TO OUR VALUED CUSTOMERS:

Welcome to the Microchip Technology Inc. ***Embedded Control Handbook (ECHB) - Volume 1.*** The *ECHB - Volume 1* is the first 'Volume' in our library system of PICmicro™ 8-Bit One-Time-Programmable (OTP) Microcontroller, Nonvolatile Memory, Secure Data Products, and other product application notes, technical briefs, and reference designs. Volume 1 replaces the 1994/1995 ECHB (released in September 1994) and 1995/1996 ECHB Update I (released in September 1995).

Microchip will continue publishing application notes, technical briefs and reference designs in a series of supplemental handbooks called 'Updates'. Updates will be published annually, providing an uninterrupted flow of current application notes, technical briefs and reference designs for our customers' convenience and use. These Updates, with revised and new documents, will be incorporated into future Volumes as appropriate.

It is our intention to provide our valued customers with the best documentation possible to ensure successful use of your Microchip product. To this end, we will continue to improve our publications to better suit your needs. Our publications will be refined and enhanced as new Volumes and Updates are introduced. We welcome your feedback.

If you have any questions or comments regarding this publication, please contact the Marketing Communications Department at facsimile 602.917.4150.

Introduction the The Embedded Control Solutions Company 1-1

SECTION 2 PIC16C5X APPLICATION NOTES

Implementation of an Asynchronous Serial I/O - AN510 2-1
PLD Replacement - AN511 2-19
Implementing Ohmmeter/Temperature Sensor - AN512 2-41
Analog to Digital Conversion Using a PIC16C54 - AN513 2-47
Software Interrupt Techniques - AN514 2-53
Implementing a Simple Serial Mouse Controller - AN519 2-57
A Comparison of 8-Bit Microcontrollers - AN520 2-69
Interfacing to AC Power Lines - AN521 2-79
Power-up Considerations - AN522 2-81
Software Stack Management - AN527 2-85
Implementing Wake-up on Key Stroke - AN528 2-89
Multiplexing LED Drive and a 4x4 Keypad Sampling - AN529 2-95
Intelligent Remote Positioner (Motor Control) - AN531 2-121
Using a PIC16C5X as a Smart I^2C^{TM} Peripheral - AN541 2-135
Using PIC16C5X Microcontrollers as LCD Drivers - AN563 2-151
PIC16C54A EMI Results - AN577 2-165
Implementing Long Calls - AN581 2-171
Macros for Page and Bank Switching - AN586 2-175
A Clock Design Using the PIC16C54 for LED Displays and Switch Inputs - AN590 2-197
Frequency Counter Using PIC16C5X - AN592 2-209
Serial Port Routines Without Using Timer0 - AN593 2-219
Modifying PIC16C54A Code for the PIC16C58A - AN618 2-225
Code Development for the PIC16C52 - AN641 2-233
D/A Conversion Using PWM and R-2R Ladders to Generate Sine and DTMF Waveforms - AN655 2-235
Decoding Infrared Remote Controls Using a PIC16C5X Microcontroller - AN657 2-253

SECTION 3 PIC16CXXX APPLICATION NOTES

Using the Analog-to-Digital (A/D) Converter - AN546 3-1
Implementing Wake-up on Key Stroke - AN552 3-21
Software Implementation of I²C™ Bus Master - AN554 3-25
Software Implementation of Asynchronous Serial I/O - AN555 3-85
Four Channel Digital Voltmeter with Display and Keyboard - AN557 3-121
Using the PORTB Interrupt on Change as an External Interrupt - AN566 3-149
Use of the SSP Module in the I²C™ Multi-Master Environment - AN578 3-153
Using the 8-Bit Parallel Slave Port - AN579 3-169
Using Timer1 in Asynchronous Clock Mode - AN580 3-177
Low-Power Real-Time Clock - AN582 3-181
Interfacing PICmicro™ Microcontrollers to an LCD Module - AN587 3-205
A PC-Based Development Programmer for the PIC16C84 - AN589 3-237
Apple® Desktop Bus (ADB™) - AN591 3-243
Using the CCP Module(s) - AN594 3-277
Implementing Ultrasonic Ranging - AN597 3-301
Air Flow Control Using Fuzzy Logic - AN600 3-319
Resistance and Capacitance Meter Using a PIC16C622 - AN611 3-339
Digital Signal Processing with the PIC16C74 - AN616 3-373
PIC14C000 Calibration Parameters - AN621 3-405
PIC14C000 A/D Theory and Implementation - AN624 3-411
Lead-Acid Battery Charger Implementation Using PIC14C000 - AN626 3-421
Adaptive Differential Pulse Code Modulation using PICmicro™ Microcontrollers - AN643 3-451
Yet Another Clock Featuring the PIC16C924 - AN649 3-491
PWM, a Software Solution for the PIC16CXXX - AN654 3-523
In-Circuit Serial Programming of Calibration Parameters Using a PICmicro™ Microcontroller- AN656 3-535
LCD Fundamentals Using PIC16C92X Microcontrollers - AN658 3-557
Smart Battery Charger with SMBus Interface - AN667 3-579

SECTION 4 PIC17CXXX APPLICATION NOTES

Servo Control of a DC-Brush Motor - AN532 4-1
Saving and Restoring Status on Interrupt (Implementing a Parameter Stack) - AN534 4-141
Using PWM to Generate Analog Output - AN538 4-143
Frequency and Resolution Options for PWM Outputs - AN539 4-145
Implementing IIR Digital Filters - AN540 4-157
Implementation of Fast Fourier Transforms - AN542 4-177
Tone Generation - AN543 4-199
Math Utility Routines - AN544 4-209
Using the Capture Module - AN545 4-259
Serial Port Utilities - AN547 4-283
Implementing Table Read and Table Write - AN548 4-295
Using the PWM - AN564 4-299
Implementation of the Data Encryption Standard Using PIC17C42 - AN583 4-311

Microchip Technology Inc.

Introduction to The Embedded Control Solutions Company®

Since its inception, Microchip Technology has focused its resources on delivering innovative semiconductor products to the global embedded control marketplace. To do this, we have focused our technology, engineering, manufacturing and marketing resources on two synergistic product lines: field-programmable 8-bit PICmicro™ microcontrollers (MCUs) and high-endurance Serial EEPROMs. Today, Microchip's expanding product portfolio is aimed at delivering a more comprehensive array of high-value solutions to a growing base of customers.

Highlights

Inside Microchip Technology you will find:

- An experienced executive team focused on innovation and committed to listening to our customers
- A focus on providing high-performance, cost-effective, field-programmable embedded control solutions
- 8-bit RISC field-programmable OTP and ROM MCUs
- The world's first 8-pin MCU
- Patented KEELOQ® code hopping technology products
- QuickASIC™ gate array conversion technology
- A full family of leadership Serial EEPROM products plus Parallel EEPROMs and EPROMs
- A variety of end-user Application-Specific Standard Products (ASSP)
- Fully integrated manufacturing capabilities
- A global network of manufacturing and customer support facilities
- A unique corporate culture dedicated to continuous improvement
- Distributor network support worldwide including certified distribution FAEs

Business Scope

Microchip Technology Inc. manufacturers and markets a variety of VLSI CMOS semiconductor components to support the market for cost-effective embedded control solutions. In particular, the company specializes in highly integrated, field-programmable RISC MCUs, application-specific standard products, secure data products, application-specific integrated circuits and related Serial EEPROM memory products to meet growing market requirements for high performance, yet economical embedded control capability in products. Microchip's products feature the industry's most economical One-Time-Programmable (OTP) EPROM, reprogrammable Flash and EEPROM, and ROM capability, along with the compact size, integrated functionality, ease of development and technical support so essential to timely and cost-effective product development by our customers.

Chandler, Arizona: Company headquarters near Phoenix, Arizona; executive offices, R&D and wafer fabrication occupy this 242,000-square-foot multi-building facility.

Tempe, Arizona: Microchip's 170,000-square-foot wafer fabrication facility provides increased manufacturing capacity today and for the future.

Market Focus

Microchip targets selected markets where our advanced designs, progressive process technology and industry-leading product performance enable us to deliver decidedly superior performance. The company has positioned itself to maintain a dominant role as a supplier of high-performance, field-programmable OTP MCUs and associated memory for embedded control applications which are found throughout the consumer, automotive, telecommunication, office automation and industrial control markets. Microchip products are also meeting the unique design requirements of targeted embedded applications including security, battery management and field-programmable gate array conversions.

Certified Quality Systems

Microchip received ISO 9001 Quality System certification for its worldwide headquarters and wafer fabrication facilities in January 1997. The company's field-programmable 8-bit MCUs, Serial EEPROMs, related specialty memory products and development systems conform to the stringent quality standards of the International Standards Organization (ISO). The company's assembly and test facility in Kaohsiung, Taiwan is ISO 9002 certified. In addition, Microchip's manufacturing and engineering systems were audited to meet the Automotive Electronics Council A100 guidelines for overall quality, reliability and demonstrated conformance to the requirements of QS-9000 in 1996.

Fully Integrated Manufacturing

Microchip delivers fast turnaround and consistent quality through total control over all phases of production. Research and development, design, mask making, wafer fabrication, and the major part of assembly and quality assurance testing are conducted at facilities wholly-owned and operated by Microchip. Our integrated approach to manufacturing along with rigorous use of advanced Statistical Process Control (SPC) and a continuous improvement culture has resulted in high and consistent yields which have positioned Microchip as a quality leader in its global markets. Microchip's unique approach to SPC provides customers with excellent costs, quality, reliability and on-time delivery.

Bangkok, Thailand: Microchip's 140,000-square-foot manufacturing facility houses the technology and assembly/test equipment for high speed testing and packaging.

A Global Network of Plants and Facilities

Microchip is a global competitor providing local service to the world's technology centers. The Company's design, technology advancement, front-end wafer fabrication, and wafer probe and sort facilities are located in Chandler and Tempe, Arizona.

The Tempe facility provides an additional 170,000 square feet of manufacturing space that meets the increased production requirements of a growing customer base, and provides production capacity which more than doubles that of Chandler. Assembly and test facilities, predominantly located in Kaohsiung, Taiwan and Bangkok, Thailand house the technology and assembly and test equipment necessary for modern plastic and ceramic packaging.

During fiscal 1996, Microchip invested more than $115 million for capital additions to its Tempe fabrication facility and for construction of the additional Bangkok testing facility in Asia. These investments have led to significant improvements in the Company's output and overall cost structure.

Sales and application offices are located in key cities throughout the Americas, Asia/Pacific, Japan and Europe. Offices are staffed to meet the high quality expectations of our customers, and can be accessed for technical and business support.

Embedded Control Overview

Unlike "processor" applications such as personal computers and workstations, the computing or controlling elements of embedded control applications are buried inside the application. The user of the product is only concerned with the very top-level user interface such as keypads, displays and high-level commands. Very rarely does an end-user know (or care to know) the embedded controller inside (unlike the conscientious PC users, who are intimately familiar not only with the processor type, but also its clock speed, DMA capabilities and so on).

It is, however, most vital for designers of embedded control products to select the most suitable controller and companion devices. Embedded control products are found in all market segments: consumer, commercial, PC peripherals, telecommunications (including personal telecommunication products), automotive and industrial. Most often embedded control products must meet special requirements: cost effectiveness, low-power, small-footprint and a high level of system integration.

Typically, most embedded control systems are designed around a MCU which integrates on-chip program memory, data memory (RAM) and various peripheral functions, such as timers and serial communication. In addition, these systems usually require complementary Serial EEPROM, display drivers, keypads or small displays.

Microchip has established itself as a leading supplier of field-programmable embedded control solutions. The combination of high-performance MCU from the PIC12CXXX, PIC16C5X, PIC16CXXX and PIC17CXXX families, along with non-volatile memory products, provide the basis for this leadership.

Microchip is committed to continuous innovation and improvement in design, manufacturing and technical support to provide the best possible embedded control solutions to you.

PICmicro MCU Overview and Roadmap

Microchip PICmicro MCUs combine high performance, low cost, and small package size, offering the best price/performance ratio in the industry. More than 100 million of these devices ship each year to cost-sensitive consumer products, computer peripherals, office automation, automotive control systems, security and telecommunication applications.

Microchip offers four families of 8-bit MCUs to best fit your needs: PIC16C5X 12-bit program word, PIC16CXXX 14-bit program word, PIC17CXXX 16-bit program word and PIC12CXXX 8-pin 12-bit/14-bit program word MCU families.

All families offer OTP, low-voltage and low-power options, as well as various packaging options. Selected members are available in ROM and reprogrammable Flash versions.

The widely-accepted PIC16C5X, PIC16CXXX and PIC17CXXX families are the industry's only 8-bit MCUs using a high-speed RISC architecture. Today, these families are joined by the industry's first and only 8-pin MCU family – the PIC12CXXX. The PIC12CXXX family combines the 8-bit high-speed RISC architecture of the PICmicro MCUs with the smallest footprint MCU. Microchip pioneered the use of RISC architecture to obtain high speed and instruction efficiency.

PIC12CXXX: 8-Pin, 8-Bit Family

The PIC12CXXX family packs Microchip's powerful RISC-based PICmicro architecture into 8-pin DIP and SOIC packages. These PIC12CXXX products have 12-bit or 14-bit wide instruction sets, low operating voltage of 2.5V, small package footprint, interrupt handling and a deeper hardware stack. All of these features provide an intelligence level to applications not previously available because of cost or size.

PIC16C5X: 12-Bit Architecture Family

The PIC16C5X is the well established base-line family offering the most cost-effective solution. These PIC16C5X products have a 12-bit wide instruction set and are currently offered in 18-, 20- or 28-pin packages. In the SOIC and SSOP packaging options, these are among the smallest footprint MCUs. Low-voltage operation, down to 2.0V for OTPs, make this family ideal for battery operated applications.

PIC16CXXX: 14-Bit Architecture Family

The PIC16CXXX family offers a wide-range of options, from 18-pin to 68-pin packages as well as low to high levels of peripheral integration. This family has a 14-bit wide instruction set, interrupt handling capability and a deep 8-level hardware stack. The PIC16CXXX family provides the performance and versatility to meet the requirements of more demanding, yet cost-sensitive, mid-range 8-bit applications.

The PIC14C000 Programmable Mixed-Signal Controller allows engineers to design intelligent controllers for smart batteries, battery chargers, battery status monitoring, uninterruptible power supplies, HVAC, and other data acquisition and processing required for managing energy. The PIC14C000 can support any battery technology including Li Ion, NiMH, NiCd, Pb acid, Zinc Air. In addition, the product's I^2C™ port enables any system OEM, battery pack VAR, and battery manufacturer to design, build, and market SBD-compliant products supporting the System Management Bus standard.

PIC17CXXX: 16-Bit Architecture Family

The PIC17CXXX family offers the world's fastest execution performance of any 8-bit MCU family in the industry. The PIC17CXXX family extends the PICmicro MCUs high-performance RISC architecture with a 16-bit instruction word, enhanced instruction set and powerful vectored interrupt handling capabilities. A powerful array of precise on-chip peripheral features provide the performance for the most demanding 8-bit applications.

PICmicro MCU Naming Convention

The PICmicro architecture offers users a wide range of cost/performance options of any 8-bit MCU family. In order to identify the families, the following naming conventions have been applied to the PICmicro MCUs.

TABLE 1: PICMICRO MCU NAMING CONVENTION*

Family		Architectural Features	Name	Technology	Products
PIC17CXXX	8-bit High-Performance MCU Family	• 16-bit wide instruction set • Internal/external vectored interrupts • DC - 25 MHz clock speed • 120 ns instruction cycle (@ 33 MHz) • Hardware multiply	PIC17C4X	OTP program memory, digital only	PIC17C42A, PIC17C43, PIC17C44

The Advantage of Field Programmability

The PICmicro MCU family provides a unique combination of a high-performance RISC processor with cost-effective OTP technology. Cost-effective OTP provides many benefits to the user at prices which can be comparable to competing ROM solutions. The benefits include:

1. Quick time-to-market.
2. Ease of code changes.
3. Ability to provide adaptable solutions to end-customer requirements.
4. Ability to meet upside potential via inventory positions at Microchip or worldwide distribution.
5. Reduced scrappage in manufacturing.
6. Reduced inventory in manufacturing.
7. Reduced work-in-process liability.

For most manufacturers, getting the product to market quickly has become the number one goal as global markets have become more competitive. Time-to-market puts pressure on all functions within the manufacturing process: development, purchasing, production, marketing and sales. Field-programmable OTP technology streamlines the process for all stages in the product life cycle. In the early product development stages, a programmable MCU allows much of the functionality to be implemented in software which can be modified more easily than hardware-only solutions.

In the manufacturing stage, the compression of the product life cycle curve puts pressure on the management of inventory and manufacturing cycle times. Minimizing inventory reduces the ability to meet upside demand. Using a traditional ROM-based MCU limits the ability to respond to the market with product enhancements or semi-customized products for specific customers. Using the standard OTP-based PICmicro MCU solves all these issues. Inventory can be managed effectively by using the same device in several systems. Costs can be reduced due to volume purchasing. Upsides can be met from either safety stock, directly from Microchip, or local distributors who regularly inventory all PICmicro MCU devices. A sudden decline in demand means no work-in-process ROM-based inventory and any excess safety stock can be consumed by the other products using the same standard device.

OTP is the 'Flexible Manufacturing' technology of the MCU world. As competition intensifies, the demand for customer-specific products increases. Having the ability to change (for example, the appearance of LCD displays or add extra features in a timely manner) can be a key competitive advantage. Programming the OTP device on the manufacturing floor allows easy customizing and internal tracking of the devices for each specific customer. Customization can significantly increase the overall product life cycle to provide better return on investment and help minimize the threat of competition.

Current PICmicro MCU product families include advanced features such as sophisticated timers, embedded analog-to-digital converters, extended instruction/data memory, inter-processor communication (I^2C bus, SPI™ and USARTs) and ROM, RAM, EPROM, EEPROM and Flash memories.

All PICmicro families are supported by user-friendly development systems including; assembler, software simulator, C Compiler, fuzzy logic development software, programmers and in-circuit emulators.

Development Systems

Microchip is committed to providing useful and innovative solutions to your embedded system designs. Our installed base of application development systems has grown to an impressive 90,000 systems worldwide. Significantly, more than half of the total system shipments over the past six years took place within the past 24 months.

Among support products offered are PICMASTER® Real-Time Universal In-circuit Emulator running under the Windows® environment. MPLAB™, a complete Integrated Development Environment (IDE), is provided with PICMASTER. MPLAB allows the user to edit, compile and emulate from a single user interface, making the developer productive very quickly. PICMASTER is designed to provide product development engineers with an optimized design tool for developing target applications. This universal in-circuit emulator provides a complete MCU design tool set for all MCUs in the PIC12CXXX, PIC16C5X, PIC16CXXX and PIC17CXXX families. A CE compliant version of PICMASTER is available for European Union (EU) countries.

ICEPIC is a low-cost in-circuit emulator solution for the Microchip PIC16C5X and PIC16CXXX MCU families. PRO MATE® II, the full-featured, modular device programmer, enables you to quickly and easily program user software into PICmicro MCUs. PRO MATE II runs under MPLAB IDE and operates as a stand-alone unit or in conjunction with a PC-compatible host system. The PICSTART® Plus and Lite development kits, are low-cost development systems for the PIC12CXXX, PIC16C5X/ PIC16CXXX and PIC17CXXX MCUs. PICDEM low-cost demonstration boards are simple boards which demonstrate the basic capabilities of the full range of Microchip's MCUs. Users can program the sample MCUs provided with PICDEM boards, on a PRO MATE II or PICSTART programmer, and easily test firmware. KEELOQ Evaluation and Programming Tools support Microchip's HCS Secure Data Products.

The Serial EEPROM Designer's Kit includes everything necessary to read, write, erase or program special features of any Microchip Serial EEPROM product including *Smart Serials*™ and secure serials. The *Total Endurance*™ Disk is included to aid in trade-off analysis and reliability calculations. The total kit can significantly reduce time-to-market and result in an optimized system.

Software Support

MPLAB is a Windows-based development platform for Microchip's PICmicro OTP MCUs. MPLAB IDE offers a project manager and program text editor, a user-configurable toolbar containing four pre-defined sets and a status bar which communicates editing and debugging information.

MPLAB is the common user interface for Microchip development systems tools including MPLAB Editor, MPASM Assembler, MPLAB-SIM Software Simulator, PICMASTER In-Circuit Emulator, PRO MATE II Programmer and PICSTART Plus Development Programmer.

Microchip's PICmicro MCUs are also supported by fuzzy logic development software, an application code generator and a C-Compiler. MP-DriveWay is an easy-to-use Windows-based Application Code Generator for visually configuring all the peripherals in a PICmicro device and, with a click of the mouse, generate all the initialization and many functional code modules in C language.

Microchip endeavors at all times to provide the best service and responsiveness possible to its customers. The Microchip Internet Home Page can provide you with the latest technical information, production released software for development tools, application notes and promotional news on Microchip products and technology. The Microchip World Wide Web address is http://www.microchip.com.

The Microchip Systems Bulletin Board Service (BBS) is one service to facilitate this service. It is a multi-faceted tool that can provide you with information on a number of different topics.

Special Interest Groups (SIGs) available through the BBS can provide you with the opportunity to discuss issues and topics of interest with others that share your interest or questions. The BBS is regularly used to distribute technical information, application notes, source code, errata sheets, bug reports, interim patches for Microchip systems products, and user contributed files for distribution.

Please see the "On-Line Technical Support" Section for more information on the Microchip BBS and WWW site.

Application-Specific Standard Products (ASSPs)

Microchip ASSPs provide value-added embedded control solutions by combining PICmicro MCU architecture, non-volatile memory, and innovative software technology for vertical applications. These products incorporate technology that offers a complete solution that is both unique to the customer and standard in manufacture to Microchip. In addition, Microchip ASSPs reduce or remove the barriers for customers to use Microchip solutions, in their products, through the use of software, embedded in secure OTP- or ROM-based MCUs. These MCUs are packaged to provide the highest integration, to the customer, at the best overall system cost.

The MTE1122 Energy Management Controller combines Microchip's proprietary PICmicro 8-bit RISC MCU technology with a unique, patent pending power management firmware algorithm in a single package. This device, by monitoring and controlling the supply requirements into an AC induction motor, effectively reduces the power consumed by the motor. The MTE1122 is available in both plastic DIP and space-saving SOIC packages, and operates over commercial and industrial temperature ranges.

Future ASSP products will include advanced features such as mixed analog and digital capability as well as an ever broadening family of turnkey software solutions for the embedded control market.

Application-Specific Integrated Circuits (ASICs)

Microchip offers the QuickASIC™ Mask Gate Array (MPGA) family which replaces standard field-programmable gate arrays (FPGAs) and complex programmable logic devices (CPLDs) with a MPGA at a substantially reduced price per unit compared to programmable logic devices. Microchip's QuickASIC family offers turnkey digital design conversion of most FPGA/CPLD devices by transforming its net list into a masked gate array – with very fast lead times of four weeks from design signoff to prototype. QuickASIC devices can be used for any application prototyping with FPGAs/CPLDs including multimedia, data communications, telecommunications and computer peripherals.

In addition, Microchip plans call for customers being given the opportunity to combine Microchip's powerful RISC-based PICmicro MCU core with configurable gate arrays, providing a much wider range of flexibility, power ranges and custom functionality.

Serial EEPROM Overview

Microchip offers one of the broadest selections of CMOS Serial EEPROMs on the market for embedded control systems. Serial EEPROMs are available in a variety of densities, operating voltages, bus interface protocols, operating temperature ranges and space saving packages.

Densities:

Currently range from 128 bits to 64K bits with higher density devices in development.

Bus Interface Protocols:

All major protocols are covered: I^2C, Microwire® and SPI.

Operating Voltages:

In addition to standard 5V devices there are two low voltage families. The "LC" devices operate down to 2.5V, while the breakthrough "AA" family operates, in both read and write mode, down to 1.8V, making these devices highly suitable for alkaline and NiCd battery powered applications.

Temperature Ranges:

Like all Microchip devices, Serial EEPROMs are offered in Commercial (0°C to +70°C), Industrial (-40°C to +85°C) and Extended (-40°C to +125°C) operating temperature ranges.

Packages:

Small footprint packages include: industry standard 5-lead SOT-23, 8-lead DIP, 8-lead SOIC in JEDEC and EIAJ body widths, and 14-lead SOIC. The SOIC comes in two body widths; 150 mil and 207 mil.

Technology Leadership:

Microchip's Serial EEPROMs are backed by a 10 million Erase/Write cycle guarantee. Microchip's erase/write cycle endurance is among the best in the world, and only Microchip offers such unique and powerful development tools as the Total Endurance disk. This mathematical software model is an innovative tool used by system designers to optimize Serial EEPROM performance and reliability within the application.

The Company has also developed the world's first 64K Smart Serial EEPROM. Device densities range from 128 bits up to 64K bits. Another first is the 24LC21, a single chip DDC1/DDC2™-compatible solution for plug-and-play video monitors. In addition, Microchip released a high-speed 1 MHz 2-wire Serial EEPROM device ideal for high-performance embedded systems.

Microchip is a high-volume supplier of Serial EEPROMs to all the major markets worldwide including consumer, automotive, industrial, computer and communications. To date, more than 700 million units have been produced. Microchip continues to develop new Serial EEPROM solutions for embedded control applications.

Parallel EEPROM Overview

CMOS Parallel EEPROM devices from Microchip are available in 4K, 16K and 64K densities. The manufacturing process used for these EEPROMs ensures 10,000 to 100,000 erase/writecycles typical. Data retention is more than 10 years. Fast write times are less than 200 µs. These EEPROMs work reliably under demanding conditions and operate efficiently at temperatures from -40°C to +85°C. Microchip's expertise in advanced SOIC, TSOP and VSOP surface mount packaging supports our customers' needs in space-sensitive applications.

Typical applications include computer peripherals, engine control, telecommunications and pattern recognition.

OTP EPROM Overview

Microchip's CMOS EPROM devices are produced in densities from 64K to 512K. Typical applications include computer peripherals, instrumentation, and automotive devices. Microchip's expertise in surface mount Packaging on SOIC, TSOP and VSOP packages led to the development of the Surface Mount OTP EPROM market where Microchip is a leading supplier today. Microchip is also a leading supplier of low-voltage EPROMs for battery powered applications.

Secure Data Products Overview

Microchip's patented KEELOQ code hopping technology is the perfect solution for remote keyless entry and logical/physical access control systems. The initial device in the family, HCS300 encoder, will replace current fixed code encoders in transmitter applications and provide a low cost, integrated solution. The KEELOQ family is rapidly expanding with the HCS301 (high voltage encoder), HCS200 (low-end, low-cost encoder), and high-end encoders (HCS360 and HCS361) that meet OEM specifications and requirements.

Microchip provides flexible decoder solutions by providing optimized routines for Microchip's PICmicro MCUs. This allows the designer to combine the decoder and system functionality in a MCU. The decoder routines are available under a license agreement. The HCS509 and HCS512 are the first decoder devices in the KEELOQ family. These devices are single chip decoder solutions and simplify designs by handling learning and decoding of transmitters.

The KEELOQ product family is expanding to include enhanced encoders and decoders. Typical applications include automotive RKE, alarm and immobilizer systems, garage door openers and home security systems.

Ease of Production Utilizing Quick Turn Programming (QTP) and Serialized Quick Turn Programming (SQTP SM)

Recognizing the needs of high-volume manufacturing operations, Microchip has developed two programming methodologies which make the OTP products as easy to use in manufacturing as they are efficient in the system development stage.

Quick Turn Programming allows factory programming of OTP products prior to delivery to the system manufacturing operation. PICmicro, EPROM and Serial EEPROM products can be automatically programmed, with the users program, during the final stages of the test operation at Microchip's assembly and test operations in the Philippine Islands, Taiwan and Thailand. This low-cost programming step allows the elimination of programming during system manufacturing and essentially allows the user to treat the PICmicro and memory products as custom ROM products. With one- to four-week lead times on QTP products, the user no longer needs to plan for the extended ROM masking lead times and masking charges associated with custom ROM products. This capability, combined with the off-the-shelf availability of standard OTP product, ensures the user of product availability and the ability to reduce his time-to-market once product development has been completed.

Unique in the 8-bit MCU market is Microchip's ability to enhance the QTP capability with Serialized Quick Turn Programming (SQTP). SQTP allows for the programming of devices with unique, random or serialized identification codes. As each PICmicro device is programmed with the customers program code, a portion of the program memory space can be programmed with a unique ID, accessible from normal program memory, which will allow the user to provide each device with a unique identification. This capability is ideal for embedded systems applications where the transmission of key codes or identification of the device as a node within a network is essential. Taking advantage of this capability allows the system designer to eliminate the requirement for expensive off-chip code implementation using DIP switches or non-volatile memory components. The SQTP offering, pioneered by Microchip, provides the embedded systems designer with a low cost means of putting a unique and custom device into every system or node.

Future Products and Technology

Microchip is constantly developing advanced process technology modules and new products that utilize the Company's advanced manufacturing capabilities. Current production technology utilizes lithography dimensions down to 0.7 micron.

Microchip's research and development activities include exploring new process technologies and products that have industry leadership potential. Particular emphasis is placed on products that can be put to work in high-performance broad-based markets.

Equipment is continually updated to bring the most sophisticated process, CAD and testing tools online. Cycle times for new technology development are continuously reduced by using in-house mask generation, a high-speed pilot line within the manufacturing facility and continuously improving methodologies.

More advanced technologies are under development, as well as advanced CMOS RISC-based MCU, ASSP and CMOS EEPROM and EPROM, QuickASIC and other products. Objective specifications for new products are developed by listening to our customers and by close co-operation with our many customer-partners worldwide.

Implementation of an Asynchronous Serial I/O

Author: *Amar Palacherla*
Microchip Technology Inc.

INTRODUCTION

The PIC16C5X series from Microchip Technology Inc., are 8-bit, high-speed, EPROM-based microcontrollers. This application note describes an implementation of an asynchronous serial I/O using a PIC16C5X microcontroller. These microcontrollers can operate at very high speeds with a minimum cycle time of 200 ns @ 20 MHz input clock. Many microcontroller applications require chip-to-chip serial data communications. Since the PIC16C5X series has no on-chip serial ports, serial communication has to be performed in software. For many cost-sensitive high volume applications, implementation of a serial I/O through software provides a more cost effective solution than dedicated logic. This application note provides code for the PIC16C5X to simulate a serial port using two I/O pins (one as input for reception and the other as output for transmission).

IMPLEMENTATION

Two programs are provided in this application note. One program (Appendix B) simulates full duplex RS-232 communication and the other (Appendix A) provides implementation of half-duplex communication. Using half-duplex, baud rates up to 19200 can be implemented using an 8 MHz input clock. For full-duplex, the software can handle up to 9600 baud at 8 MHz and 19200 baud at 20 MHz, one or two stop bits, eight or seven data bits, no Parity and can transmit or receive with either LSb first (normal mode) or MSb first (CODEC-like mode). It should be noted that the higher the input clock the better the resolution. These options should be set up during assembly time and not during run time. The user simply has to change the header file for the required communication options. The software does not provide any handshaking protocols. With minor modifications, the user may incorporate software handshaking using XON/XOFF. To implement hardware handshaking, an additional two digital I/O pins may be used as RTS (ready to send) and CTS (clear to send) lines.

© 1997 Microchip Technology Inc.

Figure 1 shows a flowchart for serial transmission and Figure 2 shows a flowchart for reception. The flowcharts show case transmission/reception with LSb first and eight data bits. For reception, the data receive pin, DR, is polled approximately every B/2 seconds (52 µs for 9600 baud) to detect the start bit, where B is the time duration of one bit (B = 1/Baud). If a start bit is found, then the first data bit is checked for after 1.25B seconds. From then on, the other data bits are checked every B seconds (104 µs for 9600 baud).

In the case of transmission, first a start bit is sent by setting the transmit data pin, DX, to zero for B seconds, and from then on the DX pin is set/cleared corresponding to the data bit every B seconds. Assembly language code corresponding to the following flowcharts is given in Example 1 and Example 2.

The software is organized such that the communication software acts as a Real-Time Operating System (RTOS) which gives control to the user routine for a certain time interval. After this predetermined time slot, the user must give back control to the Operating System. This is true only in the case of full-duplex implementation. Timing considerations are such that the user gets control for approximately half the time of the bit rate and the rest of the time is used up by the Operating System (and software delays). Please refer to Table 1 for the delay constants and the time the user gets using an 8 MHz input clock. Delay constants and the time that the user gets at 20 MHz and 4 MHz input clock speeds are given in the source code listing of the full-duplex routine. At frequencies other than 4, 8, or 20 MHz, the delay constants and the time the user gets can be computed from the equations given in Equation 1.

For example, if the baud rate selected is 9600 bps (@ 8 MHz), then the total time frame for one bit is approximately 104 µs. Out of this 104 µs, 61 µs are used by the Operating System and the other 43 µs are available to the user. It is the user's responsibility to return control to the Operating System exactly after the time specified in Table 1. For very accurate timing (with resolution up to one clock cycle) the user may set up Timer0 with the Prescaler option for calculating the real-time. With TMR0 configured to increment on internal CLKOUT (500 ns @ 8 MHz CLKIN) and the prescaler assigned to it, very accurate and long timing delay loops may be assigned. This method of attaining accurate delay loops is not used in the RS-232 code (RTOS), so that Timer0 is available to the user for other important functions. If Timer0 is not used for other functions, the user may modify the code to replace the software delay loops by counting TMR0. For an example of using TMR0 counting for exact timing delays, refer to the "user" routine in Full Duplex code (Appendix B).

The software uses minimal processor resources. Only six data RAM locations (File Registers) are used. The RTOS uses one level of stack, but it is freed once control is given back to the user. The Watchdog Timer (WDT) and Timer0 are not used. The user should clear the WDT at regular intervals, if the WDT is enabled.

The usage of the program is described in the following sections. The user should branch to location "Op_Sys" exactly after the time specified in Table 1 or as computed from equations in Equation 1.

Whereas, the transmission is totally under user control, the Reception is under the control of the Operating System. As long as the user does not set the X_flag, no transmission occurs. On the other hand the Operating System is constantly looking for a start bit and the user should not modify the R_done flag or the RcvReg.

TRANSMISSION

Transmit Data is output on the DX pin (bit0 of PORTA). In the user routine, the user should load the data to be transmitted in the XmtReg and set the X_flag (`bsf kwn FlagRX,X_flag`). This flag gets cleared after the transmission. The user should check this flag (X_flag) to see if a transmission is in progress. Modifying XmtReg when the X_flag is set will cause erroneous data to be transmitted.

RECEPTION

Data is received on pin DR (bit1 of PORTA). The user should constantly check the "R_done" flag to see if the reception is over. If a reception is in progress, the R_flag is set. If the reception is over, the "R_done" flag is set. The "R_done" flag gets cleared when the next start bit is detected. The user should constantly check the R_done flag, and if set, then the received word is in Register "RcvReg". This register gets cleared when a new start bit is detected. It is recommended that the RcvReg, be copied to another register after the R_done flag is set. The R_done flag also gets cleared when the next start bit is detected.

The user may modify the code to implement an N deep buffer (limited to the number of Data RAM locations available) for receive. Also, if receiving at high speeds, and if the N deep buffer is full, an XOFF signal (HEX 13) may be transmitted. When ready to receive more data, an XON signal (HEX 11) should be transmitted.

00090 ; The constants marked " * " are >255. To implement these constants
00091 ; in delay loops, the delay loop should be broken into 2 or more loops.
00092 ; For example, 357 = 255+102. So 2 delay loops, one with 255 and
00093 ; the other with 102 may be used.

PLD Replacement

INTRODUCTION

PIC16C5X microcontrollers are ideal for implementing low cost combinational and sequential logic circuits that traditionally have been implemented using either numerous TTL gates or using programmable logic chips such as PLAs or EPLDs.

The PIC16C5X is a family of high-performance 8-bit microcontrollers from Microchip Technology Inc. It employs a Harvard architecture, (i.e., has a separate data bus [8-bit] and program bus [12-bit]). All instructions are single word and execute in one cycle except for program branches. The instruction cycle time is 200 ns at 20 MHz. PIC16C5X microcontrollers are ideal for PLD-type applications because:

- Very low cost
- Few external components required
- Fully programmable. PIC16C5X Microcontrollers are offered as One Time Programmable (OTP) EPROM devices.
- Available off the shelf from distributors
- Calibration in software for improved measurement accuracy
- Power savings using PIC16C5X's Sleep mode.
- PIC16C5X's output pins have large, current source/sink capability to drive LED's directly.

IMPLEMENTING A PLA

To implement a generic combinational logic function, we can simply emulate an AND-OR PLA in software. This requires the logic outputs to be described as sums of products. To describe our algorithm, we will use a simple 8-input, 8-output PLA with 24 product terms (Figure 1). We will further use the truth table in Figure 2 as the PLA function being implemented. In this example, only four inputs (A3:A0) are used and the other four inputs (A7:A4) are "don't care". On the output side, seven output pins (Y6:Y0) are used and Y7 is unused. To implement this PLA, the logic inputs A0,A1,...,A7 can be connected to PORTB pins RB0,RB1,...,RB7 respectively. The logic outputs Y0,Y1,...,Y7 will appear on PORTC pins RC0,RC1,...,RC7 respectively. PORTB is configured as input and PORTC will be configured as output. To evaluate each product term one XOR (exclusive .OR.) and one .AND. operation will be required. For example, to determine product term P3 = A3.A2.A1.A0, the expression to evaluate is:

(A7:A0 .XOR. xxxx0011b) .AND. 00001111b).

The constant with which .XOR. is performed will be referred to as P3_x in our discussion. P3_x = xxxx0011b will ensure that if A3:A0 = 0011b, then the least significant 4-bits of the result will be 0000b. The .AND. constant, referred to here as P3_a (Product term 3, .AND. constant) basically eliminates the "don't care" inputs (here A7:A4) by masking them. Therefore, if the result of the .XOR.-.AND. operation is zero then P3 = 1 else P3 = 0. Once the Product terms are evaluated they are stored in four product registers Preg_0 to Preg_3. To determine an output term:

$$Y0 = P0 + P2 + P3 + P5 + P6 + P7 + P8 + P9 + P10 + P12 + P13 + P14$$

we need to evaluate the following expression:

(Preg_a .AND. OR_a0) .OR. (Preg_b .AND. OR_b0) .OR. (Preg_c .AND. OR_c0)

In our case the constant values to implement Y0 are as follows:

OR_a0 =	1	1	1	0	1	1	0	1
	P7	P6	P5		P3	P2		P0
OR_b0 =	1	1	0	1	0	1	1	1
OR_c0 =	0	0	0	0	0	0	0	0

For a larger number of inputs, outputs, or product terms, the evaluation will be more complex but follows the same principle. Appendix A shows the assembly code to implement this 8 input x 8 output x 24 Product PLA. This example optimizes speed as well as program memory requirements. Appendix B shows a slightly different implementation (only the EVAL_Y MACRO is different) that optimizes program memory usage over speed. Table 1 shows the time and resources required to implement different size PLAs.

SPEED/RESPONSE TIME

The worst case response time of a PLA implemented in this fashion can be calculated as follows. First, we define TD = time required to execute the PLA program assuming the worst case program branches are taken. Then the maximum propagation delay time from input change to valid output = 2TD. This is because if an input changes just after the program reads the input port, its effect will not show up until the program completes the current execution cycle, re-reads the input and recalculates the output. This is shown in Figure 3. There are ways to improve the delay time, such as sample inputs several times throughout the PLA program and if an input change is sensed, return to the beginning rather than execute the rest of the evaluation code.

A Table Lookup Method for Small PLA Implementation

If the number of inputs is small (8 or less) then a simple table lookup method can be used to implement the PLA. This will improve execution time to around 5 µs (@ 8 MHz input clock). The following code implements the Binary Coded Decimal (BCD) to 7-segment conversion (Figure 2) using this technique.

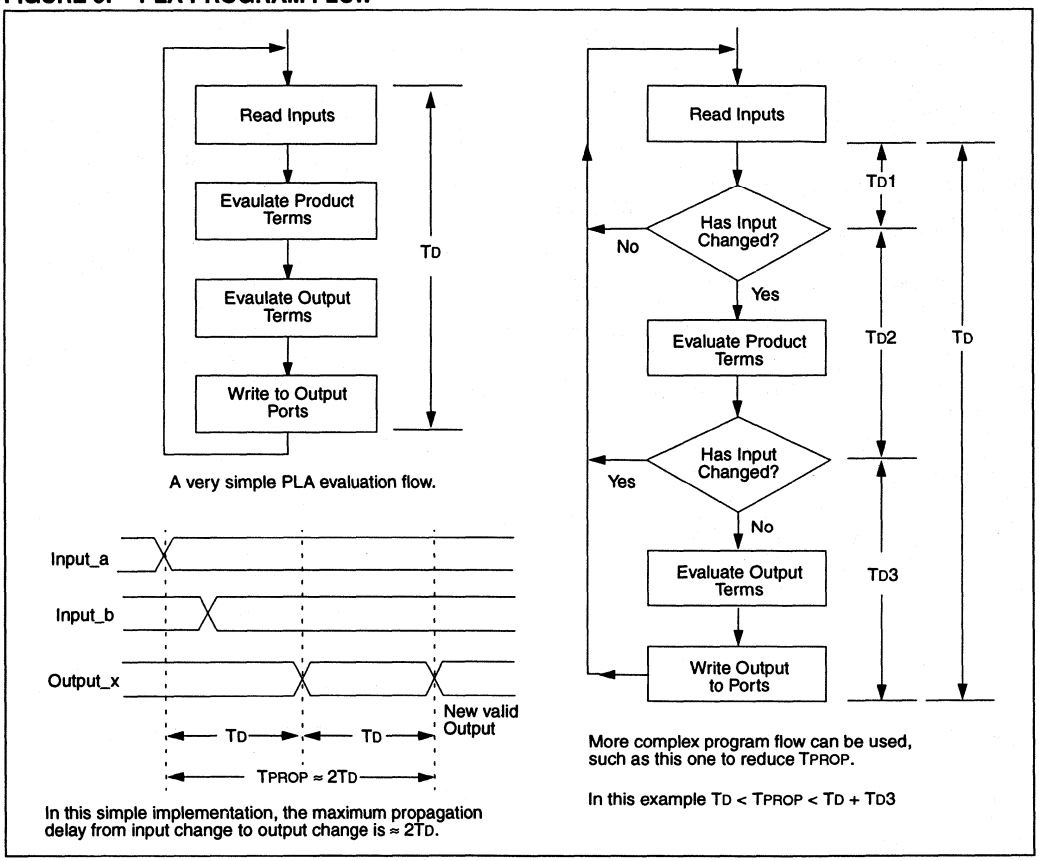

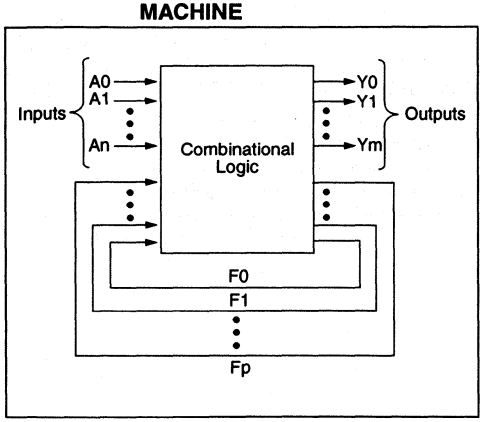

FIGURE 4: ASYNCHRONOUS STATE MACHINE

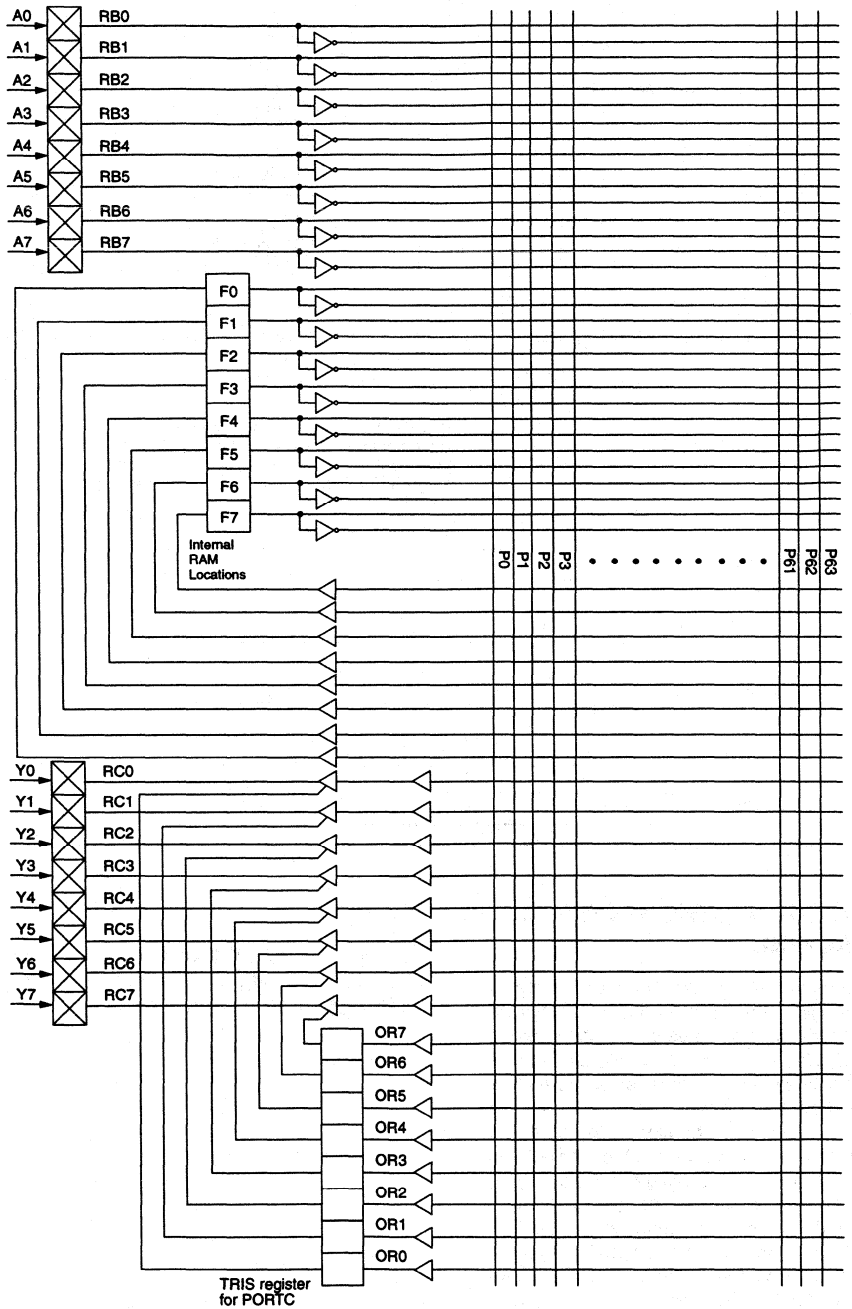

IMPLEMENTING AN ASYNCHRONOUS STATE MACHINE

The concept can be easily extended to implement sequential logic (i.e., a state machine). Figure 4 shows a state machine with n inputs (A0:An), m outputs (Y0:Ym) and p states that feedback as inputs to the PLA (F0:Fp). In a PIC16C5X the states will be stored as bits in RAM location. Input will now mean input from a port as well as from the feedback registers. Figure 5 shows an example PLA with eight inputs A0,A1,..,A7 that are connected to PORTB pins RB0,RB1,..,RB7. This example PLA has a total of 24 outputs of which eight are actual outputs, another eight are output enable control for the outputs and the other eight are feedbacks (or states). The PLA shown here, therefore, in essence implements an asynchronous state machine (i.e., there is no system clock).

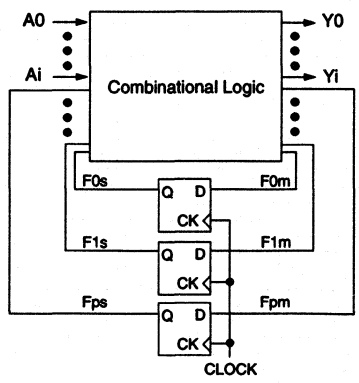

FIGURE 5: EXAMPLE OF A LARGER PLA IMPLEMENTATION

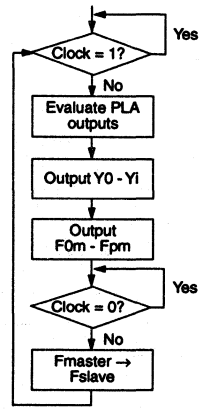

This example shows 16 inputs (including feedback), 64 product terms and 24 outputs including feedback and O/E control. This example demonstrates that O/E control is easily implementable using PIC16C5X's bi-directional ports with Tri-State® control.

FIGURE 6: SYNCHRONOUS STATE MACHINE IMPLEMENTATION

Flowchart for implementing synchronous state machine. Clock is input to an I/O port. Fmaster and Fslave are RAM locations that store state variables F0m, ... Fpm and F0s, ... Fps respectively.

IMPLEMENTING A SYNCHRONOUS STATE MACHINE

In a synchronous system (Figure 6) usually all inputs are stable at the falling (or rising) edge of the system clock. The state machine samples inputs on the falling edge, then evaluates state and output information. The state outputs are latched by the rising edge of the clock before feeding them back to the input (so that they are stable at the falling edge of the clock). To implement such a state machine, the system clock will have to be polled by an input pin. When a falling edge is detected, the PLA evaluation procedure will be invoked to compute outputs and write them to output pins. The PLA procedure will also determine the new state variables, F0m, F1m,...,Fpm and store them in RAM. The program will then wait until a rising edge on the clock input is detected and copy the "master" state variables (F0m,..,Fpm) to slave state variables (F0s,F1s,..,Fps). This step emulates the feedback flip-flops.

SUMMARY

In conclusion, the PIC16C5X can implement a generic PLA equation and provide a quick, low cost solution where system operation speed is not critical.

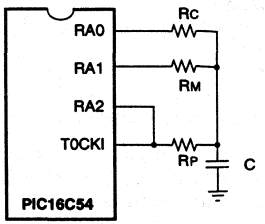
Implementing Ohmmeter/Temperature Sensor

Author: *Doug Cox*
Microchip Technology, Inc.

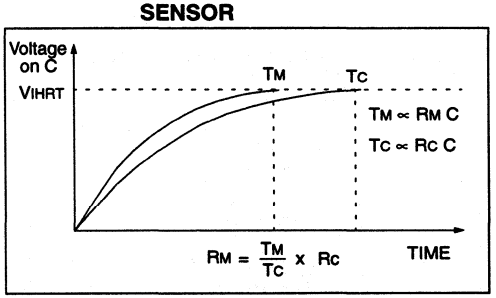
INTRODUCTION



This application note describes a method for implementing an ohmmeter or resistance type temperature sensor using the PIC16C5X series of microcontrollers. The ohmmeter requires only two external components and is software and hardware configurable for resistance measurement with resolutions from 6-bits to 10-bits with measurement times of 250 µs (6-bits at 8 MHz) or longer. This method uses a software calibration technique that compensates for voltage, time, and temperature drift as well as component errors. PIC16C5X microcontrollers are ideal for simple analog applications because:

- Very low cost
- Few external components required
- Fully programmable. PIC16C5X Microcontrollers are offered as One Time Programmable (OTP) EPROM devices.
- Available off the shelf from distributors
- Calibration in software for improved measurement accuracy
- Power savings using PIC16C5X's Sleep mode.
- PIC16C5X's output pins have large, current source/sink capability to drive LED's directly.

THEORY OF OPERATION



This application uses a capacitive charging circuit (Figure 1) to convert resistance to time, which can be easily measured using a microcontroller. First, a reference voltage (usually VDD) is applied to a calibration resistor, Rc. The capacitor C is charged up until the threshold on the chip input trips. This generates a software calibration value that is used to calibrate out most circuit errors, including inaccuracies in the capacitor, changes in the input threshold voltage and temperature variations. After C is discharged, the reference voltage is applied to the resistance to be measured (or thermistor). The time to trip the threshold is then measured and compared to the calibration value to determine the actual resistance (Figure 2). In the temperature sensing mode, the temperature is calculated using a lookup table.

FIGURE 1: OHMMETER/TEMPERATURE SENSOR

RP is a small resistor (100-200Ω) which limits peak current through RA2 while discharging, or through RA2 or T0CKI in the event of an Electro-Static Discharge (ESD) or Electrical Over Stress (EOS) related breakdown.

CIRCUIT CONFIGURATION

The values of Rc and C are selected based upon the number of bits of resolution required. Rc should be approximately one half the largest value resistance to be measured and:

$$C = \frac{-T}{R_M \bullet IN\left(1 - \frac{V_T}{V_R}\right)}$$

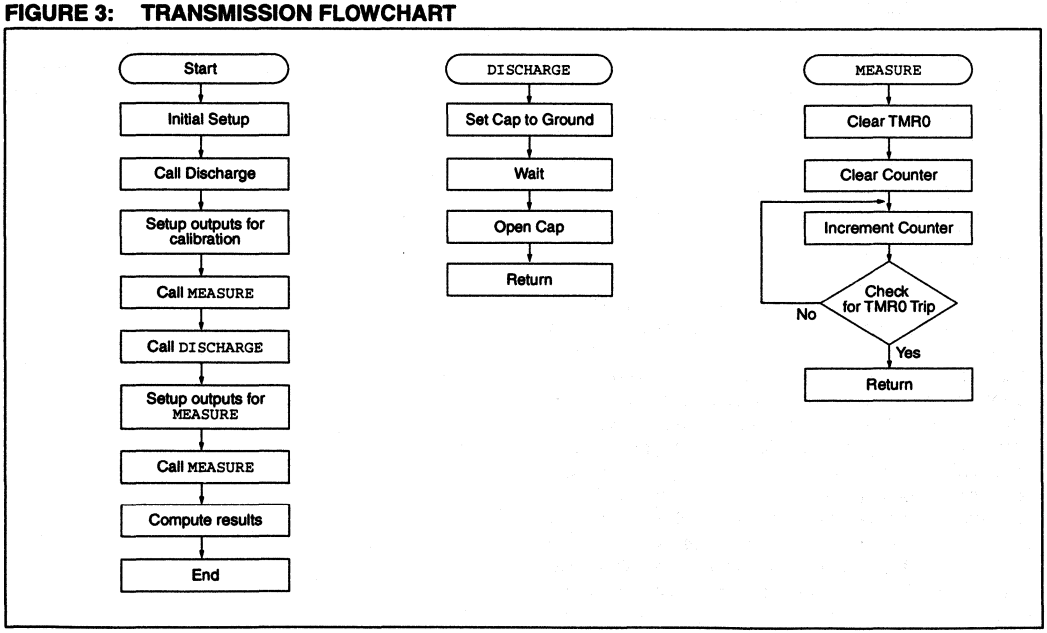
Where:

V_R = Reference voltage
T = Time to do the number of bits of resolution desired
V_T = Threshold voltage of the PIC16C5X input being used
R_M = Maximum resistance value to be measured

Actual value for C should be slightly smaller than calculated to ensure that the PIC16C5X does not overcount during the measurement.

For example use R_M = 200k for 8-bit resolution with an 8 MHz clock, V_R = 5V, V_T = 3V, Rc = 100k and 6 instruction cycles per count:

T = 256 counts • 1/8 MHz • 4 clocks/instruction • 6 instructions/count = 768 µs
C = 4200 pF [Use 3900 pF]



CIRCUIT PERFORMANCE

The calibration cycle removes all first order errors (offset, gain, C inaccuracy, power supply voltage and temperature) except R absolute accuracy. A low drift resistor should be selected for R and its value stored in software to reduce measurement errors. Other error sources are I/O pin leakage, resistor and capacitor non-linearities, input threshold uncertainty, and time measurement uncertainty (± one instruction cycle time). Measured performance shows the ohmmeter to be accurate within ±1% over one decade.

Example

The assembly code implementing the circuit of Figure 1 is listed in Appendix A. This code measures time up to 16-bits (65535 measure cycles) and calculates the results using 16-bit multiply and divide subroutines. In actual applications, it is more efficient to use 8-bit measurements if application accuracies permit. The math code will be substantially reduced and measurement time is reduced by the simpler code and shorter count.

Analog to Digital Conversion Using a PIC16C54

Author: *Doug Cox*
Microchip Technology Inc.

INTRODUCTION

This application note describes a method for implementing analog to digital (A/D) conversion on the PIC16C5X series of microcontrollers. The converter requires only five external components and is software and hardware configurable for conversion resolutions from 6-bits up to 10-bits and conversion times of 250µs or longer. The method is usable for both voltage and current conversion and uses a software calibration technique that compensates for time and temperature drift as well as component errors. PIC16C5X microcontrollers are ideal for simple analog applications because:

- Very low cost
- Few external components required
- Fully programmable. PIC16C5X microcontrollers are offered as One-Time-Programmable (OTP) EPROM devices.
- Available off the shelf from distributors
- Calibration in software for improved measurement accuracy
- Power savings using Sleep mode
- Output pins have large, current source/sink capability to drive LED's directly

THEORY OF OPERATION

The application uses a capacitive charging circuit (Figure 1) to convert the input voltage to time, which can be easily measured using a microcontroller. First, the reference voltage is applied to the input voltage to the current converter (U1). The equivalent circuit is shown in Figure 2. This circuit provides a linearly variable current as a function of input voltage. The logarithmic characteristic that would occur if the input voltage was applied directly to an RC is not present. The capacitor C is charged up until the threshold on the chip input trips. This generates a software calibration value that is used to calibrate out most circuit errors, including; inaccuracies in the resistor and capacitor, changes in the input threshold voltage, and temperature variations. After the software calibration value is measured, the capacitor is discharged (Figure 3), and the input voltage is connected to VIN. The time to the trip threshold is measured for the input voltage and compared to the calibration value to determine the actual input voltage.

CIRCUIT CONFIGURATION

The values of R and C are selected based upon the number of bits of resolution required.

$$RC = (V_I \bullet T)/V_T$$

Where:

V_I = Lowest voltage to be measured (at least ten LSb's)

T = Time to do the number of bits of resolution desired

V_T = Threshold voltage of the PIC16C5X input being used

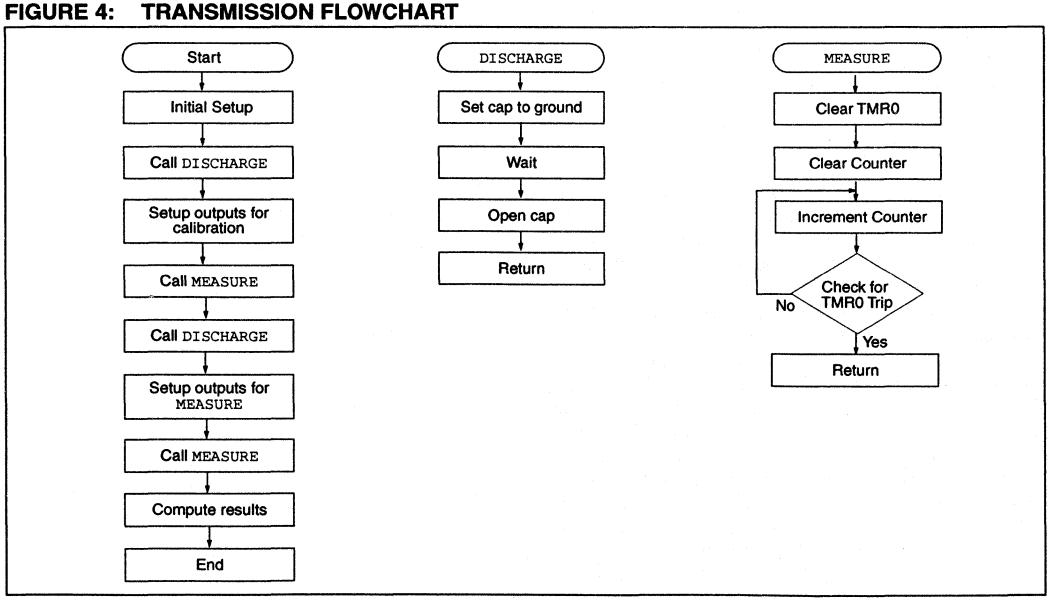
Actual value for RC should be slightly smaller than calculated to ensure that the PIC16C5X does not overcount during the measurement.

For example use a 3V input and 8-bit resolution with a 8 MHz clock and 6 instruction cycles per count:

$V_I = 100\ mV$
$T = 256 \bullet 1/8\ MHz \bullet 4\ clocks/cycle \bullet 6\ cycles = 768\ \mu s$
$V_T = 3.0V\ (est)$

For input voltages greater than 3V a resistor divider network should be used to keep the maximum voltage on V_{IN} to less than 3V. For best performance the reference voltage should be between 2V and 3V.

The circuit can also be used as a current mode A/D converter. In this case the input voltage to current converter is not needed and the reference current and input current are both routed via analog switches directly into the capacitor.



CIRCUIT PERFORMANCE

The calibration cycle removes all first order errors (offset, gain, R and C inaccuracy, power supply voltage and temperature) except the reference voltage drift. Any change in the reference voltage, including noise, between the calibration cycle and the measurement cycle may result in measurement errors. Other error sources may be analog switch leakage, resistor and capacitor non-linearities, input threshold uncertainty and time measurement uncertainty (± one instruction cycle time). Measured performance shows the converter to be accurate within ±1% of full scale.

Example

Assembly code implementing the circuit of Figure 1 is listed in Appendix A. This code measures the time up to 16-bits and calculates the results using 16-bit multiply and divide subroutines. In actual applications, if measurement accuracy permits, it may be advantageous to use 8-bits. The math code can be substantially reduced and the measure time is reduced by the simpler code and shorter count.

Software Interrupt Techniques

INTRODUCTION

This application note describes a unique method for implementing interrupts in software on the PIC16C5X series of microcontrollers. This method takes advantage of the PIC16C5X's architecture which allows changing the program counter under software control. Up to eight interrupt lines are possible, but the practical limit for simple code generation is six interrupts, or 64 possible input conditions. The interrupt detection time is under software control and standard I/O pins are used as the interrupt lines.

THEORY OF OPERATION

SOFTWARE POLLING OF I/O LINES TO REPLACE HARDWARE INTERRUPTS

The interrupt conditions are determined by detecting changes on the I/O lines that have been selected to be the interrupt lines. These changes are used to create a jump table that allows a different program response to each interrupt condition. The interrupt response time is under software control and can be as short as ten to twenty microseconds, depending on main program and interrupt subroutine program length.

CREATING THE INTERRUPT SUBROUTINE JUMP TABLE

Each I/O condition may have its own unique subroutine to respond to changes on the interrupt lines. Direct access to these routines is achieved by using the PIC16C5X's ability to change the program counter under software control. Here is an example of how two I/O lines may be polled:

```
MOVF    CONDTN,W ;LOAD I/O CONDITION INTO W
                 ;REGISTER
ANDLW   3        ;MASK OFF TOP 6 BITS
ADDWF   2,1      ;ADD INPUT TO PROGRAM COUNTER
                 ;TO CREATE JUMP TABLE
GOTO    MAIN     ;FOR NO CHANGE GOTO MAIN
                 ;PROGRAM
GOTO    INT1     ;FOR CHANGE IN BIT 0 GOTO INT1
GOTO    INT2     ;FOR CHANGE IN BIT 1 GOTO INT2
GOTO    INT3     ;FOR BOTH CHANGES GOTO INT3
```

The changes to the I/O lines have been used to create a two bit number that is added to the program counter. The GOTO that is executed depends on the new program counter address.

