Introduction

IN recent years much effort has been devoted to the closed-loop design of spacecraft with large angle slews. Vadali and Junkins[1] and Wie and Barba[2] derive a number of simple control schemes using quaternion and angular velocity (rate) feedback. Other full-state feedback techniques have been developed that are based on variable-structure (sliding-mode) control, which uses a feedback linearizing technique and an additional term aimed at dealing with model uncertainty. A variable-structure controller has been developed for the regulation of spacecraft maneuvers using a Gibbs vector parameterization,[3] a modified-Rodrigues parameterization,[4] and a quaternion parameterization.[5] In both Refs. 2 and 5 a term was added so that the spacecraft maneuver follows the shortest path and requires the least amount of control torque. The variable-structure control approach using a quaternion parameterization has been recently expanded to the attitude tracking case.[6,7] However, these controllers do not take into account the shortest possible path as shown in Refs. 2 and 5.

This Note expands upon the results in Ref. 5 to provide an optimal control law for asymptotic tracking of spacecraft maneuvers using variable-structure control. It also provides new insight using a simple term in the control law to produce a maneuver to the reference attitude trajectory in the shortest distance. Controllers are derived for either external torque inputs or reaction wheels.

Background

In this section a brief review of the kinematic and dynamic equations of motion for a three-axis stabilized spacecraft is shown. The attitude is assumed to be represented by the quaternion, defined as $q \equiv [q_{13}^T \; q_4]^T$ with $q_{13} \equiv [q_1 \; q_2 \; q_3]^T = \hat{n} \sin(\Phi/2)$ and $q_4 = \cos(\Phi/2)$, where $\hat{n}$ is a unit vector corresponding to the axis

*Assistant Professor, Department of Aerospace Engineering. Senior Member AIAA.

†Professor, Department of Aerospace Engineering. Associate Fellow AIAA.

‡Engineer, Code 571, Guidance, Navigation, and Control Center. Fellow AIAA.

of rotation and Φ is the angle of rotation. The quaternion kinematic equations of motion are derived by using the spacecraft's angular velocity (ω), given by

$$\dot{q} = \tfrac{1}{2}\Omega(\omega)q = \tfrac{1}{2}\Xi(q)\omega \tag{1}$$

where $\Omega(\omega)$ and $\Xi(q)$ are defined as

$$\Omega(\omega) \equiv \begin{bmatrix} -[\omega \times] & \vdots & \omega \\ \cdots & \cdots & \cdots \\ -\omega^T & \vdots & 0 \end{bmatrix}, \qquad \Xi(q) \equiv \begin{bmatrix} q_4 I_{3\times3} + [q_{13}\times] \\ \cdots \\ -q_{13}^T \end{bmatrix} \tag{2}$$

and $I_{n\times n}$ represents an $n \times n$ identity matrix. The 3×3 dimensional matrices $[\omega\times]$ and $[q_{13}\times]$ are referred to as cross-product matrices because $a \times b = [a\times]b$ (see Ref. 8).

Because a three degree-of-freedom attitude system is represented by a four-dimensional vector, the quaternion components cannot be independent. This condition leads to the following normalization constraint $q^T q = q_{13}^T q_{13} + q_4^2 = 1$. Also, the error quaternion between two quaternions q and q_d is defined by

$$\delta q \equiv \begin{bmatrix} \delta q_{13} \\ \cdots \\ \delta q_4 \end{bmatrix} = q \otimes q_d^{-1} \tag{3}$$

where the operator $\otimes$ denotes quaternion multiplication (see Ref. 8 for details) and the inverse quaternion is defined by $q_d^{-1} = [-q_{d_1} \; -q_{d_2} \; -q_{d_3} \; q_{d_4}]^T$. Other useful identities are given by $\delta q_{13} = \Xi^T(q_d)q$ and $\delta q_4 = q^T q_d$. Also, if Eq. (3) represents a small rotation, then $\delta q_4 \approx 1$ and δq_{13} corresponds to the half angles of rotation.

The dynamic equations of motion, also known as Euler's equations, for a rotating spacecraft are given by

$$J\dot{\omega} = -\omega \times (J\omega) + u \tag{4}$$

where J is the inertia matrix of the spacecraft and u is the total external torque input. If the spacecraft is equipped with three orthogonal reaction or momentum wheels, then Euler's equations become

$$(J - \bar{J})\dot{\omega} = -\omega \times (J\omega + \bar{J}\bar{\omega}) - \bar{u} \tag{5a}$$

$$\bar{J}(\dot{\bar{\omega}} + \dot{\omega}) = \bar{u} \tag{5b}$$

where $\bar{J}$ is the diagonal inertia matrix of the wheels, J now includes the mass of the wheels, $\bar{\omega}$ is the wheel angular velocity vector relative to the spacecraft, and $\bar{u}$ is the wheel torque vector.

