the trade-off analysis. This tool can literally reduce weeks of effort into a few minutes of point and click.

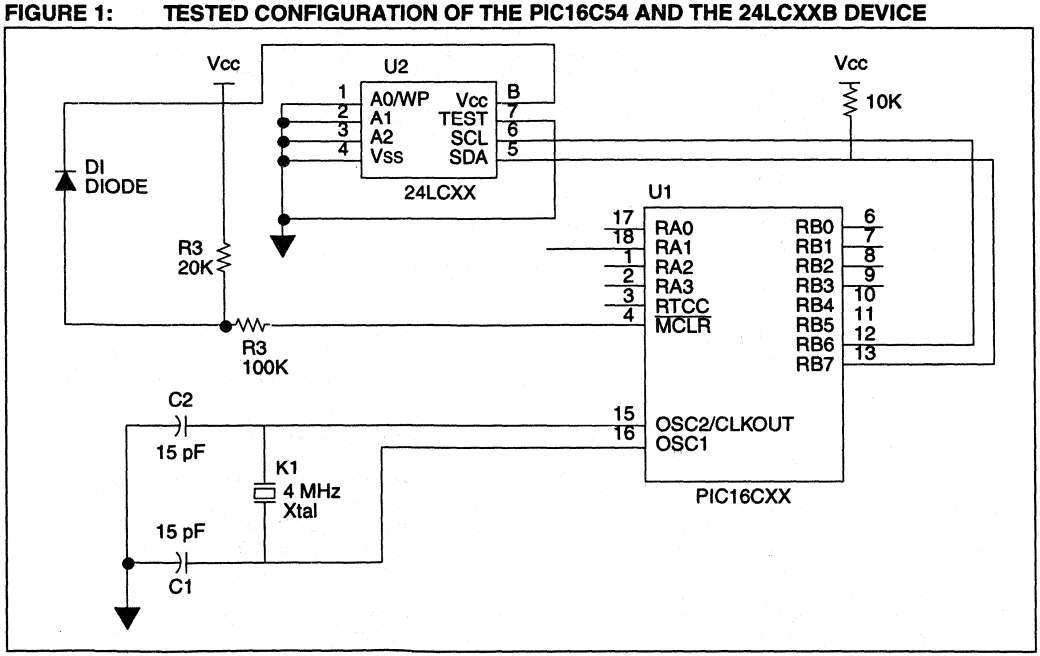
Interfacing the 24LCXXB Serial EEPROMs to the PIC16C54

Author: *Bruce Negley*
Microchip Technology Inc.



INTRODUCTION

The 24LCXXB Serial EEPROMs from Microchip Technology are I²C™ compatible, will operate in the standard 100 kHz and the 400 kHz Fast Mode. When using any serial protocol with a general microcontroller that does not have a dedicated protocol specific serial port, the designer must generate the specific code routines to accomplish the several memory access functions that the microcontroller will perform. The PIC16CXXX products from Microchip are both versatile and efficient to program. This application note is a series of stand-alone programs to perform the basic I²C interface functions on a PIC16C54 running at 4MHz in XT mode. This configuration will provide a 60 kHz serial bus rate. At this speed, the interface does not meet the 100kHz specification. If a higher clock rate is desired, the HS crystal oscillator must be used, which has a maximum frequency of 20MHz. NOTE THAT THE TIMING ROUTINES MUST BE REWRITTEN TO RUN AT THESE FASTER CLOCK RATES. The user must consult all applicable data sheets for design details. These programs have been fully tested and are being made available for general use. Figure 1 demonstrates the tested configuration of PIC16C54 and the 24LCXXB device.

This application note includes the following programs.

- 2-Wire Byte Read
- 2-Wire Byte Write
- 2-Wire Byte Write with Data Polling
- 2-Wire Page Write
- 2-Wire Sequential Read

                     00001          LIST P=16C54,c=132
                     00002 ;*****************************************************************
                     00003 ;       2-Wire Byte Write Program (123 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 24LCXX Serial EE device
                     00007 ;       and perform a byte write operation on 8 consecutive
                     00008 ;       addresses.
                     00009 ;
                     00010 ;       This routine waits approximately 10mS for the write
                     00011 ;       cycle time, which is enough time for any of the
                     00012 ;       24LCxx devices to complete a write.  A more efficient
                     00013 ;       method of determining when the write cycle is complete
                     00014 ;       is called "data polling."  The data polling method is
                     00015 ;       explained in the program "2wdpoll.asm."  That
                     00016 ;       particular program uses data polling in a byte write
                     00017 ;       mode but it can be used in exactly the same way for
                     00018 ;       a page mode write.
                     00019 ;
                     00020 ;       As an option, the user may connect a LED to pin 18
                     00021 ;       on the PIC 16C54 (use about a 1K resistor in series) as an
                     00022 ;       acknowledge fail indicator.  This LED will come on if
                     00023 ;       the serial EE fails to acknowledge correctly.
                     00024 ;
                     00025 ;       Timing is based on using the PIC 16C54 in 'XT' mode
                     00026 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00027 ;       will be approximately 60 Khz for this setup.
                     00028 ;
                     00029 ;        PIC 16C54 to Serial EE Connections:
                     00030 ;
                     00031 ;        PIC 16C54         Serial EE
                     00032 ;       ------------     ------------
                     00033 ;       Pin 12 (RB6) -->  SCLK
                     00034 ;       Pin 13 (RB7) -->  SDATA
                     00035 ;
                     00036 ;       PIN 18 (RA1) -->  Acknowledge fail LED  (Optional)

                     00001          LIST P=16C54,c=132
                     00002 ;*****************************************************************
                     00003 ;       2-Wire Byte Write With Data Polling Program (129 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 24LCXX Serial EE device.
                     00007 ;       This program performs a byte write operation on 8
                     00008 ;       consecutive addresses using the data polling method
                     00009 ;       to determine when the write cycle is complete.
                     00010 ;
                     00011 ;       When writing to a serial E≤ device, there are 2
                     00012 ;       ways to handle the internal timed write cycle
                     00013 ;       time of the device.  The simplest method is
                     00014 ;       simply to wait until the maximum cycle time
                     00015 ;       is exceeded before attempting another command.
                     00016 ;       The other, more efficient method is known as "data
                     00017 ;       polling."  Data polling is done by sending a start
                     00018 ;       bit and control byte to the part after the write
                     00019 ;       cycle has been initiated by a stop bit.  If the ack bit
                     00020 ;       is low, then the device is through writing, otherwise
                     00021 ;       the the sequence is repeated.  If no low acknowledge
                     00022 ;       is found within 40 attempts (about 10 milliseconds)
                     00023 ;       then the routine times out and sets the timeout
                     00024 ;       LED (pin 1) high.
                     00025 ;
                     00026 ;       As an option, the user can connect a LED to pin 1
                     00027 ;       on the PIC 16C54 (use about a 1K resistor in series) as a
                     00028 ;       timeout indicator.  This LED will come on if the
                     00029 ;       data polling is unsuccessful and the device being
                     00030 ;       programmed does not respond.  This can be tested by
                     00031 ;       simply running the program with no part in the socket.
                     00032 ;
                     00033 ;       Timing is based on using the PIC 16C54 in 'XT' mode
                     00034 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00035 ;       will be approximately 40 Khz for this setup.
                     00036 ;
                     00037 ;        PIC 16C54 to Serial EE Connections:
                     00038 ;

                     00001          LIST P=16C54,c=132
                     00002 ;*****************************************************************
                     00003 ;       2-Wire Page Write Program (122 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 24LCXX Serial EE device
                     00007 ;       and perform a page write operation on 8 consecutive
                     00008 ;       addresses.
                     00009 ;
                     00010 ;       All of Microchip's 2-wire serial E≤ devices have a
                     00011 ;       buffer or 'page' that can be used as a more efficient
                     00012 ;       method of writing to consecutive addresses.  Some
                     00013 ;       devices have page lengths of 2 bytes, others have
                     00014 ;       page lengths of 4,8,16 or 64 bytes.  Please consult
                     00015 ;       the databook for the page length of the device you
                     00016 ;       are using.  THIS ROUTINE IS WRITTEN FOR A DEVICE
                     00017 ;       WITH A PAGE LENGTH OF 8 OR MORE BYTES.
                     00018 ;
                     00019 ;       When using page mode, the control byte and address
                     00020 ;       are sent for the first address only.  After the data
                     00021 ;       byte for the first address is sent, the data for the
                     00022 ;       next consecutive address is clocked in.  This is
                     00023 ;       repeated as many times as needed (as long as the page
                     00024 ;       length is not exceeded) and then a stop bit is sent.
                     00025 ;       The device will still acknowledge between every byte of
                     00026 ;       data.  After the stop bit is sent, the part will
                     00027 ;       initiate the self timed write cycle.  For all of
                     00028 ;       Microchip's 24LCxx devices, the cycle time for
                     00029 ;       a byte write and a page write is the same.  Therefore,
                     00030 ;       writing 8 bytes in byte mode with a typical 5ms write
                     00031 ;       cycle consumes 40ms of wait time, while the same data
                     00032 ;       written in page mode would consume only 5ms of wait time.
                     00033 ;
                     00034 ;       This routine waits approximately 10mS for the write
                     00035 ;       cycle time, which is enough time for any of the
                     00036 ;       24LCxx devices to complete a write.  A more efficient
                     00037 ;       method of determining when the write cycle is complete
                     00038 ;       is called "data polling."  The data polling method is
                     00039 ;       explained in the program "2wdpoll.asm."  That
                     00040 ;       particular program uses data polling in a byte write
                     00041 ;       mode but it can be used in exactly the same way for
                     00042 ;       a page mode write.
                     00043 ;
                     00044 ;       As an option, the user can connect a LED to pin 18
                     00045 ;       on the PIC 16C54 (use about a 1K resistor in series) as a
                     00046 ;       acknowledge fail indicator.  This LED will come on
                     00047 ;       if the device being programmed does not send a low
                     00048 ;       acknowledge bit at the proper times.  This can be
                     00049 ;       tested by simply running the program with no part
                     00050 ;       in the socket.
                     00051 ;
                     00052 ;       Timing is based on using the PIC 16C5x in 'XT' mode
                     00053 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00054 ;       will be approximately 40 Khz for this setup.

                     00002 ;*****************************************************************
                     00003 ;       2-Wire Sequential Read Program (120 bytes)
                     00004 ;
                     00005 ;       This program demonstrates how to interface a
                     00006 ;       Microchip PIC 16C54 to a 24LCXX Serial EE device
                     00007 ;       and perform a sequential read operation.  A sequential
                     00008 ;       read involves setting the address pointer once and then
                     00009 ;       using the auto-increment ability of the part to read
                     00010 ;       consecutive addresses by simply providing more clocks.
                     00011 ;
                     00012 ;       Timing is based on using the PIC 16C54 in 'XT' mode
                     00013 ;       using a 4Mhz crystal.  Clock speeds to the serial EE
                     00014 ;       will be approximately 60 Khz for this setup.
                     00015 ;
                     00016 ;       As an option, the user may connect a LED to pin 18
                     00017 ;       on the PIC 16C54 (use about a 1K resistor in series) as an
                     00018 ;       acknowledge fail indicator.  This LED will come on if
                     00019 ;       the serial EE fails to acknowledge correctly.
                     00020 ;
                     00021 ;        PIC 16C54 to Serial EE Connections:
                     00022 ;
                     00023 ;          PIC 16C54        Serial EE

Questions and Answers Concerning Serial EEPROMs

Authors: *Bruce Negley*
Microchip Technology Inc.

Interfacing a serial EEPROM to a controller can be a confusing task, especially for first time users. Because communication with a parallel memory device is more straightforward, the advantages of serial devices are sometimes overlooked because of the time required to learn a different protocol. In order to minimize this time, Microchip provides many application notes on how to interface a controller to our serial memory products. Since every application is different, questions on different aspects of serial memories still arise. This application note provides answers to some of these commonly asked questions on using serial EEPROMs. This series of questions and answers covers a broad range of topics concerning both 2-wire and 3-wire serial EEPROMS, and covers material and/or circumstances that may not be provided in the data book.

QUESTIONS ON 2-WIRE DEVICES (24XXXX OR 85XXXX)

Q: What happens if a STOP bit is inadvertently sent to the device in the middle of a page write command?

A: It depends on which device you are using. The older 24Cxx devices will write any fully loaded bytes in the page to the device. For example if the stop bit occurs before all bits are loaded in the 5th byte, then the first 4 bytes will be written and the 5th byte will not. On the 24LCxxB or 24AAxx devices, if the stop bit occurs before all 8 bits in a byte are loaded, then the entire command will abort and no bytes will be written.

Q: What happens if a START bit is inadvertently sent to the device in the middle of command?

A: A start bit will always reset the part. It should be noted that if the device has control of the SDA line for an acknowledge bit or a read command, it may not be possible to send a start bit.

Q: I'm using interrupts in my controller code, and it is possible that I may jump out of my serial EEPROM communication routine to handle an interrupt. Is there any problem with leaving the device sitting in the middle of a command as long as the clock remains stable?

A: It is perfectly valid to leave a command in the middle indefinitely as long as the clock line remains stable.

Q: I'm using an interrupt routine in my controller code that may leave the serial EEPROM in the middle of a read command. When I return from the interrupt, is there any way to reset the part to make sure it is in a known state before I start sending it commands again?

A: If the part was in the process of outputting data, you can always get it back to standby mode by allowing the SDA line to float high and give it 9 clocks. This assures that the device will not receive the acknowledge bit at the end of the current byte and will abort the command and go to standby.

Q: I'm using a 24LCxxB in my application. What happens if the WP line goes from low (unprotected) to high (protected) in the middle of a write command?

A: The state of the WP pin is OR'd with the write control circuitry inside the device. The state of the pin is not latched at any point of the command to see if the write should be done or not. Therefore, if the WP pin went high before the stop bit was sent to initiate the command, then the array would be protected. If the WP pin went high after the stop bit was sent, then the outcome is unpredictable, because the result would vary according to how far into command the WP pin went high.

Q: I'm attempting to use a serial EEPROM in an application for the first time, and am having problems getting it to work. I have followed all the timing diagrams in the databook but when I attempt to read data from the device I only read zeros.

Q: When a read command is initiated and all the data is zeros, the problem is most likely one of two things:

1. A pull-up resistor on the SDA line is required for the device to operate correctly. Common values are 10K - 20K ohms. If this pull-up is not provided, then the device can only output zeros.
2. The controller is not releasing the bus to the device and is holding it low. Check the controller code and make sure that the SDA line has been set for input during the read command.

7

© 1997 Microchip Technology Inc.

Q: I had been using a 24C04A in my application and have switched to the 24LC04B so I can run at a lower voltage. Now the circuit is no longer working correctly. The read seems to work fine but the write seems to not work at all or only intermittently.

A: A: The problem is probably with the difference in write cycle times between the two devices. The write cycle time for the 24C04A is about 0.5ms per byte, while the cycle time for the 24LC04B is around 2-4ms per byte. Therefore, when you send consecutive write commands using the new device, it is ignoring all commands that occur while it is in the middle of a write cycle.

Q: I'm using a 24LC16B device in my application. Is there any way I can determine when the write cycle is complete instead of waiting the maximum 10ms?

A: Yes, you can determine when the write cycle is complete on any of our 2-wire devices by utilizing a simple technique called "data polling" or "acknowledge polling." Data polling is done after the stop bit has been sent to the device to initiate a write cycle. You simply send the device a start bit followed by a proper control byte with the R/W bit set low. You then check the status of the acknowledge bit. If the acknowledge bit is high, then the device is still busy writing. You can continue to send the start bit and control byte until the device acknowledges. When the acknowledge bit reads low, then the device has finished the write cycle. You can now send the address and data bytes if you are going to do a write command, or just send the address if you are going to do a read command. Of course you may also send a start bit and begin the next command from scratch.

Q: I'm confused about when the acknowledge bit from the device actually occurs; can you clarify this?

A: The device will attempt to take over the SDA line for the acknowledge bit on the falling edge of the clock for the last bit in the byte. It will then release the SDA line on the falling edge of the clock given for the acknowledge bit. For example, when the control byte is sent to the device, it will take the SDA line low on the falling edge of the clock for the R/W bit. It will then release the SDA line on the next falling edge of the clock (the acknowledge bit). The same sequence occurs for sending the device a byte of data or address.

Q: I am using a 24LC01B in my application which has an 8 byte page buffer. What happens if I load more than 8 bytes into the device before giving it the stop bit?

A: For all 24LCxxB products, the 24C04A and the 85C92, the page buffer will wrap around to the beginning of the buffer and begin to overwrite the data that has previously been loaded For the 24C01A/02A and 85C72/82, the write command will abort if more bytes than the page buffer will hold are loaded.

Q: Can I send a stop bit and a start bit with the same clock pulse?

A: Yes, this is valid as long as setup and hold times for both the start and stop bits are obeyed.

Q: What happens if I give the device a start bit and then a stop bit in the same clock pulse?

A: The 24Cxx devices will ignore the stop bit, the 24LCxxB products will accept the stop bit and go to standby mode.

Q: Does the address pointer get incremented after a current address read command?

A: A current address read command can be halted by sending a stop bit or by sending a high acknowledge bit after the data has been sent by the device. On the 24Cxx devices, ending the read command with a stop bit will increment the address pointer to the next address. Ending the command with a high ack bit will not increment the address.

For the 24LCxxB products, ending the command with either the stop bit or the high ack bit will increment the address pointer.

Q: I am using the 24LC16B and want to write to the part using the page write mode. Can I start a page write at any location in the device?

A: You can start a page write at any location in the device, but you need to be aware that the part is arranged in 16-byte pages and you cannot cross a page boundary. If you attempt a page write that goes beyond the end of the current page, data loaded will 'roll around' to the beginning of the current page instead of going to the next one. For example; the first page in the device starts at address 0x00 and ends at 0x0F. If you start a page write at address 0x0E, the first byte loaded will be written at address 0x0E, the second at 0x0F and the third byte loaded will roll around to the beginning of the page and be written to address 0x00.

QUESTIONS AND ANSWERS FOR 3-WIRE DEVICES (93XXXX)

Q: What would happen if during a write command I inadvertently sent either too many or too few clocks to the device before dropping the CS line?

A: If you send too many clocks to the device and then drop the CS line to initiate the write cycle, the extra clocks will be ignored but the command will execute. If you do not send enough clocks and then drop the CS line, then the command will abort and no write will take place.

Q: I am using a 93LC56 device in my application and am having problems getting it to work correctly. The read sequence seems to work fine but I unable to write any data to the part.

A: A problem such as this is usually caused by either not giving the part the required number of bits for the command before dropping the CS line, or not dropping the CS line at all. The write command will not commence until the CS line is brought low.

Q: I am currently using a 93C46 device and am looking to go to the 93LC46 device so I can run at a lower voltage. What are the main differences between these devices?

Q: There are several operational differences between these devices that you should be aware of:

1. The 93LC46 operates in both x8 and x16 modes; the 94C46 is x16 only.
2. The 93LC46 supports the sequential read function the 93C46 does not.
3. The write cycle on the 94LC46 begins on the falling edge of the CS line; the write cycle for tne 93C46 begins on the rising edge of the last clock.

Q: Is the 93LC46 drop-in compatible with the 93C46 or would I be better off using the 93LC46B?

A: The 93LC46 and 93LC46B are the same device with one exception; the ORG pin on the 93LC46B is internally tied so it will only operate in the x16 mode. This allows the user to leave pin 7 floating, just like you would on the 93C46. For this reason, the 93LC46B is a closer match than the 93LC46. Please note the other operational differences described in the previous question.

Q: I am confused as to whether I have to toggle the CS line low in-between every command.

A: Yes, the CS line must go low for at least 250 ns between each command. If you are doing a write command and you bring CS low to activate the data polling mode, you must toggle CS low again after the ready signal has been given by the device before the next start bit can be sent.

EEPROM Endurance Tutorial

Authors: Bruce Negley
Microchip Technology Inc.

INTRODUCTION

The endurance of an EEPROM-based device will be quoted by a manufacturer in terms of the minimum number of erase/write cycles (write cycles) that the device is capable of sustaining before failure. A write cycle is generally considered to be the operation that changes data in a device from one value to the next.

There are several EEPROM-based devices available on the market. Microchip Technology Incorporated makes three general types of EEPROM-based product: Serial EEPROMs, Parallel EEPROMs, and EEPROM-based Microcontrollers. As a manufacturer of many EEPROM products, Microchip is concerned with endurance and continues to try to educate its customers on the importance of this topic.

There are many differences in the interpretation of "endurance" that can result in misleading or inaccurate information being used in design decisions. This paper hopes to clear up any questions that the customer may have in the subject of endurance, without becoming so technical that the information given is not helpful.

There is no widely used standard for any type of endurance test. Each manufacturer will use their own endurance testing methodology. This report will describe all the testing options, and which tests Microchip performs on its EEPROM-based products.

The MIL-STD cycling test (Method 1033) has not been updated since 1977 and is well out of date as applied to EEPROM non-volatile memories. The standard does not distinguish the difference between block cycling and byte cycling, and gives a very poor failure criteria. Microchip does not use this standard.

BASIC TERMS

The definition of "endurance" (as applied to EEPROMs) in the first part of this introduction contains various words and phrases that require clear definition and understanding. As shown in the following paragraphs, different manufacturers will use different standards.

"Endurance cycling" is a test performed by all manufacturers (and some customers) to determine how many "write cycles" the product will achieve before failing.

The "minimum number of write cycles" is the least number of times that you can expect to subject the product to a "write cycle" before it fails.

"Failure" is a somewhat arbitrary definition, since a device only truly fails when it no longer meets the customer expectation, and does not operate in his system. A failure can be defined in this, the loosest of definitions, or the most stringent of definitions (whereby a device would fail if it did not meet any of the data sheet parameters), as well as a wide range in between.

For example, if the device did not correctly store data into a particular address that the customer was not using, then the device would work correctly for the customer but would fail a functional test set by the manufacturer. Likewise, if the device drew more current than the data sheet specified after some time, but the customer application could supply the current needed, the device would work in the customer application but would fail a parametric test set by the manufacturer.

Microchip uses the most stringent definition: **A failure occurs when the device fails to meet any data sheet condition under any guaranteed operating condition of temperature and voltage.**

The number of devices that can fail before a particular endurance criteria is not met is also somewhat flexible. Even the most quality conscious manufacturer will occasionally have a failure, so a failure level is defined. The industry standard conditions for many types of reliability tests are set by JEDEC (the Joint Electronic Device Engineering Council). JEDEC defines that if 5% or less of a given sample fails at a given endurance goal, then that goal has been met. For example, if a sample of 100 units are endurance cycled to 1 million cycles and 3 have failed at 100,000 cycles and a further 7 have failed at 1 million cycles, then the sample would have an endurance of 100,000 cycles.

Microchip uses a more stringent criteria for endurance: no more than 2.5% of devices can have failed for the given endurance goal to have been met.

A "write cycle" is also a somewhat flexible definition since almost every customer will write the device in a different way. For example, if the customer application uses only the first three bytes of the array to store variable data, and the remainder of the array is used as a lookup table, then a write cycle will be complete when the three data bytes have been re-written to their new data state.

© 1997 Microchip Technology Inc.

A write cycle is often described as an erase/write cycle, since almost all technologies employ an "auto-erase" before the data is actually written to the array. This is also used by Microchip, but we will use the term "write cycle" since the auto-erase is invisible to, and cannot be suppressed by, the customer.

The term "data changes" is occasionally used in place of "write cycle" or "erase/write cycle." A data change will occur when an auto-erase cycle is initiated, and a second data change will occur upon the write cycle, therefore, one "erase/write cycle" is equivalent to two "data changes." The term "data change" also implies that a different type of cycling is being used than "erase/write cycle." This will be described later.

The term "write cycle" does not define under what conditions the cycling was done (unless explicitly stated) nor does it define the type of cycling that was done. The endurance cycling can be done at any number of conditions of voltage and temperature (e.g., 85°C and 5.5V, or 25°C and 5.0V) that may or may not meet with a customer's application. The cycling mode used in endurance cycling can affect the endurance of the product. All these effects will be described later.

Microchip uses the most stringent conditions that are reasonable for endurance cycling. We use byte or page mode cycling at a temperature of 85°C at 5.5V. All data not explicitly defined at other conditions is taken at these conditions.

A "read cycle" is completed when any number of bytes of data have been read from the device. For the FLOTOX-design EEPROM-based devices made by Microchip a read cycle does not affect endurance, since the data in the EEPROM is not changed. Other technologies, such as Ferroelectric technology, may have a limited number of read cycles since data is corrupted during a read.

System Design Considerations

There are a number of design considerations that the system designer can use to maximize the endurance of an EEPROM-based device, if endurance is the application's limiting factor.

As will be described in more detail later, if the designer has any control over certain environmental or operation conditions he should observe the following basic guidelines:

- Keep the application temperature as low as possible
- Keep the application voltage (or the Vcc voltage on the EEPROM-based device) as low as possible
- Write as few bytes as possible
- Use page write features wherever possible
- Write data as infrequently as possible

With these basic guidelines applied to the fullest extent, the endurance of EEPROM-based devices can be extended well beyond the guaranteed minimum endurance. Under certain very specific conditions, Microchip Serial EEPROMs have been shown to last for well over 100 million cycles.

WRITE MODES IN EEPROMS

There are three ways that EEPROM-based devices can have the entire array data contents changed. These are: byte mode, page mode, and block (or bulk) mode. Some types of devices support all three modes, others may only support one or two modes. The mode that you use to write an EEPROM-based device will affect the long term endurance of the product.

Byte mode writing is used when the contents of the array are changed one byte at a time. For many devices this is the only user-accessible write mode available. To change the entire contents of a Serial EEPROM in this way would take up to 10 seconds (using 10 ms per page on a 64K Serial EEPROM). Parallel EEPROMs such as a 28C64, which have a faster byte write time (1 ms rather than 10 ms), but no page mode would also take up to 10 seconds.

Page mode writing is a popular feature on many new designs of EEPROM memory products. This feature allows up to 8 bytes of data to be written to the memory in the same time that one byte would normally take. In this mode, the write time for a 64K Serial EEPROM can be cut from eight seconds to one second.

Block cycle is generally a test mode used by EEPROM manufacturers to make it easier to test the products. Some types of EEPROM-based products have these modes as user options (such as the ERAL and WRAL mode in 93CXX products, or the Chip Clear mode in 28CXXX products) but generally this mode is not user accessible. A block write can be done in as little as 1 ms, allowing millions of write cycles to be completed in a few hours.

A general rule to follow in choosing write modes is that the larger the number of bytes being written in a single instruction, the longer the device will last. For example, in byte mode a device might start to fail after 300,000 cycles under a particular set of conditions, but the device may last 600,000 cycles in page mode under the same conditions. In block mode the device might last 1 million cycles, under the same conditions.

The reason for this is related to the internal design of any FLOTOX EEPROM-based product. In these devices, an internal "charge pump" takes the applied Vcc voltage (typically 2.5 to 5.5V) and increases it to 15 to 25V. This voltage is required to induce the "Fowler-Nordhiem Tunneling" or "Enhanced Emission" effects that are used to program and erase EEPROM-based devices. The specific effect that is used is manufacturer-dependent. Microchip EEPROMs program by Fouler-Nordheim Tunneling.

The charge pump voltage is used to program however many EEPROM-cells are being programmed. For example, in byte mode, all the cells in a byte (8 to 16)

© 1997 Microchip Technology Inc.

are biased with the charge pump voltage. In block mode, all the cells in the array (up to 100,000, depending on the device) are biased with the charge pump voltage. The charge pump is like a current source during conditions of high load, so the voltage put out by the charge pump will be reduced slightly if more bytes are being written. If the whole array is being programmed then the charge pump voltage will be significantly reduced, but the programming current I_{PP} will be very high.

Generally, the lower the charge pump voltage the better the endurance (there is a limit since the charge pump voltage needs to be high enough to program the cell) and so the best endurance is generally achieved by using block mode cycling. Page mode is worse than block mode, but better than byte mode. Block mode is generally not a very useful cycling mode to the end user, since the data contents in the whole array will be changed to the same value (generally 00 or FF).

When Microchip tests EEPROM-based products we use byte mode cycling on devices which do not have a page mode, and page mode cycling for those that do. We encourage our customers to use page mode writing on all products which have page mode, to ensure high endurance.

ENDURANCE TESTING METHODOLOGIES

Different manufacturers use different ways to both endurance cycle and test EEPROM-based products. There is no standard for endurance cycling, or testing devices after cycling.

There are two groups of testing that Microchip performs on all products: qualification and production. Qualification testing is done for all new products, and major changes to a product or manufacturing process. Production testing is done on all devices shipped to customers.

Qualification testing at Microchip is used to test the reliability of new products, and to guarantee that the device is reliable. A great deal of testing is done, including endurance testing on all EEPROM-based products. Endurance cycling is done at the maximum rated data book value, generally 85°C or 125°C. After the rated number of cycles (10,000, 100,000, or 1,000,000) the sample (around 300 from multiple wafer lots) is tested to a full production test program. After endurance, the units are subject to "data retention" to guarantee that the required 40 years of data retention will be achieved, after the maximum number of cycles has been completed.

Endurance cycling is done under the conditions previously described, and the data retention test is performed after this. After the data retention stress is completed (which takes six weeks) the devices are tested again, to confirm the functionality of the device to all data sheet parameters.

No more than 2.5% failures are allowed after endurance, and a failure rate higher than 100 FITs after 1000 hours of data retention stress (equivalent to more than 10 years at 55°C) is unacceptable.

Production testing is done by Microchip on all devices shipped to a customer. Production testing begins immediately after a wafer lot is finished being processed, continuing in various stages until the devices are shipped to a customer.

The first tests that are done on EEPROM-based products at Microchip are called wafersort. They are done before the wafer is cut up into dice for assembly. There is a series of tests which include large numbers of write cycles (up to 5000) to ensure reliability by weeding out weak devices so they never get shipped.

After assembly full testing is done which includes further write cycles across the guaranteed temperature range, to ensure device functionality at the temperature extremes. After the normal production testing a sample of 128 units is taken from every wafer lot, and cycled to 10,000 cycles (Parallel EEPROMs) or 1,000,000 cycles (Serial EEPROMs and EEPROM microcontrollers) at 85°C using the conditions already described. After endurance testing the devices are tested for functionality at 85°C.

Any sample of Parallel EEPROMs which shows significant failures at the end of cycling causes the entire wafer lot to be pre-cycled prior to production testing. Serial EEPROMs and EEPROM-based microcontrollers do not receive the same disposition. Lots with significant failures come under scrutiny and full failure analysis with corrective actions is done. This is, however, a rare occurrence.

The testing that Microchip does is unique. Manufacturers will generally do different testing from each other. Microchip firmly believes that our testing ensures excellent quality and reliability.

THE EFFECT OF TEMPERATURE ON EEPROM ENDURANCE

The temperature at which cycling is done will affect the number of write cycles that can be executed before the device fails. The higher the temperature, the worse the endurance will be. Generally, and approximately, a device which fails at 10 million cycles at 25°C will fail at 2 million cycles at 85°C and 1 million cycles at 125°C. The reasons for this are not conclusive (although there is much technical literature supporting one theory or another) but it is apparent that the failure mode of EEPROM cells (generally considered to be electron trapping in the tunnel dielectric causing shielding and dielectric breakdown) is strongly dependent on temperature.

Data taken by Microchip suggests that if the typical failure of an EEPROM-based device is 10 million cycles at 25°C, the mean failure will occur at other temperatures according to the following table:

© 1997 Microchip Technology Inc.

TABLE 1: TEMPERATURE MEAN FAILURE

Write Cycle Temperature	Mean Failure (Cycles)
-40°C	37.1 million
0°C	16.7 million
25°C	10.0 million
40°C	7.4 million
55°C	5.4 million
70°C	4.0 million
85°C	2.9 million
100°C	2.2 million
125°C	1.3 million

This data was taken on Microchip FLOTOX Fowler-Nordhiem Tunneling EEPROMs and formed a part of the data set used to create the Total Endurance™ disk. Other technologies (such as FLOTOX Enhanced Emission or Ferroelectric technologies) may have different characteristics.

As is clearly seen, any cycling done at 25°C can be misleading in the extreme if the application requires a device that can be cycled 10 million times at, say, 55°C.

THE EFFECT OF VOLTAGE ON EEPROM ENDURANCE

The voltage at which a device is written can also affect the endurance. This is simply because the charge pump (used to program and erase EEPROM cells) is more powerful at higher voltages. As has already been described, a higher programming voltage will reduce the endurance of an EEPROM cell, and a stronger charge pump will produce a higher voltage.

Data taken by Microchip suggests that if typical failure of an EEPROM-based device is 1 million cycles when endurance cycling is done at 5.5V, mean failure occurs at other temperatures according to the following table:

TABLE 2: VOLTAGE MEAN FAILURE

Endurance Cycling Voltage	Mean Failure (Cycles)
5.5V	1.0 Million
5.0V	1.2 Million
4.5V	1.4 Million
4.0V	1.7 Million
3.5V	2.0 Million
3.0V	2.4 Million
2.5V	2.8 Million
2.0V	3.3 Million

This data was taken on Microchip FLOTOX Fowler-Nordhiem Tunneling EEPROMs and formed a part of the data set used to create the Total Endurance disk. Other technologies (such as FLOTOX Enhanced Emission or Ferroelectric technologies) may have different characteristics.

THE EFFECT OF WRITE MODE ON EEPROM ENDURANCE

As has been discussed there are three basic ways of writing data to an EEPROM-based device:

- Byte mode
- Page mode
- Block mode

This is related to the strength of the charge pump in applying the required programming voltages to the EEPROM cells.

Data taken by Microchip suggests that if the typical failure of an EEPROM-based device is 1 million cycles when the endurance cycling is done in byte mode, the mean failure will occur in other modes according to the following table:

TABLE 3: ENDURANCE MEAN FAILURE

Endurance Cycling Mode	Mean Failure (Cycles)
Byte	1.0 Million
Page	4.6 Million
Block	13.2 Million

This data was taken on Microchip FLOTOX Fowler-Nordhiem Tunneling EEPROMs and formed a part of the data set used to create the Total Endurance disk. Other technologies (such as FLOTOX Enhanced Emission or Ferroelectric technologies) may have different characteristics. This data was taken from a Microchip 24LC16.

As you can see, the use of the block cycle data to guarantee endurance can be misleading.

THE TOTAL ENDURANCE PREDICTIVE SOFTWARE

Microchip has a Windows®-based software model called Total Endurance. This program, based on all of the customers endurance parameters, will predict the failure level at the expected end of application life. This tool is invaluable for system designers who would like to fine-tune their application in favor of endurance. It is available now from your local Microchip distributor.

How to get 10 Million Cycles Out of Your Microchip Serial EEPROM

Author: *David Wilkie*
Microchip Technology Inc.

INTRODUCTION

Microchip Technology Incorporated recently became the first manufacturer of Serial EEPROMs to rate the endurance of 1K to 16K 2-Wire protocols and 1K to 4K 3-Wire protocols at 10 million cycles. This gives the highest endurance available from any manufacturer on such a wide range of Serial EEPROMs. Microchip is also the world leader in endurance application support, including Total Endurance™ software, which allows customers to determine exactly what their endurance will be in their application. This application note will explain our 10 million cycle guarantee in the context of Total Endurance and the customer application.

ENDURANCE

Endurance is the term used to define the number of times an EEPROM-based device can be erased and re-written before an unacceptable failure rate has occurred. Microchip defines an unacceptable failure rate as 2.5%, which is half the "industry standard" (JEDEC) failure rate of 5%.

Microchip uses the industry standard cycling conditions to guarantee 10 million cycles. These are the same conditions used by the major EEPROM manufacturers, unless specifically stated otherwise. The conditions are 25°C block cycle at 5.0V. The data pattern that is written to the device is supplier-dependent. Microchip uses a checkerboard pattern to better simulate actual use.

10 MILLION CYCLE GUARANTEED

We take a great deal of data on the endurance of our devices. We run experiments over temperature, voltage, array size, data pattern, cycling type and other erase/write cycling conditions, to continually learn about our products. The data we take is continually fed back into our manufacturing process tracking, and is also used to periodically update our application predictive software, Total Endurance. The lessons that we learn are passed on to our customers.

Microchip has shown many times before that temperature has the strongest effect on endurance. The higher the temperature of your application is, the lower your endurance will be. For example, no EEPROM manufacturer can deliver a product that will achieve 1 million cycles at 125°C, but many can deliver 1 million cycles at room temperature. Microchip can provide 10 million cycles on all our Serial EEPROMs at room temperature, using the standard cycling conditions.

You can ensure the lowest possible failure rate at 10 million cycles by using the EEPROM in ways that are easiest on endurance. Use the lowest temperature possible. Use the lowest voltage possible. Write as few bytes as possible (the number of reads is unlimited), and use page modes if the device you are using has one (Typically all 2-wire protocols have a page mode, but 3-wire protocols do not).

The best way to determine the endurance of your application is to use the Total Endurance software. This will give accurate results over a very wide range of application-specific conditions, including array size, temperature, and voltage (the main effects on cycling).

The most important thing to remember is that endurance is application-specific. Each application will result in a different endurance level, based on the temperature, voltage, and other conditions under which the application operates. Currently Microchip is the only manufacturer to offer such a wide range of tools to help guide the user in his or her application of Serial EEPROMs.

Converting to 24LCXXB and 93LCXX Serial EEPROMs

Author: *Nathan John*
Microchip Technology Inc.

Microchip Technology Inc. is constantly striving to give you, our customer, greater value. In the Serial EEPROM market this means creating devices that exhibit greater reliability, that consume less power, have more features and are priced aggressively with respect to our competitors. We have created the 24LCXXB and 93LCXX families of Serial EEPROMs to meet all of these goals and more. We are proud to announce that these families of EEPROMs are the world's first to be guaranteed to 10 Million Erase/Write cycles. Please see Table 1 below for a complete list of the benefits for converting from "C" designated parts from Microchip and other vendors.

For most applications, there are no hardware or software compatibility issues in converting to the "LC" parts, you can drop them into the socket and you will be off and running. A small percentage of designs could require some modification to your hardware or software. Please review Table 2 and Table 3 to ensure that the "LC" parts will work correctly in your systems.

TABLE 1: FEATURES AND BENEFITS OF CONVERSION

Feature	Benefit
Higher Endurance	Opens new applications for Serial EEPROMs Lower FIT rate at given Write Cycle point
Smaller Die	Lower Cost
Lower Voltage / Lower Power	Enables new battery powered uses Allows for lower overall system Vcc
Smaller Process Geometry	Avoids obsolescence of older technology
Schmitt Trigger Inputs (24LCXXB)	Filtering for better noise immunity
Rotated Pinout Versions (93LCXX/SN)	Conforms to alternate industry pinout
Hardware Write Protect (24LCXXB)	Enhanced data protection

TABLE 2: CONVERSION ISSUES FOR 24LCXXB

Conversion Issue	Detail
Addressing	The "LC" versions do not have active address pins and, therefore, you can only have one of these devices on the I²C™ bus.
Write Speed	The "LC" parts have a maximum write time of 10ms, while the "C" parts have a write time of 1ms.
Write Disable Voltage	The "LC" versions will write down to 1.5V, while the "C" versions will disable writing below 4.0V.
Write Protection	The "C" parts have either no write protection or protection on one half of the array, the "LC" parts all have full array protection, implemented by connecting pin 7 to Vcc.