CREATING CONSTANT TIME POLLING

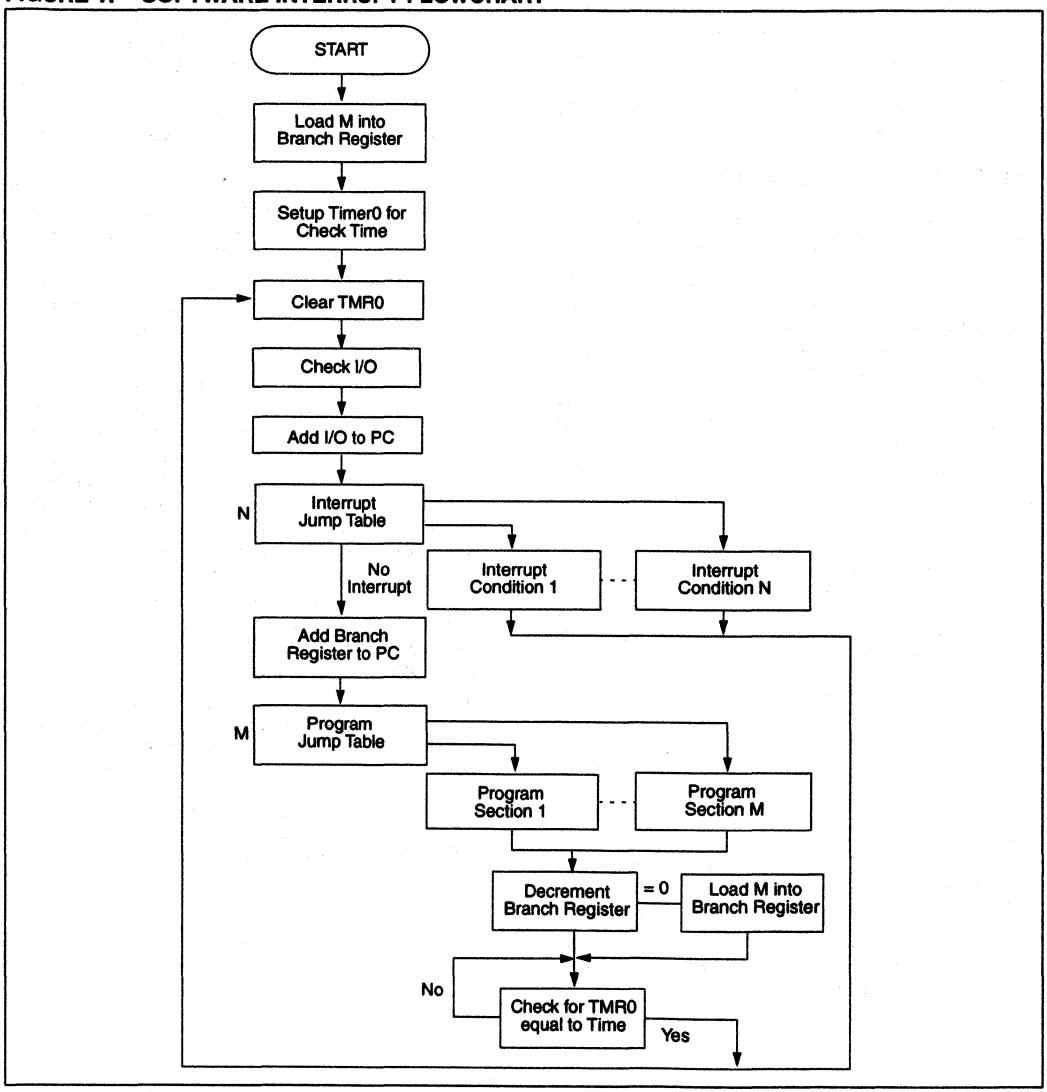
In most applications requiring interrupts, it is important to poll the interrupt lines at fixed time intervals, usually only a few microseconds in length. Two techniques may be used on the PIC16C5X to achieve this timing. One divides the main program into multiple sections and the other implements an elapsed time counter (Figure 1). Both of these techniques use the same program jump table concept that was described earlier. In the first technique, the main program is divided into several sections based on the desired I/O polling time. When MAIN is called a branch register is added to the program counter. This determines which section of MAIN code should be executed next. At the end of execution the branch register is decremented so the next section of code will be executed after the next polling. If the branch register is zero, then the number of sections of main code is added into it to start the main program over again.

In the second technique, an elapsed time counter can be implemented using the Timer0 counter. At the beginning of I/O polling the TMR0 register is cleared. It then starts counting the instruction cycles. Then after the main program subsection has been executed, the TMR0 register value is subtracted from the desired polling time. This determines how many instructions need to be executed before the next polling. A jump table is then created to execute these instructions before the next polling. An example is shown below. This example assumes from zero to 15 additional instruction cycles are needed. Actual numbers need to be computed for each individual application.

```
MOVLW   POLL   ;POLL=DESIRED POLL CYCLES-15
SUBWF   TMR0,W;DETERMINE HOW MUCH TIME TO WAIT
ADDWF   2,1    ;ADD WAIT TIME TO PROGRAM COUNTER
NOP            ;15 ADDITIONAL INSTRUCTION CYCLES
:
:              ;TOTAL OF 15 NOP'S
NOP            ;1 ADDITIONAL INSTRUCTION CYCLE
GOTO    START  ;0 ADDITIONAL INSTRUCTION CYCLES
```

© 1997 Microchip Technology Inc.

For example, if the desired instruction time is 50 cycles and the subsection we just executed has a consumed a total of 40 instruction cycles (including all overhead cycles) the value of:



$$TMR0(40) - POLL(50 - 15(= 35)) = 5$$

will be added to the program counter. The program will then jump to the sixth NOP. That NOP, plus the nine following it, will be executed for a total of ten more instruction cycles. Note that the final GOTO has two instruction cycles and these must be included in the program overhead.

Example

The following example (Figure 1 and Appendix A) is the core program for the software interrupt technique described previously. This program assumes four interrupt conditions, four main program sections, and eight additional elapsed time instructions.

Implementing a Simple Serial Mouse Controller

INTRODUCTION

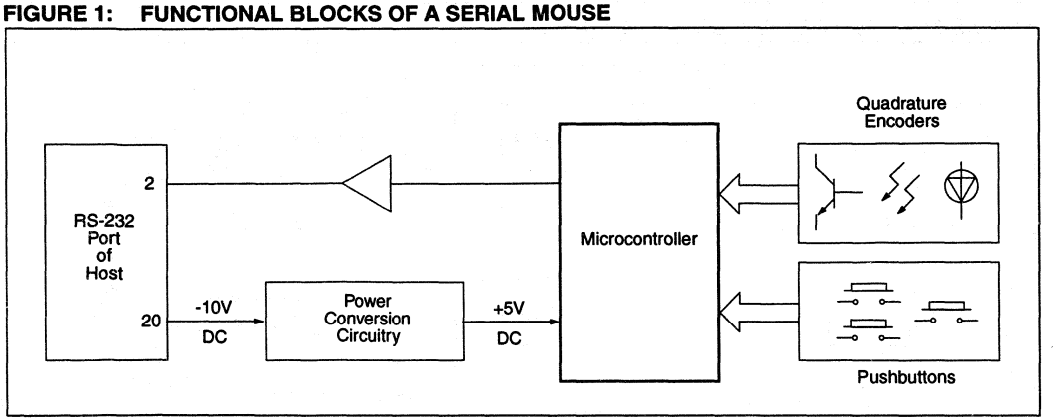
The mouse is becoming increasingly popular as a standard pointing data entry device. There is no doubt that the demand for the mouse is increasing. Various kinds of mice can be found in the market, including optical mice, opto-mechanical mice, and their close relative, trackballs. The mouse interfaces to the host via a dedicated interface card or an RS-232 port. Their mechanisms are very similar. The major electrical components of a mouse are:

- Microcontroller
- Photo-transistors
- Infrared emitting diode
- Voltage conversion circuit

The intelligence of the mouse is provided by the microcontroller, therefore the features and performance of a mouse is greatly related to the microcontroller used.

This application note describes the implementation of a serial mouse using the PIC16C54. The PIC16C54 is a high speed 8-bit CMOS microcontroller offered by Microchip Technology Inc. It is an ideal candidate for a mouse controller.

THEORY OF OPERATION



A mouse can be divided into several functional blocks:

- Microcontroller
- Button detection
- Motion detection
- RS-232 signal generation
- 5V DC power supply unit

A typical functional block diagram is shown in Figure 1.

In Figure 2, three pushbuttons are connected to the input ports of the PIC16C54. When a switch opening or closure is detected, a message is formatted and sent to the host. The X and Y movements are measured by counting the pulses generated by the photo-couplers. In the case of an opto-mechanical mouse, the infrared light emitted by the infrared diode is blocked by the rotating wheel, so that the pulses are generated on the photo-transistor side. In case of an optical mouse, the infrared light emitted by the infrared diode is reflected off the reflective pad patterned with vertical and horizontal grid lines. It is then received by the photo-transistor in the mouse. When any X or Y movement is detected, a message is formatted and sent to the host.

The Microsoft® Mouse System and the Mouse Systems® device both use serial input techniques. The Mouse System protocol format contains five bytes of data. One byte describes the status of three push buttons, two bytes for the relative X movements and two bytes for the relative Y movements. The Microsoft protocol format contains three bytes of data describing the status of two push buttons and the relative X and Y movements. The details of these protocols are given in Table 1.

Three lines are connected to the host via the RS-232 port:

- Signal Ground
- Received Data
- Request to Send

"Received Data" carries the message sent by the mouse. While "Request to Send" provides a –10 VDC for voltage conversion circuitry. A voltage of +5 VDC is required for electronic components inside the mouse, however, +5 VDC is not part of an RS-232 port, so voltage conversion circuitry is required. This circuit is typically composed of a 555 timer, Zener diodes, and capacitors.

An example circuit is shown in Figure 3. Since the current supplied through the RS-232 port is limited to 10 mA, the mouse cannot be designed to consume more than 10 mA current unless an external power supply is provided. The PIC16C54, running at 4 MHz (1 µs instruction cycle) can provide a very high tracking speed. An 8 MHz version of PIC16C54 is also available if higher performance is desired.

ABOUT THE SOFTWARE

The major tasks performed by the software are button scanning, X and Y motion scanning, formatting and sending serial data to the host. These tasks need to be performed in parallel in order to gain better tracking speed. The pulses generated by the photo-couplers are counted while transmitting the serial signals to the RS-232 port. The number of pulses reflects the speed of the movement. The more pulses, the faster the movement.

The directions of movement are determined by the last states and the present states of the outputs of the photo-transistors. In Figure 4, XCLOCK and XDATA are outputs from the photo-transistors corresponding to the X-axis movement. XDATA is read when a rising or a falling edge of XCLOCK is detected. For right movement, XDATA is either LOW at the rising edge of XCLOCK or HIGH at the falling edge of XCLOCK. The up and down movement detections follow the same logic. In Table 1, X7:X0 are data for relative movement. If X is positive, it implies that the mouse is moving to the right. If X is negative, it implies a movement to the left. Similarly, if Y is positive, it indicates that the mouse is moving down and if Y is negative, it indicates that the mouse is moving up. The pulses generated by the photo-couplers are checked before every bit is sent. A bit takes 1/1200 second to send, if the distance between the grid lines is 1 mm, the tracking speed will be up to 1200 mm/second.

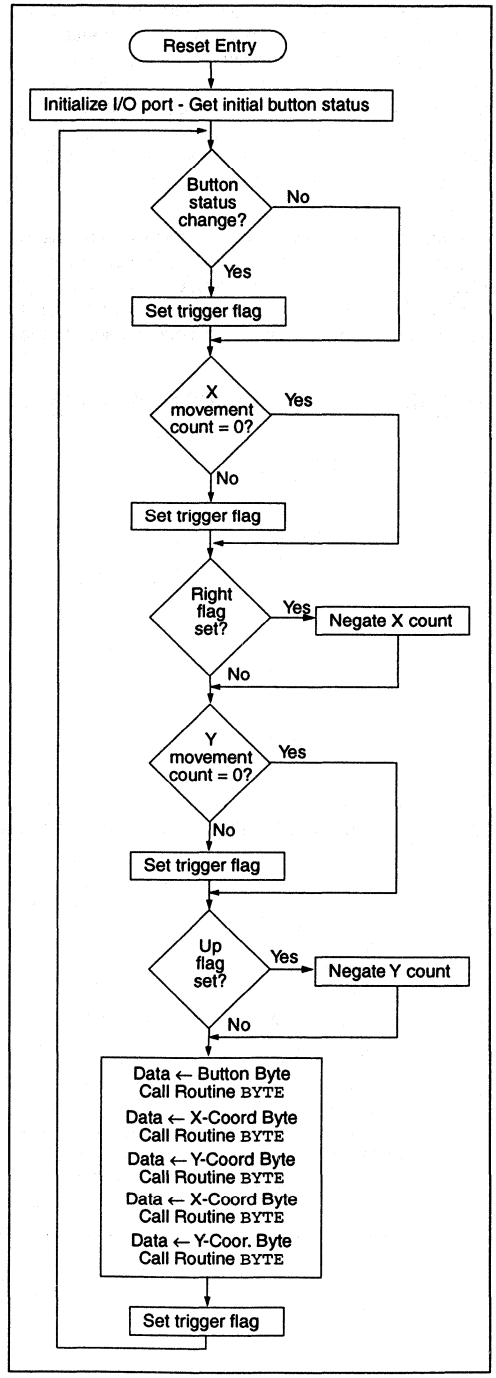
The buttons are scanned after a message is sent and the time used to send the message is used as the debouncing time. The message is in an RS-232 format with 1200 baud, eight data bits, no parity, and two stop bits.

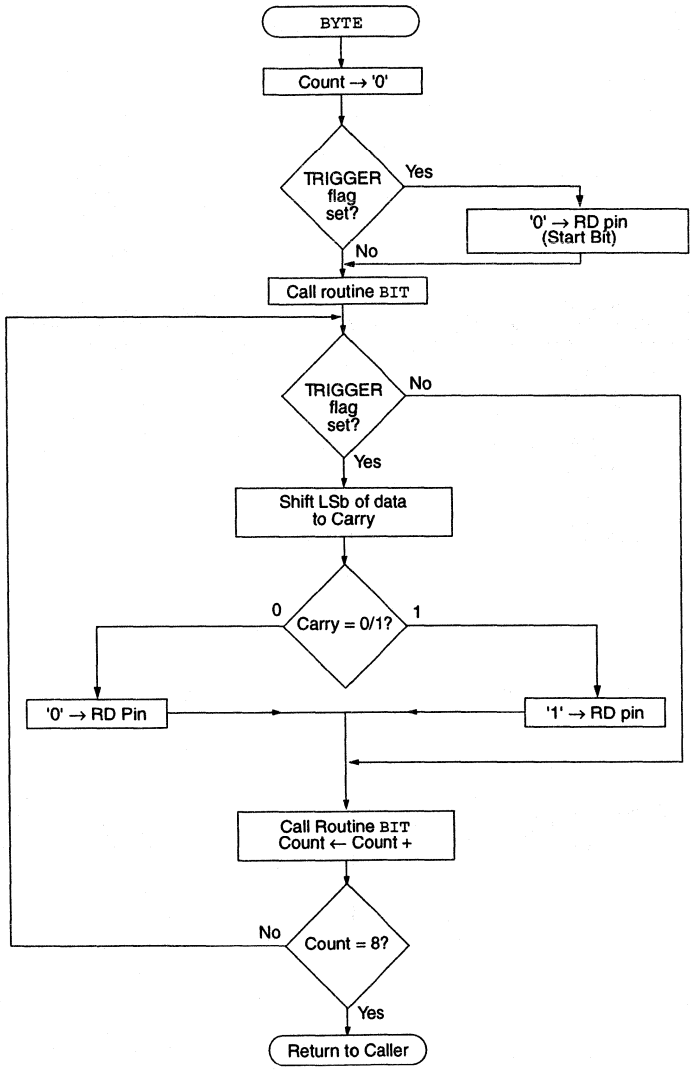
The flowcharts of the main program, subroutine BYTE and subroutine BIT are shown in Figure 5, Figure 6, and Figure 7. Figure 5 shows that the trigger flag is set when any change in button status or X/Y movement is detected. Subroutine BYTE is called in the main program five times to send five bytes of information. Subroutine BYTE controls the status of the "Received Data" (RD) pin. If Trigger Flag is clear, RD will always be HIGH. Hence, no message will be sent even when subroutine BYTE is called. Figure 7 shows that subroutine BIT counts the number of pulses from the outputs of the photo-transistors, determines the directions, and generates a 1/1200 second delay to get 1200 baud timing.



The mouse has been tested in Mouse System Mode and functions properly. The setup and software have been tested and function within the given guidlines. A listing of the source program is given in Appendix A.

SUMMARY

The PIC16C54 from Microchip Technology Inc. provides a very cost-effective, high performance mouse implementation. Its low power consumption (typically< 2 mA at 1 µs instruction cycle), small package (18-pin) and high reliability (on-chip watchdog timer to prevent software hang-ups) are some of the many reasons why the PIC16C54 is uniquely suitable for mouse applications.



Note: This application note provides the user with a simple, fully functional serial mouse implementation. The user may use this as a starting point for a more comprehensive design.

A Comparison of 8-Bit Microcontrollers

Author: *Mark Palmer*
Microchip Technology Inc.

INTRODUCTION

The PIC16C5X/XX microcontrollers from Microchip Technology Inc., provide significant execution speed and code-compaction improvement over any other 8-bit microcontroller in its price range.

The superior performance of the PIC16C5X/XX microcontrollers can be attributed primarily to its RISC architecture. The PIC16C5X/XX devices employ a Harvard architecture (i.e., has separate program memory space and data memory space [8-bit wide data]). It also uses a two stage pipelining instruction fetch and execution. All instructions are executed in a single cycle (200 ns @ 20 MHz clock) except for program branches which take two cycles, and there are only 33 instructions to remember.

Separation of program and data space allows the instruction word to be optimized to any size (12-bit wide for PIC16C5X devices and 14-bit wide for PIC16CXX devices). This makes it possible, for example, to load an 8-bit immediate value in one cycle. First, because there is no conflict between instruction fetch and data fetch (as opposed to von Neumann architecture) and secondly because the instruction word is wide enough to hold the 8-bit data.

In the following sections we will compare the PIC16C5X/XX devices @ 20 MHz with:

- SGS-Thomson ST62 @ 8 MHz
- Motorola MC68HC05 @ 4.2 MHz
- Intel 8051 @ 20 MHz
- Zilog Z86CXX @ 12 MHz
- National COP800 @ 20 MHz

Several coding examples will be considered. While the comparisons are not entirely scientific, they will demonstrate to the reader the relative superior performance of the PIC16C5X/XX devices. The examples chosen are used frequently in microcontroller applications.

PACKING BINARY CODED DECIMAL (BCD)

This example will take two bytes in RAM or registers, each containing a BCD digit in the lower nibble and create a packed BCD data byte, which is stored back in the register or RAM location holding the low BCD digit.

PIC16C5X/XX

		Byte/Words	Cycles
SWAPF	REGHI,W	1	1
IORWF	REGLO	1	1
		2	2

0.4 µs

COP800

		Byte/Words	Cycles
X	A,[B+]	1	2
SWAP	A	1	1
OR	A,[B]	1	1
X	A,[B]	1	1
		4	5

B is pointing to the higher BCD digit initially. After auto-increment, it points to the lower BCD digit.

5 µs

ST62

		Byte/Words	Cycles
LD	A,REGHI	2	4
RLC	A	1	4
RLC	A	1	4
RLC	A	1	4
RLC	A	1	4
ADD	A,REGLO	2	4
LD	REGLO,A	2	4
		10	28

REGHI and REGLO are registers addressable by short direct addressing mode.

45.5 µs

MC68HC05

		Byte/Words	Cycles
LDA	REGHI	2	3
ROLA		1	3
ROLA		1	3

		10	22

10.5 µs

Z86CXX

		Byte/Words	Cycles
SWAP	REGHI	2	8
OR	REGHI,REGLO	2	6
		4	14

REGHI and REGLO are addressable via the working register addressing mode.

5.33 µs

8051

		Byte/Words	Cycles
MOV	A,Rx	1	1
SWAP	A	1	1
ORL	A,Ry	1	1
MOV	Ry,A	1	1
		4	4

Register Rx contains higher BCD digit, Ry holds lower BCD digit.

LOOP CONTROL

This example is one of simple loop control where a register containing a loop count is decremented, tested for zero, and if not zero, then branched back to the beginning of the loop.

PIC16C5X/XX

		Byte/Words	Cycles

SHIFTING OUT 8-BIT DATA & CLOCK

We will now consider the task of serially shifting out an 8-bit data and clock. Data and clock outputs are generated under program control by toggling two output pins.

Data is transmitted on the rising edge of the clock. No attempt is made to make the clock output symmetrical in order to make the code efficient. Data out is guaranteed on the falling edge of the clock. These conditions are satisfactory for most applications.

SOFTWARE TIMER

Microcontrollers quite often need to implement time delays. Debouncing key input, pulse width modulation, and phase angle control are just a few examples. Implementing a 10 ms time delay loop subroutine will be considered in this section.

SUMMARY

Table 1 summarizes code sizes for different microcontrollers. The overall relative code size number is an average of the individual relative code sizes. Given that the program word size of the PIC16C5X/XX is 12- or 14-bit (compared to an 8-bit program memory of all the other microcontrollers), a compaction of 1.5 is expected. Clearly, the PIC16C5X/XX meets this compaction (except for the COP800) and exceeds the compaction ratio in most comparisons.

Table 2 summarizes relative execution speed. The overall speed is an average of relative speed numbers. For example, the COP800 will, on average, exhibit 27% of the code execution speed of a PIC16C5X/XX devices. In other words, a PIC16C5X/XX will be (1/0.27) 3.7 times faster than a COP800 on average.

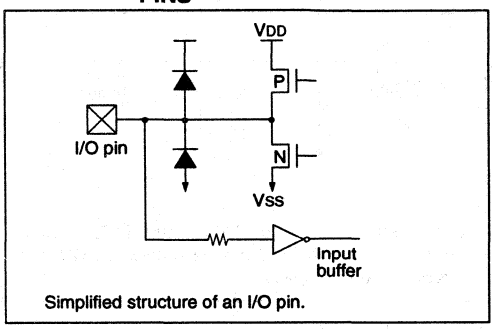
Interfacing to AC Power Lines

Author: *Doug Cox*
Microchip Technology Inc.

INTRODUCTION

This application note describes a simple method for measuring parameters from the AC power line. Parameters such as zero crossing, frequency, and relative phase can be measured. This method is useful for measurements on 50, 60, and 400 Hz power systems with voltages up to several hundred volts. The method requires only one external component, a resistor, and is more reliable than previously published methods using capacitors or bulky, expensive transformers.



APPLICATIONS

This measurement method can be used in any application where power line parameters are used for system measurements or control. Typical applications are; switch timing (what part of the power cycle should the system be activated), power factor correction, power measurement, and power line monitor. An additional application is to generate timing or clock functions using the relatively stable power line frequency. This method is also useful for calibrating oscillator frequency for accurate timing measurements when an inaccurate reference such as an RC oscillator is used to clock the PIC16C5X.

THEORY OF OPERATION

This application takes advantage of the input static protection circuitry that exists on all I/O pins of a CMOS PIC16C5X. These protection circuits are designed to short the inputs to the power supplies when a large overvoltage is applied, thus protecting the chip from static electricity spikes. On PIC16C5X microcontrollers, this protection circuit is two large P-N diodes on each input (Figure 1). These diodes will short any voltage higher than VDD to the VDD supply and any voltage less than VSS to the VSS supply. They can take several milliamps of current without any damage to the chip. High voltages can be applied directly to the chip inputs as long as they are current limited.

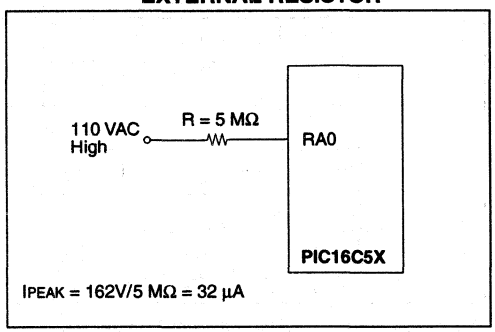


FIGURE 1: PIC16C5X SERIES INPUT PROTECTION CIRCUIT ON I/O PINS

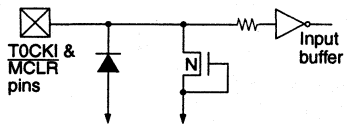
Simplified structure of an I/O pin.

The least expensive method to limit current is to use a high value resistor. A block diagram is shown in Figure 2. The power line voltage is current limited by the resistor and then clamped by the input protection diodes internal to the PIC16C5X. A typical input waveform is shown in Figure 5. A 115 VAC, 60 cycle sine wave will traverse from 0 to 2V in 32 µs, therefore a typical threshold of 2V on a PIC16C5X I/O port will permit zero crossing detection accuracy of about 30 µs. If the typical capacitance on an I/O pin is 5 pF, then R should be (t = RC) 6 MΩ or less for best zero crossing accuracy. A 5 MΩ resistor with 115 VAC applied to it will limit current to 32 µA, a value which is well within the safety margin of the PIC16C5X.

FIGURE 2: LIMITING CURRENT USING AN EXTERNAL RESISTOR



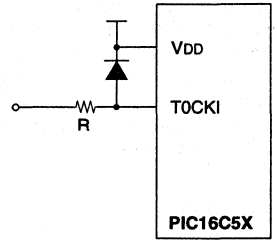
IPEAK = 162V/5 MΩ = 32 µA

© 1997 Microchip Technology Inc.

The user needs to be aware that the circuit required to connect the T0CKI input to an AC power line is slightly different than the other I/O pins. Each of the I/O pins has two diodes for input protection whereas the T0CKI pin has only one protection diode connected to Vss (Figure 3). Therefore, it is necessary to connect a diode externally between the T0CKI pin and VDD in order to clamp the voltage on the T0CKI pin to VDD + 0.6V (approximately). See Figure 4. It is also recommended that resistor R be at least 2 MΩ.

FIGURE 3: INPUT STRUCTURE OF $\overline{MCLR}$ AND T0CKI PINS

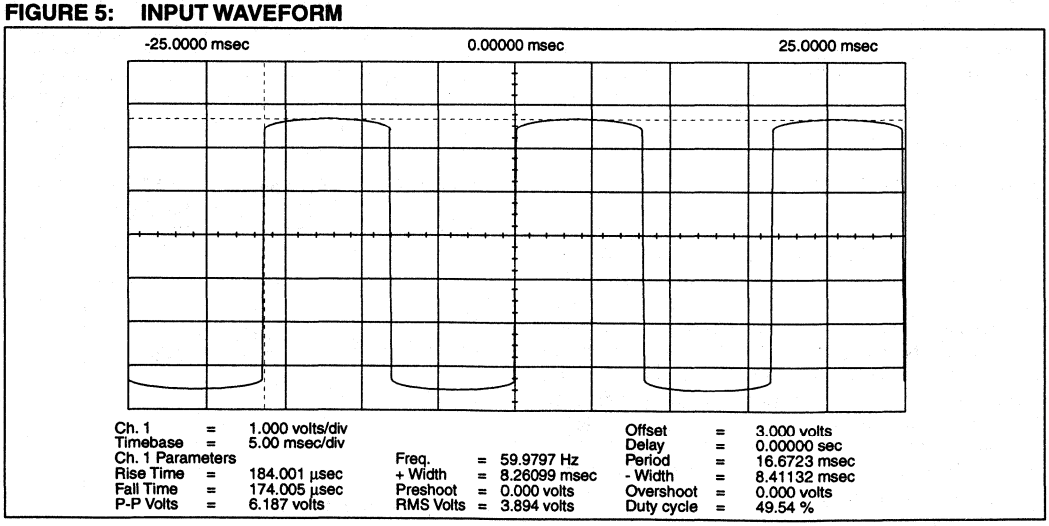
Simplified structure of T0CKI and $\overline{MCLR}$ pins. Grounded gate NMOS device provides ESD and overvoltage protection.



RELIABILITY

Reliability of production devices that are directly connected to AC power is always a concern. Two failure modes are possible. First, the series resistor of Figure 1 might fail short, destroying the microcontroller.

A short is the most unlikely failure mode for a resistor, and resistors are more reliable than transformers or capacitors, which are the alternate components for measuring line parameters. This reliability can be enhanced even further by using two resistors in series. Both would have to fail short to cause catastrophic failure, a very unlikely event.



The second possible failure mode is that excessive injection of current into the PIC16C5X might cause the protection diode to open. This would allow the input to go to power line peak voltage (162V) and short the input transistor gate oxide, causing device failure. The maximum continuous injection current into an I/O pin is specified at ± 500 µA.

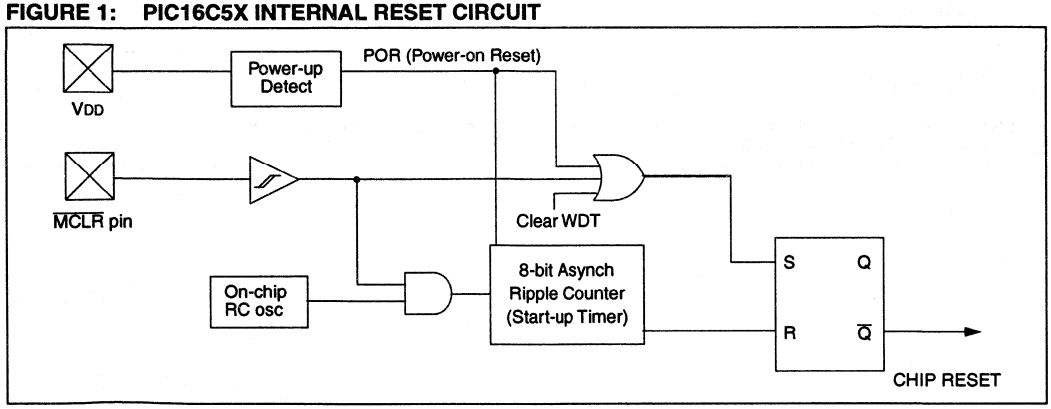
Power-up Considerations

Author: Sumit Mitra
Microchip Technology Inc.

INTRODUCTION

When powering up any microcontroller it is necessary for the power supply voltage to traverse voltage ranges, where the device is not guaranteed to operate, before the power supply voltage reaches its final state. Since some circuits on the device (logic) will start operating at voltage levels lower than other circuits on the chip (memory), the device may power-up in an unknown state. To guarantee that the device starts up in a known state, it must contain a power-up reset circuit. PIC16C5X microcontrollers are equipped with on-chip Power-on Reset circuitry, which eliminates the need for external reset logic. This circuit will function in most power-up situations where VDD rise time is fast enough (50 ms or less). This application note describes the typical power-up sequence for PIC16C5X microcontrollers. Methods of assuring reset on power-up and after a brown-out are discussed and simple, low-cost external solutions are discussed for power-up situations where the PIC16C5X's internal circuitry cannot provide the reset.



POWER-UP SEQUENCE

The PIC16C5X incorporates complex Power-on Reset (POR) circuitry on-chip which provides a solid, reliable internal chip reset for most power-up situations. To use this feature, the user merely needs to tie the $\overline{MCLR}$ pin to the VDD pin. A simplified block diagram of the on-chip reset circuitry is shown in Figure 1. On power-up, the reset latch and the start-up timer are reset to appropriate states by the Power-on Reset (POR). The start-up timer will begin counting once it detects $\overline{MCLR}$ to be high (i.e., external chip reset goes inactive). After the time-out period, which is typically 18 ms long, the timer will reset the reset latch and thus end the on-chip reset signal.

Figure 3 and Figure 4 are two power-up situations with relative fast rise time on VDD. In Figure 2, VDD is stable when $\overline{MCLR}$ is brought high (i.e., reset pulse is being provided by external source). The chip actually comes out of reset about TOST ms after that, where TOST = Time of the Oscillator Start-up Timer. (The timer is called Oscillator Start-up Timer because the time-out was incorporated primarily to allow the crystal oscillator to stabilize on power-up). In Figure 3, the $\overline{MCLR}$ and VDD are tied together and clearly the on-chip reset mechanism is being used. VDD is stable before the start-up timer expires and there is no problem with proper reset.

In Figure 4, where the VDD rise time is much greater than TOST (typically 18 ms) this is clearly a potentially problematic situation. The POR pulse comes when VDD is about 1.5V. Most CMOS logic, including the start-up timer, starts functioning between 1.5V to 2.0V. When the start-up timer times out, the chip reset is ended and the chip attempts to execute. If by this time VDD has reached the VDD min. value, then all circuits are guaranteed to function correctly and power-up reset is successful. If, however, the VDD slope was too slow and had not reached VDD min., then the chip is not guaranteed to function properly.

FIGURE 2: EXTERNAL RESET PULSE

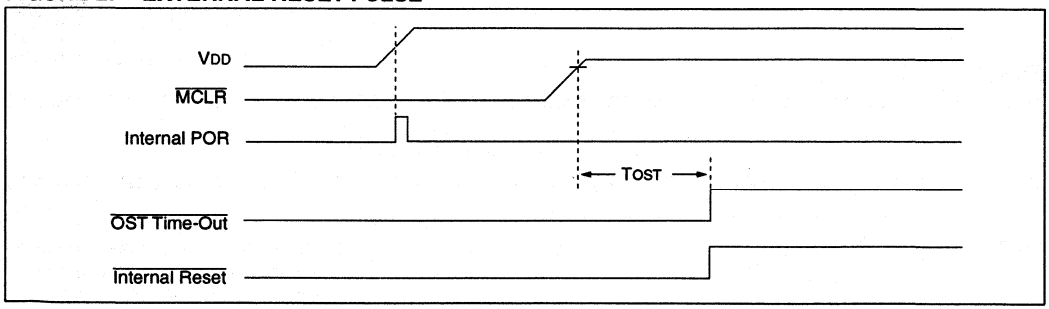

FIGURE 3: INTERNAL RESET (VDD AND MCLR TIED TOGETHER)

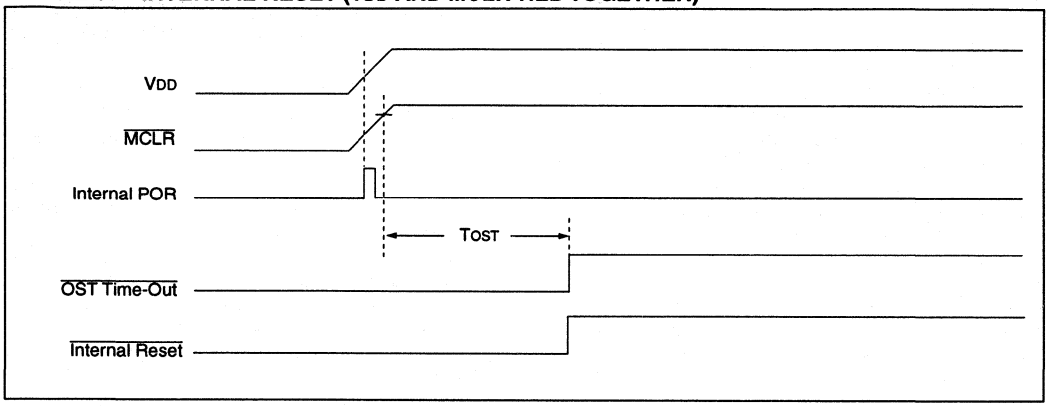

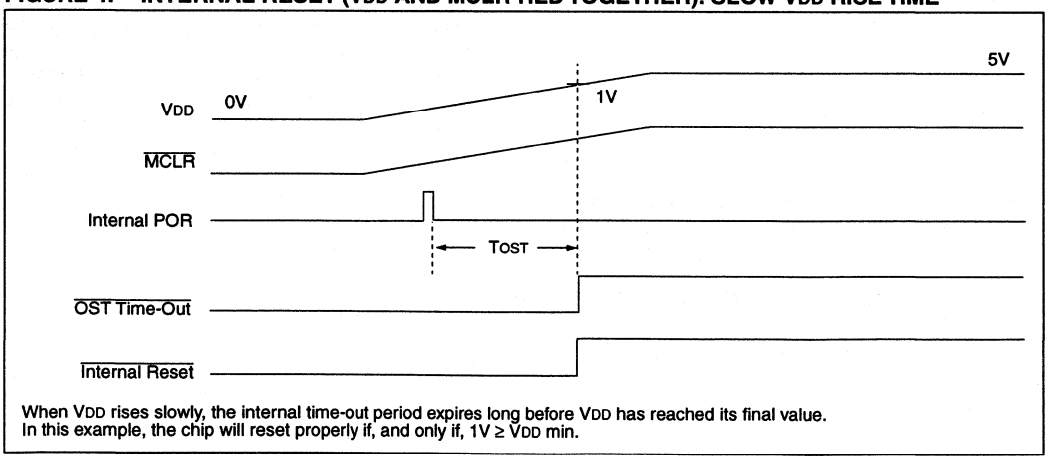

FIGURE 4: INTERNAL RESET (VDD AND MCLR TIED TOGETHER): SLOW VDD RISE TIME

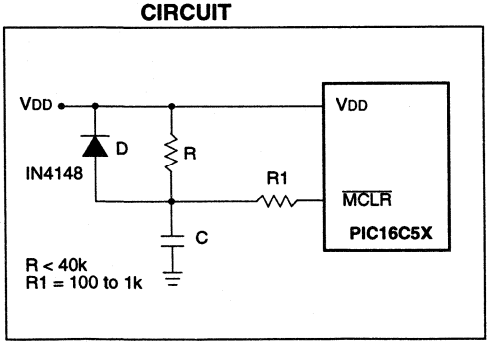

When VDD rises slowly, the internal time-out period expires long before VDD has reached its final value.
In this example, the chip will reset properly if, and only if, 1V ≥ VDD min.

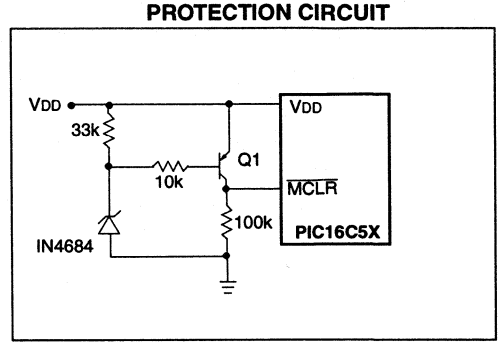
EXTERNAL POWER-ON RESET CIRCUIT

To use power supplies with slow rise times it is necessary to use an external power-on reset circuit such as the one shown in Figure 5. This circuit uses an external RC to generate the reset pulse. The time constant of the RC should be long enough to guarantee that the reset pulse is still present until VDD has reached VDD min. R should be 40k or less to guarantee that $\overline{MCLR}$ will pull to within 0.2 volts of VDD (since the leakage spec on $\overline{MCLR}$ is ±5 µA, a resistor larger than 40k may cause input high voltage on this pin to be less than VDD – 0.2V, the required spec). The diode *(D)* is used to rapidly discharge the capacitor on power-down. This is very important as a power-up reset pulse is needed after a short power-down (less than the time constant of RC) or after a power spike. The resistor *(R1)* protects against a high current flowing into the *$\overline{MCLR}$* pin from fully charged capacitor *(C)*, in the event the $\overline{MCLR}$ pin breakdown is induced via ESD (electrostatic discharge) or EOS (electrical overstress). The circuit, however, does not protect against brown-out situations where power does not drop to zero, but merely dips below VDD min. In such a situation, voltage at the $\overline{MCLR}$ pin will not go low enough (i.e., below VIL) to guarantee a reset pulse. The following section presents an example circuit to protect against such brown-outs.

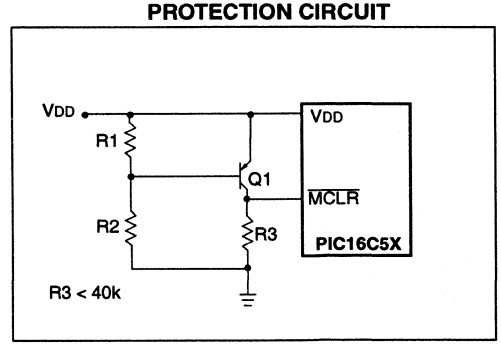
FIGURE 5: EXTERNAL POWER-ON RESET CIRCUIT



BROWN-OUT PROTECTION

In many applications it is necessary to guarantee a reset pulse whenever VDD is less than VDD min. This can be accomplished using a brown-out protection circuit such as the one shown in Figure 6. This is a simple circuit that causes a reset pulse whenever VDD drops below the zener diode voltage plus the VBE

$$V_{BE} = V_{DD} \bullet R1 / (R1 + R2)$$



of *Q1*. A 3.3V zener will produce a reset pulse whenever VDD drops below about 4V. This circuit has a typical accuracy of about ±100 mV.

FIGURE 6: EXTERNAL BROWN-OUT PROTECTION CIRCUIT

A less expensive, albeit less precise, brownout circuit is shown in Figure 7. Transistor *Q1* turns off when VBE falls below 0.7V allowing *R3* to pull down the $\overline{MCLR}$ input.

Software Stack Management

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

The PIC16C5X has a stack which is only 2 deep, and, as a result, only two nested calls can be made (i.e., only one call within a call routine). If more than two levels of subroutine nesting is required, this application note can be used to implement a stack manager to handle the flow of the calls.

Note: Since the amount of RAM on the PIC16C5X is limited, it would be prudent to determine the maximum number of nested calls which have to be made in a program and define the stack length appropriately.

IMPLEMENTATION

This application note implements a 5-deep stack, so 5 nested calls can be made without overflowing the stack. `NCALL` is defined as a MACRO which will be used instead of the mnemonic `CALL`, when a subroutine call is made. The `NCALL` routine, "pushes" the return PC value on the "stack" and then executes the called subroutine. At the end of the subroutine, instead of using the `RETLW k` instruction, a `GOTO RETURN` is executed, where `RETURN` is a routine which "pops" the return PC value from the "stack" and resumes the normal flow of the program.

Note: Since Software Stack Management utilizes the FSR register, and indirect addressing, the user should restore the "original" values to the FSR register if it is used elsewhere in the program.

The routines, as described in this application note, will work only if the called routine is within the first 256 words for each program. If the user desires to branch over to the other low 256-byte program pages, as in the PIC16C57, then the status byte should be saved along with the PC.

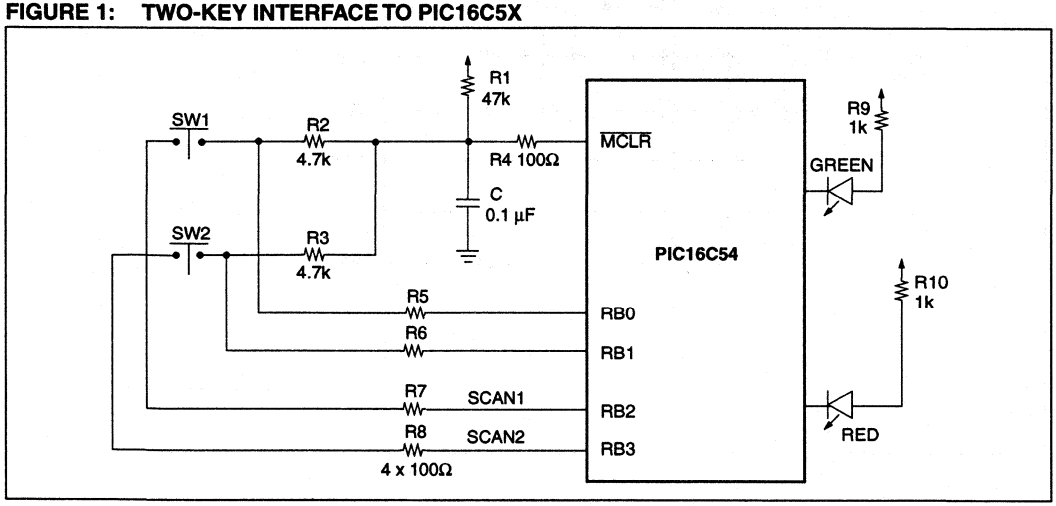
Implementing Wake-up on Key Stroke

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

In certain applications, the PIC16CXXX is exercised only when a key is pressed, (e.g., remote keyless entry). In such applications, the battery life can be extended by putting the PIC16CXXX to sleep during inactive states and when a key is pressed, the PIC16CXXX wakes up, performs the task, and then goes back to sleep.

IMPLEMENTATION



The circuit, shown Figure 1, depicts an application with two keys. The PIC16C54 is normally in SLEEP mode consuming very little operating current. If either of the two keys is pressed, the PIC16C5X "wakes up", scans the keys and turns on one or both of the LED's. When SW1 is pressed, the green LED is lit and when SW2 is pressed the red LED is lit. The LED's are used purely for demonstration purposes. In real life applications, a transmission would be completed before putting the PIC16C5X back to sleep. This example can be extended to handle more than two keys.

In sleep mode, the scan outputs (SCAN1 and SCAN2) are both set to a low logic level. In this state, the capacitor C is fully charged and a high logic level is present at the $\overline{MCLR}$ pin. When a key is pressed, C discharges through either R2 or R3 (depending on which switch is being pressed). The voltage across C falls rapidly (approx. 1 ms), causing a low level at the $\overline{MCLR}$ pin, which in turn causes the device to wake-up and enter its reset state. In reset, the SCAN1 and SCAN2 outputs default to a hi-impedance mode, which blocks the discharge path for capacitor C which it charges to a high level through resistor R1. Note that the RC values have been chosen such that the discharge and charge cycles times are less than the reset time for the device (approx. 18 ms), and certainly far less than the minimum duration of a key-press (approx. 50-100 ms).

After the reset cycle is completed, the code execution momentarily takes the SCAN1 and SCAN2 outputs low in order to sample the key stroke(s). This does not cause the capacitor to discharge since the duration of the low is of the order of 10 µs.

Once the keystroke function has been executed, the program loops until the key has been released, sets the SCAN1 and SCAN2 outputs low and "goes back to sleep". Resistors R4-R8 are not required for functionality, but are recommended to provide protection from electrostatic discharge (ESD). Switches SW1 and SW2, when pressed, may pass ESD to the PIC16C54.

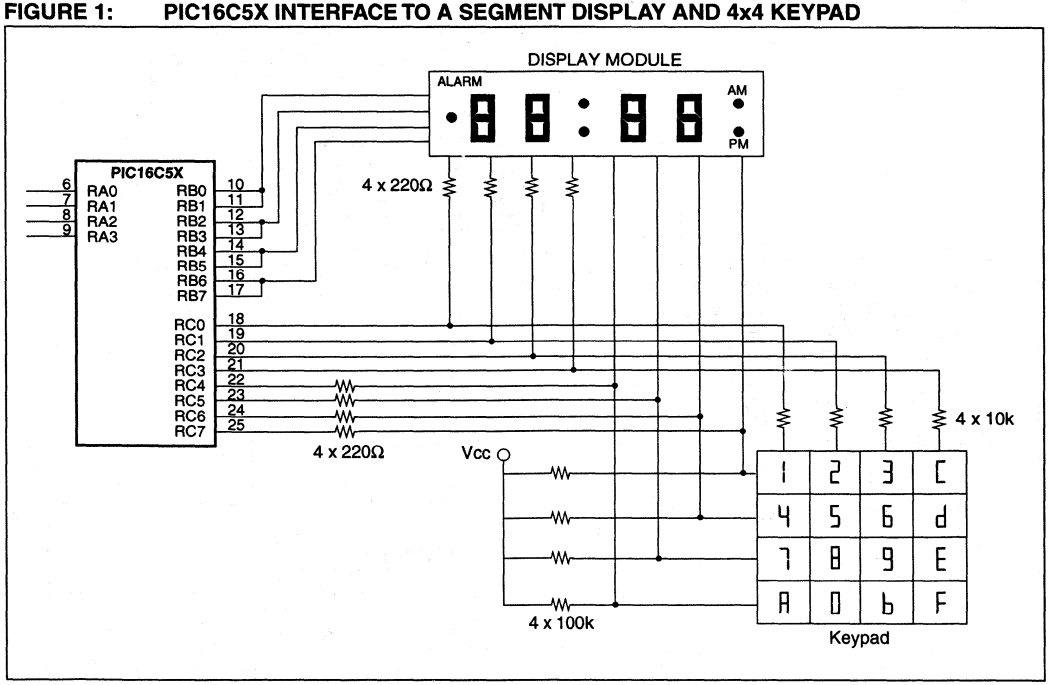
Multiplexing LED Drive and a 4x4 Keypad Sampling



Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

Many applications require driving LEDs along with an interface to a keypad. Implementing such designs usually involves using up significant amounts of the processors I/O lines. This application note describes a method which uses only 16 I/O pins of a PIC16C5X microcontroller to sample a 4x4 keypad matrix, and directly drive four 7-segment LEDs (Figure 1). Direct drive of the LEDs is possible, because of the high sink and source capabilities of PIC16C5X microcontroller, thus eliminating the use of an external drive transistor, and results in a reduction in both cost and complexity of the overall circuit.

Typically applications having LEDs and keypads also keep track of real-time, in order to synchronize certain related events. An Industrial Clock/Timer example has been used in this application note as a demonstration of these functions. The software overhead to keep track of real time is minimal and the user can modify the code to significantly expand the functionality of this circuit.

PART A: 4x4 KEY MATRIX SAMPLING

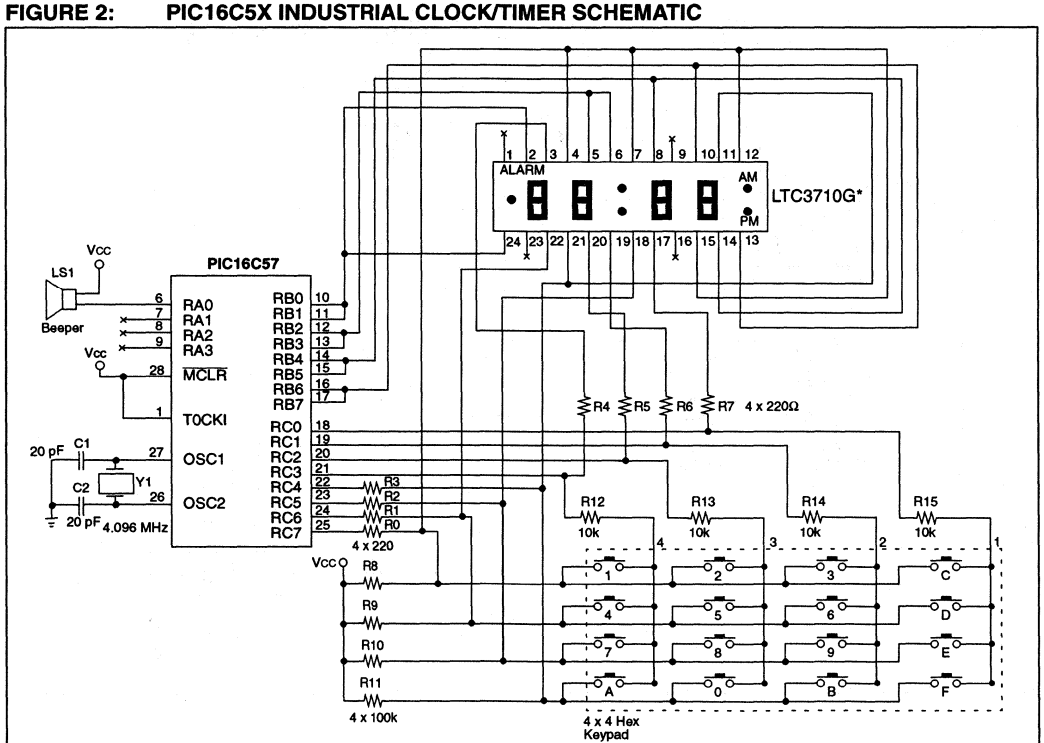
Implementation

The 4x4 Key Matrix is connected to PORTC of the PIC16C5X (Figure 2). The four columns are connected to RC0-RC3 and the four rows are connected to RC4-RC7. Each digit is refreshed every 20 ms. with a 5 ms pulse. The keypad is sampled every 20 ms with four 3 µs pulses (Figure 4).

The keypad sampling is as follows:

a) The columns are connected to output pins, and the rows are connected to input pins.

b) Each column is sequentially driven to a low voltage while at the same instance the four rows are sampled. Since the rows are all held high with pull-up resistors, all four inputs will normally be high. If a key is pressed in a column which is at a low level, that low level will be conducted to the input pin through the closed key and the corresponding row will be sensed as a low.



c) Before a new column is brought low, care should be taken to discharge the input pins (see code section for details).

d) A 50 ms key debounce technique has been implemented in the software, in order to eliminate multiple key strokes.

Note 1: Resistors R8-R11 and R12-R14 have been selected such that their ratio is 1:10. This will insure a 0.5V level at the input, when a key is pressed. Also R8-R14 should have a value such that their current contribution to the LEDs segments is negligible.

Note 2: In circuits where there is substantial interference between the key matrix and the LED drive circuit, the alternative circuit of Figure 3 should be utilized. Diodes in the path of all pins connected to the keypad insure that there is minimal interference from the keypad, when it is not being sampled.

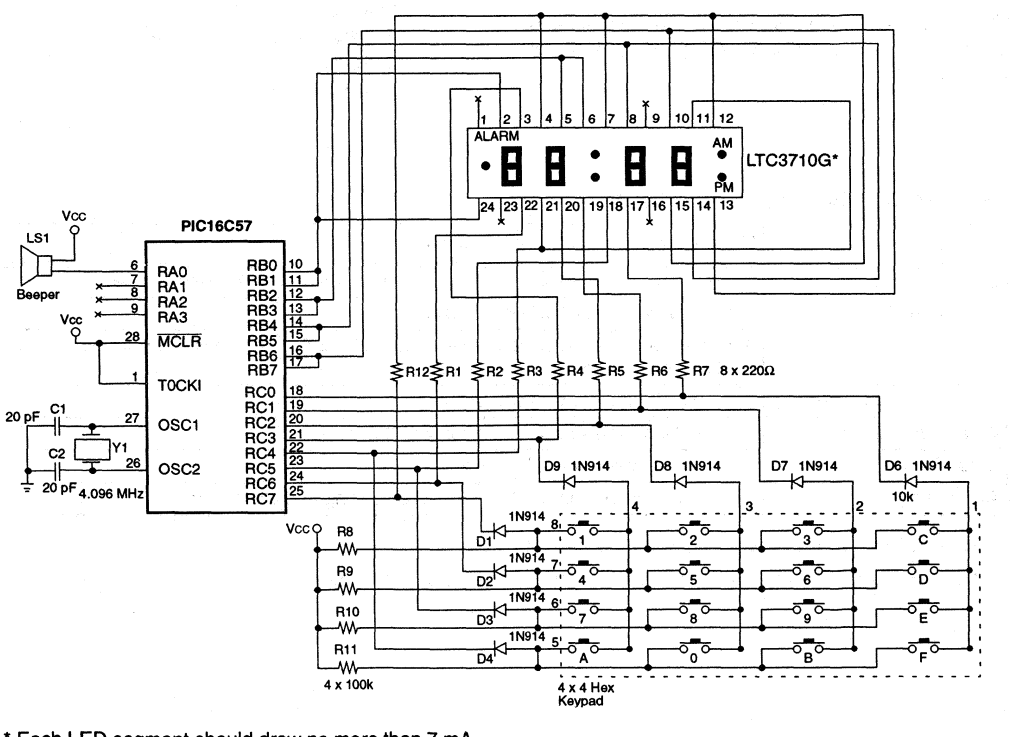
PART B: INDUSTRIAL CLOCK/TIMER

Clock Selection

The 4.096 MHz crystal oscillator is the time-base. The PIC16C5X internally divides the clock by 4 to give an internal clock of 1.024 MHz. This clock is further divided by 32 (by the prescaler in the OPTION register) to give a clock of 32 kHz which is used to increment the TMR0 in the PIC16C5X. If the TMR0 is initialized to 96, it would overflow to zero in 5 ms.

$$(256\text{-}96) \times (1/32000) = 5.000 \text{ ms}$$



This 5 ms is used to count the seconds, minutes and hours in the clock/timer. It is also used as a time-base to update the display digits and sample the keyboard. The clock speed being 4.096 MHz, each instruction will execute in 1 µs. Therefore in 5 ms, approximately 5000 instructions can be executed. This gives sufficient time to execute a large section of code and not miss the overflow in TMR0.

Using a 3.579545 MHz color burst crystal oscillator as a time-base

Some users may want to use a color burst crystal oscillator as a time-base, because of its low cost. If a 3.579545 MHz crystal is used, then the internal clock will be 1.117 µs. If this is prescaled by 32, TMR0 will be incremented every 35.758 µs. Initializing the TMR0 with 116 will cause it to overflow to 0 in 5.006 ms. giving an error of 0.12%. This error can be corrected in software by making time adjustments every minute and/or every hour.

FEATURES

The Flowchart (Figure 5) shows the sequence of events in the clock/timer software. The clock has the following features:

- 12 hour clock with a.m./p.m.
- 12 hour alarm with a.m./p.m.
- Full function Hex keypad (Figure 5).
- AA audible alarm for 1 minute.
- 10 minute alarm disable.

SETTING CLOCK/TIMER FUNCTIONS

Function	Key Sequence to Activate Function
Set Real Time	Set → Hours (tens) →Hours → Minutes (tens) → Minutes → AM/PM → Set
View Alarm Time	Alarm (alarm time is displayed for 5 seconds)
Set Alarm Time	Alarm → Set (must be pressed when alarm LED is flashing) → Hours (tens) → Hours → Minutes (tens) → Minutes → AM/PM → Set
Enable/Disable Alarm	Alarm → Alarm (toggles alarm status)
Disable AA Alarm	Disable Alarm (disable audible beep for 10 minutes)
Clear Alarm	Clear Alarm (clears audible alarm)
Abort Entry	Clear Entry (aborts data entry mode when setting real alarm time)

Note 1: Valid key strokes will be acknowledged with a beep.

Note 2: Hours and minutes used above correspond to digits 0 - 9 on the keyboard.

SUMMARY

This Application Note demonstrates a simple method of interfacing a PIC16C5X device to both 7-segment LEDs and a keypad. The key features of the PIC16C5X which made this possible are:

- High sink/source of the I/O ports.
- Fast instruction cycle for quick key-scan.
- RISC processor allowing minimal overhead for real-time clock maintenance.
- Reconfigurable I/O ports, enabling dual functionality of ports.

Figure 7 depicts a block diagram connecting a PIC16C54/56 to a 4-digit, 7-segment LED display and a 4x4 hex keypad. Since only 12 I/O pins are available in the PIC16C54/56, an external npn transistor will have to be utilized to sink the current from each digit.

Intelligent Remote Positioner (Motor Control)

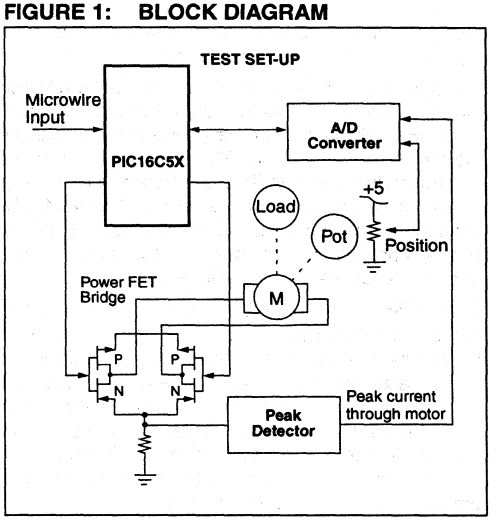
Author: *Steven Frank*
Vesta Technology Inc.

INTRODUCTION

The excellent cost/performance ratio of the PIC16C5X makes it well suited as a low-cost proportional D.C. actuator controller. This application note depicts a design for a remote intelligent positioning system using a D.C. motor (up to 1/3 hp) run from 12V to 24V. The position accuracy is one in eight bits or 0.4%. The PIC16C5X receives its command and control information via a Microwire® serial bus. However, any serial communication method is applicable.

IMPLEMENTATION

The PIC16C5X based controller receives movement commands from a host, compares them to the actual position, calculates the desired motor drive level and then pulses a full H-bridge (Figure 2). In this way it serves as a remote intelligent positioner, driving the load until it has reached the commanded position. It can be used to control any proportional D.C. actuator (i.e., D.C. motor or proportional valve).



This system is ideally suited for remotely positioned valves and machinery. It can be used with D.C. motors to easily automate manual equipment. Because of the 5-wire serial interface, the positioner can be installed near its power supply and load. The remote intelligent positioner can then be linked to the central control processor by a small diameter easily routed cable. Since the positioner is running its own closed-loop PID algorithm (Figure 3), the host central processor needs only to send position commands and is therefore free to service the user interface, main application software and command multiple remote positioners.

The limit switch inputs provide a safety net which keeps the system from destroying itself in the event that the feedback device is damaged. The optional current sense input can be used to determine if the load has jammed and prevent overheating of the actuator and drive electronics.

The commanded positions are presented to the PIC16C5X via a microwire type protocol at bit-rates of up to 50 Kbs for a 4 MHz part. As currently implemented in this application note, the position request is the only communication. There are several variable locations available which could be used to down-load the loop gain parameters, read positioner information, or set a current limit. The host that is sending the position request must set the chip select low, and wait for the PIC16C5X to raise the "busy" (DO) line high. At this point, eight data bits can be clocked into the PIC16C5X. The requested position is sent most significant bit first and can be any 8-bit value. Values 1 through 255 represent valid positions with 0 being reserved for drive disable.

The PIC16C5X acquires its data by way of a Microwire® A/D converter. This part was chosen for low cost while providing adequate performance. In Figure 1 the second channel of the A/D converter is shown connected to a peak current detector. If the user desires, the PIC16C5X could monitor and protect the motor from overcurrent conditions by monitoring the second channel.

The H-bridge power amplifier will deliver 10 or more amps at upto 24V when properly heat-sinked. It is wired for a modified 4-quadrant mode of operation. One leg of the bridge is used to control direction and the other leg pulses the low FET and the high FET alternately to generate the desired duty-cycle. In this way the system will operate well to produce a desired "speed" without the use of a separate speed control loop. This allows use of the PIC16C5X to control the PID algorithm for position directly while having reasonable speed control. The capacitance at the gates of the FETs combined with the impedance of the drive circuits provides for turn-off of the upper FET before the lower FET turns on... an important criteria.

The PID algorithm itself is where most of the meat of this application note is located so let's look at it more closely. The algorithm is formed by summing the contribution of three basic components. The first calculation is the error upon which the other terms are based.

The **error** is the requested position minus the actual position. It is a signed number whose magnitude can be 255. In order not to lose resolution, the error is stored as an 8-bit magnitude with the sign stored separately in the FLAGS register under ER_SGN. This allows us to resolve a full signed 8-bit error with 8-bit math.

The **proportional term** is merely the algebraic difference of the requested position minus the actual position. It is scaled by a gain term (K_P) called the "proportional gain". The sign (+,-) of this term is important for it tells the system which direction it must drive to correct the error. The proportional term is limited to ±100. Increasing the proportional gain term will improve the dynamic and static accuracy of the system. Increasing it too much will cause oscillations.

The next term that gets calculated is the **integral term (K_I)**. This term is traditionally formed by integrating the error over time. In this application it is done by integrating the K_I term over time. When the error is zero, no integration is performed. This is a more practical way to handle a potentially large number in 8-bit math. By increasing the K_I term the D.C. or static gain of the system is improved. Increasing the integral gain too much can lead to low frequency oscillations.

The **differential term** (K_D) is a stabilizing term that helps keep the integral and proportional terms from overdriving the system through the desired position and thus creating oscillations. As you use more proportional and integral gain you will need more differential gain as well. The differential gain is calculated by looking at the rate of change of the positional error with respect to time. It is actually formed as "delta error/delta time" with the delta time being a program cycle.

The three terms (proportional, integral, differential) are summed algebraically and scaled to produce a percentage speed request between 0 and 100%. The sign of the sum is used to control the direction of the H-bridge. The loop calculations run approximately 20 times per second on a 4 MHz part. This yields sufficient gain-bandwidth for most positioning applications. If higher system performance is desired, the number of pulses can be reduced to 20 and a 16 MHz PIC16C5X can be used. Your loop gains (K_P, K_I, K_D) will have to be recalculated, but the system sample rate will be increased to 400 Hz. This should be sufficient to control a system that has a response time of 20 milliseconds or more.

The key to using the PIC16C5X series parts for PID control and PWM generation is to separate the two into separate tasks. There simply is not the hardware support or the processing speed to accurately do both concurrently. It is fortunate therefore that it is not necessary to do both concurrently. Most systems can be stabilized with a much lower information update rate than the PWM frequency. This supports the approach of calculating the desired percentage, outputting the PWM for a period of time and then recalculating the new desired percentage. Using this technique, the inexpensive PIC16C5X can implement PID control, PWM generation, and will still have processing time left over for monitor or communication functions.

