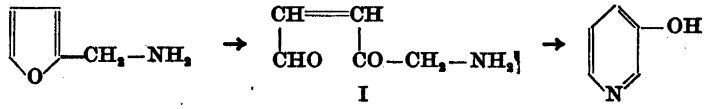
Preparation of 3-Pyridols from Furans

NIELS CLAUSON-KAAS, NIELS ELMING and ZDENĚK TYLE

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

A new method for the preparation of 3-pyridols from 2-(α-aminoalkyl)-furans or their acyl derivatives is described.

Many furans are under certain conditions oxidized to unsaturated 1,4-dicarbonyl compounds or their equivalent [1]. When oxidized in this way, furfurylamine should give a dicarbonylamine having the structure I. Since the double bonds in I are *cis*oid one might expect such a compound to condence intramolecularly to yield 3-pyridol.

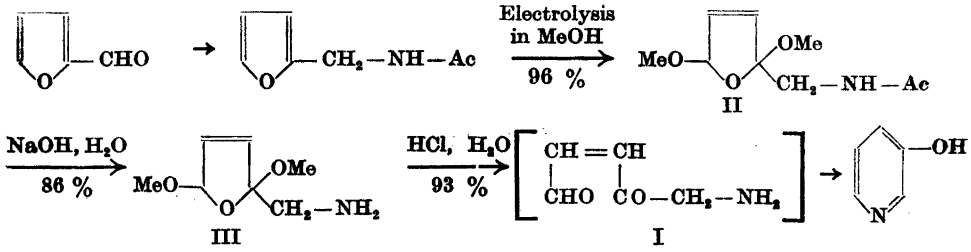


We have indeed found that the transformation of furfurylamine to 3-pyridol is feasible and have worked out reaction conditions, which may be generally used for the preparation of 3-pyridols from 2-(α-aminoalkyl)-furans*. The latter, in turn, are easily obtained by reductive amination of furan-2-carboxaldehydes or furan-2-ketones.

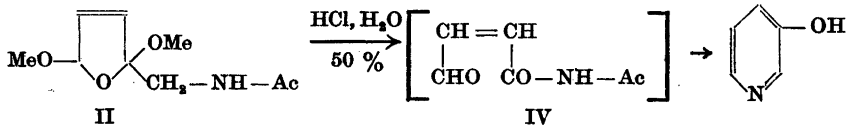
Direct oxidations of furans to unsaturated dicarbonyl compounds are usually difficult to carry out in good yields. If, however, the furans are first electrolytically methoxylated to yield 2,5-dimethoxy-2,5-dihydrofurans and these are subsequently hydrolyzed, yields from 60 to 95 % of dicarbonyl compounds can be obtained.

Electrolytic methoxylation of furfurylamine gave only a low yield of the corresponding dimethoxydihydrofuran (these unsuccessful experiments are not described in the experimental part). Probably the amine group interferes with the methoxylation reaction. But, as has been reported previously [2], 2-(acetamidomethyl)-furan gives an almost quantitative yield of 2,5-dimethoxy-2-(acetamidomethyl)-2,5-dihydrofuran II. Alkaline hydrolysis of II gave the desired 2,5-dimethoxy-2-(aminomethyl)-2,5-dihydrofuran III, which by boiling with *N* hydrochloric acid was transformed into 3-pyridol (yield 93 %).

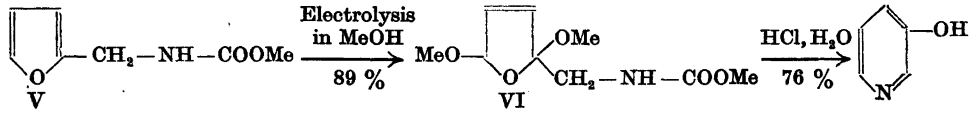
* Patent pending.



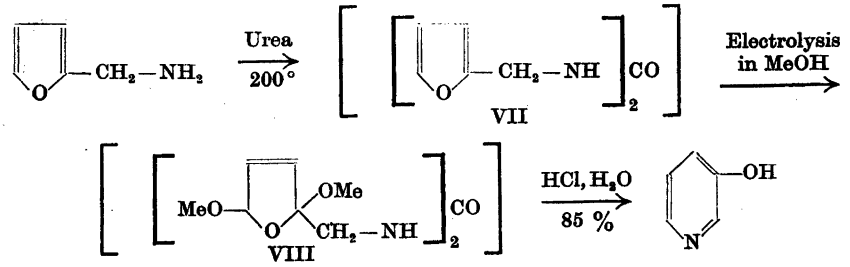
3-Pyridol was also obtained by boiling II with hydrochloric acid, but the yield was only 50 % and the reaction mixture turned dark-red. We believe that the intramolecular condensation of the intermediate dicarbonylamide IV proceeds more slowly than the condensation of the dicarbonylamine I, since the former must hydrolytically lose acetic acid in the course of the condensation. Part of the dicarbonylamide therefore reacts differently due to the prolonged reaction time.



Consistent with this assumption is the fact that an easily hydrolyzed acyl derivative of III, *viz.* the carbamate VI, which was prepared by electrolytic methoxylation of the corresponding furan (V), gave, by boiling with hydrochloric acid, a higher yield of 3-pyridol (76 %).



The above yields of 3-pyridol based upon furfurylamine were 73, 46 and 55 %, respectively. However, by proceeding through *sym*-difurfurylurea VII and the corresponding dimethoxydihydrofuran VIII, an 85 % yield of 3-pyridol was obtained. This reaction sequence, in which the intermediates need not be isolated pure, represents the most convenient way of preparing 3-pyridol from furfurylamine.

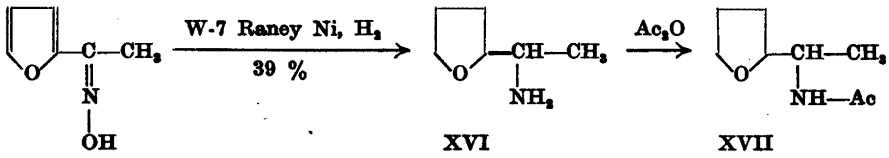


In order to illustrate the general applicability of the new method 2-methyl-3-pyridol was prepared from 2-acetylfuran oxime by the following reactions:

Routes to 2-methyl-3-pyridol from 2-acetylfuran.

The structure of compounds III, V—VI and VIII—XV follows from the methods of their preparation and from analyses. They have all been prepared by known reactions and in only one case, *viz.* the reductive amination of 2-acetylfuran to 2-(α-aminoethyl)-furan (XII) were any difficulties encountered. Under the same conditions as those used for the preparation of furfurylamine from furfural and ammonia, no reaction took place, and attempts to catalytically reduce 2-acetylfuran oxime showed that it was difficult to reduce the oxime group without at the same time reducing the furan nucleus (these experiments are not described in the experimental part). Only when reduced with palladium charcoal in the presence of hydrochloric acid (method of Hartung [3]) did the oxime give a 47 % yield of the amine. Furthermore it was found that reduction of 2-acetylfuran oxime in acetic anhydride with Raney nickel gave a 64 % yield of 2-(α-acetamidoethyl)-furan (IX), in contradiction to the statement of Adkins and Shriner [4] that this catalyst cannot be used in acetic anhydride.

2-(α-Aminoethyl)-tetrahydrofuran (XVI) was prepared by catalytic reduction of 2-acetylfuran oxime with the very active W-7 Raney nickel catalyst. Acetylation of XVI gave the expected 2-(α-acetamidoethyl)-tetrahydrofuran XVII. Refractive indices of these compounds were of value in following the course of the above reductions.



EXPERIMENTAL

Microanalyses by E. Boss, K. Glens and G. Cornali

2,5-Dimethoxy-2-(aminomethyl)-2,5-dihydrofuran (III). 2,5-Dimethoxy-2-(acetamidomethyl)-2,5-dihydrofuran (II, mixture of the *cis* and the *trans* isomer as obtained by the synthesis [2]) (6.96 g, 0.034 mole) was heated under reflux (16 hr) with sodium hydroxide (3 *N*, 100 ml). The mixture was continuously extracted with ether overnight and the amine distilled. The yield was 4.72 g (86 %) of III (colorless liquid, b.p.$_{12}$ 95—96°, n_D^{25} 1.4589).

Sublimation (150°/0.2 mm) gave perfectly white crystals, m.p. 106—109° (sintering from 102°). 3-Pyridol hydrochloride has previously been prepared by Fischer and Renouf [5] and by Kao [6], but no physical constants were reported.

3-Pyridol from II. The crystalline isomer of II (4.04 g, 0.020 mole) was heated under reflux (15 min) with hydrochloric acid (*N*, 22 ml) and the dark-red solution evaporated to dryness in a vacuum. To the semisolid black residue containing 3-pyridol hydrochloride was added anhydrous potassium carbonate (2.0 g) and so much water, that the total volume was about 10 ml. The resulting suspension was continuously extracted with ether.

Evaporation of the ether and crystallization of the light-brown residue from benzene gave 0.92 g (48 %) of 3-pyridol (m.p. 125—126°). Sublimation did not change the m.p.

3-Pyridol from VI. VI (4.34 g, 0.020 mole) was heated under reflux with hydrochloric acid (*N*, 22 ml) and the light-brown solution worked up as above. The yield was 1.45 g (76 %) of 3-pyridol (m.p. 125—126°).

Found C 63.1 H 5.3 N 14.4

3-Pyridol from furfurylamine. Furfurylamine (19.4 g, 0.20 mole) and urea (commercial product, 6.60 g, 0.11 mole) were mixed and heated under reflux (1 hr) in an oil bath (190—210°) (method of Davis and Blanchard [10]). Ammonia was evolved. The light-brown crystalline reaction product was dissolved in a solution of ammonium bromide (5.00 g) in methanol (260 ml) and the resulting solution electrolyzed in the usual way [2] (11.9 amp-hr (111 %) were used). After electrolysis, the liquid in the cell was almost colorless in the upper part of the cell and yellow near the bottom. The liquid was poured into a solution of sodium methoxide (from 1.20 g of sodium) in methanol (20 ml) and the methanol and the ammonia evaporated in a vacuum. The semisolid residue was heated under reflux (15 min) with hydrochloric acid (*N*, 240 ml) and the clear yellowish-brown solution evaporated in a vacuum to dryness. Potassium carbonate (22 g) and water (75 ml) were added and the 3-pyridol isolated as above. The yield was 16.1 g (85 %) of 3-pyridol (m.p. 124—127°).

Found C 63.1 H 5.1 N 14.9

In separate experiments *sym*-difurfurylurea (VII) and one of the 3 possible stereoismers of *sym*-(2,5-dimethoxy-2,5 dihydro-2-furfuryl) urea (VIII) were isolated in a pure state.

VII was obtained as white crystals from ethanol (m.p. 129—131°). Further crystallization did not change the m.p. (previously found 128° [11]).

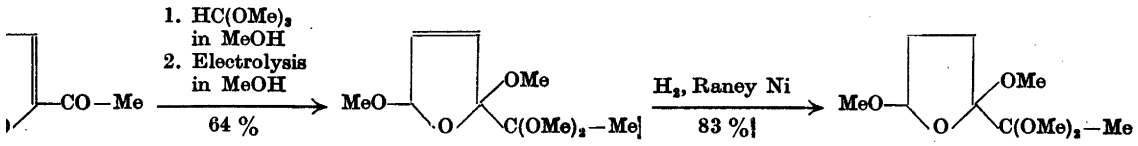
Electrolytic Methoxylation of 2-Acetylfuran

JØRGEN TORMOD NIELSEN, NIELS ELMING and NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

2-Acetylfuran has been methoxylated by transformation into the dimethyl ketal and electrolysis in methanol. Reaction of the resulting 2,5-dimethoxy-2-(α,α-dimethoxyethyl)-2,5-dihydrofuran (I) with an aqueous solution of hydroxylamine hydrochloride gave 2-methyl-3,6-pyridinediol-1-oxide (IV). This compound has previously been prepared by Vargha, Ramonczai and Bite, who believed it to be an aldoxime of 2-hexene-4,5-dione-1-al(III). I was catalytically hydrogenated to 2,5-dimethoxy-2-(α,α-dimethoxyethyl)-tetrahydrofuran (II), which by heating with dilute hydrochloric acid yielded pyrocatechol.

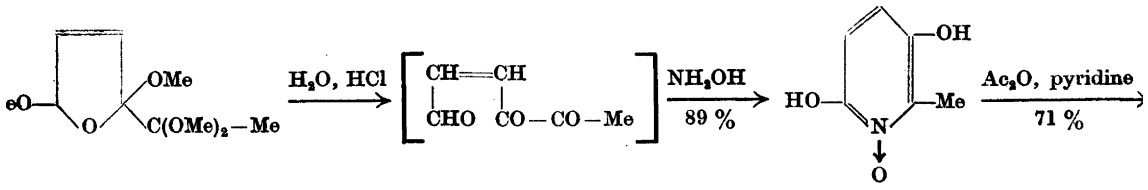
As part of an investigation of the electrolytic methoxylation of furans, reaction conditions have been worked out for the methoxylation of 2-acetylfuran. The furan is first heated under reflux with methanol, methyl orthoformate and a trace of *p*-toluenesulfonic acid, and the resulting solution, which probably contains 2-acetylfuran dimethyl ketal, is then electrolyzed. Analyses showed the reaction product to be the expected 2,5-dimethoxy-2-(α,α-dimethoxyethyl-2,5-dihydrofuran (I). Catalytic hydrogenation of I gave the corresponding tetrahydrofuran II.



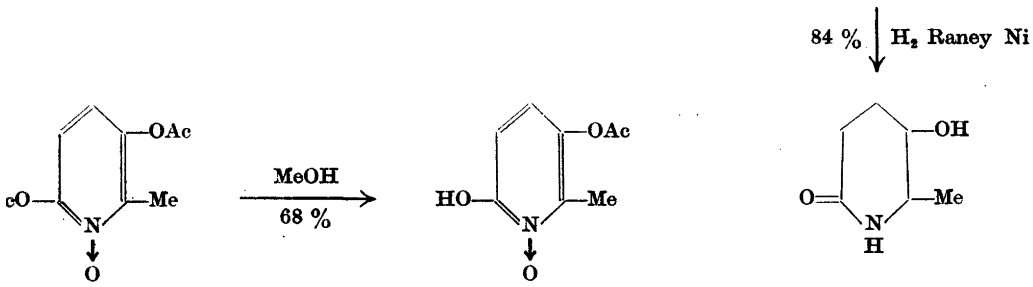
I II

By reaction of I with an aqueous solution of hydroxylamine hydrochloride an 89 % yield of a compound $C_6H_7O_3N$ (m.p. 236°), which was soluble in alkali, sparingly soluble in water and alcohol and insoluble in ether, was obtained. It gave a strong violet ferric chloride reaction. Acetylation of this compound yielded a diacetate, which was transformed by solution in methanol into a monoacetate. The diacetate gave a red ferric chloride reaction after some seconds, while the monoacetate gave the same reaction immediately. Catalytic

hydrogenation of the $C_6H_7O_3N$-compound yielded a compound $C_6H_{11}O_2N$, which gave no ferric chloride reaction. Assuming the $C_6H_7O_3N$-compound to be 2-methyl-3,6-pyridinediol-1-oxide (IV), these experiments may be explained as shown below.

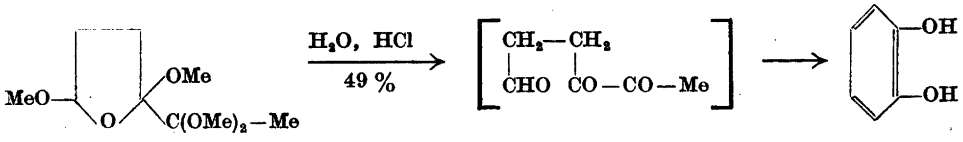


I III IV



V VI VII

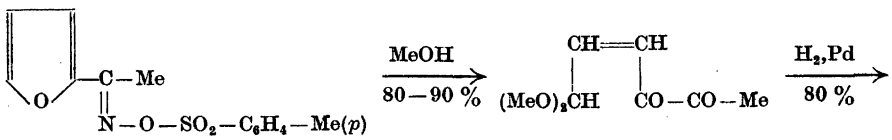
By heating of II with dilute hydrochloric acid, pyrocatechol is formed in a 49 % yield. Evidently hydrolysis to hexane-4,5-dione-1-al (VIII) followed by intramolecular condensation takes place.



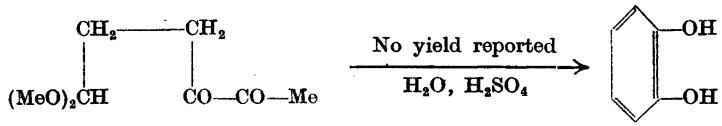
II VIII

Vargha, Ramonczai and Bite[1] have reported that treatment of the *p*-toluenesulfonate of 2-acetylfuran oxime (IX) with methanol results in the formation of a liquid $C_8H_{12}O_4$, which may be catalytically hydrogenated to another liquid $C_8H_{14}O_4$. The $C_8H_{12}O_4$-liquid gave, with an aqueous solution of hydroxylamine hydrochloride, a compound $C_6H_7O_3N$ with properties similar to our $C_6H_7O_3N$-compound (2-methyl-3,6-pyridinediol-1-oxide (IV)). The $C_8H_{14}O_4$-liquid gave pyrocatechol by heating with dilute sulfuric acid. These reactions were explained by Vargha, Ramonczai and Bite as shown below.

The $C_6H_7O_3N$-compound was assumed to be an aldoxime of 2-hexene-4,5-dione-1-al (III).



IX X



XI

Vargha, Ramonczai and Bite did not report any spectra, refractive indices or methoxy values for their liquids, so that it is not certain whether these actually have been pure compounds with the proposed structures (X and XI) or not. It is, however, apparent from the published data, and also in conformity with our findings, that the liquids as claimed are derivatives of 2-hexene-4,5-dione-1-al (III) and hexane-4,5-dione-1-al (VIII), respectively. The $C_6H_7O_3N$-compound, which evidently is identical with our $C_6H_7O_3N$-compound, must on the other hand be 2-methyl-3,6-pyridinediol-1-oxide (IV).

EXPERIMENTAL

Microanalyses by E. Boss and K. Glens

2,5-Dimethoxy-2-(α,α-dimethoxyethyl)-2,5-dihydrofuran (I). 2-Acetylfuran (3.30 g, 0.030 mole) and methyl orthoformate (3.50 g, 0.033 mole) was added to a solution of *p*-toluenesulfonic acid (8.6 mg) in anhydrous methanol (10 ml) and the mixture heated under reflux (10 min). After cooling a solution of ammonium bromide (0.60 g) in methanol (30 ml) was added and the mixture electrolyzed in the small cell described previously [2] (temperature of cooling-bath −18°).

Time hr	Current amp	Potential across the cell during electrolysis volt	Ampere hours (per cent of theoretical amount)	
0.1	1.0	4.8	0.09	(6 %)
0.5	0.9	5.0	0.43	(27 %)
1.0	0.8	5.1	0.81	(50 %)
2.5	0.6	5.2	1.68	(104 %)

After electrolysis the yellow liquid was poured into a solution of sodium methoxide (from sodium (147 mg) in methanol (5 ml)) and the methanol and the ammonia evaporated in a vacuum. Anhydrous ether (50 ml) was added, the precipitate removed by filtration and the filtrate distilled in a vacuum.

Fraction (g)	B.p.$_{14}$ °C	n_D^{25}
1 (0.30)	108–112	1.4502
2 (3.37)	112–113	1.4498
3 (0.48)	113–115	1.4499

The yield (all fractions) was 4.15 g (64 %, current efficiency 62 %) of I (colorless liquid). A portion of fraction 2 was analyzed.

$C_6H_8O(OCH_3)_4$ (218.2)	Calc.	C	55.0	H	8.3	OCH_3	56.9
	Found	»	55.1	»	8.2	»	55.4

All fractions gave a positive Beilstein test for halogens, thus indicating, that the product is contaminated by a small amount of some bromine-containing impurity.

2,5-Dimethoxy-2-(α,α-dimethoxyethyl)-tetrahydrofuran (II). I (3.00 g), anhydrous methanol (15 ml) and potassium hydroxide (11 mg) were shaken (4 hr) with Raney nickel (0.3 g) under hydrogen (100 atm). The product was isolated by distillation.

Fraction (g)	B.p.$_{14-15}$ °C	n_D^{25}	Calc. for $C_6H_8O(OCH_3)_4$ (220.3)		
			C 54.5%	H 9.2%	OCH_3 56.4%

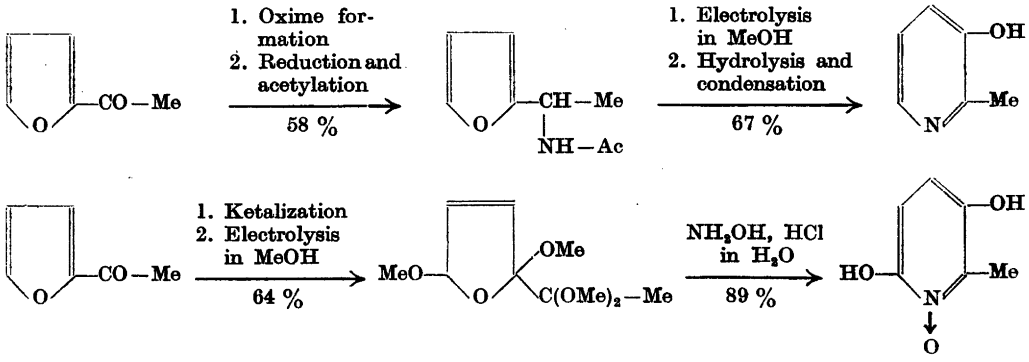
New Methods for the Transformation of Furans into Pyridines

NIELS CLAUSON-KAAS and POUL NEDENSKOV

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

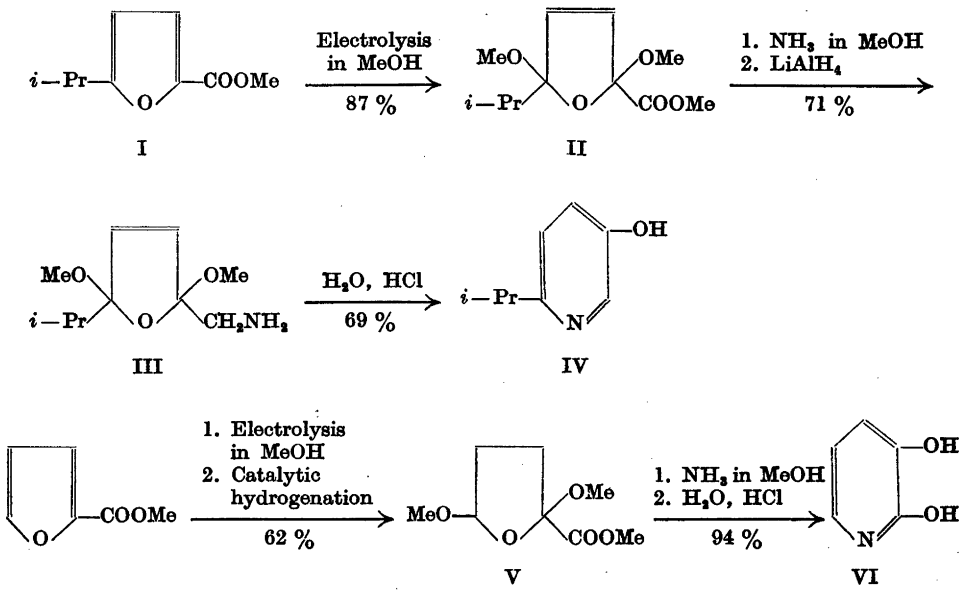
The preparation of 6-*iso*propyl-3-pyridinol (IV) and of 2,3-pyridinediol (VI) from 2-carbomethoxy-5-*iso*propylfuran (I) and methyl furoate, respectively, is described.

Two routes from furan-2-carboxaldehydes or furan-2-ketones to pyridines have recently been reported [1,2]. These may be exemplified by the transformation of 2-acetylfuran into 2-methyl-3-pyridinol and 2-methyl-3,6-pyridinediol-1-oxide, respectively.



Two routes from furan-2-carboxylic acid esters, many of which are easily accessible, to 3-pyridinols and 2,3-pyridinediols, respectively, are described here. The first route is exemplified by the transformation of 2-carbomethoxy-5-*iso*propylfuran (I) into 6-*iso*propyl-3-pyridinol (IV), the second by the transformation of methyl furoate into 2,3-pyridinediol (VI).

The preparation of pyrocatechol from 2-acetylfuran reported in the foregoing article [2] represents a sequence of reactions similar to the reactions described here. The main feature of these transformations of furans into other



compounds with aromatic character is an intramolecular condensation of a straight chain of atoms including a 1,4-dicarbonyl C_4-unit, the latter coming into existence by oxidation of a furan compound. We believe that many other heterocyclic or homocyclic aromatic compounds can be prepared by the same type of reactions by employing suitable 2-substituted furans.

EXPERIMENTAL

Microanalyses by E. Boss and K. Glens

2,5-Dimethoxy-2-aminomethyl-5-isopropyl-2,5-dihydrofuran (III). II[3] (3.45 g, 0.015 mole) was mixed at −50° with a solution of ammonia (2.2 ml, measured at −80°) and water (0.3 ml) in methanol (6 ml) and the resulting solution left standing (7 days) at room temperature and then evaporated in a vacuum from a water-bath (60°). The residue was dissolved in anhydrous ether and evaporated once more to dryness, at last under 0.1 mm, in order to remove traces of water and methanol. The residue was dissolved in ether (90 ml) and the etheral solution added with stirring to a suspension of lithium aluminum hydride (0.97 g, 0.026 mole) in ether (60 ml). After stirring at room temperature for 20 hr the mixture was cooled to −20°, and water (20 ml) and then sodium hydroxide solution (20 %, 25 ml) were added dropwise. The cloudy reaction mixture was continuously extracted with ether, the etheral solution dried with magnesium sulfate and distilled. The yield was 2.13 g (71 %) of III (colorless liquid, b. $p_{\cdot 13-12}$ 121−126°, n_D^{25} 1.4625).

$C_8H_{13}ON(OCH_3)_2$ (201.3)	Calc.	C 59.7	H 9.5	N 7.0	OCH_3 30.8

New Examples of Electrolytic Methoxylation of Furans

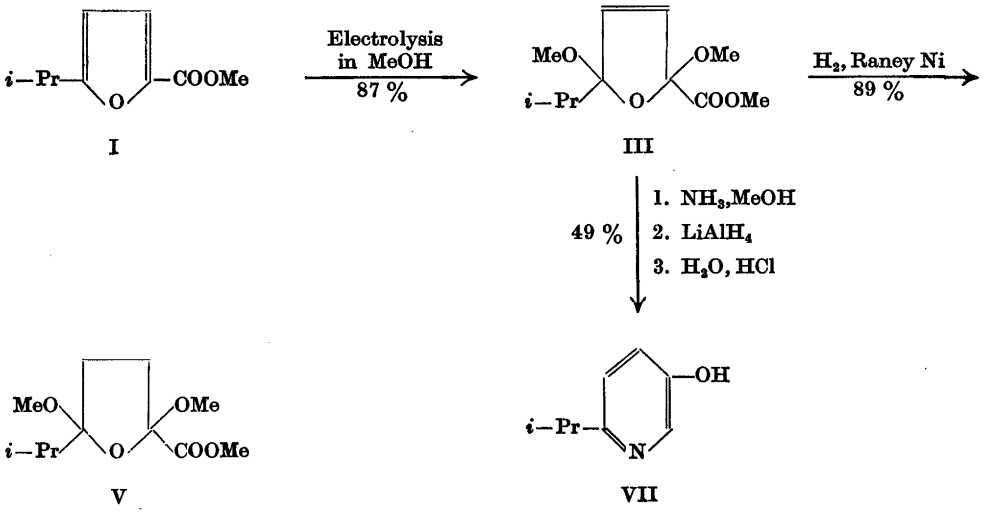
POUL NEDENSKOV, NIELS ELMING, JØRGEN TORMOD NIELSEN and NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

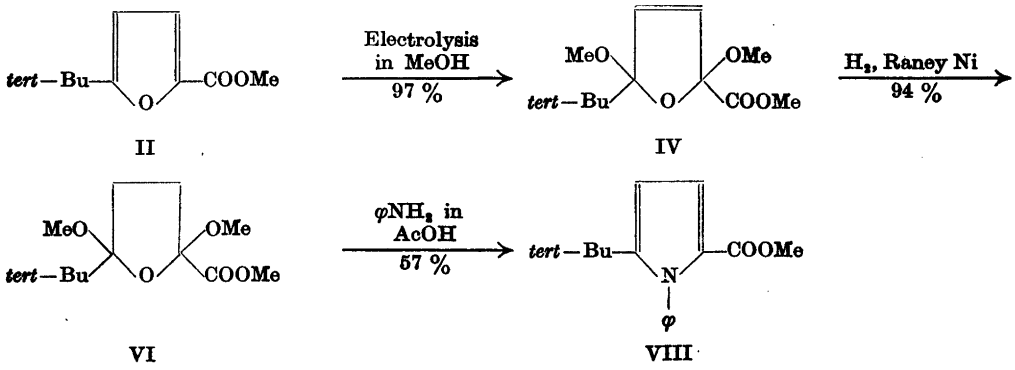
Four new 2,5-dimethoxy-2,5-dihydrofurans have been prepared by electrolytic methoxylation of the corresponding furans.

In connection with an investigation of certain furan compounds[1] four new dimethoxydihydrofurans have been prepared by the electrolytic methoxylation method[2,3]. In all 20 different furans have now been electrolytically methoxylated.

2-Carbomethoxy-5-*iso*propylfuran[4] (I) and 2-carbomethoxy-5-(*tert*butyl)-furan[4] (II) were electrolyzed in a sulfuric acid electrolyte[3]. Both dimethoxydihydrofurans (III and IV) were catalytically hydrogenated to the corresponding tetrahydrofurans (V and VI). The transformation of III into the 3-pyridinol VII[5] proves the structures of III and V. The structures of IV and VI were proved by transformation of VI into the pyrrole VIII (*cf.*[6]).

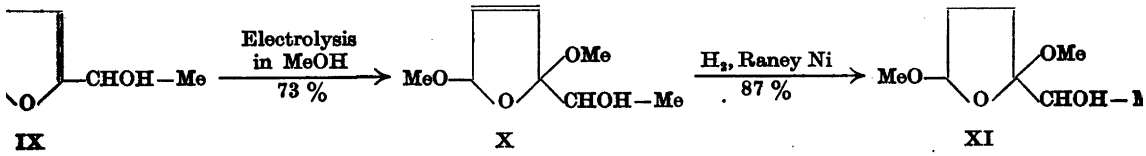


I III V VII

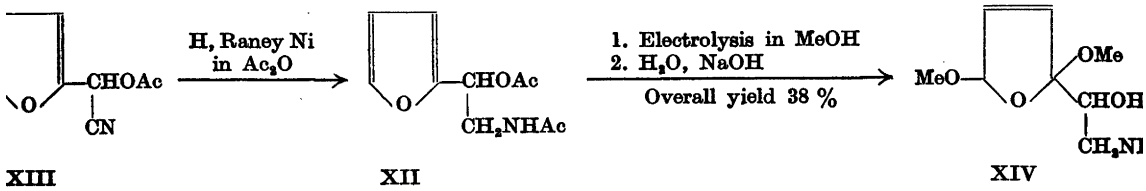


The Zeisel methoxy determination of 1-phenyl-2-carbomethoxy-5-(*tert*-butyl)-pyrrole (VIII) gave consistently 16—17 % of "methoxy" instead of the calculated 12.1 %. We believe that the unexpectedly high values come from the splitting off of methyl groups as methyl iodide from the *tert*-butyl group. Huang and Morsingh[7] have reported another instance in which certain dimethylalkylaryl methanes behaved similarly.

2-(α-Hydroxyethyl)-furan[8] (IX) was electrolyzed in an ammonium bromide electrolyte[2] and the resulting dimethoxydihydrofuran X catalytically hydrogenated to the tetrahydrofuran XI.



2-(α-Acetoxy-β-acetamidoethyl)-furan (XII), prepared by catalytic hydrogenation of furfural cyanohydrin acetate[9] (XIII) in acetic anhydride, was also electrolyzed in an ammonium bromide electrolyte. The reaction product was not isolated pure, but hydrolyzed with sodium hydroxide to 2,5-dimethoxy-2-(α-hydroxy-β-aminoethyl)-2,5-dihydrofuran (XIV), which was obtained pure by distillation.



We consider that it now may be regarded as an established fact that alkoxylation of furans always takes place at the α-carbons. The structures of the new compounds X, XI and XIV are therefore proved by the syntheses.

EXPERIMENTAL

Microanalyses by E. Boss, K. Glens and W. Egger

2,5-Dimethoxy-2-carbomethoxy-5-isopropyl-2,5-dihydrofuran (III). 2-Carbomethoxy-5-*iso*propylfuran (I)[4] (10.5 g, b.p.$_{14}$ 106–107°, n_D^{25} 1.4834) was mixed with anhydrous methanol (45 ml) and concentrated sulfuric acid (0.375 g, 0.0038 mole) and the solution electrolyzed in the small cell described previously[10] (temperature of cooling-bath −20°).

Time hr	Current amp	Potential across the cell during electrolysis volt	Ampere hours (per cent of theoretical amount)
1.0	0.9	8.0	0.82 (25 %)
3.0	0.8	7.9	2.40 (72 %)
5.0	0.7	7.8	3.62 (108 %)
5.9	0.6	7.7	4.20 (125 %)

After electrolysis the yellow liquid was poured into a solution of sodium methoxide (from 175 mg of sodium (0.0076 mole)) in methanol (7 ml) and the methanol evaporated in a vacuum. Anhydrous ether (50 ml) was added to the oily, light-brown residue, a precipitate of sodium sulfate removed by filtration and the filtrate distilled in a vacuum.

Fraction (g)		B.p.$_{0.1}$ °C	n_D^{25}	OCH_3 Calc. 40.4 %

Furfural cyanohydrin acetate (XIII). This compound was prepared from furfural (96 g) after the directions of Lukeš, Kastner, Gut and Herben[9]. The yield was 122 g (74 %) (b.p.$_{0.1}$ 67—68°, n_D^{25} 1.4683); previously found[9] b.p.$_{10}$ 115°. Two crystallizations from ether gave white crystals, m. p. 27—29°.

$C_6H_4O_2N(COCH_3)$ (165.1)	Calc.	C	58.2	H	4.3	N	8.5	$COCH_3$ 26.1

2,5-Dimethoxy-2-(α-hydroxy-β-aminoethyl)-2,5-dihydrofuran (XIV). XIII (33.0 g, 0.20 mole) and acetic anhydride (200 ml) were shaken (2 hr) with Raney nickel (4.0 g) under hydrogen (100 atm, 50—58°). After filtration the solvent was evaporated in a vacuum, finally under 0.1 mm at 55—60°. The residue was dissolved in methanol (250 ml), ammonium bromide (5.0 g) was added and the mixture electrolyzed with the set-up described previously[2] for the electrolytic methoxylation of furan.

Time hr	Current amp	Potential across the cell during electrolysis volt	Ampere hours (per cent of theoretical amount		Temperature in the cell °C
0.1	3.0	4.9	0.3	(3 %)	—13
0.5	2.9	4.8	1.5	(14 %)	—13
1.0	2.7	4.7	2.9	(27 %)	—14
3.5	2.3	5.3	9.2	(86 %)	—14
4.8	1.9	5.6	11.8	(110 %)	—14

After electrolysis the liquid was poured into a solution of sodium methoxide (from 5.8 g of sodium in methanol (70 ml)) and the methanol and the ammonia evaporated in a vacuum. Sodium hydroxide (3 *N*, 200 ml) was added, the mixture heated under reflux (20 hr), continuously extracted with ether and the etheral solution distilled. The yield was 14.5 g (38 % based upon furfural cyanohydrin acetate) of XIV (colorless liquid, b.p.$_{0.1}$ 91–93°, n_D^{25} 1.4836).

$C_4H_4O_2N(OCH_3)_3$ (189.2)	Calc.	C	50.8	H	8.0	N	7.4	OCH_3 32.8
	Found	»	50.9	»	8.2	»	7.6	» 32.3

In a separate experiment 2-(α-acetoxy-β-acetamidoethyl)-furan (XII) was isolated pure by crystallization from ether (white crystals, m. p. 64–67°).

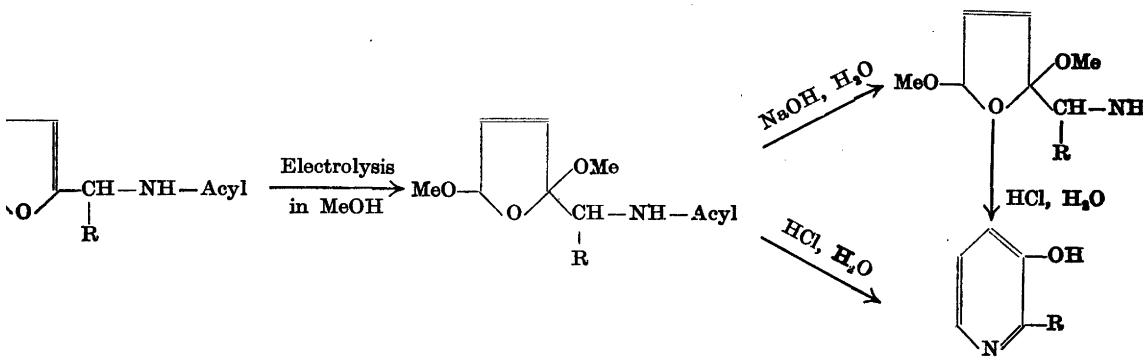
A New Synthesis of Pyridoxine

NIELS ELMING and NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

A new synthesis of pyridoxine from 2-(α-acetamidoethyl)-3,4-bis(acetoxymethyl)-furan is described.

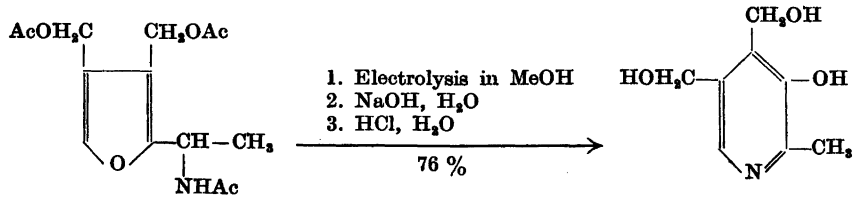
A new method for the preparation of 3-pyridols from N-acyl derivatives of 2-(α-aminoalkyl)-furans has recently been described[1]. The furan was first electrolytically methoxylated to the corresponding 2,5-dimethoxy-2,5-dihydrofuran and the latter was then heated under reflux with dilute hydrochloric acid to give the desired 3-pyridol. In order to obtain a good yield of the pyridol certain acyl derivatives required alkaline hydrolysis of the amide group prior to treatment with hydrochloric acid. The method was used for the preparation of 3-pyridol (I) and 2-methyl-3-pyridol (II) from various acyl derivatives of furfurylamine (III) and 2-(α-aminoethyl)-furan (IV).



III (R=H)
IV (R=CH_3)

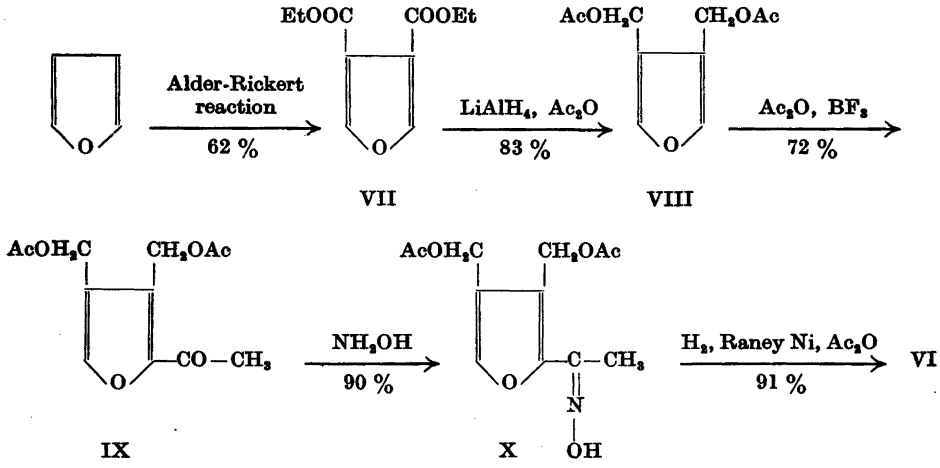
I (R=H)
II (R=CH_3)

We have used the above method for a synthesis of pyridoxine (2-methyl-4,5-bis(hydroxymethyl)-3-pyridol) (V) from 2-(α-acetamidoethyl)-3,4-bis(acetoxymethyl)-furan (VI). The overall yield of the three-step synthesis without isolation of the intermediate dimethoxydihydrofurans was 76 %.



VI V

VI was prepared from furan by the sequence of standard reactions shown below. The structure of compounds VI and VIII—X follows from their method of preparation and from analyses.



EXPERIMENTAL

Microanalyses by Ernst Boss and Kirsten Glens

3,4-Dicarbethoxyfuran (VII)[2]. Furan (13.0 g, 0.19 mole) and diethyl acetylenedicarboxylate (29.0 g, 0.17 mole) were mixed and heated (100°, 18 hr) under hydrogen (about 140 atm). After cooling acetone (120 ml) and 10 % palladium charcoal (0.22 g) were added and the mixture shaken (1 hr) under hydrogen (15—20 atm). The catalyst was removed by filtration and the filtrate distilled in a vacuum, whereby a pale-yellow liquid (28 g, b. $p._{18-15}$ 158—198°) was obtained. Redistillation through a short packed column gave 22.4 g (62 %) of VII (colorless liquid, b. $p._{13}$ 154—157°, n_D^{25} 1.4690, previously found[2] b. $p._{11}$ 140—165°). (Found: C 56.8; H 6.0; OC_2H_5 42.2. Calc. for $C_6H_2O_3(OC_2H_5)_2$ (212.2): C 56.6; H 5.7; OC_2H_5 42.5).

3,4-Bis(acetoxymethyl)-furan (VIII). 3,4-Dicarbethoxyfuran (3.18 g, 0.015 mole) in dry ether (15 ml) was added dropwise (10 min) to a stirred mixture of lithium aluminum hydride (0.69 g, 0.018 mole) and dry ether (20 ml). Stirring was continued for 5 minutes. Acetic anhydride (20 ml) was added during 5 minutes. The reaction flask was placed in an oil-bath and the temperature of the bath gradually raised to 110° whereby the ether distilled. The temperature of the bath was then maintained at 115—120° for 3 hours. After cooling, ether (40 ml) was added, the mixture filtered and the ether distilled. Distillation of the residue gave 2.63 g (83 %) of VIII (as a colorless liquid, which crystallized on cooling (b. p.$_{0.1}$ 88—90°, n_D^{25} 1.4672, m. p. 29—31° (Hershberg apparatus, corr.)). (Found: C 56.9; H 5.9; $COCH_3$ 40.0. Calc. for $C_6H_6O_3(COCH_3)_2$ (212.2): C 56.6; H 5.7; $COCH_3$ 40.6).
After crystallization from ether the m. p. was raised to 30—32°.

2-Acetyl-3,4-bis(acetoxymethyl)-furan (IX) [3]. VIII (22.0 g) was dissolved in acetic anhydride (25 ml) and a solution of boron fluoride etherate (1.3 ml) in acetic anhydride (20 ml) was added in one portion with stirring. The temperature rose to 40°. The mixture was heated to 85—90° and maintained at this temperature for 10 minutes. After cooling, water (40 ml) was added and stirring continued for 10 minutes. The dark-brown mixture was extracted with 80 ml and then with 50 ml of ether. The etheral extracts were washed with water, potassium hydrogen carbonate (2 *M*), water and dried. Distillation gave 18.9 g (72 %) of IX (almost colorless liquid, b. p.$_{0.1}$ 127—129°, m. p. 48—51°). (Found: C 56.9; H 6.0; $COCH_3$ 32.2. Calc. for $C_8H_8O_4(COCH_3)_2$ (254.2): C 56.7; H 5.6; $COCH_3$ 33.9).
After crystallization from ether the m. p. was raised to 51—53°.

2-Acetyl-3,4-bis(acetoxymethyl)-furan oxime (X). IX (18.5 g), anhydrous sodium acetate (8.2 g) and hydroxylamine hydrochloride (6.2 g) were mixed and heated under reflux (5 h) with ethanol (80 ml). The hot mixture was filtered and the ethanol evaporated in a vacuum. There remained an almost colorless liquid, which crystallized to a white solid after addition of water and cooling. Filtration, washing with water and drying gave 17.6 g (90 %) of X (m. p. 78—81°). (Found: C 53.6; H 5.9; N 5.4; $COCH_3$ 32.4. Calc. for $C_8H_9O_4N(COCH_3)_2$ (269.3): C 53.5; H 5.6; N 5.2; $COCH_3$ 32.0).
After crystallization from ether the m. p. was 79—81°.

2-(α-Acetamidoethyl)-3,4-bis(acetoxymethyl)-furan (VI). X (2.50 g) and acetic anhydride (20 ml) were shaken (1 hr) with Raney nickel (0.4 g) under hydrogen (100 atm, 70—80°). After filtration, the solvent was evaporated in a vacuum, finally under 0.1 mm at 60—70°. The residue was shaken with anhydrous ether (20 ml) whereupon white crystals were formed. About 10 ml of ether was distilled, the crystals were removed by filtration, washed twice with ether and dried. The yield was 2.52 g (91 %) of 2-(α-acetamidoethyl)-3,4-bis(acetoxymethyl)-furan (white crystals, m. p. 92—94°). (Found: C 56.3; H 6.4; N 4.5; $COCH_3$ 42.5. Calc. for $C_8H_{10}O_3N(COCH_3)_3$ (297.3): C 56.6; H 6.4; N 4.7; $COCH_3$ 43.4).
After crystallization from benzene-ether the m. p. was raised to 95—96°.

In another experiment the reaction product was isolated by distillation (yield 79 %, b. p. 170—190° at about 0.1 mm). The pale-yellow liquid crystallized after standing for some days. Crystallization of 500 mg from ether gave 350 mg of white crystals, m. p. 65—68°, which were readily soluble in ether. (Found: C 56.5; H 6.6; N 4.7; $COCH_3$ 42.4). Another crystallization from ether gave 280 mg, m. p. 66—68°.

An etheral solution of this product was seeded with the product from the first experiment (m. p. 95—96°) whereupon white crystals, m. p. 95—96°, which were slightly soluble in ether, were obtained.

VI may thus crystallize in two forms, of which the higher melting, slightly soluble form is apparently the one usually obtained.

Pyridoxine (V). VI (2.50 g) and ammonium bromide (300 mg) were dissolved in methanol (20 ml) and the solution electrolyzed with the set-up described previously [4] (temperature of cooling-bath −21°).

Time hr	Current amp	Potential across the cell during electrolysis volt	Ampere hours (per cent of theoretical amount)	
0.1	0.7	6.2	0.07	(16 %)
0.3	0.7	6.3	0.20	(44 %)
0.6	0.7	6.3	0.30	(67 %)
0.8	0.5	6.5	0.50	(110 %)

After electrolysis, the liquid in the cell was yellow. The liquid was poured into a solution of sodium methoxide (from 458 mg of sodium) in methanol (5 ml) and the methanol and the ammonia evaporated in a vacuum. Sodium hydroxide (3 *N*, 8.5 ml) was added, the mixture heated under reflux (21 hr) and then continuously extracted with ether (48 hr). The ether was evaporated in a vacuum and the residue heated under reflux (20 min) with hydrochloric acid (*N*, 15 ml). The mixture was evaporated to dryness in a vacuum and the residue was crystallized from 99 % ethanol. The yield was 1.19 g (69 %) of pyridoxine hydrochloride (white crystals, m. p. and mixed m. p. with authentic pyridoxine hydrochloride 207–209° (dec.)). The product was further characterized by the infrared absorption spectrum, which was identical over the whole range with that of pyridoxine hydrochloride. (Found: C 46.9; H 6.0; N 6.8; Cl 17.4. Calc. for $C_8H_{12}O_3NCl$ (205.6): C 46.7; H 5.9; N 6.8; Cl 17.2).

From the mother liquor a further 100 mg of pyridoxine hydrochloride (6 %) was obtained (almost white crystals, m. p. 206–208° (dec.)). (Found: C 46.8; H 5.9; N 6.8; Cl 17.3).

The extraction with ether was continued for 24 hours and the extract worked up as above. The yield was 20 mg (1 %) of pyridoxine hydrochloride (white crystals, m. p. 207–209° (dec.)). (Found: C 47.0; H 5.9; N 6.6; Cl 17.3).

The total yield of pyridoxine hydrochloride was thus 1.31 g (76 %).

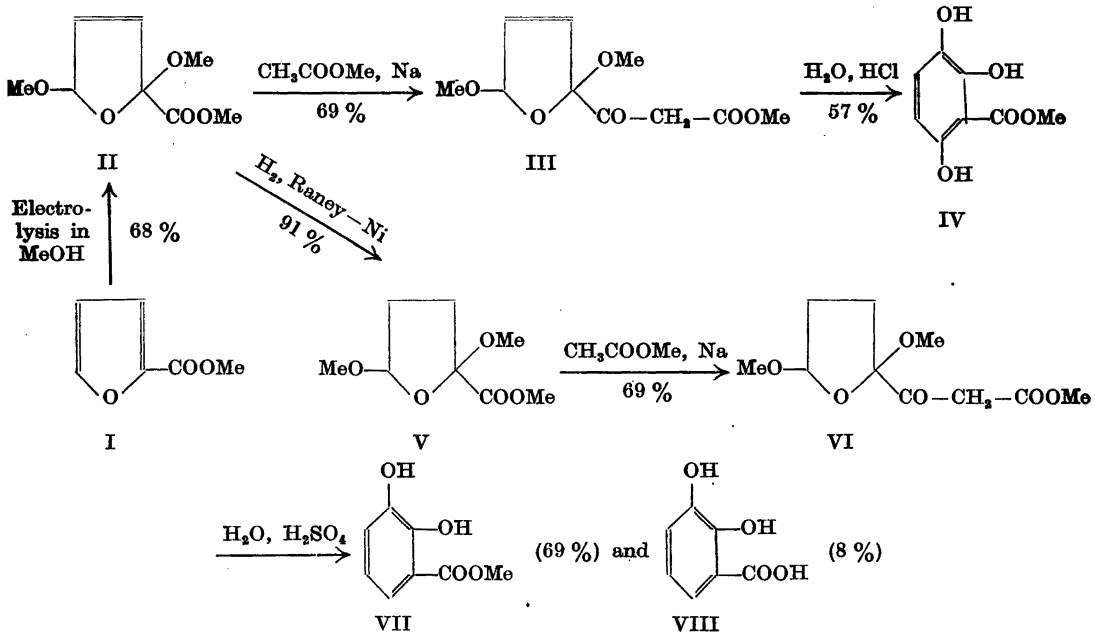
Preparation of Certain Methyl Polyhydroxybenzoates from Methyl Furoate

NIELS CLAUSON-KAAS and POUL NEDENSKOV

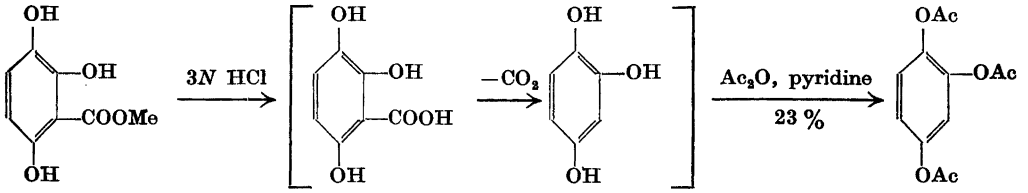
Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

The methyl esters of 2,3-dihydroxybenzoic acid (VII) and 2,3,6-trihydroxybenzoic acid (IV) have been prepared from methyl furoate (I).

Furans with suitable substituents in the 2-position may be transformed into other systems with aromatic character by methoxylation to cyclic acetals of 1,4-dicarbonyl compounds, followed by intramolecular condensation in acid solution[1-4]. Further application of this principle has led to the preparation of the methyl esters of 2,3-dihydroxybenzoic acid (VII) and of 2,3,6-trihydroxybenzoic acid (IV) from methyl furoate (I) by the reactions shown below. A small amount of the free 2,3-dihydroxybenzoic acid (VIII) was also isolated.



Compounds III, IV and VI are new. Their structures follow from the syntheses and from analyses. The structure of IV was confirmed further by transformation into the known triacetate (X) of hydroxyhydroquinone (IX). With the preparation of the methyl ester of 2,3,6-trihydroxybenzoic acid (IV), all the six theoretically possible trihydroxybenzoic acids have been prepared, either as esters or as free acids.



IV IX X

EXPERIMENTAL

Microanalyses by Ernst Boss and Kirsten Glens

2,5-Dimethoxy-2,5-dihydro-2-furoyl acetic acid methyl ester (III) (cf.[5]*).* II[6] (51.7 g, 0.275 mole) is placed in a 0.5-liter three-necked flask fitted with a Hershberg stirrer, a dropping funnel and a reflux condenser and heated with stirring to 90°. 0.7 mm sodium wire (18.5 g, 0.81 mole) and methyl acetate (60.7 g, 0.82 mole) are added at 30—60 minutes intervals in six portions of equal size. During each addition of sodium the stirrer is stopped. As the reaction mixture becomes more and more viscous, benzene (70 ml in all) is added. After the reaction, methanol (30 ml) is added dropwise to remove residual sodium and the mixture left standing with stirring and heating over-night. The solution is cooled to −10° and poured in one portion with efficient stirring into a mixture of concentrated hydrochloric acid (90 g, 0.89 mole) and 170 g of cracked ice. The dark brown mixture is extracted rapidly with cold ether (500 + 100 + 100 ml) and the etheral solution washed with a 2 *M* solution of potassium hydrogen carbonate (300 ml) and dried with magnesium sulfate. The ether is removed by distillation and the residue distilled further under 0.1—0.2 mm from an oil bath (60—120°). After a fore-run of methyl acetoacetate, 43.4 g (69 %) of III is obtained [slightly yellow oil, b. p. 87—114° (main portion 104—114°), n_D^{25} 1.4588]. (Found: C 52.6; H 6.3; OCH_3 39.4. Calc. for $C_7H_5O_3(OCH_3)_3$ (230.2): C 52.2; H 6.1; OCH_3 40.4).

2,3,6-Trihydroxybenzoic acid methyl ester (IV). III (2.30 g) was shaken for 10 minutes with hydrochloric acid (0.1 *N*, 20 ml) under carbon dioxide. Hereby a homogeneous solution was obtained, which was left standing for 8 days. A light-violet precipitate was removed by filtration, washed with water and dried. The yield was 1.05 g (57 %) of IV [m. p. 131—135° (Hershberg apparatus, corr.)]. (Found: C 52.4; H 4.4; OCH_3 16.8. Calc. for $C_7H_5O_4(OCH_3)$ (184.1): C 52.2; H 4.4; OCH_3 16.9).

The product gave a reddish-brown ferric chloride reaction. After two crystallizations from methanol-water the m. p. was raised to 138°. Further crystallization did not change the m. p.

2,5-Dimethoxytetrahydro-2-furoyl acetic acid methyl ester (VI). This compound was prepared from 2,5-dimethoxy-2-carbomethoxy-tetrahydrofuran[6] (28.5 g) and methyl acetate (34.1 g) as described above for the preparation of III. The yield was 24.0 g (69 %) of VI (light-yellow liquid, b. $p._{0.1-0.2}$ 98—99°, n_D^{25} 1.4559). (Found: C 52.8; H 7.3; OCH_3 38.8. Calc. for $C_7H_7O_3(OCH_3)_3$ (232.2): C 51.7; H 6.9; OCH_3 40.1).

2,3-Dihydroxybenzoic acid methyl ester (VII) and 2,3-dihydroxybenzoic acid (VIII). VI (1.00 g) was heated under reflux (15 min) with sulfuric acid (0.1 *N*, 5 ml). After cooling, a precipitate was removed by filtration, washed with water and dried. The yield was 500 mg (69 %) of VII (almost white crystals, m. p. 73—74°). (Found: C 56.9; H 5.0; OCH_3 17.1. Calc. for $C_7H_6O_3(OCH_3)$ (168.1): C 57.1; H 4.8; OCH_3 18.5)

The product gave a blue ferric chloride reaction. After crystallization from benzene-petroleum ether the m. p. was raised to 77—78° (previously found [7] 78—79°).

The mother liquor was heated further under reflux (10 min) and continuously extracted with ether. Hereby 50 mg (8 %) of VIII was isolated (white crystals, m. p. 204—205°). (Found: C 54.7; H 4.1. Calc. for $C_7H_6O_4$ (154.1): C 54.6; H 3.9).

The product gave a violet ferric chloride reaction. After crystallization from benzene the m. p. was raised to 207° (previously found [8] 206°).

Hydroxyhydroquinone triacetate (X). IV (300 mg) was heated under reflux (3 hr) with hydrochloric acid (3 *N*, 10 ml) in an atmosphere of nitrogen. The solution was extracted with ether (15 + 15 ml), the etheral solution dried with magnesium sulfate and the ether distilled. The oily residue was heated under reflux (10 min) with a mixture of acetic anhydride (3 ml) and pyridine (3 ml). The reaction mixture was evaporated to dryness under 0.5 mm on a water-bath (60°) and the oily residue dissolved in ether (15 ml). The etheral solution was purified with carbon black and most of the ether removed by distillation. Hereby 95 mg (23 %) of X crystallized (white crystals, m. p. 86—88°). (Found: C 56.4; H 5.0; $COCH_3$ 51.0. Calc. for $C_6H_3O_3(COCH_3)_3$ (252.2): C 57.1; H 4.8; $COCH_3$ 51.2).

The infrared spectrum of the product was identical with that of an authentic sample. After crystallization from benzene-petroleum ether the m. p. was raised to 95° (previously found [9] 96—97°).

ACTA CHEMICA SCANDINAVICA 9 (1955) 30—33

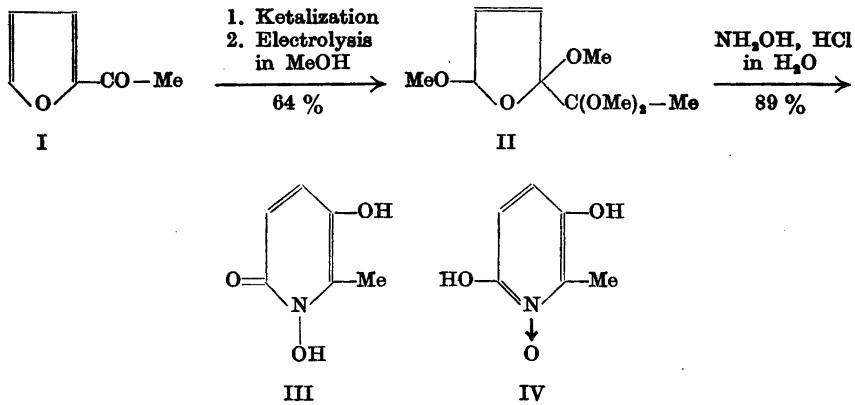
Some New Cyclic Hydroxamic Acids

JØRGEN TORMOD NIELSEN, NIELS ELMING and NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

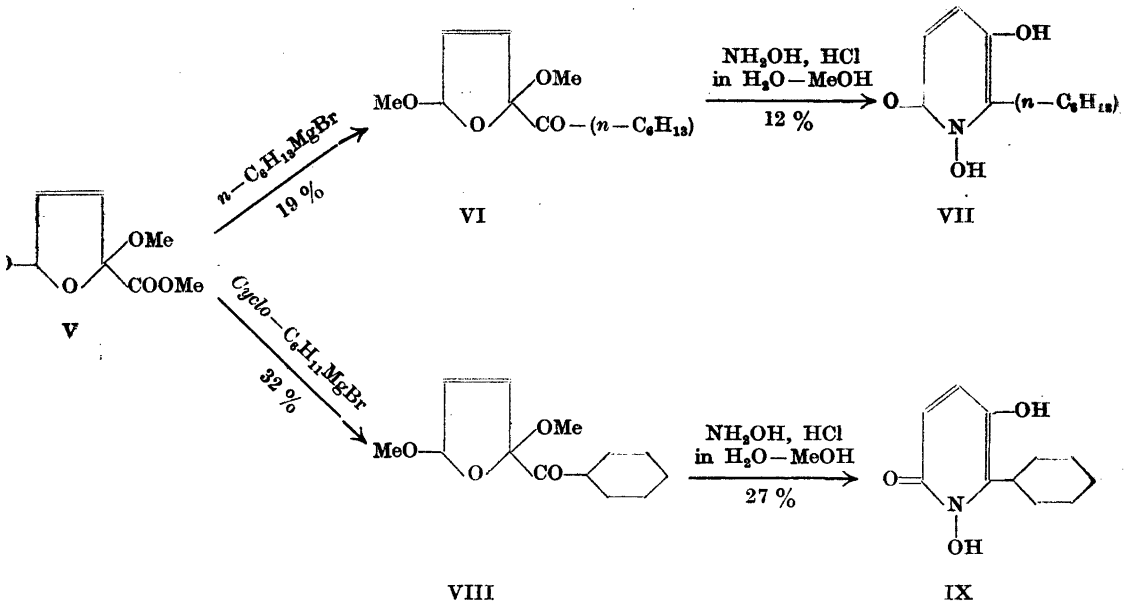
A compound prepared from 2-acetylfuran and previously [1] claimed by us to be 2-methyl-3,6-pyridinediol-1-oxide (IV) we now believe to be the tautomeric hydroxamic acid 1,5-dihydroxy-6-methyl-2-pyridone (III). Three similar cyclic hydroxamic acids have been prepared from methyl furoate (VII and IX) and furfural (XII), respectively.

We have recently found [1] that 2-acetylfuran (I) may be transformed by a two-step reaction into a compound, which was formulated as 2-methyl-3,6-pyridinediol-1-oxide (IV). Having become acquainted with experiments by Shaw, *et al.* [2-5], on certain cyclic hydroxamic acids related to the antibiotic aspergillic acid, we now think that our compound, rather than being a 2-hydroxypyridine-1-oxide, is the tautomeric hydroxamic acid 1,5-dihydroxy-6-methyl-2-pyridone (III).

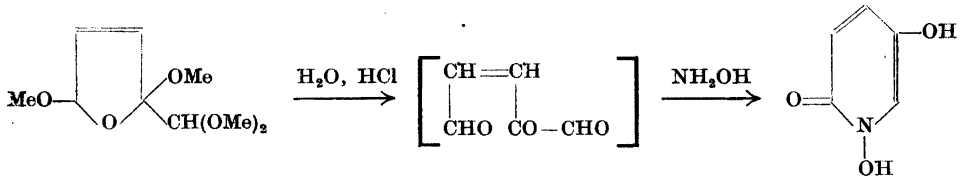


I II III IV

The new reaction has been used for the preparation of two more hydroxamic acids (VII and IX) by the reactions shown below. Compounds VI—IX are new. Their structures follow from the syntheses and from analyses.

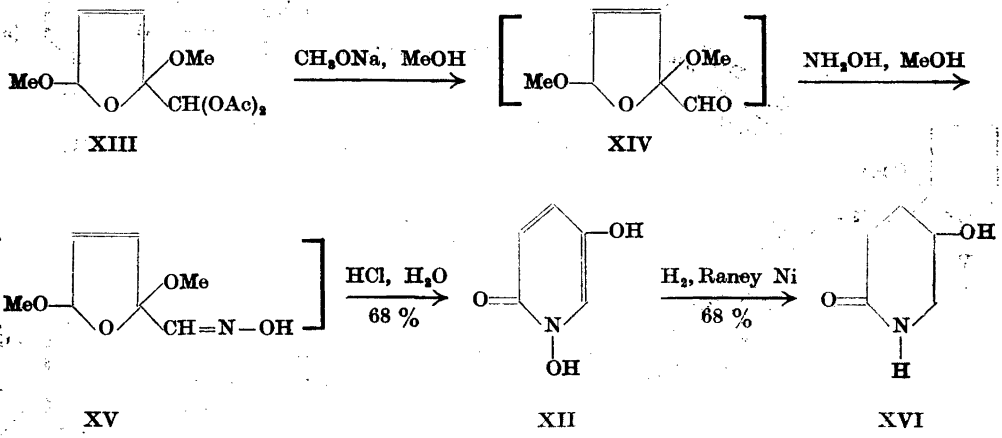


The corresponding unsubstituted hydroxamic acid (1,5-dihydroxy-2-pyridone) (XII) has also been prepared though under somewhat different reaction conditions. One might expect any easily hydrolyzable derivative of 2-*cis*-pentene-1,5-dial-4-one (XI) to react with hydroxylamine hydrochloride to give (XII). 2,5-Dimethoxy-2-dimethoxymethyl-2,5-dihydrofuran [6] (X) gave, however, only a dark reaction mixture, from which no XII could be isolated. The mixture nevertheless gave a strong violet ferric chloride reaction indicating that a small amount of XII actually was formed.



A good yield of XII was obtained by using 2,5-dimethoxy-2,5-dihydrofurfural [7] (XIV) as a starting material. A methanolic solution of this compound was prepared from 2,5-dimethoxy-2-diacetoxymethyl-2,5-dihydrofuran (XIII), the solution treated with hydroxylamine and the reaction product hydrolyzed and condensed to XII. Probably the reaction proceeds through the oxime XV or its equivalent, the initial attachment of the hydroxylamine mole-

cule to the organic molecule thus taking place at one of the ends of the chain of carbon atoms as required for the formation of XII.



XIII XIV XV XII XVI

The structure of the new hydroxamic acid XII was proved by catalytic hydrogenation to the known 5-hydroxy-2-piperidone XVI.

EXPERIMENTAL

Microanalyses by E. Boss and K. Glens

2,5-Dimethoxy-2-(α-oxo-n-heptyl)-2,5-dihydrofuran (VI). An etheral solution of *n*-hexylmagnesium bromide [from *n*-hexyl bromide (36.0 g, 0.22 mole) and 70 ml of ether] was added at −60° to a solution of V[8] (37.6 g, 0.20 mole) in 150 ml of ether. A saturated solution of ammonium chloride (32 ml) was added at 5° and the etheral solution removed by decantation. The residue was extracted twice with 35 ml of ether. Distillation of the combined etheral solutions through a 5 cm column [9] first gave a forerun (13 g, b.p.$_{17}$ 68–157°) consisting mainly of V, and then 9.1 g (19 %) of VI (almost colorless liquid, b.p.$_{17}$ 157–159°, n_D^{25} 1.4483). (Found: C 64.6; H 9.0; OCH_3 25.6. Calc. for $C_{11}H_{16}O_2(OCH_3)_2$ (242.3): C. 64.4; H 9.2; OCH_3 25.6).

About 15 ml of a higher boiling residue, consisting mainly of the corresponding tertiary alcohol, remained in the distillation flask.

1,5-Dihydroxy-6-(n-hexyl)-2-pyridone (VII). VI (1.21 g, 0.0050 mole) was dissolved in methanol (3 ml) and the solution added to a solution of hydroxylamine hydrochloride (0.44 g, 0.0063 mole) in methanol (3 ml) — water (2.5 ml). After standing (17 hr) the light-brown reaction mixture was evaporated to dryness in a vacuum from a water bath (25°). The residue was dissolved in ammonium hydroxide (20 %, 4.0 ml) and continuously extracted with ether. The etheral solution was evaporated to dryness and the residue crystallized from ether. The yield was 126 mg (12 %) of VII [almost white crystals, m.p. 86–88° (Hershberg app., corr)]. The crystals gave a strong violet ferric chloride reaction. (Found: C 62.8; H 8.4; N 6.5. Calc. for $C_{11}H_{17}O_3N$ (211.3): C 62.5; H 8.1; N 6.6).

2,5-Dimethoxy-2-[α-oxo-α-(cyclohexyl)-methyl]-2,5-dihydrofuran (VIII). This compound was prepared from cyclohexyl bromide (24.0 g) and V (25.0 g) as described for the preparation of VI. The yield was 10.2 g (32 %) of VIII (almost colorless liquid, b.p.$_{14}$ 160–162°, n_D^{25} 1.4732). (Found: C 64.8; H 8.2; OCH_3 25.8. Calc. for $C_{11}H_{14}O_2(OCH_3)_2$ (240.3): C 65.0; H 8.4; OCH_3 25.8).

1,5-Dihydroxy-6-cyclohexyl-2-pyridone (IX). This compound was prepared from VIII (1.20 g) as described for the preparation of VII. The crude product was crystallized from methanol-ether. The yield was 286 mg (27 %) of IX (almost white crystals, m.p. 180—182°). The crystals gave a strong violet ferric chloride reaction. (Found: C 62.9; H 7.4; N 6.5. Calc. for $C_{11}H_{15}O_3N$ (209.2): C 63.1; H 7.2; N 6.7).

1,5-Dihydroxy-2-pyridone (XII). XIII (500 mg, 0.0019 mole) was dissolved in methanol (2.0 ml) and the solution added to a solution of sodium methoxide [from 44 mg of sodium (0.0019 mole) in methanol (1.0 ml)]. After standing for 15 minutes a solution of hydroxylamine hydrochloride (0.16 g, 0.0023 mole) and anhydrous sodium acetate (0.050 g) in methanol (2.0 ml) was added, the mixture left standing for 20 minutes and a precipitate of sodium chloride removed by filtration. The almost colorless filtrate was heated under reflux (8 min) and then evaporated in a vacuum from a water bath (30—40°) to about 1 ml. Water (1 ml) and then *N* hydrochloric acid (2.5 ml) were added and the solution left standing for 10 minutes. A precipitate of white crystals of XII was removed by filtration and washed with water, ethanol and ether. The yield was 164 mg (68 %); m.p. in an evacuated tube 216—225° (dec.). Crystallization from ethanol gave 138 mg (57 %), m.p. 215—223°. The product gave a strong violet ferric chloride reaction. (Found: C 47.3; H 4.2; N 10.8. Calc. for $C_5H_5O_3N$ (127.1): C 47.3; H 4.0; N 11.0).

In a similar experiment starting from 2,5-dimethoxy-2,5-dihydrofurfural (XIV) (600 mg) practically the same yield of XII (330 mg = 69 %) was obtained. (Found: C 46.9; H 4.2; N 10.8).

In an attempt to prepare XII from 2,5-dimethoxy-2-dimethoxymethyl-2,5-dihydrofuran (X), X (0.41 g) and hydroxylamine hydrochloride (0.21 g) were dissolved in water (7 ml) and the solution left standing over-night. The next day the dark reaction mixture gave a strong violet ferric chloride reaction but isolation of pure XII failed.

5-Hydroxy-2-piperidone (XVI). XII (0.47 g) and anhydrous methanol (25 ml) were shaken (1 hr) with Raney nickel (0.2 g) under hydrogen (100 atm., 100°). The Raney nickel was removed by filtration and the filtrate evaporated in a vacuum. The crystalline residue was crystallized from methanol-ether. The yield was 0.29 g (68 %) of XVI (almost colorless crystals, m.p. 144—146°, previously found 145—146° [10, 11]). (Found: C 51.9; H 7.7; N 12.0. Calc. for $C_5H_9O_2N$ (115.1): C 52.2; H 7.9; N 12.2.)

Recrystallization from methanol-ether did not change the m.p.

Studies on the 7α-Hydroxylation of Taurodesoxycholic Acid in Rat Liver Homogenates. Bile Acids and Steroids 18

SUNE BERGSTRÖM and URS GLOOR

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Fractionation of rat liver homogenate into a particle free supernatant (1 hr, 100 000 × g) and a crude residue containing microsomes, mitochondria *etc.* has been carried out. It is shown that the particle-free medium is capable of hydroxylating taurodesoxycholic acid in the 7 α-position yielding taurocholic acid. About 40 % of the amount hydroxylated in total homogenates is hydroxylated by supernatant alone.

The addition of ATP greatly stimulates the hydroxylation. Supernatant from 1 g liver can hydroxylate almost 1 mg of taurodesoxycholic acid in 2 hours. Versene increases the yield at a certain concentration range but inhibits in greater concentrations.

The conversion of desoxycholic acid into taurocholic acid has been demonstrated to occur in the rat *in vivo* [1] as well as *in vitro* in liver slices [2] and homogenates [3,4,5]. We are now presenting some results of experiments on the 7α-hydroxylation of taurodesoxycholic acid-24-^{14}C in rat liver homogenates. These homogenates have also been fractionated and the effect of different additions on the hydroxylation has been investigated.

EXPERIMENTAL

Taurodesoxycholic acid-24-^{14}C was prepared according to Bergström and Norman [6] from desoxycholic acid-24-^{14}C[7]. We are indebted tc Dr. A. Norman and fil.kand. K. Pääbo, respectively, for preparing these compounds.

The method used for paper chromatography of free and conjugated bile acids has been described by Sjövall [8] and the measurement of the radioactivity of the paper strips has been described earlier [3]. The homogenizing technique used has been described earlier but we have now used the medium proposed by Bucher [9,10] with only minor changes. One litre of the medium contained 10.8 g of monobasic potassium phosphate, 3.2 g of potassium hydroxide, 1 g of magnesium chloride (6 H_2O) and 3.6 g of nicotinic acid amide. The pH was 7.5 ± 0.1. The incubation vessel, a small pyrex test tube containing 1 ml of homogenate or homogenate fraction with the additions indicated was shaken in a water bath at 37° for 2 hours. The reaction was stopped by the addition of five volumes of ethanol and the resulting mixture was filtered and worked up as described earlier [3].

The crude homogenates were centrifuged in a precooled tube of an ordinary centrifuge at 400 × g for 10 minutes, yielding what is referred to as "total homogenate" in the following. To prepare a particle-free supernatant of this homogenate it was centrifuged at 100 000 × g for 60 min. in a preparative Spinco ultracentrifuge. The fatty top layer was then carefully pipetted off and the rest of the supernatant used for the incubations. In some experiments the whole sediment (mitochondria, microsomes, "fluffy" layer) was stirred up in the appropriate amount of homogenizing medium and used without further differentiation and is referred to as "crude residue". The supernatant contained about 2 mg of nitrogen per ml (corrected for the content of nicotinamide) whereas the total homogenate contained about 3.4 mg of N per ml.

RESULTS

The total homogenate was first separated into sediment and particle-free supernatant at 100 000 × g. The 7α-hydroxylation of taurodesoxycholate to taurocholate and the conjugation of cholic acid with taurine was then investigated with the supernatant and with the resuspended sediment.

The results of 4 representative experiments of each type are shown in Tables 1 and 2.

Table 1. 7α-hydroxylation of 50 μg taurodesoxycholic acid-24-^{14}C in rat liver homogenate and fractions thereof. 1 ml incubation medium corresponding to about 200 mg rat liver fresh weight. Incubation: 2 hours; pH 7.5; air.

Average values	39	6.3	6.5	38

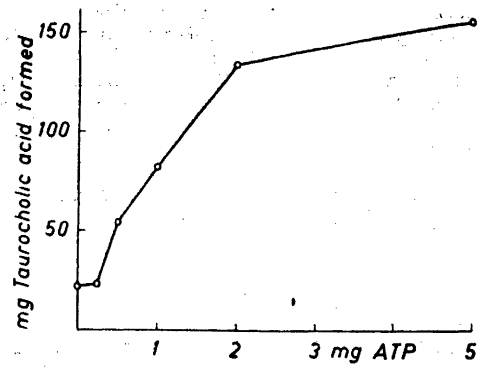

Fig. 1. Effect of increasing amounts of ATP on 7 α-hydroxylation of taurodesoxycholate-24-^{14}C. (0.2 mg). Reaction time: 2 hours at 37°, air.

These results show that the supernatant without any additions has approximately 40 % of the hydroxylating capacity of the total homogenate whereas the conjugation only occurred to about 15 % of that of the total homogenate or of the recombined fractions. Further data on the conjugation of bile acids in fractionated liver homogenates are being published by Bremer [18].

The effect of adenosinetriphosphate (ATP) on hydroxylation is illustrated in Fig. 1. In this experiment one ml of the supernatant hydroxylated about 22 μg taurodesoxycholate whereas this amount increased to a maximum of 134 μg after addition of 2 mg of ATP.

The effect of ATP on the hydroxylation was more marked in the supernatant than in the total homogenate where presumably the structural element contains both energy yielding and consuming systems. In one experiment similar to that shown in Fig. 1, 5 mg of ATP caused a seven fold increase to

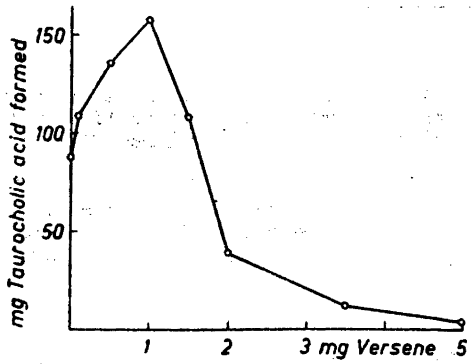

Fig. 2. Effect of versene on hydroxylation of taurodesoxycholate. Each vessel: Rat liver supernatant (1 ml) + taurodesoxycholic acid-24-^{14}C + ATP (1 mg). Incubation 2 hours at 37° in air.

Table 3. Influence of ATP, DPN and fumarate on 7 α-hydroxylation of taurodesoxycholate (50 μg) in 1 ml of supernatant. Incubation at 37° in air for 2 hours.

	μg taurocholic acid found

Supernatant	17
» + 2 μmoles ATP	37
» + 1 μmole DPN	15
» + 1 μmole fumarate	14
» + DPN + fumarate	13
» + ATP + DPN	36
» + ATP + fumarate	35
» + ATP + DPN + fumarate	34

188 μg of hydroxylated product in 1 ml of the supernatant whereas the total homogenate only reached 92 μg with the same addition.

We found earlier that the hydroxylating system is very sensitive to some heavy metal ions, and have therefore investigated the influence of a chelating agent, versene, *i. e.* ethylenediamine tetraacetic acid.

A typical experiment is shown in Fig. 2 in which increasing amounts of versene were added to 1 ml of the supernatant to which, furthermore, 2 mg of ATP had been added.

There was almost a doubling of the yield after the addition of 1 mg (3 μmoles) of versene but larger amounts rapidly caused an almost complete inhibition. Sweat [13] reported some inhibition of the 11 α-hydroxylase with versene.

The effect of fumarate and diphosphopyridine nucleotide (DPN) either alone or in combination with ATP is shown in Table 3. From these results it can be concluded that in the present system ATP is the only compound showing any noticeable effect. Some experiments with addition of TPN, reduced DPN and cytochrome c did not cause any noticeable changes in the results. Work is now in progress to fractionate the supernatant in order to facilitate further studies of the enzymic mechanisms involved.

The 7 α-hydroxylase system studied is thus contained mainly in the particle-free supernatant and the activity is greatly stimulated by ATP.

This is thus at variance with the 11 α-hydroxylase [12-13] from adrenals that has been shown to be contained in the particles isolated between 2 000 × g and 19 000 × g [13] or at 5 000 × g [14] whereas the supernatant has been found to be practically inactive in this respect.

The 17α- and 21-hydroxylases are, however, apparently contained mainly in the supernatant (*cf.*[14], page 175, footnote 2).

This work is part of an investigation supported by "*Statens Medicinska Forskningsråd*", "*Knut och Alice Wallenbergs Stiftelse*" and "*Magn. Bergvalls Stiftelse*".

The Complex Formation between Iron(III)Ion and Some Phenols. III. Salicylaldehyde, *o*-Hydroxyacetophenone, Salicylamide and Methyl salicylate

ALLAN ÅGREN

Department of Chemistry, Royal Pharmaceutical Institute, Stockholm, Sweden

The complex formation between iron(III)ion and the following phenolic substances has been investigated: salicylaldehyde, *o*-hydroxyacetophenone, salicylamide and methyl salicylate. All measurements have been made at 25.0° ± 0.1° C and in solutions with a concentration of ClO_4^- of 3 000 mC. By potentiometric and photometric methods the complexity constants, defined as follows have been determined

$$\varkappa_n = \frac{[H^+]^n[FeR_n^{3-n}]}{[RH]^n[Fe^{+3}]} \quad (n = 1 \text{ or } 2)$$

RH is the phenolic substance concerned. Further the molar extinctions (1 000 ε_n) have been determined. The results are listed in Table 12.

In the previous works in this series the complex formation between iron(III)-ion and some chelating phenols have been studied, namely sulfosalicylic acid [1], salicylic acid and *p*-aminosalicylic acid [2]. In this work the complex formation with salicylaldehyde, *o*-hydroxyacetophenone, salicylamide and methyl salicylate is investigated. All these substances may give chelate complexes with iron(III)ion.

Symbols used in the text (mC denotes millimoles/liter).

h = hydrogen ion concentration, mC.
[] = concentration of substance indicated, mC.
$[]_t$ = stoichiometrical concentration, mC.

RH = 
$$b = \frac{[Fe^{+3}]_t - [Fe^{+3}]}{[Fe^{+3}]}$$

ε = extinction, $cm^{-1}mC^{-1}$
E = extinction, cm^{-1}
$\varkappa_n$ = complexity constant
$\varkappa_{nm}$ = complexity constants of the hydroxyl complexes $Fe_n(OH)_m$

$$\varkappa' = \frac{\varkappa_{11}}{h} + \frac{\varkappa_{12}}{h^2} + \frac{2\varkappa_{22}[Fe^{+3}]}{h^2}$$

The signs for the electrical charges are omitted when there is no risk of confusion.

The complexes are formed according to the following equation

$$Fe + n\ RH = n\ H + FeR_n$$

and the complexity constants are defined as follows:

$$\varkappa_n = \frac{h^n[FeR_n]}{[RH]^n[Fe]} \quad (n = 1,\ 2\ldots) \tag{1}$$

The same equations are valid whether or not chelates are formed. In either case only one hydrogen ion is set free per RH molecule.

In determining the complexity constants the same methods have been used as in the previous works [1,2]. However, in this investigation some complications are met with. The substances studied are only slightly soluble (5—15 mC) in the medium used, 3 000 mC $NaClO_4$, at 25° C. Due to this only the lowest complexes are formed, FeR and perhaps FeR_2. More than two molecules R per atom Fe have not been found. Due to the low complex forming tendency and the low concentration of R the hydroxyl complexes of iron(III)ion have been formed in higher amounts, appreciably influencing the calculations.

In the potentiometric determinations the following equation, derived before, has been used:

$$\frac{(b-\varkappa')h}{[RH]} = \varkappa_1 + \varkappa_2 \frac{[RH]}{h} + \ldots \tag{2}$$

$\varkappa'$, which in the earlier investigations was a small correction term, is now of the same order as b. This causes uncertainties in the results.

In the photometric determinations the following equations, also derived before, have been used:

$$\frac{c}{E} = \frac{1}{\varepsilon_1} + \frac{h}{[RH]} \frac{1}{\varkappa_1\varepsilon_1} \tag{3}$$

which is valid when $[Fe]_t = [R]_t = c$, and when only FeR is formed in measurable amount.

$$\frac{[Fe]_t}{E} = \frac{1}{\varepsilon_1} + \frac{h}{[RH]} \frac{1}{\varepsilon_1\varkappa_1} \tag{4}$$

$$\frac{[Fe]_t}{E} = \frac{1}{\varepsilon_2} + \frac{h}{[RH]} \frac{E-[Fe]_t\varepsilon_1}{E} \frac{\varkappa_1}{\varepsilon_2\varkappa_2} \tag{5}$$

Equations (4) and (5) are valid when $[R]_t \gg [Fe]_t$. Equ. (4) is used in a range where only FeR is formed in measurable amount. Equ. (5) is used when FeR and FeR_2 are formed, but no other forms of Fe are present.

Equations (3)—(5) were derived assuming that no appreciable amounts of hydroxyl complexes are formed.

Apparatus and chemicals. The same apparatus has been used as in previous investigations [1].

The preparation and quantitative determination of $Fe(ClO_4)_3$, $Fe(ClO_4)_3$ and $NaClO_4$ have been described earlier.

Salicylaldehyde was purified as the bisulfite compound and by freezing out. *o*-Hydroxyacetophenone was made according to Rosenmund and Schnurr [3] by heating phenyl

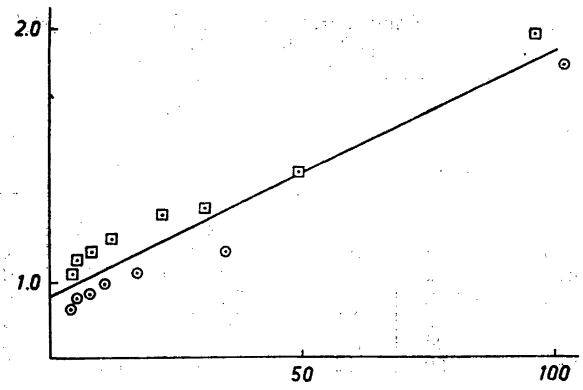

Fig. 1. Salicylaldehyde. Potentiometric determination of $\varkappa_1$ *and* $\varkappa_2$. $\frac{(b-\varkappa')h}{[RH]}$ *vs.* $\frac{[RH]_t}{h}$.
○ : Fe(III) = 0.1051 mC, □ : Fe(III) = 0.0496 mC.

acetate and water-free $AlCl_3$. The raw product was purified by steam distillation. This product was colourless. The salicylamide used had a melting point 138–139° C.

The quality of the methyl salicylate used was controlled according to the Swedish Pharmacopeia Ed. XI. It contained no free acid.

All the solutions were made up by weight, and $NaClO_4$ added to a total concentration of 3 000 mC ClO_4^-. Under these conditions it is assumed that the activity factors are constant and hence the concentrations may be used instead of activities in the equilibria.

SALICYLALDEHYDE

The complex formation between iron(III)ion and salicylaldehyde has been studied by Herbst and coworkers [4] and by Broumand and Smith [5]. They have shown, using the method of continuous variations [6] that the complex is built up from one molecule of salicylaldehyde per atom Fe. The complex formation between salicylaldehyde and bivalent metals has been thoroughly investigated

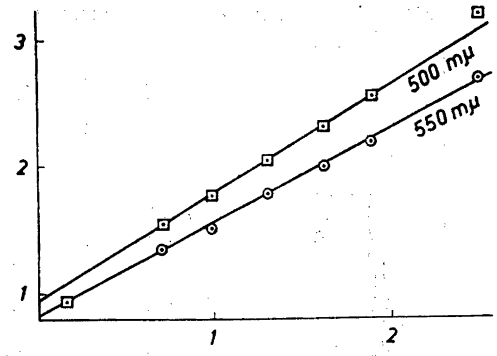

Fig. 2. Salicylaldehyde. Photometric determination of $\varkappa_1$. $[Fe]_t/E$ *vs.* $h/[RH]$.
$[R]_t$ = 6.664 mC, $[Fe]_t$ = 0.696 mC.

16.67	0.263	0.160	0.218	0.259	0.208	0.131	0.072

and it is generally assumed that a chelate is formed. Some of these metals form complexes with 1 or 2 molecules of aldehyde per metal atom.

In the potentiometric investigation of this complex formation, this author has shown that complexes with 1 and 2 molecules per atom Fe are formed. However, the higher complex has such a low stability that it was impossible to make a photometric investigation because only a very small fraction of the complex-bound iron was contained in the form of the complex FeR_2 even when [RH]/h was made as high as possible.

Salicylaldehyde is slightly soluble (*ca.* 10 mC) in 3 000 mC $NaClO_4$ at 25° C. Thus, it was impossible to work with high concentrations of iron without the OH-complexes becoming dominant. Only two concentrations of Fe(III) have been studied in the potentiometric measurements. The results of these experiments are shown in Fig. 1. From these curves the values of $\varkappa_1$ and $\varkappa_2$ are calculated and given in Table 12.

The photometric determinations are shown in Table 1 and Fig. 2. This figure shows the curves at two wave lengths, the values being calculated with equ. (3). The results are given in Table 12.

o-HYDROXYACETOPHENONE

Recently, Jatkar and Mattoo [11] have published a work where they show the formation of complexes with one molecule of *o*-hydroxyacetophenone per atom Fe. They have determined the complexity constant $K_1 = [Fe][R]/[FeR] = 14 \cdot 10^{-4}$ C, where they assume [R] = [RH]. However, this value of the constant is of little interest as no pH measurements seem to have been made.

Table 5. Salicylamide. Potentiometric determination of $\varkappa_1$ and $\varkappa_2$. $[Fe]_t = 0.484$ mC. Results: $\varkappa_1 = 13.7$; $\varkappa_2 = 0.21$.

0.9226	2.3944	2.395	0.316

The present author [10] has determined the acidity constant of *o*-hydroxyacetophenone to be $1.5 \cdot 10^{-11}$ C, and thus their assumption must be wrong.

The solubility of *o*-hydroxyacetophenone is of the same order as that of salicylaldehyde. Thus the same restrictions have to be made here. No tendency to form the complex FeR_2 or higher complexes has been found.

The results of the potentiometric experiments are shown in Table 2 and 3. The calculated value of $\varkappa_1$ is given in Table 12. There is a remarkable difference in the results of these two experiments. However, this difference is not due to the formation of multinuclear complexes. If it were so, then the higher concentration of Fe would give a higher value of $\varkappa_1$. Instead the difference is due to the uncertainty in the results, owing to the influence of the OH-complexes on the measurements.

The photometric experiments are shown in Table 4 and Fig. 3. The calculated results are given in Table 12.

SALICYLAMIDE

The complex formation between iron(III)ion and salicylamide has been used by Hernández-Gutiérrez and Pulido-Cuchi [7] in a photometric method of determination of salicylamide. They suppose the complex to be $Fe(O \cdot C_6H_4 \cdot CONH_2)_6^{-3}$ and to be more stable than that of salicylic acid.

Table 11. Methyl salicylate. Photometric determination of $\varkappa_1$.
$[Fe]_t = 49.71$ mC, $[R]_t = 2.166$ mC.

h	Extinction at wave length							
	400	450	500	550	600	625	650	700
41.62	0.318	0.440	0.797	0.921	0.738	0.612	0.488	0.280
36.33	0.343	0.478	0.861	0.991	0.794	0.655	0.507	0.306
33.62	0.290	0.460	0.889	1.028	0.838	0.690	0.540	0.320
31.32	0.300	0.489	0.937	1.080	0.881	0.724	0.556	0.331
28.43	0.372	0.545	1.005	1.160	0.940	0.779	0.604	0.363
25.39	0.333	0.548	1.053	1.230	1.000	0.830	0.635	0.370

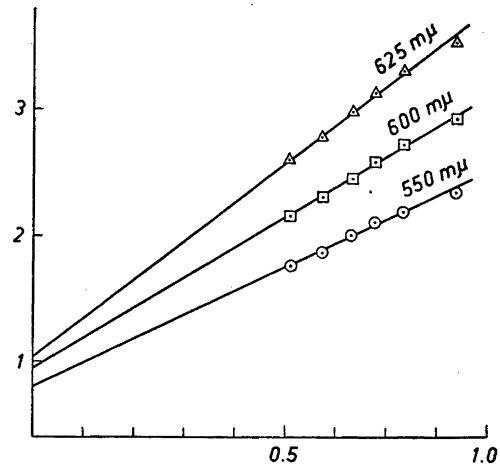

Fig. 7. Methyl salicylate. Photometric determination of $\varkappa_1$. $[R]_t/E$ *vs.* h/[Fe]. $[R]_t = 2.166$ mC, $[Fe]_t = 49.71$ mC.

Here the complex forming tendency is greater than that with either salicylaldehyde or *o*-hydroxyacetophenone, but the low solubility restricts the complex formation to FeR and FeR_2 only.

The results of the potentiometric experiments are shown in Tables 5—7, and the calculated values of $\varkappa_1$ and $\varkappa_2$ are given in Table 12.

Here the complex formation is so strong that both FeR and FeR_2 could be studied photometrically. From the potentiometrically calculated values of $\varkappa_1$ and $\varkappa_2$, Fig. 4 is constructed. From this figure, the suitable ranges of [RH]/h were chosen in which to make the photometrical experiments. These ranges are shadowed in the figure.

The results of the photometric determination of $\varkappa_1$ and ε_1 are shown in Table 8 and some of these results are used in calculating the curves of Fig. 5, equation (3) being used in the calculations. From the measurements on one of the most acidic solutions, ε_1 at other wave lengths could be calculated.

Table 12. Survey of the results of this investigation.

Substance	Potentiometry		Photometry					
	$\varkappa_1$	$\varkappa_2$	$\varkappa_1$	ε_1	$\lambda_{max.}$	$\varkappa_2$	ε_2	$\lambda_{max.}$
Salicylaldehyde	0.90 ± 0.05	$9.0 \cdot 10^{-3} \pm 0.5 \cdot 10^{-3}$	1.00 ± 0.05	1.2	550	—	—	—
o-Hydroxyacetophenone	0.5 ± 0.1	—	0.50 ± 0.05	1.3	550	—	—	—
Salicylamide	13.5 ± 0.5	0.3 ± 0.1	15.5 ± 1.0	1.5	525	0.40 ± 0.05	2.9	475
Methyl salicylate	0.35 ± 0.05	—	0.40 ± 0.05	1.2	550	—	—	—

In the same manner $\varkappa_2$ and ε_2 were calculated from some of the figures of Table 9, which resulted in the curves of Fig. 6. Here equation (5) was used. The results of the photometric determinations are collected in Table 12.

METHYL SALICYLATE

The complex formation with iron(III)ion was studied by Babko [8], using a photometric method. He found the complex FeR. The dissociation constant was determined $K = \frac{[R][Fe]}{[FeR]} = 4 \cdot 10^{-8}$C. This is twice the value of the corresponding constant of phenol. The difference, according to Babko, is due to methyl salicylate being a stronger acid.

The dissociation constant of the acid methyl salicylate was determined by Babko to $1.6 \cdot 10^{-8}$. This constant has been determined by Goldschmidt and Scholz [9] to be $1 \cdot 10^{-11}$. This author [10] has found the value $6.5 \cdot 10^{-11}$ in 3 000 mC ClO_4^-. The difference to Babkos value is striking. However, if the values found by Babko are used to calculate $\varkappa_1$, defined by this author, the value 0.4 is found, which is in good agreement with the results of this author.

In this work the results of a potentiometric titration are given in Table 10 and of the photometric determinations in Table 11 and Fig. 7. The constants calculated from these results are given in Table 12.

The Complex Formation between Iron(III) Ion and Some Phenols. IV. The Acidity Constant of the Phenolic Group

ALLAN ÅGREN

Department of Chemistry, Royal Pharmaceutical Institute, Stockholm, Sweden

By an ultra violet photometric method the dissociation constant of the phenolic group of some phenols has been determined. Among them, the following phenols have not been studied before: sulfosalicylic acid, *p*-amino salicylic acid, *p*-amino salicylamide and salicylamide.

In order to determine the dissociation constants of very weak acids, several methods have been used. King and Marion [1] used the catalytic effect of hydroxyl ion, Konopik and Eberl [2] made colorimetric determinations using colour indicators while photometric determinations in ultraviolet light (UV) have been used by others [3, 20]. Potentiometric or conductometric methods are not useful for the study of very weak acids.

This author has investigated the complex formation between iron(III)ion and the following phenols: sulfosalicylic acid [4], salicylic acid, *p*-amino salicylic acid (PAS)[5], salicylaldehyde, *o*-hydroxyacetophenone, salicylamide, methyl salicylate [6] and *p*-amino salicylamide (PAS-amide) [21]. In this investigation the dissociation constant of the phenolic group of these substances and of ordinary phenol has been determined. The values of these constants lie between the limits 10^{-9} and 10^{-14} C. Thus, the stronger ones of these acids could be studied by potentiometric measurements, but this could not easily be done with the weaker ones. Further, some of the substances concerned are sparingly soluble and this fact will make potentiometrical methods impractical. Hence all the substances were studied by photometric measurements in UV. Vandenbelt and coworkers [20] have demonstrated the agreement between photometric and potentiometric measurements where both could be used.

The results of previous work on the dissociation of the phenolic group of the substances studied here are collected in Table 1. Most of the substances have been studied in UV. Some recent works in this field are collected in Table 2. By comparing Table 1 and Table 2 it may be seen that in only two of the works cited have the measurements been used to determine the dissociation constant. This method has also been used by for example Flexser and coworkers [12], who studied some very weak acids and bases.

The authors cited in Table 1 have not used the same conditions as the present author used in his investigations on the complex formation with iron(III)-ion. The value given for methyl salicylate is very old and is said by the authors to be only approximate. For the substances studied previously by other authors, the results of the present author are given in Table 9, but no details on the measurements.

Studies of sulfosalicylic acid, PAS, PAS-amide and salicylamide in order to determine the dissociation constant of the phenolic group have not previously been performed. The results are given here in Table 9, with details in Tables 4—8.

THEORETICAL

When a phenol dissociates to phenolate there is usually a change in the UV absorption. Both the wave length of maximum extinction and maximum extinction itself become larger. In some cases there is a considerable change (about 20—50 mμ, *cf.* Fig. 4) and the dissociation is then measured at the wave length where the phenolate has its maximum extinction.

In other cases, for example salicylic acid, PAS, and PAS-amide, the wave length shift is very small (5—10 mμ, Figs. 2 and 3) but the extinction value is

Table 2. Substances previously studied in UV.

Substance	Ref.
Phenol	3, 20
Salicylic acid	8
Methyl salicylate	19
Salicylaldehyde	8, 19, 20
o-Hydroxyacetophenone	8, 20
Salicylamide	8
PAS	9, 10, 11

considerably changed. If the measurements are made at the wave length where the phenolate or phenol has its extinction maximum, the accuracy in the results will be rather small. Instead the measurements ought to be made at a wave length, where the extinction of phenolate is great and that of phenol is small. But as this is not the case near a maximum or minimum, large errors may be introduced if the wave length is only slightly changed during a series of measurements. If the apparatus is not changed the calculated value of the dissociation constant may be accurate, but the extinction value will be of little theoretical or practical interest.

The dissociation constant of a phenol is defined in the following equation

$$K_a = \frac{h\ [R]}{[RH]} \tag{1}$$

where h is the hydrogen ion concentration, [RH] and [R] are the concentration of phenol and phenolate, respectively. All concentrations are expressed in mC (= millimoles/liter). All electrical charges are omitted.

The total concentration, $[R]_t$, of the phenol is

$$[R]_t = [R] + [RH] \tag{2}$$

It is assumed that no other forms are present in measurable amounts, as for example RH_2 or RH_3. This is true for all substances studied in this work at such h-values where the phenolic group is appreciably dissociated.

The extinction, E, at a definite wave length is

$$E = \varepsilon_R\ [R] + \varepsilon_{RH}\ [RH] \tag{3}$$

where ε is extinction per mC and cm.

From equations (1)—(3) the following equation is derived

$$\frac{[R]_t}{E} = \frac{1}{\varepsilon_R} + \left[h\,\frac{E - \varepsilon_{RH}\,[R]_t}{E}\right]\frac{1}{K_a\,\varepsilon_R} \tag{4}$$

If $[R]_t/E$ is plotted against the expression within the brackets a straight line should be obtained, the intercept being $1/\varepsilon_R$ and the slope $1/K_a\,\varepsilon_R$.

If ε_{RH} is also unknown, several values may be tried. Only the right value will give a straight line (compare a previous work by this author [5]).

APPARATUS AND CHEMICALS

In the photometric measurements an Uvispek photometer with 1 cm quartz cells was used. For the determination of hydrogen ion concentration, a glass electrode was used and as a reference a silver-silver chloride electrode. In solutions with large concentrations of hydroxyl ion, a hydrogen-platinum black electrode was used. The hydrogen gas was freed from oxygen using a Meyer-Ronge [22] oven. In order to avoid evaporation of the solution to be measured, the gas was bubbled first through a 3 000 mC solution of $NaClO_4$.

The measurements were made at 25.0° ±0.1° C. Further details are described in previous works [4,5]. All experiments were made in solutions with a total concentration of 3 000 mC ClO_4^-. In this medium it is assumed that the activity factors are constant and hence that the concentrations may be used instead of activities in the equilibria.

The purity of the phenol used was controlled according to the Swedish Pharmacopeia Ed. XI. From this substance a 90 % solution was prepared and the concentration determined bromometrically according to Pharmacopeia Danica 1948. This stock solution was then diluted with water and $NaClO_4$.

PAS-amide was made according to Jensen and coworkers [23]. Its melting point was 160° C. The solutions were made up immediately before use.
The quality of the other chemicals used has been described earlier [4-6].