7

© 1997 Microchip Technology Inc.

TABLE 3: CONVERSION ISSUES FOR 93LCXX

Conversion Issue	Detail
Write Speed	The "LC" versions have a maximum write time of 10ms, compared to 1ms for "C."
Write Disable Voltage	The "LC" parts will write down to 1.5V while the "C" parts will only write down to 4.0V.
Start of Write Cycle	The "LC" versions start the write cycle on the low going edge of chip select, the "C" versions start on the last data bit clock.

Interfacing Microchip Serial EEPROMs to Motorola® 68HC11 Microcontroller

Author: *Keith Pazul*
Microchip Technology Inc.

INTRODUCTION

There are many different microcontrollers on the market today that are being used in embedded control applications. Many of these embedded control systems need non-volatile memory. Because of their small footprint, byte level flexibility, low I/O pin requirement, low power consumption and low cost, Serial EEPROMs are a popular choice for non-volatile storage.

Microchip Technology Incorporated addresses this need by offering a full line of Serial EEPROMs covering industry standard serial communication protocols for 2-wire and 3-wire communication. The theory, operation and differences of these two protocols are discussed in detail in Microchip's application note AN536. The reader should refer to AN536 if unfamiliar with 2-wire and/or 3-wire communication protocols. Serial EEPROM devices are available in a variety of densities, operational voltage ranges and packaging options.

Microchip realizes that its customer base is very broad, and because of this, different microcontrollers are used to interface to Serial EEPROMs. One of the microcontrollers used in these applications is the Motorola® 68HC11. In order to simplify the design process, Microchip has written a 68HC11 assembly code to communicate with our 2-wire and 3-wire parts that is verified and tested to function properly.

There are 13 programs written for inclusion in this application note. A listing of one of the programs is included with this application note as an example. The source code for all of the programs is available for downloading via Microchip's Bulletin Board (BBS). Users may consult the index of the *Microchip Embedded Control Handbook* for log-on instructions for the BBS. Once logged on to the Microchip BBS, select the FILE LIBRARY (download files) option from the main menu. Next, select a library. This application note is located in the MEM_APPS file library. Once in the MEM_APPS file library, the proper application note can be selected and downloaded by following the directions supplied by the BSS system. Only one file needs to be downloaded from the Microchip BBS to get all of the source code. All source code files are combined and compressed into one downloadible file called AN609.zip.

For Microchip 2-wire devices (24CXXA, 24LCXX, 24LCXXB, 24AAXX devices, excluding 24XX32 and 24XX65 devices), there are three programs to perform some of the basic communication functions.

- SRDMT2W.ASM - 2-Wire Sequential Read
- BW4MT2W.ASM - 2-Wire Sequential Write
- BW4PMT2W.ASM - 2-Wire Byte Write with Data Polling

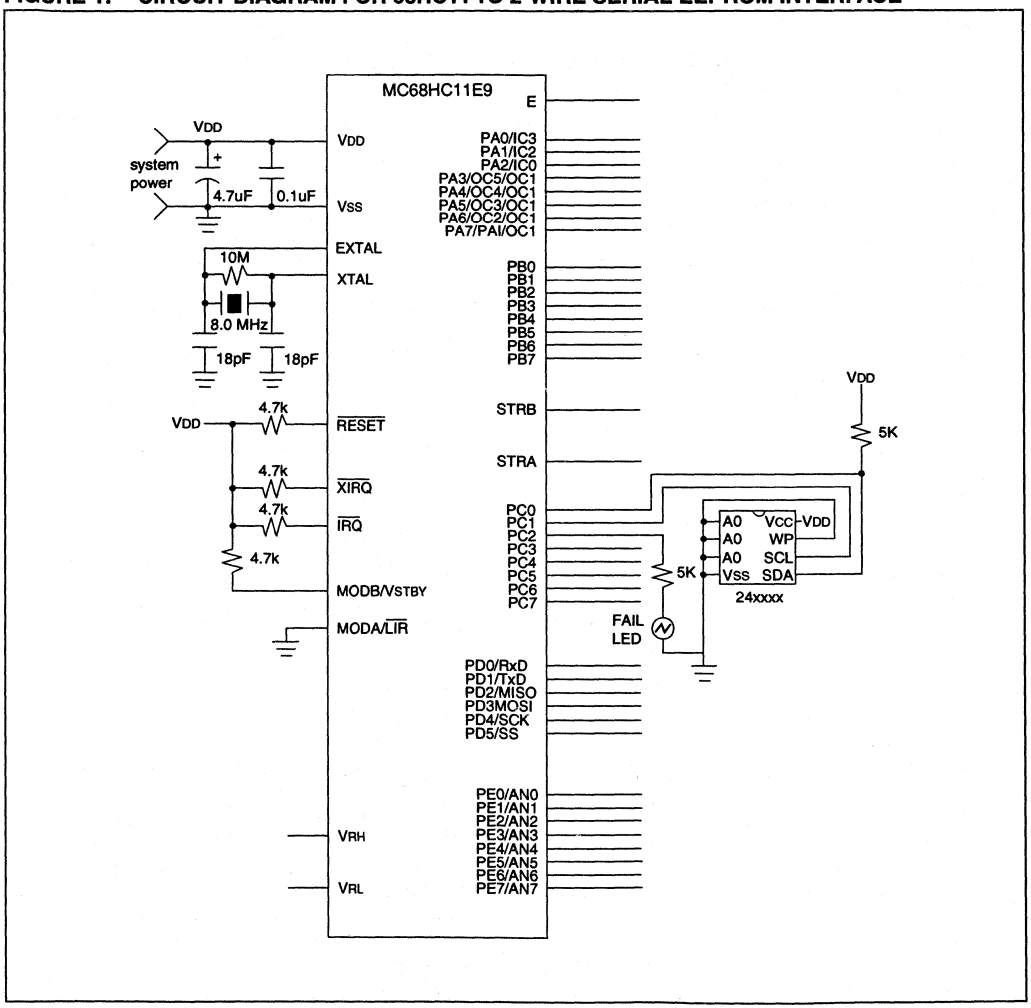
Refer to the data sheets in the Microchip *Data Book* for the 2-wire devices listed above for explanations of sequential read, sequential write and data polling.

Microchip also offers a powerful and flexible family of products referred to as Smart Serial™. These devices use the same 2-wire interface as described above, but have added intelligence not found on Microchip's other 2-wire devices. These devices include the 24C32, 24LC32, 24AA32, 24C65, 24LC65, and 24AA65. Among Smart Serial features are: split erase/write cycle endurance (user selectable regions of the device with two different endurance ratings), a 64-byte write cache and the ability to permanently write protect part or all of the array.

- RRDMT65.ASM - Random Read from 64K Smart Serial
- SRDMT65.ASM - Sequential Read from 64K Smart Serial
- CACWMT65.ASM - Full Cache Write to 64K Smart Serial
- WR8MMT65.ASM - Sequential Byte Write to 64K Smart Serial
- WR8PMT65.ASM - Sequential Byte Write with Data Polling to 64K Smart Serial
- HEMT65.ASM - Setting of High Endurance block for 64K Smart Serial
- SECMT65.ASM - Setting Security Features for 64K Smart Serial

Refer to individual data sheets of the parts listed for the definition and explanation of the functions.

For Microchip 3-wire devices (93CXX, 93LCXX 93LCXXB, and 93AAXX devices), there are three programs included to perform some of the basic communication functions.



- MT4BR3W.ASM - 3-Wire Multiple Word Read
- MT4BW3W.ASM - 3-Wire Multiple Word Write
- MT4BW3PW.ASM - 3-Wire Multiple Word Write with Data Polling

© 1997 Microchip Technology Inc.

Refer to the individual data sheets of the 3-wire devices listed for explanations of multiple word read, multiple word write and data polling.

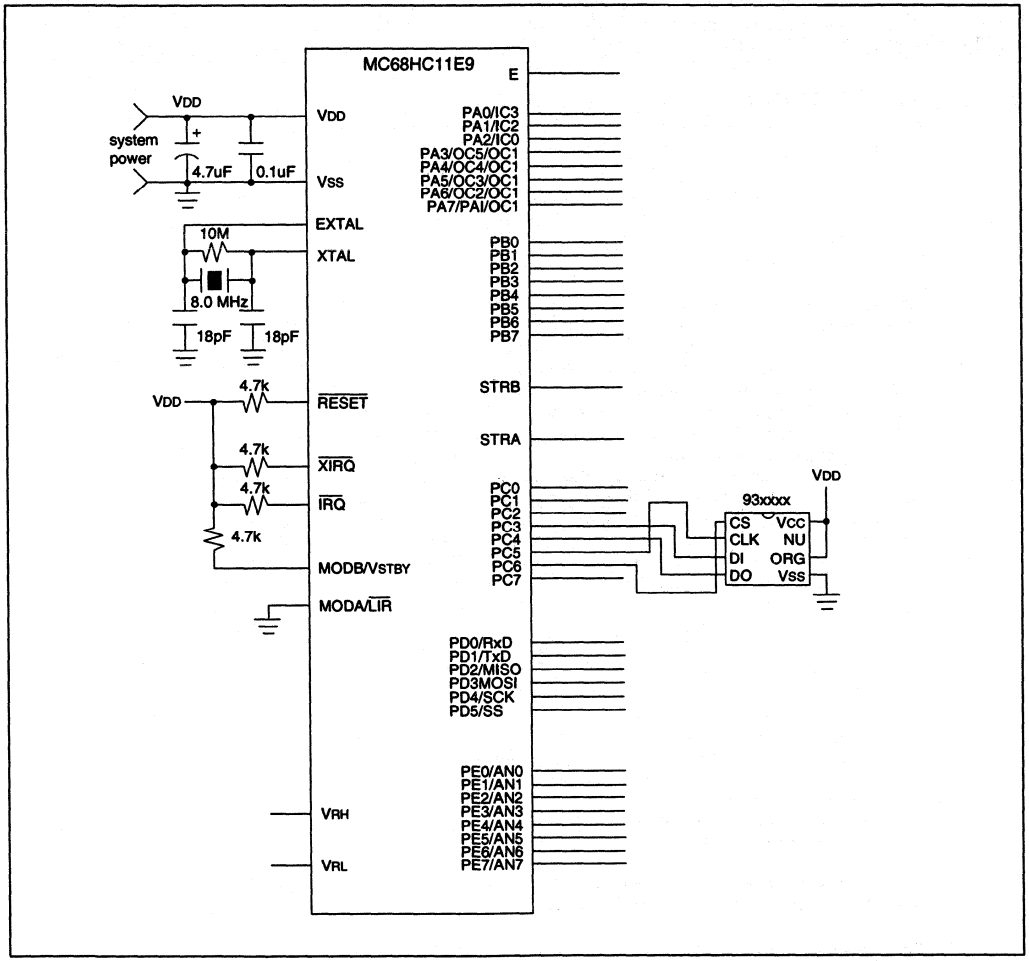


Figure 1 describes the hardware schematic for the interface between Microchip's 2-wire devices and the Motorola 68HC11E9. This schematic applies to the connection of the Smart Serial devices as well. Figure 2 describes the hardware schematic used to connect Microchip's 3-wire devices to the Motorola microcontroller. The schematics show the connections necessary between the microcontroller and the serial EEPROM, and the software was written assuming these connections.

APPENDIX A: SOURCE CODE

```
        ; ***************************************************************************
        ; 2-Wire Sequential Write Program (225 bytes)
        ;
        ; This program (bwr4mt2w.*) writes 4 bytes of $A5 to a Microchip 24LCxx
        ; beginning at location $10 using a Motorola 68HC11 microcontroller.
        ; This code has been verified that it writes properly to a Microchip
        ; 24LCxx serial EEPROM.
        ;
        ; This program was written using a 68CH11EVBU evaluation board.
        ; This board has a monitor program in firmware of the 68HC11 which
        ; allows single stepping, register viewing, modifying, etc. Since this
        ; is the case, the program code will be loaded into the on-chip EEPROM.
        ; This EEPROM begins at $B600. The control registers are left to their
        ; default location of $1000 and the RAM is left to its default location.
        ; RAM locations of $48-$ff are used by the monitor program and are not
        ; available for program use. Therefore, the stack pointer is set a $47
        ; and will be able to use all of the RAM to $00, and the RAM variables
        ; begin at location $100 and go up from there.  I cannot program the
        ; reset vector since it is ROM space (at $FFFE), so the way I run this
        ; program is to use the monitor program that comes with the evaluation
        ; board to set the program counter to the starting address of my user
        ; program ($B600) and begin from there.  For users who do have access
        ; to the reset vector, the label of the beginning program (in my case, it
        ; is called START) should be loaded at location $FFFE.  This program was
        ; not assembled using a Motorola assembler, but was assembled using
        ; Universal Cross-Assemblers Cross-32 Meta-Assembler.  It has the
        ; ability to assemble just about any microcontroller code.  There are
        ; certain commands that are unique to the cross-assembler.  These
        ; commands will be commented differently than other comments to
        ; be recognizable.  They will look like this:

        ;+++++++++++++++++++++++++++++++++
        ; Special cross-assembler command(s)
        ;+++++++++++++++++++++++++++++++++

        ; I do not know the exact assembler commands required to accomplish
        ; assembly using a Motorola assembler.
        ;
        ; The crystal that comes with the evaluation board is 8 Mhz.
        ; With this used as the clock input, this code will output a serial
        ; data stream at approximately 32khz.  Although this does not
        ; meet I2C spec of 100 khz, it communicate with the Microchip
        ; 24LCxx parts properly.  If a different frequency crystal is used,
        ; the code may need to be modified to meet timing specifications.

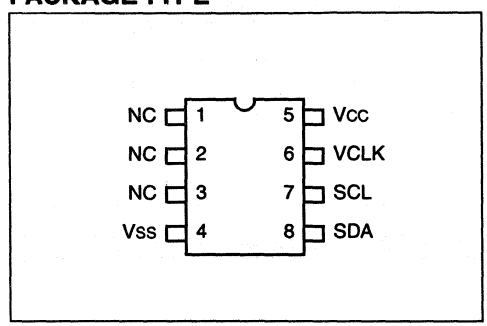
Using the 24LC21 Dual Mode Serial EEPROM

Author: *Bruce Negley*
Microchip Technology Inc.

INTRODUCTION

The Microchip Technology Inc. 24LC21 is a 1K-bit (128 x 8) dual mode serial EEPROM that was developed primarily for use in computer monitors. This part was developed with inputs from several computer monitor manufacturers, in accordance with the VESA® (Video Electronics Standards Association) monitor committee. This committee has developed a serial communication protocol called Data Display Channel (DDC™) which was created to eliminate the need to change dip switches when configuring a new system or adding a new monitor or video card. The 24LC21 device is used in the monitor to store and transmit the EDID (extended display ID) table which contains all set-up parameters needed by the video card to operate with a particular monitor. With this system, the user can now plug any compatible monitor into any compatible graphics board and the graphics board will automatically know what type of monitor is being used and configure itself accordingly. This automatic configuration is the cornerstone for Microsoft®'s 'Plug and Play' capability being built into the new 'Windows 95™' release.

DEVICE OPERATION



The 24LC21 can operate in two modes of operation. These two modes of operation are the transmit only mode and bi-directional mode. Upon power-up, the device will always be in the transmit-only mode. Transmit only mode is also referred to as DDC1 mode. The transmit only mode only allows the video card to read the contents of the 24LC21 in a sequential manner, one bit at a time. Writing to the device is not possible in transmit only mode.

The device will automatically transition to the bi-directional mode whenever a falling edge is seen on the SCL pin. Bi-directional mode is also referred to as DDC2 mode, and is implemented as the standard I^2C™ protocol. This allows a controller to read and write specific addresses in the device like a standard I^2C Serial EEPROM device. Once the device has transitioned to the bi-directional mode, there is no way to return to transmit only mode other than to reset (power-down) the device.

TRANSMIT ONLY MODE (DDC1)

The 24LC21 will always power-up in the transmit only mode. In this mode, the 24LC21 will output one bit of data at the SDA pin for every rising edge on the VCLK pin. The data will be transmitted in 8-bit words, with each word followed by a 9th null bit. This null bit will always be high. A timing diagram for transmit only mode is shown in Figure 1. As long as VCLK is present and no falling edges on SCL are received, the 24LC21 will repeatedly cycle through the entire memory array.

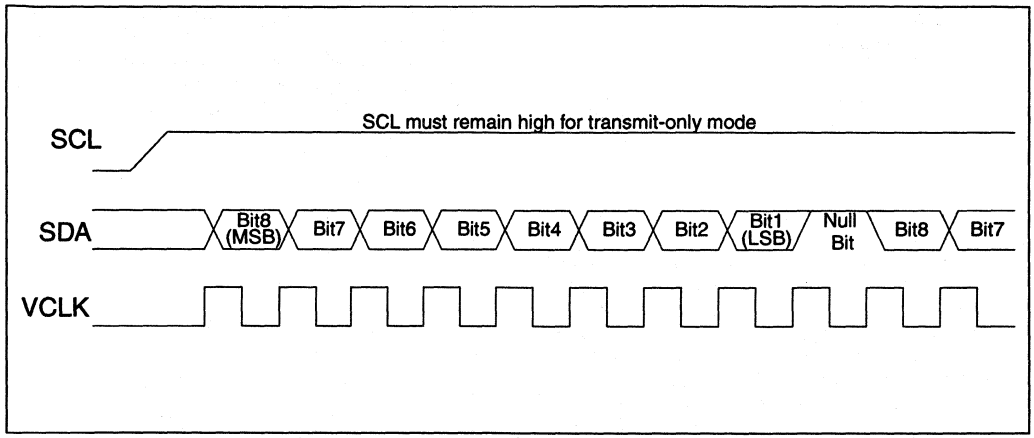
PACKAGE TYPE

Upon power-up, the device will not output valid data until it has been initialized. This initialization procedure (Figure 1) data will not be available until after the first 9 clocks are sent to the device. The exact memory location that the 24LC21 begins to transmit data is unknown at power-up, and the initialization procedure only initializes the device, not the starting address or bit location. In order to for a controller to determine what address is being read, a 'framing' or 'syncing' procedure must be executed by the video card.

© 1997 Microchip Technology Inc.

A framing procedure involves looking for the header portion of the EDID table which is a byte of 00H followed by 6 bytes of FFH and another byte of 00H. A framing routine would continue to clock data from the 24LC21 until this unique header has been found. At this point, the current location in the EDID table has been determined and the controller has now synchronized itself with the device. Care must be taken while using the device in the transmit only mode to prevent noise on the SCL pin, as a falling edge seen on this pin will immediately send the part into the bi-directional mode. In a DDC1-only monitor, SCL is not connected to the VGA connector, but must still be terminated to Vcc through a pullup resistor.

FIGURE 1: TRANSMIT ONLY MODE



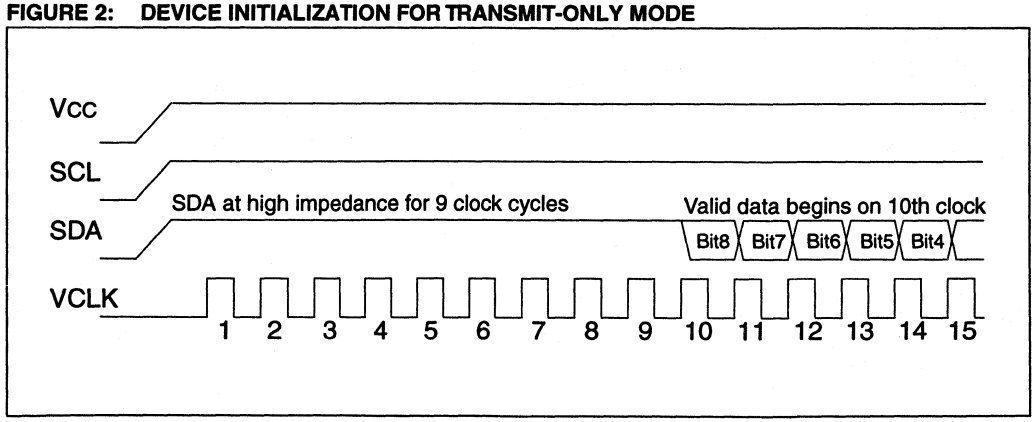


FIGURE 2: DEVICE INITIALIZATION FOR TRANSMIT-ONLY MODE

BI-DIRECTIONAL MODE (DDC2)

Bi-directional mode is essentially the standard I^2C protocol and allows the controller to read and write to the device. The 24LC21 supports byte and page writes and byte and sequential reads in the bi-directional mode. This mode will be used primarily before the monitor leaves the factory to load the EDID table into the device, but it also provides a means of updating the table if necessary. It is also used for faster (up to 100 kHz) data transmission, or transmission of only specific requested data in a DDC2 system. (The I^2C protocol allows the host to request data from a specific portion of the EDID table rather than waiting for the entire table.) When writing to the device, the VCLK pin must be held high while the write command is being loaded or the write will be aborted and no data will be written. Note that this is the opposite of the 24LC01B, where the WP pin must be held low for the device to be written.

EDID TABLE

The EDID table is the Extended Display ID table, specified by VESA, that will be stored in the 24LC21 and contains information about what type of display it is and the capabilities of the display. The basic EDID table consists of 128 bytes of data. A breakdown of the table is shown below in Table 1. A complete description of the table can be found in the VESA DDC Specification.

TABLE 1: EDID TABLE DESCRIPTION

Bytes	Description
8	Header
10	Vendor/Product Description
2	EDID Version/Revision
15	Basic Display Parameters/Features
19	Established/Standard Timings
72	Detailed Timing Descriptions (18 bytes each)
1	Extension Flag
1	Checksum

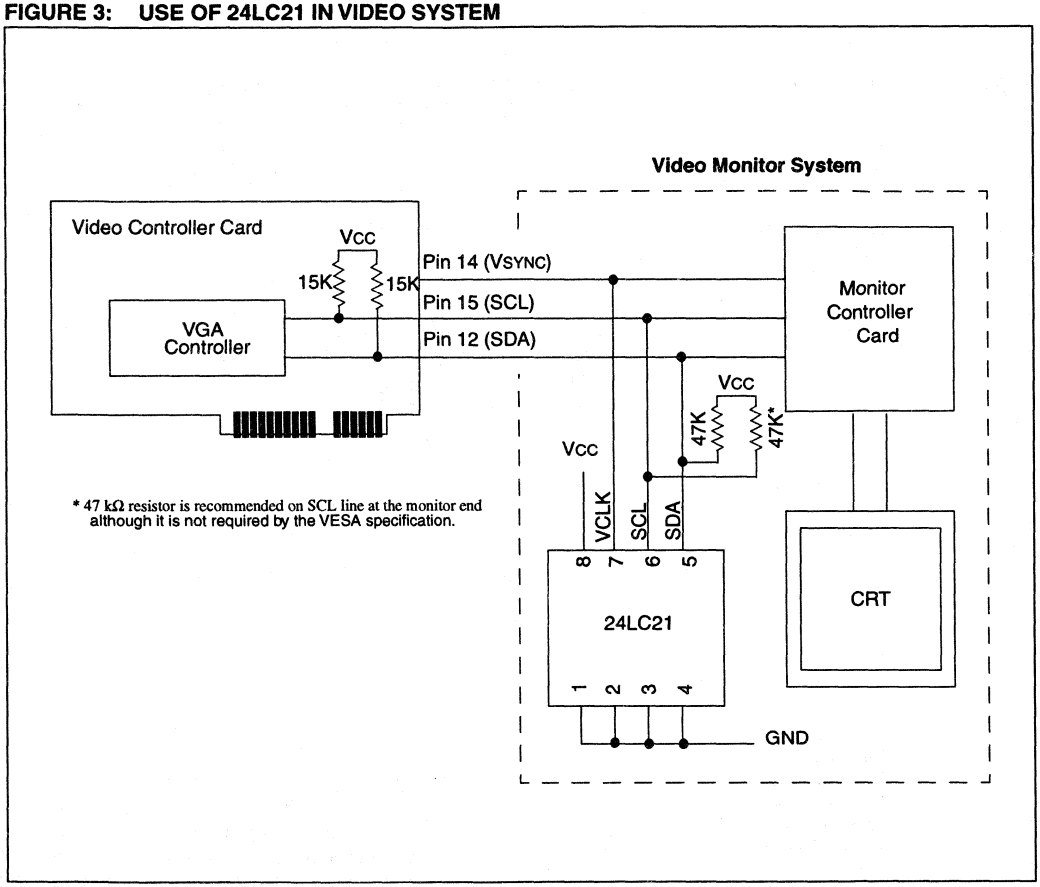
USING THE 24LC21 IN A SYSTEM

In order to use the 24LC21 in a monitor system, it must be programmed with a proper EDID table and then properly connected to the signals coming from the video controller card. The VESA committee has specified that the connections for DDC transmission can be part of the standard 15-pin VGA connector. A table of pinouts for this connector are shown in Table 2. Signals that pertain to the use of the 24LC21 are highlighted.

Programming of the 24LC21 can be accomplished via Microchip Technology's SEEVAL programming and evaluation system or by any final test system at the customer site which can communicate over the I^2C bus.

TABLE 2: VGA CONNECTOR DESCRIPTION



Pin	Standard VGA	DDC1 Host	DDC2 Host	DDC1.2 Display
1	Red Video	Red Video	Red Video	Red Video
2	Green Video	Green Video	Green Video	Green Video
3	Blue Video	Blue Video	Blue Video	Blue Video

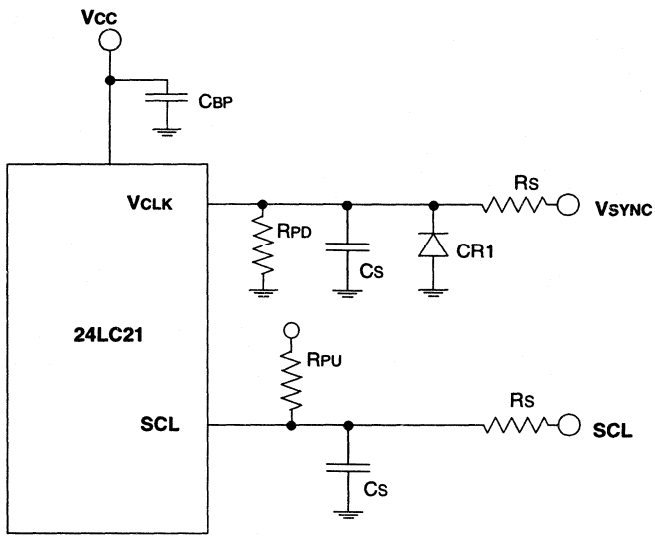
SYSTEM CONFIGURATION

A typical system configuration is shown below. The DDC specification states that a 47 kΩ pull-up resistor is required on the SDA line at the monitor end. It also states that a 15K pullup resistor is needed on both the SCL and SDA lines at the video controller end.

FIGURE 3: USE OF 24LC21 IN VIDEO SYSTEM



7

POTENTIAL PROBLEMS CAUSED BY NOISE IN A VIDEO SYSTEM

Because the typical application for the 24LC21 is in a computer monitor where electronic noise is prevalent, some precautions may need to be made in order for this device (or any other CMOS device) to work properly. The diagram below (Figure 4) shows a filter circuit that can be used to reduce the amount of noise seen by the device on the SCL and VCLK pins.

FIGURE 4: RECOMMENDED FILTER CIRCUIT FOR MONITOR APPLICATIONS

CBP = 1 µF
RS = 100 - 300 Ω
RPD = 4.7 kΩ
CS = 100 - 1000 pF
RPU = 47 kΩ

CBP	Bypass capacitor
RPD	Can be as a termination resistor on VGA cable. Also will discharge the series capacitor going to the MCU and horizontal/Vertical processor.
CS and RS on VCLK	Acts as low pass filter to clean-up noise on VSYNC line
CS and RS on SCL	Acts as low pass filter to clean-up noise and dampen power transient spikes that may cause accidental mode switching from DDC1 to DDC2
RPU on SCL	Keeps SCL pulled high, although a high enough value is used that the host will not power the 24LC21. Lets the 24LC21 reset when the monitor power is turned off
CR1	Eliminates undershoot on VSYNC

Using Microchip 93 Series Serial EEPROMs with Microcontroller SPI™ Ports

Author: *Keith Pazul*
Microchip Technology Inc.

INTRODUCTION

Systems requiring embedded control are becoming more and more sophisticated, with microcontrollers required to control these systems increasing in complexity. Many microcontrollers today are being designed with built-in serial communication capability to be able to easily access other features that are not built in to the microcontroller itself. Devices like EEPROMs, A/Ds, D/As, LCDs etc. are all being built with a serial interface to reduce cost, size, pin count, and board area. There are many different serial interfaces on the market used to interface peripherals (I^2C™, Microwire®, SPI, for example). One of the serial interfaces that is gaining in popularity is SPI (Serial Peripheral Interface). It is becoming more popular because of its communication speed, simultaneous full-duplex communication, and ease of programming.

Microchip PIC16C64/74 microcontrollers have a built-in serial port that can be configured as an SPI port. Currently, the Microchip Serial EEPROM product line does not support SPI interface Serial EEPROMs, however it is possible to use the 93 series devices on the SPI port. Any version of Microchip's 93 series devices can be communicated with via the SPI port of a PIC16C64/74. The code for this application note is written for a Microchip 93LC56/66, but talking to other 93 series devices can be accommodated with minor code changes. See the *Theory of Operation* section of this application note for more details on how this is accomplished. This code was verified by downloading to Microchip's PICMASTER™ in-circuit emulator (run at full speed with a 10 MHz crystal) and tested to make sure it writes (polling ready/busy pin to verify write cycle completion) and reads properly. A schematic (Figure 1) is included in this application note to describe exactly how the 93LC56/66 was connected to the PIC16C64/74.

The SPI interface was popularized by the Motorola 68HCXX microcontrollers. Microchip receives many requests for Motorola assembly code that uses the SPI port of the 68HC11 or 68HC05 to talk to Microchip serial EEPROMs. Because of this, Microchip has written 68HC11 assembly code to communicate with its 93 series devices via its SPI port. The program was downloaded to a 68HC11 evaluation board and tested to make sure it writes (polling ready/busy pin to verify write cycle completion) and reads properly. A schematic (Figure 2) is included in this application note to describe exactly how the 93LC56/66 was connected to the microcontroller.

THEORY OF OPERATION

To use an SPI port to communicate with Microchip's 93 series Serial EEPROMs, the bytes to be output to the 93XXXX must be aligned such that the LSB of the address is the 8th bit (LSB) of a byte to be output. From there, the bits should fill the byte from right to left consecutively. If more than 8 bits are required, then two bytes will be required to be output. This same method will work for any 93 series device. A 93LC66 was chosen as the device to write this application note code for, so the following example will be for that particular device. The theory explained below will work for any 93 series device.

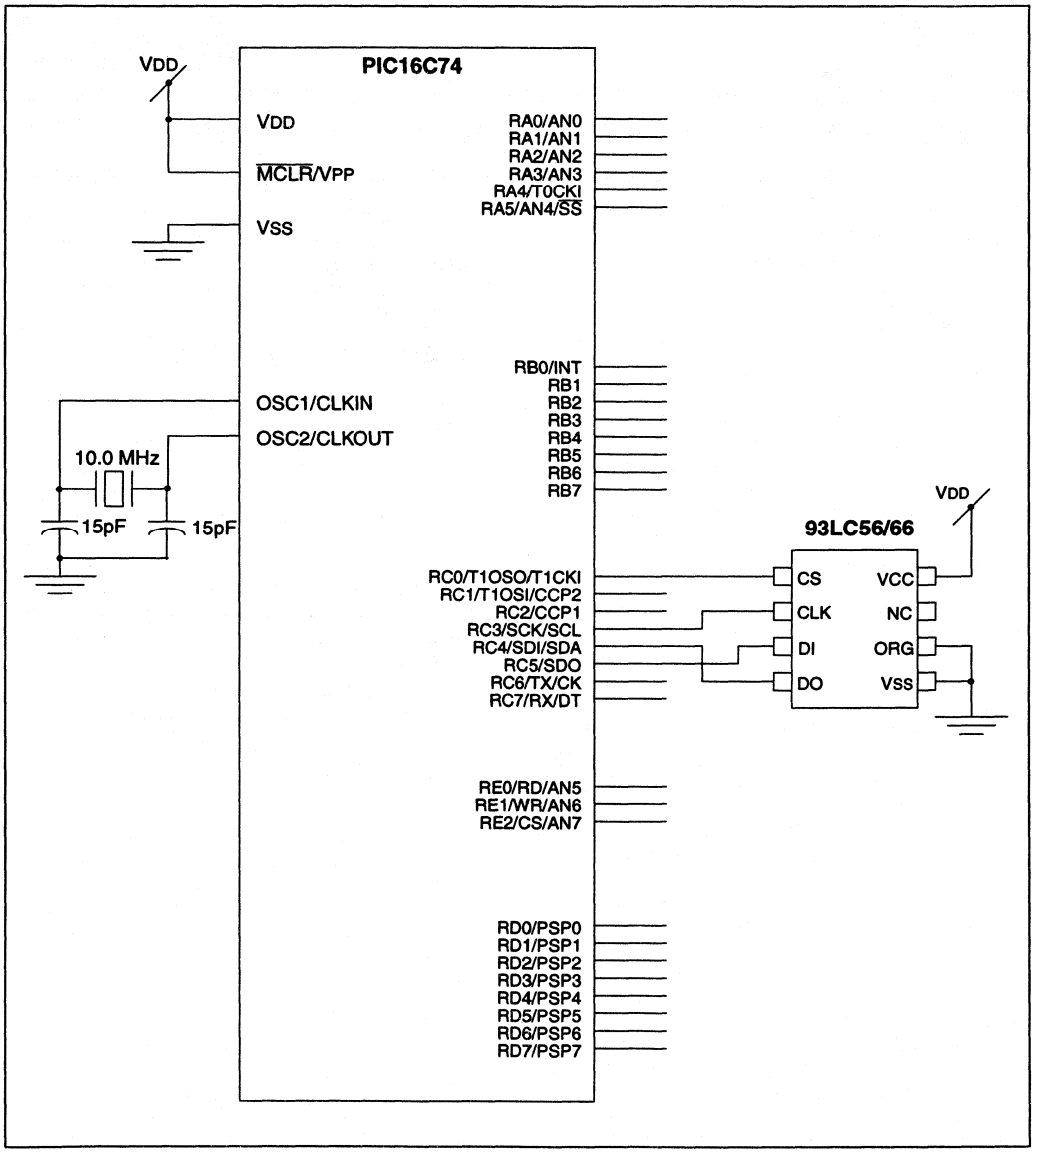
Since more than 8 bits are required to control a 93LC66, two consecutive bytes are required.

High Byte (where the start bit, op code bits, and address MSB reside)

| 0 | 0 | 0 | 0 | SB | OP1 | OP0 | A8 |

The High Byte is configured in the following format: SB is the start bit, OP1 is op code MSB, OP0 is op code LSB, and A8 is the 9th address bit that is required to address 512 bytes. The CS can be set before the byte is output because the leading 0's output to the 93xxxx prevent a start bit from being recognized by the 93xxxx until the first high bit is sent.

Low Byte (8 address LSBs)



| A7 | A6 | A5 | A4 | A3 | A2 | A1 | A0 |

The Low Byte contains A7-A0, which are the rest of the address bits required to access 512 bytes.

Data output from master MUST be set up on the falling edge of the clock so that it can be read from the 93XXXX on the next rising edge. Receiving data from the 93XXXX MUST also happen on the falling edge of the clock because the data is output from the 93XXXX on the rising edge of the clock. THIS REQUIRES THE CLOCK PHASE BIT OF THE SPI PORT TO BE OPPOSITE FOR RECEIVING THAN IT IS FOR TRANSMITTING. The clock phase needs to be toggled between 0 for transmitting data and 1 for receiving data. See source code for the exact spot where the clock phase bit needs to be changed.

APPENDIX B: MOTOROLA 68HC11 SOURCE CODE

```
;*************************************************************************
; 3-Wire byte write and byte read using SPI port (220 bytes)
;
; This program (hc11sp66.*) writes 4 bytes of $5A to a Microchip 93LC66
; using the SPI port of the Motorola 68HC11 microcontroller.  Ready/busy
; polling is used to determine when the current byte is done writing and
; the next byte is ready to be written to the 93LC66.  After the 4 bytes
; are written, they are read back and stored in RAM locations $100-$103.
; The evaluation board can be stopped after receiving the 4 bytes to
; view RAM locations and verify that what was written to the 93LC66 is
; what is read back.
;
; This code was written by Keith Pazul on 3/7/95.
;
; This is the way the bytes will be aligned to be sent to the 93LC56/66:
;
; First byte (where start bit, op codes reside)
;
; |  0  |  0  |  0  |  0  | SB  | OP1 | OP0 | A8  |
;
; where SB is start bit, OP1 is op code msb, OP0 is op code lsb,
; and A8 is address msb.
;
; Next byte (address)
;
; | A7  | A6  | A5  | A4  | A3  | A2  | A1  | A0  |
;
; where A8-A0 are address bits required to address 4k bits of memory.
;
; This code will work for any 93 series device.  The only difference
; is that the number of address bits is adjusted and the start bit
; and op code bits are adjusted to follow directly after the address
; MSB.
;
; THE 93LC56 or 66 IS ASSUMED TO BE IN x8 MODE.  IT REQUIRES
; THE USER TO TIE THE ORG PIN TO Vss.
;
; This program was written using a 68CH11EVBU evaluation board.
; This board has a monitor program in firmware of the 68HC11 which
; allows single stepping, register viewing, modifying, etc.  Since this
; is the case, the program code will be loaded into the on-chip EEPROM.
; This EEPROM begins at $B600.  The control registers are left to thier
; default location of $1000 and the RAM is left to its default location.
; RAM locations $48-$ff are used by the monitor program and are not
; available for program use.  Therefore, the stack pointer is set a $47
; and will be able to use all of the RAM to $00, and the RAM variables
; begin at location $100 and go up from there.  I cannot program the
; reset vector since it is ROM space (at $FFFE), so the way I run this
; program is to use the monitor program that comes with the evaluation
; board to set the program counter to the starting address of my user
; program ($B600) and begin from there.  For users who do have access
; to the reset vector, the label of the beginning program (in my case, it
; is called START) should be loaded at location $FFFE.  This program was
; not assembled using a Motorola assembler, but was assembled using
; Universal Cross-Assemblers Cross-32 Meta-Assembler.  It has the
; ability to assemble just about any microcontroller code.  There are
; certain commands that are unique to the cross-assembler.  These
; commands will be commented differently than other comments to
; be recognizable.  They will look like this:
```

© 1997 Microchip Technology Inc.