                    00232 ; servo makes its desire known by setting the chip select to the positioner
                    00233 ; low.  It then monitors the busy (Data Out) line from the positioner.  When
                    00234 ; the positioner sets the busy line high, the host may begin sending its 8 bit
                    00235 ; request.  The data bits should be valid on the rising edge of the clock.
                    00236 ; After 8 bits have been received by the positioner it will begin operation
                    00237 ; to send the system to the received position.  It can be interrupted at any
                    00238 ; point during the positioning process by the host sending a new command.  The
                    00239 ; opportunity to update the command is issued every 100 pwm pulses (every 50
                    00240 ; milliseconds).
                    00241 ; If the host sends a zero positional command the positioner will stop the
                    00242 ; system and remain inactive.
                    00243 ; If the host does not successfully complete a microwire transmission of 8

                   00396 ; The integral term is an accumulation of the error thus far.  Its purpose
                   00397 ; is to allow even a small error to effect a large change.  It does this
                   00398 ; by adding a small number into an accumulator each cycle through the program.
                   00399 ; Thusly even a small error that exists for a while will build up to a large
                   00400 ; enough number to effect an output sufficient to move the system.  The effect
                   00401 ; that this integral accumulator has is modulated by the integral gain term KI.
                   00402 ; The integral of the error over time is multiplied by KI and the result is its
                   00403 ; contribution to the final summation for determining the output value.  This

                   00458 ;****CALCULATING THE DIFFERENTIAL TERM*************************
                   00459 ; The differential term examines the error and determines how much
                   00460 ; it has changed since the last cycle.  It does this by subtracting the
                   00461 ; old error from the new error.  Since the cycle time is relatively fixed
                   00462 ; we can use it as the "dt" of the desired "de/dt".  This derivative of the
                   00463 ; error is then multiplied by the differential gain term KD and becomes the
                   00464 ; differential term contribution for the final summation.

Using a PIC16C5X as a Smart I²C™ Peripheral

Author: *Don Lekei*
NII Norsat International Inc.

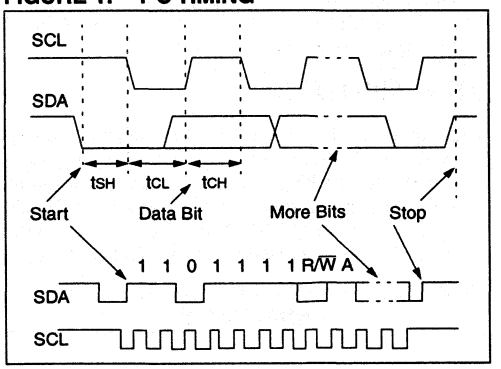
INTRODUCTION

PIC16C5X microcontrollers from Microchip are ideally suited for use as smart peripheral devices under the control of the main processors in systems, due to their low cost and high speed. They are capable of performing tasks which would simply overload a conventional microprocessor, or require considerable logic circuitry, at a cost competitive with lower mid-range PLDs. To minimize the engineering overhead of adding multiple controllers to a product, it is convenient for the auxiliary controllers to emulate standard I/O peripherals.

A common interface found in existing products is the I²C bus. This efficient, two-wire, bi-directional interface allows the designer to connect multiple devices together, with the microprocessor able to send data to and receive data from any device on the bus. This interface is found on a variety of components, such as PLLs, DACs, video controllers, and EEPROMs. If a product already contains one or more I²C devices, it is simple to add a PIC16C5X emulating a compatible component.

This application note describes the implementation of a standard slave device with multiple, bi-directional registers. A subset of the full I²C specification is supported, which can be controlled by the same software which would talk to a Microchip 24LCXX series EEPROM.

THE I²C BUS



The I²C bus is a master-slave two-wire interface, consisting of a clock line (SCL) and a data line (SDA). Bi-directional communication (and in a full, multi-master system, collision detection, and clock synchronization) is facilitated through the use of a "wire-and" (i.e., active-low, passive-high) connection.

The standard mode I²C bus supports SCL clock frequencies up to 100 kHz. The fast-mode I²C bus supports clock rates up to 400 kHz. This application note will support the 100 kHz (standard-mode) clock rate.

Each device has a unique seven bit address, which the master uses to access each individual slave device.

During normal communication, the SDA line is only permitted to change while the SCL line is low, thus providing two violation conditions (Figure 1) which are used to signal a start condition (SDA drops while SCL is high) and a stop condition (SDA rises while SCL is high), which frame a message.

FIGURE 1: I²C TIMING

Each byte of a transfer is 9-bits long (see timing chart in the program listing). The talker sends 8 data bits followed by a '1' bit. The listener acknowledges the receipt of the byte and gives permission to send the next byte by inserting a '0' bit over the trailing '1'. The listener may indicate "not ready for data" by leaving the acknowledge bit as a '1'.

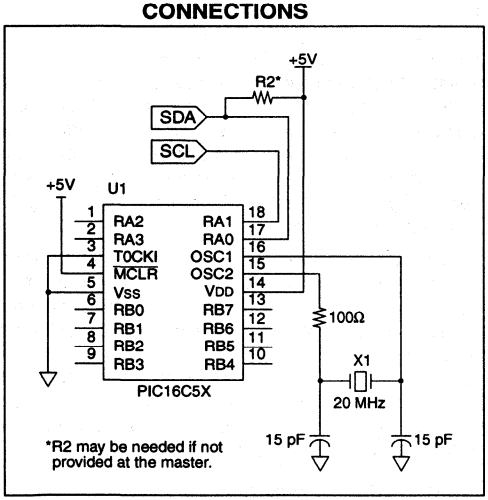
The clock is generated by the master only. The slave device must respond to the master within the timing specifications of the I²C definition otherwise the master would be required to operate in slow mode, which most software implementations of I²C masters do not actually support. The specified (standard-mode) t_{CL} is 4.7 µs, and t_{CH} is only 4 µs, so it would be extremely difficult to achieve the timing of a hardware slave device with a conventional microcontroller.

MESSAGE FORMAT

A message is always initiated by the master, and begins with a start condition, followed by a slave address (7 MSbs) and direction bit (LSb = '1' for READ, '0' for WRITE). The addressed slave must acknowledge this byte if it is ready to communicate any data. If the slave fails to respond, the master should initiate a stop condition and retry.

If the direction bit is '0' the next byte is considered the sub-address (this is an extension to I²C used by most multi-register devices). The sub-address selects which "register" or "function" subsequent read or write operations will affect. Any additional bytes will be received and stored in consecutive locations until a stop is sent. If the slave is unable to process more data, it could terminate transfer by not acknowledging the last byte.

© 1997 Microchip Technology Inc.



If the direction bit is '1', the slave will transfer successive bytes to the master (the master holds the line at '1'), while the master acknowledges each byte with a '0' in the ninth bit. The master can terminate the transfer by not acknowledging the last byte, while the slave can stop the transfer by generating a stop condition.

The start address of a read operation is set by sending a write request with a sub-address only (no data bytes). For a detailed set of timing diagrams and different communication modes, consult any of the Microchip 24LCXX EEPROM specifications. This program communicates using the same formats.

IMPLEMENTATION

The chip will respond to slave address "DEVICE_ADDRESS", which by default is $D6_{16}$ ($D7_{16}$ for read). This address was chosen because it is the fourth optional address of a Philips PCF8573 clock /calender or a TDA8443 tipple video switch (unlikely that a product would contain four of those).

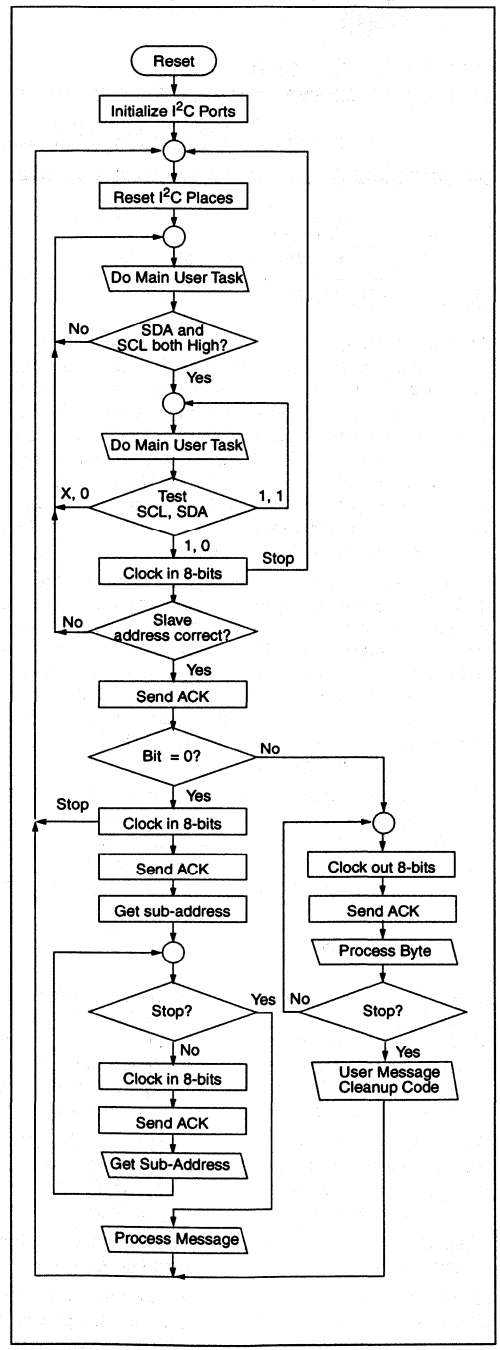


FIGURE 2: SCHEMATIC OF I²C CONNECTIONS

The connections to the device are shown in Figure 2. The use of RA0 for data input is required. Data is shifted directly out of the port. The code could be modified to make it port independent, but the loss of efficiency may hinder some real-time applications.

This application emulates an I²C device with 8 registers, accessed as sub-addresses 1 through 8 (module 7), plus a data channel (0). The example code returns an ID string when the data channel is accessed. When bytes are written to sub-addresses other than 0, they are stored in I2CR0-I2CR7 (I2CR0 gets data written to sub-address 8).

FIGURE 3: I²C DEVICE FLOWCHART

© 1997 Microchip Technology Inc.

When the initial subaddress is 0, the flag B_ID is set. This is used to indicate access to a special channel. In this case, the data channel is used to return an ID message, or output data to PORTB, however the natural extension would be to use this as a data I/O channel.

To make the basic device routines easily adaptable to a variety of uses, macros are used to implement the application specific code. This allows the developer the option of using subroutine calls, or in-line code to avoid the 4 clock cycle overhead and use of the precious stack.

Macro	User Code Function
USER_MAIN	Code to execute in the main loop while not in a message. If this code takes too long, tSH of 4 µs will be violated (Figure 1). The slave will simply miss the address, not acknowledge, and the master will retry.
USER_Q	This would be quick user code to implement real-time processes. In most applications, this macro would be empty. If used, this routine should be kept under 4 µs if possible.
USER_MSG	This would be user code to process a message. It is inserted after a message is successfully received.
USER_RECV	This would be user code to process a received byte. It allows the user to add extra code to implement special purpose sub-addresses such as FIFOs.
USER_XMIT	This would be user code to prepare an output byte. In the default routine, it traps sub-address 0 and calls the ID string function.

Using PIC16C5X Microcontrollers as LCD Drivers

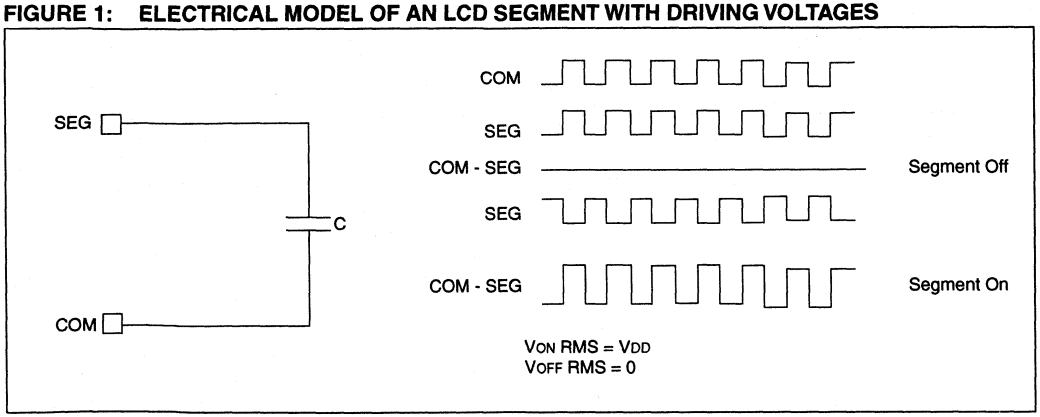
INTRODUCTION

This application note describes an LCD controller implementation using a PIC16C55 microcontroller. This technique offers display capabilities for applications that require a small display at a low cost, together with the capabilities of the standard PIC16C55 microcontroller. We start by an overview of LCD devices and their theory of operation followed by software implementation issues of the controller. The source code for controlling a multiplexed LCD display is included in Appendix A.

LIQUID CRYSTAL DISPLAYS

The Liquid Crystal Display (LCD) is a thin layer of "Liquid Crystal Material" deposited between two plates of glass. The raw LCD is often referred to as "glass". Electrodes are attached to both sides of the glass. One side is referred to as common or backplane, while the other side is referred to as segment.

An LCD is modeled as a capacitor, with one side connected to the common plane and the other side connected to the segment, as shown in Figure 1. LCDs are sensitive to Root Mean Square Voltage (VRMS) levels. When a VRMS level of zero volts is applied to the LCD, the LCD is practically transparent.



To turn an LCD segment "on," which makes the segment turn dark or opaque, an LCD RMS voltage that is greater than the LCD threshold voltage is applied to the LCD. The RMS LCD voltage is the RMS voltage across the capacitor *C* in Figure 1, which is equal to the potential difference between SEG and COM values.

Different LCDs have different characteristics; Figure 2 shows typical voltage vs relative contrast characteristics. Notations on the curve show operating points for multiplex operation with the threshold voltage set to 1.7 VRMS. This voltage is often used as the measure of voltage for the LCD to be "off" or transparent. The curve is normalized and assumes a viewing angle of 90° to the plane of the LCD.

Contrast control, the process of turning on a segment, is achieved by moving the operating point of the LCD. This is achieved by applying a voltage to the LCD that is greater than the LCDs threshold voltage. A typical circuit to accomplish this task is shown in Figure 3.

Driving a liquid crystal display at direct current (DC) will cause permanent damage to the display unit. In order to prevent irreversible electrochemical action from destroying the display, the voltage at all segment locations must reverse polarity periodically so that a zero net voltage is applied to the device. This process is referred to as AC voltage application. There are two LCD driving methods available: Static and multiplexed.

FIGURE 1: ELECTRICAL MODEL OF AN LCD SEGMENT WITH DRIVING VOLTAGES

Conventional LCDs have separate external connections for each and every segment plus a common plane. This is the most basic method that results in good display quality. The main disadvantage of this driving method is that each segment requires one liquid crystal driver. The static driving method uses the frame frequency, defined as a period of the common plane signal, of several tens to several hundred Hz. A lower frequency would result in blinking effects and higher frequencies would increase power requirements. To turn a segment on, a voltage that has an opposite polarity to the common plane signal must be applied resulting in a large RMS voltage across the plates. To turn off a segment, a voltage that is of the same polarity to the common plane signal is applied. This drive method is universal to driving LCD segments. Figure 1 shows an example of this driving method.

The LCD frequency is defined as the rate of output changes of the common plane and segment signals, whereas the frame rate is defined as

$$F_{FRAME} = \frac{F_{FRAME}}{N}$$

where *N* is the multiplex rate or number of backplanes. Typically, FFRAME ranges from 25 Hz to 300 Hz. The most commonly used frame frequency is 40-70 Hz. A lower frequency would result in flicker effects and higher frequency would increase power requirements.

Multiplexed LCDs maintain their liquid crystal characteristics. They have a low power consumption, a high contrast ratio under high ambient light levels, and they reduce the number of external connections necessary for dot matrix and alphanumeric displays. The multiplex driving method reduces the number of driver circuits, or microcontroller I/O pins if a software method is used. The method of drive for multiplexed displays is Time Division Multiplex (TDM) with the number of time divisions equal to twice the number of common planes used in a given format. In order to prevent permanent damage to the LCD display, the voltage at all segment locations must reverse polarity periodically so that zero net voltage is applied. This is the reason for the doubling in time divisions; each common plane must be alternately driven with a voltage pulse of opposite polarity. The drive frequency should be greater than the flicker rate of 25 Hz. Since increasing the drive frequency significantly above this value increases current demand by the CMOS circuitry, an upper drive frequency level of 60 Hz is recommended by most LCD manufacturers. We have chosen a drive rate of 50 Hz for this application note which results in a frame period of 20 ms. The most commonly available formats are 2x4, 3x3, and 5x7. In this report we use a 2x4 format LCD to display hexadecimal digits.

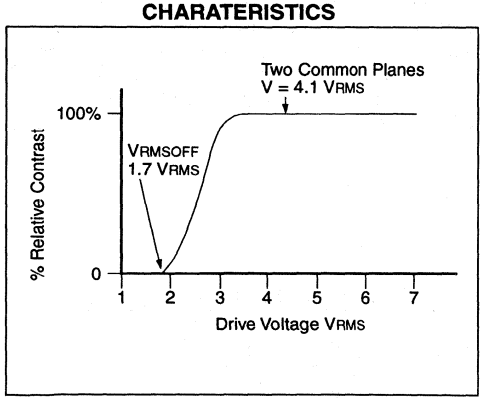

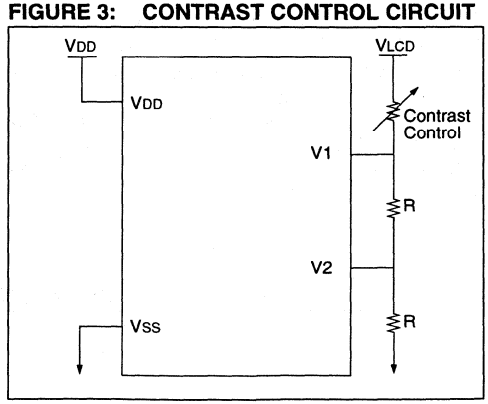

FIGURE 3: CONTRAST CONTROL CIRCUIT

To better understand multiplexed LCD control it is best to look at the general case. The segments in a multiplexed LCD are arranged in an X-Y grid form as shown in Figure 4. The common plane signals maintain their relative shape at all times, as shown in Figure 5. To turn on segment 1 (SEG1), we need to apply a voltage V_D, such that $V_S + V_D$ turns the segment on and $V_S - V_D$ turns the segment off. Note that the segment signal V_D is symmetrical. This is a consequence of the intervals that the common plane signal is not present at all times. Use of nonsymmetrical waveform will result in a higher V_{RMS} present on the unaddressed segments.

The symmetrical nature of the waveforms theoretically result in zero DC voltage levels. CMOS drivers (e.g., microcontrollers) operate at 0 to +5V levels (rail voltage levels). This would require driving voltages beyond the range of operation. This constraint is addressed by a technique referred to as "level shifting" or "biasing". Level shifting allows application of voltages in the range of 0 to +2.5V, which is compatible with these drivers. This would require an additional voltage level of +2.5V, which can be implemented through a simple resistive voltage divider circuit.

IMPLEMENTATION

The ideas presented in the previous section can be applied to any size multiplexed LCD display. In our implementation we used a 4-digit LCD from Ocular Inc. [1]. The circuit diagram used in this application note is shown in Figure 6. Each I/O pin on the PIC16C55 device controls the state of two segments (Figure 6) which requires a total of 16 I/O pins. The reference voltages are generated through a simple resistive voltage divider circuit.

The voltage levels are generated by taking advantage of PIC16C5X I/O pin set to input, which tri-states the voltage level seen on the pin. This method uses 4 I/O pins to generate the proper voltage levels. Figure 7 shows the truth table for generating the voltage levels. Figure 8 shows how to create a bitmap for different digits. Figure 9 shows the waveforms generated for the accompanying software which implements a hexadecimal counter.

CONCLUSION

In this application note we have demonstrated the use of PIC16C5X devices to implement a simple LCD controller. As discussed earlier, it is important to keep the generated DC voltage to a minimum to extend the life of the LCD. Ideally one should switch all the I/O lines simultaneously, however, implementation of software of the LCD controller will necessarily introduce a delay which is proportional to the instruction cycle of the microcontroller, as shown in Figure 10. Therefore it is necessary to keep the switching time to a minimum. Our implementation introduced less than 50 mV of DC voltage on the segment lines which is below the manufacturer's recommended DC offset voltage of 60 mV.

PIC16C54A EMI Results

Author: *Mark Palmer*
Ohmmeter Board Setup: *Stan D'Souza*
Testing: *Compatible Electronics*

INTRODUCTION

This paper discusses the EMI results of the PIC16C54A. These measurements were taken by an independent consulting firm that specializes in electromagnetic testing. These results are for a specific system design, each design will have its own results.

DEVICES USED

These tests were done on a randomly selected PIC16C54A device, and should be considered as typical results. Initial testing was done on three boards/devices. The device frequency of the boards were, respectively, 32 kHz, 4 MHz, and 20 MHz. As would be expected there was a substantial difference in EMI lives (decrease) at the low frequency as compared to the higher frequencies. The difference between the 4 MHz operation and the 20 MHz operation was marginal. The final testing of the device was done at 4 MHz, and was according to the FCC measurement procedure MP-4.

SYSTEM USED

The PIC16C54A device was tested in the Microchip OHMMETER board. This board is a three layer board, with a ground plane. Power and ground planes greatly help in the compliance of designs to the FCC part 15 subpart B testing. This board had minimal external components, so that the electromagnetic measurements could mostly be attributed to the device and design of the system. To reduce the noise that comes from a power supply, a 10 nF bypass capacitor was attached to the power / ground of the input jack.

EMI TESTING

The testing of electromagnetic noise (EMI) on a system has two types of commonly used testing environments, internal and external. The internal test is performed in a screen room to reduce the amount of stray EMI. The indoor test is useful in determining the source of EMI radiation. The external test is performed outdoors. This places the equipment under test in an environment to measure radiated emissions (EMI). The FCC only requires the outdoor testing of devices. The Equipment Under Test (EUT) was positioned to maximize the emissions.

INTERNAL TESTS

The Equipment Under Test (EUT) was placed on a wooden test bench, inside a screen room, 0.8 meters above the earth ground plane (Figure 1). The EUT was powered through the Line Impedance Stabilization Network (LISN) bonded to the ground plane. The LISN power was filtered and the filter was bonded to the ground plane. The EUT was positioned on the table with the minimum distance from any conductive surface, as specified in MP-4. The excess power cord was wrapped in a figure-8 pattern to form a bundle approximately 8 cm in length. The EUT configuration was set for the highest emission frequency, and data was collected under the program control of the host computer. The spectrum analyzer collected the maximum peak readings over each spectrum. The six highest emission levels and corresponding frequencies were sorted and are listed in Table 1.

TABLE 1: CONDUCTED EMISSIONS RESULTS

Frequency (MHz)	Emission Level dBμV	Emission Level μV	Specification Limit μV

11.62	33.4	47	250
13.41	33.8	49	250

While in the screen room additional analyses on the device was done. First a local probe was used to test the emission levels around the board and device. There were no measurable emissions at the I/O pins or their corresponding trace lines. Emissions were measured at the jack to the power supply. The power supply and cord were the greatest source of emissions for the EUT. This is due to the power cord being an antenna which emitted the noise from the power supply. Designers should attempt to minimize antennas which emit EMI. Antennas could be the power supply cord, as well as traces on the system board.

Second the PIC16C54A was monitored for susceptibility, following the IEC 801-3 specification. This test was measured from 27 MHz to 500 MHz in 10 kHz steps. The device did not display any signs of susceptibility (Table 2).

EXTERNAL TESTS

The open field site used for radiated emission testing was set up according to FCC bulletin OST 55.

Figure 2 shows the layout of the open field test site. The EUT was mounted on a turntable. The position of the turntable was remotely controlled to determine the highest emission levels. Initial testing was done with a broad band mounted on the antenna mast at a distance of 3 meters. Further investigation was done to determine the EUT positions that produced the maximum level of emissions. The receiving antenna was mounted on the antenna mast. The antenna height was varied to find the highest level of radiated emissions at each frequency. The six highest emission levels and corresponding frequencies were sorted and are listed in Table 3. Figure A-1 and Figure A-2 show the dBμV vs. MHz graphs.

Implementing Long Calls

Author: *Mark Palmer*
Microchip Technology Inc.

INTRODUCTION

This application note discusses how to implement "long calls" in the PIC16C5X architecture. The use of long call can simplify the partitioning of the application program with minimal software overhead.

In the PIC16C5X architecture, the program memory page size is 512 words. Depending on the device, the program memory may be as large as 2K words (as in the PIC16C57 or PIC16C58 devices). The program counter (and stack) width range from 9- to 11-bits, depending on the amount of program memory. Table 1 shows the width of the Program Counter (PC) and Stack for the various devices.

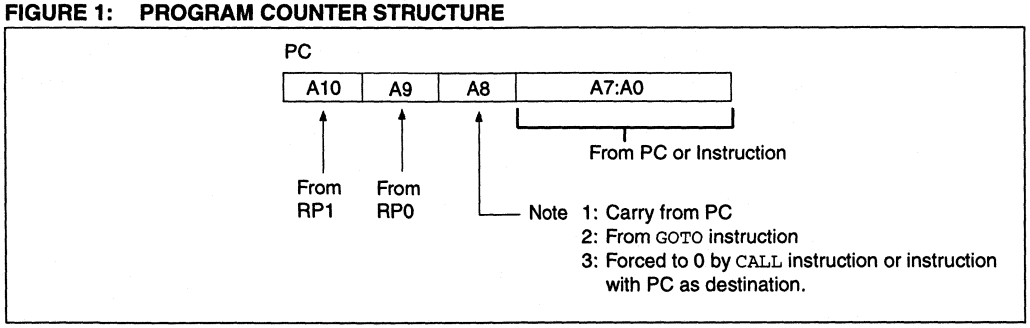
The low order 8-bits of the program counter are accessible by the user program. These bits are contained in the PC register.

TABLE 1: PC AND STACK WIDTH

DEVICE	Width (bits)		Program Memory (Words)
	Program Counter	Stack	
PIC16C54 / PIC16C55	9	9	512
PIC16C56	10	10	1K
PIC16C57 / PIC16C58	11	11	2K

Figure 1 shows the structure of the PC. Since A8 is forced to 0 by CALL instructions, the start address of subroutines must be in the first 256 words of each program memory page. Depending on the size and number of called subroutines, this limitation may become a burden to the software developer. The implementation of a "long call" eases this, by allowing the subroutine to be anywhere in the program memory page. The three important concepts for understanding the implementation of the long call are:

1. A CALL instruction loads the entire PC onto the Stack.
2. A GOTO instruction does not affect the Stack.
3. A GOTO instruction can branch to any location in a program memory page.



Also to select the desired page, the PA1 and PA0 bits (STATUS<6:5>) must be programmed accordingly. These bits do not get loaded into A10:A9, of the PC, until one of the following occurs:

- A CALL instruction
- A GOTO instruction
- An instruction that modifies the PC register (PC<:7:0>), such as `ADDWF PC,F`.

So a CALL instruction followed by a GOTO instruction will always remain in the same page as the intended call. This allows the developer to place "call vectors" at the first 256 words of each page. The instruction at the "call vector" then executes a GOTO instruction to the subroutine anywhere in that page. The RETLW instruction, of the subroutine, will then POP the stack. The Stack contains the PUSHed PC value from the CALL instruction.

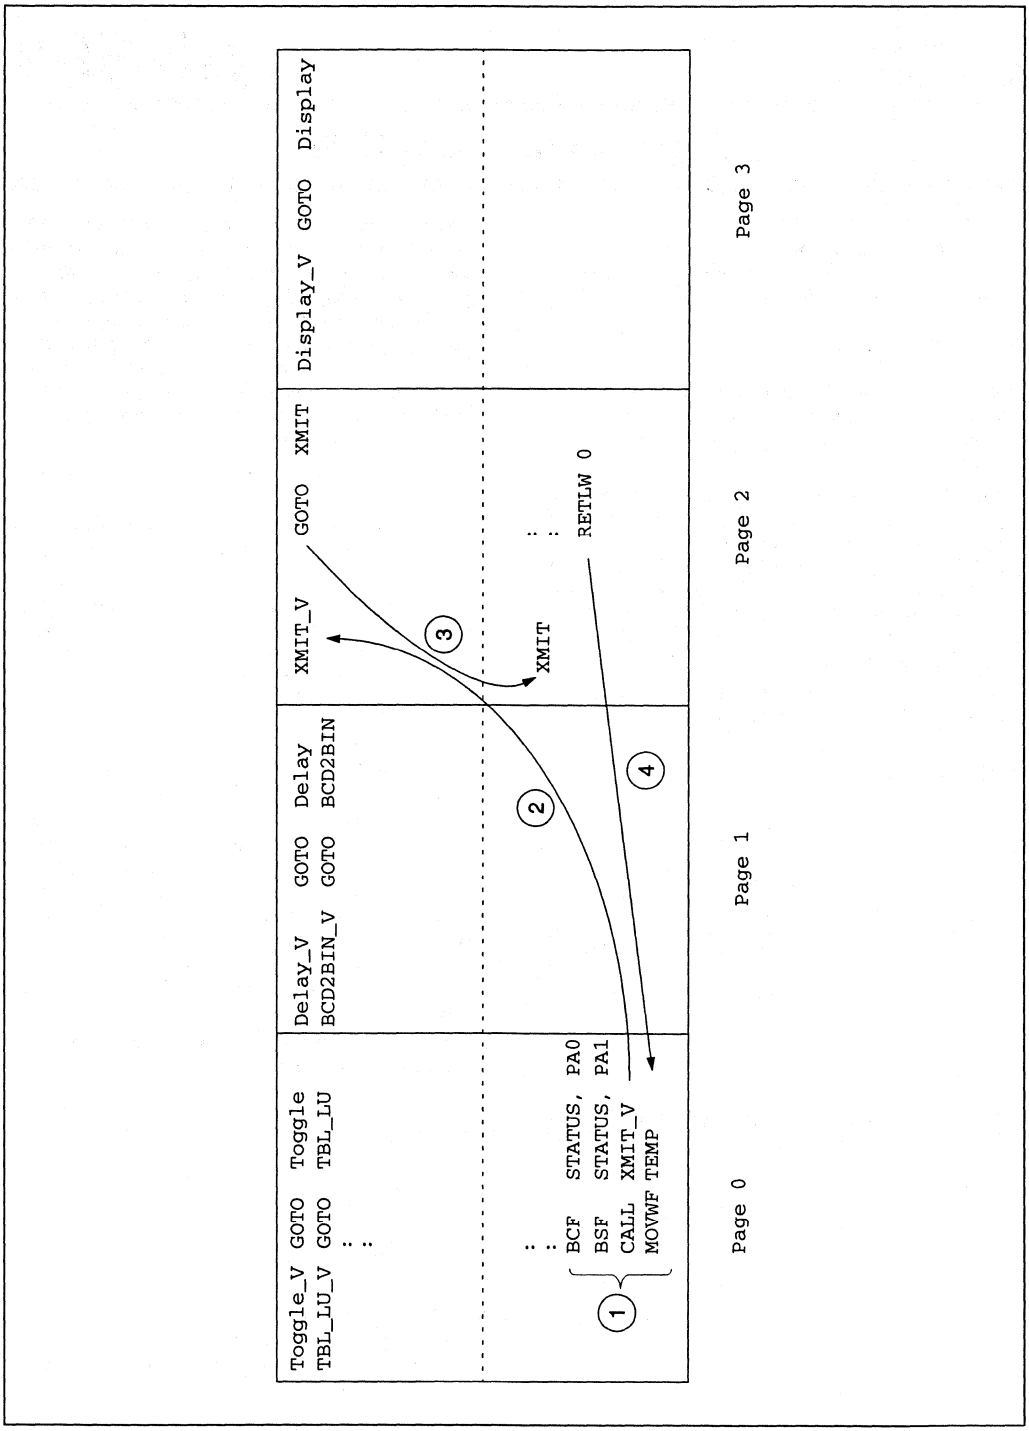


Figure 2 shows an example of a "long call" sequence in a device with 2K-words.

FIGURE 1: PROGRAM COUNTER STRUCTURE

FIGURE 2: EXAMPLE OF A "LONG CALL" SEQUENCE

© 1997 Microchip Technology Inc.

The flow that occurs in Figure 2 is as follows:

1. Select the program memory page of the desired subroutine and execute the call to that subroutine.
2. The program loads the Stack with the PC + 1 address, branches to the selected page and specified address of the "call vector" (must be in the first 256 locations of the page).
3. Executes a GOTO instruction, to have access to the entire program memory page. Then executes the subroutine.
4. Executes the RETLW instruction, which POPs the new PC value from the Stack. This causes program execution to continue at the instruction after the CALL instruction.

The use of "long calls" could be used to place all the subroutines in selected page(s), since the entire page can contain the subroutines (not restricted to the top half of the page). The placing of all subroutines in fewer program memory pages can reduce the overhead of specifying the required pages, since they are changed less frequently.

Use of the MPASM assembler can ease in verifying that CALL vectors and the CALL routine are in the same program memory page. Example 1 shows the use of assembler directives to print user defined warning or error messages in the listing file. These are shown as the shaded conditional statements. These messages are only printed in the listing file, and no indication of these messages is shown at the completion of assembly.

CONCLUSION

The use of "long calls" may ease the development of application programs. For minimal overhead, the application program can execute a subroutine from anywhere in the program memory, and return to the desired location. This eases the development of the application program by reducing the mapping of subroutine in the first 256 words of each program memory page. The use of "long calls" is possible in any of the PIC16C5X devices, but is most useful in devices with more than one program memory page. For devices with more than one page of program memory, the assembler directives can be used to verify that the subroutines are in the program memory page.

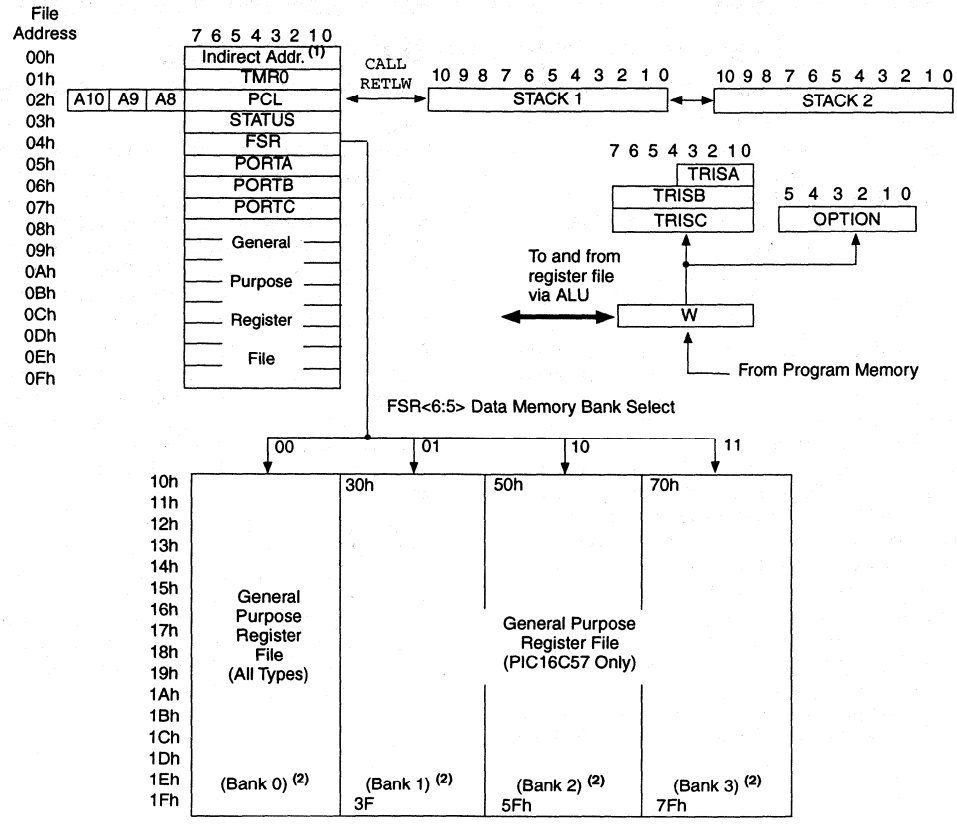
Macros for Page and Bank Switching

Author: *Mark Palmer*
Microchip Technology Inc.
Contributions: *Mike Morse*
Sr. Field Applications Engineer
(Dallas)

INTRODUCTION

This application note discusses the use of the MPASM assembler's conditional assembly to automatically switch between program memory pages or to set the data memory banks. These macros, along with the long call technique (Application Note AN581), ease the development of software. Though the use of these macros can simplify program memory paging and data memory banking with minimal software overhead, the use of these macros without thought can cause unnecessary (duplicate) instructions to be used, by setting page or bank bits unnecessarily.



The PIC16C5X family of devices has an architecture in which program memory has up to four pages of program memory (512 words / page) and four banks of data memory (16 bytes / bank). Two bits in the STATUS register, PA1:PA0, are used to manage the program memory pages. Two bits of the FSR register, bits 6 and 5, manage the data memory banks. We will call the FSR<5> bit RP0 and the FSR<6> bit RP1 (for Register Page 0 and 1). The naming of these bits RP1 and RP0 should not be confused with the similarly named bits in the PIC16CXX family (PIC16C64, PIC16C71, etc.). The RP bits for the PIC16CXX family are found in the STATUS register, as opposed to the FSR register for the PIC16C5X family. The use of these macros can be modified to support the PIC16CXX family.

The program memory organization is shown in Figure 1 and the data memory organization is shown in Figure 2. To use the macros for the data memory, the data memory locations must be EQUated for the absolute address, and not the relative address in the bank. The relative address is the lower 5-bits of the data memory address.

When the address of the data memory has the MSb (bit4) of the direct address cleared, or FSR<4> cleared (for indirect addressing), the address 0h through 0Fh is accessed. That is, when accessing addresses 0h through 0Fh the bank selection (FSR<6:5>) bits are ignored. This means that data memory addresses 'xxx0 xxxx'b access the data memory address 0xh (x is anywhere from 0 - F).

The use of MPASM's conditional assembly, allows the selection of source code to be assembled based on the address of the symbol / label. The macros supplied are show in Table 1.

They can be grouped into three categories:

1. Configuring of the program memory pages.
2. Configuring of the data memory banks.
3. Other.

TABLE 1: MACROS

Program Calling Paging	Operands	Operation
CALLM	address	Sets page bits, then CALLs the specified routine
GOTOM	address	Sets page bits, then GOTOs the specified address
PAGE_MAC	address	Sets the specified page bits
Data Memory Banking		
ADDWF_MAC	Reg, dest	Sets Bank bits, then executes the ADDWF
ANDWF_MAC	Reg, dest	Sets Bank bits, then executes the ANDWF
BCF_MAC	Reg, bit	Sets Bank bits, then executes the BCF
BSF_MAC	Reg, bit	Sets Bank bits, then executes the BSF
BTFSC_MAC	Reg, bit	Sets Bank bits, then executes the BTFSC
BTFSS_MAC	Reg, bit	Sets Bank bits, then executes the BTFSS
CLRF_MAC	Reg	Sets Bank bits, then executes the CLRF
COMF_MAC	Reg, dest	Sets Bank bits, then executes the COMF
DECF_MAC	Reg, dest	Sets Bank bits, then executes the DECF
DECFSZ_MAC	Reg, dest	Sets Bank bits, then executes the DECFSZ
INCF_MAC	Reg, dest	Sets Bank bits, then executes the INCF
INCFSZ_MAC	Reg, dest	Sets Bank bits, then executes the INCFSZ
IORWF_MAC	Reg, dest	Sets Bank bits, then executes the IORWF
MOVF_MAC	Reg, dest	Sets Bank bits, then executes the MOVF
MOVWF_MAC	Reg	Sets Bank bits, then executes the MOVWF
RLF_MAC	Reg, dest	Sets Bank bits, then executes the RLF
RRF_MAC	Reg, dest	Sets Bank bits, then executes the RRF
SUBWF_MAC	Reg, dest	Sets Bank bits, then executes the SUBWF
SWAPF_MAC	Reg, dest	Sets Bank bits, then executes the SWAPF
XORWF_MAC	Reg, dest	Sets Bank bits, then executes the XORWF
BANK_MAC	Reg	Sets the specified Bank bits
Other		
SAVE_W_STATUS	-	Saves the W and STATUS registers
RESTORE_W_STATUS	-	Restores the W and STATUS registers

These macros (Appendix A) ease the development of programs, but care should be taken in their use so that redundant instructions are not caused. An example of this (Example 1) is if you wanted to do the operations, INCF and BTFSS, on data memory location CNTR (in Bank 3) and the FSR was pointing to some other bank. The use of the macros for both operations would cause six program memory locations to be assembled, while with some thought only four words are needed (Example 2).

CONCLUSION

The use of these macros simplify program development by managing the memory resources of the PIC16C5X device. If the application program becomes too large for the device's program memory, it is recommended to study the listing file for any unnecessary code due to non-optimum usage of these macros. The MAC_TST.ASM file, is supplied to show how these macros work in a program.

EXAMPLE 1: GENERATION OF UNNECESSARY CODE

```
INCF_MAC    CNTR, F    ->    BSF     FSR, 5
                             BSF     FSR, 6
                             INCF    CNTR, F
BTFSS_MAC   CNTR, 5    ->    BSF     FSR, 5     ; Unnecessary, already in bank
                             BSF     FSR, 6     ; Unnecessary, already in bank
                             BTFSS   CNTR, 5
```

EXAMPLE 2: GENERATION OF OPTIMUM CODE

```
INCF_MAC    CNTR, F    ->    BSF     FSR, 5
                             BSF     FSR, 6
                             INCF    CNTR, F
BTFSS       CNTR, 5    ->    BTFSS   CNTR, 5
```

A Clock Design Using the PIC16C54 for LED Displays and Switch Inputs

Author: *Dan Matthews*
Microchip Technology Inc.

INTRODUCTION

The purpose of this application note is to design a clock while multiplexing the features as much as possible, allowing the circuit to use the 18-pin PIC16C54. Other devices in the Microchip line expand on this part, making it a good starting point for learning the basics. This design is useful because it utilizes every pin for output and switches some of them to inputs briefly to read the keys. For a more extensive clock design, consult application note AN529.

THE DESIGN

This design is a simple time-of-day clock incorporating four seven-segment LED displays and three input switches. There is also an additional reset switch that would not normally be incorporated into the final design. The schematic is illustrated in Figure 1.

CONNECTIONS

The individual segments of each display are connected together, A-A-A-A, B-B-B-B, etc. The displays are numbered from the right, or least significant digit. The second display from the right is flipped upside down to align its decimal with the third display, creating the center clock colon. Therefore the segments are not tied together evenly straight across on the board, but must compensate for the change in one display's orientation. The common cathode for each display is turned on with transistors connected to the four I/O lines of PORTA. The connections are RA0-CC4/Digit4, RA1-CC3/Digit3, RA2-CC2/Digit2, RA3-CC1/Digit1. A low output turns on the PNP transistor for the selected display. The PORTB pins activate the LED segments. For this design only the center colon decimal points were connected. The connections are RB0-dp, RB1-A, RB2-B, RB3-C...RB7-G.

The switches are also connected to PORTB I/O pins. PORTB pins RB1, RB2, and RB3 are pulled low with 10 kΩ resistors. This value is high enough to not draw current away from the LEDs when they are being driven on. Inputs are detected by pulling the pins high with a switch to V_{DD} through 820Ω resistors. This value is low enough to pull the pin high quickly when the outputs have been turned off, and to create a 90% of V_{DD} high input.

OPERATION

Switches

When no buttons are pressed, the circuit will display the current time, starting at 12:00 on reset. Pressing SW1 will cause seconds to be displayed. The time is set by pressing SW2 to advance minutes, and SW3 to advance hours. Since each of the segments are tied together across all displays, only one display should be turned on at a time, or all displays turned on would display duplicate data. The displays are turned on right to left, with each display's value being output in its turn. This is done fast enough so that there is no perceived flicker. The switches are read between display cycles.

Timing

The PIC16C5X prescaler is assigned to TMR0 as a 1:16 divide. The T0CKI pin is tied low since it is not used. The OPTION Register is loaded with 03h to initialize this prescaler setup. The software is written with timing based on a 4.000 MHz crystal. The instruction clock is 1.000 MHz after the internal divide by four. The 8-bit TMR0 register rolls over every 256 cycles, for a final frequency of 244.1406 Hz. (exactly a 4.096 ms period) A variable named sec_nth is used to count 244 roll-overs of TMR0 for one second. The benefit of keeping time with a nth variable is that it can be written to as needed to adjust time in "nths" of a second, allowing almost any odd crystal frequency to be used. Simply determine the best prescale and "nth" divider, and compute the "nth" adjustment needed for each minute, hour, twelve hour roll-over. Time can be kept accurately to two "nths" a day (an "nth" is 1/244 of a second in this case). In this circuit, 9 "nths" are subtracted each minute, 34 "nths" are added each hour, and 6 "nths" subtracted every twelve hour roll-over. This leaves a computed error of 1.5 seconds/year except for crystal frequency drift. Another possible solution is to initialize TMR0 to some value that causes a roll-over at a predetermined time interval. Writing to TMR0 causes two clock cycles to be missed while clock edges realign, which would have to be accounted for. This is described in the *Microchip Data Book*.

Displays

The program contains portions of code that act as a display driver. A variable exists for each of the four displays. A hex value from 0 to 9 can be written to these variables and they will be converted to display code and output to the displays. Only one display is actually on at a time, and its code is output into it in its turn. Another section of code takes the seconds, minutes, or hours value and separates it into the two digits needed for each display. In other words, 48 seconds would be separated into a "4" and an "8" and written to the appropriate display variable. The displays used were common cathode and turned on with transistors to avoid trying to sink too much current into the PIC16C5X. A display is enabled with a zero at the appropriate pin. 100Ω resistors were used in series with the segments to obtain the desired brightness. Different values may be required if different displays are used. Since each display is on less than one fourth of the time, the resistor value must be low enough to compensate for the needed forward current.

CONCLUSION

The instruction execution speed of the PIC16C54 (and the rest of the PICmicro™ series) allows many functions to be implemented with only a few pins, by multiplexing them in software. User inputs, Timer0 Counter, and multiple LED displays are all accommodated with little or no sacrifice in functionality.

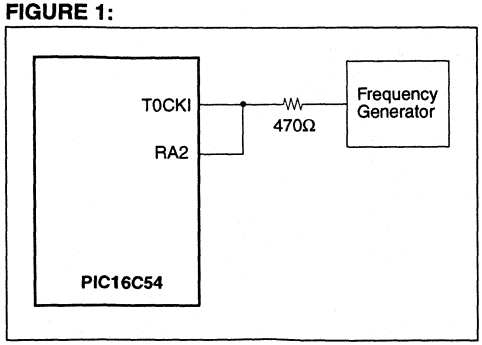
Frequency Counter Using PIC16C5X

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION



The PIC16C5X has one 8-bit timer (Timer0), which can be used with an 8-bit prescaler. The prescaler runs asynchronously, hence it can count a very high frequency. The minimum rise and fall times of the input frequency are specified to be 10 ns, so the fastest clock rate the TMR0 can count is 50 MHz. The prescaler must be used when measuring high frequency. Since the prescaler can be configured as a divide by 256 counter, the maximum resolution at which the input frequency can be measured is 16-bits. However, the prescaler cannot be directly read like a file register. This application note depicts a unique method by which the user can "extract" the 8-bit value in the prescaler, whereby the resolution of the measurement is 16-bits with the high 8-bits in TMR0 and the low 8-bits in the prescaler.

IMPLEMENTATION

A frequency counter which can read frequencies from 50 Hz to 50 MHz was implemented in this application note in order to demonstrate this method of measuring the 16-bit counter value from the prescaler and TMR0.

The basic hardware for the measurement circuit is depicted in Figure 1. It consists of the frequency input at TMR0 or T0CKI (pin 3 in a PIC16C54). T0CKI is connected to RA2. The input frequency is connected to T0CKI through a 470Ω resistor.

FIGURE 1:

TMR0 is configured to measure the input frequency, at T0CKI of the PIC16C54. The input frequency is "gated" for a precise duration of time. Before starting this precise "gate", TMR0 is cleared (which also clears the prescaler), and the RA2 pin is configured as an input. The precise "gate" is implemented in software as an accurate delay. At the end of the delay, the RA2 pin is configured as an output going low. This will cause the input to TMR0 to be "halted" or "stopped". A 16-bit value of the input frequency is now saved in TMR0 and the 8-bit prescaler. The high 8 bits are in TMR0 and can be easily read. The low 8 bits have to be "shifted out". The 8 bits in the prescaler are "shifted out" by toggling RA2 with a "BSF" and a "BCF" instruction. After every toggle, the value in TMR0 is checked to see if TMR0 has incremented. If the number of toggles required to cause TMR0 to increment by 1 is N, then the 8-bit value in the prescaler can be calculated to be = (256 - N). By concatenating the calculated value and the original value from TMR0, the 16-bit value for the frequency is determined.

To measure a wide range of frequencies, the following intermediate steps were taken:

Frequency Range	Precise "gate" delay	Resolution
50 MHz - 10 MHz	1 ms	±10 kHz
10 MHz - 1 MHz	5 ms	±2 kHz
1 MHz - 100 kHz	50 ms	±200 Hz
100 Hz - 10 kHz	200 ms	±50 Hz
50 Hz - 50 Hz	50 ms (†)	±2 Hz

Note: In this case, TMR0 uses the internal 4 MHz clock and counts the number of instances of the external clock. The maximum time required is 50 ms to make a ± 2 Hz accurate measurement for 10 kHz input frequency.

The check for the correct frequency is performed automatically starting with the high frequency and ending with the low frequency. The maximum time required for each conversion is approximately 310 ms. In other words, three frequency checks are done every second.

CONCLUSION

The PIC16C5X family can be used to make a 16-bit measurement of input frequency with a small overhead of one resistor and one I/O port.

                     00009 ;This program implements the concepts for the frequency counter
                     00010 ;using a PIC16C54. In this program, RA0 is connected directly
                     00011 ;to the tmr0 input. Tmr0 input is connected thru a 470 ohm
                     00012 ;resistor to the freq source. Please note that the
                     00013 ;the input freq. is required to be a 50% duty cycle, square
                     00014 ;wave. Though none of the internal calculations are based
                     00015 ;on this requirement, waveforms which deviate drastically
                     00016 ;for the one specified were not tested using these routines.
                     00017 ;The routines written in this program, automatically measure
                     00018 ;waveforms from 50MHz to 50hz in a period of approx. 300 mS.
                     00019 ;After a period of approx 300 mS, the 16 bit "measured" value of
                     00020 ;the freq. is read and saved in the location "flo" and "fhi".
                     00021 ;A "range" flag is set to indicate if the measurement belongs to
                     00022 ;the five ranges measured namely:
                     00023 ;       RANGE:                  Flag name
                     00024 ;       50Mhz to 10Mhz -->  Mhz 50 to 10
                     00025 ;       10Mhz to 1Mhz  -->  Mhz 10 to 1

                     00028 ;       10Khz to 50hz  -->  Hz 10K to 50
                     00029 ;The freq. check is repeated to give approx 3 samples/sec.
                     00030 ;The "measured" value now has to go through a calculation to
                     00031 ;get the actual value. Please use the math routines mentioned
                     00032 ;elsewhere in the Embedded Control Handbook to determine
                     00033 ;the actual value of the freq.

Serial Port Routines Without Using Timer0

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

The PIC16C5X has one 8-bit timer (Timer0) which can use an 8-bit prescaler. In some instances, the user would like to use this timer for some other purpose and yet, be able to do a transmit and receive using the serial port. This application note offers routines to do a simple 8-bit transmit and receive with no handshake, at baud rates from 1200 to 9600. Please note that these routines use a timed loop which is as accurate as the clock which drives the PIC16C5X. The user enters the frequency and baud rate desired. The calculated value "delay" in the serial routine has to be an 8-bit value only. If the value is greater than 8-bits, the frequency and baud rate values have to be changed.

CONCLUSION

Simple transmit and receive routines can be written without using Timer0 to generate the baud rate.

Modifying PIC16C54A Code for the PIC16C58A

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

Code written for a PIC16C54A device can be easily modified and used in a PIC16C58A. Therefore, a PIC16C58A may be used in place of a PIC16C54A. The PIC16C58A and the PIC16C54A are pin-compatible devices. Also, the PIC16C58A has more than enough memory (program and data) to support PIC16C54A code.

Device	Pins	EPROM/ROM	RAM
PIC16C54A	18	512	25
PIC16C58A	18	2048	73

PROGRAM MEMORY

The PIC16C54A has 512 words of EPROM program memory, while the PIC16C58A has 2048 words. Figure 1 and Figure 2 depict the memory organization for each of these devices. For this application, Page 0 of the PIC16C58A On-chip Program Memory will be used in place of the PIC16C54A On-chip Program Memory. However, the Reset vector location will change from 1FFh for the PIC16C54A to 7FFh for the PIC16C58A. (See the discussion on Reset in the next section.)

The PC, or program counter, is used on both devices to access program memory locations. Eight of the nine bits required to access the 512 words of program memory in the PIC16C54A are provided by the PCL file register (Figure 3). The most significant 9th bit is provided from the instruction word during a GOTO instruction. A CALL instruction, on the other hand, forces a '0' into the most significant 9th bit of the PC. Hence, all subroutines must reside in the top half (00h to FFh) of the program memory.

On the PIC16C58A, bits 0 through 8 of the PC operate the same as bits 0 through 8 of the PIC16C54A PC for GOTO and CALL instructions (Figure 4). The PIC16C58A PC differs from the PIC16C54A PC in the addition of two most significant bits. These 10th and 11th bits are provided by the PA0 and PA1 values of the STATUS register. The bits signify the program memory page for the PIC16C58A (i.e., 00 = Page 0, 01 = Page 1, etc.).

After a power-up reset, the PA1:PA0 bits are reset to '0'. So, if these two bits are not modified by the PIC16C54A program, the same program will correctly access the Page 0 program memory space on a PIC16C58A.

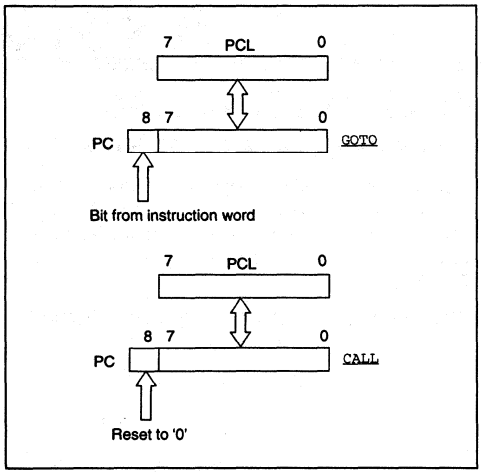
FIGURE 3: LOADING OF PIC16C54A PC FOR BRANCH INSTRUCTIONS



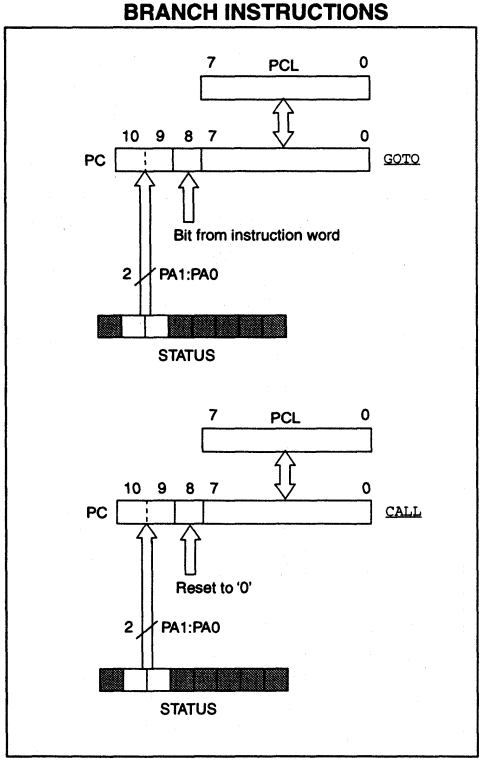


FIGURE 4: LOADING OF PIC16C58A PC FOR BRANCH INSTRUCTIONS

Reset Address

The reset address on the PIC16C54A is at location 1FFh. Normally, a "GOTO Start" instruction is placed at this location, where Start is the beginning of the program. If the user has used such an instruction, then in order for the program to operate correctly on a PIC16C58A the "GOTO Start" instruction should be moved to location 7FFh, the reset address for the PIC16C58A.

Operation in a Noisy Environment

What happens if the PA1 or PA0 bit value gets corrupted due to noise or some other external event? The PA1:PA0 bits are not directly mapped into PC<11:9>, but the PA1:PA0 bit values are loaded into PC<11:9> during a CALL or GOTO instruction. So, if the PA1:PA0 bit values get corrupted (ex: PA1:PA0 = 11 instead of 00), the program will go to a program memory page other than 0 when a CALL or GOTO instruction occurs. The program will then start executing "unimplemented" code space.

Normally the user would program "unimplemented" code space with the default FFFh value (XORLW FFh instruction). The PC would increment sequentially until it hit the last location (7FFh) or the Reset address, which is normally recommended to be a "GOTO Start" instruction. However, since the value in PA1:PA0 is still corrupted (PA1:PA0 = 11 in our example), the program execution will still be in Page 3. In other words, the program would get locked in an endless loop.

In order to avoid the above situation, each "unimplemented" page should be filled with the instruction "GOTO Recover". The Recover subroutines (Three will be required for the three (3) unimplemented pages of the PIC16C58A) should clear the PA1:PA0 bits in the STATUS register and execute a "GOTO Start" instruction.

EXAMPLE 1: RECOVER CODE

```
RECOVER  BCF STATUS, PA1
         BCF STATUS, PA0
         GOTO START
```

Please note that operation in a noisy environment is very application-dependent and may not affect the majority of the users. However, due to the presence of extra code space on the PIC16C58A, additional steps may have to be taken as mentioned above. Please check Appendix A for an example of the code implementation.

DATA MEMORY

Figure 5 and Figure 6 depict the data memory registers for the PIC16C54A and the PIC16C58A. Banks 1, 2 and 3, which are not present in the PIC16C54A, are R/W memory RAM locations on the PIC16C58A. These locations are accessed using the FSR<6:5> bits. On the PIC16C54A, these bit values are ignored. However, they are not cleared during a power-up reset on any PIC16C5XA device. Therefore, the FSR<6:5> bits on the PIC16C58A should be cleared at the very start of the program and always maintained in that manner during the course of the program.

Operating in a Noisy Environment

The FSR<6:5> bits can get corrupted due to noise or some external conditions just like the PA1:PA0 bits of program memory. As part of that recovery, the user should also clear the FSR<6:5> bits. Please see Appendix A for a code example.

SUMMARY

Code transfer from a PIC16C54A to a PIC16C58A may be accomplished easily by remembering the following points:

- The reset address has to be re-located from 1FFh to 7FFh.
- The PA1:PA0 bits of the STATUS register must be kept cleared.
- The FSR<6:5> bits must be kept cleared.

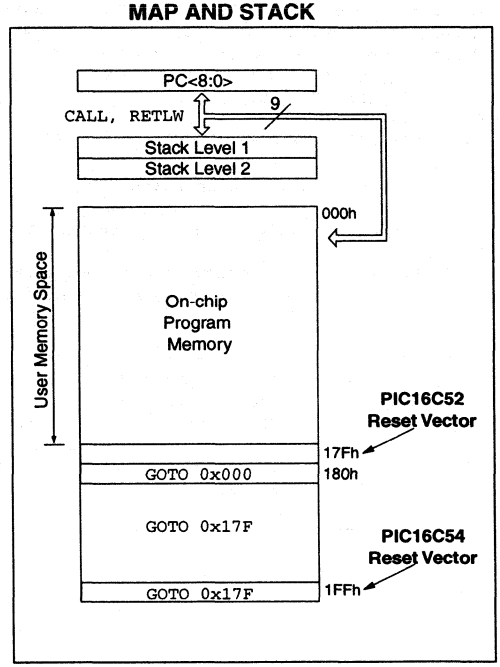
Code Development for the PIC16C52



Author: *Stan D'Souza*
Microchip Technolgoy Inc.

CODE DEVELOPMENT PROCEDURE

To develop code on a PIC16C52 device, a PIC16C54/JW part can be used. In order to use a PIC16C54/JW device, the following conditions should be followed:

1. A PIC16C54/JW has 512 words (0x1FF) of program memory, whereas a PIC16C52 has 384 bytes (0x17F) of program memory. The "extra" locations should be programmed as follows:
   a) Location 0x180 should be programmed with a "`GOTO 0x00`" instruction
   b) Locations 0x181 through 0x1FF should be programmed with a "`GOTO 0x17F`" instruction.
   See Figure 1 for details, and for a standard "skeleton" program, use the code in Example 1.
2. The PIC16C54/JW has a Watchdog Timer (WDT), while the PIC16C52 does not. Therefore, the WDT on the PIC16C54/JW must be disabled. The "__CONFIG" command used in Example 1 disables the WDT.
3. The PIC16C54/JW has four oscillator modes, while the PIC16C52 has two. Therefore, only RC and XT oscillator modes should be used. The "__CONFIG" command used in Example 1 takes care of programming the XT Oscillator mode, if required.

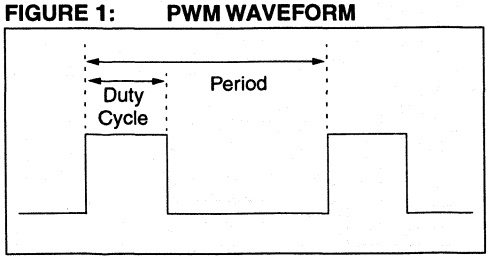
D/A Conversion Using PWM and R-2R Ladders to Generate Sine and DTMF Waveforms

Authors: Rob Stein and John Day
Microchip Technology Inc.

INTRODUCTION



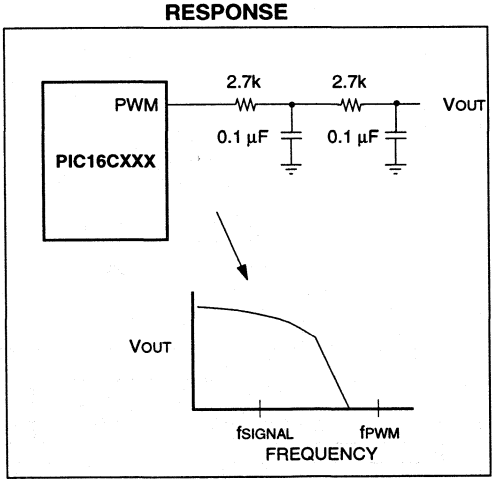
Many embedded applications require the generation of analog signals. Although separate D/A converter IC's exist on the market today, their extra price makes them prohibitive in cost sensitive embedded control designs. The following application note describes two DAC designs for generation of complex analog waveforms.: (PWM and R-2R Ladder). Both the Pulse Width Modulation (PWM) and resistor ladders require only a few external components to create a D/A converter with the PICmicro™ microcontroller series.

These techniques can be used to generate dual-tone multiplexed frequencies (DTMF) for telephone dialing, controlling the speed of a motor, generating sound and complex waveforms, and generating variable voltages in a power supply.

PULSE WIDTH MODULATION

Pulse Width Modulation (PWM) involves the generation of a series of pulses at a fixed period and frequency. The duty cycle defines the width of each pulse which is varied to generate waveforms. A simple low pass filter is then used to generate an output voltage directly proportional to the average time spent in the HIGH state (i.e., 50% duty cycle is equal to 2.5 volts when V_{DD} = 5.0V).

FIGURE 1: PWM WAVEFORM



This D/A technique is used to produce slow moving analog outputs (from 0 to 100's of Hz). The software `SINE.ASM`, written for the PIC16C620, produces a 60 Hz sine function at a 5-bit resolution (32 steps). For each step that is generated the software allows ~ 10 PWM cycles for the low pass to settle. The number of PWM cycles for the low pass to settle varies from one application to another. The designer should experiment with this value to find the most optimal number for the application. These two criteria (sine frequency and # of steps) lead to the required PWM frequency:

$$\begin{aligned} PWM_Freq &= (Sine_freq) \bullet (\#\ of\ steps) \bullet 10 \\ &= 60 \bullet 32 \bullet 10 \\ &= 19.2\ kHz \end{aligned}$$

A simple RC low pass filter is the only external component needed to complete the circuit. A two pole filter is used in the example to pass the 60 Hz signal while eliminating the step (1920 Hz) and the PWM (19 khz) frequencies.