Selection of Switching Surfaces

Optimal Control Analysis

We first consider a sliding manifold for a purely kinematic relationship, with ω as the control input. The variable-structure control design is used to track a desired quaternion q_d and corresponding angular velocity ω_d. As shown previously for regulation,[5] under ideal sliding conditions the trajectory in the state space moves on the sliding manifold. For tracking the following loss function is minimized to determine the optimal switching surfaces:

$$\Pi(\omega) = \frac{1}{2} \int_{t_s}^{\infty} \left[\rho \delta q_{13}^T \delta q_{13} + (\omega - \omega_d)^T (\omega - \omega_d) \right] dt \tag{6}$$

subject to the bilinear system constraint given in Eq. (1). Note that ρ is a scalar gain and t_s is the time of arrival at the sliding manifold. Minimization of Eq. (6) subject to Eq. (1) leads to the following two-point-boundary-value problem:

$$\dot{q} = \tfrac{1}{2}\Xi(q)\omega \tag{7a}$$

$$\dot{\lambda} = -\rho\Xi(q_d)\Xi^T(q_d)q + \tfrac{1}{2}\Xi(\lambda)\omega \tag{7b}$$

where λ is the costate vector. The optimal ω is given by

$$\omega = -\tfrac{1}{2}\Xi^T(q)\lambda + \omega_d \tag{8}$$

Next, the following sliding vector is chosen:

$$(\boldsymbol{\omega} - \boldsymbol{\omega}_d) + k\Xi^T(\boldsymbol{q}_d)\boldsymbol{q} = 0 \qquad (9)$$

where k is a scalar gain. The sliding vector is optimal if the solution of Eq. (9) minimizes Eq. (6). This can be proven by first substituting Eq. (9) into Eq. (8), yielding

$$\boldsymbol{\lambda} = -2k\boldsymbol{q}_d \qquad (10)$$

Next, using the fact that the desired quaternion can be obtained from the following

$$\dot{\boldsymbol{q}}_d = \tfrac{1}{2}\Xi(\boldsymbol{q}_d)\boldsymbol{\omega}_d \qquad (11)$$

leads directly to

$$\dot{\boldsymbol{\lambda}} = -k\Xi(\boldsymbol{q}_d)\boldsymbol{\omega}_d \qquad (12)$$

Comparing Eq. (12) to Eq. (7b) and using Eq. (9) now leads to the following relationship:

$$-k\Xi(\boldsymbol{q}_d)\boldsymbol{\omega}_d = -\rho\Xi(\boldsymbol{q}_d)\Xi^T(\boldsymbol{q}_d)\boldsymbol{q} - k\Xi(\boldsymbol{q}_d)\boldsymbol{\omega}_d$$
$$+ k^2\Xi(\boldsymbol{q}_d)\Xi^T(\boldsymbol{q}_d)\boldsymbol{q} \qquad (13)$$

Equation (13) is satisfied for $k = \pm\sqrt{\rho}$. Therefore, the sliding condition in Eq. (9) leads to an optimal solution [i.e., minimum Π in Eq. (6)].

For this special case the value of the loss function in Eq. (6) is given by

$$\Pi^* = 2k[1 - \delta q_4(t_s)] \qquad (14)$$

where k must now be strictly positive. Because δq_4 corresponds directly to the cosine of half the angle error of rotation, both $\boldsymbol{\delta q}$ and $-\boldsymbol{\delta q}$ represent the same rotation; however, the value of the loss function in Eq. (14) is significantly different for each rotation. One rotation ($\boldsymbol{\delta q}$) gives the shortest distance to the sliding manifold, whereas the other ($-\boldsymbol{\delta q}$) gives the longest distance. To give the shortest possible distance, the following sliding vector is chosen:

$$(\boldsymbol{\omega} - \boldsymbol{\omega}_d) + k\,\mathrm{sgn}[\delta q_4(t_s)]\Xi^T(\boldsymbol{q}_d)\boldsymbol{q} = 0 \qquad (15)$$

For a discussion on using $\mathrm{sgn}[\delta q_4(t_s)]$ in a control law, see Refs. 2 and 5. Using this sliding condition leads to the following value for the loss function:

$$\Pi^* = 2k[1 - |\delta q_4(t_s)|] \qquad (16)$$

which yields a minimal value for any rotation.