```
;*********************************
; Special cross-assembler command(s)
;*********************************

; I do not know the exact assembler commands required to accomplish
; assembly using a Motorola assembler.
;
; The crystal that comes with the evaluation board is 8 Mhz.
;
; The SPI port in on port D.  The bits are defined as follows:
;
;           MISO        PORT D, PIN 2 (pin 22 on package)
;           MOSI        PORT D, PIN 3 (pin 23 on package)
;           SCK         PORT D, PIN 4 (pin 24 on package)
;           SS\         PORT D, PIN 5 (pin 25 on package)
;           CS          PORT C, PIN 6
;
; Note that only the CS pin resides on port C.

Interfacing the 8051 with 2-wire Serial EEPROMs

Author: *Mike Rosenfield*
Microchip Technology Inc.

INTERFACING MICROCHIP SERIAL EEPROMS TO THE INTEL 8051 FAMILY OF MICROCONTROLLERS

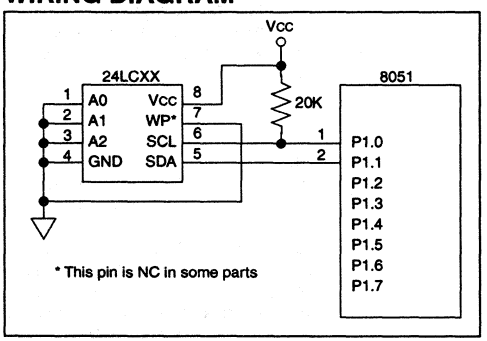
Many designers today are implementing embedded systems that require low cost non-volatile memory. Microchip has addressed this need with a full line of serial EEPROMs, in a variety of memory configurations, using the industry-standard 2- or 3-wire communication protocols. The theory and application of these protocols are addressed in detail in Microchip's application note AN536.

Microchip recognizes that its broad customer base uses a variety of micro-controllers; many firmware related questions have been asked concerning interfacing the 8051 family and its derivatives.

The purpose of this app note is to provide assembly language examples of 8051 code for the various serial EEPROMs available from Microchip. These routines are intended to provide the basic operating kernels for storing data to or retrieving data from a serial EEPROM.

All of the routines in this app note are available, as source code, for downloading from Microchip's BBS. Information on the BBS is available elsewhere in the Embedded Control Handbook. The file to download is AN614213.zip.

This app note covers all of Microchip's 2-wire serial devices. Note that some devices have features not supported in others, and therefore, some sections of the code presented here may not be applicable to a particular part. We have attempted to label those special sections to minimize confusion.



The code includes a simple loop-type shell to enable it to be executed (with an emulator) without the user having to write any other routines. The various address and data pointers must be set to the desired values by hand, before each execution cycle.

TIMING DATA

Clock and data timing is accomplished by software. There are two sets of timing specifications: 100 kHz and 400 kHz. Assuming a 12 MHz 8051 clock, extra NOP's have been added to slow timing down to 100 kHz. See Note 1 in the listing. If a 16 MHz clock is used, additional NOP's are required for 100 kHz operation. See Note 2 in the listing. For 400 kHz operation, the NOP's labelled Note 1 or Note 2 are not needed. If not needed, NOP's may be left out.

Below is the connection diagram used for this app note. Do not forget the pull-up resistor!.

              12   ;Port 1 bit 0 is data
              13   ;Port 1 bit 1 is clock
              14   ;
              15   ;       These routines assume chip address = 0
              16   ;
              17   ;       The oscillator frequency assumed for this app note is 12 MHz.
              18   ;
              19   ;       These routines use software timing loops. They may have to be
              20    ;      adjusted if a different oscillator frequency is used.
              21   ;
              22   ;NOTE 1 These NOP'S added for timing delays only on 'C' parts, OR 'LC' parts
              23   ;       where Vcc is less than 4.5 V. and the oscillator frequency is 12 MHz.
              24   ;       This allows a bit rate of 100kHz.
              25   ;NOTE 2 Use these NOP's with a 16 MHz oscillator and 100kHz bit rate.
              26   ;       For 400kHz bit rate, the NOP's in Note 1 and Note 2 are not required.
              27   ;
              28   ; The EEPROM will be busy after a write cycle is initiated (by a stop condition)
              29   ; for between 1mS to 10 mS per page (or per byte if a byte write). This app note
              30   ; assumes the user will program appropriate wait times after a write, or check
              31   ; for Busy status. A subroutine is provided to check the Busy Status.

```
                51  ;*******************************************************************************
                52  ; This section contains test loop routines. They form a simple operating shell
                53  ; to allow the 2-wire interface code to be tested in a stand-alone mode. Using
                54  ; an emulator, change  "NONE" to one of the four listed routines
                55  ; to test that funcion. The address and data constants can also be set as
                56  ; desired.
                57  ; If using a 24XX32 or 24XX65, change the called routines by adding 'L' to the
                58  ; end of the name. This is required because these parts use TWO address bytes.
                59  ; The 'L' routines send out the extra address byte.

MICROCHIP

AN619

Interfacing the 93XX76 and 93XX86 to a PIC16C5X

Author: *Keith Pazul*
Microchip Technology Inc.

INTRODUCTION

Microchip's newest offerings in the 3-wire Serial EEPROM family are the 93XX76 and 93XX86 devices. These are 8 Kbit and 16 Kbit versions of our 93 series Serial EEPROMs with a couple of differences from the standard 93XX46, 93XX56 and 93XX66 devices:

1. These devices have a Program Enable (PE) pin, which is used as a hardware write protect. Tying the PE pin to Vcc enables the array to be written to, while tying it to Vss prohibits the array from being written to. There is an internal pull-up resistor on the PE pin that allows the array to be written to when there is no connection to the PE pin.
2. The internal write cycle begins on the rising edge of the last data bit (D0) for the 93XX76 and 93XX86 devices, where the existing 93XX46, 93XX56 and 93XX66 devices begin their internal write cycle on the falling edge of Chip Select ($\overline{CS}$) after the last data bit has been sent. Software written for the 93XX46, 93XX56 and 93XX66 devices will still be compatible, however the internal write cycle will begin slightly earlier on the new 93XX76 and 93XX86 devices. The only changes to the code required are the number of address bits necessary to access the larger memory arrays.

The code that is written for this application note was taken from AN560 and the only modifications were the number of address bits output. Please refer to AN560 for more details about the original code. If the reader is new to Serial EEPROMs, please refer to application note AN536 for a more basic tutorial. This application note is intended to provide the engineer with stand-alone code modules for accomplishing all of the necessary functions required to utilize these devices in an application. See Figure 1 for a schematic of how the PIC16C54 was connected to the 93XX76 and 93XX86.

Although these devices are called 3-wire devices, they have essentially 4 I/O pins:

CS	Chip Select
CLK	Clock
DI	Data In
DO	Data Out

These devices use a series of commands to accomplish standard memory functions. These are READ, WRITE, EWEN, ERASE, ERAL, WRAL, EWDS. These functions are discussed in more detail in the datasheets for any of the 93 series devices.

The following programs are included in this application note and are fully functional stand-alone modules. The source code for these modules can be downloaded from the Microchip BBS. They are located in the MEM_APPS file library as one zipped up file, AN619.zip. Please consult page 8-1 of the *1995/1996 Non-Volatile Memory Products Data Book* or page 6-3 of the *1995/1996 Embedded Control Handbook Update* for more information on how to use the Microchip BBS.

The following are the programs included in this application note, along with the subroutines they call:

Byte Read Program (7686byrd.asm)

- Start Bit Routine
- Bin In Routine
- Receive Data routine
- Bit Out Routine
- Transmit Data Routine
- Power-up Routine

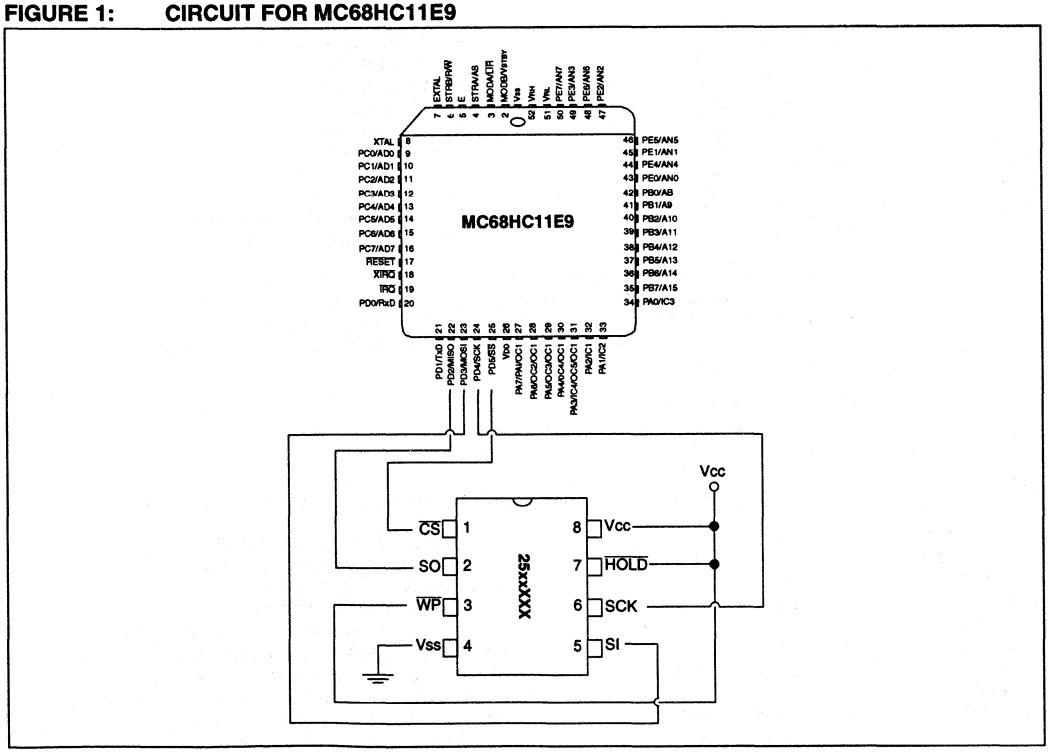
Interfacing Motorola 68HC11 to Microchip SPI™ Serial EEPROMS

Author: *Shannon Poulin*
Microchip Technology Inc.

INTRODUCTION



There are many different microcontrollers on the market today that are being used in embedded control applications. Many of these embedded control systems need non-volatile memory. Because of their small footprint, byte level flexibility, low I/O pin requirement, low power consumption, and low cost, Serial EEPROMs are a popular choice for non-volatile storage.

Microchip addresses these needs by offering a full line of Serial EEPROMs covering industry standard serial communication protocols for 2-wire, 3-wire, and SPI communication. Serial EEPROM devices are available in a variety of densities, operational voltage ranges, and packaging options.

Microchip realizes that its customer base is very broad, and because of this, different microcontrollers are used to interface to SPI Serial EEPROMs. One of the microcontrollers used in these applications is the Motorola 68HC11. In order to simplify the design process, Microchip has written an assembly code routine to communicate with our SPI parts that is verified and tested to function properly on a 68HC11.

Figure 1 describes the hardware schematic for the interface between Microchip's SPI devices and the Motorola 68HC11E9. The schematic shows the connections necessary between the microcontroller and the serial EEPROM, and the software was written assuming these connections. Appendix A contains a listing of the SPI source code.

APPENDIX A: SOURCE CODE

```
an646.asm               Assembled with CASM   03/19/1997  16:10  PAGE 1

                         1  ;*****************************************************************
                         2  ;* This code demonstrates how the Microchip SPI Devices
                         3  ;* can be interfaced to the SPI port of the 68HC11 microcontroller.
                         4  ;* The interface uses the three SPI lines (SCK,MOSI and MISO) on
                         5  ;* the 68HC11 Microcontroller for the clock (SCK), data out (SO)
                         6  ;* and data in (SI). A chip select (CS) is generated with a
                         7  ;* general purpose port line (PD5). The 68HC11 is placed into the
                         8  ;* master mode which allows use of the slave select input (SS) for
                         9  ;* other things.  The code uses the 0 mode (CPOL = 0,  CPHA = 0)
                        10  ;* of operation to define clock polarity and phase. MODE 3
                        11  ;* (CPOL = 1, CPHA = 1) could also have been used.  The  baud rate
                        12  ;* set at one eighth of the clock frequency (SPR0 = 0,  SPR1 = 0)
                        13  ;*
                        14  ;* This code shows a read and write operation, as well  as data
                        15  ;* polling, setting the write enable latch, clearing the  write
                        16  ;* enable latch, writing and reading the block protect
                        17  ;* register

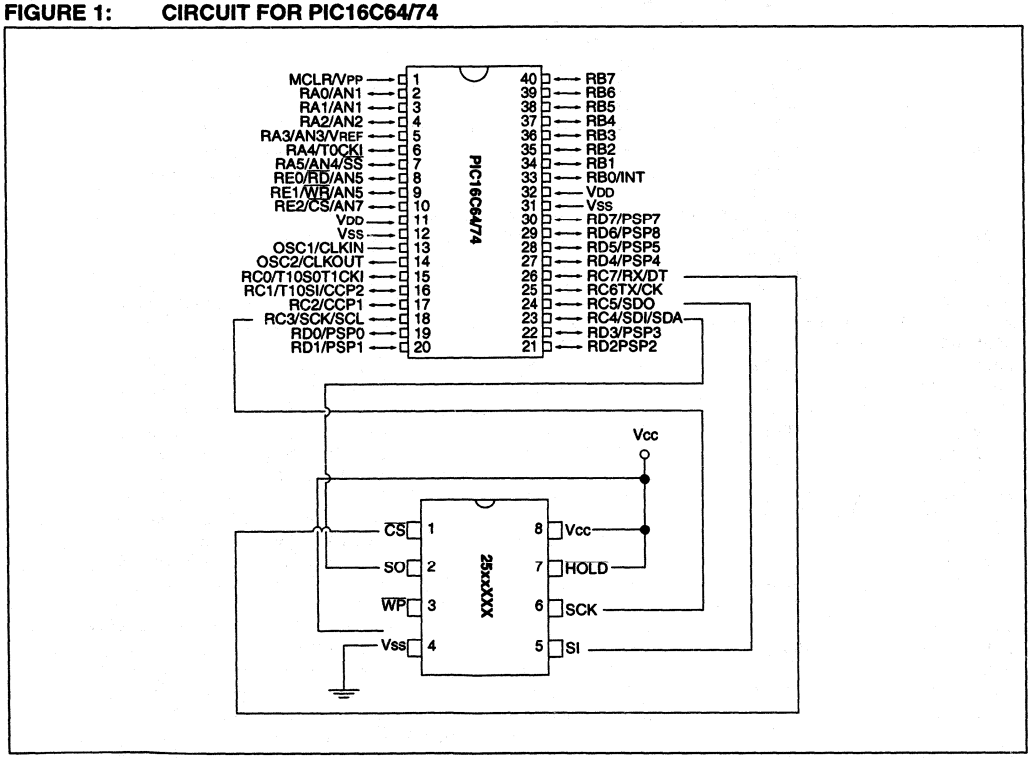
Interfacing Microchip PIC16C64/74 to Microchip SPI™ Serial EEPROMs

Author: *Shannon Poulin*
Microchip Technology Inc.

INTRODUCTION



There are many different microcontrollers on the market today that are being used in embedded control applications. Many of these embedded control systems need non-volatile memory. Because of their small footprint, byte level flexibility, low I/O pin requirement, low power consumption, and low cost, serial EEPROMs are a popular choice for non-volatile storage.

Microchip addresses these needs by offering a full line of serial EEPROMs covering industry standard serial communication protocols for two-wire, three-wire, and SPI communication. Serial EEPROM devices are available in a variety of densities, operational voltage ranges, and packaging options.

This application note provides assistance and source code to ease the design process of interfacing a Microchip mid-range PIC16C6X/7X microcontroller and a Microchip SPI serial EEPROM. The hardware SPI port on the microcontroller provides a simple three-wire connection to the EEPROM and no external "glue" logic is required

Figure 1 describes the hardware schematic for the interface between Microchip's SPI devices and the Microchip PIC16C64/74 Microcontroller. The schematic shows the connections necessary between the microcontroller and the serial EEPROM, and the software was written assuming these connections. Appendix A contains a listing of the SPI source code.

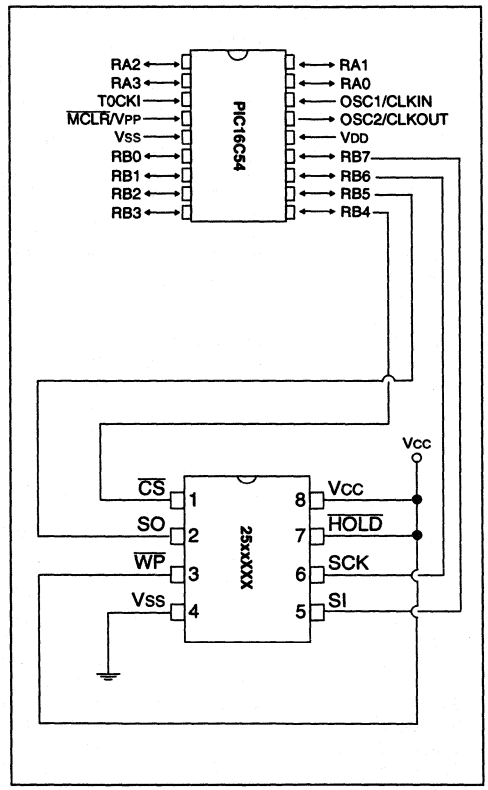
Interfacing Microchip PIC16C54 to Microchip SPI™ Serial EEPROMs

Author: *Shannon Poulin*
Microchip Technology Inc.

INTRODUCTION



There are many different microcontrollers on the market today that are being used in embedded control applications. Many of these embedded control systems need non-volatile memory. Because of their small footprint, byte level flexibility, low I/O pin requirement, low power consumption, and low cost, serial EEPROMs are a popular choice for non-volatile storage.

Microchip addresses these needs by offering a full line of serial EEPROMs covering industry standard serial communication protocols for 2-wire, 3-wire, and SPI communication. Serial EEPROM devices are available in a variety of densities, operational voltage ranges and packaging options.

This application note provides assistance and source code to ease the design process of interfacing a Microchip PIC16C54 microcontroller and Microchip SPI serial EEPROMs. The connections will be made using port pins from the microcontroller to interface to the memory device. Bit manipulation will be used to provide the proper logic necessary to write and read the part.

Figure 1 describes the hardware schematic for the interface between Microchip's SPI devices and the Microchip PIC16C54 Microcontroller. The schematic shows the connections necessary between the microcontroller and the serial EEPROM, and the software was written assuming these connections. Appendix A contains a listing of the SPI source code.

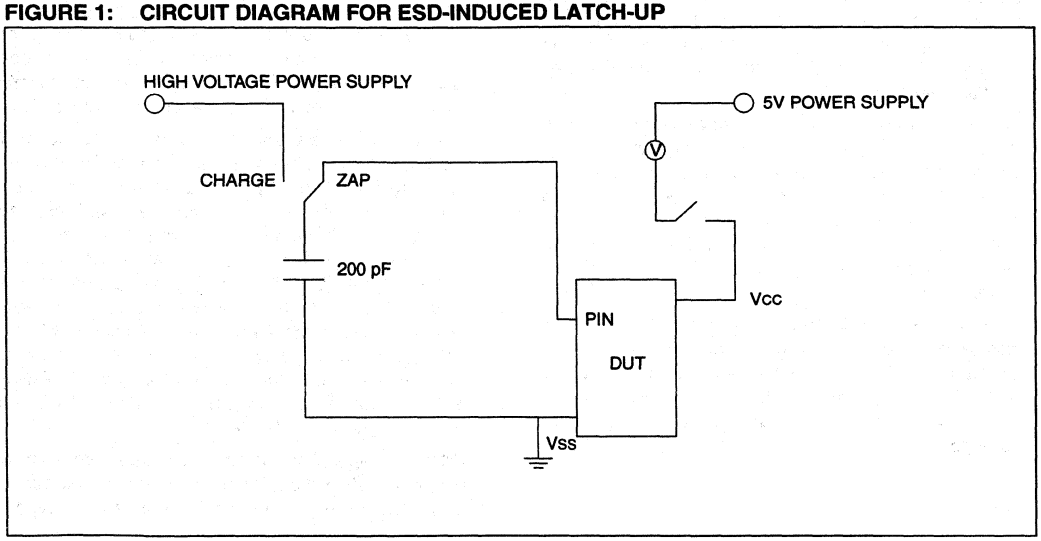
Improving the Susceptibility of an Application to ESD

Author: *David Wilkie*
Microchip Technology

INDUCED LATCH-UP

All semiconductor devices are sensitive to electrostatic discharge (ESD) damage to varying degrees. This is true whether they are soldered to a PC board in an application, or whether they are unattached in the shipping or application assembly process. Good handling techniques such as groundstraps, static free work stations and ionizers can reduce the risk of static build up during assembly. Often more attention is paid to reducing ESD during assembly than is paid to reducing ESD risk during the lifetime of the application.



When a device is installed in an application, it is still susceptible to damage due to ESD. This can take on a different form when the application is powered up and running. If power is supplied to a CMOS device such as a memory product or a microcontroller when an ESD event occurs, the device can be triggered into a "latch-up" condition. This is a high current mode where internal circuitry can be disturbed into making a short circuit (or a circuit with very low resistance) between power (Vcc) and ground (Vss) on a device. This condition is self-sustaining; it does not require subsequent ESD events to continue the latch-up condition.

This short circuit will tend to reduce the voltage level on the application (particularly if the application is battery powered) and will do a great deal of damage to the device which has latched-up. The only way to halt this condition is to remove power from the device.

Microchip uses careful design practices to reduce the susceptibility of all products (microcontrollers or memories) to ESD events. However, the protection level varies from pin to pin, reflecting the different functions of each pin. Certain types of pins (notably supply pins) are much more susceptible to latch-up caused by ESD pulses than other pins. This is due to the different design and layout considerations that reduce the effectiveness of ESD protection.

There is a great deal that the system designer can do to improve (by up to an order of magnitude) the level of protection of a device from latch-up inducing ESD events. This tutorial is intended as a guide for helping designers choose protection. This type of protection is application dependent, so consideration should be made of the type of environment that the application, or the device, will be in.

ELECTROSTATIC DISCHARGE

Electrostatic discharges can come from a variety of sources. The traditional ESD pulse is caused by a body at very high potential coming into contact, or near contact, with a grounded object. This could be a human body, a piece of electrical equipment, or even a piece of furniture.

In a dry environment, where static dissipation is low, a human body can develop tens of thousands of volts of potential. Almost everyone has experienced the shock of walking across a new carpet and touching a door handle. An audible snap can be heard when the potential difference between the person and the door handle is around 5,000V.

Any piece of equipment which has metal components moving against other metal components can develop a charge. An automated device handler will generally have a metal tray where devices move around, with pins in occasional contact with the tray. Static build up can reach hundreds of volts and can damage the devices in the same way as an ungrounded human handler can.

Incorrectly placed ionizers, meant to improve static dissipation, can build large potentials on office or laboratory furniture. Any person touching such a piece of furniture might feel a shock. Any devices being placed on a table with a large potential can suffer damage.

All these situations can be avoided by careful handling procedures. Groundstraps for manual handling of devices is essential, as are grounded tables and work surfaces with anti-static surfaces such as metal or specially designed plastic mats. Equipment can be carefully grounded wherever the potential exists for static build up.

ELECTROSTATIC DISCHARGE IN A POWERED APPLICATION

Once the device has been mounted to a board or installed in an application, most types of ESD events will no longer occur. For example, unless the PC board is out in the open, it is very unlikely to be touched by the user, and so a direct ESD pulse will not be a concern.

However, there are several sources of indirect ESD pulses, or noise pulses which are very similar in nature and magnitude to ESD pulses. ESD pulses can induce currents in nearby wiring. So, for example, if the user creates an ESD event on the casing of an application, the magnetic field of the pulse can induce currents inside the casing, in the wiring of an application. This electromagnetic interference can occasionally be seen in other ways, such as a noisy TV picture when a vacuum cleaner is being used, or a "click" heard on the radio when a light switch is turned on. This type of event is often called Radio Frequency Interference (RFI) or Electromagnetic Interference (EMI).

Often the application itself can induce noise spikes during operation. If one component in that application is a high speed, high current transistor or other type of

© 1997 Microchip Technology Inc.

switch, the sudden change in current can induce a noise spike which could be seen by that component, or other components in the system. This switching noise is endemic in systems with metal wires, and can not be removed completely. Large magnitude pulses of switching noise can induce latchup on sensitive CMOS devices.

The effects of switching noise or EMI can be catastrophic to an application with sensitive components. Even components which are not particularly sensitive or already have some built-in protection (such as Microchip Technology Inc.'s products) can still be latched-up by noise pulses if they are of a large enough magnitude.

PROTECTING AGAINST ESD PULSES

Basic protection can be provided by a simple decoupling capacitor, placed as close as possible to the power and ground pins of components. Each component should have its own capacitor; simply decoupling the whole application at the supply points will not be sufficient if a component in the application is producing noise.

If the value of the capacitor is chosen to match the device, then non-supply pins can also benefit from a decoupling capacitor between power and ground. A single capacitor can not filter out all the frequencies associated with a noise spike, but it can still offer very effective and low cost protection.

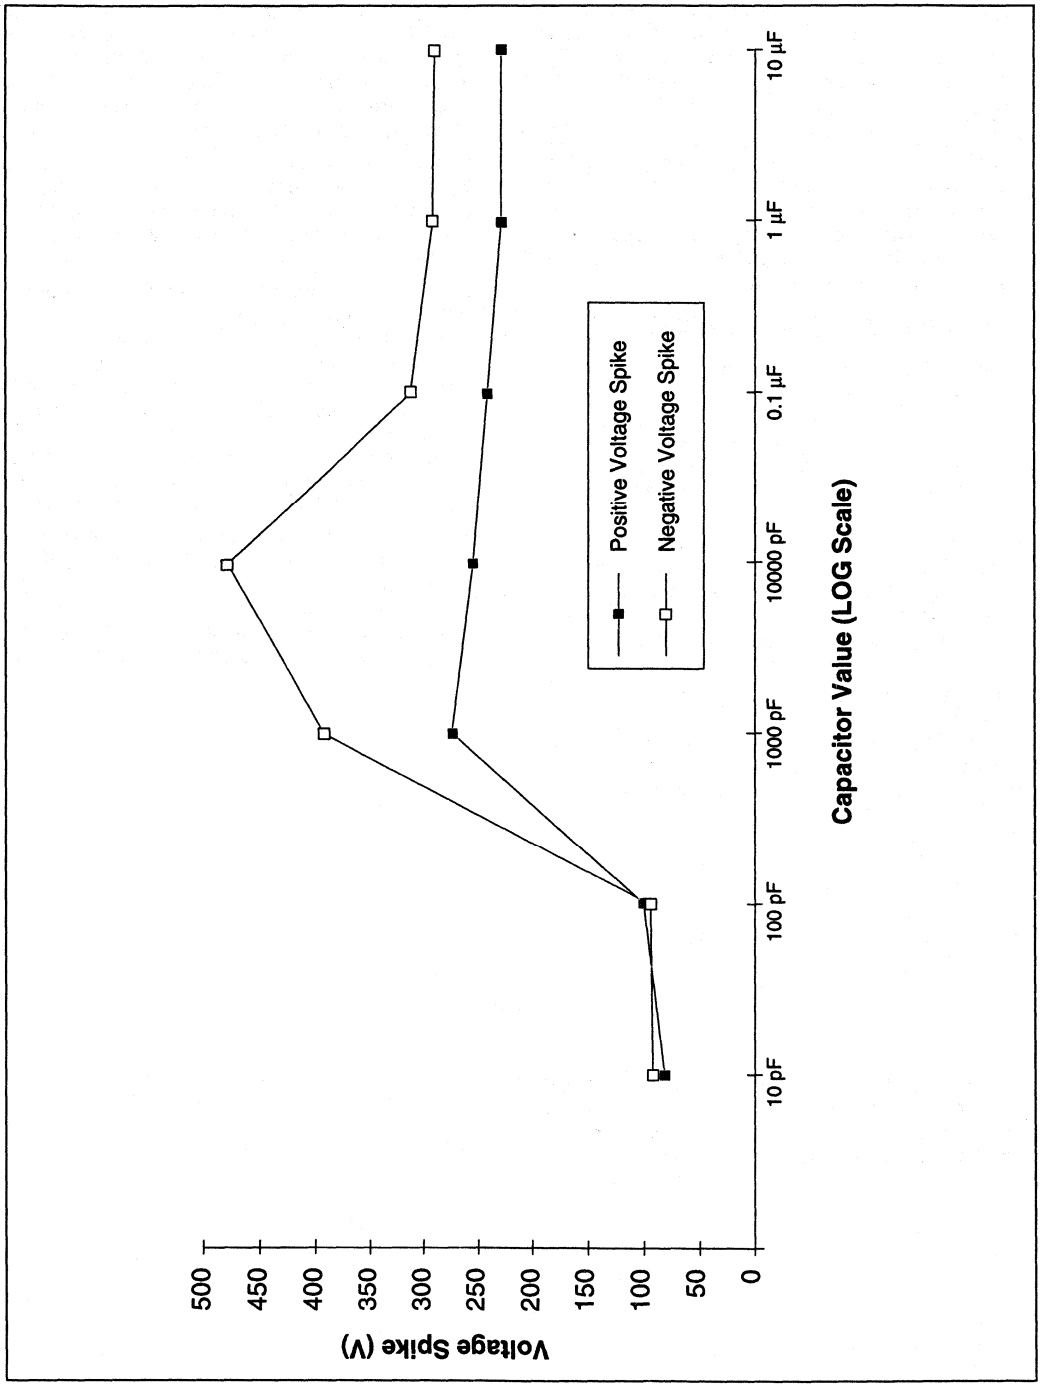
We used a simple test circuit to accurately model an ESD-induced noise spike. The test circuit is shown in Figure 1. A 200 pF capacitor was charged to various voltages and then switched to discharge directly into the device being tested. The waveform is a high frequency (≈14 MHz) and short period (≈100 ns) decaying oscillation. The resulting waveform, measured through a Tektronix CT-1 current probe with a 10X attenuator, is shown in Figure 2. The testing was conducted at 25°C.

The period of the oscillation is governed by the relationship:

$$\omega = \sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}}$$

where L, C, and R are the inductance, capacitance, and resistance of the oscillating circuit, and w is the frequency of the oscillation. Since R and L are very small, and C is 200pF, the oscillation period is very fast.

Two devices were tested. A typical serial EEPROM, the 24LC04B, was tested on all function and supply pins. The results, shown in graphical form (Figure 3 through Figure 7) show that, even with a capacitor placed between power (Vcc) and ground (Vss) other pins, such as SDA can have increased protection. From the figures it is clear that the best all-round protection can be obtained from a 10,000 pF capacitor.



Particular applications may be different. For example, the designer may know that there is a better chance for a noise spike on the SDA signal, and so may want to use a 1,000 pF capacitor to improve the protection level of SDA.

A PIC16C54 microcontroller in XT mode was tested on all functional and supply pins. The results are shown in Figure 8 through Figure 17. From these results, it is clear that the particular application environment will be much more important in determining which capacitor value to use. Some pins, such as $\overline{\text{MCLR}}$, do not respond at all to a decoupling capacitor. Others, such as the RA ports, respond strongly to a capacitor. Note that for the RA and RB graphs, the pin with the lowest latch-up threshold was used. All other pins are higher.

It is important for the designer to be aware of the potential problems associated with noise in a powered application. A combination of using sound design techniques to reduce causes of noise and an awareness of the protection levels of the components being used can make the problems of ESD manageable.

Plastic Packaging and the Effects of Surface Mount Soldering Techniques

Author: *John Barber*
Microchip Technology Inc.

PURPOSE

This application note is intended to inform and assist the customers of Microchip Technology Inc. with Surface Mount Devices (SMD's). The process of packaging a semiconductor in plastic brings to pass a somewhat unlikely marriage of different materials. In order to minimize potential adverse effects of surface mount solder techniques, it is worthwhile to understand the interaction of the package materials during the time they are subjected to thermal stress. Understanding both the limits of thermal stressing that SMD's can withstand and how those stresses interact to produce failures are crucial to successfully maintaining reliability in the finished product. A recommended Infrared (IR) solder profile is provided as a reference later.

The electronics industry has moved to smaller and thinner surface mount packaging in the progress toward miniaturization of circuits. This trend has necessitated the use of lower profile and smaller footprint packages. There has been an increase in reliability problems corresponding with the shrinking size of plastic SMD's. These problems manifest themselves in such ways as moisture sensitivity, cracked packages, open bond wires and intermittent continuity failures. Problems of this type are not present in the devices prior to assembly onto printed circuit boards but are the result of thermally induced stressing to the part during assembly or any rework such as desoldering.

WHAT CAN HAPPEN DURING THE SOLDER PROCESS

In surface mount soldering both the body and leads are intentionally heated. This direct heating of the reduced sized device package is at the heart of the problems experienced with Surface Mount Technology (SMT). Older techniques were concerned with the heating of the leads only. Some degree of heating was present in the body due to the thermal conductivity of the leadframe but this did not produce the same level of stress that devices are now subject to with SMT.

The heat from soldering causes a buildup of additional stresses within the device that were not present from the manufacturing process. Board level solder processes, such as IR reflow and Vapor phase reflow, are well-known areas where temperatures can reach levels sufficient to cause failure of the package integrity. A plastic semiconductor package forms a rigid system where the various components are locked together. Differences in the physical expansion rate of materials will result in internal package stresses because the constituent parts cannot move. When a package is heated, the stresses in the device are applied to the die in such a way that the maximum areas of stress[1] are at the corners. Forces can build to the point where the areas of adhesion between different components of the package give way causing device failure. Failure modes associated with excess stress include delamination of surfaces, fracturing of bond wires, die cracking, cratering of bond pads and package cracking.

Moisture sensitivity of plastic packages has been a concern for semiconductor manufacturers. Moisture can and will permeate any molding compound. The rate of permeation will vary with package compound thickness and type. Relative humidity will also play a role in the time required to saturate a device.

Moisture content will affect the ability of a device to withstand the stresses of surface mount soldering. If sufficient moisture is present inside of a device during soldering, high temperatures can cause steam which has the potential to crack the package. This type of damage is commonly called "pop-corning"[2].

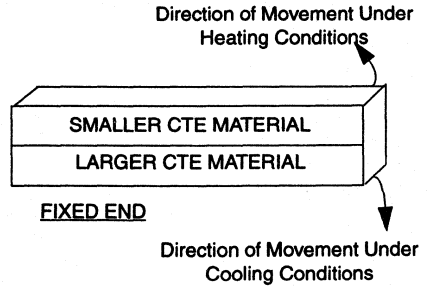
Moisture can lead to corrosion of exposed aluminum metallization inside the device. Fortunately, a film of water is required[3] for corrosion to take place. Water vapor alone is not sufficient to produce the onset of corrosion. It is difficult to collect a film of water inside a package where there is no defect.

Chemical compatibility is important to control corrosion of aluminum (especially in the presence of moisture). Most molding compounds and die attach epoxies contain free ions that can lead to corrosion under conditions where moisture is available to support the chemical reaction(s). Careful selection and handling of materials minimize the number of chemical impurities in the device that could lead to corrosion.

© 1997 Microchip Technology Inc.

MATERIAL INTERACTIONS

To understand the significance of what is happening to a device during solder reflow, it is necessary to understand something about a few specific material properties and how those properties interact. Physical properties of interest[4] are listed for reference in Table 2. These properties will be defined as needed to explain various concepts.



There are five major components used in a plastic package. Basic package components are: (1) epoxy molding compound, (2) leadframe made of copper or Alloy 42, (3) die attach epoxy, (4) silicon die and (5) gold bond wires. Molding compounds have several significant contributing factors that define their performance. These must be considered by the manufacturer when a selection is made. These items are Temperature of Glass Transition (Tg), Coefficient of Thermal Expansion (CTE), moisture absorption characteristics, flexural modulus and strength, and thermal conductivity. In reality, molding compound suppliers provide the test bed for development of compounds, only a few of the very large semiconductor manufacturers have published data[5] suggesting independent experimentation into this area. Leadframes used by Microchip are copper with a silver plated area for die attach and wire bonding. Die attach material is typically a silver filled epoxy. The silver is added for thermal and electrical conduction. Plastic devices have gold bond wires.

Thermally induced transients generated during surface mount soldering can have a significant impact on the reliability of plastic encapsulated devices in the field. In most cases, thermal transients below 125°C are not of sufficient magnitude to cause damage to the part. As a device experiences a significant thermal transient, such as would result from IR reflow soldering, the differing materials expand and contract at unequal rates. The CTE describes the behavior of a material as it expands or contracts when subjected to a temperature change. Materials with similar expansion coefficients will have similar thermal behavior if the phase boundaries are not approached. The CTE characterizes performance over a given temperature range. Table 2 shows that there is a change in the coefficient (ΔCE) of roughly 12.9 (16 - 3.1 = 12.9) between a copper leadframe and silicon, and a ΔCE of 4.4 (7.5 - 3.1 = 4.4) between silicon and lowest stress molding compounds available. The rate of expansion and contraction is not a simple linear relationship with temperature change. The rate can vary dramatically with the phase of the material. For example, molding compounds will greatly increase the rate of expansion when temperatures above the Tg is reached.

In general terms, Tg is the temperature where the material changes from a solid to something more like a plastic or vice versa. More precisely, the temperature of glass transition would be the temperature at which atoms, in chains of 30 to 40 atom groups, start to move. Generally, Tg is in the area of 170°C for molding compounds. Several factors affect Tg such as the basic formulation of the resin from the supplier, cure time and the temperature used in the manufacturing process. A common misconception when trying to relate to these concepts is to assume that the entire package is at the same temperature at any given moment in time. This is not the case.

To aid in understanding the effects of CTE mismatching, take, for example, a bi-metallic strip. They can be found in every automobile and are used in turn signal flasher units for controlling the flashing action of the lights used as turn indicators. Inside the flasher unit the contact arm is formed by use of a bi-metallic strip to make and break electrical contact.

The metals used in the construction of a bi-metallic strip have different CTE's and are specifically chosen to produce a desired effect. These two materials are bonded so that they move together. In the automobile example, current flowing through the bi-metallic strip causes local heating of the strip. Due to the unequal CTE's, the strip will bend away from the contact as it is heated which causes the circuit to open. When current stops flowing in the strip, heating also stops. The bending action of the strip is produced by unequal expansion on one side of the strip. As the strip cools, it will move back thus making contact again allowing current induced heating which starts the cycle over again. In similar fashion as bi-metallic strip, the die in a plastic package will be stressed when subjected to a thermal transient.

Adhesion of materials is a matter of importance since it is in areas of delamination that moisture can collect. The collecting of moisture can lead to corrosion problems.

Differing rates of expansion and contraction can make joining two materials a distinct challenge. Especially if the materials are significantly different in other characteristics that affect surface adhesion. Some materials that are not suitable for use in the packaging system require special adhesion promoting modifications of the surfaces. The topic of adhesion is beyond the scope of this work, but is an important factor and should be given careful attention[6].

© 1997 Microchip Technology Inc.