MEASUREMENTS

Some of the phenols studied are appreciably dissociated at rather small hydroxyl ion concentrations. In these cases the hydrogen ion concentration was determined directly. In other cases where large hydroxyl ion concentrations were needed a direct measurement of the hydrogen ion concentration was avoided. Here the h values were calculated from the stoichiometrical concentration of hydroxyl ion and the ionic product of water, the value of which was determined in the medium used. A solution of $NaClO_4$ was "titrated" with NaOH of known concentration and the hydrogen ion concentration determined with the hydrogen electrode. The results of such a titration are given in Table 3.

The extinction curves of sulfosalicylic acid, PAS, PAS-amide and salicylamide are shown in Figs. 1—4. The extinction of undissociated phenol was measured in a neutral or weakly alkaline solution. Under these conditions the carboxyl group of sulfosalicylic acid and PAS is not appreciably dissociated since the dissociation constant is 2.13 and 0.0826 mC, respectively [4, 5]. Thus, no other forms of the substances were present in measurable amounts. The extinction of the phenolate ion was calculated from the measurements in strongly alkaline solutions and equation (4).

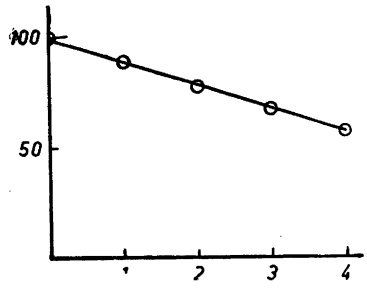

Fig. 5. Methyl salicylate. Extinction at 330 mμ (in per cent) *vs.* time (in hours).

Table 9. Survey of the results of this investigation.

Substance	K_a	pK_a (= 3−log K_a)
PAS	$(1.8 \pm 0.2) \cdot 10^{-11}$	13.74 ± 0.05
Salicylic acid	$(7.6 \pm 0.5) \cdot 10^{-11}$	13.12 ± 0.05
Sulfosalicylic acid	$(1.8 \pm 0.2) \cdot 10^{-9}$	11.74 ± 0.05
o-Hydroxyacetophenone	$(1.5 \pm 0.2) \cdot 10^{-8}$	10.82 ± 0.05
Methyl salicylate	$(6.5 \pm 0.8) \cdot 10^{-8}$	10.19 ± 0.07
Phenol	$(3.0 \pm 0.3) \cdot 10^{-7}$	9.52 ± 0.05
PAS-amide	$(7.7 \pm 0.8) \cdot 10^{-7}$	9.11 ± 0.05
Salicylamide	$(1.3 \pm 0.2) \cdot 10^{-6}$	8.89 ± 0.05
Salicylaldehyde	$(1.6 \pm 0.2) \cdot 10^{-6}$	8.80 ± 0.05

The results of the measurements in solutions of varying alkalinity are given in Tables 4 and 5 for sulfosalicylic acid and PAS, respectively. In these experiments the hydrogen ion concentration was calculated from the ionic product of water.

PAS-amide, salicylamide and methyl salicylate are stronger acids than the two foregoing ones. Here buffer solutions of sodium bicarbonate and sodium hydroxide were used to fix the hydrogen ion concentration. The measurements in these cases were made with the glass electrode or the hydrogen electrode. The results are given in Tables 6—8.

These three substances are not quite stable in alkaline solutions but may be hydrolyzed to the corresponding carbonic acid. If the change in extinction is due to hydrolysis the change is supposed to be slow and should not reverse when the solution is acidified again. The amides were studied in this respect but no change could be found within three hours. When acidified again the calculated extinction value was obtained.

The change in extinction may be due to a dissociation of the amide group. When benzamide was studied no change in extinction could be found even in very strongly alkaline solution. Thus this reaction is improbable.

Methyl salicylate is hydrolyzed more easily under the conditions used here. In order to estimate the speed of this reaction the extinction of one solution in 100 mC NaOH was measured during four hours. In Fig. 5, the decreasing values (in per cent) obtained are shown. For the determination of the dissociation constant more weakly alkaline solutions were used and the extinction was measured within five minutes. During this time the hydrolysis is surely not greater than 1 % and thus does not appreciably influence the results.

All the dissociation constants determined in this work are collected in Table 9.

ACTA CHEMICA SCANDINAVICA 9 (1955) 57—67

Half-Life and Radiations of the Long-Lived Isotope of Niobium (^{94}Nb)

MARIO A. ROLLIER*, EINAR SÆLAND, ARMANDO MORPURGO* and ALBERTINA CAGLIERIS*

Joint Establishment for Nuclear Energy Research, Kjeller, Norway

In order to investigate the half-life and radiation energies of ^{94}Nb, spectroscopically pure metallic niobium was irradiated for 23 days with thermal neutrons in the JEEP pile. The short-lived 6.6 minutes ^{94m}Nb beta activity was confirmed. The bulk of the slow decaying activity is due to ^{182}Ta beta and gamma radiations. Many ways were tried to free efficiently the niobium metal from the tantalum impurity: anion exchange column, coprecipitation of Ta as potassium fluotantalate and Ta/Nb solvent extraction using di-*iso*propyl ketone. Only the last of these proved successful. The residual activity of the purified Nb_2O_5 is very low. From an Al-absorption curve the beta energy can be estimated to be between 0.5 and 0.6 MeV. The gamma spectrum, investigated with a scintillation spectrometer, points to three energies, namely 0.73 MeV, 0.90 MeV and 1.63 MeV. The counting rate of the beta activity, corrected for counting efficiency, indicates a half-life for the ^{94}Nb of $1.77 \cdot 10^4$ years ($\pm$ 25 %).

The formation of a 6.6 minutes activity in neutron irradiated niobium has been reported by several authors [1]. This activity has been ascribed to an isomeric state, ^{94m}Nb, which, except for 0.1% beta decay leading to ^{94m}Mo, decays by gamma emission to a more stable ^{94}Nb. The properties of the latter long-lived nuclide had, until recently, not been observed directly but only inferred from other experimental data. Thus some authors [2] assigned to it a beta decay and a half-life much greater than 100 years, while others [3] indicated a lower limit of the half-life of $5 \cdot 10^4$ years. The aim of the present work, of which a preliminary report has already been given [4], was to investigate the beta emission of the long-lived ^{94}Nb and assign to it a better approximated half-life. The recent work by Douglas, Mewherter and Schuman [5] on the long-lived niobium activity was not known to us, our results obtained independently and with different methods confirm the findings already reported by these authors.

* Istituto di Chimica Generale e Analitica del Politecnico di Milano, Italy.

IRRADIATIONS AND CHEMICAL SEPARATION METHODS

Many pure niobium salts have been irradiated in the JEEP pile and in particular: (a) niobium pentoxide obtained from Kahlbaum's K_2NbF_7, (b) niobium pentoxide obtained by hydrolysing niobium pentachloride of Schuchardt, and (c) spectroscopically pure niobium metal of Johnson &

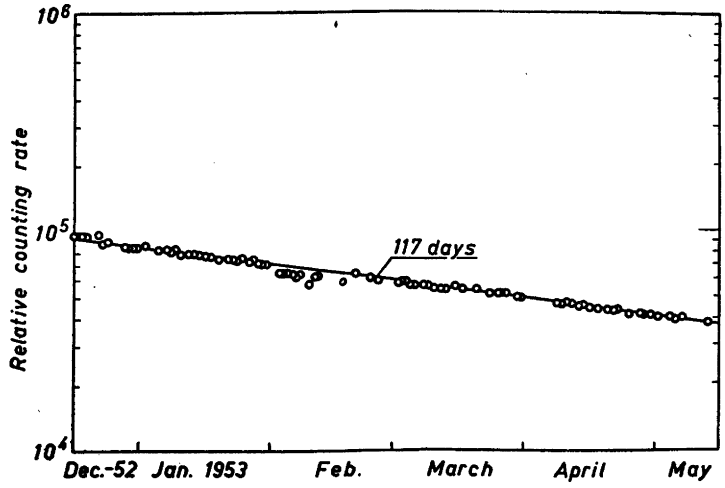

Fig. 2. Decay curve of the irradiated specpure niobium without any previous chemical processing. The 117-day half-life is due to ^{182}Ta.

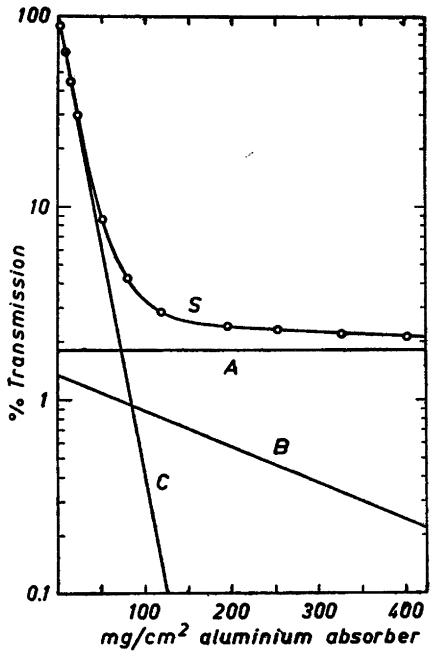

Fig. 3. Aluminium absorption curve of irradiated specpure niobium after (insufficient) ion-exchange purification. S experimental absorption curve, A hard gamma background, B soft gamma, C 0.53 MeV beta activity. (Counting tube Amperex 100 CB, sample-to-window distance 9 mm.)

Matthey. Two irradiations were carried out, a short one of half an hour, in order to follow the decay of the short-lived ^{94m}Nb, and a long one lasting 23 days, in order to accumulate a fairly good amount of the long-lived nuclide.

From the decay curve of a metal sample irradiated for a short time the half-life of the ^{94m}Nb was confirmed, the value being 6.6 minutes (Fig. 1). In the absence of any chemical processing the decay curve, followed for 5 months on a metal sample irradiated for 23 days, was a straight line giving a half-life of 117 days (Fig. 2). This half-life belongs to the 182 tantalum activity. It is easy to draw the conclusion that, owing to the large cross section of 21 barns of natural 181 tantalum (as compared to the cross section of 1.1 barns for the natural occurring niobium) and the respective half-lives of the produced nuclides, this activity should be present, even for a very small tantalum impurity in the spectroscopically pure niobium metal. By a simple activation analysis the tantalum impurity in this sample was found to be of the order of 0.2 %.

It thus appeared necessary to purify the irradiated niobium and this was tried in many ways:

(A) Ion-exchange column. The dissolved niobium (4 g) was treated in an anion-exchange column using a hydrofluoric-hydrochloric solution as elutriant. The process is rather time-consuming. Most of the niobium is collected in the first fractions whereas tantalum is eluted later.

The solid matter contents of one of the first fractions evaporated to dryness still showed an activity that had to be assigned to the ^{182}Ta after an aluminium absorption curve was taken. It has been reported [6] that ^{182}Ta is perhaps the

most prolific emitter of electron lines of all the known radioactive isotopes. A lead absorption curve taken of the activity of this column fraction gave an absorption coefficient $\mu_x = 0.7$ cm^{-1} equivalent to an energy of 1.12 MeV. This is the energy[7] of the most intense λ-radiation emitted by ^{182}Ta. A further purification thus became necessary. One of the first fractions gathered from the ion exchange column was dried, redissolved, a large amount of hydrofluoric solution of pure tantalic acid (H_3TaO_4) added and the tantalum precipitated as potassium fluotantalate. This treatment was repeated twice, a large amount of active tantalum being eliminated in the precipitate. The niobium was precipitated from the filtrate, purified by complexing with oxalic acid [8], and finally precipitated as Nb_2O_5, dried on a Pt disc, and ignited in a crucible for 5 hours. 5 ½ months after the end of the irradiation, a sample thus treated still showed a considerable specific activity. The activity measured was 102 c/m per mg Nb_2O_5 counted on shelf 2 of a standard Geiger-counter sample holder (9 mm sample-to-window distance) using an Amperex tube model 100 CB.

An Al absorption curve, S, was plotted (Fig. 3). After subtracting the hard gamma background, A, (1.12 MeV from ^{182}Ta) two components were left: a component B of 160 mg/cm^2 half-thickness and a beta component C of 14 mg/cm^2 half-thickness. The latter is due to the 0.53 MeV beta activity of ^{182}Ta and the former to the softer λ-radiations from ^{182}Ta.

No new activity from ^{94}Nb was apparent. A second Al absorption curve of the same sample, taken about 4 months later (9 months and 19 days after removal from the reactor) when the specific activity, with the same counter geometry, had reduced to about 49 c/m per mg Nb_2O_5, gave exactly the same results.

(B) A second attempt to free 850 mg of irradiated niobium from ^{182}Ta activity by ten successive additions of decreasing amounts of dissolved natural tantalum, each followed by a tantalum precipitation as K_2TaF_7 yielded no better results. The end product was a niobium pentoxide sample with specific activity, at same geometry, of 87 c/m per mg Nb_2O_5, measured 12 months and 18 days after removal from the reactor.

(C) The decisive results were obtained by the procedure due to Stevenson and Hicks [9], of separating tantalum from niobium by extraction into certain polar organic solvents. The solvent used was di-*iso*propyl ketone. The aqueous solution used was 0.4 *M* HF, 3 *M* HCl, in which irradiated niobium and inactive tantalum, transformed into the respective fluorides, were dissolved. 4 successive extractions were carried out in this way. After the 3rd extraction it seemed difficult to free the precipitate from some chemical impurity introduced during the extractions. The precipitate was therefore purified by complexing the niobium with oxalic acid and treating the solution with concentrated nitric acid and $KBrO_3$. The same purification was performed after the 4th extraction.

14 months after the end of the irradiation the final purified and ignited Nb_2O_5 showed a relative specific activity of 14.3 c/m per mg Nb_2O_5 counted on shelf 1 as compared to 13 000 c/m per mg Nb_2O_5 for the untreated sample. In order to compare these figures with those previously given for the separation methods A and B, it should be noted that 14.3 c/m on shelf 1 is equivalent to 9.5 c/m on shelf 2. The decay of this residual activity was further followed

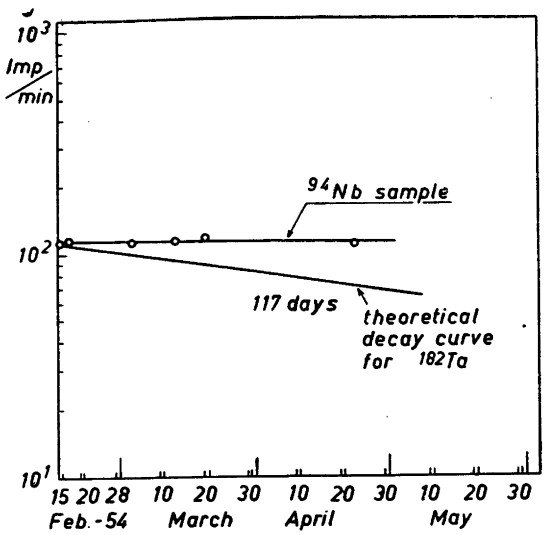

Fig. 4. Decay curve of irradiated niobium purified by solvent extraction (Method C). Constant activity indicates absence of ^{182}Ta.

for more than 2 months but no decrease in the activity (indicating ^{182}Ta) was detectable (Fig. 4).

The radiation energies and half-life of this long-lived activity were then determined in the following way.

ENERGY OF RADIATIONS

An aluminium absorption curve of the residual activity in a Nb_2O_5 sample resulting from the separation method (C) is shown in Fig. 5. The curve indicates a beta component with a half-thickness in Al of about 15.5 mg/cm^2 corresponding to a beta energy of 0.5—0.6 MeV (*cf.*[10]). No very exact determination of the beta energy was attempted because of the weakness of the sample which made difficult the correction for the contribution of the hard component measuring only a few counts per minute.

The gamma activity was first roughly checked by an ordinary gamma scintillation counter. A lead absorption curve indicated a gamma energy of about 0.9 MeV. The detailed investigation of the gamma spectrum was done by Dr. E. Germagnoli first at Kjeller and later at the laboratories of C. I. S. E., Milan, Italy. The final results were obtained using a 1'' NaI crystal, a phototube Dumont, a model 100 (Los Alamos type) linear amplifier and the 99 channel built by Gatti [11].

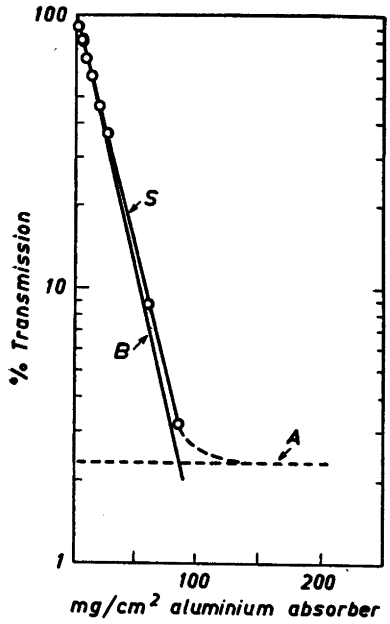

Fig. 5. Aluminium absorption of the sample purified by solvent extraction. S experimental absorption curve, A ~ 2.5 % gamma contribution, B beta contribution probably due to ^{94}Nb. (Counting tube Amperex 100 NB, sample-to-window distance 14.5 mm.)

The scintillation spectrogram obtained is shown in Fig. 6 a and the energy calibration by means of the radiations from ^{60}Co and ^{137}Cs in Fig. 6 b. The following gamma energies are found:

$$E_1 = 0.726 \text{ MeV}$$
$$E_2 = 0.903 \text{ MeV}$$
$$E_3 = 1.65 \text{ MeV (measured)}$$
$$1.63 \text{ MeV (as } E_1 + E_2)$$

These results are in good agreement with the values obtained by Douglas, Mewherter and Schuman [5], namely: $E_\beta = 0.50 \pm 0.05$ MeV, $E_1 = 0.70 \pm 0.01$ MeV, $E_2 = 0.87 \pm 0.01$ MeV and $E_3 = 1.57 \pm 0.02$ MeV.

SPECIFIC ACTIVITY AND HALF-LIFE

The knowledge of the absolute disintegration rate of the sample containing long-lived ^{94}Nb is needed for its half-life determination.

The absolute beta counting, using an end-window Geiger tube, was carried out according to the procedures described by Zumwalt and Burtt and computing the absolute number of disintegrations per minute (d/m) according to the well known formula [12, 13].

$$\text{d/m} = \frac{(\text{c/m})_{\text{extrap.}} \cdot 100}{G \cdot f_A \cdot f_B \cdot f_H \cdot f_{ssa}}$$

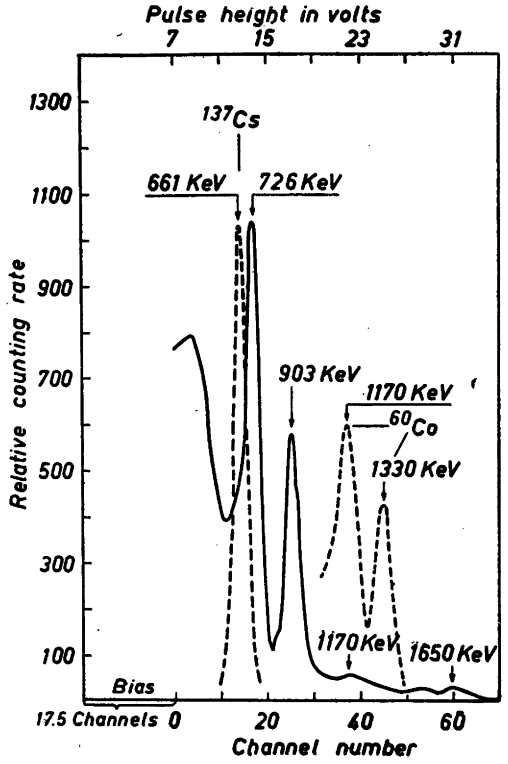

Fig. 6 a. Scintillation spectrogram of gamma radiation from irradiated niobium purified by solvent extraction (Method C). The dotted lines give the peaks of ^{137}Cs and ^{60}Co which were used as references.

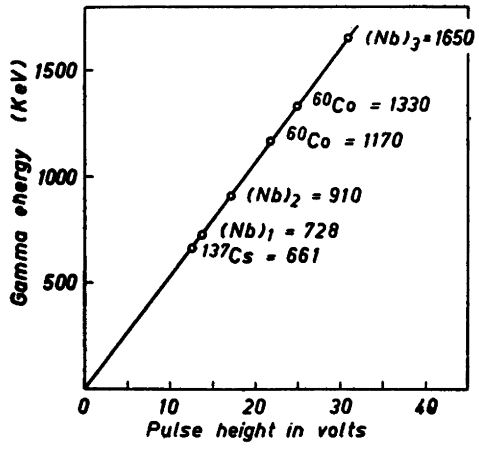

Fig. 6 b. Calibration curve used for the scintillation spectrogram giving the gamma energy as a function of pulse height.

where:

$(c/m)_{extrap.}$ = observed counts per minute corrected for coincidence and background and extrapolated from an Al absorption curve to zero absorber.

G = geometry of the counting set up.

f_A = factor for the effect of air in scattering beta particles into the counter.

f_B = factor for the increase in counting rate due to backscattering by the material supporting the source.

f_H = housing effect (support and walls of source housing).

f_{ssa} = correction factor for the self-scattering and self-absorption due to thickness of sample.

The 12.1 mg sample counted in Milan with an Amperex 100 CB end-window tube gave an observed counting rate of 113.36 c/m at 9 mm sample-to-window distance. No gammas were detected during this measurement owing to the low sample activity. Introducing the theoretical correction factors [12, 13] the value of 875 d/m for the absolute disintegration rate of the sample was first obtained and from this a half-life of $2.7 \cdot 10^4$ years was computed and reported in our preliminary communication [4]. Intercomparison of the same sample and countings performed at Kjeller lead to the qualitative detection of the gamma radiation and also revealed that a too high counting efficiency had been assumed for the counting performed in Milan. After a careful check we had to assign an overall counting efficiency of only 8.26 % for this measurement. This gives for the absolute disintegration rate of the 12.1 mg sample:

$$\mathrm{d/m} = \frac{113.36 \cdot 100}{8.26} - 2.5\ \% = 1\,337$$

where the 2.5 % subtracted is due to the gamma activity.

The specific activity, S, in curies per g of the target niobium metal, freed from any other activity due to impurities is given by:

$$S = \frac{(\mathrm{d/m}) \cdot 10^3}{60 \cdot a \cdot 3.7 \cdot 10^{10}}$$

where a (= mg Nb of measured sample) is obtained subtracting 2 % (due to inactive Ta_2O_5 left from the ketone extraction) from the sample weight and multiplying by the factor 0.7 (as Nb_2O_5 contains 70 % Nb). This gives $a = 8.29$, thus

$$S = \frac{1.337 \cdot 10^6}{60 \cdot 8.29 \cdot 3.7 \cdot 10^{10}} = 7.25 \cdot 10^{-8}\ \text{curies/gram}$$

For active nuclides whose half-life, as in this case, is long compared to the irradiation time, the simplified formula for calculating the half-life is:

$$T_d = \frac{1.136\ \sigma\ F\ t}{A\ S}$$

where

T_d = half-life in days of the nuclide formed
t = irradiation time in days
F = neutron flux in neutrons per cm^2 per second $\times 10^{-11}$
σ = activation cross section in barns = 1.1 [14]
S = specific activity in curies/gram of the target element on removal from the pile
A = atomic weight of the element = 93

The average flux during the 23 days irradiation was $1.5 \cdot 10^{11}$ n cm^{-2}sec^{-1} thus:

$$T_d = \frac{1.136 \cdot 1.1 \cdot 1.5 \cdot 23}{93 \cdot 7.25 \cdot 10^{-8}} = 6.4 \cdot 10^6 \text{ days}$$

corresponding to a half-life of $1.77 \cdot 10^4$ years.

Taking into account the approximate values used it is safe to assume that the half-life of ^{94}Nb is not determined with an accuracy greater than $\pm$ 25 %. The value found is in good agreement with the value of $(2.2 \pm 0.5) \cdot 10^4$ years proposed by Douglas, Mewherter and Schuman [5].

EXPERIMENTAL

(A) The ion-exchange column used with hydrofluoric elutriant solution was made of plastic tubing of 3 mm diameter, 7.1 mm^2 cross section and 450 mm length. The ion-exchange resin was Dowex No. 1. A small finely perforated platinum disc closed the bottom of the column and held the resin. All the tubing was made of polyvinyl plastic and the containers of polythene. In front of the column, driven by a small electric motor so that it could move along the whole length of the column in about 15 minutes time, was a Geiger counter connected with a scaler, rate-meter and a Brown recorder. This made possible the automatic recording of the activity as a function of the position in the column. The ion-exchange resin was converted to the chloride form and the niobium contaminated with tantalum activity was added in the form of niobium chloride solution. Up to 150 mg of $NbCl_5$ were added at a time. This ion-exchange process has already been described elsewhere [15]. For the solution used (9 M HCl, 0.5 M HF) the elution constants were:

$$E_{Nb} = 70 \qquad E_{Ta} = 5$$

so that the ratio was $E_{Nb}/E_{Ta} = 14$

in which $E = d \times A/V$, where d = length in cm covered by activity maximum after V ml of elutriant have passed through a column the cross section of which is A cm^2. A lead screen provided with a small central slit, was mounted on the Geiger counter window. The motor was provided with a reverse gear and a speed reductor. The fractions were collected in polythene containers in which they were dried under a heat-lamp, treated many times with HCl in order to get rid of the hydrofluoric acid, and then mounted on standard watch glasses and counted. The elution speed was kept at about 1 ml in 20 minutes. In a second ion-exchange column of 7 mm diameter and 38.5 mm^2 cross section the elution speed was kept at 8 ml for 30 minutes. The automatically recorded elution curves are collected in Fig. 7.

The precipitation of 182 tantalum with pure natural tantalum as a carrier was carried out collecting the fractions containing niobium from the ion-exchange procedure. These fractions were dried and then dissolved in 1/1 solution of conc. HNO_3 and H_2F_2. To this solution a hydrofluoric solution of pure H_2TaO_4 was added and the tantalum then precipitated as potassium fluotantalate by addition of KHF_2. The precipitate was centrifuged and the solution treated a second time in the same way.

Fig. 7. Automatically recorded activities of the ion-exchange column containing 182 tantalum. The number near each curve indicates the number of hours elapsed from the beginning of the elution, till the moment the column was recorded.

The first precipitate was very active as measured with a GM-survey meter, the second one much less so. After the tantalum precipitation the acidic niobium solution was neutralized with ammonium hydroxide, in order to precipitate the niobic acid $HNbO_3$. This was centrifuged and thoroughly washed with ammonium hydroxide and water. The precipitate was then dissolved in 2 ml of saturated oxalic acid solution to which 10 drops of concentrated nitric acid had been added. The complexing action of oxalic acid on niobium leads to a complex of the type $M_3(NbO(C_2O_4)_3)$ which is often hydrated. In this case the soluble acid complex $H_3(NbO(C_2O_4)_3)$ is found which is hydrated with a number of water molecules ranging from 1 to 4. The complex is stable in the presence of an excess of oxalic ions, but it is easily hydrolyzed and Nb_2O_5 is precipitated when these are destroyed. In order to obtain this result 1 g of $KBrO_3$ was added and the precipitated niobic acid was centrifuged, washed with 6 *N* HNO_3, with 6 *N* NH_4OH and with distilled water. A fraction of this precipitate was slurried over a platinum disc, dried with a heat-lamp and then calcinated. The thin film of Nb_2O_5 left was heated for 3 hours at a light red heat in a furnace to get rid of all possible volatile impurities.

(C) The only successful Ta/Nb separation was carried out by extraction with di-*iso*-propyl ketone using a technical grade reagent from the British Drug Houses Ltd. Stevenson and Hicks [9] reported that tantalum goes into the organic layer and that, starting with equal amounts of Ta and Nb, the precipitate from the aqueous layer after one extraction contains 98 % Nb and 2 % Ta as the pentoxides.

In our first extraction 200 mg irradiated niobium metal were fluorinated with conc. HF and 7 *M* HNO_3, dried, and 90 mg Ta added in the form of TaF_5 (made from Kahlbaum's K_2TaF_7). The fluorides were dissolved in 50 ml 0.4 *M* HF, 3 *M* HCl solution and extracted twice with 40 ml di-*iso*propyl ketone. The organic layer was discarded, and the aqueous layer added to 4 ml saturated H_3BO_3 solution in a centrifuge cone, in order to complex any fluoride present. Ammonium hydroxide was added to precipitate the hydrated oxide

of niobium. This was washed with diluted NH_4NO_3 solution, centrifuged and dissolved again in 25 ml 0.4 *M* HF, 3 *M* HCl solution in which 45 mg Ta were also dissolved. The second extraction was carried out with 2 times 25 ml of di-*iso*propyl ketone, and the precipitation from the aqueous layer repeated. The 3rd extraction was performed adding 30 mg Ta, dissolving in 15 ml acid solution, and extracting twice with 15 ml ketone.

The precipitate from the 3rd extraction was purified by complexing with oxalic acid, as mentioned earlier, (p. 60), and ignited. From this Nb_2O_5 a sample containing 15 mg Nb was fluorinated again, 15 mg Ta in the form of TaF_5 added, and both dissolved in 7.5 ml 0.4 *M* HF, 3 *M* HCl solution. For the 4th extraction the solution was treated twice with 7.5 ml ketone and the whole procedure repeated, including purification by complexing with oxalic acid. The sample was carefully ignited on a platinum disc before being transferred to an aluminium disc for beta counting. Using the data of Stevenson and Hicks [9] we calculate the composition of the final sample to be 97.9 % Nb and 2.1 % Ta. This is taken into account when calculating the specific activity of the niobium from the activity of the sample.

This work was carried out partly at the Joint Establishment for Nuclear Energy Research, (J. E. N. E. R.) Kjeller, Norway and partly at the Polytechnic, Milan, Italy. The stay of one of us (M. A. Rollier) at Kjeller was made possible by a fellowship from the *Italian National Research Council.* The equipment at Milan Polytechnic was purchased partly by private (SNIA and Ing. G. Cesoni) and partly by *National Research Council* grants: the kind interest of these private and public organisations is gratefully acknowledged.

The authors wish to give special thanks to Dr. E. Germagnoli, C. I. S. E., Milan for carrying out the measurements with the scintillation spectrometer and to Mrs. M. Lykaas and Mr. K. Samsahl, both of J. E. N. E. R., for helpful assistance in various parts of the work.

Magnetic Measurements on Crystallized Fe-Transferrin Isolated from the Blood Plasma of Swine

ANDERS EHRENBERG and CARL-BERTIL LAURELL

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The paramagnetic susceptibility of the iron in Fe-transferrin is determined to be 15 700 ($\pm$ 500) · 10^{-6} cgs emu at 20° C, which corresponds to an effective magnetic moment of 6.08 ($\pm$ 0.10) Bohr magnetons. The iron is thus trivalent and bound with essentially ionic bonds. Some magnetic interaction between the two iron atoms in each protein molecule is possible. After reduction and decolorisation with hydrosulfite the iron is present as free or bound divalent ions with an effective moment of 5.1 Bohr magnetons. The diamagnetic gram susceptibility of transferrin was determined to be -0.586 ($\pm$ 0.007) · 10^{-6} cgs emu.

The biochemical and physico-chemical properties of the serum protein, transferrin (siderophilin), and its role as an iron transporting factor in blood have recently been reviewed [1]. The molecular weight of transferrin is about 90 000 [2,3], and it is capable of reversible combination [2,4,5] with two atoms of iron per molecule of protein [2,3,6]. The compound between iron and transferrin, Fe-transferrin, is optically characterized by a relatively broad absorption band with its maximum at 470 mμ. The formation of Fe-transferrin when di- or trivalent ionic iron is added to a solution of transferrin can thus be followed colorimetrically. Such experiments disclose the interesting fact that in plasma under aerobic conditions the Fe-transferrin is formed more rapidly with ferrous than with ferric ions [5], while in solutions of purified transferrin the ferric ions react faster than the ferrous ions do [4,6,7]. Colorimetrically judged the formed compound is identical in all these cases. The effect might be due to different rates of autoxidation of ferrous iron [6].

Since most chemical evidence points in the direction that the iron of Fe-transferrin is trivalent, this is commonly believed to be the case. No direct proof of this hypothesis has yet been obtained, and the mode of binding of iron in Fe-transferrin is still obscure. Michaelis, however, made magnetic measurements on Fe-transferrin, but his results are only published as a personal communication to Koechlin [6] and no experimental data are given. Koechlin simply states that Michaelis had found the iron to be trivalent in the red complex, and that he also had found "that hydrosulfite reduced the ferric iron and dis-

charged the red color in the complex at reactions where dissociation of the complex would not normally have occurred".

For further discussion of the role of transferrin in the iron transporting mechanism of the blood it is important to know as much as possible about the state of iron in the compound, Fe-transferrin. As the above statements are only qualitative in nature, we have reinvestigated the magnetic properties of Fe-transferrin in a highly purified form.

MATERIAL AND METHODS

Iron-saturated Fe-transferrin was prepared from swine plasma according to Laurell [8] and recrystallized four to six times. During the steps of the preparation, which were performed at a pH below 6, a small amount of ferrous ammonium sulfate was added to prevent dissociation of the Fe-transferrin compound. The excess of iron was eliminated during the later preparative steps. Since it was difficult to remove all of the non-specifically bound iron in this way, one sample (No. 2) was run through a column containing the ion exchange resin, IRA 120, pretreated with $M/15$ phosphate buffer of pH 7.8. In this way the iron content was brought to 0.125 %. An iron content of 0.124 % is to be expected from a molecular weight of 90 000 and two atoms of iron per molecule. The other samples contained 0.127 to 0.134 % iron (See Table 1). The recrystallizations were repeated until no more hemi-muco-β-globulin could be spectrophotometrically detected [8].

To get iron-free transferrin for the determination of its diamagnetism, one sample of Fe-transferrin was dialysed at pH 3.5 in the presence of cysteine and *o*-phenanthroline. After twenty-four hours all the iron was in the form of the ferrous *o*-phenanthroline complex, which was dialysed away against glass-distilled water.

All samples were analysed for dry weight (at 110° C) and for iron. For the iron determinations two colorimetric methods were used, with sulfo-salicylic acid or with *o*-phenanthroline as complexing agents. They gave closely agreeing values in all cases.

The extinction values were determined in a Beckman spectrophotometer, Model DU. The magnetic measurements were carried out with the apparatus constructed by Theorell and Ehrenberg and a solution of nickel chloride was used as calibration agent [9]. All measurements were made in the temperature range 20 to 22° C.

RESULTS

Four samples of Fe-transferrin from different preparations were investigated for the paramagnetism of the iron by measurements on their salt-free solutions. The results are given in Table 1 together with the characteristics of the samples. The extinction at 470 mμ is proportional to the amount of specifically bound iron. Sample *2* contains practically all of its iron as Fe-transferrin compound. Samples *3* and *4* are saturated with specifically bound iron and contain above that level respectively 2.9 and 9.0 % of iron non-specifically bound to the protein. Sample *1* may be impure or partly denatured since, according to the extinction value, 9 % of its specific sites are unoccupied by iron in spite of an iron content slightly above the theoretical saturation level.

The susceptibility values are calculated per gram atom of iron and reduced to 293° K with the assumption that Curie's law is valid. The spreading of the separate determinations on every sample gives a standard deviation of the mean of about $\pm 150 \cdot 10^{-6}$ cgs emu. Another error of $\pm 350 \cdot 10^{-6}$ cgs emu is due to uncertainties in the diamagnetic correction and has the same sign in all determinations. As is seen, the different and small amounts of non-specifically bound iron do not influence the average susceptibility to any detect-

ible extent. The non-specifically bound iron has thus much the same susceptibility as the specifically bound. As a mean value of the susceptibility of the iron in Fe-transferrin we accept 15 700 ($\pm$ 500) $\cdot$ 10^{-6} cgs emu at 293° K. This corresponds to an effective magnetic moment, μ_{eff} = 6.08 ($\pm$ 0.10) Bohr magnetons. Preliminary measurements on three samples, containing slightly less iron than those described in the table, also indicated a μ_{eff} of about 6.1. No foreign heavy metal ions that could contribute to the paramagnetism of the solution could be detected by common chemical methods.

One part of sample No. *4* was diluted with phosphate buffer of pH 6.5 to final concentrations of 3.19 % protein and *M*/30 phosphate. When hydrosulfite, 5 mg per ml solution, was added, the solution started to decolorize rather slowly. The extinction values in the wavelength region, 420—600 mμ, decreased in proportion. The process could not be followed to the end as turbidity occurred. When the extinction at 470 mμ had diminished to 50 %, the solution, which was still clear, was measured in the magnet. The result showed that the decolorized iron had a susceptibility of 11 000 $\cdot$ 10^{-6} cgs emu corresponding to μ_{eff} = 5.1 Bohr magnetons.

Table 1.

Sample No.	Protein conc. mg/ml	Fe conc. γ/ml	Fe/protein ‰	$\beta_{470m\mu} \times 10^{-7}$ cm²/g AtFe	Number of magnetic determ.	$\chi_{Fe,\ 293°\ K}$ 10^{-6} cgs emu
1	27.3	34.7	1.27	0.486	4	15 900
2	22.7	28.4	1.25	0.556	4	15 500
3	44.5	56.4	1.27	0.540	4	15 800
4	63.8	85.2	1.34	0.506	3	15 600

The diamagnetism of the protein was determined by a series of five measurements on an "iron free" sample with 21.4 mg protein per ml and 2.0 γ iron per ml. The mean difference reading on the micrometer could be used immediately for diamagnetic correction of the readings in the experiments already described, if the iron contents were properly reduced because of the small but not negligible iron content of the "iron free" sample. To evaluate the true diamagnetism of the protein we have corrected for the paramagnetic contribution of this iron. For the partial specific volume of transferrin we take the figure 0.725, determined by Oncley, Scatchard and Brown [10] on a 70 % pure material. If we assume that Wiedemann's additivity law is applicable and that the gram susceptibility of water is equal to —0.7200 $\cdot$ 10^{-6} cgs emu we find the gram susceptibility of transferrin to be —0.586 ($\pm$ 0.007) $\cdot$ 10^{-6} cgs emu at 293° K. A small correction has been made, due to the physically dissolved oxygen, but it does not amount to more than one unit in the third decimal.

DISCUSSION

As already mentioned the transferrin molecule is capable of combining with two atoms of iron. There is some doubt whether this reaction takes place in one step or two, or, whether the active sites of the molecule are close enough

to each other to bring about an interaction between them [11]. Different possible structures have to be proposed and their theoretical magnetic moment has to be compared with the value $\mu_{eff} = 6.08$ ($\pm$ 0.10) B. m. (Bohr magnetons) obtained in the present investigation.

We first assume that *no interaction* exists between the two iron atoms bound to the same protein molecule. In this case the possibility of divalent iron can be ruled out at once, as it would exhibit a maximal effective moment of 4.90 B. m. or slightly higher, due to incomplete quenching of the orbital moment. All experimental values of μ_{eff} of ionic ferrous iron in magnetically dilute solids or solutions lie between 5.1 and 5.6 B. m., which is definitely lower than the 6.08 B. m. of Fe-transferrin. Ferric iron, however, would give $\mu_{eff} = 5.92$ B. m., if it is bound with essentially ionic bonds. Experimental values are often close to that figure, but usually lower, probably due to deviations from the Curie law. Higher values seem to be rare, if any. Because of the small difference between 6.08 ($\pm$ 0.10) B. m. and 5.92 B. m. a structure with ionic trivalent iron is rather possible in the case of Fe-transferrin.

The other extreme possibility is that *complete magnetic coupling* occurs between the two iron atoms in Fe-transferrin. This means that they can be treated as an entity and, if the electronic spins only are magnetically active, the effective magnetic moment per iron atom can be calculated according to the formula $\mu_{eff} = \sqrt{\frac{1}{2} n(n+2)}$ B. m., where n is the total number of odd electrons in the entity. Two trivalent iron atoms with five odd electrons each would thus give $\mu_{eff} = \sqrt{60} = 7.75$ B. m. The large difference between this figure and the experimental one makes the proposed structure improbable. Two trivalent iron atoms, one with five and one with three odd electrons, or two divalent iron atoms with four odd electrons each would both give $\mu_{eff} = 6.33$ B. m. Since the orbital contribution has been overlooked, the figure 6.33 is probably somewhat too low but anyhow close enough to the experimental value to require discussion. The strong magnetic coupling assumed here calls for a rather compact and stable structure, especially in the case of trivalent iron, where a kind of resonance between the iron atoms must be postulated. Such a stable structure is not easy to reconcile with the fact that the combination between iron and transferrin is an easily reversible reaction. From a chemical point of view the case of divalent iron is further improbable. On these grounds we believe that strong interaction does not occur between the iron atoms of Fe-transferrin.

The best explanation of the experimental value $\mu_{eff} = 6.08$ ($\pm$ 0.10) B. m. seems to be that the iron in Fe-transferrin is trivalent and bound with essentially ionic bonds. The fact that the observed value is higher than the expected one of 5.92 B. m. might be interpreted as due to a weak interaction between the two iron atoms in each protein molecule, which in such a case may not be situated too far from each other. To illuminate the proposed interaction further magnetic measurements over a temperature range and detailed studies of the coupling reaction between ionic iron and transferrin are highly desirable.

The value $\mu_{eff} = 5.1$ B. m. obtained for the iron after decolorisation is just what would be expected for divalent ionic iron. We can thus state that if transferrin forms a compound with ferrous iron, it is either uncolored and ionic or it is unstable in the presence of phosphate ions at pH 6.5.

The authors wish to thank Professor H. Theorell for his interest in the work and one of us (A. E.) is indebted to *Magnus Bergvalls Stiftelse* for financial support.

Studies on Arsenic Trichloride as a Solvent

II. On the Constitution of Solutions in Arsenic Trichloride

INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The importance of ionic transfer processes in acid-base reactions in $AsCl_3$ is discussed, and the way in which they differ from Lewis' acid-base concept is pointed out. A program for experimental studies to explore the constitution of solutions in arsenic trichloride is suggested. It is partly based on a discussion of the possible similarities with aqueous solutions.

ACID-BASE CONCEPT

In connection with studies on non-aqueous solvents three main acid-base concepts have been advanced: the solvent system concept, the protonic concept and the electronic theory. They are excellently reviewed by Audrieth and Kleinberg [1] in the book "Non-aqueous solvents". In a recent paper [2] a development has been made of the solvent system concept, focussing the interest on the ionic transfer processes possible in different solvents. This represents at the same time an extension of the protonic concept to non-protonic solvents. Flood's [3] treatment of oxide melts is also included.

The new concept defines acids and bases in $AsCl_3$ in the following way: acid + Cl^- = base (*cf.* acid = base + H^+) *or* base + solvent = acid + Cl^- (*cf.* acid + solvent = base + H^+ in some cases [5]).

$AsCl_3$ is an ampholytic solvent and can react as an acid as well as a base: $AsCl_3 + Cl^- = AsCl_4^-$ and $AsCl_3 = AsCl_2^+ + Cl^-$. It has therefore a characteristic auto-ionization: $2\ AsCl_3 = AsCl_2^+ + AsCl_4^-$, which is the basis for the solvent system definition.

$AsCl_4^-$ evidently corresponds to H_3O^+ in aqueous solutions and when the discussion is limited to $AsCl_3$ solutions we can therefore use the term Cl^- in the same way as we use H^+ in aqueous solutions.

Acids will decrease and bases will increase the Cl^- concentration in $AsCl_3$ (*cf.* the H^+ concentration in aqueous solutions).

Examples of acids are $FeCl_3$ and $SnCl_4$ which can form the ions $FeCl_4^-$ and $SnCl_6^{2-}$ and thus consume Cl^- ions.

A typical base is $(CH_3)_4NCl$ which as a salt contributes Cl^- ions to the solution. Another base to be discussed later is pyridine.

The new concept is more to be considered as a *method* for a *unified treatment* of what we call *acid-base reactions* in non-aqueous solvents and salt melts than as a contribution to the discussion of the *formal definition* of *acids and bases*. For that purpose there exist more symmetrical definitions [4] which, however, are purely formal.

It is of particular interest to compare the new concept with Lewis' theory, according to which an acid is an electron pair acceptor, a base is an electron pair donor. The difference in the two concepts is best shown in the two different ways of considering the reaction between pyridine and arsenic trichloride:

$$C_5H_5N: + AsCl_3 = C_5H_5N:AsCl_3 = C_5H_5N:AsCl_2^+ + Cl^-$$

The acid-base process is here, according to Lewis, the first step, that is *the formation of an electron pair bond*. That reaction would not change the Cl^- concentration in $AsCl_3$, however. The acid-base process described as *a transfer of chloride ions* would obviously be the second step.

The two definitions evidently have different aims. The reactions included in the Lewis theory are the same as those which cause the colour changes of indicators. The new concept on the other hand focuses interest on the transfer processes of ions, which can be studied indirectly with indicators but more directly with electrochemical methods.

THE EXPERIMENTAL STUDY OF IONIC TRANSFER PROCESSES

If the chloride ion transfer is the fundamental reaction in $AsCl_3$ there must exist $AsCl_2^+$ and $AsCl_4^-$ ions. The existence of such ions has only been proved indirectly and we have no knowledge of their structures.

The simplest indirect experimental evidence is obtained by preparations of compounds that may contain those groups. Thus the compound $AsSbCl_8$ has been interpreted as $AsCl_2SbCl_6$ [7], and the formula $(CH_3)_4NAsCl_4$ [7] as an indication of the presence of a $AsCl_4^-$ ion. These ideas have also been checked by conductometric neutralisation titrations [7], and must be considered to be well founded, although not conclusively so. Successive heating of the compound $(CH_3)_4NAsCl_4 \cdot 2\ AsCl_3$ also indicates that one $AsCl_3$ is more strongly bound than the two others [8].

If we thus confidently assume the existence of groups $AsCl_2^+$ and $AsCl_4^-$ it remains to be found whether there is any sense in speaking of a Cl^- concentration in $AsCl_3$. The existence of a pCl value is a condition for a successful quantitative application of the set of formulae already developed in the Brönsted theory to describe protolytic processes. In H_2O the pH values can be determined by electrochemical methods and the analogy would demand the possibility of determining pCl in a similar way. The problem is of course to find a reversible Cl^- sensitive electrode. AgCl is classified as very slightly soluble in $AsCl_3$ [7] and the possibility is then given of measuring concentration elements in $AsCl_3$. The cell would be

$$Ag,\ AgCl \mid Cl^-\ (C_1)\ in\ AsCl_3 \parallel Cl^-\ (C_2)\ in\ AsCl_3 \mid AgCl,\ Ag$$

Such measurements have been made and will be reported in a following paper [9]. It is a difficult task to determine Cl^- concentrations in this way because of the large activity correction connected with the low dielectric constants of $AsCl_3$. ($SeOCl_2$ would be a more suitable solvent for exact investigations.) The shape of titration curves, pCl (emf.) against acid added to a base, show, however, without doubt the analogy with pH measurements in water. It also proves the existence of a defined ionic product $C_{AsCl_4^+} \cdot C_{AsCl_4^-} = K$, characteristic for auto-ionized solvents.

Measurements of electrical conductivity have mostly been used in connection with conductometric titrations [7], but an effort has recently been made to prove the validity of the Onsager-Debye-Hückel theory for a strong electrolyte in $AsCl_3$ and to determine the acidity constants of some weak acids (V. Gutmann [10]). Determinations of transference numbers would also be of interest. Of course, measurements of all kinds of osmotic properties would give interesting information, too.

Studies of frequency shifts in As—Cl vibration spectra with different methods might give valuable indications about the degree of association in liquid $AsCl_3$ and about the interaction between acids or bases and $AsCl_3$.

COMPARISON WITH WATER AND AQUEOUS SOLUTIONS

The preliminary experimental investigations indicate the importance of chloride ion transfer in acid-base reactions in $AsCl_3$. The effect on pCl can be considered as a formal expression of an ionic transfer process but does not give any information about the mechanism of the transfer. An atomistic description of the constitution of $AsCl_3$ solution has still to be given. No structural work has as yet been done but a comparison with water and aqueous solutions may lead to a crude hypothetical picture apt to incite essential experimental studies.

The present state of knowledge about water and the compounds obtained from aqueous solutions is here briefly summarized for the purpose of comparison without any pretentions of completeness.

The structure of ice is well established. Each oxygen atom is surrounded tetrahedrally by four others. (This low coordination may be compared with 12 for dense packing.) The hydrogen atoms are distributed between the oxygen atoms, two hydrogen atoms being closely associated with each oxygen atom. The O—H...O bond is called a hydrogen bond.

When ice melts the lattice is partly broken down [11, 12], because part of the hydrogen bonds are broken [11, 12] or bent [13]. As a result of the partial dense packing, the average coordination number of oxygen is increased [11] from 4 to 4.9 at 80° C. The resulting differential increase of density is compensated at 4° C by the thermal expansion which makes the average distances longer. There is no doubt about the association of the water molecules to an ice-like structure, it may then be described as a "broken down ice structure" [11] or as a "network of pliable, branched chains of tetrahedra" [12].

The crystal structures of the compounds $HNO_3 \cdot H_2O$[14] and $HNO_3 \cdot 3\,H_2O$[15] show that there are hydrogen bonds between oxygen atoms in the nitrate groups and the water molecules. It has even been possible to prove the complete proton transfer from HNO_3 to H_2O in $HNO_3 \cdot 3\,H_2O$. The structure

suggested for aqueous HNO_3 solutions [16] is not quite in agreement with the structure found in the solid state. The discrepancy is probably due to the fact that Finbak [16] has overemphasized the importance of the tetrahedral coordination around the water molecules. In the solid state water molecules are found, which actually have triangular coordination [14, 15]. The assumption of an arrangement of the H_2O molecules around HNO_3 in such a way as to permit a proton transfer from HNO_3 to H_2O along hydrogen bonds is not influenced by this discrepancy. In dilute solutions of the strong acid HNO_3 the proton transfer is complete while only part of the protons are transferred from a weak acid to H_2O (or hydrogen bonds are formed with other acid molecules). The hydrogen bonds have of course a dynamical character in solutions, they are broken and redistributed and there is an average number of hydrogen bonds [12] determined by the temperature and by the nature and concentration of the solute.

In the same way NH_3 molecules form hydrogen bonds with the water molecules along which protons are partly transferred from H_2O to NH_3 forming NH_4^+ and OH^- ions.

An addition of acid evidently results in an excess of protons in the water structure, symbolized as H_3O^+. In a similar way a base gives rise to a proton deficiency symbolized as OH^-. The pH value of a solution is dependent on this proton excess or proton deficiency.

The arrangement of water molecules around ions which do not function as acids or bases has been extensivily studied in the solid state structures of salt hydrates. It has been shown in an excellent review [17] that the water molecule does not exhibit any tetrahedral character in such compounds but demonstrates one positive and one negative side. The hydration of ions in aqueous solutions is usually explained in a similar way. In the case of large ions with small charges, such as Cs^+, the water molecules around the ion will still belong to the water structure. With decreasing size or increasing charge hydrated ions such as $Mg(H_2O)_6^{2+}$ are formed. A further change will lead to a proton repulsion as in the case of Al^{3+}, causing the acidic properties of an $AlCl_3$ solution.

It seems as if proton transfer is intimately connected with the existence of hydrogen bonds along which the transfer can take place without any other structural changes. There are, however, acid-base reactions which involve drastic structural changes: $7\ MoO_4^{2-} + 8\ H^+ = Mo_7O_{24}^{6-} + 4\ H_2O$.

The existence of hydrogen bonds may be considered as due to the smallness of the proton which makes any other oxygen coordination than two around the protons very little probable. The hydrogen bond thus cannot be expected necessarily to have an analogy in other ionic transfer processes.

As a basis for discussion of the constitution of $AsCl_3$ solutions we have no more knowledge than of the structure of the free $AsCl_3$ molecule [18], a pyramid with the As—Cl distances 2.16 ± 0.03 Å and the Cl—As—Cl angles $103 \pm 3°$. It can also be described as a slightly distorted tetrahedron with one vacant position. The cohesive forces in the solid $AsCl_3$ are probably determined by the interaction between such molecules. It would therefore be interesting to know the coordination around an $AsCl_3$ molecule and whether the structure is such as to permit the existence of chlorine bonds and thus ionic transfer (at the autoionization) without any other structural changes. It is easy to derive such

structures making different assumptions, but it is not worth-while to discuss them all because they are quite arbitrarily obtained. To demonstrate the principles one single case will be mentioned, namely the formation of chains of distorted $AsCl_4$ tetrahedra in the structure. That would include chlorine bonds from one arsenic atom to the other

$$\begin{matrix} & Cl & & Cl & & Cl & \\ \ldots Cl- & As & \ldots Cl- & As & \ldots Cl- & As & . \\ & Cl & & Cl & & Cl & \end{matrix}$$

Formation of $AsCl_2^+$ and $AsCl_4^-$ would then be possible by a simple transfer process without any further structural changes.

For many reasons this hypothesis is not very probable. It is recognized that the lone electron pair in $AsCl_3$ is of importance for the structure, and it is often arbitrarily assumed to be situated in the fourth corner of the tetrahedron Cl
:As—Cl. In the same way the structure of $AsCl_4^-$ would be determined by the Cl
following electron distribution  and thus have a trigonal bipyr-

amidal structure with one vacant position and not a tetrahedral structure.

Only structure determinations can give a definite answer to this problem and thus indirectly to the question how a chloride ion excess or deficiency is distributed in the liquid structure.

Comparison with the structures of some other solid non-aqueous solvents supports, however, the idea that chlorine bonds do not exist. If the structure of the solids is mainly preserved in the liquid state ionic transfer without other structural changes is not possible in SO_2[19] or $COCl_2$[20].

A consideration of the solution of $SnCl_4$ in $AsCl_3$ will give further aspects of the problem. The $SnCl_4$ molecule has a tetrahedral structure and must increase its coordination to an octahedral structure in the acid-base reaction $SnCl_4 + 2AsCl_3 = SnCl_6^{2-} + 2AsCl_2^+$. The chloride ion transfer here is connected with a complete change in the distribution of the chloride ions around the Sn atoms. Of course there is a possibility that an intermediate compound $SnCl_4(ClAsCl_2)_2$ exists with an octahedral coordination. This possibility has a perfe ct analogy in aqueous solutions: $CO_2 + H_2O = H_2CO_3 = H^+ + HCO_3^-$.

Evidently such molecules or ions will function as acids which have a chloride ion affinity. This may partly be determined by purely geometrical considerations. The low chloride ion affinity of bases can in some cases be explained as a repulsion effect. There is thus an analogy between the two reactions:

$$C_5H_5NAsCl_3 = C_5H_5NAsCl_2^+ + Cl^- \quad \text{(N—Cl repulsion)}$$

and

$$Al(OH_2)_6^{3+} = Al(OH)(OH_2)_5^{2+} + H^+ \quad \text{(Al—H repulsion)}$$

Whatever is the mechanism of the ionic transfer processes in $AsCl_3$, it will result in chloride ion excess or deficiency, which can be measured.

All the problems discussed here are evidently very much dependent on the charge distribution in $AsCl_3$. Ions such as $(CH_3)_4N^+$ are probably surrounded by $AsCl_3$ molecules turning their negative sides against the positive ion. The knowledge of the structures of solvates is thus of fundamental importance for any effort to discuss solvation processes or to obtain a picture of the structure of solutions in $AsCl_3$.

PERTINENT STRUCTURAL PROBLEMS

An attempt has been made to show that our present knowledge permits only vague ideas about the constitution of $AsCl_3$-solutions and to point out some pertinent structural problems which are here summarized:

1. The structure of solid and liquid $AsCl_3$ is of basic importance in any structural discussion of $AsCl_3$ solutions.

2. The structures of the ions $AsCl_2^+$ and $AsCl_4^-$ might explain how Cl^- excess or deficiency is manifested in the liquid structure.

3. The knowledge of the structures of solid solvates is necessary for any detailed discussion of solubility and solvation conditions in $AsCl_3$-solutions.

Of course these points apply directly to the study of other auto-ionizing solvents.

Studies on Arsenic Trichloride as a Solvent

III. Potentiometric Acid-base Titrations in $AsCl_3$

LARS HENRIK ANDERSSON and INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Potentiometric titrations have been carried out in $AsCl_3$ solutions using Ag, AgCl electrodes. The idea of a Cl^- ion concentration governing the acid-base processes has been confirmed by these measurements.

In the preceding paper [1] the importance of potentiometric measurements of pCl in $AsCl_3$ solutions was pointed out and the use of Ag, AgCl-electrodes was suggested. This paper will deal with the possibilities of measuring large pCl changes in potentiometric acid-base titrations in $AsCl_3$. The definition acid $+ Cl^- =$ base leads to the use of the following concentration cell:

$$Ag,\ AgCl \mid Cl^-\ (C_1) \parallel Cl^-\ (C_2) \mid Ag,\ AgCl$$

Titrations have been carried out with the acid $FeCl_3$ against the bases $(CH_3)_4NCl$, C_5H_5N, $(C_2H_5)_2NH$ and with the base $(CH_3)_4NCl$ against the acids $FeCl_3$ and $SbCl_5$.

A comparison with a conductometric titration has also been made.

EXPERIMENTAL

Chemicals used. Commercial $AsCl_3$ was purified by two distillations at a final boiling point of 229° C. The conductance of the distilled $AsCl_3$ was measured in the part A of the receiver (Fig. 1). (The instrument used was a Philips Philoskop, type GM 4140, and the measurements were performed at a frequency of 1 000 p/s.) As long as the conductance was considered to be too high the liquid was poured out through K to B. When the purity was satisfactory the liquid was permitted to pass through the syphon S to C. Table 1 shows the results of one such distillation. The fractions following 7 gave the same conductance and were all collected in the flask C. The conductance was constant after 12 hours. The lowest value [2] previously measured in $AsCl_3$ seems to be $1.4-1.6 \cdot 10^{-7}$ ohm^{-1} cm^{-1} at 0° C. Our value obtained at + 19° C is considerably lower, although the conductance of $AsCl_3$ has a positive temperature coefficient [2].

The other chemicals were all purified by standard methods, with particular care to keep them dry.

Electrodes. The Ag, AgCl electrodes were made according to Brown [3]. Before use they were left in ethyl ether for 24 hours and then heated to 130° C during one hour.

The design of the cell is shown in Fig. 2 a. The reference electrode R is filled with a solution of $(CH_3)_4NCl$ in $AsCl_3$. The carefully ground-in stopper at J still permits an equilibrium potential to be obtained. Emf was measured with a vacuum tube voltmeter (*Ermi*).

Apparatus. Preliminary experiments showed that it was most unsatisfactory to use stopcocks in the apparatus because of the creeping out of the $AsCl_3$ solution and because of chemical reactions with every available type of grease. A special titration apparatus was therefore designed to avoid stopcocks or any contact between solution and greased parts (Fig. 2 a and b). The reagent solution is passed from the vessel V into the U-tube system consisting of tubes A and B. The addition of reagent to the solution in K takes place in the following way. The whole apparatus, Fig. 2 a, is tilted clockwise in the plane of the paper. The buret is then turned around S so that the solution will rise in A. The solution will begin to flow from A to C at about 90° rotation and the bent tip at T will then point downwards allowing a drop-wise addition of solution. (The amount of solution in A—B must be such that it can be completely transferred to A.) The apparatus could readily be manipulated in such a way that the solution in C would flow back into A—B. By means of a calibrated scale attached to A—B volume readings were taken before and after the addition of solution through C. During the conductometric titration a conductance cell (of the same shape as shown in Fig. 1) replaces the electrode system.

Results. The results are summarized in Table 2 and Figures 3—5.

DISCUSSION OF THE RESULTS

The ionic character of the reactions studied here has previously been established by conductometric titrations [4]. The fact that the potentiometric titrations give as satisfactory results as indicated by Table 2 shows further,

Table 1.

Fraction no.	Spec. cond. ohm^{-1} cm^{-1}
1	$5.7 \cdot 10^{-6}$
2	$1.8 \cdot 10^{-6}$
3	$1.0 \cdot 10^{-6}$
4	$5.6 \cdot 10^{-7}$
5	$2.8 \cdot 10^{-7}$
6	$1.2 \cdot 10^{-7}$
7	$1.0 \cdot 10^{-7}$

Table 2.

Solution in K		End.-point (ml)		Solution in V		Fig. no.
Solute	mmole solute / 1 000 g $AsCl_3$	Calc.	Found	Solute	mmole solute / 1 000 g $AsCl_3$	
$(CH_3)_4NCl$	0.21	2.55	2.56	$FeCl_3$	1.4	3 a
C_5H_5N	0.50	6.36	6.54	$FeCl_3$	1.4	3 b
$(C_2H_5)_2NH$	0.3	2.2	2.34	$FeCl_3$	1.4	3 c
$FeCl_3$	0.26	2.69	2.68	$(CH_3)_4NCl$	1.7	4 a
$SbCl_5$	0.47	2.96	3.01	$(CH_3)_4NCl$	1.7	4 b

Fig. a. b. Potentiometric titration curves (see Table 2).

that the Ag, AgCl electrode behaves at least roughly as a pCl electrode. There is thus reason to speak of a Cl^- concentration in the $AsCl_3$ solution and to write, *e.g.*, the reaction between $(CH_3)_4NCl$ and $FeCl_3$ as

$$Cl^- + FeCl_3 = FeCl_4^-$$

The existence of an ionic product and of a scale of acid and base strength follows from the confirmation of the existence of a Cl^--concentration. The former may be best studied by conductometric methods [5].

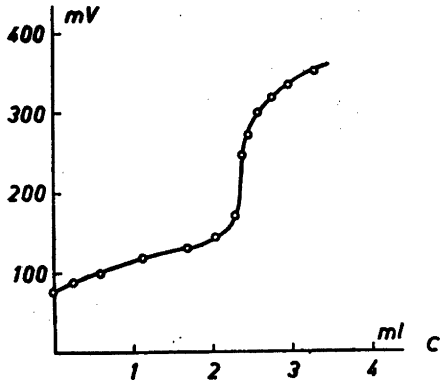

Fig. 3 c. Potentiometric titration curves (see Table 2).

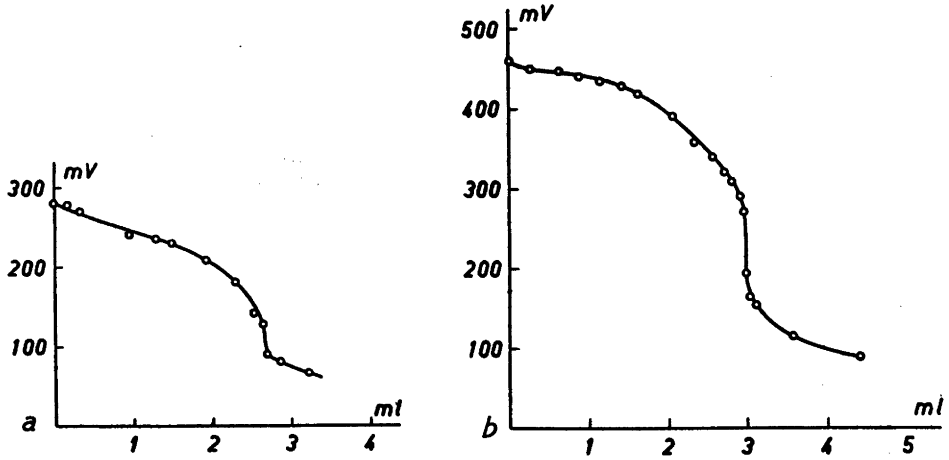

Fig. 4. Potentiometric titration curves (see Table 2).

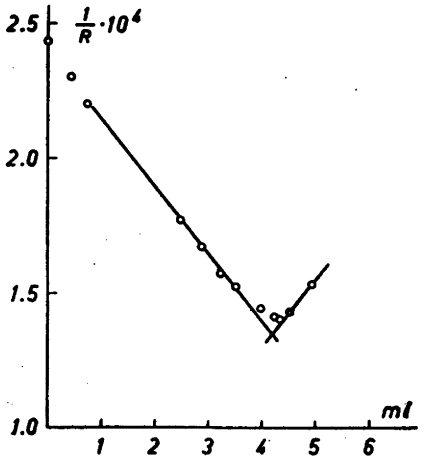

Fig. 5. Conductometric titration curve (see Table 2).

A maximum value can be obtained for the product $K = C_{AsCl_2}^{+} \cdot C_{AsCl_4}^{-}$ if we assume that the liquid junction potential can be neglected and that $(CH_3)_4NCl$ as well as $SbCl_5$ are strong electrolytes in $AsCl_3$. We obtain from Fig. 4 b

$$^1/_2\ pk = \frac{460—215}{60} - \log C_{SbCl_5},$$

giving $pk > 15$ and $C_{AsCl_2}^{+} \cdot C_{AsCl_4}^{-} < 10^{-15}$.

We cannot hope to come further with the potentiometric methods without elaborate experiments and extended theoretical calculations. There are different reasons to expect difficult problems:

1. The unknown liquid junction potential.
2. The unknown degree of dissociation of the acid and base solutions in $AsCl_3$.
3. The unknown acid-base behavior and solubility product of the slightly soluble AgCl in $AsCl_3$.
4. The difficulties involved in determining the activity factors in solvents with low dielectric constants.

These problems are too complex to give much hope of a very accurate treatment. We intend, however, to explore further the possible usefulness of the potentiometric methods for studying ionic reactions in $AsCl_3$ and other solvents.

This work has been supported by a grant from the *Swedish Natural Science Research Council* which is here gratefully acknowledged. We also wish to thank professor G. Hägg for all facilities put at our disposal and Mr. N. Larsson for valuable help with the glass blowing.

The Alkylation of Lignin with Alcoholic Hydrochloric Acid

ERICH ADLER and JOSEF GIERER

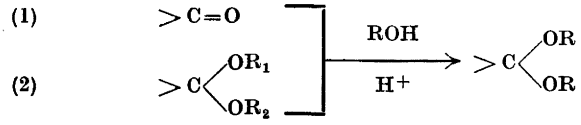
Institute of Organic Chemistry, Chalmers Technical University, Gothenburg, and Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

Brauns' "native lignin" from spruce was shown to contain 0.12 CO groups per methoxyl. By reduction with sodium borohydride a practically carbonyl-free preparation was obtained. The original as well as the reduced lignin were subjected to treatment with 0.5 % methanolic hydrochloric acid either during 48 hours at room temperature or during 2.5 hours under reflux. Extensive methylation took place in each case, the ratio OCH_3 introduced/OCH_3 orig. present ranging from 0.41 to 0.52.

From these results it is concluded that the methylation is not due to acetal formation. The most probable explanation is the etherification of benzyl alcohol groups and the re-etherification of benzyl ether groups present in "native lignin".

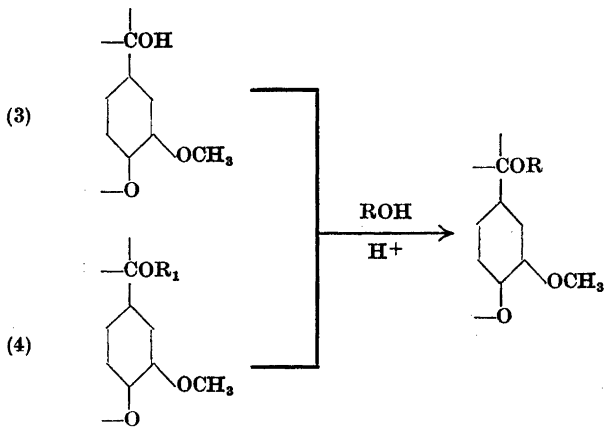
In 1893, Klason [1] made the observation that some lignin was brought into solution when spruce wood was heated with ethanol containing a small amount of hydrogen chloride. This reaction has been studied more closely by Holmberg [2,3], who found that the formation of the "ethanol lignin" involves the uptake of approximately 0.5 ethoxyl groups for every methoxyl present in the lignin. Several alcohol lignins have been prepared from wood by using alcohols other than ethanol, and in all cases alkylation of the lignin was demonstrated [4,5]. Similarly, "native lignin", isolated according to Brauns' method, *i. e.*, a lignin fraction which is extracted from wood by ethanol at room temperature and which amounts to a few per cent of the total lignin, is methylated when heated with methanolic hydrochloric acid [6].

This alkylation of lignin has been interpreted mainly in two ways. Holmberg and Runius [2] assumed that lignin contains carbonyl groups partly involved in an acetal-like linkage between lignin and carbohydrates. Heating with alcoholic hydrochloric acid was then believed to bring about an acetalization (1) of free carbonyl groups or a re-acetalization (2) of bound carbonyl groups.



This view, which was shared by several other authors, seemed to find support in the fact that the alkoxyl groups were removed when the alcohol lignin was treated with strong acids [7].

An alternative explanation was suggested by Holmberg [8] in 1935. On the basis of experiments with model substances, such as α-phenyl ethyl alcohol and benzhydrol, he assumed the presence in lignin of exceedingly reactive alcoholic hydroxyl or ether groups, *viz.*, benzyl alcohol or benzyl ether groupings. The alkylation reaction was then considered as an etherification of benzyl alcohol groups (3) or a re-etherification of benzyl ether groups (4), or both.



The same types of groups were assumed to be responsible for other typical lignin reactions such as the sulphonation with sulphite solutions and the formation of lignothioglycolic acids.

Concerning the two last-mentioned reactions, and especially the sulphonation, Holmberg's benzyl alcohol and benzyl ether hypothesis has been supported by a vast amount of experimental work (*cf.* Lindgren [9]).

The alkylation of lignin, however, has been comparatively little studied and, until recently, has been interpreted in the sense of Holmberg's older theory. Thus, Brauns expressed the view that the methylation, which takes place when isolated "native lignin" is heated with methanolic hydrochloric acid, is probably due to the acetalization of carbonyl groups [6, 10]. It is known, however, that *p*-hydroxybenzyl alcohols are readily etherified by alcoholic hydrochloric acid, and also that corresponding benzyl alkyl ethers are re-etherified under very mild conditions [11]. With this fact in mind it was attempted to find conclusive evidence for the mechanism of the alkylation reaction.

The lignin material used in the present work was „native lignin" isolated according to Brauns [6] from spruce (*Picea excelsa*). The preparation contained 14.67 % OCH_3. By potentiometric titration of the hydrochloric acid which was liberated when the lignin was treated with hydroxylamine hydrochloride, the preparation was found to contain 1 CO group per 8.3 OCH_3 groups ($CO/OCH_3 = 0.12$). Since "native lignin" contains roughly one coniferyl aldehyde group per forty methoxyl groups [12], about every tenth guaiacyl

propane monomer thus carries a carbonyl group not belonging to a coniferyl aldehyde structure.

On treatment of the "native lignin" with sodium borohydride in aqueous ethanol, a reduced "native lignin" with a methoxyl content of 15.19 % was obtained, in which only traces of carbonyl groups (about 3 % of the amount originally present) could be detected (see Fig. 4). The presence of carbonyl groups in the original preparation and their elimination on sodium borohydride reduction was also demonstrated by infrared absorption measurements *. Whereas the original "native lignin" shows a definite band in the C=O region (about 1 660 cm^{-1}), only a slight inflection is observed at this position in the absorption curve of the reduced lignin (Fig. 1, a and b).

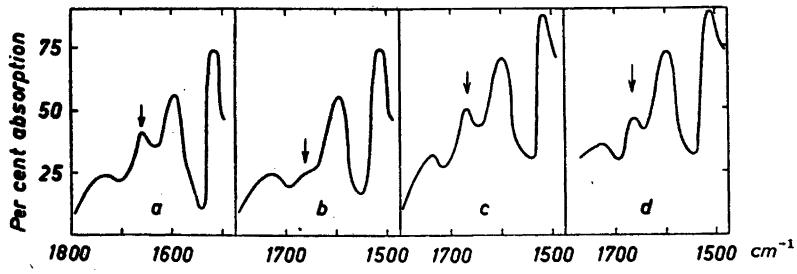


Fig. 1. Infrared absorption curves. a. "Native lignin". b. "Native lignin", reduced with sodium borohydride. c. "Native lignin", methylated with 0.5 % $CH_3OH-HCl$ (48 h, room temp.). d. "Native lignin", methylated with 0.5 % $CH_3OH-HCl$ (2.5 h, reflux). The arrows mark the position of the C=O absorption.

Fig. 2 shows the ultraviolet absorption curves of the original and the reduced "native lignins". The reduced product gives a considerably lower absorption in the range above 300 mμ compared with the original preparation. The decrease must be partly due to the reduction of coniferyl aldehyde residues, which cause a comparatively high extinction in this wavelength range [13], yielding coniferyl alcohol groups. This is also indicated by the fact that the reduced product does not give the colour reaction with phloroglucinol and hydrochloric acid, in contrast with the original preparation [14]. Further, the nearly white colour of the reduced product suggests that quinoid groupings have been eliminated.

The original as well as the reduced lignin were subjected to methylation with methanol containing 0.5 % hydrogen chloride, *i. e.*, the reagent used by Brauns [6] in the methylation of "native lignin" from black spruce *(Picea mariana)*. In Brauns' experiments the reaction mixture was heated under reflux for 2.5 hours. It was found, however, that treatment at room temperature during 48 hours was sufficient to produce extensive methylation, and therefore the experiments were carried out both at room temperature (48 hours) and under reflux (2.5 hours).

* The authors are indebted to Dr. K. Almin for kindly carrying out the infrared measurements.

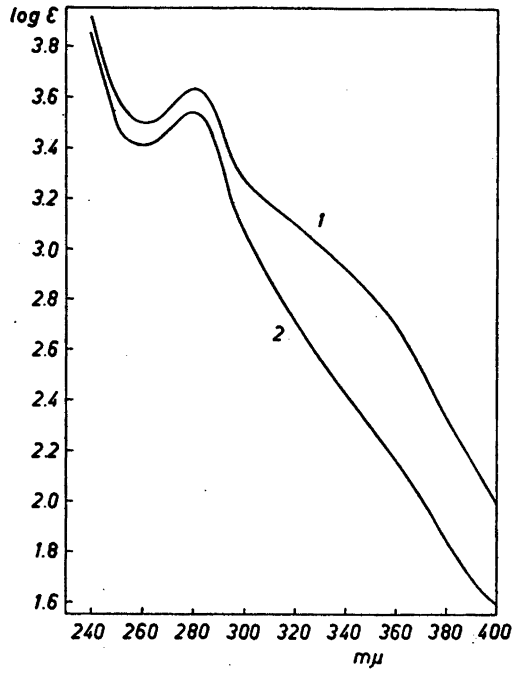

Fig. 2. Ultraviolet absorption curves. Curve 1: "Native lignin". Curve 2: "Native lignin", reduced with sodium borohydride. Based on methoxyl concentration. Solvent: 96 % ethanol.

The ultraviolet absorption curves of the resulting methylated products (Fig. 3) do not reveal any distinct structural changes due to the methylation when compared with the absorption of the corresponding starting materials (Fig. 2).

The analytical findings are summarized in Table 1. From the increase in the methoxyl content after methylation at room temperature, it can be calculated that the original "native lignin" acquired 0.47 new OCH_3 groups for

Table 1.

Lignin preparation	Before methylation % OCH_3	After methylation at room temp., 48 h		After methylation at reflux, 2.5 h	
		% OCH_3	$\frac{OCH_3 \text{ introd.}}{OCH_3 \text{ orig.pres.}}$	% OCH_3	$\frac{OCH_3 \text{ introd.}}{OCH_3 \text{ orig.pres.}}$
"Native lignin"	14.67	20.49	0.47	21.09	0.52
Reduced "native lignin"	15.19	20.46	0.41 [0.47]	21.02	0.46 [0.51]

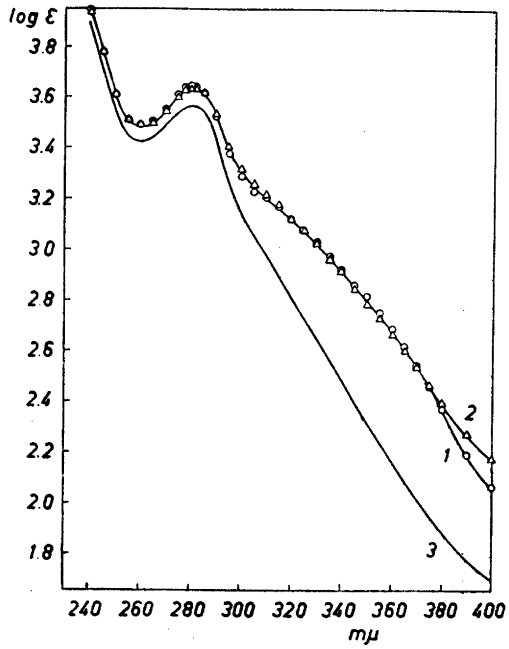

Fig. 3. Ultraviolet absorption curves. Curve 1: "Native lignin", methylated with 0.5 % $CH_3OH-HCl$ (48 h, room temp.). Curve 2: "Native lignin", methylated with 0.5 % $CH_3OH-HCl$ (2.5 h, reflux). Curve 3: Sodium borohydride-reduced "native lignin", methylated with 0.5 % $CH_3OH-HCl$ (2.5 h, reflux). All curves based on concentration of OCH_3 present in unmethylated starting material. Solvent: 96 % ethanol.

every OCH_3 originally present. The corresponding value, 0.52, obtained when the reaction was performed under reflux, is in good agreement with the result reported by Brauns [6] in the case of black spruce "native lignin".

The most important finding shown in Table 1 is that the reduced lignin preparation behaves similarly to the original lignin. The methoxyl values of the methylated reduced preparations are practically identical with those of the methylated non-reduced lignins.

Due to the fact that the methoxyl value of the reduced lignin (15.19 %) is slightly higher than that of the original lignin (14.67 %), the ratio OCH_3 introduced/OCH_3 orig. present becomes somewhat lower in the first case than in the latter one. One might assume that the comparatively high methoxyl value of the reduced lignin is caused by an etherification of some highly reactive hydroxyl groups by the ethanol used as a solvent in the sodium borohydride reduction and also present during the recovery of the reduced product. Unintentional temporary acidification after completed reduction (*cf.* experimental part) might be sufficient to bring about such slight ethylation. If this assumption is accepted, the alkylation values given in brackets are obtained. These "corrected values" are nearly identical with those obtained in the methylation of the non-reduced lignin.

But even if no consideration is taken of such a correction, it is obvious that methylation takes place to a very similar extent irrespective of the presence or

absence of carbonyl groups in the lignin material. Hence, the methylation cannot be due to acetal formation.

This conclusion is further supported by the fact that the carbonyl band of the infrared absorption curve of "native lignin" does not disappear on methylation (see Fig. 1, c and d) *. Obviously, the carbonyl groups present in spruce "native lignin" do not form stable acetals. If there is any acetalization during the interaction of the methanolic hydrochloric acid, the acetals or ketals formed must be hydrolyzed again during the isolation of the methylated product. It may also be noted that the carbonyl groups present in the original "native lignin" (0.12 CO/OCH_3), if completely acetalized, could give rise to at most 0.24 $OCH_{3\ introduced}$ per $OCH_{3\ orig.\ present}$, whereas the figures actually obtained are 0.47 and 0.52.

The question now arises which types of groups are responsible for the methylation.

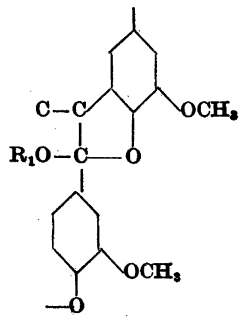
It was found that the methoxyl content (20.1 % OCH_3) of a methylated product obtained by treatment of "native lignin" at room temperature for 24 hours with 0.5 % methanolic hydrochloric acid, remained practically unchanged in 0.1 *N* aqueous sodium hydroxide (48 hours, room temperature), the recovered product containing 19.8 % OCH_3. This result shows that the introduced methoxyl groups are not present as ester groups. It is in agreement with the alkali stability of the methoxyl and ethoxyl groups in methanol and ethanol lignins from spruce wood as reported by Hibbert and Brauns [7], and by Holmberg and Runius [2].

Since acetalization and ester formation can be excluded, the alkylation must be due to the reaction of hydroxyl groups in the lignin. There are three possible types of such groups which are sufficiently reactive to undergo alkylation with alcoholic hydrochloric acid.

One type to be considered is the α-ketol structure, the hydroxyl group of which is known to be etherified by alcoholic hydrochloric acid [16]. It is also known by the work of Hibbert [17] that monomeric α-ketol ethers are formed if wood or isolated lignin is heated for 48—72 hours with ethanolic hydrochloric acid. The appearance of side-chains with an α-ketol structure with subsequent etherification of its hydroxyl group during the treatment of native lignin with methanolic hydrochloric acid might therefore be considered possible. In this case, the alkylation of lignin would be expected to be accompanied by the formation of keto groups. By means of the hydroxylamine hydrochloride method it was found, however, that sodium borohydride-reduced and subsequently methylated "native lignin" (methylation during 2.5 hours under reflux) was practically free of carbonyl groups. Hence, the methoxyl groups introduced into the lignin are not present as α-ketol ether groupings.

Some years ago, Erdtman [18] suggested the presence of cyclic hemiacetal structures (I) in lignin. The open hydroxyl group (OR_1, R_1 = H) or an alkyl derivative of it (—OR_1) would be the site of the typical lignin reactions such as sulphonation and alkylation with alcoholic hydrochloric acid. Sulphonation

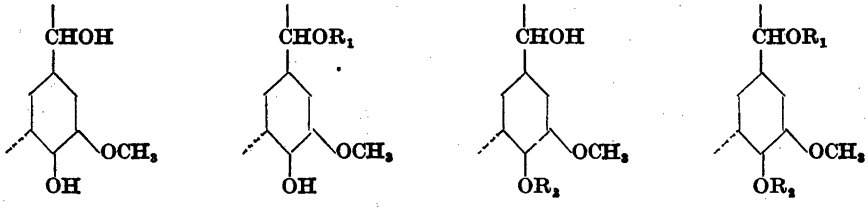
* The opposite observation has been reported by Jones [15], who states that the absorption band in the spectrum of black spruce „native lignin" at 1 663 cm^{-1} is no longer found in the spectrum of the CH_3OH—HCl methylated lignin. The reason for this discrepancy is obscure.



I

studies with a model substance [18] containing a structure not very closely related to I constitute the only experimental support hitherto available, and further model experiments would be highly desirable. Although, at present, the possibility of structures like I being responsible for the alkylation and other reactions of lignin cannot be excluded, it appears that its further discussion must be postponed until more experimental material has been collected.

The benzyl alcohol and benzyl ether concept of lignin structure seems to provide an excellent basis for the explanation of the alkylation with alcoholic hydrochloric acid. In addition, the results reported in the present paper strongly support this concept. The following structures, *a*—*d*, previously suggested to be present in lignin of coniferous wood mainly as a result of sulphonation studies (*cf.* Ref. [9]), can undergo alkylation in the benzyl position:



a *b* *c* *d*

The *p*-hydroxybenzyl alcohol structure *a* and the *p*-alkoxybenzyl alcohol structure *c* will be alkylated by etherification, whereas the *p*-hydroxybenzyl (alkyl) ether structure *b* and the *p*-alkoxybenzyl (alkyl) ether structure *d* will react by re-etherification.

Direct experimental evidence for the occurrence in lignin of the phenolic structures *a* and *b* has recently been provided. Thus, the "quinone methide reaction" of "native lignin", briefly reported by Adler and Gierer [19], is probably due to the presence of one or both of these structures, and the „indophenol reaction" of wood and isolated "native lignin", which has been described by Gierer [20], has to be ascribed to structure *a*.

The extent of methylation (about 0.5 OCH_3 introduced / OCH_3 orig. present) indicates that the methylatable structures *a*—*d* constitute together about

50 % of the guaiacyl propane monomers of spruce "native lignin". This, of course, is true only if not more than one OCH_3 is introduced into each of the methylatable monomers. According to Gierer [20] structure *a* occurs in 12—14 % of the monomers.

If the carbonyl groups in "native lignin" (0.12 CO per OCH_3), apart from those belonging to coniferylaldehyde residues (about 0.025 per OCH_3), were keto groups in the α-position of the side-chain, *i. e.*, adjacent to the aromatic nucleus, sodium borohydride reduction of the lignin would be expected to produce about 0.1 new methylatable aryl carbinol group of the types represented by structures *a* and *c*. However, the methylation values of the reduced lignin are not higher than those of the original preparation. This seems to indicate that the carbonyl groups are mainly not in the α-position of the side-chains. In agreement herewith, Gierer [20] arrived at the conclusion that phenolic units with α-keto groups seem not to be present in "native lignin", since the amount of groups *a*, estimated by the „indophenol reaction", was not increased after reduction of the lignin with sodium borohydride.*

It can be expected that the four structures *a—d* will differ in their reactivity towards alcoholic hydrochloric acid. In fact, model experiments, which are still under progress [21], have shown that *p*-hydroxybenzyl alcohols (type *a*) react faster than *p*-alkoxybenzyl alcohols (type *c*), and, in addition, there are certain differences in reactivity between free benzyl alcohols (*a*, *c*) and benzyl ethers (*b*, *d*). Furthermore, sharp dissimilarities have been found in the behaviour of different benzyl ethers. Whereas ethers, in which R_1 (in formulae *b* and *d*) is an open alkyl residue, are readily re-etherified, cyclic ethers such as dehydro-di*iso*eugenol and pinoresinol are more or less resistant to methanolic hydrochloric acid under the conditions used in the present investigation. Finally, it has been found that the course of the alkylation of aryl propane derivatives containing the structures *a—d* is greatly dependent upon the chemical nature of the substituents present at the β- and γ-positions of the propane side-chain. Thus, a closer examination of the alkylation of lignin, in comparison with the behaviour of appropriate model substances, seems to offer a new means of elucidating the principles of lignin structure. In this connection, the finding that alkylation takes place under very mild conditions is of considerable interest.

EXPERIMENTAL

Reduction of "native lignin" with sodium borohydride. The procedure has already been described in a preceding paper by Gierer [20]. In the present case, the reduction was carried on for two days at room temperature, and the alkaline reaction mixture neutralized with hydrochloric acid.

Estimation of carbonyl groups. Brauns' "native lignin" [6] from spruce wood meal or the sodium borohydride-reduced product (100 mg) was dissolved in 25 ml 96 % ethanol. The pH of the solution was adjusted to 3.5 by the addition of dilute aqueous hydrochloric acid. A solution of 0.17 g NH_2OH-HCl in 10 ml ethanol, likewise adjusted to pH 3.5, was added. A stream of nitrogen was bubbled through the mixture, which after certain

* *Note added in proof:* In a recent publication a similar result was reported by G. Aulin-Erdtman [*Svensk Papperstidn.* **57** (1954) 745], who found by spectrophotometric measurements on different lignin preparations that the sum of α-keto groups and C—C double bonds conjugated with the aromatic ring can not be greater than 0.01—0.02 per OCH_3.

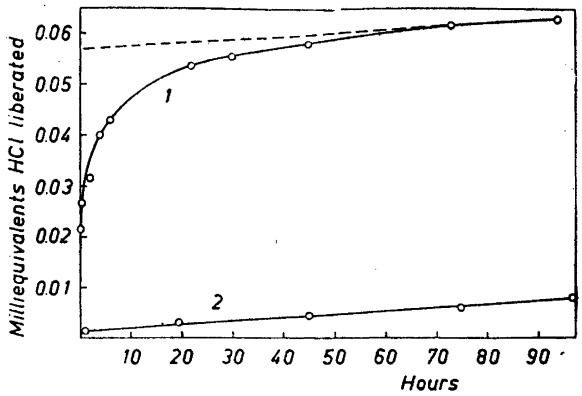


Fig. 4. Estimation of carbonyl groups. Curve 1: "Native lignin". Curve 2: Sodium borohydride-reduced "native lignin".

time intervals was titrated with 0.0099 *N* NaOH to pH 3.5 (glass electrode). The consumption of sodium hydroxide is shown in Fig. 4. The slow liberation of hydrochloric acid indicated by the nearly linear slope of the right part of the curves is caused by some oxidative decomposition of hydroxylamine, due to incomplete exclusion of air. The true consumption of sodium hydroxide due to oxime formation was found by extrapolation to time zero.

"Native lignin" (curve 1): 100 mg lignin with 14.67 % OCH_3, *i.e.*, 0.47 mequ. OCH_3, consumed 0.057 mequ. NaOH, corresponding to 0.057 mequ. CO. $CO/OCH_3 = 0.12$.

The reduced lignin (15.19 % OCH_3) consumed about 0.002 mequ. NaOH (curve 2). $CO/OCH_3 = 0.004$.

Methylation with 0.5 % methanolic hydrochloric acid. The procedure was similar to that already reported by Gierer [20]. The lignin preparation (200 mg) was dissolved in 4 ml absolute methanol, and 1 ml methanol containing 0.25 g hydrogen chloride was added. The mixture was either allowed to stand at room temperature for 48 hours or refluxed for 2.5 hours, then neutralized with a few drops of 2 *N* Na_2CO_3 solution and evaporated *in vacuo* to dryness. The residue was dissolved in 2 ml absolute methanol-acetone mixture (1 : 1), filtered, and washed with a few ml of the same solvent. The solution was poured into 60 ml of water. The precipitate, after standing overnight, was collected on a glass filter, washed thoroughly with water and dried *in vacuo* over phosphorus pentoxide. The yield of this product was about 60 %. It was dissolved in dioxan and re-precipitated in ethyl ether [5]. Yield about 50 % of the original lignin.

The calculation of the ratio OCH_3 introduced/OCH_3 orig. present may be illustrated by the following example:

Methylation of "native lignin" in boiling CH_3OH—HCl, 2.5 hours. "Native lignin", 14.67 % OCH_3; methylated product, 21.09 % OCH_3.

If methylation is assumed to involve the etherification of hydroxyl groups, the increase in weight is $CH_2 = 14$ for every introduced methoxyl group. If it is assumed to involve the re-etherification of ether bridges, the corresponding increase is $CH_3OH = 32$. The mean value of 23 has been adopted for the present calculation.

The two equations

$$\frac{31.034 \cdot 100}{x} = 14.67,$$

and

$$\frac{(1 + y) \cdot 31.034 \cdot 100}{x + y \cdot 23} = 21.09$$

give x (= the weight of one OCH_3 equivalent in "native lignin") = 211.5, and y (= OCH_3 introduced/OCH_3 orig. present) = 0.52.

The Catalatic Decomposition of Hydrogen Peroxide and Its Retardation by Azide

LIS SKOVSTED

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

It is confirmed that at low concentrations of hydrogen peroxide its catalatic decomposition follows a first order law. A linear relationship between the reciprocal rate constant and the concentration of azide ion is found. From the experiments the equilibrium constant for the equilibrium between an inactive catalase-azide complex and active catalase is determined.

Zeile and Hellström [1] have shown that catalase is a hemoprotein in which the hematin acts as a prostetic group.

In the present work horse kidney catalase is used. According to Bonnichsen [2] it has four hemine groups per molecule, while horse liver catalase contains three hemines and one verdohemochromogen group.

Several theories have been advanced to explain the decomposition of hydrogen peroxide by catalase. Theorell [3] and Chance [4] both find that two hydrogen peroxide molecules react with one catalase molecule. According to Theorell each hydrogen peroxide molecule is attached to one hematin group and from two such groups oxygen and water are subsequently released. Chance, however, assumes that one hydrogen peroxide molecule is bound to one hematin group and that this group then reacts with a free hydrogen peroxide molecule.

The decomposition of hydrogen peroxide by means of catalase is a first-order reaction provided the catalase concentration is about 10^{-9} M [6]. Svendsen [7] has found that a first-order reaction is also obtained if the catalase concentration is about 10^{-10} M provided the substrate concentration is low.

Experiments at low hydrogen peroxide concentrations (*ca.* 10^{-3} M) were carried out and confirmed that the enzyme under these circumstances is not (or at least only very slowly) inactivated by the hydrogen peroxide: The first-order reaction constant was determined from 4—5 titrations during a time corresponding to one or two half-periods. After a further 5—6 half-periods fresh hydrogen peroxide was added to make the concentration up to about the original and measurements were again taken over about two half-periods to give a new determination of the rate constant. Most frequently the two

determinations were identical; still it happened that the last was only say eighty per cent of the first. But according to Svendsen [8] this decrease in activity is probably not an irreversible inactivation, but due to adsorption of the catalase to the glass-walls, setting in slowly when the hydrogen peroxide is nearly used up. At least within two half-periods the catalase is of practically constant activity and the first-order constant measures its concentration.

Table 1.

(Exp. 15 24/10, 52. $t = 20°$ C. $C_{Catalase} = 10^{-10}$ *M*. $C_{H_2O_2} \sim 10^{-3}$ *M*. pH = 7.0)

$k' = 0.0625$

The catalase was prepared from horse kidney after Bonnichsens prescription [5]. It was kept in a *ca.* $2 \cdot 10^{-8}$ *M* solution with 0.01 *M* potassium chloride added to prevent adsorption to the glass walls (Svendsen [8]); the activity is then constant for some months. The catalase molarity was determined with a Beckman-Spectrophotometer, setting the extinction in millimolar solution at 405 mμ and 1 cm column to 380.

In Table 1 $k' = 0.0625$ is the constant at 20° C using decadic logarithms and the minute as time-unit and with a catalase molarity of 10^{-10}. Therefore:

$$k = \frac{0.0625}{0.4343} \cdot \frac{1}{60} \cdot 10^{10} = 2.40 \cdot 10^7 \text{ l} \cdot \text{moles}^{-1} \cdot \text{sec}^{-1}$$

This value is smaller than Svendsen's value: $2.65 \cdot 10^7$ (also for horse kidney catalase) and much less than that of Bonnichsen: $3.5 \cdot 10^7$ (for horse erythrocyte catalase). This is probably due to impurities in the catalase preparation, which was not perfectly crystalline.

The influence of azide on the first-order rate constant k' was studied in the following way, using Svendsen's [7] technique. Buffer-solution (1/1500 *M* Na_2HPO_4 + 1/1500 *M* KH_2PO_4, pH ~ 6.95), peroxide and azide are mixed in a black-painted reaction flask; at the time t_0 catalase is added from a micropipette, the flask is shaken, put into the thermostat at 20° C and the stopwatch is started. At intervals a sample is withdrawn, blown into a weighed flask containing enough 5 *M* sulphuric acid to make the solution about 0.5 *M* and weighed. Hydrogen peroxide is then titrated with 0.02 *M* ceric sulphate using "Ferroin" as indicator.

The konstant k' was determined with azide-concentrations varying from 10^{-8} to $1.2 \cdot 10^{-6}$ M and with pH $\sim$ 6.95. Plotting C_{azide} against $1/k'$ one gets a straight line which indicates the soundness in assuming a mass-action law behavior. Setting

$$\frac{C_{\text{active catalase}} \cdot C_{azide}}{C_{\text{inactive catalase}}} = K$$

and

$$\frac{C_{\text{active catalase}}}{C_{\text{inactive catalase}}} = \frac{k'}{k_0' - k'}$$

we get

$$C_{azide} = \frac{K k_0'}{k'} - K$$

$k_0' = 0.0645$ was found by extrapolation to $C_{azide} = 0$, consistent with the value found in Table 1 (0.0625) and other experiments without azide. $K = 0.92 \cdot 10^{-7}$ M was found from the slope of the line ($= K \cdot k_0'$).

Table 2. Comparison between the experimental values of k' for different azide concentrations and values calculated from

$$k'_{calc.} = \frac{0.92 \cdot 10^{-7} \; 0.0645}{C_{azide} + 0.92 \cdot 10^{-7}}$$

(pH = 6.95 ± 0.05; T = 20° C).

Azide conc.'s in moles/liter	k'_{exp}	$k'_{calc.}$	% deviation
12.05 10^{-7}	0.00448	0.00457	+ 2.0
10 —	0.00521	0.00543	+ 4.1
9 —	0.00604	0.00598	— 1.0
8 —	0.00641	0.00665	+ 3.6
6 —	0.00843	0.00857	+ 1.6
5 —	0.0103	0.01001	— 3.0
4 —	0.0131	0.01206	— 8.6
2 —	0.0211	0.0203	— 4.0

0.1 —	0.0614	0.0582	— 5.5
0	(0.0645) extrapol.		

Table 2 shows that a simple equilibrium is established between catalase and azide (at azide concentrations below $1.2 \cdot 10^{-6}$ M) with a mass action constant $K = 0.92 \cdot 10^{-7}$ moles/l at pH = 7 *. The interesting point is that one

* From a recent paper of Chance [9] one extrapolates the value $K \sim 10^{-3}$ (pH = 7), apparently for the same constant. The great difference between the two values seems to indicate, that our K is the mass-action constant of an equilibrium between azide plus a complex of catalase with hydrogen peroxide on one side and a complex with both hydrogen peroxide and azide on the other, whereas no hydrogen peroxide enters the equilibrium measured by Chance.

Our constant depends also on pH; the correct form for the equilibrium may therefore be:
active hydrogen peroxide catalase + N_3^- ⇌ inactive complex + $^{\cdot}OH^-$
The C_{OH^-} (at constant pH = 7) is incorporated in K.

single azide-ion is capable of inactivating the whole catalase molecule with its four hemin groups; these four groups must therefore be considered as a unity in spite of the fact, that the catalatic activity against hydrogen peroxide is not depending upon the existence of four groups; in horse-liver catalase there are only three and in spinach catalase one or two [10].

Acknowledgements: My sincere thanks are due to dr. E. Güntelberg and to dr. A. Svendsen for valuable information and help during the course of the work.

Steady State. Treatment of Kinetc Results Concerning the Catalatic Decomposition of Hydrogen Peroxide

J. A. CHRISTIANSEN

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

To account for experimental results concerning the reaction in question a flow sheet is proposed which also implies an explanation of its retardation by azide ion. The essence is that azide acts as a competitive inhibitor by forming, reversibly, a stable complex with catalase containing one azide and at least one hydrogen peroxide.

It is known that at low hydrogen peroxide concentrations its catalatic decomposition up till nearly 100 % decomposition obeys the chronometric integral

$$kt = \ln\, h/x$$

where x is the concentration of hydrogen peroxide at time t, h the same at time zero and k the usual rate constant. The simplest reaction pattern which agrees with this result is

$$\begin{array}{ll} X_1 + H_2O_2 \rightleftharpoons X_2 & \pm 1 \\ X_2 + H_2O_2 \rightarrow 2H_2O + O_2 + X_1 & 2 \end{array}$$

X_1 may be either free catalase or catalase combined with one or several molecules of hydrogen-peroxide. Kinetics alone is unable to distinguish between these possibilities. X_2 obviously contains one molecule peroxide more than X_1.

Assuming steady state the usual procedure yields

$$\begin{aligned} x_1/s &= 1/w_1(1 + w_{-1}/w_2) \\ x_2/s &= 1/w_2 \end{aligned}$$

If furthermore the enzyme is either in the state X_1 or in X_2 we have $x_1 + x_2 = E$, where E is the total concentration of enzyme.

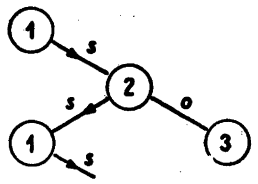

Fig. 1. The diagram is a flow sheet showing the transitions

$$X_1 + H_2O_2 \rightarrow X_2$$
$$X_2 + H_2O_2 \rightarrow 2H_2O + O_2 + X_1$$

and the equilibrium

$$X_2 + N_3^- \rightleftharpoons X_3.$$

The displacement of the two containers for X_1 indicates that there is a decrease in free energy by the overall reaction.

From the reaction pattern we conclude $w_1 = k_1x$, $w_{-1} = k_{-1}$; $w_2 = k_2x$, where x is the peroxide concentration. Insertion yields

$$-E\frac{dt}{dx} = (1 + k_{-1}/k_2x)/k_1x + 1/k_2x = E/s$$

This agrees only with the experimentally determined chronometric integral for small concentrations of peroxide if, for all accessible values of x, $k_{-1}/k_2x \ll 1$ and we thus get for the rate constant k : $1/k = 1_1/k_1 + 1/k_2$ which is in complete agreement with Beers and Sizer's [1] results.