Lyapunov Analysis

The sliding vector shown in Eq. (15) can also be shown to be stable using a Lyapunov analysis. The time derivative of $\boldsymbol{\delta q}_{13}$ can be shown to be given by

$$\boldsymbol{\delta \dot{q}}_{13} = \tfrac{1}{2}\delta q_4(\boldsymbol{\omega} - \boldsymbol{\omega}_d) + \tfrac{1}{2}[\boldsymbol{\delta q}_{13}\times](\boldsymbol{\omega} + \boldsymbol{\omega}_d) \qquad (17)$$

Next, the following candidate Lyapunov function is chosen:

$$V_s = \tfrac{1}{2}\boldsymbol{\delta q}_{13}^T\boldsymbol{\delta q}_{13} \qquad (18)$$

Using the sliding vector in Eq. (15), the time derivative of Eq. (18) is given by

$$\dot{V}_s = -\tfrac{1}{2}k|\delta q_4|\boldsymbol{\delta q}_{13}^T\boldsymbol{\delta q}_{13} \le 0 \qquad (19)$$

Hence, V_s is indeed a Lyapunov function for $k > 0$. This analysis generalizes the results shown in Ref. 7, where the spacecraft's attitude is restricted in the workspace defined with $q_4 > 0$.

Variable-Structure Tracking

The preceding section showed the effectiveness of using $\mathrm{sgn}[\delta q_4(t_s)]$ in the sliding manifold. In this section we consider a variable-structure controller for the complete system (i.e., including the dynamics). The goal of the variable-structure controller is to track a desired quaternion $\boldsymbol{q}_d$ and corresponding angular velocity $\boldsymbol{\omega}_d$. The variable-structure control design with external torques only is given by {sgn[$\delta q_4(t)$] is now being used instead of sgn[$\delta q_4(t_s)$]}

$$\boldsymbol{u} = [\boldsymbol{\omega}\times]J\boldsymbol{\omega} + J\left\{\tfrac{1}{2}k\,\mathrm{sgn}(\delta q_4)\left[\Xi^T(\boldsymbol{q})\Xi(\boldsymbol{q}_d)\boldsymbol{\omega}_d \right.\right.$$
$$\left.\left. - \Xi^T(\boldsymbol{q}_d)\Xi(\boldsymbol{q})\boldsymbol{\omega}\right] + \dot{\boldsymbol{\omega}}_d - G\boldsymbol{\vartheta}\right\} \qquad (20)$$

where G is a 3×3 positive definite, diagonal matrix, and the ith component of $\boldsymbol{\vartheta}$ is given by

$$\vartheta_i = \mathrm{sat}(s_i, \varepsilon_i), \qquad i = 1, 2, 3 \qquad (21)$$

As already stated, the term $\mathrm{sgn}(\delta q_4)$ is used to drive the system to the desired trajectory in the shortest distance. The saturation function is used to minimize chattering in the control torques. This function is defined by

$$\mathrm{sat}(s_i, \varepsilon_i) \equiv \begin{cases} 1 & \text{for} & s_i > \varepsilon_i \\ s_i/\varepsilon & \text{for} & |s_i| \le \varepsilon_i \\ -1 & \text{for} & s_i < -\varepsilon_i \end{cases} \qquad i = 1, 2, 3 \quad (22)$$

where ε is a small positive quantity. The sliding manifold is given by

$$\boldsymbol{s} = (\boldsymbol{\omega} - \boldsymbol{\omega}_d) + k\,\mathrm{sgn}(\delta q_4)\Xi^T(\boldsymbol{q}_d)\boldsymbol{q} \qquad (23)$$

The stability of the closed-loop system using this controller can be evaluated using the following candidate Lyapunov function:

$$V = \tfrac{1}{2}\boldsymbol{s}^T\boldsymbol{s} \qquad (24)$$

Using Eqs. (4), (20), and (23), the time derivative of Eq. (24) can be shown to be given by $\dot{V} = -\boldsymbol{s}^T G\boldsymbol{\vartheta}$, which is always less than or equal to zero as long as G is positive definite. Hence, stability is proven.