FIGURE 2: RC FILTER FREQUENCY RESPONSE

For this application note a software implementation was used to generate the PWM due to it's inherent lower cost. If greater resolution or frequency is required, a PICmicro family microcontroller with a hardware PWM should be used.

The TMR0 interrupt is used to generate precise PWM transitions. The time to service this interrupt will limit the minimum and maximum duty cycle for the PWM and hence the min/max voltage that can be produced. Therefore the interrupt service routine has been written to use as few cycles as possible.

A table lookup technique is used to generate one period of a sine function. Other waveforms, such as DC voltage ramps, triangles, sounds etc., can be produced

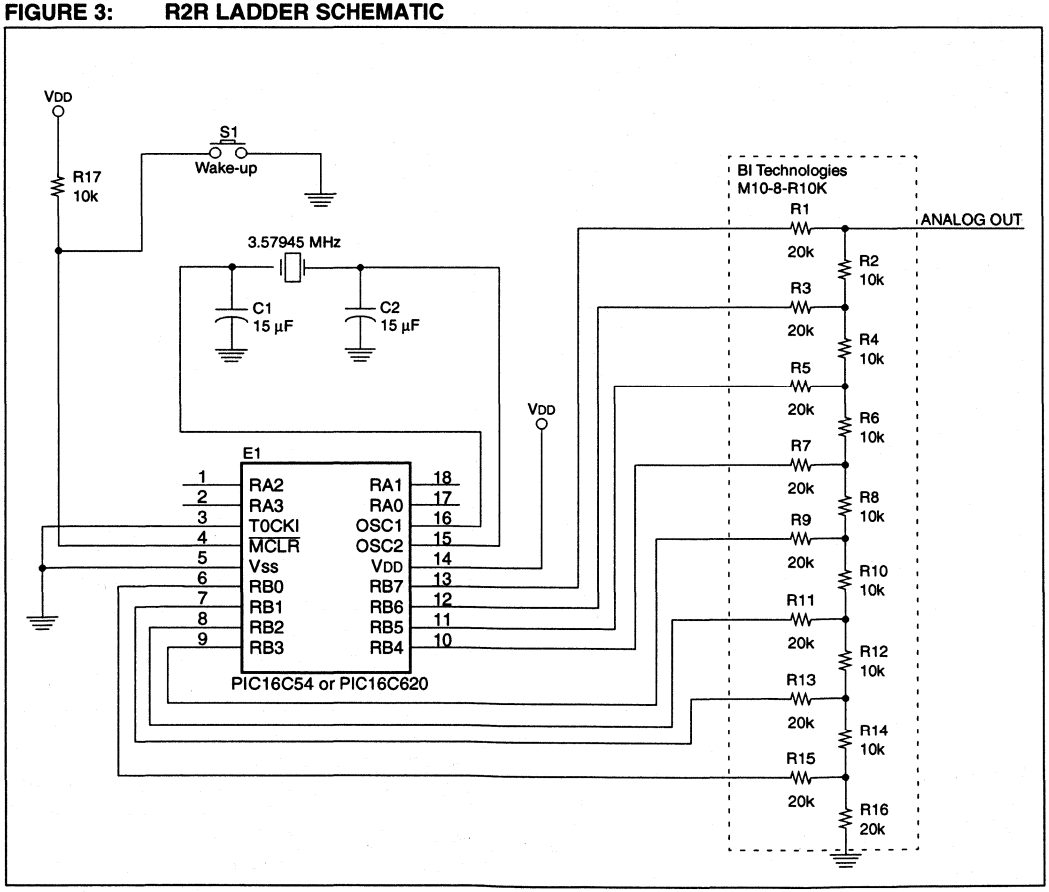
from this technique as well. The number of table entries is equal to the resolution required. The designer should carefully investigate the tradeoffs between PWM frequency, RC settling time, waveform resolution, and waveform frequency.

SINE.ASM SOURCE CODE



The `SINE.ASM` code example consists of four major code segments:

1. A main routine for counting and timing the 32 steps of the sine wave.
2. The `SetPWM` subroutine to pass a new PWM high and low counter value to the interrupt service routine at each step transition.
3. A table lookup to hold the 32 separate steps for the sine wave.
4. An interrupt service routine which creates the precise timing for the high and low PWM cycles.

R-2R LADDER

Many D/A converters are constructed with an internal resistor network driven by digital output drivers. The resistors are wired in a ladder fashion, with resistors of the same value being used for the rails, and resistors with 2x that value being used for the digital port outputs. Figure 3 shows the connection of a R2R ladder.

FIGURE 3: R2R LADDER SCHEMATIC

Implementation of a R2R ladder can be very inexpensive. BI Technologies sells a single SIP package for 8-bit and 10-bit R2R ladder networks. 8-bit R2R networks can also be manually constructed using 16 discrete resistors. Either way, R2R ladder networks have low EMI emissions, and reduced high frequency harmonics, eliminating the need for a low pass filter in most designs.

Microchip's microcontrollers have I/O pins with very low drive impedance (<75 Ohms at 5V) for both driving logic '1' and '0'. This allows direct connection to the R2R ladder without any external transistor drivers. To achieve 1 LSb accuracy using an 8-bit D/A, it is important to select resistors whose source impedance (in this case, 20k) is ≥ 256 times the driver source impedance.

To test the linearity of this design a +5V power supply was used. Each bit pattern was selected, then the output voltage was measured. The results show the transfer function in Figure 4.

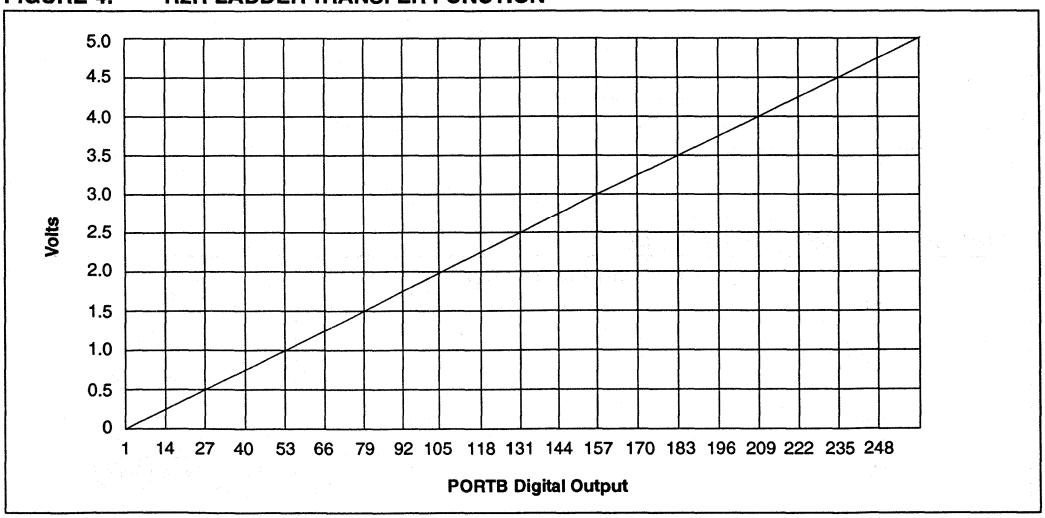
SINE WAVE FUNCTIONS

The simplest way to generate sine waves is through a lookup table. One simply needs to determine the maximum allowable distortion along with the maximum operating frequency. Using these two criteria, the number of sample points needed can be determined:

Sample points = 100 / (% allowable voltage step inaccuracy)

Sample time = (Sample Points) • (Frequency)

Example:



2 kHz Sine wave, <8% voltage step inaccuracy

Sample points = 100/5 = 20 points

Sample time = 20 • 2,000 = 40 kHz = 50 µs/Sample

To generate a single sine wave, the user simply needs to create a lookup table with the correct number of sample points. Next the software steps through each sample point and moves this value to the PORT output register, sending the correct voltage out of the R2R ladder. It is critical to ensure that the every sample point value be moved to the port output register using the same timing interval.

DTMF GENERATION

Many telecom applications, such as auto dialers, telephone keypads and security systems, require DTMF transmission for dialing and data transmission. Using the R2R ladder and seven sine lookup tables, an entire 12-key keypad of DTMF patterns can be generated with a 3.579545 MHz color burst crystal.

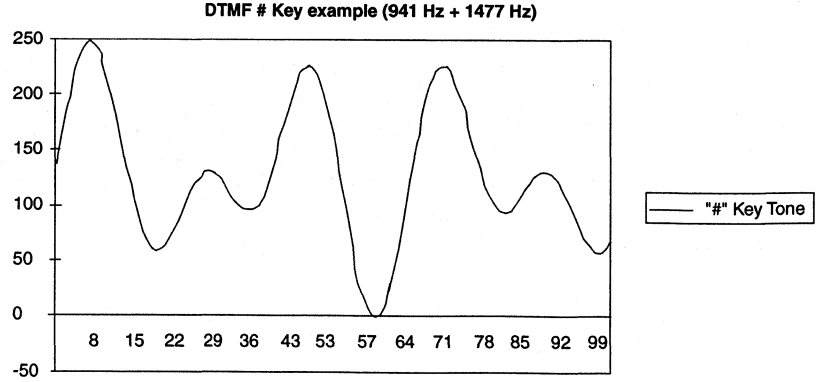
The DTMF standard was originally developed by Bell Labs for use by AT&T in telephone systems. There are several specifications that have fallen out of the original standard which come from AT&T, CEPT, CCITT, etc,. The variations from one standard to another are typically deviations in frequency tolerance, power, power difference between two tones, and speech immunity. The CCITT standard is located in Recommendations Q.23 and Q.24 in Section 4.3 of the CCITT Red Book, Volume VI, Fascicle VI.1. The other standards are listed in the References section at the end of this chapter.

A telephone keypad is broken up into 4 rows and 3 columns for a total of 12 keys. Each row and column is represented by a frequency; therefore, each key is uniquely represented by the sum of a row and column as follows:

TABLE 1: 12-KEY KEYPAD FREQUENCY

	1209	1336	1477
697	1	2	3
770	4	5	6
852	7	8	9
941	*	0	#

As an example, the '1' key is represented by a tone of 697 and 1209 Hz simultaneously.



DTMF.ASM SOURCE CODE EXAMPLE

The source code `DTMF.ASM` shows how to generate the complete DTMF table for all keys. The complete DTMF generation algorithm requires only 285 words of code space, including all 7 sine lookup tables. The first 220 words of code space is used for the 7 sine lookup tables. Each sine wave lookup table ends with a value of 127 decimal to show the end of the sine wave pattern. The next section contains a look-up table for each key number which is used to look-up the sine wave pattern frequency number.

The `senddtmf` routine is used to beep the DTMF for 320 ms. Prior to calling the `senddtmf` routine, the key's number is loaded into the W register. The sine wave addresses for that key are first calculated and the `WAVEABASE` and `WAVEBBASE` registers are loaded with the sine addresses. Next, each sine wave sample point is looked up and the sum of the two sine waves is moved to PORTB. Lastly, the pointer is reset to the sine base address if the value is equal to 127 decimal.

The test program loads each key into W and then calls `senddtmf`, showing all possible key patterns. The following figure shows a trace of the # key tones:

FIGURE 5: DTMF # KEY EXAMPLE

Note: This is a basic circuit. It is left to the designer to ensure that the final application conforms to the DTMF standard.

CONCLUSION

Using either PWM or R-2R ladder design techniques, many PICmicro microcontroller embedded designs will benefit from their low cost and component count. The following table compares the characteristics of the software and hardware PWM, R-2R ladder and external DAC design alternatives and their respective advantages and disadvantages.

TABLE 2: COST / PERFORMANCE TRADEOFF CHART

Cost / Performance Tradeoffs				
	S/W PWM	**H/W PWM**	**R2R Ladder**	**External DAC**
Cost	Low	Medium	Low	High
# of External Components	Low (1)	Low (1)	Low/Medium (2)	Low
I/Os Required	One	One	Eight (3)	Two/Nine (4)
Accuracy	Good (5)	Good (5)	Good (6)	Good/Excellent (7)
Resolution	Excellent (8)	Excellent (8)	Excellent (9)	Excellent (9)
Bandwidth	Low (10)	Low/Medium(10)	High	High
Harmonic Distortion	High	Medium	Low	Low

Note 1: One capacitor and one resistor for the low pass filter.
2: Multiply the required resolution times two for the number of external resistors or purchase one resistor SIP (16 resistors are required for 8-bit resolution).
3: The number of I/O's are directly proportional to resolution (8 I/O's for 8-bit resolution).
4: Separate DAC IC's are available with serial or parallel communication.
5: Absolute accuracy is dependent upon supply voltage.
6: Absolute accuracy is dependent upon supply voltage and resistor ladder tolerance.
7: Depends upon D/A reference source (supply voltage or a separate voltage reference).
8: Resolution is a dependent upon the PWM resolution.
9: Resolution is dependent upon the number of resistors in the ladder.
10: The waveform bandwidth is limited by the maximum PWM frequency and the settling time for the low pass filter. For an 8-bit resolution PWM the maximum frequency of operation is 19.5 kHz for a software PWM, and 80 kHz for a hardware PWM.

               00067 ;       This interrupt routine is entered via an overflow of TMR0 from
               00068 ;       0xFF to 0x00.  A test of RB1 determines if the next time state
               00069 ;       is a high or low cycle.  The next interrupt will occur based the
               00070 ;       TMR0 reload value (OUTLOW or OUTHIGH).
               00071 ;
               00072 ;       The interrupt routine was designed to use a minimial number of
               00073 ;       instruction cycles.  This was done to maximize the PWM duty cycle
               00074 ;       range (ie. a 5 % to 95 % range is achievable with this ISR).  Note
               00075 ;       that 'swapf' instructions are used to perform register moves without
               00076 ;       effecting the STATUS flags (this saves instruction cycles by
               00077 ;       eliminating the need to temporarily save the STATUS register).

Decoding Infrared Remote Controls Using a PIC16C5X Microcontroller

Author: William G. Grimm
Consultant

INTRODUCTION

For many years the consumer electronics industry has been employing infrared remote controls for the control of televisions, VCR's, and cable boxes. This same technology has recently started to appear in industrial applications to eliminate keypads.

Decoding most of the infrared signals can be easily handled by PIC16C5X microcontrollers. This application note describes how this decoding may be done.

The only mandatory hardware for decoding IR signals is an infrared receiver. The use of two types is described here. Both are modular types used often by the consumer electronics industry. The first type responds to infrared signals modulated at about 40 kHz. The second responds to non-modulated infrared pulses and has a restricted range. The hardware costs of each approach will be less than two dollars.

Three PIC16C5X application programs are described, and instructions on how they can be used to create an algorithm that can decode just about any remote control signal. Each PIC16C5X application program represents a step in mapping out a pre-existing infrared format. The final application is a fully implemented example of decoding and interpreting the infrared signals of a type of Teknika TV remote.

THE THREE LAYERS OF AN INFRARED SIGNAL

The typical infrared signal used by remote controls has three layers. The names used for these layers has not been standardized. In this application note they are called the infrared, the modulation, and the serial data.

The infrared layer is the means of transmission. Infrared is light whose wavelength is too long to see. Although you cannot see the infrared beam, it behaves the same as light, so if you cannot see the target device, you cannot control it with an infrared signal. To control around corners or through opaque materials, RF, usually UHF signals are used. Although this application note does not further mention RF, much of what is presented here can be used with an RF transmission medium.

The modulation layer refers to the fact that each burst of infrared signal is often modulated at a frequency between 32.75 kHz and 56.8 kHz. This is done to diminish the effects of ambient light. This layer, however, is optional. Some infrared formats do not modulate their outputs, sending pulses of unmodulated infrared light instead. This is done to extend the remote control's battery life and to reduce the cost of the remote control device.

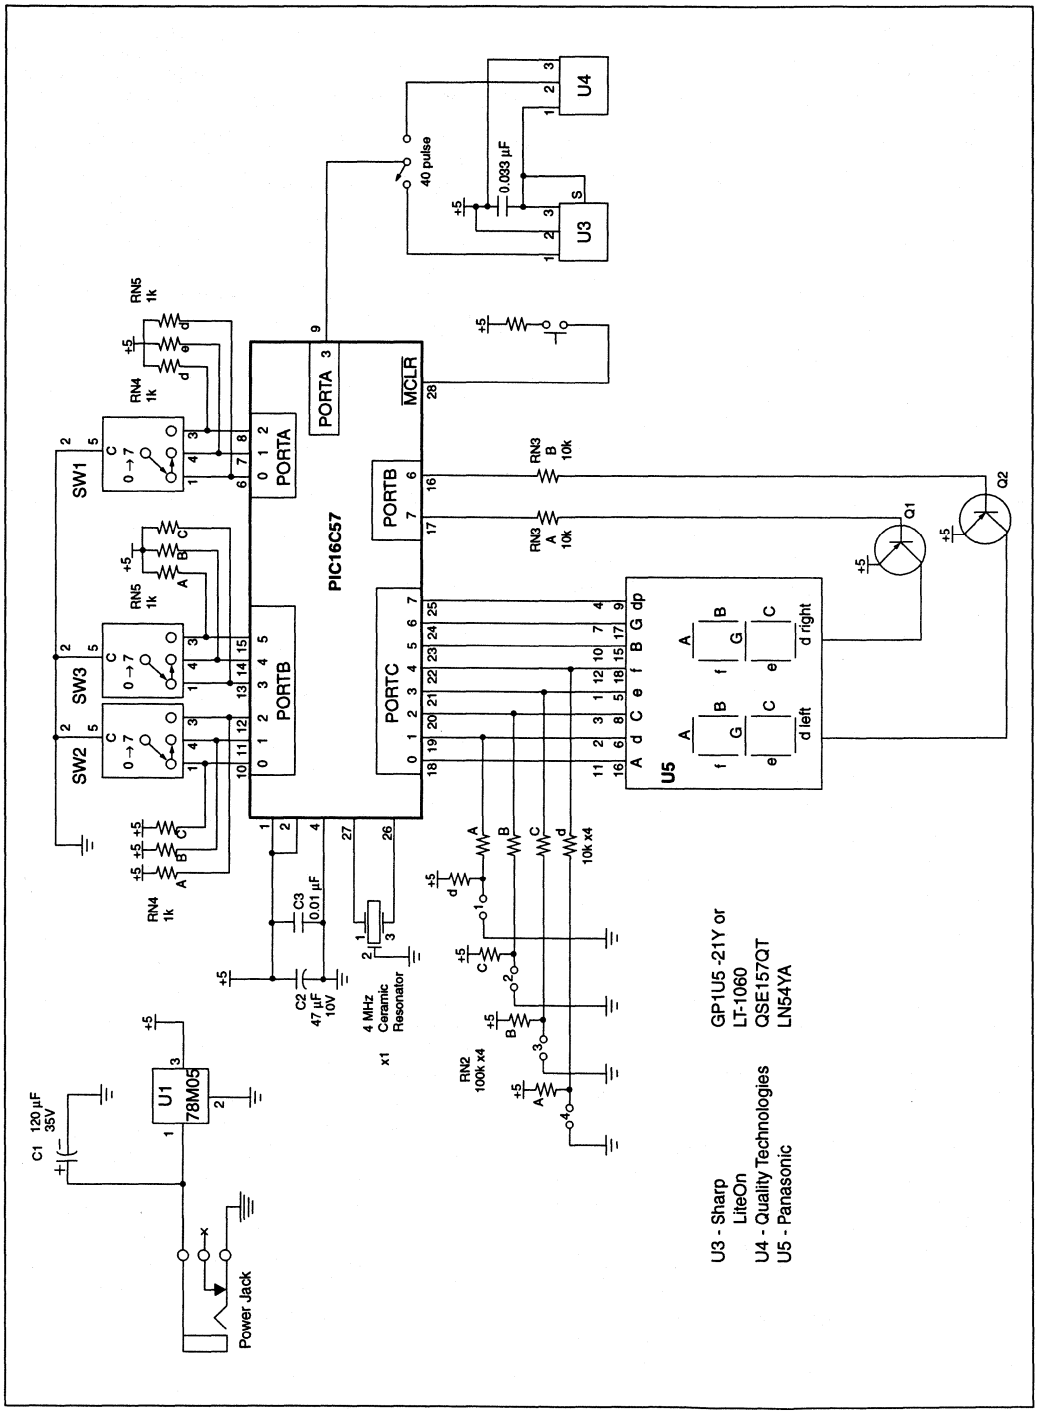
The serial data layer has the information containing a command. This is typically coded in the lengths of infrared bursts or in the lengths of gaps between infrared bursts. A long gap or burst is interpreted as a '1', a short gap or burst is interpreted as a '0'.

HARDWARE DESCRIPTION

The schematic in Figure 1 shows a tool that can be made to aid development of infrared receiver code. The schematic consists of a PIC16C57 connected to one of two available infrared receivers. One receiver is for non-modulated signals, the other for modulated signals. Modulated receivers are available from Sharp and LiteOn, part numbers GP1U521Y and LT-1060 respectively. The non-modulated type is available from Quality Technologies part number QSE157QT.

The choice of the PIC16C57 is not indicative of the processing power required for decoding. Typical IR receiver code can fit into less than half the ROM space available in a PIC16C54, and uses four RAM locations. The choice of a PIC16C57 in this case was driven by the need to store a lot of signal lengths for later reading.

A ceramic resonator clocks the PIC16C57. It will give adequate frequency accuracy to determine pulse and gap lengths. A RC network does not usually have adequate accuracy.



A button is available for resetting the PIC16C57, and four jumpers are provided to control the application start-up. The two digit display is multiplexed and driven through Q1 and Q2.

Three octal switches are used as inputs to control the OPTION register and which file is displayed.

The whole circuit derives its power from a 9V, 200 mA wall mounted supply. U1 regulates the 9V down to 5V for the PIC16C57 and associated circuitry.

DESCRIPTION OF SOFTWARE TO AID DEVELOPMENT

This application uses four different firmware files. IRMAIN.ASM controls the selection of the three application files. The first file is MEASURE.ASM which stores the infrared burst and gap lengths into memory and allows playback of that information. IR6121.ASM decodes NEC6121 infrared format and displays the received codes on the LED display. The final file, TECNICKA.ASM, shows the final firmware for decoding the infrared format for a Teknika Television.

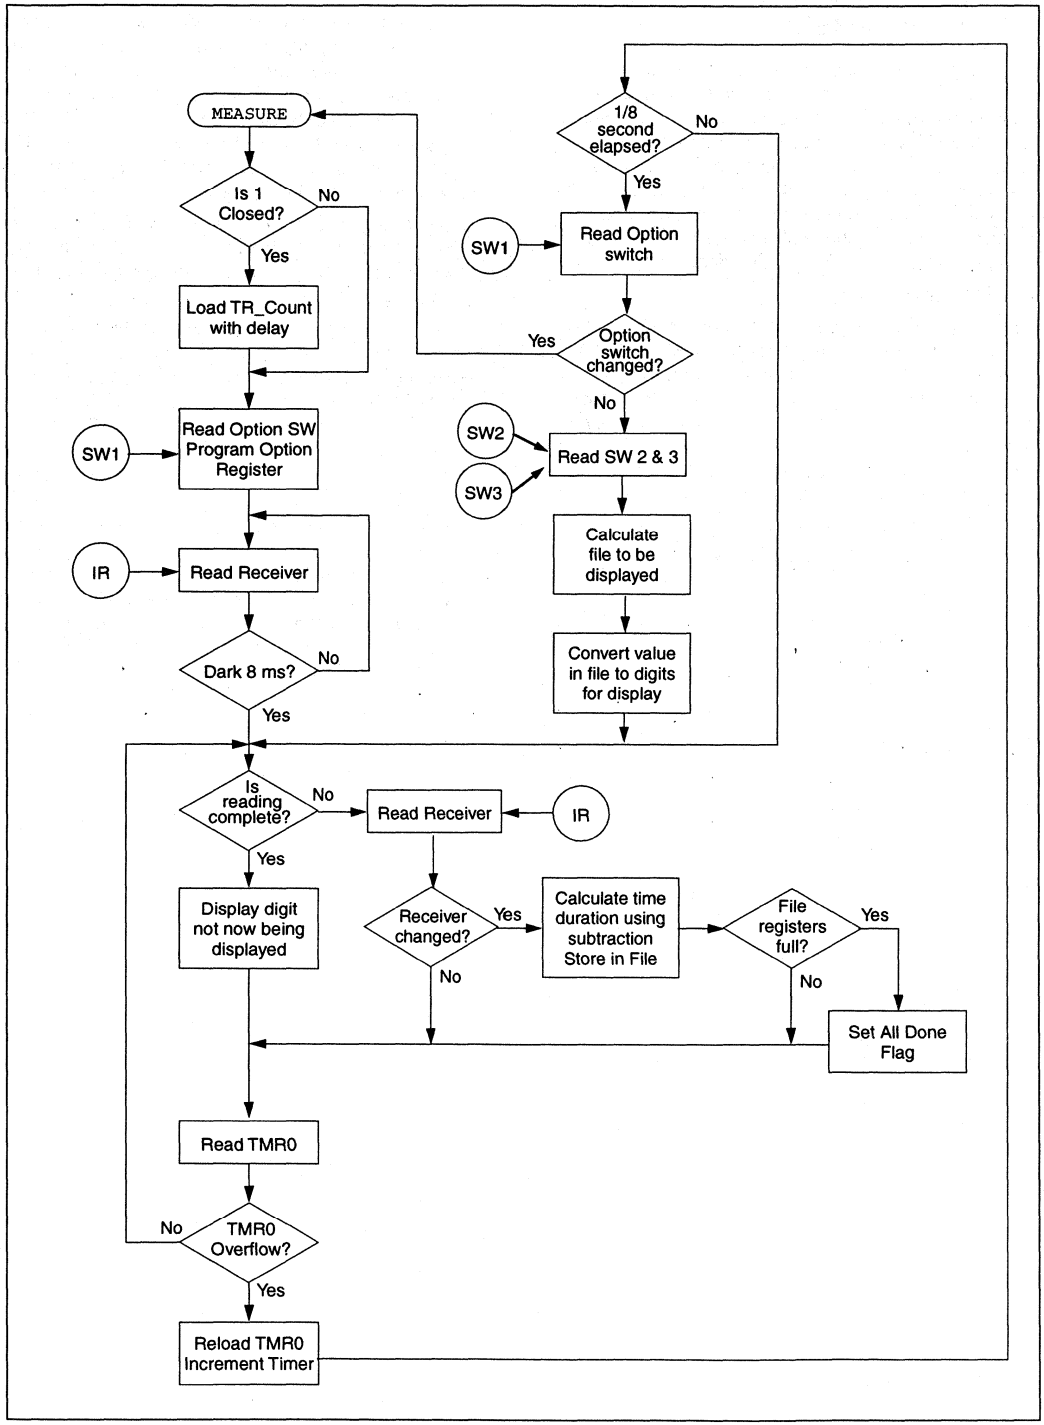
IRMAIN.ASM

The firmware listed includes three applications that will aid in designing an infrared control system. IRMAIN.ASM reads jumpers 1 and 2 and directs program flow after reset to one of the three applications. Having no jumper in 2 will direct program flow to MEASURE.ASM. A jumper in 2 only will direct program flow to IR6121.ASM. Jumpers in both 1 and 2 will direct program flow to TEKNIKA.ASM. Jumpers 3 and 4 are not used.

FIGURE 2: IRMAIN FLOWCHART

MEASURE.ASM

This is the most basic and most useful of the three applications. This program stores the infrared burst and gap lengths into memory, allowing playback of the measurements through the two digit display. It allows external control of the OPTION register also, through SW1. The setting of SW1 is read directly into the OPTION register prescaler value for TMR0. If SW1 is changed during program operation, the PIC16C57 resets.



Upon start-up a "hyphen" will be displayed in the left digit space until the infrared input settles to the dark logic indicating that the unit is ready to receive an infrared signal.

As an infrared signal comes in, the lengths of bursts of infrared, and the lengths of gaps between burst are stored in consecutive file locations until all four pages of the PIC16C57's memory files are filled. If a jumper had been in 1, the program throws away the first 32 pulse and gap lengths and starts storing pulse and gap lengths with the thirty third pulse length. This allows the decoding of very long formats.

When all four pages of file memory are filled with pulse and gap lengths, a number and decimal point are displayed. The decimal point indicates that the unit is done reading. The number is a gap or pulse length. SW2 and SW3 control the time sequence of the pulse or gap length displayed. These are in octal with SW3 being the more significant digit.

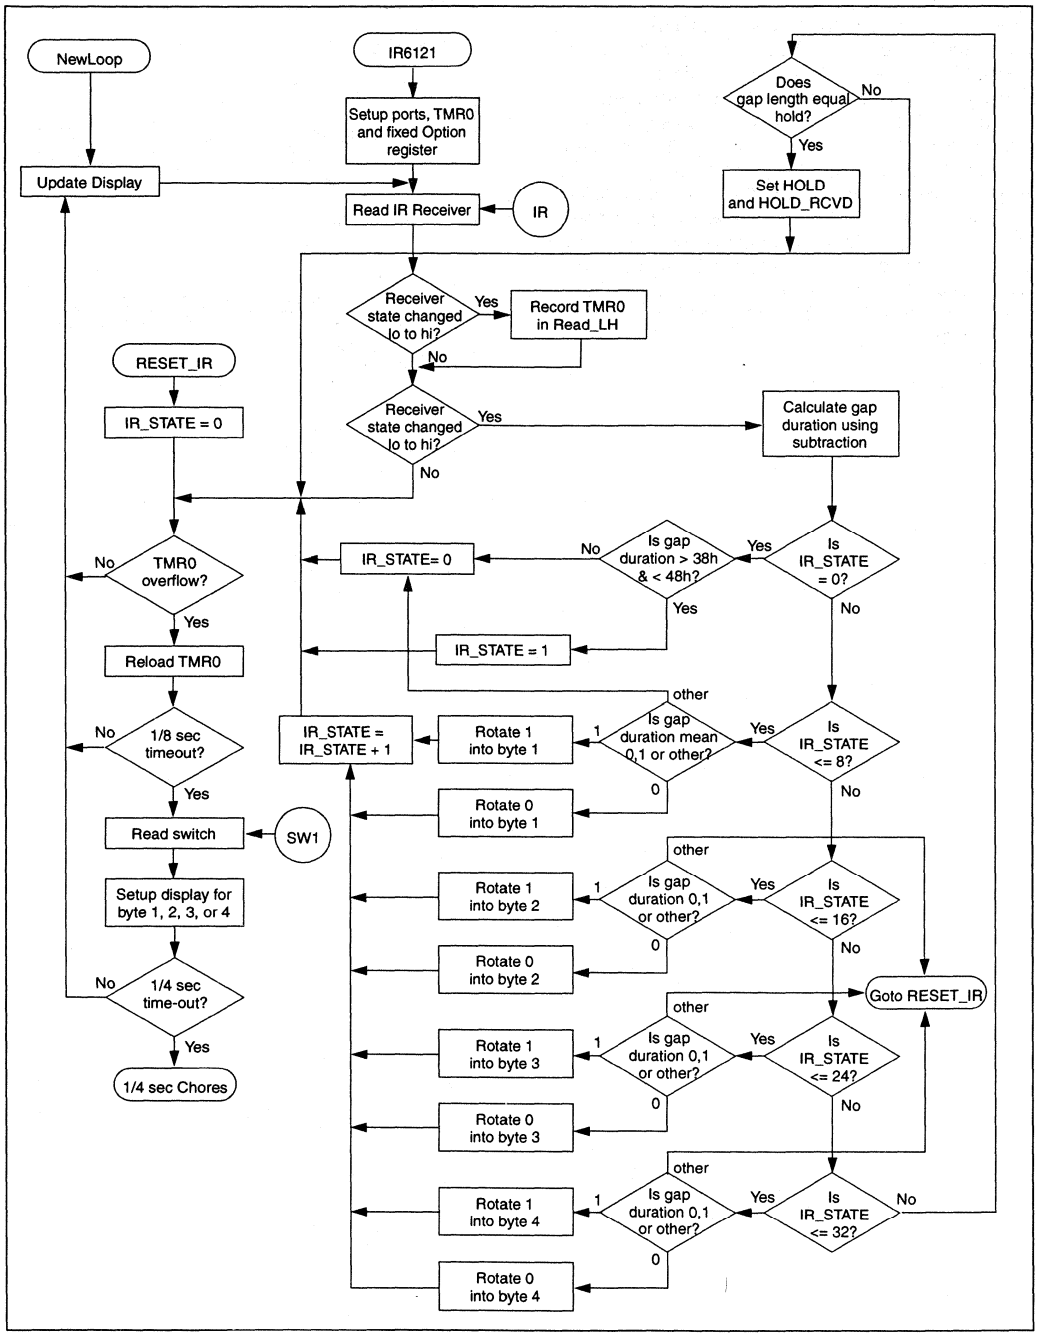
IR6121.ASM



This is an example of the next stage in development. It uses the IR receiver, PIC16C57 clock frequency, OPTION prescaler value and characteristic time length constants that were found after using MEASURE.ASM with an infrared remote control based on the NEC6121 infrared controller[1]. The resulting algorithm is able to decode the infrared bit stream and display it as four bytes on the two digit display. The bytes are switched using SW1 (changing it will not cause this application to reset). From it, or such a program customized to your particular remote control, a list can be made of how each button on a remote control resolves to a set of bytes in memory. This allows the creation of a button lookup table.

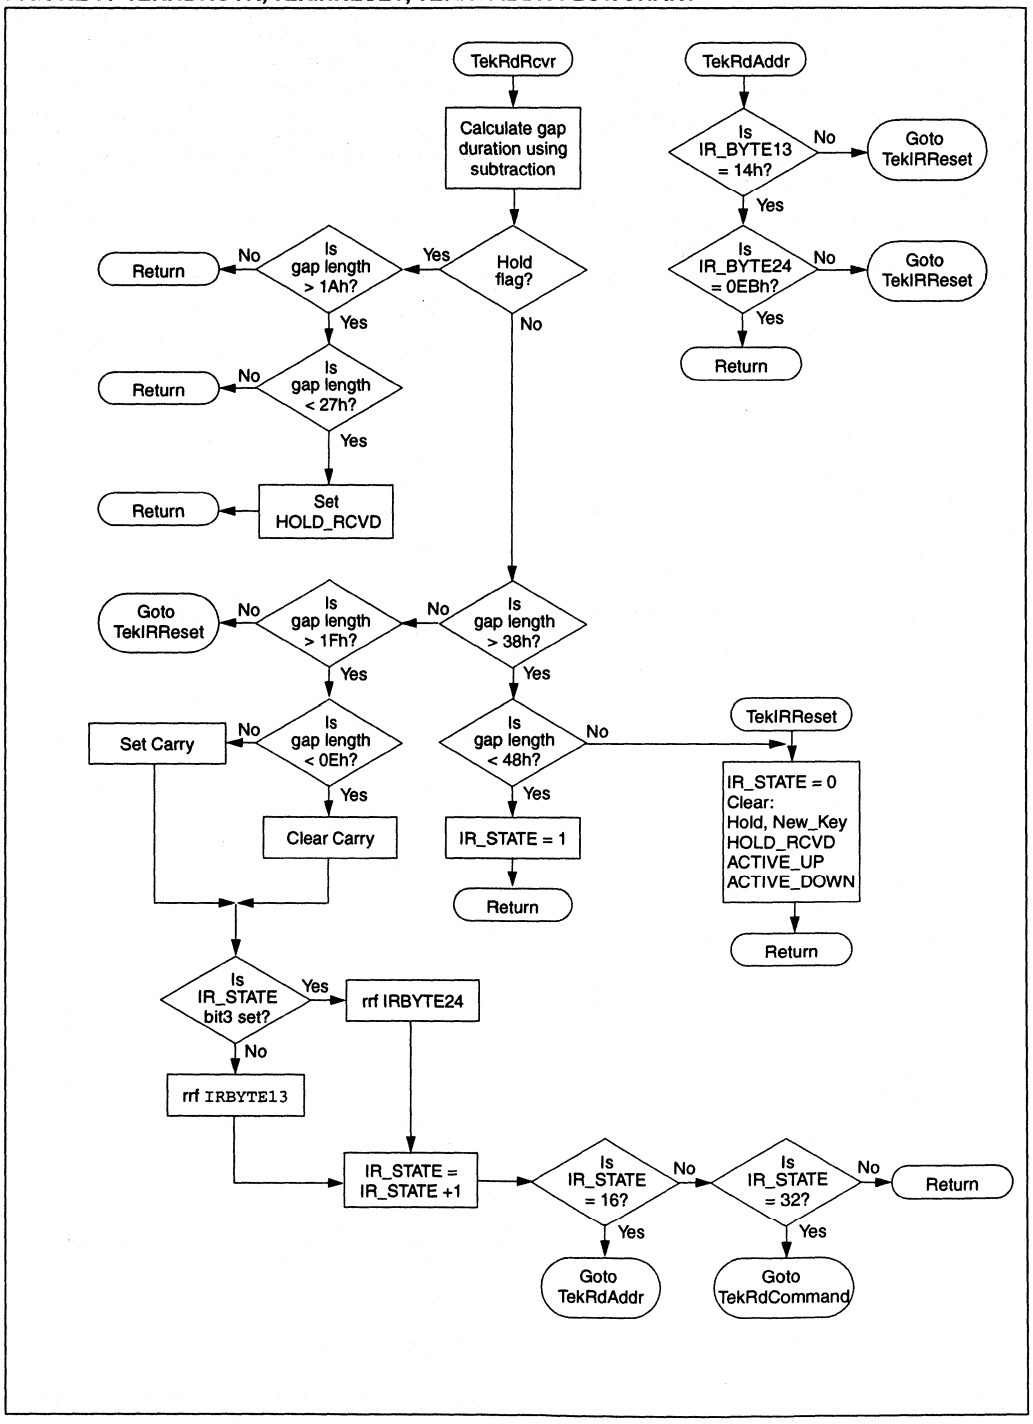
TEKNIKA.ASM

This is an example of a finished product. This program fully decodes the infrared format of a Teknika Television. When a number is pressed on the remote control it is displayed on the display. When channel up or channel down is pressed, the displayed number increases or decreases.



It incorporates the final step in implementing a remote control decoder, that of cross referencing codes to button numbers. The algorithm will only respond if the first two bytes are 14h and EBh, the characteristic of this type of Teknika television. Byte 3 and byte 4 are checked to see if they are complements. If so, byte 3 is sent through a lookup table to determine which button the received byte corresponds to, then the appropriate action is taken. The lookup table was made by using IR6121 and recording byte 3 with the button pressed. Similar tables can be made using other remote controls.

INSTRUCTIONS ON WRITING AN ALGORITHM TO DECODE IR REMOTES

1. To design a system that uses an infrared remote control, the first step is to choose a remote control. Self designed or off the shelf, modulated or unmodulated are the primary technical decisions.
2. Once a remote control has been chosen or designed, its modulation frequency, if it has one, must be determined. This controls the kind of hardware used to receive the infrared signal.
3. The next step is to determine the time-base of the data, that is, if the pulses and gaps are short or long in reference to the PIC16C57 clock. The OPTION switch, SW1, is used to get optimum length pulse and gap counts from TMR0. This defines the value of the OPTION prescaler.
4. Fourth, definition is made as to what, in the format, defines a '1', and what, in the format, defines a '0'. This could be gap counts, pulse counts, or a combination of both.
5. Fifth, determination is made of the full length of commands. This enables the determination as to whether a button is being held down or if a new command of the same type as previous is being issued.
6. The sixth step requires the writing of code. The code will resolve the gap and pulse lengths and command lengths into bits and bytes. Each button on the remote will decode to a unique series of bits.
7. The seventh and final step takes these codes that are received and converts them to button numbers or commands, using a lookup table.

Step 1: Choosing a remote control

Depending on your application, you may choose to have an off the shelf remote control or design one yourself. Typically they have small 4-bit microcontrollers in them, preprogrammed for a serial format. Some companies such as General Instrument sell them as complete units, others such as NEC sell the main component which can be customized by external diodes to not interfere with other applications. It is also possible to program a PIC16C57 to generate a signal that can be sent to an infrared LED for transmission. Yet another approach is to use a programmable remote control to generate any number of infrared formats and use them right off the shelf to control the target device.

Step 2: Determining a modulation frequency

For this and the next step the MEASURE.ASM program will be used. To start out, use the non-modulated receiver and a PIC16C57 running the MEASURE.ASM application. Select 1 on the option selector. Press a button until the decimal point comes on. Using the jumpers switch through the memorized pulse durations that the PIC16C57 will have stored in its memory.

If all of the reading except the first are below 40h, the infrared format is a modulating one. If half or more of the values show up as 0FFh, then the remote is non-modulating.

Step 3: Determine time-base

If the remote control is modulated, switch to a demodulating IR receiver. With the option selector still at 1, press a button on the remote control again until the decimal point comes on. The series of memorized pulse durations will now probably include a lot of FFh values. If so, move the Option selector up until the values are in the 7h to 1Fh range. The Option selector has the optimum value for the option divisor to be used in the TMR0 register.

To optimize range and reliability, several demodulating receivers may be tried. These are available from Sharp or LiteOn. The modulating frequencies that are presently used are 32.75 kHz, 35.0 kHz, 36.0 kHz, 36.7 kHz, 38 kHz, 39 kHz, 40 kHz, 41.7 kHz, 48 kHz, and 56.8 kHz[2]. The most common are round 40 kHz. The best match for your remote control will give the longest range and most consistent results.

Step 4: Decoding ones and zeros

The next step is to map out the characteristic pulse and gap lengths that represent ones and zeros. By pressing the same button on the remote, write down the series of numbers read by the PIC16C57 running the `MEASURE.ASM` program. Each odd numbered entry is the duration of a burst of IR from the remote control. Each even numbered entry is the duration of a gap between bursts of infrared. The lengths of these gaps and bursts define ones and zeros. Their order will depend on which button is pressed. Once the characteristic lengths have been discovered for a one and a zero, an algorithm can then be created with a counter to translate the lengths into ones and zeros.

Step 5: Finding the Command Length

Press the same button again. The command duration can also be found. This is necessary to determine if a button is being held down or a new command of the same type is being issued. Most remote controls repeat the command as long as the button is held down, the repetitions separated by a long dark time, usually 0FFh on an even numbered transition. If no long even numbered counts can be found, consider that some commands can be longer than 64 transitions. The option to delay counting is available for this reason. Insert jumper 1 and `MEASURE.ASM` will only start storing transition times after the 32nd transition.

Step 6: Translating lengths to bits

Once the characteristic lengths of ones and zeros have been found and the length of the typical command has been found, a program can then be written to decode

© 1997 Microchip Technology Inc.

these lengths to ones and zeros and display them on the two digit display. Also a HOLD flag can be created which will be true as long as the button is being held down. Usually 1/8 second between commands indicates a new command. Use this value to time out HOLD times and times between commands. IR6121.ASM is an example of a program that translates the gap lengths of the NEC6121 format to the four bytes that make up the information in each command.

Step 7: Create a button to code cross reference table

TEKNIKA.ASM implements a lookup table to translate the codes received to the actual button pressed. A counter is loaded with the highest number button that can be pressed, and the code is then looked up and compared with the code that was received. If no match, the counter is decremented until a match is found. When found, the counter then has the button number that was pressed.

Note too, that more checking may be done at this level on some formats, such as having an address, a complement of the code following the code itself for checking.

The result from all of the steps in decoding is that if a button is pressed on a remote control, that button number appears in a PIC16C57 file location. A command such as channel up or channel down will appear as two set flags, one to indicate the command, the other to indicate that it is active, HOLD. From this point the application can access these flags and files to respond appropriately.

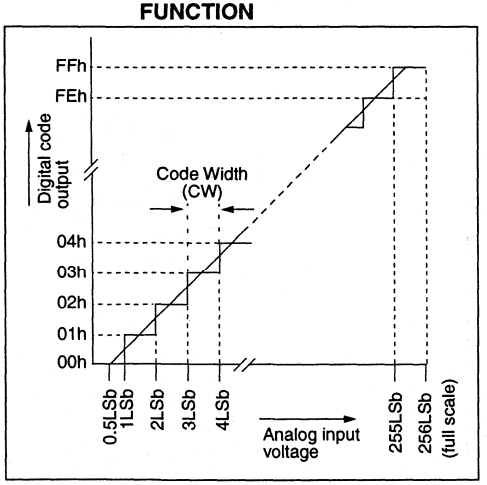
INTRODUCTION

This application note is intended for PIC16C7X users with some degree of familiarity with analog system design. The various sections discuss the following topics:



- Commonly used A/D terminology
- How to configure and use the PIC16C71 A/D
- Various ways to generate external reference voltage (VREF)
- Configuring the RA3:RA0 pins

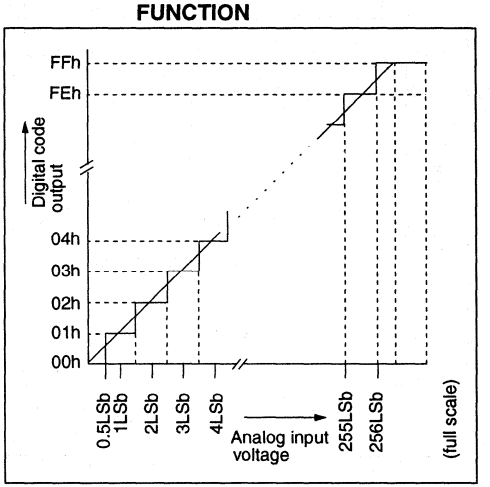
COMMONLY USED A/D TERMINOLOGY

The Ideal Transfer Function

In an A/D converter, an analog voltage is mapped into an N-bit digital value. This mapping function is defined as the transfer function. An ideal transfer is one in which there are no errors or non-linearity. It describes the "ideal" or intended behavior of the A/D. Figure 1 shows the ideal transfer function for the PIC16C7X A/D.

FIGURE 1: PIC16C7X IDEAL TRANSFER FUNCTION

Note that the digital output value is 00h for the analog input voltage range of 0 to 1LSb. In some converters, the first transition point is at 0.5LSb and not at 1LSb as shown in Figure 2. Either way, by knowing the transfer function the user can appropriately interpret the data.



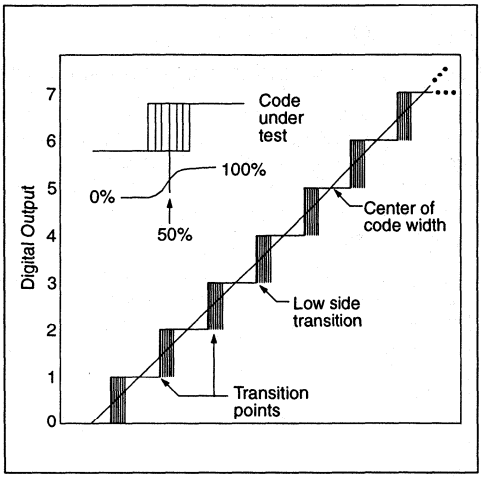
Transition Point

The analog input voltage at which the digital output switches from one code to the next is called the "Transition Point." The transition point is typically not a single threshold, but rather a small region of uncertainty (Figure 3). The transition point is therefore defined as the statistical average of many conversions. Stated differently, it is the voltage input at which the uncertainty of the conversion is 50%.

Code Width

The distance (voltage differential) between two transition points is called the "Code Width." Ideally the Code Width should be 1LSb (Figure 1).

FIGURE 2: ALTERNATE TRANSFER FUNCTION

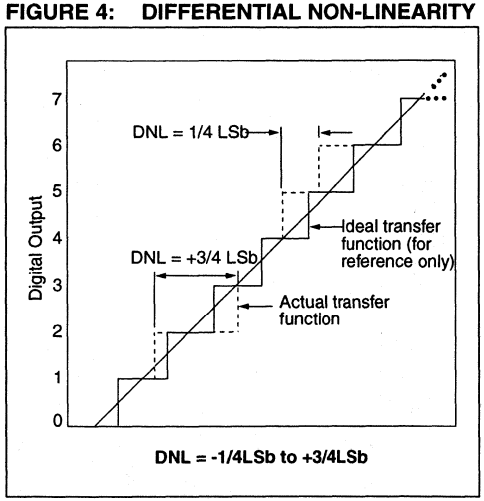


© 1997 Microchip Technology Inc.

Center of Code Width

The midpoint between two transition points is called the "Center of Code Width" (Figure 3).

FIGURE 3: TRANSITION POINTS



Differential Non-Linearity (DNL)

It is the deviation in code-width from 1LSb (Figure 4). The difference is calculated for each and every transition. The largest difference is reported as DNL.

It is important to note that the DNL is measured after the transfer function is normalized to match offset error and gain error.

Note that the DNL cannot be any less than -1LSb. In the other direction, DNL can be >1LSb.

FIGURE 4: DIFFERENTIAL NON-LINEARITY

Absolute Error

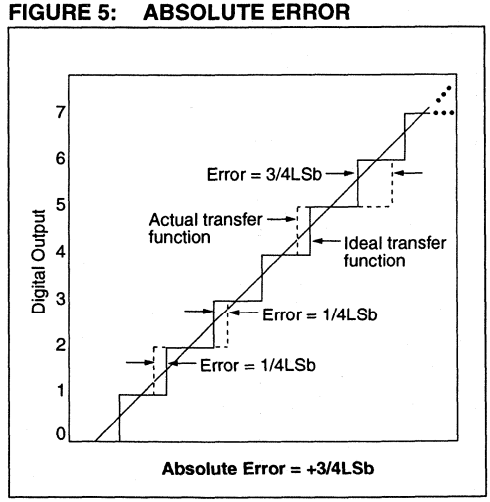
The maximum deviation between any transition point from the corresponding ideal transfer function is defined as the absolute error. This is how it is measured and reported in the PIC16C7X (Figure 5). The notable difference between absolute error and integral non-linearity (INL) is that the measured data is not normalized for full scale and offset errors in absolute error.

Absolute Error is probably the first parameter the user will review to evaluate an A/D. Sometimes absolute error is reported as the sum of offset, full-scale and integral non-linearity errors.

Total Unadjusted Error

Total Unadjusted Error is the same as absolute error. Again, sometimes it is reported as the sum of offset, full-scale and integral non-linearity errors.

No Missing Code



No missing code implies that as the analog input voltage is gradually increased from zero to full scale (or vice versa), all digital codes are produced. Stated otherwise, changing analog input voltage from one quantum of the analog range to the next adjacent range will not produce a change in the digital output by more than one code count.

Monotonic

Monotonicity guarantees that an increase (or decrease) in the analog input value will result in an equal or greater digital code (or less). Monotonicity does not guarantee that there are no missing codes. However, it is an important criterion for feedback control systems. Non-monotonicity may cause oscillations in such systems.

The first derivative of a monotonic function always has the same sign.

Ratiometric Conversion

Ratiometric Conversion is the A/D conversion process in which the binary result is a ratio of the supply voltage or reference voltage, the latter being equal to full-scale value by default. The PIC16C7X is a ratiometric A/D converter where the result depends on VDD or VREF.

In some A/Ds, an absolute reference is provided resulting in "absolute conversion".

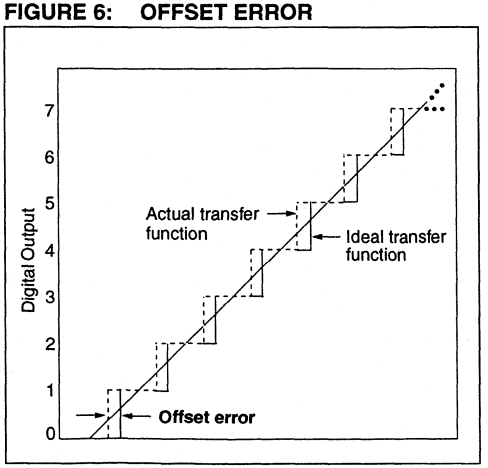
Sample and Hold

In sample and hold type A/D converters, the analog input has a switch (typically a FET switch in CMOS) which is opened for a short duration to capture the analog input voltage onto an on-chip capacitor. Conversion is typically started after the sampling switch is closed.

Track and Hold

Track and Hold is basically the same as sample and hold, except the sampling switch is typically left on. Therefore the voltage on the on-chip holding capacitor "tracks" the analog input voltage. To begin a conversion, the sampling switch is closed.

The PIC16C7X A/D falls in this category.



Sampling Time

Sampling Time is the time required to charge the on-chip holding capacitor to the same value as is on the analog input pin. The sampling time depends on the magnitude of the holding capacitor and the source impedance of the analog voltage input.

Offset Error (or Zero Error)

Offset Error is the difference between the first actual (measured) transition point and the first ideal transition point as shown in Figure 6. It can be corrected (by the user) by subtracting the offset error from each conversion result.

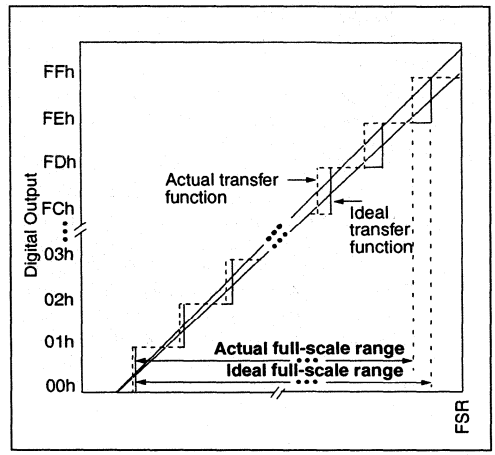


FIGURE 6: OFFSET ERROR

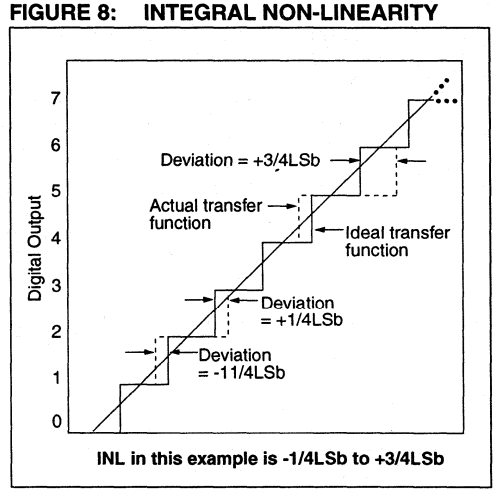
Full Scale Error (or Gain Error)

Full Scale Error is the difference between the ideal full scale and the actual (measured) full scale range (Figure 7). It is also called gain error, because the error changes the slope of the ideal transfer function creating a gain factor. It can be corrected (by the user) by multiplying each conversion result by the inverse of the gain.

FIGURE 7: FULL SCALE ERROR



Integral Non-Linearity (INL), or Relative Error

The deviation of a transition point from its corresponding point on the ideal transfer curve is called "Integral Non-Linearity" (Figure 8). The maximum difference is reported as the INL of the converter.

It is important to note that Full Scale Error and the Offset Error are normalized to match end transition points before measuring the INL.

FIGURE 8: INTEGRAL NON-LINEARITY

HOW TO USE THE PIC16C71 A/D

The A/D in the PIC16C71 is easy to set up and use. There are a few considerations:

1. Select either VDD or VREF as reference voltage. (More on using VREF input later)

   Select A/D conversion clock (TAD): 2TOSC, 8TOSC, TOSC or TRC (internal RC clock). For the first three options, make sure that TAD ≥ 2.0 µs. If deterministic conversion time is required, select TOSC time-base. If conversion during SLEEP is required, select TRC.
2. Channel Selection: If only one A/D channel is required, program the ADCON1 register to 03h. This configures the A/D pins as digital I/O. If multiple channels are required, prior to each conversion the new channel must be selected.
3. Sampling and Conversion: After a new channel is selected, a minimum amount of sampling time must be allowed before the GO/$\overline{\text{DONE}}$ bit in ADCON0 is set to begin conversion. Once conversion begins, it is OK to select the next channel, ***but sampling does not begin until current conversion is complete***. Therefore, it is always necessary to ensure the minimum sampling time is provided for:
   i) after a conversion
   ii) after a new channel is selected
   iii) after A/D is turned on (bit ADON = 1)
4. Reading Result: Completion of a conversion can be determined by polling the GO/$\overline{\text{DONE}}$ bit (cleared), or polling flag bit ADIF (set), or waiting for an ADIF interrupt.

Additional tips:

a) Do not set bits GO/$\overline{\text{DONE}}$ and ADON in the same instruction. First, turn the A/D is on by setting bit ADON. Then allow at least 5 µs before conversion begins (setting the GO/$\overline{\text{DONE}}$ bit), longer if sampling time requirement is not met within 5 µs.

b) Aborting a conversion: A conversion can be aborted by clearing bit GO/$\overline{\text{DONE}}$. The A/D converter will stop conversion and revert back to sampling state.

c) Using the ADRES register as a normal register: The A/D only writes to the ADRES register at the end of a conversion. Therefore, it is possible to use the ADRES register as a normal file register between conversions and when A/D is off.

The following four examples provide sample code on using the A/D module.

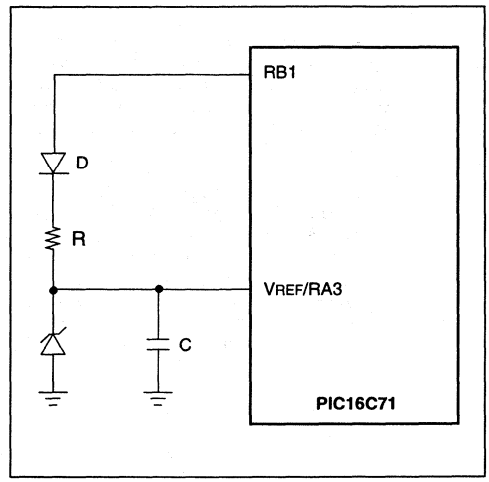
USING EXTERNAL REFERENCE VOLTAGE

When using the external reference voltage, keep in mind that any analog input voltage must not exceed VREF.

An inexpensive way to generate VREF is by employing a zener diode (Figure 9). Most common zener diodes offer 5% accuracy. Reverse bias current may be as low as 10 µA. However, larger currents (1 mA - 20 mA) are recommended for stability, as well as lower impedance of the VREF source.

FIGURE 9: LOW COST VOLTAGE REFERENCE



POWER MANAGEMENT IN USING VREF

In power sensitive applications, the user may turn on a VREF generator using another I/O pin (Figure 10). Drive a '1' on pin RB1, in this example, when using the A/D. Drive a '0' on pin RB1 when not using the A/D converter.

Note that this way RB1 is not floating. Even if VREF decays to some intermediate voltage, it will not cause the input buffer on RB1 to draw current.

Alternately, use RA0, RA1 or RA2 pin to supply the current instead of RB1. Configure the RA pin as analog (this will turn off its input buffer). Then use it as a digital output (Figure 11).

FIGURE 10: POWER-SENSITIVE APPLICATIONS #1

ZENERS AND REFERENCE GENERATORS

Finally, various reference voltage generator chips (typically using on-chip band-gap reference) are available. They are more accurate.

TABLE 1: ZENERS AND REFERENCE GENERATORS

VREF IMPEDANCE AND CURRENT SUPPLY REQUIREMENTS

Ideally, VREF should have as low a source impedance as possible. Referring to Figure 9, VREF source impedence ≈ R. However, smaller R increases current consumption. Since VREF is used to charge capacitor arrays inside the A/D converter and the holding capacitor, Chold ≈ 51 pF, the following guideline should be met:

$$TAD = 6(1k + R)51.2pF + 1.677\mu s$$

TAD = conversion clock. For TAD = 2 µs and for CHOLD = 50 pF, VREF ≈ 50Ω.

For VREF impedance higher than this, the conversion clock (TAD) should be increased appropriately.

FIGURE 11: POWER-SENSITIVE APPLICATIONS #2

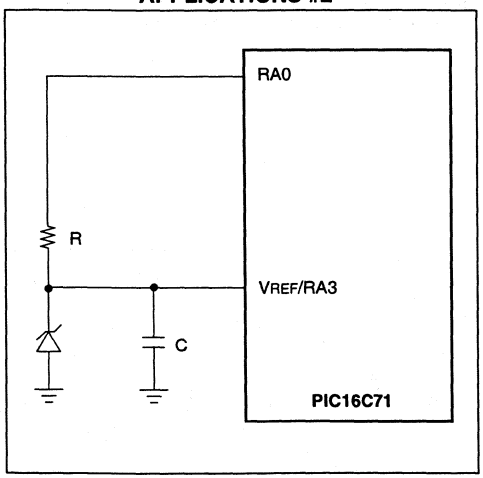

Table 2 gives examples of the maximum rate of conversion per bit, relating to the voltage reference impedance.

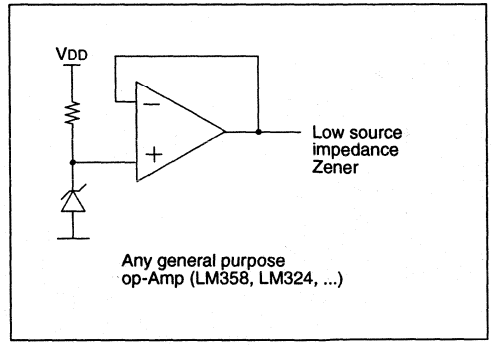

TABLE 2: MAXIMUM RATE OF CONVERSION / BIT

RVREF	TAD (Max)
1k	2.29 µs
5k	3.52 µs

To achieve a low source impedance when using a Zener diode, a voltage follower circuit is recommended. This is shown in Figure 12.

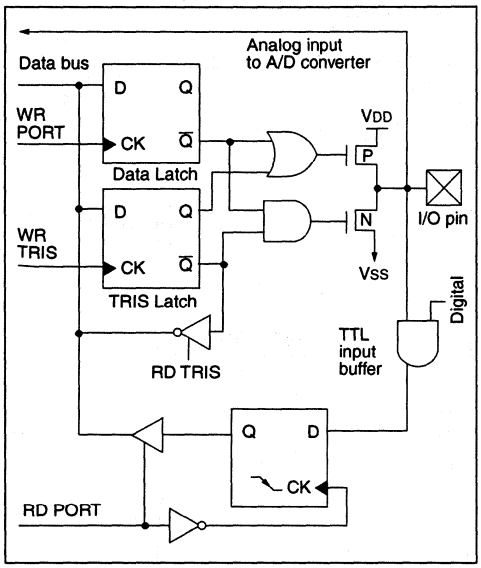
FIGURE 12: VOLTAGE FOLLOWER CIRCUIT

CONFIGURING PORTA INPUTS AS ANALOG OR DIGITAL

Two bits in the ADCON1 register, PCFG1 and PCFG0, control how pins RA3:RA0 are configured.

When any of these pins are selected as analog:

- The digital input buffer is turned off to save current (Figure 13). Reading the port will read this pin as '0'.
- The TRIS bit still controls the output buffer on this pin. So, normally the TRIS bit will be set (input).
- However, if the TRIS bit is cleared, then the pin will output whatever is in the data latch.



When any of these pins are selected as digital:

- The analog input still directly connects to the A/D and therefore the pin can be used as analog input.
- The digital input buffer is not disabled.

The user has, therefore, great flexibility in configuring these pins.

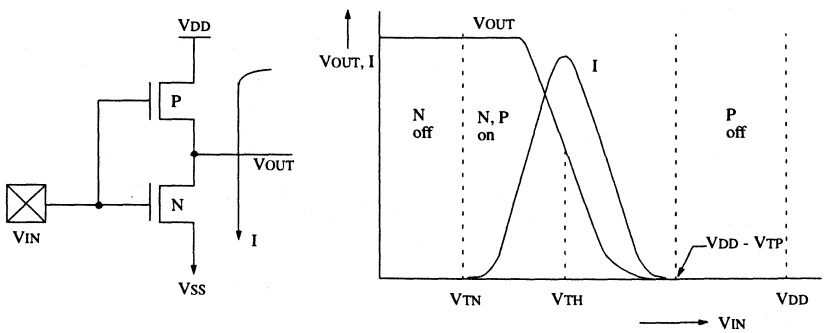
3

FIGURE 13: BLOCK DIAGRAM OF RA3:RA0 PINS

CURRENT CONSUMPTION THROUGH INPUT BUFFER

A CMOS input buffer will draw current when the input voltage is near its threshold (Figure 14).

In power-sensitive applications, the RA pins, when used as analog inputs, should be configured as "analog" to avoid unintended power drain.