Mrs. Skovsted's results concerning retardation by azide can be adequately interpreted by means of the flow-sheet (Fig. 1). We get as before

$$(x_1 + x_2)/s = 1/w_1 + 1/w_2.$$

But in this case $E = x_1 + x_2 + x_3$. x_3 is determined by the consideration that to preserve steady state the rate s_{23} must be zero, that is X_2 and X_3 are in equilibrium according to the chemical equation.

$$X_2 + A = X_3$$

which immediately yields $x_3 = Kax_2$. x_2 and x_3 are the concentrations of X_2 and X_3 respectively, while a is the concentration of azide. a may be considered as a constant if it is essentially larger than E. As $x_2/s = 1/w_2$ we thus get

$$(x_1 + x_2 + x_3)/s = E/s = 1/w_1 + (1 + Ka)/w_2$$

or

$$-x\,E\frac{dt}{dx} = 1/k_1 + (1 + Ka)/k_2 = 1/k'$$

where $k'E = k$ is the experimentally determined rate-constant. The expression obviously agrees completely with Mrs. Skovsted's results. The slope of $1/k'$ against a yields the numerical value of K/k_2. At present we have no means to determine k_1 and k_2 separately and it is therefore impossible to determine the numerical value of K. The result may also be written as follows

$$1/k = (1/k_1 + 1/k_2)/E + aK/k_2E$$
$$= (1/k_1 + 1/k_2)\,(1 + aKk_1/(k_1 + k_2))/E$$

Mrs. Skovsted's results may be written

$$1/k = (1 + 1.08 \cdot 10^7\ a)/0.0645 \cdot 2.303$$

Comparison yields

$$1/k_1 + 1/k_2 = E/0.0645 \cdot 2.303 \quad \text{where } E \sim 10^{-10} \text{ mole/liter}$$

and

$$Kk_1/(k_1 + k_2) = 1.08 \cdot 10^7.$$

Assuming that k_1 is essentially larger than k_2 we get

$$k_2 = 2.303 \cdot 0.0645/E$$

and

$$K = 1.08 \cdot 10^7$$

The large value of K indicates that X_2 which is catalase combined with at least one molecule peroxide has a very strong affinity for azide-ion.

It may also have a strong affinity for peroxide or peroxide anion, but while the complex with azide-ion is stable, the peroxide complex obviously explodes immediately after its formation.

Über die Umsetzung von Formaldehyd mit Ketocarbonsäuren

II. Lävulinsäure *

Synthese des 3,5,5-Trimethylol-dihydro-desoxy-patulinsäure-lactons **

SIGURD OLSEN

Universitetets Kjemiske Institutt, Blindern-Oslo, Norwegen

Bei der erschöpfenden Oxymethylierung der Lävulinsäure in saurem Medium entsteht über die intermediär gebildete 3,3,5,5,5-Pentamethylol-lävulinsäure durch Wasserabspaltung das 3,5,5-Trimethylol-dihydro-desoxy-patulinsäurelacton, das aus dem Reaktionsgemisch als Methylenäther direkt isolierbar ist. Der Methylenäther lässt sich durch Alkali bzw. Formalin-Alkali zu einem Gemisch isomerer Methylenäther des 3,5,5-Trimethylol-tetrahydro-desoxy-patulinsäure-lactons reduzieren.

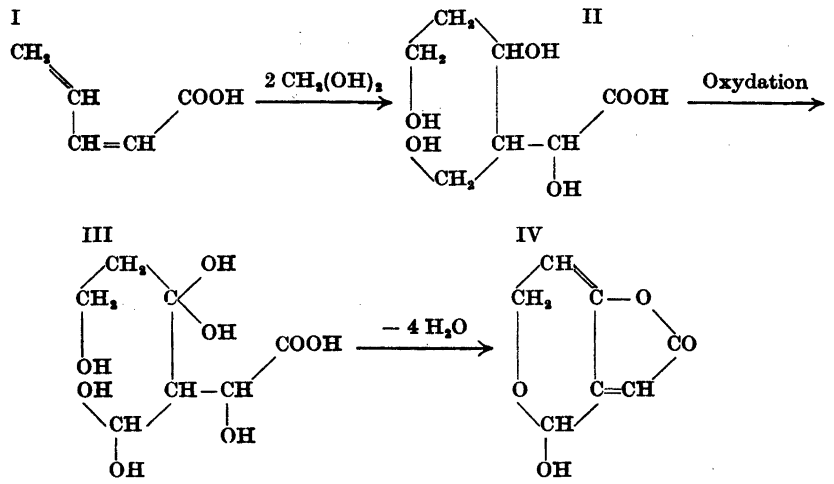
Unsere bisherigen Untersuchungen über die Umsetzung des Formaldehyds mit Carbonylverbindungen in saurem Medium haben zu dem Ergebnis geführt, dass bei Ketonen [1] und der Brenztraubensäure [2] im Anschluss an den vollständigen Methylolaufbau durch überschüssigen Formaldehyd eine Reduktion der Carbonylgruppe zur Carbinolgruppe nicht erfolgt. Dieser bezüglich der Ketocarbonylgruppe beobachtete und durch das saure Milieu bedingte Abschirmungseffekt trat auch bei neueren Untersuchungen an Ketocarbonylverbindungen [3] ausnahmslos in Erscheinung, so dass an dessen Allgemeingültigkeit nicht mehr zu zweifeln ist. Dieser Effekt ermöglicht die mühelose Synthese von Systemen mit einer β-Ketonalkohol-Gruppierung, die nach Tollens nur schwer fixierbar sind.

In der vorliegenden Untersuchung sollten diese Verhältnisse an der Lävulinsäure studiert werden, die aus einem ganz besonderen Grunde unser Interesse beanspruchte. In Verbindung mit Arbeiten in der Patulinreihe haben wir früher die Frage behandelt, ob sich mit Hilfe einer Formaldehyd-Olefin-Reaktion an der *Vinyl-acrylsäure* (I) die Synthese des Antibiotikums *Patulin* (IV) verwirklichen liesse. Theoretisch ergäbe sich die Aufbaumöglichkeit über

* I. Brenztraubensäure *Acta Chem. Scand.* **8** (1954) 47.

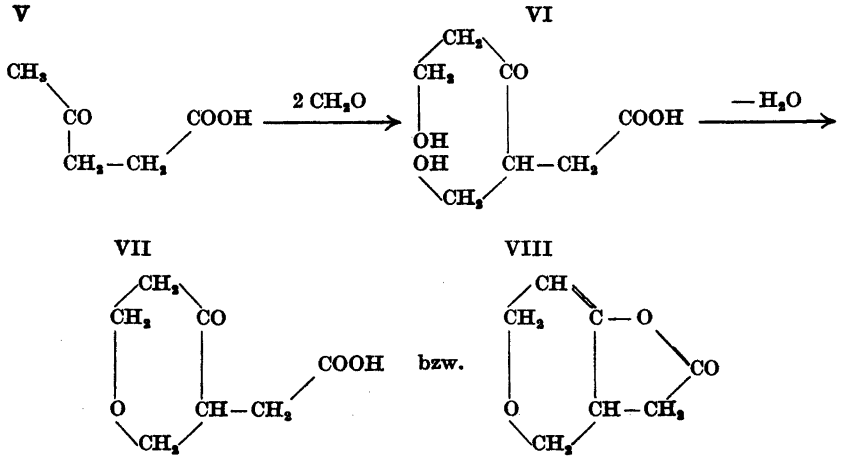
** 3. Mitt. über synthetische Versuche in der Reihe des Patulins und verwandter Verbindungen.

die Zwischenstufen II und III, die in ihrer verblüffenden Einfachheit die Frage aufdrängte, ob nicht möglicherweise die Natur diesen oder einen ähnlichen Weg beschreitet [4]:

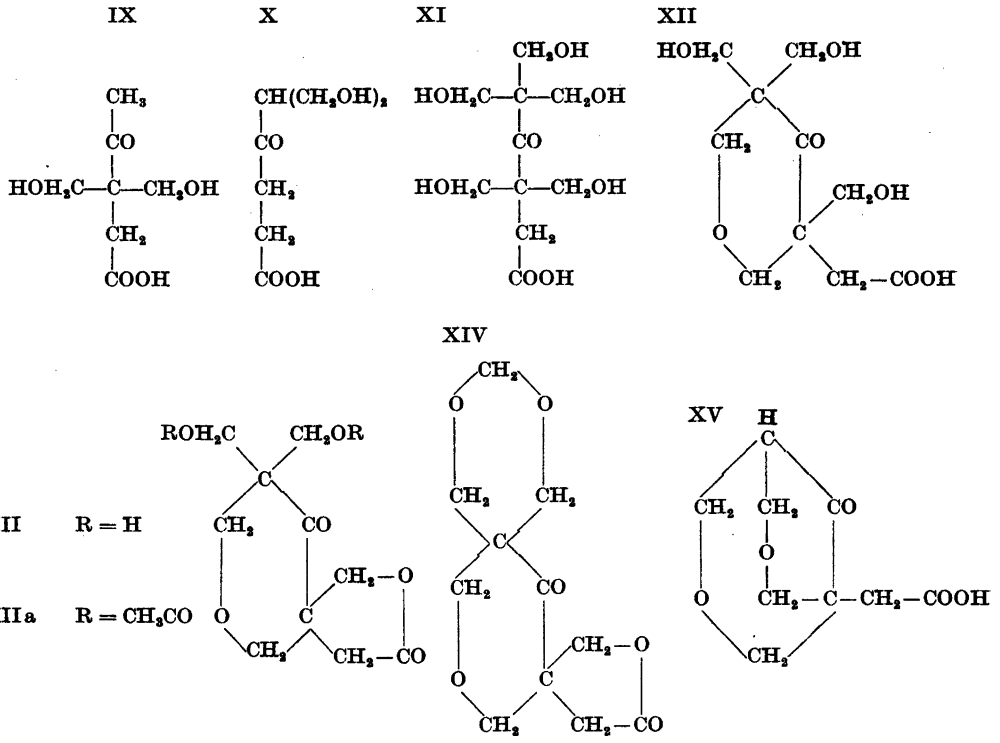


Obwohl man mit Hilfe der Formaldehyd-Olefin-Reaktion auch die Bildung einer Reihe anderer Naturstoffe erklären könnte, haben wir derartige Erwägungen aus naheliegenden Gründen vorläufig ganz in den Hintergrund gestellt.

Umsomehr überraschte es uns, als wir auf Grund der speziellen Reaktionsweise von Carbonylverbindungen das mögliche Resultat des Formaldehyd-Aufbaues an der *Lävulinsäure* (V) erwogen. Auch in diesem Falle führte unsere Überlegung über eine ebenso einfache Reaktionsfolge (V → VI → VII bzw. VIII) wieder in die Reihe des Patulins, nämlich zur *Dihydro-desoxy-patulinsäure* (VII) bzw. deren *Lactol* (VIII), wenn man annimmt, dass zwei Moleküle Formaldehyd reagieren:



Ein solcher Reaktionsverlauf hat zur Voraussetzung, dass sich die beiden Methylolgruppen am β- und δ-Kohlenstoffatom der Lävulinsäure verankern, während man natürlich mit der Möglichkeit rechnen muss, dass zuerst zwei Methylolgruppen am β- oder δ-Kohlenstoffatom ausgebaut werden, wodurch sie dann an einen für die Bildung der *Dihydro-desoxy-patulinsäure* falschen Platz gerieten (IX, X):



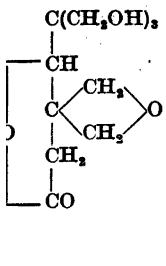
Bei Anwendung eines Formaldehyd-Überschusses (mehr als 5 Mol Formaldehyd) durfte man dagegen *mit Sicherheit* eine erschöpfende Oxymethylierung zur *Pentamethylol-lävulinsäure* (XI) erwarten, die sich durch Wasserabspaltung theoretisch in verschiedener Weise stabilisieren kann. Abspaltung von *einem* Molekül Wasser unter Tetrahydro-γ-pyron-Ringschluss führt zur *3,5,5-Trimethylol-dihydro-desoxy-patulinsäure* (XII). Für die Abspaltung eines *zweiten* Moleküls Wasser aus dieser Säure sind zwei Möglichkeiten zu erneuter Ringschlussbildung vorhanden, nämlich Bildung des *γ-Lactons* (XIII) oder — im Falle eines nochmaligen Tetrahydro-γ-pyron-Ringschlusses — der *Säure* (XV).

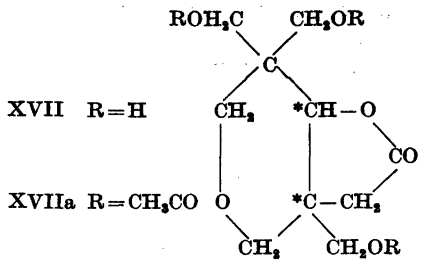
In der vorliegenden Studie haben wir uns hauptsächlich um die Synthese und die Chemie des "Per"-Oxymethylierungsproduktes der Lävulinsäure, der *Trimethylol-dihydro-desoxypatulinsäure* (XII) bzw. deren stabile "*Anhydroverbindungen*" (XIII bzw. XV) bemüht und daher die genaue Untersuchung

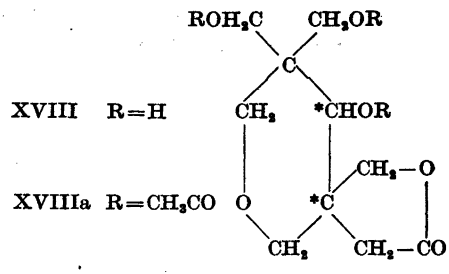
der Reaktions-Zwischenstufen — unter denen möglicherweise auch die *Dihydro-desoxy-patulinsäure* vertreten ist — einem späteren Zeitpunkte vorbehalten. Immerhin haben wir zur Orientierung Lävulinsäure und Formaldehyd auch in den Molverhältnissen 1 : 1, 1 : 2 und 1 : 3 umgesetzt und die *Dihydro-desoxy-patulinsäure* neben anderen Reaktionsprodukten nach Überführung in Methylestergemische durch fraktionierte Kristallisation der 2,4-Dinitro-phenylhydrazone vergeblich nachzuweisen versucht. Dieser Nachweis gelang auch nicht nach der Destillation der Methylestergemische, was vielleicht auf die Thermolabilität bestimmter Syntheseprodukte zurückzuführen ist, die auch bei geringen Drucken leicht Formaldehyd und Wasser abspalten unter Bildung ungesättigter Abbauprodukte. Im experimentellen Teil wird ein entsprechender Versuch beschrieben. Bei der Destillation erhielten wir neben einer Reihe anderer, bisher nicht näher untersuchter Substanzen ein farbloses Öl vom Sdp.$_9$ 153° von ungesättigtem Charakter. Die Analyse stimmt einigermassen auf die Summenformel $C_6H_8O_3$. Es handelt sich wahrscheinlich um die β- oder die *δ-Methylenlävulinsäure*, obwohl es merkwürdig ist, dass unter den angewendeten Bedingungen nicht der Methylester entstand. Aus diesem Grunde haben wir das isomere *β-Acetylbutyrolacton*, das als Reaktionsprodukt durchaus möglich wäre, in Erwägung gezogen. Tatsächlich gibt die Substanz mit Brady's Reagenz ein *2,4-Dinitrophenylhydrazon* $C_{12}H_{12}O_6N_4$ vom Schmp. 189—190°, was gegen das Vorliegen einer Methylenlävulinsäure spricht, da diese unter Brady's Bedingungen hätte methyliert werden müssen unter Bildung des *Methylester-2,4-dinitro-phenylhydrazons* $C_{13}H_{14}O_6N_4$. Andererseits konnte man aus der Substanz $C_6H_8O_3$ mit Hydrazinhydrat ein Derivat $C_6H_8ON_2$ vom Schmp. 225—226° gewinnen, für das nur die Formel des *Pyridazinon-Derivates* einer der beiden *Methylenlävulinsäuren* offensteht. Das ausserdem dargestellte *Semicarbazon* $C_7H_{11}O_3N_3$ vom Schmp. 194—195° lässt auch keine eindeutige Entscheidung zwischen den in Rede stehenden Isomeren zu. — Aus dem gleichen Versuch konnten wir ein weiteres 2,4-Dinitrophenylhydrazon $C_{13}H_{15}O_7N_4$ vom Schmp. 165—166° isolieren, das sich wahrscheinlich vom *Methylester der β-Methylol- oder δ-Methylol-lävulinsäure* ableitet.

Nach diesen orientierenden Versuchen über partielle Oxymethylierung haben wir uns ganz der erschöpfenden Oxymethylierung der Lävulinsäure zugewendet. Bei Anwendung eines Formaldehyd-Überschusses durften wir damit rechnen, die *3,5,5-Trimethylol-dihydro-desoxy-patulinsäure* bzw. deren *Anhydroderivat* aus dem Reaktionsgemisch direkt als *Methylenäther* abscheiden zu können, von dem aus wir nach Reduktion und Methylenätherspaltung den Anschluss an eine frühere Arbeit von Rave und Tollens [5] herzustellen hofften. Diese hatten nämlich bei der alkalischen Kondensation der Lävulinsäure mit überschüssigem Formaldehyd eine Verbindung $C_{10}H_{16}O_6$ vom Schmp. 174—176° erhalten und hierfür die Formel eines *Anhydro-pentamethylol-hydroxy-valeriansäure-lactons* (XVI) aufgestellt, die wegen des Widerspruches zwischen dem darin angenommenen Trimethylenoxydring und der Überführbarkeit der Verbindung in ein *Triacetat* nicht richtig sein kann und durch eine der anschliessend näher zu begründenden Formeln eines *Trimethylol-tetrahydro-desoxy-patulinsäure-lactons* (XVII bzw. XVIII) ersetzt werden muss.

XVI







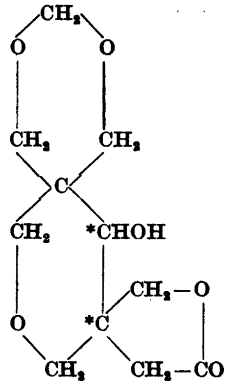
Bei der Umsetzung der Lävulinsäure mit Formaldehyd im Molverhältnis 1 : 7 bis 1 : 10 in Eisessig-Schwefelsäure erhielten wir aus dem Reaktionsgemisch ohne weiteres eine schön kristallisierende Verbindung $C_{11}H_{14}O_6$ vom Schmp. 162—163° in guter Ausbeute, die sich durch die folgenden Reaktionen als der *Methylenäther des 3,5,5-Trimethylol-dihydro-desoxy-patulinsäure-lactons* (kurz "Ketomethylenäther") (XIV) erwies. Dieser "Ketomethylenäther" reagiert in der Kälte nicht mit salzsaurem 2,4-Dinitro-phenylhydrazin. Beim Erwärmen mit diesem Reagenz in Gegenwart überschüssiger Salzsäure wird Formaldehyd unter Bildung des *Formaldehyd-2,4-dinitro-phenylhydrazons* abgespalten. Ausser durch Salzsäure gelingt die Spaltung der Methylenäther-Bindung durch Destillation mit methylalkoholischer Schwefelsäure nach Price und Krishnamurti [6]. Die besten Erfahrungen haben wir jedoch bei der Destillation mit Eisessig-Schwefelsäure gemacht, bei der der als Methylenäther gebundene Formaldehyd quantitativ abgespalten wird unter Entstehung eines bisher nicht rein dargestellten *Acetates* (XIII a), das sich mit methylalkoholischer Salzsäure leicht zum *3,5,5-Trimethylol-dihydro-desoxy-patulinsäure-lacton* (XIII) vom Schmp. 129—132° umestern liess. Die Richtigkeit der Formel XIII und die Ausschliessung der Säureformel XV ergibt sich aus den Eigenschaften der Verbindung. Sie ist in Wasser leicht löslich. Die Carbonylgruppe lässt sich darin — wie vom 2,2,6,6-Tetramethylol-cyclohexanon her bekannt [7] — mit Carbonylreagenzien nicht nachweisen. Die Verbindung setzt aus Bicarbonatlösung kein Kohlendioxyd in Freiheit und reagiert in methanolischer Lösung nicht mit Diazomethan. Eine schwach alkalische Thymolphthaleinlösung wird nur langsam entfärbt. Nach Zusatz überschüssiger Lauge lässt sich die Substanz gegen Phenolphthalein scharf titrieren. Bemerkenswerterweise werden durch sie Tollenssche und Fehlingsche Lösung reduziert. Wir werden auf die Chemie dieser Verbindung in Kürze in einer gesonderten Abhandlung zurückkommen.

Der "*Ketomethylenäther*" (XIV) besitzt die Eigenschaft, beim Erhitzen mit wässrigem Alkali zum Teil in ein Gemisch isomerer *reduzierter Methylenäther* (kurz "Oxymethylenäther") überzugehen. Aus diesem Gemisch haben wir vorerst zwei isomere "Verbindungen" * $C_{11}H_{16}O_6$ mit den Schmelzpunkten

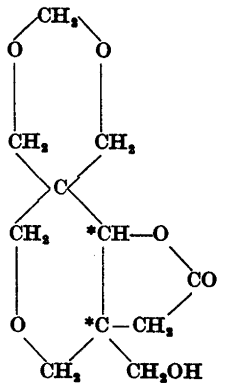
* Es ist möglich, dass die hier als "Verbindungen" bezeichneten "Oxymethylenäther" keine völlig einheitlichen Individuen darstellen, sondern isomerenverunreinigt sind, worauf das Verhalten beim Umkristallisieren und beobachtete Schmelzpunktsanomalien hindeuten. Unter diesem Vorbehalt sprechen wir im folgenden die "Oxymethylenäther" der angegebenen Schmelzpunkte als Verbindungen an.

184—187° bzw. 205—206° herauspräpariert, die sich vom *3,5,5-Trimethyloltetrahydro-desoxy-patulinsäure-lacton* (XVII bzw. XVIII) ableiten und denen daher eine der Formeln XIX oder XX zukommt.

XIX



XX



Die Reduktion des "Ketomethylenäthers" kommt offenbar dadurch zustande, dass dieser durch Alkali teilweise unter Abspaltung von Formaldehyd zerlegt wird, der dann — wie bei der Schlussphase der Tollensschen Reaktion — die Carbonylgruppe zur Carbinolgruppe reduziert. Bei diesem Reaktionsverlauf sollte man unter den Reaktionsprodukten auch das *3,5,5-Trimethyloltetrahydro-desoxy-patulinsäure-lacton* (XVII bzw. XVIII) erwarten, dessen Nachweis uns an dieser Stelle jedoch bisher, wahrscheinlich infolge der komplexen Natur der Gemische, noch nicht gelang. Bei der Reduktion des "Ketomethylenäthers" entsteht ein neues asymmetrisches Kohlenstoffatom, weshalb man ausser den durch die Formeln XIX und XX gekennzeichneten Strukturisomeren mit dem Vorliegen der entsprechenden Stereoisomeren rechnen muss. Diese Verhältnisse machen es zunächst unmöglich, den beiden isolierten "Oxymethylenäthern" eine bestimmte Formel zuzuschreiben, da hier strukturelle und sterische Fragestellungen ineinander greifen. Der niedriger schmelzende "Oxymethylenäther" vom Schmp. 184—187° liess sich durch Erhitzen mit Formalin-Salzsäure in das höher schmelzende Isomere vom Schmp. 205—206° umlagern. Die gleichen "Oxymethylenäther" erhielten wir in etwas besserer Ausbeute bei Versuchen, den "Ketomethylenäther" mit Formalin-Natronlauge bzw. Formalin-Kalilauge zu reduzieren. Im Gegensatz hierzu liess sich der "Ketomethylenäther" nicht mit Formalin-Salzsäure reduzieren. Die Möglichkeit zur Reduktion erschöpfend oxymethylierter Carbonylverbindungen durch Formalin-Alkali ergibt sich als eine logische Konsequenz der Tollensschen Reaktionsbedingungen. Während man aber beim Tollensschen Aufbau von Ketonen mit überschüssigem Formaldehyd in alkalischem Milieu die Reduktion der Carbonylgruppe nicht verhindern kann, hat man es nun in der Hand, durch saure Kondensation das "Per"-Oxymethylierungsprodukt als Methylenäther abzufangen und durch Milieuwechsel (sauer → alkalisch), falls erwünscht, den Reduktionshub getrennt zu besorgen.

In gleicher Weise wie den "Ketomethylenäther" haben wir versucht, die daraus erhaltenen "*Oxymethylenäther*" (XIX bzw. XX) an den Methylen-

ätherbrücken zu spalten, um so möglicherweise zu dem von Rave und Tollens beschriebenen Isomeren $C_{10}H_{16}O_6$ vom Schmp. 174—176° zu gelangen, obwohl wir — u.a. wegen der leichten Umlagerungsmöglichkeit des Lactonringsystems — auf die Entstehung eines schwer zu trennenden Isomerengemisches gefasst sein mussten. Merkwürdigerweise haben Rave und Tollens von derartigen Schwierigkeiten nichts erwähnt. Bei der Spaltung unseres höher schmelzenden "Oxymethylenäthers" vom Schmp. 205—206° mit Salzsäure-Aluminiumchlorid erhielten wir eine Substanz $C_{10}H_{16}O_6$ vom Schmp. 154—156°, für deren Einheitlichkeit wir uns aber aus den angeführten Erwägungen einstweilen nicht verbürgen können. Bei der Behandlung eines uneinheitlichen Präparates des "Oxymethylenäthers" mit Eisessig-Schwefelsäure enstand ein *Triacetat* $C_{16}H_{22}O_9$ (XVII a bzw. XVIII a) von unscharfem Schmp. 120—125°, während Rave und Tollens für das von ihnen dargestellte Triacetat einen Schmp. 161° angeben. Eine genauere Untersuchung der bei den "Oxymethylenäthern" vorliegenden Isomerieverhältnisse ist in Aussicht genommen. Aus den gleichen Gründen, wie für die "Oxymethylenäther" angeführt, können wir bezüglich der von uns dargestellten Substanz $C_{10}H_{16}O_6$ zwischen den für das *3,5,5-Trimethylol-tetrahydro-desoxy-patulinsäure-lacton* zur Wahl stehenden Formeln XVII und XVIII noch keine Entscheidung treffen. Wir nehmen jedoch als sicher an, dass sowohl die Verbindung von Rave und Tollens als auch unsere eigene Substanz Vertreter der durch diese Formeln beschriebenen Isomeren sind.

EXPERIMENTELLER TEIL

Unter Mitarbeit von Gustav Havre

I. Umsetzung der Lävulinsäure mit Formaldehyd (Molverh. 1:3)

Eine Mischung von 107 g Lävulinsäure (dargestellt nach Mentzer und Billet [8]), 85 g Paraformaldehyd, 250 ml Eisessig und 10 ml konz. Schwefelsäure wurde allmählich unter Rückflusskühlung erhitzt. Nach dem Abklingen der bei etwa 100° einsetzenden exothermen Reaktion wurde 3 Stunden gekocht. In der dann portweinroten Lösung liess sich nach dem Erkalten mit Fuchsinschwefliger Säure kein freier Formaldehyd mehr nachweisen. Zwecks Spaltung von Methylenäthern wurde die Flüssigkeit an der Brücke destilliert unter gleichzeitigem Zutropfen von Eisessig, wobei das Flüssigkeitsvolumen im Kolben konstant gehalten wurde. Nachdem 500 ml überdestilliert waren, wobei die Destillationstemperatur von 104° auf 118° anstieg, liess sich im Destillat mit salzsaurem 2,4-Dinitro-phenylhydrazin kein Formaldehyd mehr nachweisen. Das Reaktionsgemisch wurde mit 500 ml Wasser versetzt und mehrmals ausgeäthert. (Wässrige Flüssigkeit *A*.) Die Ätherauszüge wurden vereinigt, mit gesättigter Natriumsulfatlösung gewaschen und über wasserfreiem Natriumsulfat getrocknet. Die Ätherlösung, die noch viel Essigsäure enthielt, wurde vom Äther befreit und nach Zusatz von methylalkoholischer Salzsäure zwecks Veresterung der Essigsäure und Umesterung von Acetaten eine Zeitlang unter Rückflusskühlung gekocht. Anschliessend destillierte man unter Zutropfen von absolutem Methanol, bis beim Sdp. 65° nur noch reines Methanol überging. Zur Vervollständigung der Veresterungsreaktion behandelte man die eingedampfte Methanollösung mit überschüssigem Diazomethan. Bei der Destillation erhielt man als Hauptmenge (18 g) eine Fraktion von hellgelber Farbe und vom Sdp$_9$ 153°. Die Substanz, die in Wasser leicht löslich ist, entfärbt eine Brom-Chloroformlösung und gibt eine positive Baeyer-Reaktion.

β-Methylen-lävulinsäure (?) bzw. *δ-Methylen-lävulinsäure* (?) bzw. *β-Acetyl-butyrolacton* (?). (Gef. C 55,78, H 6,39. Ber. für $C_6H_8O_3$ (128,1): C 56,24, H 6, 29.)

2,4-Dinitro-phenylhydrazon: Eine Probe der Substanz wurde in Methanol mit Brady's Reagenz versetzt. Hellgelbe Kristalle aus Methanol. Schmp. 189—190°. (Gef. C 46,77; H 3,95; N 18,40. Ber. für $C_{13}H_{12}O_6N_4$ (308,3): C 46,75; H 3,93; N 18,18.)

Pyridazinonderivat: Beim 2-stündigen Erwärmen der Substanz mit Hydrazin-hydrat (85%) in methylalkoholischer Lösung auf dem Wasserbade erhielt man farblose Kristalle, die aus Methanol umkristallisiert bei 225—226° schmolzen. (Gef. C 58,09; H 6,55; N 22,75. Ber. für $C_6H_8ON_2$ (124,1): C 58,05; H 6,49; N 22,57.)

Semicarbazon: Farblose Blättchen aus Methanol. Schmp. 194—195° (zers.) (Gef. C 45,47; H 6,03. Ber. für $C_7H_{11}O_2N_3$ (185,2): C 45,39; H 5,99.)

Die *wässrige Flüssigkeit A* wurde zwecks Neutralisation der Schwefelsäure mit der berechneten Menge gesättigter Sodalösung versetzt, wobei sich ein braunes Öl am Boden abschied, das abgetrennt und nicht berücksichtigt wurde. Die nunmehr hellgelbe Flüssigkeit wurde mit Salzsäure kongosauer gemacht und auf dem Wasserbade eingedampft. Nach Verreiben des nicht ganz trockenen Eindampfrückstandes mit etwas wasserfreiem Natriumsulfat extrahierte man im Soxhletapparat 4 Stunden mit Äther, wobei sich am Boden ein zähflüssiges Öl abschied, das von der Ätherlösung durch Dekantieren getrennt wurde. Eine Probe des Öles wurde mit Brady's Reagenz versetzt. Der entstehende rotgelbe Niederschlag liess sich durch fraktionierte Kristallisation in eine Reihe verschiedener Substanzen zerlegen. Vorläufig wurde nur eine davon in reiner Form isoliert; die aus Methanol erhaltenen orangegelben Kristalle schmelzen bei 165—166° (Nach dem Wiedererstarren hat die Substanz den Schmp. 175°!). *2,4-Dinitrophenylhydrazon des Methylesters der β-Methylol- oder δ-Methylol-lävulinsäure* (?). (Gef. C 46,42; H 4,42; N 16,05. Ber. für $C_{13}H_{16}O_7N_4$ (340,3): C 45,88; H 4,74; N 16,47.)

II. Umsetzung der Lävulinsäure mit Formaldehyd (Molverh. 1 : 7,5)

Eine Mischung von 100 g Paraformaldehyd, 180 ml Eisessig, 13 ml konz. Schwefelsäure und 50 g Lävulinsäure wurde wie unter I. beschrieben zur Reaktion gebracht. Das hellbraune Reaktionsgemisch kristallisierte beim Stehen in der Kälte. Beim Absaugen erhielt man 43 g farbloser Kristalle, aus der Mutterlauge eine weitere Menge. Die Substanz, die durch Paraformaldehyd verunreinigt ist, kristallisierte man zuerst aus Wasser, dann aus Alkohol um. Schmp. 162—163°. V.Z. 243,0 (ber. 231,6). Die Verbindung spaltet beim Kochen mit Salzsäure Formaldehyd ab.

Methylenäther des 3,5,5-Trimethylol-dihydro-desoxy-patulinsäure-lactons (XIV), "*Ketomethylenäther*". (Gef. C 54,50; H 5,78. Ber. für $C_{11}H_{14}O_6$ (242,2): C 54,54; H 5,83.)

III. Spaltung des "Ketomethylenäthers" zum 3,5,5-Trimethylol-dihydro-desoxy-patulinsäure-lacton (XIII)

a) *mit Salzsäure-Aluminiumchlorid.* Eine Mischung von 5 g "Ketomethylenäther" und 5 g Aluminiumchlorid wurde vorsichtig mit 50 ml ca. 6 *N* Salzsäure versetzt. Die erhaltene Lösung wurde sodann unter gleichzeitigem Zutropfen von 6 *N* Salzsäure destilliert, bis sich im Destillat mit 2,4-Dinitro-phenylhydrazin-Hydrochlorid kein Formaldehyd mehr nachweisen liess. Die Flüssigkeit dampfte man im Vakuum weitgehend ein und verrieb den noch etwas feuchten Eindampfrückstand mit wasserfreiem Natriumsulfat zu einem trockenen Pulver, das im Soxhletapparat 12 Stunden mit abs. Äther extrahiert wurde. Man erhielt aus dem Ätherextrakt 4 g Rohprodukt, das aus Essigester umkristallisiert wurde (2,5 g). Schmp. 129—132°. Beim Erhitzen über den Schmelzpunkt spaltet die Verbindung langsam Formaldehyd ab. Sie reagiert in der Kälte nicht mit salzsaurem 2,4-Dinitrophenylhydrazin, reduziert Tollenssche und Fehlingsche Lösung und lässt sich in methylalkoholischer Lösung nicht mit Diazomethan methylieren. (Gef. C 52,38; H 6,14. Ber. für $C_{10}H_{14}O_6$ (230,2): C 52,17; H 6,13.)

b) *mit methylalkoholischer Schwefelsäure.* Die gleiche Verbindung wurde auch bei der Spaltung mit methylalkoholischer Schwefelsäure erhalten (Zuerst Kochen am Rückflusskühler, dann Abdestillieren des gebildeten Methylals unter gleichzeitigem Zutropfen von Methanol).

c) *mit Eisessig-Schwefelsäure* 450 g des rohen "Ketomethylenäthers" (verunreinigt durch Paraformaldehyd und Spuren Schwefelsäure) wurden mit 1 200 ml Eisessig und 5 ml

konz. Schwefelsäure * an der Brücke destilliert unter gleichzeitigem Zutropfen von reinem Eisessig, so dass das Flüssigkeitsvolumen im Kolben während der 3,5 Stunden dauernden Destillation annähernd konstant blieb (Wichtig!). Nach dieser Zeit war im Destillat kein Formaldehyd mehr mit 2,4-Dinitro-phenylhydrazin-Salzsäure nachweisbar und die Destillationstemperatur auf 118° gestiegen. Die im Kolben befindliche hellrote Flüssigkeit, die neben dem Diacetat (XIII a) überschüssige Essigsäure enthielt, wurde zwecks Veresterung der Essigsäure und gleichzeitiger Umesterung des Diacetates mit absolutem Methanol eine Zeitlang unter Rückflusskühlung gekocht und anschliessend unter Zutropfen von absolutem Methanol destilliert, bis die Siedetemperatur durch Abdestillieren des Methylacetates den Siedepunkt des reinen Methanols erreicht hatte. Aus der etwas eingeengten Lösung kristallisierten in der Kälte 330 g Rohprodukt, das durch Umkristallisieren aus Äthylacetat rein erhalten wurde. Auf diese Weise ist es leicht möglich, das 3,5,5-Trimethylol-dihydro-desoxy-patulinsäure-lacton in Ausbeuten von 70 % und darüber (bezogen auf Lävulinsäure!) zu erhalten.

IV. Verhalten des "Ketomethylenäthers" (XIV) gegenüber Alkali

Eine Mischung von 10 g des "Ketomethylenäthers", 15 g Kaliumhydroxyd und 50 ml Wasser wurde 2 Stunden gekocht. Das gelbe Reaktionsgemisch wurde nach dem Ansäuern mit Salzsäure (kongosauer!) ausgeäthert. Aus der über Natriumsulfat getrockneten Ätherlösung schied sich beim Eindampfen eine kristalline Substanz ab, die abgesaugt (1,8 g) (Mutterlauge *A*) und aus Methanol umkristallisiert wurde. Schmp. 205—206°. Die Verbindung reagiert nicht mit 2,4-Dinitro-phenylhydrazin-Salzsäure. V.Z. 255,5 (ber. 229,5). *Methylenäther des 3,5,5-Trimethyloltetrahydro-desoxy-patulinsäure-lactons* (XIX bzw. XX) (*"höherschmelzende"* Form). (Gef. C 53,98; H 6,60. Ber. für $C_{11}H_{16}O_6$ (244,2): C 54,09; H 6,60.)

Aus der *Mutterlauge A* kristallisierte nach einiger Zeit eine farblose Substanz (0,6 g). Schmp. 184—187° (aus Methanol). *Methylenäther des 3,5,5-Trimethylol-tetrahydro-desoxy-patulinsäure-lactons* (XIX bzw. XX) (*"niedrigerschmelzende" Form*). (Gef. C 53,98; H 6,69. Ber. für $C_{11}H_{16}O_6$ (244,2): C 54,09; H 6,60.)

Die gleichen Substanzen wurden bei der Behandlung des "Ketomethylenäthers" mit Natronlauge erhalten.

V. Reduktion des "Ketomethylenäthers" (XIV) mit Formalin-Natronlauge bzw. Kalilauge

Man löste 20 g des "Ketomethylenäthers" und 40 g Natriumhydroxyd in 400 ml Wasser, fügte 40 ml Formalinlösung (45 %) hinzu und erwärmte das Gemisch 7 Stunden auf dem Wasserbade. Die gelbe Flüssigkeit wurde mit konz. Salzsäure kongosauer gemacht und 5 mal mit je 200 ml Äther ausgeschüttelt. (Wässrige Schicht *A*). Beim Eindampfen der über Natriumsulfat getrockneten Ätherlösung schieden sich Kristalle aus, die abgesaugt und aus Methanol umkristallisiert wurden. Schmp. 184—187°. Mischprobe mit dem unter IV. beschriebenen "Oxymethylenäther" $C_{11}H_{16}O_6$ ("niedrigerschmelzende" Form) unverändert. — Beim Stehen der *wässrigen Flüssigkeit A* schied sich eine farblose Substanz vom Schmp. 202—205° ab, die sich bei der Mischprobe mit der "höherschmelzenden" Form des "Oxymethylenäthers" $C_{11}H_{16}O_6$ identisch erwies. — Bei der Umsetzung des "Ketomethylenäthers" mit Formalin-Kalilauge erhielt man nach dem Eindampfen des angesäuerten Reaktionsgemisches zur Trockne und Extraktion im Soxhletapparat nur die *"niedrigerschmelzende"* Form $C_{11}H_{16}O_6$ vom Schmp. 184—186° in 25 % Ausbeute.

---

* Enthält das Ausgangsmaterial Spuren Schwefelsäure, lassen sich an Stelle der Schwefelsäure mit Vorteil 10—20 ml konz. Salzsäure verwenden, wodurch man nach der Umesterung leichter zu einem völlig farblosen Präparat gelangt.

VI. Umlagerung der "niedrigerschmelzenden" Form des "Oxymethylenäthers (XIX bzw. XX) in die "höherschmelzende" Form

0,8 g des "Oxymethylenäthers" $C_{11}H_{16}O_6$ vom Schmp. 184—187° wurde in einer Mischung von 15 ml Formalin und 15 ml konz. Salzsäure kalt gelöst und die Lösung 3 Stunden auf dem Wasserbade erhitzt. Die nun gelbe Flüssigkeit dampfte man weitgehend ein. Nach 2 Tagen hatten sich Kristalle ausgeschieden, die abgesaugt und aus Methanol umkristallisiert wurden. Schmp. und Mischschmp. mit dem "höherschmelzenden" Isomeren $C_{11}H_{16}O_6$ unverändert 204—206°.

VII. Spaltung des "höherschmelzenden Oxymethylenäthers" (XIX bzw. XX) mit Salzsäure-Aluminiumchlorid

1 g des "Oxymethylenäthers" vom Schmp. 204—206° wurde, wie unter III a) für den "Ketomethylenäther" beschrieben, mit 1 g Aluminiumchlorid und 6 *N* Salzsäure behandelt und aufgearbeitet. Man gewann so 0,2 g farblose Kristalle vom Schmp. 154—156° (aus Essigester): *3,5,5-Trimethylol-tetrahydro-desoxy-patulinsäure-lacton* (XVII bzw. XVIII). (Gef. C 51,71; H 6,93. Ber. für $C_{10}H_{16}O_6$ (232,2): C 51,72; H 6,95.)

VIII. Spaltung des "Oxymethylenäthers" (XIX bzw. XX) mit Eisessig-Schwefelsäure

2 g "Oxymethylenäther" (Isomerengemisch; Schmp. ca. 170—195°) wurden mit 150 ml Eisessig und 2 ml konz. Schwefelsäure unter Zutropfen von reinem Eisessig destilliert. Nach 90 Minuten liess sich im Destillat mit 2,4-Dinitro-phenylhydrazin-Hydrochlorid kein Formaldehyd mehr nachweisen. Der Kolbeninhalt wurde nach Zusatz von 6 g wasserfreiem Natriumacetat im Vakuum zur Trockne eingedampft. Durch Extraktion des Eindampfrückstandes im Soxhletapparat mit abs. Äther erhielt man farblose Kristalle, die nach mehrfachem Umkristallisieren aus Eisessig unscharf zwischen 120—125° schmolzen.

Triacetat des 3,5,5-Trimethylol-tetrahydro-desoxy-patulinsäure-lactons (XVII a bzw. XVIII a). (Gef. C 53,82; H 6,29. Ber. für $C_{16}H_{22}O_9$ (358,3): C 53,63; H 6,19.)

Note on the Preparation of Acetals of Alkoxysuccinaldehydes

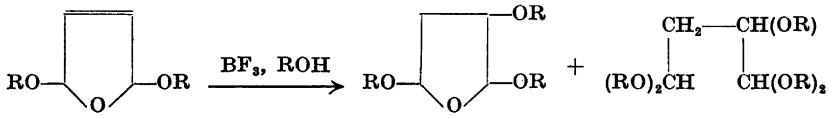
NIELS CLAUSON-KAAS, JØRGEN TORMOD NIELSEN and ERNST BOSS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

Acetals of alkoxysuccinaldehydes have been prepared by interaction of alcohols and 2,5-dialkoxy-2,5-dihydrofurans in the presence of catalytic amounts of boron fluoride etherate. The use of a new setup for laboratory fractional batch distillations is demonstrated.

Stoll, Lindenmann and Jucker [1] have prepared 2,3,5-trialkoxytetrahydrofurans by interaction of equimolar amounts of 2,5-dialkoxy-2,5-dihydrofurans and hydrogen bromide in alcoholic solution. These authors suggest that the reaction takes place through an intermediate 2,5-dialkoxy-3-bromotetrahydrofuran in which the bromine is replaced by a metathetic reaction with the solvent.

We have obtained trimethoxy- and triethoxytetrahydrofurans by interaction of the alcohol and the dihydrofuran in the presence of an acid catalyst, preferably boron fluoride etherate (*cf.*[2]). At the same time a certain amount of the tetraalkyl acetal of the alkoxysuccinaldehyde is formed



55 % (R = Et)
33 % (R = Me)

16 % (R = Et)
32 % (R = Me)

The reaction mixtures were analyzed by fractional distillation and, as expected (*cf.*[3]), it was found that the trialkoxytetrahydrofurans consisted of mixtures of two or more stereoisomers. It was also found that the reaction mixture from 2,5-dimethoxy-2,5-dihydrofuran contained 9 % of malealdehyde tetramethyl acetal.

We believe that the experiments of Stoll, Lindenmann and Jucker [1] are also acid-catalyzed alcohol additions rather than two-step reactions proceeding through an intermediate bromo compound.

The results of the distillations are given in detail in order to demonstrate the use of a new setup for laboratory fractional batch distillations [4].

Table 1. Distillation of 56.76 g of ethyl acetals under 14 mm; heat input 4.0 watt; take-off every 2.4 minutes; change of fraction every 1.0 hour; total yield of distillate 55.75 g (98.2 %).

EXPERIMENTAL

Microanalyses in part by K. Glens

Addition of ethanol to diethoxydihydrofuran. Diethoxydihydrofuran [5] (150.0 g), ethanol (anhydrous, 560 ml) and boron fluoride etherate (15.0 ml) were mixed and heated under reflux (90 min). A solution of sodium ethoxide [from sodium (7.5 g) and ethanol (60 ml)] was added and the mixture heated further under reflux (30 min). This was done in order to destroy traces of compounds with a free aldehyde group. After cooling, the borofluoride was removed by filtration and washed with ether. The ethanol and the ether were distilled in a vacuum from a water-bath (70°). The excess of sodium ethoxide was removed by centrifugation and washed twice with ether. The reaction product combined with the etheral washings was then distilled. The yield was 167.0 g of a colorless liquid, $b.p._{17}$ 101—135°. The product slowly forms peroxides on standing.

The product was fractionally distilled in a previously described setup including a 12 cm column [4]. The result of the distillation is shown in Table 1.

The yield of triethoxytetrahydrofuran (fractions 3—22) was 36.24 g (55 %) and of ethoxysuccinaldehyde tetraethyl acetal (fractions 24—32) 14.81 g (16 %). The yield of the mixture of acetals is 52.83 g (fractions 3—32) (74 %).

It is apparent from Table 1 that the triethoxytetrahydrofuran consists of a mixture of two or more stereoisomers. Stoll, Lindenmann and Jucker [1] report $b.p._{15}$ 91—98° for their triethoxytetrahydrofuran.

Addition of methanol to dimethoxydihydrofuran. A mixture of acetals of methoxysuccinaldehyde was prepared from dimethoxydihydrofuran [6] (100.0 g), methanol (dried with magnesium, 400 ml) and boron fluoride etherate (10.0 ml) as described above. The yield was 121.0 g of a colorless liquid, $b.p._{15}$ 75—102°. The product was distilled through a 25 cm column [4] (Table 2). During the distillation a low boiling product (0.58 g in all, n_D^{25} 1.3531), probably consisting mainly of methanol, accumulated in the cooling trap. In order to reduce this splitting off of methanol, the product rate was increased towards the end of the distillation.

In the article describing the setup for fractional distillation [4] it was claimed that when a pure compound is distilled at constant boil-up rate and a fixed setting of the timer, the product rate remains constant within 3 %. In the above distillations this is only true for the distillation shown in Table 1, but not for the distillation shown in Table 2. We believe that the reason for this is the very slight decomposition which takes place during the latter distillation. The formation of gas causes small variations of the pressure in the still-pot and the column, whereby the boil-up rate and thereby the product rate is changed. In our experience, a slight decomposition is actually indicated more clearly by variations of the product rate, rather than by variations of the boiling point or the purity of the product (*e. g.* as measured by the refractive index).

The yield of trimethoxytetrahydrofuran (fractions 2—12) was 40.79 g (33 %), of malealdehyde tetramethyl acetal (fractions 15—18) 12.28 g (9 %) and of methoxysuccinaldehyde tetramethyl acetal (fractions 20—32) 50.46 g (32 %). The yield of the mixture of acetals (fractions 2—32) is 113.76 g (81 %).

The malealdehyde tetramethyl acetal (previously found [7] $b.p._{760}$ 198—199°, n_D^{25} 1.4282) was identified by transformation into malealdehyde bis-phenylhydrazone as described previously [6]. The yield was 74 mg (72 %), m. p. 170—171° (Kofler stage, corr.). The hydrazone was further characterized by the infrared absorption spectrum (in potassium bromide), which was identical with that of an authentic specimen prepared from dimethoxydihydrofuran. (Found: C 72.3; H 6.2; N 21.5. Calc. for $C_{16}H_{16}N_4$ (264.3): C 72.7; H 6.1; N 21.2).

It is apparent from Table 2 that the trimethoxytetrahydrofuran is a mixture of two or more stereoisomers. Stoll, Lindenmann and Jucker [1] report $b.p._{15}$ 78—82° for their product. Kebrle and Karrer [8] report b $p._{13}$ 85—86° and n_D^{20} 1.4300 for a product prepared by methylation of a 2,5-dimethoxy-3-hydroxytetrahydrofuran.

Table 2. Distillation of 119.6 g of methyl acetals under 25 mm; heat input 3.6 watt; take-off every 6.9 minutes; change of fraction every 8 hours. After about half of fraction 26 was collected and until the end of the distillation the take-off valve was opened every 1.7 minutes and the fractions changed every 4 hours. The total yield of distillate, including the product in the cooling trap, was 116.9 g (97.7 %).

Studies of Absorption Spectra

VIII. Three and More d-Electrons in Cubic Crystal Fields

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The first order splitting of d^n-terms in relatively weak crystal fields of cubic symmetry is obtained by application of the diagonal sum rule to the intermediate crystal field case, first studied by Bethe. In some of the cases, where the same crystal field quantum number Γ_n applies to two or more levels of the same multiplicity, the method can only give the average value of the term splitting. Terms of d^5, which are only represented once, cannot show first order splitting in the cubic field.

Bethe [1] found the number of levels, originating from a term with a given L by group-theoretical means for any type of crystal field symmetry. In the simplest case, the cubic symmetry, the terms of two d-electrons were investigated by Ilse and Hartmann [2]. The present paper gives some of the analogous results for d^3, d^4 and d^5-systems. The splitting of d^{10-n}-terms is inverted, respectively to the corresponding d^n-terms. When two or more terms with the same combination of L and S occur, or when two levels of the same term have the same [1] crystal field quantum number Γ_n, only the average value of the splitting of the combined levels can be found by this method. As shown below, the splitting of D- and H-terms with the same S cannot be found separately, because of a similar conformity.

In strong crystal fields the levels can be classified [1] according to their number of γ_3- and γ_5-electrons, while they have no fixed L as the terms in the free ion. Table 1 gives the distribution of the levels for the different electron numbers. The cubic crystal field quantun numbers Γ_n can be found by factorizing the group products of γ_3 and γ_5 of the occurring electrons * as linear combinations of the character system of Γ_n, given in Table 1, Ref[1]. The multiplicity $2S + 1$ of the levels can be found by consideration of the degene-

* When two or more electrons with the same γ_n are present, their group product must be restricted by Pauli's exclusion principle. This can be done by comparison with the number of terms in the free ion, split by a cubic crystal field, or by comparison with the number of totally non-degenerate states in fields of lower (tetragonal or rhombic) symmetry.

racy number $(2S + 1)\,e$, where $e = 1, 1, 2, 3, 3$ for Γ_n with $n = 1, 2, 3, 4, 5$, respectively. The total sum of degeneracy numbers is given in the last column of Table 1.

The following relation between d^{10-n}-levels and d^n-levels can be used for higher numbers of d-electrons:

$$\gamma_5^a \gamma_3^b \equiv \gamma_5^{6-a} \gamma_3^{4-b} \tag{1}$$

Special cases of this analogy to Pauli's equivalence theorem are $\gamma_5^a \equiv \gamma_5^{6-a}$ and $\gamma_3^b \equiv \gamma_3^{4-b}$.

If E_1 is the energy of a γ_3-electron and E_2 of a γ_5-electron, the energy of the d^n-levels can be written:

$$E = E(\text{free ion}) + NE_1 + (n-N)E_2 \tag{2}$$

It is often convenient to fix the zero-point of the energy scale by defining the energy $\frac{2n}{5} E_1 + \frac{3n}{5} E_2$ which is constant for all levels of the n electrons to be $= 0$, and thus to write:

$$E = E(\text{free ion}) + (N - \frac{2n}{5})(E_1 - E_2) \tag{3}$$

The second part of the expression gives the deviation of the level from the centre of gravity of the term, defined according to Bethe [1]. The Orgel diagram [3] is E of equ. 3 as function of (E_1-E_2). This parameter indicates the relative strength of the crystal field and is the energy difference between the two states of one d-electron in the same cubic field. In some cases, the value of N changes from a limiting value for small (E_1-E_2) to another value for large (E_1-E_2), as pointed out by Santen and Wieringen [4]. The latter limiting values can be found in Table 1 as the number of γ_3-electrons.

However, in the cases, where only one level ${}^{2S+1}\Gamma_n$ occurs in a given electron number in Table 1, N is invariable for all values of (E_1-E_2). Thus, the d^2-levels have $N = 1$ in ${}^1\Gamma_4$ and ${}^3\Gamma_5$, corresponding[2] to the first-order values $E_1 + E_2$ for ${}^1G$ and ${}^3F$ and $N = 2$ in ${}^3\Gamma_2$ from ${}^3F$. For d^3-systems is $N = 0$ in ${}^4\Gamma_2({}^4F)$ and $N = 1$ in the three cases ${}^2\Gamma_1({}^2G)$, ${}^2\Gamma_2({}^2F)$ and ${}^4\Gamma_5({}^4F)$. For d^4-systems is $N = 1$ for ${}^3\Gamma_1({}^3G)$. As also found by Santen and Wieringen[3] is $N = 1$ for ${}^5\Gamma_3({}^5D)$ and $N = 2$ for ${}^5\Gamma_5({}^5D)$.

In the cases where two or more ${}^{2S+1}\Gamma_n$ are represented, the total number of γ_3-electrons occurring in the levels must equal the total sum of N for any value of (E_1-E_2). This is analogous to the diagonal sum rule of Condon and Shortley [5]. *E.g.*, in d^2-systems, the two ${}^3\Gamma_4$ have together [2] $N = \frac{4}{5} + \frac{1}{5} = 1$ and the two ${}^1\Gamma_3$ have together $N = \frac{8}{7} + \frac{6}{7} = 2$.

The distribution of the N-sum on the individual levels for $(E_1-E_2) \to 0$ can be found from the theorems of Bethe [1] on the deviations from the centre of gravity of the original term. For S- and P-terms, which do not split up in a cubic field, N is invariably $\frac{2n}{5}$. For D-terms the energy can be expressed:

$$E(\Gamma_3) = E(D) + 3\eta(D) \text{ and } E(\Gamma_5) = E(D) - 2\eta(D) \tag{4}$$

Table 1. Distribution of d^n levels in strong crystal fields of cubic symmetry.

$\gamma_5^3\gamma_3$	$^1\Gamma_1 + {}^3\Gamma_1 + {}^1\Gamma_2 + {}^3\Gamma_2 + {}^1\Gamma_3 + 2\,{}^3\Gamma_3 + {}^5\Gamma_3 + 2\,{}^1\Gamma_4 + 2\,{}^3\Gamma_4 + 2\,{}^1\Gamma_5 + 2\,{}^3\Gamma_5$	80
γ_5^4	$^1\Gamma_1 + {}^1\Gamma_3 + {}^3\Gamma_4 + {}^1\Gamma_5$	15
d^5: $\gamma_5\gamma_3^4$	$^2\Gamma_5$	6
$\gamma_5^2\gamma_3^3$	$^2\Gamma_1 + {}^2\Gamma_3 + 2\,{}^2\Gamma_3 + 2\,{}^2\Gamma_4 + {}^4\Gamma_4 + 2\,{}^2\Gamma_5 + {}^4\Gamma_5$	60
$\gamma_5^3\gamma_3^2$	$2\,{}^2\Gamma_1 + {}^4\Gamma_1 + {}^6\Gamma_1 + {}^2\Gamma_2 + {}^4\Gamma_2 + 3\,{}^2\Gamma_3 + 2\,{}^4\Gamma_3 + 4\,{}^2\Gamma_4 + {}^4\Gamma_4 + 4\,{}^2\Gamma_5 + {}^4\Gamma_5$	120
$\gamma_5^4\gamma_3$	$^2\Gamma_1 + {}^2\Gamma_3 + 2\,{}^2\Gamma_3 + 2\,{}^2\Gamma_4 + {}^4\Gamma_4 + 2\,{}^2\Gamma_5 + {}^4\Gamma_5$	60
γ_5^5	$^2\Gamma_5$	6

The parameter $\eta(D)$ describes thus the splitting of the D-term and $E(D) = E(D \text{ free ion}) + \frac{2n}{5}E_1 + \frac{3n}{5}E_2$. According to Bethe [1], it is further possible to write for F-terms and G-terms:

$$\begin{aligned} E(\Gamma_2) &= E(E) + 6\eta(F) & \qquad E(\Gamma_1) &= E(G) + 14\eta(G) \\ E(\Gamma_4) &= E(F) - 3\eta(F) & \qquad E(\Gamma_3) &= E(G) + 2\eta(G) \\ E(\Gamma_5) &= E(F) + \eta(F) & \qquad E(\Gamma_4) &= E(G) + 7\eta(G) \\ & & \qquad E(\Gamma_5) &= E(G) - 13\eta(G) \end{aligned} \tag{5}$$

The parameters η can be compared with the Lande interval factor ζ for multiplet splitting[5] due to coupling between L and S.

When equ. 5 is applied to the case of $^2\Gamma_4$ in d^3-systems (or $^3\Gamma_4$ in d^4-systems) by use of the known values of $\eta(F)$ and $\eta(G)$, it can be concluded that the splitting of H-terms is of the form

$$\text{average of two} \quad \begin{aligned} E(\Gamma_3) &= E(H) + 3\eta(H) \\ E(\Gamma_4) &= E(H) \\ E(\Gamma_5) &= E(H) - 2\eta(H) \end{aligned} \tag{6}$$

Since similar results are not known for I-terms, $S = 0$ has not yet been treated in d^4-systems by the present method.

Table 2. Multiplet splitting factors $\eta(L)$ of systems with two, three and four d-electrons, expressed in units of (E_1-E_2).*

d^2	S	d^3	S	d^4	S
$\eta(D)=+4/35$	0	$2\eta(D_{av})+\eta(H)=+8/105$	$^1/_2$	$\eta(D)=-1/5$	2
$\eta(F)=+1/5$	1	$\eta(F)=-1/5$	$^3/_2$	$\eta(D)+\eta(H)=-5/21$	1
$\eta(G)=+1/35$	0	$\eta(F)=-1/30$	$^1/_2$	$2\eta(F_{av})=-1/60$	1
		$\eta(G)=-1/70$	$^1/_2$	$\eta(G)=-3/70$	1

* Finkelstein and Van Vleck[11] have given the matrices for d^3 in cubic fields. $\eta(H)$ is separately $\frac{1}{15}(E_1-E_2)$ and η of the two ^2D-terms $\frac{1}{10}$ and $\frac{-19}{210}$, giving the sum in Table 2. The first-order deviations of the two $\Gamma_4(^2H)$ levels are given[11] as $\pm$ 0.261 (E_1-E_2) which is an energy of the same order of magnitude as the non-diagonal elements in the matrices.

Equ. 6 has the interesting consequence that only the sum $\eta(D)+\eta(H)$ can be determined by this method in cases where D- and H-terms have the same S, since $\eta(D)$ and $\eta(H)$ only occur in proportional equations. This is connected with the fact that the character systems can be written

$$C(H) = 2C(P) + C(D) \tag{7}$$

This is not a sufficient cause for the peculiar degeneracy of equ. 6. Thus the expression

$$C(G) = C(S) + C(P) + C(D) \tag{8}$$

has no significant effect of the energy expressions. Generally the character systems can be written as a linear combination with the coefficients $A_n \geq 0$ of only four (and not five) fundamental character systems:

$$C(L) = A_0C(S) + A_1C(P) + A_2C(D) + A_3C(F) \tag{9}$$

Thus, the number of Γ_5 levels at a given L is always equal to A_2+A_3, the sum of Γ_3 and Γ_2 levels.

The results of Table 2 are obtained from the diagonal sum arguments above and equations 4—6. The subscript "av" denotes the average energy of the terms in the cases where two terms with the same combination of L and S are found in the free ion [5].

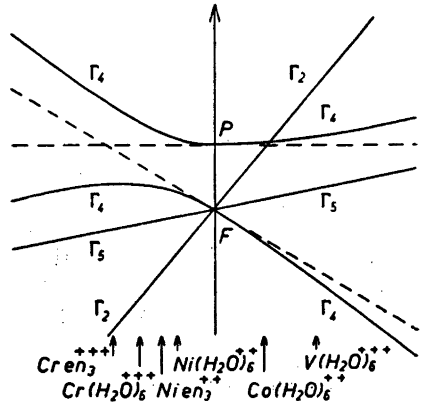

Fig. 1. Orgel diagram for terms of highest multiplicity in cubic crystal fields. Left-hand side d^3- and d^8-systems in octahedral complexes with negative ions or dipoles as ligands. Right-hand side d^3- and d^7-systems.

When the method is applied to d^5, all the $\eta(L)$ are 0. This could also be inferred from the inversion of the first order term splittings in d^{10-n} relative to d^n, since d^5 is its own hole-equivalent. The observed splittings [6] of ^4G in Mn^{++} and Fe^{+++} are thus due to second order effects of $(E_1—E_2)$ in stronger crystal fields (here acting on $^4\Gamma_4$ and $^4\Gamma_5$ for the two first bands). Since these terms usually have only small distances in the free ions with d^3, d^4 and d^5-configurations, their interaction can be described by the non-diagonal elements in the matrix of the form given by Orgel[6] which are presumably quite prominent for S smaller than the maximum value. E (free ion) of equ. 3 is also intermixed of the different interacting states, originating in the weak crystal field.

As an example of the transition from weak to strong crystal fields, Fig. 1 illustrates the interaction of levels with the same Γ_n in the case where the highest multiplicity is represented by F- and P-terms. The right-hand side is the Fig. 3 of Ref.[3], valid for d^2 and d^7, while the left-hand side applies to d^3 and d^8 in octahedral complexes [4]. Some concrete examples of crystal field strengths are given by the vertical arrows. The corresponding observed wave numbers are given in Table 3. It is seen that $\Gamma_5(F)$ is lower in d^3 and d^8-systems than the lowest of the two Γ_4. At high values of $(E_1—E_2)$, Γ_4 should in these systems be placed a constant amount below Γ_5 according to Orgel [3]. This is supported by the tetragonal splitting of the first band of mono- and trans-di-substituted chromium(III) complexes, since Γ_4 has first order tetragonal effects in contrast to Γ_5. Nevertheless, a crossing of Γ_4 and Γ_5 seems highly improbable. Rather the wave-functions are intermixed [1] by passing from weak to strong crystal fields. The third band in chromium(III) complexes, corresponding to the transition to the highest Γ_4 is predicted far in the ultra-violet.

Table 3. Maxima of observed absorption bands in cm^{-1}.

Shoulders are given in parenthesis. "en" = ethylenediamine. The energy difference between the P and F term of highest multiplicity is given for the free ion, known from atomic spectroscopy [10].

Analogous to the generalization from the d^2-levels to most of the d^n-levels in cubic crystal fields, Ballhausen and the author will publish elsewhere[12] results on d^n-levels in crystal fields of tetragonal and rhombic symmetry. These will utilize the calculations on one and two d-electrons in fields of low symmetry, according to Ballhausen [7,8,9], where the electron distributions in strong crystal fields on the individual tetragonal and rhombic quantum numbers γ_n can also be connected with the energy expressions in weak crystal fields of the corresponding symmetry for most d^n-systems.

Acknowledgment. I am very much indebted to Professor Jannik Bjerrum for his interest in this work, and to Mr. C. J. Ballhausen for many valuable discussions.

The Crystal Structure of $(NH_4)_2SbCl_5$

MAJA EDSTRAND, MATS INGE and NILS INGRI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Sweden

$(NH_4)_2SbCl_5$ has been investigated by X-ray methods. It is monoclinic, space group No. 12, $C2/m$-C_2^{3h} with 4 formula units in the unit cell. The cell dimensions are: $a = 11.9_8$ Å, $b = 7.7_6$ Å, $c = 11.9_7$ Å, $\alpha = 114.7°$ and $V = 1003.2$ Å^3, the atomic coordinates are given on p. 130, and the interatomic distances in Table 3. The antimony and chlorine positions were determined from Patterson projections and by applying the "Vector Convergence Method". The parameters were refined by electron density projections, from which the ammonium positions also were discovered. The ammonium positions were checked from space considerations.

The structure is represented in Figs. 11, 12, 13, and 14. Antimony is surrounded by five chlorine at five of the corners of a distorted octahedron forming an isolated $SbCl_5^{2-}$ group. The chlorine and ammonium form together a distorted close-packing with some vacant positions.

The structure determinations of the antimony(III)oxide halogenides $Sb_4O_5X_2$ where X = Cl or Br (Edstrand [1]), SbOCl (Edstrand [2]) and two other oxide halogenides with the idealized formulae $Sb_8O_{10}(OH)_2X_2$ where X = Cl, Br or I and $[Sb_8O_8(OH)_4]Cl_{2+x}[(OH)_{2-x}(H_2O)_{1+x}]$ (Edstrand[3]) have made it seem of interest to investigate the distances between trivalent antimony and the halogenide ions in the solid state, and also to obtain some more information regarding the coordination of trivalent antimony. In SbOCl there are two different types of Sb—Cl distances, one of the magnitude 2.4 Å and the other of the magnitude 3 Å. In $Sb_4O_5Cl_2$ we have only Sb—Cl distances of the magnitude 3 Å and larger. The distance of about 2.4 Å is of the same magnitude as the Sb—Cl distances found for $SbCl_3$ in the gas phase. Gregg, Hampson, Jenkins, Jones, and Sutton [4] found it to be 2.37 ± 0.02 kX by electron diffraction methods, and Kisliuk [5] found it to be 2.325 ± 0.005 Å by microwave methods.

Trivalent antimony seems to have different coordination numbers in different compounds. We shall here give a short review, which is not supposed to be complete, of the coordinations which have been found.

3-Coordination.

A more or less regular trigonal pyramid with antimony at the top: $SbCl_3$, $SbBr_3$, and SbI_3 in the gas phase [4,6], SbF_3 in the solid state [7], KSb_4F_{13} [8], Sb_2O_3 cubic [9,10] and orthorhombic [11], $ZnSb_2O_4$ [12], Tetrahedrite Cu_3SbS_3 [13,14], and Wolfsbergite $CuSbS_2$ [15,16].

In the following compounds there are Sb(III) atoms with different coordination numbers, one of which is three: $Sb_4O_5Cl_2$ and $Sb_4O_5Br_2$ [1], SbOCl [2], Sb_2S_3 [16,17] and the isotypic Sb_2Se_3 [18], and Berthierite $FeSb_2S_4$ [19].

4-Coordination.

I. Tetrahedral coordination: Berthierite $FeSb_2S_4$ [19].

II. A square pyramid with antimony at the top: Nadorite $PbSbO_2Cl$ [20].

III. A deformed trigonal bipyramid with antimony in the centre and with one of the equatorial corners unoccupied: $Sb_4O_5Cl_2$ and $Sb_4O_5Br_2$ [1], SbOCl [2], $Sb_8O_{10}(OH)_2X_2$ where X = Cl, Br, or I [3], and $[Sb_8O_8(OH)_4]Cl_{2+x}[(OH)_{2-x}(H_2O)_{1+x}]$ [3].

IV. A deformed trigonal bipyramid with antimony in the centre and with one of the tops unoccupied: $CsSb_2F_7$ [21].

5-Coordination.

A more or less regular octahedron with antimony in the centre and with one of the corners unoccupied: K_2SbF_5 [22], $KSbF_4$ [23], and $NaSbF_4$ [24]. In these papers there are also discussions of the different coordinations found in some complex antimony(III)fluorides. It seems as if half of the antimony atoms in Sb_2S_3 [16,17,25] have a coordination which can be interpreted as a 5-coordination of this type.

6-Coordination.

A more or less regular octahedron with trivalent antimony in the centre: $(NH_4)_2SbBr_6$, Rb_2SbCl_6, and Rb_2SbBr_6 [26], Sb_2O_4 and $SbTaO_4$ [27], and the idealized structure for Miargyrite $AgSbS_2$ [28].

8-Coordination.

Around the trivalent antimony in Sb_3O_6OH [29].

9-Coordination.

In SbSX [30] and the isotypic SbSeX [31] where X = Br or I. There is, however, close contact between Sb and only some of the 9 anions. To us the constitution of the double bands of Sb, S, and X seems to suggest 5-coordination.

In some of the examples the positions of the light atoms might be a little uncertain on account of the difficulty of locating them from the X-ray data and, accordingly, there might also be some uncertainty in the coordination number. In the cases of the coordination number 3, the results might have been influenced by a preconception that this should be the normal coordination of trivalent antimony.

For the investigation of antimony-halogen distances in the solid state it seemed more convenient to use the complex antimony(III)halogenides than the simple halogenides, as some of the former are more stable in air than the

latter. It also seemed best to start with a compound with a fairly simple formula and which did not contain any water of crystallization.

After the structure determination of $(NH_4)_2SbCl_5$ was finished, there appeared a structure determination of the complex chloride $Cs_3Sb_2Cl_9$ by Yamatera and Nakatsu[32]. They report that it has the same type of structure as $Cs_3As_2Cl_9$[33]. From the data by Yamatera and Nakatsu it does not seem as if the coordinations of As and Sb are the same in these compounds. In $Cs_3As_2Cl_9$ there is only a pseudocoordination of six around As as it is in close contact with only three Cl atoms. The data for $Cs_3Sb_2Cl_9$, however, seem to indicate six coordination for Sb, and when calculating the Sb—Cl distances we find them to be 2.7 Å, which seems rather large. The structure determination has been based on powder data, but is going to be re-examined by single crystal methods according to a private communication by Dr. K. Nakatsu.

PREPARATION

Complex antimony(III)halogenides have been prepared by many investigators. A number of complex compounds in the system NH_4Cl-$SbCl_3$ are described in Gmelin[34]. $(NH_4)_2SbCl_5$ was first prepared by Jacquelain[35] who obtained it from an acid solution of the two salts in mole proportions according to the formula and described it as a dodecahedron derived from a regular hexahedral prism. Dehérain[36] prepared it by treating $SbCl_3 \cdot 2NH_3$ with hydrochloric acid and described it as yellow hexagonal plates.

In the present investigation, $SbCl_3$ and NH_4Cl were mixed in the mole proportions 3:4 in water with or without hydrochloric acid. The solution was then evaporated by heat or by means of a vacuum. When a solution was evaporated by heating to the beginning of crystallization a lot of hexagonal leaves precipitated during the cooling and after that needle-shaped crystals were formed as four-sided prisms. An example is: 0.646 g NH_4Cl was dissolved in 2.5 ml of 1 *M* HCl and then mixed with 2.06 g $SbCl_3$. This solution was then evaporated by boiling to a volume of about 1 ml. A few hexagonal plates precipitated. It was then kept in a vacuum desiccator above sulfuric acid for 20 hours during which the main part crystallized as four sided prisms. As far as we know these four sided prisms have not been described in the literature before, unless they are identical with a compound found by Poggiale[37]. He described it as crystallizing in beautiful rectangular prisms and ascribed to it the formula $3NH_3$, HCl; $SbCl_3 + 1.5H_2O$. We used these crystals for the structure determination. They were fairly stable in air, but on long exposure to air they were hydrolysed.

ANALYSIS

Since we could not take any reliable powder photographs on account of the hygroscopic character of the substance, we had to pick out a single crystal from each preparation and take a rotation or Weissenberg photograph for the identification of the substance. To be sure that these crystals really represented the main part we proceeded in the following way. In one preparation we obtained a very large crystal. From this crystal we cut off a small fragment, of which we took a Weissenberg photograph. The rest of the crystal we used for antimony analysis, and found that it gave the same result as the other preparations.

For the antimony determination, the substance was dissolved in hydrochloric acid and titrated with potassium bromate according to Smith and May[38] with naphthol blue-black as indicator. For the determination of chlorine, the substance was boiled with a concentrated solution of sodium carbonate in a platinum dish. After filtration the chloride was titrated by the Volhard method in the presence of nitrobenzene. Ammonium was determined according to Kjeldahl.

	Ammonium %	Antimony %	Chlorine %
Calc. for $(NH_4)_2SbCl_5$	10.77	36.33	52.90
Found	10.37, 10.57	36.47, 36.17	52.13, 51.86

UNIT CELL AND SPACE GROUP

Single crystals were selected. To avoid their decomposition they were coated with Apiezon grease, which protected them fairly well. Rotation and Weissenberg photographs were taken round two of the axes with Cu-radiation. We had the following series of Weissenberg photographs (double films): *h*0*l*, *h*1*l*, *h*2*l*, *h*3*l*, *h*4*l*, *hk*0, *hk*1, *hk*2, *hk*3, *hk*4, *hk*5, *hk*6, and *hk*7. Relative intensities of the reflections were estimated visually by comparison with an intensity scale obtained by exposing an interval of the zero layer line, containing a strong reflection, with different exposure times on a pack of four double films. They were then corrected for the Lorentz and polarization factors using the curves given by Kaan and Cole [39].

The crystals proved to be monoclinic with the *b*-axis coinciding with the needle-axis. The cell dimensions were determined from the Weissenberg photographs, as we could not obtain reliable powder photographs. Using $\lambda_{CuK\alpha_1} = 1.54051$ Å, where the α_1 and α_2 reflections were separated, and $\lambda_{CuK\alpha} = \frac{1}{3}(2\lambda_{\alpha_1} + \lambda_{\alpha_2}) = 1.54176$ Å, where these reflections were not separated, we found the following values:

$a = 11.9_8$ Å, $b = 7.7_0$ Å, $c = 11.9_7$ Å, $\beta = 114.7°$ and $V = 1003.2$ Å^3

If 4 formula units are assumed per unit cell, the density would be $d_{calc} = 2.22$, we found $d_{obs} = 2.26$, 2.24.

The density of the crystals was determined from the loss of weight in carbon tetrachloride, as this liquid was found not to decompose the crystals. The density of carbon tetrachloride was taken from Beilstein [40].

In the Weissenberg photographs all reflections with $(h + k)$ odd are systematically absent, which is characteristic of the space groups No. 12, $C2/m$—C^3_{2h}, No. 5, $C2$—C^3_2, and No. 8 Cm—C^3_s [41]. To try to decide between these three space groups, we applied the method of intensity statistics [42, 43] to the zero zones *h*0*l* (see Fig. 1) and *hk*0 (see Fig. 2). It is apparent that the intensity distributions in both cases seem to indicate symmetry centres in

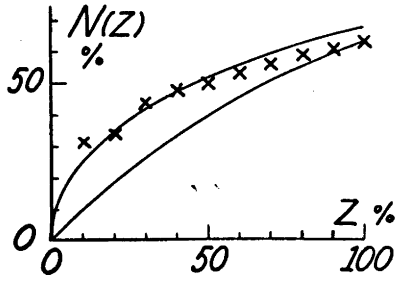

Fig. 1. Intensity statistics for h0l. × represents the experimental intensity distribution compared with the theoretical centric distribution (upper curve) and the theoretical acentric distribution (lower curve).

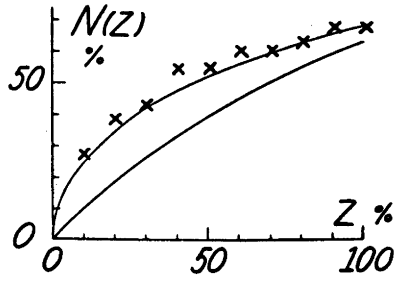

Fig. 2. Intensity statistics for hk0. × represents the experimental intensity distribution compared with the theoretical centric distribution (upper curve) and the theoretical acentric distribution (lower curve).

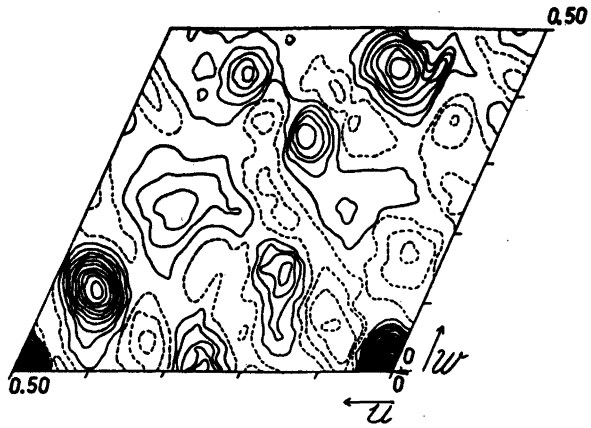

Fig. 3. P(UpW). Contours at an interval of 200 arbitrary units. Negative values dotted.

the projections, and thus it appeared reasonable to assume the space group to be No. 12, $C2/m$—C_{2h}^3, since this is the only one which has symmetry centres in both projections.

PATTERSON SYNTHESES AND VECTOR CONVERGENCE DIAGRAMS

It seemed probable that the positions of the four antimony atoms would be found from Patterson projections. The calculated $P(UpW)$-projection is given in Fig. 3 and the $P(UVp)$-projection in Fig. 4. Considering the space group $C2/m$, the antimony atoms can be situated either in one of the fourfold positions or in a combination of two twofold positions. Combinations of the twofold positions $2(a) + 2(c)$, $2(a) + 2(d)$, $2(b) + 2(c)$, and $2(b) + 2(d)$ all require maxima of the weight 2 in the $P(UpW)$-projection at $u = 0, w = \frac{1}{2}$ and at $u = \frac{1}{2}, w = \frac{1}{2}$. As we can see there are practically no observed maxima at these coordinates, and thus it seems reasonable to exclude the combinations mentioned. Combinations of the twofold positions $2(a) + 2(b)$ and $2(c) + 2(d)$ require maxima of the weight 2 in the $P(UVp)$-projection at $u = 0$, $v = \frac{1}{2}$. The observed maximum is, however, one of the lowest in this projection, and

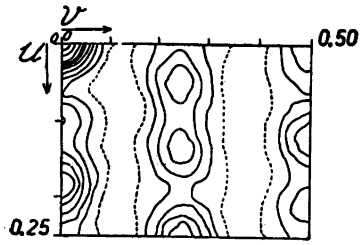

Fig. 4. P(UVp). Contours at an interval of 100 arbitrary units. Negative values dotted.

thus these combinations do not seem very probable. It therefore seems possible to exclude all the twofold positions. In the Patterson space $P(UVW)$ the fourfold positions give the following vectors:

I within 4(*e*) and 4(*f*) of weight 4	A	$0,\frac{1}{2},0$
	B	$\frac{1}{2},\frac{1}{2},0$
	C	$\frac{1}{2},0,0$
II within 4(*g*) and 4(*h*) of weight 4	A	$\frac{1}{2},\frac{1}{2},0$
of weight 2	B	$\pm(0,2y,0)$
	C	$\pm(\frac{1}{2},\frac{1}{2}+2y,0)$
III within 4(*i*) of weight 4	A	$\frac{1}{2},\frac{1}{2},0$
of weight 2	B	$\pm(2x,0,2z)$
	C	$\pm(\frac{1}{2}+2x,\frac{1}{2},2z)$

As the maximum in the $P(UVp)$-projection corresponding to the vector IA is among the lowest, it seems possible to exclude the positions 4(*e*) and 4(*f*). The only maximum corresponding to the vector IIB in $P(UVp)$, which is of reasonable height, is situated at the origin. As this corresponds to $y = 0$ or $\frac{1}{2}$, this would mean that the fourfold position corresponds to two twofold positions, which does not seem probable from what has been stated above.

We then have to consider only the position 4(*i*) and the corresponding vectors of group III, which ought to be among the highest maxima found in the projections. The vector IIIB corresponds to the following series of possible maxima in $P(UVp)$ with $u = 2x = 0$, 0.1025, 0.1847, 0.2908, 0.3818, 0.5000, 0.6182, 0.7092, 0.8153, 0.8975, 1.000 ..... where the maxima at $u = 0.1847$ and 0.8153 are the highest after that the origin. In $P(UpW)$ the two maxima next in height to that at the origin are at a) $u = 0.4403$, $w = 0.1198$, which corre-

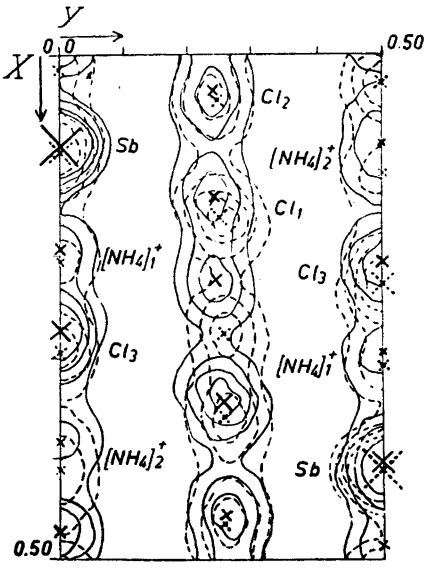

Fig. 5. The xy-vector convergence diagram. Only the lowest positive contours in P(UVp) have been drawn. The centers of the peaks are marked with crosses, the size of which are proportional to the heights. One set of Patterson maxima is marked with full lines and the other with dotted lines. The finally accepted atomic positions are indicated at the points of convergence.

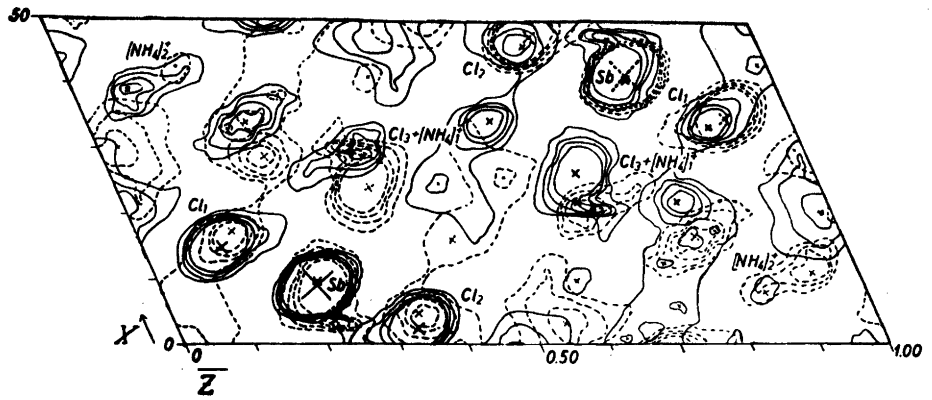

Fig. 6. The xz-vector convergence diagram. Only the lowest positive contours in P(UpW) have been drawn. The centers of the peaks are marked with crosses, the size of which are proportional to the heights. One set of Patterson maxima is marked with full lines and the other with dotted lines. The finally accepted atomic positions are indicated at the points of convergence.

sponds to the following series of u-values: 0.4403, 0.9403, 0.0597, and 0.5597 and b) $u = 0.1743$, $w = 0.4422$, which corresponds to the following series of u-values: 0.1743, 0.6743, 0.3257, and 0.8257. We can see that the u-values of the series a) and b) which are sufficiently close to values in the series from $P(UVp)$ are $u = 0.1743$ and 0.8257 (in $P(UVp)$ 0.1847 and 0.8153). These two u-values with corresponding maxima give four different sets of atomic coordinates, which, however, can be transformed into each other by translations of $\frac{1}{2}$ along the axes. We now choose the coordinates $x = \frac{1}{2}(\frac{1}{2}\ 0.1743 + \frac{1}{2}\ 0.1847) = 0.090$, $y = 0$, and $z = \frac{1}{2}\ 0.4422 = 0.221$ for Sb.

We also have to locate 20 chlorine atoms and 8 ammonium ions. It seemed quite probable that some of the other observed maxima in the Patterson projections would correspond to Sb—Cl vectors. This made it worth while to try the "Vector Convergence Method" described by Beevers and Robertson [44] on the projections starting with the previously found coordinates for Sb in 4(*i*). In this way we obtained the *xy*-projection in Fig. 5 and the *xz*-projection in Fig. 6. There are quite clear indications of the Cl-positions and it is also possible to guess something about the NH_4^+-positions. An interpretation of the diagrams gave the following set of approximate parameters, where the NH_4^+-positions are omitted since they did not seem quite certain.

		x	*y*	*z*
Sb	in 4(*i*)	0.090	0	0.221
Cl_1	in 8(*j*)	0.159	0.245	0.120
Cl_2	in 8(*j*)	0.048	0.243	0.350
Cl_3	in 4(*i*)	0.286	0	0.360

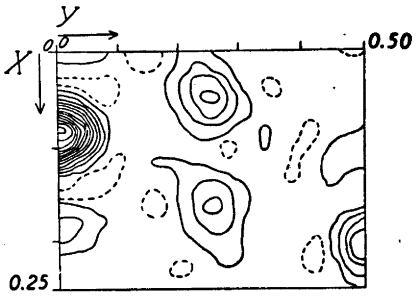

Fig. 7. ϱ (XYp). Contours at an interval of 100 arbitrary units. Negative values dotted.

A rough calculation of the interatomic distances with these preliminary parameters showed that the distances were of reasonable magnitude, and that Sb is surrounded by 5 Cl at five of the corners of a deformed octahedron. Since a coordination of this type has been reported previously for the SbF_5^{2-}-ion in K_2SbF_5 by Byström and Wilhelmi [22], the Cl-positions seemed quite likely. It can be mentioned that $(NH_4)_2SbCl_5$ and K_2SbF_5 are not isomorphous.

FOURIER SYNTHESES

The best way to refine the parameters of antimony and chlorine and try to find the ammonium positions was by Fourier syntheses. In this case the coordination around antimony is of much more interest than the coordination around the ammonium ions, and thus it does not seem necessary to find the ammonium parameters with very large accuracy. The Fourier syntheses have been calculated with $F_{obs} = \sqrt{\frac{I}{Lp}}$ where F is the structure factor, I is the estimated intensity, Lp are the combined Lorentz and polarization factors. In all syntheses the value of $F(000)$ has been omitted. Correction for absorption has not been applied. The maxima have been located by the interpolation table given by Booth [45].

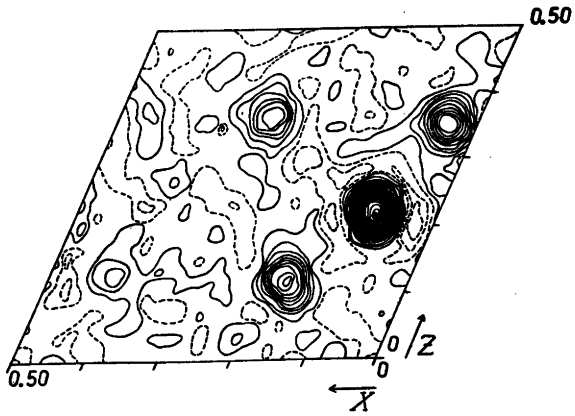

Fig. 8. ϱ (XpZ). Contours at an interval of 200 arbitrary units. Negative values dotted.

The refinement proceeded by successively calculating several $\varrho(XYp)$- and $\varrho(XpZ)$-projections, including more and more F-values. The final $\varrho\,(XYp)$-projection is given in Fig. 7, and the final $\varrho(XpZ)$-projection in Fig. 8. The antimony and chlorine peaks are clearly resolved, and we see that, in the $\varrho\,(XpZ)$-projection, the eightfold chlorine positions Cl_1 and Cl_2 are higher than the fourfold chlorine position Cl_3 as can be expected. There are also indications of the ammonium positions, which seem to be situated in the fourfold positions 4(*i*). One of them, $(NH_4^+)_1$, is quite clear in $\varrho\,(XYp)$ but is masked in $\varrho\,(XpZ)$ by Cl_3, since the two atoms are situated practically above each other. The $(NH_4^+)_2$-maximum in $\varrho\,(XpZ)$ is the maximum next in height to the Cl_3-peak. It is also found in ϱ (XYp) but here it is rather low. We then arrived at the following set of parameters, where x_1 indicates the parameter from $\varrho\,(XpZ)$, x_2 the parameter from $\varrho\,(XYp)$, x_{mv} the mean value of the two, and $\triangle x = |x_1 - x_2|$.

		x_1	x_2	x_{mv}	y	z	$\triangle x$
4 Sb	in 4(*i*)	0.0860	0.0867	0.086_3	0	0.220_8	0.0007 = 0.008 Å
8 Cl_1	in 8(*j*)	0.1692	0.1650	0.16_7	0.24_0	0.11_9	0.0042 = 0.05
8 Cl_2	in 8(*j*)	0.0375	0.0492	0.04_3	0.24_1	0.35_2	0.0117 = 0.14
4 Cl_3	in 4(*i*)	0.2903	0.2937	0.29_2	0	0.36_8	0.0034 = 0.04
4 $(NH_4^+)_1$	in 4(*i*)	0.2097	0.1875	0.19_9	0	0.63_3	0.0222 = 0.27
4 $(NH_4^+)_2$	in 4(*i*)	0.4113	0.3931	0.40_2	0	0.12_9	0.0182 = 0.22

From the values of $\triangle x$ we obtain an approximate estimation of the accuracy of the x-parameters, and it seems probable that the accuracy of the y- and z-parameters is about the same if we measure them in Å units. The maximum value of $\triangle x_{Cl}$ is 0.14 Å, which seems to indicate that the Sb—Cl distances are accurate to within $\pm$ 0.25 Å, and the Cl—Cl distances to within

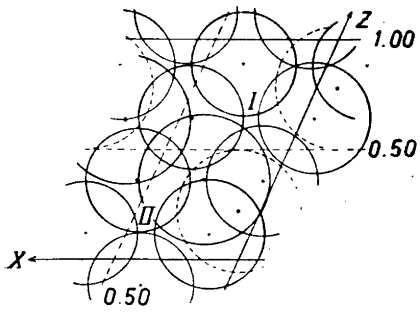

Fig. 9. Cut at $y = 0$ to locate NH_4^+. + projection of centre of Cl. ⊙ projection of centre of Sb. Full circle = forbidden area around Cl and dotted circle = forbidden area around Sb. There are room for the $8NH_4^+$ in two fourfold positions inside the areas marked I and II.

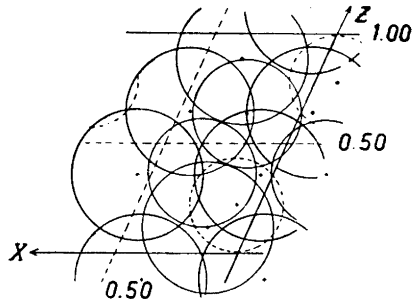

Fig. 10. Cut at $y = 1/4$ to locate NH_4^+. + projection of centre of Cl. ⊙ projection of centre of Sb. Full circle = forbidden area around Cl and dotted circle = forbidden area around Sb. Here is no room for NH_4^+.

$\pm$ 0.5 Å. Considering, however, that the distances Sb—Cl_1 and Sb—Cl_2 are equal (*cf.* Table 3) the real accuracy might be a little better than that stated above.

Because the parameters of the eight NH_4^+ are the least accurate, it is advisable also to ascertain their possible positions from space considerations. They can be situated either in two fourfold positions or in one eightfold position. The sum of ionic radii are NH_4^+—Cl^- 3.24 kX (Goldschmidt, from Internationale Tabellen [46]). Not knowing much about the minimum distance between antimony and ammonium, we assumed it could not be shorter than 3 Å. Considering that the *b*-axis is 7.70 Å, and that there are mirror planes at $y = 0$ and $\frac{1}{2}$, the only possible *y*-parameters are $y = 0$, $y = \frac{1}{2}$, and y approximately 1/4. Spheres of appropriate radii, inside which no ammonium centers could occur, were considered around the chlorine and antimony centers. Cuts were made at $y = 0$, see Fig. 9, and at $y = 1/4$, see Fig. 10. We see that there is only room for the ammonium ions in the cut $y = 0$ inside the areas marked I and II. As the ammonium positions found from the Fourier projections fall inside these two areas, it seems justified to assume these positions. As the exact NH_4^+—Cl distances are not of any particular interest in this case, we did not try to refine the ammonium parameters any further.

F-values were then calculated as

$$F_{calc} = \text{const} \left[f_{Sb} A_{Sb} + f_{Cl} \sum_1^3 A_{Cl_i} + f_N \sum_1^2 A_{NH_4^+} \right]$$

where f_{Sb}, f_{Cl} and f_N are the atomic scattering factors of antimony, chlorine and nitrogen with due consideration taken to their variation with Θ [46]. The calculated and observed *F*-values are given in Tables 1 (for *h0l*) and 2 (for *hk*0).

The reliability factor $R = \dfrac{\sum \big| |F_o| - |F_c| \big|}{\sum |F_o|}$ is 0.24 (0.27 without NH_4^+) for *h0l* and 0.23 (0.27 without NH_4^+) for *hk*0 when only the observed reflections have been included. The values of *R* calculated with an without the NH_4^+-parameters also indicate that these positions are probable.

DISCUSSION OF THE STRUCTURE

As mentioned on p. 129 Sb is surrounded by five Cl at the corners of a deformed octahedron, where the sixth corner is unoccupied, giving an isolated $SbCl_5^{2-}$ group, see Fig. 11. This type of coordination has been postulated by Pauling [47] for an atom with five bonds and one unshared electron pair, which occupies the sixth corner. The distances in the $SbCl_5^{2-}$ group are: Sb—4Cl (approximately in one plane) 2.6_2 Å and Sb—Cl (opposite the empty corner) 2.3_6 Å. We see that the Sb—Cl distance opposite the empty corner is shorter than the others and that the difference is perhaps too large to be explained entirely by the errors in the distances. As a comparison we have the following Sb—Cl distances in the solid state: in Rb_2SbCl_6 2.47 $\pm$ 0.03 kX [26], in SbOCl 2.2_9 and $2.4_7 \pm 0.3$ Å [2]. As to the distances in the gasphase see p. 122.

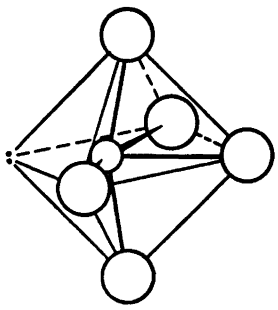

Fig. 11. The $SbCl_5^{2-}$ group with the assumed stereochemically active unshared electron pair occupying the sixth corner of the octahedron.

The $SbCl_5^{2-}$ group is isotypic with the SbF_5^{2-} group in K_2SbF_5[22], where, however, the Sb—F distance opposite the empty corner seems to be larger than the others. For the similarly five coordinated antimony in the complex $Sb_4F_{16}^{4-}$ in $KSbF_4$[23] this Sb—F distance is the shortest. If we interpret the coordination around one of the antimony atoms in Sb_2S_3[16,17] as a five coordination of this sort we find the Sb—S distance opposite the empty corner to be the shortest. An analogous coordination is also found in TlI [48] around both Tl and I, although we have not isolated complexes here. In this case the distance opposite the empty corner is the shortest.

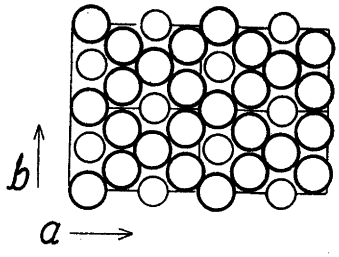

Fig. 12. Approximately close-packed layer at $z \approx 0.36$ projected orthogonally on the ab-plane with four adjacent unit cells. The radii of the circles are equal to the ionic radii of Cl^- (1.81) and NH_4^+ (1.43).

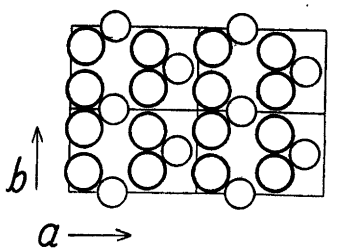

Fig. 13. Approximately close-packed layer with vacant positions at $z \approx 0.12$ projected orthogonally on the ab-plane with four adjacent unit cells. The radii are equal to the ionic radii of Cl^- (1.81) and NH_4^+ (1.43).

We can describe the structure of $(NH_4)_2SbCl_5$ schematically in the following way. The Cl^- and NH_4^+ form together a distorted close-packing with some vacant positions. In this packing we have two types of layers: A, with all positions occupied, see Fig. 12; B, with vacant positions, see Fig. 13. The sequence of the layers is: A,A′,B,B′,A,A′,B,B′, ... These layers are approximately parallel with the *ab*-plane. The Sb atoms are situated in some of the octahedral holes in such a way that one Sb is surrounded by five Cl and with the unshared electron pair directed at the empty position in the close-packing. Orthogonal projections of the structure of $(NH_4)_2SbCl_5$ are given in Fig. 14. The interatomic distances are given in Table 3.

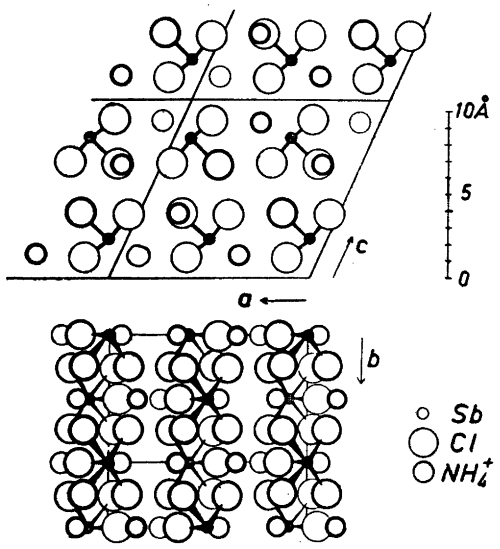

Fig. 14. Orthogonal projections of the structure of $(NH_4)_2SbCl_5$. Parts of adjacent unit cells are given.

Table 3. Interatomic distances in $(NH_4)_2SbCl_5$. Å units. The numeral 2 × before a distance means that it occurs twice.

	In $SbCl_5^{2-}$ group.							
Sb — 5 Cl	$2 \times 2.6_2$			$2 \times 2.6_2$	2.3_6			
Cl — Cl	3.7_0	3.7_2		$2 \times 3.6_6$	$2 \times 3.2_9$	$2 \times 3.4_6$		
Sb — 4Cl (at the "empty" side of the group)	$2 \times 4.3_4$	$2 \times 5.0_6$						
$(NH_4^+)_1$—11 Cl	$2 \times 3.3_9$	$2 \times 3.5_1$	$2 \times 3.6_1$	$2 \times 3.6_2$	3.7_7	$2 \times 3.8_6$		
$(NH_4^+)_2$—9 Cl	$2 \times 3.1_9$	$2 \times 3.3_2$	$2 \times 3.3_8$	3.6_1	$2 \times 3.8_0$			
Cl_1—Sb	2.6_2							
Cl_1—4 NH_4^+	3.1_9	3.3_2	3.3_8	3.3_9				
Cl_2—Sb	2.6_2							
Cl_2—4 NH_4^+	3.1_9	3.5_1	3.6_1	3.6_2				
Cl_3—Sb	2.3_6							
Cl_3—4 NH_4^+	3.6_1	3.7_7	$2 \times 3.8_6$					
Cl_1—7 Cl	3.2_9	3.6_6	3.7_0	3.8_3	4.0_0	4.0_9	4.1_9	
Cl_2—8 Cl	3.4_6	3.6_6	3.6_8	3.6_8	3.7_2	3.9_8	4.0_9	4.1_9
Cl_3—8 Cl	$2 \times 3.2_9$	$2 \times 3.4_6$	$2 \times 3.6_8$	$2 \times 3.6_8$				
$(NH_4^+)_1$—$2NH_4^+$	4.4_4	4.4_8						
$(NH_4^+)_2$—$2NH_4^+$	4.4_4	4.6_0						
Sb—Sb	4.8_1							
Sb—7 NH_4^+	$2 \times 4.3_4$	4.3_5	4.4_3	4.5_4	$2 \times 4.5_6$			
$(NH_4^+)_1$—4 Sb	4.4_3	4.5_4	$2 \times 4.5_6$					
$(NH_4^+)_2$—3 Sb	$2 \times 4.3_4$	4.3_5						

The NH_4^+ ions have a fairly irregular coordination with most of the NH_4^+-Cl distances longer than the sum of the ionic radii, which is 3.24 kX[46]. The long distances might perhaps be explained by the fact that NH_4^+ and Cl^- form a sort of close-packing although they have not the same size.

The authors wish to thank Professor A. Ölander for his encouraging interest and for valuable discussions. The investigation has been financially supported by *Statens Naturvetenskapliga Forskningsråd*.

The Crystal Structure of Ni_3P. (Fe_3P-Type)

BERTIL ARONSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The structure of Ni_3P (Fe_3P-type) has been determined using single crystal data. The space-groups is $S_4^4—I\bar{4}$ and all atoms occupy general positions 8(*g*). The structure is rather close-packed, resulting in high coordination numbers. The phosphorus atoms have 9 nickel neighbours at an average distance of 2.30 Å. The relation to some other types of transition metal phosphides is discussed and the similarity between the Mo_5Si_3-phase (usually described as "Mo_3Si_2") and the Fe_3P-type is noted.

The first X-ray crystallographic investigation of Fe_3P was made by Hägg [1]. The unit cell was found to be bodycentered tetragonal with the axial lengths $a = 9.090$ kX and $c = 4.446$ kX. The cell contained 8 formula units and the Laue symmetry was $C_{4h}—4/m$. The appearence of 0,0,2 excluded all space-groups except $S_4^2—I\bar{4}$, $C_4^5—I4$ and $C_{4h}^5—I4/m$. The first of these groups was considered to be the most probable one, owing to the external form of the crystals.

In more recent investigations the following isomorphous phases have been found: Mn_3P[2], Cr_3P[3], Ni_3P[4], Mo_3P[5], V_3P[6] * and Ti_3P[7]. A determination of the Fe_3P-structure was, therefore, considered to be of some interest. Ni_3P was chosen for this investigation, because it permitted the use of Cu*K*-radiation without disturbance from fluorescent radiation.