If wheels are used to control the spacecraft, then the sliding mode controller is given by the following:

$$\bar{\boldsymbol{u}} = (J - \bar{J})\left\{\tfrac{1}{2}k\,\mathrm{sgn}(\delta q_4)\left[\Xi^T(\boldsymbol{q}_d)\Xi(\boldsymbol{q})\boldsymbol{\omega} - \Xi^T(\boldsymbol{q})\Xi(\boldsymbol{q}_d)\boldsymbol{\omega}_d\right] \right.$$
$$\left. - \dot{\boldsymbol{\omega}}_d + G\boldsymbol{\vartheta}\right\} - [\boldsymbol{\omega}\times](J\boldsymbol{\omega} + \bar{J}\bar{\boldsymbol{\omega}}) \qquad (25)$$

The stability of the control system with wheels in Eqs. (5) and (25) can also be easily proven using the Lyapunov function in Eq. (24).

Analysis

In this section an analysis of using $\mathrm{sgn}(\delta q_4)$ for all times in the control law is shown. We first assume that the desired angular velocity is zero ($\boldsymbol{\omega}_d = 0$) and that the matrix G is given by a scalar times the identity matrix ($gI_{3\times3}$). We further assume that the thickness of the boundary layer ε and the gain g are sufficiently large so that

$$G\boldsymbol{\vartheta} = \beta\boldsymbol{\omega} + \beta k\,\mathrm{sgn}(\delta q_4)\boldsymbol{\delta q}_{13} \qquad (26)$$

where $\beta = g/\varepsilon$. Using Eqs. (4), (17), and (20), the closed-loop dynamics for $\boldsymbol{\omega}$ now become

$$\dot{\boldsymbol{\omega}} = -\tfrac{1}{2}k\,\mathrm{sgn}(\delta q_4)\{\delta q_4 I_{3\times3} + [\boldsymbol{\delta q}_{13}\times]\}\boldsymbol{\omega}$$
$$- \beta\boldsymbol{\omega} - \beta k\,\mathrm{sgn}(\delta q_4)\boldsymbol{\delta q}_{13} \qquad (27)$$

Taking two time derivatives of $\delta q_4 = \boldsymbol{q}^T\boldsymbol{q}_d$ and using both Eq. (27) and the quaternion constraint equation $\boldsymbol{\delta q}^T\boldsymbol{\delta q} = 1$ yields

$$\delta\ddot{q}_4 + \left(\tfrac{1}{2}k|\delta q_4| + \beta\right)\delta\dot{q}_4 + \left(\tfrac{1}{2}\beta k|\delta q_4| + \tfrac{1}{4}\boldsymbol{\omega}^T\boldsymbol{\omega}\right)\delta q_4$$
$$= \tfrac{1}{2}\beta k\,\mathrm{sgn}(\delta q_4) \qquad (28)$$

Equation (28) represents a second-order nonlinear spring-mass-damper type system with an exogenous step input. The stability of Eq. (28) can be evaluated by considering the following candidate Lyapunov function:

$$V_{\delta q_4} = \tfrac{1}{2}\delta\dot{q}_4^2 + \tfrac{1}{2}\left(\tfrac{1}{4}\boldsymbol{\omega}^T\boldsymbol{\omega}\right)\delta q_4^2 + \tfrac{1}{2}\beta k[1 - \delta q_4\,\mathrm{sgn}(\delta q_4)] \qquad (29)$$

Table 1 Cost function values for various Φ

	Value of $\frac{1}{2}\int_0^{t_f} s^T s\, dt$	
Φ, deg	Gain = k	Gain = $k\,\mathrm{sgn}[\delta q_4(t)]$
210	1.0787	0.9313
240	0.8988	0.6543
270	0.6136	0.3566
300	0.3185	0.1300
330	0.1095	0.0194

The last term in Eq. (29) is always greater or equal to zero because $\beta > 0$, $k > 0$, and $0 \le \delta q_4\,\mathrm{sgn}(\delta q_4) \le 1$. Taking the time derivative of Eq. (29) and using Eqs. (27) and (28) gives

$$\dot{V}_{\delta q_4} = -\left(\tfrac{1}{2}k|\delta q_4| + \beta\right)\delta\dot{q}_4^2 - \tfrac{1}{4}\left(\beta + \tfrac{1}{2}k|\delta q_4|\right)(\omega^T\omega)\delta q_4^2 \quad (30)$$

Hence, because $\beta > 0$ and $k > 0$, Eq. (29) is indeed a Lyapunov function. The advantage of using $\mathrm{sgn}(\delta q_4)$ in the control law at all times (even before the sliding manifold is reached) now becomes clear. The step input in Eq. (28) is a function of $\mathrm{sgn}(\delta q_4)$. Therefore, the response for δq_4 will approach $\mathrm{sgn}(\delta q_4)$ for any initial condition. This tends to drive the system to the desired location in the shortest distance. Furthermore, this inherently takes into account the rate errors as well. For example, say that $\delta q_4(t_0)$ is positive and that a high initial rate is given which tends to drive the system away from $\delta q_4 = 1$. The control law will automatically begin to null the rate. But, if the initial rate is large enough and the control dynamics are relatively slow, then δq_4 can become negative. Because $\mathrm{sgn}(\delta q_4)$ is used in the control system, then from Eq. (28) the control law will subsequently drive the system toward $\delta q_4 = -1$. Therefore, using $\mathrm{sgn}(\delta q_4)$ at all times produces an optimal response for any type of initial condition error.