Other considerations and tips:

1. If possible, avoid any digital output next to analog inputs.
2. Avoid digital inputs that switch frequently (e.g., clocks) next to analog inputs.
3. If VREF is used, then ensure that no analog pin being sampled exceeds VREF.

SUMMARY

The PIC16C71 A/D converter is simple to use. It is versatile and has low power consumption.

FIGURE 14: A SIMPLE CMOS INPUT BUFFER

VTH = Threshold of the inverter

VTN = Device threshold of NMOS pull-down

-VTP = Device threshold of PMOS pull-up

I = On-current (or through current) of the inverter

IMAX = Maximum on-current occurs when VIN = VTH. Value of IMAX depends on the sizes of the devices. The larger the devices, the faster the input buffer, and the larger the value of IMAX. Typically, IMAX is 0.2 mA – 1 mA.

Implementing Wake-up on Key Stroke

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

Microchip's PIC16CXXX microcontroller family are ideally suited to directly interface to a keypad. The high 4-bits of PORTB (RB7:RB4) have internal pull-ups and can trigger a "change on state" interrupt. This interrupt, if enabled, will wake the microcontroller from SLEEP. In most battery powered applications, a microcontroller is exercised when a key is pressed (e.g., in a remote keyless entry system). The life of the battery can be extended by using PIC16CXXX microcontrollers. This is done by putting the PIC16CXXX microcontroller into SLEEP mode for most of the time and wake-up only when a key is pressed.

IMPLEMENTATION

Figure 1 depicts an application where four keys are connected to RB7:RB4. Internal pull-ups are used to maintain a high level on these inputs. In this example, LEDs are connected to RB3:RB0. When SW1 is pressed, LED1 is turned on and when SW2 is pressed, LED2 is turned on and so on. The PIC16CXXX is normally in SLEEP mode with the "change on state" interrupt enabled. When SW1 is pressed, RB4 goes low and triggers an interrupt. Since the PIC16CXXX is in SLEEP, it first wakes up and starts executing code at the interrupt vector. Note that if the global interrupt is enabled, the program execution after an interrupt is at the interrupt vector, if the global interrupt is not enabled, the program starts executing the first line of code right after the `SLEEP` instruction.

After waking up, a 20 - 40 ms de-bounce delay is executed which checks the port for a key hit and, depending on which key is hit, its associated LED is turned on. The LEDs are used purely for demonstration purposes. In a remote keyless entry application, the remote code would be transmitted when the appropriate key is hit.

Figure 2 depicts a 4x4 keypad interface to a PIC16CXXX microcontroller. When using the PIC16CXXX in a keypad application, the internal pull-ups on RB7:RB4 can be enabled, eliminating the need for external pull-up resistors. The series 100Ω resistors are used for Electrostatic Discharge (ESD) protection, and are recommended in keypad interface applications.

SUMMARY

The PIC16CXXX is ideally suited to interface directly to a keypad application. Built in pull-up resistors and very low current consumption during sleep make it a very good candidate for battery powered remote operations and applications. Appendix A provides an example of the code.

                     00001 ;This program demonstrates the wake-up on Keystroke feature of
                     00002 ;the PIC16C71. Port B pins RB4 - RB7 can be configured as inputs with
                     00003 ;internal pull up resistors, also the interrupt associated with the
                     00004 ;change on input on RB4 - RB7 can be set up to wake the chip from
                     00005 ;sleep.  If the global interrupt is enabled just before sleep, the
                     00006 ;program will vector to the interrupt vector (0004). If not, the chip
                     00007 ;will continue execution just after the next instruction following
                     00008 ;sleep. In this example code, port B is initialized to input 4
                     00009 ;push-buttons at RB4 - RB7. RB0 - RB3 are configured to drive LEDs
                     00010 ;corresponding to which pushbutton is hit (LED on RB0 when RB4 is
                     00011 ;hit and so on). Sleep is executed. When any key is hit, the
                     00012 ;processor wakes up and jumps to the interrupt vector. The
                     00013 ;corresponding LED is turned on and after the key is released, the
                     00014 ;whole process is repeated.

Software Implementation of I²C™ Bus Master

Author: *Amar Palacherla*
Microchip Technology Inc.

INTRODUCTION

This application note describes the software implementation of I²C interface routines for the PIC16CXXX family of devices. Only the master mode of I²C interface is implemented in this application note. This implementation is for a single master communication to multiple slave I²C devices.

Some PIC16CXXX devices, such as the PIC16C64 and PIC16C74, have on-chip hardware which implements the I²C slave interface, while other PIC16CXXX devices, such as the PIC16C71 and PIC16C84, do not have the same on-chip hardware.

This application note does not describe the I²C Bus specifications and the user is assumed to have an understanding of the I²C Bus. For detailed information on the bus, the user is advised to read the I²C Bus Specification document from Philips/Signetics (order number 98-8080-575). The I²C Bus is a two-wire serial bus with multiple possible masters and multiple possible slaves connected to each other through two wires. The two wires consists of a clock line (SCL) and a data line (SDA) with both lines being bi-directional. Bi-directional communication is facilitated through the use of wire and connection (the lines are either active-low or passive high). The I²C Bus protocol also allows collision detection, clock synchronization and hand-shaking for multi-master systems. The clock is always generated by the master, but the slave may hold it low to generate a wait state.

In most systems the microcontroller is the master and the external peripheral devices are slaves. In these cases this application note can be used to attach I²C slaves to the PIC16CXXX (the master) microcontroller. The multi-master system is not implemented because it is extremely difficult to meet all the I²C Bus timing specifications using software. For a true slave or multi-master system, some interface hardware is necessary (like START & STOP bit detection).

In addition to the low level single master I²C routines, a collection of high level routines with various message structures is given. These high level macros/routines can be used as canned routines to interface to most I²C slave devices. As an example, the test program talks to two Serial EEPROMs (Microchip's 24LC04 and 24LC01).

IMPLEMENTATION

Two levels of software routines are provided. The low-level routines "`i2c_low.asm`" are provided in Appendix A and the high level routines "`i2c_high.asm`" are provided in Appendix B.

The messages passed (communicated on the two wire network) are abbreviated and certain notation is used to represent Start, Stop and other conditions. These abbreviations are described in Table 1.

TABLE 1: DESCRIPTION OF ABBREVIATIONS USED

Abbreviations	Explanation
S	Start Condition
P	Stop Condition
SlvAR	Slave Address (for read operation)
SlvAW	Slave Address (for write operation)
A	Acknowledge condition (positive ACK)
N	Negative Acknowledge condition (NACK)
D	Data byte, D[0] represents byte 0, D[1] represents second byte

© 1997 Microchip Technology Inc.

Message Format

In the high level routines, the basic structure of the message is given. Every I²C slave supports one or more message structures. For example, Microchip's 24LC04 Serial EEPROM supports the following message (to write a byte to Serial EEPROM at current address counter) S-SlvAW-A-D-A-P which basically means the following sequence of operations are required:

a) Send Start Bit
b) Send Slave Address for Write Operations
c) Expect Acknowledge
d) Send Data Byte
e) Expect Acknowledge
f) Issue a STOP Condition

Slave Address

Both 10-bit and 7-Bit addressing schemes are implemented as specified by the I²C Bus specification. Before calling a certain sub-routine (high level or low-level), the address of the slave being addressed must be loaded using either "LOAD_ADDR_8" (for 7-bit address slaves) or "LOAD_ADDR_10" macro (for 10-bit address slaves). These macros not only load the address of the slaves for all the following operations, but also setup conditions for 7- or 10-bit addressing modes. See the macros section for more details.

CLOCK STRETCHING

In the I²C Bus, the clock (SCL line) is always provided by the master. However, the slave can hold the line low even though the master has released it. The master must check this condition and wait for the slave to release the clock line. This provides a built-in wait state for the I²C Bus. This feature is implemented and can be turned on or off as an assembly time option (by configuring the _ENABLE_BUS_FREE_TIME flag to be TRUE or FALSE). If the clock is held low for too long, say 1 ms, then an error condition is assumed and a T0CKI interrupt is generated.

ARBITRATION

The I²C Bus specifies both bit-by-bit and byte mode arbitration procedures for multi-master systems. However, the arbitration is not needed in a single master system, and therefore is not implemented in this application note.

HARDWARE

Two I/O pins are used to emulate the Clock Line, SCL, and the Data Line, SDA. In the example test program, RB0 is used as the SCL line and RB1 as the SDA line. On initialization, these I/O lines are configured as input pins (tri-state) and their respective latches are loaded with '0's. To emulate the high state (passive), these lines are configured as inputs. To emulate the active low state, the pins are configured as outputs (with the assumption of having external pull-up resistors on both lines).

For devices that have the on-chip I²C hardware (SSP module), slope control of the I/O is implemented on the SCK and SDA pins. For software not implemented on the SCK and SDA pins of the SSP module, external components for slope control of the I/O may be required by the system.

I²C ROUTINES

Status Register (File Register "Bus_Status")

The bit definitions of the status register are described in the table given below. These bits reflect the status of the I²C Bus.

Bit #	Name	Description
0	_Bus_Busy	1 = Start Bit transmitted 0 = STOP condition
1	_Abort	It is set when a fatal error condition is detected. The user must clear this bit. This bit is set when the clock line, SCL, is stuck low.
2	_Txmt_Progress	1 = transmission in progress
3	_Rcv_Progress	1 = reception in progress
4	_Txmt_Success	1 = transmission successfully completed 0 = error condition
5	_Rcv_Success	1 = reception successfully completed 0 = error condition
6	_Fatal_Error	1 = FATAL error occurred (the communication was aborted).
7	_$\overline{\text{ACK}}$_Error	1 = slave sent $\overline{\text{ACK}}$ while the master was expecting an ACK. This may happen for example if the slave was not responding to a message.

Control Register (File Register "Bus_Control")

The bit definitions of the control register are described in the table given below. These bits must be set by the software prior to performing certain operations. Some of the high level routines described later in this section set these bits automatically.

Bit #	Name	Description
0	_10BitAddr	1 = 10-bit slave addressing 0 = 7-bit addressing.
1	_Slave_RW	1 = READ operation 0 = WRITE operation.
2	_Last_Byte_Rcv	1 = last byte must be received. Used to send $\overline{\text{ACK}}$.
3, 4, 5	—	Unused bits, can be used as general purpose bits.
6	_SlaveActive	A status bit indicating if a slave is responding. This bit is set or cleared by calling the I2C_TEST_DEVICE macro. See description of this I2C_TEST_DEVICE macro.
7	_TIME_OUT_	A status bit indicating if a clock is stretched low for more than 1 ms, indicating a bus error. On this time out, the operation is aborted.

Lower Level Routines

Function Name	Description
InitI2CBus_Master	Initializes Control/Status Registers, and set SDA & SCL lines. Must be called on initialization.
TxmtStartBit	Transmits a START (S) condition.
TxmtStopBit	Transmits a STOP (P) condition.
LOAD_ADDR_8	The 7-bit slave's address must be passed as a constant parameter.
LOAD_ADDR_10	The 10-bit slave's address must be passed as a constant parameter.
Txmt_Slave_Addr	Transmits a slave address. Prior to calling this routine, the address of the slave being addressed must be loaded using LOAD_ADDR_8 or LOAD_ADDR_10 routines. Also the Read/Write condition must be set in the control register.
SendData	Transmits a byte of data. Prior to calling this routine, the byte to be transmitted must be loaded into DataByte file register.
GetData	Receives a byte of data in DataByte file register. If the data byte to be received is the last byte, the _Last_Byte_Rcv bit in control register must be set prior to calling this routine.

MACROS

High Level

The high level routines are implemented as a mixture of function calls and macros. These high level routines call the low level routines described previously. In most cases only a few of the high level routines may be needed and the user can remove or not include the routines that are not necessary to conserve program memory space. Examples are given for a few functions.

I2C_TEST_DEVICE

Parameters : None

Purpose : To test if a slave is present on the network.

Description : Before using this macro, the address of the slave being tested must be loaded using LOAD_ADDR_8 or LOAD_ADDR_10 macro. If the slave under test is present, then "_SlaveActive" status bit (in Bus_Control file register) is set. If not, then this bit is cleared, indicating that the slave is either not present on the network or is not listening.

Message : S-SlvAW-A-P

Example :

```
LOAD_ADDR_8       0xA0                  ; 24LC04 address
I2C_TEST_DEVICE
btfss             _SlaveActive          ; See If slave is responding
goto              SlaveNotPresent       ; 24LC04 is not present
                                        ; Slave is present
                                        ; Continue with program
```

I2C_WR

Parameters : _BYTES_, _SourcePointer_

BYTES Number of bytes starting from RAM pointer _SourcePointer_

SourcePointer Data Start Buffer pointer in RAM (file registers)

Purpose : A basic macro for writing a block of data to a slave

Description : This macro writes a block of data (# of bytes = _BYTES_) to a slave. The starting address of the block of data is _SourcePointer_. If an error occurs, the message is aborted and the user must check Status flags (e.g. _Txmt_Success bit)

Message : S-SlvAW-A-D[0]-A.....A-D[N-1]-A-P

Example :

```
btfsc             _Bus_Busy             ; Check if bus is free
goto              $-1
LOAD_ADDR_8       _Slave_1_Addr
I2C_WR            0x09, DataBegin       ;
```

© 1997 Microchip Technology Inc.

I2C_WR_SUB

Parameters : _BYTES_, _SourcePointer_, _Sub_Address_
- _BYTES_ Number of bytes starting from RAM pointer _SourcePointer_
- _SourcePointer_ Data Start Buffer pointer in RAM (file Registers)
- _Sub_Address_ Sub-address of the Slave

Purpose : Write a block of data to a slave starting at slave's sub-addr

Description : Same as `I2C_WR` function, except that the starting address of the slave is also specified. For example, while writing to an I^2C Memory Device, the sub-addr specifies the starting address of the memory. The I^2C may prove to be more efficient than this macro in most situations. Advantages will be found for Random Address Block Writes for Slaves with Auto Increment Sub-addresses (like Microchip's 24CXX series Serial EEPROMs).

Message: S-SlvAW-A-SubA-A-D[0]-A.....A-D[N-1]-A-P

Example :

```
LOAD_ADDR_8   _Slave_2_Addr                ; Load addr of 7-bit slave
I2C_WR_SUB    0x08, DataBegin+1, 0x30
```

In the above example, 8 Bytes of data starting from addr (DataBegin+1) is written to 24LC04 Serial EEPROM beginning at 0x30 address

I2C_WR_SUB_SWINC

Parameters : _BYTES_, _SourcePointer_, _Sub_Address_
- _BYTES_ Number of bytes starting from RAM pointer _SourcePointer_
- _SourcePointer_ Data Start Buffer pointer in RAM (file Registers)
- _Sub_Address_ Sub-address of the Slave

Purpose : Write a block of data to a slave starting at slave's sub-addr

Description : Same as `I2C_WR_SUB` function, except that the sub-address (incremented) is sent after every data byte. A very inefficient message structure and the bus is given up after each data byte. This is useful for when the slave does not have an auto-increment sub-address feature.

Message : *S-SlvAW-A-(SubA+0)-A-D[0]-A-P*

I2C_WR_BYTE_MEM

Parameters : _BYTES_, _SourcePointer_, _Sub_Address_

BYTES	Number of bytes starting from RAM pointer _SourcePointer_
SourcePointer	Data Start Buffer pointer in RAM (file Registers)
_Sub_Address_	Sub-address of the Slave

Purpose : Write a block of data to a slave starting at slave's sub-address

Description : Same as `I2C_WR_SUB_SWINC`, except that a delay is added between each message. This is necessary for some devices, like EEPROMs, which accept only a byte at a time for programming (devices without on-chip RAM buffer) and after each byte a delay is necessary before a next byte is written.

Message :

S-SlvAW-A-(SubA+0)-A-D[0]-A-P
Delay 1 ms
S-SlvAW-A-(SubA+1)-A-D[1]-A-P

and so on until #of Bytes

I2C_WR_BUF_MEM

Parameters : _BYTES_, _SourcePointer_, _Sub_Address_, _Device_BUF_SIZE_

BYTES	Number of bytes starting from RAM pointer _SourcePointer_
SourcePointer	Data Start Buffer pointer in RAM (file Registers)
_Sub_Address_	Sub-address of the Slave
_Device_BUF_SIZE_	the slaves on-chip buffer size

Purpose : Write a block of data to a slave starting at slave's sub-addr

Description : This Macro/Function writes #of _BYTES_ to an I^2C memory device. However some devices, especially EEPROMs, must wait while the device enters into programming mode. But some devices have an on-chip temperature data hold buffer and is used to store data before the device actually enters into programming mode. For example, the 24C04 series of Serial EEPROMs from Microchip have an 8-byte data buffer. So one can send 8 bytes of data at a time and then the device enters programming mode. The master can either wait until a fixed time and then retry to program or can continuously poll for $\overline{ACK}$ bit and then transmit the next block of data for programming.

Message : `I2C_SUB_WR` operations are performed in loop and each time data buffer of BUF_SIZE is output to the device. Then the device is checked for busy and when not busy another block of data is written.

© 1997 Microchip Technology Inc.

I2C_READ

Parameters : _BYTES_, _DestPointer_

BYTES Number of bytes starting from RAM pointer _SourcePointer_

DestPointer Data Start Buffer pointer in RAM (file Registers)

Purpose : A basic macro for reading a block of data from a slave

Description : This macro reads a block of data (number of bytes = _BYTES_) from a slave. The starting address of the block of data is _DestPointer_. If an error occurs, the message is aborted and the user must check Status flags (e.g. _Rcv_Success bit). Note that on the last byte to receive, NACK is sent.

Message : S-SlvAR-A-D[0]-A-.....-A-D[N-1]-N-P

Example :

```
LOAD_ADDR_10    _Slave_3_Addr
I2C_READ_SUB    8, DataBegin
btfss           _Rcv_Success
goto            ReceiveError
goto            ReceiveSuccess
```

In the example above, 8 bytes of data is read from a 10-bit slave and stored in the master's RAM starting at address DataBegin.

© 1997 Microchip Technology Inc.

I2C_READ_SUB

Parameters : _BYTES_, _DestPointer_, _SubAddress

BYTES Number of bytes starting from RAM pointer _SourcePointer_
DestPointer Data Start Buffer pointer in RAM (file Registers)
SubAddress Sub-address of the slave

Purpose : A basic macro for reading a block of data from a slave

Description : This macro reads a block of data (# of bytes = _BYTES_) from a slave starting at slave's sub-address _SubAddress. The data received is stored in master's RAM starting at address _DestAddress. If an error occurs, the message is aborted and the user must check Status flags (e.g. _Rcv_Success bit).

This MACRO/Subroutine reads a message from a slave device preceded by a write of the sub-address between the sub-address write and the following reads, a STOP condition is not issued and a "REPEATED START" condition is used so that another master will not take over the bus, and also that no other master will overwrite the sub-address of the same slave. This function is very commonly used in accessing Random/Sequential reads from a memory device (e.g., 24CXX serial of Serial EEPROMs from Microchip).

Message : *S-SlvAW-A-SubAddr-A-S-SlvAR-A-D[0]-A-.....-A-D[N-1]-N-P*

Example :

```
LOAD_ADDR_10  _Slave_3_Addr
I2C_READ      8,  DataBegin, 0x60
btfss         _Rcv_Success
goto          ReceiveError
goto          ReceiveSuccess
```

In the example above, 8 bytes of data is read from a 10-bit slave (starting at address 0x60h) and stored in the master's RAM starting at address DataBegin.

I2C_READ_BYTE *or* I2C_READ_STATUS

Parameters : _DestPointer_

DestPointer Data Start Buffer pointer in RAM (file Registers)

Purpose : To read a Status Byte from Slave

Description : Several I^2C Devices can send a Status Byte upon reception of the control byte. This Macro reads a Status byte from a slave to the master's RAM location _DestPointer_. This function is basically the same as `I2C_READ` for a single byte read. As an example of this command, the 24Cxx serial Serial EEPROM from Microchip will send the memory data at the current location when `I2C_READ_STATUS` function is called. On successful operation of this command, W register = '1' else W register = '0' on errors.

I2C_WR_SUB_WR

Parameters : _Bytes1_, _SrcPtr1_, _SubAddr_, _Bytes2_, _SrcPtr2_

Bytes1	Number of bytes in the first data block
SrcPtr1	Starting address of first data block
SubAddr	Sub-address of the slave
Bytes2	Number of bytes in the second data block
SrcPtr2	Starting address of second data block

Purpose : To send two blocks of data to a slave at its sub address

Description : This Macro writes two blocks of data (of variable length) starting at slave's sub-address _SubAddr_. This Macro is essentially the same as calling `I2C_WR_SUB` twice, but a STOP bit is not sent in-between the transmission of the two blocks. This way the Bus is not given up.

This function may be useful for devices which need two blocks of data in which the first block may be an extended address of a slave device. For example, a large I^2C memory device, or a teletext device with an extended addressing scheme, may need multiple bytes of data in the first block that represents the actual physical address and is followed by a second block that actually represents the data.

Message : *S-SlvW-A-SubA-A-D1[0]-A-....-D1[N-1]-A-D2[0]-A-.....A-D2[M-1]-A-P*

I2C_WR_SUB_RD

Parameters : _Count1_, _SrcPtr_, _SubAddr_, _Count2_, _DestPtr_

Count1	Length of the source buffer
SrcPtr	Source pointer address
SubAddr	Sub-address of the slave
Count2	Length of the destination buffer
DestPtr	Address of destination buffer

Purpose : To send a block of data and then receive a block of data

Description : This macro writes a block of data (of length _Count1_) to a slave starting at sub-address _SubAddr_ and then reads a block of data (of length _Count2_) to the master's destination buffer (starting at address _DestPtr_). Although this operation can be performed using previously defined Macros, this function does not give up the bus in between the block writes and block reads. This is achieved by using the Repeated Start Condition.

I2C_WR_COM_WR

Parameters : _Count1_, _SrcPtr1_, _Count2_, _SrcPtr2_

Count1	Length of the first data block
SrcPtr1	Source pointer of the first data block
Count2	Length of the second data block
SrcPtr2	Source pointer of the second data block

Purpose : To send two blocks of data to a slave in one message.

Description : This macro writes a block of data (of length _Count1_) to a slave and then sends another block of data (of length _Count2_) without giving up the bus.

For example, this kind of transaction can be used in an I^2C LCD driver where a block of control and address information is needed and then another block of actual data to be displayed is needed.

Message : *S-SlvW-A-D1[0]-A-.....A-D1[N-1]-A-D2[0]-A-.....-A-D2[M-1]-A-P*

APPLICATIONS

The I^2C Bus is a simple two wire serial protocol for inter-IC communications. Many peripheral devices (acting as slaves) are available in the market with I^2C interface (e.g., serial EEPROM, clock/calendar, I/O Port expanders, LCD drivers, A/D converters). Although some of the PIC16CXXX devices do not have on-chip I^2C hardware interface, due to the high speed throughput of the microcontroller (250 ns @ 16 MHz input clock), the I^2C bus can be implemented using software.

00293 ;   This Macro/Function writes #of _BYTES_ to an I2C memory device. However
00294 ;   some devices, esp. EEPROMs must wait while the device enters into programming
00295 ;   mode. But some devices have an onchip temp data hold buffer and is used to
00296 ;   store data before the device actually enters into programming mode.
00297 ;   For example, the 24C04 series of Serial EEPROMs from Microchip
00298 ;   have an 8 byte data buffer. So one can send 8 bytes of data at a time
00299 ;   and then the device enters programming mode. The master can either wait

Software Implementation of Asynchronous Serial I/O

Author:	*Amar Palacherla* *Microchip Technology*
Code Update:	*Scott Fink* *Microchip Technology Inc.*

INTRODUCTION

PIC16CXXX microcontrollers from Microchip Technology, Inc., high-performance, EPROM-based 8-bit microcontrollers. Some of the members of this series (like the PIC16C71 and PIC16C84) do not have an on-chip hardware asynchronous serial port. This application note describes the interrupt driven software implementation of Asynchronous Serial I/O (Half Duplex RS-232 Communications) using PIC16CXXX microcontrollers. These microcontrollers can operate at very high speeds with a minimum of 250 ns cycle time (with input clock frequency of 16 MHz). To test the RS-232 routines, a simple Digital Voltmeter (DVM)/Analog Data Acquisition System has been implemented using a PIC16C71, in which, upon reception of a command from host (IBM PC-AT®), an 8-bit value of the selected A/D channel is transmitted back to the host.

IMPLEMENTATION

A half duplex, interrupt driven, software implementation of RS-232 communications, using a PIC16C71, is described in detail below. The transmit pin used in the example code is RB7 and the receive pin is connected to the RA4/T0CKI pin (Figure 2). Of course these pins are connected with appropriate voltage translation to/from RS-232/CMOS levels. Schematics describe the voltage translation in the hardware section of this application note.

Transmit Mode

Transmit mode is quite straight-forward to implement in software using interrupts. Once input clock frequency and baud rate are known, the number of clock cycles per bit can be computed. The on-chip Timer0 timer with its prescaler can be used to generate an interrupt on TMR0 overflow. This TMR0 overflow interrupt can be used as timing to send each bit. The Input clock frequency (`_ClkIn`) and Baud Rate (`_BaudRate`) are programmable by the user and the TMR0 time-out value (the period for each bit) is computed at assembly time. Whether the prescaler must be assigned to Timer0 or not is also determined at assembly time. This computation is done in the header file `rs232.h`. Note that very high speed transmissions can be obtained if transmission is done with "software delays" instead of being "every interrupt" driven, however, the processor will be totally dedicated to this job.

Transmission of a byte is performed by calling the `PutChar` function and the data byte in the TxReg is transmitted out. Before calling this function (`PutChar`), the data must be loaded into TxReg and ensure the serial port is free. The serial port is free when both the _txmtProgress and the _rcvOver bits are cleared (see description of these bits in the Serial Status/Control Reg table given later).

Summary of `PutChar` *function:*

1. Make sure _txmtProgress & _rcvOver bits are cleared
2. Load TxReg with data to be transmitted
3. Call `PutChar` function

Receive Mode

The reception mode implementation is slightly different from the transmit mode. Unlike the transmit pin (TX in the example code is RB7, but could be any I/O pin), the receive pin (RX) must be connected to pin RA4/T0CKI. This is because, in reception, the Start Bit, which is asynchronous in nature, must be detected. To detect the Start bit, when put in Reception mode, the Timer0 module is configured to Counter mode. The OPTION register is configured so the Timer0 module is put in Counter mode (increment on external clock on RA4/T0CKI Pin) and set to increment on the falling edge of pin RA4/T0CKI with no prescaler assigned. After this configuration setup, TMR0 (File Reg 1) is loaded with 0xFF. A falling edge on the T0CKI pin makes TMR0 roll over from 0xFF to 0x00, thus generating an interrupt indicating a Start Bit. The RA4/T0CKI pin is sampled again to make sure the transition on TMR0 is not a glitch. Once the start bit has been detected, the Timer0 module is reconfigured to increment on internal clock and the prescaler is assigned to it depending on input master clock frequency and the baud rate (configured same way as the transmission mode).

The software serial port is put in reception mode when a call is made to function `GetChar`. Before calling this function make sure the serial port is free (i.e., _txmtProgress and _rcvOver status bits must be '0'). On completion of a reception of a byte, the data is stored in RxReg and the _rcvOver bit is cleared.

Summary of `GetChar` *function:*

1. Make sure _txmtProgress & _rcvOver bits are cleared.
2. Call `GetChar` function.
3. The received Byte is in TxReg after the _rcvOver bit is cleared.

Parity Generation

Parity can be enabled at assembly time by setting the "_PARITY_ENABLE" flag to TRUE. If enabled, parity can be configured to either EVEN or ODD parity. In transmission mode, if parity is enabled, the parity bit is computed and transmitted as the ninth bit. On reception, the parity is computed on the received byte and compared to the ninth bit received. If a match does not occur the parity error bit is set in the RS-232 Status/Control Register (_ParityErr bit of SerialStatus reg). The parity bit is computed using the algorithm shown in Figure 1. This algorithm is highly efficient using the PIC16CXXX's `SWAPF` and `XORWF` instructions (with ability to have the destination as either the file register itself or the W register) and the sub-routine (called `GenParity`) is in file `txmtr.asm`.

FIGURE 1: AN EFFICIENT PARITY GENERATION SCHEME IN SOFTWARE

Assembly Time Options

The firmware is written as a general purpose routine and the user must specify the parameters shown in Table 1 before assembling the program. The Status/Control register is described in Table 2.

TABLE 1: LIST OF ASSEMBLY TIME OPTIONS

`_ClkIn`	Input clock frequency of the processor.
`_BaudRate`	Desired Baud Rate. Any valid value can be used. The highest baud rate achievable depends on input clock frequency. 600 to 4800 Baud was tested using a 4 MHz Input Clock. 600 to 19200 Baud was tested using a 10 MHz Input Clock. Higher rates can be obtained using higher input clock frequencies. Once the _BaudRate & _ClkIn are specified, the program automatically selects all the appropriate timings.
`_DataBits`	Can specify 1 to 8 data bits.
`_StopBits`	Limited to 1 Stop Bit. Must be set.
`_PARITY_ENABLE`	Parity Enable Flag. Configure it to TRUE or FALSE. If PARITY is used, then configure it to TRUE, else FALSE. See "_ODD_PARITY" flag description below.
`_ODD_PARITY`	Configure it to TRUE or FALSE. If TRUE, then ODD PARITY is used, else EVEN Parity Scheme is used. This Flag is ignored if _PARITY_ENABLE is configured to FALSE.
`_USE_RTSCTS`	RTS & CTS Hardware handshaking signals. If configured to FALSE, no hardware handshaking is used. If configured to TRUE, RTS & CTS use up 2 I/O Pins of PORTB.

TABLE 2: BIT ASSIGNMENT OF SERIAL STATUS/CONTROL REGISTER (SERIALSTATUS REG)

Bit #	Name	Description
0	_txmtProgress	1 = Transmission in progress. 0 = Transmission line free.
1	_txmtEnable	Set this bit on initialization to enable transmission. This bit may be used to abort a transmission. The transmission is aborted if in the middle of a transmission (i.e., when _txmtProgress bit is '1') _txmtEnable bit is cleared. This bit gets automatically set when the PutChar function is called.
2	_rcvProgress	1 = Middle of a byte reception. 0 = Reception of a byte (in RxReg) is complete and is set when a valid start bit is detected in reception mode.
3	_rcvOver	0 = Completion of reception of a byte. The user's code can poll this bit after calling the GetChar function and check to see if it is set. When set, the received byte is in RxReg. Other status bits should also be checked for any reception errors.
4	_ParityErr	1 = Parity error on reception (irrespective of Even Or Odd parity chosen). Not applicable if No Parity is used.
5	_FrameErr	1 = Framing error on reception.
6		Unused
7	_parityBit	The 9th bit of transmission or reception. In transmission mode, the parity bit of the byte to be transmitted is stored in this bit. In receive mode, the 9th bit (or parity bit) received is stored in this bit. Not Applicable if no parity is used.

Hardware

The hardware is primarily concerned with voltage translation from RS-232 to CMOS levels and vice versa. Three circuits are given below and the user may choose whichever best applies. The primary difference between each solution is cost versus number of components. Circuits in Figure 3 and Figure 4 are very low cost but have more components than the circuit in Figure 2. The circuit in Figure 2 interfaces to a RS-232 line using a single chip (MAX-232) and single +5V supply. The circuit in Figure 3 is a low cost RS-232 Interface but requires two chips and a single +5V supply source.

Figure 4 shows a very low cost RS-232 Interface to an IBM PC-AT with no external power requirements. The circuit draws power from the RS-232 line (DTR) and meets the spec of drawing power less than 5 mA. This requires that for the host to communicate it must assert lines DTR high and RTS low. The power is drawn from the DTR line and this requires that DTR be asserted high and must be at least 7V. The negative -5 to -10V required by LM339 is drawn from the RTS line and thus the host must assert RTS low. This circuit is possible because of the low current consumption of the PIC16C71 (typical 2 mA).

Test Program

To test the transmission and reception modules, a main program is written in which the PIC16C71 waits to receive a command from a host through the RS-232. On reception of a byte (valid commands are 0x00, 0x01, 0x02 & 0x03), the received byte is treated as the PIC16C71's A/D channel number and the requested channel is selected. An A/D conversion is started and when the conversion is complete (in about 20 µs) the digital data (8-bits) is transmitted back to the host. A Microsoft® Windows® program running on an IBM PC/AT was written to act as a host and collect the A/D data from the PIC16C71 via an RS-232 port. The Windows program (DVM.EXE) runs as a background job and displays the A/D data in a small window (similar to the CLOCK program that comes with MS Windows). The windows program and the PIC16C71 together act like a data acquisition system or a digital voltmeter (DVM). The block diagram of the system is shown in Figure 2. The input clock frequency is fixed at 4 MHz and RS-232 parameters are set to 1200 Baud, 8-bits, 1 Stop Bit and No Parity. The program during development stage was also tested at 1200, 2400, 4800 Baud Rates @ 4 MHz Input Clock and up to 19200 Baud @ 10 MHz input clock frequency (all tests were performed with No Parity, Even Parity and Odd Parity at 8 and 7 Data Bits).

Source Code

The PIC16CXXX source code along with the Microsoft Windows DVM Program (executable running on an IBM PC/AT under MS Windows 3.1 or higher) is available on Microchip's BBS. The assembly code for PIC16CXXX must be assembled using Microchip's Universal Assembler, MPASM. The code cannot be assembled using the older assemblers without significant modifications. It is suggested that user's who do not have the new assembler MPASM, change to the new version.

The MS Windows Program (DVM.EXE) runs under MS Windows 3.1 or higher. The program does not have any menus and shows up as a small window displaying A/D Data and runs as a background job. There are a few command line options which are described below.

-Px : x is the comm port number (e.g., - P2 selects COM2). Default is COM1.

-Cy : y is the number of A/D channels to display. Default is one channel (channel #1).

-Sz : z is a floating point number that represents the scaling factor (For example - S5.5 would display the data as 5.5*<8bit A/D>/256). The default value is 5.0 volts.

-S0 : will display the data in raw format without any scaling.

;
;  Description :
;               Half Duplex RS-232 Mode Is implemented in Software.
;               Both Reception & Transmission are Interrupt driven
;               Only 1 peripheral (TMR0) used for both transmission & reception
;               TMR0 is used for both timing generation (for bit transmission & bit polling)
;               and Start Bit Detection in reception mode.
;               This is explained in more detail in the Interrupt Subroutine.
;               Programmable Baud Rate (speed depending on Input Clock Freq.), programmable
;               #of bits, Parity enable/disable, odd/even parity is implemented.
;               Parity & Framing errors are detected on Reception
;
;                                   RS-232 Parameters
;
;The RS-232 Parameters are defined as shown below:
;
;               _ClkIn          :       Input Clock Frequency of the processor
;                                       NOTE : RC Clock Mode Is Not Suggested due to wide variations)
;               _BaudRate       :       Desired Baud Rate. Any valid value can be used.
;                                       The highest Baud Rate achievable depends on Input Clock Freq.
;                                       300 to 4800 Baud was tested using 4 Mhz Input Clock
;                                       300 to 19200 Baud was tested using 10 Mhz Input Clock
;                                       Higher rates can be obtained using higher Input Clock Frequencies.
;                                       Once the _BaudRate & _ClkIn are specified the program
;                                       automatically selects all the appropriate timings
;               _DataBits       :       Can specify 1 to 8 Bits.
;               _StopBits       :       Limited to 1 Stop Bit. Must set it to 1.
;               _PARITY_ENABLE  :       Parity Enable Flag. Set it to TRUE or FALSE. If PARITY
;                                       is used, then set it to TRUE, else FALSE. See "_ODD_PARITY" flag
;                                       description below
;               _ODD_PARITY     :       Set it to TRUE or FALSE. If TRUE, then ODD PARITY is used, else
;                                       EVEN Parity Scheme is used.
;                                       This Flag is ignored if _PARITY_ENABLE is set to FALSE.
;
;
;  Usage :
;               An example is given in the main program on how to Receive & Transmit Data
;               In the example, the processor waits until a command is received. The command is interpreted
;               as the A/D Channel Number of PIC16C71. Upon reception of a command, the desired A/D channel
;               is selected and after A/D conversion, the 8 Bit A/D data is transmitted back to the Host.
;
;                       The RS-232 Control/Status Reg's bits are explained below :
;
;       "SerialStatus"          : RS-232 Status/Control Register
;
;       Bit 0   :       _txmtProgress   (1 if transmission in progress, 0 if transmission is
;                                       complete) After a byte is transmitted by calling "PutChar" function
;                                       the user's code can poll this bit to check if transmission is
;                                       This bit is reset after the STOP bit has been transmitted complete.
```

```
;       Bit 1   :       _txmtEnable     Set this bit to 1 on initialization to enable transmission.
;                                       This bit can be used to Abort a transmission while the
;                                       transmitter is in progress (i.e when _txmtProgress = 1)
;       Bit 2   :       _rcvProgress    Indicates that the receiver is in middle of reception.
;                                       It is reset when a byte is received.
;       Bit 3   :       _rcvOver        This bit indicates the completion of Reception of a Byte. The
;                                      user's code can poll this bit after calling "GetChar" function.Once
;                                       "GetChar" function is called, this bit is 1 and clear to 0 after
;                                       reception of a complete byte (parity bit if enabled & stop bit)
;       Bit 4   :       _ParityErr      A 1 indicates Parity Error on Reception (both even & odd parity)
;       Bit 5   :       _FrameErr       A 1 indicates Framing Error On Reception
;
;       Bit 6   :       _unused_        Unimplemented Bit
;
;       Bit 7   :       _parityBit      The 9th bit of transmission or reception (status of PARITY bit
;                                       if parity is enabled)
;
;       To Transmit A Byte Of Data :
;                       1) Make sure _txmtProgress & _rcvOver bits are cleared
;                       2) Load TxReg with data to be transmitted
;                       3) CALL  PutChar function
;
;       To Receive A Byte Of Data :
;                       1) Make sure _txmtProgress & _rcvOver bits are cleared
;                       2) CALL GetChar function
;                       3) The received Byte is in TxReg after _rcvOver bit is cleared

;                               Interrupt Service Routine
;
; Only TMR0 Interrupt Is used. TMR0 Interrupt is used as timing for Serial Port Receive & Transmit
; Since RS-232 is implemented only as a Half Duplex System, The TMR0 is shared by both Receive &
; Transmit Modules.
;       Transmission :
;                       TMR0 is setup for Internal Clock increments and interrupt is
;                       generated whenTMR0 overflows. Prescaler is assigned, depending on The
;                       INPUT CLOCK & the desired BAUD RATE.
;       Reception :
;                       When put in receive mode, TMR0 is setup for external clock mode
;                       (FALLING EDGE) and preloaded with 0xFF. When a Falling Edge is
;                       detected on T0CKI Pin, TMR0 rolls over and an Interrupt is generated
;                       (thus Start Bit Detect). Once the start bit is detected, TMR0 is
;                       changed to INTERNAL CLOCK mode and TMR0 is preloaded with a certain
;                       value for regular timing interrupts to Poll T0CKI Pin (i.e RX pin).

                     0014 ;                Half Duplex RS-232 Mode Is implemented in Software.
                     0015 ;                Both Reception & Transmission are Interrupt driven
                     0016 ;                Only 1 peripheral (Timer0) used for both transmission & reception
                     0017 ;                TimerR0 is used for both timing generation (for bit transmission & bit polling)
                     0018 ;                and Start Bit Detection in reception mode.
                     0019 ;                This is explained in more detail in the Interrupt Subroutine.
                     0020 ;                Programmable Baud Rate (speed depnding on Input Clock Freq.), programmable
                     0021 ;                #of bits, Parity enable/disable, odd/even parity is implemented.
                     0022 ;                        Parity & Framing errors are detected on Reception
                     0023 ;
                     0024 ;                                  RS-232 Parameters
                     0025 ;
                     0026 ;The RS-232 Parameters are defined as shown below:
                     0027 ;
                     0028 ;                _ClkIn          :       Input Clock Frequency of the processor
                     0029 ;                                        (NOTE : RC Clock Mode Is Not Suggested due to wide variations)
                     0030 ;                _BaudRate       :       Desired Baud Rate. Any valid value can be used.
                     0031 ;                                        The highest Baud Rate achievable depends on Input Clock Freq.
                     0032 ;                                        300 to 4800 Baud was tested using 4 Mhz Input Clock
                     0033 ;                                        300 to 19200 Baud was tested using 10 Mhz Input Clock
                     0034 ;                                        Higher rates can be obtained using higher Input Clock Frequencies.
                     0035 ;                                        Once the _BaudRate & _ClkIn are specified the program
                     0036 ;                                        automatically selectes all the appropiate timings

0043 ;                                    EVEN Parity Scheme is used.
0044 ;                                    This Flag is ignored if _PARITY_ENABLE is set to FALSE.
0045 ;
0046 ;
0047 ;  Usage :
0048 ;              An example is given in the main program on how to Receive & Transmit Data. In the
0049 ;              example, the processor waits until a command is received. The command is interpreted as
0050 ;              the A/D Channel Number of PIC16C71. Upon reception of a command, the desired A/D channel
0051 ;              is selected and after A/D conversion, the 8 Bit A/D data is transmitted back to the Host.
0052 ;
0053 ;                       The RS-232 Control/Status Reg's bits are explained below :
0054 ;
0055 ;       "SerialStatus"          : RS-232 Status/Control Register
0056 ;
0057 ;       Bit 0   :       _txmtProgress   (1 if transmission in progress, 0 if transmission is complete)
0058 ;                                       After a byte is transmitted by calling "PutChar" function, the
0059 ;                                       user's code can poll this bit to check if transmission is
0060 ;                                       complete. This bit is reset after STOP bit has been transmitted.
0061 ;       Bit 1   :       _txmtEnable     Set this bit to 1 on initialization to enable transmission.
0062 ;                                       This bit can be used to Abort a transmission while the
0063 ;                                       transmitter is in progress (i.e when _txmtProgress = 1)
0064 ;       Bit 2   :       _rcvProgress    Indicates that the receiver is in middle of reception. It is
0065 ;                                       reset when a byte is received.
0066 ;       Bit 3   :       _rcvOver        This bit indicates the completion of Reception of a Byte. The
0067 ;                                       user's ode can poll this bit after calling "GetChar" function.
0068 ;                                       Once "GetChar"is called, this bit is 1 and cleared to 0 after
0069 ;                                       reception of a complete byte (parity bit if enabled & stop bit)
0070 ;       Bit 4   :       _ParityErr      A 1 indicates Parity Error on Reception (both even & odd parity)
0071 ;       Bit 5   :       _FrameErr       A 1 indicates Framing Error On Reception
0072 ;
0073 ;       Bit 6   :       _unused_        Unimplemented Bit
0074 ;
0075 ;       Bit 7   :       _parityBit      The 9 th bit of transmission or reception (status of PARITY bit
0076 ;                                       if parity is enabled)
0077 ;
0078 ;       To Transmit A Byte Of Data :
0079 ;                       1) Make sure _txmtProgress & _rcvOver bits are cleared
0080 ;                       2) Load TxReg with data to be transmitted
0081 ;                       3) CALL  PutChar function
0082 ;
0083 ;       To Receive A Byte Of Data :
```

```
0084 ;                      1) Make sure _txmtProgress & _rcvOver bits are cleared

Four Channel Digital Voltmeter with Display and Keyboard

Author: *Stan D'Souza*
Microchip Technology Inc.

INTRODUCTION

The PIC16C71 is a member of the mid-range family of 8-bit, high-speed microcontrollers, namely the PIC16CXXX. The salient features of the PIC16C71 are:

- Improved and enhanced instruction set
- 14-bit instruction word
- Interrupt capability
- On-chip four channel, 8-bit A/D converter

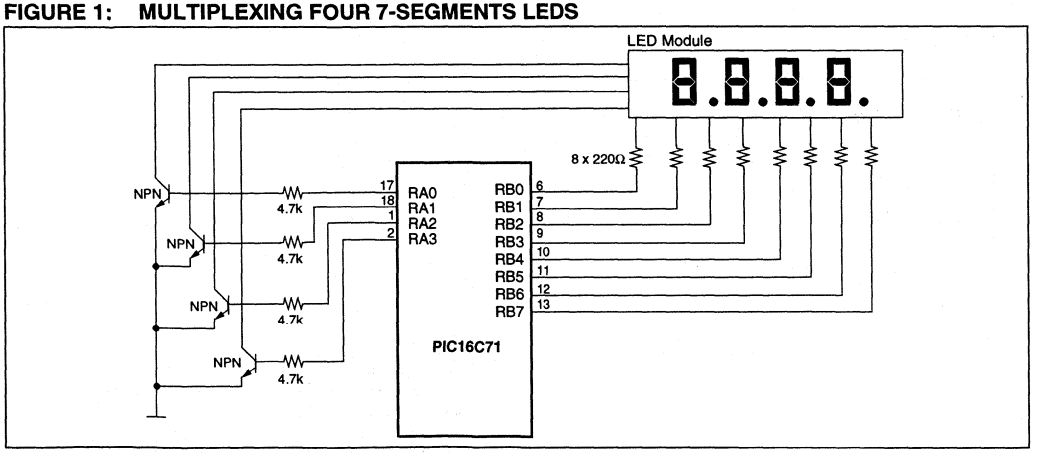
This application note demonstrates the capability of the PIC16C71. This application note has been broken down into four subsections:

Multiplexing Four 7-Segment LED Displays

Multiplexing Four 7-Segment LED Displays and Scanning a 4x4 Keypad

Multiplexing Four 7-Segment LED Displays and the A/D Channel0

Multiplexing Four 7-Segment LED Displays with a 4x4 Keypad and 4 A/D Channels



MULTIPLEXING FOUR 7-SEGMENT LED DISPLAYS

Hardware

The PIC16C71's I/O ports have an improved sink/source specification. Each I/O pin can sink up to 25 mA and source 20 mA, in addition total PORTB source current is 100 mA and sink current is 150 mA. PORTA is rated for 50 mA source current and 80 mA sink current. This makes the PIC16C71 ideal for driving 7-segment LEDs. Since the total number of I/O pins is limited to 13, the 8-bit PORTB is used to drive the 4 LEDs, while external sink transistors or MOSFETs are used to sink the digit current (Figure 1). Another alternative is to use ULN2003 open collector sink current drivers, which are available in 16-pin DIP or very small SO-16 packages. Each transistor on the ULN2003 can sink a maximum of 500 mA and the base drive can be directly driven from the PORTA pins.

Software

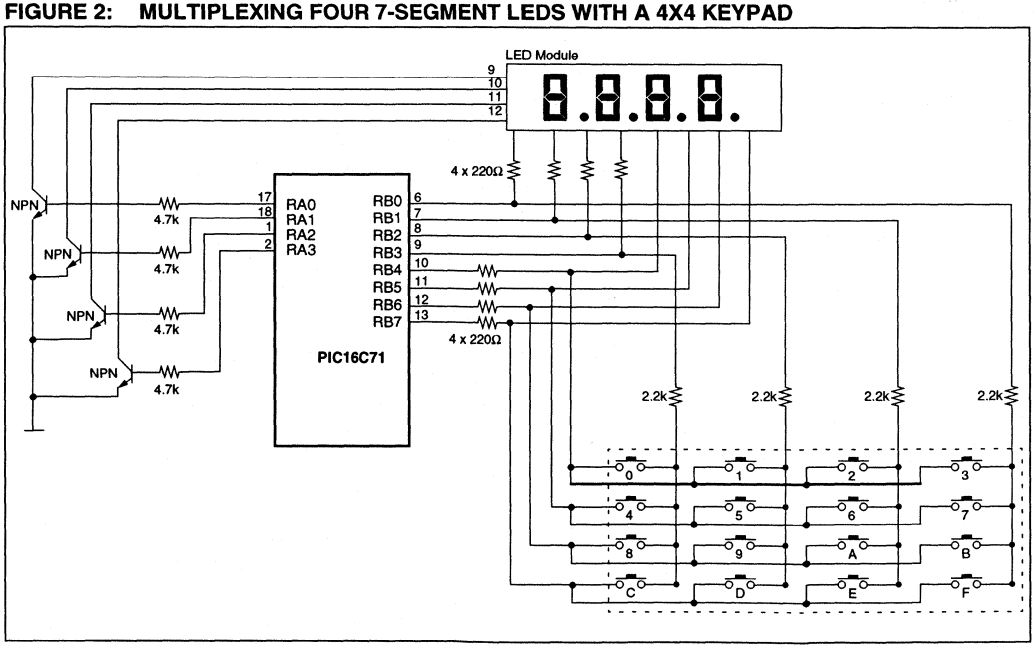
The multiplexing is achieved by turning on each LED for a 5 µs duration every 20 µs. This gives an update rate of 50 Hz, which is quite acceptable to the human eye as a steady display. The 5 µs time-base is generated by dividing the 4.096 MHz oscillator clock. The internal prescaler is configured to be a divide by 32 and assigned to Timer0. TMR0 is pre-loaded with a value = 96. TMR0 will increment to FFh and then roll over to 00h after a period =
(256-96)•(32•4/4096000) = 5 µs.

When TMR0 rolls over, flag bit T0IF flag is set, and because bits T0IE and GIE are enabled, an interrupt is generated.

The software implements a simple timer which increments at a 1 second rate. Every second, the 4 nibble (two 8-bit registers MsdTime and LsdTime) are incremented in a BCD format. The lower 4 bits of LsdTime correspond to the least significant digit (LSD) on the display. The high 4 bits of LsdTime correspond to the second significant digit of the display and so on. Depending on which display is turned on, the corresponding 4-bit BCD value is extracted from either MsdTime or LsdTime, and decoded to a 7-segment display. The TMR0 interrupt is generated at a steady rate of 5 µs and given an instruction time of 1 µs. The entire display update program can reside in the interrupt service routine with no chance of getting an interrupt within an interrupt. The Code Listing for this section is in Appendix A.

MULTIPLEXING FOUR 7-SEGMENT LED DISPLAYS AND SCANNING A 4x4 KEYPAD

Hardware



A 4x4 keypad can be very easily interfaced to the PIC16C71's PORTB (Figure 2). Internal pull-ups on pins RB7:RB4 can be enabled/disabled by clearing/setting bit $\overline{\text{RBPU}}$ (OPTION<7>). The internal pull-ups have a value of 20k at 5V (typical). In order to sense a low level at the input, the switch is "connected" to ground through a 2.2 kΩ resistor. A key hit normally lasts anywhere from 50 ms to as long as a person holds the key down. In order not to miss any key hits, the keypad is sampled every 20 µs (just after the update of the MSD).

Software

To sample the keypad, the digit sinks are first disabled. PORTB is then configured with RB7:RB4 as inputs and RB3:RB0 as outputs driven high. The pull-ups on RB7:RB4 are enabled. Sequentially RB3:RB0 are made low while RB7:RB4 are checked for a key hit (a low level). One key hit per scan is demonstrated in this program. Multiple key hits per scan can very easily be implemented. Once the key hit is sensed, a 40 ms debounce period elapses before key sampling is resumed. No more key hits are sensed until the present key is released. This prevents erroneous key inputs.

The program basically inputs the key hit and displays its value as a hexadecimal character on the multiplexed 7- segment LEDs. The Code Listing for this section is in Appendix B.

MULTIPLEXING FOUR 7-SEGMENT LED DISPLAYS AND THE A/D CHANNEL0

Hardware

The four analog channels are connected to RA3:RA0. If any of these pins are used normally as digital I/O, they can momentarily be used as analog inputs. In order to avoid interference from the analog source, it is advisable to buffer the analog input through a voltage follower op-amp, however, it is not always necessary. Figure 3 and Figure 4 show some typical configurations. In this application, the analog input is a potentiometer whose wiper is connected through an RC network to Channel0. The RC is necessary in order to smooth out the analog voltage. The RC does contribute to a delay in the sampling time, however the stability of the analog reading is greatly improved.

Software

The analog input is sampled every 20 ms. The digit sinks and the drivers are turned off (i.e., PORTA is configured as an input and PORTB outputs are made low). A 1 ms settling time is allowed for the external RC network connected to the analog input to settle and then the A/D conversion is started. The result is read then converted from an 8-bit binary value to a 3-digit Binary Code Decimal (BCD) value which is then displayed on the 7-segment LEDs. The Code Listing for this section is in Appendix C.

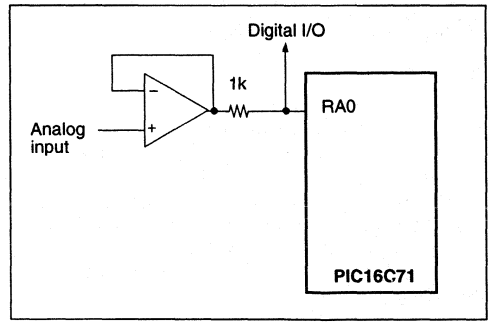

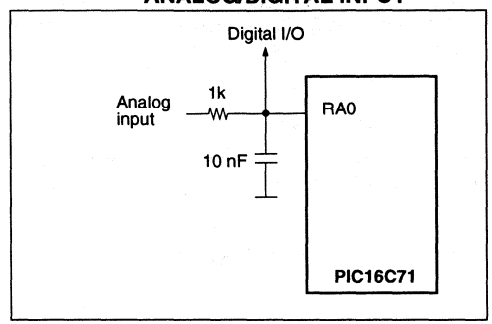

FIGURE 4: TYPICAL CONNECTION FOR ANALOG/DIGITAL INPUT

MULTIPLEXING FOUR 7-SEGMENT LED DISPLAYS WITH A 4x4 KEYPAD AND 4 A/D CHANNELS

Hardware

This section essentially incorporates the previous three sections to give a complete four channel voltmeter. Figure 5 shows a typical configuration. The analog channels are connected through individual potentiometers to their respective analog inputs and are sampled every 20 ms in a round robin fashion. The sampling rate can be increased to as fast as once every 5 µs if required. The keypad sampling need not be any faster than once every 20 µs.

Software

The program samples the analog inputs and saves the result in four consecutive locations starting at "ADVALUE", with Channel0 saved at the first location and so on.

KEY 0 → Channel0

or

KEY 1 → Channel0

Key hits greater than 3 are ignored. The code listing for this section is in Appendix D.

CONCLUSION

The four A/D channels on the PIC16C71 can be multiplexed with digital I/O, thus reducing overall pin counts and improving I/O pin usage in an analog application.

                     00002 ;This program is to demonstrate how to multiplex four 7 segment LED
                     00003 ;digits and a 4x4 keypad using a PIC16C71.
                     00004 ;The four digits will start as '0000' and when a key is hit
                     00005 ;it is displayed on the 7 segment leds as a hex value 0 to F. The last
                     00006 ;digit hit is always displayed on the right most led with the rest of
                     00007 ;the digits shifted to the left. The left most digit is deleted.
                     00008 ;The LEDs are updated every 20mS, the keypad is scanned at a rate of 20
                     00009 ;mS. The TMR0 timer is used in internal interrupt mode to generate the

                     00002 ;This program demonstrates how to multiplex four 7 segment LED
                     00003 ;digits and a 4X4 keypad along with 4 A/D inputs using a PIC16C71.
                     00004 ;The four digits will first display the decimal a/d value of ch0.
                     00005 ;When keys from 0 - 3 are hit the corresponding channel's a/d value
                     00006 ;is displayed in decimal.
                     00007 ;The LEDs are updated every 20mS, the keypad is scanned at a rate of 20
                     00008 ;mS. All 4 channels are scanned at 20mS rate, so each channel gets
                     00009 ;scanned every 80mS. A faster rate of scanning is possible as required
                     00010 ;by the users application.
                     00011 ;Timer0 is used in internal interrupt mode to generate the

Using the PORTB Interrupt on Change as an External Interrupt

Author: *Mark Palmer*

INTRODUCTION

The PICmicro™ families of RISC microcontrollers are designed to provide advanced performance and a cost-effective solution for a variety of applications. To address these applications, there is the PIC16CXXX microcontroller family of products. This family has numerous peripheral and special features to better address user applications.

The feature this application note will focus on is the Interrupt on Change of the PORTB pins. This "interrupt on change" is triggered when any of the RB7:RB4 pins, configured as an input, changes level. When this interrupt is used in conjunction with the software programmable weak internal pull-ups, a direct interface to a keypad is possible. This is shown in application note AN552, Implementing Wake-up on Key Stroke. Another way to use the "interrupt on change" feature would be as additional external interrupt sources. This allows PIC16CXXX devices to support multiple external interrupts, in addition to the built-in external interrupt on the INT pin.

This application note will discuss some of the issues in using PORTB as additional external interrupt pins, and will show some examples. These examples can be easily modified to suit your particular needs.

USING A PORTB INPUT FOR AN EXTERNAL INTERRUPT

The interrupt source(s) cannot simply be directly connected to the PORTB pins, and expect an interrupt to occur the same as on the interrupt (INT) pin. To develop the microcontrollers hardware/software to act as an interrupt by an external signal, we must know the characteristics of the external signal. After we know this, we can determine the best way to structure the program to handle this signal. The characteristics that we need to consider when developing the interrupt include:

1. The rising edge and falling edges.
2. The pulse width of the interrupt trigger (high time / low time).

It is easy to understand the need of knowing about which edge triggers the interrupt service routine for the external interrupt. This allows one to ensure that the interrupt service routine is only entered for the desired edge, with all other edges ignored. Not so clear is the pulse width of the interrupt's trigger. This characteristic helps determine the amount of additional overhead that the software routine may need.

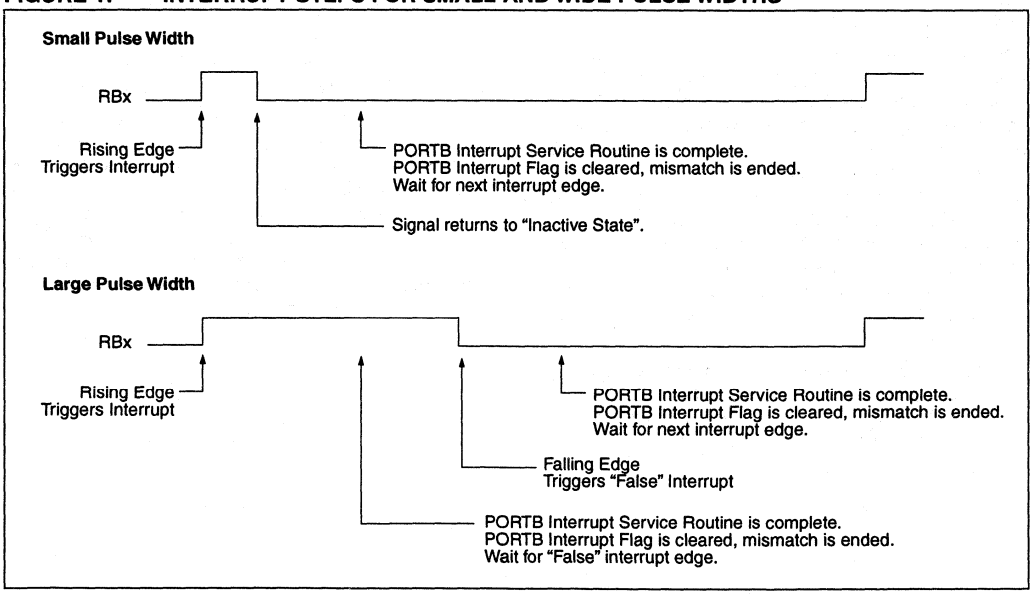

Figure 1 shows the two cases for the interrupt signal verses the time to complete the interrupt service routine. The first waveform is when the signal makes the low-to-high-to-low transitions before the interrupt service routine has completed (interrupt flag cleared). When the interrupt flag has been cleared, the interrupt signal has already returned to the inactive level. The next transition of the signal is due to another interrupt request. An interrupt signal with this characteristic will be called a small pulse width signal.

The second waveform is when the signal only makes the low-to-high transitions before the interrupt service routine has completed (interrupt flag cleared). The next transition (high-to-low) will return the interrupt signal to the inactive level. This will generate a "false" interrupt, that will need to be cleared. Then the following transition (low-to-high) will be a "true" interrupt. An interrupt signal with this characteristic will be called a wide pulse width signal.

An interrupt pulse with a small pulse width requires less overhead than a wide pulse width. A small pulse width signal must be less than the minimum execution time of the interrupt service routine, while a wide pulse width must be greater then the maximum time through the interrupt service routine.

Example 1 shows a single interrupt source on PORTB (RB7), which executes the interrupt service routine on a rising edge. The interrupt source has a small pulse width. In this case, since the interrupt pulse width is small, the pulse has gone high and then low again before PORTB is read to end the mismatch condition. So when PORTB is read it will read a low signal and will again be waiting for the rising edge transition.

FIGURE 1: INTERRUPT STEPS FOR SMALL AND WIDE PULSE WIDTHS

EXAMPLE 1: SINGLE INTERRUPT WITH A SMALL PULSE WIDTH

```
PER_INT         BTFSS   INTCON, RBIF        ; PortB interrupt?
                GOTO    OTHER_INT           ; Other interrupt
                        :                   ; Do task for INT on RB7
                        :                   ;
CLR_RBINTF      MOVF    PORTB, 1            ; Read PortB (to itself) to end
                                            ; mismatch condition
                BCF     INTCON, RBIF        ; Clear the RB interrupt flag.
                RETFIE                      ; Return from interrupt
OTHER_INT               :                   ; Do what you need to here
                        :
                RETFIE                      ; Return from interrupt
```

Example 2 shows a single interrupt source on PORTB (RB7), which executes the interrupt service routine on a rising edge. The interrupt source has a wide pulse width. In this case since the interrupt pulse width is large, the pulse is still high before PORTB is read to end the mismatch condition. So when PORTB is read it will read a high signal and will generate an interrupt on the next falling edge transition (which should be ignored).

EXAMPLE 2: SINGLE INTERRUPT WITH A WIDE PULSE WIDTH

```
PER_INT       BTFSS  INTCON, RBIF        ; PortB interrupt?
              GOTO   OTHER_INT           ; Other interrupt
              BTFSC  PORTB, RB7          ; Check for rising edge
              GOTO   CLR_RBINTF          ; Falling edge, clear PortB int
              :                          ;   flag
                     :                   ; Do task for INT on RB7
                     :
CLR_RBINTF    MOVF   PORTB, 1            ; Read PortB (to itself) to end
                                         ;    mismatch condition
              BCF    INTCON, RBIF        ; Clear the RB interrupt flag.
              RETFIE                     ; Return from interrupt
OTHER_INT              :                 ; Do what you need to here
                       :
              RETFIE                     ; Return from interrupt
```

Example 3 shows an interrupt on change with the interrupt source on PORTB (RB7). This executes the interrupt service routine on a both edges. The interrupt source must have a minimum pulse width to ensure that both edges can be "seen". The minimum pulse width is the maximum time from the interrupt edge to the reading of PORTB and clearing the interrupt flag.

EXAMPLE 3: INTERRUPT ON CHANGE

```
PER_INT       BTFSS  INTCON, RBIF        ; PortB interrupt?
              GOTO   OTHER_INT           ; Other interrupt
CLR_RBINTF    MOVF   PORTB, 1            ; Read PortB (to itself) to end
                                         ;    mismatch condition
              BCF    INTCON, RBIF        ; Clear the RB interrupt flag.
                     :                   ; Do task for INT on RB7
                     :                   ;
              RETFIE                     ; Return from interrupt
OTHER_INT                                ; Do what you need to here
                     :
              RETFIE                     ; Return from interrupt
```

USING PORTB INPUTS FOR MULTIPLE INTERRUPTS

The previous examples have been for a single external interrupt on PORTB. This can be extended to support up to four external interrupts. To do this requires additional software overhead, to determine which of the PORTB pins (RB7:RB4) caused the interrupt. Care should be taken in the software to ensure that no interrupts are lost.

In this example, the interrupt sources on RB7, RB5, and RB4 have a small pulse width, while the interrupt source on pin RB6 is wide and should cause a trigger on the rising edge.

SUMMARY

The PORTB interrupt on change feature is both a very convenient method for direct interfacing to an external keypad, with no additional components, but is also versatile in its uses the ability to add up to four additional external interrupts. Of course hybrid solutions are also possible. That is, for example, using PORTB<6:1> as a 3x3 keypad, with PORTB<7> as an external interrupt and PORTB<0> as a general purpose I/O. The flexibility of this feature allows the user to implement a best fit design for the application.