EXPERIMENTAL

The preparation of Ni_3P was made according to the method, described by Haughton [8] and Hägg [1]: Pastilles of red phosphorus were dropped into molten nickel. The nickel was molten in a N_2-atmosphere in a high frequency induction furnace. After cooling the melt was crushed in a steel mortar. Powder photographs were taken in a camera of the Guinier type using Cu*Ka* radiation. Some crystal fragments were selected and the one that gave the best reflexions was used in the single crystal work. For the Weissenberg photographs Mo*K* radiation was used. The crystal was rotated around the *c*-axis and the layer lines 0—4 were recorded. With the aid of Lu's [9] curves, relative $|F|^2$-values were calculated

* Schönberg [12] has not been able to verify the existence of this phase. It seems probable, however, that it does exist.

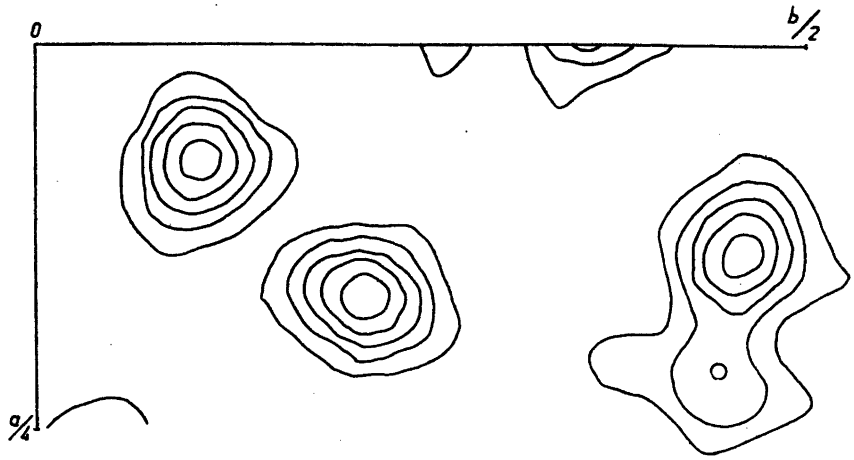

Fig. 1. Final Fourier projection $\varrho x,y$. Contours drawn at intervals of approximately 15e Å^{-2}. 1/8 of the unit cell is given.

from the visually estimated intensities. No corrections were made for adsorption and thermal movement. The computations of the Patterson sections $P(x,y,z_n)$ (z_n = 0, 2/60, 5/60, 10/60, 15/60) and the Fourier projection $\varrho(x,y)$ were made on the Hägg-Laurent machine [10].

DETERMINATION OF THE STRUCTURE

The dimensions of the bodycentered tetragonal cell were determined from the powder photographs. The lengths of the axes are $a = 8.952$ Å and $c = 4.388$ Å ($\pm$ 1 ‰). The Weissenberg photographs showed that $F_{khl} \neq F_{khl}$ and as $F_{0,0,2} \neq 0$ the only possible spacegroups were S_4^2—$I\bar{4}$, C_4^5—$I4$ and C_{4h}^5—$I\frac{4}{m}$. An inspection of the Patterson section $P(x,y,0)$ immediately showed that the fourfold axis could not be a rotation axis. Thus, the spacegroup was found to be S_4^2—$I\bar{4}$— in agreement with the supposition made by Hägg [1]. A further analysis of the Patterson function gave the approximate Ni-positions, which corresponded to general positions 8(g). Successive Fourier-projections $\varrho(x,y)$ refined the x and y parameters of the Ni-atoms and in addition gave those of the P atom, which was also found to occupy a general position 8(g). The conspicuous similarity between the layer lines 0 and 4 as well as the layer lines 1 and 3 indicated that all the atoms must lie very near the planes $z = 0, \frac{1}{4}, \frac{1}{2}$ and $\frac{3}{4}$. This fact was confirmed by the Patterson function, where all the maxima were found in the sections $P(x,y,0)$ and $P(x,y,\frac{1}{4})$.

Fig. 1 shows the final Fourier projection from which the final coordinates were obtained. The maximum corresponding to the P atom is very flat and does not permit an accurate determination of the parameters of this atom. In order to obtain these, different positions of the P atom were tried, until the best agreement between observed and calculated intensities was obtained.

The resulting parameters are

		x	y	z
Ni_I	in 8(g)	0.080	0.109	0.25
Ni_{II}	in 8(g)	0.363	0.030	0
Ni_{III}	n 8(g)	0.164	0.220	0.75
P	n 8(g)	0.290	0.042	0.50

Assuming these parameters to be correct all the maxima of the Patterson function can be explained.

THE STRUCTURE

The structure may be considered as rather close-packed, resulting in high coordination numbers. The environment of each atom is given in Table 1.

One of the Ni-atoms has 12 nickel neighbours (as in pure nickel) but the other two have 10 neighbours. The intermetallic distances are on the average 8 % longer than in the pure metal. The weakening of the metal-metal bonds in comparison with pure nickel is compensated by the metal-phosphorus bonds created here.

The phosphorus atom has 9 nickel neighbours at an average distance of 2.30 Å. Half on the P atoms in Fe_2P[11] and the isomorphous Ni_2P[4] have a similar environment — even the spatial arrangement of the 9 metal neighbours around the P atom is almost the same.

By the determination of the Fe_3P-structures another type of transition metal phosphide has been added to those recently discussed by Schönberg [12]. The way in which an increase of the non-metal concentration results in a decrease of the metallic properties is illustrated by the sequence Fe_3P, Fe_2P and FeP. The coordination numbers become lower. The P atom, for example, has 9 close metal neighbours in Fe_3P. In Fe_2P half of the P-atoms have also 9 neighbours, while the other half have 6, as have the P atoms in FeP. The structures become less densely packed. Assuming $r_{Fe} = 1.26$ Å and $r_P = 1.06$ Å, the volume occupied by each atom in Fe_3P is 6.35 r^3, in Fe_2P 6.8 r^3 and in FeP 7.25 r^3. (The corresponding values are 6.16 r^3 for α-Fe and 5.66 r^3 for γ-Fe.) The shortest P—P distances, being 3.9 Å, 3.6 Å and 2.6 Å, become smaller.

As was mentioned in the introduction several phosphides of the Fe_3P-type have been found among the transition metals (represented in the phosphide systems of Ti, V, Cr, Mn, Fe, Ni and Mo). As the experimental difficulties make

Table 1. (Only distances < 3Å have been given.)

	Interatomic distances in Å
Ni_I — 12 Ni	2.44; 2.52 (2); 2.56 (2); 2.72; 2.79 (5) 2.86
— 2 P	2.25 (2)
Ni_{II} — 10 Ni	2.43; 2.50; 2.54; 2.71 (2); 2.83 (4); 2.86
— 4 P	2.29 (3) 2.32
Ni_{III} — 10 Ni	2.43; 2.52 (3); 2.71; 2.75 (4) 2.78
3 P	2.25 (2) 2.44
P — 9 Ni	2.25 (4); 2.29 (3); 2.33 2.44

the preparation of these compounds rather difficult, it is too early to say definitely which factors determine the occurrence of the Fe_3P-type phosphide. Evidently, it is only formed by the transition metals, belonging to the groups IV—VIII of the periodic system, and most readily by the lightest of those — the only exception between Ti and Ni being Co. In Co_2P, the structure of which has been determined by Nowotny [13], the P atoms have a very similar environment to that of the P atoms in Fe_3P — according to Nowotny the average of the 9 Co—P distances is 2.30 Å. There is no Cu-compound of this type. Cu_3P has a different structure which has been determined by Steenberg [14]. To what extent the Fe_3P-type phosphide is formed by the heavier transition elements cannot yet be stated with certainty.

Another question is whether any other non-metal forms a similar phase with the transition metals. The Mo—Si and W—Si systems have recently been investigated at this institute and the phases usually described as "Mo_3Si_2" and "W_3Si_2" have been found to possess a bodycentered tetragonal structure with $a = 9.617$ Å, $c = 4.899$ Å ("Mo_3Si_2") and $a = 9.645$ Å, $c = 4.969$ Å ("W_3Si_2"). The correct formulae are Mo_5Si_3 and W_5Si_3 with 4 formula units in the elementary cell. Thus, the elementary cell of this structure resembles very strikingly that of Fe_3P. A structure determination of W_5Si_3, which has recently been completed at this institute, shows, however, that this similarity is not caused by any deeper analogies between the Fe_3P and W_5Si_3 structures. (The space group of W_5Si_3 is $I\bar{4}2m$; 16 W are situated in 16 (j) with $x = 0.277$, $y = 0.074$, $z = 0.25$, 2 W in 2 (b), and 2 W in 2 (a), while the probable positions of Si are 8 Si in 8 (i) with $x = 0.17$, $z = 0.75$ and 4 Si in 4 (c)).

Acknowledgements. The author wishes to thank professor G. Hägg for his very kind and encouraging interest and Mr. N. Schönberg for many valuable discussions.

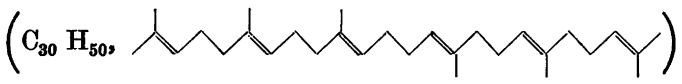
The Crystal Structures of the Isomeric Squalene Hexahydrochlorides

HARALD SÖRUM and JOHANNES DALE

Forsvarets Forskningsinstitutt, Kjeller, Norway

The structures of two isomeric squalene hexahydrochlorides have been investigated by the aid of X-ray methods, supported by the study of the infrared absorption spectra. Detailed molecular structures are proposed for both forms, and their relation to other long carbon chain molecules such as β-guttapercha, rubber hydrochloride and geranylamine hydrochloride is discussed. It is shown that the reason for the isomerism lies in the steric orientation of chlorine atoms and methyl groups at the four asymmetric carbon atoms, and the two crystalline isomers have been identified as the two possible *meso*-forms of the molecule. These structure determinations constitute an independent proof of the accepted structure of the carbon skeleton of the squalene molecule.

Both natural and synthetic squalene



upon saturation with hydrogen chloride yield a mixture of crystalline hexahydrochlorides, which can be separated into two fractions, one of which constitutes about 80 % and melts at 108—110° C, while the other one constitutes about 20 % and melts at 143—145° C (see for instance Karrer and Helfenstein [1]). Sometimes two low melting isomers have been reported in the literature. We have found, by repeated crystallizations, that all crystal crops with deviating melting points are mixtures of the higher melting form and the lower melting form mentioned above (in this paper designated by h.m. form and l.m. form, respectively).

Both isomers have the same composition ($C_{30}H_{56}Cl_6$) and give very similar, though not identical, X-ray diffraction patterns. Nevertheless, they are distinctly different as evidenced by their melting points, solubility properties, specific gravities, X-ray data and infrared absorption spectra. No attempt to clarify the reason for this isomerism has hitherto been made. It could scarcely be connected with isomerism of the parent hydrocarbon for several reasons:

1) Regeneration of the hydrocarbon from both isomers gives indistinguishable products; 2) Both these products, and also synthetic squalene made by different methods, give with hydrogen chloride the same mixture of hexahydrochlorides as obtained from squalene itself, although these hydrocarbons differ from natural squalene with respect to double bond orientation around at least some of the substituted carbon atoms (*cf.* Dauben *et al.*[2]).

It would appear that the only reasonable cause for this isomerism is to be found in the steric orientation of the chlorine atoms and methyl groups at the four asymmetric carbon atoms of the chain, making the fair assumption that chlorine adds to the methylsubstituted carbons according to Markownikoff's rule. The only difficulty is that out of the 6 possible diastereoisomers only two are obtained in crystalline form and in so widely different quantities. Evidently, the addition mechanism must favour the formation of the lower melting isomer. Thus, the structure determination of these crystal modifications is of interest from two points of view, *i. e.*, the stereochemistry of polymeric carbon chains, and the mechanism of the addition of hydrogen chloride to unsaturated hydrocarbons.

The present paper reports the results of X-ray investigations on the structures of the two isomers of squalene hexahydrochloride, supported by chemical and optical observations.

UNIT CELLS AND SPACE GROUPS

Both isomers of squalene hexahydrochloride crystallize in thin transparent plates with perfect cleavage parallel to the plane of the plates. Cleavage in several directions perpendicular to these planes is also observed, giving the small plates a pseudo-hexagonal cross-section. This is most pronounced for the higher melting form, which also looks more homogeneous under the microscope in polarized light than the lower melting one. Both isomers show sharp extinction in polarized light, from which the lack of optical activity may be inferred. No difference can be detected in their X-ray powder photographs. The unit cell dimensions and rules for systematic absences were determined from oscillation and Weissenberg photographs obtained with Cu$K\alpha$-radiation.

For the h.m. form: $a = 56.7_0 \pm 0.1$ Å; $b = 10.23 \pm 0.02$ Å; $c = 5.99_2 \pm 0.01$ Å; $\gamma = 93.2° \pm 0.2°$.

$V = 3\,468$ Å^3, $d_{calc.} = 1.205$ g/cm^3, $Z = 4$ mol./u.c.

For the l.m. form: $a = 56.7_1 \pm 0.1$ Å; $b = 10.40 \pm 0.02$ Å; $c = 5.98_4 \pm 0.01$ Å; $\gamma = 92.0° \pm 0.2°$.

$V = 3\,526$ Å^3, $d_{calc.} = 1.185$ g/cm^3, $Z = 4$ mol./u.c.

Thus, both isomers are monoclinic and pseudo-orthorhombic, but only very small differences are revealed in their cell dimensions. The small but significant difference in specific density has been confirmed by determinations by the floating method, which gave 1.20_8 and 1.18_2 for h.m. and l.m. form, respectively.

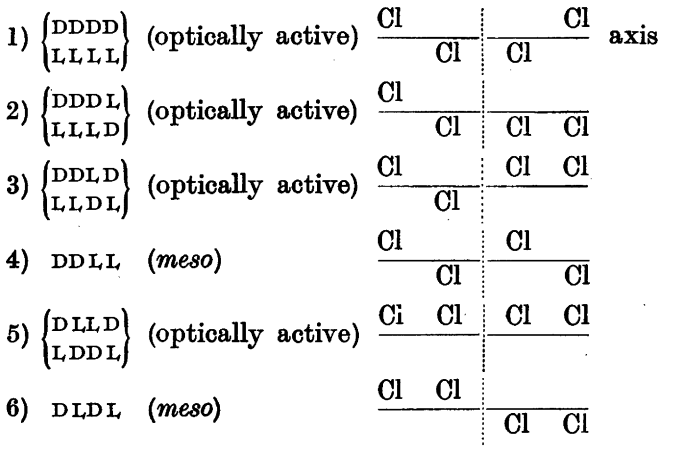
The same systematic absences and pseudo-absences are found for both forms:

$h00$ for h odd; $0k0$ for k odd; $00l$ for l odd; $h0l$ for $h + l$ odd; $hk0$ for k odd.

Since the angle γ deviates from 90° for both forms, only the third and the fifth rule could be strictly valid, the other rules must be due to pseudo-symmetries, but it may be of interest to note that all these rules together would indicate the orthorhombic space group *Pnma* (D_{2h}^{16}) (with the *a*-axis and the *b*-axis interchanged). The systematic absences $00l$ for l odd and $hk0$ for k odd indicate a screw axis parallel to [001] and a glide plane parallel to (001) with translation $b/2$. This corresponds to the space group $P2_1/b(C_{2h}^5)$.

POSSIBLE ISOMERIC STRUCTURES

Six possible diastereo-isomers of squalene hexahydrochloride, four D,L-forms and two *meso*-forms, may be anticipated from the disposition of the chlorine atoms and methyl groups. These six possible isomers may be visualized schematically in the following way:



To the left are given the sequences of the four *asymmetric* orientations, to the right the resulting orientations in the crystal lattice. The horisontal line represents the approximate "plane" of the folded carbon zig-zag chain, which will fit with the length of the unit cell axis (*a*) and which has been shown by Bunn and Garner [3] to exist in the structure of rubber hydrochloride in crystalline form. The chlorine atoms will then have to lie either above or below this "plane".

THE DETERMINATION OF THE STRUCTURES

The Weissenberg photographs of the equatorial layer lines around the principal axes of the crystals show fairly sharp and well-defined reflexions, especially the $h00$-reflexions, for which even orders until the 62nd are observed. Most of the $hk0$-reflexions are very weak, and only very small differences are observed between the intensities for the h.m. form and the l.m.form. The glide plane of symmetry implies that the x-coordinates for corresponding atoms of molecules, lying beside each other in the *b*-axis direction, are the same. This means that a fairly good resolution of the electron density variation might be expected in a Fourier projection on the crystallographic *a*-axis direction. Clear differences in intensities might probably be expected first for the hkl-reflexions. These, however,

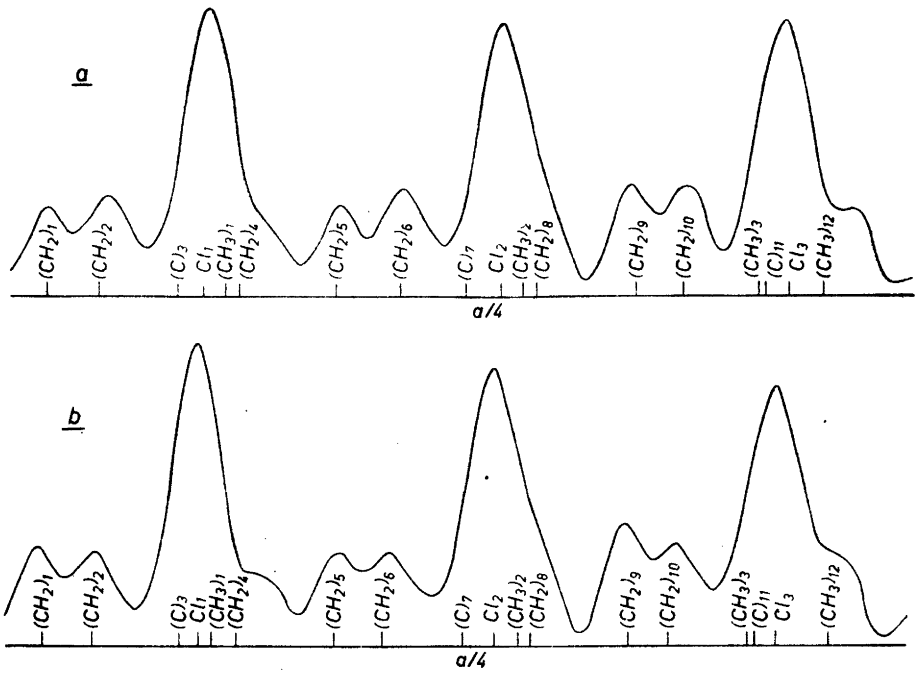


Fig. 1. Projections of electron density on [100] *a) for the higher melting form, b) for the lower melting form of squalene hexahydrochloride. Atomic co-ordinates, as derived by the method of least squares, are indicated.*

would in an ordinary Weissenberg photograph with Cu$K\alpha$ radiation be separated only by about 0.5 mm, and it was in fact found that the reflexions on higher levels are smeared out into lines, making the determinaticn of intensities difficult and uncertain.

In this position it was found that the best way of attacking these structures would be to obtain a maximum of informations from one-dimensional projections of electron densities on [100]. The intensities of the $h00$-reflexions were estimated visually, using a graduated intensity scale of reflexions with approximately the same size and form as those to be determined. The reading of the intensities were repeated five times on different photographs, and corrected in the usual way, the absorption error being neglected since the crystals used were very small (0.1—0.2 mm).

The successive determinations of the signs for the $h00$-reflexions, by means of a direct method to be described elsewhere, led to the projections of electron densities on the long axis for the h.m. form and the l.m. form as shown in Fig. 1. Differences in structure for the two forms could hardly be deduced from these projections, because of the strong overlapping of the densities for the chlorine atoms and the nearest carbon atoms. The carbon skeleton of the chain and the positions of the chlorine atoms and methyl groups were, however, at once evident from these projections. In order to bring out some possible differences between the structures of the two forms, and possibly also a decision for one or the other of the 6 isomeric structures discussed above, both series of x-coordinates were subjected to repeated least squares refinements. This treatment brought out some conspicuous differences in the projected bond lengths, especially for the C—C-bonds on the central sides of the asymmetric carbon atoms. The final x-coordinates and the projections of the bond lengths along the carbon chain are set out in Table 1. The observed and calculated structure factors are listed for both forms in Table 2. The reliability index is 0.126 for the h.m. form and 0.115 for the l.m. form.

THE STRUCTURE OF THE SQUALENE HEXAHYDROCHLORIDES

In order to reconstruct the skeleton of the carbon chain from the knowledge of the projected C—C distances it was necessary to make the assumption of 1.54 Å for the C—C bond length. This value may, however, be considered as very well established and there should be no reason to expect any remarkable deviation from this value in the present case. Secondly, the assumption of 114° for the angle between the bond directions at the chain carbons was preliminarily introduced. In the course of the calculation this value can be corrected, and it was found that the present data would suggest a value of about 115° for the bond angles, with the exception of those at the tetrasubstituted carbons, for which values of 108—109° would fit better with the present observations. The angle ε between a C—C bond and the a-axis direction is calculated for both forms and may be found in Table 1.

There might be some doubt as to the sequence of chain carbons and methyl groups in the projection, for example, whether the fourth or the fifth carbon should be ascribed to the methyl group. If, however, the fifth one were assumed to be the methyl group, the fourth one being a chain carbon, the projection of the C—C bond length of the chain would be 1.73 Å for the h.m. form and 1.93 for the l.m. form, whereas the same projected bond lengths come out to be 1.52 Å and 1.54 Å, respectively, if the fourth carbon belongs to the methyl group and the fifth to the chain. It seems justified to consider these data as a decisive proof of the sequence —C*—Cl—CH_3—CH_2— in the projection, and a similar argument indicates the same sequence at the second

Table 1. Atomic co-ordinates (Θ_1) in degrees, projected bond-lengths on the a*-axis in Å, and angle between bond and* a*-axis for the squalene hexahydrochloride isomers. The middle point of a molecule has been chosen as origin.*

$(CH_3)_2$	102.2	102.7					
$(CH_3)_3$	148.9	148.1					

tetrasubstituted carbon. Stereochemical considerations will also show that the chlorine atoms and the methyl groups must be connected to the third, eighth and fourteenth carbons of the projection, because the deviations from a planar zig-zag carbon chain are found at these carbon atoms (see below). Furthermore, it is seen that the chlorine atom connected to a tetrasubstituted carbon for both forms, lies closer to the carbon in the projection, than does the methyl group connected to the same carbon.

The structures which emerge from the data given in Table 1 may be described as follows: The four carbons, constituting the central part of the molecule, lie approximately in a plane, which makes an angle of about 40° with the chain direction (*a*-axis), this angle being larger for the l.m. form than for the h.m. form. From the two asymmetric carbons, towards the ends of the molecule, there extend planar groups of four carbons, the planes of these groups being parallel to the *a*-axis. The bonds from the asymmetric carbons, towards the central side, linking the planar groups together, are tilted an angle (ε) of about 30—40° away from the planes of these groups, these angles being appreciably larger for the h.m. form than for the l.m. form. (Strictly ε denotes the angle between a C—C bond and the *a*-axis, but since the planes of the planar groups in question are approximately parallel to the *a*-axis, ε will also approximately indicate the tilting of these bonds with respect to the planar groups). This difference in the tilting of the bonds, linking the planar 4 C-groups together, is the only feature which clearly discriminates between the structures of the two isomeric forms. The result is a more pronounced folding of the carbon chain for the h.m. form than for the l.m. form.

The folding of the chain at each tetrasubstituted carbon atom may be necessary to provide place for the methyl group and chlorine atom, and from molecular models it may also seem likely that the non-planar structure here is mainly due to repulsion between CH_2-groups of the chain.

Only two models can be derived such that they satisfy the requirements of the present observations. First, the bond on the central side of both asymmetric carbons are tilted in the same direction away from the planes of the planar 4 C-groups, the chlorines Cl_1 and Cl_2 must be on the same side of the chain in order to appear on the central side of the methyl group in the projection. Secondly, if these bonds are tilted in opposite direction, the chlorines must, for the same reason, lie on opposite sides of the chain (the argument is, in both cases, based on the assumption of an approximately tetrahedral arrangement of bonds from the asymmetric carbons).

The two structures, which result from these considerations, are indicated in Fig. 2, and may be seen to correspond to models Nos. 4 and 6, *i. e.*, the two *meso*-forms of the six possible diastereoisomers. The other models would correspond to asymmetric molecules, which would give rise to odd orders of the $h00$-reflexions, provided they would be strong enough to be observed. The structure factors F_{h00} are, however, very sensitive to an all over displacement of the atoms. The absence of odd orders of $h00$, therefore, speaks clearly in favour of the two symmetric forms Nos. 4 and 6 above, and consideration of the packing of the molecules points in the same direction. The projection of electron density on [100] can, of course, give no information about the orientation of the molecules around this axis. The packing of the molecules, as well

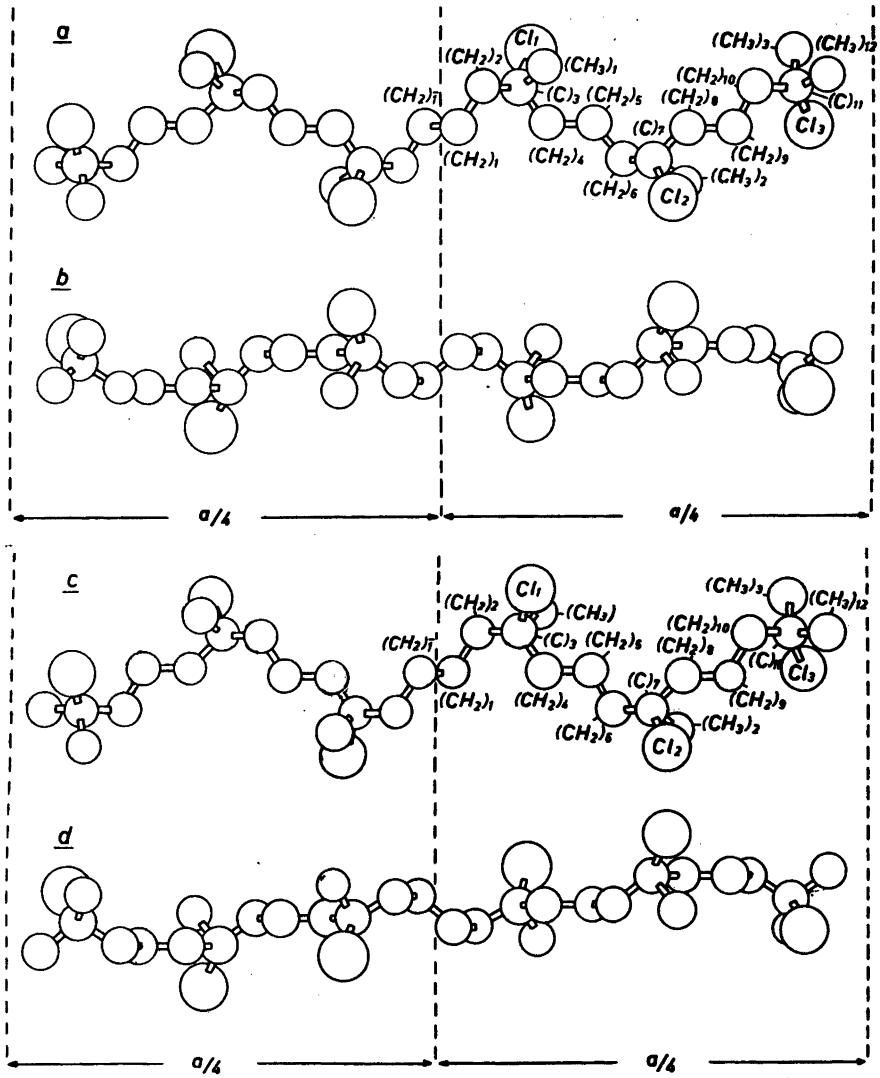

Fig. 2. Molecular structure models for the two crystalline isomers of squalene hexahydrochloride, a) and b) for the higher melting form, c) and d) for the lower melting form. In a) and c) the molecules are viewed along the c*-axis direction, in b) and d) along the* b*-axis direction.*

as comparison with the apparently closely related structure of rubber hydrochloride [3] would suggest that the main plane of the molecule is approximately parallel to the (001)-plane, which implies that the C—Cl-bonds and the C—CH_3-bonds are mainly pointing in the direction of the *c*-axis of the crystal.

As to the orientation of the arrangement around the end tetrasubstituted carbons, this could hardly be deduced with certainty from the obtained pro-

* Strictly, these indices should be doubled.

jections, especially because the arrangement apparently deviates considerably from a regular one. The obtained projections indicate, however, that the end groups could not possibly have a similar orientation as the groups around the other tetrasubstituted carbons, but more likely be turned about 90° away from these orientations; *i. e.*, about 90° around the single C—C bond on the central side of the end tetrasubstituted carbon (see Fig. 2). The direction of the tilting of this bond cannot be derived unequivocally from the one-dimensional projection, but considering the all over directions of these very long chain molecules, the directions indicated in Fig. 2 may reasonably be assumed as the most likely ones.

The question now remains as to which of these structures should be ascribed to the h.m. form and which to the l.m. form. It may then be seen from Fig. 2 that structure model No. 6 has the bonds, connecting the planar 4 C-groups, tilted in the same direction, which implies that the molecule will lie somewhat inclined to the *a*-axis in the crystal. This inclination of the molecules is likely

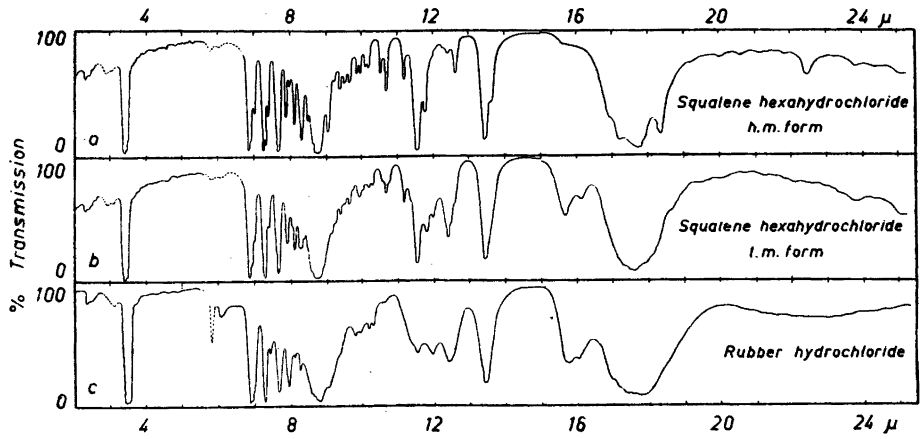

Fig. 3. Infrared absorption spectra from 2—15 μ (NaCl-prism) and from 15—25 μ (KBr-prism) of a) h.m. and b) l.m. squalene hexahydrochloride as pressed KBr-disks and of c) commercial rubber hydrochloride film containing 29 % Cl, or 85 % of the theoretical value.

to reduce the tightness of packing and put a restriction on the deviation from a planar structure. Considering the values of the angle ε in Table 1 for the bonds C_2—C_3 and C_6—C_7, which are 26° and 36° for the l.m. form, against 37° and 47° for the h.m. form, it may be reasonable to suggest that the l.m. form has a structure, corresponding to model No. 6, indicated in Fig. 2 c and d. In structure model No. 4, (Fig. 2) the bonds between planar 4 C-groups are tilted in alternating directions, leaving the main direction of the molecule parallel to the crystallographic *a*-axis. Thus, no strong restriction on the inclination of these bonds is present for this case, and it is likely that the h.m. form has the molecular structure indicated in Fig. 2 a and b. The study of the infrared absorption spectra seems to support this point of view (See next section).

INFRARED ABSORPTION SPECTRA

The infrared absorption spectra of the two squalene hexahydrochlorides are shown in Fig. 3. They were recorded in a Perkin-Elmer double beam instrument, Model 21, as pressed potassium bromide disks. As might be expected the two spectra are rather similar. The most conspicuous differences are the bands at 9.05 μ, 12.6 μ, 18.35 μ and 22.5 μ, present in the h.m. form but absent in the l.m. form, and the bands at 12.4 μ and around 16 μ (15.7 and 16.1 μ) present in the l.m. form but absent in the h.m. form. That these differences are mainly due to differences in crystal structures, is shown by the fact that solutions and undercooled melts give practically identical spectra; thus, the h.m. form most strikingly loses its bands at 18.35 and 22.5 μ and develops a band at around 16 μ. The non-crystallizing mother liquor also gives roughly the same spectrum.

It may be noted that the broad band at 17—18 μ, which is due to the C—Cl stretching vibration and agrees very well with the value 570 cm^{-1} found for *tert*-butylchloride and *tert*-amylchloride [4, 5], and the band (or band group) at 8.5—9 μ, which are the two most prominent bands in both spectra, show more detail in the h.m. form than in the l.m. form. Incidentally, the frequency of the band group at 8.5—9 μ is just twice that of the C—Cl stretching frequency. No overtone is involved, however, since the same strong band is present also in the spectra of the squalene hexahydrobromides.

For comparison the spectrum of a commercial sample of rubber hydrochloride has been recorded (as film) and included in Fig. 3. It is evident that it resembles the l.m. form much more than the h.m. form, although, of course, many details occurring in the squalene hexahydrochloride spectra are lacking in that of rubber hydrochloride. This is taken as a confirmation of the result of the structure determination, indicating that the general shape of the l.m. form, *i. e.* with the chlorines of each half on the same side, is more similar to rubber hydrochloride than is the h.m. form, where the chlorines are alternately on opposite sides and to a greater extent are surrounded by chlorine atoms of neighbouring molecules. The molecules of the h.m. form so to say fit into each other like cog-wheel teeth, and one would expect greater van der Waals forces between molecules, as actually evidenced by tighter packing, higher melting point, lower solubility and thinner plates of the crystals.

DISCUSSION

The present structure determinations of the isomers of squalene hexahydrochloride have been worked out on the basis of a relatively limited amount of experimental data. A two-dimensional projection of electron density on, for example, (001) would possibly give more definite informations, provided that all signs of the numerous weak reflections were obtained with certainty, a task which would involve a vast amount of calculation, and even considerably more if a three-dimensional synthesis were intended. It is reasonable to believe that the intensities of the *h*00 reflexions are fairly accurate, and the method used in deriving the projection of electron density on [100] involved no assumptions as to the structure in beforehand. The present structure determination, therefore, constitutes a direct and completely independent proof of the accepted structure of the carbon skeleton of the squalene molecule. As to the type and location of the double bonds it can only be said from this work that they have to involve the substituted carbon atoms.

The characteristic feature of planar segments of four carbon atoms in the chain connected by C—C bonds at angles of 30—40° is reminiscent of the structures proposed for rubber and β-guttapercha (*cf.* Bunn [6] and Jeffrey [7]) and established in geranylamine hydrochloride by Jeffrey [8]. In these cases the planar isoprene groups are necessitated by the double bond in the middle of each group, whereas the planar groups in the squalene hexahydrochlorides are displaced two carbons along the saturated chain. Molecular models show clearly that the reason for these tilted bonds between planar 4 C-groups is the same in all cases; *viz.* a consequence of steric repulsions between CH_2, CH_3 and CH groups in the former case, and chiefly between CH_2 groups in the latter case. The same structural features are, therefore, to be expected in rubber hydrochloride, in particular since the structure proposed by Bunn and Garner demands unusually large distortions of the tetrahedral arrangement around the substituted carbons (*cf.* the criticism advanced by Jeffrey [7]).

On Ion Exchange Equilibria

III *. An Investigation of Some Empirical Equations

ERIK HÖGFELDT

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm, Sweden

Empirical equations by the following authors for representing ion exchange equilibria are discussed: Kroeker, Vageler, Weisz, Boedeker, "Freundlich", Wiegner-Jenny, van Dranen and Rothmund-Kornfeld (*cf.* Table 1). Also an empirical equation recently given by Yamabe and Sato is discussed in a note. Discussion is limited to exchange between monovalent ions except when discussing the Rothmund-Kornfeld equation. It is shown that the linear plots used for determining the constants in the empirical equations are too insensitive to be used for testing the applicability of the equation under consideration. A more sensitive plot is obtained if the constants in the empirical equation are used for calculating the equilibrium quotient curve $\varkappa$ (β). There are three different kinds of equilibrium quotient curves recorded in literature: falling, rising and curves with maximum or minimum (*cf.* Fig. 1). No empirical equation except the one of "Freundlich" is capable of representing all of these types. The most useful equation seems to be that of Rothmund and Kornfeld which can be extended in a very simple manner to all three types of equilibrium quotient curves. In connection with this equation some different methods for finding an approximate value of the thermodynamic equilibrium constant are discussed, and it is shown that $k^{1/p}$ (where k and p are the empirical constants in the Rothmund-Kornfeld equation) and $\varkappa_{B,A(\beta=0.5)}$ may be useful first approximations to the thermodynamic equilibrium constant.

In the earlier work on ion exchange a number of empirical equations were used for representing equilibrium data. Later various forms of the law of mass action were used and, at present, it is very common to represent ion exchange equilibrium data by plotting the equilibrium quotient (see eq. (2) below) against some function of the ionic concentrations. Such plots show that, in most cases, the equilibrium quotient varies. For cases where the variation is large it has been suggested [1] that other expressions *e.g.* some empirical equation, may be more useful. The present paper deals with the possibility of representing variations in the equilibrium quotient by empirical equations.

* For parts I and II see Refs. 7 and 18.

Discussion is limited to cation exchange equilibria and, for the sake of simplicity, to exchange between monovalent ions. Only when discussing the Rothmund-Kornfeld equation will exchange between multivalent ions be considered.

For the ion exchange reaction:

$$B^+ + AR \rightleftharpoons A^+ + BR \tag{1}$$

where A^+ and B^+ are the two exchanging cations and R the anion framework of the exchanger an equilibrium quotient can be defined as follows:

$$\varkappa_{B,A} = \frac{\{A^+\} \cdot [BR]}{\{B^+\} \cdot [AR]} \tag{2}$$

where $\{\}$ denotes activity and [] concentration.

The following mole fractions are used:

$$\alpha = \frac{[B^+]}{[A^+] + [B^+]} = \frac{[B^+]}{a_0}; \quad \beta = \frac{[BR]}{[AR] + [BR]} = \frac{[BR]}{s_0} \tag{3}$$

where a_0 is the total ionic concentration of the solution (which is here equal to the ionic strength) and s_0 is the saturation capacity of the exchanger. From (2) and (3) the following expression for $\varkappa_{B,A}$ is obtained:

$$\varkappa_{B,A} = \frac{f_A(1-\alpha)\beta}{f_B\alpha(1-\beta)} \tag{4a}$$

where f_A and f_B are the activity factors of A^+ and B^+ in the liquid phase. In dilute solutions $f_A = f_B$ and

$$\varkappa_{B,A} = \frac{(1-\alpha)\beta}{\alpha(1-\beta)} \tag{4b}$$

CHOICE OF GRAPHICAL REPRESENTATION

It has proved convenient to plot $\varkappa$ against β, and the three different types of $\varkappa(\beta)$-curves reported in the literature are given in Fig. 1. In the following, curves with $\frac{d\varkappa}{d\beta} < 0$ are referred to as type I, with $\frac{d\varkappa}{d\beta} > 0$ as type II and curves with a maximum or minimum as type III. Hitherto type I has been most usual but examples of the other two types can be found in papers by Argersinger *et al.*[2,3], Bonner and Rhett [4], Duncan and Lister [5,6], Högfeldt *et al.*[7] and Marinsky [8].

The empirical equations used give a simple relation either between the amount of a certain ion added and the amount sorbed by the exchanger at equilibrium, or between the equilibrium concentration in solution and the amount sorbed by the exchanger. In the latter case the empirical equation gives a relation of the type:

$$\alpha = \varphi(\beta) \tag{5}$$

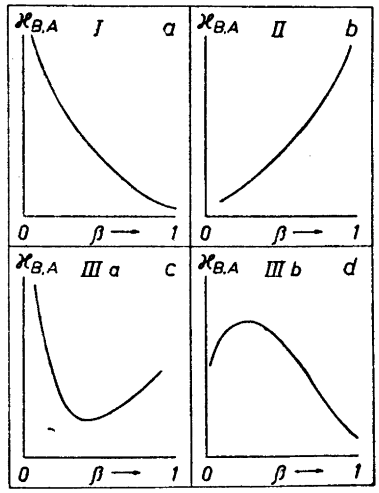

Fig. 1. The three different types of $\varkappa(\beta)$-curves. Fig. 1a represents a falling curve, Fig. 1b a rising curve and Figs. 1c and 1d are examples of curves with a minimum or maximum.

where $\varphi(\beta)$ is a function of β, which inserted in (4b) gives a function $\varkappa(\beta)$ which can be studied and compared with curves obtained experimentally. In the first case a relation between α,β and the total amount of the ion under consideration is required. Such a relation is given by the conservation of mass and takes the following form if the exchanger saturated with A^+ is equilibrated with V litres of solution of B^+ of initial concentration c_0, and A^+ of initial concentration a_0—c_0:

$$\beta s_0 + V\alpha a_0 = Vc_0 \tag{6}$$

From (6) and the empirical equation:

$$Vc_0 = \psi(\beta) \tag{7}$$

where $\psi(\beta)$ is a function of β, an expression for $\varkappa(\beta)$ can be obtained.

In order to be able to use (6) one must make experiments under such conditions that V, a_0 and s_0 are held constant.

The type of curve obtained if $\varkappa_{A,B} = \varkappa_{B,A}^{-1}$ is plotted against $(1-\beta)$ instead of $\varkappa_{B,A}$ against β may now be considered. The three types of $\varkappa(\beta)$-curves are characterized by the sign of $\frac{d\varkappa}{d\beta}$. For $\frac{d\varkappa}{d\beta} < 0$ we have type I, for $\frac{d\varkappa}{d\beta} > 0$ type II and for $\frac{d\varkappa}{d\beta} \gtrless 0$ type III.

The sign of $\frac{d\varkappa}{d\beta}$ is known and the sign of $\frac{d\varkappa^{-1}}{d(1-\beta)}$ is required:

$$\frac{d\varkappa^{-1}}{d(1-\beta)} = \frac{-d(1/\varkappa)}{d\beta} = \frac{1}{\varkappa^2}\frac{d\varkappa}{d\beta}$$

Thus $\frac{d\varkappa}{d\beta}$ has the same sign as $\frac{d\varkappa^{-1}}{d(1-\beta)}$. If $\varkappa(\beta)$ belongs to type I or II, $\varkappa^{-1}(1-\beta)$ belongs to the same type. If, however, $\varkappa(\beta)$ belongs to type IIIa,

$\varkappa^{-1}(1-\beta)$ belongs to type IIIb and *vice versa*. This depends upon the reversal in orientation to the two axes. The corresponding $\varkappa^{-1}(1-\beta)$-curves can be visualised by turning the $\varkappa(\beta)$-curves in Fig. 1 upside down.

It is of course an arbitrary matter which kind of curve one chooses to plot. One conveniently takes B^+ as the most strongly sorbed ion. The equilibrium quotient then becomes larger than unity and the $\varkappa(\beta)$-curve gives the variation of selectivity with concentration for that ion over the other. For curves with a maximum or minimum the distinction between types IIIa and IIIb is only a consequence of this convention as one could equally well plot the reciprocal function and transform IIIa to IIIb, or *vice versa*, and only make use of one of them.

RESULTS

Expressions for $\varkappa(\beta)$ have been calculated as outlined above from the empirical equations given by the following authors: Boedeker [9], van Dranen [10], "Freundlich" [11], Kroeker [12], Rothmund-Kornfeld [13-14], Vageler [15], Weisz [16] and Wiegner-Jenny [17].

In Table 1 the different empirical equations and the corresponding $\varkappa(\beta)$-functions are summarized. From this table it can be seen that the equations of Kroeker and van Dranen contain only one constant whereas all others contain two constants which may be determined from the linear plots indicated in the fourth column. For the equations of Kroeker, Vageler, Boedeker and Wiegner-Jenny one must keep a_0, $\bar{V}$ and s_0 constant in order to be able to use (6) for calculating $\varkappa(\beta)$. The numbers I—III in the last column but one refer to the different types of $\varkappa(\beta)$-curves given in Fig. 1. From the last column but one of Table 1 it can be seen that no empirical equation but the one of "Freundlich" is capable of representing all types of $\varkappa(\beta)$-curves found in the literature. These results suggest the possibility of arranging the empirical equations according to the type of $\varkappa(\beta)$-curve which may be derived from them.

The applicability of the different empirical equations for representing experimental data has been tested by using the data of Högfeldt *et al.*[7] for the Ag^+—H^+ exchange on Wofatit KS and Dowex 50, for which the $\varkappa(\beta)$-curves belong to types I and III respectively. These measurements were made at so low an ionic strength that the variation in the activity of water could be neglected [18] at least to a first approximation. Also the condition $f_{H^+} \cdot f_{Ag^+}^{-1} \approx 1$ is approximately valid[35] and (4b) has been used for calculating $\varkappa$.

The Kroeker equation: This equation was tested by calculating $\log \frac{[Ag]^+_{tot}}{[Ag^+]} = \log \frac{Vc_0}{V\alpha a_0} = q_1$ using the data in Tables 7a and 8a in Ref. 7. Some corresponding values of β and q_1 are given in Table 2. β is the mole fraction of silver in the resin. If the Kroeker equation were valid q_1 should be constant but it is apparent that q_1 decreases with increasing mole fraction. This decrease is systematic and so large that it cannot be due to experimental error, but must be taken as an indication of the inapplicability of the Kroeker equation to the data under consideration. That the Kroeker equation cannot be strictly applicable to either of the two systems is evident from the fact that it must give

Table 1. The relation between the empirical equations and the function $\varkappa(\beta)$.

Author	Equation	Linear plot	$\varkappa(\beta)$	Type	Condition
Kroeker [13]	$\log(Vc_0/Va a_0)=km=q_1$		$\varkappa_{B,A}=\dfrac{(1-q_2\beta)}{q_2(1-\beta)}$ $q_2=s_0/(Va_0(10^{q_1}-1))$	(I) II	$q_2>1$ $q_2<1$
Vageler [15]	$\beta s_0=SVc_0/(Vc_0+k)$	$1/\beta s_0$; $1/Vc_0$	$\varkappa_{B,A}=\dfrac{[q_1-(1+q_2q_3)\beta-q_2\beta^2]}{q_2(1-\beta)(q_3+\beta)}$ $q_1=S/s_0;q_2=s_0/Va_0;q_3=(k-S)/s_0$	I III	$q_1\leq 1+q_2+q_2q_3$ $q_1>1+q_2+q_2q_3$
Weisz [16]	$\beta=Sa/(a+k)$	$1/\beta$; $1/a$	$\varkappa_{B,A}=\dfrac{S-(1+k)\beta}{k(1-\beta)}$	(I) II	$k+1>S$ $k+1<S$
Boedeker [9]	$\beta s_0=k(Vc_0)^p$	$\log\beta s_0$; $\log Vc_0$	$\varkappa_{B,A}=\dfrac{(1+q_1q_2\beta-q_1\beta^{1/p})}{q_1(1-\beta)(\beta^{1/p-1}-q_2)}$ $q_1=s_0{}^{1/p}/Va_0k^{1/p};q_2=k^{1/p}/s_0{}^{1/p-1}$	II III	$p\geq 1$ $p<1$
"Freundlich" [11]	$\beta=ka^p$	$\log\beta$; $\log a$	$\varkappa_{B,A}=\dfrac{k^{1/p}-\beta^{1/p}}{\beta^{1/p-1}(1-\beta)}$	II III (I) (III)	$p\geq 1$ $p<1$ $p\leq 1$ $p>1$
Wiegner-Jenny [17]	$\beta s_0=k\cdot[Va a_0/(Vc_0-Va a_0)]^p$	$\log\beta$; $\log a$	$\varkappa_{B,A}=\dfrac{(1-q_1\beta^{1/p+1})}{q_1(1-\beta)\beta^{1/p}}$; $q_1=\dfrac{s_0{}^{1/p+1}}{Va_0k^{1/p}}$	III (I)	$q_1<1$ $q_1\geq 1$
van Dranen [10]	$\sec\dfrac{\pi}{2}\beta=(\cos\dfrac{\pi}{2}\beta)^{-1}=ka+1$	$\sec\dfrac{\pi}{2}\beta$; a	$\varkappa_{B,A}=\dfrac{\beta(k+1-\sec\frac{\pi}{2}\beta)}{(1-\beta)(\sec\frac{\pi}{2}\beta-1)}$	(I)	
Rothmund-Kornfeld [13-14]	$\beta/(1-\beta)=k[a/(1-a)]^p$	$\log\dfrac{\beta}{1-\beta}$; $\log\dfrac{a}{1-a}$	$\varkappa_{B,A}=k^{1/p}\left(\dfrac{1-\beta}{\beta}\right)^{1/p-1}$	I II	$p<1$ $p>1$

The symbols for the empirical constants are not always the original ones, but are those used in the present work. The terms q_i, $i = 1, 2, 3$ are derived quantities, which are constant under certain experimental conditions. S, k and p are constants, and m is the mass of exchanger. In the last column but one giving the type of $\varkappa(\beta)$-curve obtained the values within paranthesis refer to those curves, which are not valid within the whole concentration range $0 \leq \beta \leq 1$ because of lacking physical meaning.

Table 2. Determination of q_1 in the Kroeker equation.

0.9153	0.08	0.9038	0.25

$\varkappa(\beta)$-curves belonging to type II for q_1-values less than 1, whereas the two systems studied belong to types I and III.

Wiegner [19] has tested the Kroeker equation on the ammonium-calcium-permutit system and also obtained decreasing q_1-values with increasing ammonium concentration in the exchanger.

The Vageler equation: The test of this equation was performed as follows. As indicated in Table 1 a plot of $1/\beta\, s_0 = 1/[AgR]$ against $1/Vc_0 = 1/[Ag^+]_{tot}$ would be a straight line if the Vageler equation were applicable. Quite good straight lines were obtained for the two sets of measurements, but the data for Wofatit KS showed a greater spread than those for Dowex 50. The best straight lines were drawn through the experimental points, and the constants S and k were determined. Experimental conditions were such that $a_0 = 100.0$ mC, $V = 0.100$ litre and $s_0 = 1.75$ for Wofatit KS and $s_0 = 3.83$ for Dowex 50. The s_0-values are average values taken from Tables 7a and 8a in Ref. 7. Using these values for a_0, V and s_0 and the values of S and k from the linear plots, the constants q_1, q_2 and q_3 (see Table 1) and the function $\varkappa(\beta)$ were calculated. In Figs. 2 and 3 the full curves give $\varkappa(\beta)$ calculated from the Vageler equation. From these figures it is apparent that the Vageler equation is applicable to a rather large concentration range. Agreement seems to be better for Wofatit KS despite the larger spread in the linear plot. According to Vageler [15], S in his equation should be equal to the saturation capacity s_0. From the linear plots S was found to be 2.0 for Wofatit KS and 10.1 for Dowex 50. These figures are not in agreement with the values of s_0 determined experimentally, especially for Dowex 50. An analogous result was obtained by Weisz [16] for zeolites.

The Weisz equation: The constants S and k (see Table 1) were determined from the plot of $1/\beta$ against $1/\alpha$. This plot yielded a good straight line for Dowex 50, but for Wofatit KS the deviations were greater. From Table 1 it is seen that for $k + 1 > S$ the $\varkappa(\beta)$-curve belongs to type I and for $k + 1 < S$ it belongs to type II. These two conditions were fulfilled for the data on Wofatit KS and Dowex 50 respectively. From Table 1 it is seen that for $\beta = S/(1 + k)$

$\varkappa(\beta) = 0$. This means that the curve has physical meaning only in the range $0 \leq \beta \leq S/(1 + k)$. For Wofatit KS this value of β is ~ 0.47, a value for which $\varkappa(\beta) = 0$ differs so largely from that for $\beta = 0.47$ in Fig. 2 that the Weisz equation does not appear to be applicable in this case. Although the data on Dowex 50 give a $\varkappa(\beta)$-curve of type III it seems worth-while to test the Weisz equation on the rising part of the curve. In Fig. 3, $\varkappa(\beta)$ is given for Dowex 50 and there is good agreement with the Weisz equation within the interval $0.2 \leq \beta \leq 0.8$. For lower and larger β-values the deviations are large. The occurrence of deviations for small β-values follows from the existence of the minimum in the $\varkappa(\beta)$-curve which cannot be accounted for by the Weisz equation.

Weisz introduced the equation discussed above in his study of various empirical equations [16]. When comparing it with the Vageler equation, he found the latter to give a better numerical agreement. This may perhaps be due to the fact that the Vageler equation is capable of describing curves of both types I and III, while the Weisz equation can only describe part of a curve of type I and curves of type II and should thus have less applicability.

The equation introduced by Weisz can be considered to be a special case of the one used by Wolff [20]:

$$\beta s_0 - k_0 = \frac{S \cdot a}{a + k} \tag{8}$$

where k_0 is a third empirical constant.

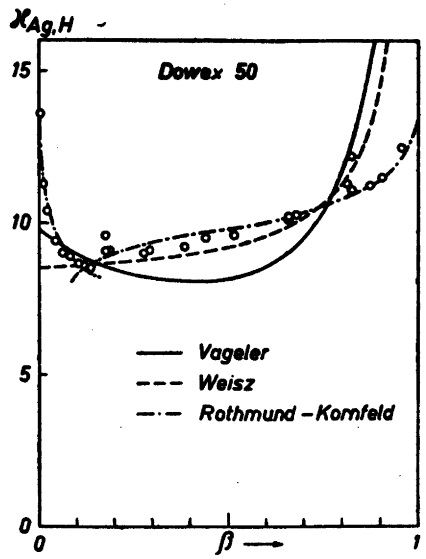

Fig. 3. Comparison between experimental and approximate $\varkappa(\beta)$-curves using the data on Dowex 50.

O *Experimental points.*
——— $\varkappa(\beta)$ *calculated from the Vageler equation.*
– – – – » » » *Weisz* »
– · – · – » » » » *Rothmund-Kornfeld equation.*

When using the Rothmund-Kornfeld equation the two parts of the $\varkappa(\beta)$-curve have been approximated with two different equations, one for the falling and the other for the rising part.

The existence of the constant k_0 means that the equilibrium quotient tends towards infinity as $\beta \rightarrow k_0/s_0$. For a number of cases $\varkappa(\beta)$ increases largely with decreasing β, but in the cases studied right down to the tracer level [21,22] finite and constant limiting values of $\varkappa$ have been obtained. These results imply that k_0 must be very small and the Wolff equation becomes practically equal to the Weisz equation. For such cases the Weisz equation must be preferred even if a better numerical agreement can be obtained from the Wolff equation over a limited concentration range since it contains three empirical constants.

The Boedeker equation: The constants k and p (see Table 1) were first determined from the plot of log βs_0 against log $[Ag^+]_{tot}$ for the two systems. Quite good straight lines were obtained except for the highest values of β, where the experimental points tend towards the log $[Ag^+]_{tot}$-axis. Agreement was better for the data on Dowex 50 than on Wofatit KS, and this can be understood from the fact that the Boedeker equation is applicable to $\varkappa(\beta)$-curves of types II and III only. For this reason the $\varkappa(\beta)$-curve was calculated for Dowex 50 but not for Wofatit KS. The graphical method for finding the constants proved to be too insensitive as it gave a $\varkappa(\beta)$-curve far from the one obtained experimentally. For that reason the method of averages [23] was used for the calculation of k and p. In Fig. 4 the corresponding $\varkappa(\beta)$-curve is plotted. As is seen from this figure agreement is quite good for values of $\beta \lesssim 0.4$. For

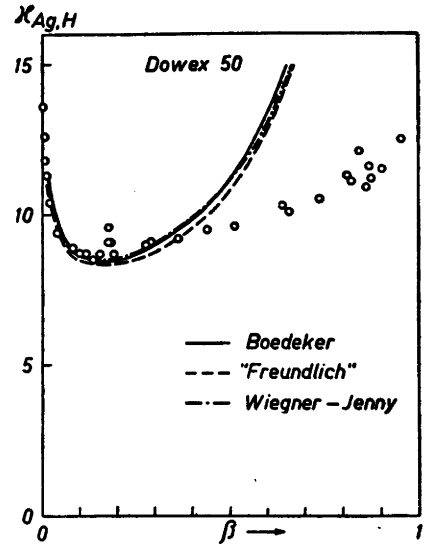

Fig. 4. Comparison between experimental and approximate $\varkappa(\beta)$-curves using the data on Dowex 50.

—·—·— » » » *Wiegner-Jenny equation.*

higher values of β the curve tends rapidly towards infinity and deviations from the experimental curve are large. This might be ascribed to the fact that the Boedeker equation (as well as the "Freundlich" and Wiegner-Jenny equations discussed below) is of an exponential type and does not indicate the existence of an upper limit for the amount to be exchanged.

The "Freundlich" equation: The constants k and p (see Table 1) were determined from the plot of log β against log α for Dowex 50. The $\varkappa(\beta)$-curve has been plotted in Fig. 4. The close agreement with the $\varkappa(\beta)$-curve obtained from the Boedeker equation is to be noted and the same arguments are applicable to them both. When testing the equation with the data on Wofatit KS k proved to be > 1 and for $k > 1$ the "Freundlich" equation is inapplicable to a $\varkappa(\beta)$-curve of type I and the $\varkappa(\beta)$-curve was not calculated.

Freundlich's name is given within quotation marks, because van Bemmelen [24] (as is pointed out by McBain [25]) was the originator of the equation, although it has become associated with Freundlich's name.

The Wiegner-Jenny equation: This is a modification of the "Freundlich" equation put forward in order to indicate that the ion exchange equilibrium is independent of dilution for exchange between ions of equal valence. The quantities p and q_1 (q_1 constant under the experimental conditions) were determined from the plot of log α against log β. That this plot should give a straight line is seen by the following argument:

The Wiegner-Jenny equation:

$$\beta s_0 = k \cdot \left(\frac{V a a_0}{V c_0 - V a a_0} \right)^p$$

and the requirement of conservation of mass (6) give:

$$a = q_1 \beta^{1/p+1} \qquad q_1 = \frac{s_0^{1/p+1}}{V a_0 k^{1/p}} \tag{9}$$

From (9) it is seen that for the case of constant V and a_0 the Wiegner-Jenny equation becomes a special case of the "Freundlich" equation. It is also seen that by plotting log a against log β a straight line should be obtained giving the values of $1/p + 1$ and q_1. $\varkappa(\beta)$ calculated from the Wiegner-Jenny equation, is plotted in Fig. 4 for the Ag^+—H^+ exchange on Dowex 50. The measurements on Wofatit KS were not used for the same reasons as for the Boedeker and "Freundlich" equations. The $\varkappa(\beta)$-curves in Fig. 4 from the "Freundlich" and Wiegner-Jenny equations should have coincided. The observed differences are due to small differences in the constants ($\sim$ 1 %) depending upon the limited accuracy in their determination from the linear plot and shows the sensitivity of the $\varkappa(\beta)$-curve to variations in the constants.

The van Dranen equation: Recently van Dranen [10] has proposed the equation given in Table 1 containing only one parameter and having an upper limit equal to the saturation capacity. The equation was tested by calculating $k = (\sec \frac{\pi}{2} \beta - 1)/a$ for the two sets of measurements. No constant values were obtained as is shown in Table 3, where some of the results for Wofatit KS are given. The variation in k is large and the results show that this equation is not applicable to the data under consideration. An analogous result was obtained for Dowex 50, but this can be understood from the inapplicability of the van Dranen equation to a $\varkappa(\beta)$-curve of type III.

The form of a $\varkappa(\beta)$-curve calculated from the van Dranen equation, has been obtained by using the value $k = 2.74$ and the resulting curve is given in Fig. 2.

Table 3. Determination of $k = (\sec \frac{\pi}{2} \beta - 1)/a$ *in the van Dranen equation using the data on Wofatit KS.*

The Rothmund-Kornfeld equation: Monovalent ions. In Fig. 2 the curve denoted by —·—·— gives $\varkappa(\beta)$ obtained by applying the Rothmund-Kornfeld equation (for brevity called the R—K equation in the following) to the data on Wofatit KS. k and p were determined from the plot of $\log \frac{\beta}{1-\beta}$ against $\log \frac{\alpha}{1-\alpha}$ which yielded a good straight line. Agreement is seen to be good over the whole concentration range. That the R—K equation (types I or II) is not applicable to the data on Dowex 50 (type III) can be seen as a small non-linearity of the insensitive double-logarithmic plot. The R—K equation can, however, be applied to curves of type III by proceeding as follows. The rising part of the curve is approximated by a R—K equation with $p > 1$ and the falling part by a R—K equation with $p < 1$. The four parameters k_1, p_1 and k_2, p_2 can all be determined from the double-logarithmic plot because, in the case of a curve of type III, the double-logarithmic plot can be approximated by two straight lines intersecting at the point corresponding to the minimum or maximum.

In Fig. 3 the curve denoted by —·—· gives $\varkappa(\beta)$ obtained using two different R—K equations intersecting at $\beta = 0.12$. Agreement is seen to be quite good.

Multivalent ions: The R—K equation seems to be the most useful one, as it can be applied to all three types of $\varkappa(\beta)$-curves and gives good numerical agreement for the two experimental studies considered here. For that reason, the discussion concerning multivalent ions will be limited to this equation. When considering multivalent ions, two approaches are possible as discussed in a previous paper[18]: "choice" (E) ("equivalents") and "choice" (M) ("moles").

Choice (E) gives the following ion exchange reaction:

$$z_A B^{z_B+} + z_A z_B (A_{1/z_A})R \rightleftharpoons z_B A^{z_A+} + z_A z_B (B_{1/z_B})R \qquad (10)$$

The equilibrium quotient $\varkappa_{B,A}$ for reaction (10) is defined by:

$$\varkappa_{B,A} = \frac{\{A^{z_A+}\}^{z_B}}{\{B^{z_B+}\}^{z_A}} \left(\frac{[(B_{1/z_B})R]}{[(A_{1/z_A})R]}\right)^{z_A z_B} = \frac{\{A^{z_A+}\}^{z_B}}{\{B^{z_B+}\}^{z_A}} \left(\frac{\beta}{1-\beta}\right)^{z_A z_B} \qquad (11)$$

if the concentrations in the exchanger are expressed by the equivalent fractions:

$$\beta = \frac{[(B_{1/z_B})R]}{s_0} \text{ and } 1-\beta = \frac{[(A_{1/z_A})R]}{s_0} \qquad (12)$$

The R—K equation then takes the following form:

$$\left(\frac{[(B_{1/z_B})R]}{[(A_{1/z_A})R]}\right)^{z_A z_B} = k \left(\frac{\{B^{z_B+}\}^{z_A}}{\{A^{z_A+}\}^{z_B}}\right)^{p} \qquad (13)$$

where k and p are empirical constants.

From (11) and (13) the following expression for $\varkappa(\beta)$ can be deduced:

$$\varkappa_{B,A} = k^{1/p} \left(\frac{(1-\beta)}{\beta}\right)^{z_A z_B (1/p - 1)} \qquad (14)$$

$\varkappa_{B,A}$ belongs to type I if $p < 1$
» » » » II » $p > 1$

Choice (M) gives the following ion exchange reaction:

$$z_A B^{z_B+} + z_B AR_{z_A} \rightleftharpoons z_B A^{z_A+} + z_A BR_{z_B} \tag{15}$$

and the equilibrium quotient for reaction (15) is defined by:

$$\lambda_{B,A} = \frac{\{A^{z_A+}\}^{z_B} [BR_{z_B}]^{z_A}}{\{B^{z_B+}\}^{z_B} [AR_{z_A}]^{z_B}} \tag{16}$$

The R—K equation now gives:

$$\frac{[BR_{z_B}]^{z_A}}{[AR_{z_A}]^{z_B}} = k \left(\frac{\{B^{z_B+}\}^{z_A}}{\{A^{z_A+}\}^{z_B}} \right)^p \tag{17}$$

From (16) and (17):

$$\lambda_{B,A} = k^{1/p} \frac{(1-X_B)^{z_B(1/p-1)}}{X_B^{z_A(1/p-1)}} \tag{18}$$

where the mole fractions X_B and $(1-X_B)$ are defined by:

$$X_B = \frac{[BR_{z_B}]}{[AR_{z_A}] + [BR_{z_B}]} \text{ and } 1-X_B = \frac{[AR_{z_A}]}{[AR_{z_A}] + [BR_{z_B}]} \tag{19}$$

From (18) it is seen:

For $p < 1$ $\lambda_{B,A}$ belongs to type I
» $p > 1$ $\lambda_{B,A}$ » » » II

For these two cases too, curves of type III can be approximated using the extension discussed for monovalent ions.

The thermodynamic equilibrium constant: The R—K equation can also be used for obtaining an approximate value for the thermodynamic equilibrium constant for the ion exchange process. This quantity is of value when discussing ion exchange affinities.

Argersinger *et al.*[26,27] as well as Högfeldt *et al.*[18,28–30] have shown that the thermodynamic equilibrium constant ($K_{B,A}$) can be obtained by graphical integration of the log $\varkappa_{B,A}(\beta)$-curve. For the calculation of $K_{B,A}$ the following expression can be used:

$$\ln K_{B,A} = \int_0^1 \ln \varkappa_{B,A}(\beta) d\beta \tag{20}$$

When taking the variation in the activity of water into consideration a more complex expression may be obtained [27,31].

Inserting the expression for $\varkappa_{B,A}$ from the R—K equation in (20) and integrating the following expression for $K_{B,A}$ is obtained:

$$K_{B,A} = k^{1/p} \tag{21}$$

This quantity, $k^{1/p}$, can be obtained directly from the double-logarithmic plot, where the intercept on the abscissa gives $-\log k^{1/p}$. For multivalent ions only choice (E) gives the same result as that given by (21).

Equation (20) can also be applied to the other empirical equations discussed in this paper, but the R—K equation gives the simplest and most straight-forward method for getting an approximate value for $K_{B,A}$.

In connection with equation (21) it may be noted that it has been proposed [32] that the $\varkappa$-value for $\beta = 0.5$ is a good measure for the relative affinity of the ions for the exchanger. For a system, which can be approximated by the R—K equation, it is found from equation (21) that:

$$\varkappa_{B,A(\beta=0.5)} = K_{B,A} \tag{22}$$

For systems with a maximum or minimum in the $\varkappa(\beta)$-plot, the following approximate expression obtained from (20) and the R—K equation may be useful:

$$\log K_{B,A} \approx \beta_m \log k_1^{1/p_1} + (1-\beta_m) \log k_2^{1/p_2} \tag{23}$$

where β_m is the β-value for the maximum or minimum and k_1, p_1 and k_2, p_2 are the parameters for the two parts of the $\varkappa(\beta)$-curve.

In order to test the usefulness of the different approximate expressions for $K_{B,A}$, $K_{Ag,H}$ was calculated for the two studies of the Ag^+—H^+ exchange on Wofatit KS and Dowex 50 and compared with $\varkappa_{Ag,H(\beta=0.5)}$ and $K_{Ag,H}$-values obtained by graphical integration [18]. The results are given in Table 4.

Table 4. A comparison between approximate and integrated $K_{Ag,H}$-values.

Exchanger	k_1	p_1	k_2	p_2	β_m	$\varkappa_{Ag,H}$ $\beta = 0.5$	$K_{Ag,H}$ from (21) or (23)	$K_{Ag,H}$ integrated
Wofatits KS	3.59	0.75	—	—	—	5.4	5.50	5.16
Dowex 50	5.01	0.89	11.2	1.04	0.14	9.6	9.42	9.90

From Table 4 it is seen that, for the two cases studied, the approximation from the R—K equation gives results in agreement with the integration within $\pm$ 10 % — an accuracy which may often be sufficient. It is also seen that the simpler method using $\varkappa_{B,A(\beta=0.5)}$ is also of sufficient accuracy and for a first approximation it may be useful in a large number of cases.

Recently the authors attention has been called to a paper by Yamabe and Sato [33] which describes the use of an empirical equation which in our notation becomes:

$$\log \frac{\beta}{\alpha} = p \log \frac{(1-\beta)}{(1-\alpha)} + \log k \tag{24}$$

where p and k are empirical constants. A plot of $\log \frac{\beta}{\alpha}$ against $\log \frac{(1-\beta)}{(1-\alpha)}$ should be a straight line. In their test of the equation to exchange between mono- and divalent ions the authors claim that better agreement was obtained by plotting $\log \frac{\beta s_0}{V a a_0}$ against $\log \frac{s_0(1-\beta)}{V a_0(1-\alpha)}$. In testing this equation with the data of Högfeldt *et al.*[7] V, a_0 and s_0

are practically constant so that the test can equally well be performed on (24) as on the alternative. In order to calculate $\varkappa(\beta)$ from (24) it is convenient to express $\beta(\varkappa)$ as:

$$\beta = \frac{\varkappa(k^{1/(p-1)} - \varkappa^{1/(p-1)})}{k^{1/(p-1)}(\varkappa - 1)} \tag{25}$$

From (25) it can be deduced that:

$\left.\begin{matrix} p>1 \\ k>1 \end{matrix}\right\}$ type I $\left.\begin{matrix} p>1 \\ k<1 \end{matrix}\right\}$ type II $\left.\begin{matrix} p<1 \\ k>1 \end{matrix}\right\}$ type II $\left.\begin{matrix} p<1 \\ k<1 \end{matrix}\right\}$ type I

and thus (24) can be used on $\varkappa(\beta)$-curves of types I and II.

The equation was tested with the data on Wofatit KS but no straight line was obtained. It did not seem worth-while calculating $\varkappa(\beta)$ as the insensitive double-logarithmic plot showed large deviations from linearity. As Yamabe [34] has obtained good agreement with experimental data for higher concentrations than 0.1 C the present results suggest that his equation may be less useful at lower concentrations.

It is a pleasure to acknowledge the valuable aid of Professor Hidetake Kakihana with the translation and discussion of the Japanese paper.

DISCUSSION

From Figs. 2—4 it is seen that it always seems possible to find an empirical equation applicable to a limited concentration range, whereas it may be hard to find one applicable to the whole concentration range. An indispensible condition is that the empirical equation can give a $\varkappa(\beta)$-curve of the same type, I—III, (see Fig. 1 and Table 1) as the experimental one.

The linear plots (which are often logarithmic) used to determine the constants in the empirical equations seem to be too insensitive to test agreement between the empirical equation and the experimental data. They may, however, be used for smoothing out experimental data.

For the two sets of measurements on which the empirical equations have been tested the best agreement is found with the R—K equation. Although the R—K equation is only applicable to $\varkappa(\beta)$-curves of types I and II it is relatively easy to extend its usefulness to all types. None of the other equations seems to offer this extension in such a simple manner. However, from a test on only two experimental $\varkappa(\beta)$-curves, no general deductions can be made about its accuracy in other cases.

The present conclusion, that the R—K equation is the most useful one, is in contradiction with the results of Weisz [16], who found that the Vageler equation gave better numerical agreement with experimental data on zeolites than the equations of "Freundlich", Rothmund-Kornfeld, Wiegner-Jenny and himself. Weisz tested the empirical equations on several systems containing both monovalent and multivalent ions, but the concentration ranges were not as broad as in the present investigation. However, Weisz found, as in this investigation, that the exponential curves ("Freundlich", Wiegner-Jenny) did not give as good an agreement as curves of the hyperbolic type (Vageler, Weisz). This may be due to the fact that the hyperbolic curves (in agreement with experience) have an upper limit for the exchange not shown by the exponential ones.

Future work: There are a number of theoretical approaches in the literature giving a functional connection between α and β. In a following paper they will be discussed in an analogous manner.

Über die Eigenschaften des Lösungsmittels, die die Kinetik der alkalischen Esterhydrolyse bestimmen. I. Der Zusammenhang zwischen Aktivierungswärme und Protonenübergangswärme

AULIS KOIVISTO

Chemisches Institut der Universität Helsinki, Finnland

Die Geschwindigkeit der durch Alkalien hervorgerufenen Esterhydrolyse hängt viel vom Lösungsmittel ab. Es fragt sich, in welcher direkten Weise die katalytische Aktivität des alkalihaltigen Lösungsmittels gemessen werden kann. Die Antwort lautet, dass die Messung mittels einem dem Aktivierungsprozess ähnlichen Prozess ausführbar ist.

Man ist der Ansicht, dass der Aktivierungsprozess der alkalischen Esterhydrolyse von der Bildung des Additionsproduktes EOH^- aus Estermolekül E und Hydroxylion bedingt ist [1]. Dieser Fall lässt sich, abweichend vom Üblichen, durch die Gleichung $E + H_2O \rightleftharpoons EOH^- + H^+$ beschreiben. Die Gleichung für die Autoprotolyse des Lösungsmittels HL ist $[H^+] = K[HL]/[L^-]$. Diese beiden Gleichungen ergeben (1) $[EOH^-]/[E][H_2O] = K^*[L]/[HL]$. Die Konstante K^* des Aktivierungsgleichgewichts hängt natürlich von der Art des Lösungsmittels HL ab.

Die Form der Gleichung (1) unterscheidet sich von der der üblichen Säure-Basen-Gleichgewichtsgleichung (2) $[A^-]/[HA] = K[L^-]/[HL]$ nur darin, dass erstere Gleichung 3, letztere 2 neutrale Moleküle enthält. Experimentell ist belegt, dass die relative Säurestärke der Protonenspender nicht sehr viel vom Lösungsmittel abhängt [2]. Dies bedeutet, dass der Einfluss des Lösungsmittels auf das Verhältnis der Aktivitätskoeffizienten der Säure und ihres Anions bei den verschiedenen Säuren gleichgross ist. Es ist anzunehmen, dass dies auch für Gleichung (1) gültig ist, wobei $[E]\,[H_2O]$ sich also wie [HA] verhält.

Auf Grund des Vorstehenden sollte also das Verhältnis K^*/K der Gleichgewichtskonstanten der Gleichungen (1) und (2) unabhängig vom Lösungsmittel HL sein, und da das Vorstehende nicht auf eine bestimmte Temperatur beschränkt ist, so muss der Einfluss der Temperatur auf das Verhältnis K^*/K unabhängig vom Lösungsmittel sein. Durch Anwendung der van't Hoffschen Gleichung erhält man $RT^2(d\ln K^* - d\ln K)/dT = \triangle H^* - H =$ unabhängig vom Lösungsmittel. $\triangle H^*$ ist die Aktivierungswärme der Hydrolyse im Lösungsmittel HL, $\triangle H$ ist die Wärme der Protonenübergangsreaktion $HA + L^- \rightarrow A^- + HL$. Bezeichnet man die dem Lösungsmittel L_1 entsprechenden Wärmen mit $\triangle H_1^*$ und $\triangle H_1$, die dem Lösungsmittel L_2 entsprechenden mit $\triangle H_2^*$ und $\triangle H_2$, so ist $\triangle H_1^* - \triangle H_2^* = \triangle H_1 - \triangle H_2$. Die »Neutralisierungswärme» kommt somit der Aktivierungswärme zugute.

Die Protonenübergangswärmen wurden kalorimetrisch gemessen, 25° C, unter Verwendung von Phenol und Essigsäure, in einigen Fällen auch Ameisensäure, Bernsteinsäure und Benzoesäure als Protonenspender. Bei diesen Substanzen war die Protonenübergangswärme in ziemlich gleicher Weise vom Lösungsmittel abhängig [3].

Aus den in der Literatur beschriebenen Versuchen über die alkalische Hydrolyse der Ester geht hervor, dass der Einfluss des Lösungsmittels bei verschiedenen Estern von ziemlich gleicher Art ist, wie es oft der Fall ist bei Reaktionen von gleichem Typus. Die vom Verfasser ausgeführten Versuche bekräftigen diese Auffassung. (Wegen der Umesterung lässt sich in viel Alkohol enthaltenden Lösungsmitteln nur die Hydrolysengeschwindigkeit des Esters des betreffenden Alkohols messen.) Die in

den Versuchen verwendeten Lösungsmittel, neben rein wässrigen Lösungen, und Ester, sind die folgenden:

Die Numerierung der Lösungsmittel in den Figuren ist dieselbe wie im vorstehenden Verzeichnis.

	Lösungsmittel	Ester
1.	Wasser — Phenol	Äthylacetat, *n*-Propylacetat
2.	» — Rohrzucker	Methyl-, Äthyl- und Propylacetat
3.	» — Glyzerin	Äthylacetat
4.	» — Äthylenglykol	»
5.	» — Methanol	Methylacetat und -benzoat
6.	» — Aceton	Äthylacetat
7.	» — Äthanol	»
8.	» — *n*-Propanol	» , *n*-Propylacetat, Äthylbenzoat
9.	» — *i*-Propanol	» , *i*-Propylacetat
10.	» — *tert.* Butanol	» , Methylacetat, Äthylbenzoat

Als Katalysator diente NaOH. Die Ergebnisse der Versuche sind in den Figuren 1—3 wiedergegeben, von denen Figur 1 die Abhängigkeit der Aktivierungswärme vom Lösungsmittel, Figuren 2 und 3 die entsprechende Abhängigkeit der Protonenübergangswärme darstellen. Falls die Aktivierungswärmen unter Verwendung verschiedener Ester im gleichen Lösungsmittel bestimmt worden sind, so entsprechen deutlichkeitshalber die Punkte der Figur 1 dem Mittelwert. Als Protonenspender dienten Phenol (Fig. 2) und Essigsäure (Fig. 3). Der Deutlichkeit halber zeigen die Figuren nur die Änderungen $\triangle H - \triangle H_0$ dieser Wärmen in Bezug auf den in wässriger Lösung vorliegenden Wert $\triangle H_0$.

Die Gleichartigkeit der Figur 1 mit den Figuren 2 und 3 zeigt auf das Deutlichste, dass die beschriebene Protonenübergangswärme in die Aktivierungswärme der alkalischen Hydrolyse der Ester eingeht. Die Übereinstimmung kann natürlich nicht völlig quantitativ sein, schon weil der zweite Energiefaktor, der die relative Säurestärke mitbestimmt, die Protonenübergangswärme, offenbar zu einem gewissen Grade vom Lösungsmittel abhängt, wie auch die relative Säurestärke selbst (Figuren 2 und 3). Aber obwohl die benutzten Protonenspender, Phenol und Essigsäure, auf Grund ihrer allgemeinen chemischen Eigenschaften zu verschiedenen Substanzgruppen gehören, so sind die

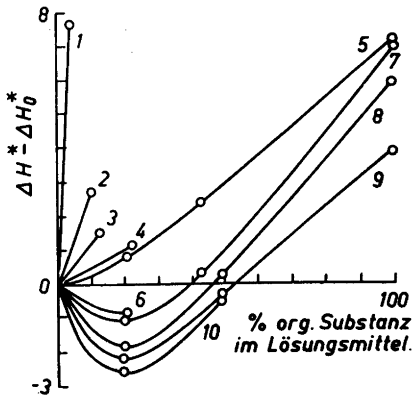

Fig. 1. Abhängigkeit der Aktivierungswärme vom Lösungsmittel.

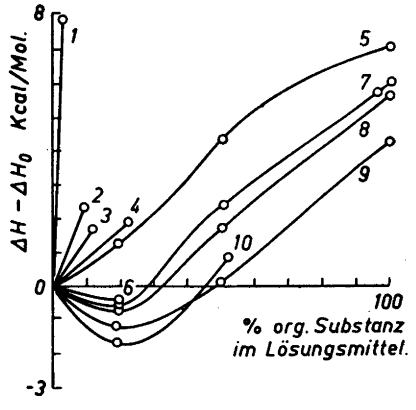

Fig. 2. Abhängigkeit der Protonenübergangswärme vom Lösungsmittel. Protonenspender: Phenol.

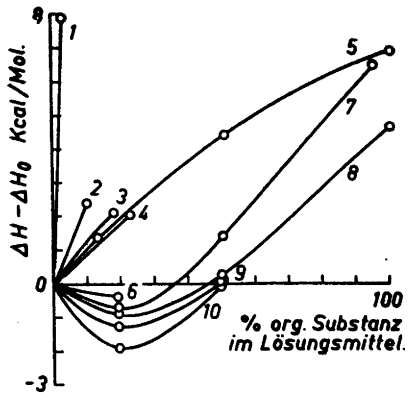

Fig. 3. Abhängigkeit der Protonenübergangswärme vom Lösungsmittel. Protonenspender: Essigsäure.

Unterschiede lange nicht so gross, dass sie das Gesamtbild veränderten.

Es ist auffallend, dass der Protonenübergang an das Alkoxyl-Ion in alkoholischer Lösung viel weniger Wärme befreit als derjenige an das Hydroxyl-Ion in wässriger Lösung.

Low-molecular Carbohydrates in Algae

VII *. Investigation of *Fucus spiralis* and *Desmarestia aculeata*

HANS BOUVENG and BENGT LINDBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

In Parts I [1], IV [2] and V [3] of this series, studies on the brown algae *Fucus vesiculosus*, *Pelvetia canaliculata* and *Laminaria cloustoni* were reported. These algae all contained mannitol, 1-mannitol β-glucoside and 1,6-mannitol di-(β-glucoside). 1-Mannitol acetate was isolated from *F. vesiculosus* and *L. cloustoni*, volemitol and its mono- and di-glucosides from *P. canaliculata* and a substance, laminitol, later proved to be a C-methyl inositol (Part VI) from *L. cloustoni*. It was therefore of interest to investigate other brown algae to see if some of these substances were characteristic for the whole group, and in the present communication the investigation of *Fucus spiralis* and *Desmarestia aculeata* is reported. Mannitol, 1-mannitol β-glucoside and laminitol were isolated from both and the presence of 1,6-mannitol diglucoside was demonstrated by paper chromatography. It is most probable that laminitol was overlooked in *F. vesiculosus* and *P. canaliculata* and that this substance, as well as mannitol and its glucosides, is characteristic for brown algae in general. 1-Mannitol acetate was isolated from *F. spiralis* but not from *D. aculeata* and it seems significant that this substance has been obtained in a good yield only from the *Fucus* species. Volemitol was not found in either of the two algae now investigated. It has thus so far only been found in *P. canaliculata* but it is intended to investigate its possible occurrence in other brown algae.

The algae, *Fucus spiralis* (740 g) and *Desmarestia aculeata* (240 g) were kindly supplied by Institutt for Tang- og Tareforskning, Trondheim. They were extracted and the extracts worked up as described in previous communications [3]. After fractionation on carbon columns and, when necessary, further separation on thick filter paper, the following substances were isolated:

Fucus spiralis. Laminitol, 0.18 g (0.025 %). M. p. 245–247° (slight decomp.).

Mannitol, 23 g (3.1 %). M. p. 160–162°.

1-Mannitol acetate, 0.70 g (0.1 %). M. p. 121–122°.

1-Mannitol β-glucoside, 0.30 g (0.04 %). M. p. 141–142°.

1,6-Mannitol di-(β-glucoside), about 0.03 g (0.004 %). Amorphous, chromatographically indistinguishable from authentic material.

Desmarestia aculeata. The crude laminitol was purified as acetate. Yield 20 mg (0.004 %, calculated as laminitol). M. p. 147–148°.

Mannitol, 13.5 g (5.6 %). M. p. 162–163°.

Low-molecular Carbohydrates in Algae

VII *. Investigation of *Fucus spiralis* and *Desmarestia aculeata*

HANS BOUVENG and BENGT LINDBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

In Parts I [1], IV [2] and V [3] of this series, studies on the brown algae *Fucus vesiculosus*, *Pelvetia canaliculata* and *Laminaria cloustoni* were reported. These algae all contained mannitol, 1-mannitol β-glucoside and 1,6-mannitol di-(β-glucoside). 1-Mannitol acetate was isolated from *F. vesiculosus* and *L. cloustoni*, volemitol and its mono- and di-glucosides from *P. canaliculata* and a substance, laminitol, later proved to be a C-methyl inositol (Part VI) from *L. cloustoni*. It was therefore of interest to investigate other brown algae to see if some of these substances were characteristic for the whole group, and in the present communication the investigation of *Fucus spiralis* and *Desmarestia aculeata* is reported. Mannitol, 1-mannitol β-glucoside and laminitol were isolated from both and the presence of 1,6-mannitol diglucoside was demonstrated by paper chromatography. It is most probable that laminitol was overlooked in *F. vesiculosus* and *P. canaliculata* and that this substance, as well as mannitol and its glucosides, is characteristic for brown algae in general. 1-Mannitol acetate was isolated from *F. spiralis* but not from *D. aculeata* and it seems significant that this substance has been obtained in a good yield only from the *Fucus* species. Volemitol was not found in either of the two algae now investigated. It has thus so far only been found in *P. canaliculata* but it is intended to investigate its possible occurrence in other brown algae.

The algae, *Fucus spiralis* (740 g) and *Desmarestia aculeata* (240 g) were kindly supplied by Institutt for Tang- og Tareforskning, Trondheim. They were extracted and the extracts worked up as described in previous communications [3]. After fractionation on carbon columns and, when necessary, further separation on thick filter paper, the following substances were isolated:

Fucus spiralis. Laminitol, 0.18 g (0.025 %). M. p. 245–247° (slight decomp.).

Mannitol, 23 g (3.1 %). M. p. 160–162°.

1-Mannitol acetate, 0.70 g (0.1 %). M. p. 121–122°.

1-Mannitol β-glucoside, 0.30 g (0.04 %). M. p. 141–142°.

1,6-Mannitol di-(β-glucoside), about 0.03 g (0.004 %). Amorphous, chromatographically indistinguishable from authentic material.

Desmarestia aculeata. The crude laminitol was purified as acetate. Yield 20 mg (0.004 %, calculated as laminitol). M. p. 147–148°.

Mannitol, 13.5 g (5.6 %). M. p. 162–163°.

* Part VI, *Acta Chem. Scand.* **8** (1954) 1875.

1-Mannitol β-glucoside 0.11 g (0.045 %). M. p. 138–139°.

1,6-Mannitol di-(β-glucoside), about 5 mg (0.002 %). Amorphous, chromatographically indistinguishable from authentic material.

The melting points of all the crystalline compounds were undepressed on admixture with authentic specimens.

Low-molecular Carbohydrates in Algae

VIII *. Investigation of Two Green Algae

BENGT LINDBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Two green algae, one marine, *Enteromorpha compressa*, and one fresh water alga, *Chlorella*, strain Tx 14–10, have been investigated, using the same technique previously applied to brown algae (Part V [1]).

Sucrose was isolated in good yield from both algae and evidence for the occurrence of *meso*-inositol in the two algae was also obtained. A small amount of mannitol was isolated from *E. compressa*, but this might have come from contaminating brown algae. From the *Chlorella* maltose and maltotriose were isolated. These substances certainly have some connection with starch, either as precursors in its biosynthesis or as products of a post-mortal, enzymatic hydrolysis. In addition, the presence of several unidentified substances, occurring in small amounts, was demonstrated by paper chromatography.

Enteromorpha compressa (250 g), kindly supplied by Marinbotaniska Institutionen, Göteborg, was extracted and worked up as previously described for the brown algae [1]. The carbohydrate fraction was separated on a carbon column, using the gradient elution technique. Mannitol (90 mg), m. p. 158–162° and sucrose (1.4 g), m. p. 178–179° were isolated, and the presence of *meso*-inositol demonstrated by paper chromatography.

Chlorella, strain Tx 14–10, (160 g), kindly supplied by Docent L. E. Enebo, Kungl. Tekniska Högskolan, Stockholm, was refluxed for 4 hours with 75 % ethanol (2 000 ml), the extract separated by centrifugation and the residue re-extracted and treated in the same manner. The combined extracts were worked up as above, separated on a carbon column and further fractionated on thick filter paper. The following substances were isolated:

meso-Inositol (0.22 g), m. p. 216–217°. Acetate, m. p. 209–211°. Sucrose (3.8 g), m. p. 182–183°.

Maltose (80 mg) was isolated by further separation of a fraction from the carbon column on thick filter paper. It was amorphous and not quite pure, $[\alpha]_D^{20} + 110°$ (c, 2.0 in water), but was chromatographically indistinguishable from authentic maltose and on hydrolysis yielded glucose only.

Maltotriose (270 mg) was isolated from another fraction in the same manner. It was also amorphous and not quite pure, $[\alpha]_D^{20} + 139°$ (c, 2.0 in water), but chromatographically indistinguishable from authentic maltotriose and on partial hydrolysis yielded glucose and maltose (identified by paper chromatography).

The melting points of all the crystalline compounds were undepressed on admixture with authentic materials.

4-Hydroxy-Piperidine-2-Carboxylic Acid in Green Plants

ARTTURI I. VIRTANEN and SIGRID KARI

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

We recently isolated a new piperidine-carboxylic acid from *Rhapis flabelliformis* and identified it as 5-hydroxy-piperidine-2-carboxylic acid [1]. By paper chromatography this substance was found also in *Acacia* species. In this case, however, also another spot in connection with the spot of 5-hydroxy-piperidine-2-carboxylic acid could be seen on the paper chromatogram (Fig. 1). The colour produced with ninhydrin of this spot was at first yellow but turned after heating gradually sky blue, while the spot given by the 5-hydroxy acid was blue tinged with violet. Without this difference in colour it had been difficult at first to observe that two different substances together formed the large spot.

We have now isolated this other amino acid from a 70 % alcohol extract of *Acacia pentadena*. The solution of 655 g of fresh plants (= 346 g dry material, 764 mg soluble N) was first run through an Amberlite IR-120 column (1.5 × 43 cm, 80 ml resin). The amino acids remained in the column and were eluted with 1 *N* ammonia whereby all amino acids came out in fractions Nos. 4—19 of 17 ml each. Ammonia was evaporated *in vacuo* from these fractions. The syrupy residue was dissolved in 10 ml of 1.5 *N* HCl and the solution obtained was passed into a Dowex 50 column (4 × 64 cm, 800 ml resin). The resin had previously been treated with 1.5 *N* HCl. The amino acids were eluted with 1.5 *N* HCl. 400 fractions of 9 ml were collected. The unknown amino acid came out in fractions Nos. 201—260. Fractions 201—220 contained besides α-amino acids (serine, threonine and asparagine) only the unknown amino acid, fractions 221—260 also 5-hydroxy-piperidine-2-carboxylic acid. Fractions 201—220 were therefore used for the isolation of the unknown amino acid. In order to destroy the α-amino acids they were deaminated with nitrogen oxides. The solution was then passed through an Amberlite IR-120 column and the amino acid in question, which was not deaminated, was eluted with ammonia. After evaporation to a small volume the unknown amino acid crystallized in fine flakes. The yield was 180 mg corresponding to about 18 mg N (2.4 % of the soluble N in *Acacia*). When the amount of this amino acid in the mother liquid and in fractions 221—260 are taken into account about 2.7 % of the soluble N in *Acacia* belongs to the unknown amino acid. Analysis of the recrystallized substance; Found: C 49.25; H 7.67; N (Dumas) 9.63. Calc. for hydroxy-piperidine-carboxylic acid $C_6H_{11}O_3N$: C 49.65; H 7.59; N 9.66. M. p. determination: turned brown at 250° C, decomposed at 270° C.

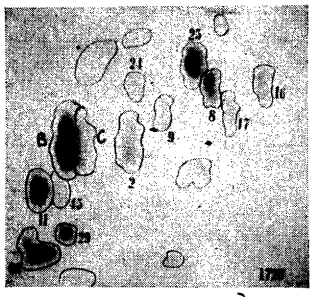

Fig. 1. Two-dimensional paper chromatogram (butanol-acetic acid + phenol-NH_3) from a 70 % alcohol extract of Acacia pentadena. 2 = ala, 8 = ser, 9 = threo, 11 = pro, 16 = asp, 17 = glu, 24 = glu-NH_2, 25 = asp-NH_2, 29 = γ-aminobut. acid, 45 = ethanolamine, 60 = piperidine-2-carboxylic acid (pipecolic acid), B = unknown amino acid, C = 5-hydroxy-piperidine-2-carboxylic acid.

This amino acid could be clearly distinguished from 5-hydroxy-2-piperidine-carboxylic acid by paper chromatography, because it moved somewhat faster in phenol. R_F-values (Whatman No. 4 paper):

	Phenol-NH_3	Butanol-acetic acid
5-hydroxy-piperidine-2-carboxylic acid	0.783	0.254
4-hydroxy-piperidine-2-carboxylic acid (unknown amino acid)	0.826	0.232
α-alanine	0.609	0.247

The new amino acid did not reduce alkaline permanganate solution. Upon reduction with 66 % HI (*d* 1.96) and red phosphorus at 140° C piperidine-2-carboxylic acid (pipecolic acid) was formed (Fig. 2).

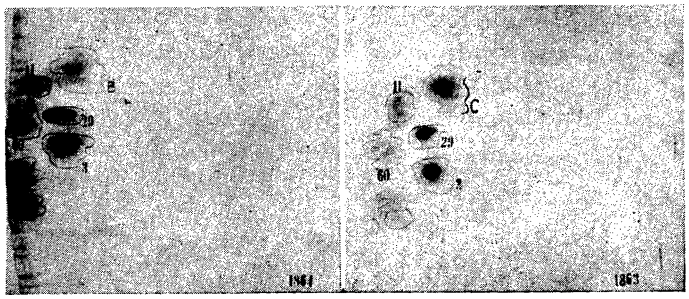

Fig. 2. Products formed from unknown amino acid B and 5-hydroxypiperidine-2-carboxylic acid C after reduction with HI and P. B = unknown amino acid which partly remained unchanged, C = 5-hydroxy - piperidine - 2-carboxylic acid which partly remained unchanged, 60 = pipecolic acid formed from B and C; amino acids 3, 11, and 29 added for comparison. Two lower spots on the chromatograms are unknown, probably I containing substances.

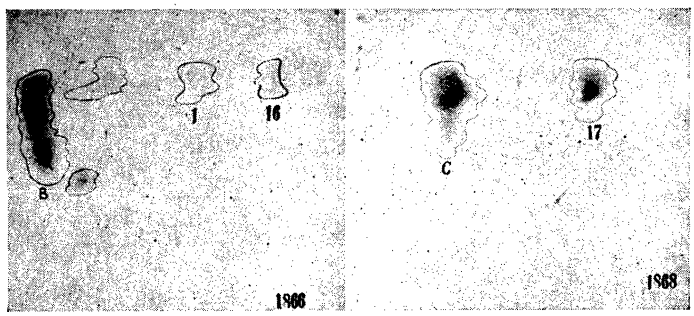

Fig. 3. Products formed from unknown amino acid B and 5-hydroxypiperidine-2-carboxylic acid by oxidation with $KMnO_4$ in H_2SO_4-solution. B = unknown amino acid which partly remained unchanged, C = 5-hydroxypiperidine-2-carboxylic acid which partly remained unchanged, 16 = asp, 17 = glu, 1 = gly.

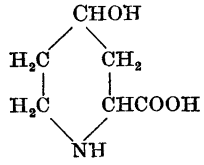
Accordingly, some hydroxy-piperidine-2-carboxylic acid was in question, having its OH group in another position than 5. On oxidation with potassium permanganate in sulphuric acid solution the substance gave, in addition to two substances not closer investigated, aspartic acid and a smaller amount of glycine, but no glutamic acid (Fig. 3). In parallel experiments our 5-hydroxy-piperidine-2-carboxylic acid gave only glutamic acid. Accordingly the unknown amino acid is 4-hydroxypiperidine-2-carboxylic acid.



In our previous paper we advanced the hypothesis that 5-hydroxy-piperidine-2-carboxylic acid could be formed from δ-hydroxylysine. Correspondingly 4-hydroxy acid could be formed from γ-hydroxylysine. This acid has not yet been found in nature.

In addition to *Acacia pentadena*, *Acacia retinoides* and *Strelitzia reginae* contained both 4- and 5-hydroxy-piperidine-2-carboxylic acid. *Albizzia lophantha* again contained only 4-hydroxypiperidine-2-carboxylic acid.

We wish to thank Professor A. Kalela for the plant material obtained from the University Botanical Gardens.

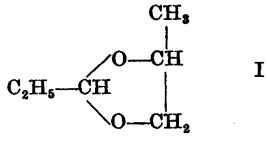
"Dimethyldioxan" Obtained from Propylene Glycol and Sulphuric Acid Identified as 2-Ethyl-4-Methyl-1,3-Dioxolan

ELSE AUGDAHL and O. HASSEL

Universitetets Kjemiske Institutt, Blindern — Oslo, Norway

In the course of studies related to addition compounds of ethers we wanted to prepare 2,6- or 2,5-dimethyl-1,4-dioxan. According to Levene and Walti [1] the 2,6-compound is obtained when 1,2-propanediol is distilled with concentrated sulphuric acid. I.G. Farbenindustrie in a patent also states that dimethyl-1,4-dioxan is formed in this way without, however, indicating the positions of the methyl groups [2]. According to another patent, however, of The Standard Oil Development a structural isomeric compound, the cyclic acetal 2-ethyl-4-methyl-1,3-dioxolan (I) is formed under the conditions mentioned above [3].



I

When 1,4-dioxan is prepared by distilling ethylene glycol with sulphuric acid small quantities of a cyclic acetal, *viz.* 2-methyl-1,3-dioxolan, is known to be formed. It therefore appears possible that in the analogous reaction with 1,2-propanediol both dimethyldioxans and 2-ethyl-4-methyl-1,3-dioxolan are formed. The latter may be expected to result from the reaction between 1,2-propanediol and propionaldehyde in the presence of a water-attracting substance like sulphuric acid. Moreover 1,2-propanediol may partially be transformed into propionaldehyde under the conditions prevailing during the distillation process [4]. When fractionating the distillation product considerable quantities of an aldehyde were actually observed.

Levene and Walti believed the substance which they obtained when distilling bis(2-hydroxypropyl)ether with concentrated sulphuric acid to be identical with the substance they prepared from 1,2-propanediol. This was their reason for concluding that the latter is 2,6-dimethyl-1,4-dioxan. The identity of the two liquid products was established only by means of elementary analysis. However, since both dimethyldioxan and the acetal have the formula $C_6H_{12}O_2$ this result is not decisive. On distilling bis(2-hydroxypropyl) ether with sulphuric acid aldehyde was formed. It therefore does not appear impossible that the acetal is produced also under these conditions. The purity of the two products was also somewhat questionable, as the boiling interval reported for the substance obtained from 1,2-propanediol was 117—125°, for the substance obtained from the ether 110—119°.

We also have observed that the product obtained from 1,2-propanediol splits off aldehyde by hydrolysis even after repeated treatment with Tollens' reagent. We further observed that on addition of an acid solution of 2,4-dinitrophenylhydrazine to the substance a precipitate was formed, which was identified as the 2,4-dinitrophenylhydrazone of propionaldehyde. The maximum quantity of the hydrazone obtained by adding a sufficient quantity of 2,4-dinitrophenylhydrazine corresponded to 94 % of the theoretical value calculated under the assumption that the aldehyde is formed by complete hydrolysis of the cyclic acetal. From the products obtained by hydrolysis experiments with diluted acids both 1,2-propanediol and propionaldehyde could indeed be isolated. We have, on the other side, heated a mixture of 1,2-propanediol and propionaldehyde to 160° C in a sealed tube. The substance thus obtained turned out to be identical with the substance resulting from distillation of 1,2-propanediol with sulphuric acid. Their identity follows from the identity of their infrared absorption spectra. We may add that under similar conditions 2,4-dimethyl-1,3-dioxolan has been prepared from 1,2-propanediol and acetaldehyde [5].

According to I. R. investigations the purity of the acetal obtained by the method of I. G. Farbenindustrie for preparing dimethyldioxan is higher than the purity of the products obtained by the methods described by Levene and Walti and in the Standard Oil patent. The main difference is that in the I.G. Farbenindustrie process the 1,2-propanediol is added successively during the distillation. In this case the raw product will — after neutralisation and drying — distill below 117° C, the main part between 114—117° C. The distillation intervals for the purified products reported by Levene and Walti and in The Standard

Oil patent are 117—125° C and 116—121°, respectively.

From our experiments the conclusion must be drawn that *if* dimethyldioxans are formed when propylene glycol is distilled with sulphuric acid, the amounts are at least insignificant.

Experimental: Hydrolysis of the acetal. The acetal is sparingly soluble in water, but on heating with 1 % hydrochloric acid and shaking the acetal layer soon disappeared, propionaldehyde being evolved. The solution was kept for some time in an evacuated desiccator with phosphorus pentoxide and the remaining liquid distilled. The temperature rose rather rapidly to the boiling point of 1,2-propanediol. The distillate was viscous, miscible with water in all proportions and the taste sweet.

Reaction with 2,4-dinitrophenylhydrazine. 5 ml of concentrated sulphuric acid was added to 1.0 g of the reagent, then — drop by drop — 7.5 ml water and finally 25 ml ethanol (96 %). This solution was added to a solution of 0.250 g acetal in 10 ml ethanol (96 %). The precipitate (0.478 g) after repeated crystallisation from 96 % ethanol melted at 153.5°. The melting point showed no depression on addition of specially prepared propionaldehyde-2,4-dinitrophenylhydrazone. (Found: C 45.54; H 4.31; N 23.51. Calc. for $C_9H_{10}O_4N_4$: C 45.37; H 4.23; N 23.53).