The property known as "Fracture Toughness" is the ability of the material to resist the propagation of a fracture once the defect has been initiated. Silicon has a very low fracture toughness, therefore, a fracture will readily propagate in silicon. An example of a material at the other end of the spectrum would be Gold, one of the ductile metals, which has a high fracture toughness. This property is responsible for the tendency for glass or tungsten carbide to shatter rather than simply chip or crack. In semiconductor devices, fracture toughness should be considered when cratering and die cracking are a problem.

The closest point to a zero stress state in a plastic package is at the temperature used to cure the molding compound (≅175°C). Present plastic molding compounds are thermosetting polymers. Thermosetting means that the compound sets up and becomes hard as a result of being heated. A cooling cycle after the set up period does not undo the process. The molding compound is held at an elevated temperature for the time period required to harden or cure. During the subsequent cooling, after cure, stresses are trapped in the package because of the differing CTE's. This trapping of stress results in a net compressive force, at room temperature, on the die surface in a plastic molded device. As external stresses such as thermal stress from soldering are presented, if stresses are of sufficient magnitude, the material strength will be exceeded resulting in package damage. Manufacturing processes tend to leave stresses trapped inside the devices. Thickness of the die attach material is regulated to control stressing levels due to its presence. A thin die attach will result in higher tensile stress on the die surface after die attach. The interaction of the die attach material and the molding compound result in the compressive stress on the die surface[7] after packaging. Low stress molding compounds are used on SMD's to minimize the thermal stresses generated during soldering operations.

FAILURE MODES AND MECHANISMS

Let us now review the types of damage that may be seen as a result of SMT soldering. Package damage may be manifested in several ways and may not always result in immediate device failure. Following is a list of failure types and their morphology:

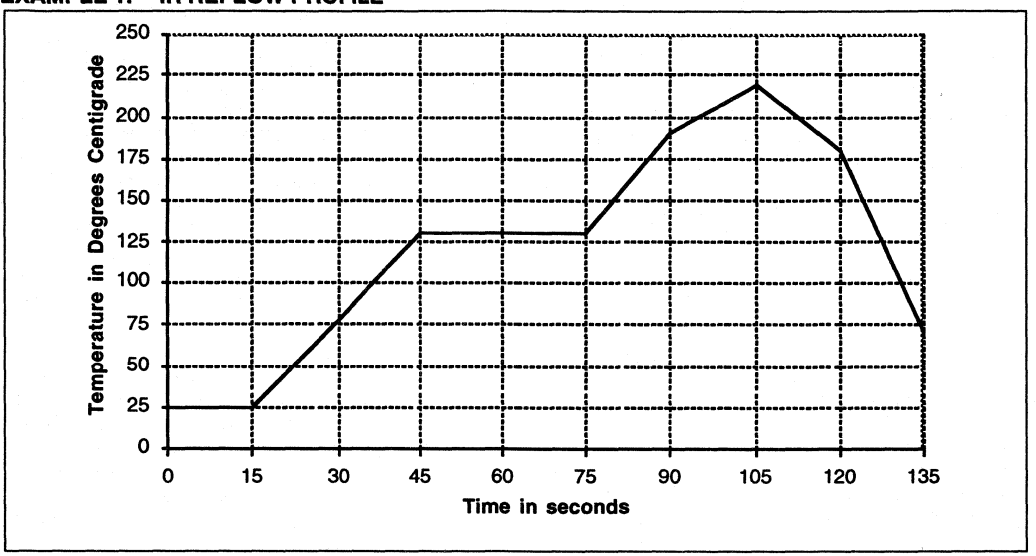
1. Delamination of the molding compound along the leadframe interface and or die surface can take place. This delamination, or separation, can provide a path for moisture and contaminant ingress and pooling along the interfaces where the materials are no longer adhering to each other. This condition may lead to corrosion related problems[8].
2. Cracking of the mold compound can produce immediate failure if the crack crosses a bond wire or it can allow similar moisture effects[9] as in delamination. It can also produce intermittent contact problems.
3. Cracking of the die is generally seen as a functional failure but can be temperature sensitive if the crack is in a more benign area of the die.
4. Cratering of wire bonds is characterized as a phenomenon where portions of the silicon below the ball bond are fractured. The ball bonds pull up "plugs" or "chunks" of silicon, thereby, leaving crater shaped damaged spots in the bulk silicon below the bond pad. Cratering is a possible result of lateral stress on ball bonds. A cratering failure will typically but not always show up during electrical testing. However, it can lay dormant until another temperature excursion comes along which causes the Al metal conductor (bond pad) to open. This is a result of the soft nature of the aluminum used for interconnects in semiconductor devices. The silicon below a bond pad can be damaged without breaking contact in the aluminum. Intermittent or thermally sensitive continuity failures may be produced.
5. Moisture inside the device may collect in the die attach, along material interfaces (primarily leadframe to mold compound and leadframe to die surface) or in the molding compound. Rapid heating causes pressure build up as the moisture expands. This results in delamination and cracking of the package along with the failure modes associated with those phenomena.
6. Corrosion is heavily related to moisture effects and is intensified by delamination and cracks. The typical failure mode for corrosion is loss of continuity since the area most often affected is in the bond pads where there is no passivation layer to give additional protection to the metal.

HOW TO CORRECT THIS PROBLEM: A CASE STUDY

After the device leaves the factory there are two things that need to be done to maintain reliability.

1. The exposure to thermal stressing needs to be minimized. This is not always an easy task in light of the varied components that may go onto a single board. Some will require different conditions to solder due to there bulk size.

   Microchip carried out a partial factorial experiment on 32-lead PLCC devices with the intent of verifying an industry standard profile and providing a specification for our various customers. The devices were subjected to IR solder reflow profiles with ramp rates ranging from 1.5°C/second to 4°C/second and maximum temperatures from 220°C to 310°C (Table 1).



© 1997 Microchip Technology Inc.

TABLE 1: 32-LEAD PLCC PACKAGE PARTIAL FACTORIAL EXPERIMENT

Variables used in the analysis	Conditions

R = Ramp Rate (C/second)	1.5	2	3	4				4
P = Number of Passes	1	2						2

56 Total Conditions

EXAMPLE 1: IR REFLOW PROFILE

1. (Continued)

No drypack state was employed and the parts were allowed to sit on the shelf in excess of 30 days prior to temperature exposure. The RH of the room was not recorded but is estimated to be approximately 60%. This condition was employed to insure that worst case conditions were evaluated.

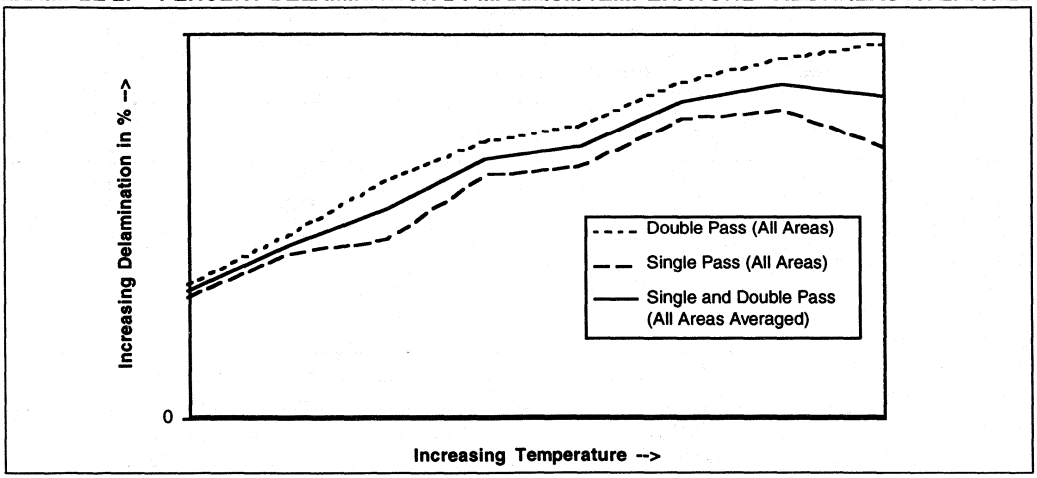
Our experiments, to determine optimum soldering temperatures, indicated that a maximum temperature of 220°C should be observed during solder processing. The temperature ramp rate was found to be a less significant factor but should be kept in the range of 2 to 5°C per second. Very slow ramp rates, i.e. those of less than 2°C per second, show a slight decrease in performance. Ramp rates of 3°C showed the best performance and should be used whenever possible. Results from the experiment independently confirm the exposure recommendations set forth in IPC-SM-786[10]. A sample profile for IR reflow is illustrated by the graph in Example 1.

Prior to exposure to the IR temperature profiles all parts were electrically good and were examined by Scanning Acoustic Microscopy (SAM) to verify a defect free state and establish a baseline. After exposure to the IR profiles, all parts were again tested electrically and examined via SAM. Delamination can be easily detected by use of SAM. No package cracks were observed after temperature exposure. Only limited electrical failures occurred and all were at temperatures above 220°C.

In the experiments a thermocouple was interfaced to the exterior of a device and passed through an IR reflow oven. Both the maximum temperature and ramp rate were recorded in this manner. General trends for temperature sensitivity in relationship to maximum temperature and ramp rate are presented in the graphs shown in Example 2 and Example 3.

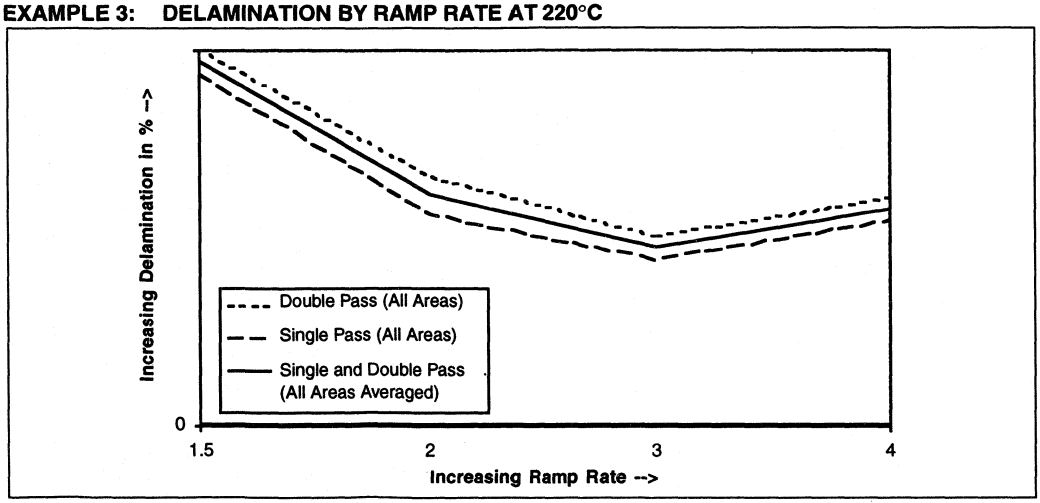
Pass/fail criteria for the experiments was primarily the extent of delamination, observed by Scanning Acoustic Microscopy, after exposure to two passes through an IR reflow oven. Top side die delamination and delamination in areas of the leadframe where the bonds are made are classed as unacceptable. Some delamination along non critical areas are classed as acceptable (i.e., no delamination extending to the exterior of the

© 1997 Microchip Technology Inc.



package or covering more than minor portions of the leadframe). Specific information on pass/fail criteria can be found in IPC - SM - 786.

Maximum temperature should not exceed 220°C.
Temperature ramp rate should be between 2 to 5°C per second.



Use of the above temperature profile will increase the reliability of the device following board level assembly.

2. The second item that must be observed is the dry packing of SM devices. Dry packing is a standard product packaging procedure for surface mount devices. This practice guarantees to the customer that devices are shipped in a dry state. All devices are sealed inside plastic bags with a moisture indicator to monitor moisture when they are shipped. Customers should be aware of this practice and maintain the dry packed state until the time of use. Shelf life[11] for opened parts is a function of package style and ambient conditions. A small increase in failure rate will be experienced if the drypack condition is violated.

© 1997 Microchip Technology Inc.

CONCLUSION

Significant thermal stressing can cause a diverse list of package or device failures. To minimize any damage caused by high temperature exposure, moisture content needs to be controlled in electronic devices.

Experiments conducted by Microchip validate the recommendation of IPC - SM - 786 to limit maximum temperature exposure during surface mount soldering to 220°C. A temperature ramp rate of 2°C/second to 5°C/second will also serve to safeguard the reliability of the device.

Microchip is committed to the principles of continuous improvement. Product reliability and customer satisfaction are a primary focus. For this reason, new packaging technology enhancements are continually evaluated to improve the performance of Microchip devices.

TABLE 2: PHYSICAL PROPERTIES OF COMMON MATERIALS USED IN PLASTIC PACKAGING OF SEMICONDUCTOR DEVICES

Material	Coefficient of Thermal Expansion in 10^6/°C (CTE)	Temp. of Glass Transition in °C (Tg)	Modulus of Elasticity in 10^6 psi (10^3 MPa.) (E)	Tensile Strength in 10^3 psi

Microchip Technology Inc.

INTRODUCTION TO MICROCHIP'S CULTURE

The corporate culture at Microchip Technology Inc. is embodied in our *Guiding Values*. This culture has been key to our success in business because of its emphasis on customer satisfaction, quality, continuous improvement, empowerment and communication. The synergy of these values has created a very dynamic, very successful culture. They have impacted many aspects of Microchip, including the EEPROM Technology Team. Two of our *Guiding Values* in particular have steered this group.

Continuous Improvement is Essential

We utilize the concept of "Vital Few" to establish our priorities. We concentrate our resources on continuously improving the Vital Few while empowering each employee to make continuous improvements in their area of responsibility. We strive for constructive and honest self-criticism to identify improvement opportunities.

Products and Technology Are Our Foundation

We make ongoing investments and advancements in the design and development of our manufacturing process, device, circuit, system, and software technologies to provide timely, innovative, reliable, and cost effective products to support current and future market opportunities.

We recognized in the late 1980's that the industry as a whole did not have great endurance on EEPROMs. We were no exception. And this was at a 10,000 E/W cycle level, which is orders of magnitude less than where we are today. We also recognized that there were many uncertainties in the interaction of design, process and customers applications with respect to endurance performance and expectations. It was also clear that the customers were not educated enough on these interactions to be able to say clearly what they needed in a product. This was clearly an "improvement opportunity" that could allow us "to support current and future market opportunities."

THE EEPROM TECHNOLOGY TEAM

Microchip had been using the team approach to problem solving and continuous improvement activities such as new product introduction in the development groups and defect reduction in the manufacturing area. These had been in place for some time, and were beginning to work extremely well in bringing fast, well thought out and researched solutions to problems that crossed organizational boundaries.

A cross functional team was formed at Microchip that would be the technology management for an entire family of products. The team was comprised of engineers from design, process, test, product, quality, reliability, and yield enhancement, who reported in to different functional groups in the regular organizational structure. This team was charged with setting the technical direction for all EEPROMs at Microchip. This included both areas of development and sustaining, which were always in competition for the same resources.

The Microchip EEPROM Technology team went through the typical early phases of team development. The initial elation of having a great group of technical contributors wore off after a while. The competition for resources lead to some rough areas at the start, but this was overcome with the help of management support and direction. A balance developed, where the development side really understood the need to improve yields today, while the sustaining side understood the need for new products and innovations for the future. The emphasis on the Guiding Values and strong support from management for the team concept greatly helped the group through the early phases.

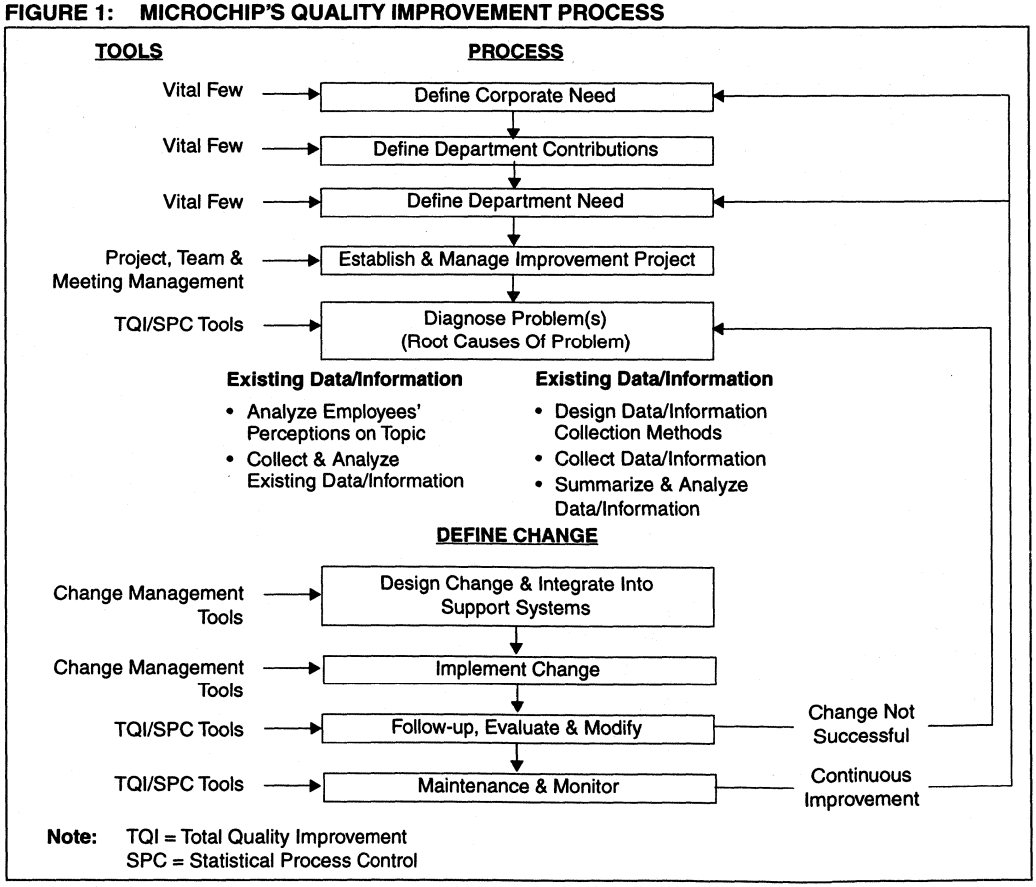
THE PROCESS



There is a team training program at Microchip that teaches high performance team leadership, and provides training on a set of tools for teams to use. These tools are aimed at improving the teams ability to identify problems, more importantly to identify the real root causes of the problems, to use the Pareto and other techniques to establish the "Vital Few", to brainstorm ideas on solutions, to investigate solutions prior to implementing, to execute implementations smoothly and accurately, to follow-up to ensure that the fix is as expected, and to re-examine the process to see what other improvements are needed. The key elements of this process are shown in the flowchart (Figure 1).

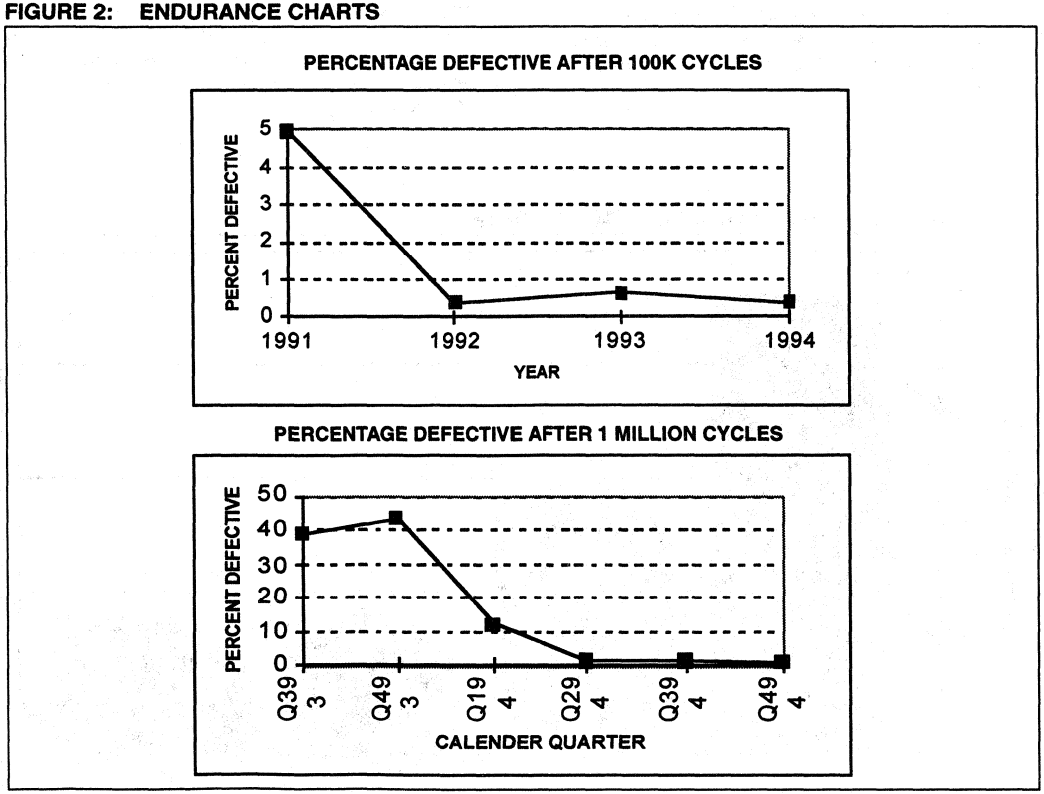
This process lead to improvements in every area of Microchip's EEPROM technology: design, process, product, test, quality, reliability, and yield. Most of these changes are confidential and proprietary, and several have been patented. These can only be discussed here in general terms.

The actual EEPROM cell design has been the subject of repeated studies. There have been improvements made to the original that have increased process tolerance, increased yield, and of course dramatically increased endurance performance. "Repeated studies" sounds as if we did not get it right the first time, but in fact is just an acknowledgment that continuous improvement is essential. We have the best design in the industry today, but the EEPROM technology team is still working on improving it.

The process also has gone through many iterations of improvement. During some of the early studies, it was determined that new equipment with better control was needed to ensure the reproducibility of the product. This equipment was purchased, installed, and carefully monitored based on the recommendation from the team. We saw the expected improvement as a results. There have also been ongoing studies to improve control, reproducibility, and defect reduction in many other areas of the process.

FIGURE 1: MICROCHIP'S QUALITY IMPROVEMENT PROCESS

© 1997 Microchip Technology Inc.



Improvements to the product itself have often shown up in the data sheet. These include reduction in current consumption, or improved timings as a result of improved design as verified by characterization on test equipment. We have greatly expanded the package variety for our Serial EEPROMs as a response to market needs. These activities have all been prioritized by the team with management input, evaluated, and implemented by the team.

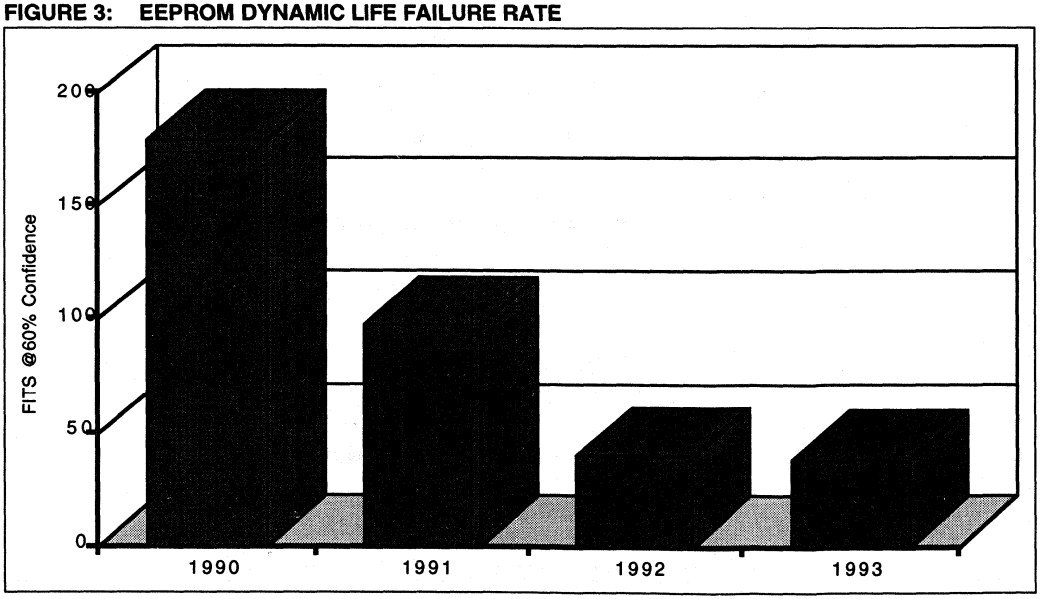
The example of a new package introduction highlights the value of the team. A new package requires new test hardware, verification of the test program with the package and hardware, qualification of the package with the reliability group, assurance of acceptable yields based on the yield enhancement engineers involvement, and continued monitoring of the final products outgoing quality. Other companies often have these disciplines separated, with communication by memos back and forth. This is a cumbersome way to do business, and often details are overlooked, or the opportunity for synergy between groups to go the extra step is lost.

Testability is a vital concern for microelectronics. As the feature set grows, the ability to test them accurately can be lost. The introduction of the 64K-bit Serial EEPROM, with its security block and programmable endurance options, presented a concern for testability. By having even the initial design objective discussions in the team environment, with a test engineer, the designers were able to ensure that the new features could be tested thoroughly and cost effectively. This greatly improved our time to market, as well as the quality of the part that reached our customers.

The quality group has been a tremendous contribution to the success of the team. There were initial concerns on some members parts that this group would hold back progress by acting as "policeman" for the status quo. Quite the opposite, the quality group brought the statistical ability to measure the results of proposed changes with accuracy and confidence. So changes that really lead to improvement were actually implemented more quickly than they might have been without quality engineering input at the beginning. The team was also able to move on quickly from proposed changes that did not give measurable improvement as a result of having these measurement tools.

FIGURE 2: ENDURANCE CHARTS

8



The quality engineering group is also more directly exposed to customer needs than some of the other groups. They heard first hand what some of the areas for improvement were from the field. These inputs were brought directly into the team environment, where the breadth of engineering expertise we had was able to apply Microchip's Quality Improvement Process to them.

The dramatic improvement to the endurance performance of Microchip's Serial EEPROMs was a direct result of the reliability group's involvement with the team. This group was able to establish standard methods for testing and measuring endurance on products. This was the first step in determining that this was another area for continuous improvement. Inputs from the business unit were that this was going to develop into a critical point of competition in the industry. We found out later that our standards were significantly higher than most competitors. The reliability group set up competitive analysis and bench marking between vendors that put us on a level playing field. We found that Microchip's endurance was much better than we thought! Even so, the Microchip EEPROM Technology team drove programs for improving endurance that gave impressive results (Figure 2). And the elimination of the root causes of endurance problems gave equally impressive gains in other areas of reliability. This is shown is the reduced failure rates for both dynamic life testing and retention bake (Figure 3 and Figure 4).

The group also kept one eye on the bottom line through the years. Yields have always been a concern, since continuous improvement in that area is also vital to the business. The yield enhancement engineers, like the other groups, brought tools with which to measure and identify problems. As with the others, they were dependent on the rest of the team to help find and implement solutions. They also acted as a conduit to the front end teams that were implementing defect density reduction and process control improvements in the manufacturing process across product families. This coordination between the teams lead to a whole new level of synergy that allowed other products to benefit from improvements from the EEPROM team, and the EEPROM product line to piggyback on improvements aimed primarily at other areas. These other teams were focused on plant wide areas of continuous improvement: oxide integrity, the poly-silicon modules, the metal modules, defect reduction, wafer handling techniques, etc. The result of this cross functional synergy is shown is the yield trend (Figure 5).

As we grew and learned together, each member developed increasing respect and trust for the others. This was critical to the team's development. Not all of the proposed changes were successful. In the stages of implementing, follow-up, and maintenance, some proposals did not hold up. Either they did not really fix a root cause, or the implementation caused other problems to surface. Only by having established respect and trust was the team able to raise and address these issues quickly.

FIGURE 3: EEPROM DYNAMIC LIFE FAILURE RATE

© 1997 Microchip Technology Inc.

THE RESULTS

The improvements to both areas that this team has made are spectacular. At the time of formation, the industry standard was 10,000 E/W cycles of endurance, and 4K bits of memory. The Microchip lead the world when the efforts of the team lead to introducing:

- The first 10,000,000 E/W cycle guarantee
- The very first 64K bit Serial EEPROM
- The first to put a 64K bit Serial EEPROM in an 8-pin SOIC package
- The first family of Serial EEPROMs to operate at 1.8V
- The first VESA busing compatible Serial EEPROMs

These improvements are orders of magnitude increases in critical areas of market need. They establish Microchip Technology Inc. as the technical leader in EEPROM technology. This is what the EEPROM Technology team set out to do.

The team's efforts continue today to make sure Microchip remains a technical leader. We have the best products in the market today. But that will not be good enough tomorrow. Continuous improvement is essential.

Secure Learning RKE Systems Using KEELOQ® Encoders

Author: Chris R. Burger
Microchip Technology Inc.

INTRODUCTION

Learning capability in Remote Keyless Entry (RKE) and remote-controlled security systems is regarded as essential by most manufacturers. The logistical problems associated with the supply of replacement and additional transmitters for personalized decoders quickly become overwhelming if any dealer intervention is required.

In the case of a learning system, the user can purchase a preprogrammed transmitter off the shelf and then add that transmitter to the decoder system without assistance. Dealer intervention is completely unnecessary, and only one type of transmitter needs to be stocked for a particular product line. Each transmitter is pre-programmed with a unique serial number and key.

However, learning systems need to be properly managed to ensure that they maintain an adequate level of security. A badly implemented learning system could provide an outsider with access to the system. On the other hand, a well-designed learning system should not reduce the security level of the basic code-hopping system at all.

SINGLE-ALGORITHM SYSTEMS

Code hopping systems often use a single encoding and decoding algorithm for all transmitters in a particular product line. Most of the systems on the market fall into this category.

Learning is really simple—the decoder simply decodes the incoming transmission during learning and stores the resultant parameters for later use. For their security, these systems rely on the assumption that the algorithm will remain secret. In this era of Internet and instant worldwide communications, the probability that a widely-used algorithm will permanently remain secret is low and the assumption naive.

THE KEELOQ KEY-BASED SYSTEM

The KEELOQ system uses a separate 64-bit key for each transmitter. Such a key is simply a very large random number, unique to that transmitter. Effectively, this arrangement provides a unique encoding and decoding algorithm for each transmitter. An outsider that does not know the key, cannot decode the variable code portion of a transmission and consequently cannot determine the identity parameters of the originating transmitter.

This uniqueness of each transmitter's encoding algorithm complicates learning. The key cannot be determined from the variable code transmission, and no information can be derived from the transmission without the key.

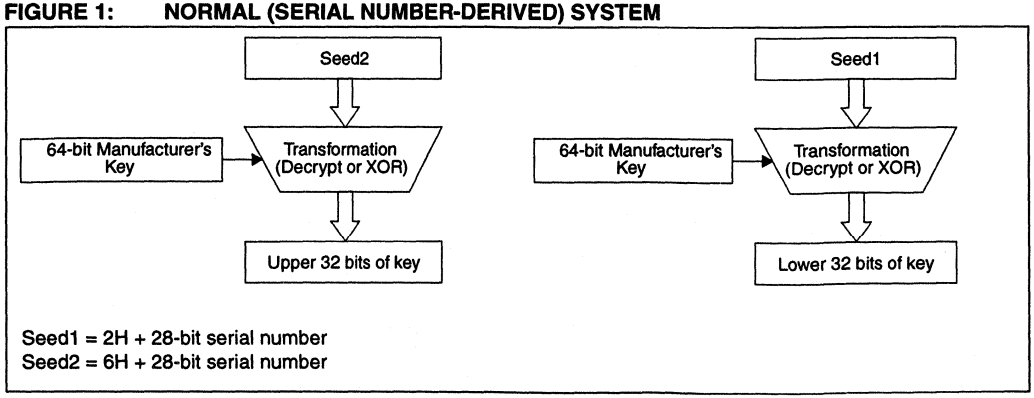
Obviously, some other piece of information must be transmitted during learning to enable the decoder to calculate the correct key. Two approaches are suggested. Each approach has pros and cons, which will be the subject of a comparative discussion in a later section.

KEELOQ Normal (Serial Number-derived) System

Each KEELOQ transmitter contains a unique serial number, programmed into the transmitter on the production line. This serial number is transmitted as part of the fixed code portion of every transmission.

When a transmission has been received, decoders typically use this serial number to determine the identity of the originating transmitter. The serial number is compared with those stored in memory. If a match is found, the decoder knows the identity of the transmitter, and therefore also knows which key and counter to use to process that transmission.

Each transmitter is also programmed with a key, calculated from the serial number using a secret learning algorithm. The relationship between the serial number and the key is very complex. This ensures that the relationship is not evident to outsiders.



During learning, the decoder calculates the key for that transmitter, using the same secret learning algorithm used for programming the transmitter. Once the key has been determined, the decoder can decode the transmission and store the parameters associated with that transmitter, including the key.

This learning procedure offers simplicity and high security—provided that the learning algorithm remains secret. To reduce the possibility of the learning algorithm being jeopardized, the KEELOQ system uses a learning algorithm that is only implemented in custom ICs. The first decoder to use this algorithm is slated to become available during 1996. As an interim solution, customers with a requirement for unusually robust learning security can enquire about coprocessor-based solutions.

In addition, the system relies on a manufacturer's key to determine the learning relationship. The manufacturer's key is protected by a smart card-based system and is stored in EEPROM inside the custom IC. Even if the learning algorithm itself becomes known, each manufacturer has a second line of defence in the manufacturer's key. Should a single manufacturer allow their key to become public knowledge, other manufacturers are not endangered.

One final comment—the envelope encryption capability on some of the KEELOQ encoders does not materially alter the nature of the learning algorithm. All devices in a particular product line share a single envelope encryption key, and any decoder in that product line can readily decode an incoming serial number. Once the serial number has been determined, the learning algorithm proceeds exactly as detailed.

FIGURE 1: NORMAL (SERIAL NUMBER-DERIVED) SYSTEM

© 1997 Microchip Technology Inc.

KEELOQ Secure (Seed-derived) System

The ultimate in secure learning is a system where no reliance is placed on the secrecy of any of the algorithms, or a single manufacturer's key.

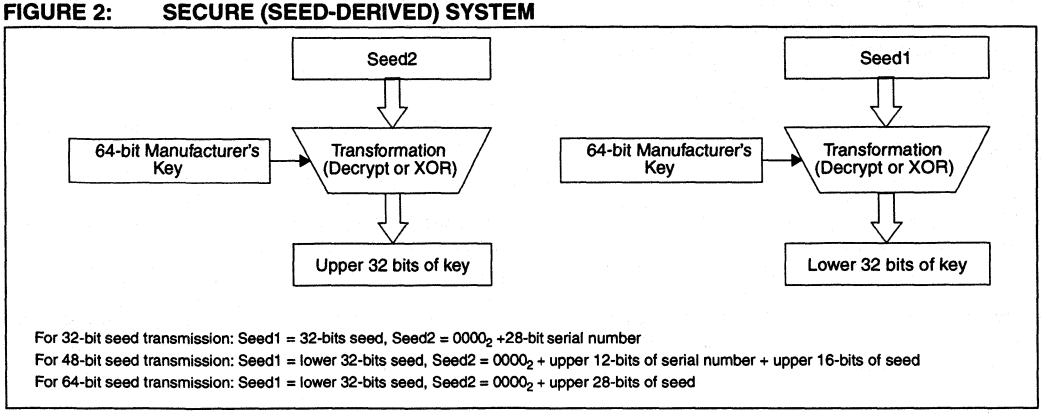
The KEELOQ code hopping system was designed under this assumption. Even if an outsider has the code hopping algorithm, a particular transmitter's transmissions are still incomprehensible if that transmitter's secret key is not known.

Determining the key by analyzing a number of transmissions is also not feasible. In 1995, it was estimated that an attacker with access to the algorithm requires a custom-designed $1,000,000 computer (designed exclusively to analyze KEELOQ transmitters) and 37 days of computer time per transmitter to find the secret key. Also, if a particular transmitter is jeopardized, no harm has been done to the security of other transmitters, even from the same product line.

To extend the security advantages of open algorithms to learning systems, the KEELOQ developers have applied for patents covering a novel learning technique. The learning technique does not rely on the secrecy of the learning algorithm at all.

On the production line, each transmitter is programmed with a serial number, a learning seed, and a key. There should not be any deterministic or mathematical relationship between the serial number and the key. Instead, a fixed (but complex) relationship exists between the learning seed and the key. The learning seed is only transmitted during learning. A special action is required from the user to activate transmission of the learning seed.

The learning seed is never transmitted during normal operation.



The HCS300 encoder can transmit a learning seed when all the function inputs are activated simultaneously. The 32-bit variable code is then replaced by a 32-bit learning seed, retrieved from the encoder's EEPROM memory. The decoder can derive the key from the learning seed alone, or from both the learning seed and the serial number.

Seed transmission in the HCS360 can be activated in two ways, details of which can be found in the following section and in the device specifications. During seed transmission, the HCS360 replaces both the 32-bit variable code and 16 bits of the serial number with fixed information retrieved from EEPROM, in essence transmitting a 48-bit seed. Also, additional protection against attack is provided. If desired, the transmitter can be configured to completely lose its ability to transmit the learning seed once the learning process has been completed. The mechanism works by permanently disabling seed transmission capability when the synchronization counter reaches 128. The user does not need to take any conscious action, as seed transmission is automatically inhibited after a few normal code hopping transmissions and cannot be activated again unless the encoder is reconfigured in total.

Because the learning seed and the key are both stored in read-protected EEPROM, there is no way to obtain the learning seed or the key from the transmitter, once the seed transmission capability has been inhibited.

A major advantage of seed based learning systems is that the security is not reliant upon a single key (or algorithm) that must be present in every decoder. However, a secret manufacturer's key that determines the relationship between the seed and the key still ensures protection against situations where access to the transmitter is possible (i.e. servicing, valet, etc.) and against the manufacturing of pirate transmitters.

FIGURE 2: SECURE (SEED-DERIVED) SYSTEM

For 32-bit seed transmission: Seed1 = 32-bits seed, Seed2 = 0000_2 +28-bit serial number
For 48-bit seed transmission: Seed1 = lower 32-bits seed, Seed2 = 0000_2 + upper 12-bits of serial number + upper 16-bits of seed
For 64-bit seed transmission: Seed1 = lower 32-bits seed, Seed2 = 0000_2 + upper 28-bits of seed

USING LEARNING SEED TRANSMISSION (HCS300, HCS301, HCS200, HCS360, AND HCS361)

HCS300/301

The HCS300 transmits a fixed code (stored in EEPROM) when all four control inputs are activated (i.e. $S_3S_2S_1S_0 = 1111$).

HCS200

The HCS200 transmits a fixed code (stored in EEPROM) when all three control inputs are activated (i.e. $S_2S_1S_0 = 1$).