Use of the SSP Module in the I²C™ Multi-Master Environment

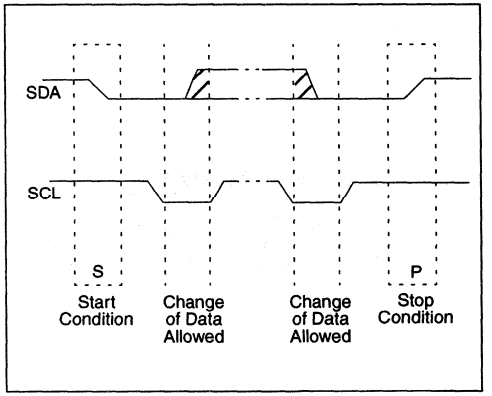
INTRODUCTION

The Inter-IC (I^2C) bus is a two-wire serial interface developed by Philips/Signetics. The specification supports data transmission up to 400 Kbps.

The I^2C interface employs a comprehensive protocol to ensure reliable transmission and reception of data. When the bus is active, one device is the Master (generates the clock and the handshaking signals), while all the other devices are Slaves. The current bus Master can both read-from and write-to any of the Slave units by addressing them individually. On a Multi-Master bus the Masters follow an arbitration scheme to ensure that the bus is not corrupted.



Each device attached to the I^2C bus is assigned a unique address. When a Master wishes to initiate a data transfer, it first transmits the address of the device that it wishes to "talk" to. All devices "listen" to see if this is their address. Within this address, a bit specifies whether the Master wishes to read-from or write-to the Slave device.

The output stages of each device on the bus, attached to the clock (SCL) and data (SDA) lines, must have an open-drain or open-collector in order to perform the wired-AND function of the bus. External pull-up resistors are used to ensure a high level when no device is pulling the line down. The only limitation on the number of devices that may be attached to the bus is the maximum bus loading specification. For complete bus specifications, refer to Philips/Signetics document "The I^2C-bus and How to Use It" (www.semiconductors.philips.com).

INITIATING AND TERMINATING DATA TRANSFER

During times of no data transfer (idle time), both the SCL and SDA lines are pulled high. A Master device which wishes to take control of the bus must first generate a START condition. A START is defined as a high to low transition of SDA when SCL is high. When the Master has completed all data transmissions and wishes to relinquish the bus, it generates a STOP condition. A STOP is defined as a low to high transition of SDA while SCL is high. Because the START and STOP conditions are defined as transitions of the SDA when the SCL line is high, the SDA line can only change when SCL is low during the actual data transmission. Figure 1 shows the relationship between SCL and SDA for the various conditions.

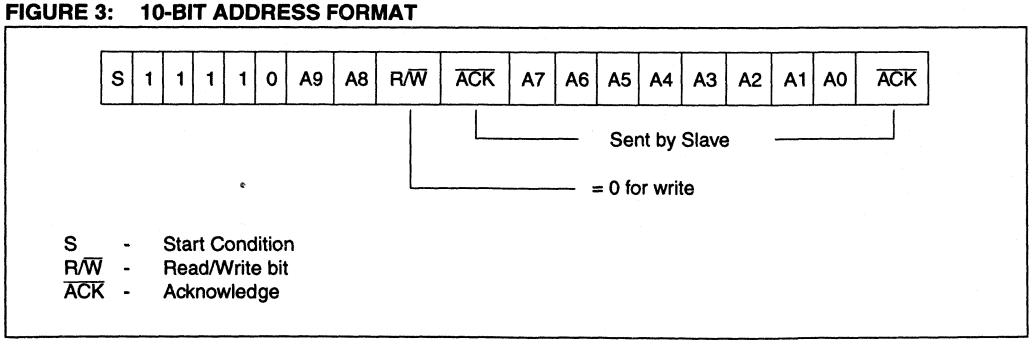
ADDRESSING I²C DEVICES

There are two address formats. The simplest of these is the 7-bit address format with a R/$\overline{W}$ bit (Figure 2). The more complex is the 10-bit address with a R/$\overline{W}$ bit (Figure 3). For 10-bit addressing, two bytes must be transmitted with the first five bits specifying this to be a 10-bit address. Only 7-bit addressing is used in this application note.

FIGURE 2: 7-BIT ADDRESS FORMAT

TRANSFER ACKNOWLEDGE

Slave as Receiver



All data is transmitted as bytes, with no limit to the number of bytes transmitted per data transfer. After each byte, the slave-receiver generates an acknowledge bit ($\overline{ACK}$) by pulling the SDA line low. When a slave-receiver doesn't acknowledge the slave address or received data, the master aborts the transfer. Whether the $\overline{ACK}$ bit is generated or not, the SDA line must be released by the slave so that the master can generate the STOP condition.

Master as Receiver

If the master is receiving the data, it generates an acknowledge signal for each received byte of data except for the last byte. To signal the end of data to the slave-transmitter, the master does not generate an acknowledge. The slave then releases the SDA line so the master can generate the STOP condition. The master can also generate the STOP condition during the acknowledge pulse for valid termination of data transfer.

If the slave needs to delay the transmission of the next byte, holding the SCL line low will force the master into a wait state. Data transfer continues when the slave releases the SCL line. This allows the slave to move the received data or fetch the data it needs to transfer before allowing the clock to start. This wait state technique can also be implemented at the bit level.

MULTI-MASTER

The I^2C protocol allows a system to have more than one master. When two or more masters try to transfer data at the same time, arbitration and synchronization occur.

Arbitration

Arbitration takes place on the SDA line while the SCL line is high. The master which transmits a high when the other master transmits a low loses arbitration (Figure 4) and turns off its data output stage. A master which lost arbitration can generate clock pulses until the end of the data byte where it lost arbitration. When the master devices are addressing the same device, arbitration continues into the data.

Clock Synchronization

Clock synchronization occurs after the devices have started arbitration. This is performed using a wired-AND connection to the SCL line. A high to low transition on the SCL line causes the concerned devices to start counting off their low period. Once a device clock has gone low, it will hold the SCL line low until its SCL high state is reached. The low to high transition of this clock may not change the state of the SCL line, if another device clock is still within its low period. The SCL line is held low by the device with the longest low period. Devices with shorter low periods enter a high wait-state, until the SCL line comes high. When the SCL line comes high, all devices start counting off their high periods. The first device to complete its high period will pull the SCL line low. The SCL line high time is determined by the device with the shortest high period (Figure 5).

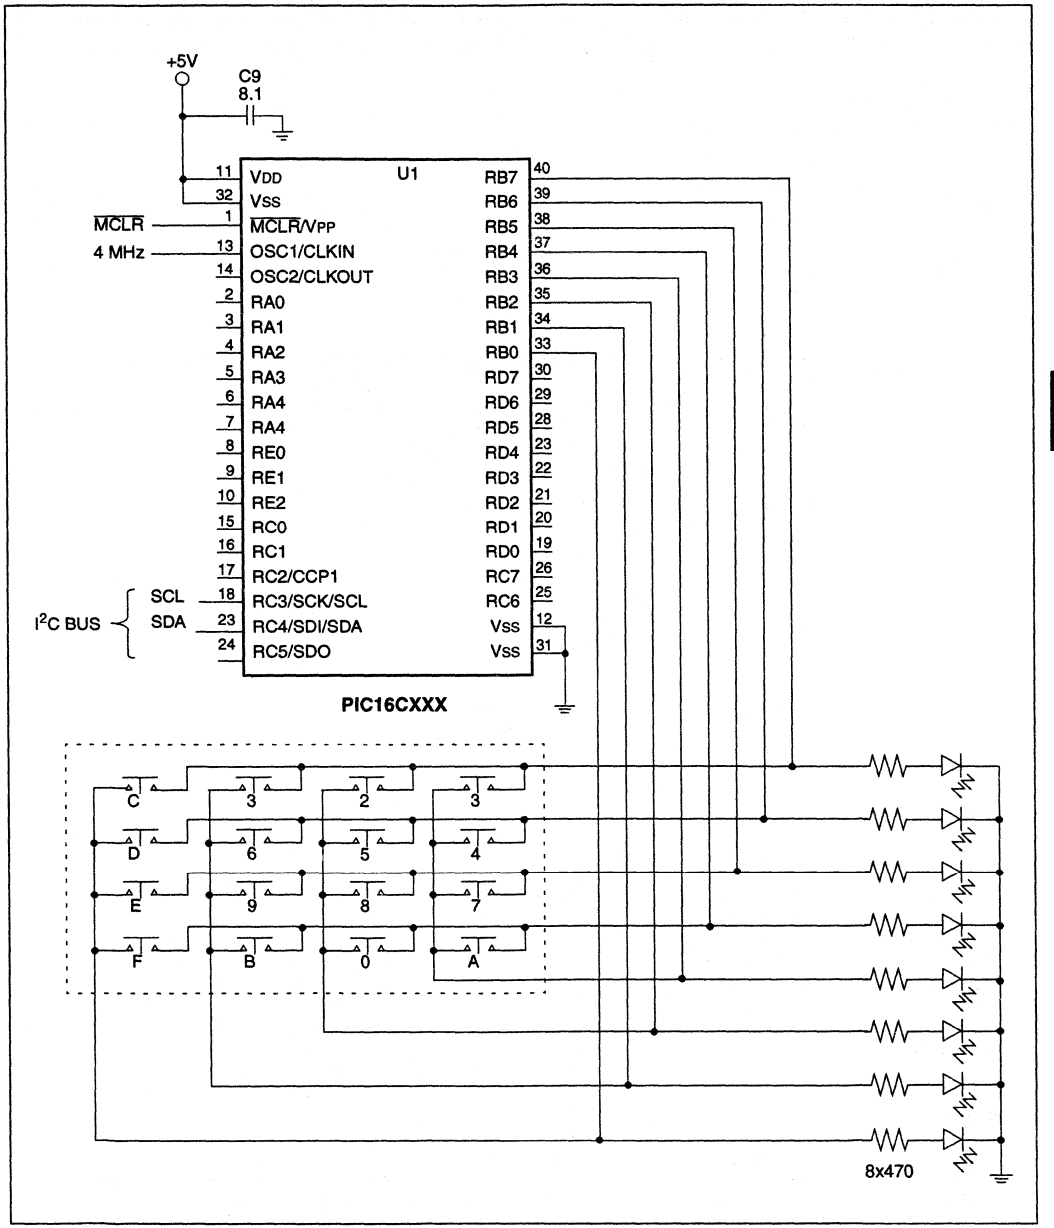
IMPLEMENTATION IN THE PIC16CXXX

This Application Note uses the PIC16CXXX in a Multi-Master I^2C environment. The PIC16CXXX acts as both a Master and a Slave on the bus.

Hardware

The demonstration hardware consists of a keypad multiplexed with eight LEDs on PORTB and connections to the I^2C bus through the RC3/SCL and RC4/SDA pins (Figure 6).

Software



The software transmits in Master mode and receives data in Slave mode.

The **transmit** routine scans the keypad, debounces the keypresses, and transmits their encoded value in Master mode over the I^2C bus to slave address A6. Before transmitting, the status of the Synchronous Serial Port (SSP) is checked. No data is sent until the SSP status register indicates that a Stop bit was received. If the transmission causes any errors, the error code will be displayed on the LEDs, and transmission will again be attempted.

Data **received** in Slave mode at address A2 from the bus is displayed on the LEDs. Slave reception is interrupt driven. When a complete word is received with the proper address, the processor is interrupted, and the program verifies that an SSP interrupt was received. Once it has been verified that the interrupt was caused by the SSP module, and that the buffer is full, the data word is read and output to the LEDs.

Using the 8-Bit Parallel Slave Port

Author: *Scott Fink*
Microchip Technology Inc.

INTRODUCTION

PIC16C64/74 microcontrollers from Microchip Technology Inc. can be interfaced with ease into a multi-microprocessor environment using its built-in Parallel Slave Port (PSP). With their very high operating speeds (cycle times as low as 200 ns with a clock rate of 20 MHz), and an array of on-chip peripherals, these microcontrollers make ideal smart interfaces to the real world.

IMPLEMENTATION

PORTD operates as an 8-bit wide Parallel Slave Port, with PORTE providing the control signals. In parallel slave mode, PORTD is asynchronously readable and writable by the external world through the chip select (RE2/$\overline{CS}$), Read (RE0/$\overline{RD}$), and Write (RE1/$\overline{WR}$) control inputs.

In order to use the Parallel Slave Port, the data direction bits in the TRISE register corresponding to $\overline{RD}$, $\overline{WR}$, and $\overline{CS}$ (TRISE<2:0>) must be configured as inputs (set = 1) and control bit PSPMODE (TRISE<4>) must be set.

The port pins are connected to two 8-bit latches, one for data output (from the PIC16CXXX) and one for data input. The PIC16CXXX sends data by writing to the output latch, and receives data by reading the input latch (note that the input and output latches are at the same address). In PSP mode the TRISD register is ignored, since the external device connected to the slave port controls the direction of data flow.

When the external device performs either a read or a write operation to the PIC16CXXX, interrupt flag, PSPIF (PIR1<7>), will be set and the processor interrupted if bit PSPIE (PIE1<7>) is set and interrupts are enabled (enable bits GIE and PEIE, (INTCON<7:6>) set). When the interrupt is serviced, bit PSPIF must be cleared by software.

The read-only status flag bit IBF, Input Buffer Full (TRISE<7>), is set if a received word is waiting to be read. Bit IBF is cleared upon read of the input buffer latch. If another word is received prior to the first being read, status flag bit IBOV (TRISE<5>) is set. Bit IBOV can be cleared by software.

The Output Buffer Full status bit, OBF (TRISE<6>), is set if a word written to PORTD latch is waiting to be read by the external bus.

When not in Parallel Slave Port mode the IBF and OBF bits are cleared. If flag bit IBOV was previously set, however, it must be cleared by software.

Note that the following registers are for a PIC16C74 and not all peripherals are available on the PIC16C64.

TABLE 1: SUMMARY OF PARALLEL SLAVE PORT REGISTERS

Register Name	Function	Address	Power-on Reset Value
PORTD	Parallel slave port Read/Write Data	08h	xxxx xxxx
TRISD	PORTD data direction register	88h	1111 1111
PORTE	Read/Write/Chip Select signals	09h	---- -xxx
TRISE	Control bits for PORTD slave port	89h	0000 -111
INTCON	peripheral and global interrupt enable bits	0Bh	0000 000x

TABLE 2: PORTE FUNCTIONS

Name	Bit#	Buffer Type	Function
RE0/$\overline{RD}$/AN5	bit0	ST/TTL(1)	Input/output port pin or read control input in parallel slave port mode or analog input: $\overline{RD}$ 1 = Not a read operation 0 = Read operation. Reads PORTD register (if chip selected)
RE1/$\overline{WR}$/AN6	bit1	ST/TTL(1)	Input/output port pin or write control input in parallel slave port mode or analog input: $\overline{WR}$ 1 = Not a write operation 0 = Write operation. Writes PORTD register (if chip selected)
RE2/$\overline{CS}$/AN7	bit2	ST/TTL(1)	Input/output port pin or chip select control input in parallel slave port mode or analog input: $\overline{CS}$ 1 = Device is not selected 0 = Device is selected

Legend: ST = Schmitt Trigger input TTL = TTL input
Note 1: Input buffers are Schmitt Triggers when in I/O mode and TTL buffers when in Parallel Slave Port Mode.

1 = The USART receive buffer is full (cleared by reading RCREG)
0 = The USART receive buffer is empty

bit 4: **TXIF**: USART Transmit Interrupt Flag bit
1 = The USART transmit buffer is empty (cleared by writing to TXREG)
0 = The USART transmit buffer is full

bit 3: **SSPIF**: Synchronous Serial Port Interrupt Flag bit
1 = The transmission/reception is complete (must be cleared in software)
0 = Waiting to transmit/receive

bit 2: **CCP1IF**: CCP1 Interrupt Flag bit
Capture Mode
1 = A TMR1 register capture occurred (must be cleared in software)
0 = No TMR1 register capture occurred
Compare Mode
1 = A TMR1 register compare match occurred (must be cleared in software)
0 = No TMR1 register compare match occurred
PWM Mode
Unused in this mode

bit 1: **TMR2IF**: TMR2 to PR2 Match Interrupt Flag bit
1 = TMR2 to PR2 match occurred (must be cleared in software)
0 = No TMR2 to PR2 match occurred

bit 0: **TMR1IF**: TMR1 Overflow Interrupt Flag bit
1 = TMR1 register overflowed (must be cleared in software)
0 = TMR1 register did not overflow

Note 1: PIC16C73/73A/76 devices do not have a Parallel Slave Port implemented, this bit location is reserved on these devices, always maintain this bit clear.

Interrupt flag bits get set when an interrupt condition occurs regardless of the state of its corresponding enable bit or the global enable bit, GIE (INTCON<7>). User software should ensure the appropriate interrupt flag bits are clear prior to enabling an interrupt.

Using Timer1 in Asynchronous Clock Mode

Author: *Mark Palmer*
Microchip Technology Inc.

INTRODUCTION

This application note discusses the use of the PIC16CXXX Timer1 module as an asynchronous clock. The Timer1 module has it own oscillator circuitry, which allows the timer to keep real-time, even when the device is in SLEEP mode. When the device is in sleep, the oscillator will continue to increment TMR1. An overflow of the TMR1 register causes a TMR1 Overflow Interrupt (if enabled) and will wake the processor from sleep. The interrupt service routine can then perform the desired task.

OVERVIEW

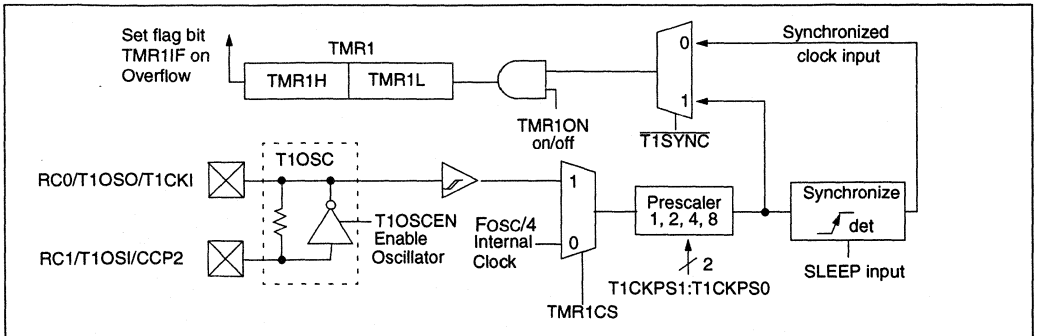
Timer1 is a 16-bit counter with a 2-bit prescaler. Timer1 can be incremented from an internal clock, an external clock, or an external oscillator. Timer1 can be configured to synchronize or not synchronize the external clock sources. Asynchronous operation allows Timer1 to increment when the device is in sleep. Figure 1 is a block diagram of Timer1.

To set up Timer1 for asynchronous operation the Timer1 control register, T1CON, must have the following bits configured:

- TMR1CS set (external clock source)
- T1CKS1:T1CKS0 configured for the desired prescaler
- $\overline{\text{T1SYNC}}$ set (asynchronous operation)
- TMR1ON set (enables Timer1)
- T1OSCEN set, if using an external oscillator

In asynchronous operation, if the clock source is an external clock, it is input on the T1CKI pin. If the clock source is a crystal oscillator, the crystal is connected across the T1OSO and T1OSI pins.

When using Timer1 in Asynchronous mode, the use of an external clock minimizes the operating and sleep currents. This is because the timer's internal oscillator circuitry is disabled. Though the external clock may give the lower device currents, the use of a crystal oscillator may lead to lower system current consumption and system cost.



System current consumption can also be reduced by having the TMR1 Overflow Interrupt wake the processor from SLEEP at the desired interval, With a 32.768 kHz crystal, Timer1's overflow rate ranges from 2 to 16 seconds, depending on the prescaler chosen. Table 1 shows Timer1 overflow times for various crystal frequencies and prescaler values.

TABLE 1: TIMER1 OVERFLOW TIMES

	Frequency (kHz)		
Prescale	**32.768**	**100**	**200**
1	2	0.655	0.327
2	4	1.31	0.655
4	8	2.62	1.31
8	16	5.24	2.62

Overflow times in seconds.

FIGURE 1: TIMER1 BLOCK DIAGRAM

When the T1OSCEN bit is cleared, the inverter and feedback resistor are turned off. This eliminates power drain.

As can be seen the 32 kHz crystal, gives very nice overflow rates. These crystals, referred to as watch crystals, also can be relatively inexpensive. In many applications the 2 second overflow time, of a 32 kHz crystal, is too long. An easy way to reduce the overflow time is to load the TMR1H register with a value, during the interrupt service routine. Table 2 shows the overflow times, depending on the value loaded into the TMR1H register and a prescale of 1.

TABLE 2: TMR1H LOAD VALUES / TIMER1 OVERFLOW TIMES

TMR1H Load Value	Overflow Time (@ 32.768 kHz)
80h	1 Second
C0h	0.5 Second
E0h	0.25 Second
F0h	0.125 Second

Note: The loading of either TMR1H or TMR1L causes the prescaler to be cleared. When Timer1 is in operation, extreme care should be taken in modifying either the TMR1H or TMR1L registers, since this automatically configures the prescaler to 1.

The code segment shown in Example 1 configures the Timer1 module for asynchronous operation, enables the Timer1 interrupt, and the interrupt service routine loads the TMR1H register with a value.

CONCLUSION

Timer1 gives designers a powerful time-base function. The asynchronous operation and internal oscillator circuitry gives designers the ability to easily keep real-time, while minimizing power consumption and external logic.

Low-Power Real-Time Clock

Author: *Mark Palmer*

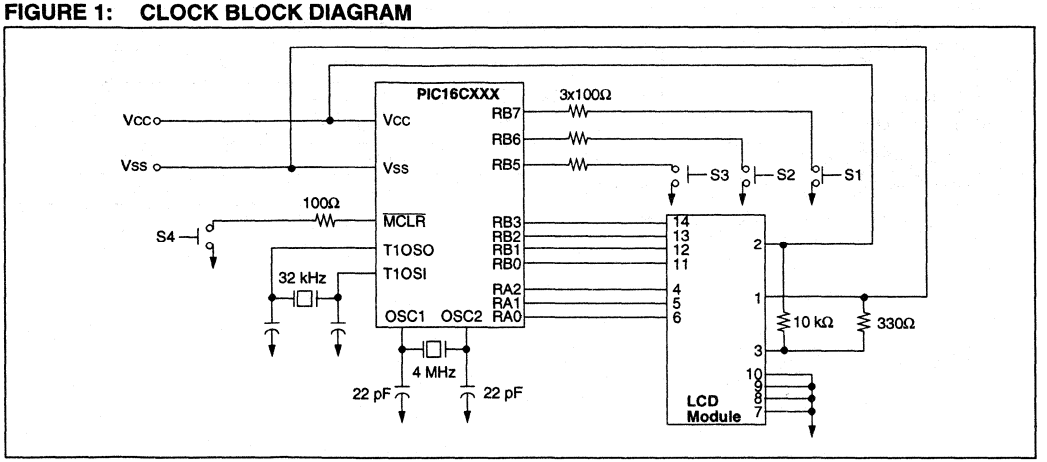
INTRODUCTION

This application note uses the Timer1 module, from a mid-range PIC16CXXX microcontroller, to control a low-power real-time clock. Timer1 was chosen because it has its own crystal which allows the module to operate during sleep. The two events that will wake the device from sleep (for this application) are a keypress and a Timer1 overflow.

OPERATION



Upon power-up, the device is initialized with the display starting at 12:00 PM, and Timer1 is configured to generate an interrupt (every second). The Timer1 overflow interrupt wakes the device from sleep. This causes the time registers (HRS, MIN, SECS) to be updated. If the SECS register contains an even value (SECS<0> = 0), the colon (":") is not displayed. This gives a visual indication for each second. Then the device returns to sleep.

There are three keys for the setting of the clock. The SELECT_UNITS Key (S1) selects which units are to be modified (hours, minutes, off). The selected units are blanked for a second then flashed for one second. The INC Key (S2) increments the selected units. While incrementing, the selected units values are displayed. Upon key release, the Timer counts out one second and begins flashing the selected units. The CLR_MIN Key (S3) clears the minutes and seconds. CLR_MIN is useful for exactly setting the time to the "top of the hour" as announced in radio broadcasts. After the INC or SELECT_UNITS keys are depressed, the user has ten seconds to depress the next key. If no keypress is detected within ten seconds, the unit returns to the clock mode.

To simplify the design time and minimize cost, a standard Hitachi LCD display module is used. Most applications that require LCDs use a custom LCD display. The LCD interface software would need to be modified to suit the specific LCD display driver being used.

Figure 1 is a block diagram of the design. The RA2:RA0 pins are the control signals to the LCD display, RB3:RB0 acts as a 4-bit data bus, and RB7:RB5 are the input switches. The OSC1 pin is connected to an RC network, which generates an approximate 4 MHz device frequency. Because Timer1 operates asynchronously to the device, the device's oscillator can be configured for RC mode. RC oscillator mode is the least expensive and has the quickest start-up time. Timer1 is where an accurate frequency is required. Timer1's crystal is connected to the T1OSI and T1OSO pins. A good choice for a crystal is a 32.786 kHz (watch) crystal. Table 1 is a list of the components and their part numbers.

Relative to most microelectronics, LCD's are slow devices. A good portion of the time spent in the Interrupt Service Routine, is talking to and updating the LCD module. To minimize power consumption, the device should be in SLEEP mode as much as possible.

By using the conditional assembly, if a flag (called Debug) is true, the total time spent in the subroutine can be seen on the PORTD<0> pin (the high time). Measuring this time on an oscilloscope displayed a typical time of 800 µs that the device is awake. This 800 µs operation is out of the 1 second time that the device needs to service the interrupt (a Timer1 overflow).

The accuracy of a real-time clock using Timer1 depends on the accuracy of the crystal being used. The more accurate the crystal, the higher the cost. So as always there is a cost / performance trade-off to be made. A crystal rated with an accuracy of 20 PPM (parts per million), could cause an error of about 1.7 seconds per day. For many applications, this should be adequate (said from someone who doesn't wear a watch).

The program written for this application note shows one method for a real-time clock. Trade-offs between code size, current consumption and desired operation have been made. Some possible alternative implementations are:

1. When displaying the time, update only the characters that changed.
2. Turn off the display during sleep
3. LCD module data interface of 8-bits, as-opposed-to the 4-bit interface.

Alternative 1 can reduce the time awake by keeping track of which characters need to be updated. The majority of the time it will be only the position which contains either the ":" or the " ". Next would be the ones place of the minutes, then the tens place of the minutes, etc. The display would only need to be completely updated 2 times every 24 hours. This would reduce the amount of time talking with the LCD display at the cost of some program / data memory.

Depending on the requirements of the application and the characteristics of the display, Alternative 2 could be implemented by turning the power off and on (at a given rate) to the display. This technique may lead to a lower system current consumption. Evaluation of the desired display / display driver is recommended.

Alternative 3 uses the LCD module in an 8-bit mode, which will reduce the size of the display routines (save about 20 words of program memory) at the cost of four additional I/O lines. For some applications this may be a good trade-off to get the additional program memory space. The percentage of operating time saved is slight and should not give substantial power savings.

CONCLUSION

The Timer1 module allows many applications to include a real-time clock at minimal system cost. This time function can be useful in consumer applications (display time) as well as in industrial applications (data time stamp). The accuracy of the time is strictly dependent on the accuracy of the crystal. Table 2 shows the program resource requirements.

Interfacing PICmicros™ to an LCD Module

Author: *Mark Palmer*
Code: *Mark Palmer/Scott Fink*
Microchip Technology Inc.

INTRODUCTION

This application note interfaces a micrange PICmicro device to a Hitachi® LM032L LCD character display module, with a two line by twenty character display. LCD modules are useful for displaying text information from a system. In large volume applications, the use of custom LCD displays becomes economical. The routines provided should be a good starting point for users whose applications implement a custom LCD. This source code should be compatible with the PIC16C5X devices, after modifications for the special function register initialization, but has not been verified on those devices.

OPERATION

The Hitachi LM032L LCD character display module can operate in one of two modes. The first (and default) mode is the 4-bit data interface mode. The second is the 8-bit data interface mode. When operating in 4-bit mode, two transfers per character / command are required. 8-bit mode, though easier to implement (less program memory) requires four additional I/O lines. The use of 8-bit mode is strictly a program memory size vs. I/O trade-off. The three most common data interfaces from the microcontroller are:

1. An 8-bit interface.
2. A 4-bit interface, with data transfers on the high nibble of the port.
3. A 4-bit interface, with data transfers on the low nibble of the port.

The LCD module also has three control signals, Enable (E), Read/Write (R_W), and Register Select (RS). The function of each control signal is shown in Table 1.

TABLE 1: CONTROL SIGNAL FUNCTIONS

Control Signal	Function
E	Causes data/control state to be latched Rising Edge = Latches control state (RS and R_W) Falling Edge = Latches data
RS	Register Select Control 1 = LCD in data mode 0 = LCD in command mode
R_W	Read / Write control 1 = LCD to write data 0 = LCD to read data

A single source file, with conditional assembly is used to generate each of these three options. This requires two flags. The flags and their results are shown in Table 2.

TABLE 2: CONDITIONAL ASSEMBLY FLAGS

Flags		
Four_bit	Data_HI	Result
1	0	4-bit mode. Data transferred on the low nibble of the port.
1	1	4-bit mode. Data transferred on the high nibble of the port.
0	x	8-bit mode.

Figure 1, Figure 2, and Figure 3 show the block diagrams for the three different data interfaces. The LCD_CNTL and LCD_DATA lines are user definable to their port assignment. This is accomplished with EQUate statements in the source code. See Appendices B, C, and D.

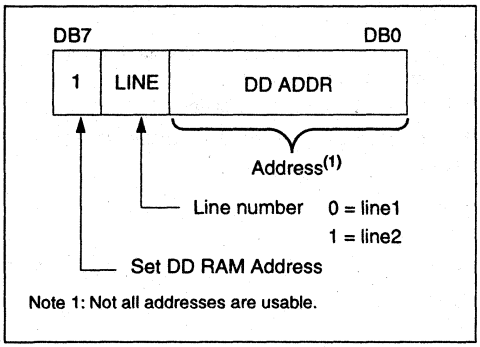
LCD's (drivers) are slow devices when compared to microcontrollers. Care must be taken from having communication occur too quickly. The software will need to control communicaton speed and timing to ensure the slow LCD and fast microcontroller can stay synchronized. The timing requirements of the LM032L are shown in Appendix A. We recommend that the complete specifications of the LM032L be acquired from Hitachi or a Hitachi distributor. The literature numbers are CE-E613Q and M24T013 for a LM032L display driver.

When the module powers up, the default data transfer mode is 8-bit. The initialization sequence only requires commands that are 4-bit in length. The last initialization command needs to specify the data transfer width (4-or 8-bit). Then a delay of 4.6 ms must be executed before the LCD module can be initialized. Some of the LCD module commands are:

- 1 or 2 lines of characters
- Display on /off
- Clear display
- Increment / do not increment character address pointer after each character
- Load character address pointer



The initialization flow for the module is shown in Figure 4.

FIGURE 4: INITIALIZATION FLOW FOR LCD MODULE

After initialization, each character address is individually addressable. Figure 5 shows the structure of the command to specify the character address.

FIGURE 5: CHARACTER ADDRESS COMMAND FORMAT

The Hitachi Display Drive (HD44780A) has 80 bytes of RAM. The LM032L modules only use 40 bytes of the available RAM (2 x 20 characters). It is possible to use the remaining RAM locations for storage of other information.

Figure 6 shows the display data positions supported by the display driver as well as the characters actually displayed by the module (the non-shaded addresses).

The program example implemented here uses the character auto increment feature. This automatically increments the character address pointer after each character is written to the display.

CONCLUSION

The Hitachi LM032L character display module is well suited for displaying information. The selection of 4-bit or 8-bit data transfer mode is strictly a program memory size vs. I/O resource trade-off. The supplied code is easily used in any of three common data interfaces. The source is easily modifiable to a designers specific application needs. Other display modules/drivers maybe implemented with the appropriate modifications. Table 3 shows the resource requirements for the three subroutines `SEND_CHAR`, `SEND_COMMAND`, and `BUSY_CHECK` in the various data interface modes.

11	DB4	H/L		
12	DB5	H/L		
13	DB6	H/L		
14	DB7	H/L		

In the HD44780, the data can be sent in either two 4-bit operations or one 8-bit operation, This flexibility allows an interface to both 4- and 8-bit MPUs.

Note 1: When interface data is 4-bits long, data is transferred using only 4 lines of DB7:DB4 (DB3:DB0 are not used). Data transfer between the HD44780 and the MPU completes when 4-bits of data is transferred twice. Data of the higher order 4 bits (contents of DB7:DB4 when interface data is 8-bits long) is transferred first and then lower order 4 bits (contents of DB3:DB0 when interface data is 8-bits long).

2: When interface data is 8-bits long, data is transferred using 8 data lines of DB7:DB0.

                     00004 ; This program interfaces to a Hitachi (LM032L) 2 line by 20 character display
                     00005 ; module. The program assembles for either 4-bit or 8-bit data interface, depending
                     00006 ; on the value of the 4bit flag. LCD_DATA is the port which supplies the data to
                     00007 ; the LM032L, while LCD_CNTL is the port that has the control lines ( E, RS, RW ).
                     00008 ; In 4-bit mode the data is transfer on the high nibble of the port ( PORT<7:4> ).

A PC-Based Development Programmer for the PIC16C84

Author: *Robert Spur*
Analog Design Specialist, Inc.

INTRODUCTION

This application note describes the construction of a low cost serial programmer which uses a PC with a parallel (Centronix printer) port to control a PIC16C84. This programmer has the capability of programming a PIC16C84 microcontroller, and reading back internal data without removing the device from the target circuit.

This feature is very useful in applications where changes in program code or program constants are necessary to compensate for other system features. For example, an embedded control system may have to compensate for variances in a mechanical actuator's performance or loading. The basic program can be programmed and tested during design phase. The final program and control constants can be easily added later in the production phase without removing the microcontroller from the circuit.

Automatic software and performance upgrades can also be implemented in-system. Upon receiving new system software via disk or modem, a control processor with the included programming code could perform in-circuit reprogramming of other microcontrollers in the system.

This programmer can load program code, part configuration, and EEPROM data into the PIC16C84. In read back mode, it can verify all data entries.

PROGRAMMING DESCRIPTION

The PIC16C84 microcontroller is placed into programming mode by forcing a low logic level on RB7 (pin 13) and RB6 (pin 12) while $\overline{MCLR}$ (pin 4) is first brought low to reset the part, and then brought to the program/verify voltage of 12 to 14V. The $\overline{MCLR}$ pin remains at the program/verify voltage for the remainder of the programming or verification.

After entering programming mode, RB7 is used to serially enter programming modes and data into the part. A high to low transition on RB6, the clock input, qualifies each bit of the data applied on RB7. Please refer to the PIC16C84 Programming Specification (DS30189) for details on the figures. The serial command-data format is specified in Figure 1.2.1.3 of the Microchip PIC16C84 Programming Specification (DS30189). The first 6 bits form the command field, and the last 16 bits form the data field. Notice that the data field is composed of one zero starting bit, 14 actual data bits, and one zero stop bit. The increment address command, shown in Figure 1.2.1.5 (PIC16C84 Programming Specification, DS30189), is comprised of only the command field. Table 1.2.1.1 (see DS30189) summarizes the available commands and command codes for serial programming mode.

Read mode is similar to programming mode with the exception that the data direction of RB7 is reversed after receiving the 6-bit command to allow the requested data to be returned to the programmer. Figure 1.2.1.4 (see DS30189) shows this sequence which starts by shifting the 6-bit command into the part. After the read command is issued, the programmer tri-states its buffer to allow the part to serially shift its internal data back to the programmer. The rising edge of RB6, (the clock input), controls the data flow by sequentially shifting previously programmed or data bits from the part. The programmer qualifies this data on the falling edge of RB6. Notice that 16 clock cycles are necessary to shift out 14 data bits.

Accidental in-circuit reprogramming is prevented during normal operation by the $\overline{MCLR}$ voltage which should never exceed the maximum circuit supply voltage of 6 VDC and the logic levels of port bits RB7 and RB6.

After program/verification the $\overline{MCLR}$ pin is brought low to reset the target microcontroller and then electrically released. The target circuit is then free to activate the $\overline{MCLR}$ signal. In the event $\overline{MCLR}$ is not forced by the target circuit, R4 (a 2 kΩ pull-up resistor in the programmer) provides a high logic level on the target microcontroller which enables execution of its program independent of the programmer connection. Provisions should be made to prevent the target circuit from resetting the target microcontroller with $\overline{MCLR}$ or affecting the RB7 and RB6 pins during the programming process. In most cases this can be done without jumpers.

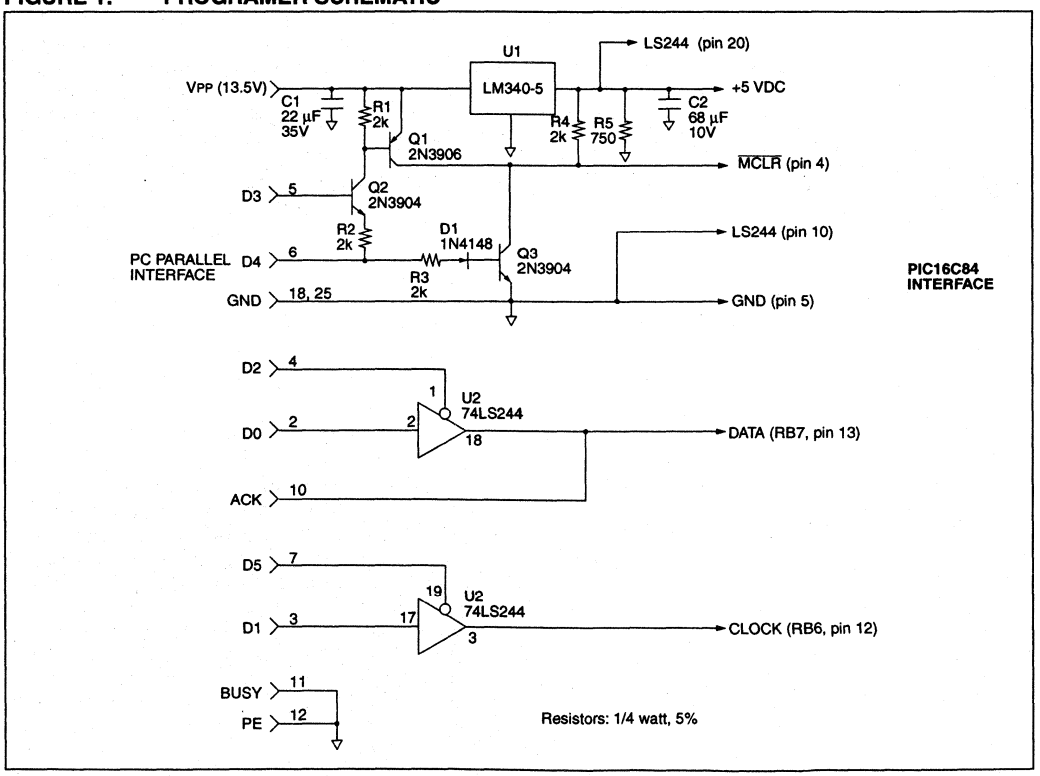
DETAILED CIRCUIT DESCRIPTION

A logic high on PC parallel interface latch bit D4 turns on Q3 causing the $\overline{MCLR}$ pin to go low which places the target part in reset mode. The reset condition is then removed and the program/verify voltage is applied by placing a logic high on D3 and a logic low on D4 which turns off Q3 and turns on Q2 and Q1. Circuit protection of Q1 and Q3 is obtained from connecting the emitter of Q2 to latch bit D4 which prevents a simultaneous reset and program/verify voltage mode. Q2, a 2N3904, has a reverse emitter base breakdown voltage of 6V which will not be exceeded when 5V logic is used on the parallel interface.

Resistors R1, R2, R3, and diode D1 provide a logic level interface to the analog circuitry. R4 provides a $\overline{MCLR}$ (master clear) pull-up function during target circuit run mode. The programming voltage is supplied and adjusted by an external lab supply. This supply should have a current limit in the 100 mA range. 5V for U2 (LS244) is locally regulated from programming supply voltage by U1. R5 (750Ω resistor) is connected to the regulator output to insure proper 5V regulation when the 13.5V programming voltage is applied through the pull-up resistor R4.



Data and clock are connected to the part via tri-state buffer, U2. PC parallel port interface bit D0 is used for data and port bit D1 is used for clock. During programming mode both clock and data buffers are enabled by port bits D2 and D5. During read mode, the data buffer is tri-stated via D2 and the printer data acknowledge signal line is used to receive verification data from the part.

After program/verification mode both the data and clock lines are tri-stated via D2 and D5, allowing these lines to be used by the target circuit. This allows the programmer to remain physically, but not electrically connected to the target system.

An optional 5V line was included in the 3-foot programming interconnect cable for convenience. Short interconnection leads and good grounding are always good construction practice.

To meet the programming/verification specification, the target part's supply voltage should first be set to the maximum specified supply voltage and a program/data read back should then be performed. This process is then repeated at the lowest specified supply voltage.

SOFTWARE DESCRIPTION

The listed code provides a hardware-software interface to a standard PC parallel (Centronix) interface port. The code can be adapted to a microprocessor parallel interface port by substituting an output command for the "biosprint" command.

Control software can transfer the PIC16C84 program, configuration bits, and EEPROM data from a standard PROM interface file into the target system by reading the file and calling the function in Example 1 using the appropriate command name in the definition table, and the data to be programmed. The command names are repeated here for reference.

LOAD_CONFIG	Sets PIC16C84 data pointer to configuration.
LOAD_DATA	Loads, but does not program, data.
READ_DATA	Reads data at current pointer location.
INC_ADDR	Increments PIC16C84 data pointer.
BEGIN_PROG	Programs data at current data pointer location.
PARALLEL_MODE	Puts PIC16C84 into parallel mode (not used).
LOAD_DATA_DM	Loads EEPROM data.
READ_DATA_DM	Reads EEPROM data.

Function "int ser_pic16c84(<command>,<data [or 0]>) is called to perform command. Function returns internal data after read commands.

Do not forget to initiate the programming mode before programming, increment the addresses after each byte is programmed, and put the programmer in run mode after programming.

Apple® Desktop Bus (ADB™)

INTRODUCTION

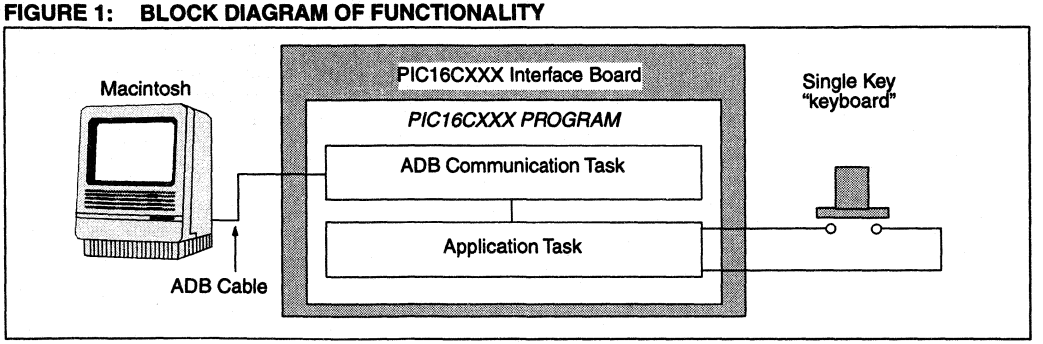
The purpose of this application note is to introduce a PIC16CXXX based ADB interface which can be used as a basis for the development of custom ADB devices. This application note describes; the hardware involved, a general purpose ADB protocol handler, and an example application task. The example software application supports a single key keyboard to the Macintosh® computer (Figure 1).

OVERVIEW

ADB licensing from Apple Computer.

Described as a peripheral bus used on almost all Macintoshes (except for the Macintosh 128, 512K, and Plus) for keyboards, mice, etc.

Communication between the ADB task and the application task takes place using several flags. The flags indicate whether there is data received that needs to be sent to the Macintosh, or if data from the Macintosh needs to be sent by the application.



EXPLANATION OF ADB TECHNOLOGY

ADB is an asynchronous pulse-width communication protocol supporting a limited number of devices. All devices share a single I/O wire in a multi-drop master/slave configuration in which any slave device may request service. This is accomplished through a wired OR negative logic arrangement.

The ADB cable is composed of four wires: +5V, gnd, ADB signal, and power-on (of the Macintosh). The signal wire communicates ADB input and output using an open collector type signal. The number of devices is limited by the addressing scheme and a maximum current draw of 500 mA.

Every ADB device has a default address at start-up assigned by Apple. If there are device address conflicts, the protocol supports the reassignment of device addresses at start-up. The software in the PIC16CXXX discussed here is designed to easily modify the device address to make the PICmicro™ appear as another ADB device for testing and development.

No device issues commands, except the host. However, devices are permitted to request service during specific time intervals in the signal/Command protocol. A Service Request is referred to as an "Srq" The signal protocol communication is accomplished by pulling the ADB line low for various time intervals.

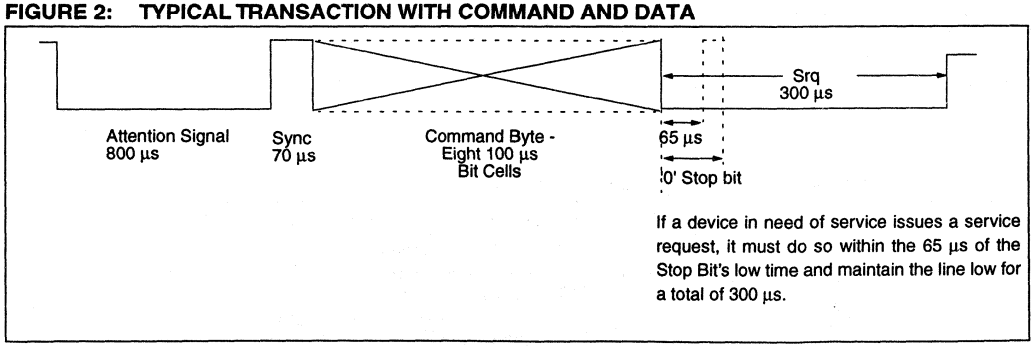
The host controls the flow of data through issuance of specific signal sequences and by issuing several types of Commands. The basic command types are Talk, Listen, Flush, and Reserved. Each command has a component called a "Register" indicator which specifies the storage area affected by the command type. The following is a summary explanation of the each of the commands. The complete specifications are available from Apple, as listed in the Resources section of this application note.

PROTOCOL ASSUMPTIONS

The ADB protocol is defined with a number of general assumptions about its use. These assumptions have driven the general philosophy of the communication sequences. It is assumed that the devices on the ADB are used for human input and each are used one at a time, such as a keyboard and a mouse. It is also assumed that the user's transfer time from one device to another is relatively slow. This does not mean that the protocol is limited to these assumptions but rather that the protocol is optimized towards this type of use. This is made very evident in the host polling logic, where the host continues to poll the last device communicated with until another device issues an Srq. Consequently, if another device issues an Srq, the device being communicated with (or the host) may need to retransmit.

ADB Elements:

The ADB protocol has two components, a Signal protocol and a Command/Data protocol. These two elements are intertwined. The Signal protocol is differentiated in most cases by timing periods during which the ADB signal is low. The Apple ADB specification allows ± 3% tolerance timing of the signals from the host and ± 30% by the devices. The signals are:



- Reset: signal low for 3 ms.
- Attention: signal low for 800 µs.
- Sync: signal high for 70 µs.
- Stop-to-Start-Time (`Tlt`): signal high for between 65 and 160 µs.
- Service Request (`Srq`): signal low for 300 µs.

After device initialization, in general, all communication through the ADB is accomplished through the following event sequence initiated by the host:

1. Attention signal
2. Sync signal
3. command packet
4. Tlt signal
5. data packet transfer

Depending upon the command, the device may or may not respond with a data packet. Service requests are issued by the devices during a very specific time at the end of the reception of the command packet.

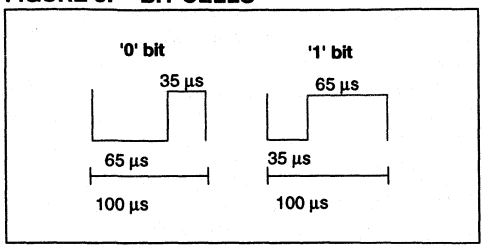


FIGURE 2: TYPICAL TRANSACTION WITH COMMAND AND DATA

© 1997 Microchip Technology Inc.

The command packets and the data packets are the constructs used to communicate the digital information. The method of representing data bits is accomplished in a signal timing construct called a **bit cell**. Each **bit cell** is a 100 µs period. Data '1's and '0's are defined by the proportions of the bit cell time period when the line is low and then high. A '1' bit is represented by the line low for 35 µs, and high for 65 µs. Conversely, A '0' bit is represented by the line low for 65 µs, and high for 35 µs (Figure 3).

FIGURE 3: BIT CELLS

The **Command Packet**, received from the host, follows an Attention signal and a Sync signal. It consists of an 8-bit command byte and a '0' command stop bit. The command byte may be broken down into two nibbles. The upper nibble is a 4-bit unique device address. The lower nibble is defined as a Global or Reserved command for all devices, or a Talk, Listen, or Flush Command for a specific device. Also contained in the lower nibble is a "Register" designator which further details the Command. The importance of the Command Stop Bit Cell is that Srqs' can only be issued by a device to the host during the Command Stop Bit Cell low time if the device address is not for the device wishing service. The Host controls when Srq's are allowed through the Command protocol. The Tlt signal and Data Packet transfer, which are part of every Command packet signal sequence, are overridden if an Srq is issued by any device.

A **Data Packet** is the data sent to, or received from, the host. Its length is variable from 2 to 8 bytes. The structure is a '1' start bit, followed by 2 to 8 bytes, ending with a '0' stop bit. The Apple ADB documentation refers to the data packet sent or requested as Device Data "Registers". This does not necessarily indicate a specific place in memory. In this PIC16CXXX implementation, each Data Register has been limited to two PIC16CXXX register bytes. The ADB specification allows each Data Register to hold between two and eight bytes. They are referenced in the Command byte as "register" 0, 1, 2, or 3. Data Register 3 has special significance. It holds the special status information bits (such as whether Srq's are allowed), the Device Address, and the Device Handler ID. Commands are further defined by the "register id" sent in the Command data packet.

For example, if the Host issues the Command in binary of `0010 1100`, it would be interpreted as "Device 2, Talk Register 0". The complete definition of the Commands and data registers are described in detail in the ADB specifications supplied by Apple.

PIC16CXXX ADB PROTOCOL PROGRAM EVENT SEQUENCE

Overview

At power-on the host will generate a Reset signal. The purpose of Reset is to initialize the devices on the ADB line. This includes determining the addresses of each device, and resolving device address conflicts if there are any. Once the device addresses are determined, each device waits to be commanded or issues an Srq if it requires service from the host and is not being addressed by the host. After Reset processing, the ADB Protocol Task monitors the ADB line for the Attention/Sync/Command signal sequence. The PIC16CXXX program differentiates the signal timing.

Note: The signal detection routines check to see if the Application Task needs service after each event and after the falling edge of the Attention signal is detected.

Command interpretation is accomplished during the low signal time of the Stop Bit cell of the Command packet. Response to the Command must occur after the minimum time of the Stop to Start time period (Tlt), which is 160 µs. but before the max Tlt time of 240 µs. When a device has issued an Srq, it waits to be addressed by the host. If the next Command received is not for that device, it issues the Srq again. The normal response to an Srq will be a Talk Command from the host.

Detailed Description

Start-up

Upon start-up, the Reset routine is executed, looking for the ADB line to be high. When the line is high, an initialization routine is executed during which registers are cleared or loaded with default values. The only exception is a register for generating a random address used in the address conflict resolution process.

Reset

During a Reset condition, default values are loaded, such as the Default Device Address and Handler ID (a piece of information used by the host to identify the type of device). If more than one device has the same address, there is a sequence of events to resolve address conflicts described in the Implementation section. The host assigns a unique address to each device. The Reset condition only takes place once, during start-up, except under unusual conditions, such as testing this program.

© 1997 Microchip Technology Inc.

Attention Routine

When the Reset routine is complete, the Attention Signal routine is executed, looking for the line to go low and then high. This low time is monitored to be within range of the Attention Signal Timing. If the timing is below the minimum threshold, the routine aborts to start over again looking for the line to go low at the beginning of the Attention Signal. If the low time is exceeded, the routine aborts to the Reset Signal routine.

Sync Signal Routine

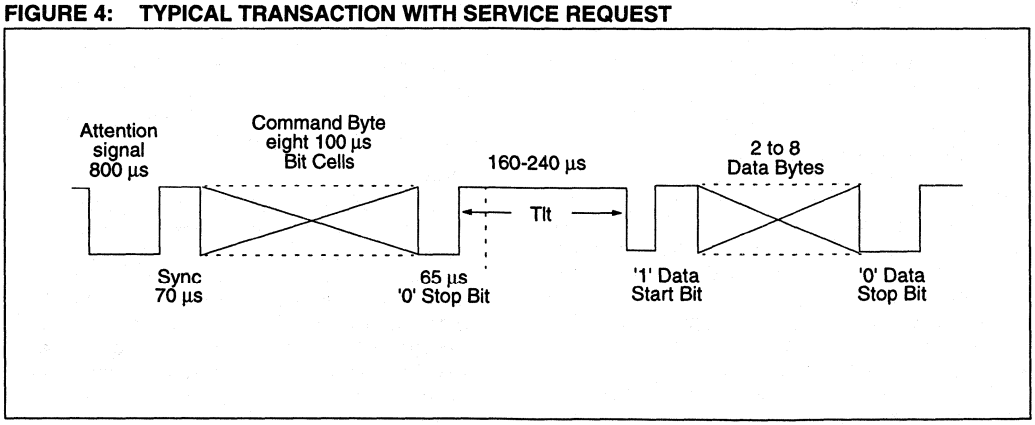
When the line transitions to high, the Sync Signal routine looks for the line to go low at the start of the first bit of the Command Byte. If the Sync high time is exceeded, the routine aborts to the Attention Signal.

Command Routine

The Command routine detects and decodes the next 8 bit-cells as the Command Byte. The routine must first determine if the device address given is for itself. If the routine determines that the device address in the Command matches the stored device addresses, then it may do one of two things; issue an Srq to the host by holding the line low, or go on to check if the Command is Global to all devices. If the command is Global, the routine determines the specific Command and executes the routine for that Global Command. After execution of the Command routine it then goes back to look for the Attention Signal.

When a device is addressed, it determines whether the Command is to Talk, Listen, or Flush data, for the specified Data Register number. If the Command is for Data Register 3, there are special considerations described for this program in the Implementation section later in this application note. If the Command is to Flush, the routine clears the data in the specified register. The ADB specification defines the action of the Flush Command to be device specific. For a Talk Command or Listen Command, the device then waits for the Tlt signal. When the Command is to Talk, the device sends the data bytes from the specified register and a Data Stop Bit after the Tlt minimum time. For a Listen Command, the device receives data for the specified register.

When the data has been Flushed, Sent, or Received, the device then returns to monitoring for the Attention signal again.



Note 1: In this PIC16CXXX program, the Application Task is serviced before looking for the Attention signal.

Note 2: If at any time the line is low or high outside of the timing ranges, the program aborts to check if an Attention or Reset signal has been issued by the Host. In the case of sending Data, the program goes first to the Collision routine.

Sending Data to the Host

Data is sent only in response to a Talk Command. For every data bit cell, the line is tested to go high at the proper time. If the line is still low, a collision has occurred. When a collision is detected, a collision flag is set, and the program aborts to look for a Command signal sequence.

IMPLEMENTATION

Hardware

The hardware of this circuit is fairly simple. The circuit is powered via the +5V and GND wires of the ADB cable. The ADB I/O wire is connected to pin RA0 with a pull-up resistor to 5V. The T0CKI pin is tied to GND. The Master Clear ($\overline{MCLR}$) pin is tied to 5V.

This circuit uses a 4 MHz crystal as a timing reference, but higher values may be substituted. The software is designed to accommodate higher frequencies.

A pushbutton switch is used as the single key of the "keyboard." One side is connected to port RB1 with a pull-up resistor to 5V, and the other side to GND. An LED is used to indicate that the 'key' has been pressed, with the positive side connected to pin RB0 and the negative side to GND.

Software

The program designated as "Application Tasks," has two sections, one is setup to switch between a protocol support task for the ADB signal decode and processing, and the other section is the Application Task, in this case a single key "keyboard" routine. The ADB protocol task has priority. The first section of the code is the ADB protocol task, the second section is the Application Task, "Keyboard." The two tasks communicate through flags which indicate that data needs to be sent, or that data has been received.

The Keyboard Task is run at two times; 1) during the Attention Signal, 2) between the end of the Data Stop Bit and the beginning of the Attention Signal. The Keyboard Tasks is given up to 500 µs during the Attention Signal, and 900 µs during the time between the end of the Data Stop Bit and the beginning of the Attention Signal. It is important to note here that the other tasks MUST NOT AFFECT TMR0 or the ADB time variable that the Attention Signal is using to keep track of the RTCC.

Timing

Timing is accomplished by first loading a constant into a time variable. This constant represents the maximum limit for the current routine, which may not necessarily be the maximum timing range for the current Signal. The TMR0 value is loaded into the working register, and subtracted from the time variable. The Carry bit of the STATUS register is tested to see if it is set or clear. If the bit is clear, the current timing limit has been exceeded. Further action is taken based on this status. It is important to keep the constant away from 255, or rollover may occur, giving inaccurate results. The prescaler is applied to the TMR0 as necessary.

The following are the timing ranges used by this program for ADB signals:

Reset	> 824 µs
Attention	776-824 µs
Sync	72 µs
Bit Cell	Up to 104 µs
'1' Bit low time	< 50 µs
'0' Bit low time	> 50 < 72 µs
Stop bit	0 Bit
Stop to Start (Tlt)	140-260 µs
Service Request (Srq)	300 µs

Note: The range of values given for 0 Bit, 1 Bit and Tlt timing are slightly wider than those given in the ADB specification.

How Address Conflicts are Resolved

During the start-up process the host sends a "Talk Register 3" command to each device address, and waits for a response. When a device recognizes that the Host issued a "Talk Register 3" command, it responds by sending a random address. During the transfer of each Bit Cell of the random address the signal line is monitored for the expected signal level. If the signal is not what is expected there is an address conflict. If the address is sent successfully, the host will respond with a Listen Command to that device. The command will have a new Device Address to which that device will move. The device then only responds to commands at the new address.

If there is a conflict, where two devices have the same default address, and respond at the same time, the device that finds the line low when it expects it to be high, immediately stops transmitting because it has determined that a collision has occurred. The device which detected the collision marks its address as unmovable and therefore ignores the address move Command, a Listen Register 3 Command. The device maintains the unmovable address condition until it has executed a successful response to the Talk Register 3 Command.

The host continues sending a Talk Register 3 Command at the same address until there is a time-out and no device responds. This is how conflicts are resolved when more than one device has the same address; for example, if two keyboards are connected.

Program Sequence:

Words in parenthesis, ( ), accompanying the TITLES are Labels of procedures in the corresponding code.

Start-up / IDLE (`Start`)

Start by configuring the ADB pin on PORTA and the Switch Pin on PORTB as inputs, and tri-stating the rest of PORTA and PORTB as outputs.

INITIALIZE DEFAULT VALUES WHEN THE LINE IS HIGH (`Reset`)

Look for the line to be high, and when it is, clear or initialize registers to default values.

LOOK FOR ATTENTION OR RESET (`AttnSig`)

Look for the line to go low, when it does, clear TMR0 and time how long it is low. An Attention Signal has occurred if the line went high between 776 and 824 µs. If the low time is measured to less than 776 µs, another signal has occurred and the program aborts, looking for the Attention Signal again. When the low time is measured to greater than 824 µs, the program interprets this timing as a Reset Signal. The program starts over again, waiting for the line to be high, and when it is, performs a Reset initialization.

Note: The keyboard task is performed during the Attention Signal (Task_2).

LOOK FOR SYNC SIGNAL (`SyncSig`; calls `Srq`)

The Sync Signal is the high time between the rising edge of the Attention Signal and the falling edge of the first bit of the Command.

GET THE COMMAND (Command; calls `Get_Bit`)

Look for the Command; a combination of eight '0' and '1' bits. The MSb is sent first. This is achieved by calling the `Get_Bit` routine, which checks whether the maximum Bit Cell time is exceeded, if not, it looks for the rising edge at the end of the bit. When the bit is received, it is rotated into a variable, and the end of the bit cell is expected. When the falling edge of the next bit is detected, the routine clears TMR0 and returns to Command, which calls `Get_Bit` again until all 8-bits of the Command have been received.

ISSUE A SERVICE REQUEST IF NECESSARY (`Srq`)

If data needs to be sent to the Host, a Service Request (`Srq`) is issued by holding the line low while the Stop Bit is being received during the Stop-to-Start time (`Tlt`) which is between the end of the Command Stop Bit and the beginning of the Data Start Bit.

LOOK FOR STOP BIT (`CmdStop`)

Look for the Stop Bit (a '0' bit of 65 µs) that comes after the last Command Byte.

INTERPRET THE COMMAND (`AddrChk`)

After the command has been received, determine if the address belongs to this device. If the address is not for this device, determine if the command is global for all devices and if so, do that command. If this is not a Global/Reserved Command, call the Service Request (Srq) Routine to see if an Srq should to be issued to the Host, and do so if necessary, then return to get the Attn Signal. If the Address is for this device determine whether it is a Talk, Listen, or Flush Command, and go to the specified Command routine.

SENDING DATA (Talk; calls `Tlt`)

If the command was interpreted to be a Talk Command addressed to this device, call the Stop-to-Start Time (Tlt) routine. When the `Tlt` routine has completed, determine if this is a Talk Register 3 Command. If so, return a Random Address as part of the two bytes sent to the Host. If this is not a Talk Register 3 Command, determine if data needs to be sent. If so, send the Data Start Bit (a '1'), two bytes of data from the indicated register, and a Stop Bit (a '0'). If not, abort to the Attention Signal. If at any time the transmission of Data is interrupted, abort to the Collision routine. Only after a complete transmission should the flags be cleared indicating a successful transmission.

Note: The ADB Specification indicates data may be between two and eight bytes long. The limitations of the PIC16C54/55/56 parts allow only two bytes of data to be sent by this program due to limited register space. If more than two bytes of data must be sent, use the PIC16C57.