The reaction between propionaldehyde and 1,2-propanediol. 17 g of propionaldehyde and 13 g of 1,2-propanediol were heated in a sealed tube to 160° during 68 hours. On fractionating it was found that the liquid distilling below 50° C consisted essentially of propionaldehyde. Between 50° and 86° a two-layer fraction was obtained. Subsequently the temperature rose rapidly to 160° C. The upper layer of the middle fraction was dried with anhydrous sodium sulphate before refractionating. After repeated fractionation the infrared absorption spectrum of the fraction 114—117° was compared with the spectrum of a corresponding fraction obtained from the distillation of 1,2-propanediol with sulphuric acid. The two fractions were found to consist of the same chief component, the contents of free propionaldehyde being somewhat different.

The molecular weight of the acetal prepared according to the I. G. Farbenindustrie patent was determined cryoscopically: Found 115.8, calc. 116.3.

Thanks are due to Mr. J. Lothe for taking the infrared spectra.

A Preliminary Note on the Composition of the Non-hydratable Soyabean Phosphatides

KAJ NIELSEN

Dansk Sojakagefabrik A/S, Copenhagen, Denmark

Degummed soyabean-oil, *i. e.* soyabean-oil from which the "mucilages" and the phosphatides have been removed by treatment with steam or hot water, still contains some phosphorus-containing compounds ordinarily referred to as non-hydratable phosphatides. The composition of these has never been fully established.

From a soyabean-oil extracted from american-grown beans and degummed by treatment with steam the non-hydratable phosphatides corresponding to more than 80 % of the remaining phosphorus-content have been isolated.

The nitrogen-content of the isolated phosphatides was only 0.3 %, whereas the ash-content normally was 21—22 %. The ash consisted mainly of Ca and Mg-phosphates, indicating that the isolated phosphatides were present as Ca and Mg-salts.

After converting the salts into free acids, the ether-soluble part, which contained about 75 % of the phosphorus, was fractionated using the countercurrent technique developed by Craig [1].

Fig. 1 shows the distribution-curves of weight, phosphorus, nitrogen and fatty acids obtained when using the solvent system: 62 volumes of carbon tetrachloride, 35 volumes of methanol and 3 volumes of water [2].

Oil patent are 117—125° C and 116—121°, respectively.

From our experiments the conclusion must be drawn that *if* dimethyldioxans are formed when propylene glycol is distilled with sulphuric acid, the amounts are at least insignificant.

Experimental: Hydrolysis of the acetal. The acetal is sparingly soluble in water, but on heating with 1 % hydrochloric acid and shaking the acetal layer soon disappeared, propionaldehyde being evolved. The solution was kept for some time in an evacuated desiccator with phosphorus pentoxide and the remaining liquid distilled. The temperature rose rather rapidly to the boiling point of 1,2-propanediol. The distillate was viscous, miscible with water in all proportions and the taste sweet.

Reaction with 2,4-dinitrophenylhydrazine. 5 ml of concentrated sulphuric acid was added to 1.0 g of the reagent, then — drop by drop — 7.5 ml water and finally 25 ml ethanol (96 %). This solution was added to a solution of 0.250 g acetal in 10 ml ethanol (96 %). The precipitate (0.478 g) after repeated crystallisation from 96 % ethanol melted at 153.5°. The melting point showed no depression on addition of specially prepared propionaldehyde-2,4-dinitrophenylhydrazone. (Found: C 45.54; H 4.31; N 23.51. Calc. for $C_9H_{10}O_4N_4$: C 45.37; H 4.23; N 23.53).

The reaction between propionaldehyde and 1,2-propanediol. 17 g of propionaldehyde and 13 g of 1,2-propanediol were heated in a sealed tube to 160° during 68 hours. On fractionating it was found that the liquid distilling below 50° C consisted essentially of propionaldehyde. Between 50° and 86° a two-layer fraction was obtained. Subsequently the temperature rose rapidly to 160° C. The upper layer of the middle fraction was dried with anhydrous sodium sulphate before refractionating. After repeated fractionation the infrared absorption spectrum of the fraction 114—117° was compared with the spectrum of a corresponding fraction obtained from the distillation of 1,2-propanediol with sulphuric acid. The two fractions were found to consist of the same chief component, the contents of free propionaldehyde being somewhat different.

The molecular weight of the acetal prepared according to the I. G. Farbenindustrie patent was determined cryoscopically: Found 115.8, calc. 116.3.

Thanks are due to Mr. J. Lothe for taking the infrared spectra.

A Preliminary Note on the Composition of the Non-hydratable Soyabean Phosphatides

KAJ NIELSEN

Dansk Sojakagefabrik A/S, Copenhagen, Denmark

Degummed soyabean-oil, *i. e.* soyabean-oil from which the "mucilages" and the phosphatides have been removed by treatment with steam or hot water, still contains some phosphorus-containing compounds ordinarily referred to as non-hydratable phosphatides. The composition of these has never been fully established.

From a soyabean-oil extracted from american-grown beans and degummed by treatment with steam the non-hydratable phosphatides corresponding to more than 80 % of the remaining phosphorus-content have been isolated.

The nitrogen-content of the isolated phosphatides was only 0.3 %, whereas the ash-content normally was 21—22 %. The ash consisted mainly of Ca and Mg-phosphates, indicating that the isolated phosphatides were present as Ca and Mg-salts.

After converting the salts into free acids, the ether-soluble part, which contained about 75 % of the phosphorus, was fractionated using the countercurrent technique developed by Craig [1].

Fig. 1 shows the distribution-curves of weight, phosphorus, nitrogen and fatty acids obtained when using the solvent system: 62 volumes of carbon tetrachloride, 35 volumes of methanol and 3 volumes of water [2].

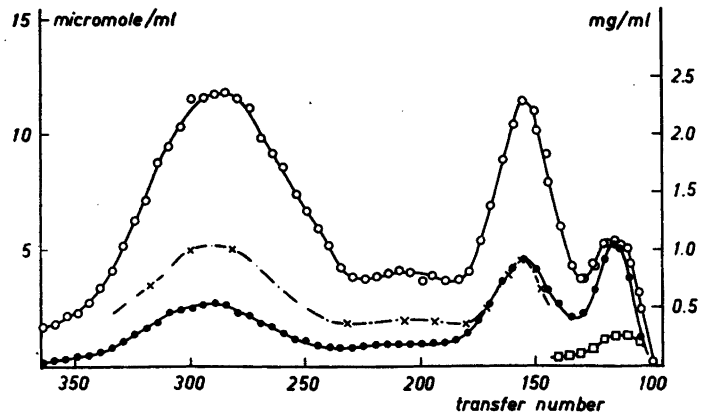

Fig. 1. Distribution curves.

○——○ *weight*, ●——● *phosphorus*,
□——□ *nitrogen*, ×——× *fatty acids*.

The curves exhibit three distinct maxima at transfer Nos. 116, 154 and 285, obviously representing three different components or groups of components, and a less pronounced maximum at transfer No. 205, probably representing a fourth component.

On mild acid hydrolysis the components at transfer No. 116 yielded glycerophosphoric acid and inositolmonophosphoric acid. The latter contained about 12 % of the total phosphorus present at this maximum.

The components at the three other maxima yielded on mild acid hydrolysis glycerophosphoric acid as the only phosphorus-containing ester.

As 1) phosphorus and fatty acids are present in equimolar quantities, 2) nitrogen is not present and 3) glycerophosphoric acid is the only phosphorus-containing ester, the component represented by the maximum at transfer No. 154 is in all probability lysophosphatidic acid (monoacyl-glycerophosphoric acid).

The two maxima at transfer No. 205 and No. 285 both contain phosphorus and fatty acids in a mole ratio of 1:2. As nitrogen is not present and the only phosphorus-containing ester is glycerophosphoric acid, the maxima are thought to represent two groups of phosphatidic acids (diacylglycerophosphoric acids), which are differing in chain length and degree of unsaturation of the fatty acids.

The small nitrogen-content derives from ethanolamine and serine, the latter contains about 10 % of the total nitrogen present. They are in all probability present as esters of phosphoric acid and glycerophosphoric acid.

Based on this distribution, it is possible to state the composition of the investigated mixture, leaving out the nitrogen-containing components, as follows:

inositolmonophosphoric acid	2 %
glycerophosphoric acid	15 %
lysophosphatidic acid	28 %
phosphatidic acid	55 %

γ-Hydroxyglutamic Acid in Green Plants

ARTTURI I. VIRTANEN and PENTTI K. HIETALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

When it was found that the amino acid preparation which Dakin [1] more than 30 years ago isolated from proteins, and which he believed to be β-hydroxyglutamic acid, was a mixture of commonly occurring amino acids [2], hydroxyglutamic acid definitely disappeared from the list of amino acids occurring in nature. We have now, however, found γ-hydroxyglutamic acid in the green parts of *Phlox decussata*.

A 70 % alcohol extract (13 l) of *Phlox* (3.5 kg of fresh plants = 1.18 kg dry substance, = 24.8 g N, = 6.57 g soluble N) was prepared. A two-dimensional paper chromatogram (butanol-acetic acid and phenol-NH_3) of the extract gave a spot immediately above that of aspartic acid (Fig. 1). In paper electrophoresis the amino acid in question (X) showed to be acidic. The isolation of X was performed as follows: the alcohol extract was passed through an Amberlite IR 120 column. The amino acids remained in the column and were eluted with 1 *N* ammonia. The ammonia was evaporated *in vacuo* and acidic amino acids were separated from the neutral and basic ones in an Amberlite IR-4B column. The acidic amino acids which remained in the column were eluted with 0.4 *N* hydrochloric acid. The solution was evaporated *in vacuo* to a syrup, which was dissolved in 200 ml of water. As the solution still contained great amounts of dark colcuring matter it was neutralized with NaOH. At a pH about 3.5 a dark precipitate was formed. When this precipitate had been separated by filtration the clear but still brown solution was neutralized to pH 7 and once more passed through an Amberlite IR 120 column. This procedure was repeated, ammonia being evaporated in the

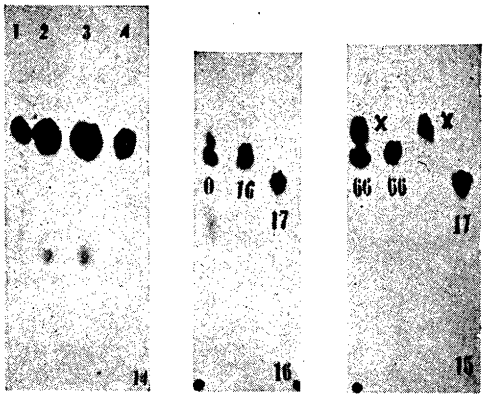

Fig. 2. Paper chromatogram of the pure preparation of X after reduction with HI and red P. 1, 2, and 3 = the reduction products of the amino acid X (increasing concentration of X from 1 to 3), 4 = glutamic acid. Solvent butanol-acetic acid.

Fig. 3. Paper chromatogram of the pure preparation of X after oxidation with $KMnO_4$ in sulphuric acid solution. O = the oxidation products of the amino acid X, 16 = aspartic acid, 17 = glutamic acid. Solvent butanol-acetic acid.

Fig. 4. Paper chromatogram of X and β-hydroxyglutamic acid (synth.). From left: a mixture of X and β-hydroxyglutamic acid (66), pure β-hydroxyglutamic acid (66), pure X and pure glutamic acid.

meantime. The solution was finally evaporated to dryness *in vacuo*, and the light solid substance remaining in the flask was dissolved in a small amount of water. 5 g of cellulose powder was poured into the flask after which the mass was evaporated to dryness, and placed on the top of a cellulose powder column (5.5 × 110 cm) containing as indicator 20 mg of methylorange. The elution was performed with a solution of butanol-acetic acid. After the indicator had come out 125 fractions of 36 ml were taken. Fractions 45—62 contained glutamic acid, 55—99 aspartic acid, and 71—125 the amino acid X. Fractions 100—125 contained only the unknown amino acid. They were evaporated to dryness *in vacuo*, the substance was dissolved in water and the solution poured into a glass jar. The solution was evaporated on a waterbath until crystallization began. After cooling the crystalline substance was separated by centrifugation and dried in a vacuum desiccator. The yield was 124 mg. M.p. 187° C (decomp.). Fractions 71—99 contained, besides a small amount of aspartic acid, about 620 mg of the amino acid X. 3.5 kg of fresh *Phlox* (= 6.57 g sol. N) thus contained about 750 mg (65 mg N) of the unknown amino acid (1.0 % of soluble N). Through crystallization a part of the amino acid X in fractions 71—99 could be separated from aspartic acid.

By the following experiments we established the structure of the amino acid X:

1. By reduction with 66 % HI (*d* 1.96) and red phosphorus at 140° C for 4 h glutamic acid was found to be formed (Fig. 2) from which we conclude that the amino acid X is a hydroxyglutamic acid.

2. Analysis of the amino acid X: C 36.82; H 5.35; N 8.60. Calc. for $C_5H_9O_5N$: C 36.81; H 5.52; N 8.59. Titration with phenolphtalein as indicator: 2.281 mg used 1.36 ml 0.00977 *N* NaOH. Calc. for monohydroxyglutamic acid 1.43 ml. The amino acid thus has the same empirical formula as monohydroxyglutamic acid.

3. Upon heating the amino acid X at pH 3.3 and 125° C for 4 h the amino N (van Slyke) diminished by 95 %; accordingly hydroxypyrrolidonecarboxylic acid was formed. From glutamic acid pyrrolidonecarboxylic acid is formed correspondingly (decrease of amino N 90 %).

4. By oxidation with potassium permanganate in sulphuric acid solution (10 mg of X + 7.5 mg of $KMnO_4$ in 189 µl of water + 90 µl of 20 % H_2SO_4) at + 10° C aspartic acid was formed (Fig. 3).

5. Potentiometric titration in parallel experiments gave the following pK-values (values approximate, taken from titration curves).

	pK_2	pK_3
Glutamic acid	4.2	9.7
Aspartic acid	3.7	9.6
β-Hydroxyglutamic acid	4.2	9.3
γ-Hydroxyglutamic acid (X)	3.6	9.7

6. Synthetic β-hydroxyglutamic acid can be distinguished from our γ-hydroxyglutamic acid on the paper chromatogram (butanol + acetic acid) (Fig. 4).

	butanol + acetic-acid	phenol + NH_3
R_F-value for γ-hydroxyglutamic acid (X)	0.06	0.17
» » β-hydroxyglutamic acid (synth.)	0.09	0.17
» » γ-hydroxy-α-amino pimelic acid [3]	0.15	0.34
» » glutamic acid	0.14	0.31

The new amino acid found in *Phlox* has thus been established as γ-hydroxyglutamic acid, HOOC · CHOH · CH_2 · $CHNH_2$ · COOH. On the basis of the paper chromatogram *Linaria vulgaris* also contains γ-hydroxyglutamic acid. The acid has not been isolated from this plant.

γ-Hydroxyglutamic acig is found also in the protein fraction of *Phlox*.

We are very grateful to Dr. Karl Pfister, Rahway, New Jersey, for a preparation of synthetic β-hydroxy-glutamic acid.

Oxidation of Diphenylmethane and Benzyltoluene with Dilute Nitric Acid at High Temperature and Pressure

ERIK B BENGTSSON

AB Bofors, Nobelkrut, Bofors, Sweden

Senff [1] boiled *m*-benzyltoluene for 4 days with dilute nitric acid and obtained an impure *m*-benzylbenzoic acid. In a similar way Zincke [2] prepared *p*-benzylbenzoic acid from *p*-benzyltoluene and obtained *p*-toluenephenylketone as a by-product. Rivkin [3] boiled diphenylmethane for several hours with 65 % HNO_3 and obtained benzophenone in good yield together with α-nitrodiphenylmethane. Nothing is mentioned about ring nitrated by-products.

It has now been shown that the methylene group in diphenylmethane and benzyltoluene can be oxidized to a CO-group in high yields and in a very short reaction time if dilute nitric acid is used at high temperature and pressure [4]. The oxidation is performed with nitric acid of a concentration around 30 % at temperatures around 200° C and pressures around 30 kg/cm².

A very quick reaction occurs under such conditions and benzyltoluene can be converted to crude benzoylbenzoic acid in yields of 90 % or more. The oxidation can be carried out in a very convenient way from a technical point of view. By treating the mixture of benzoylbenzoic acid isomers with hot conc. sulphuric acid the *o*-isomer is converted to anthraquinone [5]. (The *p*-isomer can be esterified to give valuable plasticizers.) It seems not impossible that this route to anthraquinone might have economic possibilities, provided low-priced benzyltoluene is available. Benzyltoluene is a by-product from the manufacture of benzaldehyde by oxidation of toluene with MnO_2 and can also be obtained as the main product from this oxidation [6].

Experimental: Oxidation of diphenylmethane. The oxidations were performed in an autoclave of stainless steel according to a general procedure reported in a previous paper [7]. Diphenylmethane and nitric acid of 30 % concentration in a 30 % equivalent excess were heated in the autoclave with stirring to 150° C. At this temperature the reaction started and no more external heating was needed. The pressure rose to 25 kg/cm² and the temperature to 195° C in a few minutes. Then the temperature was kept around 195° C for approximately 15 minutes. After cooling the reaction mixture was filtered (the mother liquid contained 6.1 % HNO_3), and the reaction product was washed with water and dilute Na_2CO_3-solution. It was then fractionated to give a main fraction with the analytical data tabulated in Table 1. As a comparison, data on benzophenone and diphenylmethane from the literature have been tabulated.

Table 1.

Oxidation of benzyltoluene. Benzyltoluene (mixture of isomers, $D_4^{20}=0.999$, $n_D^{20}=1.5723$) 72 g, and HNO_3 of 15 % concentration in a 20 % equivalent excess (for the oxidation of benzyltoluene to benzoylbenzoic acid and reduction of HNO_3 to NO), were heated in a 2.5 liter autoclave. When the reaction had started, the temperature rose to 200° C and the pressure to 25 kg/cm² in a few minutes. The autoclave was then allowed to cool off and after filtering and washing with water and drying a yellow product was obtained. This was dissolved in NaOH of 10 % concentration and after filtration reprecipitated with HCl. The yield was 72 g. Part of the crude product (20 g) did not dissolve in NaOH (melting point 104—109° C). Another experiment (No. 2) was run in the same way but using a 50 % excess of nitric acid. The temperature rose to 203° C and the pressure to 32 kg/cm². This product was not reprecipitated from the Na-salt but analysed directly after washing with water and drying. Yield 73 %. The values may be seen from Table 2. As a comparison theoretical values for benzoylbenzoic acid are tabulated.

Another three experiments were run in the same way at the same temperature and pressure as No. 2. The mother liquid from these experiments contained 3.4, 3.5 and 4.2 % HNO_3, respectively, and the crude acids contained 0.7—0.9 % N (Dumas) and had the equivalent weights 231.4, 232.5 and 246.6,

Table 2.

	Crude product No. 1	No. 2	Theoretical data
Equiw. weight	231	228	226
N %	0.9	0.8	—
C %	72.9	72.0	74.3
H %	4.3	4.3	4.4
Ash %	0.12	0.29	—

respectively. The average yield of crude product was 88 %.

Also tried was the oxidation of benzyltoluene according to this method, without excess of nitric acid. Using 91 g benzyltoluene and the equivalent amount of HNO_3 a temperature of 206° C and a pressure of 22 kg/cm² were reached. The reaction product was oily and could be separated into 26 g of solid material and 70 g of oil. After washing with benzene the solid material weighed 11 g and had the equivalent weight 237 and melting point 192—193° C. (Literature value for *p*-benzoylbenzoic acid 194° C.)

Finally some experiments were run with HNO_3 of 15 % concentration in a 50 % excess but this time the nitric acid was charged in two portions. Half of the acid was charged from the beginning and at 135—140° C the temperature and pressure began to rise quickly, the temperature reaching 180° C and the pressure 30—40 kg/cm² in a few minutes. When the temperature and pressure failed to rise any more but started to decrease, the other half of the nitric acid was placed into the autoclave and the temperature was brought up to about 200° C by external heating. The reaction was comparatively slow during this second phase. Operating this way an increase in capacity was possible. In each experiment 182 grams of benzyltoluene was oxidized in a 2.5 liter autoclave. The result of this series may be seen from Table 3. As usual the figures for temperature and pressure refer to maximal values.

Table 3.

Temperature °C	Pressure Kg/cm²	Yield %	Equiv. weight	N (Dumas) %
197	34	94.0	225.7	0.6
201	36	93.0	228.2	0.8
200	39	97.5	234.6	0.7
198	40	88.5	218.4	0.7

Such a crude acid mixture was purified with SO_2 in alkaline solution according to a procedure described in a previous paper [8] and was then free from nitro compounds. (Yield 79 %). It was heated (100 g) in 96 % H_2SO_4 at 130° C for 1 hour and after cooling the solution was diluted with water. After washing with water the precipitate was treated with Na_2CO_3. The part of the product which was not soluble in Na_2CO_3 was washed with water and dried. The melting point was 278° C. (Literature values for antraquinone 273—286° C.) Yield 41 g. The product was identified in ultraviolet spectrophotometer as antraquinone. The Na_2CO_3-solution was acidified with H_2SO_4 and 47 g of a product, melting at 190° C was obtained. (Literature value for *p*-benzoylbenzoic acid 194° C.)

The author wishes to thank Dr. Allan Dahlén and Dr. Bo af Ekenstam for their helpful interest in this work and for valuable discussions.

1,2-Dithiolane-3-carboxylic Acid

GÖRAN CLAESON

Chemical Institute, University of Uppsala, Uppsala, Sweden

As early as 1938 Fredga [1,2] had studied α,α′-dimercaptoadipic acid and its cyclic oxidation product 1,2-dithiane-3,6-dicarboxylic acid and pointed out the importance of studying aliphatic α,α′-dimercapto dicarboxylic acids and their oxidation to cyclic disulphides.

Schotte has continued the investigation and prepared 1,2-dithiolane-3,5-dicarboxylic acid (1,2-dithia*cyclo*pentane-3,5-di-

carboxylic acid) [3] and 1,2-dithia*cyclo*heptane-3,7-dicarboxylic acid [4].

The expectations of Fredga [1] have been realised by the discovery of "6-thioctic acid" (6,8-dithio-*n*-octanoic acid) and the important role this acid plays as a coenzyme [5] and in the photosyntheses [6]. It is the author's intention to synthesize lower homologues of 6-thioctic acid, to study the labile 1,2-dithiolane ring and to investigate the characteristics of these compounds as a function of the length of the side chain. The investigation is in progress. This publication deals with the synthesis of *rac.*-1,2-dithiolane-3-carboxylic acid and preliminary experiments on its optical resolution.

Methyl α,γ-dibromo-butyrate (prepared from α,γ-dibromo-butyryl bromide [7]) was treated with potassium thiol-acetate [8] and hydrolyzed with alkali to give α,γ-dimercapto-butyric acid. Oxidation of the mercapto-acid was carried out with iodine [9], oxygen [10] and hydrogen peroxide, but mostly polymeric products were formed. Experiments on oxidation to get a higher yield of the monomeric five-membered cyclic disulphide are in progress. The dithiolane-carboxylic acid was extracted with benzene in which the polymeric products are insoluble. Extraction with ether is unsuitable because part of the polymers is soluble in that solvent. The acid was obtained as a beautifully crystalline product of pale-yellow colour. On heating it is readily polymerized to a tough rubber-like mass. Attempts to distil the acid in vacuum also gave a polymeric mass.

Reduction of 1,2-dithiolane-3-carboxylic acid with zinc powder in ammoniacal solution yielded dimercapto-butyric acid. This indicates that the structure $>S=S$ for the disulphide group is excluded.

1,2-dithiolane-3-carboxylic acid was obtained in two different crystalline forms having the melting points 80–82° and 147°. Their ultraviolet absorption spectra are identical, with an absorption peak at 280 mμ, which means a shift from λ_{max} 330 mμ for 1,2-dithiolane and 6-thioctic acid. When another carboxylic group is inserted, the shift to shorter wavelengths is still greater. Schotte [11] has found that 1,2-dithiolane-3,5-dicarboxylic acid has λ_{max} 250 mμ.

The dissociation constant of the acid was preliminarily determined by measuring the pH of a solution of equivalent quantities of the acid and its sodium salt.

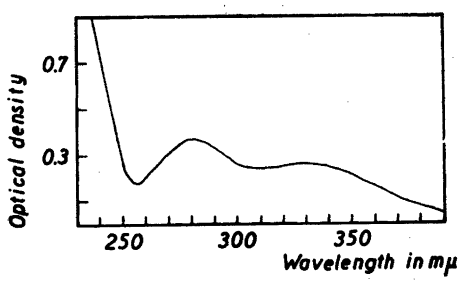

Fig. 1. Ultraviolet absorption spectra of 1,2-dithiolane-3-carboxylic acid in 95 % ethanol, 1.55 × 10⁻³ M.

Preliminary experiments on resolution have been carried out. With brucine and quinidine no crystals could be obtained and (+)-α-phenylethylamine gave a salt containing inactive acid. A dextrorotary acid was, however, obtained from the cinchonidine salt, crystallized from dilute alcohol. The mother liquor yielded crystals of different form containing excess of (−)-acid.

Experimental. Methyl α,γ-dibromobutyrate. The ester was obtained from abs. methanol and α,γ-dibromobutyryl bromide (B.p. 106—107°/9 mm. Plienninger gives no boiling point) in quantitative yield. B.p. 101—102°/9 mm.

Methyl-α,γ-di-thiolacetoxy-butyrate. 139 g of methyl α,γ-dibromobutyrate in 200 ml methanol was treated with an ethanolic solution of potassium thiolacetate prepared by neutralizing 90 g of thiolacetic acid with a solution of 66 g of potassium hydroxide in 200 ml methanol. There was an immediate precipitation of potassium bromide, which after standing overnight was filtered off and the methanol evaporated. Water was added, and the oil extracted with ether. The dried ethereal solution was evaporated and distilled to give 107 g (80 %) of pale yellow ester b.p. 178—179°/10 mm. About 10 gram distilled over below 178° and was shown to contain bromine.

α,γ-Dimercapto-butyric acid. 55 g of the ester was treated with 800 ml (675 ml of methanol and 125 ml of water) 2 *N* sodium hydroxide. After standing over-night, the methanol was distilled at 760 mm in nitrogen atmosphere in order to avoid oxidation. By treating the residue with dilute sulfuric acid and extracting with ether 38 g crude mercapto-acid was obtained as a yellow oil. The acid contained some acetic acid.

1,2-Dithiolane-3-carboxylic acid. The crude mercapto-acid was neutralized with 1 000 ml of dilute sodium-bicarbonate solution, and 2 ml 1 % ferric chloride was added, resulting in a solution of deep blue colour. With mechanical stirring and cooling with ice, 30 % hydrogen peroxide was added until the blue colour disappeared. The solution was acidified with sulfuric acid and extracted with benzene. (Part of the product was insoluble in benzene, but could be extracted with ether.) The benzene solution was dried and distilled. The crystallized residue weighed 5 g (15 % calculated on methyl α,γ-di-thiolacetoxy-butyrate). Recrystallization from *cyclo*hexane-benzol gave very pale yellow crystals m. p. 81—82°. (Found: Eq. wt. 150.6; S 42.61; Mol. wt. 147. Calc. for $C_4H_8O_2S_2$: Eq. wt. 150.2; S 42.69; Mol. wt. 150.2.) The molecular weight was determined ebullioscopically in acetone. From the acetone solution the acid was recovered as large crystals m. p. 147°.

Oxidation with gaseous oxygen using ferric chloride as catalyst and oxidation with iodine gave about the same yield as the peroxide oxidation.

Reduction. The polymeric acid was almost quantitatively reduced to the mercapto-acid with zinc powder [1]. (Titr. with NaOH and I_2 gave: Eq. wt. 152.8 and 160.1; Calc. for $C_4H_8O_2S_2$: Eq. wt. 152.2.)

Preliminary experiments on resolution. 0.15 g (0.001 mole) of rac. 1,2-dithiolane-3-carboxylic acid and 0.29 g (0.001 mole) of cinchonidine were dissolved in 2 ml ethanol and 1 ml water was added. Crystallization overnight yielded 0.20 g of salt. The acid was liberated from its salt in the usual manner. The rotatory power was measured in alcohol. M. p. 60—62°.

$$[\alpha]_D^{25} = + 158°$$

Preliminary value of the dissociation constant. In a solution of 1.090×10^{-4} moles of 1,2-dithiolane-3-carboxylic acid and 1.090×10^{-4} moles of its sodium salt in 15 ml water the pH was found to be 3.42.

Crystal Field Stabilization of First Transition Group Complexes

CHR. KLIXBÜLL JØRGENSEN and JANNIK BJERRUM

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The crystal field of Bethe [1] has been applied to the first transition group by Ilse and Hartmann [2], Santen and Wieringen [3] and Orgel [4]. Ballhausen and the present authors [5-8] have extended these applications, and in this communication special attention will be drawn to the energy decrease due to crystal field perturbations on complex ions with an unfilled 3d-shell.

Table 1 gives the data for crystal fields with cubic symmetry (originating from octahedral and tetrahedral complexes). In the cases where the complexes with different total spin quantum number are known, also the lowest value of S observed in complexes is considered. The stabilization parameter is defined: $\varrho = 2a - 3b$, where a is the number of γ_5- and b the number of γ_3-electrons in a strong crystal field of cubic symmetry [3,8]. The two states γ_5 and γ_3 of one d-electron have the energies E_2 and E_1 respectively [2]. The energy difference $(E_1 - E_2)$ in tetrahedral complexes [5] equals $-\frac{4}{9}(E_1 - E_2)$ in octahedral complexes. Thus, the tetrahedral configuration gives much lower crystal field influences than the corresponding octahedral configuration. The energy of the groundstate in terms of ϱ is decreased by $\frac{\varrho}{5}(E_1 - E_2)$ relative to a similar ion of spherical symmetry, *i. e.* a closed shell with $L = 0$. Since $(E_1 - E_2)$ in octahedral complexes in the first transition group is of the order of magnitude [6] 10 000 cm^{-1}

Crystal Field Stabilization of First Transition Group Complexes

CHR. KLIXBÜLL JØRGENSEN and JANNIK BJERRUM

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The crystal field of Bethe [1] has been applied to the first transition group by Ilse and Hartmann [2], Santen and Wieringen [3] and Orgel [4]. Ballhausen and the present authors [5-8] have extended these applications, and in this communication special attention will be drawn to the energy decrease due to crystal field perturbations on complex ions with an unfilled 3d-shell.

Table 1 gives the data for crystal fields with cubic symmetry (originating from octahedral and tetrahedral complexes). In the cases where the complexes with different total spin quantum number are known, also the lowest value of S observed in complexes is considered. The stabilization parameter is defined: $\varrho = 2a - 3b$, where a is the number of γ_5- and b the number of γ_3-electrons in a strong crystal field of cubic symmetry [3,8]. The two states γ_5 and γ_3 of one d-electron have the energies E_2 and E_1 respectively [2]. The energy difference $(E_1 - E_2)$ in tetrahedral complexes [5] equals $-\frac{4}{9}(E_1 - E_2)$ in octahedral complexes. Thus, the tetrahedral configuration gives much lower crystal field influences than the corresponding octahedral configuration. The energy of the groundstate in terms of ϱ is decreased by $\frac{\varrho}{5}(E_1 - E_2)$ relative to a similar ion of spherical symmetry, *i. e.* a closed shell with $L = 0$. Since $(E_1 - E_2)$ in octahedral complexes in the first transition group is of the order of magnitude [6] 10 000 cm^{-1}

Table 1. Stabilization of ground-states in strong crystal fields of cubic symmetry.

Electron number	Examples	Total spin S	Octahedral complexes Stabilization parameter ϱ	Octahedral complexes Orbital degeneracy e	Tetrahedral complexes Stabilization parameter $-\varrho$	Tetrahedral complexes Orbital degeneracy e

(= 28 kcal/mole) with divalent ions and 20 000 cm^{-1} with trivalent ions, this stabilization energy can be considerable [4] even though it must be subtracted from the energy of the (often intermixed) excited states of the free ion in the magnetically anomalous complexes.

Another feature of the stabilization first mentioned by Orgel [4] will be discussed in this note: The preference for γ_5-electrons in the octahedral complexes corresponds to high electron densities in the eight directions [1] between the ligands, while the missing γ_3-electrons are directed towards the six ligands. Thus, the electrostatic potential near the ligands will be higher than corresponding to the external charge of the complex, *e. g.* in diamagnetic cobalt(III) complexes, the effective external charge might be expected to vary between + 9 in the direction of the ligands and −3 between the ligands. But a closer electrostatic calculation shows that the screening is not only determined by the number of d-electrons situated directly between the ligand and the cobalt(III) nucleus. Actually, only a variation between +4 and +2 can be present. Nevertheless, the result supports the idea that complexes like $[Co(NH_3)_6]^{+++}$ can be held together by electrostatic forces.

The current theories [9] on covalency in coordination compounds assume donation of twelve electrons from the ligands to the central ion in octahedral complexes, forming hybridizations of the d^2sp^3-type. It does not seem accidental that precisely the two empty γ_3-orbitals are used for this operation. The deviation from the spherical symmetry of the d-shell (*i. e.* ϱ being $\neq 0$) corresponds to a preferred location of ligands in the directions of the empty γ_3-orbitals, which are the spherically symmetric complement to the filled γ_5-orbitals. In the authors' opinion, it does not seem necessary to explain the electrostatic energy decrease by further addition of electron-pair formation of donated character. The tetrahedral sp^3-hybridizations, which are said to occur in ions with no crystal field perturbations, constitute as peculiar a hypothesis in coordination chemistry. While the explanation of chemical bonding between four hydrogen atoms each with one un-paired electron and a carbon atom with four un-paired electrons is so successful, the similar treatment of zinc(II) or beryllium(II) complexes does not easily compete with the electrostatic picture according to Fajans [10].

In Table 1, the orbital degeneracy e is also given for all the groundstates except

when it cannot be certainly predicted from atomic spectroscopy. Only in the cases for which $e = 1$ are the complexes stable [11] for crystal fields of purely cubic symmetry. For other e values the crystal fields must be somewhat distorted; for $e = 2$, to tetragonal, and for $e = 3$, to rhombic or tetragonal symmetry. Crystal field calculations explain easily [5,7] the occurrence of tetragonal symmetry in copper(II) or in diamagnetic nickel(II) complexes with no need of dsp^2-hybridization. If complexes are classified according to $e = 1$ and $e = 2$ or 3, it is interesting to compare the absorption spectra as well as the consecutive complexity constants in the various cases. Thus displacements of bands towards lower wavenumbers by increasing symmetry of the crystal field are found only in systems with $e > 1$ (*e. g.* in the cupric ammonia system) and irregularities in the rest effects are found *e. g.* to a higher degree in the cobalt(II) ammonia system than in the nickel(II) system [12,p.67].

The activation energies are high only when $\varrho(E_1 - E_2)$ is large and $e = 1$. Bjerrum and Poulsen [13] found empirically that half-completed and completed d-shells (with $\varrho = 0$) and nearly complete d-shells (with $e > 1$) give low activation energies, which increase with the oxidation state for purely electrostatic reasons, just as do the complexity constants. In the robust complexes (*e.g.* $\varrho = 6$ and $e = 1$ in chromium (III) and nickel(II)) the activation energy increases with the value of $(E_1 - E_2)$, which [6] is 17 400 cm^{-1} in $[Cr(H_2O)_6]^{+++}$ and 7 600 cm^{-1} in $[Ni(H_2O)_6]^{++}$. If the magnetism is changed during a consecutive complex formation, a sudden change of activation energies and complexity constants are expected, as found in the cyanide and α,α'-dipyridyl complexes of iron(II)[14]. Magnetically anomalous, octahedral complexes should only be possible when $\frac{\varrho}{5}(E_1 - E_2)$ is larger than the energy of the excited states in the free ion with low S, and they are mainly restricted to the electron configurations d^5 and d^6 with the highest value of ϱ. These facts will be discussed in the following papers of the series "Studies of Absorption Spectra"[15].

Note on the Structure of Dimethoxydihydrofurfural Diacetate

JØRGEN TORMOD NIELSEN, NIELS CLAUSON-KAAS and PAUL DIETRICH

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

By the action of bromine in methanol on furfural diacetate Clauson-Kaas and Fakstorp [1] obtained an 81 % yield of an oily dimethoxydihydrofurfural diacetate which by hydrolysis and oxidation with periodic acid gave *cis*-β-formylacrylic acid. Therefore the product must be a derivative of 2-pentene-1,5-dial-4-one (II) and it was assumed to have structure I in analogy with other dimethoxydihydrofurans.

When repeating the synthesis of dimethoxydihydrofurfural diacetate a somewhat lower yield (about 65 %) was regularly obtained while the reaction product at the same time contained about 15 % of unreacted furfural diacetate. Since the methoxylation of furfural diacetate is a slower reaction than the usual furan methoxylation reactions, the discrepancy may be due to a catalytic effect.

when it cannot be certainly predicted from atomic spectroscopy. Only in the cases for which $e = 1$ are the complexes stable [11] for crystal fields of purely cubic symmetry. For other e values the crystal fields must be somewhat distorted; for $e = 2$, to tetragonal, and for $e = 3$, to rhombic or tetragonal symmetry. Crystal field calculations explain easily [5,7] the occurrence of tetragonal symmetry in copper(II) or in diamagnetic nickel(II) complexes with no need of dsp^2-hybridization. If complexes are classified according to $e = 1$ and $e = 2$ or 3, it is interesting to compare the absorption spectra as well as the consecutive complexity constants in the various cases. Thus displacements of bands towards lower wavenumbers by increasing symmetry of the crystal field are found only in systems with $e > 1$ (*e. g.* in the cupric ammonia system) and irregularities in the rest effects are found *e. g.* to a higher degree in the cobalt(II) ammonia system than in the nickel(II) system [12,p.67].

The activation energies are high only when $\varrho(E_1 - E_2)$ is large and $e = 1$. Bjerrum and Poulsen [13] found empirically that half-completed and completed d-shells (with $\varrho = 0$) and nearly complete d-shells (with $e > 1$) give low activation energies, which increase with the oxidation state for purely electrostatic reasons, just as do the complexity constants. In the robust complexes (*e.g.* $\varrho = 6$ and $e = 1$ in chromium (III) and nickel(II)) the activation energy increases with the value of $(E_1 - E_2)$, which [6] is 17 400 cm^{-1} in $[Cr(H_2O)_6]^{+++}$ and 7 600 cm^{-1} in $[Ni(H_2O)_6]^{++}$. If the magnetism is changed during a consecutive complex formation, a sudden change of activation energies and complexity constants are expected, as found in the cyanide and α,α'-dipyridyl complexes of iron(II)[14]. Magnetically anomalous, octahedral complexes should only be possible when $\frac{\varrho}{5}(E_1 - E_2)$ is larger than the energy of the excited states in the free ion with low S, and they are mainly restricted to the electron configurations d^5 and d^6 with the highest value of ϱ. Note on the Structure of Dimethoxydihydrofurfural Diacetate

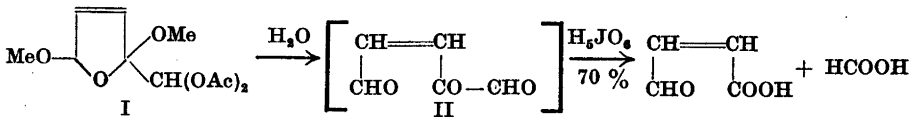
JØRGEN TORMOD NIELSEN, NIELS CLAUSON-KAAS and PAUL DIETRICH

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

By the action of bromine in methanol on furfural diacetate Clauson-Kaas and Fakstorp [1] obtained an 81 % yield of an oily dimethoxydihydrofurfural diacetate which by hydrolysis and oxidation with periodic acid gave *cis*-β-formylacrylic acid. Therefore the product must be a derivative of 2-pentene-1,5-dial-4-one (II) and it was assumed to have structure I in analogy with other dimethoxydihydrofurans.

When repeating the synthesis of dimethoxydihydrofurfural diacetate a somewhat lower yield (about 65 %) was regularly obtained while the reaction product at the same time contained about 15 % of unreacted furfural diacetate. Since the methoxylation of furfural diacetate is a slower reaction than the usual furan methoxylation reactions, the discrepancy may be due to a catalytic effect.



On standig, a crystalline isomer was precipitated from the oily dimethoxydihydrofurfural diacetate (yield 14 %). Treatment of this crystalline dimethoxydihydrofurfural diacetate with sodium methoxide in methanol gave a liquid with the formula $C_5H_4O_2(OMe)_2$. Catalytic hydrogenation gave a liquid $C_5H_6O(OMe)_2(OAc)_2$, which with sodium methoxide gave a third liquid $C_5H_6O_2(OMe)_2$. We think that these reactions are best explained as shown below, where structure I (either the *cis* or the *trans* form) is assigned to the crystalline dimethoxydihydrofurfural diacetate, while the three liquids are proposed to be the new 2,5-dimethoxy-2,5-dihydrofurfural (III), 2,5-dimethoxytetrahydrofurfural diacetate (IV) and 2,5-dimethoxytetrahydrofurfural (V), all having the same steric configuration as I at the α-carbons.

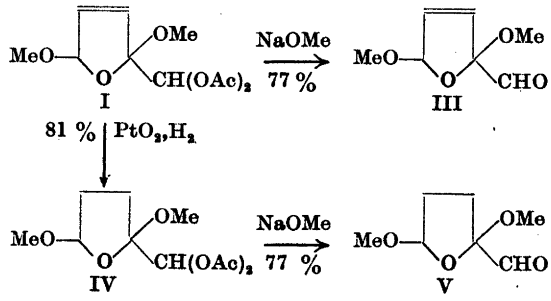
The mother liquor from the crystalline dimethoxydihydrofurfural diacetate (I) gave, with sodium methoxide, a dark red solution, from which 9 % of the liquid $C_5H_4O_2(OMe)_2$ (2,5-dimethoxy-2,5-dihydrofurfural (III)) was isolated. The main part of the reaction product remained as a red mass. Very probably III is formed from a certain amount (about 11 %) of I, which has remained in the mother liquor, the total yield of I thus being about 22 %. The major component of the mother liquor can, on the other hand, not be one of the two stereoisomeric forms of I, but must be another derivative of 2-pentene-1,5-dial-4-one (II). So far we have not been able to elucidate its structure.

Experimental. (Microanalyses by E. Boss and K. Glens). *Isolation of crystalline dimethoxydihydrofurfural diacetate (I).* Furfural diacetate (39.6 g) was methoxylated as described by Clauson-Kaas and Fakstorp [1]. The yield of the reaction product (slightly yellow oil, b.p.$_2$ 119—125°, n_D^{25} 1.4494) was 31.1 g (60 %, three other preparations gave 61, 63 and 67 %) (Found: C 50.8; H 6.4; OCH_3 20.4; $COCH_3$ 34.6. Calc. for $C_5H_4O_2(OCH_3)_2(COCH_3)_2$ (260.2) containing 15 % of $C_5H_4O_2(COCH_3)_2$ (198.2): C 51.3; H 6.0; OCH_3 20.4; $COCH_3$ 34.7).

30.0 g of the reaction product was left standing at room temperature for five weeks, a precipitate of white crystals of I removed by filtration (4.26 g = 14 %) and the filtrate (n_D 1.4498) analysed (Found: C 50.8; H 6.4; OCH_3 19.0; $COCH_3$ 34.8. Calc. for $C_5H_4O_2(OCH_3)_2(COCH_3)_2$ (260.2) containing 18 % of $C_5H_4O_2(COCH_3)_2$ (198.2): C 51.5; H 6.0; OCH_3 19.6; $COCH_3$ 34.9).

The crystals were crystallized from methanol (4.5 ml) and washed twice with methanol (4 ml in all). Hereby 3.04 g of a product melting at 110—111° (Hershberg apparatus corr.) was obtained. Further crystallization did not change the m.p. (Found: C 50.8; H 6.3; OCH_3 23.6; $COCH_3$ 33.5. Calc. for $C_5H_4O_2(OCH_3)_2(COCH_3)_2$ (260.2): C 50.8; H 6.2; OCH_3 23.9; $COCH_3$ 33.1).

The acetyl determinations were carried out by acidimetric titration at room temperature (phenolphthalein indicator). In the usual determinations (distillation of acetic acid from a 48 % sulfuric acid solution) acetyl values about 30 % higher than the calculated amount were obtained. We believe this to be due to hydrolytic cleavage of 2-pentene-1,5-dial-4-one (II) with the formation of formic acid.



2,5-Dimethoxy-2,5-dihydrofurfural (III). I (3.01 g, 0.116 mole) was dissolved in methanol (10 ml) and the solution added to a solution of sodium methoxide (from 0.266 g of sodium; 0.0116 mole) in methanol (15 ml). After standing at room temperature for 15 minutes the methanol and the methyl acetate formed by the reaction were distilled in a vacuum. Ether (50 ml) was added to the colorless residue, a precipitate of sodium acetate (0.88 g = 93 %) removed by filtration and the ether solution distilled. The yield was 1.40 g (77 %) of III (colorless liquid, b.p.$_{10}$ 88°, n_D^{25} 1.4430) (Found: C 53.3; H 6.8; OCH_3 39.6. Calc. for $C_5H_6O_2(OCH_3)_2$ (158.2): C 53.2; H 6.4; OCH_3 39.3).

On standing the product changes into a more viscous liquid with a higher refractive index. Probably polymerization takes place. Redistillation of 1.20 g after 10 days gave 0.74 g of the original product (b.p.$_{20}$ 98°, n_D^{25} 1.4431).

2,5-Dimethoxytetrahydrofurfural diacetate (IV). I (2.34 g) was dissolved in dioxan (50 ml) and the solution shaken (3 hr) with Adams platinum oxide catalyst (100 mg) under hydrogen (70 atm). The product was isolated by distillation. The yield was 1.92 g (81 %) of IV (colorless liquid, b.p.$_{0.3}$ 97—99°, n_D^{25} 1.4398) (Found: C 50.7; H 7.2; OCH_3 23.5; $COCH_3$ 31.8. Calc. for $C_5H_6O_3(OCH_3)_2(COCH_3)_2$ (262.3): C 50.4; H 6.9; OCH_3 23.7; $COCH_3$ 32.8).

2,5-Dimethoxytetrahydrofurfural (V). IV (3.00 g) was treated with sodium methoxide as described above for the preparation of III. The yield was 1.40 g (77 %) of V (slightly yellow liquid, b.p.$_{14}$ 82—84°, n_D^{25} 1.4307) (Found: C 52.9; H 7.9; OCH_3 38.9. Calc. for $C_5H_6O_3(OCH_3)_2$ (160.2): C 52.5; H 7.6; OCH_3 38.7).

The following day the refractive index of the product had risen to 1.4323. Redistillation of 1.23 g gave 1.02 g of the original product (colorless liquid, b.p.$_{14}$ 82—83°, n_D^{25} 1.4306). Apparently V, like the corresponding dihydrofuran III, polymerizes on standing.

Reaction of liquid dimethoxydihydrofurfural diacetate with sodium methoxide. A portion (15.0 g) of the mother liquor from the isolation of I was treated with sodium methoxide in methanol and the red reaction mixture worked up as described for the preparation of III. The yield was 0.82 g (9 %) of III (b.p.$_{11}$ 93—94°, n_D^{25} 1.4450) (Found: C 53.0; H 6.6; OCH_3 39.2).

Fixation of Nitrogen by Nodules Excised from Illuminated and Darkened Pea Plants

ARTTURI I. VIRTANEN, TAUNO MOISIO and R. H. BURRIS*

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland, and Department of Biochemistry, University of Wisconsin, Madison, Wisconsin, U.S.A.

In the symbiotic nitrogen fixing system of leguminous plant and root nodule bacteria, the photosynthesizing plant must translocate substrates to the nodule to support its general respiration and growth, to supply energy for nitrogen fixation, and to accept the fixed nitrogen. There is little information to indicate how rapidly these substrates are exhausted after photosynthesis ceases. Lindstrom, Newton and Wilson [1] have demonstrated a progressive and marked decrease in nitrogen fixation by red clover plants when they are darkened. Virtanen [2] has reported the conversion of leghaemoglobin to a green pigment in the nodules of plants kept in the dark, and found that such a conversion is connected with the inactivation of the nitrogen fixing system. The present experiments show that there is a striking and rapid decay in the nitrogen fixing capacity of nodules on darkened plants.

Torstai peas were planted in a sand substrate on June 30, were inoculated with *Rhizobium leguminosarum* strain H-43, and were furnished a nitrogen-free nutrient solution during their period of growth in a greenhouse. The plants, in early flower, were approximately 6 weeks old at the time of the experiments, and they were green, vigorous, and well nodulated. The nodules had red centers indicative of the presence of abundant leghaemoglobin.

At harvest the sand was rinsed from the roots, and the nodules were removed from the roots and placed immediately in a small respirometer vessel. The vessel on a Warburg manometer was evacuated [3], flushed twice with O_2 and reevacuated; a mixture

Fixation of Nitrogen by Nodules Excised from Illuminated and Darkened Pea Plants

ARTTURI I. VIRTANEN, TAUNO MOISIO and R. H. BURRIS*

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland, and Department of Biochemistry, University of Wisconsin, Madison, Wisconsin, U.S.A.

In the symbiotic nitrogen fixing system of leguminous plant and root nodule bacteria, the photosynthesizing plant must translocate substrates to the nodule to support its general respiration and growth, to supply energy for nitrogen fixation, and to accept the fixed nitrogen. There is little information to indicate how rapidly these substrates are exhausted after photosynthesis ceases. Lindstrom, Newton and Wilson [1] have demonstrated a progressive and marked decrease in nitrogen fixation by red clover plants when they are darkened. Virtanen [2] has reported the conversion of leghaemoglobin to a green pigment in the nodules of plants kept in the dark, and found that such a conversion is connected with the inactivation of the nitrogen fixing system. The present experiments show that there is a striking and rapid decay in the nitrogen fixing capacity of nodules on darkened plants.

Torstai peas were planted in a sand substrate on June 30, were inoculated with *Rhizobium leguminosarum* strain H-43, and were furnished a nitrogen-free nutrient solution during their period of growth in a greenhouse. The plants, in early flower, were approximately 6 weeks old at the time of the experiments, and they were green, vigorous, and well nodulated. The nodules had red centers indicative of the presence of abundant leghaemoglobin.

At harvest the sand was rinsed from the roots, and the nodules were removed from the roots and placed immediately in a small respirometer vessel. The vessel on a Warburg manometer was evacuated [3], flushed twice with O_2 and reevacuated; a mixture

* Fellow of the John Simon Guggenheim Memorial Foundation; supported in part by the Research Committee of the Graduate School, University of Wisconsin.

of N_2 and O_2 to give a pN_2 of 0.1 atmosphere and a pO_2 of 0.2 atmosphere was added followed by argon to atmospheric pressure. The N_2 contained 60 atom % ^{15}N excess. The process of preparing the nodules and gassing them required from 16 to 33 minutes. The nodules, after being shaken in the respirometer for 2 hours, were ground with a mortar in 1.0 *N* HCl, and centrifuged. The sedimented material was discarded and only the acid-soluble portion of the nodules was analyzed (Table 1).

When the experiment was initiated, some of the pots of peas were placed in a large dark room, and the others remained in the greenhouse where they received unsupplemented summer daylight. The experiment was started at 12 noon on August 9, a bright day. After 24 hours in the dark some of the plants were returned to the greenhouse. August 10 and 11 were dull, rainy days, but the morning of August 12 again was sunny.

Although there was but one sample at the initial harvest, it is notable that on this day, when the plants were exposed to high light intensity, their nodules gave the highest fixation of N_2. Fixation by nodules from the lighted plants was much less at the 8 o'clock harvest August 10 than initially; fixation improved somewhat by noon but decreased again by noon August 11. At noon August 12, a bright day, the nodules maintained approximately the same level of fixation as on the previous day.

One sample from the darkened plants retained considerable nitrogen fixing capacity at 8 o'clock August 10, but the amount of nitrogen fixed by nodules harvested from darkened plants at 12 o'clock was very low. The ability to fix nitrogen continued to decay for the next 2 days. The plants returned to the greenhouse after 24 hours in the dark recovered their nitrogen fixing capacity only partially.

No gross change in the pigment of the nodules from the darkened compared to the illuminated plants was apparent after 24 hours, and only a slight decrease in pigment of the darkened plants occurred in 48 hours. At the final harvest (72 hours) the nodules of the darkened plants remained firm but were distinctly green inside

Table 1. Influence of illuminating and darkening pea plants on fixation of nitrogen by their excised nodules. All data are given as atom% ^{15}N excess in the portion of the ground nodules soluble in 1.0 N HCl.

* The normal daylight in the greenhouse was not supplemented with artificial illumination. Nights are still comparatively light about August 10 in Helsinki, but the morning in question was cloudy and rainy why light intensity was low. The poor effectivity of the nodules probably depends on this.

** We wish to thank Mr. Wayne E. Magee and Mr. Michael K. Bach for the analysis of the samples for ^{15}N.

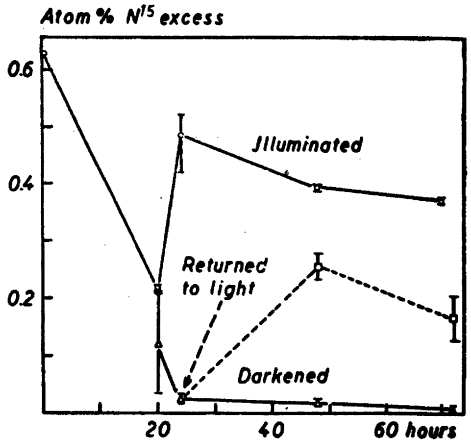

Fig. 1. Influence of illumination of pea plants on fixation by their nodules when exised. Vertical lines define the extreme values of replicate samples.

and exhibited a marked decrease in leghaemoglobin. The nodules from the illuminated plants were indistinguishable from those of the darkened plants which had been returned to light.

It seems most likely that the rapid decay of the nitrogen fixing capacity of nodules from plants kept in the dark for 24 h for the most part arises from depletion (and their rapid recovery in the light from renewal) of substrates furnished normally by the photosynthesizing plant, but partly also from the decrease in leghaemoglobin in the nodules. Virtanen [2] has shown that the oxydation of this pigment to a green one checks N_2-fixation, and a recent investigation by Virtanen and Berg has shown that a smaller part of leghaemoglobin is destroyed even during 24 h in darkness. Thus it can be understood that the transfer of plants to light causes a partial recovery of the effectivity of the root nodules, but far from the whole of it.

Whatever the basis for the observed response may be, the data clearly show that the nodules from pea plants kept in the dark have far less capacity for fixing N_2 than nodules from illuminated plants, and that the lost activity can be partially recovered by returning the plants to the light. It would be of interest to employ the isotopic method to determine in greater detail the rate of decay and recovery of nitrogen fixing capacity, the time required before the injury to the nitrogen fixing capacity becomes irreversible, and the influence of light intensity on the fixation process.

Estimation of Keto Acids in Plants

MAGNUS ALFTHAN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In the study of keto acids the paper chromatography of their 2,4-dinitrophenylhydrazones has been used. As the hydrazones of keto acids form multiple spots on the chromatogram, thus making the identification of the spots uncertain, unknown keto acids are difficult to discover. In order to elucidate unknown acid hydrazones in urine, Kulonen [1] reduced the hydrazones to the corresponding amino acids with aluminium amalgam according to the old method reported by Fischer [2], and investigated the amino acids by paper chromatography. Later Towers, Thompson, and Steward [3] used a similar method, the reduction being made catalytically. We have also developed a modification of the procedure which has already given some interesting results regarding keto acids in plants [4,5]. An account of it is given in the present paper. In our method the reduction is achieved by tin in an alcoholic hydrochloric acid solution, the yield of hydrogenolysis being comparatively good. The purification of the acid hydrazones obtained from the plant material was made according to Virtanen *et al.*[6]

Procedure. 1. *Preparation of the plant extract.* The plant material (usually about 100 g fresh wt.) was homogenized 3 times in a

Estimation of Keto Acids in Plants

MAGNUS ALFTHAN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In the study of keto acids the paper chromatography of their 2,4-dinitrophenylhydrazones has been used. As the hydrazones of keto acids form multiple spots on the chromatogram, thus making the identification of the spots uncertain, unknown keto acids are difficult to discover. In order to elucidate unknown acid hydrazones in urine, Kulonen [1] reduced the hydrazones to the corresponding amino acids with aluminium amalgam according to the old method reported by Fischer [2], and investigated the amino acids by paper chromatography. Later Towers, Thompson, and Steward [3] used a similar method, the reduction being made catalytically. We have also developed a modification of the procedure which has already given some interesting results regarding keto acids in plants [4,5]. An account of it is given in the present paper. In our method the reduction is achieved by tin in an alcoholic hydrochloric acid solution, the yield of hydrogenolysis being comparatively good. The purification of the acid hydrazones obtained from the plant material was made according to Virtanen *et al.*[6]

Procedure. 1. *Preparation of the plant extract.* The plant material (usually about 100 g fresh wt.) was homogenized 3 times in a

tungstic acid solution prepared just before use by mixing water, 10 % sodium tungstate, and 2/3 *N* sulphuric acid in the proportion 60:20:20 (v/v) according to Cavallini and Frontali [7]. The homogenate was filtered through a cheese cloth, the filtrates were combined and refiltered, this time through filter paper. The proportion between plant material and total extracting solution was in most cases 1:5 (w/v).

2. *Reaction with dinitrophenyl hydrazin.* The combined extracts were mixed with a 1 % solution of 2,4-dinitrophenyl hydrazine in 5 *N* H_2SO_4 (1 ml/g fresh wt. of plant material, Virtanen *et al.*[6]), and the reaction mixture was allowed to stand at room temperature for about 1 h. If a heavy precipitate was formed during the reaction the mixture was filtered once more.

3. *Extraction.* The reaction mixture was extracted according to Virtanen *et al.*[6] with ethyl acetate, and the ethyl acetate solution was extracted with 10 % Na_2CO_3. The combined soda phases were then acidified to about pH = 1 with 3 *N* H_2SO_4 and extracted with ethyl acetate. By this treatment the keto acid hydrazones could be separated from most of the amino acids and neutral carbonyl compounds in the original plant extract.

4. *Hydrogenolysis.* The final ethyl acetate extract was evaporated *in vacuo*, the residue was dissolved in 95 % ethanol and an aliquot (usually 2/3 or 4/5 of the solution, 1/3—1/5 being used as a control; see steps 6 and 7) was hydrogenated with tin by passing gaseous hydrochloric acid through the solution until a strong evolution of hydrogen gas started. Previously prepared HCl-ethanol was used in some cases. The vessel used in the hydrogenation was kept in an ice-water bath. The reaction time used varied from 12—20 h.

5. *Precipitation of the tin.* The reaction mixture was filtered, diluted with water, and the tin-ions were precipitated with hydrogen sulphide. The precipitate was then filtered off and the filtrate taken to dryness *in vacuo*.

6. *Purification with ion-exchange.* The residue was dissolved in water and passed through an Amberlite IR-120 column (25 × 1.3 cm). After washing the column with water the amino acids formed during the hydrogenolysis were displaced with 1 *N* NH_3. The amino acid solution which often had a brown colour was concentrated *in vacuo* or on a waterbath. The colour did not seriously interfere with the subsequent paper chromatography. The remaining non-hydrogenated keto acid hydrazones from step 4 were treated with Amberlite IR-120 in a similar way.

7. *Paper chromatography.* The amino acids formed were identified by two-dimensional chromatography using Whatman No. 4 paper and butanol-acetic acid and phenol + NH_3 as solvents. A corresponding amount of the similarly treated non-hydrogenated keto acid hydrazones was chromatographed as a control. It never contained more than traces of some amino acids present as contaminants.

Quantitative considerations. As to the quantitativity of the method we have obtained the following yields when treating known amounts of keto acids in accordance with the directions above: pyruvic acid 78 %, α-keto-butyric acid (impure prep.) 32 %, oxalacetic acid 61 %, and α-ketoglutaric acid 43 %. The values are approximate obtained by comparing the spots of the amino acids formed with spots of the corresponding amino acids in different concentrations. By starting directly from the synthetic hydrazones the yield for α-keto-butyric acid rises to about 60 %. Towers, Thompson, and Steward [3], using catalytical hydrogenation, got a yield of 65.3 % with pyruvic acid hydrazone, 97 % with glyoxylic acid hydrazone, but only 33.0 % and 36 % with the hydrazones of oxalacetic and α-ketoglutaric acid, respectively. Kulonen [1] in turn reports that the method of Fischer which he used for reduction is very unsatisfactory for the investigation of α-ketoglutaric acid, or of other dicarboxylic keto acids. The method for reduction used by us has, as mentioned above, given relatively good results both with ketodicarboxylic acids and keto-monocarboxylic acids. This has made the discovery of several new ketodicarboxylic acids possible [4,5]. The above mentioned values show that quantitative considerations are possible only if the yield of the hydrazone hydrogenolysis is known for each keto acid in question, the actual amounts may thus be 30—70 % higher than the amounts found on the chromatograms, in some cases possibly even higher. Our experiments in agreement with those of Towers, Thompson, and Steward [3] have also shown that 2,4-dinitrophenylhydrazone + ascorbic acid or dehydroascorbic acid does not give rise to noticeable amounts of amino acids during the hydrogenation procedure. The ninhydrin spots on chromatograms made from plant extracts by this method accordingly do not contain compounds derived from the above-mentioned substances.

New α-Keto Acids in Green Plants. II. β-Hydroxy- and γ-Hydroxy-α-Ketobutyric Acid in Cowberries

ARTTURI I. VIRTANEN and MAGNUS ALFTHAN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Using the method mentioned in our earlier paper [1] and in detail described in a later paper [2] we have identified a couple of new α-keto acids in some berries and green plants.

In berries of cowberry *(Vaccinium vitis idaea)* we identified the following α-keto acids (Fig. 1) (in brackets the amino acids formed by hydrogenolysis of the 2,4-dinitrophenylhydrazones of the corresponding keto acids): oxalacetic acid (aspartic acid), α-ketoglutaric acid (glutamic acid), hydroxypyruvic acid (serine), glyoxylic acid (glycine), γ-hydroxy-α-ketobutyric acid (homoserine), β-hydroxy-α-ketobutyric acid (threonine), and pyruvic acid (alanine). β- and γ-hydroxy-α-ketobutyric acid are new α-keto acids which have not earlier been found in any organism. The relatively intense spots T and Y represent unknown amino acids, and the corresponding keto acids are therefore also unknown.

If we assume that about 60 % of the keto acids [2] found in fresh cowberries (10.2 % dry substance, 0.93 % tot. N of dry subst., 10.5 % sol. N of tot. N) are reduced to amino acids when our method

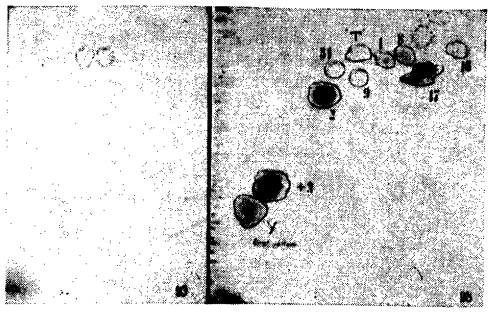

Fig. 1. Berries of Vaccinium vitis idaea. Left: Two-dimensional paper chromatogram (phenol-NH_3 and butanol-acetic acid) of the non-reduced 2,4-dinitrophenylhydrazones. Practically no spots of amino acids. Right: Two-dimensional paper chromatogram of the reduced hydrazones. 1 = gly, 2 = ala, 8 = ser, 9 = threo, 16 = asp, 17 = glu, 51 = homoser, T and Y = unknown amino acids. + 3 = valine added.

is used, the amount of different keto acids in 100 g of fresh cowberries are roughly the following: oxalacetic acid 25 μg, α-ketoglutaric acid 220 μg, pyruvic acid 130 μg, hydroxypyruvic acid 40 μg, glyoxylic acid 30 μg, γ-hydroxy-α-ketobutyric acid 20 μg, and β-hydroxy-α-ketobutyric acid 10 μg. As found by Alfthan and Virtanen [2] the 60 % yield which has been the basis for these calculations does not hold good for all amino acids. As, however, only yields

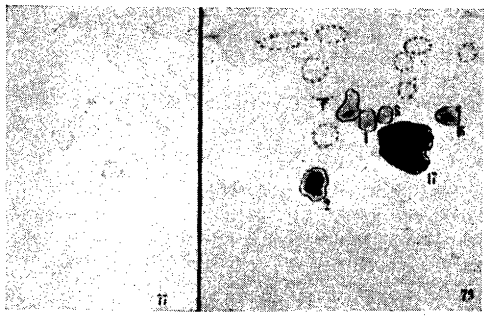

Fig. 2. Berries of Oxycoccus quadripetalus. Left: Two-dimensional paper chromatogram of the non-reduced 2,4-dinitrophenylhydrazones. Practically no spots of amino acids. Right: Two-dimensional paper chromatogram of the reduced hydrazones. Note the very strong spot of 17.

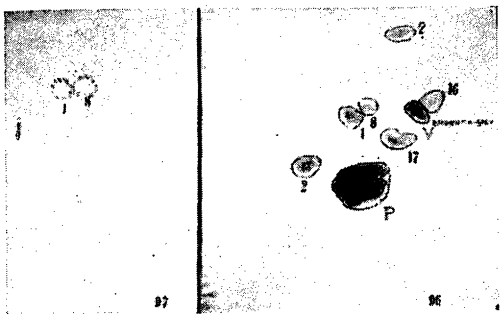

Fig. 3. Phyllitis scolopendrium. Left: Two-dimensional paper chromatogram of the non-reduced 2,4-dinitrophenylhydrazones. Practically no spots of amino acids, except extremely weak spots of 1 and 8. Right: Two-dimensional paper chromatogram of the reduced hydrazones. In addition to 1, 2, 8, 1ℓ, 17 the unknown amino acids V and P.

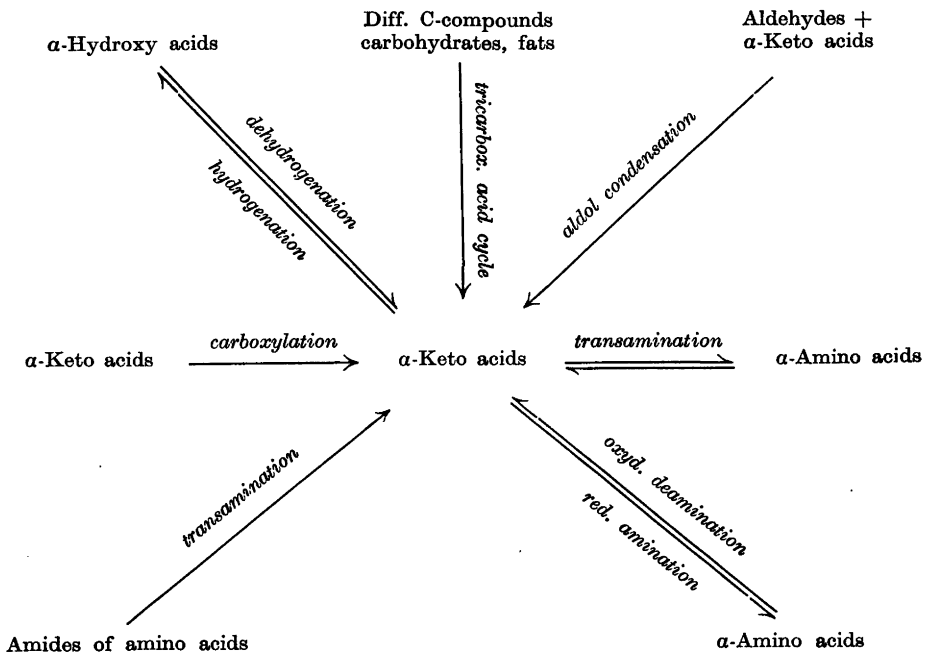
of a few amino acids formed from keto acids are known we have used the above mean yield.

In berries of mossberry *(Oxycoccus quadripetalus)* the keto acids are qualitatively nearly the same as in cowberry (Fig. 2). The keto acid corresponding to threonine was not, however, to be found in cowberry, at least not in the concentration used. The keto acid corresponding to the unknown amino acid Y was also lacking. The great amount of α-ketoglutaric acid in mossberry is especially remarkable.

Using the same basis for calculation as before the amount of different keto acids in mossberry (100 g of fresh berries) are roughly the following: oxalacetic acid 50 μg, α-ketoglutaric acid 2 700 μg, pyruvic acid 130 μg, hydroxypyruvic acid 25 μg, and glyoxylic acid 35 μg.

In a fern *(Phyllitis scolopendrium)* Virtanen and Berg [3] have found very large amounts of an unknown acidic OH-containing amino acid P, and a smaller amount of another amino acid V. (*cf.* Fig. 3). These authors are going to give a more detailed account of the isolation, structure, and properties of these new amino acids. Our keto acid determinations show (Fig. 3) that the keto acid corresponding to the amino acid P occurs very abundantly in this plant as compared with other keto acids, as, according to Virtanen and Berg, the amount of this amino acid is also by far the greatest when compared with other free



amino acids. The amount of the keto acid corresponding to the amino acid V is much smaller as is also that of the amino acid V in comparison with other free amino acids.

It is often to be noted that a great amount of an amino acid corresponds to a great amount of keto acid, at least when uncommon free amino acids are in question. This gives support to the conception that these amino acids may be formed from the corresponding keto acids *via* transamination.

The occurrence of a number of different α-keto acids corresponding to different amino acids in plants is due to the fact that these keto acids are either precursors to, or deamination products of, the corresponding amino acids. If deamination occurs *via* transamination the keto acids are both deamination products and precursors because the reaction is reversible, the equilibrium depending on the concentration of keto and amino acids participating in the transamination. Also the keto acid formed *via* oxidative deamination can be transformed into the corresponding amino acid *via* transamination. From amino acids which are formed from other amino acids *via* specific reactions (as *e. g.* homoserine from aspartic acid, threonine from homoserine *etc.*) the corresponding keto acid can be formed *via* deamination, and from this again *via* transamination the corresponding amino acid. The following scheme presents different possible pathways for the formation of α-keto acids in organisms and also for the formation of amino acids and amides, respectively, from α-keto acids.

The appearance of numerous widely different α-keto acids in plants gives further proof for the importance of these acids in plants.

We are very grateful to Dr H. Huber, Basel, for *Phyllitis scolopendrium*.

Effects of Ions on the Activity of Enzyme Systems

W. J. Rutter and B. Rolander

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm

The observed activity of many enzyme systems is a function of the ion population of the medium. Recent kinetic studies from Theorell's laboratory [1-3] have emphasized the role of anions in determining the rates of certain enzyme reactions. In an effort to determine the generality and the order of magnitude of these ion effects, several additional systems have been studied. The activity of the glucose-6-phosphate dehydrogenase system was markedly (as much as six fold) stimulated by low concentrations of various ions, while at higher concentration an inhibition was observed *. The magnitude of the stimulation and the onset of inhibition depended upon an interrelationship between the concentration of the substrate, TPN, and the concentration of the specific ions present. The older experiments [4,5], which indicated only a strong inhibition by phosphate are probably a result of a very low effective concentration of the substrate. Studies with various salts indicated that the observed effects were primarily determined by the particular anion species present. The order of magnitude of stimulation is roughly

$$F^- > PO_4^{=} > Cl^- > Br^- > SO_4^{=} > I^- > SCN^-.$$

Large anions like glycyl-glycine and TPN are poor activators, but the substrate, glucose-6-phosphate is an effective "anion activator". The differences in stimulation produced by various cations was generally related to the magnitude of contribution to the ionic strength of the medium. The overall results favor the concept of a non-specific ionic effect rather than an interpretation which involves a heavy metal requirement [6,7].

The observed activity of certain coupled systems, for example the Zwischenferment-old yellow enzyme system and the succinate oxidase system is also related to the kind and concentration of anions present.

These effects have been interpreted according to the general principles of solvation of chemical reactions.

The Variation in the Structure of Water on Gelation

Bertil Jacobson

Department of Biochemistry, Karolinska Institutet, Stockholm, Sweden

X-ray diffraction patterns of various gels were studied at 20° C in a Guinier camera employing Cu$K\alpha$ radiation. The intensity curves, obtained in the usual way from photometer determinations of film densities, were corrected for polarization and absorption.

Dilute gels (0.3—2.0 %) of certain polyelectrolytes (desoxyribonucleic acid, carboxymethylcellulose) and of a low molecular weight substance (dibenzoylcystin) give similar diffraction patterns with small but characteristic differences from that of pure water at the same temperature. The major peak at $(\sin\Theta) / \lambda = 0.16$ Å^{-1} shifts toward smaller angles and the height of the minor peak at 0.23 Å^{-1} increases relative to the properties of pure water. There also seems to be a tendency for the minor peak to shift toward larger angles.

From diffraction data it is known that the structure of water changes with temperature [1]. With decreasing temperature the tendency of a water molecule to bond itself tetrahedrically to four other neighboring molecules increases. This is observed as a shift in the major peak towards smaller angles and of the minor peak towards larger angles and in an increase in the height of the minor peak.

Thus the changes on gelation are qualitatively similar to those obtained in pure water when the temperature is decreased; that is, the gel-forming substances produce a decrease in the "structural temperature" of the water. The effect is opposite to that found with electrolytes which are known to increase the "structural temperature" [2].

The experimental results confirm the Forslind theory of gelation [3] according to which the thermal vibrations in the water lattice are reduced through a specific coupling to the non-aqueous component of the gel. The stabilization of the water is the result of a structural similarity between the ideal, four-coordinated water lattice and the positions of the hydrogen bond forming atoms on the surface of the non-aqueous phase.

An identical theory was developed in order to explain certain physico-chemical properties of desoxyribonucleic acid solutions [4]. Dielectric properties, viscosity and proton magnetic resonance data were explained through assuming the existence of large hydration shells with a higher degree of water lattice order than that prevailing in pure water. The present X-ray diffraction data are in agreement with the theory that certain asymmetric macromolecules can stabilize the water lattice over distances of some hundred Å.

Carboxymethyl Chitin, a New Substance Suitable for the Determination of Chitinase Activity

Eskil Hultin

Institutet för organisk kemi och biokemi, University, Stockholm, Sweden

The chitinases have not hitherto been investigated as extensively as could be expected for enzymes that break down such a common substance as chitin. This substance occurs in large quantities both in several animals (*e. g.*, crustaceans, insects and molluscs) and in various plants (*e. g.*, fungi). Chitinases are also known from various sources, *e. g.*, the "liver" of snails, insect larvae, sperm, a variety of bacteria, molds, and almonds.

The following substrates have been used for the determination of chitinase activity: native chitin, regenerated chitin (precipitated by diluting a solution of chitin in cold concentrated hydrochloric acid), chitosan (deacetylated chitin), chitotriose and chitobiose. As chitin is insoluble in water, it is not suitable as a substrate for the determination of enzymic activity. Chitosan is better for it is soluble in buffer solutions with pH less than about 6.5. In more alkaline solutions it is insoluble and hence not suitable. It is surely not the same enzyme [1,2] that attacks chitin and its oligosaccharides (*cf.* amylase and maltase).

A new chitin derivate, not described previously, carboxymethyl chitin, is suggested now as a substrate for the determination of chitinase activity. It has not the disadvantages of the substances used previously.

The preparation of carboxymethyl chitin. Raw chitin is prepared in the well-known way, *e. g.*, by treating shells of crustaceans with a dilute acid. The chitin is dissolved in supersaturated cold hydrochloric acid and precipitated by adding water or alcohol. The regenerated chitin is heated on a water bath with chloroacetic acid and a strong solution of sodium hydroxide in the way well-known for the preparation of carboxymethyl cellulose. Native chitin does not react with sodium hydroxide and chloroacetic acid under these conditions. The reaction product is dissolved in water and after neutralization the sodium salt of carboxymethyl chitin is precipitated by adding alcohol.

The determination of chitinase activity. A solution of carboxymethyl chitin is rather viscous, and so it is possible to run the determination of chitinase activity viscosimetrically in the well-known way [3]. This is advantageous

Carboxymethyl Chitin, a New Substance Suitable for the Determination of Chitinase Activity

Eskil Hultin

Institutet för organisk kemi och biokemi, University, Stockholm, Sweden

The chitinases have not hitherto been investigated as extensively as could be expected for enzymes that break down such a common substance as chitin. This substance occurs in large quantities both in several animals (*e. g.*, crustaceans, insects and molluscs) and in various plants (*e. g.*, fungi). Chitinases are also known from various sources, *e. g.*, the "liver" of snails, insect larvae, sperm, a variety of bacteria, molds, and almonds.

The following substrates have been used for the determination of chitinase activity: native chitin, regenerated chitin (precipitated by diluting a solution of chitin in cold concentrated hydrochloric acid), chitosan (deacetylated chitin), chitotriose and chitobiose. As chitin is insoluble in water, it is not suitable as a substrate for the determination of enzymic activity. Chitosan is better for it is soluble in buffer solutions with pH less than about 6.5. In more alkaline solutions it is insoluble and hence not suitable. It is surely not the same enzyme [1,2] that attacks chitin and its oligosaccharides (*cf.* amylase and maltase).

A new chitin derivate, not described previously, carboxymethyl chitin, is suggested now as a substrate for the determination of chitinase activity. It has not the disadvantages of the substances used previously.

The preparation of carboxymethyl chitin. Raw chitin is prepared in the well-known way, *e. g.*, by treating shells of crustaceans with a dilute acid. The chitin is dissolved in supersaturated cold hydrochloric acid and precipitated by adding water or alcohol. The regenerated chitin is heated on a water bath with chloroacetic acid and a strong solution of sodium hydroxide in the way well-known for the preparation of carboxymethyl cellulose. Native chitin does not react with sodium hydroxide and chloroacetic acid under these conditions. The reaction product is dissolved in water and after neutralization the sodium salt of carboxymethyl chitin is precipitated by adding alcohol.

The determination of chitinase activity. A solution of carboxymethyl chitin is rather viscous, and so it is possible to run the determination of chitinase activity viscosimetrically in the well-known way [3]. This is advantageous

because viscosimetric methods usually are considerably more sensitive than other methods. As the substrate is a polyvalent acid, the ionic strength in the reaction mixture must be kept constant (*e. g.*, 0.1), and the concentration of multivalent cations should be as low as possible. Addition of cysteine or other compounds containing sulphydryl groups causes a steady decrease in the viscosity of carboxymethyl chitin solutions. However, this difficulty can be overcome — in the same way as in the case of carboxymethyl cellulose [4] — by adding a small amount of potassium ferricyanide.

Senju and Okimasu [5] have described the preparation of hydroxyethylchitin, which is probably a suitable substrate for chitinase determination but this has not yet been proved.

The Zimmermann Method

Sven Arrhenius

Kemiska Avdelningen, Kungl. Veterinärhögskolan, Stockholm, Sweden

This method [1] is the most frequently used in steroid analysis. The sample is dissolved in ethanol, made alkaline with KOH, and stained with *m*-dinitrobenzene. If the sample contains steroids with a ketogroup in position 17, the extinction curve will show a flat maximum at 5 300 Å. In their absence the curve will only slope towards longer wave-lengths. The reactions causing the staining are not known. None of the many variants of the method is accurate. One source of error is the oxidation of ethanol by the nitro compounds. The aldehyde thus formed polymerises in alkaline solution.

m-Dinitrobenzene is soluble in most organic solvents. As no staining will occur unless $pOH < 2$, the only suitable solvents for the reaction are the simplest alcohols. The tertiary butanol is the only alcohol not oxidised by *m*-dinitrobenzene. It was used for an investigation of the Zimmermann reaction. The following results were obtained:

1. Alcaline solutions of pure *m*-dinitrobenzene in tert. butanol have the same extinction curves as those described for stained 17-ketosteroids.

2. The intensity of the colour depends mainly on the concentration of OH^-. It explains why the colours disappears after a couple of days.

3. Some carbonyl compounds as acetaldehyde, acetone, *cyclo*hexanone, and 17-ketosteroids increase the extinction, and shift the absorbtion maximum over to longer wavelengths (5 600 Å). Easily enolised ketones and formaldehyde have no or only slight influence on the colour.

The Incorporation *in vivo* of Amino Acids into Subfractions of Cytoplasmic Particles

Tore Hultin

The Wenner-Gren Institute, Stockholm, Sweden

It has been shown previously [1,2] that in chick liver the incorporation *in vivo* of labeled amino acids is particularly high in the submicroscopic particulate components of the cytoplasm.

C^{14}-glycine, N^{15}-glycine, or N^{15}-DL-alanine were injected intravenously into chicks or rats. The animals were killed 1—5 minutes after the administration of the isotope. Fractions of large and small submicroscopic particles were prepared from homogenates of the livers by differential centrifugation. (After removal of the mitochondrial fractions, the homogenates were centrifuged for 20 minutes at 20 000 g, and subsequently for 40 minutes at 105 000 g). After several washings, the particles were repeatedly treated at 0° C with 0.2 *M* $NaHCO_3$, pH 8.4, and with 0.6 % desoxycholate, pH 8.4. The cholate extracts were further fractionated by means of ethanol at low temperatures [3].

The isotope contents of the proteins were consistently higher in the large microsomes than in the small ones. In both fractions, the carbonate extracts (which contained a major part of the ribonucleic acid of the particles) showed the highest isotope contents. In the desoxycholate extracts, the proteins of the higher ethanol fractions showed a higher isotope level than the proteins of the more readily precipitable fractions. The non-soluble residues obtained after the desoxycholate treatments, had considerably lower isotope contents.

because viscosimetric methods usually are considerably more sensitive than other methods. As the substrate is a polyvalent acid, the ionic strength in the reaction mixture must be kept constant (*e. g.*, 0.1), and the concentration of multivalent cations should be as low as possible. Synthesis of Ureidosuccinic Acid (USA) from Citrulline with Rat Liver Enzymes

Peter Reichard and Lloyd H. Smith Jr.

Department of Biochemistry, Karolinska Institutet, Stockholm, Sweden

The isotope from citrulline-ureido-C^{14} is incorporated into position 2 of polynucleotide pyrimidines of the pigeon *in vivo* [1] and into orotic acid by rat liver slices [2]. It has been proposed that this incorporation takes place *via* argininosuccinic and ureidosuccinic acids (citrulline + aspartate → argininosuccinate → USA → orotate → polynucleotide pyrimidines).

With enzyme preparations from rat liver mitochondria evidence has earlier been obtained for the following reactions in the biosynthesis of USA [3]:

$NH_3 + CO_2 + ATP$ + acetylglutamate → Compound X + ADP (1)

Compound X + aspartate → USA + acetylglutamate + P_i (2)

Reaction (1) has been described by Grisolia and Cohen [4] as one step in citrulline formation, the other being:

Compound X + ornithine → Citrulline + acetylglutamate + P_i (3)

The possibility has now been investigated that USA might be formed from citrulline by a reversed reaction (3) followed by reaction (2) rather than by the proposed mechanism *via* argininosuccinate. The rat liver mitochondrial enzyme system which forms USA from aspartate, CO_2 and NH_3 was used for the investigation. The formation of labeled USA from citrulline-ureido-C^{14} could readily be demonstrated in the presence of acetylglutamate, L-aspartate and P_i. Addition of ATP and an ATP regenerating system greatly stimulated the formation of USA. It seems therefore possible that USA is formed by reactions (4) + (2)

C^{14}-citrullin e + acetylglutamate + ATP → C^{14}-compound X + ornithine + ADP (4)

rather than by a reversed reaction (3) + reaction (2).

The formation of compound X from labeled citrulline could be studied directly if aspartate was omitted from the system. Under those circumstances the CO_2 that was fixed in compound X could be released at acid pH and measured as $C^{14}O_2$. Maximal amounts of labeled CO_2 were obtained only in the presence of acetylglutamate and ATP. Significant enzymatic breakdown of C^{14}-citrulline also took place without acetylglutamate, though the presence of this compound increased $C^{14}O_2$ formation up to ten times. When arsenate was substituted for phosphate, 4—6 times more $C^{14}O_2$ was observed. The arsenate reaction was not stimulated by acetylglutamate or by ATP. It seems likely that this enzyme system contains a "citrullinase" comparable to that previously described in bacteria.

On the Nature of the Salt Inhibition of the Phosphoribomutase Reaction

Hans Klenow

Institute of Cytophysiology, University of Copenhagen, Denmark

The inhibitory effect of salts on the reaction:

Glucose-1,6-diphosphate (GDP) + Ribose-1-phosphate (R-1-P) ⇌ Ribose-1,5-diphosphate + Glucose-6-phosphate

which is catalyzed by phosphoglucomutase preparations from muscle extract has been studied. The reaction was assayed spectrophotometrically in the presence of triphosphopyridine nucleotide and an excess of Zwischenferment. Comparison of the effect of a number of different salts suggest that the inhibition is caused by anions. The influence of the concentration of R-1-P indicates that the salt inhibition can be overcome at infinitely high concentration of R-1-P. The inhibition is, therefore, probably due to competition of anions with R-1-P for the enzyme. The K_m

because viscosimetric methods usually are considerably more sensitive than other methods. As the substrate is a polyvalent acid, the ionic strength in the reaction mixture must be kept constant (*e. g.*, 0.1), and the concentration of multivalent cations should be as low as possible. Addition of cysteine or other compounds containing sulphydryl groups causes a steady decrease in the viscosity of carboxymethyl chitin solutions. However, this difficulty can be overcome — in the same way as in the case of carboxymethyl cellulose [4] — by adding a small amount of potassium ferricyanide.

Senju and Okimasu [5] have described the preparation of hydroxyethylchitin, which is probably a suitable substrate for chitinase determination but this has not yet been proved.

The Zimmermann Method

Sven Arrhenius

Kemiska Avdelningen, Kungl. Veterinärhögskolan, Stockholm, Sweden

This method [1] is the most frequently used in steroid analysis. The sample is dissolved in ethanol, made alkaline with KOH, and stained with *m*-dinitrobenzene. If the sample contains steroids with a ketogroup in position 17, the extinction curve will show a flat maximum at 5 300 Å. In their absence the curve will only slope towards longer wave-lengths. The reactions causing the staining are not known. None of the many variants of the method is accurate. One source of error is the oxidation of ethanol by the nitro compounds. The aldehyde thus formed polymerises in alkaline solution.

m-Dinitrobenzene is soluble in most organic solvents. As no staining will occur unless $pOH < 2$, the only suitable solvents for the reaction are the simplest alcohols. The tertiary butanol is the only alcohol not oxidised by *m*-dinitrobenzene. It was used for an investigation of the Zimmermann reaction. The following results were obtained:

1. Alcaline solutions of pure *m*-dinitrobenzene in tert. butanol have the same extinction curves as those described for stained 17-ketosteroids.

2. The intensity of the colour depends mainly on the concentration of OH^-. It explains why the colours disappears after a couple of days.

3. Some carbonyl compounds as acetaldehyde, acetone, *cyclo*hexanone, and 17-ketosteroids increase the extinction, and shift the absorbtion maximum over to longer wavelengths (5 600 Å). Easily enolised ketones and formaldehyde have no or only slight influence on the colour.

The Incorporation *in vivo* of Amino Acids into Subfractions of Cytoplasmic Particles

Tore Hultin

The Wenner-Gren Institute, Stockholm, Sweden

It has been shown previously [1,2] that in chick liver the incorporation *in vivo* of labeled amino acids is particularly high in the submicroscopic particulate components of the cytoplasm.

C^{14}-glycine, N^{15}-glycine, or N^{15}-DL-alanine were injected intravenously into chicks or rats. The animals were killed 1—5 minutes after the administration of the isotope. Fractions of large and small submicroscopic particles were prepared from homogenates of the livers by differential centrifugation. (After removal of the mitochondrial fractions, the homogenates were centrifuged for 20 minutes at 20 000 g, and subsequently for 40 minutes at 105 000 g). After several washings, the particles were repeatedly treated at 0° C with 0.2 *M* $NaHCO_3$, pH 8.4, and with 0.6 % desoxycholate, pH 8.4. The cholate extracts were further fractionated by means of ethanol at low temperatures [3].

The isotope contents of the proteins were consistently higher in the large microsomes than in the small ones. In both fractions, the carbonate extracts (which contained a major part of the ribonucleic acid of the particles) showed the highest isotope contents. In the desoxycholate extracts, the proteins of the higher ethanol fractions showed a higher isotope level than the proteins of the more readily precipitable fractions. The non-soluble residues obtained after the desoxycholate treatments, had considerably lower isotope contents.

The experiments show that the submicroscopic liver cell particles are not homogeneous but are composed of subordinate proteins with different anabolic backgrounds or different rates of rebuilding.

Synthesis of Ureidosuccinic Acid (USA) from Citrulline with Rat Liver Enzymes

Peter Reichard and Lloyd H. Smith Jr.

Department of Biochemistry, Karolinska Institutet, Stockholm, Sweden

The isotope from citrulline-ureido-C^{14} is incorporated into position 2 of polynucleotide pyrimidines of the pigeon *in vivo* [1] and into orotic acid by rat liver slices [2]. It has been proposed that this incorporation takes place *via* argininosuccinic and ureidosuccinic acids (citrulline + aspartate → argininosuccinate → USA → orotate → polynucleotide pyrimidines).

With enzyme preparations from rat liver mitochondria evidence has earlier been obtained for the following reactions in the biosynthesis of USA [3]:

$NH_3 + CO_2 + ATP$ + acetylglutamate → Compound X + ADP (1)

Compound X + aspartate → USA + acetylglutamate + P_i (2)

Reaction (1) has been described by Grisolia and Cohen [4] as one step in citrulline formation, the other being:

Compound X + ornithine → Citrulline + acetylglutamate + P_i (3)

The possibility has now been investigated that USA might be formed from citrulline by a reversed reaction (3) followed by reaction (2) rather than by the proposed mechanism *via* argininosuccinate. The rat liver mitochondrial enzyme system which forms USA from aspartate, CO_2 and NH_3 was used for the investigation. The formation of labeled USA from citrulline-ureido-C^{14} could readily be demonstrated in the presence of acetylglutamate, L-aspartate and P_i. Addition of ATP and an ATP regenerating system greatly stimulated the formation of USA. It seems therefore possible that USA is formed by reactions (4) + (2)

C^{14}-citrullin e + acetylglutamate + ATP → C^{14}-compound X + ornithine + ADP (4)

rather than by a reversed reaction (3) + reaction (2).

The formation of compound X from labeled citrulline could be studied directly if aspartate was omitted from the system. Under those circumstances the CO_2 that was fixed in compound X could be released at acid pH and measured as $C^{14}O_2$. Maximal amounts of labeled CO_2 were obtained only in the presence of acetylglutamate and ATP. Significant enzymatic breakdown of C^{14}-citrulline also took place without acetylglutamate, though the presence of this compound increased $C^{14}O_2$ formation up to ten times. When arsenate was substituted for phosphate, 4—6 times more $C^{14}O_2$ was observed. The arsenate reaction was not stimulated by acetylglutamate or by ATP. It seems likely that this enzyme system contains a "citrullinase" comparable to that previously described in bacteria.

On the Nature of the Salt Inhibition of the Phosphoribomutase Reaction

Hans Klenow

Institute of Cytophysiology, University of Copenhagen, Denmark

The inhibitory effect of salts on the reaction:

Glucose-1,6-diphosphate (GDP) + Ribose-1-phosphate (R-1-P) ⇌ Ribose-1,5-diphosphate + Glucose-6-phosphate

which is catalyzed by phosphoglucomutase preparations from muscle extract has been studied. The reaction was assayed spectrophotometrically in the presence of triphosphopyridine nucleotide and an excess of Zwischenferment. Comparison of the effect of a number of different salts suggest that the inhibition is caused by anions. The influence of the concentration of R-1-P indicates that the salt inhibition can be overcome at infinitely high concentration of R-1-P. The inhibition is, therefore, probably due to competition of anions with R-1-P for the enzyme. The K_m

for R-1-P and the inhibition constants for chloride, phosphate and sulphate have been determined. While GDP inhibits, when it is present at certain high concentrations, no such inhibitory effect has been observed for R-1-P. Since the constants obtained suggest that the binding is dependent primarily on the charge of the anion the experiments indicate that the group of the enzyme which "activates" R-1-P binds this and any other anion by a salt linkage. This linkage might be of the same type which is found in some synthetic anion exchangers. The results also indicate that when GDP serves as a substrate in the reaction it is attached to a group of the enzyme which is different and possibly of different nature from that to which R-1-P is attached.

The Content of Polyglucose of Glycogenic Nature * during the First Hours of Growth in *Escherichia coli* B

H. Palmstierna

Chemical Department, Karolinska Institutet, Stockholm, Sweden

The following experiment is intended to elucidate the normal metabolism of *E. coli* B as measured by the "glycogen" content at different states of growth.

Experimental. Freeze-dried cells of *E. coli* B were inoculated into, and grown in a salt medium (pH 7) and cultivated for 18 hours with Na-lactate as the only source of carbon [1]. The volume of the culture was 5 liter. After centrifuging and washing the bacteria with fresh medium an amount of bacteria was inoculated into two 50-liter bottles, each containing 40 liter of the medium, to give a density of approximately 10^8 bacteria/ml. The praeculture and the 40-liter cultures were constantly shaken at 37° C and aerated through sterile cottonwool filters at a rate of 1 liter per minute and liter of medium. The bacterial suspension was cooled to 6° C within three minutes after harvest of culture fluid. The specimens obtained at different times after inoculation were centrifuged at 0° C for two hours at 2 500 r.p.m. in an International refrigerated centrifuge with four 1-liter cups. The bottom was covered with a net of stainless steel and the cup was divided into four chambers by means of a baffle in order to prevent the bacteria from whirling up when the speed of the centrifuge slowed down. In this way it was possible to spin down the bacteria quantitatively with a loss not exceeding 1.7—2.4 %. The bacteria were washed with 0.9 % NaCl and freeze-dried.

The "glycogen" was isolated by the usual alkali treatment and precipitation with alcohol. The precipitate was hydrolyzed for three hours in 0.6 *N* HCl. The glucose thus obtained was purified by passing the hydrolysate through Dowex 50 in the H+-form and Dowex 2 in the acetate-form. No other sugar than glucose was found on the paper-chromatogram. The "glycogen" could be hydrolyzed by salivary amylase.

The estimations of glucose were performed according to Dische [2].

Results. A very rapid increase of "glycogen"/mg of dry cells was found, reaching its maximum at 30 minutes (Table 1). This indicates that the "glycogen" synthesis precedes the synthesis of the bulk of the cell-material.

Table 1.

Time after inoculation minutes	Number of cells/ml $\times 10^{-6}$	"Glycogen" % of dry weight	Mg "glycogen" per 1 000 ml culture	"Glycogen"/cell mg $\times 10^{-12}$
0	111	1.1	0.3	1.7
15	112	10.9	3.6	17.3
30	111	12.8	4.4	19.5
60	110	11.9	7.1	31.7
90	111	9.8	7.6	34.1
120	175	5.6	7.4	21.0
240	665	1.2	3.5	2.6
360	1 509	1.0	7.4	2.5

"Glycogen"/cell ratio reaches its maximum at 90 minutes after inoculation or immediately before the first cell divisions.

A very rapid decrease in "glycogen"/1 000 mls of culture was found between 90 and 240 minutes, indicating that "glycogen" synthesized during the "lag-phase" of growth was utilized during the first two hours of the logarithmic phase of growth. During this period the number of bacteria/ml increased six times.

Between 240 and 360 minutes after inoculation the amount of "glycogen"/cell remained approximately constant at a level slightly higher than that found in the bacteria at the

* For the sake of brevity called "glycogen".

The experiments show that the submicroscopic liver cell particles are not homogeneous but are composed of subordinate proteins with different anabolic backgrounds or different rates of rebuilding.

Synthesis of Ureidosuccinic Acid (USA) from Citrulline with Rat Liver Enzymes

Peter Reichard and Lloyd H. Smith Jr.

Department of Biochemistry, Karolinska Institutet, Stockholm, Sweden

The isotope from citrulline-ureido-C^{14} is incorporated into position 2 of polynucleotide pyrimidines of the pigeon *in vivo* [1] and into orotic acid by rat liver slices [2]. It has been proposed that this incorporation takes place *via* argininosuccinic and ureidosuccinic acids (citrulline + aspartate → argininosuccinate → USA → orotate → polynucleotide pyrimidines).

With enzyme preparations from rat liver mitochondria evidence has earlier been obtained for the following reactions in the biosynthesis of USA [3]:

$NH_3 + CO_2 + ATP$ + acetylglutamate → Compound X + ADP (1)

Compound X + aspartate → USA + acetylglutamate + P_i (2)

Reaction (1) has been described by Grisolia and Cohen [4] as one step in citrulline formation, the other being:

Compound X + ornithine → Citrulline + acetylglutamate + P_i (3)

The possibility has now been investigated that USA might be formed from citrulline by a reversed reaction (3) followed by reaction (2) rather than by the proposed mechanism *via* argininosuccinate. The rat liver mitochondrial enzyme system which forms USA from aspartate, CO_2 and NH_3 was used for the investigation. The formation of labeled USA from citrulline-ureido-C^{14} could readily be demonstrated in the presence of acetylglutamate, L-aspartate and P_i. Addition of ATP and an ATP regenerating system greatly stimulated the formation of USA. It seems therefore possible that USA is formed by reactions (4) + (2)

C^{14}-citrullin e + acetylglutamate + ATP → C^{14}-compound X + ornithine + ADP (4)

rather than by a reversed reaction (3) + reaction (2).

The formation of compound X from labeled citrulline could be studied directly if aspartate was omitted from the system. Under those circumstances the CO_2 that was fixed in compound X could be released at acid pH and measured as $C^{14}O_2$. Maximal amounts of labeled CO_2 were obtained only in the presence of acetylglutamate and ATP. Significant enzymatic breakdown of C^{14}-citrulline also took place without acetylglutamate, though the presence of this compound increased $C^{14}O_2$ formation up to ten times. When arsenate was substituted for phosphate, 4—6 times more $C^{14}O_2$ was observed. The arsenate reaction was not stimulated by acetylglutamate or by ATP. It seems likely that this enzyme system contains a "citrullinase" comparable to that previously described in bacteria.

On the Nature of the Salt Inhibition of the Phosphoribomutase Reaction

Hans Klenow

Institute of Cytophysiology, University of Copenhagen, Denmark

The inhibitory effect of salts on the reaction:

Glucose-1,6-diphosphate (GDP) + Ribose-1-phosphate (R-1-P) ⇌ Ribose-1,5-diphosphate + Glucose-6-phosphate

which is catalyzed by phosphoglucomutase preparations from muscle extract has been studied. The reaction was assayed spectrophotometrically in the presence of triphosphopyridine nucleotide and an excess of Zwischenferment. Comparison of the effect of a number of different salts suggest that the inhibition is caused by anions. The influence of the concentration of R-1-P indicates that the salt inhibition can be overcome at infinitely high concentration of R-1-P. The inhibition is, therefore, probably due to competition of anions with R-1-P for the enzyme. The K_m

for R-1-P and the inhibition constants for chloride, phosphate and sulphate have been determined. While GDP inhibits, when it is present at certain high concentrations, no such inhibitory effect has been observed for R-1-P. Since the constants obtained suggest that the binding is dependent primarily on the charge of the anion the experiments indicate that the group of the enzyme which "activates" R-1-P binds this and any other anion by a salt linkage. This linkage might be of the same type which is found in some synthetic anion exchangers. The results also indicate that when GDP serves as a substrate in the reaction it is attached to a group of the enzyme which is different and possibly of different nature from that to which R-1-P is attached.

The Content of Polyglucose of Glycogenic Nature * during the First Hours of Growth in *Escherichia coli* B

H. Palmstierna

Chemical Department, Karolinska Institutet, Stockholm, Sweden

The following experiment is intended to elucidate the normal metabolism of *E. coli* B as measured by the "glycogen" content at different states of growth.

Experimental. Freeze-dried cells of *E. coli* B were inoculated into, and grown in a salt medium (pH 7) and cultivated for 18 hours with Na-lactate as the only source of carbon [1]. The volume of the culture was 5 liter. The Occurrence of Phosphoproteins in Bacteria

Gunnar Ågren, Carl-Henric de Verdier and John Glomset

Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

In connection with investigations of rat organ phosphoproteins [1,2], it was of interest to determine whether similar substances exist in bacteria and whether they are involved in bacterial growth. In these studies an aerobic (*Escherichia coli*) and a facultative anaerobic (*Lactobacillus casei* 7469) organism have been used.