HCS360/361

In the HCS360, the seed transmission capability is optional. If this option is selected during programming, transmission can be initiated in two ways: either $S_3S_2S_1S_0 = 0011$ and delayed mode is active (i.e. after about 3 seconds of variable code transmission), or $S_3S_2S_1S_0 = 1000$.

The fixed code capability can be permanent or temporary, depending on the setting of another EEPROM configuration bit. If the temporary mode has been selected, fixed code capability is disabled when either of the hopping code counters reaches a value of 128. The user can transmit the learning seed as many times as required to complete learning, and then originate up to 128 code hopping transmissions. The HCS360 will then protect the learning seed against readback and transmission for the remainder of its lifetime. If a number of transmissions less than 128 is required, the initial counter value can be increased accordingly.

Transmission Format

Normal HCSxxx encoder transmissions consist of a 32-bit hopping code, a 28-bit serial number, a 4-bit function code, and a flag field. These bits include a low voltage warning flag, a transmission repetition flag, and CRC bits for error checking. The flag field differs for the two encoders, and is not germane to this discussion. More information appears in the specification documents for each of the encoders.

H_0	Hopping	H_{31}	N_0	Serial	N_{27}	$S_2S_1S_0S_3$	Flags

The HCS200's and HCS300's seed transmission mode is identical, except that the 32 bit variable code is replaced by a 32-bit seed value, retrieved from EEPROM.

K_0	Seed	K_{31}	N_0	Serial	N_{27}	$S_2S_1S_0S_3$	Flags

In the HCS360's seed transmission mode, the fixed code is composed of a 48-bit learning seed, bits 16 to 27 of the serial number (the first 16 bits are replaced by seed bits), the 4 function bits, and the flag field.

K_0	Learning seed	K_{47}	N_{16}	Serial	N_{27}	$S_2S_1S_0S_3$	Flags

If compatibility between HCS300/301 and HCS360/361 transmitters is required, the HCS360 can simply be programmed so that the upper portion of the seed (bits K_{32} to K_{47}) corresponds to the lower portion of the serial number (bits N_0 to N_{15}). The resulting transmissions are then identical, except for possible differences in the flag field.

© 1997 Microchip Technology Inc.

DECIDING ON A LEARNING SOLUTION

Factors to be Considered

Any security system is a compromise between convenience to the user, cost and security. The KEELOQ system has made very high security available at low prices, all but eliminating cost as a consideration. The designer must therefore decide on the relative importance of security and user-friendliness in the system.

If security is of paramount importance, a seed-based system with automatic seed inhibition is preferred. However, this system has the disadvantage that the user must place both the transmitter and the receiver in learning mode, and that the transmitter can only be learned by a decoder once during its lifetime.

If user-friendliness is more important, a seed-based system without seed inhibition or a serial number-based system can be used. In the case of a serial number-based system, the user does not have to memories any special button combinations for use exclusively during learning. In the case of a seed-based system, the user needs to know the special button combination, but the transmitter retains its learning capability indefinitely.

TABLE 1: PROS AND CONS OF THE DIFFERENT LEARNING SYSTEMS

Learning Mode	How Used	Advantages	Disadvantages
Serial Number-based Learning	During learning, the key is derived from a serial number, included as part of every transmission from the transmitter.	The user does not need to activate a special encoder mode to conduct learning. Normal transmissions are used during learning, and the key is derived from the included serial number information. Also, a transmitter can be re-learned at any time if required.	The security of the system is dependent on the secrecy of the learning algorithm and/or manufacturer's key. This disadvantage can be overcome by using a learning algorithm implemented in a custom IC. However, for the largest OEM product lines, syndicates may still find it worth their while to reverse-engineer the custom IC.
Seed-based Learning With Seed Inhibition	During learning, a special learning seed is transmitted. The decoder derives the key from this learning seed. During normal operation, the transmitter loses its ability to transmit the learning seed. The seed is also stored in read-protected EEPROM, fully protected against outside access.	The security of the system is independent of the secrecy of the learning algorithm. The learning algorithm can thus be implemented on any platform, including generic microprocessors, without fear of jeopardizing the security of the system.	The user must operate a special button or combination of buttons on the transmitter to transmit the learning seed. Also, the transmitter cannot be re-learned once seed transmission has been disabled.
Seed-based Learning Without Seed Inhibition	During learning, a special learning seed is transmitted. The decoder derives the key from this learning seed. During normal operation, the transmitter does not transmit the learning seed. The system is therefore not susceptible to outside attack, even from someone that knows the learning algorithm and manufacturer's key. However, the transmitter permanently retains its ability to transmit the learning seed, and can be re-learned at any time.	The security of the system is independent of the secrecy of the learning algorithm, as the learning seed is not transmitted during normal operation. The learning algorithm can be implemented on any platform, including generic microprocessors, without fear of jeopardizing the security of the system. The transmitter can be re-learned at any time, as required.	The user must operate a special button or combination of buttons on the transmitter to transmit the learning seed. Also, there is some risk of the learning seed being revealed, as an outsider with temporary access to the transmitter can cause the transmitter to transmit the learning seed.

© 1997 Microchip Technology Inc.

IMPLEMENTATION ISSUES

This section presents hardware and software issues surrounding various implementations and should be read as a guide to implementation once a solution has been chosen.

Serial Number-based Systems

Proceed to implement a decoder as indicated in the relevant KEELOQ documents. Pay attention to the platform being used. ROM-based microprocessors should only be used as a last resort. If possible, use a KEELOQ decoder or coprocessor to ensure that the learning algorithm remains secret.

Three stages can be identified in the learning process. These three stages involve two different transmissions. The user presses the button, causing a normal code hopping transmission from the transmitter. During the first stage, the serial number is stored in EEPROM, and the corresponding key is calculated. During the second stage, the decoder decodes the incoming transmission using that key and stores the decoded parameters (function, integrity testing information and synchronization counter) in EEPROM. Some form of user feedback is then provided, prompting the user to press the transmitter button again. The third stage consists of decoding the resulting transmission, comparing the integrity testing information to the stored version, and ensuring that the two counter values are successive.

If code space is at a premium, or the simplicity of the user interface is paramount, the second transmission (and hence the third stage) can be omitted. Some integrity is sacrificed, as the second transmission is used to ensure that the transmitter's key has been correctly calculated and that the transmitter actually belongs to the same product line as the decoder. If the second transmission is forfeited, the system designer should ensure that the integrity testing information bits are subject to some convention, failing which any incoming transmission would be accepted as valid during learning. A possible programming convention is to use the lower 12 bits of the serial number as integrity testing information.

Learning Seed-based Systems

a) Decide on the user interface during learning. Would it make more sense to press a separate secret button, which normally requires disassembly of the transmitter, or to press a combination of two buttons?

   For two button transmitters based on the HCS360, no additional hardware is required to implement a secure learning system. If the two transmitter buttons are pressed together, the transmitter transmits a normal hopping code, and then reverts to fixed code mode after approximately 3 seconds. The decoder can determine the 28-bit serial number from the initial transmission and then calculate the key from the learning seed when the transmitter reverts to fixed code encoder mode.

   During a further transmission, the decoder can decode the incoming transmission to determine and store the counters and integrity testing information. The designer may elect to include a third transmission to verify the correctness of the decoding operation. Similar considerations to those mentioned in Section apply.

   After the predetermined number (up to 128) of code hopping transmissions has been made, the transmitter loses the ability to transmit the learning seed. From this point, pressing the two buttons together for more than 3 seconds results in a delayed function transmission with a function code of 0011.

   For other HCS360-based transmitters, activation of S3 results in transmission of the learning seed. S3 may be activated by installing a temporary link on the board, or even by a separate push button.

   After the predetermined number (up to 128) of code hopping transmissions has been made, the transmitter loses the ability to transmit the learning seed. From this point, activating S3 results in a normal hopping code transmission with a function code of 1000. For multi-button transmitters, this option opens up the possibility of using a normal button (i.e. fully accessible from outside) for learning, as the button regains full functionality after the fixed code transmission mode is disabled.

   For HCS300/301-based systems, all control inputs (S_0 to S3) must be high to activate seed transmission. The designer should include special provisions for forcing all these inputs high, especially in the case of a transmitter with less than four buttons.

b) Modify the decoder algorithm to calculate the key from the learning seed rather than from the serial number.

c) Choose the number of hopping code transmissions allowed before the encoder loses the ability to transmit the learning seed.

   Remember that the transmitter cannot be re-learned once the fixed code transmission has been disabled. If permanent re-learning capability is required, fixed code transmission should be left active permanently, or a serial number-based learning technique should be implemented. In most consumer products, the security level offered by the normal learning technique is perfectly adequate and sacrificing the convenience of re-learning is not justified.

MICROCHIP

TB003

An Introduction to KEELOQ® Code Hopping

Author: Kobus Marneweck
Microchip Technology Inc.

INTRODUCTION

Remote Control Systems

Remote control via RF or IR is popular for many applications, including vehicle alarms and automatic garage doors. Conventional remote control systems are based on unidirectional transmission and have limited security. More sophisticated devices based on bi-directional transmission are also available but, because of their high cost and certain practical disadvantages, they are not widely used in commercial remote control devices.

The popular unidirectional transmission systems currently have two very important security shortcomings: the codes they transmit are usually fixed and the number of possible code combinations is relatively small. Either of these shortcomings can lead to unauthorized access.

Code Scanning

The limited number of possible combinations available in most remote control systems makes it possible to transmit all possible combinations in a relatively short time. A hand held microprocessor-based system for this purpose (called a code scanner) can easily be constructed.

In systems using eight DIP switches (256 combinations), this scanning process can typically be accomplished in less than 32 seconds (when trying eight combinations per second). Even in systems using 16-bit keys (yielding roughly 65,000 combinations), only 2.25 hours would be required to try all possible combinations. It should also be noted that the scanner may gain access in far less than this maximum time—the average time would in fact be half of the total time.

Scanning is counteracted by increasing the number of possible code combinations. A 66-bit code will yield 7.3×10^{19} combination and will take 2.3×10^{11} years to scan.

Code Grabbing

A far easier way of gaining unauthorized access to a security system is freely available—such a unit is being advertised as a tool for the "legal repossession of vehicles." To understand its operation, it is useful to know something about remote controls.

A remote control transmitter of the type normally used in vehicle security systems, is nothing but a small radio transmitter that transmits a code number on a certain frequency. This code number is normally generated by an integrated circuit encoder. The transmit frequency is normally fixed by legislation within a particular country, enabling anybody to build a simple receiver that can receive signals from all such transmitters.

It is a simple matter to build a circuit to record such transmissions captured by the receiver. Such a device is known as a code or key grabber. A would-be vehicle thief would typically lurk in a parking lot, waiting until a vehicle owner arms his alarm with a remote control. The key grabber would capture the transmitted code, enabling the thief to retransmit this code as soon as the owner leaves the parking lot. Typically, this would leave the alarm and/or immobilizer disabled and even the central locking unlocked.

The Solution

It is apparent that secure remote control systems can only be implemented if two conditions are met. The KEELOQ® code hopping system meets both these conditions with ease.

- A large number of possible combinations must be available.

  A 66-bit transmission code is used to make scanning impossible. The 32-bit encrypted portion provides for more than 4 billion code combinations. A complete scan would take 17 years! If the 34-bit fixed portion is taken into account, the time required for a complete scan jumps to 5,600 billion years!
- The system may never respond twice to the same transmitted code.

  The random code algorithm will never respond to the same code twice over several lifetimes of a typical system.

Every time a remote control button is pushed, the system will transmit a different code. These codes appear random to an outsider – there is no apparent relationship between any code and the previous or next code.

Once the system has responded to a valid code, about 65,000 valid codes will have to be received before the same code will be used again. If the remote control is used eight times daily, 22 years will pass before the system responds to the same code again - once! Therefore, a retransmitted code (like when a code grabber is used) will never activate the system.

KEELOQ is a registered trademark of Microchip Technology Inc.

© 1997 Microchip Technology Inc.

The KEELOQ algorithm also features sophisticated synchronization techniques. The system will continue to function even if the transmitter is activated repeatedly while not in range of the receiver (as would happen if a child played with the remote control). If a button is pressed out of range more than 16 times, synchronization will be lost. However, two successive transmissions in range will restore synchronization. When no response occurs to a transmitter operation, the user's natural reaction is to press the button a second time. Synchronization will be restored when he does. Operation is totally transparent — the user may not even become aware that synchronization has been lost and restored.

These obvious security benefits are attainable at a cost comparable to existing fixed code systems. The revolutionary nature of the KEELOQ algorithm, full custom IC implementation, and reduced external component requirements help to make this level of cost effectiveness possible.

The KEELOQ Algorithm

KEELOQ is a proprietary block cipher based on a block length of 32 bits and a key length of 64 bits. The algorithm is characterized by a very economical hardware implementation, while retaining a level of security comparable to Data Encryption Standards (DES). This level of security makes it eminently suitable for code communication applications such as code hopping antitheft or access control devices.

Information regarding transmitter identity and synchronization is encoded so as to render it unintelligible to an outsider. For decoding, it is necessary to have the same 64-bit key originally used for encoding. Therefore, even though the decoder (which has the key) can identify the transmitter unambiguously, an outsider (who does not have access to the key and/or the algorithm) can glean no information at all from the transmissions.

As it is impossible to insert information into the system from outside, strategies used to attack FEAL and other DES-like ciphers are not usable against this system.

The KEELOQ algorithm is designed to make it impossible for a potential assailant to predict the next code that will be transmitted by a valid transmitter. Even if the assailant makes a reasonable guess regarding the way in which transmitted information changes with each transmission, the algorithm obscures this information sufficiently that the next code can not be anticipated. In particular, even if the transmitted information (before encoding) differs only in one bit from the information in the previous transmission, the next transmission will be totally different.

Checks exist that can be used to verify the security characteristics of an encoding algorithm and, in this instance, to determine whether the next transmitted code is predictable to any degree. The Avalanche Effect and a subset thereof, the Strict Avalanche Criterion, have been tested on the KEELOQ algorithm. The results give a good indication of the security offered by the system.

- Avalanche Effect (AE)

  A block cipher satisfies the AE if changing one bit of the information causes, on average, half of the bits in the transmission to change. In the KEELOQ algorithm, this implies that changing one bit in the function and/or synchronization information will cause an average of 16 of the 32 bits in the transmitted code to change.

- Strict Avalanche Criterion (SAC)

  The SAC requires that, if one bit of the encoded information is changed, each bit in the output must have a chance of 0.5 of changing as well. Consequently, the probability of guessing any one bit correctly is 0.5, and the probability of guessing an entire 32-bit string correctly is one in about 4,300,000,000!

  The tests involved using a random 64-bit key and a Gray counter (starting at zero) as input to the algorithm. In each case, the output was compared with a reference (SAC) or with the previous code (AE). In both cases, the results were as expected: For the AE, the average number of bits changed was 16.0 (50%), with a standard deviation of 2.83 (8.8%). For the SAC, each individual bit changed an average of 50% of the time, with a standard deviation of 8.8%.

DEFINITIONS USED IN CODE HOPPING

Transmitter Serial Number	Each transmitter is programmed with a unique 28- or 32-bit serial number at the time of transmitter manufacture. This ensures that each transmitter will be unique within a system.
Secret Key	This 64-bit secret key is generated by a key generation function from the 28- or 32-bit serial number or the 32- or 48-bit seed and 64-bit manufacturer's key as inputs. A manufacturer's key can be used to control the key generation function. The secret key is not readable and is never transmitted.
Seed	The seed is a 32- or 48-bit value that is programmed into the encoder. This can be programmed to be the same as one half of the key or be used in key generation. It is only transmitted when a specific button combination is activated and can be disabled once learning is completed.
Key Generation	The key generation function is used to generate a unique key for each transmitter from the serial number or seed value. It is preferable that the function is nonlinear. This function is performed by the programming station to generate keys to be programmed into transmitters.
Manufacturer's Key	The manufacturer's key is necessary in the receiver if a key generation function with a manufacturer's was used to generate the secret keys. The manufacturer's key must be programmed into the receiver during manufacture.
Normal Learn (Serial Number Derived)	The receiver uses the same information that is transmitted during normal operation to derive the transmitter's secret key, decrypt the discrimination value and the synchronization counter. All the transmitter information is then stored.
Secure learn (Seed Derived)	The transmitter is activated through a special button combination to transmit a stored 32- or 48-bit value (seed) that can be used for key generation or be part of the key. Transmission of the random seed can be disabled after learning is completed.
Discrimination value	The discrimination value is a 12-bit fixed portion of the encrypted word. It is used as a post decryption check.
Synchronization counter	A16-bit counter that is incremented on every activation of the encoder. It is stored on the receiver controller and compared to determine if a transmission is a previously received transmission, in which case it is ignored or falls within a forward window in which case it is accepted.

FEATURES

A full perspective of the capabilities of the KEELOQ system would involve describing the unique features of each device separately. However, the entire product range has certain characteristics that may or may not be applicable to a specific member of the product range. The most important characteristics are listed to enable the prospective user to get a global view of the KEELOQ system. The specifications for a particular encoder or decoder should be consulted to determine the applicability of these features to that device.

Encoders

Security

- Programmable 28/32-bit serial number
- Programmable 64-bit encryption key
- Each transmission is unique
- 66/67 bit transmission length
- 32-bit hopping code
- 34/35-bit fixed code (28/32-bit serial number, 4/0-bit function, VLOW, Rpt/2-bit CRC)
- Encryption key is read protected

Operating

- One (3.0V) or two (6.0V) Lithium battery operation
- One (9.0V or 12.0V) Alkaline battery operation
- 3 or 4 button inputs - 7 or 15 functions
- Selectable baud rate
- Automatic power down after transmission
- Battery low signal transmitted
- Nonvolatile synchronization data
- IR modulation capability

Other

- On-chip EEPROM
- On-chip oscillator and timing components
- On-chip reset circuit
- Button inputs have internal pull-down resistors
- Current limiting on LED output

Decoders

Security

- KEELOQ code hopping technology
- Secure storage of manufacturers key
- Secure storage of transmitters keys
- Normal learning mode and Secure learning mode
- Four or more transmitters can be learned

Operating

- 2.0V to 6.0V operation
- 4 MHz RC oscillator
- Learning indication
- Auto baud rate detection

Decoder

- Single chip decoder available
- On-chip EEPROM
- Four binary function outputs - 15 functions
- One or two wire serial interface
- Battery low indication

TYPICAL APPLICATIONS

- Automotive remote entry systems
- Automotive alarm systems
- Automotive immobilizers
- Gate and garage openers
- Electronic door locks
- Identity tokens
- Burglar alarm systems
- Remote control toys/fixed code applications

ENCODER FUNCTIONS

General Description

The KEELOQ code hopping remote control encoders are intended for secure remote control systems. They are suitable for use in remote control applications using infrared (IR), microwave or other radio frequency (RF) transmitters.

The encoders have several basic modes of operation. Some of these modes may be combined in a particular device, and the means of selecting the mode may differ, but the principle of operation remains the same.

Unidirectional Authentication

Unidirectional authentication is used where it is impractical or cost prohibitive to use a bi-directional link such as remote keyless entry. In this mode, an encoder functions as a code generator for a transmitter. A suitable transmission medium (RF, ultrasonic, microwave, infrared, or magnetic coupling) must be provided in addition to the KEELOQ encoder to implement a complete link. The encoder is activated by a push button or by a magnetic field in the case of a transponder.

Bi-directional Authentication

Bi-directional authentication is used where a bi-directional link such as a direct connection is available. Bi-directional authentication mode implements an IFF (Identification Friend or Foe) system. In this mode, a 16/32-bit string (the challenge) is sent to the KEELOQ device. In the device, an encryption operation is performed on the challenge, using a 64-bit key. The resultant 16/32-bit string (the response) is then transmitted. This 32-bit string is unique for a given challenge and key. KEELOQ devices may contain several keys.

Transmission Format

The KEELOQ devices use a 66/67-bit transmission format. A 66-bit transmission is composed of a 32-bit encrypted string, a 28-bit fixed string, 4-bit function code, battery low indicator, and a repeat indicator. A 67-bit transmission is available on high-end encoders and is composed of a 32-bit encrypted string, a 28- or 32-bit fixed string, 4- or 0-bit function code, battery low indicator, and a 2-bit CRC. The fixed string is the serial number of the encoder and remains constant for all transmissions from a particular transmitter. However, the 32-bit encrypted string is unique for each transmission.

© 1997 Microchip Technology Inc.

Transmitter Activation

The encoder has an internal power switch which turns on when any of the button inputs are taken high. When a button is pressed, the encoder is turned on and the inputs are sampled after a debounce delay. The encoder then transmits a code, based on the correct key, synchronization information, and function codes.

If the time-out option is selection, the encoder will shut-down after a complete transmission. This mode prevents battery depletion when a push button is inadvertently activated for an extended period. To activate the device again, the buttons have to be released and activated again.

With 28-bit serial number selected:

Hop code			Serial number			Function	Status/CRC
LSB	32 bits	MSB	LSB	28 bits	MSB	4 bits	2/3 bits

With 32-bt serial number selected:

Hop code			Serial number			Status/CRC
LSB	32 bits	MSB	LSB	32 bits	MSB	2/3 bits

Three data rates are used: 833, 1667, and 3333 bits per second. At the lower transmission rate, a complete transmission requires approximately 100ms, at the higher rate 50ms, and at the highest rate 25ms. All encoders will transmit the codes repeatedly while the transmitter is activated.

© 1997 Microchip Technology Inc.

Special Features

Code Word Completion

Code word completion is an automatic feature that makes sure that the entire code word is transmitted, even if the button is released before the transmission is complete. A KEELOQ encoder powers itself up when a button is pushed and powers itself down after the command is finished, if the user has already released the button. If the button is held down beyond the time for one transmission, then multiple transmissions will result. If another button is activated during a transmission, the active transmission will be aborted and the new code will be generated using the new button information.

Blank Alternate Code Word

Federal Communications Commission (FCC) part 15 rules specify the limits on fundamental power and harmonics that can be transmitted. Power is calculated on the worst case average power transmitted in a 100ms window. It is therefore advantageous to minimize the duty cycle of the transmitted word. This can be achieved by minimizing the duty cycle of the individual bits and by blanking out consecutive words. Blank Alternate Code Word (BACW) is used for reducing the average power of a transmission. This is a selectable feature that is determined in conjunction with the baud rate selection bits. Using the BACW allows the user to transmit a higher amplitude transmission if the transmission length is shorter. The FCC puts constraints on the average power that can be transmitted by a device, and BACW effectively prevents continuous transmission by only allowing the transmission of every second or every fourth code word. This reduces the average power transmitted and hence, assists in FCC approval of a transmitter device.

Envelope Encryption Option

Envelope Encryption is a user selectable option which is meant to offer a higher level of security for a code hopping system. During a normal transmission with the envelope encryption turned off, the 28-bit serial number and 4-bit function code is transmitted in the clear (unencrypted). If envelope encryption is selected, then the serial number is also encrypted before transmission. The encryption for the serial number and 4-bit function code is done using a different algorithm than the transmission algorithm. The envelope encryption scheme is not nearly as complex as the KEELOQ algorithm and, hence, not as secure. When the envelope encryption is used, the serial number must be decrypted using the envelope key and envelope decryption. After the serial number is obtained, the normal decryption method can be used to decrypt the hopping code. All transmitters in a system must use the same envelope key.

Auto-shutoff

The Auto-shutoff function automatically stops the device from transmitting if a button inadvertently gets pressed for a long period of time. This will prevent the device from draining the battery if a button gets pressed while the transmitter is in a pocket or purse. This function can be enabled or disabled and is selected by setting or clearing the Auto-shutoff bit. Time-out period is approximately 25 seconds.

VLOW: Voltage LOW indicator

The VLOW bit is transmitted with every transmission and will be transmitted as a one if the operating voltage has dropped below the low voltage trip point. The trip point is selectable between two values, based on the battery voltage being used. This VLOW signal is transmitted so the receiver can give an indication to the user that the transmitter battery is low.

© 1997 Microchip Technology Inc.

DECODER FUNCTIONS

General Description

The KEELOQ decoders can be used for secure remote control systems. To gain a full understanding of the modes of KEELOQ decoder operation, several concepts have to be understood.

Decoder Features

Output Activation

The function information contains information on the buttons that were activated. The function code is embedded in the encrypted portion of the transmission and is also transmitted in the clear if selected. The decoder will activate the switch outputs corresponding to the switch inputs on the encoder as long as the transmitter is activated. A minimum activation time of 500ms is used to allow for dropout in the signal. Buttons are usually assigned to different functions. In a vehicle alarm system one button might be used for arming and locking, another for disarming and unlocking and a third for trunk release. If any button is activated for more than say 2 seconds a panic siren can be activated.

Key Management

For a decoder to respond to an encoder's transmissions, the decoder has to have access to several items of information:

- The *serial number* which is unique for each transmitter. KEELOQ encoders feature 28- or 32-bit serial numbers.
- The *synchronization history* of that transmitter. This information is used to determine whether the transmission is a valid one, or whether it has been transmitted by a code grabber. The form in which this history is maintained makes it possible to re-synchronize the decoder with the transmitter, even if the transmitter has been pressed repeatedly out of range of the receiver.
- The *buttons* used to activate the transmitter.
- The *key* being used by that transmitter. All KEELOQ devices use 64-bit keys. This information is essential to enable the decoder to decrypt the transmission and gain access to the information contained in the encrypted code portion.
  - Single key system
    In a single key system the decoder stores a single key and uses that key for interpreting the transmissions from all transmitters. It follows that all transmitters to be used with that decoder, must be set up with the same key. A single key system is not very secure but the program is simplified and the storage requirements are less.
    The serial number is used to distinguish between different transmitters. The decoder still has to maintain separate synchronization information for each transmitter. This information is maintained in a separate location in the EEPROM memory for each transmitter. The history record for a particular transmitter is updated every time a valid transmission is received, enabling the decoder to keep track of each transmitter independently. Even if one transmitter is used regularly while another is stored away (with or without power), both transmitters will work the first time when activated.
  - Independent key system
    An independent key system is much more secure as the preferred method and is used in all KEELOQ decoders. In independent key systems, the decoder maintains a separate key for each transmitter. The serial number or derivative is used to locate the correct key. Once the correct location has been determined, the key is retrieved and used to decrypt the 32-bit encrypted portion. The correct history record is then retrieved and used to determine whether a valid code has been received.

Learning

Learning is a feature of KEELOQ decoders that allows the addition of new transmitters to the system without having to reprogram the system from outside.

The decoder's learning capability simplifies replacement of lost transmitters. When a transmitter is lost, the user can "teach" the decoder the key of a new transmitter. The previous transmitter's key will be written over, thereby excluding that transmitter from the system.

Once the self learning procedure has been followed, the receiver has learned the new transmitter's identity and (if applicable) the output functions that have to be activated for that transmitter. The new transmitter may then be used normally to activate the decoder.

© 1997 Microchip Technology Inc.

Normal learning mode (Serial Number Derived)

- Transmission format in normal learn mode.

With 28-bit serial number selected:

Hop Code			Serial Number			Function	Status/CRC
LSB	32 bits	MSB	LSB	28 bits	MSB	4 bits	2/3 bits

With 32- bit serial number selected:

Hop Code			Serial Number			Status/CRC
LSB	32 bits	MSB	LSB	32 bits	MSB	2/3 bits

Operation

The user places the decoder in learning mode. When the first code word is received, the serial number is used to generate the transmitter's secret key that was programmed into the transmitter during the production stage. The secret key is used to decrypt the hopping code. The decoder then waits for a second transmission (must be activated a second time). The serial number is compared to the first received serial number. If equal the hopping code is decrypted and the validation checks performed. The final check is to check that the codes are sequential. All the transmitter information is then stored.

Secure learn mode (Seed Derived)

- Transmission format in secure learn mode

With 32 bit serial number selected:

Seed			Serial number			Function	Status/CRC
LSB	32 or 48 bits	MSB	LSB	28 or 12 bits	MSB	4 bits	2/3 bits

With 32 bit serial number selected:

Seed			Serial number			Status/CRC
LSB	32 or 48 bits	MSB	LSB	32 or 24 bits	MSB	2/3 bits

Operation

The user places the decoder in learning mode. During the first stage of learn, the user must press a specific button. The hopping code part of the transmission will be replaced by the 32/48-bit seed stored in the encoder. The key is derived from the seed instead of the serial number in this case. During the second stage of learning, any other button combination can be pressed. A normal hopping code transmission is sent during the second stage. The generated key is used to decrypt the hopping code, and all the transmitter information is stored.

Since the seed is only transmitted during the learning process, and is required to generate the key a normal transmission cannot be intercepted, a key generated and the hopping code decrypted to predict the next hopping code.

As a further security measure, the transmission of the random seed can be disabled after 1 to 128 operations of the transmitter once the transmitter has been learned. That means that even if someone had physical access to the encoder, it would not be possible to get the random seed which is needed for key generation. The disadvantage is that a transmitter cannot be relearned at a later stage.

© 1997 Microchip Technology Inc.

Memory Requirements

A code hopping system typically requires nonvolatile memory such as an EEPROM to store transmitter information. This allows information to be changed when a transmitter is learned and operated but ensures that the information will not be lost if power is removed. Since the receiver needs to store information on each transmitter, the number of transmitters is determined by the available memory size. A typical system requires 16 bytes to be stored for each transmitter.

Memory map:

Transmitter	
1	Learned
2	Learned
3	← Next learn position
~	
n	

A learning pointer can be used to point to the next available learning position. Once position n is reached, the pointer will wrap to position 1.

Transmitter Replacement

The replacement of transmitters is a system implementation dependent. All transmitters can be erased by activating the learn input for 10 seconds. The wanted transmitters can then be relearned. Another method is to use a rotating buffer. Transmitters will be learned into sequential positions until the last position is reached. The next learn will then overwrite the first transmitter.

Automatic Calibration of the WDT Time-out Period

Author: *Stan D'Souza*
Microchip Technology Inc.

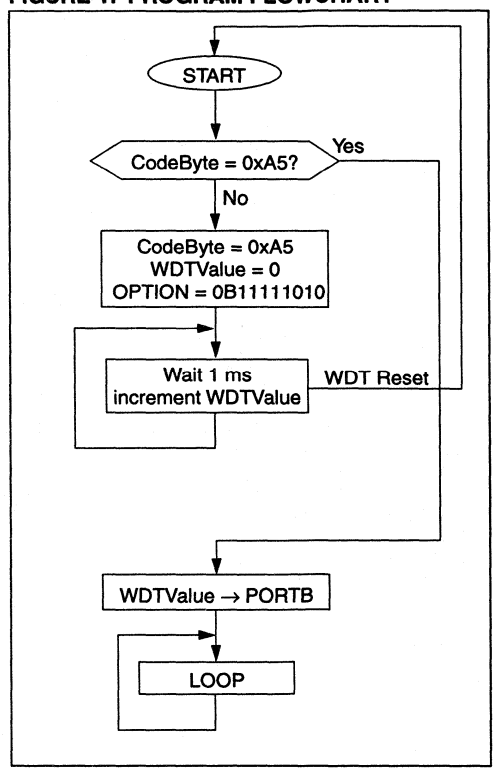
INTRODUCTION

The WDT timer is a simple RC timer with a typical time-out period of about 18 ms. This time-out period is dependent on Voltage, Temperature and Silicon process variations. Hence the tolerance on the time-out period is very wide: Min. of 9 ms to a Max. of 33 ms (please refer to appropriate datasheet for device dependent value). There are applications where an additional timer would be useful as an approximate time keeper, hence getting a more precise value of the WDT time-out is useful. This Tech Brief implements an automatic calibration of the WDT time-out period on start-up.

IMPLEMENTATION

The hardware used for this brief is the PICDEM1 board. It is assumed that the main processor oscillator is an accurate crystal or ceramic resonator running at 4 MHz. The program flowchart is depicted in Figure 1. A check is made to see if a certain **Codebyte** exists, if it does not then a power-up is assumed and the calibration is executed. Note that instead of using the 8-bit wide **CodeByte**, the $\overline{PD}$ bit in the **STATUS** register could also be used for this very same purpose. The calibration uses an internal timed 1 ms interval. To get a better resolution, the WDT is postscaled by 4 in order to measure a longer time period . Every 1 ms interval is kept track by incrementing the **WDTValue**. The WDT will eventually time-out and cause a reset. The value in **WDTValue** in then divided by 4 to get the exact WDT time-out period and displayed as a binary number on PORTB. In order to check for repeatability, just press the reset button on the PICDEM1 board and the whole calibration process will be repeated. A power-down, followed by a power-up will also have the same effect.

CONCLUSION



The calibration of the WDT is simple and takes very little overhead in a program. The code in Appendix A is written for a PIC16C84 device, but can be translated to work on any PIC16CXXX product. The code in Appendix B is written for the PIC16C5X family.

RAM Used: 2 Bytes

ROM Used: 50 Words

Execution time: Up to a max. of 132 ms from start-up.

Using External RAM with PIC17CXXX Devices

Author: *Rodger Richey*
Microchip Technology inc.

INTRODUCTION

This Technical Brief shows how to connect a PIC17CXXX device to external memory. It also provides instructions and calculations to help determine which speeds of SRAM work with which frequency crystal.

SYSTEM CONFIGURATION

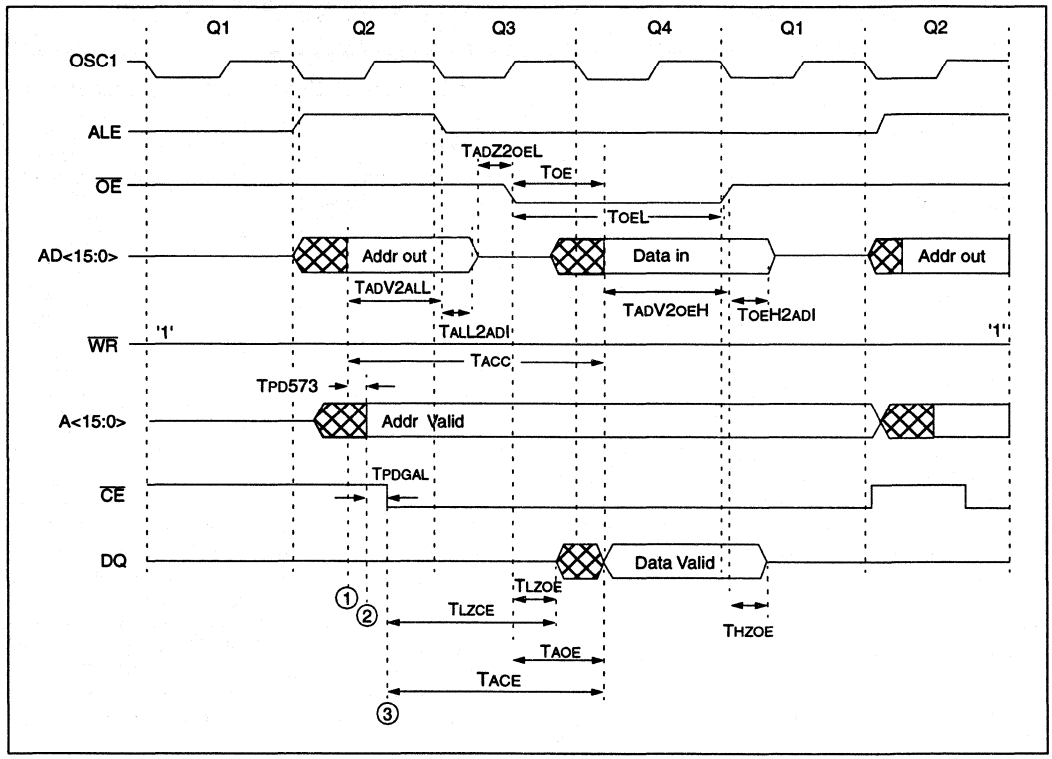
Are you doing FFT's? Storing arrays of data? Typically, low speed designs would use EEPROM to hold the data that is being generated. On the other hand, high speed designs need to use static RAM because of the faster access times. External SRAM can easily be integrated with a PIC17CXXX device to create the SRAM bank your design requires. Data storage and retrieval is accomplished through table read and table write instructions.

All the equations for lead timing can also be applied to EPROMs.

The first thing you need to know is how much RAM the system requires. Table 1 shows how much external memory can be used with the PIC17CXXX family members. The microcontroller is put into extended microcontroller mode which can access both the internal and external memory. Both the internal and external memory is 16-bits wide.

TABLE 1: INTERNAL/EXTERNAL MEMORY

Device		Size (Words)	Address Range
PIC17C42	Internal	2048	0x0000 - 0x07FF
	External	63488	0x0800 - 0xFFFF
PIC17C43	Internal	4096	0x0000 - 0x0FFF
	External	61440	0x1000 - 0xFFFF
PIC17C44	Internal	8192	0x0000 - 0x1FFF
	External	57344	0x2000 - 0xFFFF



The next step is to connect the external SRAM to the PIC17CXXX. Appendix A shows the schematic for connecting two MT5C2568 (32Kx8) SRAM devices to a PIC17C43. The MT5C2568 can be obtained from Micron Semiconductor. The only additional hardware required is two latches (74ACT373s or 74ACT573s). Both chips are octal latches but the 74ACT573 has the inputs and the outputs on opposite sides of the chip which makes interfacing to the microcontroller easier.

READ TIMINGS

Now that we know how to connect the hardware, the next step is to determine the speed grade of the SRAM. Let's first take a look at the read timings. Figure 1 shows a combined timing diagram for the read cycle of a PIC17C4X device and the MT5C2568 SRAM.

FIGURE 1: PIC17C4X/MT5C2568 READ CYCLE TIMING DIAGRAM

The value of TACE shows which speed grade of SRAM is required for the read cycle. Figure 1 has three key locations marked that help define TACE. Table 2 summarizes these locations.

TABLE 2: LOCATION MARKER DESCRIPTIONS FOR FIGURE 1

Location	Description	Value	
1	Address Setup Time. This location marks the spot where the address becomes valid out of the PIC17CXXX before ALE goes LOW. (Q2 cycle)	0.25 * TCY - 10	time in nanoseconds before the Q3 cycle (TADV2ALL)
2	Propagation delay of the 74ACT573. This is the spot where the address to the SRAM becomes valid. (Q2 cycle)	6	time in nanoseconds before the Q3 cycle (TPD573)
3	Propagation delay of the address decoder. This spot is where the CE signal from the address decoder to the SRAM goes LOW. (Q2 cycle)	TPDGAL	time in nanoseconds before the Q3 cycle

© 1997 Microchip Technology Inc.