RECEIVING DATA (Listen; calls `Tlt`)

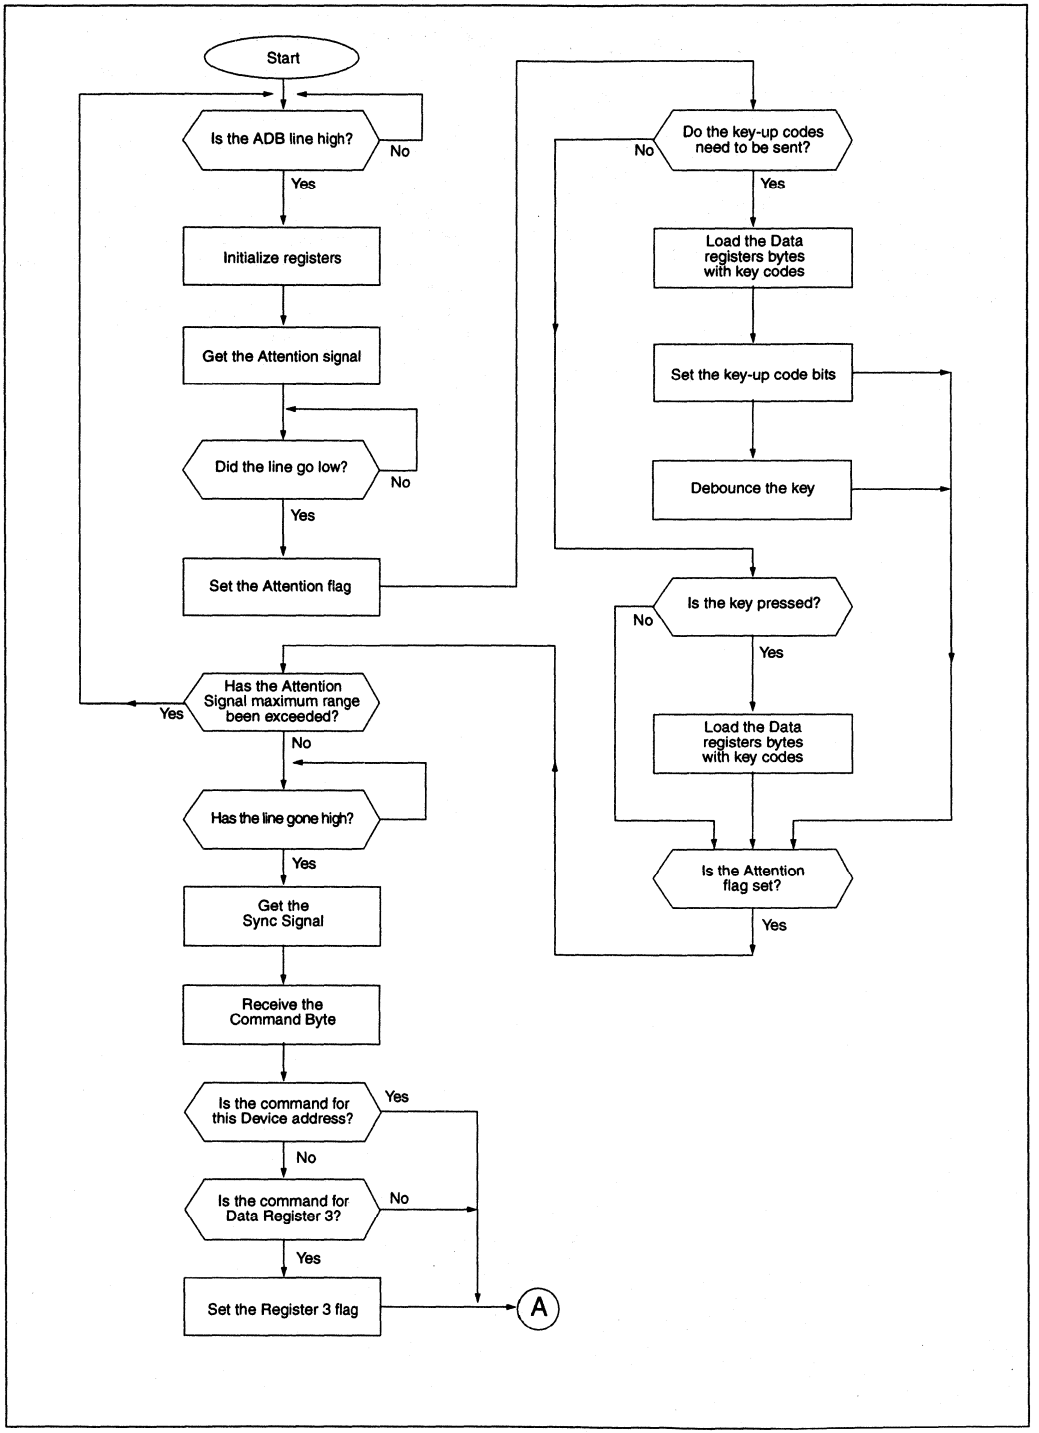
If the command was interpreted to be a Listen Command addressed to this device, call the Stop-to-Start Time (`Tlt`) routine. When the `Tlt` routine has completed, receive the rest of the Data Start Bit, 2 Data Bytes, and Data Stop Bit. When the data has been received, determine whether this is a Listen Register 3 Command. If this is a Listen Register 3 Command, interpret what the command is. If this is a conditional Address Change Command, determine if this Device's Address is moveable at this time. If not, abort to the Attention Signal. If so, change the device to the new address and go run the Second Application Task. If this is not a Listen Register 3 Command, move the data into the specified register and go run the Second Application Task.

© 1997 Microchip Technology Inc.

LOOK FOR THE STOP TO START TIME (Tlt)

After the Command and Stop Bit, the Talk or Listen routines call the Tlt routine. Tlt looks for the line to go low. If the line went low before the minimum Tlt Time, see if this is a Talk Command. If this is a Talk Command, abort to the Collision routine. If this is a Listen Command, abort to the Attention Signal.

If the minimum Tlt time passes and the line is high, see if the Talk routine called the Tlt, if so, go wait for until the middle of the Tlt, then return to the Talk routine to send the Data Start Bit, Data Bytes, and Stop Bit. If at any time the line goes low during the Tlt and the Talk routine called it, abort to the Collision routine.



If the Listen routine did call Tlt, look for the line to go low at the beginning of the Data Start Bit. When the line goes low, return for the rest of the Start Bit. If the line doesn't go low before the maximum Tlt time is up, abort to the Attention Signal.

THE KEYBOARD TASK IS PERFORMED BETWEEN THE END OF THE DATA STOP BIT AND THE ATTENTION SIGNAL (Task_2)

The Keyboard Task checks to see if the key has been pressed. When the key is pressed, indication flags are set and an LED is turned on until the key has been debounced. The flags allow the key to be debounced, Srq(s) to be sent to the Host, and indicate to the Talk routine that Data needs to be sent. Two bytes of data are loaded into Register 0 representing a key-down code and a flag is set indicating to the ADB task that data needs be sent to the host. When the key-down codes have been sent, the key-up codes are loaded into Register 0. When the key-up codes have been sent and the key has been debounced, the flags are cleared. The final routine of Task_2 decides whether to return to the beginning or middle of the Attention Signal.

SUGGESTIONS ABOUT MODIFYING THE CODE

1. If high crystal frequencies are used, a divider equate (equ) at the beginning of the timing section of the equates allows an easy adaptation for all established timing definitions.
2. The second application task may occur as a communication task with another PIC16CXXX device by using the three other I/O lines on PORTA, although test code for this has not yet been written. Two of the lines would be used as ready-to-send (one for each PIC16CXXX). The third would be used as a data line, using low signals as '0' bits, and high signals as '1' bits. Additionally, all eight lines on PORTB may be used as well.

Using the CCP Module(s)

Author: *Mark Palmer*
Microchip Technology Inc.

This application note discusses the operation of a Capture/Compare/PWM (CCP) module, and the interaction of multiple CCP modules with the timer resources.

The (CCP) module is software programmable to operate in one of three modes:

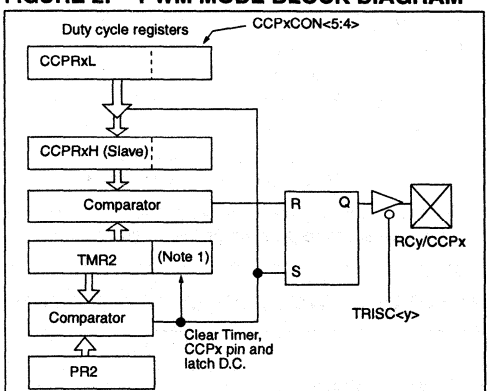
1. A Capture input
2. A Compare output
3. A Pulse Width Modulation (PWM) output

For the CCP module to function, Timer resources must be used in conjunction with the CCP module. The desired CCP mode of operation determines which timer resources are required. Table 1 shows the CCP mode with the corresponding timer resource required. Both the Capture and Compare modes require that Timer1 be operating in timer mode or synchronized counter mode.

Note: Capture and Compare modes may not operate if Timer1 is operated in the asynchronous counter mode.

TABLE 1: CCP MODE - TIMER RESOURCE

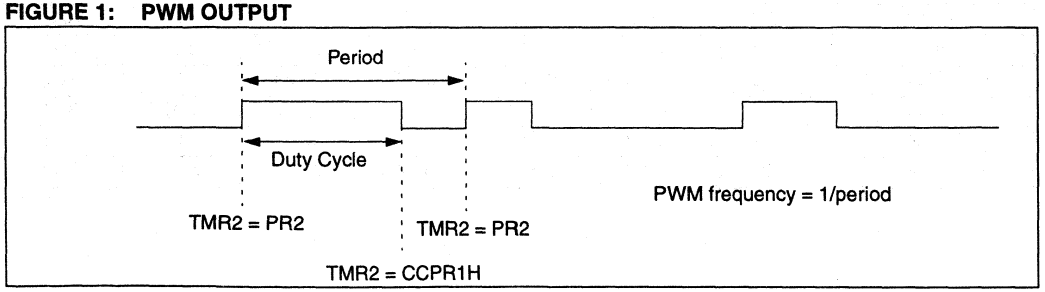
CCP MODE	Timer Resource
Capture	Timer1
Compare	Timer1
PWM	Timer2



CCP OPERATION

The following three sections discuss the operation of the CCP module in each of its modes of operation. There is a simple example program for each mode of operation. The software example for the Capture mode, also uses a second CCP module in Compare mode to generate the signal to capture.

PWM Mode



A Pulse Width Modulation output (Figure 1) is a signal that has a time-base (period) and a time that the output stays high (duty cycle). The period is the duration after which the PWM rising edge repeats itself. The resolution of the PWM output is the granularity with which the duty cycle can be varied. The frequency of a PWM is simply the inverse of the period (1/ period).

FIGURE 2: PWM MODE BLOCK DIAGRAM

Note: 8-bit timer is concatenated with 2-bit internal Q clock or 2 bits of the prescaler to create 10-bit time-base.

FIGURE 1: PWM OUTPUT

Each CCP module can support one Pulse Width Modulation (PWM) output signal, with minimal software overhead. This PWM signal can attain a resolution of up to 10-bits, from the 8-bit Timer2 module. This gives 1024 steps of variance from an 8-bit overflow counter. This gives a maximum accuracy of Tosc (50 ns, when the device is operated at 20 MHz). Figure 2 shows a block diagram of the CCP module in PWM mode. When the Timer2 overflows (timer = period register), the value in the duty cycle registers (CCPRxL:CCPRxCON<5:4>) is latched into the 10-bit slave latch. A new duty cycle value can be loaded into the duty cycle register(s) at any time, but is only latched into the slave latch when Timer2 = Timer2 Period Register (PR2).

The period of Timer 2 (and PWM) is determined by the frequency of the device, the Timer2 prescaler value (1, 4 or 16), and the Timer2 Period Register. Equation 1 shows the calculation of the PWM period, duty cycle, and the minimum and maximum frequencies.

Appendix A is a program which generates up to a 10-bit PWM output. The PWM period and duty cycle are updated after the overflow of Timer1. Upon the overflow of Timer1, ports A, B and D are read. The 10-bit duty cycle is specified by the value on PORTB:PORTA<1:0>, while the period is specified by the value on PORTD. By setting the conditional assemble flag `PICMaster` to `TRUE`, these values are read from internal registers which are dummy registers for the ports (DUMMY_Px). This allows the software to be verified without the use of hardware and external stimulus.

Since the PWM duty cycle is double buffered, the duty cycle registers are only loaded when there is sufficient time to complete the update of the 10-bit value before the Timer2 = PR2 match occurs. After the duty cycle has been updated and the Timer2 = PR2 match has occurred, the period (stored in the PR2 register) is updated. The operation of the CCP module in PWM mode is similar to the PIC17C42's PWM. Additional concepts of PWM operation can be found in Application Notes AN564 and AN539.

EQUATION 1: PWM PERIOD, DUTY CYCLE, AND FREQUENCIES

PWM Period = [(PR2) + 1] • 4 TOSC • (Timer 2 prescale value)

PWM Duty Cycle = [CCPRxL:CCPRxCON<5:4>] • 4 TOSC • (Timer2 prescale value)

PWM maximum frequency
(High Resolution mode) = 4/(PR2 • TCY)
(Low Resolution mode) = 1/(PR2 • TCY)

PWM minimum frequency
(High Resolution mode) = 4/(PR2 • TCY)
(Low Resolution mode) = 1/(PR2 • TCY)

Table 2 shows the minimum and maximum PWM frequency for different device frequencies. The Timer2 prescaler will be selected to give either the minimum or maximum frequencies as shown.

Compare Mode

In Compare mode, the 16-bit value of Timer1 is compared to the CCPRxH:CCPRxL registers. When these registers match, the S/W configured event occurs on the CCPx pin. The events that can be S/W selected are:

- Clear CCPx pin on match
- Set CCPx pin on match
- Generate S/W interrupt (CCPx pin unchanged)
- Trigger special event (CCPx pin unchanged)
  - CCP1 clears Timer1
  - CCP2 clears Timer1 and sets the A/D's GO/$\overline{\text{DONE}}$ bit

The CCPxM3:CCPxM0 control bits, in register CCPxCON, configures the operation of the CCP module. The compare function must have the data direction of the CCPx pin configured as an output, if the compare event is to control the state of the CCPx pin.

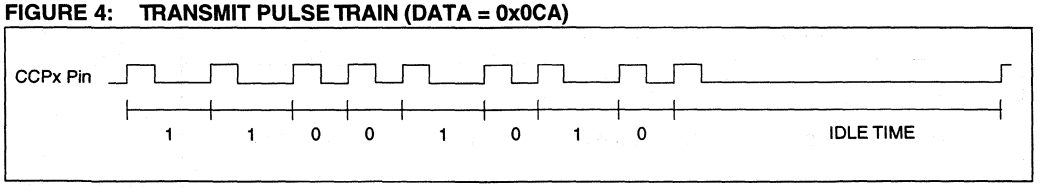

FIGURE 3: COMPARE MODE BLOCK DIAGRAM

When the CCP module is in the OFF state (CCPxM3:CCPxM0 = 0h), the CCPx output latch is forced to a low level, though the level on the CCPx pin will be determined by the value in the data latch of the port. Figure 3 shows the block diagram of the CCP module in Compare mode.

Appendix B is a program which uses the CCP module to transmit a pulse train dependent on the data byte. Timer1 is used as a free running timer, with each "new" compare value being an offset added to the present CCP compare latch value. The data is transmitted every 600 µs. Each data bit has a sync pulse (High level) of 8.8 µs. Then the data is transmitted as a low pulse. The time duration of the low pulse determines the value of the data bit. A '0' bit is low for 18.8 µs while a '1' bit is low for 37.6 µs. After the last data bit has been transmitted, another sync pulse is transmitted and the output remains low (idle time) until the 600 µs data period has completed. An example of the pulse train for the a data byte of 0x0CA is shown in Figure 4, and has an idle time of 224 µs. These pulse times are based off the device operational frequency. The program header file, `COMP.H`, calculates the values to be loaded into the compare registers from the specified Device_freq. The data to be transmitted is read from PORTB, during the idle time. By setting the conditional assemble flag `PICMaster` to `TRUE`, these values are read from internal registers which are dummy registers for the ports (DUMMY_Px). This allows the software to be verified without the use of hardware and external stimulus.

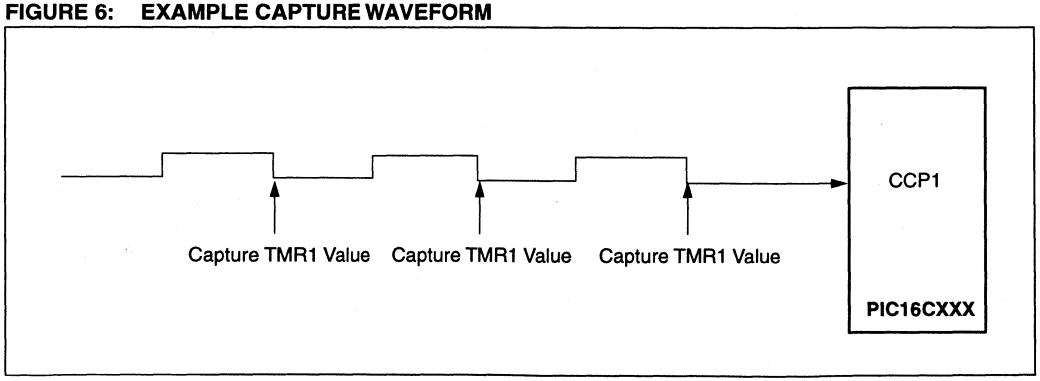
Capture Mode

In Capture mode, the 16-bit value of Timer1 is latched into the CCPRxH:CCPRxL registers, when the S/W configured event occurs on the CCPx pin. The events that can cause a capture are:

- Every falling edge
- Every rising edge
- Every 4th rising edge
- Every 16th rising edge

The CCPxM3:CCPxM0 control bits, in register CCPxCON, configures the operation of the CCP module. The capture function works regardless of the data direction of the CCPx pin (input or output). With the CCPx pin is configured as an output, a write to the CCPx pin (in PORTC) will cause a capture when the capture requirement is met.

FIGURE 5: CAPTURE MODE BLOCK DIAGRAM



The changing of the Capture mode, via the CCPxM3:CCPxM0 bits, may cause the CCPxIF bit to be set. This "false" interrupt should be cleared (ignored) after changing between capture modes. The CCP prescaler is only cleared by configuring the CCP module into the OFF state (CCPxM3:CCPxM0 = 0h). Figure 5 shows the block diagram of the CCP module in Capture mode. The use of the CCP module in Capture mode is similar to the PIC17C42's capture. Additional concepts of capture operation can be found in Application Note AN545.

Appendix C is a program which implements a 16-bit capture from a free running timer (Timer1). The capture event is configured as each rising edge. The 16-bit capture value is the "new" 16-bit capture value minus the "old" 16-bit capture value. If the time between captures is greater than 2^{16} Timer1 increments, an invalid result will occur. This invalid result is not indicated by the software. After the capture period result is calculated, the "new" capture value is loaded into the "old" register.

The waveform that is captured is generated from a second CCP module in compare mode. The value that is loaded in to the CCPR2H:CCPR2L is read from the PORTB and PORTD registers. By setting the conditional assemble flag `PICMaster` to `TRUE`, these values are read from internal registers which are dummy registers for the ports (DUMMY_Px). This allows the software to be verified without the use of hardware and external stimulus. Figure 6 shows an input into the CCPx pin, and the capture measurement points.

INTERACTION OF CCP MODULES

Due to the modularity of the PIC16CXXX peripherals, future devices with two or more CCP modules on a device are possible. Each CCP module operates independently from the others, though their interaction with the timer resources must be taken into account.

When two or more CCP modules exist on a device, there can be an interaction between the CCP modules. This interaction is shown in Table 3. These interactions do NOT include any interaction (S/W) caused by the main program nor the interrupt service routines of the CCP sources.

Interaction of Two Capture Modes

When two CCP modules are in a Capture mode, Timer1 is the time-base for both captures. This means that they will have the same capture resolution, as determined by the Timer1 prescaler and frequency of the timer/counter clock. This clock can come from an external source (on the RC0/T1OSO/T1CKI pin), but must be synchronized to the device.

Interaction of One Capture Mode and One Compare Mode

When one CCP module is in a Capture mode and a second CCP module is in Compare mode, Timer1 is the time-base for both the captures and the compare. This means that the capture and the compare will have the same resolution, as determined by the Timer1 prescaler and frequency of the timer/counter clock. This clock can come from an external source (on the RC0/T1OSO/T1CKI pin), but must be synchronized to the processor clock. Also, care must be taken in that the compare can be configured to clear TMR1 register (when in special Trigger mode). Care must be taken in system design to ensure that this clearing of the TMR1 register does not have any negative impact on the capture function.

Interaction of Two Compare Modes

When two CCP modules are in a Compare mode, Timer1 is the time-base for both compares. This means that they will have the same compare resolution, as determined by the Timer1 prescaler and frequency of the timer/counter clock. This clock can come from an external source (on the RC0/T1OSO/T1CKI pin), but must be synchronized to the processor clock. Since the compare modules can be configured to clear TMR1 register (when in special Trigger mode), care must be taken in system design to ensure that this clearing of the TMR1 register does not have any negative impact on the compare function. If both compares are configured with a special trigger, which clears the TMR1 register, then the compare register that is closest to (but greater than) the TMR1 register value is the compare value that will reset the TMR1 register. Example 1 shows a possible case.

Interaction of Two PWM Modes

When two CCP modules are in a PWM mode, Timer2 is the time-base for both PWM outputs. This means that they will have the same PWM frequency and update rates, as determined by the Timer2 prescaler and frequency of the device. The resolution of the two PWMs may be different, since each CCP module has its own CCPxX:CCPxY bits for high resolution mode. These bits are found in the CCPxCON<5:4> register.

CONCLUSION

The Capture/Compare/PWM modules offer enormous flexibility in the use of the device timer resources. As with all resources, care must be taken to ensure that no adverse system complications can occur with the interaction between multiple CCP modules. The programs for simple operation of the various CCP modes should be a good foundation for modifications to suite your particular needs.

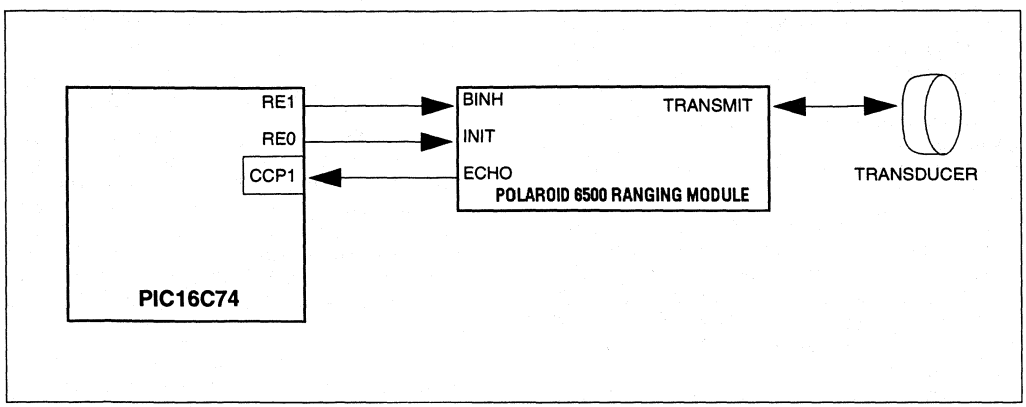
Implementing Ultrasonic Ranging

Author: *Robert Schreiber*
Microchip Technology Inc.

INTRODUCTION

Object ranging is essential in many types of systems. One of the most popular ranging techniques is ultrasonic ranging. Ultrasonic ranging is used in a wide variety of applications including:



- Autofocus cameras
- Motion detection
- Robotics guidance
- Proximity sensing
- Object ranging

This application note describes a method of interfacing PIC16CXXX microcontrollers to the Polaroid 6500 Ranging Module. This implementation uses a minimum of microcontroller resources, a CCP module and two I/O pins. The two major components of the system are:

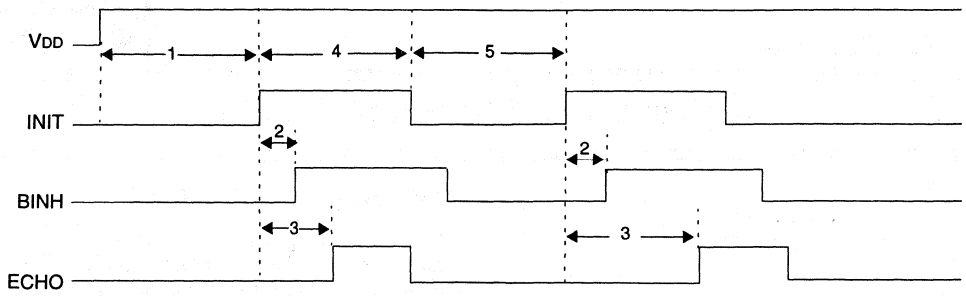
- Microcontroller
- Polaroid 6500 Ranging Module

The microcontroller performs the intelligence and arithmetic functions for ultrasonic ranging, while the Polaroid 6500 Ranging Module performs the ultrasonic signal transmissions and echo detection.

FIGURE 1: RANGING MODULE INTERFACE

THEORY OF OPERATION

Ultrasonic ranging entails transmitting a sound wave and measuring the time that it takes for the sound wave to reflect off of an object and back to the origin. The reflection time is proportional to the distance that the object is from the source. In this implementation, the sound wave is transmitted and received from the same transducer. Therefore, a blanking interval is required between signal transmission and reception to eliminate false echoes (i.e., a transmitted signal being detected as its own echo).



CIRCUIT CONFIGURATION

In this implementation, a PIC16C74 is connected to the ranging module as shown in Figure 1. The RE0 and RE1 I/O pins are configured as digital outputs and are tied to INIT and BINH, respectively. The CCP1 pin is configured as a digital input and is tied to ECHO through a pull-up resistor. The pull-up resistor is needed since the ECHO signal is an open-collector output. The CCP1 pin is configured for capture mode (CCP1CON). Figure 2 shows the timing relationship for V_{DD} and the three signal lines (INIT, BINH, and ECHO).

Note: The ranging module requires 5.0 milliseconds to stabilize during power-up.

FIGURE 2: TIMING DIAGRAM OF RANGING MODULE CONTROL LINES

Parameter Number	Symbol	Characteristic	Min	Typ	Max	Units
1	TPU	Ranging Module Stabilization Time	5.0	–	–	ms
2	TBINH	Blank Inhibit Time	0.9	2.38	–	ms
3	TECHO	Echo Time	–	–	–	–
4	TINIT_H	High Time for INIT	100	–	–	ms
5	TINIT_L	Low Time for INIT	100	–	–	ms

The PIC16C74 is configured to use one of its internal timers, Timer1, in capture mode to measure the time between signal transmission and echo detection. The resolution of the timer is determined by the microcontroller clock frequency. For this application, a 4 MHz external oscillator was used, giving a resolution of 1 ms per bit. The PIC16C74 initiates a ranging cycle by first clearing Timer1. Timer1 is then enabled and INIT is immediately asserted on the ranging module. When INIT is asserted, the ranging module transmits a series of 16 pulses on the transducer at 49.4 kHz. The transmitted pulses reflect off the object and are received back at the transducer.

The transducer is used for both transmitting and receiving sound waves. A blanking interval is needed to ensure that the transmitted signal has decayed on the transducer, in order not to receive false echoes. In normal operation, the ranging module has a blanking interval of 2.38 milliseconds, which corresponds to a minimum detection distance of approximately 17 inches. However, the BINH (blank inhibit) signal can be manipulated to reduce the blanking time on the transducer to allow for object ranging as close as 6 inches.

In this implementation, the PIC16C74 asserts the BINH signal approximately 0.9 milliseconds after signal transmission. This enables the transducer to receive reflections off objects at a distance of 6 inches. The ranging module asserts the ECHO signal when a valid reflection has been detected. The PIC16C74 uses the ECHO signal to trigger a capture of the Timer1 value. The capture register contains the 16-bit value representing the elapsed time between signal transmission and echo detection. The PIC16C74 then calculates object distance based on the Timer1 value, microcontroller clock speed, and the velocity of sound in the atmosphere. The basic equation for calculating distance is given below:

Distance (inches) = TECHO time / 147.9 microseconds

Note: The minimum high and low time for INIT is 100 milliseconds, as seen in Figure 2.

DESIGN CONSIDERATIONS

There are several design considerations which must be taken into account and are listed below.

The absolute measuring distance supported by the ranging module is 6 inches to 35 feet with an accuracy of +/- 1%.

The distance output from the ranging module can be averaged over time to filter distance calculations.

In some applications, the gain of the receiver amplifier may be too low or too high and may need to be adjusted. For example, if the transducer is mounted in a cylinder, the gain may need to be lowered to reduce false echoes within the cylinder. In this case, R1 (refer to the Polariod Ultrasonic Ranging System manual) may be replaced with a 20 kΩ potentiometer to tweak the gain of the receiver amplifier to reduce false echoes.

In order for the Polaroid 6500 ranging module to operate properly, the power supply must be capable of handling high current transients (2.5 A) during the

© 1997 Microchip Technology Inc.

transmit pulse. The instantaneous drain on the power supply can be mitigated by installing a storage capacitor across the power lines at the ranging module. A value of 500 microfarads is recommended.

A 200 millisecond interval is recommended between ranging cycles (Figure 2) to allow the transducer to clear.

The ECHO line requires a pull-up resistor (4.7 kΩ was used in this application).

There must be a common ground between the PIC16C74 circuitry and the ranging module.

Some applications may not need the resources of the higher end PIC16CXXX devices. It is still possible to do this application using a device that does not contain a CCP module (for ECHO timing). The capture function can be implemented in firmware. The effect of a firmware implementation is that the resolution of the ECHO time would be 3 TCY cycles versus 1 TCY cycle for the CCP module. Also, the firmware implementation would not allow other tasks to be performed while the capture function was occurring.

DESIGN CONSIDERATIONS IN ULTRASONICS

Range: (with user custom designed processing electronics)

Farther

a) Use an acoustic horn to "focus" the sound (narrowing the beamwidth).
b) Use two transducers – 1 receiver and 1 transmitter – facing each other.
c) Lower the transmitting frequency (which will decrease the attenuation in air).

Closer

a) Use a shorter transmit signal (such as four cycles).
a) Use two transducers – one to transmit, one to receive (eliminates waiting for damping time).

Resolution

a) Above all, know the target and range well, and design a system with them in mind.
b) Use a higher transmit frequency.
c) Look at phase differences of a given cycle of the transmitted signal and received echo (as opposed to using and integration technique).
d) Increase the clock frequency of the timer.

Accuracy: (again, you must have a well defined target)

Temperature Compensate

a) Use a second small target, as a reference, at a known distance in the ranging path (such as a 1/4" rod several feet away), process both echoes, then normalize the second distance with respect to the first, since t1/d1 = t2/d2.
b) Incorporate a temperature sensing integrated circuit to drive a VCO to do the distance interval clocking.
c) To increase sensitivity of detection circuit change the value of C4 from 3300 pF to 1000 pF on the 6500 Series Ranging Module.

Beam Width:

Increase

a) Use an acoustic lens (to disperse the signal).
b) Decrease the transmitting frequency.
c) Use several transducers to span an area.

Decrease

a) Use an acoustic horn (to focus the sound).
b) Increase the transmitting frequency.

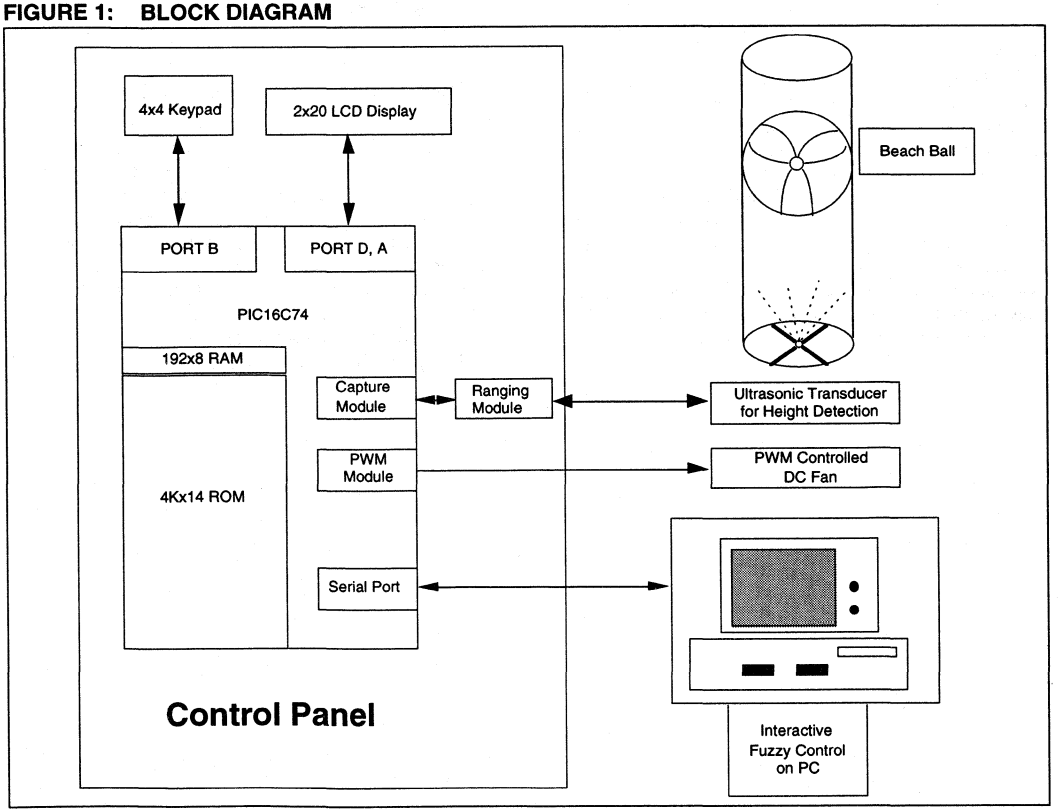
Air Flow Control Using Fuzzy Logic

Author: *Robert Schreiber*
Microchip Technology Inc.

INTRODUCTION

Fuzzy logic control can be used to implement a wide variety of intelligent functions including everything from consumer electronic goods and household appliances to auto electronics, process control, and automation.



Typically, fuzzy logic control applications fall into two categories. First, it can be used to enhance existing products with intelligent functions. Second, it can utilize sensors that continuously respond to changing input conditions. In addition, fuzzy logic simplifies dealing with non-linearities in systems, and allows for quicker product development cycles.

This application note will step the user through a fuzzy logic control design utilizing sensors. The development tool used is Inform® Software's *fuzzyTECH®-MP*. The development tool allows for an all-graphical editor, analyzers, and debug capability.

PROJECT DESCRIPTION

The block diagram of the project is shown in Figure 1 and operates as follows.

FIGURE 1: BLOCK DIAGRAM

The control panel prompts the user to enter the desired beach ball height on the 16-key keypad. The keypad input is echoed on the LCD module and the user is prompted for confirmation. Upon confirmation of user input, the control panel initiates a ranging cycle to calculate the current height of the beach ball. The desired height and current height are continually displayed on the LCD module. From the current height, the control panel calculates both the velocity and the delta height (difference in desired height from current height). This information, along with the desired height, is transmitted to the PC via an RS-232 link. The fuzzy logic algorithm, running on the PC, calculates the appropriate duty cycle of the DC fan and transmits this information to the control panel. This emulates a "real world" environment in which system level debug can be done on the PC in real-time. The control panel controls the duty cycle of the DC fan with this input. The above listed ranging process continues indefinitely until interrupted by the user.

The control panel houses an ultrasonic ranging module and the microcontroller. The microcontroller handles all of the peripheral interfaces including the 16-key keypad, the LCD display, the ultrasonic ranging module, and the RS-232 serial link. The project required a microcontroller that could handle the data throughput and all of these peripherals with little or no external components. The microcontroller used was the PIC16C74, which contains 4K of on-chip program memory and 192 bytes of on-chip data memory. Furthermore, the interrupt capabilities, I/O pins, PWM module, capture and compare modules, timer modules, Universal Asynchronous Receiver Transmitter (USART), and A/D converter make it an excellent fit for the application. In addition, the on-chip Pulse Width Modulation (PWM) module allows for a single component (FET) interface for the DC fan control and the ranging module can interface directly to the microcontroller (refer to Application Note AN597, "Implementing Ultrasonic Ranging").

FUZZY DESIGN

Fuzzy logic first translates the crisp inputs from the sensor into a linguistic description. Then it evaluates the control strategy contained in fuzzy logic rules and translates the result back into a crisp value.

The first step in fuzzy logic control design is system definition. The only possible sources of inputs to the fuzzy logic control algorithm are the ultrasonic transducer, the user, and the DC fan. The key is to decide which of these inputs are significant and which are not. Basically, the behavior of the beach ball was characterized by asking the following questions from the beach ball's perspective:

- Where am I?
- How far am I from where I want to be?
- How fast am I getting there?
- What external force will get me there?

The nice thing about fuzzy logic control is that the linguistic system definition becomes the control algorithm.

The variables were defined as follows:

- **Current Height** [Where am I?]
- **Delta Height** [How far am I from where I want to be?]
- **Velocity** [How fast am I getting there?)
- **Duty Cycle** [What external force will get me there?]

Defining the variables was the starting point, but for the algorithm to work smoothly, it isn't good enough to say "the beach ball has velocity," you need to know to what degree the beach ball has velocity. This is accomplished by defining terms that more fully describe the variable. The combination of variables and terms gives a linguistic description of what is happening to the system. From this, the Velocity variable can be described as having a "positive small velocity" or a "positive big velocity," not just a "velocity."

© 1997 Microchip Technology Inc.

There is no fixed rule on how many terms to define per variable. Typically, three to five terms are defined, but more or less may be needed based on the control algorithm. In retrospect, we probably could have reduced Current Height to three terms and Velocity to five terms. Table 1 lists the four variables that are used for the trade show demo and their associated terms.

Once the linguistic variables are defined, data types and values need to be defined. For this application, data types were defined as 8-bit integers (16-bit definition is also possible). After defining the data types, the shell and code values for each variable were specified. A shell value is used within the fuzzy logic development tool and a code value is used when the code is generated.

The best way to describe shell and code values is using the analogy of a D/A converter. If we have a 5.0V, 8-bit D/A converter, the digital input would correspond to the code value and the analog output would correspond to the shell value. This is, if we write (or pass) a value of 128 to the D/A we would get a 2.51V out. Applying this analogy to our project, we would pass a crisp value (digital) to the fuzzy world and the fuzzy world would use the fuzzy value (analog).

Therefore, when we define shell and code values, we are basically defining the "D/A converter." For example, you can define the shell value for Duty Cycle to be a minimum of 0 and a maximum of 100 (percent). Therefore, within the fuzzy logic development tool, Duty Cycle will take on a value between 0 and 100, inclusive.

The code value is limited by the data type, but can take on any or all of the digital range. That is, if the shell value is 0 to 100, the code values could be defined as 0 to 100. But to get full resolution, the code value should be defined over the entire range (i.e., 0 to 255 for 8-bit data types). The code values and shell values were defined as shown in Table 2. Note that for the height and velocity variables, the shell values are scaled by 2 (i.e., a Current Height with a crisp value of 60 would correspond to 30 inches).

Next, the membership functions were defined to further describe the variables. The fuzzy logic development tool creates the membership functions automatically. This gives a good starting point, but the membership functions still need to be fine-tuned during the debug phase. In this application, only the linear shaped functions (Pi, Z, S and Lambda types) were used as seen in Figure 2.

FIGURE 2: STANDARD MEMBERSHIP FUNCTION TYPES

FUZZIFICATION

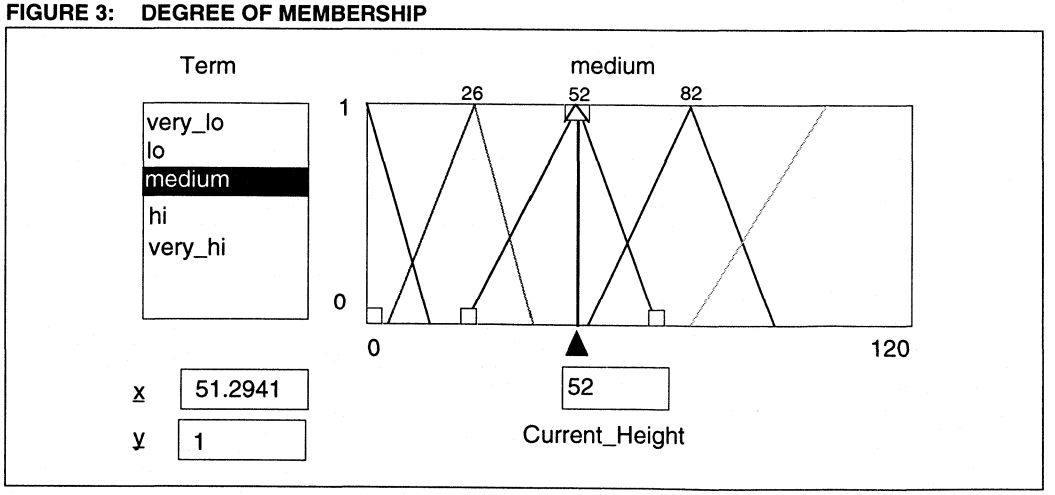
Fuzzification entails translating a crisp value into a fuzzy value. Once all of the variables have been defined, the interfaces between the variables need to be defined. The interfaces for the input variables contain the fuzzification procedures. In defining the interfaces, the input variable's fuzzification method needs to be defined. The computation of fuzzification is carried out at runtime for code efficiency. The type of fuzzification used in this project is membership function computation. This is largely due to the code space efficiency and accuracy associated with this method. Once fuzzification has taken place, the algorithm is performed in the fuzzy world according to the rule base.

FUZZY RULE BASE

The entire fuzzy inference is contained within the rule blocks of a system. For example, if the beach ball is near the top of the tube and it was commanded to be near the bottom of the tube, the rule that described the situation would be:

IF CURRENT HEIGHT = VERY HI

AND DELTA HEIGHT = NEGATIVE BIG



THEN DUTY CYCLE = SLOW

The above rule describes one situation, but the rule definition would continue until the system was adequately described The rule block is the collection of all rules that describe the system.

The rules of the rule block can also be defined in terms of how much a specific rule is supported when calculating inference. The support of a rule, or plausibility, is known as the degree of support for that rule. A plausible rule is defined by a 1.0, a totally implausible rule is defined by 0.0. In this project all rules are fully supported.

The degree to which a crisp value belongs to a term is known as the degree of membership. For example, the terms Medium and Hi for the variable Current Height were defined as a Lambda-type membership function centered around the crisp values 52 (26 inches) and 82 (41 inches), respectively, as shown in Figure 3.

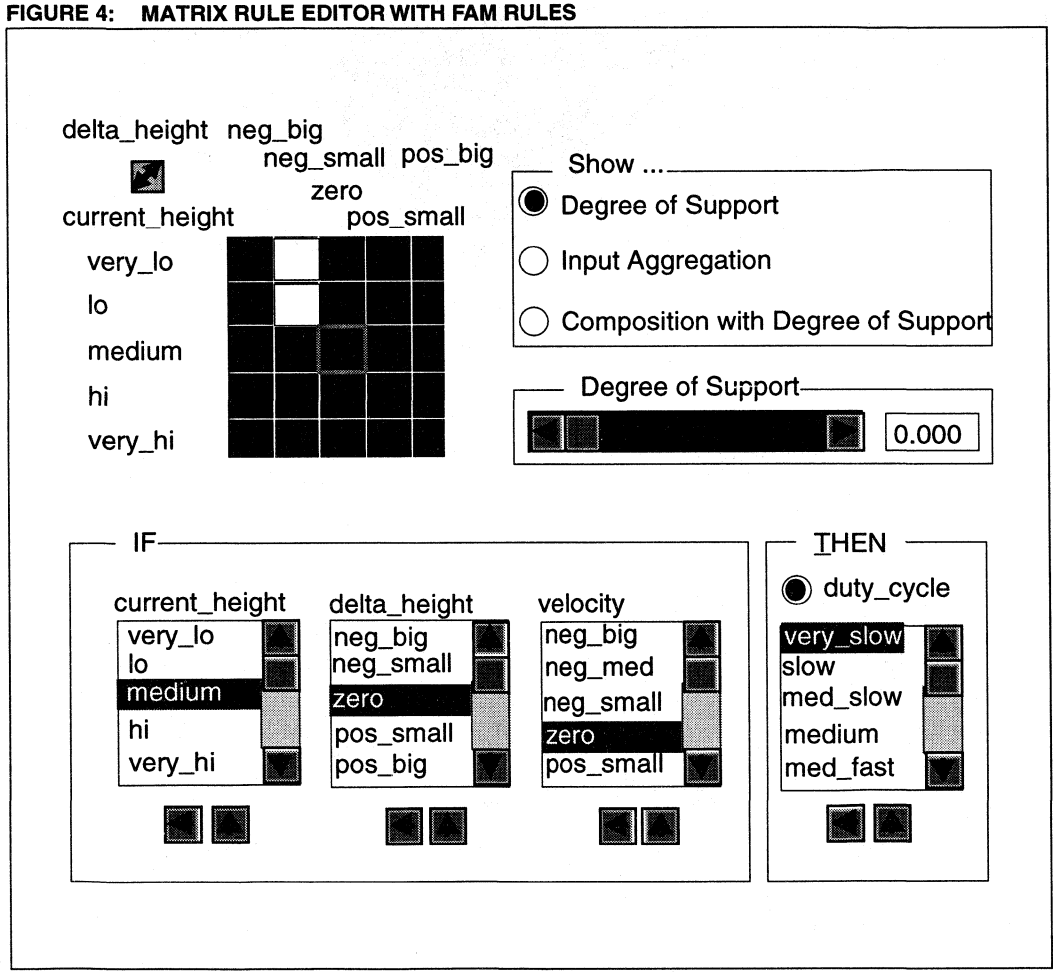
FIGURE 3: DEGREE OF MEMBERSHIP

© 1997 Microchip Technology Inc.

Therefore, if the beach ball was at 26 inches, the degree of membership would be 1.0 for Medium and 0.0 for Hi. However, as the beach ball rises in height, the degree of membership for the term Medium would decrease and the degree of membership for the term Hi would increase. The interplay of these linguistic variable terms is controlled by the rule base. The rule base defines not only the relationship between the terms, but also how much each rule is supported, as described previously.

From the list of rules, a Fuzzy Associative Map (FAM) is constructed (see below). The FAM shows the plausibility (degree of support) of each rule as seen in Figure 4 and Figure 5.

FIGURE 4: MATRIX RULE EDITOR WITH FAM RULES



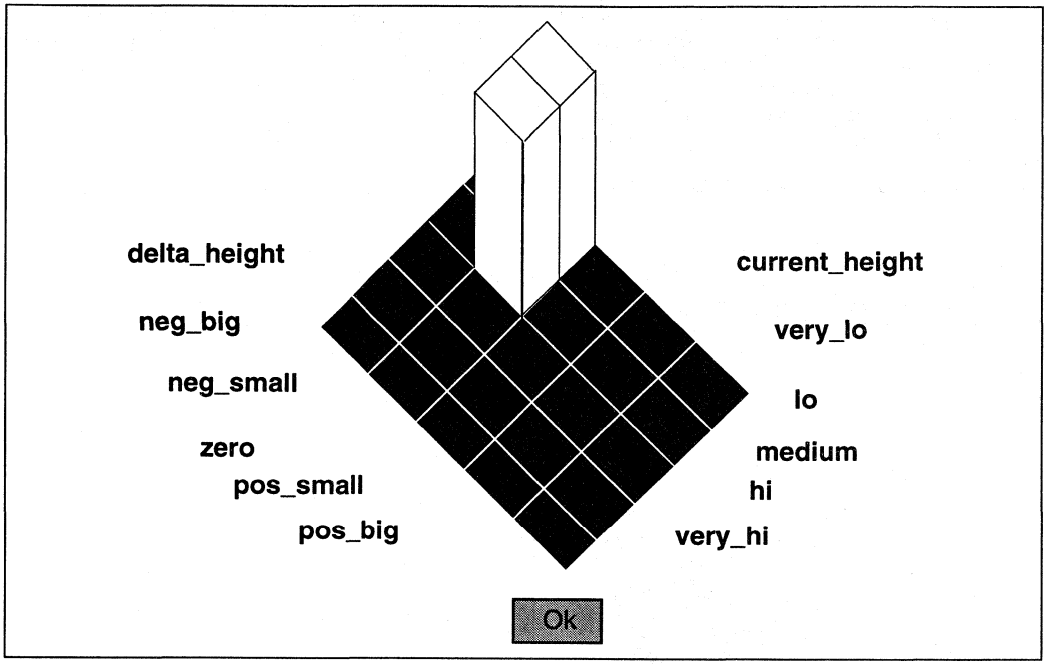


FIGURE 5: 3-D RULE DISPLAY

DEFUZZIFICATION

Defuzzification entails translating a fuzzy value to a crisp value. The interface for the output variables contains the defuzzification procedures. For most control applications (and this project), the center-of-maximum (CoM) method is used for defuzzification. CoM evaluates more than one output term as valid and compromises between them by computing a weighted mean of the term membership maxima. Example 1 and Figure 6 show the defuzzification of the linguistic variable Duty Cycle using CoM.

EXAMPLE 1: DEFUZZIFICATION OF DUTY CYCLE

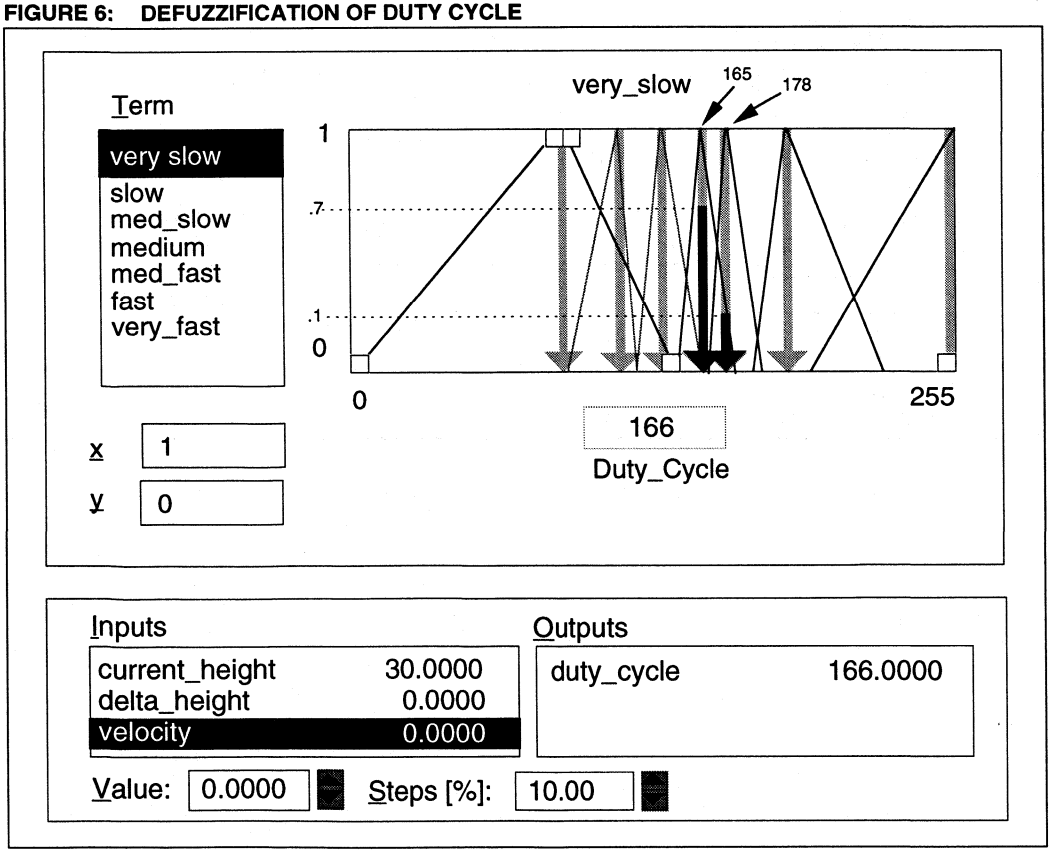
The crisp values of the three input variables are as follows:

Current Height: 30

Delta Height: 0

Velocity: 0

The crisp value can be calculated using the CoM method with the following equation.



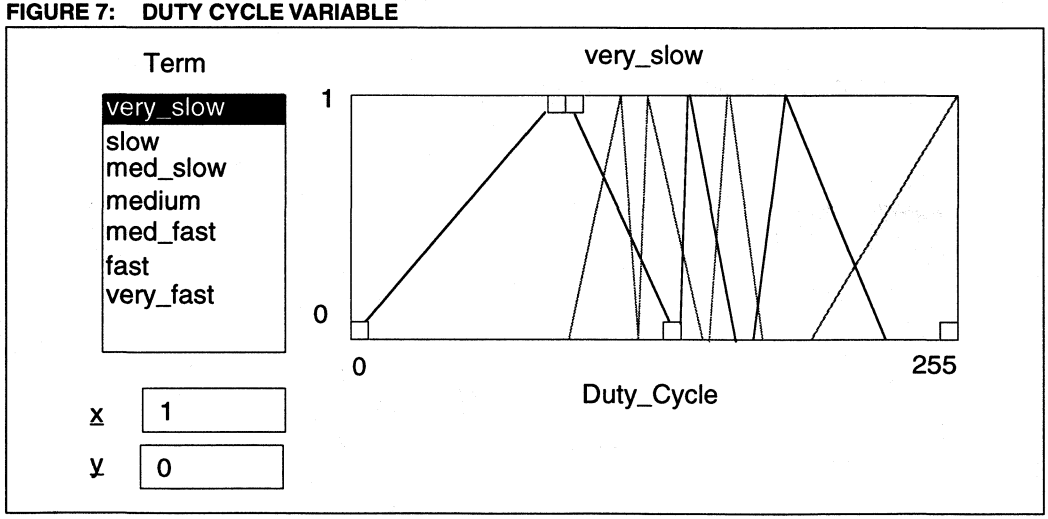
$$C = \frac{\sum_i [\, I \bullet \max_x (M) \bullet \arg(\max_x (M))]}{\sum_i I}$$

c = crisp output value
i = linguistic term
I = inference result
M = membership function of linguistic term

For this example, when the crisp values are fuzzified, the Duty Cycle variable is defined to be mostly "medium" (degree of membership of 0.7) and somewhat "medium fast" (degree of membership 0.1). The arguments for the "medium" and "medium fast" term membership maxima are 165 and 178, respectively.

$$\frac{((0.7 \bullet 1.0 \bullet 165) + (0.1 \bullet 1.0 \bullet 178))}{(0.7 + 0.1)} = 166$$

FIGURE 6: DEFUZZIFICATION OF DUTY CYCLE



DEBUGGING

In serial debug mode, one can graphically adjust the variable terms and see the results in "real time." On this project, the first variable adjusted was the Duty Cycle variable. Duty Cycle was adjusted so that the beach ball reached 30 inches (Figure 7). The Delta Height terms were fine-tuned -- negative small, zero, and positive small were bunched together -- and the beach ball stabilized at 30 inches (Figure 8). There was virtually no fluctuation in the height. In order for the system to self-correct for environmental (external) changes, the Velocity variable was used. The velocity variable is calculated by the difference in height between consecutive height calculations. A few rules were added that used the Velocity variable to nudge the ball into place when the environmental conditions changed (Figure 9).

Another advantage of fuzzy logic is that it simplifies dealing with non-linearities of the system. The system was highly non-linear, so it was tested at the extremes and moving the beach ball at different rates from one extreme to the other. The Current Height variable needed almost no adjustment (Figure 10). The variable that required the most work was the Duty Cycle variable, but in less than a day, the algorithm was working well within specifications. The beach ball could go from a resting position, with the DC fan off, to the maximum allowable height of 42 inches in less than 8 seconds with no overshoot. Operation between the minimum and maximum height was much quicker, also with no overshoot.

The final graphical representation of the linguistic variables are shown in Figure 7 through Figure 10.

INTEGRATION

The system parameters and graphical variable representations are captured in a Fuzzy Technology Language (FTL) file. The FTL file is a vendor and hardware independent language which defines the fuzzy logic based system. The FTL file for this project can be seen in Appendix A.

The FTL file is used to generate the public variable definitions and code which can be embedded in the microcontroller. The appropriate device family from the pre-assembler code are generated by simply selecting the compile pull-down menu. Once the pre-assembler file is generated, the "hooks" to the main program must be added.

The best way to embed the code is to use the template `MYMAIN.ASM`. The template for each of the families of devices (PIC16C5X, PIC16CXXX and PIC17CXX) is included in the *fuzzyTECH®-MP* development kit. The template shown in Appendix B is for the PIC16CXXX family.

The file `MYMAIN.ASM` should contain your program in the "`main_loop`" section. The only other modifications required to the template are listed below and are specified in the left hand column of Appendix B.

1. Processor Type definition
2. Code Start Address
3. Fuzzy RAM Start Address
4. Include Public Variable Definition file (myproj.var), which was created by *fuzzyTECH®-MP*
5. Include Pre-Assembler Code (`myproj.asm`) which was created by *fuzzyTECH®-MP*
6. Call Initialization (`initmyproj`) which was created by *fuzzyTECH®-MP*
7. Set Crisp Input Value(s)
8. Call Fuzzy Logic System (`myproj`)
9. Read Crisp Output Value(s)

For this project, the fuzzy logic algorithm assembled to 704 words of program memory and 41 bytes of data memory.

SUMMARY

This project demonstrates many aspects of fuzzy logic control - quick development cycle, real-time debug, sensor integration, and non-linear system control. The total development time for the application took less than a week and performed well within system specifications.

Resistance and Capacitance Meter Using a PIC16C622

Author: *Rodger Richey*
Microchip Technology Inc.

INTRODUCTION

The PIC16C62X devices create a new branch in Microchip's PIC16CXXX 8-bit microcontroller family by incorporating two analog comparators and a variable voltage reference on-chip. The comparators feature programmable input multiplexing from device inputs and an internal voltage reference. The internal voltage reference has two ranges, each capable of 16 distinct voltage levels. Typical applications such as appliance controllers or low-power remote sensors can now be implemented using fewer external components thus reducing cost and power consumption. The 18-pin SOIC or 20-pin SSOP packages are ideal for designs having size constraints.

The PIC16C62X family includes some familiar PIC16CXXX features such as:

- 8-bit timer/counter with 8-bit prescaler
- PORTB interrupt on change
- 13 I/O pins
- Program and Data Memory

Device	Program Memory	Data Memory
PIC16C620	512 x 14	80 x 8
PIC16C621	1K x 14	80 x 8
PIC16C622	2K x 14	128 x 8

This family of devices also introduce on-chip brown-out reset circuitry and a filter on the reset input ($\overline{MCLR}$) to the PIC16CXXX mid-range microcontrollers. Brown-out Reset holds the device in reset while V_{DD} is below the Brown-out Reset voltage of 4.0V, ± 0.2V. The reset filter is used to filter out glitches on the $\overline{MCLR}$ pin.

COMPARATOR MODULE

The comparator module contains two analog comparators with eight modes of operation. The inputs to the comparators are multiplexed with the RA0 through RA3 pins. The on-chip voltage reference can also be selected as an input to the comparators. The Comparator Control Register (CMCON) controls the operation of the comparator and contains the comparator output bits. Figure 1 shows the CMCON register.

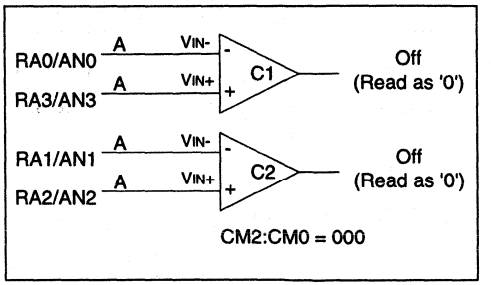
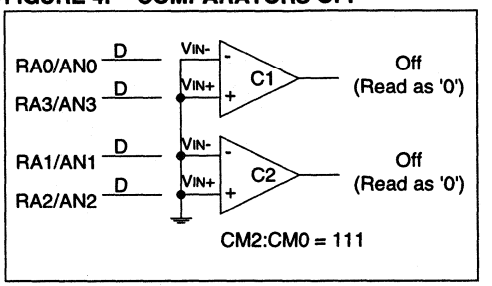
A single comparator is shown in Figure 2. The relationship between the inputs and the output is also shown. When the voltage at VIN+ is less than the voltage at VIN-, the output of the comparator is at a digital low level. When the voltage at VIN+ is greater than the voltage at VIN-, the output of the comparator is at a digital high level. The shaded areas of the comparator output waveform represent the uncertainty due to input offsets and response time.

FIGURE 2: SINGLE COMPARATOR



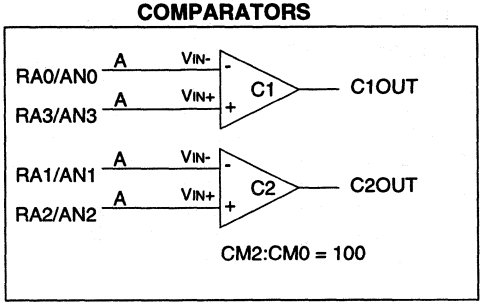
The TRISA register controls the I/O direction of the PORTA pins regardless of the comparator mode. If the comparator mode configures a pin as an analog input and the TRISA register configures that pin as an output, the contents of the PORTA data latch are placed on the pin. The value at the pin, which can be a digital high or low voltage, then becomes the input signal to the comparators. This technique is useful to check the functionality of the application circuit and the comparator module.

Comparator Operating Modes



The analog inputs to the comparator module must be between VSS and VDD and one input must be in the Common Mode Range (CMR). The CMR is defined as VDD-1.5 volt to VSS. The output of a comparator will default to a high level if both inputs are outside of the CMR. If the input voltage deviates above VDD or below VSS by more than 0.6 volt, the microcontroller may draw excessive current. A maximum source impedance to the comparators of 10 kΩ is recommended. Figure 3 through Figure 10 show the eight modes of operation.

FIGURE 3: COMPARATORS RESET



The Comparators Reset Mode (Figure 3) is considered the lowest power mode because the comparators are turned off and RA0 through RA3 are analog inputs. The comparator module defaults to this mode on Power-on Reset.

FIGURE 4: COMPARATORS OFF

The Comparators Off Mode (Figure 4) is the same as the Comparators Reset Mode except that RA0 through RA3 are digital I/O. This mode may consume more current if RA0 through RA3 are configured as inputs and the pins are left floating.

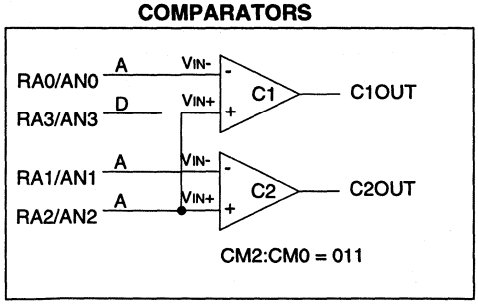
FIGURE 6: FOUR INPUTS MULTIPLEXED TO TWO COMPARATORS



The Four Inputs Multiplexed to Two Comparators Mode (Figure 6) allows two inputs into the VIN- pin of each comparator. The internal voltage reference is connected to the VIN+ pin input of each comparator. The CIS bit, CMCON<3>, controls the input multiplexing to the VIN- pin of each comparator. Table 1 shows this relationship.

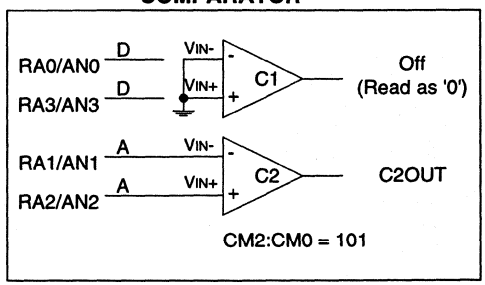
FIGURE 7: TWO COMMON REFERENCE COMPARATORS



The Two Common Reference Comparators Mode (Figure 7) configures the comparators such that the signal present on RA2 is connected to the VIN+ pin of each comparator. RA3 is configured as a digital I/O pin.

FIGURE 8: TWO COMMON REFERENCE COMPARATORS WITH OUTPUTS

The Two Common Reference Comparators with Outputs Mode (Figure 8) connects the outputs of the comparators to an I/O pin. These outputs are digital outputs only with RA3 defined as a CMOS output and RA4 defined as an open drain output. RA4 requires a pull-up resistor to function properly. The value of resistance used for the pull-up will affect the response time of comparator C2. The signal present on RA2 is connected to the VIN+ pin of both comparators.

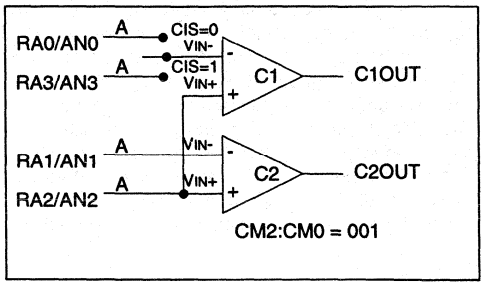


FIGURE 9: ONE INDEPENDENT COMPARATOR

The One Independent Comparator Mode (Figure 9) turns comparator C1 off making both RA0 and RA3 digital I/O. Comparator C2 is operational with analog inputs from RA1 and RA2.

FIGURE 10: THREE INPUTS MULTIPLEXED TO TWO COMPARATORS

The Three Inputs Multiplexed to Two Comparators Mode (Figure 10) connects the VIN+ pin of each comparator to RA2. The VIN- pin of comparator 2 is connected to RA1. The CIS bit, CMCON<3>, controls the input to the VIN- pin of comparator 1. If CIS = 0, then RA0 is connected to the VIN- pin. Otherwise RA3 is connected to the VIN- pin of comparator 1.

Note: Each comparator that is active will consume less power when the output is at a high level.

Clearing the Comparator Interrupt Flag

The comparator interrupt flag, CMIF, is located in the PIR1 register. This flag must be cleared after changing comparator modes. Whenever the comparator mode or the CIS bit is changed, the CMIF may be set due to the internal circuitry switching between modes. Therefore, comparator interrupts should be disabled before changing modes. Then, a delay of 10 µs should be used after changing modes to allow the comparator circuitry to stabilize.