L. casei was cultivated on a medium previously described [3] for *L. acidophilus* with the exclusion of the dried tomato juice. Moreover, in order to increase the utilization of isotopic phosphate added to the medium inorganic phosphate was also excluded, since preliminary experiments had shown that the phosphorus present in the Bactopeptone and liver furnished sufficient total phosphorus (0.03 %) for normal growth. To the medium was added 1 mC radioactive phosphate per liter, it having been shown that the presence of as much as 100 mC P^{32} per liter had no demonstrable effect on growth or acid production over a period of 72 hours.

In order to determine whether phosphoserine was present in bacterial protein, the bacteria were centrifuged down and frozen 4 hours after inoculation, by which time the weight of the freeze-dried bacteria had increased two-fold. After grinding with Ballotini-beads in 30 % ethanol, the bacteria were once again dried and then extracted as described previously [1]. To the partial acid hydrolysate of the Schneider protein was added crystalline phosphoserine and the mixture was chromatographed successively on a Dowex 50 column, a Dowex 1 column, and in two solvent systems on paper [1]. In each procedure a P^{32}-containing fraction followed and could not be separated from crystalline phosphoserine. These experiments make it highly probable that phosphoserine is present in the Schneider protein fraction from *L. casei*.

Using phosphoserine, then, as a measure of the bacterial protein phosphorus, the specific activity of the latter has been determined at successive intervals after incubation and compared with the activity of other fractions.

Details of these experiments will be published later.

Estimation of Cardiac Glycosides in the Presence of Other Steroid Derivatives

John Kahan

Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden

The chemical assay of cardiac glycosides has long presented the pharmacologist with a problem. The difficulties have chiefly been due to the presence of breakdown products and other steroid derivatives which had only little or no pharmacological activity but, in the lack of the specificity of the reactions, were estimated as cardiac glycosides.

Several attempts have been made to achieve separation of cardiac glycosides and their breakdown products by chromatographic means but the separation was associated with specific difficulties mainly due to some properties of the steroid skeleton. Firstly, cardiac glycosides are neutral compounds having an uniform stereochemistry with large relatively flat molecules. Secondly, they are unstable, being sensitive to oxidizing agents, strong acids and bases, heat and strong adsorbents. Thirdly, they have an unfavourable partition coefficient in the commoner solvent systems.

These properties make for non-ideal behaviour in chromatography systems. Fractional elution from aluminium columns resulted in large losses although aluminium has been applied with great success for the widest range of steroids. Partition chromatography methods gave good results and were reliable but they were capable of dealing with only rather limited groups of cardiac glycosides at each

time of inoculation. During this time the bacteria doubled their number only once.

The author wishes to thank Dr. S. Gardell for his advices and his help with the estimations.

In each procedure a P^{32}-containing fraction followed and could not be separated from crystalline phosphoserine. These experiments make it highly probable that phosphoserine is present in the Schneider protein fraction from *L. casei*.

Using phosphoserine, then, as a measure of the bacterial protein phosphorus, the specific activity of the latter has been determined at successive intervals after incubation and compared with the activity of other fractions.

Details of these experiments will be published later.

Estimation of Cardiac Glycosides in the Presence of Other Steroid Derivatives

John Kahan

Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden

The chemical assay of cardiac glycosides has long presented the pharmacologist with a problem. The difficulties have chiefly been due to the presence of breakdown products and other steroid derivatives which had only little or no pharmacological activity but, in the lack of the specificity of the reactions, were estimated as cardiac glycosides.

Several attempts have been made to achieve separation of cardiac glycosides and their breakdown products by chromatographic means but the separation was associated with specific difficulties mainly due to some properties of the steroid skeleton. Firstly, cardiac glycosides are neutral compounds having an uniform stereochemistry with large relatively flat molecules. Secondly, they are unstable, being sensitive to oxidizing agents, strong acids and bases, heat and strong adsorbents. Thirdly, they have an unfavourable partition coefficient in the commoner solvent systems.

These properties make for non-ideal behaviour in chromatography systems. Fractional elution from aluminium columns resulted in large losses although aluminium has been applied with great success for the widest range of steroids. Partition chromatography methods gave good results and were reliable but they were capable of dealing with only rather limited groups of cardiac glycosides at each

operation. Paper chromatography was fairly time-consuming and laborious to be applied for quantitative work.

The data now reported show that cardiac glycosides and their breakdown products may be separated quantitatively on a Dowex 50 column. Since other steroid derivatives may be eluted together with cardiac glycosides a reaction was elaborated for the specific determination of cardiac glycosides based on their specific sugar moiety. Common sugars are not eluted with the solvents.

The technique permits the estimation of the total amounts of primary glycosides, secondary glycosides and aglycones. The filter capacity of a 10 cm long column is 2—2 000 μg, but the method can be scaled up for larger amounts. The mean recovery is 95—98 %, and the experimental error of a double determination is $\pm$ 2.59 %.

The separation may be regarded as a particular application of ion exchange resins based on the swelling properties of their network structure when the alteration of the size of pore spaces is carried out by suitable pretreatment and elution. This assumption may be supported by the fact that (1) the separation can be achieved with the resin in the free-acid form as well as in the sodium form, (2) the glycosides retarded could be eluted neither with acids nor alkalis, and (3) the eluting power of the same organic solvent seems to be altered by changing the prewashing agent.

The technique seems to provide a convenient standard method of assay for cardiac glycosides and their breakdown products in the presence of steroid derivatives. The method is simple to carry out; it is accurate, gives well reproducible results and may be used over a wide concentration range. A further advantage is that separation and analysis of the fractions can be completed within 30 minutes.

Methods for Studying Nucleotide Metabolism in Synchronized Cultures of Protozoa

Paul Plesner

Institute of Cytophysiology, University of Copenhagen, Denmark

In an attempt to study the nucleotide metabolism in different phases of the cell cyclus, and to correlate the pattern of the *in vivo* findings with the *in vitro* activity of some of the cellular enzymes, the technique of Zeuthen and Scherbaum [1] has been employed to synchronize cultures of *Tetrahymena pyriformis*. An apparatus, that can accommodate 10 cultures of 150 ml each and expose them to the temperature shocks required, has been constructed. The cells are grown on a proteose-peptone-salt medium or on this medium after treating it with 5 grams of norite per liter and fortifying it with Kidder's vitamin B group [2] and 15 mg per liter of guanylic and uridylic acids each ("semisynthetic medium"). Norite absorbs all pyrimidines, purines and all their ribosides and ribotides.

The nucleotide metabolism has been studied *in vivo* by the incorporation of labelled adenine, guanine and uracil into the nucleotides of the living cells. In order to be able to incubate the cells with isotope within the limits of a well-defined phase of cell cyclus, the incubation time must not exceed 0.5 hour; to get a sufficiently high concentration of isotope in this period the semisynthetic medium is used, and simultaneously with the addition of the isotope, a dialysisbag, containing 1 g of Dowex-1 equilibrated to the semisynthetic medium without any nucleotide addition, is added. The Dowex is supposed to absorb the nucleotides, which up till this point has served as purine-pyrimidine source, while the labelled bases added should not be affected. At the conclusion of the incubation period, acetone powder is made of the cells, the powder extracted with 2 ml of buffer per 100 mg powder, and the extract dialyzed for 18 hours in the cold-room against 20 ml of the same buffer to which 100 mg of norite is added. The norite, which by now has extracted all the purine-pyrimidine bases and their derivatives, is eluted with 50 % ethanol at a slightly alkaline pH, and the eluate chromatographed on paper using a 96 % ethanol / *M* ammoniumacetate (750 : 300) solvent saturated with borate and the pH adjusted to 10 with NH_4OH. By this gentle method of differential dialysis, the activities of the acetone powder enzymes are retained and may be assayed *in vitro*. Chromatograms from different cell phases are presented as examples of the possibilities of this method. The variation in appearance of the chromatograms from phase to phase is discussed and values for the contents of nucleoside phosphorylase, phosphoglucomutase, aldolase and phosphoglyceraldehyde dehydrogenase are presented.

The Occurrence of Phosphoproteins in Bacteria

Gunnar Ågren, Carl-Henric de Verdier and John Glomset

Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

In connection with investigations of rat organ phosphoproteins [1,2], it was of interest to determine whether similar substances exist in bacteria and whether they are involved in bacterial growth. In these studies an aerobic (*Escherichia coli*) and a facultative anaerobic (*Lactobacillus casei* 7469) organism have been used.

L. casei was cultivated on a medium previously described [3] for *L. acidophilus* with the exclusion of the dried tomato juice. Moreover, in order to increase the utilization of isotopic phosphate added to the medium inorganic phosphate was also excluded, since preliminary experiments had shown that the phosphorus present in the Bactopeptone and liver furnished sufficient total phosphorus (0.03 %) for normal growth. To the medium was added 1 mC radioactive phosphate per liter, it having been shown that the presence of as much as 100 mC P^{32} per liter had no demonstrable effect on growth or acid production over a period of 72 hours.

In order to determine whether phosphoserine was present in bacterial protein, the bacteria were centrifuged down and frozen 4 hours after inoculation, by which time the weight of the freeze-dried bacteria had increased two-fold. After grinding with Ballotini-beads in 30 % ethanol, the bacteria were once again dried and then extracted as described previously [1]. To the partial acid hydrolysate of the Schneider protein was added crystalline phosphoserine and the mixture was chromatographed successively on a Dowex 50 column, a Dowex 1 column, and in two solvent systems on paper [1]. In each procedure a P^{32}-containing fraction followed and could not be separated from crystalline phosphoserine. These experiments make it highly probable that phosphoserine is present in the Schneider protein fraction from *L. casei*.

Using phosphoserine, then, as a measure of the bacterial protein phosphorus, the specific activity of the latter has been determined at successive intervals after incubation and compared with the activity of other fractions.

Details of these experiments will be published later.

A Specific Method for the Determination of Glycosides Containing Desoxymethylpentose

John Kahan

Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden

The methods proposed for the chemical estimation of cardiac glycosides depend upon (1) the unsaturated lacton ring, or (2) the steroid skeleton, or (3) the sugar moiety. These tests, however, can scarcely be regarded as specific for cardiac glycosides. The reactions based on the lacton ring or those based on the steroid skeleton codetermine not only steroid derivatives other than cardiac glycosides but also other fairly common compounds which have an active H. The reactions based on the sugar moiety also proved to be unsatisfactory: in some cases they were given even by other non-specific sugars being present in the sample analyzed, in other cases they were not strictly quantitative.

Since the sugar moiety of the cardiac glycosides consists of highly specific desoxysugars, a possibility is afforded of detecting glycosides by utilizing the specificity of the sugar component. The data recorded show that desoxymethylpentoses, *i. e.* the specific sugar compound occurring only in the cardiac glycosides, give a reaction with orcinol which may be used for the quantitative determination of these glycosides. Although a great variety of carbohydrates react with orcinol, the test, in this modified form, seems to be highly specific for desoxymethylpentoses. This permits the detection of minute amounts of cardiac glycosides even in several thousandfold excess of common sugars. All the primary and secondary cardiac glycosides of digitalis give the reaction, as do k-strophantin and oleandrin. Ouabain and the squill glycosides, both containing a methylpentose, do not react, nor do other methylpentoses or desoxypentoses. Aglycones, saponins and other steroid derivatives do not interfere with the reaction. A further advantage of the test is that all the glycosides react in relation to their theoretical sugar content. The method may be used for the quantitative determination of desoxymethylpentose in amounts of 0.5—60 μg; this amount corresponds to about 1—100 μg of glycosides. The experimental error of a double determination is $\pm$ 1.51 %.

On the Effect of Substituted Barbiturates * on Mitochondrial Respiration

Olaf Jalling**, Olov Lindberg and Lars Ernster

Wenner-Gren's Institute, Stockholm, Sweden

Substituted barbiturates have long been known to affect the cellular respiratory system. In 1949, Eiler and McEwen [1], working with brain homogenates, showed that the oxidation of pyruvate and fumarate could be blocked by pentobarbital while that of succinate was unaffected. Later investigations, performed on isolated mitochondria, did not lead, however, to a generally valid interpretation of these findings as to the mode of barbiturate action. Brody and Bain [2] reported a decrease of the phosphorylation/oxidation ratio and attempted to interpret the barbiturate action in terms of an uncoupling effect rather than a respiratory inhibition. This view, however, could not be shared by Johnson and Quastel [3]. These authors found, as an effect of barbiturates, a decreased capacity of brain mitochondria to activate acetate, but came to the conclusion that this effect might be a secondary one.

From the above mentioned results of Eiler and McEwen it may be envisaged that the effect of barbiturates must be of a rather fundamental character and may therefore also be studied in a system metabolically better defined than brain, *e. g.* liver mitochondria. In experiments with this system we have found that amytal, in a concentration of $1.8 \cdot 10^{-3}$ *M* totally inhibits the oxidation of a series of substrates (Table 1); a clearly marked exception is formed by succinate, the oxidation of which is not at all influenced by amytal. This finding — which is consistent with, and an extension of, the early results by Eiler and McEwen — indicates that the action of barbiturates is concerned with the transfer of hydrogen *via* the pyridine nucleotides.

In some preliminary experiments we were also able to obtain an indication of a correlation between narcotic power and inhibition of respiration. This is shown in Table 2 where

* pentobarbital = 5-ethyl-5-(1-methylbutyl)barbiturate; amytal = 5-ethyl-5-*iso*amylbarbiturate; hydroxy-amytal = 5-ethyl-5(3-hydroxy-*iso*amyl)barbiturate.

** Permanent address: Fysiologisk Institut, University of Århus, Denmark.

the inhibitory effects of identical concentrations of a narcotic (amytal), a sedative (pentobarbital) and a pharmacologically inactive barbiturate (hydroxyamytal) are compared.

The results suggest that pharmacologically active barbiturates exert an inhibitory effect on hydrogen transfer *via* pyridine nucleotides with a general inhibition of cell respiration as a consequence. The fact that this effect is restricted to the central nervous system *in vivo* may be interpreted as indicating that a limitation of the respiratory capacity is expressed more primarily in this tissue than in other organs.

Table 1. Effect of amytal on the oxidation of different substrates in rat liver mitochondria.

Substrate	Respiration (microatoms oxygen)	
	without amytal	*with* 1.8 m*M* amytal
L-glutamate	26.2	0
pyruvate	9.5	0
citrate	11.7	0

Yield of Oxidative Phosphorylation in the Succinic Oxidase System

Hans Löw, Lars Ernster and Olov Lindberg

Wenner-Gren's Institute, Stockholm, Sweden

We have recently shown[1] that Ca^{++}-treated rat liver mitochondria catalyze the one-step oxidation of succinate to fumarate. The addition of adenosine triphosphate and Mn^{++} to this system results in a coupled phosphorylation. At the optimal concentration of Mn^{++}, and with increasing amounts of adenosine triphosphate, the phosphorylation / oxidation (P/O) ratio asymptotically approaches the value of 1.1.

Another way of obtaining a single-step oxidation of succinate is by means of substituted barbiturates which, as shown previously (Jalling *et al.*, *cf.* p. 198), are able to block further oxidation of the fumarate formed. Eiler and McEwen [2], using 5-ethyl-5-(1-methylbutyl)barbiturate as a blocking agent, obtained a P/O ratio of about 1.4 for the one-step oxidation of succinate in rat brain homogenates. In rat liver mitochondria treated with $1.8 \cdot 10^{-3}$ *M* 5-ethyl-5-*iso*amylbarbiturate (amytal) we have obtained about the same value, 1.42 (Table 1). There is thus a significant difference in the P/O ratio between the succinic oxidase systems obtained in the two different ways. Obviously, the Ca^{++}-treated system does not yield a maximum P/O ratio.

On the other hand the data in Table 1 show that the value obtained in the Ca^{++}-treated system can be lowered further by amytal. This indicates that amytal may be able to lower the P/O ratio in the succinic oxidase system, *i. e.* that not even the value of 1.42 may be regarded as uninfluenced. The possible effect of amytal on the phosphorylation coupled with succinate oxidation is a subject of further study.

A Specific Method for the Determination of Glycosides Containing Desoxymethylpentose

John Kahan

Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden

The methods proposed for the chemical estimation of cardiac glycosides depend upon (1) the unsaturated lacton ring, or (2) the steroid skeleton, or (3) the sugar moiety. These tests, however, can scarcely be regarded as specific for cardiac glycosides. The reactions based on the lacton ring or those based on the steroid skeleton codetermine not only steroid derivatives other than cardiac glycosides but also other fairly common compounds which have an active H. The reactions based on the sugar moiety also proved to be unsatisfactory: in some cases they were given even by other non-specific sugars being present in the sample analyzed, in other cases they were not strictly quantitative.

Since the sugar moiety of the cardiac glycosides consists of highly specific desoxysugars, a possibility is afforded of detecting glycosides by utilizing the specificity of the sugar component. The data recorded show that desoxymethylpentoses, *i. e.* the specific sugar compound occurring only in the cardiac glycosides, give a reaction with orcinol which may be used for the quantitative determination of these glycosides. Although a great variety of carbohydrates react with orcinol, the test, in this modified form, seems to be highly specific for desoxymethylpentoses. This permits the detection of minute amounts of cardiac glycosides even in several thousandfold excess of common sugars. All the primary and secondary cardiac glycosides of digitalis give the reaction, as do k-strophantin and oleandrin. Ouabain and the squill glycosides, both containing a methylpentose, do not react, nor do other methylpentoses or desoxypentoses. Aglycones, saponins and other steroid derivatives do not interfere with the reaction. A further advantage of the test is that all the glycosides react in relation to their theoretical sugar content. The method may be used for the quantitative determination of desoxymethylpentose in amounts of 0.5—60 μg; this amount corresponds to about 1—100 μg of glycosides. The experimental error of a double determination is $\pm$ 1.51 %.

On the Effect of Substituted Barbiturates * on Mitochondrial Respiration

Olaf Jalling**, Olov Lindberg and Lars Ernster

Wenner-Gren's Institute, Stockholm, Sweden

Substituted barbiturates have long been known to affect the cellular respiratory system. In 1949, Eiler and McEwen [1], working with brain homogenates, showed that the oxidation of pyruvate and fumarate could be blocked by pentobarbital while that of succinate was unaffected. Later investigations, performed on isolated mitochondria, did not lead, however, to a generally valid interpretation of these findings as to the mode of barbiturate action. Brody and Bain [2] reported a decrease of the phosphorylation/oxidation ratio and attempted to interpret the barbiturate action in terms of an uncoupling effect rather than a respiratory inhibition. This view, however, could not be shared by Johnson and Quastel [3]. These authors found, as an effect of barbiturates, a decreased capacity of brain mitochondria to activate acetate, but came to the conclusion that this effect might be a secondary one.

Yield of Oxidative Phosphorylation in the Succinic Oxidase System

Hans Löw, Lars Ernster and Olov Lindberg

Wenner-Gren's Institute, Stockholm, Sweden

We have recently shown[1] that Ca^{++}-treated rat liver mitochondria catalyze the one-step oxidation of succinate to fumarate. The addition of adenosine triphosphate and Mn^{++} to this system results in a coupled phosphorylation. At the optimal concentration of Mn^{++}, and with increasing amounts of adenosine triphosphate, the phosphorylation / oxidation (P/O) ratio asymptotically approaches the value of 1.1.

Another way of obtaining a single-step oxidation of succinate is by means of substituted barbiturates which, as shown previously (Jalling *et al.*, *cf.* p. 198), are able to block further oxidation of the fumarate formed. Eiler and McEwen [2], using 5-ethyl-5-(1-methylbutyl)barbiturate as a blocking agent, obtained a P/O ratio of about 1.4 for the one-step oxidation of succinate in rat brain homogenates. In rat liver mitochondria treated with $1.8 \cdot 10^{-3}$ *M* 5-ethyl-5-*iso*amylbarbiturate (amytal) we have obtained about the same value, 1.42 (Table 1). There is thus a significant difference in the P/O ratio between the succinic oxidase systems obtained in the two different ways. Obviously, the Ca^{++}-treated system does not yield a maximum P/O ratio.

On the other hand the data in Table 1 show that the value obtained in the Ca^{++}-treated system can be lowered further by amytal. This indicates that amytal may be able to lower the P/O ratio in the succinic oxidase system, *i. e.* that not even the value of 1.42 may be regarded as uninfluenced. The possible effect of amytal on the phosphorylation coupled with succinate oxidation is a subject of further study.

Table 1. The action of different agents on the P/O ratio in the succinic oxidase system.

Agent blocking fumarate oxidation	Additions after 5 min of pre-incubation with blocking agent	Respiration (μatoms oxygen)	Phosphorylation (μmoles phosphate)	P/O
—	succinate	16.6	27.6	1.66
amytal	succinate	16.2	23.0	1.42
Ca^{++}	succinate, ATP, Mn^{++}	16.9	19.0	1.12
amytal + Ca^{++}	succinate, ATP, Mn^{++}	16.8	15.3	0.91

Each Warburg vessel contained: rat liver mitochondria (prepared in 0.25 *M* sucrose — 0.01 *M* versene), 1/12 liver; adenylic acid, 4.3 μmoles; orthophosphate, 40 μmoles; glucose, 47 μmoles; KCl, 270 μmoles; Mg^{++}, 7.5 μmoles; yeast hexokinase (prepared according to Berger *et al.*, "Step 5"), 0.1 ml. Additions (where indicated): succinate, 30 μmoles; amytal, 3.6 μmoles; Ca^{++}, 1.15 μmoles; ATP, 1.5 μmoles; Mn^{++}, 1.5 μmoles. pH 7.5. Final volume, 2.0 ml. Temp 30° C. Gas phase, air. Time of incubation, 20 min.

The Action of 5-Ethyl-5-*iso*amylbarbiturate (Amytal) on the Oxidation of Reduced Diphosphopyridine Nucleotide (DPNH) in Rat Liver Mitochondria

Lars Ernster, Hans Löw and Olov Lindberg

Wenner-Gren's Institute, Stockholm, Sweden

Previously (Jalling *et al.*, *cf.* p. 198) it has been shown that $1.8 \cdot 10^{-3}$ *M* amytal completely blocks those mitochondrial oxidations which proceed *via* pyridine nucleotides. To study further the localization of this effect within the respiratory chain, DPNH, as generated by added alcohol dehydrogenase [1] and ethanol was used as a substrate for mitochondria. As seen in Table 1, the respiration in this system is, in contrast to the case of DPNH generated by the mitochondrial dehydrogenases, but partially — about 33 % — inhibited by $1.8 \cdot 10^{-3}$ *M* amytal. The accompanying phosphorylation is, on the other hand, almost completely inhibited.

This indicates that DPNH generated by "external" dehydrogenases is probably oxidized by two pathways, only one of which is sensitive to amytal. Both pathways differ markedly with respect to the extent of phosphorylation coupled to them. In the system studied, the amytal-insensitive pathway seems to be inaccessible to DPNH generated by mitochondrial dehydrogenases.

These findings suggest a possible similarity between the action of amytal and that of antimycin A on mitochondrial DPNH- and TPNH-cytochrome *c* reductase systems, as recently studied by Reif and Potter [2] and by Pressman and de Duve [3].

Table 1. The effect of amytal on the oxidation of DPNH in rat liver mitochondria.

	Without amytal	*With* 1.8 m*M* amytal
Respiration (μatoms oxygen)	9.6	6.4
Phosphorylation (μmoles phosphate)	13.1	2.2
P / O	1.37	0.34

Trehalosemonophosphoric Acid, a Probable Intermediate in the Formation of Trehalose in Yeast

Majken Elander

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

In a recent note it has been shown by Leloir and Cabib [1] that trehalosemonophosphoric acid (THP) is formed from UDPG and G-6-P in extracts from yeast. Earlier Robison and Morgan [2] had found that this ester is normally produced during fermentation of glucose and fructose with dried yeast and zymin. Some years later Veibel [3] investigated the formation of THP during the fermentation of glucose with fresh brewers' yeast, incubated with toluene. He found that such a considerable amount of THP was formed that it could neither have been preformed in the yeast nor could it have arisen through phosphorylation of trehalose in the yeast itself. Considerably later it was shown that even formation of free trehalose occurs during fermentation of glucose with mazeration juice from brewers' yeast [4,5]. Elander and Myrbäck assumed that the disaccharide was formed through dephosphorylation of THP. Later the author has tried in vain to demonstrate THP in the same samples where trehalose was present, when the fermenting system was acetone dried bakers' yeast. The preformed trehalose of the yeast was removed by washing with phosphate buffer, pH 6.3. Coenzymes necessary for fermentation and probably also for the formation of trehalose were removed hereby, too, but were supplied through addition of boiled extract from air dried brewers' yeast which usually contains only small amounts of trehalose.

The reason of the failure to demonstrate THP in the presence of trehalose was not elucidated until close analysis of the different fractions of phosphate esters had been performed. The results will be published later in detail. Thus directly reducing esters, fructose, organic phosphate and the changes of these components at different times of hydrolysis have been determined. The optical rotations of the fractions were measured, and they were also subjected to paperchromatographic analysis. The analysis showed that one have to count with at least two hexosemonophosphoric esters which were unknown when Robison and Morgan studied the formation of THP. At this time they only had to deal with F-1,6-P, F-6-P and G-6-P, and the properties of these esters were well known. One of the new esters was G-1-P which has been shown by Cori, Colowick and Cori [6] and by Kiessling [7] to be an intermediate in the formation and degradation of glycogen in yeast. The other one has, according to the analysis, turned out to be F-1-P. Its occurrence in yeast is so far not known. The amount of the two phosphoric acids is quite considerable and they interfere with such determinations of THP as the optical rotation and the reducing power after hydrolysis. G-1-P as well as THP shows a high positive rotation. The rotation of F-1-P is negative. After acid hydrolysis G-1-P as well as THP becomes reducing. F-1-P, F-6-P and free fructose lose about 50 % of their reducing power when hydrolysed for 5 hours in 1 *N* H_2SO_4 at 100°. As the fructose esters formed a considerable part of the total esters, their decrease in reducing power will counteract the increase from THP and G-1-P.

After these investigations it was clear that a reliable determination of THP could only be performed if the concentration of G-1-P and F-1-P were known or if these esters could be removed from the fractions containing THP.

In a new series of experiments it was shown that G-1-P and F-1-P could be completely removed by precipitation with $BaAc_2$ and alcohol while the main part of THP was left in the trehalose fraction which only contained difficultly hydrolyzable organic phosphate. In fermenting mixtures THP is the only known ester with this property which is not reducing It could thus be determined as the difference between glucose equivalent of organic phosphate and the glucose equivalent of directly reducing substances. During the time of the experiments, 24 hours, the concentration of THP was rather constant while the concentration of trehalose after 4 hours reached a maximum. After that it was slowly broken

On the Intestinal Absorption of Phospholipids in the Rat

Rolf Blomstrand

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Earlier works on phospholipids by Artom and Swanson[1] and Bloom *et al.*[2] have been extended.

The mechanism concerned with the absorption of phospholipids has been studied on the rat using phospholipids, labelled in the glycerol, fatty acid or phosphate portions of the molecule and the distribution of radioactivity in the collected lymph from the thoracic duct has been studied.

The experimental data demonstrate that phospholipids are hydrolyzed to a considerable extent during their absorption. Glyceride glycerol is utilized for the synthesis of lymph phospholipids and phospholipid glycerol for glycerides indicating an interconversion of these lipids during absorption.

VI. Synthesis of D,L-"Neothyroxine", the β,β-Dimethyl Analogue of D,L-Thyroxine *

E. DUINTJER and Å. JÖNSSON

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The β,β-dimethyl analogue of D,L-thyroxine has been prepared by the reaction sequence shown in Fig. 1. A second series of reactions with the same goal was also carried out (Fig. 2) but had to be abandoned, as the hydantoins VII and VIII could not be hydrolysed to the corresponding 3,5-diiodothyroxine derivative.

The search for substances possessing antithyroid activity has lead to the preparation of a number of analogues of thyroxine. Among the compounds tested as thyroxine antagonists are aliphatic ethers of 3,5-diiodotyrosine, the sulphide analogue of thyroxine, 4-benzyloxy-3,5-diiodobenzoic acid and similar compounds, halogeno and nitro derivatives of diphenyl ether, thyronine and 4-(*p*-hydroxyphenoxy)benzoic acid [1], α-thyroxine and some derivatives of thyroxine in which the side chain had been modified by conversion of the carboxyl group into the methyl ketone [2]. Many of these compounds possessed some anti-thyroxine activity, but none of them appears to have been used clinically.

In continuation of our researches on the physiological effect of the introduction of a *gem*dimethyl group in various amino acids, hormones and other compounds of biochemical interest [3] we have now prepared the α,α-dimethyl analogue (XVI) of D,L-thyroxine, and it is the purpose of the present paper to describe the synthetic work. The results of the physiological testing of the compound will be reported elsewhere. For convenience the compound is henceforth called D,L-"*neo*thyroxine", thus indicating the analogy with *neo*pentyl derivatives.

The synthesis was started from D,L-"*neo*tyrosine" (I), the preparation of which was described in Part I of this series [3], and follows the same route, which was worked out by Burrows *et al.*[4] and by Chalmers *et al.*[5] for the preparation of thyroxine from tyrosine, with some alterations in experimental details.

Fig. 1.

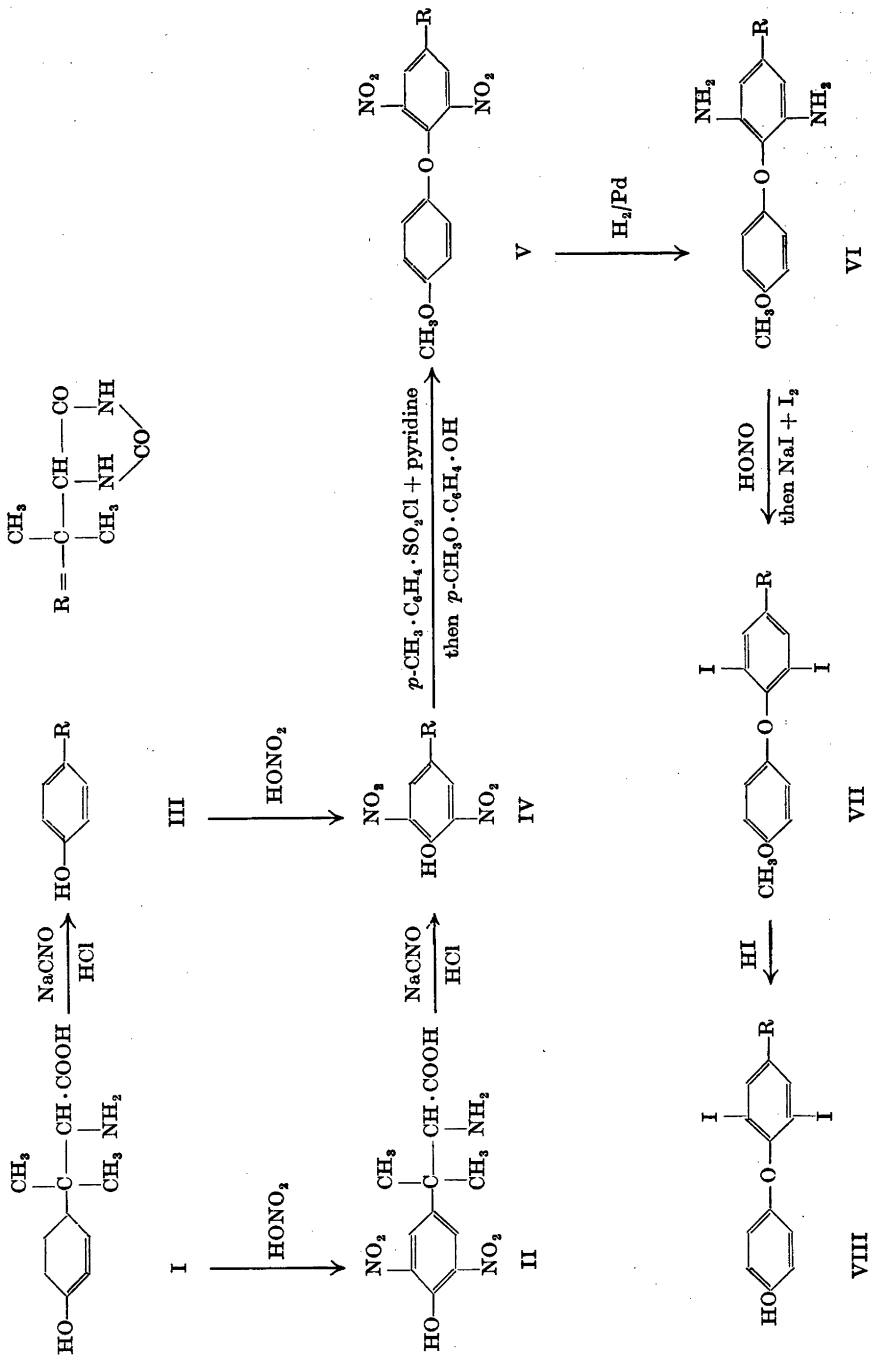

Fig. 2.

The steps involved are shown in Fig. 1. The side chain of the aminoacid was protected during these reactions by esterification of the carboxyl group and acetylation of the amino nitrogen. A series of reactions were also carried out during which the side chain was protected by conversion into a hydantoin ring. This route had, however to be abandoned as all attempts to hydrolyse 5-(α,α-dimethyl-3,5-diiodo-4-*p*-hydroxyphenoxybenzyl)hydantoin (VIII) and its methyl ether (VII) to the free aminoacid under a variety of acid and alkaline conditions failed. This was probably due to steric hindrance by the bulky substituent in position 5. (It is known that hydantoins doubly substituted in position 5 are much more resistant to hydrolysis than the monosubstituted ones. Probably a single *tertiary* alkyl group has a similar effect.) The reaction sequence is shown in Fig. 2.

The intermediate N-acetyl-3,5-dinitro-"*neo*tyrosine" (IX) was prepared by two ways, either by nitration of "*neo*tyrosine" followed by acetylation, or by carrying out these steps in the opposite order. Though it normally gave somewhat lower yield the latter method is to be preferred because the nitration of "*neo*tyrosine" was a little erratic. In most cases high yields were obtained but in a few experiments were almost zero. The reason for this could not be found.

The esterification of (X) met with some difficulties, as it was found that esterification by azeotropic distillation with chloroform, found so useful for N-acetyl-3,5-dinitrotyrosine by Chalmers *et al.*[5], was not successful with the α,α-dimethyl analogue. Esterification in a large excess of ethanol with *p*-toluenesulphonic acid as catalyst afforded a low yield of the ester; the main product was a neutral solid, which was not further investigated. (The authors cited report, that a similar result was obtained, when they tried to esterify N-acetyl-3,5-dinitrotyrosine under Fischer-Speier conditions.) It was ultimately found that esterification with a mixture of ethanol and thionyl chloride afforded the desired product in excellent yield. As the diamine (XIII) was sensitive to air at least in an impure state it was converted directly into the diiodo compound (XIV). This was obtained as a glass which could not be induced to crystallise. Simultaneous demethylation, deacetylation and hydrolysis of the ester group by hydriodic acid, however, converted the crude (XIV) into the crystalline 3,5-diiodo-D,L-"*neo*thyronine" (XV). Iodination of (XV) with iodine in aqueous ethylamine produced D,L-"neothyroxine" in a good yield.

EXPERIMENTAL *

3,5-Dinitro-D,L-"*neotyrosine*", D,L-α-*amino*-β-*(3,5-dinitro-4-hydroxyphenyl)isovaleric acid* (II). "*Neo*tyrosine" (25 g) was added in portions to concentrated sulphuric acid (90 ml) at 5 to 10°. The solution was cooled to −5° and stirred while nitric acid (17.5 ml, *d* 1.42) was added drop by drop. After the addition was complete the mixture was stirred at 0° for 15 minutes, poured onto crushed ice (400 g) and the pH brought to 4.0−4.5 by careful addition of 30 % aqueous sodium hydroxide solution, the temperature being kept below 20°. After some hours the precipitate was collected, washed with water and dried. Yellow needles. Yield 32 g (89 %). For analysis a sample was crystallised from aqueous ethanol and then melted at 222° (decomp.). (Found: C 44.2; H 4.63; N 13.8. $C_{11}H_{13}N_3O_7$ requires: C 44.2; H 4.38; N 14.0.)

* All melting points uncorrected. Petrol refers to the fraction b.p. 40—60°.

*N-Acetyl-*D,L-*"neotyrosine"* (IX). D,L-*"Neo*tyrosine (20.9 g) was dissolved in 2 *N* sodium hydroxide (225 ml) and acetylated below 20° by dropwise addition of acetic anhydride (20 ml) with constant stirring which was continued for a further hour after the addition. Excess anhydride was destroyed by stirring at 40° for ½ hour, and the reaction product was precipitated by addition of 6 *N* hydrochloric acid to the cooled solution. After storing overnight in the refrigerator the solid was filtered off. An additional amount could be obtained on concentration of the mother liquor. Total yield of product melting at 178–180° (lit.[3] 181–181.5°) 20.0 g (83 %).

*N-Acetyl-3,5-dinitro-*D,L-*"neotyrosine"* (X). *a) From N-acetyl-*D,L-*"neotyrosine"*. The foregoing N-acetylderivative (18.0 g) was added to conc. sulphuric acid (75 ml) with stirring below 10°. Nitric acid (*d* 1.42; 10 ml) was added drop by drop below −5°. Stirring was continued for one further hour after complete addition, and the reaction mixture was then poured onto ice. After some hours the solid was filtered off, carefully washed with water and dried. Yield 20.8 g (80 %). For analysis the compound was crystallised from aqueous ethanol, yellow needles, m. p. 222–225°. (Found: C 45.6; H 4.68; N 12.2. $C_{13}H_{15}N_3O_8$ requires: C 45.7; H 4.43; N 12.3.)

b) *From 3,5-dinitro-*D,L-*"neotyrosine"*. The nitrocompound was acetylated as described above for *"neo*tyrosine". Yield 90 %. M. p. 222–225° alone and in admixture with the compound just described.

*N-Acetyl-3,5-dinitro-*D,L-*"neotyrosine" ethyl ester* (XI). Thionyl chloride (7.0 ml) was added to absolute ethanol (60 ml) in dioxan (100 ml). After 15 minutes the foregoing acetylamino acid (32 g) was added and the mixture heated for 3 hours on a steam bath. Dioxan and excess ethanol were removed under reduced pressure, and the residual solid crystallised from aqueous ethanol. Yield 27.2 g (79 %) of yellow needles, m. p. 145–145.5°. (Found: N 11.2; C_2H_5O 12.0. $C_{15}H_{19}N_3O_8$ requires: N 11.4; C_2H_5O 12.2.)

*N-Acetyl-3,5-dinitro-4-p-methoxyphenoxy-*D,L-*"neophenylalanine" ethyl ester* (XII). The foregoing ester (36 g) and *p*-toluenesulphonyl chloride (19.5 g) in dry pyridine (125 ml) were heated on the water bath for ½ hour. *p*-Methoxyphenol (36 g) was added and the mixture was refluxed in an oil bath for 1 ½ hours. The solvent was removed *in vacuo* on the water bath and the residual dark oil dissolved in chloroform and washed in turn with *N* sodium hydroxide, 2 *N* hydrochloric acid and water. After drying (Na_2SO_4) the solution was filtered through a short column of aluminium oxide. Evaporation of the solvent yielded a solid, which was crystallised from aqueous ethanol and then formed yellow needles, m. p. 124–126°. Yield 33.0 g (74 %). For analysis a sample was repeatedly recrystallised and then melted at 127–128°. (Found: C 55.7; H 5.45; N 8.65. $C_{22}H_{25}N_3O_9$ requires: C 55.6; H 5.30; N 8.84.)

*3,5-Diiodo-*D,L-*"neothyronine"* (XV). The foregoing diphenyl derivative (19.5 g) in glacial acetic acid (200 ml) was hydrogenated at room temperature and pressure using a 10 % palladium on charcoal catalyst (2 g). The filtered solution was evaporated to approximately 50 ml under reduced pressure in a nitrogen atmosphere and added with stirring to conc. sulphuric acid (25 ml) below 25°. This solution was added drop by drop below 0° with constant stirring to a solution of nitrosylsulphuric acid prepared by dissolving sodium nitrite (9 g) in conc. sulphuric acid (60 ml) and dilution of this mixture with glacial acetic acid (125 ml) below 20°. Stirring was continued for a further hour after complete addition and then urea (5 g) was added. The solution was stirred for 15 minutes and then slowly poured into a stirred solution of iodine (35 g) and potassium iodide (45 g) in water (600 ml) covering a layer of chloroform (150 ml). The addition required 15 minutes, stirring being continued for one hour after complete addition. The chloroform was separated, and the aqueous layer extracted twice with chloroform. The combined chloroform solutions were washed with water, saturated with sulphur dioxide and again washed with water. The solvent was removed on the water bath, and the residual dark oil dissolved in a little benzene and filtered through a short column of aluminium oxide. The column was washed with much benzene, and the combined filtrates freed from solvent under reduced pressure. A yellow glass (15.1 g) was obtained which could not be induced to crystallise. It was refluxed for 8 hours with 57 % hydriodic acid (50 ml) and acetic acid (50 ml). The solution was evaporated *in vacuo* on the water bath and the residual syrup was dissolved in hot 50 % ethanol (75 ml) and treated with sulphur dioxide. The amino acid was precipitated from this solution by the addition of a saturated solution of sodium acetate and filtered off after keeping for some hours in the refrigerator. The crude material was purified by dissolving in boiling 50 % ethanol containing a little conc.

hydrochloric acid and decolourising with animal charcoal and then reprecipitated by the addition of a boiling solution of sodium acetate containing a little sodium sulphite to give a faintly greyish crystalline powder which melted with decomposition at 218—220°. Yield 12.2 g (53 % calculated on the nitroderivative). (Found: C 38.2; H 3.52; I 44.3. $C_{17}H_{17}I_2NO_4$ requires: C 36.9; H 3.10; I 45.9.)

D,L-"*Neothyroxine*" (XVI). The foregoing di-iodo compound (4.2 g) was dissolved in 33 % ethylamine (50 ml) and iodinated by slow addition, with stirring, of a 1.0 *N* solution of iodine in saturated aqueous potassium iodide (30.5 ml). After a short while the solution was diluted with water (200 ml) and the "*neo*thyroxine", the ethylamine salt of which had started to separate, was precipitated by addition of 4 *N* hydrochloric acid to pH 4—5. The crude product was collected after some hours and washed well with water. It was purified by dissolving in a boiling mixture of ethanol (125 ml) and 2 *N* sodium hydroxide (50 ml), decolourising with animal charcoal, filtering and reprecipitation by the addition of boiling 2 *N* hydrochloric acid to pH 4—5. Faintly yellowish crystal powder, which decomposed without melting at 192—195°. Yield 4.9 g (80 %). (Found C 25.7; H 1.82; I 61.2. $C_{17}H_{15}I_4NO_4$ requires: C 25.4; H 1.88; I 63.1.)

D,L-*5-(α,α-Dimethyl-4-hydroxybenzyl)hydantoin* (III). D,L-"*Neo*tyrosine" (31 g), sodium cyanate (20 g), and water (150 ml) were refluxed for 15 minutes, additional sodium cyanate (10 g) was added, and the mixture refluxed for a further hour, cooled and acidified with conc. hydrochloric acid. After a few hours the colourless precipitate was collected and refluxed for one hour with 6 *N* hydrochloric acid (150 ml). After cooling the solid was filtered off and washed with water. Crystallisation from aqueous acetic acid yielded small colourless needles, (24 g, 69 %), m. p. 290—295° (decomp.). (Found: C 61.6; H 6.26; N 12.0. $C_{12}H_{14}N_2O_3$ requires: C 61.5; H 6.03; N 12.0.)

D,L-*5-(α,α-Dimethyl-3,5-dinitro-4-hydroxybenzyl)hydantoin* (IV). *a) From 3,5-dinitro-*D,L-"*neotyrosine*". The hydantoin was obtained in 75 % yield when 3,5-dinitro-D,L-"*neo*tyrosine" was treated as described above for D,L-"*neo*tyrosine". Yellow prisms from ethanol, m. p. 236—237° (decomp.). (Found: C 44.7; H 3.99; N 17.3 $C_{12}H_{12}N_4O_7$ requires: C 44.5; H 3.73; N 17.3.)

b) From D,L-*5-(α,α-dimethyl-4-hydroxybenzyl)hydantoin.* This hydantoin (20 g) was added with stirring to nitric acid (100 ml, *d* 1.42) at 30—40°. After the addition the mixture was stirred for a further 2 hours and then poured into ice and water (400 ml). The solid was filtered off, washed and dried. Yield 17.5 g (63 %). M. p. and mixed m. p. with a specimen prepared by method a) 234—236°.

D,L-*5-(α,α-Dimethyl-3,5-dinitro-4-p-methoxyphenoxybenzyl)hydantoin* (V). The foregoing dinitrohydantoin (25 g), *p*-toluenesulphonyl chloride (20 g) and dry pyridine (125 ml) were mixed and refluxed on an oil bath for 15 minutes. *p*-Methoxyphenol (36 g) was added and the solution refluxed for a further hour. Most of the pyridine was removed *in vacuo* on a water bath, and the residual oil poured into *N* hydrochloric acid (500 ml). The dark oil, which separated, crystallised on cooling and scratching. The solid was filtered off, carefully washed with *N* hydrochloric acid and water, dried, and dissolved in a little boiling acetone. Some undissolved material was filtered off, and water was added to the hot solution to turbidity. The solution was allowed to cool very slowly overnight, and the yellow needles (22 g) collected. Recrystallised from aqueous acetone the product melted at 133—134°. (Found: CH_3O 7.0; N 12.8. $C_{19}H_{18}N_4O_8$ requires: CH_3O 7.2; N 13.0.)

D,L-*5-(α,α-Dimethyl-3,5-diamino-4-p-methoxyphenoxybenzyl)hydantoin* (VI). The foregoing diphenyl ether (10.4 g) in glacial acetic acid (250 ml) was hydrogenated at room temperature and pressure with 10 % palladium on charcoal catalyst (1 g). The hydrogen uptake was very slow but quantitative. After complete reduction the catalyst was filtered off and the filtrate evaporated *in vacuo*, these and subsequent operations being carried out in an atmosphere of nitrogen. A light brown gum was obtained, which was dissolved in anhydrous ethanolic hydrogen chloride, evaporated to dryness *in vacuo*, freed from excess hydrogen chloride by drying *in vacuo* overnight over potassium hydroxide, and dissolved in a small volume of anhydrous ethanol. Careful addition of much dry ether yielded a solid precipitate, which was filtered off, washed with ether, and dried *in vacuo*. Yield 9.8 g. As the product was very difficult to purify and sensitive to air when moist, it was used for the next step without further purification. (For this purpose the original gum after evaporation of the acetic acid could be used as well.)

D,L-*5-(α,α-Dimethyl-3,5-diiodo-4-p-methoxyphenoxybenzyl)hydantoin* (VII). The foregoing diamine hydrochloride (7.5 g) was dissolved in a mixture of glacial acetic acid (70 ml) and concentrated sulphuric acid (70 ml) and added dropwise with stirring below −2° to a solution of nitrosylsulphuric acid, prepared by dissolving sodium nitrite (3.5 g) in cold concentrated sulphuric acid (40 ml) and diluting with glacial acetic acid (40 ml). Stirring and cooling was continued for one hour after the addition was complete, and excess diazotising agent was destroyed by addition of a little urea and stirring for 15 minutes. This mixture was added slowly to a stirred solution of sodium iodide (20 g) and iodine (21 g) in water (350 ml), the temperature being kept below 40° by addition of ice. Stirring was continued for a further 4 to 6 hours, and the clear solution was decanted from the heavy, dark oil, which was ground with sodium bisulphite solution until completely solid and free from excess iodine. The solid was collected and thoroughly washed with water. Faintly brown crystal powder. Yield 9.2 g. This crude product was further purified by filtration in acetone solution through a short column of aluminium oxide. The filtrate was evaporated to dryness, and the solid residue crystallised from chloroform-petrol. Minute, colourless platelets, m. p. 258−259° (decomp.) (7.2 g). (Found: CH_3O 5.32; N 4.70. $C_{19}H_{18}I_2N_2O_4$ requires: CH_3O 5.24; N 4.73.)

D,L-*5-(α,α-Dimethyl-3,5-diiodo-4-p-hydroxyphenoxybenzyl)hydantoin* (VIII). The foregoing methoxydiiodocompound (7.0 g) was refluxed with a mixture of glacial acetic acid (20 ml) and 57 % hydriodic acid (20 ml). It dissolved rapidly, and the hydroxycompound soon started to separate. Heating was continued for one hour, water was added to turbidity and the mixture was stored overnight in the refrigerator. The crystals were collected and washed with aqueous acetic acid. Clusters of minute colourless spears. Yield 5.7 g. For analysis a sample was crystallised from aqueous acetic acid. The decomposition point of the compound varied between 280−290°. (Found: C 37.6; H 2.9; I 43.8; N 4.9. $C_{16}H_{16}I_2N_2O_4$ requires: C 37.4; H 2.8; I 43.9; N 4.8.)

The authors wish to acknowledge their indebtedness to *Statens Tekniska Forskningsråd* for a Fellowship to one of them (Å. J.) and to *Cancernämnden* for financial support.

Studies on Antimetabolites

VII *. Note on some Reaction Products Formed in the Oxidation of 4,6-Di-(α,α-dimethylbenzyl)pyrogallol with Alkaline Potassium Permanganate

ÅKE JÖNSSON

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

As reported earlier the oxidation of 4,6-di-(α,α-dimethylbenzyl)-pyrogallol with alkaline potassium permanganate yielded α-oxo-β-phenyl*iso*valeric acid as the main product. In addition there were isolated some α-phenyl*iso*butyric acid and two further acid products. These have now been subjected to a more detailed study and the structures II and III are proposed.

In Part I of this series it was reported that the oxidation of 4,6-di-*tert*alkyl substituted pyrogallols with alkaline potassium permanganate in aqueous solution afforded fairly good yields of the corresponding tri-substituted pyruvic acids as well as some of the α-phenyl*iso*butyric acid derivatives. The oxidation of 4,6-di-(α,α-dimethylbenzyl)pyrogallol (I) was studied in some detail and in addition to the ketoacid and α-phenyl*iso*butyric acid two further acid products, here termed A and B, were isolated from the reaction mixture. It is the purpose of the present communication to describe some reactions carried out with these products, and to propose probable structures.

Compound A melts at 174—175° and has the composition $C_{23}H_{24}O_3$. It does not dissolve in aqueous sodium bicarbonate solution and thus contains no carboxyl group, but dissolves readily in *N* sodium hydroxide. With ferric chloride an intense red colouration is obtained indicating the presence of enolic hydroxyl groups. Dimethyl sulphate and alkali converts the compound into a neutral mono-methyl ether, which does not give this colour reaction. From this evidence and the close analogy of the substance with a compound obtained by Campbell by aerial oxidation of 4,6-di-*tert*butylpyrogallol in alkaline solution for which he, as a result of thorough studies [2,3], suggests structure (IV) compound A is probably an enol of 3,5-di-(α,α-dimethylbenzyl)*cyclo*pentatrione-1,2,4.

Compound B, $C_{23}H_{26}O_6$, melts at 185—186° (decomp.) and is readily soluble in sodium bicarbonate solution. It gives a mono-*cyclo*hexylammonium salt and

* Part VI. *Acta Chem. Scand.* **9** (1955) 203.

a mono-piperidiniumsalt with excess of the basic reagents. With an excess of diazomethane it forms a mono-methyl derivative, $C_{23}H_{25}O_5(OCH_3)$, from which compound B is recovered after alkaline hydrolysis. Hence compound B obviously contains one free carboxyl group but no phenolic hydroxyl group. The presence of a free carboxyl is also demonstrated by titration with 0.1 *N* sodium hydroxide using phenolphthalein as indicator. One mole of alkali is consumed and the end-point of the titration is sharp. When compound B is boiled with 6 *N* sodium hydroxide, however, a solid di-sodium salt, $Na_2C_{23}H_{26}O_7$, separates. An aqueous solution of this salt has a strongly alkaline reaction, and compound B is recovered when the solution is made slightly acid, even in the cold. This behaviour indicates, that compound B, in addition to the free carboxyl group, contains a lactone group. A lactone (or ester) group is also suggested by the fact, that B gives a positive hydroxamate test.

All attempts to detect carbonyl functions in compound B by treatment with 2,4-dinitrophenylhydrazine or hydroxylamine were unsuccessful. Neither B nor its methyl ester gave any colouration with ferric chloride. Obviously they do not contain any enolisable carbonyl groups, and probably no other carbonyl groups. (Compound A, however, likewise failed to react with phenylhydrazine or hydroxylamine.)

When heated slightly above its melting point compound B readily loses one mole of water and is converted into an anhydrocompound, $C_{23}H_{24}O_5$, m.p. 187°. When dissolved in ethanol and treated with dilute sodium hydroxide this substance slowly consumes one mole of alkali and on acidification of the solution compound B is precipitated. The anhydrocompound is obviously the di-lactone corresponding to the mono-lactoneacid B. The presence of a free hydroxyl group in the anhydrocompound was shown by a Zerewitinoff determination, which indicated one "active" hydrogen atom.

Extensive oxidation of compound B with potassium permanganate in hot, strongly alkaline solution affords α-phenyl*iso*butyric acid. This proves, that the structural unit $C_6H_5—C(CH_3)_2—C$ is still present in compound B and the yield (58 % of theory) proves that there are two such groupings in the molecule.

From the evidence produced there seems to be little doubt, that compound B possesses structure III. The anhydrocompound must then be the dilactone V. The relation between compound B and the anhydrocompound V is also demonstrated by the formation from both the anhydrocompound and the methyl ester of compound B of the same reduction product, $C_{23}H_{32}O_5$, with lithium-aluminium hydride, the structure of which must be VI. The proposed structures are further supported by the infrared absorption spectrum of the anhydrocompound which in addition to the benzene bands shows strong bands at 2.82, 5.56 and 7.27 μ indicating the presence of respectively hydroxyl groups, α-lactone rings and methyl groups. There are no other bands in the 2.5 to 8 μ region.

Studies of molecular models allow certain conclusions to be drawn regarding the stereochemistry of the compounds. If in Formula III the lactone ring is considered to be oriented in the plane of the paper then the hydroxyl group on carbon atom 1 and the carboxyl on 3 must be on the same side of this plane in order to allow the ring closure to compound V. The two R-groups must both be on the opposite side to the above hydroxyl and carboxyl groups.

Nothing can be said about the orientation of the hydroxyl group attached to carbon atom 2. Theoretically two pairs of racemates may be formed when compounds V and VII are reconverted to III. The compound actually obtained, however, is homogeneous, which proves that the ring closure occurs with selective formation of one of these D,L-forms. In compounds V, VI and VII carbon atom 2 is not asymmetric, hence this uncertainty disappears, and these compounds are therefore derivatives of D,L-arabitol.

The behaviour of compound B and the pentol towards periodic acid in aqueous and dilute acetic acid solution was contradictory to the above arguments in favour of the proposed structures. The compounds were very slowly attacked and even after several days at room temperature the periodate consumption was only a fraction of that calculated. These results are surprising in view of the fact, that the diol (VIII), prepared by reduction of ethyl α-oxo-β-phenyl*iso*valerate with lithium-aluminium hydride, was rapidly and quantitatively split with the consumption of one mole of periodate. Studies on molecular models of compound B and the pentol show, however, that the bulky α-phenyl*iso*propyl groups leave very little space for the formation of an addition complex with the rather large periodate ion. The slow oxidation may thus be due to "steric hindrance". It is well-known, that the reaction velocity of the periodate oxidation of glycols is highly influenced by bulky neighbouring substituents (see *e.g.* Ref.[4]).

The low yield of the crystalline products II and III compared with the oily mixtures obtained on evaporation of the mother liquors suggests that further acid products (*e.g.* isomers of III) may have been formed in the oxidation of the pyrogallol derivative. This assumption is supported by the material balance. The yields of the various products obtained from 300 g of the pyrogallol derivative were:

Ethyl-α-oxo-β-phenyl*iso*valerate	118 g =	33 %
α-Phenyl*iso*butyric acid	24	9
Compound II	21	7
Compound III	15	4.5
		53.5 %

(The yields have been calculated as C_6H_5—$C(CH_3)_2$-groups recovered as the respective compound.)

EXPERIMENTAL *

Investigation of compound A, m.p. 174—175°

Compound A was isolated as described earlier [1]. The substance was obtained as colourless needles, m. p. 174—175°, with the composition $C_{23}H_{24}O_3$. (Found: C 79.4; H 7.00; neutr. equiv. 347. $C_{23}H_{24}O_3$ requires: C 79.3; H 6.94; neutr.equiv. 348.4.) It was insoluble in sodium bicarbonate solution but dissolved readily in *N* sodium hydroxide. It gave an intense crimson colouration with ferric chloride, but did not react with hydroxylamine or 2,4-dinitrophenylhydrazine.

Cyclohexylammonium salt. On addition of excess *cyclo*hexylamine to an ethereal solution of A a mono *cyclo*hexylammonium salt separated. Needles from ethanol, m. p. 186—188° (decomp.) (Found: N 3.10. $C_{29}H_{37}NO_3$ requires: N 3.13.)

* All melting points uncorrected. Petrol refers to the fraction b.p. 40—60°.

Methyl ether. Treatment of A in methanol with an excess of dimethyl sulphate and alkali gave a high yield of a neutral monomethyl ether. Needles from petrol, m. p. 72.5—73.5°. (Found: C 80.2; H 7.28; CH_3O 8.57. $C_{24}H_{26}O_3$ requires: C 79.5; H 7.23; CH_3O 8.56.) The compound gave no colouration with ferric chloride.

Investigation of compound B, m.p. 185—186°

Compound B was isolated as described earlier [1] and obtained as colourless needles from ethanol, m. p. 185—186°, with the composition $C_{22}H_{26}O_6$. (Found: C 69.2, 69.0; H 6.20, 6.55; neutr.equiv. 397/phenolphthalein. $C_{22}H_{26}O_6$ requires: C 69.3; H 6.58; neutr. equiv. 398.4.) The compound was insoluble in water, sparingly soluble in hot benzene and readily so in hot ethanol. It gave a positive hydroxamate test for ester groups and a yellow precipitate with ferric chloride.

Cyclohexylammonium salt. When an excess *cyclo*hexylamine was added to an alcoholic solution of B a mono-*cyclo*hexylammonium salt separated as long, thin needles. M. p. 213—215° (decomp.). (Found: C 69.8; H 8.21; N 2.74. $C_{28}H_{39}NO_6$ requires: C 70.0; H 8.20; N 2.82.)

Piperidinium salt. This salt was similarly prepared from B and piperidine in ethanol. Needles, which melted at 141—143°, resolidified at about 170° and then melted at 225—228°, or rhombic plates, m. p. 225—228°. (Found: C 69.4; H 7.67; N 2.85. $C_{26}H_{37}NO_6$ requires: C 69.5; H 7.71; N 2.90.)

Disodium salt. When B (1.0 g) was dissolved in the minimum amount of hot *N* sodium hydroxide, and the solution was added to boiling 6 *N* sodium hydroxide (25 ml) a disodium salt soon started to separate. After cooling the salt was filtered off, rapidly washed with ice-cold water, acetone and ether and dried. (Found: C 58.6; H 6.1; Na 10.2; neutr. equiv. 462. $C_{25}H_{26}O_7Na_2$ requires: C 60.0; H 5.7; Na 10.0; neutr. equiv. 460.4.) The neutralisation equivalent of the salt was determined by dissolving the compound in aqueous ethanol, adding standard 0.1 *N* hydrochloric acid and titrating the excess acid with 0.1 *N* sodium hydroxide, using phenolphthalein as indicator. — When an aqueous solution of this salt was acidified with hydrochloric acid compound B separated (identified by mixed m. p.).

Methyl ester of B. When an ethereal solution of III was left overnight with an excess diazomethane a monomethyl ester formed. Needles from benzene-petrol. M. p. 162°. (Found: C 69.9; H 7.10; CH_3O 7.6. $C_{24}H_{28}O_6$ requires: C 69.9; H 6.84; CH_3O 7.5.) The ester gave no colouration with ferric chloride. When refluxed with 2 *N* aqueous-ethanolic sodium hydroxide it was hydrolysed, and the acid B separated on acidification of the solution.

Dehydration of compound B. Compound B (3.0 g) was heated in a test tube inserted in an oil bath kept at 190—200° until the evolution of vapour ceased. The reaction product was crystallised from benzene-petrol. Needles (2.3 g), m. p. 187—187.5°. (Found: C 73.0; H 6.28; "active H" 0.8. $C_{22}H_{24}O_5$ requires: C 72.6; H 6.30.) In 0.1 *N* aqueous sodium hydroxide the compound slowly consumed alkali and dissolved. (Found: neutr. equiv. 384. Calculated: 380.4.)

Reduction of the methyl ester of B with lithium-aluminium hydride. The ester (3.0 g) in absolute ether (75 ml) was added with stirring to a suspension of lithium-aluminium hydride (2 g) in absolute ether (50 ml) and the mixture was refluxed overnight on the water bath. Excess hydride was destroyed by careful addition of water and the precipitated salts were dissolved with 4 *N* hydrochloric acid. The ether layer, containing the suspended reaction product, was separated from the aqueous solution, and the solid filtered off and crystallised from aqueous ethanol. Colourless needles (2.1 g) m. p. 163—164°. (Found: C 71.6; H 8.01. $C_{22}H_{32}O_5$ requires: C 71.1; H 8.30.) The compound was almost insoluble in ether and water, readily soluble in ethanol. Gentle heating of the compound with concentrated sulphuric acid produced an intense red colouration. Attempts to acetylate the compound invariably led to mixtures.

Reduction of the dehydration product from B with lithium-aluminium hydride. When the dehydration product from B was treated as just described for the ester of B a polyol resulted, m. p. 163°, which was found by mixed melting point determination to be identical with the reduction product from this ester.

Oxidation of B with alkaline potassium permanganate. Compound B (2.5 g) was refluxed with a solution of potassium hydroxide (15 g) in water (50 ml) until a solid salt started to separate. Powdered potassium permanganate (25 g) was added and the mixture heated overnight on the water bath. Excess permanganate was destroyed with sulphur dioxide, the solution acidified with dilute sulphuric acid, and repeatedly extracted with ether. On evaporation of the ether a solid was obtained, which was crystallised once from petrol. Yield 1.2 g. Several crystallisations gave needles, m. p. 78° undepressed by *α*-phenyl*iso*-butyric acid.

D,L-*1,2-dihydroxy-3-methyl-3-phenylbutane* (VIII). Ethyl *α*-oxo-*β*-phenyl*iso*valerate (20 g) in absolute ether (50 ml) was added with stirring to a suspension of lithium-aluminium hydride (7.0 g) in absolute ether (100 ml). The mixture was refluxed overnight, excess hydride was destroyed by careful addition of water, and the precipitated salts were dissolved by addition of 6 *N* hydrochloric acid. The diol was extracted with ether, washed with water and sodium bicarbonate solution and the extract dried (K_2CO_3). Removal of the ether yielded an oil, which crystallised when cooled and scratched. Crystallisation from petrol afforded colourless needles (15.4 g), m. p. 50—51°. (Found: C 73.4; H 8.78. $C_{11}H_{16}O_2$ requires: C 73.3; H 8.95.) The compound consumed 1.0 mole of periodate when treated with periodic acid in dilute acetic acid.

The author wishes to acknowledge his indebtedness to *Statens Tekniska Forskningsråd* for a Fellowship, to *Cancernämnden* for financial support, to Miss E. Duintjer for skilful assistance and to Dr. K. E. Almin for running the infrared spectrum.

Kinetics of Complex Formation

III *. The Rate of Decomposition of Hexammine Chromium(III) Ion

JANNIK BJERRUM and CARL GÖRAN LAMM

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The decomposition of hexammine chromium(III) ion in nitric acid solutions is followed by measuring the rate of dissolution of the hexammine nitrate. The aquation of the hexammine is independent of the hydrogen ion concentration and the following expression is found for the pseudo-unimolecular velocity constant

$$k_{-6} = 10^{12.3} \cdot e^{-26\,000/RT}$$

By spectrophotometric analysis it is proved that the hexammine decomposes by going through a series of lower ammines.

The complexity of the chromium(III)-ammines can apparently not be determined in aqueous ammonia-ammonium buffers. The ammines undergo various transformations and under certain conditions polynuclear salts may be formed [3]. Even in solutions with very high ammonium salt concentration a slow irreversible decomposition continues which sooner or later results in the separation of some basic precipitates. It may be mentioned that a hexammine chromium(III) solution of the composition: $C_{Cr} = 0.006\ M$, $C_{NH_3} = 2\ M$, $C_{NH_4NO_3} = 5\ M$, which was kept in the dark at 68°, remained completely homogeneous for two days, but on the third day nearly all the chromium had separated as a basic precipitate. Fig. 1a shows how the absorption spectrum of this solution changes with time at 25° and 68° C. An experiment in which charcoal was added to the same solution (see Fig. 1a) shows that heterogeneous catalysis, contrary to what is found [4] for corresponding transformations of cobalt(III)-ammines, only plays a minor role in the decomposition reactions of chromium (III)-ammines. Day-light catalyzes the decomposition to some extent, and for this reason all solutions were kept in dark bottles.

Fig. 1b shows how the absorption spectra of acidic hexammine chromium(III) nitrate solutions change with time at 50°. The family of curves shows directly that the transformations proceed independent of the hydrogen

* For the earlier papers in this series, see Refs. [1,2].

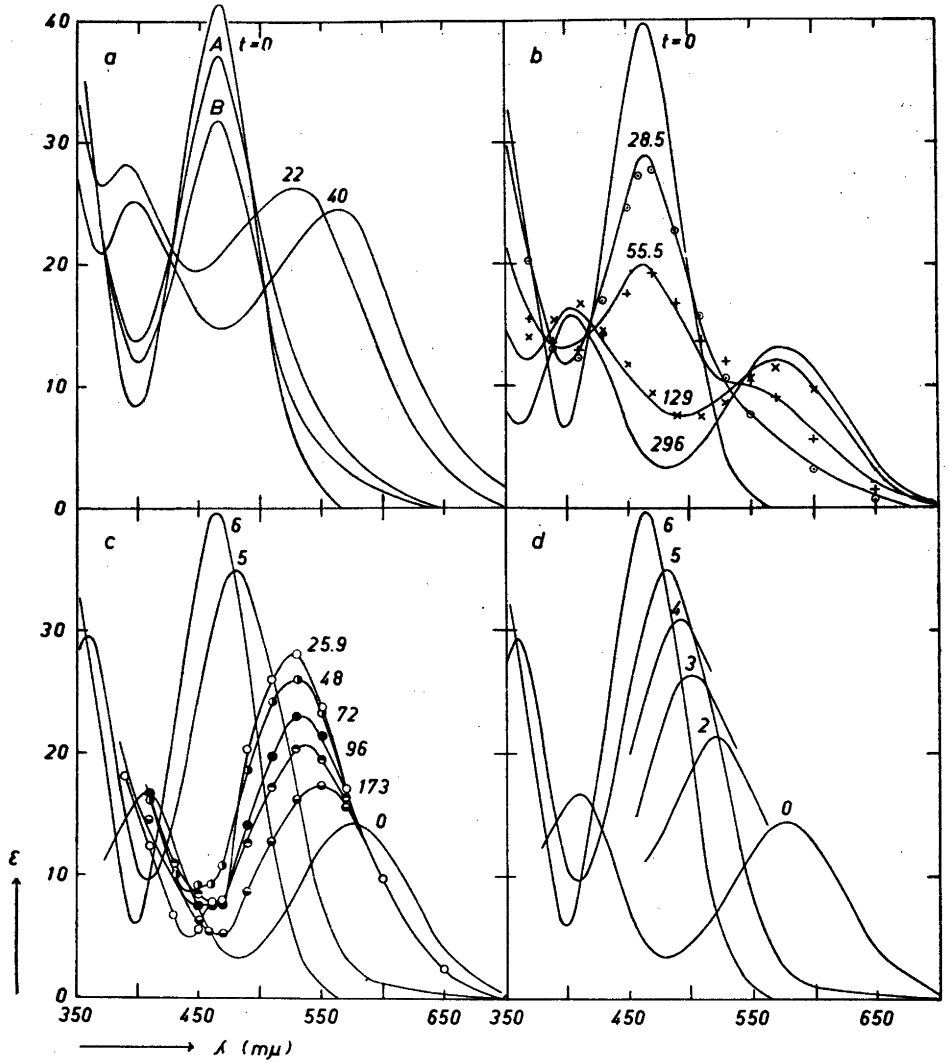

Fig. 1. Molar extinction coefficients versus wavelength in mμ.

a: A solution of the composition: $C_{Cr} = 0.006$ M, $C_{NH_3} = 2$ M, $C_{NH_4NO_3} = 5$ M *followed in time. Curve A: 100 hrs at 25° C. Curve B: 100 hrs at 25°, but with 2 g "Norite" per 100 ml. Curves after 22 and 40 hrs at 68.5° are also given.*

b: Acidic 0.005 M *hexammine chromium (III) nitrate solutions followed in time at 50° C. In 1* M HNO_3 *after 0, 28.5, 55.5, 129 and 296 hrs (full-drawn curves). In 0.5* M HNO_3 *after 29 hrs (o-points), 54.5 hrs (+ points), and in 2* M HNO_3 *after 127.5 hrs (×-points).*

c: Absorption spectra of reaction products. ε_R, λ*-curves at 40° corresponding to the experiment given in Table 1. For comparison is also given the absorption of hexammine, aquopentammine and hexaquo chromium (III) ions (curves 6, 5 and 0, respectively).*

d: Absorption spectra of aquoammine chromium (III) ions at room temperature. Hexammine and hexaquo in 1 M HNO_3 *(curves 6 and 0). Aquopentammine in 0.1* M $HClO_4$ *(curve 5) according to measurements of C. E. Schäffer. Diaquotetrammine, triaquotriammine and tetraquodiammine in water (curves 4, 3 and 2) according to Colmar and Schwartz* [5].

Table 1. Velocity of decomposition of hexammine chromium(III) ion in 1 M HNO_3 at 40° C.

t_{hours}	0	25.92	48.0	72.25	95.75	172.6
C_{NH_3}	0.1763	0.1976	0.2152	0.2359	0.2618	0.3311
$C_{NH_3}-C^{\circ}_{NH_3}$	0	0.0213	0.0389	0.0596	0.0855	0.1548
$10^8 \cdot \frac{d\ C_{Cr}}{d\ t_{sec.}}$	—	3.81	3.75	3.82	4.13	4.15
$10^6 \cdot k_{-6}$ (sec.$^{-1}$)	—	1.30	1.28	1.30	1.40	1.41

$k_{-6}(av.) = 1.34 \cdot 10^{-6}$

ion concentration in 0.5, 1 and 2 *M* nitric acid solution. After about 300 hours the absorption curve has reached an appearance which is very similar to that of the hexaquo chromium(III) ion (see Fig. 1d, where also absorption curves [5] for the intermediate chromium(III) ammines are given). The extinction coefficients in the maxima are somewhat higher than for the hexaquo ion, but polynuclear latently basic compounds perhaps exist in the solution [6].

The velocity of decomposition of the hexammine chromium(III) ion was determined directly by measuring the rate of dissolution of luteo nitrate in nitric acid solutions. Solvent and salt were vigorously shaken in a thermostat, and samples were taken from time to time, and the increase in concentration as well as the optical density at various wavelengths were determined. For convenience, the total ammonia concentration $C_{NH_3} = 6C_{Cr}$ instead of the chromium was determined by a micro-Kjeldahl distillation. Denoting the molar saturation concentrations for luteo salt with C°_{Cr} and $C^{\circ}_{NH_3}$, respectively, we have:

$$\frac{d\ C_{Cr}}{d\ time} = \frac{C_{NH_3}-C^{\circ}_{NH_3}}{6 \cdot time} = k_{-6} \cdot \frac{C^{\circ}_{NH_3}}{6}$$

and for the velocity constant

$$k_{-6} = \frac{C_{NH_3}-C^{\circ}_{NH_3}}{C^{\circ}_{NH_3} \cdot time}$$

Saturation is reached in a few minutes, and the data given in Table 1 show that it is possible by this method to get fairly constant values for the rate constant.

Denoting the optical density in general by D, and the optical density of pure hexammine in saturated solution by D°_6, we get for the mean extinction coefficient of the reaction products formed by the decomposition:

$$\varepsilon_R = \frac{D-D^{\circ}_6}{(C_{Cr}-C^{\circ}_{Cr}) \cdot d} = \frac{6\ (D-D^{\circ}_6)}{(C_{NH_3}-C^{\circ}_{NH_3}) \cdot d}$$

where d is the thickness of the absorbing layer in cm. The mean extinction coefficients of reaction products found at various times in the experiment given in Table 1 are plotted in Fig. 1c. The family of curves is not far from having an isopiestic point in common with all the known aquo ammine

Table 2. Average values for the aquation velocity constant.

$$\log k_{-6} = 12.3 - \frac{26\,000}{4.57\ T}$$

°C	$1/T°$	C°_{Cr} (solubility in 1 *M* HNO_3)	log k_{-6} ($sec.^{-1}$) obs.	calc.
25.0	0.003356	0.00964	−6.69	−6.8
40.0	0.003195	0.02938	−5.87	−5.85
63.8	0.002969	0.1260	−4.51	−4.6

chromium(III) ions except the pentammine ion (see Fig. 1d). It is, therefore, far from certain that aquo pentammine is ever important among reaction products. It is qualitatively known from direct observations that this ion is decomposed to lower ammines at a much higher rate than the luteo ion. On the other hand the relatively strong displacement of the maximum of the ε_R-curves towards red seems to exclude the possibility that the simple ammines are the only reaction products.

The mean values for k_{-6} determined at 25°, 40° and 63.8° C are shown in Table 2. By graphic interpretation of the data the activation energy E is estimated to 26 kcal/mole, and the frequency factor $Z'_{-6} = Z_{-6} \cdot C_{aq}$ to $10^{12.3}$. The values for the velocity constant computed from these values for the Arrhenii constants are also given in the table.

EXPERIMENTAL

Preparation of salts. With minor modifications the complex salts used were prepared according to methods described in the literature. Hexammine chromium(III) nitrate was prepared from the luteo chloride, which was prepared by the Christensen method from anhydrous chromium(III) chloride and liquid ammonia [7]. The hexammine nitrate was purified by repeated reprecipitations with nitric acid; the product was washed with alcohol and air-dried at 60° C, and prepared in this way it could be kept unchanged for months in a dark bottle with a tight fitting stopper. *Anal.* Calc. for $Cr(NH_3)_6(NO_6)_3$: Cr 15.3; N 37.1. Found: Cr 15.1; N 37.1. The solubility of the salt at 18.6° C was found to be 0.0117 *M* in 0.5 *M* HNO_3, 0.00543 *M* in 1.0 *M* HNO_3, and 0.00314 *M* in 2.0 *M* HNO_3.

Technique. The measurements of the rate of dissolution of the hexammine nitrate were made in a water thermostat with an arrangement for effective horizontal shaking of a bottle. At various times during an experiment the shaking was stopped for a short time, and a measured amount of the saturated solution drawn up through a glass filter, adequately diluted and cooled. In order to avoid precipitation during the transference of the saturated solution the pipette was surrounded by a glass mantle containing water at the thermostat temperature.

The optical densities were measured at a Beckman DU. Cells of 1, 2 and 5 cm were used according to wavelength and dilution.

The total ammonia concentrations of the solutions were determined by a micro-Kjeldahl distillation in a Parnas-Wagner apparatus. The solution was transferred with a syringe pipette, and the ammonia was steam-distilled into an excess of 0.01 *N* HCl. The back titration was made with a 0.01 *N* borax solution, and methylred was used as indicator. A blank was run to correct for traces of ammonia in the Kjeldahl lye.

Our thanks are due to C. E. Schäffer, who has assisted in some of the experiments.

Polarographic Processes Involving Chemical Reaction of the Product of the Electron Transfer Reaction

P. KIVALO

Institute of Analytical and Inorganic Chemistry, Åbo Akademi, Åbo, Finland

Using steady state and thermodynamical methods current-voltage equations have been derived for polarographic processes in which the product of the electron transfer reaction is involved in a subsequent chemical reaction.

The application of kinetics in the field of polarography has in recent years become increasingly popular. A better understanding of the conditions at the surface of the electrode, where the electron exchange reactions occur, has made it possible to attack problems concerning mechanisms of electrode reactions. For instance, the so-called irreversible polarographic processes, in which the electron transfer reaction is the slow step competing with the rate of diffusion, have been now thoroughly explained. Similarly, many catalytic processes that can occur at the surface of the microelectrode have been also clarified using kinetic considerations.

This investigation deals with a polarographic problem in which kinetics has been used to gain further insight into the phenomena in question. It is concerned with polarographic processes in which the product of the electron transfer reaction is involved in a subsequent chemical reaction [1]. This type of process can be represented by the general scheme:

$$\begin{gathered} A \overset{ne^-}{\rightleftharpoons} \sum B \\ \sum B + \sum C \rightleftharpoons \sum D \end{gathered} \qquad (1)$$

where A is the species undergoing reduction or oxidation and the various products of the electron transfer reaction are denoted by B, possible chemical reactants by C and the products of the chemical reaction by D. This investigation is restricted to cases where the products of the chemical reaction are not electrochemically active at the potential where A is reduced or oxidized. The so-called catalytic waves will thus be excluded from this study.

Comparatively few reports are found in the literature concerning polarographic processes involving a subsequent chemical reaction. Particulary this

is true for reduction waves, as pointed out by Tanford and Wawzonek [2]. This type of polarographic wave was first reported by Smith, Kolthoff, Wawzonek and Ruoff [3]. They studied the oxidation of hydroxychromans and hydroxycoumarans at the dropping mercury electrode. Chemical or electrochemical oxidation of these compounds produces quinones. The quinones are reversibly reduced to the corresponding hydroquinones and not to the original hydroxychromans or coumarans. On the basis of an analysis of the oxidation waves, they concluded that the electrochemical oxidation involves a reversible step, but that the oxidation product formed is unstable and is irreversibly transformed to the corresponding quinone. The authors postulated that the potential is determined by the reversible reaction

$$A + H_2O \rightleftharpoons B + 2\ H^+ + 2\ e^- \qquad (2)$$

whereas the irreversible step, the transformation of compound B into C

$$B \xrightarrow{a} C \qquad (3)$$

was pictured as an unimolecular reaction. In deriving the expression for the polarographic wave Smith *et al.* use a rather odd therminology in first considering α as a sort of equilibrium constant, $C_B = \alpha\ C_C$, but later calling it a rate constant, although it is given as a dimensionless quantity. Their equation has the form:

$$E_{d.e.} = \text{Const.} + \frac{RT}{2F} \ln \left[\frac{i}{i_d - i} \cdot \frac{k_A}{k'} \alpha \right] + \frac{RT}{2F} \ln [H^+] \qquad (4)$$

where k_A is the Ilkovic constant for compound A and k' is that for compounds B and C (diffusion coefficients practically equal).

Vavrin [4] studied a similar case in the polarographic oxidation of L-ascorbic acid. He derived an equation describing the current-voltage relationship assuming that the chemical decomposition of the oxidized form is a reversible monomolecular reaction:

$$Ox_{rev} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Ox_{irr} \qquad (5)$$

where Ox_{rev} represents the form which can be reversibly reduced and Ox_{irr} that which cannot. The rate constant of the forward reaction is denoted by k_1, that of the reverse reaction by k_2. The derivation was based upon the Nernst relationship. In the customary way $(i_d - i) = k$ Red, where k is the Ilkovic constant for the reduced form. In trying to relate the current to the surface concentration of Ox_{rev}, Vavrin seems to have used an equation of doubtful validity, *viz.*,

$$i = k\ Ox_{rev} + k_1\ Ox_{rev} - k_2\ Ox_{irr} \qquad (6)$$

where k again represents the Ilkovic constant, the same for both the oxidized and reduced forms, and Ox_{rev} and Ox_{irr} are the surface concentrations of the species involved. (The two last terms in the right hand side of equation (6) have the dimension of a rate: moles/liter/sec., whereas the term $k\ Ox_{rev}$ gives amperes). Solving for Red and Ox_{rev} and inserting these quantities into the Nernst relation gives

$$E_{\text{d.e.}} = E^\circ + \frac{RT}{nF} \ln \left[\frac{i_d - i}{i} \cdot \frac{k + k_1 + k_2}{k_1 + k_2} \right] \quad (7)$$

as Vavrin's result.

Oldham [5] has studied the reduction of certain organic mercury compounds and used steady state kinetics in elucidating some of the processes involved. He found that the second wave was irreversible at low pH values but changed to a reversible one when the hydrogen ion concentration was decreased. He offered the explanation that the rate by which the reduction product reacts with hydrogen ions was at high pH values slow enough not to interfere with the reversible electron transfer reaction but competed favorably at low pH values with the back oxidation rendering the wave irreversible.

Kern [6] has derived an equation for a process in which the reduction product is transformed irreversibly to a non-electroactive form. Koutecky's [7] mathematical treatment of linear electrode reactions coupled with chemical reaction appeared in 1951.

Steady state and thermodynamical methods will be used in the following derivations. As was mentioned earlier steady state kinetics has been employed in polarography by some investigators [5,8]. At first sight it seems to be a rather crude assumption that a steady state is attained at the dropping mercury electrode with its varying surface area and diffusion layer thickness. However, relating the mean current to the mean area and concentration during the drop-life, no serious errors are introduced. The faster the electrode reactions are, the closer does the steady state method describe the real conditions at the surface of the electrode. With slower electrode processes the error becomes greater because the concentrations are not independent of time. For instance, in the case of the completely irreversible electrode reaction (no back-reaction), the steady state method does not yield the correct current-voltage relationship, as obtained by rigorous mathematical procedure. A comparison of the two methods for this case has been made by Hush and Oldham [9]. On the other hand, the steady state method gives an illustrative picture of the relative magnitudes of the rates of reactions in schemes which would be too complex to be dealt with by rigorous mathematical methods.

The thermodynamical method has to be relied upon in even more complicated cases.

THE ELECTRODE REACTION COUPLED WITH AN UNIMOLECULAR* CHEMICAL REACTION

The simplest reaction to be considered here can be represented by the following scheme:

$$\mathrm{A} \overset{k_A}{\rightleftharpoons} \mathrm{A}^\circ + ne^- \overset{k_1}{\rightleftharpoons} \mathrm{B}^\circ \overset{k_3}{\rightleftharpoons} \mathrm{C}^\circ \overset{k_c}{\rightleftharpoons} \mathrm{C} \quad (8)$$

$$\mathrm{B}^\circ \underset{k_4}{\overset{k_2}{\rightleftharpoons}} \mathrm{B}, \quad \mathrm{B} \xrightarrow{k_B}$$

* The molecularity and the order of the reaction are considered to be identical here.

where the superscript ° refers to concentrations at the electrode surface. The various processes occurring at the electrode are considered as unimolecular rate processes. The rate constants are defined as the number of moles of substance reacting in unit time, per unit area, per unit concentration, the dimension being cm sec.$^{-1}$. The heterogeneous rate constants may be related to conventional three-dimensional rate constants by considering the "thickness" of the reaction zone. Expressions for this have been derived by various authors [8,10]. In scheme (8) the constants for the electron transfer reaction are denoted by k_1 (forward) and k_2 (backward), those for the chemical reactions by k_3 (forward) and k_4 (backward). The concentrations of the species involved are designated by A, B and C. The kinetic factors [11] which involve the activity coefficients, are here considered equal to unity for the sake of simplicity. The diffusion rate constants of the species are denoted by k_A, k_B and k_C, respectively. They are defined in the following manner:

The Ilkovic equation gives the mean diffusion current

$$i_d = \frac{6}{7}\sqrt{\frac{7}{3}} \cdot \frac{1}{\sqrt{\pi}} \left(\frac{36\pi}{d^2}\right)^{1/6} nFCD^{1/2}\, m^{2/3}\, t^{1/6} \tag{9}$$

in which the notations are the conventional ones. The expression of the mean diffusion current in the steady state treatment is given by (see below)

$$i_d = n\ F\ q\ C\ k_d \tag{10}$$

where q is the mean area of the mercury drop and k_d represents the diffusion rate constant. From equations (9) and (10) one obtains

$$k_d = \sqrt{\frac{7}{3}} \cdot \frac{1}{\sqrt{\pi}} \cdot \frac{5}{3} \cdot \frac{6}{7} \sqrt{\frac{D}{t}} = 1.231 \sqrt{\frac{D}{t}} \tag{11}$$

which is the expression for the diffusion rate constants.

The potential dependence of the rate constants of the electron transfer reaction is given by

$$k_1 = k^\circ_1 \exp \frac{-\alpha nFE}{RT} \tag{12}$$

and

$$k_2 = k^\circ_2 \exp \frac{(1-\alpha) nFE}{RT} \tag{13}$$

where k°_1 and k°_2 represent the values of the rate constants at zero applied potential [12]. The transfer coefficient α is the fraction of the potential difference which effects the reduction, whereas $(1-\alpha)$ is the fraction which effects the oxidation [2,12]. The sign of the exponent is to be taken negative for reductions (increasing k for more negative or less positive potential) and positive for oxidations.

The steady state treatment requires that the concentrations of the species involved, both in the bulk of the solution and at the electrode surface, are independent of time, *i. e.*, the sum of moles brought to the electrode by diffu-

sion or reaction equals the sum of moles removed. Applying this condition to the above-mentioned scheme, the following equations are obtained:

$$Ak_A + B^\circ k_2 = A^\circ k_A + A^\circ k_1 \quad (14)$$

$$Bk_B + A^\circ k_1 + C^\circ k_4 = B^\circ (k_2 + k_3 + k_B) \quad (15)$$

$$Ck_C + B^\circ k_3 = C^\circ k_C + C^\circ k_4 \quad (16)$$

The mean cathodic current, i, is due to the difference in the rates of reduction and oxidation:

$$i = nFq\ (A^\circ k_1 - B^\circ k_2) \quad (17)$$

Using simple algebra the expression for the current can be derived from equations (14)—(17):

$$i = nFq \left[\frac{Ak_A k_1 (k_3 k_C + k_4 k_B + k_B k_C) - Bk_A k_B k_2 (k_4 + k_C) - Ck_A k_C k_2 k_4}{k_1 (k_3 k_C + k_4 k_B + k_B k_C) + k_A (k_2 k_4 + k_2 k_C + k_3 k_C + k_4 k_B + k_B k_C)} \right] \quad (18)$$

Considering potentials at which k_1 becomes very large, all the other terms except those containing k_1 are unimportant and equation (18) then takes the form

$$i_d = nFqAk_A \quad (19)$$

where i_d represents the diffusion limited mean current, *i. e.*, complete concentration polarization prevails. From equations (18) and (19) it is then possible to get

$$\frac{i_d - i}{i} = \frac{Ak_A (k_2 k_4 + k_2 k_C + k_3 k_C + k_4 k_B + k_B k_C) + Bk_B k_2 (k_4 + k_C) + Ck_C k_2 k_4}{Ak_1 (k_3 k_C + k_4 k_B + k_B k_C) - Bk_B k_2 (k_4 + k_C) - Ck_C k_2 k_4} \quad (20)$$

which reduces to

$$\frac{i_d - i}{i} = \frac{k_A (k_2 k_4 + k_2 k_C + k_3 k_C + k_4 k_B + k_B k_C)}{k_1 (k_3 k_C + k_4 k_B + k_B k_C)} \quad (21)$$

provided B and C, the concentrations of the products in the bulk of the solution, are equal to zero, which is usually the case.

Equation (21) has been derived without recourse to considerations of the relative magnitudes of the various velocity constants. It will, therefore, apply whether or not the reactions are reversible. It represents thus a general relationship from which current-voltage equations can be derived for polarographic processes coupled with a monomolecular chemical reaction.

Depending on relative magnitude of the various rate constants different situations are encountered.

If a case, where

$$k_1,\ k_2 \gg k_3,\ k_4,\ k_A,\ k_B,\ k_C \quad (22)$$

is at hand, equation (21) then takes the form

$$\frac{i_d - i}{i} = \frac{k_2}{k_1} \left[\frac{k_4 k_A + k_A k_C}{k_3 k_C + k_4 k_B + k_B k_C} \right] \quad (23)$$

since the terms in the nominator which do not contain k_3 can be neglected. Condition (22) actually represents the criterion of polarographic reversibility which requires that the rates of the electron transfer reactions are faster than the other processes involved [5, 13]. Accordingly, the current-voltage equation of this case should yield a "reversible" log plot slope.

If desired the activity coefficients can be introduced into equation (23) at this stage conveniently. They are associated with the reaction rate constants in scheme (8) as follows:

A.....f_1k_1
B.....f_2k_2, f_2k_3
C.....f_3k_4

The connection between the diffusion rate constants and the activity coefficients is of a different nature. The diffusion rate constants are derived on the basis of the Ilkovic equation which in turn is based upon Fick's laws which are valid only under ideal conditions. Therefore the change in the rates of diffusion with change in overall ionic strength must be referred to the variation of the diffusion coefficient D [14, 15]. Because of the lack of knowledge of values of D in various media, the usual practice is to consider it constant and equal to the value at infinite dilution. After inserting the activity coefficients into equation (23) it takes the form:

$$\frac{i_d - i}{i} = \frac{k_2 f_2}{k_1 f_1}\left[\frac{f_3 k_4 k_A + k_A k_C}{f_2 k_3 k_C + f_3 k_4 k_B + k_B k_C}\right] \tag{24}$$

Combining equations (12), (13) and (24) and taking logarithms, the following relation is obtained:

$$E = \frac{RT}{nF}\left[\ln \frac{k^\circ_1}{k^\circ_2} + \ln \frac{f_1}{f_2} + \ln \frac{f_2 k_3 k_C + f_3 k_4 k_B + k_B k_C}{f_3 k_4 k_A + k_A k_C}\right] + \frac{RT}{nF} \ln \frac{i_d - i}{i} \tag{25}$$

The three terms in the parenthesis of the right hand side of equation (25) are constant for a given solution and reference electrode and they represent the half-wave potential of the reaction. Thus

$$E = E_{\frac{1}{2}} + \frac{RT}{nF} \ln \frac{i_d - i}{i} \tag{26}$$

which is the familiar equation for a reversible polarographic wave.

It has been shown that a first-order reversible chemical reaction which follows a reversible electron transfer reaction, does not alter the shape of the polarographic wave provided k_1 and k_2 are much larger than the other rate constants. The half-wave potential, however, is a function of the magnitude of the rate constants of the chemical reaction and of the diffusion rate constants.

When the first-order chemical reaction is very rapid fulfilling the condition

$$k_1,\ k_2, \gg\ll k_3,\ k_4, \gg k_A,\ k_B,\ k_C \tag{27}$$

equation (21) then takes the form

$$\frac{i_d - i}{i} = \frac{k_2}{k_1} \cdot \frac{k_4 k_A}{k_3 k_C + k_4 k_B} \tag{28}$$

from which one obtains

$$E_{\frac{1}{2}} = \frac{RT}{nF}\left[\ln \frac{k^\circ_1}{k^\circ_2} + \ln \frac{f_1}{f_2} + \ln \frac{f_2 k_3 k_C + f_3 k_4 k_B}{f_3 k_4 k_A}\right] \tag{29}$$

That the same result is found whether the rate of the chemical reaction is faster or slower than the electron transfer reaction actually means that the system is in complete equilibrium. Again the wave is a reversible one. This is to be credited to the properties of a first-order reaction; under similar conditions, second-order reactions do not in general give reversible waves.

Thermodynamic consideration of case (27) results in an identical conclusion:

The Nernst relationship which presumes reversibility of the electrode reaction, is given by

$$E = E' + \frac{RT}{nF} \ln \frac{A^\circ}{B^\circ} \tag{30}$$

where E' denotes the standard potential of reaction

$$A + ne^- \rightleftharpoons B \tag{31}$$

and the superscript ° refers to surface concentrations. According to usual polarographic practice one has that $A^\circ = (i_d - i)/k'_A$. On the other hand, the current is proportional to the sum of the concentrations of the two forms of the reduction product, provided the diffusion coefficients are nearly equal:

$$i = k'_{B,C}\ (B^\circ + C^\circ) \tag{32}$$

Using homogeneous rate constants, one may write for the chemical reaction

$$\frac{C}{B} = \frac{k_3}{k_4} = K \tag{33}$$

Hence

$$B^\circ = \frac{i}{k'_{B,C}\ (1 + K)} \tag{34}$$

and inserting the expressions for A° and B° into equation (30) one has for the half-wave potential

$$E_{\frac{1}{2}} = E' + \frac{RT}{nF} \ln \frac{k'_{B,C}\ (k_3 + k_4)}{k'_A \cdot k_4} \tag{35}$$

which is identical with equation (29) save for the activity coefficients. The case studied by Vavrin [4] falls under the category represented by condition (27). It is the opinion of the author that Vavrin should have used equation (32) rather than (6) to get the correct result.

When the first-order chemical reaction is irreversible the case can be that the following condition is fulfilled

$$k_1,\ k_2,\ \gg k_3,\ \gg k_A,\ k_B,\ k_C \tag{36}$$

From equation (21) it is then readily seen that

$$\frac{i_d - i}{i} = \frac{k_2}{k_1} \cdot \frac{k_A}{k_3} \tag{37}$$

and the expression for the half-wave potential becomes

$$E_{\frac{1}{2}} = \frac{RT}{nF}\left[\ln \frac{k^\circ_1}{k^\circ_2} + \ln \frac{f_1}{f_2} + \ln \frac{k_3}{k_A}\right] \tag{38}$$

Here the wave is reversible and the half-wave potential is a function of k_3. Similarly, a reversible wave is obtained when

$$k_1,\ k_2 \gg k_3 \simeq k_A,\ k_B,\ k_C \tag{39}$$

viz.,

$$E_{\frac{1}{2}} = \frac{RT}{nF}\left[\ln \frac{k^\circ_1}{k^\circ_2} + \ln \frac{f_1}{f_2} + \ln \frac{k_3 + k_B}{k_A}\right] \tag{40}$$

If, on the other hand, k_3 is of the same order of magnitude or greater than k_2, then the wave is irreversible, *e. g.*,

$$\frac{i_d - i}{i} = \frac{k_A}{k_1} \tag{41}$$

and thus

$$E = \frac{RT}{\alpha nF}\left[\ln k^\circ_1 + \ln \frac{f_1}{k_A}\right] + \frac{RT}{\alpha nF} \ln \frac{i_d - i}{i} \tag{42}$$

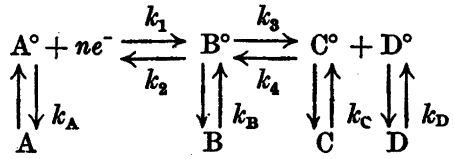
which is the equation for an irreversible polarographic wave with an "irreversible" log plot slope of $0.0591 / \alpha n$ volt.

The case investigated by Smith *et al.*[3] is one obeying condition (36). It is clear that when the rate of transformation is much faster than diffusion, k_3 will dominate and the half-wave potential will a function of it and not of the rate of diffusion. Considering $i = \alpha C_B$ in the case of Smith *et al.* one arrives at the result given by equation (38).

Equation (38) is in agreement with the equation presented by Kern[6] provided k_3 is replaced by μk_{hom}. The thickness of the reaction zone, μ, is equal to $\sqrt{D_B / k_{hom}}$ and k_{hom} is the homogeneous rate constant of the chemical decomposition. Note that Kern's case is an oxidation.

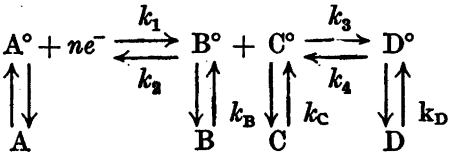
THE ELECTRODE REACTION COUPLED WITH A BIMOLECULAR CHEMICAL REACTION

Three different types of reaction are possible in this case. Firstly, the forward chemical reaction is of first order but the back-reaction is of second order, *viz.*,



(43)

Secondly, the forward chemical reaction is bimolecular, but the back-reaction is monomolecular which is illustrated by scheme (44):



(44)

The third possibility is at hand when both the forward and the reverse chemical reactions are bimolecular which, however, is a rare situation.

The steady state treatment of these schemes becomes hopelessly involved and hence only simplified cases will be considered below.

Employing Nernst relationship, the equation of the current-voltage curve for scheme (43) can be obtained in the following manner: As usual $A^\circ = (i_d - i)/k'_A$, and $i = k'_R\,(B^\circ + C^\circ)$. Assuming that the chemical reaction also is at all times in equilibrium and using homogeneous rate constants one has

$$i = k'_R\,(B^\circ + \sqrt{B^\circ k_3/k_4}) \tag{45}$$

from which, assuming further that $B^\circ \ll \sqrt{B^\circ k_3/k_4}$ it is found that

$$E = E' + \frac{RT}{nF}\ln\left[\frac{i_d - i}{i^2}\cdot\frac{(k'_R)^2}{k'_A}\cdot\frac{k_3}{k_4}\right] \tag{46}$$

In certain cases the concentration of D is approximately proportional to the current: $i = k'_R D^\circ$ and equation (46) can be written

$$E = E' + \frac{RT}{nF}\ln\left[\frac{i_d - i}{i}\cdot\frac{k'_R}{k'_A}\cdot\frac{k_3}{k_4}\right] - \frac{RT}{nF}\ln D^\circ \tag{47}$$

The constancy of the concentration of D at the surface of the electrode determines the wave form. Constant D° only gives a reversible wave, otherwise it will have irreversible characteristics, *i. e.*, owing to the proportionality between the current and D° the log plot slope will be non-linear. Scheme (43) represents a typical situation in which a metal complex is reduced to another oxidation state and the complexing agent is liberated.

Turning now to scheme (44) the current-voltage relationship is found in a similar fashion. Again $A^\circ = (i_d - i)/k'_A$ but now the current is proportional to the sum of the concentrations of B and D, *i. e.*, $i = k'_R\,(B^\circ + D^\circ)$. Assuming also here that the chemical equilibrium is attained instantaneously one has

$$B^\circ = \frac{i}{k'_R\left(1 + \frac{C^\circ k_3}{k_4}\right)} \tag{48}$$

and thus

$$E = E' + \frac{RT}{nF} \ln \left[\frac{i_d - i}{i} \cdot \frac{k'_R}{k'_A} \cdot \left(1 + C^\circ \frac{k_3}{k_4} \right) \right] \tag{49}$$

Depending on the relative magnitudes of k_3, k_4 and the surface concentration of C, different waves are found. First of all, if k_4 is very large, *i. e.*, B hardly decomposes at all, then the wave is reversible; $C^\circ k_3/k_4 = 0$. The case can be that $C^\circ k_3/k_4 \gg 1$, then depending upon the constance of C° during the electrolysis, the wave can show reversible characteristics (constant C°, high concentration of buffer or complexing agent) or can appear more or less irreversible (C° decreases on going up along the wave, *e. g.*, inadequate buffer capacity or slow rate of proton splitting). The half-wave potential will thus be a function of $(1 + C^\circ k_3/k_4)$ giving a number of various situations.

When the bimolecular chemical reaction is irreversible, steady state treatment can be applied. Consider the following, somewhat simplified reaction scheme in terms of the heterogeneous rate constants:

$$A \underset{}{\overset{k_A}{\rightleftharpoons}} A^\circ + ne^- \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B^\circ + C^\circ \xrightarrow{k_3} D^\circ \qquad B^\circ \xrightarrow{k_B} B \tag{50}$$

Assuming a steady state to be attained, one has

$$Ak_A + B^\circ k_2 = A^\circ k_A + A^\circ k_1 \tag{51}$$

$$A^\circ k_1 = B^\circ (k_2 + k_3 + C^\circ k_3) \tag{52}$$

From equations (17), (51) and (52) then

$$\frac{i_d - i}{i} = \frac{k_A}{k_1} \left[\frac{k_2 + k_B + C^\circ k_3}{k_B + C^\circ k_3} \right] \tag{53}$$

It is readily seen that when $k_2 \gg k_B + C^\circ k_3$, a reversible polarographic wave is found, otherwise it will be irreversible. As to the effect of the variation of the surface concentration of C, the same applies as was said above in connection with the reversible cases.

Numerous polarographic processes belonging to the group involving a follow-up bimolecular chemical reaction have been reported in the literature. Especially organic reductions and oxidations coupled with hydrogen ion uptake have been analyzed. Reference is made to the section of organic polarography in the monograph on polarography by Kolthoff and Lingane [16].

CONCLUSION

The results of the theoretical considerations in this paper can be summarized as follows:

1. Equation (20) represents a general relationship from which current-voltage equations can be derived for polarographic processes coupled with a

monomolecular chemical reaction. Equation (21) is valid under normal polarographic conditions and illustrates that $E_{\frac{1}{2}}$ will always be independent of the concentration of the reactant.

A *reversible* wave is found when

a) the chemical reaction is *reversible* and either of conditions (22) or (27) is satisfied;
b) the chemical reaction is *irreversible* and either of conditions (36) or (39) is fulfilled.