TABLE 3: MEMORY INTERFACE READ REQUIREMENTS

Sym	Characteristic	Min	Typ	Max	Units
TADV2ALL	AD15:AD0 (address) valid to ALE↓ (address setup time)	0.25Tcy - 10	—	—	ns
TALL2ADI	ALE↓ to address out invalid (address hold time)	5*	--	—	ns
TADZ2OEL	AD15:AD0 hi-impedance to $\overline{OE}$↓	10	—	—	ns
TADV2OEH	Data in valid before $\overline{OE}$↑ (data setup time)	35	—	—	ns
TOEH2ADI	$\overline{OE}$↑to data in invalid (data hold time)	0	—	—	ns
TOEL	$\overline{OE}$ pulse width	0.5Tcy - 35	—	—	ns
TOE	Output enable access time ($\overline{OE}$ low to Data Valid)	—	—	0.5TCY - 45	ns
TPD573	Propagation delay input to output	2	6	12	ns
TACC	Address access time	0.75Tcy - 30	—	—	ns
TPDGAL	Propagation delay input to combinatorial output	3	—	7.5 - 25	ns
TLZOE	$\overline{OE}$ to output in Low - Z	0	—	—	ns
TAOE	$\overline{OE}$ access time	—	—	5 - 8	ns
TLZCE	$\overline{CE}$ to output in Low - Z	3	—	—	ns
TACE	$\overline{CE}$ access time	—	—	10 - 25	ns
THZOE	Output disable to output in High - Z	—	—	5 - 7	ns

To determine TACE from Figure 1, the following equation can be used. Each part of the equation is related to a timing parameter or one of the marked locations in Figure 1.

TACE =	0.75 * TCY - 30	- Address access time - TACC
	- 6	- Propagation delay of the 74ACT573 - TPD573
	- TPDGAL	- Propagation delay of the address decoder

Finally, lets find some example speed grades for various crystal frequencies. One thing to remember is that this is only the read timing speed grade. You must also calculate the write timing speed grade. As you can see the speed grade for the SRAM is dependent on the address decoder. Typically, programmable array logic devices such as a 16V8 or a 22V10 are used. The propagation delays of these devices can be anywhere from 5 ns up to 30 ns.

8 MHz (TCY = 500 ns)	**16 MHz (TCY = 250 ns)**	**20 MHz (TCY = 200 ns)**	**25 MHz (TCY = 160 ns)**
TACE = 0.75 * 500 - 30 - 6 - TPDGAL	TACE = 0.75 * 250 - 30 - 6 - TPDGAL	TACE = 0.75 * 200 - 30 - 6 - TPDGAL	TACE = 0.75 * 160 - 30 - 6 - TPDGAL
TACE = 345 - 6 - TPDGAL	TACE = 157.5 - 6 - TPDGAL	TACE = 125 - 6 - TPDGAL	TACE = 90 - 6 - TPDGAL
TACE = 339 - TPDGAL	TACE = 151.5 - TPDGAL	TACE = 119 - TPDGAL	TACE = 84 - TPDGAL

To reduce the total propagation delay of the 74ACT573 and the address decoder, the address/data lines and ALE from the PIC17C4X can be routed to the address decoder. Now the address latches and the address decoding can be performed in parallel.

WRITE TIMINGS

Now that you have determined the read timing speed grade, it is time to calculate the write timing speed grade of the SRAM for your design. Figure 2 shows the combined timings for a write cycle of the PIC17C4X devices and the MT5C2568. Again, there are markings for some key locations which are described in Table 4.

FIGURE 2: PIC17C4X/MT5C2568 WRITE CYCLE TIMING DIAGRAM

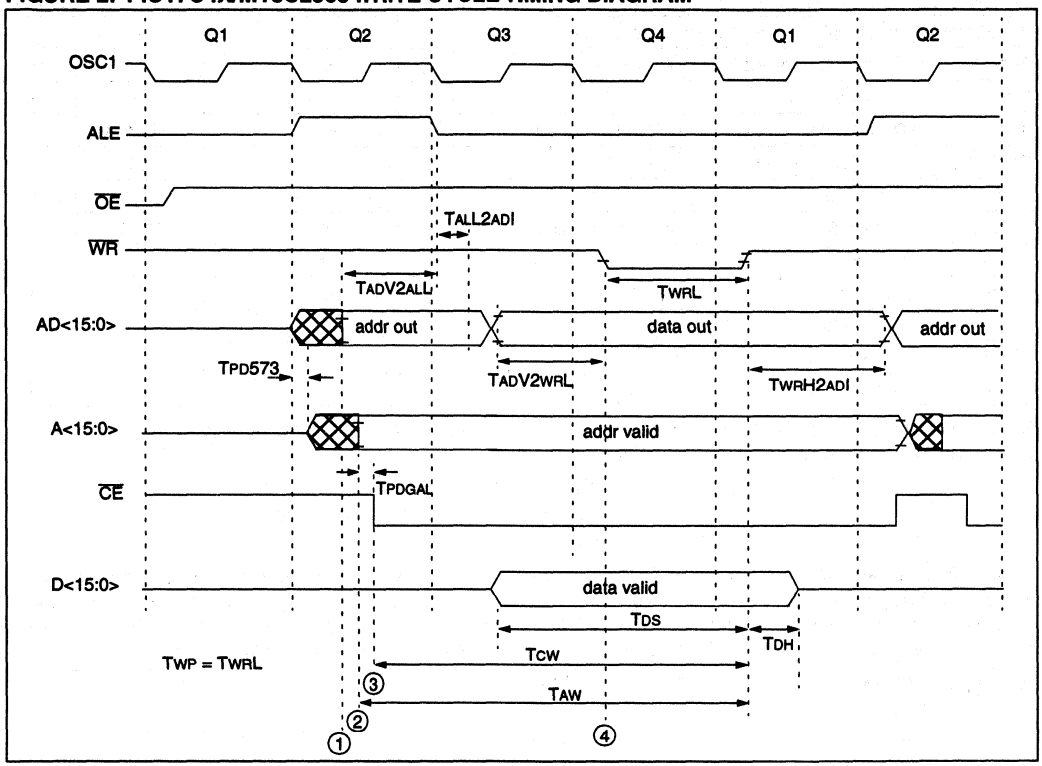

TABLE 4: LOCATION MARKER DESCRIPTIONS FOR FIGURE 3

Location	Description	Value	
1	Address Setup Time. This location marks the spot where the address becomes valid out of the PIC17CXXX before ALE goes LOW. (Q2 cycle)	0.25 * TCY - 10	time in nanoseconds before the Q3 cycle (TADV2ALL)
2	Propagation delay of the 74ACT573. This is the spot where the address to the SRAM becomes valid. (Q2 cycle)	6	time in nanoseconds before the Q3 cycle
3	Propagation delay of the address decoder. This spot is where the CE signal from the address decoder to the SRAM goes LOW. (Q2 cycle)	TPDGAL	time in nanoseconds before the Q3 cycle
4	Write pulse goes LOW. The SRAM specifies that the address at it's inputs must be valid at or before this point. (Q4 cycle)		

© 1997 Microchip Technology Inc.

TABLE 5: MEMORY INTERFACE WRITE REQUIREMENTS

Sym	Characteristic	Min	Typ	Max	Units
TADV2ALL	AD<15:0> (address) valid to ALE↓ (address setup time)	0.25Tcy - 10	—	—	ns
TALL2ADI	ALE↓ to address out invalid (address hold time)	0	—	—	ns
TADV2WRL	Data out valid to $\overline{WR}$↓ (data setup time)	0.25Tcy - 40	—	—	ns
TWRH2ADI	$\overline{WR}$↑ to data out invalid (data hold time)	—	0.25TCY	—	ns
TWRL	$\overline{WR}$ pulse width	—	0.25TCY	—	ns
TPD573	Propagation delay input to output	2	6	12	ns
TPDGAL	Propagation delay input to combinatorial output	3	—	7.5 - 25	ns
TDS	Data setup time	6 - 10	—	—	ns
TCW	$\overline{CE}$ to end of write	12 - 15	—	—	ns
TAW	Address valid to end of write	7 - 15	—	—	ns
TDH	Data hold time	0	—	—	ns
TWP	$\overline{WE}$ pulse width Low	7 - 15	—	—	ns

The critical timing specification for the write cycle is when the CE signal from the address decoder to the SRAM goes LOW. Typically the SRAM specifies this parameter (TAS for the MT5C2568). The other important SRAM specifications to check against the PIC17C4X are:

- TWP - Write enable LOW pulse width
- TDS - Data setup time, data valid before WE goes HIGH
- TDH - Data hold time, data valid after WE goes HIGH

The following are some calculations for the write cycle of various speed grades. These calculations are used to determine if any of the above specifications are invalid. The Micron MT5C2568 specifies the following values for the above parameters:

TAS - 0 ns min. for all speed grades

TWP - 15 ns min. for the 25 ns speed grade

TDS - 10 ns min. for the 25 ns speed grade

TDH - 0 ns min. for all speed grades

The PIC17C4X specifies the following values:

TWP - 0.25 * TCY	TWRL
TDS - 0.25 * TCY - 40 + TWP min.	TADV2WRL
TDH - 0.25 * TCY	TWRH2ADI

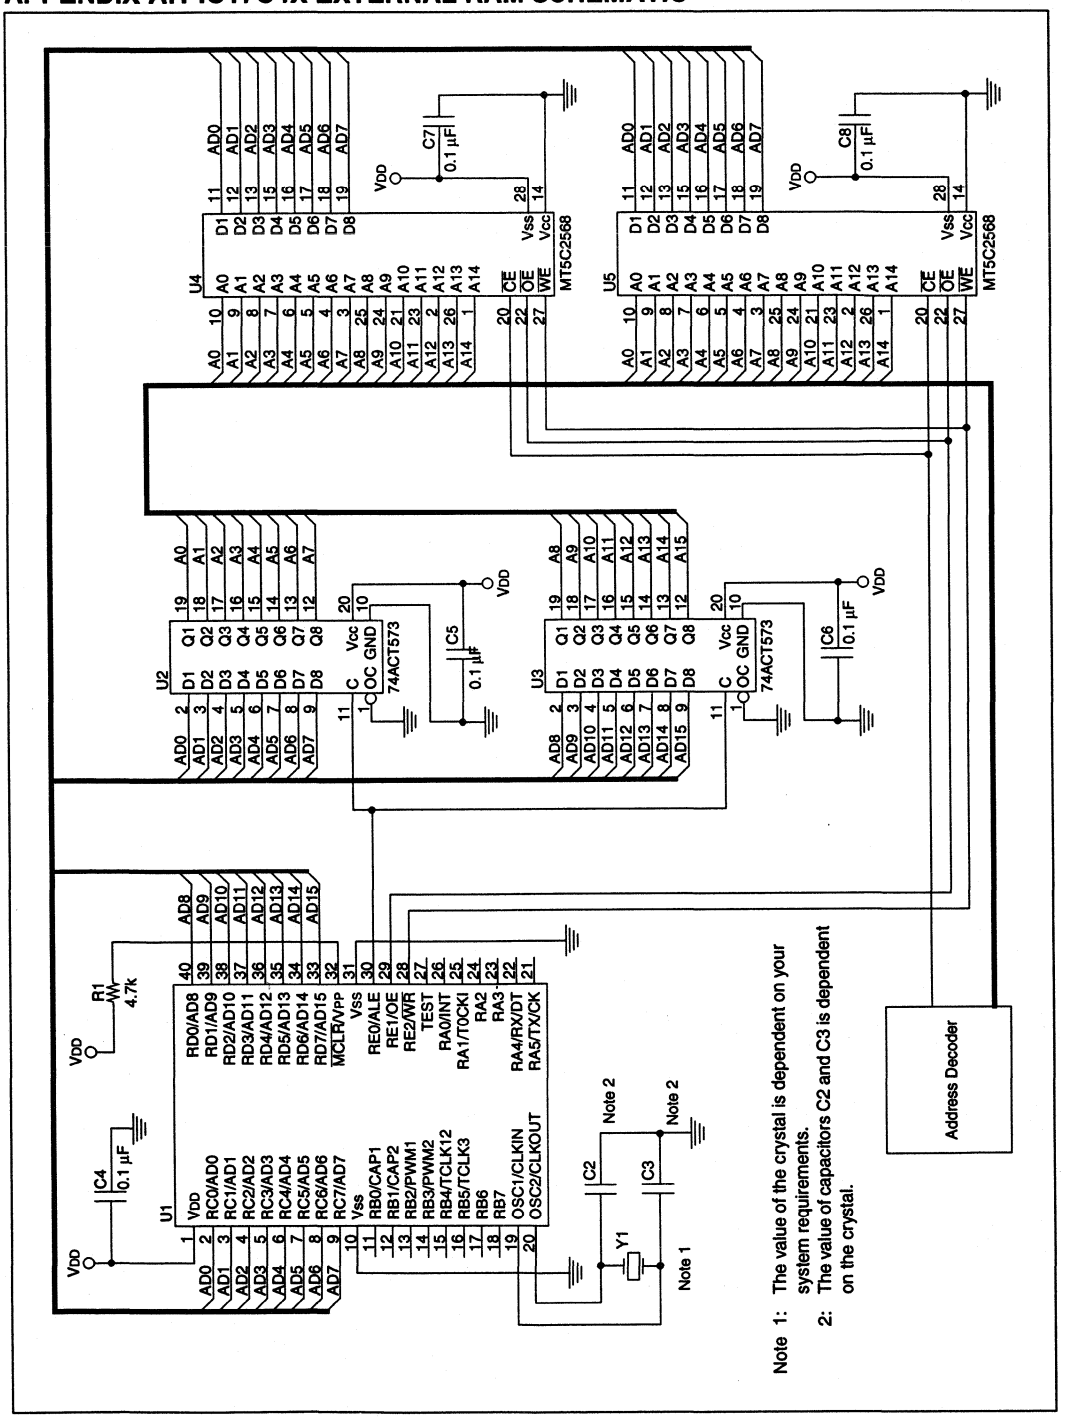
TADV2WRL = 0.25 * 500 - 40 + 0.25 * 500	TADV2WRL = 0.25 * 250 - 40 + 0.25 * 250	TADV2WRL = 0.25 * 160 - 40 + 0.25 * 160	TADV2WRL = 0.25 * 160 - 40 + 0.25 * 160
TWRH2ADI = 0.25 * 500	TWRH2ADI = 0.25 * 250	TWRH2ADI = 0.25 * 160	TWRH2ADI = 0.25 * 160
TADV2ALL = 115	TADV2ALL = 52.5	TADV2ALL = 40	TADV2ALL = 30
TAS = 95	TAS = 32.5	TAS = 20	TAS = 10
- 6	- 6	- 6	- 6
- TPDGAL	- TPDGAL	- TPDGAL	- TPDGAL
+ 125	+ 62.5	+ 50	+ 40
TWRL = 125	TWRL = 62.5	TWRL = 50	TWRL = 40
TADV2WRL = 210	TADV2WRL = 227.5	TADV2WRL = 60	TADV2WRL = 40
TWRH2ADI = 125	TWRH2ADI = 62.5	TWRH2ADI = 50	TWRH2ADI = 40
TADV2ALL = 115	TADV2ALL = 52.5	TADV2ALL = 40	TADV2ALL = 30
TAS = 214 - TPDGAL	TAS = 89 - TPDGAL	TAS = 64 - TPDGAL	TAS = 44 - TPDGAL
TWRL > 15 ns	TWRL > 15 ns	TWRL > 15 ns	TWRL > 15 ns
TADV2WRL > 15 ns	TADV2WRL > 15 ns	TADV2WRL > 15 ns	TADV2WRL > 15 ns
TWRH2ADI > 0 ns	TWRH2ADI > 0 ns	TWRH2ADI > 0 ns	TWRH2ADI > 0 ns

Assuming that a 16V8 with propagation delay of 25 ns is used for the address decoder, you can see that all crystal frequencies have a TAS greater than 0. The other parameters TADV2WRL, TWRH2ADI, and TWRL all have at least 25 ns of spare room. The parameters TADV2WRL, TWRH2ADI, and TWRL were taken from a 25 ns speed grade SRAM. Therefore, all the speed grades of the MT5C2568 can be used for the write cycle of a PIC17C4X with an external oscillator frequency up to 25 MHz.



CONCLUSION

So now that we have done the calculations, let's determine the proper SRAM speed grade for the various frequencies. The only assumption is that a 25 ns 16V8 is used for address decoding.

- 8 MHz can use up to a 300 ns SRAM
- 16 MHz can use up to a 125 ns SRAM
- 20 MHz can use up to a 90 ns SRAM
- 25 MHz can use up to a 50 ns SRAM

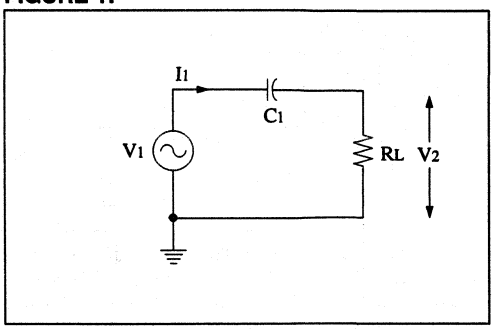
Transformerless Power Supply

Author: *Stan D'Souza*
Microchip Technology inc.

INTRODUCTION



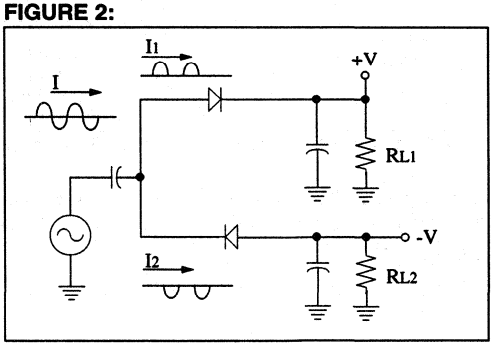
In most non-battery applications, the power to the microcontroller is normally supplied using a wall mounted transformer which is then rectified, filtered and regulated. In most applications this method of generating the regulated voltage is cost effective and can be justified. However there are applications where the PIC12/16/17 is the main controller and low voltage is not required by other components except the PIC12/16/17. In these instances the cost of the transformer becomes the sizable cost factor in the system. Transformerless power supplies, thus, have a distinct advantage in cost as well as in size. The disadvantages of using a transformerless power supply are: (1)Low current supply and (2) no isolation from the AC line voltage. The PIC12/16/17 microcontrollers draw a maximum of 10 mA, even at the highest frequency and voltage of operation, therefore low current availability is not an issue. AC line voltage isolation can be addressed by using MOVs or transient suppressors on the PIC12/16/17.

IMPLEMENTATION

When a capacitor and resistor are connected in series to an AC source, as in Figure 1, a constant current can be maintained through the resistor, so long as the reactance of the capacitors is much greater than the resistance. The current flow is dependent upon the value of the capacitor and assuming that V_1 is much greater than V_2, the value of the current can be assumed to be:

$I_{RMS} = V_1/X_C$ where X_C is the reactance of the capacitor.

FIGURE 1:

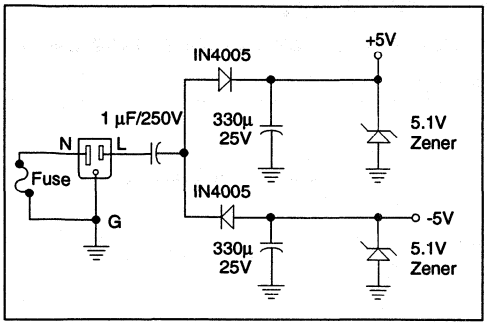


Assuming a line voltage of $V_1 = 115V$ and line frequency = 60 Hz,

$I_{RMS} = 115(2\pi 60C) = 4300C$ or $I_{RMS} \approx 40$ mA/µF.

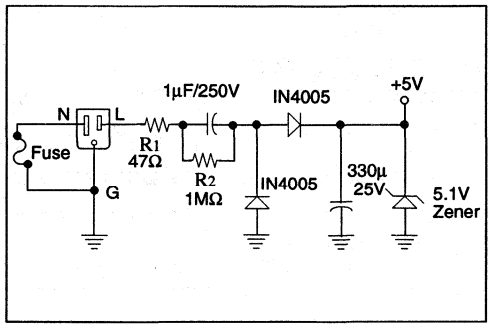
In order to get a DC voltage using this system, a pair of rectifiers and filter caps can be added as shown in Figure 2. This would give us a capability of driving one half of the current through the positive part and the other half through the negative part. So the max current on each side would be = 20 mA/µF.

FIGURE 2:



9

© 1997 Microchip Technology Inc.



In most applications the output voltage should be regulated. Figure 3 shows a diagram for a practical circuit where a +/- 5V regulated output is generated. Note that the Neutral is connected to ground, through a fuse. This would guard against improper AC wiring.

FIGURE 3:

In most PIC12/16/17 applications the negative voltage is not required. Figure 3 has been thus modified for a single ended supply as in Figure 4. Note that R1 and R2 are required for UL approval.

FIGURE 4:

Precautions:

1. As mentioned earlier, the neutral should be connected to earth ground through a fuse. This would insure protection in case of improper wiring.
2. The AC coupling capacitors and rectifier diodes should be able to withstand the peak voltage in the system. Remember $V_{RMS} = V_{PG}/2$, where $V_{PG} = V_{PEAK}$ to earth ground voltage. Hence for a 120V system the max voltage = 170V. For a 240V system the max voltage = 340V.

TABLE 1: COST ANALYSIS OF A +5V POWER SUPPLY WITH/WITHOUT A TRANSFORMER:

Components	Unit Price	Qty	Transformer P.S.	Qty.	Transformerless P.S.
1.1 VA transformer	5.65	1	5.65	0	-
1N4005 diode	0.05	2	0.10	2	0.10
1 µF/250V Cap	0.57	0	-	1	0.57
5.1V Zener	0.11	1	0.11	1	0.11
330 µF/25V Filter Cap	0.17	1	0.17	1	0.17
Total			6.03		0.95

All Prices based on 100 Qty price from Digikey Catalog.

As can be seen the cost of the transformer power supply is 6 times that of the transformerless power supply. In quantities of 100, the cost of a transformerless power supply is less than a buck.

Conclusion:

A Transformerless power supply is a low cost (under a buck), small footprint alternative by which a PIC12/16/17 can be powered.

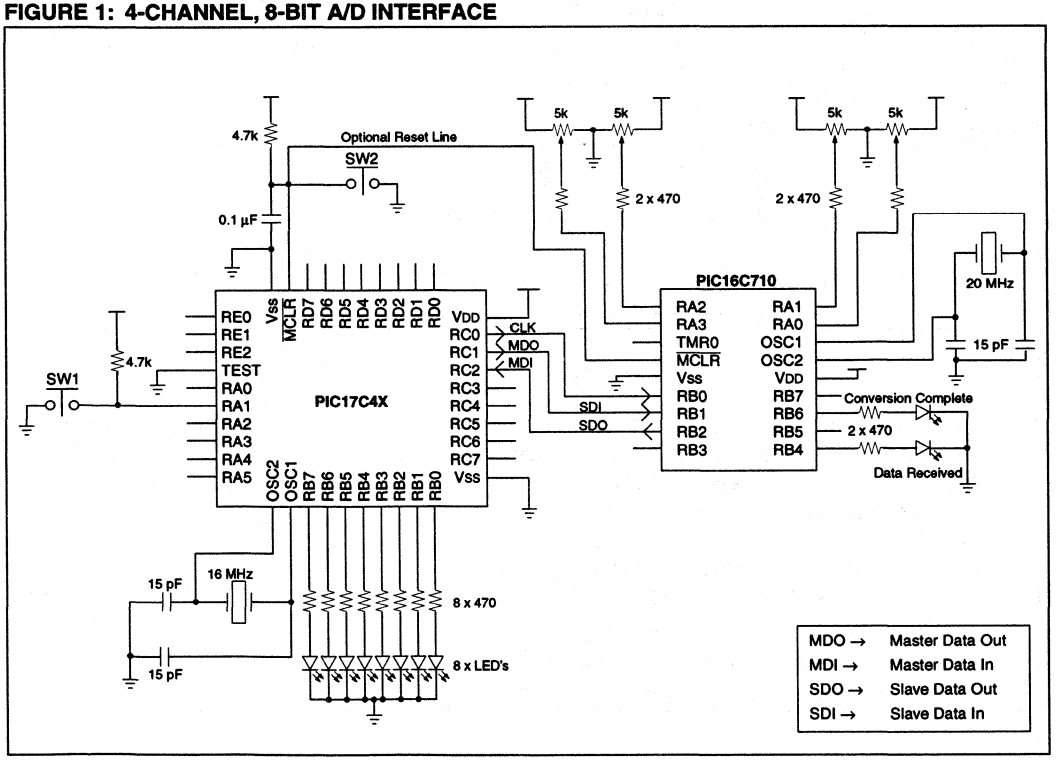
Adding a Simple 4-channel 8-bit A/D to a PIC17C4X

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION



The PIC17C4X high end microcontroller family, offered by Microchip, has many features which make it one of the fastest 8-bit microcontrollers in the industry. However one feature which is missing is an on-chip Analog-to-Digital (A/D) converter. This Technical Brief describes how to connect a PIC16C710 to a PIC17C4X through a simple Serial I/O (SIO) 3 line interface. The result is a quick method by which a user can get a fast (approx. 17 kHz transfer rate) 4-channel A/D converter.

IMPLEMENTATION

The PIC17C4X is the master device in this case, operating at 16 MHz . The master generates the CLK pulse and initiates the conversion. The PIC16C710 is the slave, operating at 20 MHz, and provides the A/D hardware. The two devices are connected using 3 I/O lines, clock, data in, and data out, as shown in Figure 1. The additional connections in Figure 1 are purely for this example and can be omitted if not needed.

The sequence of timed events are depicted in Figure 1. The Master (PIC17C4X) generates the CLK signal and initiates the conversion by transmitting the ADCON register value to the slave (PIC16C710). The slave (PIC16C710) simultaneously transmits ADRES back to the master (PIC17C4X). The ADCON register value has information requesting a new A/D value. The ADRES is the 8-bit result of the last A/D conversion

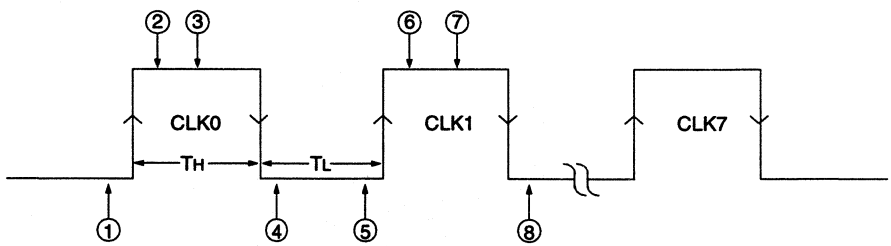
FIGURE 1: 4-CHANNEL, 8-BIT A/D INTERFACE

9

© 1997 Microchip Technology Inc.

requested. One transmission set consists of 8 clock pulses during which the rising edge of each clock pulse is used to transfer data (ADCON register value) from the PIC17C4X to the PIC16C710 and the falling edge of each clock pulse is used to transfer data (ADRES register value) from the PIC16C710 to the PIC17C4X. This method results in a quick transfer of data back and forth from the two processors. This method of transfer also implies that when the master is requesting for a new A/D value from the slave, it is receiving the A/D result of the last request. The two 8-bit register values (ADCON and ADRES) are maintained in the PIC17C4X and the PIC16C710. The PIC17C4X maintains ADCON and ADRES in general purpose RAM. The PIC16C710 maintains the ADCON in general purpose RAM and the ADRES as a special function register. As seen by its name the ADRES is the register which contains the result of the A/D conversion. ADCON register on the other hand is a merger of various bits from the ADCON0 and ADCON1 special function register defined in the PIC16C710. The definitions for ADCON bits are as below:

ADCON bit #	PIC16C710 definitions	PIC16C710 bit assignments
0	PCFG0	ADCON1<0>
1	PCFG1	ADCON1<1>
2	GO/$\overline{\text{DONE}}$	ADCON0<2>
3	CHS0	ADCON0<3>
4	CHS1	ADCON0<4>
5	Not used	Not Used
6	ADCS0	ADCON0<6>
7	ADCS1	ADCON0<7>



With this setup the user has full control and access to all the A/D configuration features of the PIC16C710. In the example code in Appendix A and Appendix B, the PORTA pins have been all selected as digital I/O and the A/D conversion clock is the internal RC oscillator.

A key feature of this arrangement is the simplicity of the interface. To minimize the number of I/O lines used, the master can reset the slave without having to use the slave's Master Clear ($\overline{\text{MCLR}}$) pin. This can be accomplished by using the PIC16C710's Watchdog Timer (WDT) enabled with a time-out of 18 ms. Once the leading edge of the transfer string is initiated, the master has 8 ms in which to complete the transfer. If the transfer takes longer than the WDT time-out, the WDT will time-out and the PIC16C710 will reset. This feature allows the master to reset the slave, at any time, by initiating a transfer but not completing it before the WDT times out. With a 1:1 prescaler setting, the PIC16C710's WDT will time out between 18 ms and 40 ms.

CONCLUSION

The addition of the PIC16C710 to a PIC17C4X gives the analog input capability to the high-end microcontroller family while only sacrificing 123 words of program memory and 2 bytes of RAM. The simple program in the PIC16C710 uses only 82 words of program memory and 3 bytes of RAM. Since only four pins on the PIC16C710 are used for analog input, the rest of the microcontroller can be used as general purpose I/O if needed.

FIGURE 1: INTERFACE TIMING

1. PIC17C4X sets MDO line = bit0 of ADCON.
2. PIC16C710 gets interrupt and reads bit0 value of ADCON on SDI line.
3. PIC16C710 sets SDO line = bit0 of ADRES.
4. PIC17C4X reads bit0 of ADRES on MDI line.
5. PIC17C4X sets MDO line = bit1 of ADCON.
6. PIC16C710 reads bit1 of ADCON on SDI line.
7. PIC16C710 sets SDO bit = bit1 of ADRES.
8. PIC17C4X reads bit1 of ADRES on MDI line.

Steps 1 through 4 are repeated till all 8-bits are received and sent.

The Clock is generated by the Master.

MDO → Master Data Out
MDI → Master Data In
SDO → Slave Data Out
SDI → Slave Data In
TH > 2 µs min.
TL > 2 µs min.

© 1997 Microchip Technology Inc.

PERFORMANCE

The conversion rate is the addition of the SIO transfer rate as well as acquisition time rate:

The calculation is as follows:

$$[(2 + 2) \bullet 8 + 25]\ \mu s = 57\ \mu s \Rightarrow 17.5\ kHz.$$

APPENDIX A: CODE FOR PIC17C4X (MASTER)

```
/* This program implements the master control of the ADC interface
   with a PIC16C710 as a simple serial ADC device for use with the
   PIC17C4X.
   The 3 wire interface is as follows:
    CLK --> RC0 output
    DO  --> RC1 output
    DI  --> RC2 input
   The PIC17C4X will transmit an 8-bit byte to the PIC16C710
   in order for it to configure registers ADCON1 and ADCON0 as follows:
    Bit 0 --> PCFG0
    Bit 1 --> PCFG1
    BIT 2 --> Start
    BIT 3 --> CHS0
    BIT 4 --> CHS1
    BIT 5 --> not used
    BIT 6 --> ADCS0
    BIT 7 --> ADCS1
   The ADCON0 and ADCON1 registers are merged into one register
   to help reduce the interface overhead. After all the 8 bits are
   received, bits 0 and 1 are placed in ADCON1 and bits 3 to 7
   are placed in ADCON0.  Depending on the state of bit 2,
   the A/D conversion is then started.

   The protocol basics are as follows:
    Two registers are maintained in the PIC17C4X which are
    used in the transfer:
    ADCON --> ADCON1 merged with ADCON0
    ADRES --> same as the AD result register
    8 clock signals are used to transmit the ADRES value
    and receive the next ADCON value. On the rising edge of
    the clock the serial ADCON value is sent whilst on the
    falling edge of the same clock the serial ADRES value
    is read.  In this manner an efficient transfer
    rate is maintained with very little overhead to software
    and more importantly rate of A/D conversion.
    The PIC16C710 also maintains a replica of ADCON and ADRES
    and does just the opposite of what the PIC17C4X does i.e
    ADCON is received and ADRES is transmitted.  The clock
    master is always the PIC17C4X, the PIC16C710 is always the
    slave.  The transfer occurs as below:
    Clock   Data IN(DI) Data OUT(DO)
    ------------------------------------------------
    Rising edge    N/A       RRF ADCON; C --> DO
    Falling edge   read DI     N/A

    This is repeated till all 8 bits are transmitted/received.

    On receiving the 8-bit value, the ADCON1 and ADCON0 registers
    configured and the A/D conversion started.  The result of the
    conversion is then stored in the ADRES register.  The next
    transfer then sends the ADRES result out.

    NOTE: The PIC17C4X has to provide enough time for sampling
          and for the conversion to complete.

    The WDT on the PIC16C710 is enabled and used in the following manner:

    The entire 8 clock and A/D conversion should be done in a
    max of 8 mS, which is the min. timeout period for the WDT.
    If this is not done the PIC16C710 will reset and wait for
    another 8 clocks. In this manner the master can reset the
    slave by toggling the clock once and waiting for 40 mS,
    which is the max. time for WDT with no postscaler.

APPENDIX B: CODE FOR PIC16C710 (SLAVE)

```
/* This program creates a serial I/O interface with a PIC17C4X
   device.  The basic intent of this interface is to use the
   PIC16C710 as a simple serial ADC device for use with the PIC17C4X.
   The 3 wire interface is as follows:
    CLK --> RB0/INT
    DI  --> RB1
    DO  --> RB2
   The PIC17C4X device will transmit an 8-bit word to the PIC16C710
   in order for it to configure the following:
    Bit 0 --> PCFG0
    Bit 1 --> PCFG1
    BIT 2 --> Start
    BIT 3 --> CHS0
    BIT 4 --> CHS1
    BIT 5 --> not used
    BIT 6 --> ADCS0
    BIT 7 --> ADCS1
   The ADCON0 and ADCON1 registers are merged into one register
   to help reduce the interface overhead. After all the 8 bits are
   received, bits 0 and 1 are placed in ADCON1 and bits 3 to 7
   are placed in ADCON0.  Depending on the state of the bit 2,
   the A/D conversion is then started.

   The protocol basics are as follows:
    Two registers are maintained in the PIC16C710 which are
    used in the transfer:
    ADCON --> ADCON1 merged with ADCON0
    ADRES --> same as the AD result register
    8 clock signals are used to transmit the ADRES value
    and receive the next ADCON value. On the rising edge of
    the clock the serial ADCON value is read whilst on the
    falling edge of the same clock the serial ADRES value
    is transmitted.  In this manner an efficient transfer
    rate is maintained with very little overhead to software
    and more importantly rate of A/D conversion.
    The PIC17C4X also maintains a replica of ADCON and ADRES
    and does just the opposite of what the PIC16C710 does i.e
    ADRES is received and ADCON is transmitted.  The clock
    master is always the PIC17C4X, the PIC16C710 is always the
    slave.  The transfer occurs as below:
    Clock   Data IN(DI) Data OUT(DO)
    ------------------------------------------------
    Falling edge   N/A     RRF ADRES; C --> DO
    Rising edge    read DI       N/A

    This is repeated till all 8 bits are transmitted/received.

    On receiving the 8-bit value, the ADCON1 and ADCON0 registers
    configured and the A/D conversion started.  The result of the
    conversion is then stored in the ADRES register.  The next
    transfer then sends the ADRES result out.

    NOTE: The PIC17C4X has to provide for enough time for sampling
    and for the conversion to complete.

   The WDT is enabled and used in the following manner:
    The entire 8 clocks and A/D conversion should be done in a
    max. of 8 mS, which is the min. timeout period for the WDT.
    If this is not done the PIC16C710 will reset and wait for
    another 8 clocks. In this manner the master can reset the
    slave by toggling the clock once and waiting for 40 mS,
    which is the max. time for WDT.

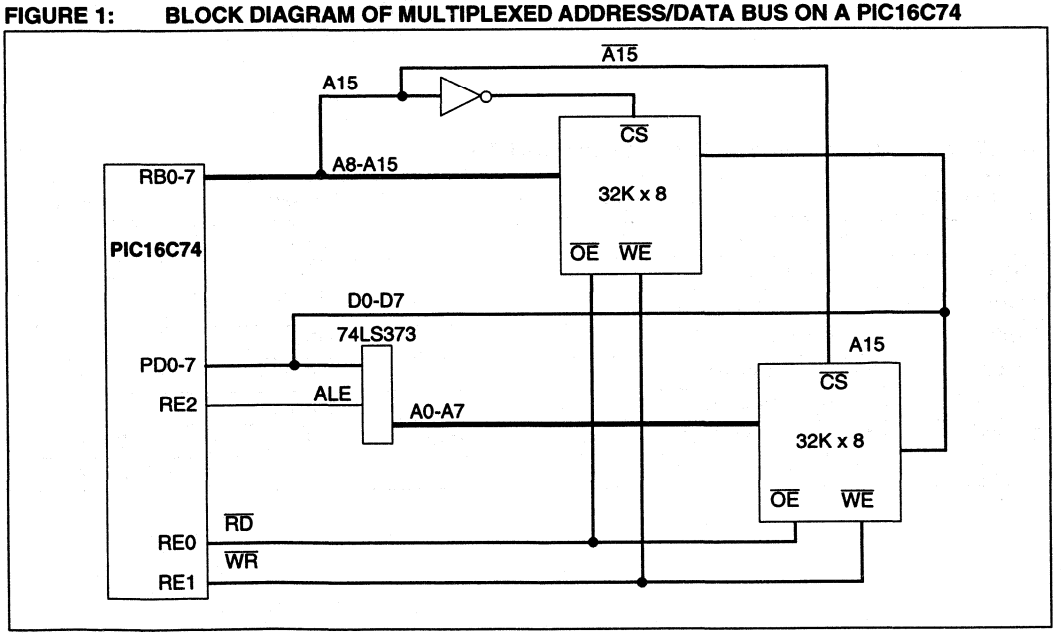
Using SRAM With A PIC16CXXX

Author: Rick Evans
Microchip Technology Inc.

INTRODUCTION

There are applications where a significant amount of data memory is required beyond what is in the microcontroller. For example, buffering communications data, creating large volatile tables and arrays. One interesting application is voice storage and playback. Some applications require relatively low frequencies, so a fast address/data bus and expensive FSRAM are not necessary.



This application note uses the PIC16C74. Since the PIC16C74 does not have an external address/data bus, one was created using the I/O ports. A software implementation of a multiplexed address/data bus is more than adequate for some applications. This application note discusses the read and write speeds achievable with the PIC16C74 running at 20 MHz, hardware connections necessary, and software routines for reading and writing to external memory.

IMPLEMENTATION

The multiplexed address/data bus was created using nineteen port pins (Figure 1). PORTD is address lines 0 through 7 multiplexed with data lines 0 through 7. PORTB is the upper address lines 8-15. PORTE<0> is the $\overline{RD}$, PORTE<1> is $\overline{WR}$ and PORTE<2> is ALE (address latch enable). One SRAM chip is address range 0000h-7FFFh, and the other SRAM chip is address range 8000h-FFFFh. The chip selecting is done using A15 and $\overline{A15}$. A 74LS373 latch is needed to demultiplex the low order address/data bus.

The software needed to initialize the ports is in the subroutine `init_muxbus` (Appendix A). The initial states of the address lines and bus control signals are shown in the comments of the subroutine.