The steps to clear the CMIF flag when changing modes are as follows:

- Change the comparator mode or CIS bit
- 10 µs delay
- Read the CMCON register to end the "mismatch" condition
- Clear the CMIF bit of the PIR1 register

The value of C1OUT and C2OUT are internally latched on every read of the CMCON register. The current values of C1OUT and C2OUT are compared with the latched values, and when these values are different a "mismatch" condition occurs. The CMIF interrupt flag will not be cleared if the CMCON register has not been read.

Using the Comparator Module

The CMCON register contains the comparator output bits C1OUT and C2OUT, CMCON<7:6>. These bits are read only. C1OUT and C2OUT follow the output of the comparators and are not synchronized to any internal clock edges. Therefore, the firmware will need to maintain the status of these output bits to determine the actual change that has occurred. The PIR1 register contains the comparator interrupt flag CMIF, PIR1<6>. The CMIF bit is set whenever there is a change in the output value of either comparator relative to the last time the CMCON register was read.

Note: If a change in C1OUT or C2OUT should occur when a read operation on the CMCON register is being executed (start of the Q2 pcycle), the CMIF interrupt flag may not be set.

When reading the PORTA register, all pins configured as analog inputs will read as a '0'. Analog levels on any pin that is defined as a digital input may cause the input buffer to consume more current than is specified.

The code in Example 1 shows the steps required to configure the comparator module. RA3 and RA4 are configured as digital outputs. RA0 and RA1 are configured as the VIN- inputs to the comparators and RA2 is the VIN+ input to both comparators.

The comparators will remain active if the device is placed in sleep mode, except for the Comparators Off Mode (CM2:CM0 =111) and Comparators Reset Mode (CM2:CM0=000). In these modes the comparators are turned off and are in a low power state. A comparator interrupt, if enabled, will wake-up the device from sleep in all modes except **Off** and **Reset**.

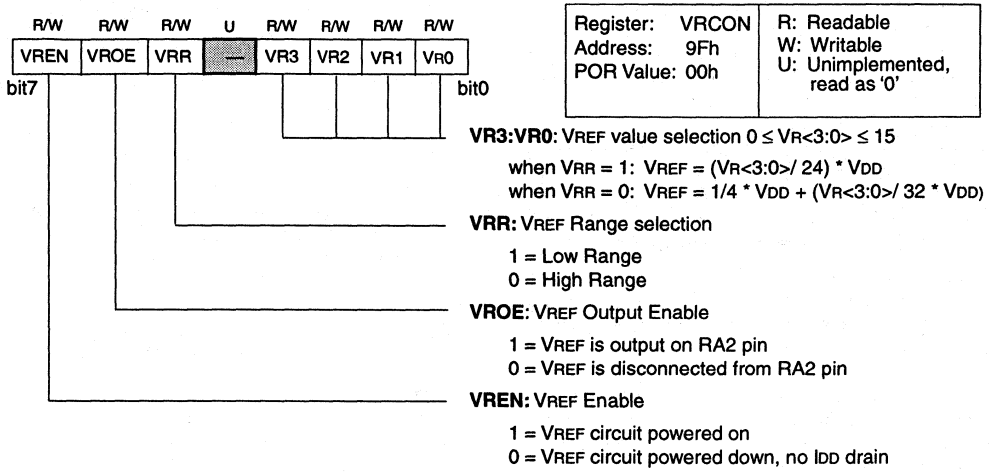
Comparator Timings

The comparator module has a response time and a mode change to output valid timing associated with it. The response time is defined as the time from when an input to the comparator changes until the output of that comparator becomes valid. The response time is faster when the output of the comparator transitions from a high level to a low level. The mode change to output valid time refers to the amount of time it takes for the output of the comparators to become valid after the mode has changed. The internal voltage reference may contribute some delay if used in conjunction with the comparators (see Voltage Reference Settling Time).

VOLTAGE REFERENCE MODULE

The voltage reference is a 16-tap resistor ladder network that is segmented to provide two ranges of VREF values. Each range has 16 distinct voltage levels. The voltage reference has a power-down function to conserve power when the reference is not being used. The voltage reference also has the capability to be connected to RA2 as an output. Figure 11 shows the Voltage Reference Control Register (VRCON) register which controls the voltage reference. Figure 12 shows the block diagram for the voltage reference module.

FIGURE 11: VRCON REGISTER



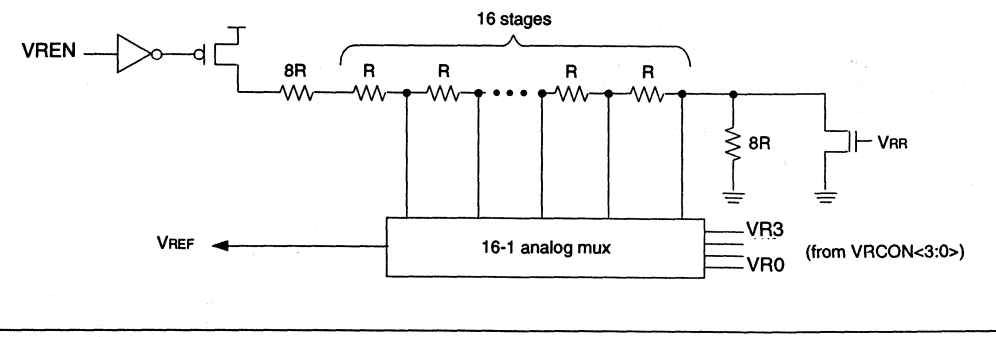


FIGURE 12: VOLTAGE REFERENCE BLOCK DIAGRAM

Note: The voltage reference is VDD derived and therefore, the VREF output changes with fluctuations in VDD.

© 1997 Microchip Technology Inc.

Using the Voltage Reference

The voltage reference module operates independently of the comparator module. The output of the voltage reference may be connected to the RA2 pin at any time by setting the TRISA<2> bit and the VRCON<6> bit (VROE). It should be noted that enabling the voltage reference with an input signal present will increase current consumption. Configuring the RA2 pin as a digital output with the VREF output enabled will also increase current consumption. The increases in current are caused by the voltage reference output conflicting with an input signal or the digital output. The amount of increased current consumption is dependent on the setting of VREF and the value of the input signal or the digital output.

The full range of VSS to VDD cannot be realized due to the construction of the module (Figure 12). The transistors on the top and bottom of the resistor ladder network keep VREF from approaching VSS or VDD. Equation 1 and Equation 2 are used to calculate the output of the voltage reference.

EQUATION 1: VOLTAGE REFERENCE EQUATION, VRR = 1

$$V_{REF} = (VR<3:0>/24) \times V_{DD}$$

EQUATION 2: VOLTAGE REFERENCE EQUATION, VRR = 0

$$V_{REF} = (V_{DD}/4) + (VR<3:0>/32) \times V_{DD}$$

An example of how to configure the voltage reference is given in Equation 2. The reference is set for an output voltage of 1.25V at a VDD of 5.0V.

EXAMPLE 2: VOLTAGE REFERENCE CONFIGURATION

```

BCF     STATUS,RP0  ;go to Bank 0
CALL    DELAY10     ;10µs delay
```

If the voltage reference is used with the comparator module, the following steps should be followed when making changes to the voltage reference.

1. Disable the comparator interrupts
2. Make changes to the voltage reference
3. Delay 10 µs to allow VREF to stabilize
4. Delay 10 µs to allow comparators to settle
5. Clear the comparator interrupt flag
   - Read the CMCON register
   - Clear the CMIF bit
6. Enable comparator interrupts

The output of the voltage reference may be used as a simple DAC. However, the VREF output has limited drive capability when connected to the RA2 pin. In fact the amount of drive the voltage reference can provide is dependent on the setting of the tap on the resistor ladder. If VREF is used as an output, an external buffer must be used.

Voltage Reference Settling Time

Settling time of the voltage reference is defined as the time it takes the output voltage to settle within 1/4 LSb after making a change to the reference. The changes include adjusting the tap position on the resistor ladder, enabling the output, and enabling the reference itself. If the voltage reference is used with the comparator module, the settling time must be considered.

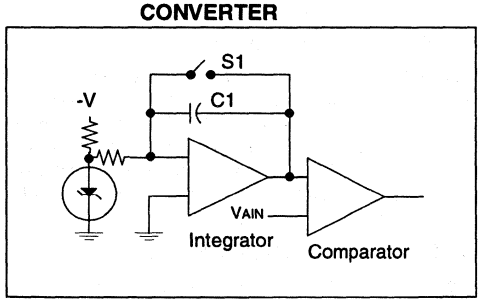
MAKING SIMPLE A/D CONVERSIONS



Linear slope integrating A/D converters are very simple to implement and can achieve high linearity and resolution for low conversion rates. The three types of converters that will be discussed are the single-slope, dual-slope, and modified single-slope converters. The following material was referenced from application note AN260, *"A 20-Bit (1ppm) Linear Slope-Integrating A/D Converter"*, found in the Linear Applications Handbook from National Semiconductor®.

Single-Slope Integrating Converter

A single-slope integrating converter is shown in Figure 13. In a single-slope converter, a linear ramp is compared against an unknown input **VAIN**. When the switch **S1** is opened the ramp begins. The time interval between the opening of the switch and the comparator changing state is proportional to the value of **VAIN**.

The basic assumptions are that the integrating capacitor **C1** and the clock used to measure the time interval remain constant over time and temperature. This type of converter is heavily dependent on the stability of the integrating capacitor.

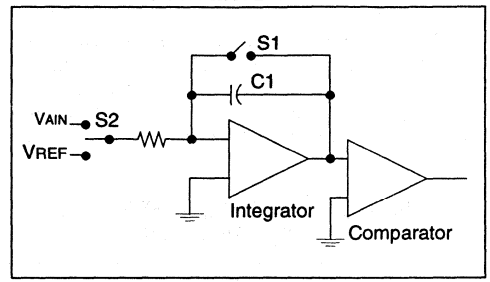


FIGURE 13: SINGLE-SLOPE INTEGRATING CONVERTER

Dual-Slope Integrating Converter

Figure 14 shows a dual-slope integrating converter. The dual-slope converter integrates the VAIN input for a predetermined length of time. The voltage reference is then switched into the integrator input, using S2, which integrates in a negative direction from the VAIN slope. The length of time the reference slope requires to return to zero is proportional to the value of VAIN. Both slopes are made with the same integrating capacitor C1 and measured with the same clock, so they need only to be stable over one conversion cycle.

FIGURE 14: DUAL-SLOPE INTEGRATING CONVERTER

The dual-slope converter essentially removes the stability factor of the integrating capacitor from a conversion, however, the dielectric absorption of C1 has a direct effect. Dielectric absorption not only creates residual non-linearity in the dual-slope converter, but causes the converter to output different values for a fixed input as the conversion rate is varied. Dielectric absorption is defined as the capacitor dielectric's unwillingness to accept or give up charge instantaneously. This effect is modeled as a parasitic RC network across the main capacitor. A charged capacitor will require some time to discharge, even through a dead short, due to the parasitic RC network and some amount of charge will be absorbed by the parasitic C after charging of the main capacitor has stopped. Typically, Teflon, polystyrene and polypropylene dielectrics offer better performance than paper, mylar, or glass. Electrolytics have the worst dielectric absorption characteristics and should be avoided for use in slope integrating converters.

© 1997 Microchip Technology Inc.

Modified Single-Slope Converter

The modified single-slope converter has been designed to compensate for the effects present in the previous converters. Resolutions of up to 16-bits can be achieved using high precision components and voltage reference source. Figure 15 shows the modified single-slope converter. Some features of this converter are:

- Continuously corrects for zero and full-scale drifts in all components of the circuit.
- The integrating capacitor C1 is charged periodically and always in the same direction. The error induced from dielectric absorption will be small and can be compensated by using an offset term in the calibration procedure.
- The ramp voltage always approaches the comparator trip point from the same direction and slew rate.
- There is no noise rejection capability because the input signal is directly coupled to the comparator input. A filter at the comparator input would cause a delay due to the settling time of the filter.

FIGURE 15: MODIFIED SINGLE-SLOPE INTEGRATING CONVERTER

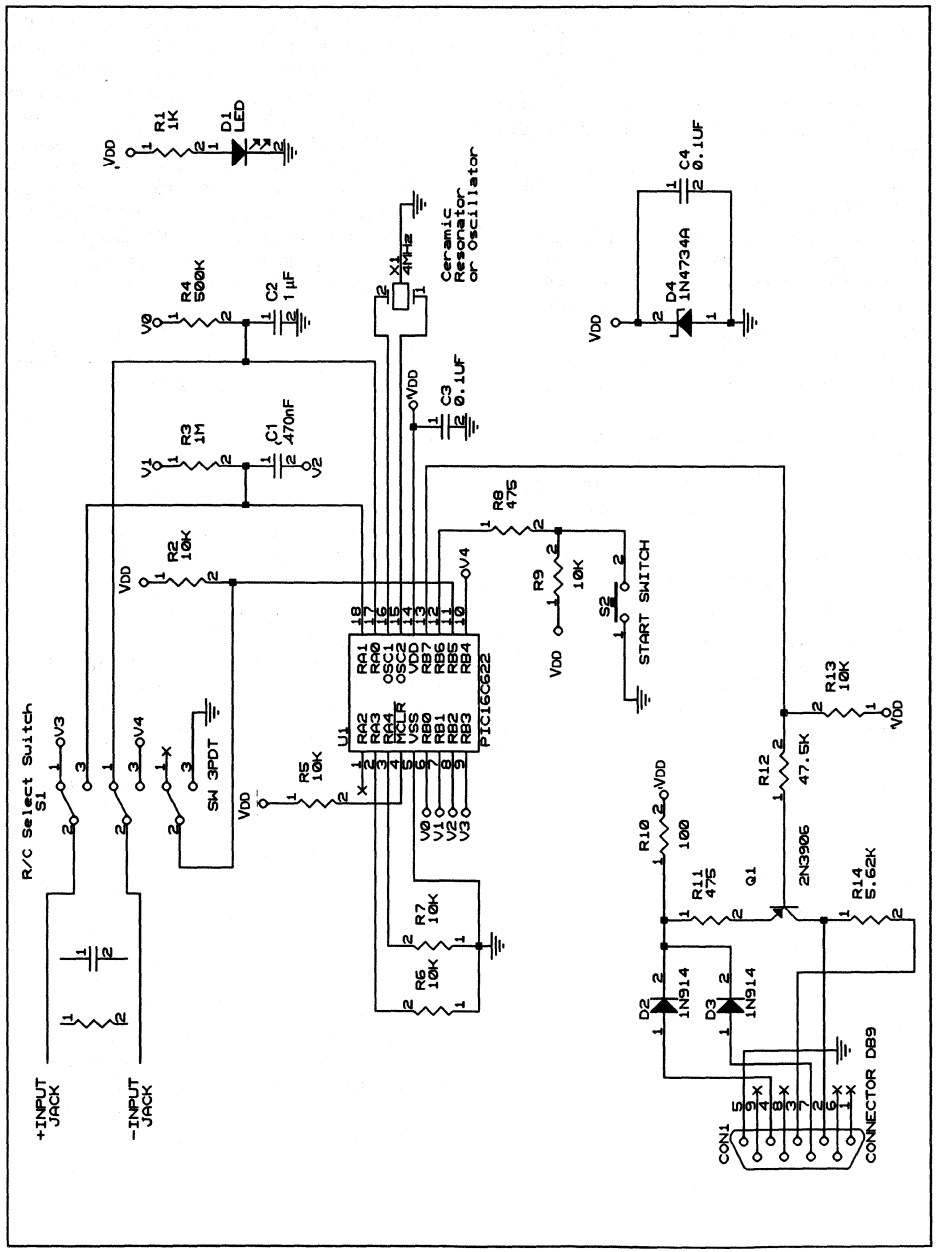
The microcontroller sends a periodic signal to switch S1 regardless of the operating mode of the system. The output of the integrator is a fixed-frequency period and height signal which is fed into the input of the comparator. The time between ramps is long enough to allow integrating capacitor C1 to discharge completely. The other input is multiplexed with ground, reference, and VAIN through switch S2. When the microcontroller starts a conversion, the ground signal is switched into the comparator and the time for the ramp to cross zero is measured and stored. The same measurements are repeated for the reference and VAIN signals. Assuming that the integrator ramps are highly linear, Equation 3 is used to determine the value of VAIN.

EQUATION 3: OUTPUT EQUATION FOR THE MODIFIED-SLOPE CONVERTER

$$V_{AIN} = \frac{t_{AIN} - t_{GND}}{t_{VREF} - t_{GND}} \times K \ mV$$

where τ_{AIN} is the measured time for the VAIN signal, τ_{VREF} is the measured time for the voltage reference signal, τ_{GND} is the measured time for the ground signal, and K is a constant (typically 10^7).

APPLICATION CIRCUIT



The application circuit, called PICMETER, uses a PIC16C622 as a resistance and capacitance meter. The PICMETER uses a variation of the single-slope integrating converter. The linear slope and integrator of Figure 13 are replaced with the exponential charge waveform of an RC. The charge time of a known component is compared against the charge time of an unknown component to determine the value of the unknown component.

A schematic of the PICMETER is shown in Figure 16. All reference designators cited in this section refer to this schematic. Results are transmitted to a PC which displays the value measured. The PICMETER can measure resistance in the range 1Ω to 999Ω and capacitance from 1 nF to 999 nF.

The following sections describe, in detail, the hardware, firmware, and PC software used in the application circuit. Appendix A shows the PICMETER firmware and Appendix B has the PC software. Appendix C contains the PCB layout.

Power

The RS-232 serial port provides power to the PICMETER. The RTS and DTR lines from the serial port output 3V to 11V to the PICMETER. The diodes D2 and D3 prevent any damage to the PC's serial port. Resistor R10 is used to current limit the Zener diode, D4. D4 is used to regulate the RTS and DTR voltage to 5.6V. Capacitors C3 and C4 provide power supply filtering to the Zener diode and the PIC16C622. This method of supplying power to devices using a serial port, such as a trackball or mouse, is very simple considering that the PICMETER requires approximately 7 mA to function.

Switches

Switch S1 is used to select either a resistor or capacitor measurement. RB5 of the PIC16C622 is used to detect what type of component is being measured. This switch also swaps the unknown component into the RC network.

If a resistor is the unknown component and a capacitor measurement is requested, the circuit reduces to a resistor divider on the VIN- pin of the comparator. This would result in a measured value of 0 pF if the voltage on the resistor divider network is greater than the voltage reference setting. Otherwise an error is detected. If a capacitor is the unknown component and a resistor measurement is selected, the circuit reduces to a capacitor divider network on the VIN- pin of the comparator. This case will also produce an error message.

Resistor measurements that are started without any component connected to the measuring terminals will cause an error. Capacitor measurements without a component connected to the measuring terminals will give a result of 0 pF.

Switch S2 is used to initiate a measurement. The switch is connected to RB6 of the PIC16C622 and the PORTB wake-up on change interrupt is used to detect a key press. A modified version of the firmware in AN552, *"Implementing Wake-up on Key Stroke"* was used to control the interrupt.

Measuring the Charge Time

The procedures for measuring a resistor or capacitor are the same except for the I/O pins used to control the RC networks. This also applies when measuring a known or unknown component.

Measurement Overview

The charge time of the unknown RC network is measured using Timer0. This value is multiplied by the known value of resistance or capacitance and stored in an accumulator. Then the charge time of the known RC network is measured. The accumulator is divided by the known RC network charge time to give the value of resistance or capacitance of the unknown component. Equation 4 shows the equation used to calculate resistance and Equation 5 shows the capacitance equation.

EQUATION 4: RESISTANCE EQUATION

$$R_{UNK} = \frac{t_{UNK} \times R_{KN}}{t_{KN}}$$

EQUATION 5: CAPACITANCE EQUATION

$$C_{UNK} = \frac{t_{UNK} \times C_{KN}}{t_{KN}}$$

RUNK and CUNK are the unknown resistor and capacitor values. RKN and CKN are the known resistor and capacitor values. τ_{UNK} and τ_{KN} are the charge times for the unknown and known components.

Detailed Measurement Description

The first step in measuring the charge time of either the known or the unknown RC networks is to reconfigure the I/O pins. The default state of the PORTA and PORTB pins connected to the RC network are all grounded outputs. This discharges all capacitors in the RC networks. The unknown component is measured first, so the known component, R4 or C1, is removed from the RC network. This is accomplished by making RB0 or RB2 on the PIC16C622 an input. Connections to the other RC network are kept grounded.

The analog modules are now initialized. The mode of the comparators is set to Four Inputs Multiplexed to Two Comparators (Figure 6). The CIS bit, CMCON<3> is cleared to select RA0 as the VIN- input to comparator 1 and RA1 as the VIN- input to comparator 2. The voltage reference is enabled, the output is disabled, and the high range is selected. The tap on the resistor ladder is set to 12. The value of 12 was selected because it is the lowest value of VREF that will trip the comparators, yet gives a time constant long enough to achieve good resolution for the measurement. After a 20 msec delay, which allows the analog modules to stabilize, the comparator flag is cleared. Comparator interrupts are enabled and Timer0 is cleared. Finally, the PEIE bit is set to enable comparator interrupts and the GIE bit is set to enable interrupts.

Now that the analog systems are ready, Timer0 is cleared again and power is applied to the unknown RC network by setting RB1 or RB3 high. Timer0 begins to increment a set of three registers which are cascaded together. These registers contain the charge time of the component. While waiting for the DONE flag, the ERROR flag is checked. See the Error Message section for an explanation of error detection. When the capacitor voltage trips the comparator, Timer0 is prevented from further incrementing the time registers and the DONE flag is set. The value in the time registers is τ_{UNK}.

The analog modules are now disabled. The comparator interrupts are disabled and the comparators are turned off (CM2:CM0=111). RA0 through RA3 and RB0 through RB4 are set up as grounded outputs to discharge the capacitors in the RC networks. This prevents a false reading during the next measurement. The voltage reference is disabled to conserve power and all interrupt flags are cleared. Extra delay loops are added at this time to ensure that the capacitors are discharged.

The charge time, τ_{UNK}, is then multiplied by the value of known resistance or capacitance. These values, in pF or Ω, were obtained by measuring the known RC networks with a Fluke meter. Each of these values is a 24-bit number. The result of multiplication is a 56-bit number which is stored in accumulators ACCb (most significant 24-bits) and ACCc (least significant 24-bits).

The process now repeats itself, except this time the charge time of the known RC network is measured. Now the unknown component is removed from the RC network by making the connections from the PIC16C622 inputs. The analog modules are initialized and the same procedure explained above is followed to measure the charge time of the known RC network. The 56-bit result previously stored in accumulators ACCb and ACCc is now divided by the charge time of the known component, τ_{KN}. This result is a 24-bit number which has the units of pF or Ω. This value is then transmitted to the PC.

RS-232 Transmission

PICMETER uses a transmit only, software implemented serial port adapted from AN593, *"Serial Port Routines Without Using the TMR0"*. Hardware hand-shaking is not used. Since the serial port is realized in software, all interrupts must be disabled during transmission otherwise the baud rate can get corrupted.

On power-up, PICMETER sends a boot message to the PC which is "PICMETER Booted!". Otherwise, a four byte packet structure with a command byte and 3 data bytes is used. The command byte contains one of four possible commands:

- ASCII '**S**' signifies that a measurement has been initiated
- ASCII '**E**' tells the PC that an **E**rror has been detected
- ASCII '**R**' tells the PC that **R**esistance data is contained in the three data bytes
- ASCII '**C**' tells the PC that **C**apacitance data is contained in the three data bytes

The first data byte for the '**R**' and '**C**' commands contain the MSB of the measured value. The last data byte contains the LSB of the measured value. The three data bytes for the commands '**S**' and '**E**' do not contain any useful information at this time.

An 'S' command is issued every time the start switch, S2, is pressed. PICMETER then sends an 'R' or 'C' command for a valid measurement or an 'E' command when an error is detected.

Since the PICMETER operates from a single supply voltage, a discrete transistor is used as a level shifter. This insures that a low output on the RS-232 TXD line is between -3V and -11V. When the TXD line, RB7, from the PIC16C622 is at a logic high level, the transistor Q1 is off. The RXD line of the computer will then be at approximately the same voltage as the TXD line, -11V to -3V. A logic low level from RB7 of the PIC16C622 will turn on transistor Q1. This will bring the RXD line of the computer to about the same voltage of the DTR or RTS line, +3V to +11V.

The pins of interest on the DB9 connector CON1 are:

- pin 2 - RXD
- pin 3 - TXD
- pin 4 - DTR
- pin 5 - GND
- pin 7 - RTS

RTS, DTR, and GND provide power and ground to the PICMETER. RXD is connected to the collector of transistor Q1. TXD is connected to RXD through resistor R14. Since hardware hand-shaking is not implemented on the PICMETER, DSR (pin 6) and CTS (pin 8) are left disconnected.

The demo board developed by Microchip was intended to connect directly to a 9-pin serial port. A 9-pin male-to-female cable may also be used. These boards were manufactured by Southwest Circuits located in Tucson, Arizona (Appendix C). The PCB layout for this demo board is shown in Appendix C.

Error Message

The error message is sent only when the PICMETER is making a measurement and detects an error. The range of resistance that the PICMETER measures is 1 kΩ to 999 kΩ. Using the value of C2, 1 µF, the range of charging times for resistance measurements is 1msec to 999 ms. The range of capacitor charging times is also 1 ms to 999 ms using the resistance value of R3, 1MΩ, and a capacitor measuring range of 1 nF to 999 nF. A ceramic resonator of 4 MHz gives Timer0 a resolution of 1 ns. Therefore, the highest count that the time registers should reach is 999,000. This is a 20-bit number. If the 21st bit should ever be set, it is assumed that the PICMETER is trying to measure the air gap between the measuring terminals, a component that is out of range, or switch S1 is not set correctly for the component in the measuring terminals.

24-Bit Math Routines

The 24-bit math routines were developed using simple algorithms found in any computer math book. These math routines include addition, subtraction, multiplication, division, and 2's complement. Four 24-bit accumulators located in the general purpose RAM area of the PIC16C622 are used by the math routines: ACCa, ACCb, ACCc, and ACCd. Table 2 shows the relationship between the math routines and the accumulators.

Computer Program

The program that receives data from the PICMETER was written in Visual Basic® from Microsoft® for the Windows® environment. Figure 17 show the display of the Windows based PICMETER program.

FIGURE 17: PICMETER PC PROGRAM

The operation of this program is simple. A functional description is given below:

a) Select the appropriate COM port by clicking on the COM1 or COM2 buttons.

b) Turn power on to the PICMETER by clicking on the PICMETER Power button.

c) The frame message should read "PICMETER Booted!", the frame contents will be cleared, and the LED on the PICMETER should be on.

d) The switch S1 selects the type of component that is in the measuring terminals.

e) Pressing the START button, S2, on the PICMETER will initiate a measurement. The frame message should read "Measuring Component" and the contents of the frame will be cleared.

f) When the measurement is complete, the frame message will read "Resistance" or "Capacitance" depending on the position of switch S1. The value of the component will be displayed in the frame as well as the units.

g) If an error is detected, the frame message will read "Error Detected". This is only a measurement error. Check the component on the measuring terminals and the position of switch S1.

h) Turn off the PICMETER by clicking on the PICMETER Power button. The frame message will change to "PICMETER Power OFF", the frame contents will be cleared, and the LED on the PICMETER will turn off.

Appendix B contains a complete listing of the Visual Basic program.

PICMETER ACCURACY

The PICMETER measures capacitance in the range of 1 nF to 999 nF. Table 3 shows a comparison of various capacitors. All capacitors have a tolerance of 10% and have various dielectrics. The average error percentage is 3%.

TABLE 3: CAPACITANCE MEASUREMENTS

Capacitance Accuracy			
Marked Value	**Fluke Value**	**PICMETER Value**	**Error %**
2.2 nF	2.3 nF	2.2 nF	4.3
2.5 nF	2.63 nF	2.5 nF	4.9
20 nF	16.5 nF	16.3 nF	1.2
33 nF	35.2 nF	35.8 nF	1.7

470 nF	508 nF	518.9 nF	2.1
940 nF	922 nF	983.1 nF	6.6

The 2.5 nF, 100 nF and 940 nF capacitors all have polyester dielectric material. The Equivalent Series Resistance (ESR) of polyester capacitors is typically high which would cause the PICMETER to have a larger error than other dielectrics. If the error percentages for these capacitors is ignored, the average error decreases to 1.9%.

The resistance range of the PICMETER is 1 kΩ to 999 kΩ. Table 4, Resistance Measurements, shows a comparison of various resistors in this range. All resistors have a tolerance of 5%. The average error percentage is 1%.

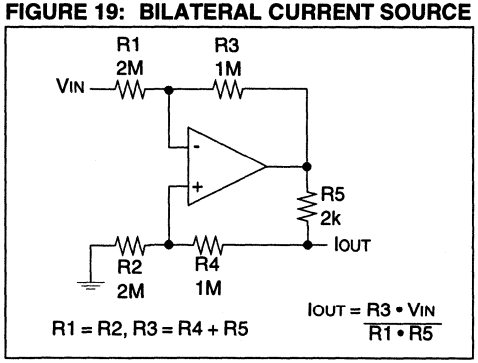
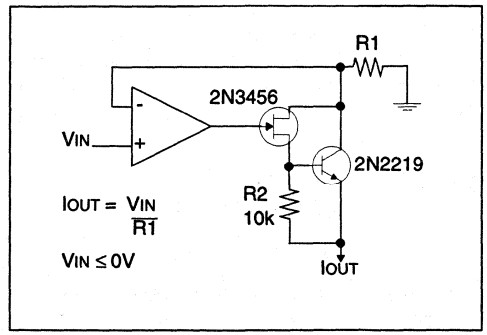
The accuracy of the PICMETER is dependent on the range of components being measured. If auto-ranging could be implemented, the accuracy of the PICMETER could be improved. The addition of capacitors in parallel with C2 of Figure 16 would allow auto-ranging for resistor measurements. Additional resistors in parallel with R3 would give auto-ranging capability to capacitor measurements. Figure 18 shows a simple implementation of auto-ranging given that the I/O pins are available. The R? and C? are the extra components that are added to the PICMETER circuit. These components should be optimized for a particular range of devices.

FIGURE 18: AUTO-RANGING TECHNIQUE

Another addition to the PICMETER that would increase the accuracy of components being measured is a constant current source. The source would feed into the resistor of the RC networks. This provides the same charging current to all RC networks being measured. Figure 19 shows a bilateral current source and Figure 20 shows a precision current source.

FIGURE 19: BILATERAL CURRENT SOURCE





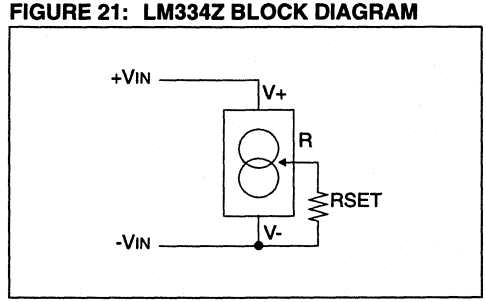


FIGURE 20: PRECISION CURRENT SOURCE

An alternative to the previous current sources is a single chip solution. A 3-terminal adjustable current source, such as a LM134/LM234/LM334 from National Semiconductor, is an ideal choice. This output current is programmable from 1 µA to 10 mA and requires a single external resistor to set the value of current. Figure 21 shows a block diagram of the LM334Z.

FIGURE 21: LM334Z BLOCK DIAGRAM

CONCLUSION

PIC16C62X devices add two significant analog features to the PIC16CXXX mid-range family: comparators and a voltage reference. The flexibility of eight operating modes for the comparator module allows the designer to tailor the PIC16C62X device to the application. The addition of an on-chip voltage reference simplifies the design by removing at least one external component and power consumption. These analog modules coupled with the PIC16CXXX mid-range family core create a new path to achieve high resolution results.

Digital Signal Processing with the PIC16C74

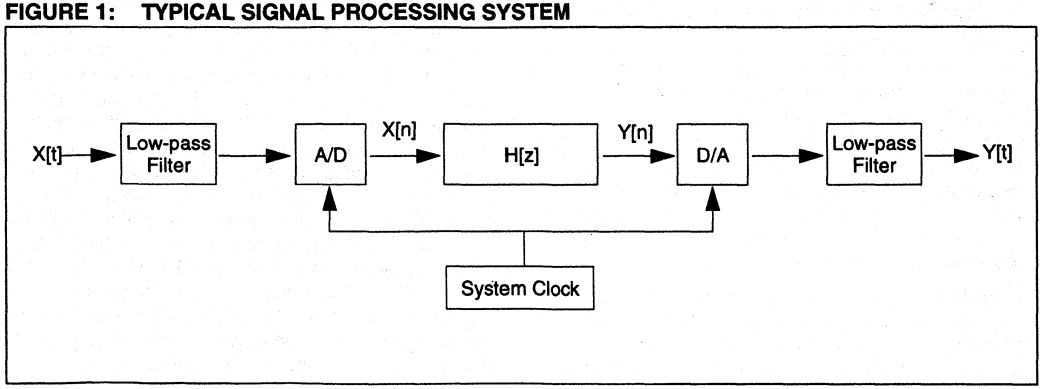
INTRODUCTION

This application note describes the basic issues that need to be addressed in order to implement digital signal processing systems using the PIC16C74 and provides application code modules and examples for DTMF tone generation, a 60 Hz notch filter, and a simple PID compensator for control systems. These routines can also be used with other PIC16C6X and PIC16C7XXX processors with minor modifications and the addition of external analog I/O devices.



The use of general purpose microcontrollers for low-end digital signal processing applications has become more commonplace these days with the availability of higher speed processors. Since most signal processing systems consist of a host processor and dedicated DSP chip, the use of a single microcontroller to perform both these functions provides a simpler and lower cost solution. In addition, the single chip design will consume less power which is ideal for battery powered applications. The PIC16C74 with its on-chip A/D, PWM module, and fast CPU is an ideal candidate for use in these low-bandwidth signal processing applications.

A typical signal processing system includes an A/D converter, D/A converter, and CPU that performs the signal processing algorithm as shown in Figure 1.

The input signal, *x(t)*, is first passed through an input filter (commonly called the anti-aliasing filter) whose function is to bandlimit the signal to below the Nyquist rate (one half the sampling frequency) to prevent aliasing. The signal is then digitized by the A/D converter at a rate determined by the sample clock to produce *x(n)*, the discrete-time input sequence. The system transfer function, *H(z)*, is typically implemented in the time-domain using a difference equation. The output sample, *y(n)*, is then converted back into the continuous-time signal, *y(t)*, by the D/A converter and output low-pass filter.

The calculation of the output signal using a difference equation requires a multiply and accumulate (MAC) operation. This is typically a single-cycle instruction on DSP chips but can take many cycles to perform on a standard microcontroller since it must be implemented in code. Since the digitization of the signal, calculation of the output, and output to the D/A converter all must be completed within the sample clock period, the speed at which this can be done determines the maximum bandwidth that can be achieved with the system. The relatively slow speed of most microcontrollers is the major limitation when they are used in DSP applications but the PIC16C74's fast instruction execution speed (as fast as 200 ns/instruction) can provide the performance required to implement relatively low bandwidth systems. In addition, the device's on-chip A/D and PWM modules provide all the functions needed for a single chip system. Only a few external components are needed to use the PIC16C74 for tone generation, filtering of transducer signals, or low bandwidth control.

CODE DEVELOPMENT TOOLS

The code for these applications was written using Byte Craft's MPC C compiler. The MPC compiler provides an Integrated Development Environment (IDE) and generates highly optimized code for the entire PICmicro™ family. For new PICmicro users that are familiar with C, this is an ideal way to quickly develop code for these processors. In addition, the listing files can be studied in order to learn the details of PICmicro assembly language. The modules and examples for this application note use C for the main program body and in-line assembly language for the time-critical routines. MPC provides interrupt support so that interrupt service routines (ISRs) can be easily written in either C or assembly. This feature was used to provide a timer ISR for one of the code modules. The compiler proved to be a valuable tool that allowed both high level and assembly language routines to be written and tested quickly.

In order to provide the double precision math functions required for this application note, a couple of existing math functions written for the PIC16C54 (AN525, *Programming PIC16C5X Devices on Logical Devices*) were converted for use with MPC. The double precision multiply and addition routines were modified by first changing all RAM declarations done in EQU statements to C "*unsigned char*" variable declarations. The main body of assembly language code was preceded by "`#asm`" and ended by "`#endasm`" preprocessor directives which tell the compiler where the in-line assembly code starts and ends. Finally, any macro sections and register names that are defined differently in MPC were changed.

The assembly language routines for tone generation and filtering were also written as C functions using the compiler. Assembly language routines written in this way can be called directly from other assembly language modules or called directly from C by using the label name as a C function. Source listings for all the modules and example programs can be found in the appendices at the end of this application note. These modules can be directly compiled using the MPC compiler or, alternatively, the assembly language sections can be used with MPASM with minor modifications.

Number Representation and Math Routines

One of the challenges of using any general purpose microcontroller for signal processing algorithms is in implementing the finite word-length arithmetic required to perform the calculations. As mentioned before, the speed at which the MAC operations can be performed limits the maximum achievable bandwidth of the system. Therefore, the routines that perform the multiplication and the main signal processing algorithms need to be optimized for speed in order to obtain the highest possible bandwidth when using the PIC16C74.

The selection of word size and coefficient scaling are also important factors in the successful implementation of signal processing systems. The effects of using a fixed word length to represent the signal and do calculations fall into three categories: signal quantization, round-off error, and coefficient quantization. The signal quantization due to the A/D converter and round-off error due to the finite precision arithmetic affect the overall signal-to-noise performance of the system. Scaling of the input signal should be done before the A/D converter to use the full input range and maximize the input signal-to-noise ratio. The use of double precision math for all calculations and storing intermediate results, even if the input and output signals are represented as 8-bit words, will help to reduce the round-off error noise to acceptable levels. Coefficient quantization occurs when the calculated coefficients are truncated or rounded off to fit within the given word length. This has the effect of moving the system transfer function poles and zeros which can change the system gain, critical frequencies of filters, or stability of the system. The successful implementation of these systems requires careful design and modeling of these effects using one of the many software programs that are available. The code written for this application note was first modeled using PC MATLAB before being implemented on the PIC16C74.

The algorithms in this application note are all implemented using fixed point two's compliment arithmetic. Two math libraries were used for the examples: one 8-bit signed multiply routine that was written specifically for the tone generation algorithm, and the modified double precision routines for the PIC16C54 that were used in the filtering routine. All numbers are stored in fractional two's compliment format where the MSB is the sign bit and there is an implied decimal point right after it. This is commonly referred to as Qx format where the number after the Q represents the number of fractional bits in the word. For instance, 16 bit words with the decimal point after the MSB would be referred to as Q15. This format allows numbers over the range of -1 to 0.99 to be represented and, because the magnitude of all numbers is less than or equal to one, has the advantage that there can be no overflow from a multiplication operation.

Since calculations are done using two's compliment arithmetic, values read by the PIC16C74's A/D converter need to be converted to this format. This can be easily done if the input is set up to read values in offset binary format. In this representation, the most negative input voltage is assigned to the number 0, zero volts is assigned the number 128, and the most positive voltage input is assigned 255. Since the PIC16C74 has a unipolar input A/D converter, a bipolar input signal must be scaled to be between 0 and 5V. One way to accomplish this is to use an op-amp scaling and offset circuit. The signal should be centered at 2.5V and have a peak to peak voltage swing of 4 to 4.5V. The offset binary number can be converted to two's compliment format by simply complimenting the MSB of the word. Once the signal processing calculations are completed, the number can be converted back to offset binary by complimenting the MSB before it is written to the PWM module. A similar level shifting circuit can be used at the PWM output to restore the DC level of the signal. Using this technique allows a wide range of analog input voltages to be handled by the PIC16C74.

A/D and D/A Conversion

The PIC16C74's internal 8-bit A/D converter and PWM modules can be used to implement analog I/O for the system. The A/D converter along with an external anti-aliasing filter provides the analog input for the system. Depending on the input signal bandwidth and the sampling frequency, the filter can be a simple single pole RC filter or a multiple pole active filter. The PWM output along with an external output "smoothing" filter provides the D/A output for the system. This can be a simple RC filter if the PWM frequency is much higher (five to ten times) than the analog signal that is being output. Alternatively, an active filter can also be used at the PWM output . Since the use of the A/D and PWM modules is covered in detail in the data sheet for the part, they will not be covered here. In addition, since the PIC16C74's A/D converter is similar to the PIC16C71 and the PWM module is the same as the PIC16C74, the use of these is also covered in application notes AN546, AN538, and AN539.

Appendix A contains the listing for the C module "*ANALOGIO.C*" that has the functions that read the A/D converter input, initialize the PWM module, and write 8-bit values to the PWM module. The number format (offset binary or two's compliment) for the A/D and PWM values as well as the PWM resolution and mode are set using "`#define`" pragmas at the beginning of the module. The `get_sample()` function takes the A/D input multiplexor channel number as an argument and returns the measured input value. The `init_PWM()` function takes the PWM period register PR2 value as an argument. The `write_PWM()` function takes the output values for PWM module1 and 2 and writes them to the appropriate registers using the specified resolution. If the second argument to the function is 0, the registers for PWM module 2 are unaffected. The PWM resolution is always 8-bits but the mode used depends on the PWM frequency.

The A/D conversions need to be performed at the system sample rate which requires that some form of sample clock be generated internally or input from an external source. One way to generate this clock internally, in software with minimal effort, is to use the Timer2 interrupt. Since Timer2 is used to generate the PWM period, enabling the Timer2 interrupt and using the Timer2 postscaler can generate an interrupt at periods that are integer divisors of the PWM period. The ISR can set a software "sample flag" that is checked by the main routine. Once the sample flag is asserted by the ISR, the main routine can then clear it and perform the signal processing operation, output the next sample, and then wait for the sample flag to be asserted true again. Alternatively, a separate timer/counter or external clock input can be used for the system sample clock. The latter two methods have the advantage that the PWM frequency can be set independent of the sampling period. For best results, the PWM frequency should be set for at least five times the maximum frequency of the analog signal that is bring reproduced. The example programs illustrate the use of both of the methods for generating an internal sample clock.

Tone Generation

For systems that need to provide audible feedback or to provide DTMF signaling for telcom applications, the PIC16C74's PWM module can be used to generate these signals. One way to do this is to output samples of a sinusoidal waveform to the PWM module at the system sampling rate. This method is relatively simple but is limited to single tones and may require large amounts of memory depending on the number of samples used per cycle of the waveform and the number of tones that need to be generated. A more efficient method of generating both single and dual-tone signals is to use a difference equation method. This method uses a difference equation that is derived from the z-transform of a sinusoid as follows:

The z-transform of a sinusoid is

$$\frac{z^{-1}\sin\omega T}{1 - 2z^{-1}\cos\omega T + z^{-2}}$$

where the period $\omega = 2\pi f$ and T is the sampling period.

If this is interpreted as the transfer function $H(z) = Y(z)/X(z)$ then the difference equation can be found taking the inverse z-transform and applying the associated shift theorem as follows:

rearranging:

$$Y(z)(1 - 2z^{-1}\cos\omega T + z^{-2}) = X(z)(z^{-1}\sin\omega T)$$

$$Y(z) = z^{-1}X(z)\sin\omega T + z^{-1}Y(z)2\cos\omega T - z^{-2}Y(z)$$

taking the inverse z-transform:

$$Z^{-1}[Y(z)] = Z^{-1}[z^{-1}X(z)\sin\omega T + z^{-1}Y(z)2\cos\omega T - z^{-2}Y(z)]$$

$$y(n) = \sin\omega T\, x(n-1) + 2\cos\omega T\, y(n-1) - y(n-2)$$

If we let $a = \sin\omega T$ and $b = \cos\omega T$, the equation can be written as:

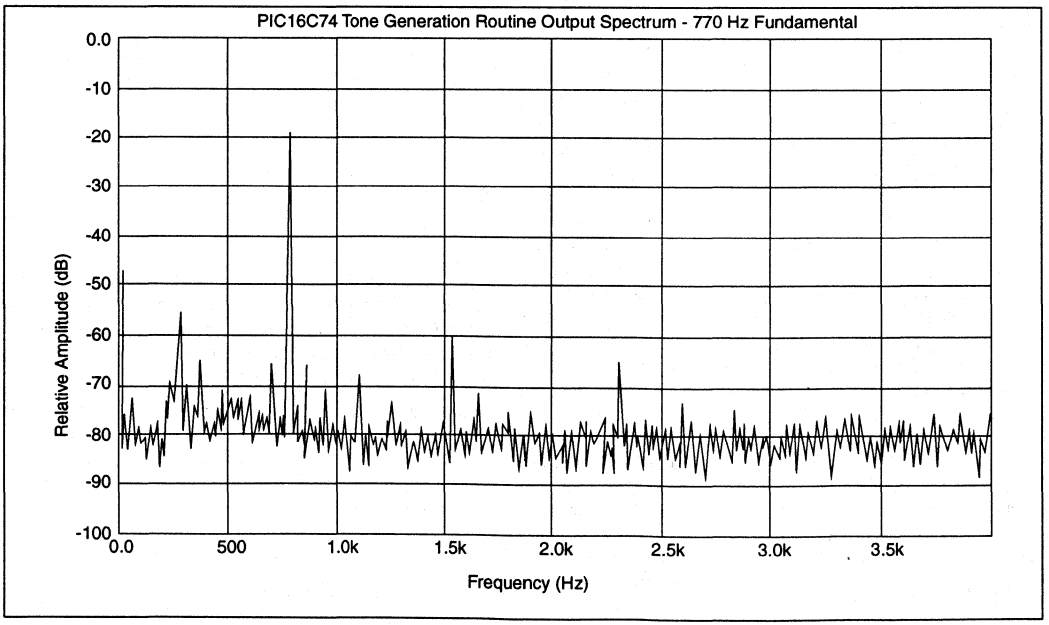
$$y(n) = a\, x(n-1) + 2b\, y(n-1) - y(n-2)$$

thus we have a difference equation with coefficients *a* and *b*. Note that only two coefficients are needed to generate a sinusoidal output sequence. These are calculated from the relationship above and stored in memory for use by the tone generation algorithm.

If we input an impulse to this system (x(n) = 1 at n = 0 and is zero elsewhere) then the output of the system will be a discrete-time sinusoidal sequence. Note that at n = 0, the output will always be 0 and x(n) is only 1 at n = 1 so the sequence becomes:

$$y(0) = 0$$
$$y(1) = a$$
$$y(n) = 2b\, y(n-1) - y(n-2)$$
for n equal to or greater than 2

© 1997 Microchip Technology Inc.



In order to further simplify the implementation of the algorithm, we can omit the first sample period. Since the output is already at 0 before starting, this will make no difference in the final output other than the fact that it will be time shifted by one sample. To generate dual tones, the algorithm is executed once for each tone and the two output samples are summed together. Since the output must be calculated and output to the D/A each sample period, a limitation exists on the frequency of the tone that can be produced for a given sample rate and processor speed. The higher the ratio of the sample clock to the tone frequency, the better, but a sample rate of at least three to four times the highest tone output should produce a sine wave with acceptable distortion.

Appendix B contains the listing for the "PICTONE.C" module which uses the difference equation method to produce variable length tones from the PWM module. Timer2 is used to generate the PWM period as well as the sample clock and tone duration timer. To send a tone, the coefficients and duration are written to the appropriate variables and then the tone routine is called. If the a2 and b2 coefficients are cleared, the routine will only generate a single tone sequence. The difference equation algorithm uses 8-bit signed math routines for the multiply operations. Using 8-bit coefficients reduces the accuracy by which the tones can be generated but greatly reduces the number of processor cycles needed to perform the algorithm since only single precision arithmetic is used. The spectrum of a single tone signal generated using this routine is shown in Figure 2.

Note that the second harmonic is better than 40 dB below the fundamental. Accuracy of this particular tone is better than 0.5%.

An example program "DTMFGEN.C" illustrates the use of the tone module to generate the 16 standard DTMF tones used for dialing on the telephone system. A sampling rate of 6.5 kHz was used which allows dual tones to be generated on a processor running at 10 MHz. Accuracy with respect to the standard DTMF frequencies is better than 1% for all tones and all harmonics above the fundamental frequency are greater than 30 dB down.

Digital Filters

Digital filters with critical frequencies up to a kilohertz or so can be implemented on the PIC16C74. Digital filters fall into two classes: Finite Impulse Response (FIR) and Infinite Impulse Response (IIR) filters. FIR filters require more coefficients and multiplication operations to implement practical filters and are not as well suited for implementation on the PIC16C74. IIR type filters are typically designed starting with an analog filter prototype and then performing an analog to digital transformation to produce the digital filter coefficients. The subject of digital filter design is not within the scope of this application note but there are many excellent texts that cover the theory and design of these filters.

The implementation of a second-order IIR filter is done by using a second-order difference equation. A second-order infinite impulse response (IIR) filter has a transfer function of the form:

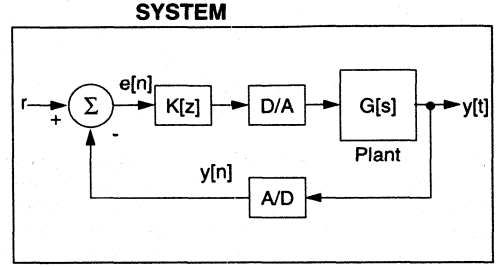
$$H(z) = \frac{b_0 + b_1 z^{-1} + b_2 z^{-2}}{1 + a_1 z^{-1} + a_2 z^{-2}}$$

Where a_1 , a_2, b_0 , b_1 , and b_2 are the coefficients of the polynomials of the system transfer function that, when factored, yield the system poles and zeros. The difference equation found by taking the inverse z-transform and applying the shift theorem is:

$$y(n) =$$

$$b_0x(n) + b_1x(n - 1) + b_2x(n - 2) - a_1y(n - 1) - a_2y(n - 2)$$

Since the transfer function coefficients are used directly in the difference equation, this is often called the "Direct Form I" implementation of a digital filter. This form has its limitations due to numerical accuracy issues but is effective for implementing second-order systems.



Appendix C contains the listing for the general-purpose filter routine "IIR_FILT.C" that can be used to implement low-pass, high-pass, bandpass, and bandstop (notch) filters. The filter() function takes an 8-bit input value x(n) and calculates the output value y(n) . The filter coefficients are stored as 16-bit two's compliment numbers and computation of the output is done using double precision arithmetic. Since the coefficients generated from the filter design program will be in decimal form, they need to be scaled to be less than 1 and then multiplied by 32,768 to put them in Q15 format. Additional scaling by factors of two may be required to prevent overflow of the sum during calculations. If this is done, the output must be multiplied by this scale factor to account for this. The "IIR_FILT.C" module contains two other subroutines required for the filtering program. One if these is a decimal adjust subroutine to restore the decimal place after two 16-bit Q15 numbers are multiplied. The subroutine shifts the 32-bit result left by one to get rid of the extra sign bit. The other routine scales the output by factors of two and is used after the output of the filter has been calculated to account for the scaling of the coefficients.

An example program "NOTCH_60.C" is provided that illustrates the implementation of a 60 Hz notch filter using the "IIR_FILT.C" module. The filter was modeled and designed using PC MATLAB before being implemented on the PIC16C74. A sample rate of 1 kHz is used which means that signals up to a few hundred hertz can be processed. The filter provides an attenuation of about 40 dB at 60 Hz and can be used to remove interference from sensor signals in a system.

Digital Control

A low bandwidth digital control system can be implemented on the PIC16C74 using the analog I/O and IIR filter routines. A typical digital control system is shown below:

FIGURE 3: TYPICAL DIGITAL CONTROL SYSTEM

The input, r, is the reference input and *y(t)* is the continuous-time output of the system. *G(s)* is the analog transfer function of the plant (controlled system) and *K(z)* is the digital compensator. The error signal is calculated by subtracting the measured output signal, *y(n)*, from the reference. The controller transfer function is essentially a filter that is implemented in the time-domain using a difference equation. Since digital control system design is a complex subject and the design of a suitable compensator depends on the system being controlled and the performance specifications, only the implementation issues will be discussed.

One popular and well understood compensator is the Proportional-Integral-Derivative (PID) controller whose transfer function is of the form:

$$K(z) = K_P + \frac{K_I}{1 - z^{-1}} + K_D(1 - z^{-1})$$

Where K_P is the proportional gain, K_I is the integral gain ,and K_D is the derivative gain. The transfer function can be implemented directly or can be put in the form of a standard second-order difference equation from the modified transfer function as shown below:

$$H(z) = \frac{(K_I T^2 + K_P T + K_D) - (2K_D + K_P T)z^{-1} + K_D z^{-2}}{T(1 - z^{-1})}$$

$$y(n) = (K_P + K_I T + \frac{K_D}{T})x(n) - (K_P + \frac{2K_D}{T})x(n - 1) + \frac{K_D}{T} x(n - 2) - y(n - 1)$$

Since the numerator coefficients will be greater than one, a gain factor K needs to be factored out so that the resulting coefficients are less than one. In this way, the IIR filter routine can be used to implement the controller. After the filter routine, the output y needs to be multiplied by K before being output to the PWM module. Since the gain can be high, this result needs to be checked for overflow and limited to the maximum 8-bit value, if required. Saturating the final result prevents the system from going unstable if overflow in the math does occur. The gains can also be applied externally at the D/A output. For example, the PWM can drive a power op-amp driver that provides a ± 20 volt swing for a DC motor.

RESULTS AND CONCLUSION

The results obtained using the PIC16C74 in these applications were impressive. The tone generation routines produce very clean sinusoidal signals and DTMF tones generated using this routine have been used to dial numbers over the telephone system with excellent results. In addition, tones used for audible feedback are more pleasing to the ear than those generated from a port pin as is typically done on processors without PWM modules. Using the PIC16C74 to generate these tones eliminates the need for special DTMF generator IC's thus reducing the cost and simplifying the design. The tone routine requires approximately 125 instruction cycles to calculate an output sample for a single tone output and 230 instruction cycles to calculate an output sample for a dual tone output.

The IIR filtering routines produce good results and have been used to filter 60 Hz signals on sensor lines and also to implement a simple PID controller system with excellent results. The IIR routine takes approximately 1670 instruction cycles to calculate the output. Table 1 shows the performance that can be expected with the PIC16C74 for various processor speeds.

In conclusion, the PIC16C74 provides the necessary performance to provide these simple, low bandwidth signal processing operations. This means that products using this device can benefit from cost and power savings by eliminating specialized components that normally perform these tasks.

* If FILTER set to 0, performs straight talkthru from A-D to PWM output.
* T0 period can be changed to cary the sample rate.

PIC14C000 Calibration Parameters

Author: Richard Fisher
Microchip Technology Inc.

Caution:

When using a WINDOWED DEVICE, the calibration data will be lost if the device is erased. Care should be exercised to ensure that factory calibration data is not lost. Microchip does not recommend using code protection in a windowed device.

Due to the photosensitivity of semiconductors, the analog peripherals may not function properly if the window protection label is not in place during device operation.

INTRODUCTION

This application note discusses the PIC14C000 calibration constants and calibration procedures.

This application note refers to the following documents:

- PIC14C000 Data Sheet (DS40122)
- AN575, "IEEE 754 Compliant Floating Point Routines" (DS00575)
- AN624 "PIC14C000 A/D Theory and Implementation" (DS00624)

The PIC14C000 has several analog peripherals. Like all CMOS circuitry the parametric values vary with process, temperature, voltage, and time.

The PIC14C000 has been designed to minimize the effect of these variations. In addition, each device is calibrated at factory test by measuring several key parameters and storing these values into EPROM at specified locations. The customer's application program may access this data and use it to mathematically compensate for device variations.

Collectively, these data values are referred to as calibration constants. They are listed in Table 4-1 in the PIC14C000 Data Sheet (DS40122).

CALIBRATION DATA

The PIC14C000 calibration constants are listed in Table 1.

TABLE 1: CALIBRATION CONSTANTS

Parameter	Symbol
A/D Slope reference ratio	KREF
Bandgap reference voltage	KBG
Temperature sensor voltage	VTHERM
Temperature sensor voltage slope	KTC
Internal oscillator frequency multiplier	FOSC
Watchdog Timer (WDT) time-out	TWDT

Table 2 show an example of PIC14C000 calibration constants and their locations.

The first four parameters in the table are in 32-bit floating point representation. Each parameter has an exponent byte, and three bytes of mantissa. (For information on floating point algorithms, refer to AN575.) The last two parameters are single-byte numbers.

TABLE 2: TYPICAL CALIBRATION CONSTANT VALUES

Constant	Address	Value	Byte 1	Byte 2	Byte 3	Byte 4
KREF	0FC0:0FC3	0.1259	7C	00	F8	DD
KBG	0FC4:0FC7	1.1842	7F	17	93	02
VTHERM	0FC8:0FCB	1.0766	7F	09	CC	CD
KTC	0FCC:0FCF	0.0037	76	75	B3	3C
FOSC	0FD0	4.65	A5	—	—	—
TWDT	0FD2	16	10	—	—	—

Note: For the 4-byte constants, Byte 1 is the exponent, while Bytes 2, 3, and 4 specify Mantissa High Byte, Middle Byte, and Low Byte, respectively. For the 1-Byte constants, the value occupies only Byte 1.

USING CALIBRATION DATA

The calibration constants should be used by the application firmware to obtain the best accuracy.

KREF and KBG are used in A/D conversions. For further details, see AN624.

VTHERM and KTC are used for the internal temperature sensor. To use these parameters to calculate temperature, see AN624.

FOSC is a 1-byte value that represents the measured internal oscillator frequency. The internal oscillator frequency can be calculated as follows:

$$f = \left(3 + \frac{FOSC}{100}\right) MHz$$

FOSC can be used to compensate device internal clock variations for time critical applications such as USART baud rate generation.

TWDT is a 1-byte value that is the watchdog time-out in milliseconds without using the postscaler counter. The postscaler counter can extend the WDT time out up to 2.5 seconds. See the PIC14C000 Data Sheet, order number DS40122, for further details.

PARAMETER VARIATION

Table 3 lists the "Maximum Parameter Variation" attainable when the calibration data is not used. This data is based on measurement over the temperature range of -40°C to +85°C and over the operating VDD range of 2.7V to 6.0V, unless otherwise specified. For further details, refer to the PIC14C000 Data Sheet.

TABLE 3: MAXIMUM PARAMETER VARIATION WITHOUT CALIBRATION (PRELIMINARY)

Symbol	Parameter	Maximum Variation
KREF	A/D slope reference ratio	+/- 2.2%
KBG	Bandgap reference voltage	+/- 4.2%
VTHERM	Temperature sensor voltage	+/- 12.4% (Note 1)
KTC	Temperature sensor coefficient	+/- 5%
TEMPINT	Calculated temperature	+/- 35°C
TWDT	WDT Time-out Period	+/- 60% (Note 2)

Note 1: At 25°C, +/- 2°C, over VDD range.
2: 7 msec to 33 msec over temperature, VDD = 5.0V

If these accuracies are adequate for the task at hand, no further calibrations are necessary. If greater accuracy is needed, the calibration constants must be used.

Table 4 lists the "Expected Parameter Variation with Calibration." This data is based on measurements using the calibration data (measured at 25°C) over the temperature range of 0°C to +50°C and at the operating VDD = 5.0V unless otherwise specified. For further details, refer to the PIC14C000 Data Sheet.

TABLE 4: EXPECTED VARIATION OF PARAMETERS WITH CALIBRATION (PRELIMINARY)

Symbol	Parameter	Maximum Variation
KREF	A/D slope reference ratio	+/- 0.13%
KBG	Bandgap reference voltage	+/- 0.058%
VTHERM	Temperature sensor voltage	+/- 0.71% (Note 1)
KTC	Temperature sensor coefficient	(NOTE 2)
TEMPINT	Calculated temperature	+/- 2°C (Note 3)
TWDT	WDT Timeout Period	+/- 13.8%

Note 1: At 25° C, +/- 2°C.
2: Calculated as the slope between 25°C and TMAX. TMAX = 70°C for commercial temperature, 85°C for industrial temperature.
3: Refer to AN624 for description of TEMPINT.

PROGRAMMING THE PIC14C000

Non-Windowed Parts

Non-windowed parts are programmed just like any PIC16CXXX processor. The calibration area is write-protected during factory calibration and will not be over-written by PRO MATE.

Windowed Parts

Caution:

Windowed parts must not be write-protected. If the parts are erased by ultraviolet light, the calibration parameters are lost and cannot be reprogrammed once the part has been write-protected.

Calibration data must be read out and saved before erasing a windowed part. There is no way to recreate these values, so if they are lost the part can no longer be calibrated.

The calibration data is read by the PRO MATE just like the rest of the code space. After reading, it must be saved as a Hex file. The entire memory space will be saved from 0 to 0xFFF. There is no way to save a part of the memory space.

To erase a windowed part:

1. Read part into the PRO MATE buffer.
2. If 000h - 0FBFh is not blank, use the Fill Prog Buffer command to set all bits to '1'.
3. Save the buffer content as a Hex file.

   Note:

   The calibration data, and hence this file, will be different for each PIC14C000. Don't forget to label the file and the part!
4. Use ultraviolet light to erase the part.
5. Load the saved Hex file (in step 3) into the PRO MATE buffer.
6. Program the part.

The part is now at the same state as it was when the factory shipped it. Load your code and program in the usual fashion.

If desired, after the calibration data file has been loaded to PRO MATE, the application program may be loaded and the whole part programmed at once.

Checksum

The checksum bytes listed in the data sheet are only for use by the PIC14C000 programmer. There is no way for an application program to utilize this checksum data. Note that there are special bytes added to this space so that the checksum of the entire calibration space totals zero. This means that the calibration factors, which vary from part to part, will not affect the user's code checksum, which may be used for program verification.

PROGRAM EXAMPLES

At the end of this application note are two code samples that may be used to access the calibration data. The first reads the entire table and stores the values in RAM. The second program can be used to restore calibration parameters, if accidentally erased.

SUMMARY

This application note has discussed the calibration constants programmed at Microchip Technology Inc. into the PIC14C000. It has discussed the effect of these calibration constants on system accuracy. It has also covered the erasing and reprogramming procedures.

PIC14C000 A/D Theory and Implementation

Author: Brian Dellacroce
Design Consultant

INTRODUCTION

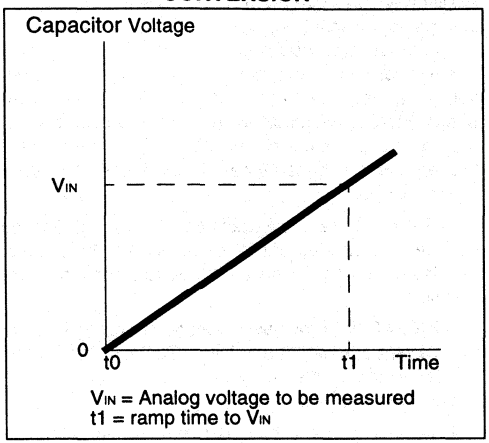
This application note presents an implementation of a data acquisition system based on a PIC14C000 microcontroller. The PIC14C000's analog front end will perform signal conditioning and analog to digital conversion of signals used in a battery monitoring application. Battery voltage, current, and temperature data will be acquired. This data will then be transmitted via RS-232 to a remote PC host.

SLOPE A/D CONVERSION

With the addition of an external capacitor, the analog front end of the PIC14C000 can be used as a slope A/D converter. The slope A/D is formed when a constant current source (CDAC pin) drives a capacitor. From basic capacitor theory, the voltage across this capacitor is described by the equation:

EQUATION 1: CAPACITOR VOLTAGE

$$V(t) = 1/C \times \int_{t0}^{t1} i(t)dt$$



Since the current $i(\tau)$ is constant, this reduces to:

EQUATION 2: VOLTAGE RAMP

$$V1 - V0 = 1/C \times I(t1 - t0)$$

This relationship describes a basic linear voltage ramp. The conversion from analog to digital occurs by measuring the time from the start of the linear ramp (*t0*) to the time (*t1*) that the voltage across the capacitor equals the analog input voltage to be converted. This time is measured by a digital counter circuit. Thus, the delta time (*t1 - t0*) value represents the magnitude of the analog voltage being converted. In this application note, the measured delta time value will simply be referred to as the "count" for the particular analog voltage being converted.