Example

A variable-structure controller has been used to control the attitude of the Microwave Anisotropy Probe spacecraft from quaternion observations and gyro measurements. Details of the spacecraft parameters and desired attitude and rates can be found in Ref. 9. The control system has been designed to bring the actual attitude to the desired attitude in less than 20 min. For the simulations the spacecraft has been controlled using reaction wheels. The gains used in the control law given by Eq. (25) are $k = 0.015$, $G = 0.0015 I_{3\times3}$, and $\varepsilon = 0.01$. To illustrate the importance of using $k\,\mathrm{sgn}[\delta q_4(t)]$, a number of simulations have been run. The initial quaternion is given by $q(t_0) = [0\ \ 0\ \ \sin(\Phi/2)\ \ \cos(\Phi/2)]^T \otimes q_d(t_0)$, and the actual velocity has been set to zero. Test cases have been executed using $\Phi = 210, 240, 270, 300$, and 330 deg. Table 1 summarizes the results of using $k\,\mathrm{sgn}[\delta q_4(t)]$ and k only in Eq. (25). The final time for the simulation runs is given by $t_f = 20$ min. Clearly, by using $k\mathrm{sgn}[\delta q_4(t)]$ in the control law, better performance is achieved in the closed-loop system than using just k.

Conclusions

A new variable-structure controller for optimal spacecraft tracking maneuvers has been shown. The new controller was formulated for both external torque inputs and reaction wheel inputs. Global asymptotic stability was shown using a Lyapunov analysis. New insight was shown for the advantage of using a simple term in the control law (i.e., producing a maneuver to the reference attitude trajectory in the shortest distance). The sliding motion was also shown to be optimal in the sense of a quadratic loss function in the multiplicative error quaternions and angular velocities. Simulation results indicated that the addition of the simple term in the control law always provides an optimal response so that the reference attitude motion is achieved in the shortest possible distance.

Parameters Selection for Baumgarte's Constraint Stabilization Method Using the Predictor-Corrector Approach

Shih-Tin Lin* and Jiann-Nan Huang†
National Chung-Hsing University,
Taichung 402, Taiwan, Republic of China

Introduction

MULTIBODY dynamics has been recognized in the past two decades as an important tool in the design and simulation of complex mechanical systems. Efficient numerical integration methods is an important research topic for high-speed multibody dynamic simulation. For constrained multibody mechanical systems the equation of motion is a differential-algebraic equation (DAE), rather than an ordinary differential equation. Several approaches have been proposed in the literature for the numerical integration of DAE.[1-10] In this study the constraint stabilization method proposed by Baumgarte[1] is used to solve the DAE system. The disadvantage of this method is that there is no reliable method for selecting the coefficients of the position and velocity term. In this Note stability analysis methods in digital control theory are used to solve this problem. Correct choice of the coefficients for the Adams–Bashforth and Adams–Moulton predictor-corrector method are found. Simulation results show that the response of constraint error is the same as we expected.

Parameters Selection of Baumgarte's Constraint Stabilization Method

The dynamic equation of a constrained multibody mechanical system has the form[11]

$$\begin{bmatrix} M(q,t) & \Phi_q^T \\ \Phi_q & 0 \end{bmatrix} \begin{bmatrix} \ddot{q} \\ \lambda \end{bmatrix} = \begin{bmatrix} Q^A(q,\dot{q},t) \\ \gamma \end{bmatrix} \quad (1)$$

where q is the generalized coordinate, M is the generalized mass matrix, Φ is the constraint function, Φ_q is the Jacobian matrix of the constraint functions, λ is the Lagrange multiplier, Q^A includes the generalized applied forces, Coriolis forces, and centrifugal forces, and $\gamma \equiv -(\Phi_q\dot{q})_q\dot{q} - 2\Phi_{qt}\dot{q} - \Phi_{tt}$. In solving Eq. (1), actually we