FIGURE 1: BLOCK DIAGRAM OF MULTIPLEXED ADDRESS/DATA BUS ON A PIC16C74

9

READ CYCLE

The software to do the read cycle is very straight forward. The read cycle drives the address onto the 16-bit bus, then latches the low order address lines 0-7 on to the memory device (Figure 2). When ALE goes low, address 0-7 is latched. Then the low order bus lines 0-7 are changed to input pins. Next, the read pin ($\overline{RD}$) goes low which turns on the output buffers of the memory device. Some time later, the data from the memory is driven on to the data lines 0-7. Then $\overline{RD}$ goes high and the output buffers of the memory device are disabled. Next, the low order data lines are changed back to outputs. The subroutine `read_extmem` shows the code used to emulate a read cycle on PORTB and PORTD.

You can ascertain from Table 1, that a slow SRAM can be used. There are three critical SRAM read cycle specifications:

TACC: Address access time
TOE: Output enable time
TDF: Data float time

The address access time TACC corresponds to the TAVDV (1.6 µs) of the emulated muxed bus. A FUJITSU MB84256C-70 has an access time of 70 ns. The output enable time TOE from the Fujitsu data sheet is 35 ns. The emulated muxed bus specification TRLDV (200 ns) corresponds to the TOE of the Fujitsu SRAM. The data float time TDF is only important if you are doing back to back bus cycles.

WRITE CYCLE

The write cycle moves data to the external SRAM. The address is driven on the sixteen address lines, then the low order address is latched by making ALE go high and then low. The data is moved to the low order address lines (data lines). Finally, the $\overline{WR}$ pin is driven low and then high. When write goes high, the data is written to the SRAM. Figure 3 shows the bus timing diagram for the write cycle.

The write cycle is even simpler to implement in software than the read cycle. The subroutine `write_extmem` shows code used to write out data to an external SRAM.

The write pulse width is an important specification in memory design as well. For the PIC16C74 emulated address/data bus the write pulse width is TWLWH. The value for the write pulse width is very large compared to actual address/data bus implementations. The TAVWH specification corresponds to the TAW specification of most memory devices. The emulated address/data bus has relatively slow bus timings compared with most memory access times such as EPROMs and SRAMs.

SUMMARY

A 40-pin PIC16CXXX device such as the PIC16C74 can interface to external memory. This application note used sixteen address lines multiplexed with eight data lines to read/write to two external SRAMs. The read/write cycle times can be calculated easily given the single cycle instruction architectures of the PIC16CXXX. Flash, EPROM and other parallel bus memory devices can be similarly utilized.

TABLE 1: READ AND WRITE CYCLE BUS TIMINGS

Timing	Description	Minimum	Maximum
TCY	Instruction cycle time @ 20 MHz	200 ns	DC
TLLLH	ALE pulse width	1 TCY	—
TAVDV	Address valid to data valid	—	7 TCY
TRLDV	Read low to data valid	1 TCY	—
TRHDZ	Read high to data float	0	1 TCY
TWLWH	WRITE pulse width	1 TCY	—
TWHDX	WRITE high to data no longer valid (data hold time)	—	2 TCY
TAVWH	Address valid to write high	—	5 TCY

RD001

Uninterruptible Power Supply Reference Design Based on PIC17C43

The PICREF-1 Reference Design offers a ready-made uninterruptible power supply solution with the flexibility of a microcontroller.

The Microchip Technology PICREF-1 Reference Design offers designers an intelligent UPS solution. This reference design is based on the "on-line" topology which provides true UPS performance.

The PIC17C43 microcontroller handles all the control of the UPS system. The PIC17C43 is unique because it provides a high performance and low cost solution not found in other microcontrollers.

The PIC17C43 PWM controls an inverter as necessary for generation of a sinusoidal AC output waveform. Fault signaling can be initiated internal or external to the PIC17C43 depending on the type of fault. A fault will disable the entire inverter. The output voltage and current will be monitored by the PIC17C43 to make adjustments "real-time" to correct for DC offset and load changes.

The PIC17C43 controls all module synchronization as well as inverter control and feedback. The PIC17C43 uses zero crossing for synchronization of input voltage/phase to output voltage/phase. All internal module synchronization is handled by the PIC17C43.

The control algorithms and software are written in C for maintainability and transportability.

To obtain a copy of the complete reference design documentation, contact your nearest Microchip Worldwide Sales and Service Representative and ask about the PICREF-1 Uninterruptible Power Supply Reference Design.

10

PICREF-1 FEATURES

- On-Line Topology
- True Sinusoidal Output
- 1400 VA Rating
- 120/240 V Input

© 1997 Microchip Technology Inc.

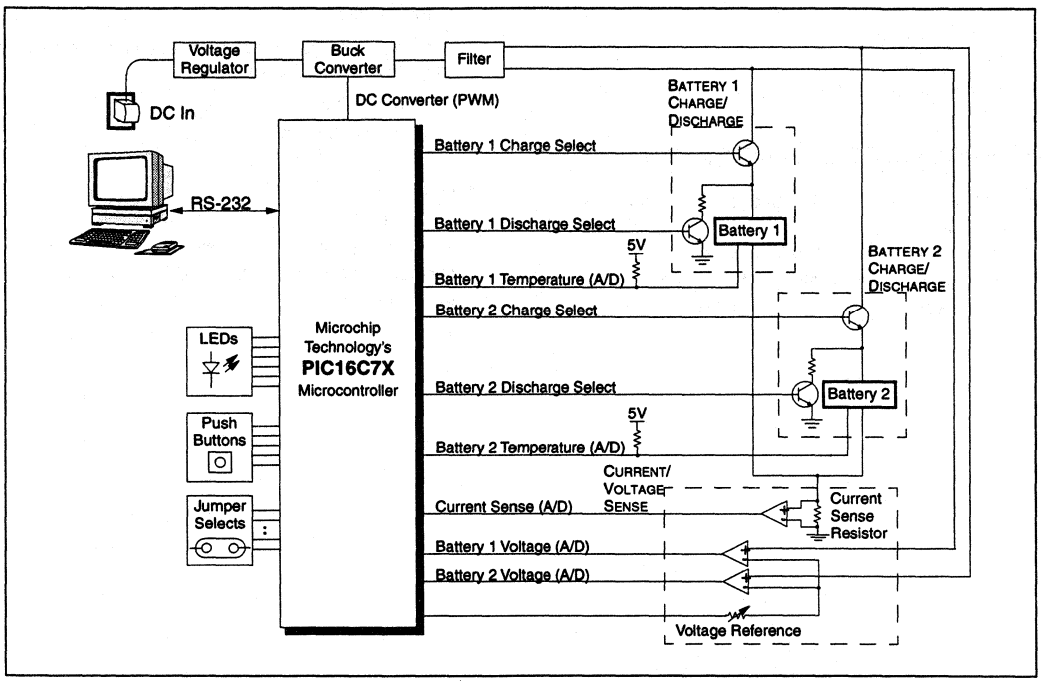
MICROCONTROLLER BENEFITS

- High Quality Sine Wave
  - Harvard Architecture
  - Hardware Multiply
  - 10-bit PWM
- Flexibility
- Transportability of Design
- Variable Loop Response
- Digital Filtering
- Parts and Complexity Reduction
- Peripheral Integration
- Ease of Interfacing
- Testability
- Time to Market

DOCUMENTATION YOU GET

- Theory and operation of UPS
- Fully documented source code
- Information on how to build a demo unit
  - Full circuit schematics
  - Bill of materials
  - PCB layout and Fab drawings
  - Unit assembly
  - Test results

Reference design material is available electronically from the following sources:



- Worldwide Web
  - www.microchip.com
  - ftp.mchip.com/biz/mchip

RD002

Intelligent Battery Charger Reference Design Based on PIC16C7X

The PICREF-2 Reference Design offers a ready-made battery charger solution that can accommodate several popular types of batteries.

With the PICREF-2 Reference Design, the user will be able to simply pick their complete battery charging system by completing the steps listed below:

1. Pick the required battery management features from the modular source code provided.
2. Pick the critical battery pack parameters and modify the global constants to those specifications.

The hardware design contains the necessary circuitry to support charging and discharging algorithms for four battery technologies (NiCd, NiMH, LiI, and Pb-Acid), four charge termination methods (-ΔV, ΔT/Δt, Absolute Voltage, and Timed Charge) and RS-232 communications.

The modular source code is written in C and consists of the four charge termination algorithms (-ΔV, ΔT/Δt, Absolute Voltage, and Timed Charge), discharge algorithm, inter-device communications and RS-232 communications modules.

The PC-based software provides a means for requesting and displaying battery status information.

To obtain a copy of the complete reference design, contact your nearest Microchip Worldwide Sales and Service Representative and ask for the PICREF-2 Intelligent Battery Charger Reference Design.

10

© 1997 Microchip Technology Inc.

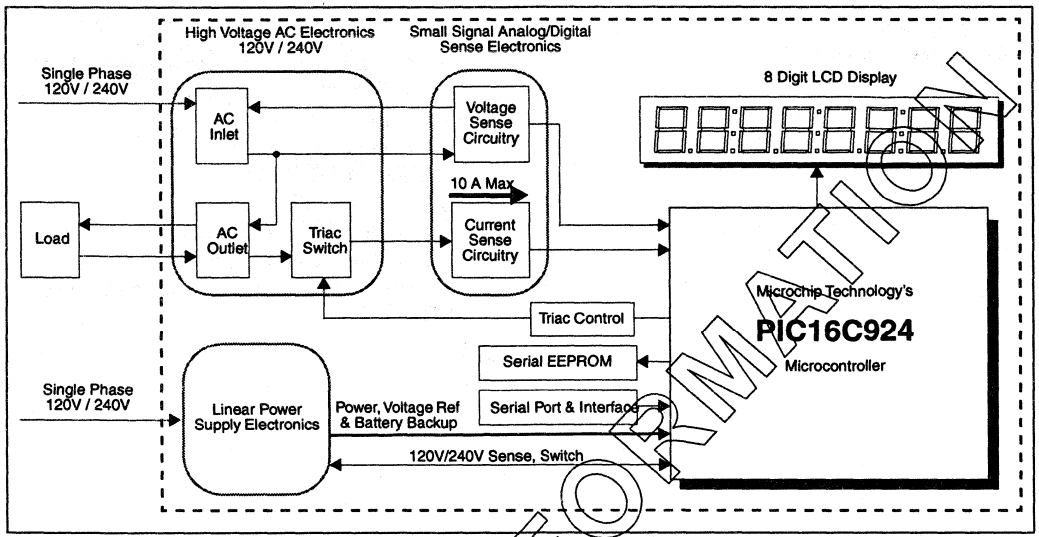
PICREF-2 FEATURES

- Compatibility Across Technologies - (NiCd, NiMH, Li-Ion and Lead Acid)
- Low Cost
- Flexible Development Environment
- Fast Charge Rate
- High Charge Current Capability
- High Discharge Current Capability for Conditioning
- Real-Time Debug
- Data Logging
- User Selectable Embedded Charger Termination Algorithm

MICROCONTROLLER BENEFITS

- Flexibility to handle different chemistries, voltages and capacities.
- Variable Voltage Generation Control
- Charge/Discharge Multiple Battery Packs
- "Windowed" A/D for High Resolution

DOCUMENTATION YOU GET



- Theory and operation of Battery Charger
- Fully documented source code
- Information on the demo unit
  - Full circuit schematics
  - Bill of materials
  - PCB layout and Fab drawings
  - Unit assembly
  - Test results

Watt-Hour Meter Reference Design Based on PIC16C924

The PICREF-3 Reference Design provides a cost-effective way to monitor and display power and energy consumption for a single 120V or 240V electrical service.

The PICREF-3 Reference Design shows how to develop a cost-effective Watt-Hour meter. Using the PIC16C924 microcontroller, the meter can interleave real-time voltage and current waveform sampling with power and energy calculations.

Single phase (120V or 240V) electricity is sensed by the high voltage AC electronics. Balanced input voltage and current signals are then provided to the Small Signal Analog/Digital Sense Electronics for input into the PIC16C924. The PIC16C924 uses the analog/digital voltage sense and analog/digital current sense to calculate the power and energy consumption of the load. The microcontroller then displays this on the 8-digit LCD. Linear Power Supply Electronics provide general device power, voltage reference, battery backup and 120V/240V sense information.

The modular source code is written in C. Software algorithms accomplish voltage and current measurements, voltage and current waveform phase shift measurements, real-time timekeeping, and calculation and display of energy consumption. In addition, there is code to display measurements on the LCD and to communicate data to the serial EEPROM or via the serial port.

To obtain a copy of the complete reference design, contact your nearest Microchip Worldwide Sales and Service Representative and ask for the PICREF-3 Watt-Hour Meter Reference Design.

PICREF-3 FEATURES

- Low Cost
- 120V/240V Automatic Switch
- Flexible Development Environment
- Battery Backup

ADVANCE INFORMATION

MICROCONTROLLER BENEFITS

- Real-Time Electrical Measurement and Power/ Energy Calculations
- Direct LCD Drive
  - Present Time and Date
  - Total Whr
  - Alternate Energy (VARhr or VAhr)
  - Maximum or Cumulative Demand
- Customization
- Quick Time to Market

ON-LINE SUPPORT

Microchip Internet and BBS Connections

ON-LINE SUPPORT

Microchip provides two methods of on-line support. These are the Microchip BBS and the Microchip World Wide Web (WWW) site.

Use Microchip's Bulletin Board Service (BBS) to get current information and help about Microchip products. Microchip provides the BBS communication channel for you to use in extending your technical staff with microcontroller and memory experts.

To provide you with the most responsive service possible, the Microchip systems team monitors the BBS, posts the latest component data and software tool updates, provides technical help and embedded systems insights, and discusses how Microchip products provide project solutions.

The web site, like the BBS, is used by Microchip as a means to make files and information easily available to customers. To view the site, the user must have access to the Internet and a web browser, such as Netscape or Microsoft Explorer. Files are also available for FTP download from our FTP site.

Connecting to the Microchip Internet Web Site

The Microchip web site is available by using your favorite Internet browser to attach to:

www.microchip.com

The file transfer site is available by using an FTP service to connect to:

ftp://ftp.futureone.com/pub/microchip

The web site and file transfer site provide a variety of services. Users may download files for the latest Development Tools, Data Sheets, Application Notes, User's Guides, Articles and Sample Programs. A variety of Microchip specific business information is also available, including listings of Microchip sales offices, distributors and factory representatives. Other data available for consideration is:

- Latest Microchip Press Releases
- Technical Support Section with Frequently Asked Questions
- Design Tips
- Device Errata
- Job Postings
- Microchip Consultant Program Member Listing
- Links to other useful web sites related to Microchip Products

Connecting to the Microchip BBS

Connect worldwide to the Microchip BBS using either the Internet or the CompuServe® communications network.

Internet:

You can telnet or ftp to the Microchip BBS at the address:

mchipbbs.microchip.com

CompuServe Communications Network:

When using the BBS via the Compuserve Network, in most cases, a local call is your only expense. The Microchip BBS connection does not use CompuServe membership services, therefore you do not need CompuServe membership to join Microchip's BBS. There is no charge for connecting to the Microchip BBS.

The procedure to connect will vary slightly from country to country. Please check with your local CompuServe agent for details if you have a problem. CompuServe service allow multiple users various baud rates depending on the local point of access.

The following connect procedure applies in most locations.

1. Set your modem to 8-bit, No parity, and One stop (8N1). This is not the normal CompuServe setting which is 7E1.
2. Dial your local CompuServe access number.
3. Depress the **<Enter>** key and a garbage string will appear because CompuServe is expecting a 7E1 setting.
4. Type **+**, depress the **<Enter>** key and "`Host Name:`" will appear.
5. Type MCHIPBBS, depress the <Enter> key and you will be connected to the Microchip BBS.

In the United States, to find the CompuServe phone number closest to you, set your modem to 7E1 and dial (800) 848-4480 for 300-2400 baud or (800) 331-7166 for 9600-14400 baud connection. After the system responds with "`Host Name:`", type `NETWORK`, depress the **<Enter>** key and follow CompuServe's directions.

For voice information (or calling from overseas), you may call (614) 723-1550 for your local CompuServe number.

© 1997 Microchip Technology Inc.

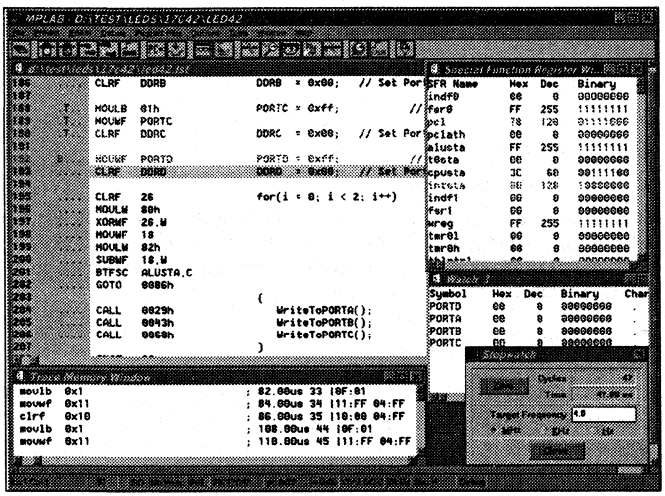
On-Line Support

Microchip regularly uses the Microchip BBS to distribute technical information, application notes, source code, errata sheets, bug reports, and interim patches for Microchip systems software products. For each SIG, a moderator monitors, scans, and approves or disapproves files submitted to the SIG. No executable files are accepted from the user community in general to limit the spread of computer viruses.

Systems Information and Upgrade Hot Line

The Systems Information and Upgrade Line provides system users a listing of the latest versions of all of Microchip's development systems software products. Plus, this line provides information on how customers can receive any currently available upgrade kits.The Hot Line Numbers are:

1-800-755-2345 for U.S. and most of Canada, and



1-602-786-7302 for the rest of the world.

MICROCHIP

MPLAB™

Integrated Development Environment Product Brief

MPLAB gives PICmicro MCU users the flexibility to edit, compile and debug from a single user interface.

MPLAB is a Windows®-based development platform for the Microchip Technology PICmicro™ one-time-programmable (OTP) MCU families. MPLAB Integrated Development Environment (IDE) offers a project manager and program text editor, a user-configurable toolbar containing four pre-defined sets and a status bar which communicates editing and debugging information.

MPLAB is the common user interface for Microchip development systems tools including MPLAB Editor, MPASM Assembler, MPLAB-SIM Software Simulator, PICMASTER® In-Circuit Emulator and PICSTART® Plus Development Programmer. Additional products may become available as add-on tools in the future.

The MPLAB desktop provides the development environment and tools for developing and debugging your application as a project, allowing you to quickly move between different development and debugging modes. With the MPLAB environment, you can debug your source code, automatically locate errors in source files for editing, debug with breakpoints based on internal register values, watch the program flow with MPLAB-SIM (software simulator) or PICMASTER, make timing measurements with a "stop watch," view variables in watch windows and find quick answers to questions from the MPLAB on-line help.

Features:

MPLAB Project Manager

- Organizes the different files that comprise your application firmware under one "Project"
- Allows you to create a project; add, edit or debug a source code file in a project; and build object files

MPLAB Editor

- Full-featured programmer's editor lets you write and edit firmware source files or other text files for PICmicro MCUs
- Creates re-usable source file templates for quick creation of new source files

MPASM Universal Assembler

- Has full-featured macro capabilities, conditional assembly and several source and listing formats
- Generates various object code formats to support Microchip development tools and third-party programmers without exiting MPLAB

MPLAB-SIM Software Simulator

- Discrete-event simulator integrated into the MPLAB IDE features debug capabilities including unlimited breakpoints, trace, examine/modify registers, watch variables and time-stamp
- Simulates the core functions as well as most peripherals of the PICmicro MCUs

MPLAB IDE

Ordering Information:

Model Name:

MPLAB

Ordering Part Number:

SW007002

Tools Supported:

PICMASTER In-Circuit Emulator

PICSTART Plus Low-cost Programmer

PRO MATE®II Device Programmer

Host System Requirements:

PC with 386 or higher processor. Pentium™ recommended

4 MB Memory, 16 MB recommended

8 MB hard disk space, 20 MB recommended

VGA or Super VGA Monitor

Microsoft Windows 3.1 or greater

System Description:

MPLAB allows you to write, debug, and optimize the PICmicro MCU applications for firmware product designs.

MPLAB IDE software package includes the following:

- MPLAB Project Manager
- MPLAB Editor
- MPASM Universal Macro Assembler for the PICmicro MCUs and other language products supporting the Common Object Description file format
- MPLAB-SIM Software Simulator

MPLAB currently supports the following systems:

- PICMASTER In-Circuit Emulator
- PICSTART Plus Development Programmer

To order or obtain more information about MPLAB IDE, contact the Microchip sales office nearest you. MPLAB software may also be downloaded from Microchip's Bulletin Board System. User's can connect to the BBS through the CompuServe® communications network.

Customer Support:

Microchip maintains a worldwide network of distributors, representatives, local sales offices, Field Application Engineers and Corporate Application Engineers as well as a multifaceted Bulletin Board System. Microchip's Internet home page can be reached at: http://www.microchip.com

MPASM Universal Assembler

Universal PICmicro™ MCU Assembler Software

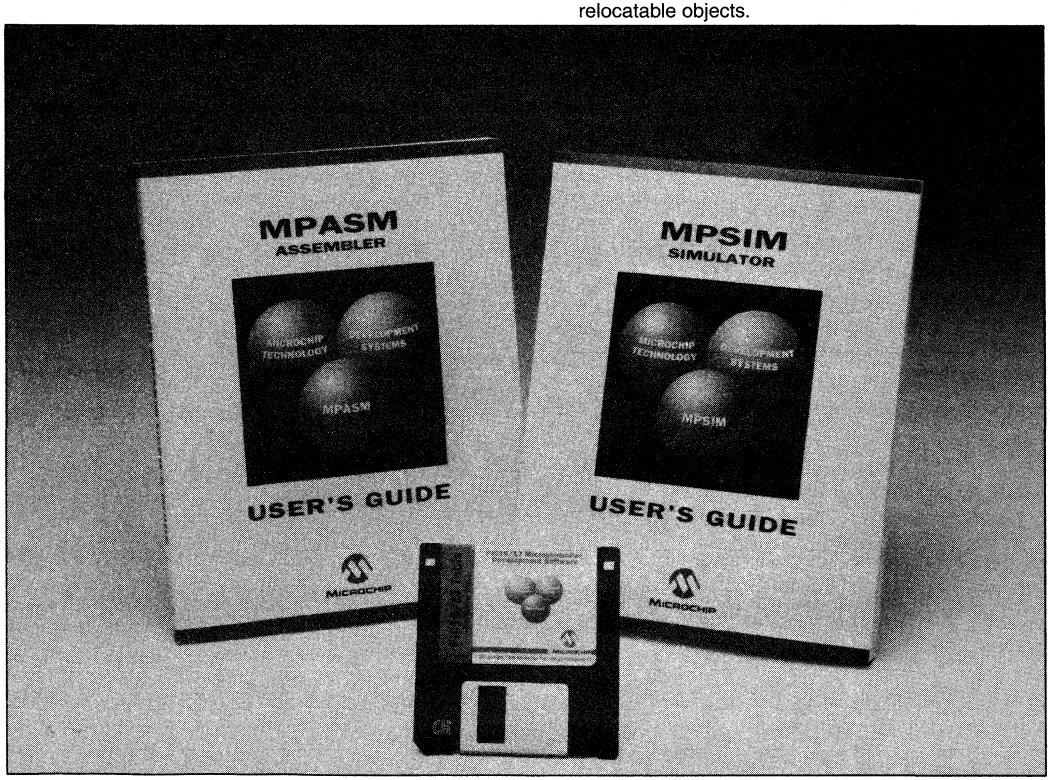
This product brief describes the technical aspects of the PICmicro MCU Assembler. The MPASM Cross Assembler is a PC hosted symbolic assembler. It supports all microcontroller series, including the PIC16C5X, PIC16CXX and PIC17CXX families.

MPASM offers fully featured Macro capabilities, conditional assembly, and several source and listing formats. It generates various object code formats to support Microchip's development tools as well as third party programmers.

MPASM allows full symbolic debugging from the Microchip Universal Emulator System (PICMASTER®).

MPASM REQUIREMENTS

MPASM will run on any IBM PC/AT® or compatible computer running DOS 5.0 or later.



MPASM ASSEMBLER FEATURES

MPASM supports the 12-bit PIC16C5X, the 14-bit PIC16CXX, and the 16-bit PIC17CXX cores.

All instructions are single-word and single-cycle, except for branches, which execute in two cycles. Most instructions operate on one or more operands.

MPASM have the following features to assist in developing software for specific user applications:

- Provides translation of Assembler source code to object code for all Microchip microcontrollers.
- Macro Assembly Capability
- Provides Object, Listing, Symbol and special files required for debugging with one of the Microchip Emulator systems.
- Supports Hex (default), Decimal and Octal source and listing formats.
- Output formats: INHX8S, INHX8M, INHX32 and relocatable objects.

11

© 1995 Microchip Technology Inc.

MPASM DIRECTIVE LANGUAGE

MPASM provides a full featured directive language represented by four basic classes of directives:

- Data Directives are those that control the allocation of memory and provide a way to refer to data items symbolically, by meaningful names.
- Listing Directives control the MPASM listing display. They allow the specification of titles and subtitles, page ejects and other listing control.
- Control Directives permit sections of conditionally assembled code.
- Macro Directives control the execution and data allocation within macro body definitions.

MPASM INSTRUCTION SET

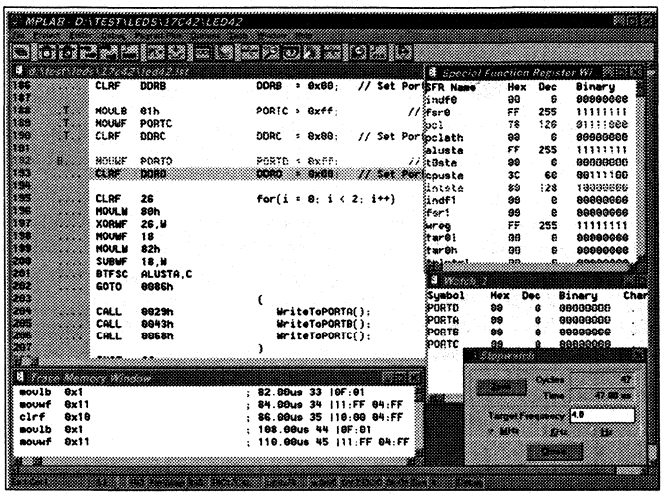
MPASM supports the entire instruction set of the PIC16C5X, PIC16CXX and PIC17CXX microcontrollers, as represented in the following four classes of instructions:

- Data Move Operations
- Arithmetic and Logical Operations
- Bit Manipulation Operations
- Special Control Operations

The Microchip microcontroller set is used to operate on data located in any of the file registers, including the I/O registers. There are:

- Data Transfer Operations
- Logical Operations
- Rotate Operations

MPASM provides bit level file register operations to manipulate and test individual bits in any addressable register, literal and control operations permitting operations on literals and branches to subroutines in program memory.



The Microchip microcontroller instruction sets allow read and write of special function registers such as the PC and status registers.

MICROCHIP

MPLAB™SIM

Software Simulator Product Brief

MPLAB-SIM takes advantage of the power of MPLAB to provide an extremely powerful and cost effective debugging solution.

The MPLAB-SIM software simulator allows the user to isolate code problems and debug firmware designs on PICmicro™ MCU devices. It simulates the core functions as well as most of the peripherals of the PICmicro MCU families. It is particularly suitable for optimizing algorithms where real-time emulation is not required.

MPLAB is a Windows®-based development platform for the Microchip Technology PICmicro one-time-programmable (OTP) MCU families. MPLAB Integrated Development Environment (IDE) offers a project manager and program text editor, a user-configurable toolbar containing four pre-defined sets and a status bar which communicates editing and debugging information.

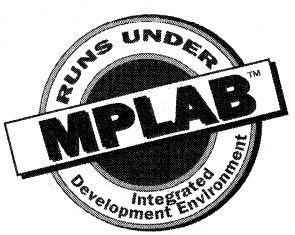
The MPLAB desktop provides the development environment and tools for developing and debugging your application as a project, allowing you to quickly move between different development and debugging modes. With the MPLAB environment, you can debug your source code, automatically locate errors in source files for editing, debug with breakpoints based on internal register values, watch the program flow with MPLAB-SIM (software simulator) or PICMASTER, make timing measurements with a "stop watch," view variables in watch windows and find quick answers to questions from the MPLAB on-line help.

Features:

MPLAB-SIM Software Simulator

- Discrete-event simulator integrated into the MPLAB IDE features debug capabilities including unlimited breakpoints, trace, examine/modify registers, watch variables and time-stamp
- Simulates the core functions as well as most peripherals of the PICmicro MCUs

MPLAB Project Manager



- Organizes the different files that comprise your application firmware under one "Project"
- Allows you to create a project; add, edit or debug a source code file in a project; and build object files

MPLAB Editor

- Full-featured programmer's editor lets you write and edit firmware source files or other text files for PICmicro MCUs
- Creates re-usable source file templates for quick creation of new source files

MPASM Universal Assembler

- Has full-featured macro capabilities, conditional assembly and several source and listing formats
- Generates various object code formats to support Microchip development tools and third-party programmers without exiting

MPLAB-SIM Software Simulator

PICMASTER In-Circuit Emulator

PICSTART Plus Low-cost Programmer

PRO MATE II Device Programmer

Host System Requirements:

PC with 386 or higher processor. Pentium™ recommended

4 MB Memory, 16 MB recommended

8 MB hard disk space, 20 MB recommended

VGA or Super VGA Monitor

Microsoft Windows 3.1 or greater

System Description:

MPLAB-SIM is a discrete event simulator software application designed to imitate operation of the PICmicro MCUs. It allows the user to debug software that will use any of these microcontrollers.

At any instruction boundary, you may examine and/or modify any data area within the processor, or provide external stimulus to any of the pins. MPLAB-SIM gives you a solid, low cost, source-level debug tool to help you through the early design verification stages of your project.

MPLAB-SIM runs under MPLAB. This allows you to write, debug, and optimize the PICmicro MCU applications for firmware product designs.

MPLAB IDE software package includes the following:

- MPLAB Project Manager
- MPLAB Editor
- MPASM Universal Macro Assembler for the PICmicro MCUs and other language products supporting the Common Object Description file format

To order or obtain more information about MPLAB-SIM, contact the Microchip sales office nearest you. MPLAB-SIM software may also be downloaded from Microchip's Bulletin Board System. User's can connect to the BBS through the CompuServe® communications network.

Customer Support:

Microchip maintains a worldwide network of distributors, representatives, local sales offices, Field Application Engineers and Corporate Application Engineers as well as a multifaceted Bulletin Board System. Microchip's Internet home page can be reached at: http://www.microchip.com

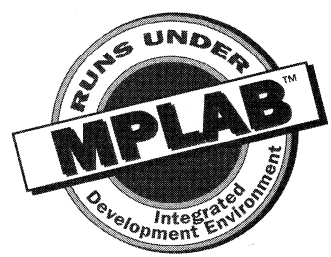
MICROCHIP

MPLAB™C

Universal C Compiler for PICmicro MCUs Product Brief

Features:

- MPLAB-compatible for source level debugging in an easy-to-use project environment
- Provides Object, Listing, Symbol and special files for debugging with MPLAB
- Supports interrupt routines
- Compares source code to target hardware definitions
- Header file register definitions compatible with MPASM Assembler
- Generates tight, efficient code
- Output formats: INHX8S, INHX8M and INHX32
- Has ability to embed assembly



MPLAB-C provides powerful integration capabilities and ease of use not found with other compilers.

The **MPLAB-C** Universal C Compiler is a complete high-level language compiler for the Microchip Technology PICmicro™ families of 8-bit one-time-programmable (OTP) MCUs. Since MPLAB-C is compatible with Microchip's MPLAB Integrated Development Environment (IDE), it functions with the PICMASTER® in-circuit emulator and the MPLAB-SIM simulator. When using MPLAB-C with MPLAB, you get full source level debugging in an easy-to-use project environment which helps you reduce development time.

The MPLAB-C C compiler generates executable code directly from the compile process. There is no need for an extra step to assemble code generated by the compiler.

MPLAB-C allows you to write code for PICmicro MCU applications in a high level language. The detailed operation of the target processor is mostly hidden which means less time is devoted to considering the details of the processors's architecture. This feature also permits easy code portability between different PICmicro MCU devices – often as simple as changing one line of source code.

MPLAB-C will run on any IBM PC/AT® or compatible computer running DOS 5.0 or later, and it supports the 12-bit, 14-bit and 16-bit Microchip microcontroller cores. MPLAB-C is a rule based compiler with expert systems tailored to each of these platforms for optimal efficiency.

11

All PICmicro MCUs

Model Name:

MPLAB-C with MP-DriveWay™

Ordering Part Number:

SW006008

Devices Supported:

MPLAB-C supports all PICmicro MCUs.

MP-DriveWay supports: PIC16C54, PIC16C54A, PIC16C55, PIC16C56, PIC16C57, PIC16C58A, PIC16CR54, PIC16CR57A, PIC16CR58A, PIC16C64, PIC16C71, PIC16C74, PIC16C84, PIC17C42, PIC17C42A, PIC17C43, PIC17C44

System Requirements:

IBM PC/AT® or compatible computer

DOS 5.0 or later operating system

System Description:

The MPLAB-C Universal C Compiler comes complete with the MPLAB IDE. The IDE allows you to quickly move between different development and debugging modes, for example, you can quickly advance from software debugging with MPLAB-SIM to hardware debugging with PICMASTER.

MPLAB-C has implemented extensions to the C language to provide specific support for microcontroller environments, including:

- I/O Ports (read only, write only and read/write)
- Read only access to the processor status register
- Read/write access to the processor index register
- Read/write access to the processor working (W) register
- Interrupt vectors
- Fix variables and functions in memory

To order or obtain more information about MPLAB-C or any other Microchip product, contact the Microchip sales office nearest you.

MP-DRIVEWAY™

Application Code Generator Product Brief

MP-DriveWay generates 'C' code for PICmicro™ MCUs.

MP-DriveWay is an easy to use Windows®-based Application Code Generator for Microchip Technology's 8-bit, one-time-programmable (OTP) PICmicro MCUs. With MP-DriveWay you can visually configure all the peripherals in a PICmicro MCU device and, with a click of the mouse, generate all the initialization and many functional code modules in C language.

The output of MP-DriveWay is fully compatible with Microchip's MPLAB-C compiler. The code produced is highly modular and allows easy integration of your own code. In fact, MP-DriveWay is intelligent enough to maintain your code through subsequent code generation.

MP-DriveWay derives code output from an extensive knowledge base. For each peripheral, the knowledge base contains an array of driver routines. For example, the USART module can be configured to be full duplex or half duplex, 8- or 9-bit, interrupt driven or polled and so on. MP-DriveWay, further allows you to specify desired operating parameters, such as baud rate. This information is used to generate all the appropriate control register values which are then plugged into the initialization code.

MP-DriveWay also generates "emulated" or "virtual" peripherals. Peripheral functions such as USART or PWM that may not exist on a selected PICmicro MCU are implemented entirely in software.

Features:

- Application Code Generator for PICmicro MCUs
- Windows-based intuitive user interface
- Describe peripheral operation at a high level
- Generates initialization and functional code
- Generates C code, compatible with Microchip's MPLAB-C
- Built in knowledge base for all peripherals
- Code generated is fully tested and documented reducing your debug time
- Specify operating parameters (such as baud rate)
- Emulated Peripherals
- IDS: Interactive Data Sheet, is an innovative on-line help
- Reduce your learning curve on a new device
- Use DriveWay to prototype quickly

MP-DriveWay support.

MPLAB-C supports all PICmicro MCUs.

Host System Requirements:

386 based PC or greater

Microsoft Windows 3.1 or higher

4 MB RAM, 5 MB free disk space

3.5 inch diskette drive

MP-DriveWay has an extensive and unique on-line interactive help called Integrated Data Sheet (IDS). It is geared towards engineers developing code. With IDS you can find all the information you need for any peripheral all in one place.

MP-DriveWay generates fully tested and documented code, reducing your debug time. Use of pre-developed code segments from the knowledge base results in highly efficient code output.

MP-DriveWay enhances your productivity. As a new user, you can reduce your learning curve. As an expert user, it allows you to prototype applications faster.

MP-DriveWay is a result of partnership effort between by AISYS Intelligent Systems Ltd. of Israel and Microchip.

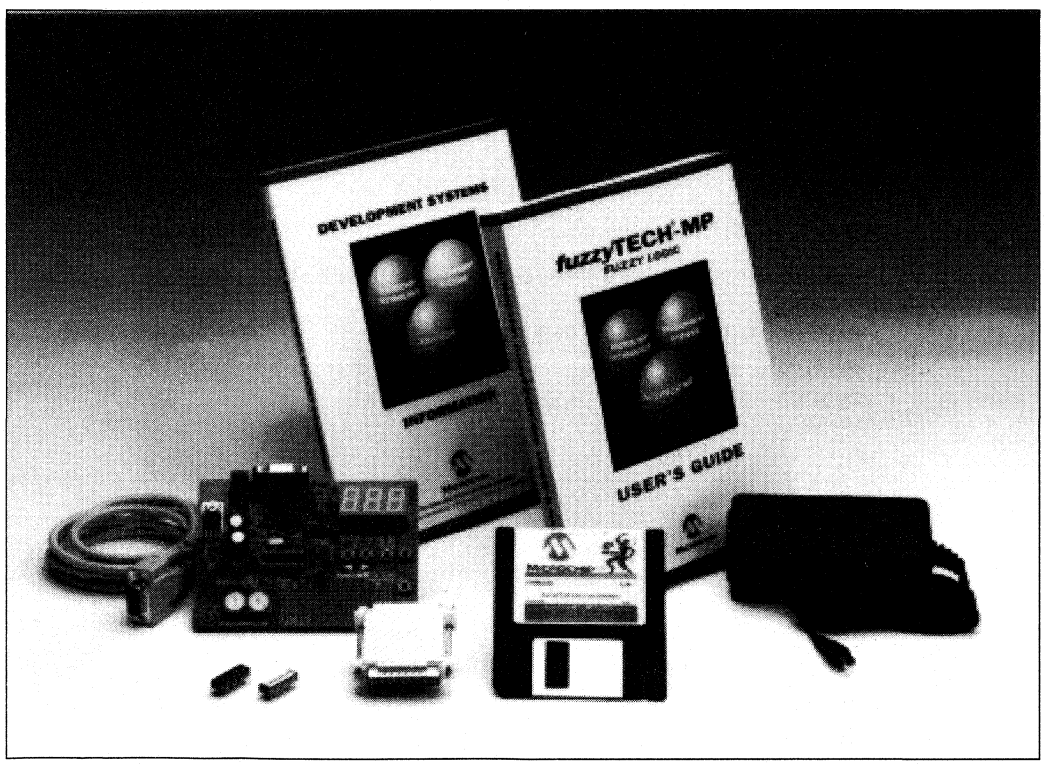
MICROCHIP

*fuzzy*TECH®MP

Fuzzy Logic Development System for PICmicro MCUs

*fuzzy*TECH-MP FOR MICROCHIP PICmicro MCUs



This product brief describes the technical aspects of the *fuzzy*TECH-MP Fuzzy Logic Development System for PICmicro MCUs developed by INFORM Software Corporation specifically for Microchip.