An *irreversible* wave is the result when

c) the chemical reaction is *reversible* and $k_2 \sim k_3 \gg k_4$;
d) the chemical reaction is *irreversible* and $k_2 \leq k_3$;
e) in all cases where k_1, $k_2 \leq k_A$, k_B, k_C or when $k_1 \gg k_2$.

2. Where a *bimolecular* chemical reaction affects the concentration of the product of the electron transfer reaction, the same general principles apply as in the previous case, except that here a situation corresponding to conditions (27) does not in general produce a reversible wave. This class is characterized by the fact that $E_{\frac{1}{2}}$ is a function of the concentration of either reactant A or C.

Acknowledgment. The author is indebted to Dr. H. A. Laitinen, University of Illinois, Urbana, Ill. U.S.A., for valuable advice and profitable discussions in connection with this research. Part of the research was carried out under the sponsorship of the *Office of Naval Research, USN*, which is gratefully acknowledged.

The Oslo Electron Diffraction Units for Gas Work

O. BASTIANSEN, O. HASSEL and EILIF RISBERG

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

A new electron diffraction sector apparatus, primarily intended for gas work and now in use for some time is described. The high tension source, electron gun and magnetic lens are of commercial type, the rest of the apparatus has been designed and constructed in our institute. The new apparatus has made it possible to increase the accuracy of the intensity measurements and to extend the intensity measurements far beyond the s-range earlier investigated. Besides the advantages thus opened with respect to precise measurements of molecular parameters it has become possible to increase very markedly the resolution power of the procedure.

The use of a rotating sector to compensate for the steep fall in the background of electron diffraction diagrams from a gas was suggested independently by Trendelenburg[1], Finbak[2] and P. P. Debye[3] in the thirties. In Oslo, the method has been in use since 1940, and the advantage of the method as compared to the visual method has since then been fully realized. A series of the problems studied in our laboratory, particularly those involving the difference procedure, would in our opinion hardly have been solved with the use of the visual method[4–15].

The first sector electron diffraction apparatus in Oslo was designed by Chr. Finbak in 1936. As this apparatus has earlier been described[16,17], and since the main principles are very much the same as for that recently designed by Brockway and Bartell[18], it will only be mentioned briefly in the present report.

The usefulness of the old apparatus may perhaps most easily be demonstrated by reproducing a photometer curve of a diagram of a comparatively large molecule. In Fig. 1 is presented, therefore, a photometer curve of *sym.* triphenylbenzene.

One of the main differences between this apparatus and that of Brockway and Bartell is the mounting of the sector. A central axle is applied in the Oslo apparatus instead of the peripherally mounted ball-bearing system. We have found the central axle simple and convenient and have, therefore, applied this type of construction also in the new apparatus. The electron source of the old

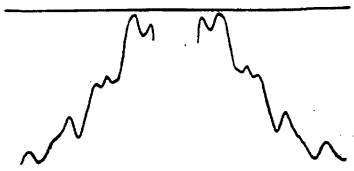

Fig. 1. Photometer record of sym. *triphenylbenzene from a diagram taken in the old sector apparatus.*

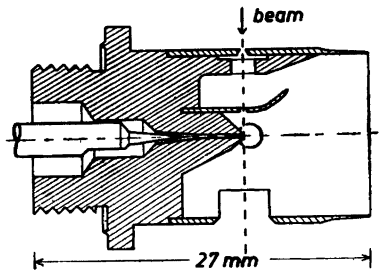

Fig. 2. Gas nozzle with needle valve used in the old apparatus (simplified).

apparatus consists of a cold-cathode discharge tube. The high voltage supply is also an old-fashioned construction but gives a stable direct current.

In order to secure the best possible construction for the new apparatus many of the details were first tried out in the old unit. For instance, a whole series of different gas-nozzle designs were tried out. A nozzle type which has been much used is illustrated in Fig. 2. Various liquid-air traps have been tried and also different sector shapes and sector screening factors. Most of the diagrams of the old apparatus were taken with an s^2 or s^3 sector.

DESCRIPTION OF THE NEW OSLO APPARATUS

The new apparatus was designed in collaboration with Professor Chr. Finbak (†). The ideas leading to many of the improvements we owe to him. The apparatus has to a great extent been built in the workshop of our institute. Exceptions are the high voltage supply and the electron gun which were purchased from Metropolitan-Vickers, England. This is standard equipment for an electron microscope. Only one magnetic lens is used for focussing the beam.

Fig. 3 is a simplified sketch and Fig. 4 a photograph of the apparatus. As may be seen from the scale, the dimensions are larger than for previously-built diffraction units. We chose this size in order to be able to place various kinds of auxiliary equipment inside the vacuum system and to avoid limitation in scattering angles due to the geometry of the apparatus. The various parts of the apparatus are fitted together with O-rings. O-rings are also used for the windows and the plate-box door.

The vacuum chamber consists of two steel cylinders, the inner diameters of which are 50 and 63 cm, respectively. The total inner height is 80 cm and the volume approximately 180 liters. The inner edge of the (shelf-like) connection between the cylinders is supported by steel pillars.

The main opening giving access to the chamber is a door (30×13 cm^2) in the bottom cylinder. Through this door the plate box may be inserted when the carriage is in its lowest position. In the top and bottom plates of the chamber and in the side walls of the upper cylinder a series of openings is present. Thus, one may introduce electron gun, pumps, gauges, cooling trap and various

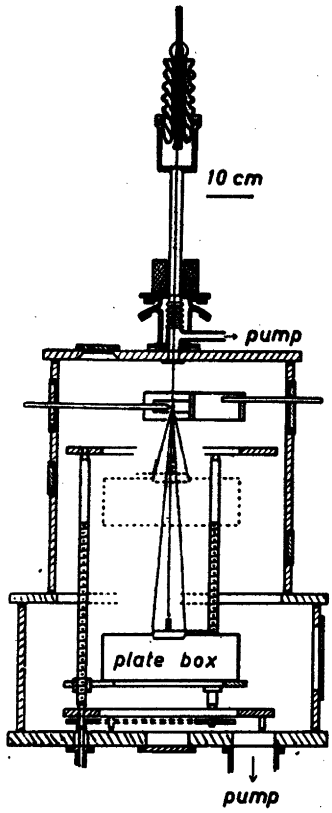

Fig. 3. Simplified section sketch of the new diffraction apparatus.

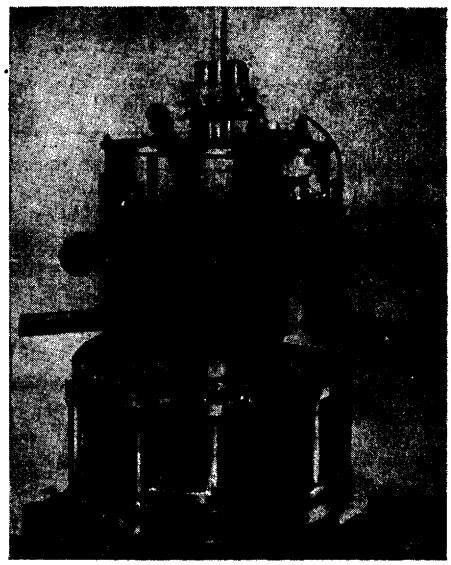

Fig. 4. Photograph of the main part of the new apparatus.

auxiliary equipment. Plexiglas windows are provided. Four standard sizes for the openings have been chosen, thereby allowing the same pieces of equipment to be moved from one position to another. This, of course, adds to the flexibility of the whole arrangement.

The plate box. The capacity of the plate box (Fig. 5) is 15 plates or more of maximum size 6 × 24 cm². The box is mounted on tracks and the loading or disloading is therefore very easy. The unexposed plates are stored in the first of three compartments. By means of a chain driven system operated by one single control, the plates may be transferred to the second compartment for exposure, and after exposure to the third compartment. The same control also opens and closes the exposure lid. In the exposure compartment, the two ends of the plates are pressed upwards against slide rails in the top of the box, the emulsion side thus being brought in a well-defined position. The plate-box mounting can be moved up and down and the distance between the photographic emulsion and the diffraction point thus be continuously varied. In order to keep the plate box exactly horizontal during this movement, the lift is

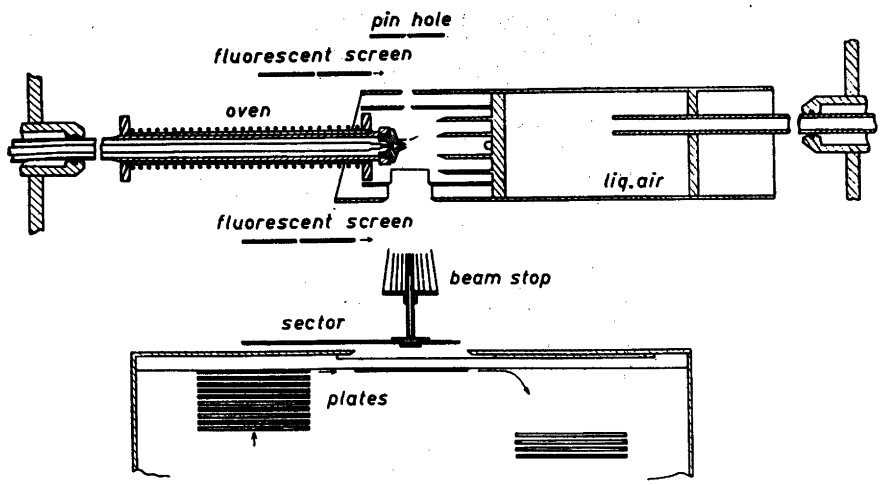

Fig. 5. Section through oven, liquid-air trap, and plate box with sector and beam stop (simplified).

operated by three screws which are rotated simultaneously by a chain connecting the toothed wheels at the end of each screw. The lift can be operated from the outside of the apparatus by means of one of the vacuum-tight shaft-bearings. By simply choosing the proper windows for nozzle and the liquid-air trap it is possible to vary the distance between the photographic plate and the diffraction point from a few centimeters to about half a meter.

The sector should be kept in a position close to the photographic plate although the nozzle-to-plate distance can be changed within wide limits. The sector mount, therefore, forms part of the carriage system. If necessary, however, it may be unfastened by a single hand operation. Gear transmissions, intended for rotation of the sector, as well as for adjustment in two horisontal directions, have been provided. If desired, the sector may also be moved out of the plate area. The carriage movements do not interfere with the operation of the sector or the plate box.

The sector found to be most satisfactory at the present time has a spiral form as shown in Fig. 6. Within the greater part of the s-interval the screening factor is approximately proportional to s^3; in the inner part, the opening is made larger than corresponds to this function. The sector is made from a phosphorus-bronze sheet of thickness 0.2 mm. To avoid deviation from planarity the sector is supported by duraluminium edges on both sides. The sector is operated by an electric motor placed outside the apparatus. The shape of the sector has been carefully studied both by direct measurement under the microscope and by diffraction experiments. From these studies, sector correction curves for use in our structure-determination work have been computed. The beam stop, mounted on the top of the sector, consists of a series of concentric cylinders. The beam stop used for the short-distance pictures, where we are mainly interested in the largest s-values, consists of seven cylin-

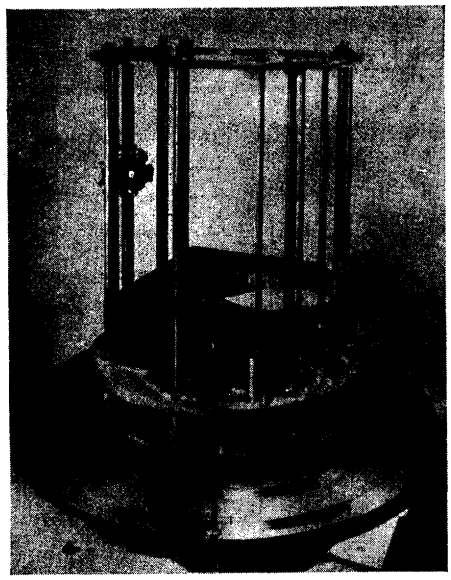

Fig. 6. Photograph showing the carriage arrangement. Sector replaced by a paper model.

ders. In the bottom of the beam stop is placed a layer of carbon black, which has a very low secondary electron emission. Colloidal graphite suspension can be used for coating the cylinder walls. The use of an effective beam stop seems to be of the greatest importance in order to obtain reliable intensity data at large s-values.

The nozzle and liquid-air trap designs seem also to be of great importance for the quality of the diffraction diagrams. Several oven- and nozzle types for various purposes have been constructed. The nozzle and the trap are placed on opposite sides of the apparatus, but at the same height. The end of the trap is a cylinder surrounding the nozzle. In this way, practically all the gas leaving the nozzle is condensed in the first trap and is accordingly prevented from reaching the rest of the apparatus. In Fig. 5, a typical nozzle-trap combination is shown.

The new apparatus has enabled us to enlarge our s-interval considerably. In the old apparatus we were able to obtain intensity values ranging from $s = 3$ Å^{-1} to nearly $s = 30$ Å^{-1}. The new apparatus gives intensity values extending from s equal to 1 Å^{-1} to s-values of about 60 Å^{-1}. Experimental curves giving intensity values over a large s-range are reproduced in Fig. 7. Corresponding theoretical curves are also given, for the sake of comparison. In our standard procedure we usually limit ourselves to three different distances between diffraction point and photographic plate, *viz.* approximately 49 cm, 19 cm and 12 cm. The experimental intensity curves like those reproduced in Fig. 7 are obtained in the usual way: A Leeds and Northrup microphotometer is used, and the plates are oscillated during the process of recording. The

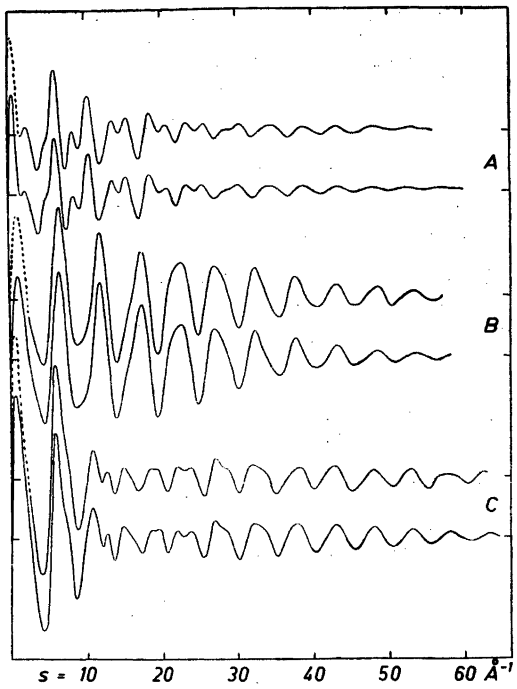

Fig. 7. Experimental and theoretical intensity curves of cyclooctatetraene *(A), NO_2 (B), and vinylacetylene (C).*

photometer curves are read off in a logarithmic scale and the blackness is transferred into intensity values before the theoretical background is subtracted.

The wavelength control is based upon diffraction pictures from gold foils or from evaporated gold films. Other reference substances have been tried, but at present we feel that gold gives the most reproducible values. An *s*-sector is used when taking calibration pictures. Without a sector, a slight decrease in wavelength with increasing *s*-values is observed. This decrease is probably due to electric charging effects in the photographic plates.

As we have found our present commercial high-voltage meter not to be sufficiently accurate for precision determinations we are building a new instrument for high voltage control. This outfit has, however, not yet been in operation and it will not be described here.

The apparatus has been briefly described by one of us in a lecture given at the Eighth Scandinavian Chemistry Congress in Oslo, June 1953 [19].

We want to express our sincere gratitude towards *Norges Teknisk-Naturvitenskapelige Forskningsråd* and *Norges almenvitenskapelige forskningsråd* for grants enabling us to build the new unit and use it for structure determinations. We are also very much indebted to Mr. S. Sørensen, senior instrument maker in our institute, for his excellent contribution to the construction work, and to our colleague cand. real. A. Almenningen

for his most valuable help in setting up the apparatus and his initiative and skill during the running-in period. Very helpful suggestions regarding technical improvements are due to him. We also want to express our gratitude to instrument maker Th. Nilsen, Trondheim, for having taken care of the construction of the plate box.

Versuche zur Darstellung optisch aktiver bororganischer Verbindungen. II.* Über Ester der Diarylborsäuren

K. TORSSELL

Institut für organische Chemie und Biochemie der Universität, Stockholm, Schweden

Arylborsäuredibutylester reagieren mit Arylmagnesiumbromid, Molverhältnis 1 : 1, bei tiefer Temperatur (−60° bis −65°) unter Bildung von Diarylborsäureester. Borverbindungen, zwei verschiedene Arylgruppen enthaltend, wurden dargestellt.

Vertreter der Diarylborverbindungen sind schon von Michaelis [1], König und Scharrnbeck [2] sowie von Mel'nikov [3,4] dargestellt worden. Nach Michaelis erhält man Diphenylborchlorid durch Einwirkung von Phenylbordichlorid auf Quecksilberdiphenyl:

$$C_6H_5BCl_2 + Hg(C_6H_5)_2 \rightarrow (C_6H_5)_2BCl + C_6H_5HgCl$$

König und Scharrnbeck stellten Diphenylborsäure in folgender Weise dar:

$$2\ C_6H_5MgX + B(OR)_3 \rightarrow (C_6H_5)_2BOR + 2\ ROMgX \xrightarrow{\text{Hydrolyse}} (C_6H_5)_2BOH$$

Torssell [5] hat einen Weg zur Darstellung von Diarylborverbindungen mit zwei verschiedenen Gruppen angegeben. Wenn eine Grignardverbindung bei tiefer Temperatur (—60° bis —65°) zu der ätherischen Lösung von einem Monoarylborsäureester im Molverhältnis 1:1 hinzugefügt wird, lässt sich die Reaktion auf der Stufe der Diarylborverbindung halten:

$$Ar'MgX + ArB(OR)_2 \rightarrow Ar'ArBOR \xrightarrow{\text{Hydrolyse}} Ar'ArBOH$$

Der bei der Grignardierung entstandene Diarylborsäureester lässt sich nicht aus der Lösung herausdestillieren, denn er wird von den Magnesiumsalzen infolge Komplexbildung festgehalten:

$$Ar'ArBOR + ROMgX \rightarrow [Ar'ArB(OR)_2]^- MgX^+$$

Das Reaktionsprodukt wird deswegen in verdünnter Schwefelsäure hydrolysiert. Die ätherische Schicht wird abgetrennt und mit etwas Wasser ge-

waschen. Nach dem Abdestillieren des Äthers wird die Diarylborsäure mit Propylalkohol verestert.

Kürzlich sind einige Arbeiten von Letsinger und Mitarbeitern [6,7] erschienen, die unabhängig von uns diese Methode ausgearbeitet haben. Es wird z. B. die Darstellung von Phenyl-α-naphtylborsäure-aminoäthylester beschrieben.

Die Diarylborsäurepropylester bilden farblose, feuchtigkeitsempfindliche Flüssigkeiten, die an der Luft allmählich bräunlich werden. Sie sind in organischen Lösungsmitteln stark löslich, dagegen in Wasser unlöslich. In Tabelle 1 sind ihre physikalischen Daten zusammengestellt. Wegen der Luftempfindlichkeit der Substanzen werden sämtliche Arbeitsoperationen unter Stickstoff durchgeführt.

Die Boranalysen sind nach der Methode von Wittig und Mitarbeitern [8] und Torssell [5] vorgenommen worden.

EXPERIMENTELLER TEIL

o-Tolyl-p-tolylborsäure-n-propylester. Ein 100 ml Kolben mit seitlichem Zuleitungsrohr für Stickstoff wurde wiederholt evakuiert und mit Stickstoff gefüllt. 9,5 g *p*-Tolylborsäuredibutylester [5] in 10 ml Äther wurden vorgelegt und auf −65° bis −60° gekühlt. Diese Temperatur wurde während der Reaktion beibehalten. 45 ml 1,05 *M* *o*-Tolylmagnesiumbromid-Lösung wurden unter Schütteln tropfenweise zugesetzt (10 % Überschuss). Man liess dann die Lösung langsam über Nacht Zimmertemperatur erreichen. Dabei entstand ein weisser Niederschlag. Die Magnesiumsalze wurden unter Stickstoff in 50 ml Eiswasser, das mit 2 ml konz. Schwefelsäure versetzt war, hydrolysiert. Die ätherische Schicht wurde abgetrennt und zweimal mit 30 ml Wasser gewaschen. Der Äther wurde bei gewöhnlichem Druck abdestilliert. 15 ml Wasser wurden zugegeben, worauf das Butanol-Wasser-Gemisch im Vakuum abgetrieben wurde. Die Badtemperatur wurde auf 75° gesteigert. Im Kolben blieb die Diarylborsäure als ein Öl zurück. 10 ml *n*-Propylalkohol wurden zugegeben, und aus der Mischung wurde zunächst über eine kleine Kolonne das konstant siedende Propanol-Wasser-Gemisch herausdestilliert. Nach dem Abdestillieren des Überschusses von Propylalkohol wurde der Rückstand im Vakuum gleichfalls über einer kleinen Kolonne destilliert. Folgende Fraktionen wurden bei 11 Torr gewonnen:

I.	→173°	0,5 ml
II.	173–176°	0,6 ml
III.	176–178°	6,0 ml

Fraktion III wurde noch einmal destilliert, wobei 5,1 g (53 %) *o*-Tolyl-*p*-tolyl-borsäure-*n*-propylester, Kp. 173—5°/10 Torr gewonnen wurden. (Gef. B 4,25. Ber. für $C_{17}H_{21}OB$ (252,2): B 4,29).

o-Tolyl-phenylborsäure-n-propylester wurde aus Phenylborsäuredibutylester [5] und *o*-Tolylmagnesiumbromid nach der oben beschriebenen Methode dargestellt. Kp. 156—9°/9 Torr. Ausbeute 41 %. (Gef. B 4,64. Ber. für $C_{16}H_{19}OB$ (238,2): B 4,54).

o-Tolyl-m-tolylborsäure-n-propylester aus *o*-Tolylborsäuredibutylester [5] und *m*-Tolylmagnesiumbromid. Kp. 173—5°/11 Torr. Ausbeute 53 %. (Gef. C 80,83; H 8,80; B 4,28. Ber. für $C_{17}H_{21}OB$ (252,2): C 80,97; H 8,39; B 4,29).

o-Tolyl-p-chlor-phenylborsäure-n-propylester aus *o*-Tolylborsäuredibutylester und *p*-Chlor-phenylmagnesiumbromid. Kp. 176—7°/10 Torr. Ausbeute 70 %. (Gef. C 71,41; H 6,79; Cl 12,68; B 4,05. Ber. für $C_{16}H_{18}OClB$ (272,6): C 70,50; H 6,65; Cl 13,00; B 3,97).

ANALYTISCHES

Da die Diarylborsäuren in Wasser unlöslich sind, wird die abgewogene Probe (~ 50 mg) in 6 ml Methanol gelöst. Unter Umschwenken werden 10 ml von einer bei Zimmertemperatur gesättigten wässrigen Quecksilberdichlorid-Lösung langsam zugetropft. Bei schnellem Zusatz scheidet sich die Diarylborsäure als ein Öl aus und wird vom Quecksilberdichlorid unvollständig angegriffen. Die quecksilberorganische Verbindung fällt allmählich aus. Man fügt 15 ml Wasser hinzu und lässt die Lösung etwa 30 Min. stehen. Natriumchlorid wird zugesetzt, worauf man mit 0,1 *N* Natriumhydroxyd-Lösung in Gegenwahrt von Methylrot und Phenolfthalein titriert. Bei der ersten Titrierung gegen Methylrot kommt es oft vor, dass der Umschlag nicht ganz stabil ist. Dies beruht darauf, dass die Umsetzung von Quecksilberdichlorid mit der Organoborverbindung noch nicht ganz beendet ist. Man setzt dabei den Natriumhydroxydzusatz so lange fort, bis die Lösung nach 5 Min. Stehen ihre blassgelbe Umschlagfarbe beibehält.

Herrn Prof. Dr. K. Myrbäck, dem Direktor des Instituts, spreche ich für sein Interesse für diese Arbeit meinen ergebensten Dank aus. Der Universität zu Stockholm bin ich für die Gewährung eines Doktorandstipendiums zu besonderem Dank verpflichtet.

ACTA CHEMICA SCANDINAVICA ● (1955) 242—245

Versuche zur Darstellung optisch aktiver bororganischer Verbindungen. III.* Über Ester der Aryl-alkylborsäuren

K. TORSSELL

Institut für organische Chemie und Biochemie der Universität, Stockholm, Schweden

Arylborsäuredialkylester setzen sich mit Alkylmagnesiumbromid, Molverhältnis 1 : 1, bei tiefer Temperatur (−60° bis −65°) unter Bildung von Aryl-alkylborsäureester um. Wenn die Grignardverbindung im Molverhältnis 2 : 1 dem Arylborsäuredialkylester zugesetzt wird, entsteht nicht das erwartete Dialkyl-arylborin, sondern es tritt eine Disproportionierung ein. Es bilden sich Trialkylborin und Triarylborin.

Durch Umsetzung von Phenylboroxyd mit Äthylmagnesiumbromid versuchten Krause und Nobbe [1] Phenyl-diäthylborin darzustellen. Die Reaktion verlief aber nicht in der erwarteten Richtung:

$$C_6H_5B{=}O + 2\ C_2H_5MgBr \rightarrow C_6H_5B(C_2H_5)_2 + (MgBr)_2O,$$

sondern es entstand eine Mischung von Triäthylborin und Triphenylborin. Phenyl-diäthylborin disproportioniert sich nach folgender Gleichung:

$$3\ C_6H_5B(C_2H_5)_2 \rightarrow (C_6H_5)_3B + 2\ (C_2H_5)_3B.$$

In der vorliegenden Arbeit wurde die Reaktion zwischen Phenylborsäuredialkylester und Alkylmagnesiumbromid studiert. Der Befund von Krause konnte bestätigt werden. Bei der Umsetzung von Propylmagnesiumbromid mit Phenylborsäuredipropylester (Molverhältnis 2:1) wurde Tripropylborin in 88 %-iger Ausbeute gewonnen. Im Kolben blieb reines Triphenylborin zurück.

$$C_6H_5B(OC_3H_7)_2 + 2\ C_3H_7MgBr \rightarrow [C_6H_5B(C_3H_7)_2] \rightarrow (C_6H_5)_3B + 2\ (C_3H_7)_3B$$

Äthylmagnesiumbromid und Phenylborsäuredibutylester ergaben Triäthylborin. Es ist zu erwarten, dass Phenyl-diäthylborin einen Siedepunkt von etwa 80°/10 Torr haben soll (vgl. den Siedepunkt des Phenyl-cyclotetrametylenborins [2]). Tatsächlich destillierte bei dieser Temperatur ein wenig Substanz über, die sich aber als sehr unrein erwies.

* II. *Acta Chem. Scand.* **9** (1955) 239.

Bei der Umsetzung von Phenyl-methyl-borsäurepropylester mit Methylmagnesiumbromid, Molverhältnis 1:1, konnte kein Phenyl-dimethylborin nachgewiesen werden.

Die Disproportionierung ist folgendermassen zu formulieren:

$$C_6H_5B(C_2H_5)_2 + C_2H_5MgX \rightarrow [(C_6H_5)\,B(C_2H_5)_3]^-MgX^+ \rightarrow C_6H_5MgX + (C_2H_5)_3B$$
$$C_6H_5MgX + C_6H_5B(C_2H_5)_2 \rightarrow [(C_6H_5)_2B(C_2H_5)_2]^-MgX^+ \rightarrow C_2H_5MgX +$$
$$+ (C_6H_5)_2B(C_2H_5) \text{ usw.}$$

Wenn man aber zum Phenylborsäuredibutylester das Grignardreagens im Molverhältnis 1:1 hinzufügt, erhält man in guter Ausbeute einen Phenylalkylborsäureester:

$$C_6H_5B(OC_4H_9)_2 + C_2H_5MgBr \rightarrow C_6H_5B\begin{matrix}C_2H_5\\OC_4H_9\end{matrix}$$

Diese Verbindung ist stabil und lässt sich unzersetzt destillieren. Eine Disproportionierung tritt also bei unseren Versuchsbedingungen nur ein, wenn alle drei Valenzen des Bors von Kohlenstoff besetzt werden. Die Ester der Monoaryl- und Diarylborsäuren [2,3] zeigen keine Neigung zur Disproportionierung.

Bei Phenyl-cyclopentamethylenborin und Phenyl-cyclotetramethylenborin [2] liess sich keine Disproportionierung feststellen. Diese wird durch die Ringkonfiguration verhindert.

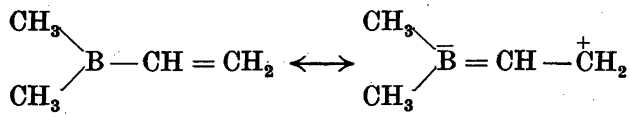
Über unsere Versuche asymmetrische Triarylborine darzustellen, soll in der nächsten Arbeit dieser Reihe berichtet werden. Die Arylverbindungen des Bors sind im allgemeinen stabiler als die Alkylverbindungen; man muss aber trotzdem mit der Möglichkeit einer Disproportionierung rechnen. Wenn diese eintritt, ist es auf diesem Wege unmöglich, optisch aktive Organoborverbindungen darzustellen.

Die Versuche von Johnson und Mitarbeitern [4] sowie von Rohtstein und Saville [5] asymmetrische Trialkylborine darzustellen, sind gescheitert. Parsons und Ritter [6] fanden, dass ungesättigte, asymmetrische Trialkylborine eine unerwartete Stabilität zeigen. Dimethyl-vinylborin disproportioniert sich nur langsam bei Zimmertemperatur. Die Disproportionierung vollzieht sich anscheinend ohne Einfluss von Lösungsmittel oder Metall-alkyl.

Die einfachste Bor-wasserstoffverbindung, BH_3, und die von Schlesinger und Mitarbeitern [7,8] dargestellten Alkyl-borhydride, die zur Disproportionierung leicht befähigt sind, liegen in ihrer dimeren Form vor. Dagegen entspricht die Gasdichte des Trimethylborins [9] der einfachen Formel $B(CH_3)_3$. Wenn man aber eine geringe Neigung zur Dimerisierung annimmt, könnte dies die Disproportionierung der asymmetrischen Trialkylborine erklären.

$$2\ R'R''_2B \rightarrow \left[\begin{matrix}R'' & & R'' \\ & B\quad B & \\ R' & & R''\end{matrix}\right] \rightarrow R''_3B + R'_2R''B$$

Bei Dimethyl-vinylborin haben wir mit zwei mesomeren Strukturen zu rechnen:



was die Disproportionierung erschwert.

Methyl-dibutylborin lässt sich aus Natrium(Kalium)-dibutylborid und Methyljodid darstellen [10]. Über die Stabilität der Verbindung wurden keine Angaben gemacht.

Die Aryl-alkylborsäureester lassen sich auch nach der Sublimat-Methode analysieren; die Reaktionsverhältnisse sind aber mehr kompliziert. Bei der Analyse von Phenyl-äthylborsäurebutylester wurde $HCl:H_3BO_3$ gleich 1:1 gefunden; das heisst, Quecksilberdichlorid zersetzt nicht die B—C_{aliph}-Bindung. Bei Phenyl-methylborsäurepropylester wurde das Verhältnis als 1:2 gefunden. Dies kann nur so erklärt werden, dass, erst wenn die Lösung bei der Titrierung etwas alkalisch wird, die Spaltung von der B—C_{aliph}-Bindung durch Einwirkung von Quecksilberdichlorid einsetzt. Tri-*n*-propylborin wird von Quecksilberdichlorid in Methanol-Wasser-Lösung äusserst langsam angegriffen.

EXPERIMENTELLER TEIL

Umsetzung von Phenylborsäuredi-n-propylester mit n-Propylmagnesiumbromid im Molverhältnis 1 : 2. In einem Kolben wurden zu 7,3 g Phenylborsäuredi-*n*-propylester in 5 ml Äther unter Stickstoff und Kühlung mit kaltem Wasser 75 ml 1,10 *M* *n*-Propylmagnesiumbromid-Lösung zugetropft (15 % Überschuss). Zwei Schichten bildeten sich. Während des Zusatzes schüttelte man kräftig um. Die Wärmetönung bei der Reaktion war gering. Die Mischung wurde eine halbe Stunde auf dem Wasserbad unter Rückfluss gekocht, worauf sie in 40 ml Eiswasser unter Stickstoff hydrolysiert wurde. Die ätherische Schicht wurde abdekantiert, und die ausgefällten Magnesiumsalze wurden mit 15 ml Äther gewaschen. Von den vereinigten Ätherlösungen wurde der Äther nach Trocknen über Calciumchlorid bei gewöhnlichem Druck abdestilliert. Bei 90 bis 100° destillierte ein wenig *n*-Propylalkohol und Wasser über. Der Rückstand im Kolben wurde im Vakuum destilliert. Es wurden bei 51—3°/10 Torr 2,9 g Tri-*n*-propylborin (60°/20 Torr) [11] gewonnen. Ausbeute 88 %. Im Kolben blieb Triphenylborin zurück, das beim Erkalten in langen weissen Prismen kristallisierte. Ein Tropfen Tri-*n*-propylborin, der auf einem Uhrglas in Berührung mit der Luft gebracht wurde, erstarrte nach kurzer Zeit und ergab blätterförmige Kristalle von *n*-Propylborsäure [11]; Schmp. 107°.

Umsetzung von Phenylborsäuredi-n-butylester mit Äthylmagnesiumbromid im Molverhältnis 1 : 2. Nach der oben beschriebenen Methode wurden 11,1 g Phenylborsäuredi-*n*-butylester mit 100 ml 1,02 *M* Äthylmagnesiumbromid-Lösung (10 % Überschuss) versetzt. Nach Hydrolysieren und Trocknen der Ätherlösung mit Calciumchlorid wurde der Äther abdestilliert. Mit dem Äther destillierte eine borhaltige Substanz über. Zwischen 80 und 100° entwich noch mehr davon zusammen mit etwas Butylalkohol und Wasser. Beim Verdampfen des Destillates auf einem Uhrglas an der Luft blieb eine weisse Substanz zurück, die als Borsäure identifiziert wurde. Triäthylborin siedet bei 95°/760 Torr und entzündet sich von selbst an der Luft [9]. Bei der nachfolgenden Vakuumdestillation wurden bei 10 Torr folgende Fraktionen gewonnen:

I.	30— 40°	2,0	ml
II.	40— 75°	0,1	»
III.	75— 90°	0,8	»
IV.	90—110°	0,3	»
V.	110—115°	0,7	»

Sämtliche Fraktionen waren farblos. Im Kolben blieb eine ölige, gelbe Flüssigkeit, ~ 1,5 ml, zurück.

Die Fraktion I bestand aus *n*-Butylalkohol. III bildete eine unangenehm riechende Flüssigkeit, die wahrscheinlich etwas Phenyldiäthylborin enthielt. V wurde als Phenyl-äthylborsäure-*n*-butylester identifiziert.

Die Fraktion III wurde noch einmal destilliert aber ergab nur uneinheitliche Produkte. Dies könnte auf einen Zerfall der Substanz während der Destillation deuten.

Umsetzung von Phenylborsäuredi-n-butylester mit Äthylmagnesiumbromid im Molverhältnis 1 : 1. Darstellung von Phenyl-äthylborsäure-n-butylester. Zu 9,5 g Phenylborsäure-di-*n*-butylester wurden unter Stickstoff und gutem Schütteln 41 ml 1,02 *M* Äthylmagnesiumbromid-Lösung tropfenweise hinzugefügt (2 % Überschuss). Die Reaktionstemperatur wurde bei −60° bis −65° gehalten. Man liess dann die Lösung langsam Zimmertemperatur annehmen. In einem Scheidetrichter wurde die ätherische Lösung auf 40 ml Eiswasser + 1,5 ml konz. Schwefelsäure gegossen. Die ätherische Schicht wurde mit 30 ml Wasser gewaschen und mit Calciumchlorid getrocknet. Der Äther wurde abdestilliert und der Rückstand mit 15 ml *n*-Butylalkohol in gewöhnlicher Weise verestert. Nach Abtreiben des Überschusses von *n*-Butylalkohol wurde der Phenyl-äthylborsäure-*n*-butylester in Vakuum destilliert. Er bildet eine farblose, luftempfindliche, unangenehm riechende Flüssigkeit vom Kp. 110−1°/9 Torr. Ausbeute 4,5 g oder 58 %. $n_D^{25} = 1{,}4864$; $d_4^{25} = 0{,}8940$. (Gef. C 75,5; H 10,22; B 5,55. Ber. für $C_{12}H_{19}OB$ (190,1): C 75,8; H 10,07; B 5,69).

Phenyl-methylborsäure-n-propylester. Aus Phenylborsäuredi-*n*-propylester und Methylmagnesiumbromid im Molverhältnis 1 : 1. Kp. 87−9°/9 Torr. $n_D^{25} = 1{,}4880$; $d_4^{25} = 0{,}8985$. (Gef. C 73,6; H 9,17; B 6,75. Ber. für $C_{10}H_{15}OB$ (162,0): C 74,1; H 9,33; B 6,68).

Phenyl-methylborsäure entsteht bei der Hydrolyse von Phenyl-methylborsäure-*n*-propylester. Sie bildet eine farblose Flüssigkeit, die mit Wasserdampf flüchtig ist. Sie ist etwas löslich in Wasser.

Umsetzung von Phenyl-methylborsäure-n-propylester mit Methylmagnesiumbromid. 2,5 g Phenyl-methylborsäure-*n*-propylester wurden mit 15 ml Methylmagnesiumbromid (7 % Überschuss) versetzt. Das Reaktionsprodukt wurde in der üblichen Weise aufgearbeitet. Es konnten Triphenylbor und eine leichtflüchtige, an der Luft selbstentzündliche Substanz (Trimethylborin ist ein Gas vom Kp. −20°) nachgewiesen werden. Phenyldimethylborin wurde nicht gewonnen.

Für die ökonomische Unterstützung dieser Arbeit bin ich *Edlunds Stipendiefond* zu besonderem Dank verpflichtet.

ACTA CHEMICA SCANDINAVICA 9 (1955) 246—250

2,4-Dihydroxyphenanthrene, a Phenanthrene Analogue of *cis*-Pinosylvin

BERNT CARNMALM

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

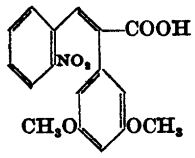
2,4-Dihydroxyphenanthrene has been prepared and was found to be less toxic than pinosylvin against certain wood-rotting fungi. The synthesis was performed according to the Pschorr procedure. The method of Cook and Hewett was not found to be satisfactory in this particular case.

Pinosylvin, 3,5-dihydroxy-*trans*-stilbene, and its monomethylether are the main toxic principles of the heartwood of pines. Their physiological properties have been studied by several authors[1-6]. 2,4-Dihydroxyphenanthrene (III) embodies the skeleton of *cis*-pinosylvin (IV) and it was considered to be desirable to prepare this phenanthrene derivative in order to compare its toxicity against wood-rotting fungi with that of pinosylvin. Similar products obtained from cheap starting materials such as resin acids might possess technical potentialities and it is interesting to note that several phenolic diterpenes have been isolated from the heartwood of various conifers [7].

2,4-Dihydroxyphenanthrene has been synthesised by a somewhat modified Pschorr procedure. 3,5-Dimethoxybenzoyl chloride was transformed by the Arndt-Eistert method into 3,5-dimethoxyphenylacetic acid (previously prepared by Mauthner [8] by a different route) and the latter compound was then condensed with *o*-nitrobenzaldehyde. The resulting *o*-nitro-α-(3,5-dimethoxyphenyl)-cinnamic acid (I) was reduced to the corresponding amino acid which after diazotisation and cyclisation yielded 2,4-dimethoxyphenanthrene-10-carboxylic acid (II). This compound, on decarboxylation followed by demethylation with pyridinium chloride, furnished 2,4-dihydroxyphenanthrene (III).

An attempt was also made to prepare 2,4-dihydroxyphenanthrene according to the method of Cook and Hewett. The crude tertiary alcohol from the reaction of 3,5-dimethoxy-β-phenyl-ethyl magnesium bromide with *cyclo*hexanone was cyclised by treatment with a sulphuric-acetic acid mixture and various dehydrogenation experiments were carried out on the product. In no case, however, could any recognisable products be isolated apart from un-

changed starting material. This result is almost certainly due to the fact that the spirane (V) and not the desired octahydro-phenanthrene (VI) is produced in the cyclisation reaction (*cf.* Cook *et al.*[9] and Barnes[10]).



I

VI

The toxicity of 2,4-dihydroxyphenanthrene and pinosylvin to some fungi has been studied by Docent E. Rennerfelt, Statens Skogsforskningsinstitut, Stockholm, to whom I am much indebted. In agar cultures no growth of the mycelia was observed with the following substances and organisms. Pinosylvin: 0.005 %, *Peniophora gigantea* and *Polyporus annosus;* 0.01 %, *Polyporus abietinus;* 0.02 %, *Fusarium culmorum* and *F. oxysporum.* (*Ophiostoma pini* was not inhibited at this concentration.) 2,4-Dihydroxyphenanthrene: 0.01 %, *Fusarium culmorum* and *Peniophora gigantea;* 0.02 %, *Fusarium oxysporum.* (*Ophiostoma pini, Polyporus abietinus* and *P. annosus* were not inhibited at this concentration.) It is thus apparent that 2,4-dihydroxyphenanthrene is a weaker fungicide than pinosylvin.

EXPERIMENTAL *

ω-Diazo-3,5-dimethoxyacetophenone. A solution of 3,5-dimethoxybenzoyl chloride (20 g) in absolute ether (300 ml) was slowly added with mechanical stirring to an excess of diazomethane in ether (prepared from 50 g of nitrosomethylurea in 600 ml of ether and dried over potassium hydroxide) at −5°. The solution was then allowed to stand for 4 hours, filtered from a small amount of a gummy impurity and evaporated *in vacuo* at about 30°. The yellow residue was dried in a vacuum desiccator. The diazo ketone could be crystallized from benzene-petroleum ether forming yellow needles melting at 72−73.5° without appreciable decomposition (the melt crystallized on cooling). At about 90°, however, decomposition took place. Yield 20.2 g. (Found: OCH_3 28.75. Calc. for $C_{10}H_{10}N_2O_3$ (206.2): OCH_3 30.01.)

ω-Chloro-3,5-dimethoxyacetophenone. To a solution of ω-diazo-3,5-dimethoxyacetophenone (200 mg) in ethanol (2 ml) was added conc. hydrochloric acid (0.3 ml). When the evolution of nitrogen had ceased the solution was heated and diluted with hot water. The chloro-ketone separated on cooling and was crystallized from ethanol (leaflets), m.p. 72.5−73.5°. (Found: Cl 16.5; OCH_3 29.13. Calc. for $C_{10}H_{11}O_3Cl$ (214.7): Cl 16.2; OCH_3 28.91.)

* All melting points uncorrected.

3,5-Dimethoxyphenylacetic acid. A solution of ω-diazo-3,5-dimethoxyacetophenone (20 g) in absolute ethanol (300 ml) was heated on a waterbath to 55—60° and silver oxide (from 30 ml of a 10 % silver nitrate solution) added in small portions with mechanical stirring during 3—4 hours. The solution was then boiled for one hour, filtered through a thin layer of animal charcoal and evaporated *in vacuo*. The residual ester was distilled yielding a colourless oil (17.4 g) b.p. 164—166°/8 mm. The ester was boiled for one hour with sodium hydroxide (100 ml: 2 *N*) and after cooling and filtering the solution was acidified and the precipitate collected (15 g) and crystallized from water. M.p. 102—103°, Mauthner [8] gives 99—100°.

o-Nitro-α-(3,5-dimethoxyphenyl)-cinnamic acid (I). A solution of 3,5-dimethoxyphenylacetic acid (12 g), *o*-nitro-benzaldehyde (9.5 g) and triethylamine (8.9 ml) in acetic anhydride (30 ml) was heated on a waterbath for 24 hours, water (6 ml) was carefully added and the heating continued for 0.5 hour. The mixture was then poured into dilute hydrochloric acid (500 ml) and the precipitated gum dissolved in dilute sodium hydroxide. After shaking with ether the alkaline solution was acidified giving a brownish yellow precipitate which was collected, dried and triturated with cold benzene (3 × 50 ml) giving a crystalline product. After one crystallization from benzene (50 ml) the yellow product (7.1 g) melted at 153—160°. It was used for the next step without further purification. After repeated crystallizations from ethanol the yellow prisms melted at 179.5—180.5°. (Found: OCH_3 18.93. Calc. for $C_{17}H_{15}NO_6$ (329.3): OCH_3 18.85.)

o-Amino-α-(3,5-dimethoxyphenyl)-cinnamic acid. The *o*-nitro-α-(3,5-dimethoxyphenyl cinnamic acid (6 g) was dissolved in aqueous ammonia (conc. ammonia 20 ml, water 30 ml) and the solution added to a hot mixture of ferrous sulphate (45 g $FeSO_4 \cdot 7\ H_2O$) and ammonia (conc. ammonia 160 ml, water 250 ml). The mixture was heated on a waterbath for 1.5 hours and after cooling the solution was filtered and carefully made slightly acid with hydrochloric acid. The greenish yellow precipitate (3.9 g) crystallized from ethanol in yellow prisms, m.p. 189—190°. (Found: OCH_3 20.39. Calc. for $C_{17}H_{17}NO_4$ (299.3): OCH_3 20.74.)

2,4-Dimethoxyphenanthrene-10-carboxylic acid (II). The *o*-amino-α-(3,5-dimethoxyphenyl)-cinnamic acid (3 g) was dissolved in sodium hydroxide solution (20 ml; 2 *N*) and precipitated with sulphuric acid (120 ml; 2 *N*). The mixture was cooled to about 0° and an aqueous solution of sodium nitrite (15 ml containing 0.8 g of sodium nitrite) was added dropwise with stirring. The stirring was continued for 4 hours and the excess of nitrite was then destroyed with urea. The yellow solution was filtered and the filtrate heated on a waterbath until it gave no colour reaction with α-naphthol. The precipitated acid was collected (2.6 g) and crystallized from ethanol (long needles), m.p. 225.5—226°. (Found: OCH_3 22.16. Calc. for $C_{17}H_{14}O_4$ (282.3): OCH_3 21.99.)

2,4-Dimethoxyphenanthrene. 2,4-Dimethoxyphenanthrene-10-carboxylic acid (2 g) was heated with Adkin's copper chromite catalyst (80 mg) in quinoline (10 ml). The evolution of carbon dioxide started at 210° and ceased after 1.5 hours at 220°. The mixture was cooled, poured into dilute hydrochloric acid and extracted with ether. The ethereal layer was washed successively with hydrochloric acid, dilute sodium hydroxide and water, dried over calcium chloride and evaporated. An oil was obtained which crystallised when triturated with a little methanol. The product (1.6 g) was distilled *in vacuo* and crystallized from ethanol (needles), m.p. 75.5—76.5°. (Found: OCH_3 25.8. Calc. for $C_{16}H_{14}O_2$ (238.3): OCH_3 26.05.)

2,4-Dihydroxyphenanthrene (III). 2,4-Dimethoxyphenanthrene (1 g) was heated with pyridinium chloride (3 g) at 180° for 2 hours and the mixture poured into dilute hydrochloric acid. A precipitate was formed which was dissolved in ether, washed with hydrochloric acid and filtered through aluminium oxide. After evaporation of the ether a light brownish residue (0.7 g) was obtained which was crystallized from water (animal charcoal) giving a slightly pink coloured product melting at 156.5—157°. (Found: C 80.35; H 4.79. Calc. for $C_{14}H_{10}O_2$ (210.2): C 79.98; H 4.79.)

2,4-Diacetoxyphenanthrene was prepared from 2,4-dihydroxyphenanthrene using acetic anhydride in pyridine. The product crystallized from ethanol in prisms, m.p. 136—137°. (Found: C 73.35; H 4.88. Calc. for $C_{18}H_{14}O_4$ (294.3): C 73.46; H 4.79.)

2,4-Dibenzoyloxyphenanthrene prepared from 2,4-dihydroxyphenanthrene by the Schotten-Baumann method crystallized from ethanol in prisms, m.p. 184—184.5°. (Found: C 80.23; H 4.38. Calc. for $C_{28}H_{18}O_4$ (418.4): C 80.37; H 4.34.)

3,5-Dimethoxy-β-phenylethyl alcohol. A solution of ethyl 3,5-dimethoxyphenylacetate (16 g) in absolute ether (100 ml) was slowly added with mechanical stirring to a slurry of lithium aluminium hydride (4 g) in dry ether (400 ml) at a rate sufficient to keep the solution boiling. The mixture was boiled for an additional 0.5 hour and the excess of hydride then destroyed by careful addition of water (15 ml) with cooling. Sulphuric acid (175 ml, 10 %) was added and the ethereal layer washed with water, dried over anhydrous sodium sulphate and the ether evaporated. The residue, distilled *in vacuo*, gave 3,5-dimethoxy-β-phenylethyl alcohol as a colourless oil (12 g), b.p. 126—130°/1—2 mm. The 3,5-dinitrobenzoate, prepared by heating the alcohol with 3,5-dinitrobenzoyl chloride in dry pyridine for a short time, crystallized from benzene-ligroin as yellow needles, m.p. 141.5—142°. (Found: OCH_3 15.33. Calc. for $C_{17}H_{16}N_2O_8$ (376.3): OCH_3 16.49.)

3,5-Dimethoxy-β-phenylethyl bromide. To a solution of 3,5-dimethoxy-β-phenylethyl alcohol (10 g) in carbon tetrachloride (20 ml) at 60° was added phosphorus tribromide (8 g) in one portion and the mixture refluxed for 45 minutes. The solution was washed with sodium carbonate solution followed by water, dried over anhydrous sodium sulphate and the solvent evaporated. The residue was distilled *in vacuo* yielding a colourless oil (8.2 g), b.p. 125—128°/1—2 mm. Redistillation followed by cooling of the distillate gave 3,5-dimethoxy-β-phenylethyl bromide as a solid, m.p. 20—22°. (Found Br 32.3; OCH_3 25.3. Calc. for $C_{10}H_{13}O_2Br$ (245.1): Br 32.6; OCH_3 25.3.) The bromide when refluxed with the silver salt of 3,5-dinitrobenzoic acid in dry benzene for 12 hours gave 3,5-dimethoxy-β-phenylethyl-3,5-dinitrobenzoate m.p. 144—145°, undepressed on admixture with a sample of the compound prepared from the alcohol as previously described.

1-β-(3,5-Dimethoxyphenyl)-ethylcyclohexanol. A mixture of 3,5-dimethoxy-β-phenylethyl bromide (7.5 g), magnesium turnings (0.8 g), a crystal of iodine and absolute ether (30 ml) was boiled until most of the metal had passed into solution. *Cyclo*hexanone (3.5 ml) in ether (10 ml) was then slowly added with cooling when a heavy oil separated. The reaction mixture was decomposed with ammonium chloride solution, the ethereal layer washed with sodium bisulphite solution followed by water and dried over anhydrous sodium sulphate. Evaporation of the ether followed by distillation gave 1-β-(3,5-dimethoxyphenyl)-ethyl*cyclo*hexanol (3.2 g) as a viscous, slightly yellowish oil, b.p. 165—170°/1—2 mm.

Cyclisation of 1-β-(3,5-dimethoxyphenyl)-ethylcyclohexanol. 1-β-(3,5-Dimethoxyphenyl)-ethyl*cyclo*hexanol (2 g) was refluxed for 1 hour with a mixture of glacial acetic acid (20 ml) and concentrated sulphuric acid (2 ml). The reaction mixture was poured into water, the product extracted with ether and the ethereal solution washed with sodium carbonate solution followed by water and dried. Evaporation of the ether gave a thick brownish yellow syrup containing some crystals. Distillation *in vacuo* (12 mm) afforded a colourless oil which immediately crystallized. Recrystallization from ethanol gave the substance as colourless prisms, m.p. 95—96°. (Found: C 78.0; H 9.07. Calc. for $C_{16}H_{22}O_2$ (246.3): C 78.01; H 9.00.)

Dehydrogenation experiments. (a) Sulphur. A mixture of cyclisation product (225 mg) and sulphur (115 mg) was heated to 210° when evolution of hydrogen sulphide commenced. After one hour at 220° the reaction mixture was distilled *in vacuo* but only a dark tar was obtained. A similar result was obtained when the reaction was carried out by heating *in vacuo* (200 mm) for one hour at 170° and then for an additional 0.5 hour at 200°.

(b) Selenium. Cyclisation product (200 mg) was heated with selenium (250 mg) at 290—300° for 12 hours. Hydrogen selenide was evolved but no recognisable product could be isolated from the reaction.

(c) Catalytic dehydrogenation. A 10 % palladium-carbon catalyst was employed under varying conditions — with the catalyst alone or with naphthalene or tetralin as solvent or with cinnamic acid as hydrogen acceptor. In all experiments either the substance was recovered unchanged or else intractable material was produced.

The Conversion of Orotic Acid to Uridine Nucleotides *in vitro*

ROBERT B. HURLBERT* and PETER REICHARD

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

The conversion of radioactive orotic acid to 5′-uridine monophosphate and three 5′-uridine pyrophosphate nucleotides was effected by dialyzed particle-free extracts from a number of animal and avian tissues. Ribose-5-phosphate, ATP and magnesium ion were required for the conversion. The conversion could also be obtained in extracts metabolizing hexose diphosphate. Chromatographic evidence indicated the 5′-uridine nucleotides to include uridine diphosphate and uridine triphosphate. Uridine and uracil were found not to be intermediates in the conversion although these compounds could be produced from the uridine nucleotides by enzymes present in the extracts.

By the use of a partially purified enzyme preparation from chicken liver it was demonstrated that ribose-5′-phosphate and ATP react to produce ribose triphosphate, presumably 5-phosphoribosyl pyrophosphate, and that this compound is the source of the ribose phosphate moiety of the uridine nucleotides. Ribose-1,5-diphosphate was inactive with this enzyme preparation, even in the presence of ATP. The 5′-uridine monophosphate was the first of the uridine nucleotides to be formed; the other nucleotides arose by the action of phosphorylating enzymes present in other enzyme fractions.

Recent evidence has demonstrated that orotic acid is a key intermediate in a series of metabolic reactions whereby the uracil of the polynucleotides is formed. Orotic acid was first found to be utilized as a specific precursor of the pyrimidines in the nucleic acids of the rat by Arvidson *et al.*[1] (*cf.* also [2]). It has since been shown to be a normal intermediate in the formation of the polynucleotides [3] and the individual steps in its enzymatic synthesis from aspartic acid, ammonia and carbon dioxide have been described [4–7]. In the liver of the living rat the compound was found to be converted almost quantitatively into the free uridine nucleotides ** which were apparently closely involved as pre-

* Fellow of the American Cancer Society, 1953—54. Present address: Universitetets Institut for Cytofysiologi, Copenhagen, Denmark.

** 5′-Uridine phosphate (UMP), 5′-uridine diphosphate (UDP), 5′-uridine triphosphate (UTP) and several 5′-uridine pyrophosphoglycosyl compounds. Other abbreviations used in this paper are: 5′-adenosine nucleotides (AMP, ADP and ATP) and diphosphopyridine nucleotide (DPN).

cursors of the polynucleotide uracil [8]. The widespread occurrence of many enzymatic reactions of the uridine nucleotides has been the subject of numerous other reports (*cf.* Ref.[9]). Further detailed study of the reaction sequences involving orotic acid is of great importance in learning the overall mechanism of the formation of the polynucleotides.

In a continuation of the investigations previously carried out with living rats and rat liver slices, we have been engaged in studying the enzymatic processes by which the orotic acid is utilized. The object of this paper is to describe studies on the formation *in vitro* of the uridine nucleotides and to attempt to correlate the *in vivo* and *in vitro* processes. During the course of this project * the publications of Kornberg *et al.*[11,12] have appeared, which elucidate the enzymatic steps whereby orotic acid reacts with 5-phosphoribosyl pyrophosphate to form orotic acid ribotide and the subsequent decarboxylation of this product to form UMP. Our work has been done with different sources and procedures and is found to confirm and supplement that of Kornberg *et al.* A preliminary publication has appeared [13].

EXPERIMENTAL

Orotic acid-2-^{14}C containing about 1 μC per μmole was prepared by oxidation of $K^{14}CN$ to KCNO, by the method of Gall and Lohman [14] and the condensation of the KCNO with aspartic acid, by the method of Nyc and Mitchell [15].

Preparation of the particle-free extracts. The tissue was homogenized [10] in 4 volumes of 0.13 *M* KCl – 0.01 *M* $MgCl_2$ – 0.015 *M* potassium phosphate, pH 7.2, in a Potter-Elvehjem homogenizer and centrifuged at 60 000 – 70 000 g for 30 minutes in a Spinco centrifuge. Fat particles were partially removed by decantation of the supernatant solution through cotton or glass wool. The extracts were dialyzed against the same medium (50 ml of extract *versus* two successive 2 liter volumes) for 12 – 15 hours. All these operations were at 0 – 5° **.

Incubation. In the "hexose diphosphate system" the amounts of substrate used were: 0.5 μmole of orotic acid-2-^{14}C, 20 μmole of hexose diphosphate, 1.5 μmole of DPN, 120 μmole of nicotinamide and 2.0 ml of the tissue extract. In the "ribose phosphate system" the amounts used were: 0.5 μmole of orotic acid-2-^{14}C, 20 μmole of ribose phosphate, 20 μmole of 3-phosphoglyceric acid, 5 μmole of ATP and 2.0 ml of the tissue extract. In some experiments 3 mg of a muscle enzyme preparation [16] were also added to ensure utilization of the phosphoglyceric acid for regeneration of the ATP. The total volumes of both incubation systems were 4.0 ml. The incubations were carried out in 25 ml. Erlenmeyer flasks, which were shaken at 37° for 40 minutes.

At the end of the incubation period, the flasks were chilled and made to 0.4 *N* perchloric acid. The precipitated proteins were centrifuged and washed once with 1 ml of cold 0.2 *N* perchloric acid. The perchloric acid was neutralized in an ice bath with KOH, using phenol red as an internal indicator. The neutralized extract was decanted onto the chromatographic column through glass wool to remove the $KClO_4$ precipitate, which was washed once with cold water. The $KClO_4$ retained less than 2 % of the ^{14}C.

Chromatography. The principle of the gradient elution procedure previously described [17] was used although the technique was simplified to permit rapid routine work. Four columns, 6 cm × 1 cm, of Dowex-2 (formate) were eluted simultaneously by increasing concentrations of eluent from one 500 ml mixing flask, which received the

* The original observation of Saffran and Scarano [10], that 5-phosphoribose is utilized by pigeon liver extracts to convert adenine to AMP, provided a valuable stimulus for the work with orotic acid.

** The activity of the extract in the "hexose diphosphate system" diminished 20—40% during the dialysis. The larger losses were found at the higher temperatures and longer times of dialysis.

concentrated eluent by gravity flow from the reservoir flask. Fractions of 5 ml volume were collected by an automatic collector. The mixing flask initially contained water and the reservoir flask 6 *N* formic acid; after 25 fractions had been collected from each column (resulting in a concentration of formic acid in the mixing flask of about 4 *N*) the reservoir flask was changed to contain 4 *N* formic acid — 1.5 *M* ammonium formate. Another 25 fractions were collected so that the final concentration of eluent in the mixing flask was about 4 *N* formic acid — 1 *M* ammonium formate. All of the ^{14}C was eluted from the columns in this way.

The light absorption of the fractions was read at 260 mμ in a Beckman spectrophotometer, Model DU, primarily to detect the adenosine nucleotide peaks. Small aliquots of each fraction were plated on aluminum planchets, dried at 60—80° to remove ammonium formate, and the radioactivity was counted 30 seconds in a Tracerlab Sc-18 windowless flow counter. The procedure could readily detect the presence in one fraction of 0.5 % of the ^{14}C used in each experiment. The fractions containing each radioactive peak were later combined and the amounts of ^{14}C were determined again by plating and counting more accurately. The amount of ^{14}C in each peak recorded in Tables 1—4 is given as the percent of the total *summated* radioactivity in the entire chromatogram. The reproducibility of recovery of the radioactivity used in the experiment was within about ± 10 %.

The location of the various peaks found on these chromatograms was as follows: Uridine and uracil ("U") were in fraction 1 (containing the effluent from the sample placed onto the column) and fraction 2, AMP was in fractions 6—7, UMP in 18—20, orotic acid and ADP in 22—24, "UX" in 32—33, "UDP" and ATP in 35—37 and "UTP" in 42—43. When the columns were identical with regard to dimensions and flow rate the position of these peaks was reproducible. The "UX", "UDP" and "UTP" peaks are so designated because their chromatographic behaviour corresponded to that of the known compounds described in previous work [17], although in the present work they were not rigorously identified.

Enzyme fractionation. The fractionation procedure was used for rat, pigeon and chicken liver preparations. It will be described here for chicken liver.

The particle-free extract from 60—80 g of liver was fractionated by the addition of solid ammonium sulfate to obtain the protein precipitable between 35 % (0.245 g of ammonium sulfate per ml) and 45 % of saturation. This fraction contained most of the activity towards orotic acid. The precipitate was dissolved in 30 ml of 0.03 *M* phosphate buffer, pH 6.6, and dialyzed against 2 successive 2 liter volumes of the same buffer, at 1—2°, for a total of 2 hours. The protein solution was made to 50 ml with the buffer and 10 ml of methanol was added at the rate of 1 ml per minute while the temperature was being lowered to —5°. After another 10 minutes the precipitate was centrifuged at —5°. This precipitate contained little activity. A mixture of 5 ml of 0.08 *M* sodium acetate buffer, pH 4, and 1 ml of methanol was added slowly at —5°, followed by centrifugation as before. This precipitate contained most of the activity. The pH of the supernatant solution was 6.0. A third precipitate obtained by lowering the pH to 5.5 in a similar way was usually inactive. The active fraction, termed the "pH 6 methanol" fraction, was dissolved in 10 ml of 0.02 *M* phosphate buffer, pH 7.2, lyophilized and stored at 0°. This preparation retained its activity well for at least 2 weeks.

Direct spectrophotometric assay of enzyme activity. With the partially purified enzyme fractions a direct spectrophotometric assay for the disappearance of orotic acid was possible. A solution of 0.3 ml volume containing 0.1 μmole of non-radioactive orotic acid, 0.2 μmole of ATP, 0.2 μmole of ribose-5-phosphate, 1.25 μmole of $MgCl_2$, 15 μmole of phosphate buffer, pH 7.4, and 0.5—1.5 mg of lyophilized enzyme was incubated for periods up to 2 hours at 37°, then chilled during the addition of 1.25 ml of cold 0.5 *N* perchloric acid, and centrifuged. For each determination a second solution was prepared and treated identically with the first except that the orotic acid was omitted. The supernatant solutions, in 1 ml quartz cuvettes, were read at 260, 280, 300 and 350 mμ against an appropriate perchloric acid blank. To obtain the change in spectrum resulting from the action of the enzymes on the orotic acid, the readings of the "minus orotic" sample were subtracted from those of the "orotic" sample. This correction was necessary because during the incubation changes in the spectrum occurred, apparently arising from the protein. As a measure of the initial concentration of orotic acid, a solution of orotic acid in perchloric acid (without substrates or enzyme) was also prepared and analyzed in

an identical way. The amount of orotic acid converted was calculated directly from the decrease in the corrected reading at 300 mμ, where neither ATP nor UMP absorb. The readings at 260 and 280 were made to check on the formation of UMP, which absorbs maximally at 260 mμ. Small corrections for the light absorption of traces of colloidal protein were made by substracting the readings made at 350 mμ from the readings at 300 mμ.

Preparation of ribose triphosphate. A solution of 25 ml volume, containing 150 μmole of ribose-5-phosphate, 100 μmole of ATP, 100 μmole of $MgCl_2$, 950 μmole of phosphate buffer, pH 7.4, 900 μmole of NaF, and 200 μmole of reduced glutathione, was incubated at 37° with 20 mg of the "pH 6 methanol" enzyme. These conditions are basically those of Kornberg, *et al.*[11]. The reaction was followed by the use of adenylic acid deaminase to determine the amount of AMP produced from the ATP [18]. For this determination, 15 μl aliquots were removed into 1.0 ml of pH 6.0 citrate buffer and the change in light absorption at 265 mμ was determined upon the addition of the deaminase. When no further formation of AMP could be detected by this test (about 1.5 hours), the reaction was stopped by pouring the solution directly onto a 12 cm × 2 cm Dowex-1 (formate) column. The column was washed well with water and gradient elution was begun with water in the 500 ml mixing flask and with 2 *M* sodium formate of pH 5 in the reservoir flask. About 100 fractions of 6 ml volume were collected; these were analyzed for their ribose content and light absorption at 260 mμ. The ribose triphosphate was eluted in 5 fractions between the AMP and ADP. These fractions were low in light absorption. The combined fractions were adjusted to pH 7.0 with KOH, 0.5 ml of 2 *M* barium acetate was added, and the ribose triphosphate was precipitated by 1 volume of cold ethanol. After one hour at 0°, the precipitate was collected by centrifugation and washed successively with cold 50 % ethanol, ethanol and ether. Analysis of the best of these preparations, used for the work described later, indicated a ratio of ribose: acid-labile phosphate: total phosphate of 1 : 2.04 : 3.01 and a purity of 42 % (calculated with 2.5 Ba per ribose).

Ribose-1,5-diphosphate was prepared from ribose-1-phosphate and glucose diphosphate with crystalline mutase according to Klenow [19]. Purification was effected by gradient elution chromatography with 1 *M* sodium formate, pH 5, and precipitation with barium acetate as described for ribose triphosphate. The substance had a ratio of ribose: acid-labile phosphate: total phosphate of 1.0 : 0.99 : 2.06 and was 77 % pure, calculated as the dibarium salt.

Uridine-2-^{14}C and uracil-2-^{14}C were prepared from radioactive UMP by hydrolysis with 98 % formic acid at 175° for 4 hours followed by chromatography on a starch column [20].

RESULTS

The conversion of orotic acid to the uridine phosphates was initially tested in homogenates of rat liver metabolizing hexose diphosphate. The chromatographic analysis for the orotic acid, uridine nucleotides and adenosine nucleotides was employed. Small conversions of the orotic acid to uridine nucleotides and the "U" peak were noted when the homogenates were metabolizing the hexose diphosphate either aerobically or anaerobically. In both systems the amount of conversion appeared to be dependent upon the length of time the ATP levels were maintained. Both the maintenance of ATP and the conversion of orotic acid were then found to be greatly improved in the glycolyzing system when the particulate cell components were first removed by high speed centrifugation. Anaerobic incubation was not necessary in the particle-free system. The enzymes metabolizing orotic acid to the uridine nucleotides occur therefore in the non-particulate portion of the cytoplasm and, judging by the recovery of total activity, appear to be located primarily in this fraction.

A large number of exploratory experiments were carried out by incubating extracts of rat and pigeon liver with various combinations of substrates, activators and inhibitors. The relative amounts of orotic acid converted to

"U" and the various uridine nucleotides as well as the relative amounts of the adenosine nucleotides were determined chromatographically. When the particle-free extracts were dialyzed they were no longer active in the conversion unless hexose diphosphate, DPN and magnesium ion were added. (The addition of ATP was not necessary; however traces of ATP, perhaps arising from AMP in the DPN, were detectable chromatographically at the end of the incubations.) Phosphoglyceric acid was capable of partially replacing hexose diphosphate in this system. No conversion was obtained in the absence of either magnesium ion or DPN, nor in the presence of the glycolysis inhibitor iodoacetate *. It was apparent that the hexose diphosphate was serving both as a source of energy (*via* glycolysis and ATP) and of the ribose moiety of the uridine nucleotides.

The dialyzed extracts of pigeon liver (but not of rat liver *) could also be activated by addition of ribose-5-phosphate, provided ATP and magnesium ion were also present. DPN was not required. The full activity of the extract was not obtained in this way, apparently due to the destruction of ATP, since no ATP was detectable at the end of the incubation. However, the ATP level could be maintained and full activity obtained in both rat and pigeon liver extracts by the addition of phosphoglyceric acid, to serve as an energy source for the regeneration of ATP. (Phosphoglyceric acid in the absence of DPN could not replace ribose phosphate in this system.) From these data and from the work of Saffran and Scarano [10], it seemed probable that the ribose phosphate was providing the ribose moiety of the uridine nucleotides much more directly than did the hexose diphosphate and that ATP was a necessary reactant. Knowledge of the multiplicity of enzymes in the extract could not permit such an assumption to be conclusive, however **.

In the chromatograms of these reaction mixtures, five radioactive peaks in addition to the orotic acid were usually obtained. The first of these, the "U" peak, was in some experiments found to contain primarily uracil and some uridine as the radioactive components. For this work a warm butanol extract of the dried "U" peak (collected from a number of experiments) was chromatographed on a starch column with butanol-water [20]. The radioactive peaks were identified by their spectrum, R values and by recrystallization with authentic carrier uracil (solvent: water) and uridine (solvent: alcohol-ethylacetate).

The second peak contained UMP, which was identified by spectrum, phosphorus and ribose content, and by liberation of the phosphate group by snake venom 5′-nucleotidase [21, 22]. The three following peaks, labeled "UX", "UDP" and "UTP", corresponded in their chromatographic behaviour to the UDP-hexose, UDP and UTP of rat liver [17, 22], and contained uridine-5′-phosphate which could be liberated by hydrolysis with 1 N H_2SO_4 at 100° for 15 minutes. From larger scale incubation mixtures, the "UX" and "UDP" peaks were isolated by rechromatography with pH 5 ammonium formate [17].

* In pigeon liver extracts, which destroyed ATP much less rapidly than did rat liver extracts, some conversion of orotic acid could be obtained in the presence of iodoacetate by the addition of sufficient ATP (10—20 μmoles).

** Ribose phosphate and magnesium ion *in the presence of DPN* were also capable of generating ATP and effecting the conversion of orotic acid.

Analysis of both peaks indicated the ratio of uridine: total phosphate to be 1 : 2. The presence of either a hexose or a pentose in the "UX" peak could not be clearly determined*. Insufficient "UTP" was obtained for clear analyses. All of these peaks were usually found in the chromatograms of both the "hexose diphosphate" and "ribose phosphate" systems. The relative amounts of the peaks varied with the length of incubation, ATP level, age of the extract and the tissue source.

A number of tissues and one micro-organism were examined for their ability to carry out these conversions in the "ribose phosphate system". In these incubations, 3 mg of a muscle enzyme preparation [16] was added to assist maintenance of ATP; the muscle preparation itself had no activity towards orotic acid in the "ribose phosphate system". The results are presented in Table 1.

Table 1. Formation of uridine nucleotides from orotic acid-2-^{14}C by particle-free extracts of various tissues.

Tissue	Percent of total ^{14}C in chromatographic peaks					
	"U"	UMP	OR	"UX"	"UDP"	"UTP"
Pigeon Liver *	1	19	36	9	22	13
Chicken Liver	2	18	0	14	25	41
Rat Liver	11	52	0	27	9	1
Mouse Liver	24	53	0	20	3	0
Chicken Pancreas	0	0	0	4	2	94
Rat Kidney	19	7	68	5	1	0
Rat Spleen	41	47	0	6	6	0
Rat Heart	0	0	98	0	2	0
Mouse Kidney	14	27	53	5	1	0
Mouse Tumor **	4	23	25	16	15	17
E. coli ***	16	9	30	8	14	23

Each extract was prepared from 400 mg of tissue and incubated for 40 minutes at 37° with 0.5 μmole of orotic acid (500 000 c/min) in the "ribose phosphate system" (see text) with the addition of phosphoglyceric acid and muscle enzyme [16]. Cold perchloric acid extracts of the reaction mixture were made and chromatographed on Dowex-2 (formate) by elution with formic acid and ammonium formate. The radioactive peaks obtained are labeled "U" for uracil and uridine, UMP for uridine monophosphate, OR for remaining orotic acid, and "UX", "UDP" and "UTP" for the uridine pyrophosphate nucleotides.

* Phosphoglyceric acid and muscle enzyme *not* added.

** Spontaneous mammary tumor from C3H mice, kindly provided by Dr. Georg Klein.

*** Cell-free extract (prepared by repeated freezing and thawing from 50 mg of lyophilized *Escherichia coli*).

* The "UX" peak of an experiment with rat liver extract, ribose phosphate and phosphoglyceric acid was later rechromatographed and found to contain 43 % UDP-Glucose and 42 % UMP (the latter arising by degradation). For the spectrophotometric demonstration of the UDPG (by means of uridyl transferase, phosphoglucomutase and Zwischenferment [18]), we wish to thank Civ. Ing. Agnete Munch-Petersen.

A number of experiments were carried out with rat and pigeon liver in attempts to determine which of the radioactive products was formed first. Time curves indicated UMP to be the dominant peak at early time intervals (*cf.* Ref.[13], Fig. 1). The addition of non-labeled UMP to the incubation mixture (Table 2) increased the relative amount of incorporation into the UMP peak initially and greatly diminished the incorporation into the uridine pyrophosphates. This indicated the UMP to be the first uridine nucleotide product. The large shift of radioactivity into the "U" peak in the later time intervals of the experiment was interpreted to mean that the "U" peak was formed primarily by degradation of the UMP*. The addition of non-radioactive uridine did not greatly affect the distribution of radioactivity, which eliminated this compound from consideration as an intermediate in the conversion. Later work with partially purified enzymes verified these interpretations.

Table 2. Formation of uridine nucleotides from orotic acid-2-^{14}C: Effect of added pools of non-radioactive UMP or uridine.

Non-radioactive pool	Incubation Time Minutes	Percent of total ^{14}C in chromatographic peaks					
		"U"	UMP	OR	"UX"	"UDP"	"UTP"
UMP	5	0.3	2.4	96.0		0.8	0.5
UMP	10	1.7	5.7	89.0		1.9	1.7
UMP	40	30.5	10.4	55.4	1.0	2.7	
Uridine	40	1.7	0.4	63.0	12.7	9.5	12.7
None	40		1.0	59.0		40.0	

Particle-free extracts from 200 mg of rat liver were incubated at 37° with 0.5 μmole of orotic acid (500 000 c/min) in the "hexose diphosphate system" (see text). Pools of non-radioactive UMP (4 μmole) or uridine (2 μmole) were added as noted. The reaction mixtures were analyzed as in Table 1.

The enzymes of the particle-free extract were fractionated in order to determine which substrates and products were immediately concerned in the utilization of orotic acid. The fractionations were carried out with preparations from rat, pigeon and chicken livers. The latter proved to be the best source for the larger scale preparations, although similar results were obtained with all these tissues. The preparation of the active 35—45 % ammonium sulfate and the "pH 6 methanol" fractions is described earlier.

The 35—45 % ammonium sulfate fraction was tested in the "ribose phosphate system" (with the addition of the muscle enzyme preparation) and analyzed by chromatography. The results (Table 3) indicated that the enzymes

* That the "U" peak may be further metabolized is indicated by Fig. 1 [13], in which the "U" peak was formed initially and disappeared at later time intervals. This may represent conversion back to the uridine nucleotides or possibly complete degradation [24]. In other experiments with rat liver extracts plus phosphoglyceric acid and muscle enzyme, some formation of uridine nucleotides from uridine has been noted (unpublished).

degrading UMP to "U" were nearly eliminated and that the enzymes phosphorylating the UMP were diminished. Other experiments showed that the destruction of ATP by this preparation was not rapid.

Table 3. Formation of uridine nucleotides from orotic acid-2-^{14}C by 35—45 % Am_2SO_4 enzyme fraction from rat liver.

Incubation Time Minutes	Percent of total ^{14}C in chromatographic peaks					
	"U"	UMP	OR	"UX"	"UDP"	"UTP"
5		1.5	95.0	1.0	2.0	0.5
10		5.5	85.5	5.5	2.5	1.0
20	1.0	12.5	67.0	9.0	7.5	3.0
40	5.0	41.0	30.0	12.0	11.0	1.0

An amount of the ammonium sulfate fractionated enzyme containing 23 mg of protein was incubated in the "ribose phosphate system" with phosphoglyceric acid and muscle enzyme [16] (see text).

The "pH 6 methanol" enzyme preparation was tested with ribose phosphate, ATP and magnesium ion by both the chromatographic and spectrophotometric analyses. When relatively small amounts of ATP and large amounts of ribose phosphate were employed (Table 4) only UMP was formed from the orotic acid, indicating that the enzymes causing the degradation of the UMP were absent and that ATP-ase activity was negligible. Although the inclusion of phosphoglyceric acid and the muscle enzyme in the incubation mixture caused the formation of small amounts of the uridine pyrophosphates, the results indicated that the enzymes phosphorylating the UMP had been greatly reduced by the fractionation and were not essential for the reaction. Table 4 also shows that when either radioactive uridine or uracil replaced orotic acid in the incubation mixture there was no formation of uridine nucleotides. The UMP was thus demonstrated to be the first of the uridine phosphate compounds to be formed.

It appeared likely from the work of Kornberg *et al.*[11,12] that this enzyme preparation contained at least three enzymes concerned with the orotic acid utilization. In order to test for the reactions described by Kornberg *et al.*, ribose triphosphate was prepared using the "pH 6 methanol" fraction. The isolated ribose triphosphate (presumably 5-phosphoribosyl pyrophosphate) was found to be capable of replacing ribose monophosphate and ATP, when tested with the "pH 6 methanol" fraction in the direct spectrophotometric assay (Table 5). No activity was observed with the ribose triphosphate in the absence of magnesium ion. A sample of authentic ribose diphosphate, prepared according to Klenow [19] was found to be inactive with this preparation, even in the presence of ATP. Since no accumulation of orotic acid ribotide could be detected with any of the extracts or enzyme preparations employed it was not possible to make further tests for the mechanism described by Kornberg *et al.*

Table 4. Formation of uridine nucleotides from orotic acid-2-^{14}C by "pH 6 methanol" enzyme fraction. Test of activity with uracil and uridine.

Experiment	Radioactive Substrate	Time, Minutes	Percent of total ^{14}C in chromatographic peaks					
			"U"	UMP	OR	"UX"	"UDP"	'UTP"
I	Orotic acid	5		2	98			
I	»	10		6	94			
I	»	20		22	78			
I	»	40		32	68			
I	»	60		42	58			
I	Uridine	20	100					
I	Uracil	20	100					
II	Orotic acid	30		40	50		2	8

Experiment I: The incubation mixtures contained 5 μmole of ribose-5-phosphate, 0.6 μmole of ATP, 20 μmole of $MgCl_2$, 60 μmole of phosphate buffer, pH 7.4 and 8 mg of lyophilized enzyme (6.8 mg of protein). The radioactive substrates were 0.5 μmole of orotic acid (500 000 c/min) or 0.05 μmole of uridine (37 500 c/min) or 1 μmole of uracil (750 000 c/min). Total volumes were 2.5 ml.

Experiment II: The incubation mixture contained 3 μmole of ribose-5-phosphate, 3 μmole of ATP, 20 μmole of $MgCl_2$, 60 μmole of phosphate buffer, pH 7.4, 0.5 μmole of orotic acid (500 000 c/min) and 15 mg of lyophilized enzyme (10.5 mg of protein) in a total volume of 3.0 ml.

Different enzyme preparations were used in Experiments I and II. The incubation temperature was 37°.

Table 5. Conversion of orotic acid by "pH 6 methanol" enzyme fraction. Test of ribose phosphate, ribose diphosphate and ribose triphosphate in direct spectrophotometric assay.

Ribose compound	μmoles of orotic acid converted at given incubation times			
	15 min.	30 min.	45 min.	60 min.
RMP				0.000

RDP + ATP				0.000
RTP	0.012	0.023	0.028	0.031
RTP + ATP				0.036

1.0 mg of lyophilized enzyme (containing 0.8 mg of protein) was used for each determination in the direct spectrophotometric assay (see text). The initial amounts of the reactants in the assay were: 0.10 μmole of non-radiactive orotic acid, 0.20 μmole of ribose-5-phosphate (RMP), 0.15 μmole of ribose-1,5-diphosphate (RDP), 0.12 μmole of ribose triphosphate (RTP), and 0.20 μmole of ATP.

DISCUSSION

The objective of this work has been to examine some of the enzymatic steps in the utilization of orotic acid for synthesis of the polynucleotides in living tissues. It has been established that the initial reaction in the utilization is the condensation of orotic acid and ribose triphosphate with the subsequent formation of UMP. The enzymes of the non-particulate portion of the cytoplasm were responsible for these reactions. (It was, however, not determined whether such enzymes are *absent* in the cell particles.) Other enzymes of this cytoplasmic fraction were found to be capable of splitting the UMP to produce uracil and uridine, as well as of phosphorylating it to form several uridine pyrophosphate nucleotides. A different cell fraction, the mitochondrial fraction of the cytoplasm, appears to be responsible for the reactions leading to the *formation* of orotic acid [5].

Kornberg *et al.*[11, 12], have described the intermediate steps in the conversion of orotic acid to UMP. An enzyme prepared from pigeon liver reversibly catalyzed the reaction of ATP with ribose-5-phosphate to form 5-phosphoribosyl pyrophosphate. Enzymes from both pigeon liver and yeast caused coupling of the latter compound with orotic acid by elimination of pyrophosphate, followed by decarboxylation of the product to form UMP. The reversible formation of orotic acid ribotide as an intermediate was demonstrated with a yeast preparation freed of orotic acid ribotide decarboxylase activity. The decarboxylation step appeared to be essentially irreversible. We have confirmed the initial coupling of orotic acid with ribose triphosphate and, although our enzyme preparation was not free of decarboxylase activity so that the formation of orotic acid ribotide was not demonstrated, it seems probable that our system followed the reactions described by Kornberg *et al.*

A number of tissues have been examined for their ability to convert orotic acid to uridine nucleotides. Of these, liver, pancreas and spleen were relatively active, tumor and kidney were less active and heart muscle was nearly inactive. The amount of activity toward orotic acid appears to correlate roughly with the content and "turnover" of the ribonucleic acid in the tissues examined. The differences in the relative amounts of the uracil compounds formed by these tissues probably reflects different balances among the various enzyme activities involved. Such differences may be of value in preparative work; the high yield of "UTP" with the chicken pancreas is especially noteworthy in this respect. In previous work [2] a rapidly growing Flexner-Jobling tumor and other extrahepatic tissues of the *living* rat utilized only small amounts of the injected orotic acid for nucleic acid synthesis, in apparent discrepancy with work on other precursors in *in vitro* systems. The present report supports the suggestion that many tissues (including tumors) have the potential ability to utilize orotic acid, but that factors such as circulation and absorption greatly affected the results obtained *in vivo*. The conversion of orotic acid to uridine nucleotides has also been found to occur in *E. coli* (present report), yeast [11, 12], *S. aureus* [23] and mouse ascites tumor *.

* The conversion of orotic acid-4-^{14}C to the free uridine and cytidine nucleotides has also been found in ascites tumor by Dr. Hanns Schmitz (personal communication) and in oxidizing fortified homogenates of rat liver by Liselotte I. Hecht (presented at the Meeting of the American Association for Cancer Research in April, 1954).

With regard to the activity of the enzyme system converting orotic acid to UMP, the extract from 1 gram of liver could convert 1.25 μmole of orotic acid in 30—40 minutes. Although this activity does not appear great, it may be calculated that the total uridine nucleotides of the liver (about 1 μmole per gram of fresh weight) could thus be renewed from orotic acid in about one-half hour. This rate does not seem to be grossly inadequate for the supply of the uracil moiety entering the nucleic acids. (The total ribonucleic acid contains roughly 3 μmole of uracil per gram fresh weight of liver and the renewal time of the polynucleotides is of the order of many hours [2]). Whether the rate of *formation* of orotic acid in the liver is adequate to account for the uridine nucleotides formed remains to be determined. Reichard [5] has shown the rate of synthesis of ureidosuccinic acid, a precursor of orotic acid, to be more than adequate. Other pathways of uridine nucleotide formation may well exist; in fact work with other organisms indicates that uracil and possibly uridine may also be utilized to varying extents [23-26] for synthesis of polynucleotides. Whether or not this utilization proceeds through the uridine nucleotides has not been established.

The cytosine of the polynucleotides becomes labeled when orotic acid is used as precursor in living rat [1,2]. Under these conditions the free cytidine nucleotides of the liver also become labeled to a specific activity one-fourth to one-half that of the uridine nucleotides *. In the present work with the particle-free extracts, no significant formation of radioactive cytidine phosphate was noted. This negative finding may indicate either that the system used was inadequate with regard to substrates or that some of the cell particulates are involved. Further investigation of the formation of cytidine phosphate is in progress.

Acknowledgements. The authors wish to thank Mrs. Tosia Anderson and Miss Blenda Carlsson for their valuable assistance in this project. Robert B. Hurlbert also wishes to express his gratitude to Professor E. Hammarsten and the other members of the Biochemical Department for their constant encouragement and hospitality during this work. The authors would also like to express their appreciation to Drs. H. M. Kalckar and H. Klenow, in whose laboratory the preparation of the ribose phosphates was carried out.

Some Copolymers of Vinyl Alcohol-Acrylonitrile

SVEN SÖNNERSKOG*

Stockholms Superfosfat Fabriks A-B, Ljunga Verk, Sweden

Copolymers of vinyl alcohol and acrylonitrile were prepared by selective hydrolysis of emulsions of the corresponding vinyl acetate-acrylonitrile compounds with ammonia at slightly elevated temperature. The presence of acrylonitrile groups in the polyvinyl alcohol chains does not lead to increased molar cohesion and a corresponding increase in filogenic properties. However, the polymers are compatible with pure polyacrylonitrile in solution (solvent: dimethyl formamide) and synthetic fibres can be prepared from such binary systems. Compared with pure polyacrylonitrile fibres the most obvious changes are the enhanced affinity for dispersed (acetate) and acid dyestuffs. The observed decrease in tenacity and increase in elongation at break is expected.

It seems hard to understand why polyvinyl acetate has never been obtained in a crystalline state when it is remembered that the polyvinyl alcohol, obtained by alkaline hydrolysis of the acetate, is often easily crystallizable. The degree of regularity in structure is almost identical in both polymers, provided that saponification is complete. The head-to-tail arrangement in the structures dominates, as is well established by degradation studies [1]. One interpretation of the X-ray diffraction pattern of polyvinyl alcohol [2] even indicates that all of the hydroxyl groups are placed on the same side of the polymer chain. (In the light of recent investigations [3] this seems far from being a general rule. The alternating distribution of the hydroxyl groups seems to be most common.) A *branching* effect is unlikely to be responsible for the poor crystallizability. It is not more probable for vinyl acetate than for other vinyl monomers — in any case it should have been indicated by a change in the physical behavior in solution. The solubility parameters E/V (cohesive energy density) and δ ($= \sqrt{E/V}$, corrected for dipole interaction related to polarizability of solvent) for polyvinyl acetate have been recently computed from molar attraction constants [4] and found to be close to those for polystyrene or polymethyl methacrylate. This implies that special deviations from the behavior of ordinary straight polymers are not to be expected in

* Present address: AB Svenskt Konstsilke, Borås, Sweden.

solvents showing a moderate or high cohesive energy density, such as acetone (c.e.d. 4 cal.ml^{-1} at 20° C) or dimethyl formamide (c.e.d. about 12 cal.ml^{-1} at 20° C).

Additional studies on the crystallizability of certain types of polyvinyl alcohol copolymers [5] are very illuminating. Generally speaking crystallization may occur, even if the second mer component is distributed at random along the head chain, provided that the side groups can be "contained" in the space unit cell of polyvinyl alcohol. This is possible with mer units such as ethylene and tetrafluorethylene, but surely not in the case of vinyl acetate.

Thus it seemed interesting to find out something about the crystallizability of the copolymers of vinyl alcohol and *acrylonitrile*. Such a copolymer is obtained by selective hydrolysis of the corresponding vinyl acetate-acrylonitrile compound. The small difference in the space occupations of hydroxyl and nitrile groups permits a cautious supposition that the conditions for crystallizability might be fulfilled in this case, at least at some proper balance between the mer units of the polymer in a highly oriented state, such as a wet spun fibre. The main point of uncertainty is whether this class of copolymers retains the fibre-forming properties found in polyvinyl alcohol and polyacrylonitrile. Several factors of steric and energetic origin influence the softening point, melting point and second order transition temperature of the finished copolymer. This needs further discussion.

As is known from earlier investigations [6] the introduction of nitrile groups leads to increased density and a gradual increase in the intermolecular forces. This effect is, to a certain extent, counterbalanced by a melting point depression originating from the entropy changes caused by the introduction of a new structural element in the polymer chains. According to Flory [7,8] the melting point depression T_o—T is given by the formula

$$1/T - 1/T_o = -R/\Delta H \cdot \ln N_x$$

where R = the gas constant (in cals); ΔH = molar heat of fusion of the repeating head unit; N_x = mole fraction of the crystallizing constituent.

The formula applies to random copolymers and corresponds exactly to the classical expressions for freezing point depression and solubility-temperature gradients in dilute solutions of small molecules. For higher fractions of the new mer unit the cited formula evidently represents an oversimplification, but indicates that the melting point depression is mostly dependent upon the molar heat of fusion of the main repeating unit. It can be generalized by taking into account the interaction parameter between solvent and solute [9]. The molar heat of fusion of vinyl alcohol is not known — the simplest assumption is that it approximates the value for acrylonitrile. In the case of straight acrylonitrile polymer the large melting range (softening and decomposition) [8] indicates a high molar heat of fusion and a low entropy of fusion — the ratio between these magnitudes represents the hypothetical melting point T_o of the crystalline polymer. A high heat of fusion means a low melting point depression on the introduction of a second component. From thermodynamic viewpoint this only indicates limited flexibility of the molecular chains in the liquid state, possibly originating from repulsion between identical groups *along* the same chain [8]. But conditions are obviously different in a polymer where two mer

units are randomly distributed. The repulsion effect must be changed in some way, usually giving a more flexible molecule, capable of curling in the melt [10]. In this way the entropy change on melting is considerably increased and, for a given heat of fusion, the melting point is lowered in relation to the entropy gain. It seems probable already from these considerations that the second order transition range of the vinyl alcohol-acrylonitrile polymers is far below 100° C, because this magnitude generally follows the first order transition according to the Beamans rule [11], $T_{\text{melting}}/T_{\text{sec. order trans.}} = 1.5$.

EXPERIMENTAL

Preparation of the copolymers. The copolymers of acrylonitrile and vinyl acetate are easily prepared in emulsion systems. The dispersions show very good heat and frictional stability, unlike the corresponding polyacrylonitriles where stable emulsions are rare. It is apparent that the dispersed state offers the most convenient medium for the selective hydrolysis of the acetyl groups. In fact preliminary tests showed that a careful hydrolysis (pH 10, temp. 65° C, time 120 min) in the presence of (excess) ammonia did not attack the nitrile groups, as a blank of pure polyacrylonitrile immediately showed, but gave an acetyl content of the saponified copolymer usually below 0.75 %.

Table 1. Copolymerization of acrylonitrile-vinyl acetate.

Apparatus: Three-necked flask, volume 1 000 ml, equipped with thermometer, agitator and reflux condensor. Rate of stirring 300—400 r.p.m.

Composition of reaction mixture: Water 1 500 g; Activator: potassium persulphate 6 g; Emulsifier: Sodium lauryl sulphate 8 g; Amount of monomers 240 g; Ratio of monomers: See below; Time of reaction 120 min; Temp. of reaction 65—70° C.

Note. The reaction mixture was flushed with nitrogen before initiation of polymerization. The monomers were mixed and dispersed in the aqueous phase at room temperature before adding activator. After reaction, excess of monomer was removed at 65° C in vacuum using a slow current of nitrogen through the emulsion.

Prep. No.	1	2	3	4

acetyl content of saponified polymer, %	0.81	0.44	1.19	1.01
Solubility of saponified polymer in				
a. Dimethylformamide	Clearly soluble, 20 % solutions are easily prepared			
2. Acetone	Insol.	Insol.	Sol.	Sol.
Av. visc. molecular weight in dimethylformamide *	78 000	57 000	42 000	37 000

* Calculated from a speculated K_m-value of 1.5×10^{-4}, and approximating the shape exponent in $[\eta] = K \cdot M^a$ to unity.

Remarks. The polymers obtained are all somewhat sticky when heated above 50° C. It is therefore necessary to carry out the precipitation of the hydrolyzed polymer emulsion at a low temperature — preferably below room temperature. If this direction is observed the polymer is obtained as a finely divided powder — similar in appearance (and colour) to sawdust.

VISCO-ELASTIC BEHAVIOR OF THE SAPONIFIED POLYMERS

After drying at 50° C, the polymers were dissolved in dimethylformamide at room temperature. Solutions containing 10 % polymer were easily filtered through sheets of cotton linters. The de-airated dopes were spread on glass plates and the solvent removed by drying at 100° C. The films were cut into strips and oriented by stretching over a hot surface. Some observations should be mentioned here:

1. At higher acrylonitrile contents (prep. 1—2) plastic flow on stretching occurs above 50° C, the oriented films being split into fibrilla in the flow direction by a high instantaneous load. The creep recovery is low after the stretching operation. The elongation on rupture at 20° C is about 20 %. A stretch ratio of 1 : 4 is obtainable in both specimens.

2. At lower contents of acrylonitrile (prep. 3 and 4) a creep recovery on stretching was detectable. Oriented films are not split into fibrilla by a sudden heavy load, on the contrary a pronounced rubbery character is apparent. Only a low resistance to plastic flow can be noticed above 50° C, indicating a *small* increase in orientation. No critical "draw limit" can be found and the typical "necking" effect on drawing has disappeared.

These observations indicate that the introduction of acrylonitrile groups into polyvinyl alcohol do not increase the fibre-forming properties. At higher contents of acrylonitrile the characteristics of acrylic fibres make their appearance, which is trivial in our present case.

Some indirect information, however, can be obtained from another aspect. It was observed that solutions of the "hydrolysed" copolymers in dimethylformamide are miscible in all proportions with solutions of pure polyacrylonitrile in the same solvent. This is to be expected, even if mutual miscibility of polymers is by no means an ordinary phenomenon. In this way a two-component fibre can be prepared where the influence of the copolymer, acting as a diluent, can be identified by comparison with the single-component fibrer, prepared under identical spinning conditions. Such a test was carried out with copolymer 4, and a pure acrylonitrile polymer, in accordance with the performance described below.

It is apparent from table 2 that the copolymer mainly acts as a "diluent" for the acrylic polymer, which is reflected in the decrease in tenacity and the increase in ultimate elongation. This might partly be due to an additive effect, derived from the fact that the copolymer units interfere with the structural elements of the polyacrylonitrile, thus both preventing and retarding orientation and final crystallization to a smaller extent. In any case both effects should co-operate in changing the structural elements in the Maxwell model of the two-component fibre which corresponds with the measurements above. From this point of view one is not allowed to negate the

Table 2. Wet spinning of a two-component fibre of polyacrylonitrile and a vinyl alcohol-acrylonitrile copolymer.

Blank (Sol. I): Solution of polyacrylonitrile (av. visc. M. W. = 70 × 10^3) in dimethylformamide, 15 % by weight.
(Sol. II) Spinning dope: One part by weight of copolymer 4 dissolved in dimethylformamide (15 %), mixed with three parts of Solution I.
Coagulating agent: Odourless Kerosene. Temp. of coag. agent: 135° C. Type of spinnerette: Nickel, 100 holes. Diam. of holes: 0.15 mm. Stretch ratio: 8. Rate of extrusion: 80 metres min^{-1}. Washing of the fibres: Boiling water. Drying: Room temperature.
Properties of the fibres obtained:

Type of fibre	Acrylic polymer	Acrylic polymer + copolymer
Denier	122	158
Tenacity, g. $denier^{-1}$	3.4	3.0
Elongation at break, %	17.1	23.6
Dyeability with dispersed (acetate) dyestuffs at 95° C*	1	3
Dyeability with acid dyestuffs at 95° C	0	2

3 = good.

contribution of the copolymer to the mechanical strength. The decrease in crystallizability of the main component might alone be sufficient to account for the main part of the decrease in tenacity in the two-component fibre. The increase in elasticity is a necessary consequence from high polymer thermodynamics. The enhanced affinity of the modified fibre for dispersed dyestuffs is also in agreement with the changes mentioned above.

The Conjugation of Glycine with Cholic Acid and Benzoic Acid in Rat Liver Homogenate. Bile Acids and Steroids 21

JON BREMER*

Department of Physiological Chemistry, University of Lund, Sweden, and Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

The formation of glycocholic and taurocholic acid has been shown to take place in a system containing microsomes and supernatant from rat liver, whereas the hippuric acid formation also requires the presence of mitochondria.

The taurine present in the rat liver has been shown to be quantitatively conjugated with cholic acid in spite of the presence of considerably greater amounts of glycine.

We have recently shown that both the "microsome fraction" and the "supernatant fraction" of rat liver homogenate are essential for the conjugation of cholic acid with taurine[1,2]. We have now been able to separate the system responsible for the taurocholic and glycocholic acid formation from that forming hippuric acid.

Taurocholic acid was formed in preference to glycocholic acid when both taurine and glycine were present.

EXPERIMENTAL

Liver homogenate of male rats (weight 200—250 g) was separated into "mitochondria fraction", "microsome fraction" and "supernatant fraction" as described elsewhere [2]. The homogenate fractions tested for enzyme activity were incubated with cholic acid, benzoic acid, ^{14}C-labeled glycine and ^{35}S-labeled taurine as shown in Fig. 1. The incubates were then extracted with 1/3 volume *n*-butanol [1], but the contents of the vessels had to be acidified to pH 1 to make also the hippuric acid extractable. This procedure has been shown to leave the free taurine in the water phase whereas taurocholic acid is extracted by the butanol [1]. Fig. 1 shows that also the glycine stays almost quantitatively in the water phase whereas the glycocholic and hippuric acids are extracted.

* Fellow of the *"Norwegian Cancer Society"*, Oslo, Norway. Present address: Norsk Hydro's Inst. for Cancer Research.

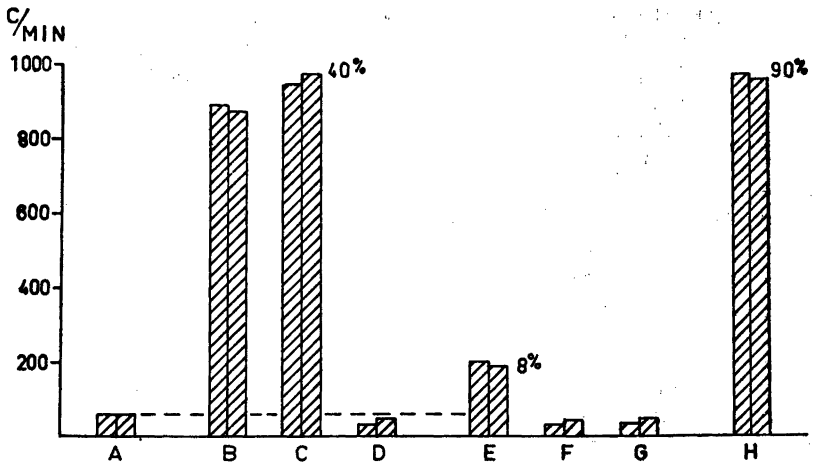

Fig. 1. Total volume of the vessels 1.75 ml. 1 ml 20 % homogenate added to each vessel. Concentrations: Potassium phosphate buffer pH 7.7 0.037 M, *sucrose 0.080* M, *nicotinamide 0.017* M, *magnesium chloride 0.00065* M. *ATP 1.2 μmole/vessel, versene 0.5 mg/vessel.*

A. 1 ml homogenate centrifuged at 400 g for 5 min. 1.8 μmole glycine-^{14}C representing 15 000 c/min/vessel.
B. As A + 2.5 μmole cholic acid.
C. 1 ml homogenate centrifuged at 12 000 g for 10 min. 1.8 μmole glycine-^{14}C + 2.5 μmole cholic acid.
D. 1 ml homogenate centrifuged at 100 000 g for 30 min. 1.8 μmole glycine-^{14}C + 2.5 μmole cholic acid.
E. As A + 2.5 μmole benzoic acid.
F. As C, but with benzoic acid instead of cholic acid.
G. As D, but with benzoic acid instead of cholic acid.
H. 1 ml homogenate centrifuged at 12 000 g for 10 min. 0.4 μmole taurine-^{35}S representing 7 250 c/min/vessel. + 2.5 μmole cholic acid.

Each vessel acidified with 0.1 ml conc. HCl and extracted with 0.62 ml of butanol. 0.1 ml butanol plated and counted. The double columns represent parallels.

The distribution of hippuric acid between the butanol/*N* hydrochloric acid phases in the concentration range used was estimated spectrophotometrically at 2 700 Å. The partition coefficient butanol/*N* hydrochloric acid was found to be 5.2. After equilibration of the acidified reaction mixture the volume of the aqueous phase was about 1.94 ml and that of the butanol phase 0.54 ml.