The *fuzzy*TECH-MP Development System comes in two versions. The first, the Explorer, contains everything you need to gain a comprehensive working knowledge about fuzzy-logic system design. It is easy-to-use, all graphic editors and tools guide you step-by-step through the development phases of fuzzy systems. The Explorer supports two input variables and one output variable.

The full-featured *fuzzy*TECH-MP Edition offers all of the capabilities of the Explorer, plus it has the additional flexibility of eight input variables and four output variables for designing more complex systems. The full features are enabled with a hardware key lock attached to the parallel port of the PC.

Included in both versions is *fuzzy*LAB™, a fully functional demonstration board, to give customers hand-on experience with fuzzy logic systems implementation. *fuzzy*LAB is a simple heating thermostat consisting of a PWM-controlled resistor configured to heat a thermistor to a preset temperature. Using the two fuzzy algorithms provided, a designer can set a target temperature and observe the thermostat response to the set point.

Both systems generate assembly code compatible with the MPASM, Microchip's Universal Assembler, that can be integrated into your application. Examining this code provides you with further insights into the fabrics of fuzzy logic systems.

11

© 1995 Microchip Technology Inc.

*fuzzy*TECH-MP System Requirements

*fuzzy*TECH-MP will run on any IBM PC® (386 or higher) or compatible computer, running DOS 4.1 or later, and Microsof®t Windows® 3.0 or later. Because *fuzzy*TECH-MP makes extensive use of graphics, a color graphic monitor (VGA) is required, and higher resolutions of 800 x 600 or 1024 x 768 are recommended.

What is Fuzzy Logic?

Fuzzy logic is a technology that enhances mode-based system designs using both intuition and engineering heuristics. Fuzzy logic uses elements of everyday language to represent desired system behavior, thus circumventing the need for rigorous mathematical modeling.

It is an efficient way of designing, optimizing and maintaining highly complex systems transparently.

Fuzzy Logic Applications

Fuzzy logic finds its home in unique applications:

- When no adequate mathematical model for a given problem is readily apparent.
- When non-linearities, time constraints or multiple parameters exist.
- When engineering know-how about the given problem is available or can be acquired during the design process.

The *fuzzy*TECH-MP Implementation

*fuzzy*TECH-MP provides the following standard features:

- Windows Compatible with full graphical user interface
- 8-Input variables (2 for the Explorer version)
- 4-Output variables (1 for the Explorer version)
- 8-Bit resolution on input and output variables
- 16-Bit computation resolution for the PIC16CXX and PIC17CXX microcontrollers
- No theoretical limit on rules, antecedents and linguistic conjunctions (chip limitations will place a practical limit on these)
- MAX-MIN and MAX-DOT inference methods
- CoM and MoM defuzzification methods
- MPASM Compatible
- PICMASTER™ Compatible

*fuzzy*TECH-MP

*fuzzy*TECH-MP is available directly from Microchip Technology and its authorized distributors. Contact your local sales office for more information.

SALES AND SUPPORT

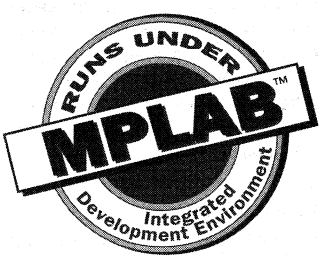
PICMASTER®CE

CE Compliant In-Circuit Emulator Product Brief

CE compliant PICMASTER offers design engineers maximum power, flexibility and rapid design turn-around!



The PICMASTER-CE in-circuit emulator systems from Microchip Technology provide a high-quality, universal platform for emulating the entire line of Microchip 8-bit, one-time-programmable (OTP) microcontrollers. PICMASTER-CE is identical in user functionality with the popular PICMASTER emulators, but features additional enhancements.

PICMASTER-CE is a high-performance, real-time in-circuit emulator. Included in the complete system are the emulator, MPLAB™ integrated development environment, MPASM full-featured macro assembler, and MPLAB-SIM, an unusually sophisticated simulator program. Systems may be purchased that also include a device programmer (see ordering information on reverse side). Sample programs are provided to help quickly familiarize the user with the development system and the PICmicro 8-bit OTPMCU families. The MPLAB IDE user interface features a built-in text editor, project management, and full integration with MPASM and high level languages that support the Common Object Description format (i.e. MPLAB-C and MPC).

PICMASTER-CE meets or exceeds the stringent Electromagnetic Compatibility requirements known as CE compliance directives established by the European Union (EU) countries. These include limiting radiated emission, improving susceptibility to radiated emission and improving susceptibility to Electrostatic Discharge (ESD).

Features:

- High-performance PC-based development system for PICmicro MCUs
- Real-time in-circuit emulation
- Program memory emulation and memory mapping capability up to 64k words
- Real-time trace
- Unlimited hardware breakpoints
- External break with AND/OR capability with identical breakpoints
- Trigger out
- Multi-processor emulation
- Highly shielded cable to connect pod and prober
- Supported by MPLAB IDE for Windows
- Assembly and C source level debugging
- Includes MPLAB Project Manager
- Includes MPLAB Editor
- Includes MPASM Universal Assembler
- Includes MPLAB-SIM Simulator

- PC-compatible computer: 386DX, 486 or PENTIUM™ based with ISA or EISA bus
- EGA, VGA, 8514/A, Hercules graphic card (EGA or higher recommended)
- MS-DOS®/PC-DOS® v. 5.0 or greater
- Microsoft Windows 3.1 or greater in 386 enhanced mode
- 4 MB RAM, 4 MB free disk space
- 3.5 inch diskette drive
- One 8-bit PC/AT (ISA) I/O expansion slot (half size)

System Description:

The PICMASTER-CE emulator systems feature real-time instruction emulation with program memory emulation and memory mapping capability up to 64K words. Instruction execution can be mapped into either emulation memory or user prototype memory. An unlimited number of hardware breakpoints can be set anywhere in the program memory.

The multiprocessor emulation capability allows for up to four PICMASTER-CE emulators to be synchronized on a single PC. PICMASTER-CE is capable of full symbolic debugging with symbolic display and alter of all register files, special purpose registers, stack registers and bank registers.

Interchangeable target probes allow the system to be easily reconfigured for emulation of different processors. PIC16C5X probes operate to 20 MHz, PIC17CXX to 16 MHz and PIC16CXX to 10 MHz. The universal architecture of the PICMASTER-CE allows expansion to support all new microcontroller architectures with data and program memory paths to 16 bits.

To order or obtain more information about PICMASTER-CE or any other Microchip product, contact the Microchip sales office nearest.

MICROCHIP

PICMASTER®

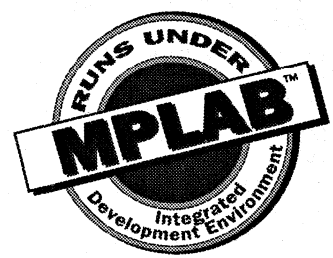
Full-Featured Modular In-Circuit Emulator

FEATURES:

- Hi-performance PC-based development system for PICmicro MCUs

Emulator System Components:

- Host Interface Card connects emulator system to a PC compatible system
- The Emulator Control Pod contains emulation memory, trace memory, event and cycle timers and trace/ breakpoint logic
- A Target-specific Emulator Probe configures the universal system for emulation of a specific microcontroller
- MPLAB IDE provides the user with quick editing, debugging, optimization and control of the system under emulation



PICMASTER development systems offer maximum power, flexibility and rapid design turn-around!

The PICMASTER systems from Microchip Technology are full-featured, professional quality emulator systems. This flexible in-circuit emulator system provides a high-quality, universal platform for emulating the entire line of Microchip 8-bit, one-time-programmable (OTP) microcontrollers. PICMASTER systems are sold worldwide, with a CE compliant model available for European Union (EU) countries.

Provided with the PICMASTER emulator systems are the MPLAB™ integrated development environment; a high performance, real-time In-Circuit Emulator; an EPROM programmer unit (PRO MATE II); a macro assembler program (MPASM); and an unusually sophisticated simulator program (MPLAB-SIM). Sample programs are provided to help quickly familiarize the user with the development system and the PICmicro 8-BIT OTP MCU families. The MPLAB IDE user interface features a built-in text editor, project management, and full integration with MPASM and high level languages that support the Common Object Description format (i.e. MPLAB-C and MPC).

The PICMASTER emulator systems feature real-time instruction emulation with program memory emulation and memory mapping cabability up to 64K words. Instruction execution can be mapped into either emulation memory or user prototype memory. An unlimited number of hardware breakpoints can be set anywhere in the program memory.

The multiprocessor emulation capability allows for up to four PICMASTER emulators to be synchronized on a single PC. PICMASTER is capable of full symbolic debugging with symbolic display and alter of all register files, special purpose registers, stack registers and bank registers.

MICROCHIP

ICEPIC™

Low-Cost PIC16CXXX In-Circuit Emulator Product Brief

ICEPIC: Affordable PIC16CXXX In-Circuit Emulation Solution.

ICEPIC is a low-cost in-circuit emulation solution for the Microchip Technology PIC16C5X and PIC16CXXX families of 8-bit one-time-programmable (OTP) microcontrollers. The modular system can support different subsets of PIC16C5X or PIC16CXXX products through the use of interchangeable personality modules or daughter boards. The emulator is capable of emulating without target application circuitry being present.

ICEPIC is designed to operate on PC-compatible machines ranging from 286-AT® systems through the new Pentium™ based machines. The ICEPIC development software runs under Microsoft Windows® 3.X environment, allowing the operator access to a wide range of supporting software accessories.

The ICEPIC development software provides a user-friendly operating environment with an easy-to-use toolbar; unlimited number of breakpoints; single, multiple and procedure step; ability to display and modify any register; user-selectable processor speeds via an oscillator module; full context-sensitive help and an RS-232 serial port.

ICEPIC is fully compatible with Microchip's MPASM Universal Assembler and MPLAB-C Compiler.

Features:

- Real time, non-intrusive emulation of PIC16C5X and PIC16CXXX microcontrollers
- 8K words of emulation memory
- Full speed, real time emulation to 20 MHz for PIC16C5X family
- Up to 10 MHz real time emulation for PIC16CXXX family
- Microsoft Windows® compatible
- Source level debug capability in assembly or C
- Symbolic debug capability
- 8K hardware breakpoints
- Custom watch points
- PC communication via serial interface at speeds up to 57K baud
- Display and modify any register (Program or Data)
- User selectable processor speeds (via oscillator module)

Base Unit Only Without Daughter Board:		
ICEPIC POD	EM167200	All

System Description:

The low-cost PC-based ICEPIC In-Circuit Emulator system comes with an emulator unit (mother board), power supply, RS-232 cable, probe header cable(s) to connect to the application circuit, and one device-specific personality daughter board.

These interchangeable personality modules or daughter boards are contained with the mother board within one housing, connecting to the target application via a connector cable that extends from the housing. The mother board incorporates the common emulation logic while the daughter board is for device-specific emulator logic. This economical system allows the user to purchase a new daughter board for a new processor group as needed, at approximately 30% of the full system cost.

ICEPIC was designed by NEOSOFT Inc. and is manufactured under license by RF Solutions Ltd. To order or obtain more information about ICEPIC or any other Microchip product, contact the Microchip sales office nearest you.

PRO MATE®II

Universal Device Programmer Product Brief

CE Compliant PRO MATE II makes programming easy.

The PRO MATE II device programmer tool allows development engineers to program user software into Microchip Technology's entire line of PICmicro™ 8-bit one-time-programmable (OTP) MCUs. PRO MATE II is CE compliant, meaning it meets or exceeds all the directives for safety, emissions, ESD and susceptibility (to radiated emission) requirements set forth by the European Union (EU) countries.

The PRO MATE II device programmer is designed to be robust and reliable with: enhanced socket module alignment with four auto alignment pins; three levels of over-current protection and superior electrostatic discharge immunity for rugged environments; a small and compact univeral IEC power supply and improved LCD display and buttons.

The PRO MATE II device programmer is easy to use and operates either as a stand-alone unit or in conjunction with a PC-compatible host system. This time-saving tool comes complete with all the accessories needed to connect to a host system including interface cables and a universal input power supply.

In addition to the programmer unit, the PRO MATE II system contains Microchip's popular discrete event software simulator (MPLAB-SIM), a universal PICmicro macro assembler (MPASM), and host operating software which offers file display and editing and transfer to and from the programming unit.

Features:

- Programs EPROM and/or EEPROM program and data memory for all Microchip PICmicro MCUs
- Operates as stand-alone or with PC-host system
- Three operating modes:
  - Host Mode
  - Safe Mode
  - Stand-Alone Mode
- Complete line of interchangeable socket modules supports all package options (sold separately)
- Universal platform can quickly and easily support future Microchip products
- SQTP^{SM} serialization adds a unique serial number to each device programmed (in PC host mode)
- Safe Mode prevents accidental corruption of master code
- Saves and restores "environment" including all device settings, object file and more
- Indexed on-line help
- Complete documentation including all User's Guides

RUNS UNDER MPLAB™ Integrated Development Environment

System Description:

Microchip's PRO MATE II makes it easy to program the company's entire line of 8-bit OTP RISC microcontrollers, operating either as a stand-alone unit or in conjunction with a PC-compatible host system. When connected to a host system, PRO MATE II provides an exceptionally user-friendly interface to give the developer complete control over the programming session.

The new PRO MATE II software provides many user interface features. These include a "safe mode" targeting production environments where accidental corruption of master code is prevented; the ability to save and restore "environment," including all device settings, object file and more; and complete indexed on-line help. The PRO MATE II system also contains Microchip's popular discrete event software simulator (MPLAB-SIM) and a universal PICmicro macro assembler (MPASM).

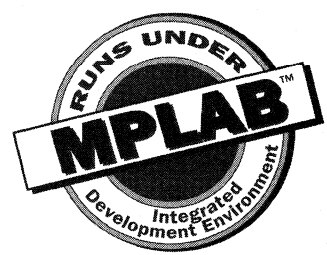
MICROCHIP

PICSTART®PLUS

Low Cost Development Kit Product Brief

PICSTART Plus makes designing with Microchip MCUs simple and affordable.

The **PICSTART Plus** development system from Microchip Technology provides the product development engineer with a highly-flexible low-cost microcontroller design tool set for all PIC14000, PIC16C5X, PIC16CXX and PIC17CXX 8-bit one-time-programmable (OTP) devices (DIP packages up to 40 pins).



The PICSTART Plus development system operates on any PC-compatible machine running under the Windows® 3.1 operating system. PICSTART Plus is easy-to-use and features Microchip's highly acclaimed MPLAB™ Integrated Development Environment, with its built-in editor, assembler and Windows-based MPLAB-SIM simulator. The PICSTART Plus development system includes full documentation, software, development programmer and a device sample.

The CE compliant PICSTART Plus development programmer features a molded plastic enclosure and special circuit design techniques to enhance ESD protection. PICSTART Plus is a development programmer and is not recommended for use in a production environment.

Sample software programs are provided to help the developer quickly become familiar with the PICSTART Plus development system and with Microchip's microcontroller families. The PICSTART Plus system also includes Microchip's new CD-ROM containing a complete databook and Embedded Control Handbook (Application notes).

Features:

- Operates with PC-compatible host system running Windows under MPLAB™ environment
- Reads, programs, verifies EPROM and EEPROM program and data memory
- Reads, programs, verifies all configuration bits
- Programs and verifies an address range
- Displays, edits, and transfers device contents to and from programmer unit
- MPLAB Project support to automatically download object file to PICSTART Plus
- MPASM Assembler translates assembler source code to object code for all PICmicro devices
- MPLAB-SIM Windows-based simulator designed to model operation of all PICmicro MCUs
- Complete with RS-232 cable, 9 volt universal IEC power supply and power cable
- PICmicro MCU device sample
- Complete documentation, User's Guides and CD-ROM

System Description:

The PICSTART Plus development system includes the PICSTART Plus development programmer and the MPLAB IDE.

The PICSTART Plus programmer gives the product developer the ability to program user software into any of the supported microcontrollers. The PICSTART Plus software running under MPLAB provides for full interactive control over the programmer.

The MPASM macro assembler provides programmable memory data files, listing files and special files required for symbolic debug. The MPLAB-SIM software simulator allows the user to isolate code problems and debug firmware designs on PICmicro devices. It simulates the core functions as well as most of the peripherals of the PICmicro MCU families. It is particularly suitable for optimizing algorithms where real-time emulation is not required.

PICSTART®LITE

Ultra Low Cost Development Kit Product Brief

Features:

- Very low-cost introductory microcontroller design tool set
- DOS-based
- Operates with a PC-compatible host system
- Reads, programs and verifies EPROM Memories of PIC16C5X and PIC16CXXX microcontrollers
- PC Host Software provides file display, editing, and transfer device contents to and from programmer unit
- RS-232 interface cable
- Programmer unit connects to standard PC serial port
- MPASM Assembler for translation of assembler source code to object code for all PICmicro devices
- MPSIM, an MS-DOS based discrete-event simulator, is designed to model operation of all PIC16C5X and PIC16CXXX microcontrollers and debug
- PIC16C5X or PIC16CXXX device sample

PICSTART Lite makes designing with PIC16CXXX MCUs simple and affordable.

The PICSTART Lite development systems from Microchip Technology provide the product development engineer with a fast, easy and very low-cost way to begin evaluation and code development for base-line PIC16C5X and mid-range PIC16CXXX 8-bit one-time-programmable (OTP) microcontroller products where full real-time emulation is not required. PICSTART Lite is available in two versions, the PICSTART Lite-16B1 (28-pin DIP socket) and the PICSTART Lite-16C (40-pin DIP socket).

The PICSTART Lite development systems operate on any PC-compatible machine running the DOS operating system. Each development system includes an MS-DOS®-based software simulator (MPSIM), a macro assembler (MPASM), a microcontroller EPROM programmer board and a product sample. All supporting documentation and user's guides are supplied on 3-1/2" disks.

Sample software programs to run on the simulator are provided to help the development engineer quickly become familiar with the PICSTART Lite development system and PIC16C5X and PIC16CXX microcontroller families. A user need only provide his or her own preferred text editor and the system is ready for development of end products using one of Microchip's base-line or mid-range MCUs. PICSTART Lite is designed as a development programmer and is not recommended for use in a production environment.

System Description:

The PICSTART Lite Development Programmer operates from a user supplied 9 volt power supply and connects with the supplied RS-232 (9 pin-D connector) cable to a serial port on the host PC. A full screen, user-friendly software program is provided for full interactive control over the programmer. Parts may be read, programmed, blank checked and verified. Configuration bits and ID locations may be specified.

The MPASM macro assembler provides translation of Assembler source code to object code with INHX8S, INHX8M and INHX32 output formats. The MPSIM discrete event software simulator models operation of PICmicro MCUs and allows the user to debug software that will use any of these devices. MPSIM features include program load and save, disassembler, symbolic debug, execution trace and breakpoints.

KEELOQ® Programming System

KEELOQ HCSXXX Device Programmers

Features:

- Set up HCSXXX encoder/decoder programming options
- Multiple algorithms for key generation
- Smartcard protection of manufacturer's keys
- Automatic serialization of encoders
- Logging to disk for factory record keeping
- Interface to automated test equipment
- Menu-driven user-friendly software includes:
  - Smartcard initialization program
  - Setup program to configure the various encoder/decoder programming options
  - Transmitter programming software
  - Receiver programming software
- Comprehensive User's Guide with easy-to-follow, step-by-step *Getting Started*

Programs KEELOQ Encoders and Decoders in manufacturing environment

The **KEELOQ® Programmer** provides manufacturing with the capability to program large quantities of HCS200, HCS300, HCS301, HCS360, HCS361 encoders and HCS509 and HCS512 decoders. The Code Hopping Encoder devices are used in the transmitter portion and the decoder devices in the receiver portion of secure RKE systems. The devices use the KEELOQ code hopping algorithm which combines high security, a small package outline and a very low cost to make this an ideal solution for unidirectional RKE systems.

Primary applications for the KEELOQ devices include automobile keyless entry and security systems, garage door openers, home security systems, central locking systems, gate openers, transaction cards, pre-paid telephone cards, vehicle immobilizers, identity tokens, electronic tagging, passive (batteryless) transponders, point-of-sale readers/adaptors and a growing list of other applications.

The KEELOQ Programmer is supplied with software to automate the programming of HCSXXX devices in the customer's factory production environment, and comes complete with accessories to be used with a host PC computer system. The KEELOQ Programmer includes an interface PCB, Smartcard reader, Smartcards and set of probes.

The versatility and security of the hardware-based key generation allow product range protection.

KEELOQ Programming System

Ordering Information:

Model Name:

KEELOQ Programmer

Ordering Part Number:

PG306001

Devices Supported:

HCS200	Encoder
HCS300	Encoder
HCS301	Encoder
HCS360	Encoder
HCS361	Encoder
HCS509	Decoder
HCS512	Decoder

Host System Requirements:

- PC-compatible computer: 386DX, 486 or PENTIUM™ based with ISA or EISA bus
- EGA, VGA, 8514/A, Hercules graphic card (EGA or higher recommended)
- MS-DOS®/PC-DOS® v. 5.0 or greater
- Microsoft Windows 3.1 or greater in 386 enhanced mode
- 4 MB RAM, 4 MB free disk space
- 3.5 inch diskette drive
- One 8-bit PC/AT (ISA) I/O expansion slot (half size)

System Description:

The KEELOQ Programming System Hardware consists of a Key generation card used to securely generate encryption and decryption keys. The card may be plugged into a standard ISA bus slot on a PC. Also included is a Smartcard used to securely store the Manufacturer's Key, which is further protected by a PIN. A Smartcard reader and a set of spring-probes for connection to the transmitter PCB to be programmed complete the programming station hardware.

The accompanying user-friendly menu-driven Software, is supplied on 3.5" diskette and includes all the necessary software for programming large quantities of HCSXXX code hopping devices.

To order or obtain more information about KEELOQ or any other Microchip product, contact the Microchip sales office nearest you.

MICROCHIP

KEELOQ® Evaluation Kit

KEELOQ HCSXXX Evaluation Kit Product Brief

Features:

- Transmit hopping code messages using HCSXXX encoders
- Display the fixed and changing parts of hopping code messages on a PC
- Receive and decode hopping code transmissions using a PIC16C56 decoder and 93C46 EEPROM
- Learn new HCSXXX encoders onto the PIC16C56/93C46 decoder
- Program HCSXXX encoders
- Comprehensive User's Guide
- Schematics for transmitter and receiver

Let's you evaluate the capabilities of Microchip's code hopping devices

The KEELOQ Evaluation Kit demonstrates the capabilities of Microchip Technology's code hopping technology. The Code Hopping Encoder devices are designed to be the transmitter portion and the Decoder devices the receiver portion, of secure RKE* systems. The devices use the KEELOQ code hopping algorithm which combines high security, a small package outline and a very low cost to make this an ideal solution for unidirectional RKE systems.

Primary applications for the KEELOQ HCSXXX devices include automobile keyless entry and security systems, garage door openers, home security systems, central locking systems, gate openers, transaction cards, pre-paid telephone cards, vehicle immobilizers, identity tokens, electronic tagging, passive (batteryless) transponders, point-of-sale readers/adaptors and a growing list of other applications.

The KEELOQ Demonstration Kit includes all the necessary hardware to evaluate a code hopping system, as well as a basic demonstration software program, which is suppiied on a PC-compatible 3.5" diskette.

PIC16C56 Decoder

Host System Requirements:

- PC-compatible computer: 386DX, 486 or PENTIUM™ based with ISA or EISA bus
- Serial Port
- EGA, VGA, 8514/A, Hercules graphic card (EGA or higher recommended)
- MS-DOS®/PC-DOS® v. 5.0 or greater
- Microsoft Windows 3.1 or greater in 386 enhanced mode
- 4 MB RAM, 4 MB free disk space
- 3.5 inch diskette drive
- One 8-bit PC/AT (ISA) I/O expansion slot (half size)

System Description:

Hardware

- PIC16C56/93C46 EEPROM-based decoder
- RF Receiver module
- On-board +5V regulator and filtered rectifier for direct input from 9V AC/DC wall adapter
- Multiple radio frequency transmitters using HCS300 hopping code encoders
- RS232 socket and associated hardware for direct connection to RS232 interface
- Six bright LEDs connected to decoder outputs

Also includes all necessary software to program transmitters and to display codes or messages.

To order or obtain more information about KEELOQ or any other Microchip product, contact the Microchip sales office nearest you.

PICDEM-1

Low-Cost PICmicro™ Demonstration Board

PRODUCT INFORMATION

The PICDEM-1 is a simple board which demonstrates the capabilities of several Microchip microcontrollers. The microcontrollers supported are: PIC16C5X (PIC16C54 to PIC16C58), PIC16C62X, PIC16C61, PIC16C62X, PIC16C71, PIC16C84, PIC17C42, PIC17C43 and PIC17C44. All necessary hardware is included to run basic demo programs, which are supplied on a 3.5" disk. The users can program the samples (one each of PIC17C42, PIC16C71 and PIC16C55) provided with the PICDEM-1, on a PRO MATE®or PICSTART® programmer and easily debug/test the sample code, or the user can connect the PICDEM-1 with the PICMASTER™ emulator and download the sample code to the emulator and debug/test the code. Additionally, a generous 200-hole prototype area is available for the user to build some additional hardware and connect it to the microcontroller socket(s).

FEATURES:

Hardware:

- 40-pin, 28-pin and 18-pin Precision sockets for all supported microcontrollers.
- On board +5V regulator and filter rectifier for direct input from 9V AC/DC wall adapter.
- RS-232 socket and associated hardware for direct connection to RS-232 interface.
- 5K pot to simulate analog input for PIC16C71.
- Three push button Key for external stimulus and RESET.
- Eight bright LEDs connect to PORTB, help in displaying 8-bit binary values on PORTB.
- Socket for "canned" crystal Oscillator.
- Unpopulated holes provided for Xtal connection
- Jumper to disconnect on board RC Oscillator.
- 200-hole prototype area for user's hardware.

© 1995 Microchip Technology Inc.

Software:

- Program for PIC16C71 to demonstrate on-chip A/D features.
- Program for PIC16C84 to demonstrate on-chip EEPROM.
- Program for PIC17C42 to demonstrate on-chip USART.
- Program for PIC16C5X to demonstrate key input capability.
- All demo programs supplied on 3.5" disk,
- Additional programs available on Microchip's BBS.

DOCUMENTATION

- A comprehensive User's Guide with easy to follow step-by-step Getting Started and a Tutorial.
- Schematics for the entire circuit.

SAMPLES

Several UV erasable devices supplied are included. The device types may change from time to time. The supplied devices are typically:

- PIC17C42
- PIC16C71
- PIC16C55

SALES AND SUPPORT

To order or to obtain information, e.g., on the pricing or delivery, please use the listed part numbers, and refer to the listed sales offices.

PART NUMBER	DESCRIPTION
DM163001	Low-cost Demonstration Board for PIC16C5X, PIC16C61, PIC16C62X, PIC16C71, PIC16C84, PIC17C42, PIC17C43 and PIC17C44.

MICROCHIP

PICDEM-2

Low-Cost PIC16CXX Demonstration Board

PRODUCT INFORMATION

The PICDEM-2 is a simple board which demonstrates the capabilities of several Microchip microcontrollers, including PIC16C62, PIC16C63, PIC16C64, PIC16C65, PIC16C73 and the PIC16C74. All necessary hardware is included to run basic demo programs, which are supplied on a 3.5" disk. A programmed sample is included, and the user may erase it and program it with the other sample programs using the PRO MATE® or PICSTART® programmer and easily debug and test the sample code. The PICDEM-2 is also usable with the PICMASTER® emulator, and all of the sample programs can be run and modified using the PICMASTER. Additionally, a generous prototype area is available for user hardware.

FEATURES:

Hardware:

- 40- and 28-pin DIP sockets
- On board +5V regulator for direct input from 9V AC/DC wall adapter or 9V battery.
- RS-232C socket and associated hardware for direct connection to RS-232C interface.
- 5K pot for analog inputs for the PIC16C73/74
- Three push button keys for external stimulus and RESET.
- Eight bright LEDs connected to PORTB for displaying 8-bit binary values.
- Socket for "canned" crystal oscillator.
- Unpopulated holes provided for crystal connection
- 128 x 8 Serial EEPROM.
- LCD module header.
- Keyboard header.
- Unpopulated holes for ACCESS.bus™ connector.

11

© 1995 Microchip Technology Inc.

Hardware (continued):

- Jacks for connection of 9V battery.
- Jumper to disconnect on-board RC oscillator.
- Prototype area for user hardware.

Software:

- Program for PIC16C74 to demonstrate on-chip A/D feature.
- Program for PIC16C64 to demonstrate I^2C™ Serial EEPROM usage.
- All demo programs supplied on 3.5" disk.
- Additional programs available on Microchip's BBS.

DOCUMENTATION:

- A comprehensive User's Guide with easy to follow, step-by-step Getting Started and Tutorial.
- Full schematics.

Samples:

Several UV erasable devices supplied are included. The device types may change from time to time. The supplied devices are typically:

- PIC16C64
- PIC16C74

SALES AND SUPPORT

MICROCHIP

PICDEM-3

Low-Cost PIC16C9XX Demonstration Board

PRODUCT INFORMATION

The PICDEM-3 is a simple board which demonstrates the capabilities of Microchip's microcontroller LCD family. All necessary hardware is included to run basic demo programs, which are supplied on a 3.5" disk. A programmed sample is included, and the user may erase it and program it with the other sample programs using the PRO MATE® or PICSTART®Plus programmer. The PICSTART Plus requires a 68- to 40-pin converter socket.

The PICDEM-3 is also usable with the PICMASTER® emulator, and all of the sample programs can be run and modified using the PICMASTER. Additionally, a generous prototype area is available for user hardware.

All software is written in C using the MPLAB-C/demo version.

FEATURES:

Hardware:

- 68-pin PLCC sockets
- Unpopulated 44-pin PLCC socket for future 44-pin versions
- On board +5V regulator for direct input from 9V AC/DC wall adapter or 9V battery
- RS-232C socket and associated hardware for direct connection to RS-232C interface
- 5K pot for analog input to the PIC16C9XX
- Thermistor for use with A/D converter
- Three push button keys for external stimulus and RESET
- LCD Panel with 4 backplanes and 12 segments
- On-board LCD charge pump circuit with "unpopulated" external resistor ladder supported
- Socket for "canned" crystal oscillator
- Unpopulated holes provided for crystal or ceramic resonator connection
- Supports custom LCD Panel connection (up to 4 common, up to 28 segment) with common/segment header
- LCD pixel data converted to a digital result. Requires external hardware with SPI interface
- Serial port to communicate LCD pixel data to PC for display
- Keyboard header
- Jacks for connection of 9V battery
- Jumper to disconnect on-board RC oscillator
- Prototype area for user hardware

Software:

- MPLAB-C demo for PIC16CXX
- Sample programs which demonstrate:
  - real-time clock and display
  - temperature sensor and display
  - volt meter
  - USART using the SPI port
  - PC software to display LCD pixel information
- All demo programs supplied on 3.5" disk.
- Additional programs available on Microchip's BBS.

DOCUMENTATION:

- A comprehensive User's Guide with easy to follow, step-by-step Getting Started and Tutorial.
- Full schematics.

A UV erasable device is supplied. The device type may vary depending upon availability. The supplied devices are either:

- PIC16C924
- PIC16C923

SEEVAL®
DESIGNER'S KIT

Microchip Serial EEPROM Designer's Kit

FEATURES

- Includes everything necessary to begin developing Serial EEPROM-based applications
- Microchip *Total Endurance*™ software model
- Microchip *SEEVAL* evaluation and programming board
- Microchip *SEEVAL* software
- Microchip Serial EEPROM handbook
- Microchip Serial EEPROM sample pack
- RS-232 serial cable
- Power supply

SYSTEM REQUIREMENTS

- DOS 3.1 or higher
- Windows® 3.1
- VGA monitor
- 386 or 486 processor recommended
- Math coprocessor recommended

DEVICE SUPPORT

- Microchip 2-wire 24CXX/24LCXXB/85CXX
- Microchip *Smart Serial*™ 24XX65
- Microchip 3-wire 93CXX/93LCXX series
- Microchip 4-wire 59C11

11

Designer's Kit

DESCRIPTION

Now designers of Serial EEPROM-based applications can enjoy the increased productivity, reduced time to market, and the ability to create a rock-solid design that only a well-thought-out development system can provide. Microchip's new Serial EEPROM Designer's Kit includes everything necessary to quickly develop a robust and reliable Serial EEPROM-based design and greatly reduce the time required for system integration and hardware/software debug.

The **Total Endurance software model** enables designers to quickly choose the best Serial EEPROM for the specific application and perform trade-off analysis with voltage, temperature, write cycle and other system parameters in order to achieve the desired Erase/Write endurance (specific ppm rate) or product lifetime. Total Endurance is the new standard of excellence in understanding and predicting the Erase/Write endurance of Serial EEPROMs. An on-line endurance tutorial is included, along with hypertext help files.

Microchip's **SEEVAL Serial EEPROM evaluation and programming system** will accept any Microchip Serial EEPROM in DIP package and enable the designer or system integrator to read, write, or erase any byte or the entire array. SEEVAL also provides the following advanced features to aid in system integration and debug:

- Program special user functions like *Smart Serial* configurations
- Hexadecimal display of array contents
- Pre-set or user-defined repeating patterns
- User-configurable functions like continuous read/write, programmable delay, etc.
- Upload/download files between the Serial EEPROM and disk

Another industry first, the **Microchip Serial EEPROM Handbook** provides a plethora of information crucial to the designers of Serial EEPROM-based systems. Along with data sheets on Microchip Serial EEPROMs, this resource provides application notes regarding Erase/Write endurance, interfacing with different protocols and many, many others. A cross-reference and selector guide are also included, plus article reprints and qualification reports on Microchip Serial EEPROMs.

USING SEEVAL AND TOTAL ENDURANCE

Both software packages can be loaded from Windows by choosing FILE RUN and entering SETUP.EXE from the Program Manager. The applications will install themselves; then a double mouse-click will start either application. The first step in either program is to select a device from the device list.

In Total Endurance, the user has simply to choose a Microchip Serial EEPROM device from the device-list menu and begin entering the application parameters. The entire process can take literally seconds to complete, and the model will output the PPM level and FIT rate of the device vs. the number of Erase/Write cycles. If the user has specified an application lifetime, the model will output PPM and FIT rates at that point in time. Alternately, the user may input a desired PPM level and the model will calculate the application lifetime which will result in that survival rate. The user may then trade-off any of the parameters (device type, voltage, application life, temperature, # of bytes per cycle, # of cycles per day etc.) to arrive at an optimal solution for the intended application.

Whenever a parameter is changed, calculation of the ppm/application life is automatic. An "update" box will appear inside the graph to indicate that new data has been entered and the graph should be redrawn. A single click in the "draw" box will redraw the plot of ppm vs. cycles; a click in the "Resize" box will take the plot to full-screen display for a closer view. The plot data can be saved to a file or the plot itself can be copied to the clipboard to be pasted into another application.

In **SEEVAL**, the user may choose to load a file from disk to program the Serial EEPROM, or read data from the EEPROM and save it to disk. The screen displays the contents of a software buffer. The buffer may be manipulated before programming data to the Serial EEPROM, or data can be written to the Serial EEPROM directly on-line. An area of memory can be highlighted (selected) and programmed with a predefined pattern or user-specified pattern. Alternately, the entire device can be programmed with any repeating pattern.

Both SEEVAL and Total Endurance allow the user to save any configuration as default. This configuration (device and application settings) will then automatically load at boot time.

TOTAL ENDURANCE™

Microchip Serial EEPROM Endurance Model

FEATURES

- IBM® PC compatibility
- Windows® 3.1 or DOS 3.1 compatibility
- Automatic or manual recalculation
- Real-time update of data
- Full-screen or windowed graphical view
- Hypertext on-screen help
- Key or slide-bar entry of parameters
- On-screen editing of parameters
- Single-click copy of plot to clipboard
- Numeric export to delimited text file
- On-disk Endurance Tutorial

SYSTEM REQUIREMENTS

- DOS 3.1 or higher
- Windows 3.1
- 1MB memory
- 386 or 486 processor recommended
- Math coprocessor recommended

DEVICE SUPPORT

- Microchip 2-wire 24CXX/24LCXXB/24AAXX/ 85CXX

Total Endurance™

DESCRIPTION

Microchip's revolutionary Total Endurance Model provides electronic systems designers with unprecedented visibility into Serial EEPROM-based applications. This advanced software model (with a very friendly user interface) eliminates time and guesswork from Serial EEPROM-based designs by accurately predicting the device's performance and reliability within a user-defined application environment. Design trade-off analysis which formerly consumed days or weeks can now be performed in minutes...with a level of accuracy that delivers a truly robust design.

Users may input the following application parameters:

- Serial EEPROM device type
- Bytes to be written per cycle
- Cycling mode - byte or page
- Data pattern type - random or worst-case
- Temperature in °C
- Erase/Write cycles per day
- Application lifetime or target PPM level

The model will respond with FIT rate, PPM level, application life and a plot of the PPM level vs. number of cycles. The model is available in both DOS and Windows versions.

BACKGROUND

Microchip's research into the Erase/Write endurance of Serial EEPROMs has resulted in the conclusion that endurance depends upon three primary effects: the physical properties of the EEPROM cell, the internal error-correction technology employed, and the application environment. EEPROM endurance specified as a "typical" value in device data sheets must therefore be evaluated on a case-by-case basis, taking into account the manner in which the device will be used in the application. The Microchip Total Endurance™ software applies the user-defined application parameters to a complex mathematical model in order to emulate the EEPROM's performance and reliability in the system.

USING THE MODEL

The user has simply to choose a Microchip Serial EEPROM device from the device-list menu and begin entering the application parameters. The entire process can take literally seconds to complete, and the model will output the PPM level and FIT rate of the device vs. the number of Erase/Write cycles. If the user has specified an application lifetime, the model will output PPM and FIT rates at that point in time. Alternately, the user may input a desired PPM level and the model will calculate the application lifetime which will result in that survival rate. The user may then trade-off any of the parameters (device type, voltage, application life, temperature, # of bytes per cycle, # of cycles per day etc.) to arrive at an optimal solution for the intended application.

Whenever a parameter is changed, calculation of the ppm/application life is automatic. An "update" box will appear inside the graph to indicate that new data has been entered and the graph should be redrawn. A single click in the "draw" box will redraw the plot of ppm vs. cycles; a click in the "Resize" box will take the plot to full-screen display for a closer view. The plot data can be saved to a file or the plot itself can be copied to the clipboard to be pasted into another application.

ACCURACY OF THE MODEL

The accuracy of the Microchip Total Endurance model has been verified against test data to within ten percent of the actual values. However, Microchip makes no warranty as to its accuracy or applicability of the information to any given application. It is intended to be used as a guide to aid designers of Serial EEPROM-based systems in performing trade-off analysis and developing robust and reliable designs.