The distribution of glycocholic acid between the butanol/*N* hydrochloric acid phase was assumed to be the same as for taurocholic acid [1].

The amounts of the conjugates extracted with butanol was determined by measuring the radioactivity of aliquots plated directly under standard conditions [1].

RESULTS AND DISCUSSION

The two separate experiments done gave similar results. One of the experiments is shown in Fig. 1.

The liver homogenate used in this experiment was nearly five times as efficient in conjugating cholic acid with glycine (Fig. 1 B) as in conjugating

benzoic acid with glycine (Fig. 1 E). The 1.8 μmole glycine-^{14}C added to the systems gave under identical conditions rise to 0.72 μmole glycocholic acid and 0.15 μmole hippuric acid, respectively. Since some free glycine was presumably present in the liver homogenate, these amounts must represent the minimal amounts of newly formed conjugated acids. A content of 0.2 mg of free glycine per g rat liver has been reported by Wu[8].

Furthermore, there is a distinct difference in the localization of rat liver systems responsible for the formation of the glycocholic and hippuric acids. The "microsome" plus "supernatant" fractions retained in full the activity to synthesize glycocholic acid (Fig. 1 C), but were unable to bring about the formation of hippuric acid (Fig. 1 F). The finding that the mitochondria are essential for the hippuric acid synthesis is in accordance with the results of Kielly and Schneider[3] in mouse liver homogenate.

Both the "microsome" fraction and the "supernatant" are essential for the formation of glycocholic acid (Fig. 1 C, D). This localization is similar to that of the system forming taurocholic acid[2].

In order to compare the conjugation of cholic acid with taurine and with glycine, the concentration of preformed taurine in the homogenate had to be determined. Two vessels with homogenate from the same liver were incubated with 0.4 μmole taurine labeled with ^{35}S (Fig. 1 H). The activity recovered as taurocholic acid correspond to 90 % of the amount added. Spectrophotometric determination according to Sjövall [4,5,1] showed, however, that a total amount of 0.70 μmole taurocholic acid had been formed, *i.e.*, the total amount of taurine present at the start of the experiment must have been about 0.78 μmole, of which only 0.4 μmole was the labeled material added.

Similarly spectrophotometric determination of the formation of taurocholic acid when the system in addition to cholic acid and preformed taurine also contained ^{14}C-labeled glycine (1.8 μmole) (Fig. 1 C) showed the taurine to be almost quantitatively conjugated in spite of the glycine present. This finding agrees with the earlier observations of Bergström and Gloor[6] in human liver homogenates.

The enzymic systems conjugating cholic acid with taurine and glycine in the rat must therefore have greater preference for taurine; the cited results give a good explanation of the fact that rat bile contains only 5—10 % of the cholic acid conjugates in the form of glycocholic acid[7] in spite of the relatively high glycine content in rat liver. The glycine content of rat liver has been reported to be three times that of taurine on a molar base[8].

Whether the conjugation of cholic acid with glycine and taurine is performed by the same enzyme system is as yet an open question.

The author wishes to express his appreciation to L. Eldjarn and P. Fritzson, Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway, for the synthesis of ^{35}S-labeled taurine.

The author is also indebted to J. Sjövall, Department of Physiological Chemistry, University of Lund, Sweden, for the use of his unpublished method for the quantitative determination of bile acids by paper chromatography.

On the Ferric-ion Catalyzed Decomposition of Hydrogen-Peroxide

J. A. CHRISTIANSEN

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

It is agreed that a reaction pattern proposed by J. Koefoed, which implies the closed sequence

$$Fe^{++} + FeO_2H^{+2} \rightleftharpoons Fe_2O_2H^{+4} \quad 12$$
$$Fe_2O_2H^{+4} \rightleftharpoons Fe^{+3} + FeO_2H \quad 23$$
$$FeO_2H^{+} + H_2O_2 \rightarrow O_2 + H_2O + HO + HO^{-} + Fe^{+2} \quad 31$$

and which can be made to agree with Sten Andersen's experiments is in better agreement with general experimental evidence than an open sequence formerly proposed by Sten Andersen and the present author. On the basis of tracer experiments from elsewhere it is concluded that the intermediate FeO_2H^+ is a ferrous perhydroxo complex and not, as advocated by J. Koefoed, an oxo-hydroxo derivative of Fe(IV).

Recently J. Koefoed [1] proposed a reaction pattern for the ferric-catalyzed decomposition of hydrogen-peroxide which
1) agrees with Sten Andersen's chronometric integral [2] $t = A_1 \ln a/x + A_2 (1/x - 1/a)$ (x concentration of hydrogen-peroxide at time t, a the same at $t = 0$),
2) has the property of containing a closed sequence (a chain mechanism) which the pattern proposed by Sten Andersen and the present author has not, and finally 3) operates with ferrous ion as an intermediate which the one mentioned above does not.

As it is an experimental fact that the decomposition in question is strongly retarded by small amounts of certain substances and that during the decomposition ferrous ions can be analytically [3] detected it is obvious that Koefoed's pattern is in better general agreement with the experimental facts taken at their face-value than the one mentioned above.

There is, however, one detail in Koefoed's pattern which may need a little discussion and another which seems to be in disagreement with well established experimental findings. We shall begin with a discussion of the latter.

Koefoed admits the well known fact that kinetics can tell nothing about the constitution of the intermediates.

He tries, however, by using arguments from elsewhere to make it probable that the intermediate of the composition FeO_2H^+ is not a ferrous-perhydroxo complex but an oxo-hydroxo compound of Fe(IV), *viz.* $O : \overset{+}{F}eOH$. His arguments can best be discussed by means of his closed sequence which is

$$Fe^{+2} + FeO_2H^{+2} \rightleftharpoons Fe_2O_2H^{+4} \qquad 12$$

$$Fe_2O_2H^{+4} \rightleftharpoons FeO_2H^+ + Fe^{+3} \qquad 23$$

$$FeO_2H^+ + H_2O_2 \rightarrow O_2 + H_2O + HO^- + Fe^{+2} \qquad 31$$

This is so constructed that it makes it possible to remain in agreement with all Sten Andersen's results on the ferric ion catalyzed reaction.

It is a fact that during the overall reaction a pair of antiparallel electronic spins are converted into a pair of parallel spins and Koefoed now argues that this conversion takes place during the step 23, which would support the assumption of the constitution $O\overset{+}{F}eOH$ for the intermediate. His argument seems, however, to be highly artificial: There is complete agreement in views on the constitution of FeO_2H^{+2} as a perhydroxo analogue to $FeOH^{+2}$ and on the constitution of $Fe_2O_2H^{+4}$ as the perhydroxo analogue to a ferrous-ferric hydroxo complex of well known type. Why not therefore assume that the ferrous and the ferric ions in 12 and 23 simply keep their spins and assume, as we then must, that the "spin-conversion" takes place in the irreversible reaction 31? One might even say that such an assumption is probable in view of the strong tendency for ferrous ions to form coordinated complexes with certain anions. This would lead in our case to an accumulation of two perhydroxo ligands around the central ion, the resulting complex being so to speak explosive. Anyhow there is direct evidence in favour of the view that FeO_2H^+ is actually a ferrous-perhydroxo ion and not an oxo-hydroxo derivative of Fe(IV). Two groups of authors, Baertschi [4] on one side and Cahill and Taube [5] on the other, agree in stating, on the basis of numerous tracer experiments, that in the reactions of hydrogen-peroxide the evolved oxygen is derived "cleanly from the hydrogen-peroxide" (Cahill and Taubes expression) that is, there is no measurable reversible exchange of oxygen between the perhydroxide and the solvent water. This is true in all the cases investigated and particularly in our case which has actually been investigated by Cahill and Taube. Now from general knowledge and from experiments it appears that oxygen in metal-hydroxo compounds is readily exchangeable with oxygen in the solvent water. It would therefore be a lengthy and, as the present author believes, an impossible task to prove that the assumption of FeO_2H^+ being an oxo-hydroxo compound does not contradict the tracer experiments.

Koefoed has, however, another argument which according to him should make the assumption, that FeO_2H^+ be a perhydroxo compound, improbable: Let us add to the equations 12 and 23 the equation for the reaction

$$HO^-_2 + Fe^{+3} = FeO_2H^{+2}$$

We then get as the resultant of the three processes

$$Fe^{+2} + HO^-_2 = FeO_2H^+$$

in other words: ferric ions should catalyze the latter reaction. (Koefoed prefers to add the equilibrium

$$H_2O_2 + Fe^{+3} = FeO_2H^{+2} + H^+$$

with a corresponding change in the resultant equation, but the difference is so far as we can see to all intents and purposes immaterial.) He now says that it is not very likely that the reaction in question "should be much promoted by this catalyst", in other words the direct formation of FeO_2H^+ from Fe^{+2} and HO^-_2 (the bye-pass) should be faster than that through the reactions 12 and 23. However, as shown in the appendix the problem in question cannot be decided that way. A rational treatment shows 1) that only the kinetic experiments themselves can decide whether the existence of the bye-pass is of significance or not, 2) that Sten Andersen's experiments indicate that its existence is insignificant in the range of ferric ion concentrations investigated and 3) that this result would be *a priori* probable rather than improbable.

We see therefore no reason to admit other assumptions than that the intermediate FeO_2H^+ simply is a ferrous perhydroxo compound in which way any contradiction with the tracer-experiments automatically disappears.

We now pass on to the minor first point. As initiator Koefoed assumes the net reaction $FeO_2H^{+2} + Fe^{+3} + 2\ H_2O \rightarrow 2\ FeO_2H^+ + 3\ H^+$ divided into two steps as follows

$$H_2O + FeO_2H^{+2} \rightarrow FeO_2H + HO + H^+$$
$$HO + Fe^{+3} + H_2O \rightarrow FeO_2H^+ + 2H^+$$

Actually, in agreement with Koefoed's statement, only the left hand side of the first partial reaction is known from the kinetics, water of cause being kinetically unimportant. Therefore if we don't like to state more than we know the equation ought to be written

$$H_2O + FeO_2H^{+2} \rightarrow Y \qquad 0y$$
$$Y + Fe^{+3} + H_2O \rightarrow 2FeO_2H^+ + 3H^+ \qquad y3$$

Anyhow it seems certain that in Koefoed's initiating reaction part of the perhydroxide must come from the solvent water. This will however probably not contradict the tracer experiments because of his basic and most probably correct assumption of a large chain length. Even a low value of say 100 would probably prevent its detection if only the chain-mechanism itself does not give rise to exchange of oxygen with the solvent water. We have therefore no objection in principle to Koefoed's initiating sequence.

The present author has also something to say about Koefoed's treatment of Sten Andersen's experimental results concerning the cupric-ferric ion catalyzed reaction. But this discussion can only be completed in cooperation with Sten Andersen, a cooperation which because of Sten Andersen's temporary absence must be postponed to a later date. Be it enough to state here that it may (not must) be true that Sten Andersen's experiments admit mechanisms (reaction patterns) which do not lead strictly to his chronometric integral of the type $t = A_1\ln(a/x) + A_2(1/x - 1/a)$, which the one proposed by Koefoed admittedly does not.

It must be added, however, that a reaction-pattern including Koefoed's chain-mechanism has been constructed which agrees strictly with Sten Andersen's chronometric integral, and with the aid of which his numerical values for A_1 and A_2 can be reproduced with some accuracy.

APPENDIX

Let us assume, besides the reaction

$$Fe^{+2} + FeO_2H^{+2} \rightleftharpoons Fe_2O_2H^{+4} \qquad 12$$
$$Fe_2O_2H^{+4} \rightleftharpoons Fe^{+3} + FeO_2H^{+} \qquad 23$$

also the bye-pass

$$Fe^{+2} + HO^{-}_2 \rightleftharpoons FeO_2H^{+}$$

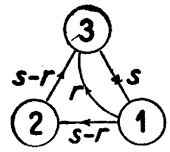

Fig. 1. Flow sheet for the closed sequence 12, 23, 31 with bye-pass 13. The steady state currents are as shown by the letters and arrows.

The flow-sheet of the reaction is shown in Fig. 1, where the currents corresponding to steady state have been indicated. Denoting the probabilities of the reaction of the intermediates Fe^{+2} and FeO_2H^{+} according to the bye-pass reaction by u_{13} and u_{31} respectively we get

$$x_1 = r/u_{13} + su_{31}/u_{13}w_{31}$$
$$x_1 = (s—r)(1 + w_{21}/w_{23})/w_{12} + sw_{21}w_{32}/w_{12}w_{23}w_{31}$$

From the principle of microscopic reversibility we have the equation

$$w_{12}w_{23}u_{31} = w_{21}w_{32}u_{13}$$

which means that, with $w_{21}/w_{23} \gg 1$

$$sw_{21}/w_{12}w_{23} = r(1/u_{13} + w_{21}/w_{12}/w_{12}w_{23})$$
$$r/s = 1/(w_{12}w_{23}/w_{21}u_{13} + 1) = 1/(w_{32}/u_{31} + 1)$$
$$= u_{31}/(w_{32} + u_{31})$$

This yields

$$\frac{x_1}{s} = \frac{u_{31}}{u_{13}}\left(\frac{1}{w_{32}+u_{31}} + \frac{1}{w_{31}}\right)$$

For x_2/s we similarly get

$$\frac{x_2}{s} = \left(1—\frac{r}{s}\right)/w_{23} + w_{32}/w_{23}w_{31}$$
$$= \frac{w_{32}}{w_{23}}\left(\frac{1}{w_{32}+u_{31}} + \frac{1}{w_{31}}\right)$$

Replacing u_{31}/u_{13} by $w_{32}w_{21}/w_{12}w_{23}$
we finally get

$$\frac{x_1x_2}{s^2} = \frac{w_{21}}{w_{12}}\left(\frac{w_{32}}{w_{23}}\right)^2\left(\frac{1}{w_{32}+u_{31}} + \frac{1}{w_{31}}\right)^2$$

which is identical with the corresponding expression obtained without the bye-pass if $u_{31} \ll w_{32}$.

Now u_{31} is the probability in unit time that FeO_2H^+ shall dissociate into Fe^{++} and HO^-_2 and w_{32} the probability that it shall unite with a ferric ion to form $Fe_2O_2H^{+4}$. It would seem *a priori* rather probable that the former probability is much less than the latter at reasonable concentrations of ferric ions. As, however, w_{32} must be of the form k_{32} $[Fe^{+3}]$ it might be possible by making experiments at very low ferric ion concentrations to detect the influence of the bye-pass, but on account of the low concentration of the catalyst such experiments would last an exceedingly long time. Anyhow, only the kinetic experiments themselves can decide with reasonable certainty on the ratio u_{31}/w_{32} and the actual result derived from Sten Andersen's experiments, that $u_{31}/w_{32} \ll 1$, is not at all improbable *a priori*, or rather, it seems to be probable and quite natural.

Utilization of Ion Exchangers in Analytical Chemistry

XXIX. Sorption and Elution of Some Low-Molecular-Weight Organic Acids

SVANTE BERNTSSON and OLOF SAMUELSON

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

The sorption and elution of glycolic, oxalic, pyruvic, gluconic, maleic, and *p*-toluenesulfonic acids using the strongly basic resin Dowex 2 (acetate form) and the weakly basic resin Dowex 3 (free-base form) have been studied. All acids except gluconic acid can be taken up quantitatively by the resins.

Glycolic, oxalic, gluconic, and maleic acids can be quantitatively displaced from both types of resins by means of sulfuric acid or ammonium carbonate. From the strongly basic resin, pyruvic acid can be displaced quantitatively only by means of acid elutriants. The elution of this acid from the weakly basic resin is in no case quantitative. Hydrochloric acid is the most effective elutriant for *p*-toluenesulfonic acid when the strongly basic resin is concerned, whereas the weakly basic resin is most easily regenerated with sodium hydroxide.

Several authors have used anion exchange resins for the isolation of organic acids. The results are summarized in Samuelson's monograph [1]. This topic has also been studied in some more recent papers [2-6]. The uptake of the acids does not seem to have caused any troubles whereas in some cases it has been reported that the recovery in the elution step is incomplete. Most authors have been interested in the chromatographic separation of different acids from each other. Very little attention has been given to the question of whether the recovery in the regeneration step can, from an analytical point of view, be considered as quantitative. For this reason it seemed to be appropriate to study in greater detail the uptake and especially the elution of different types of organic acids.

EXPERIMENTAL TECHNIQUE

Ion Exchange Column. The ion exchange column was of common construction (Ref.[1], Fig. 23). The diameter and length of the resin bed were 9 mm and 170 mm. The resin had the particle size 0.20—0.30 mm in an air-dry condition. The acetate form of the resin was prepared by passing 400 ml *M* sodium acetate solution through the column and sub-

sequent washing with water. In order to transform the resin into the free-base form it was instead treated with the same amount of *M* sodium hydroxide solution, precautions being taken to exclude carbon dioxide. Dowex 2 was regenerated according to the ordinary column technique whereas the regeneration of Dowex 3 was achieved by a combined batch and column operation to avoid channeling due to the swelling of the resin. Fifty ml of the elutriant was placed in the funnel attached to the column. After placing a stopper in the upper end of the funnel the column was shaken in order to transfer the resin into the funnel. The resin was then allowed to settle in the column and the elutriant passed through.

The resins are not quite stable in water and interference occurred because of dissolution of resin material. In order to eliminate as far as possible this source of error the resin was conditioned with 500 ml *M* sodium hydroxide solution and afterwards with 500 ml of the elutriant. The conditioning was repeated several times.

In all experiments the added amount of acid was about 2 meq and the flow rate about 2 ml/min. All figures given in the tables are expressed in per cent of the added amount.

Determination of the Acids. Glycolic, gluconic, and maleic acids were determined by oxidation with dichromate in sulfuric acid solution according to the following scheme.

$$\begin{aligned} C_2H_4O_3 + 3\ O &\longrightarrow 2\ CO_2 + 2\ H_2O \\ C_6H_{12}O_7 + 11\ O &\longrightarrow 6\ CO_2 + 6\ H_2O \\ C_4H_4O_4 + 6\ O &\longrightarrow 4\ CO_2 + 2\ H_2O \end{aligned}$$

The equivalent weights of glycolic, gluconic, and maleic acids are 1/6, 1/22 and 1/12 of the molecular weights, respectively.

The acid was introduced into a 1-liter flask and 0.5 *N* $K_2Cr_2O_7$-solution, to an excess of at least 1 meq, was added from a micro-buret. After addition of water to 60 ml volume, 100 ml conc. sulfuric acid was added under shaking. The flask was allowed to stand for 30 min and then cooled. After adding 500 ml distilled water, the flask was again cooled to room temperature. The excess potassium dichromate was determined in the usual manner by adding potassium iodide and titrating with sodium thiosulfate. In control experiments with the pure acids, the error was in all cases less than 0.5 %.

Oxalic acid was determined by oxidation with permanganate. Pyruvic acid was analyzed according to a colorimetric method [7]. *p*-Toluenesulfonic acid was determined spectrophotometrically in ultraviolet at 260 mμ. The spectrophotometric readings were made with a Beckman spectrophotometer model DU.

Blank experiments were run in order to obtain a correction for the dissolution of organic matters from the resin. The correction was in no case greater than 2 %.

RESULTS

The experiments with glycolic, oxalic, pyruvic, maleic, and *p*-toluenesulfonic acids show that all these acids can be taken up quantitatively by the acetate form of a strongly basic resin and by the free-base form of a weakly basic resin. The uptake of gluconic acid is incomplete with both types of resin. The amount of acid which passes through the column is indicated under the Tables 1 and 2. The fact that gluconic acid is not retained quantitatively is explained by the presence of lactones.

The results presented in Tables 1 and 2 show that glycolic, oxalic, gluconic, and maleic acids can be easily displaced from both types of resins by means of 0.5 *M* sulfuric acid or 0.5 *M* ammonium carbonate solutions. As can be seen from Table 3, oxalic acid is eluted with 150 ml of *M* HCl, 0.5 *M* H_2SO_4, 0.5 *M* $(NH_4)_2SO_4$, 0.5 *M* $(NH_4)_2CO_3$, or *M* NaOH.

The behavior of pyruvic and *p*-toluenesulfonic acids is much more complicated. Table 4 shows that pyruvic acid is recovered quantitatively from the strongly basic resin with hydrochloric acid or sulfuric acid, whereas unsatis-

Table 1. Elution of acids from the strongly basic resin Dowex 2 (acetate form).

Acid	Elution with 150 ml 0.5 *M* H_2SO_4 %		Elution with 150 ml 0.5 *M* $(NH_4)_2CO_3$ %	
Glycolic acid	99.0;	99.8	99.1;	99.5
Oxalic acid	99.2;	99.3	99.8;	100.2
Pyruvic acid	99.3;	99.9	55.9;	58.9
Gluconic acid *	76.8;	77.0	78.8;	76.6
Maleic acid	99.5;	100.1	99.7;	99.9
p-Toluenesulfonic acid	1.2;	2.0	0.0;	0.0

* The amount of gluconic acid in the effluent from the sorption step was 22.8, 23.0, 23.1, and 23.1 % respectively.

Table 2. Elution of acids from the weakly basic resin Dowex 3 (free-base form).

Acid	Elution with 150 ml 0.5 *M* H_2SO_4 %		Elution with 150 ml 0.5 *M* $(NH_4)_2CO_3$ %	
Glycolic acid	99.0;	99.4	99.1;	99.7
Oxalic acid	99.4;	100.2	99.3;	99.7
Pyruvic acid	24.2;	30.9	27.6;	28.9
Gluconic acid *	79.4;	78.6	79.6;	78.5
Maleic acid	100.0;	100.1	100.1;	100.1
p-Toluenesulfonic acid	25.6;	27.8	65.3;	68.9

* The amount of gluconic acid in the effluent from the sorption step was 20.1, 20.7, 20.1, and 20.6 % respectively.

Table 3. Elution of oxalic acid from the strongly basic resin Dowex 2 (acetate form) and the weakly basic resin Dowex 3 (free-base form) with 150 ml of different elutriants.

Elutriant	Elution from Dowex 2 %		Elution from Dowex 3 %	
M HCl	99.4;	100.0	99.7;	100.3
0.5 *M* H_2SO_4	99.4;	99.3	99.4;	100.2
0.5 *M* $(NH_4)_2SO_4$	99.7;	99.9	100.0;	100.1

M NaOH	100.1;	100.1	99.8;	100.1

factory results are obtained with the other elutriants. From the free-base form of the weakly basic resin, pyruvic acid can be removed only to a limited extent even when large quantities and high concentrations of the elutriants are used.

Table 4. Elution of pyruvic acid from the strongly basic resin Dowex 2 (acetate form) and the weakly basic resin Dowex 3 (free-base form).

acid could be detected in the effluent from the regeneration step when the solution was investigated by the colorimetric method. Similar experiments in which the resin was treated with ammonium carbonate or sodium hydroxide instead of ammonium sulfate gave the same results. In some experiments with pyruvic acid, the determinations were made by an alkalimetric titration. The results indicate that the incomplete recovery of pyruvic acid is due to a decomposition of the acid during the ion exchange cycle.

The data given in Table 5 show that, for the elution of *p*-toluenesulfonic acid from the strongly basic resin, hydrochloric acid is more effective than sulfuric acid and sodium hydroxide. It is interesting to note that no traces of the acid have been detected in the effluent after treatment with large amounts of ammonium sulfate and ammonium carbonate solutions in the elution step. The influence of the strength of hydrochloric acid used as elutriant for *p*-toluenesulfonic acid has been studied. The results are given in Table 6. As can be seen from the table, 3 *M* hydrochloric acid is an effective elutriant. As a complement to the data presented in the tables two elutions with 500 ml 3 *M* hydrochloric acid were performed. The recovery was 100.0 % in both experiments.

From the weakly basic resin, *p*-toluenesulfonic acid is eluted quantitatively by means of sodium hydroxide solution (Table 5). The other elutriants investigated are less effective and are unsatisfactory for practical use.

Separate experiments show that *p*-toluenesulfonic acid is not fixed in an irreversible manner by any of the elutriants used in the present investigation. After the passage of 150 ml of the elutriants giving an incomplete elution from the strongly basic resin, a quantitative displacement is achieved on subsequent treatment with 500 ml 3 *M* hydrochloric acid. In similar experiments with the weakly basic resin a complete recovery is obtained by final displacement with 300 ml *M* sodium hydroxide.

As already mentioned gluconic acid is not taken up quantitatively under the conditions used in the experiments described above. A quantitative uptake of gluconic acid can be achieved by passing a solution of the sodium salt through a column filled with a strongly basic resin in the acetate form. From an acid solution, gluconic acid can be conveniently taken up by shaking the solution with an excess of the free-base form of the weakly basic resin for 24 h. The acid can then be eluted completely with 150 ml 0.5 *M* H_2SO_4 from both the strongly basic and the weakly basic resin.

The State Technical Research Council (Statens Tekniska Forskningsråd) has supported the research financially, which support is gratefully acknowledged.

Alternative Mechanisms of the Fe- and the Cu-Fe-catalyzed Decomposition of Hydrogen Peroxide

JØRGEN KOEFOED

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

To describe the kinetic results of Sten Andersen [1,2] new schemes of reactions are proposed which agree better than his own schemes with the ideas of other authors regarding feasibility of the assumed intermediates. The schemes include a ferro-ferric or a cupro-cupric cycle, and the correct functional form of the kinetic equations is obtained through moderation of the cyclic reaction not as usual through an equilibrium, but through another irreversible cyclic process, which is considered slow in comparison with the total rate. Free radicals seem to appear in the cycles only bound to the metal ions.

The recent work of Andersen [1,2] has greatly increased our knowledge of the rates of decomposition of hydrogen peroxide at varying concentrations of ferric, cupric and hydrogen ions. Arguing from his results Andersen and Christiansen [3] have maintained the impossibility of a cyclic mechanism involving the shift of ferric to ferrous ions and hydroxyl radicals as has been first proposed by Haber and Weiss. The object of the present paper is to show, that although this closed sequence as well as other previous ones are in disagreement with experimental results, it is nevertheless possible to construct one which fits just as well as the open sequence of Andersen [1]. Several features in the general nature of the reaction indicate a closed sequence, a chain reaction. The inhibitor action of several organic compounds is the most obvious.

The scheme to be proposed below shares with schemes by Weiss, by Barb, Baxendale, George and Hargrave and by Uri the desirable feature that shifts in electron spin pairing occur only when mediated by iron or copper. The disagreement between these previous schemes and Andersen's experiments is overcome mainly through that further assumption that free radicals in the presence of cupric and ferric ions will be so strongly bound to these that they will appear as $FeOH^{+++}$, FeO^{++}, $OFeOH^{+}$, $CuOH^{++}$, CuO^{+} and similar ions. This feature had to be introduced in order to obtain the right dependence of rate constants on ferric ion concentration. It seems not unlikely that such complexes might be relatively stable due to resonance between structures with tetravalent and trivalent iron.

The fact that reaction of hydrogen peroxide with ceric ions leads only to reduction of ceric ions and not to catalytic decomposition is in accordance with the assumption of ferric-complexes as intermediates in preference to free hydroxyl radicals, as the latter might just as well be formed through reaction with ceric as with ferric ions.

The results reported from experiments with ^{18}O labelled hydrogen peroxide [4] require that the final evolution of oxygen (reaction 31 below) takes place as a dehydrogenation of H_2O_2, *e.g.* through a hydride ion (H^-) transfer plus dissociation of a proton (*cf.* the enzymatic dehydrogenation according to Westheimer and Vennesland [5]).

THE FERRO-FERRIC CYCLE

The cycle to be proposed is:

$$Fe^{++} + \dot{F}eO_2H^{++} \rightleftharpoons Fe\dot{F}eO_2H^{+4} \qquad 12$$

$$Fe\dot{F}eO_2H^{+4} \rightleftharpoons \dot{O}\dot{F}eOH^{+} + \dot{F}e^{+++} \qquad 23$$

$$\dot{O}\dot{F}eOH^{+} + H_2O_2 \rightarrow Fe^{++} + \dot{O}_2 + OH^- + H_2O \qquad 31$$

The level at which this cycle operates is determined by a "moderator cycle", consisting of two irreversible reactions 0.33′ and 12.0 together with 31 and the protolysis of the ferric hexaquo ion:

$$\dot{F}eOH^{++} + H_2O_2 \rightleftharpoons \dot{F}eO_2Haq^{++} \rightarrow \dot{O}\dot{F}eOH^{+} + \dot{O}H + H^+ \qquad 0(0')33'$$

$$\dot{F}eaq^{+++} + \dot{O}H \rightleftharpoons \dot{O}\dot{F}eOH^{+} + 2H^+ \qquad 3'3$$

$$Fe^{++} + Fe\dot{F}eO_2H^{+4} + H_2O \rightarrow 3\ \dot{F}eOH^{++} \qquad 12.0$$

$$\dot{F}eaq^{+++} \rightleftharpoons \dot{F}eOH^{++} + H^+ \qquad ie$$

Reaction 0.33′ starts with the formation of the wellestablished brown ferric perhydroxo complex in equilibrium with ferric ions, hydrogen ions and hydrogen peroxide. The rate determining step is an excitation of this complex ion and we picture it here as a splitting off of a hydroxyl radical which immediately afterwards attaches itself to a ferric ion. Bimolecular reaction between the complex ion and ferric ion to form two active particles would give a different kinetic expression. The ion $FeFeO_2H^{+4}$ is a perhydroxo dimeric analogue of the well-known polynuclear ions which in alkaline solution grow to colloid or macroscopic size. It is presumably stabilized by valence shift between the iron atoms.

The ion written as $OFeOH^+$ might for its composition be a ferro perhydroxo complex, and kinetic data obviously cannot exclude that. That would be rather unlikely, however, in consideration of its role in the scheme.

Reaction 12 and 23 can be interpreted so, that $OFeOH^+$ is formed from Fe^{++} and H_2O_2 catalyzed by $FeOH^{++}$, and it seems not very likely that the interchange of a coordinated water molecule with hydrogen peroxide should be much promoted by this catalyst. Furthermore, the only significant way of deactivation is 12.0 and the only feasible reason why a reaction 13.0 between Fe^{++} and $OFeOH^+$ does not contribute to the deactivation is that $OFeOH^+$ is the most energy-rich of the three cyclic reactants and therefore the most rare. This is in accordance with our assumption below that 12 is virtually in equilibrium.

The basic physical event which has to occur during the cycle is the splitting up of one pair of electrons with mutually compensating spin into two single electrons with parallel spin corresponding to the change from diamagnetic hydrogen peroxide to paramagnetic oxygen. Is this splitting up most likely to occur in 12, in 23 or in 31? To help the general views, dots have been placed to indicate unpaired electrons, the first four on iron being

omitted. In 23 a ferric ion leaves the binuclear complex with one electron less than the ferro ion brought into it in 12, and yet with one more unpaired. Hence 23 is the obvious place for the actual splitting and $OFeOH^+$ is most likely to have six unpaired electrons and no O—O bond.

On the other hand, the total back reaction 32, 21, 0'0 leads to some exchange of oxygen between water and peroxide, and the results of Cahill and Taube [4] may force us to assume that the O—O bond is first broken in the irreversible 31 reaction.

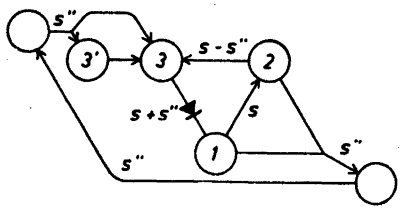

Fig. 1.

The diagrammatic representation of the reaction cycle with the active intermediates X_1, X_2, X_3 and X_3, representing Fe^{++}, $FeFeO_2H^{+4}$, $OFeOH^+$, and OH is given in Fig. 1.

We have supplemented Christiansens way of drawing such flow diagrams by the introduction of the symbol of a rectifier corresponding to the irreversible step. It is easily seen that the kinetic equations depend on where this step is placed in the cycle. In the work with a problem like the present one it is very convenient if the diagram unambiguously characterizes a scheme of reactions to which a certain set of kinetic expressions can be attached.

To comply with stationarity, the flow in the reactions 0.33' and 12.0 where two active particles appear or disappear, has to be the same: $s_{0.33'} = s_{12.0} = s_i''$, and this flow is considered negligible compared to the flow, s_i, in the oxygen producing cycle:

$$s_{31} = s_i + s_i'' \simeq s_{12} = s_i \simeq s_{23} = s_i - s_i'' \qquad (1)$$

Proceeding as Christiansen we obtain the following equations between the concentrations x_1, x_2, x_3 of the intermediates, X_1, X_2, X_3, the concentration of ferric ion, c_i, and of $FeOH^{++}$, c_e; the probabilities w_{ij} of the intermediate X_i to react under formation of X_j, the corresponding rate constants, k_{ij}, and the H_2O_2 concentration, x. K_i is the dissociation constant of $Feaq^{+++}$ (reaction ie), K_0 the equilibrium constant of the hydrolyzed ferric perhydroxo complex (reaction 00').

$$\begin{aligned} s_i &= x_1w_{12} - x_2w_{21} \\ &= x_2w_{23} - x_3w_{32} \\ &= x_3w_{31} \end{aligned} \qquad (2) \qquad \begin{aligned} s_i'' &= w_{0.33'} = k_{0.33'}\, c_e x \\ &= w_{12.0} = k_{12.0}x_1x_2 \end{aligned} \qquad (3)$$

(2) and (3) express that there is stationarity: the same net flow all through in each of our cycles. The equations (2) are solved with respect to x_1, x_2 and x_3:

$$x_1/s_i = (1 + w_{21}/w_{23}(1 + w_{32}/w_{31}))/w_{12} \qquad (4)$$

$$x_2/s_i = (1 + w_{32}/w_{31})/w_{23} \qquad (5)$$

$$x_3/s_i = 1/w_{31} \qquad (6)$$

The unknown concentrations of the intermediates, x_1, x_2 and x_3 are eliminated between (3), (4), (5) and (6), giving:

$$\begin{aligned}\frac{1}{s_i^2} &= \frac{k_{12.0}}{w_{0.33'}} \cdot \frac{x_1}{s_i} \cdot \frac{x_2}{s_i} \\ &= \frac{k_{12.0}}{w_{0.33'} w_{12} w_{23}} \left(1 + \frac{w_{21}}{w_{23}} \left(1 + \frac{w_{32}}{w_{31}}\right)\right) \left(1 + \frac{w_{32}}{w_{31}}\right) \\ &= \frac{k_{12.0}}{k_{0.33'} c_e x k_{12} K_0 c_e x k_{23}} \left(1 + \frac{k_{21}}{k_{23}} \left(1 + \frac{k_{32} c_i}{k_{31} x}\right)\right) \left(1 + \frac{k_{32} c_i}{k_{31} x}\right).\end{aligned} \tag{7}$$

If $k_{21} \gg k_{23}$ we get the same result as we would have obtained by assuming equilibrium in reaction 12 ($k_{12}/k_{21} = K_{12}$):

$$-\frac{dt}{d\ln x} = \frac{x}{2s_i} = \frac{A_i}{c_i} \left(1 + \frac{k_{32} c_i}{k_{31} x}\right) \tag{8}$$

$$A_i = \frac{c_{H^+}}{2k_{23} K_i} \sqrt{\frac{k_{12.0} k_{21}}{k_{0.33'} k_{12} K_0}}$$

with the required functional dependence on c_{H^+}, c_i and x. The formulae of the various ions appearing in the cycle are to some extent arbitrary as any of the steps may cover details which do not influence the kinetic equations, *e.g.* changes in the protolytic state or in aquotisation. By no means any change in this respect is permissible, however, but any scheme will cover an appreciable number of varieties.

To compare the scheme presented here with previous ones, we may consider Christiansen's calculations on a free radical-ferro-ferric cycle (Ref. 3, p. 1060). In that case the level at which the cycle works is moderated through an equilibrium of two cyclic reactants with energy-rich peroxide:

$$\dot{F}eOH^{++} + H_2O_2 \rightleftharpoons Fe^{++} + H\dot{O}_2 + H_2O$$

and it is proved that this leads to an equation of the form

$$-x \frac{dt}{dx} = -\frac{dt}{d\ln x} = A_1 \sqrt{1 + \beta/x} \tag{9}$$

while the experiments require:

$$-\frac{dt}{d\ln x} = A_1 \left(1 + \frac{\alpha}{x}\right). \tag{10}$$

In a similar way the present cycle leads to a mono-molecular proces ($\alpha = 0$) if it is moderated by reaction 0.33′ in equilibrium, $w_{12.0}$ being zero. In both cases it is seen that $-dt/d\ln x$ increases too slowly or not at all as the reaction proceeds (falling values of x). In the derivations above this is corrected through the combination of the irreversible 0.33′ production of active intermediates with the irreversible 12.0 destruction of activity. This makes the level sink more rapidly with falling H_2O_2 concentration. In consideration of the energy levels through which the "moderator cycle" 0.33′, 3′3, (31 + 32), 12.0 will be running, it seems reasonable that the reverse reactions 33′.0 and 0.12 can safely be neglected ($w_{0.12} \ll w_{0.33'}$; $w_{33'.0} \ll w_{12.0}$).

THE PROMOTING ACTION OF COPPER

Adopting the scheme above for the ferric-ion catalysis we need not restrict ourselves to the very limited class of reactions considered by Andersen for the description of the copper promotion, and possibilities are opened to get through without introduction of entropy producing *perpetuum mobile* reactions as Andersen's cycle: 12—23—33′—3′1 in his final scheme (his symbols).

We will not attempt to reproduce Andersen's results in the same mathematical form, which is adapted to his special class of reactions. We fix our attention to the fact which appears directly from the data given in Table 2, Ref. 2, that at copper ion concentrations greater than 0.0004 his A_1 values become practically independent of copper concentration, while at a given copper concentration, A_1 tends to become proportional to the square root of iron concentration. At the same time A_2/A_1, corresponding to α in equation (10), grows independent of iron concentration. In copper-free solutions A_2/A_1 was proportional to iron concentration such as to make A_2 itself independent of iron.

To obtain a pattern of reactions which corresponds to the behavior at *high Cu-concentrations*, we will assume the initiating reaction 0.33′ to be unchanged by the presence of copper. Once formed the radical activity is supposed to be taken over by copper intermediates through the equilibrium 36 in which the ions on the right hand side are supposed to predominate:

$$\dot{O}\dot{F}eOH^{+} + \dot{C}u^{++} \rightleftharpoons \dot{F}eOH^{++} + \dot{C}u\dot{O}^{+} \qquad 36$$

CuO^+ is called X_6 and is part in a copper cycle 4564 in which X_4 is Cu^+ and X_5 is $CuO_2H_2^+$:

$$Cu^{+} + H_2O_2 \rightleftharpoons CuO_2H_2^{+} \qquad 45$$

$$CuO_2H_2^{+} \rightleftharpoons \dot{C}u\dot{O}^{+} + H_2O \qquad 56$$

$$\dot{C}u\dot{O}^{+} + H_2O_2 \rightarrow Cu^{+} + \dot{O}_2^{\cdot} + H_2O \qquad 64$$

and deactivation occurs through:

$$Cu^{+} + CuO_2H_2^{+} \rightarrow 2\ \dot{C}u^{++} + 2OH^{-} \qquad 45.0$$

Neglecting the iron cycle 1231 we obtain equations identical with the previous ones when 1, 2 and 3 are substituted by 4, 5 and 6 except in $w_{0.33'}$, which is kept unchanged:

$$x_4/s_u = (1 + w_{54}/w_{56}(1 + w_{65}/w_{64}))/w_{45} \qquad (11)$$

$$x_5/s_u = (1 + w_{65}/w_{64})/w_{56} \qquad (12)$$

$$x_6/s_u = 1/w_{64} \qquad (13)$$

$$\frac{1}{s_u^2} = \frac{k_{45.0}}{w_{0.33'}w_{45}w_{56}}\left(1 + \frac{w_{54}}{w_{56}}\left(1 + \frac{w_{65}}{w_{64}}\right)\right)\left(1 + \frac{w_{65}}{w_{64}}\right) = \frac{k_{45.0}}{k_{0.33'}c_e x k_{45} x k_{56}}\left(1 + \frac{k_{54}}{k_{56}}\left(1 + \frac{k_{65}}{k_{64}x}\right)\right)\left(1 + \frac{k_{65}}{k_{64}x}\right) \qquad (14)$$

and if $k_{54} \gg k_{56}$:

$$-\frac{dt}{d\ln x} = \frac{x}{2s_u} = \frac{A_u}{\sqrt{c_i}}\left(1 + \frac{k_{65}}{k_{64}x}\right) \tag{15}$$

$$A_u = \frac{1}{2k_{56}}\sqrt{\frac{k_{45.0}k_{54}}{k_{0.33'}k_{45}K_i}} \cdot \sqrt{c_{H^+}}$$

We have no experimental evidence to show whether the dependence on c_{H^+} is right or wrong, and it is easily changed by changing the protolytic state of the reactants.

The dependence on the square root of ferric ion concentration and the independence of copper concentration are as required, but whereas the square root dependence may safely be taken as evidence for the reality of a closed-sequence iron cycle, too much weight should certainly not be laid upon the way in which copper ions enter the present scheme.

It makes no difference in the final expression if 45 is catalyzed by ferric ion, as we have actually assumed equilibrium in this step. 45 may therefore be substituted by for instance:

$$Cu^+ + FeO_2H^{++} \rightleftharpoons CuO_2H_2^+ + FeOH^{++} \qquad 45\ (a)$$

In the region of *low Cu-concentrations* we must take both cycles into consideration. This can be done in several ways, but in order not to make things too complicated we will stick to the class of reactions already laid out and add only two reactions:

$$Fe^{++} + CuO_2H_2^+ \rightarrow \dot{F}eOH^{++} + \dot{C}u^{++} + OH^- \qquad 15.0$$

$$Cu^+ + Fe\dot{F}eO_2H^{+4} + H_2O \rightarrow \dot{C}u^{++} + 2\dot{F}eOH^{++} + OH^- \qquad 42.0$$

They are deactivation reactions and their velocities are s_{iu}'' and s_{ui}''.

With reaction 36 in equilibrium we have: $x_6c_e = K_{36}x_3c_u$ and when s_i and s_u are the rates of the two generating cycles (*cf.* eq. 2):

$$s_i = x_3w_{31} \qquad s_u = x_6w_{64} \qquad s = s_u + s_i \tag{16}$$

$$\frac{s_u}{s_i} = \frac{k_{64}K_{36}c_u}{k_{31}c_e} = \frac{\gamma c_u}{c_i} \qquad (\gamma = \gamma_0 c_{H^+}) \tag{17}$$

$$\frac{1}{s} = \frac{1}{s_i}\,\frac{1}{1 + \gamma c_u/c_i} \tag{18}$$

For the moderator cycle we now get (*cf.* eq. 3):

$$\begin{aligned} s'' &= w_{0.33'} = k_{0.33'}\, c_e x \\ &= s_i'' + s_{ui}'' + s_{iu}'' + s_u'' \\ &= k_{12.0}x_1x_2 + k_{15.0}x_1x_5 + k_{42.0}x_4x_2 + k_{45.0}x_4x_5 \end{aligned} \tag{19}$$

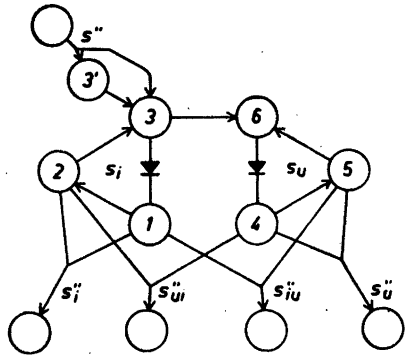

Fig. 2.

We still neglect s'' in comparison with s_i and s_u. Equations 4, 5, 6, 11, 12 and 13 then remain valid, and we can derive the following equations in a similar way and under similar conditions as before ($k_{21} \gg k_{23}$ and $k_{54} \gg k_{56}$):

$$\frac{1}{s^2} = \frac{1}{w_{0.33'}\,(1+\gamma c_u/c_i)^2}\left\{k_{12.0}\frac{x_1}{s_i}\frac{x_2}{s_i} + \frac{\gamma c_u}{c_i}\left(k_{15.0}\frac{x_1}{s_i}\frac{x_5}{s_u} + k_{42.0}\frac{x_4}{s_u}\frac{x_2}{s_i}\right) + \left(\frac{\gamma c_u}{c_i}\right)^2 k_{45.0}\frac{x_4}{s_u}\frac{x_5}{s_i}\right\}$$

$$= \frac{4}{(1+\gamma c_u/c_i)^2}\frac{1}{x^2}\left\{\frac{A_i^2}{c_i^2}\left(1+\frac{k_{32}c_i}{k_{31}x}\right)^2 + \frac{\gamma c_u}{c_i}\left(\frac{A_{iu}^2}{c_i^2}+\frac{A_{ui}^2}{c_i}\right)\left(1+\frac{k_{32}c_i}{k_{31}x}\right)\left(1+\frac{k_{65}}{k_{64}x}\right) + \left(\frac{\gamma c_u}{c_i}\right)^2\frac{A_u^2}{c_i}\left(1+\frac{k_{65}}{k_{64}x}\right)^2\right\}$$

$$A_{iu}^2 = \frac{k_{15.0}k_{21}}{4\,k_{0.33'}K_0k_{12}k_{23}k_{56}K_i^2}\,c_H^2 + \qquad (20)$$

$$A_{ui}^2 = \frac{k_{42.0}k_{54}}{4\,k_{0.33'}K_ik_{45}k_{23}k_{56}}\,c_H +$$

At given concentrations of iron and copper this gives an expression of the form

$$-\frac{dt}{d\ln x} = A_1\sqrt{1+\beta/x+\alpha^2/x^2} \qquad (21)$$

Only when $\beta = 2\alpha$ will this reduce to the form of (10), but in quite wide intervals it will not be very far off. The exclusive ability of the integrated equation (10) to represent the experimental results appears to be somewhat overestimated by Andersen. In the published results of a typical experiment with both copper and ferric ions (Ref. 2, Table 1) the deviations between calculated and experimental values vary in a systematic way culminating at 71 min. with —0.84 min.

The possibility of choosing $\beta \neq 2a$ introduces one more parameter and must invariably make it possible to obtain a better agreement with a given experiment. To test whether the obtained values of the parameters are in agreement with our expression we would need the complete experimental material, but only one series of measurements is published in full.

It may be of some interest in judging the significance of an obtained agreement between observed and calculated values in kinetic experiments in general to print here a table of deviations from various integrals to equation (21) corresponding to different values of $\beta/a = n$:

$$t = y_n = \int_{x_0}^{x} A_1 \sqrt{1 + na/x + a^2/x^2}\ \mathrm{dlog}\ (a/x) \qquad (22)$$

The chosen values of the parameters are:

1. $n = 3$, $A_1 = 14.37$, $\log a/x_0 = \bar{1}.050$
2. $n = 3$, $A_1 = 14.59$, $\log a/x_0 = \bar{1}.035$
3. $n = 1$, $A_1 = 16.50$, $\log a/x_0 = \bar{1}.120$

and for comparison Andersen's parameter values, which correspond to:

4. $n = 2$, $A_1 = 15.29$, $\log a/x_0 = \bar{1}.056$

Table 1. $\triangle = t_{calc.} - t_{obs.}$

The integral (22) can be solved in terms of the ordinary functions and the choice between using the solutions or using a numerical integration becomes a matter of taste and of available calculating machines. The values of Table 1 were actually calculated by numerical methods in the following way [6]:

a. $f = \sqrt{1 + na/x + a^2/x^2}$ was tabulated at intervals of 0.1 in $\log a/x$ for $n = 1$ and $n = 3$ and controlled through the differences of first, second, and third order f^1, f^2, f^3.
b. From a plot of the experimental values of t *versus* $-\log x$ was found where $-dt/d\log x$ had increased to twice the value at $t = 0$.
c. In each of the tables of f is found where f doubles up within a similar interval in $\log a/x$.
d. Starting at the beginning of this interval the sums of first order ^1f were formed and corrected to form a table of the integral.
e. A_1 was chosen to fit the initial slope.
f. $\log a/x_0$ was chosen such as to make a fit at $t = 100$ min.

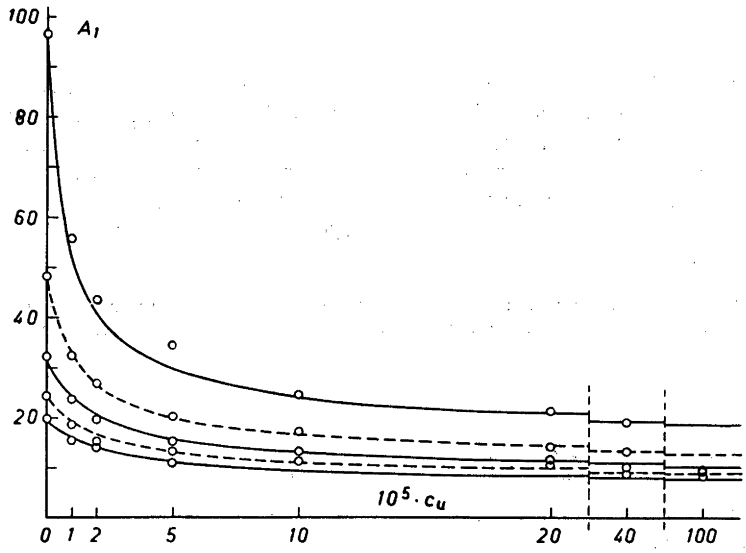

Fig. 3. Sten Andersen's experimental values of A_1 *(points) compared with curves calculated from eq. (23).*

g. The agreement was improved by trial and error with small changes in A_1 and log a/x_0.
h. For the final choice of parameters values were interpolated in the tabulated values of the integral using the f^1 and f^2 values as values of the differences of second and third order.

This procedure was adopted in order to obtain results which were directly comparable with Andersen's, although undue weights are actually placed on the initial measurements.

Equation (20) contains many adjustable parameters. Until experimental data from a wider range of iron concentrations and with variation of acidity appear, the only thing in the way of investigating quantitatively the applicability of (20) that can feasibly be done is to consider the constant A_1. If we suppose that it does not influence the value of A_1 very much whether it is chosen to fit an integral derived from (21) or from (10), we can take the experimental values from Table 2, Ref. 2, and try to fit them into the form required by (20) and (21):

$$A_1 = \frac{1}{1 + \gamma c_u/c_i} \frac{A_i}{c_i} \sqrt{1 + (\delta + \varepsilon c_i)\gamma c_u/c_i + \mu c_i(\gamma c_u/c_i)^2} \qquad (23)$$

In Fig. 3 the points represent the experimental values (Table 2, Ref. 2) and the lines equation (23) with $A_i = 0.0965$, $\gamma = 143$, $\delta = 0{,}50$, $\varepsilon = 0$, $\mu = 0{,}032$. A better fit could be obtained with negative values of ε.

Other equations to fit A_1, but to which no kinetic scheme has been found, are:

$$A_1 = \frac{0.555}{\sqrt{c_i}} \frac{4.9 + 10^5 c_u}{28\sqrt{c_i} + 10^5 c_u} \qquad (24)$$

$$A_1 = \frac{0.555}{\sqrt{c_i}} \frac{1.38 + 10^5 c_u + 4.13/10^3 c_i}{0.75 + 10^5 c_u + 250\ c_i} \qquad (25)$$

CONCLUSIONS

The reaction with pure iron seems accounted for by the present scheme in a very satisfactory way. For the combined action of copper and iron the scheme is far from final, though it is probably to be preferred to Andersen's original schemes as basis for further investigations. A more general conclusion concerns the danger of placing too much confidence in a scheme of reactions because it fits the kinetic data, even though a great number of others have been ruled out.

Except for the calculations in the last part, the content of this paper was presented in an *ex auditorio* opposition at the formal defense of the thesis of V. Sten Andersen on June the 15th, 1954.

On the Use of a Thallic-thallous System as a pH Indicator

E. RANCKE-MADSEN and T. KJÆRGÅRD

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

In a former paper Rancke-Madsen, Skarbye-Nielsen and Østergaard [1] have shown that the ceric-cerous redox system on the addition of a suitable redox indicator can be used as pH indicator.

In the present paper it has been shown that an indicator system can be prepared in a similar way by the thallic-thallous redox system upon addition of potassium iodide and starch. The result is an indicator with two transition intervals in the pH scale, one of which is clear, reproducible and reversible. The transitions take place within a narrow pH range. Further it has been shown that this indicator system can be used as an indicator in the titration of carbonate ion as a monovalent base.

THE INDICATOR SYSTEM

The redox potential in a solution of a thallic + thallous salt is determined by:

$$E = E_o + \frac{0.06}{2} \cdot \log \frac{[Tl^{+++}]}{[Tl^{+}]}$$

E_o is reported [2] to be 1.280 volt. In the above expression $[Tl^+]$ is independent of pH, whereas $[Tl^{+++}]$, owing to the hydrolysis of the thallic ions and a possible precipitation of the sparingly soluble thallic oxide, is strongly dependent on pH (except at low pH values) [2]. It is stated [3] that thallic oxide is precipitated within a pH-range of *ca.* 1—2.5.

A suitable redox indicator must be added to the thallic-thallous system in order that the resulting system may be used as a pH indicator. Potassium iodide + starch proved to be applicable as a redox indicator. On addition of potassium iodide thallous iodide is precipitated, for which reason $[Tl^+]$ in the above expression is dependent on the amount of iodide added; but the resulting $[Tl^+]$ is still independent of pH. Iodide-starch changes from colourless to blue at $E = 0.60$—0.65 volt, and again from blue to colourless at $E = ca.\ 0.90$ volt (in both cases at pH = 7) [4].

In the indicator system mentioned here E increases with decreasing pH, and both the transitions mentioned have been observed.

EXPERIMENTAL

Solutions: Thallous nitrate: A 0.060 *M* $TlNO_3$ solution was prepared by dissolving the calculated weight of the salt in an appropriate amount of water.

Thallic nitrate: Thallous nitrate was oxidized with chlorine in a basic solution to yield a precipitate of thallic oxide. This substance was dissolved in concentrated nitric acid, and this solution was diluted such that the resulting solution of thallic nitrate was *ca.* 2 *M* with respect to nitric acid. It was necessary to acidify the solution rather strongly in order to prevent extensive hydrolysis of the thallic ions.

The content of thallic salt in this solution was determined by thiosulphatimetric titration: To 25 ml of the solution 2 g of potassium iodide were added, causing the formation of a dark-coloured precipitate ($\rightarrow TlI + I_3$). Then 2 ml of 1 % starch solution and 15 ml of ligroine were added, after which titration was performed with standard 0.1 *N* sodium thiosulphate until the iodine colour disappeared from the ligroine phase. The advantage of using ligroine (instead of a more dense liquid such as chloroform) is that ligroine is lighter than the water phase, and the precipitate therefore does not interfere with observations made on the top layer. The observation of the transition in this titration is not possible unless ligroine or a similar substance is added. The solution prepared in this way was found to be a 0.0642 *M* $Tl(NO_3)_3$.

Potassium iodide: The concentration of iodide in the *ca.* 0.1 *M* solution used was determined by argentometric titration, using dichlorofluorescein as adsorption indicator.

Apparatus: Values of pH and *E* were measured by means of a "pH meter 22" (Radiometer, Copenhagen). Reference electrode: Calomel electrode.

Experimental technique: 1) In a 100 ml beaker the following mixture was made: 25 ml water, 3 ml 1 % starch, *ca.* 5 ml 0.1 *M* sodium hydroxide.

2) A thallic nitrate solution was added (from a semi-micro burette), causing the solution to turn deeply yellow. The thallic hydroxide formed must be supposed to be in colloid solution. The pH in this solution was now *ca.* 11—12.

3) Thallous nitrate solution was added (from semi-micro burette).

4) Potassium iodide solution was added (from semi-micro burette), causing the formation of a yellow precipitate of thallous iodide. The solution was a deep yellow.

5) Nitric acid (0.1 *M*) was then added dropwise until the first colour transition (blue iodine-starch colour) was reached. The solution before this transition was yellow and the colour changed from yellow past green to blue. The deep green colour (situated between yellowish green and bluish green) has been regarded as a transition (first transition) in the experiments described in this paper.

6) pH and *E* were measured.

7) Nitric acid (0.1 *M*) was again added dropwise until the blue colour disappeared (second transition).

8) pH and *E* were measured.

RESULTS

Using the above method, a number of experiments were performed in which the added quantities of thallic and thallous nitrate were constant, but the quantity of potassium iodide was varied. Table 1 shows the mean values found in some series of experiments. On the addition of a very small quantity of iodide (series 1) no transition took place. The addition of a slightly larger quantity of iodide (series 2) produced a just observable — but indistinct — colour transition. It was not until a still larger quantity of iodide (series 3) was added that clear and distinct transitions were observed. The individual experiments in series 3 are recorded in Table 2. The figures in the last four columns refer to the reproducibility of the transitions: When the equivalence point has been determined for the first time, a little 0.1 *M* sodium hydroxide was added, causing the colour to change back. Then some more 0.1 *M* nitric acid was added, and when the transition occurred the pH and *E* values were again

Table 1. Mean values of pH and E in 1st and 2nd transitions of the indicator system thallic-thallous to which were added potassium iodide and starch.

The series of experiments were carried out at the temperature $t°$. In all experiments 0.20 ml of 0.0642 *M* $Tl(NO_3)_3$ and 0.20 ml of 0.060 *M* $TlNO_3$ were used. This means that the solution contains 0.02568 milliequivalents Tl^{+++} as oxidizing agent. A 0.01078 *M* KI was used. The *E*-values were corrected in order to have them stated in millivolt relative to the normal hydrogen electrode.

Series of Expts.	$t°$	ml KI	= milli-equivalents I^-	1st transition		2nd transition	
				pH	*E*	pH	*E*
1	22	0.20	0.00216		—	—	—
2	25	0.40	0.00432	7.15	757	3.92	1 040
3	24	0.50	0.00539	7.27	754	3.94	1 020
4	22	1.00	0.01078	7.85	707	3.61	1 036
5	22	1.50	0.01617	8.28	679	3.12	1 050
6	22	2.00	0.02156	8.45	667	2.08	1 058
7	25	2.25	0.02426	8.46	664	1.64	1 062
8	25	2.30	0.02479	8.47	662	—	—
9	25	2.50	0.02695	8.53	659	—	—

determined. The first transition proved to be easily reproducible at exactly the same values of pH and *E*; this was the case in all the other series of experiments, in which analogous tests were made. As regards the second transition, this can be satisfactorily reproduced, but it takes place at a higher pH and a lower *E* value. The other series gave the same results. These results may be due to the fact that some iodine is irreversibly oxidized to a higher oxidation number that that of free iodine.

*Table 2. Individual experiments in series No. 3 (*cf. *Table 1).*

The pH and *E*-values at the 1st and 2nd transitions of the indicator system thallic-thallous to which were added potassium iodide and starch are given in the four first columns. The pH and *E*-values in the four last columns refer to the reproducibility of the transitions (*cf.* the text). $t = 24°$. In all the experiments 0.20 ml of 0.0642 *M* $Tl(NO_3)_3$, 0.20 ml of 0.060 *M* $TlNO_3$ and 0.50 ml of 0.01078 *M* KI were used. The *E*-values were corrected in order to have them stated in millivolt relative to the normal hydrogen electrode.

m = mean value. μ = uncertainty on the single determination. μ_m = uncertainty on the mean value of the determinations.

8	7.20	760	3.91	1 022	7.21	755	—	—
9	7.30	749	4.00	1 020	7.25	755	—	—
10	7.30	750	3.81	1 030	—	—	4.10	1 000
m	7.27	754	3.94	1 020	7.26	753	4.21	999
μ	0.06	5	0.15	19	0.04	2	0.16	11
μ_m	0.02	2	0.05	6	0.02	1	0.08	6

The results of the rest of the series are shown in Table 1. The uncertainty in these series was in no case more unfavourable for the first transition than that stated for series of experiments No. 3. The first transition proved to be distinct, reproducible and reversible all the way through. The second transition on the other hand, became less and less clear. Already in series No. 6 it was difficult to observe when the last blue colouring disappeared. It also became more and more difficult to reproduce the second transition. As the second transition implies that all iodide has been oxidized to free iodine, an excess of iodide ions in proportion to thallic ions will involve that the second transition cannot take place. Thus, the use of more than 2.38 ml of the potassium iodide solution represents an excess, but even the use of 2.30 ml (series No. 8) caused the nonappearance of the second transition.

As will be noticed, the E values at the transitions for all the experiments were higher that those stated in the literature [4] at the transitions for iodine-starch: 0.60—0.65 volt and *ca.* 0.90 volt, respectively. This may be due to the fact that owing to the yellow colour of the solution an excess of acid must be added in order to produce a distinct transition of colour. The excess of acid brings about a lower pH and consequently a higher E value.

In order to investigate the influence of the concentrations of thallic and thallous ions on the results, some series of experiments were performed, the results of which are shown in Table 3. It is seen that particularly the first transition is not greatly influenced by minor alterations of the concentrations mentioned.

Table 3. The mean values of pH and E *at the 1st and 2nd transitions of the indicator system thallic-thallous with potassium iodide and starch added.*

$t = 24°$. 0.0642 M $Tl(NO_3)_3$, 0.060 M $TlNO_3$ and 0.01078 M KI were used. The E-values have been corrected in order to have them stated in millivolt relative to the normal hydrogen electrode.

TITRATION OF CARBONATE

The indicator system mentioned above (first transition) was tested in the titration of carbonate ion as monovalent (monobasic, monoacid) base:

$$CO_3^{--} + H^+ \rightarrow HCO_3^-$$

The equivalence point is at $pH = \frac{1}{2}(pk_1 + pk_2) = ca.$ 8.3, depending to a certain degree on the ionic strength.

EXPERIMENTAL

Solutions: Sodium carbonate: Dried, anhydrous Na_2CO_3 *p.a.* was weighed, and a solution of known concentration was prepared. The concentration was also checked by titration with standard 0.1 *M* nitric acid after carbon dioxide had been boiled out. Result: The solution made was found to be a 0.2471 *M* Na_2CO_3.

Nitric acid: The standard solution was a 0.1055 *M* HNO_3.

Thallous nitrate, thallic nitrate and potassium iodide: The solutions described earlier in this paper were used.

Experimental technique: Since the thallic nitrate solution used for the production of the indicator system is strongly acid, it was necessary to adjust the indicator system at the pH value required (*ca.* 8.3) before the addition of the sample (*in casu* the solution of sodium carbonate).

Production of the indicator system: 25 ml water, 3 ml 1 % starch, *ca.* 5 ml 0.1 *M* sodium hydroxide, 0.20 ml thallic nitrate (*i.e.* 0.013 millimole), 0.20 ml thallous nitrate (*i.e.* 0.012 millimole), and 1.50 ml potassium iodide were, as in the earlier experiments, brought to the first transition by means of 0.1 *M* nitric acid. According to previous experiments pH is equal to 8.28.

10.201 ml of 0.2471 *M* Na_2CO_3 was added, after which titration was carried out with 0.1055 *M* HNO_3 to the same transition; the end volume was *ca.* 70 ml. In this solution the ionic strength was different from that in the indicator system before the addition of sodium carbonate. An experimental investigation shows that at the equivalence point the pH = 8.20 in the final volume. However, experiments also show that the quantity of acid which has to be used in order to change pH in the solution of the indicator system from 8.30 to 8.10—8.20 is very small and equal to *ca.* 0.02 ml. This means that the error which is made when fixing the solution of the indicator system at pH = 8.28 instead of pH = 8.20 can be considered negligible.

RESULTS

a) After various experiments the above indicator system was found to be the one that gave the most detectable change of colour at the equivalence point pH = 8.20.

The colour changes were found by fixing the indicator system at pH = 8.28. Then a little 0.1 *M* sodium hydroxide was added. The solution was diluted with water, and then 0.1 *M* nitric acid was added dropwise until the final volume was *ca.* 70 ml. The following colour changes were observed:

pH > 8.45—8.50	yellow
pH = 8.45—8.50	incipient dark-colouring
pH = 8.25—8.30	faint green
pH = 8.20	green (point of equivalence)
pH = 8.10	bluish green
pH = 8.00—8.05	blue
pH = 7.90—7.95	deep blue

Table 4. Titration of carbonate ion as monovalent base.

Indicator system: Thallic-thallous with potassium iodide and starch added. Titrand: 10.201 ml of 0.2471 *M* Na_2CO_3. Titrator: 0.1055 *M* HNO_3. As real value is considered: 23.89 ml HNO_3.

m = mean value. μ = uncertainty on single determination. μ_m = uncertainty on the mean value of the determinations.

b) The known solution of carbonate was titrated visually to the above-mentioned green colour. Sixteen experiments were carried out each with the same quantity of carbonate. The results are given in Table 4. Since the solutions were all of the same known concentration, calculations can be made to the effect that 23.89 ml 0.1055 *M* HNO_3 is equivalent to the quantity of carbonate used. It will be seen that the mean values of the results of the experiments (23.90 ml) is in good agreement with this, and that the individual results are in the interval 23.89 ml $\pm$ 1 %. Whenever titrations are carried out quickly, there is a tendency to use too much acid, possibly because this causes a local evolution of carbon dioxide from the solution.

The titrations were repeated with new solutions with results corresponding to those mentioned above.

Therefore, the results show that the indicator system in question can be used for the titration of carbonate ion to hydrogen carbonate ion. The method is fairly accurate, but cannot be characterized as a quick method.

On the Method of Continuous Variations

FLEMMING WOLDBYE

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The implications and the validity of the assumptions made in the theory and in the application of the method of continuous variations as used in complex chemistry have been examined, and the results of such applications from numerous references (22 of which are given in the article) have been compiled and compared to results obtained by different methods where possible. On the basis of this it appears that the method can in general not be considered very reliable and that results obtained by the method must in general be considered as indications rather than solutions. In particular, most of the complexity constants so obtained must be considered erroneous in cases where the ligand number exceeds one. The method of continuous variations is compared to J. Bjerrum's method of corresponding solutions, the latter being superior in that it, for systems to which it is applicable, furnishes quantitative results.

Since the invention of the method of continuous variations (in the following referred to as c.v.) and especially since the work of Vosburgh and Cooper [1] this method has been extensively used in investigations of complex compound formation in solution. Furthermore c.v. has been adopted by standard works on physico-chemical methods for the investigation of reactions in solution [2,3]. It has therefore been of interest to compile some of the data obtained by means of c.v. for a critical review of the implications and the validity of the method.

The invention of c.v. is usually ascribed to P. Job [4,5]. It deserves mentioning that the principles of the method were already outlined by Denison [6] in 1912.

We shall have to consider two different applications of the method:

1) The application to cases in which the reactants, M and A, form only one complex, whereby it is possible not only to establish the stoichiometric composition of the complex but also to calculate its formation constant.

2) The application to cases in which M and A form several complexes, whereby only the composition of (some of) the complexes can be determined.

In the following discussion C denotes total concentrations, [A] the actual concentration of species A and x the "mole fraction" $\frac{C_A}{C_M + C_A}$.

FORMATION OF ONE COMPLEX ACCORDING TO

$$mM + nA \rightleftharpoons M_mA_n$$

Briefly resuming the theory (for details see Ref.[5]) we shall consider the systems formed by mixing $(1—x)$ volumes of a solution of M ($C_M = C_o$) with x volumes of a solution of A ($C_A = rC_o$), x varying from 0 to 1 (volume changes being neglected). Assuming constant activity coefficients so that the law of mass action is valid in terms of concentrations, the systems, in which the equilibrium $mM + nA \rightleftharpoons M_mA_n$ is supposed to be established, are governed by the equations:

$$K \cdot [M]^m \cdot [A]^n = [M_mA_n];$$
$$C_o(1—x) = [M] + m[M_mA_n];$$
$$rC_ox = [A] + n[M_mA_n];$$

where K denotes the formation constant of M_mA_n. Differentiation of these with respect to x, setting $\frac{d[M_mA_n]}{dx}$ equal to zero and elimination of [M], [A] and $[M_mA_n]$ yield:

$$K \cdot C_o^{m+n-1} \cdot r^{n-1} \cdot m^{1-n} \cdot n^{1-m} \cdot ((n+mr)x_{max} - n)^{m+n} = (r-1)^{m+n-1} \cdot (n-(n+m)x_{max}) \quad (1)$$

where x_{max} denotes the value of x which renders $[M_mA_n]$ maximum. The necessary and sufficient condition for x_{max} to be independent of C_o is:

$$((n + mr)x_{max} — n) = (n — (n + m)x_{max}) = 0$$

from which one obtains:

$$x_{max} = \frac{n}{n+m}; \text{ and } C_M = C_A;$$

This means that on mixing equimolar solutions of M and A the concentration of the complex M_mA_n will reach its maximum value at $x_{max} = \frac{n}{n+m}$, while on mixing non-equimolar solutions x_{max} will depend on C_o, r and K. Therefore, if x_{max} can be determined experimentally it is possible

(I) to determine the stoichiometric ratio of M and A in the complex from experiments with equimolar solutions, and

(II) to calculate the value of K from experiments with non-equimolar solutions.

It is to be noticed that from the first type of experiments we do not obtain the values of m and n but only their ratio. Their actual values can be obtained from the second type of experiments by trial and error, since only insertion of correct values in (1) will lead to a constant value of K.

The value of x_{max} can be determined experimentally from measurements of the value, P, of a particular physical property of the solutions if, and only if P is of the form:

$$P = s_1 [M] + s_2 [A] + f([M_mA_n]);$$

where s_1 and s_2 are constants. The procedure is to evaluate the difference, Y, between the measured value of P and the value of P calculated under the

assumption of no complex formation. The function $Y = Y(x)$ will show an extremum at $x = x_{max}$. In order to verify this let us evaluate dY/dx:

$$\frac{dY}{dx} = \frac{d[M_mA_n]}{dx} \cdot \left[\frac{df([M_mA_n])}{d[M_mA_n]} - (s_1m + s_2n)\right]$$

It is seen that for well-behaved functions $f([M_mA_n])$

(I) Y will have an extremum at $x = x_{max}$ (except in the trivial case where $Y = 0$ for all x),

(II) if Y has more extrema than the one at $x = x_{max}$, the x values at which these other extrema are found will vary with C_o in the equimolar experiments.

In particular, if $f([M_mA_n]) = k[M_mA_n]$, Y can have only one extremum.

The assumptions made in the above mathematical treatment are the following:

1) Each of the reactants corresponds to one particular formula, *i. e.*, the reactants do not partake in equilibria (*e. g.* association, protolysis) other than the one in question;

2) The law of mass action is valid in terms of concentrations;

3) The reactants form only one complex.

Assumption No. 1 will often be justified. In case that an equilibrium of the type $A + bB \rightleftharpoons AB_b$ (*e. g.* A being a base taking up protons) is involved, the treatment will still be valid provided special precautions regarding concentrations are taken [7] (in the example chosen pH must be kept constant).

In order to fulfil condition No. 2 the experiments must be carried out at constant ionic strength or better in a constant salt medium of relatively high concentration. This imposes certain restrictions on the choice of property to be measured, excluding for instance such properties as freezing-point depression and other colligative properties, Faraday-effect, conductivity *etc.* rendering the accuracy obtainable by these methods too low. Results of early investigations utilizing such properties and neglecting the fulfilment of condition No. 2 must be considered unreliable (experimental proof of this has been given recently [8]). Recent investigations for the most part have been based on measurements of optical density, this being generally considered the most — and probably the only — satisfactory property. Exceptions are Refs.[9,10].

By far the most important limitation is introduced by assumption No. 3, especially since cases where only one complex is formed seem to be rare exceptions *. Failure to meet this requirement is the reason why most of the complexity constants determined by c.v. must be considered erroneous. In order to detect whether the assumption of only one complex is justified in a particular system Job [5] recommended the application of c.v. to the system utilizing the largest possible intervals of C_o and r. It is obvious that the formation of several complexes generally will influence the experimental values of x_{max} in such a way that the calculations will not lead to a constant value of K. If a constant value of K is obtained this therefore according to Job can be taken as a criterion for the justification of the assumption. An example will show how

* This and the following discussion do, of course, not apply to systems in which the highest complex formed is MA. In such cases the application of c.v. has sometimes proved successful [11].

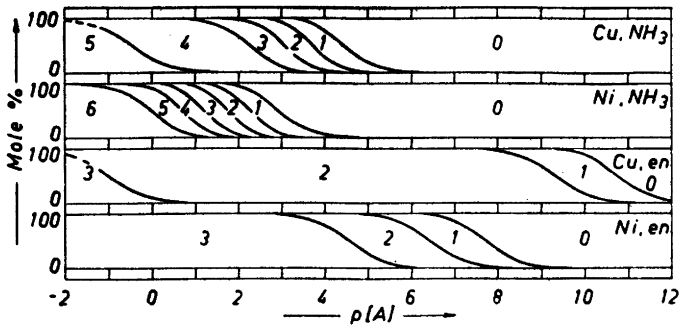

Fig. 1. Ranges of existence for the systems Cu++, NH_3; Ni++, NH_3; Cu++, en; and Ni++, en.

The constants for Cu++, en have been taken from Bjerrum and Nielsen[24], the others from Bjerrum [12]. The symbols 0,1,...6 designate the species M,MA...MA_6. The abscissa is p[A] = −log [A] and for concentrations higher than ~ 1 *M* an activity function of the free amine (see Refs.[12, 24]).

this procedure in some cases has led to erroneous conclusions due to the fact that the largest experimentally available intervals in C_o and r were not sufficiently large or were not employed.

Job [5] applied c.v. to the system cupric nitrate-ammonia measuring the optical density of the mixtures at 615 mμ. Experiments with equimolar solutions were carried out at C_o values between 0.05 and 0.20 mole/l, yielding $x_{max} = 0.80$. Consideration of the ranges of existence for the consecutive cupric ammine complexes (Fig. 1) indicates that in the equimolar experiments almost the total content of cupric ions was employed in the complex $Cu(NH_3)_4^{++}$ at $x = 0.81$—0.82 this complex having a concentration of 0.18—0.19 C_o, while for instance at $x = 0.50$ the cupric ions were distributed approximately as follows: 0.12 C_o Cu^{++}, 0.25 C_o $Cu(NH_3)^{++}$ and 0.12 C_o $Cu(NH_3)_2^{++}$, the total concentration of complexes being approximately 0.37 C_o. Since the lower complexes have considerably smaller extinction coefficients at 615 mμ than the cupric tetrammine ion, it is to be expected that the maximum in *Y* will occur close to $x = 0.80$ indicating the formation of this complex only.

If lower values of C_o had been used, deviations would have been found. Performing experiments at $C_o = 0.00102$ mole/l in order to check this, the present author has found a little pronounced maximum in the *Y* curve at $x = 0.67$ (see Fig. 2, curve I).

In the experiments with non-equimolar solutions Job varied C_{NH_3} between 0.2 and 1.0 mole/l and r between 5.4 and 102. Under these circumstances the position of the maximum in *Y* will essentially be determined by the formation of the cupric tetrammine ion yielding satisfactorily constant, but quite erroneous values of *K* (log $K = 9.3$, correct value log $K = 13.4$, extrapolated from data in Refs.[12, 13]).

If values of r smaller than 4 and low values of C_o had been employed, deviations would certainly have been found. Fig. 2 shows two experiments by the present author. Curve II represents measurements in which $C_o = 0.0102$

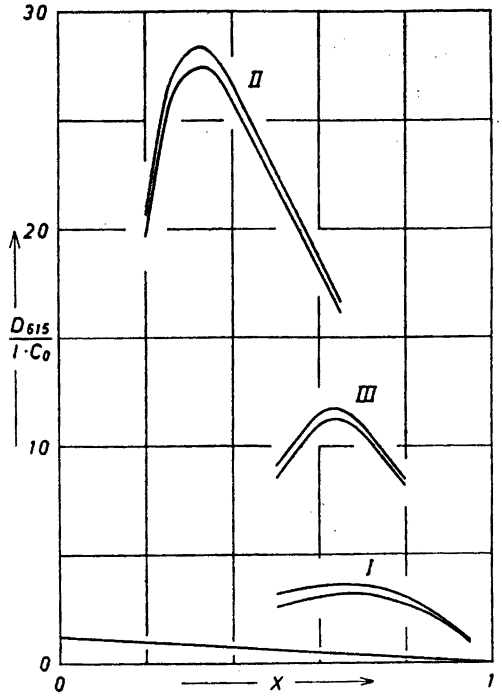

Fig. 2. Continuous variation experiments on the system Cu++, NH_3 in 2 M NH_4NO_3.

The ordinate is the optical density of the solutions at 615 mμ divided by the cell length, *l*, in cm and by the molar concentration of the Cu++ stock solution, C_o. The straight line represents the extinction due to the cupric ions under the assumption of no complex formation. In each pair of curves the upper curve connects the experimental points while the lower curve is the *Y*-curve.

	C_o	r	*l*	x_{max}
I	0.00102	1	10	0.67
II	0.0102	10.3	2	0.33
III	0.0102	2	5	0.64

The measurements were carried out by means of a Beckman DU spectrophotometer with photomultiplier attachment which was kindly put at my disposal by Professor M. Kilpatrick at Illinois Institute of Technology.

mole/l, r = 10.3, whereby $x_{max} = 0.33$ and log $K = 9.89$ which is still in fairly good agreement with Job's value. When decreasing values of r are employed the maximum of the curve moves towards higher x values and should, if the assumption of only one complex were correct, reach $x = 0.8$ at r = 1. However, at $C_o = 0.01$ mole/l the lower complexes become more important so that the maximum is found at an increasing distance to the left of the expected position as r → 1. As a result of this the term $((n+mr)x_{max} - n)$ in (1) decreases so as to reach zero at a value of r greater than one and then becomes negative.

Curve III represents measurements at $C_o = 0.0102$ mole/l, $r = 2$ whereby $x_{max} = 0.64$ which renders the meaningless value of $K = -8.8 \cdot 10^{10}$.

While thus the procedure actually can give the information that the assumption of one complex only is not justified in this case, it is seen that the variations in C_o and r employed by Job were not sufficiently large to reveal this. Similar criticism may be directed towards several c.v. investigations, *e. g.* Refs.[14, 17].

The uncertainty always present as to whether condition No. 3 is fulfilled is a very serious weakness of this application of c.v. which renders the results so obtained quite inconclusive. Different methods for the calculation of the complexity constant have been suggested [2, 6, 10, 11, 18]. None of these, however, remedies the difficulty elucidated in the above example.

FORMATION OF CONSECUTIVE COMPLEXES ACCORDING TO

$$M + nA \rightleftharpoons MA_n; \qquad MA_n + pA \rightleftharpoons MA_{n+p}; \qquad MA_{n+p} + qA \rightleftharpoons MA_{n+p+q};$$

C.v. was first applied to cases of this kind by Vosburgh and Cooper [1], and the most general treatment has been given by Katzin and Gebert [19] who confining themselves to the measurements of optical densities (or any other property depending linearly on the concentrations of M and the complexes) derived the conditional equation:

$$\frac{x_{max}}{1-x_{max}} = n + \frac{p[(e_2-e_o)c_2 + (e_3-e_o)c_3] + q(e_3-e_o)c_3}{(e_1-e_o)c_1 + (e_2-e_o)c_2 + (e_3-e_o)c_3} \cdot \left[1 + \frac{n(c_1+c_2+c_3) + p(c_2+c_3) + qc_3}{C_o(1-x_{max})}\right] - \frac{p(p+n)(c_2+c_3) + q(q+n+2p)c_3}{C_o(1-x_{max})} \qquad (2)$$

in which x_{max} indicates such values of x for which the Y function has extrema, $e_o, \ldots e_3$ indicate the molar extinction coefficients of M and the complexes MA_n, MA_{n+p} and MA_{n+p+q}, and c_1, c_2, c_3 the molar concentrations of the same complexes, while C_o is the concentration of the equimolar solutions of M and A being mixed.

From (2) the conditions for the x values rendering c_1, c_2 and c_3 maximum are obtained by inserting $e_1 \neq e_o$, $e_2 = e_3 = e_o$ and so on as follows:

$$\frac{x}{1-x} = n - \frac{p(p+n)(c_2+c_3) + q(q+n+2p)c_3}{C_o(1-x)} \qquad (3)$$

$$\frac{x}{1-x} = (n+p) + \frac{npc_1 - q(n+p+q)c_3}{C_o(1-x)} \qquad (4)$$

$$\frac{x}{1-x} = (n+p+q) + \frac{n(p+q)c_1 + q(n+p)c_2}{C_o(1-x)} \qquad (5)$$

(3) and (4) being identical with those derived by Vosburgh and Cooper [1] for the case of two complexes only (insertion of $c_3 = 0$):

$$\frac{x}{1-x} = n - \frac{p(p+n)c_2}{C_o(1-x)}; \qquad \frac{x}{1-x} = (n+p) + \frac{npc_1}{C_o(1-x)}$$

These equations make possible an approximate calculation of n and p in cases where the values of the consecutive complexity constants warrant the assumption that c_1 is small when c_2 is maximum and vice versa, provided the corresponding x values can be determined experimentally.

On differentiation of the Y function for the case of two complexes:

$$Y = e_o c_o + e_1 c_1 + e_2 c_2 - C_o(1-x)e_o$$

and of the equation

$$c_o = C_o(1-x) - c_1 - c_2$$

with respect to x and combination of the results one obtains

$$\frac{dY}{dx} = (e_1 - e_o)\frac{dc_1}{dx} + (e_2 - e_o)\frac{dc_2}{dx} \qquad (6)$$

Depending on the sign of the two parentheses, Y may have one or two extrema the positions of which generally bear no simple relation to the composition of the complexes.

However, by a suitable choice of the wavelengths at which the measurements are carried out, it becomes possible in some cases to obtain valuable information.

a) If the wavelength can be so chosen that one of the parentheses in (6) vanishes (*e. g.*, $e_2 = e_o$, $e_1 \neq e_o$) Y will assume its extremum value at the x value which renders one of the complex concentrations maximum (in the example mentioned c_1).

b) If $e_1 = e_2$ the extremum condition for Y reduces to

$$\frac{dc_1}{dx} + \frac{dc_2}{dx} = 0$$

Provided the consecutive complexity constants have sufficiently high values this will take place at an x value close to that at which $\frac{dc_1}{dx} = 0$ ($\frac{dc_2}{dx}$ still being small in this range).

c) If $e_2 \gg e_1 > e_o$ and the consecutive constants are high, Y will continue to increase after c_1 has reached its maximum. Letting Y_1 denote the difference between the experimental value of P and the value calculated under the assumption that all M is converted into MA_n at $x/(1-x) = n$ and that MA_n does not react further with A, and keeping in mind that the high values of the consecutive constants mean that c_o will be vanishingly small when c_2 assumes considerable values, we obtain the following maximum condition for Y_1:

$$(e_2 - e_1)\frac{dc_2}{dx} = 0$$

Y_1 consequently will have its maximum at the x value that renders c_2 maximum.

In cases where more complexes are formed a discussion similar to the above can be carried out, still under the assumption that the consecutive

constants are high enough so that it is possible to divide the Y curve into intervals in each of which one or more of the concentrations may be neglected.

The choice of wavelengths in accordance with the above requirements is usually made in the way suggested by Vosburgh and Cooper, namely as follows. Solutions containing M and A in ratios such as $C_M/C_A = 1:1, 1:2, \ldots, 1:6$ are made up and their spectra recorded. It is assumed that these spectra then constitute close enough approximations to the spectra of the complexes of the corresponding composition as to permit the determination of wavelengths fulfilling conditions of the types mentioned in a), b) and c). A somewhat different approach has been employed by Underwood, Toribara and Neuman [20] but the fundamental assumption is the same.

The usefulness of c.v. in this form has been very differently estimated by different authors [7, 8, 21-24]. We shall undertake a closer examination of the general validity of the assumptions involved.

Let us first direct our attention towards the assumption that the consecutive constants are of sufficiently high values to make the above treatment valid. This assumption is also involved in the methods by which suitable wavelengths are chosen. Before attacking this problem it is appropriate to stress a fact that has mainly been emphasized by N. Bjerrum [25] and J. Bjerrum [12], namely that the distribution of the central ion on the different complexes in a given solution is determined solely by the free ligand concentration. In accordance with this conception the conditions in the solutions under consideration can be very conveniently represented by graphs similar to those in Fig. 1.

Considering such graphs we observe two important facts. In the first place, the initial concentrations of the solutions employed should be high enough to keep the complex under consideration at a high degree of formation. For example, in a solution in which $C_{Ni^{++}}=0.5$ and $C_{NH_3} = 3.0$ the Ni^{++} will not for the most part be present as the 1:6 complex but will be distributed approximately as follows: 50 % $Ni(NH_3)_5^{++}$, 25 % $Ni(NH_3)_6^{++}$ and 25 % $Ni(NH_3)_4^{++}$. At least four times as concentrated solutions must be used in order to make the 1:6 complex prevail. In picking wavelengths it would therefore be wise to examine whether the spectra recorded for the 1:1, 1:2 ... solutions vary considerably with the total concentration. Such examinations have in general not been published in c.v. investigations.

We observe further that in order to justify the above treatment the ranges of existence must be wide enough (the consecutive constants high enough) so that the most part of the central ion can be present in the form of the particular complex under consideration at some appropriate value of the free ligand concentration. As is seen from the graphs this is not always the case. In fact, very often not more than 50 % of the content of central ion can be present in the form of one particular complex at any value of the free ligand concentration. In the case of bi- and poly-dentate ligands the assumption is frequently valid, but in the investigation of unknown systems it is obviously not safe to make predictions regarding these conditions.

In view of these observations it is readily explained why c.v. in many cases has rendered incomplete results. For if the assumptions are not correct, c.v. plots will in general still show maxima, but the interpretation of such data

is apt to lead to unreliable results. An example is the investigation of the cupric-ammonia system by Vosburgh and Cooper [1], to which both of the above objections are valid.

In some cases difficulties of a different nature may arise. The mathematical treatment remains valid if M or A partake in protolytic equilibria provided pH is held constant (see p. 301). It breaks down, however, if polymerizations are involved. Not only will the x values rendering the Y functions maximum be displaced, but if the polymerization products are coloured this may further influence the results. Caution is therefore necessary in cases such as for instance the one referred to by Martell and Calvin [3] as simple and clear-cut, namely the investigation of the uranyl-sulfosalicylate system by Foley and Anderson [26], in which polymerization and hydrolysis of the uranyl ion are likely to take place at the higher pH values.

In recent work [19,27,35] Katzin and co-workers have utilized the light absorption in the ultraviolet of some ligands (NO_3^-, SCN^-) in c.v. experiments. While Beer's law usually holds within the experimental error for transition metal ions in aqueous solution, the optical density of for instance nitrate solutions is not proportional to the formal nitrate concentration. It appears reasonable to expect that the formation of ion pairs or similar aggregates of ions in which the distance between the ions is small will influence the spectra of the ions involved, and more so the less solvated and the more polarizable the ions. In organic solvents of low dielectric constant such interaction is likely to take place to a higher degree than in water. The spectral behaviour of the colourless anions in aqueous and organic solutions is not very thoroughly investigated but at least the spectrum of the nitrate ion appears to be dependent to a considerable degree on the surroundings. Such phenomena may seriously affect the validity of the assumptions involved in c.v., and it is suggested that the validity of Beer's law for the species in question be tested whenever c.v. is extended to fields where this is not already well established.

COMPARISON BETWEEN C. V. AND J. BJERRUM'S METHOD OF CORRESPONDING SOLUTIONS

Finally attention should be called to the fact that another purely optical method of similar experimental simplicity is available for the solution of problems of the type to which c.v. is generally applied, namely J. Bjerrum's method of corresponding solutions [28]. This method may be applied to systems in which complexes of the type MA_n are formed by reversible step reactions, the only condition for the application being that the spectra of the species M, MA ... MA_n are different.

Two solutions (referred to by subscripts 1 and 2) of different total concentrations of M and A are said to be corresponding if:

$$\bar{n}_1 = \bar{n}_2, \text{ and therefore } [A_1] = [A_2],$$

where $\bar{n} = \frac{C_A - [A]}{C_M}$ is the formation function. Procedures for finding corresponding solutions have been devised [28]. Since C_{A1}, C_{A2}, C_{M1} and C_{M2} are known it is possible to calculate [A] and n so that each pair of corresponding

solutions yields one point of the formation curve. When the formation curve has been determined the complexity constants may be calculated by standard procedures [30] assuming that all the steps MA ... MA_{n-1} are represented in the equilibrium. This assumption seems to be of a very general if not universal validity. The fact that the formation curves for some systems may be adequately described in terms of fewer parameters than all of the consecutive complexity constants as pointed out by Wormser [29] does not make the logically more satisfactory and in some cases clearly proven conception of a stepwise formation less probable. If in a particular system some of the steps are not employed this will find its expression in the values of the corresponding constants.

The method of corresponding solutions has been applied to the cupric-ammonia system [28] in which case the results were in agreement with those obtained by other methods, to the cupric-chloride system [31] and to the stepwise formation of aquo metallic ions in alcoholic solution [32]. Olerup has independently applied a similar principle to the ferric-chloride system [33].

The method of the corresponding solutions has two advantages over the method of continuous variations:

(I) When applicable, it furnishes quantitative results in terms of complexity constants.

(II) When not applicable, *i. e.*, when the complexity constants or the extinction coefficients have values which make the experimental accuracy low, this is clearly indicated by the experimental results.

The failure of c.v. in this respect makes it an indicative rather than a conclusive method.

Acknowledgment. I wish to express my gratitude to professor J. Bjerrum for having suggested this investigation and for his kind encouragement and criticism during the work.

Enzymatic Hydrolysis of Organophosphorus Compounds

V. Effect of Phosphorylphosphatase on the Inactivation of Cholinesterases by Organophosphorus Compounds *in vitro*

KLAS-BERTIL AUGUSTINSSON and GUNILLA HEIMBÜRGER

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

The effect of phosphorylphosphatase of human serum on the inactivation of cholinesterases by organophosphorus compounds *in vitro* was studied.

The esterase inactivation is a progressive reaction. Phosphorylphosphatase cannot reactivate inactivated cholinesterases when the former is added after maximum esterase inactivation is reached. On the other hand, phosphorylphosphatase stops the inactivation at a certain level when added before maximum inactivation is reached.

The results are discussed from a kinetic point of view.

The existence of enzymes, phosphorylphosphatases, catalysing the hydrolytic breakdown of organophosphorus compounds has been reported recently [1,2]. A series of previous papers discussed some properties of the phosphorylphosphatase ("tabunase") of human blood serum [3], the effect of reversible cholinesterase inhibitors on that enzyme [4], and the enzyme specificity [5]. In the present paper the effects were studied when a phosphorylphosphatase preparation was added to cholinesterases, inactivated by various organophosphorus compounds.

METHODS AND MATERIAL

Phosphorylphosphatase and cholinesterase activities were measured by the Warburg technique [1,6]. Fraction IV-1 of human postpartum serum was used as enzyme source for phosphorylphosphatase. Acetylcholinesterase (AChE) was a partly purified preparation of the electric tissue of *Torpedo marmorata*, and Fraction IV-6 of human serum was used as a (butyryl-) cholinesterase (ChE) preparation.

The following organophosphorus compounds were used: tabun (dimethylamidoethoxy-phosphoryl cyanide), DFP (di*iso*propoxyphosphoryl fluoride), TEPP (tetraethylpyrophosphate), and mintacol (E 600, diethyl-*p*-nitrophenyl-phosphate). Acetylcholine chloride was employed as substrate for cholinesterases; its concentration during the esterase determination was usually 1.10×10^{-2} *M* (total volume of the reaction mixture, 2.00 ml).

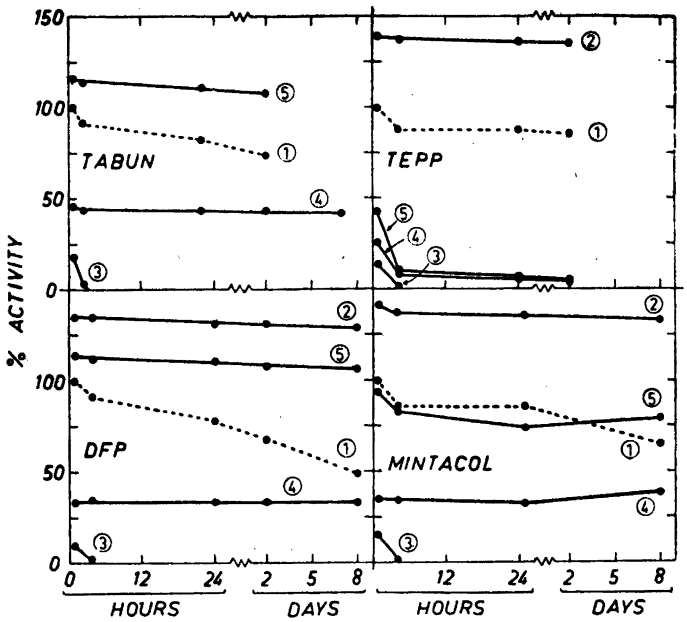

Fig. 1. Effect of phosphorylphosphatase (Fraction IV-1) on acetylcholinesterase (AChE, electric tissue) and on the inhibition of this esterase by various organophosphorus compounds (P) tested after various periods of time. Esterase activity tested against acetylcholine (1.10 × 10^{-2} M). Total volume of the incubation mixture, 1.6 ml, kept at 4° C. Esterase and phosphatase respectively were incubated 15 minutes with the organoposhphorus compound prior to further treatment. Concentrations of the organophosphorus compounds during incubation: tabun, 4.65 × 10^{-6} M; DFP, 1.17 × 10^{-3} M; TEPP, 1.58 × 10^{-5} M; mintacol, 7.42 × 10^{-5} M. 1) AChE; N.B. the phosphatase preparation has an esterase activity which is appr. 9 % of that of AChE; 2) AChE + phosphatase; 3) AChE + P; 4) (AChE + P) + phosphatase; 5) (Phosphatase + P) + AChE.

RESULTS

The effect of phosphorylphosphatase on inactivated cholinesterases. Acetylcholinesterase (AChE) and cholinesterase (ChE) were incubated for 15 minutes with an organophosphorus compound (P). Phosphorylphosphatase was then added and the first measurement of the esterase activity was performed after a further period of 45 minutes (Figs. 1 and 2, No. 4). In another series the phosphorus compound was incubated for 15 minutes with phosphorylphosphatase; then the cholinesterase was added and the activity of the latter determined (No. 5). The concentration of the phosphorus compound in each case was chosen to give 95 % or more inactivation of cholinesterases when the esterase was incubated for 45 or 60 minutes prior to the addition of substrate (acetylcholine) (No. 3). In a control series, the effect of phosphorylphosphatase on the cholinesterase activity was determined (Nos. 1 and 2). All five reaction mixtures were kept at 4° C and the cholinesterase activities tested after various periods of time. The results thus obtained with tabun, DFP, TEPP and mintacol are recorded in Fig. 1 (AChE) and Fig. 2 (ChE).

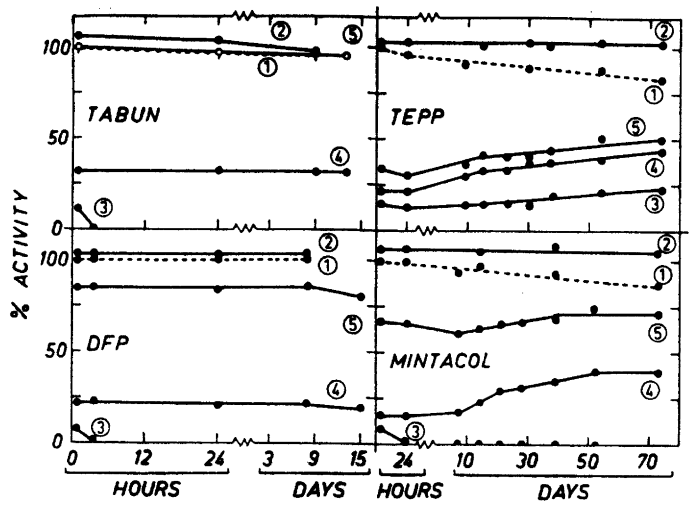

Fig. 2. Effect of phosphorylphosphatase (Fraction IV-1) on serum cholinesterase (Fraction IV-6) and on the inhibition of this esterase by various organophosphorus compounds (P) tested after various periods of time. Concentrations of the organophosphorus compounds during incubation: tabun, 2.33 × 10^{-6} M; DFP, 9.36 × 10^{-7} M; TEPP, 8.44 × 10^{-7} M; mintacol, 4.45 × 10^{-6} M. Numbers and further explanations as in Fig. 1.

It will be noted that the phosphatase preparation (Fraction IV—1) has a weak cholinesterase activity not exceeding 10 % of the activity of the cholinesterase preparation used.

Acetylcholinesterase (Fig. 1). A characteristic property of the phosphatase preparation is that it activates the acetylcholinesterase activity but not the (butyryl)cholinesterase activity (*cf.* Fig. 2). This activation (curve No. 2) will be discussed in a forthcoming publication. As was expected from the results described earlier —, the esterase inhibiting effect of tabun is lost by incubation with phosphatase (No. 5). This is also true for DFP. In both these cases the activating effect of the phosphatase preparation is partly retained even after incubation with the phosphorus compound. The latter effect, however, is lost when phosphatase hydrolysed mintacol. The situation is completely different for TEPP. We know that TEPP is enzymatically hydrolysed by the phosphatase preparation, but contrary to the other compounds tested the degradation products of TEPP seem to have a strong esterase inhibiting effect (No. 5).

The effect of phosphatase on inactivated acetylcholinesterase is seen in curve No. 4. After 15 minutes incubation with tabun, DFP and mintacol, the addition of phosphatase stops the esterase inactivation at a certain level, but there is no reactivation of the esterase activity even after 15 days (not indicated in Fig. 1) of incubation with phosphatase. TEPP seems to inactivate acetylcholinesterase to a maximum more rapidly (in 15 minutes or less) than do the other compounds tested. We conclude from these results that phosphatase stops the progressive irreversible inactivation of acetylcholinesterase

when added before the maximum effect of the inactivator is reached. Phosphatase, however, is not capable of reactivating the inactivated acetylcholinesterase under the experimental conditions used.

The effect of phosphatase on the process of acetylcholinesterase inactivation has been studied further and is discussed below.

Cholinesterase (Fig. 2). Phosphatase has no activating effect on human serum cholinesterase: there is a small increase of cholinesterase activity in the presence of phosphatase, but this effect is due to the weak esterase activity of the phosphatase preparation itself. A great part of the cholinesterase inactivating effect of phosphorus compounds is lost after incubation with phosphatase. The reaction products from this hydrolytic procedure, however, are still effective as inactivators of cholinesterase; this is contrary to the results obtained with acetylcholinesterase.

Phosphatase has no reactivating effect on cholinesterase inactivated by tabun or DFP (No. 4). For mintacol a slow but significant reactivation was observed. This reactivation must be catalysed by the phosphatase present, since a control experiment in the absence of phosphatase did not show this phenomenon. For TEPP, however, a spontaneous reactivation by hydrolysis is known to occur from previous observations [7,8]; phosphatase seems to catalyse this reactivation procedure (No. 4) to a small extent during the first days. From these experiments we conclude that phosphatase has no (as far as tabun and DFP are concerned) or a very weak reactivating effect on inactivated cholinesterase. However, as in the case of acetylcholinesterase, phosphatase stops the inactivation of cholinesterase when it is added before maximum inactivation is reached.

The progressive nature of the cholinesterase inactivation by tabun. The reaction rate at which cholinesterases are inactivated by an organophosphorus compound is different for various compounds and is also dependent on the nature of the enzyme preparation and on the concentration of the phosphorus compound used. This progressive nature of cholinesterase inactivation by tabun is illustrated in Fig. 3. Acetylcholinesterase was incubated with tabun and the esterase activity was then measured after 0, 10 and 20 minutes by adding acetylcholine to the incubation mixture (Fig. 3, A). The concentration of tabun used was such that after 60 minutes incubation of the esterase, the activity of the latter was reduced 95 %. It is seen in Fig. 3 that after 10 minutes incubation the esterase activity is reduced to 58.5 % and after 20 minutes to 39 %.

In a previous paper [9] it was demonstrated that acetylcholinesterase is protected by acetylcholine against the inactivation by tabun if the acetylcholinesterase is added before or at the same time as the inactivator. In Fig. 3 (B) the results are shown when acetylcholine is present from zero time and tabun is added to the enzyme-substrate mixture 10 and 20 minutes afterwards. The protective effect of the substrate against esterase inactivation by tabun is significantly demonstrated in this experiment.

The effect of phosphorylphosphatase on the process of cholinesterase inactivation. In a preliminary experiment, performed with acetylcholinesterase, and somewhat different from those described above, the effect of phosphorylphosphatase on the tabun-inactivated esterase was studied (Table 1) by simul-

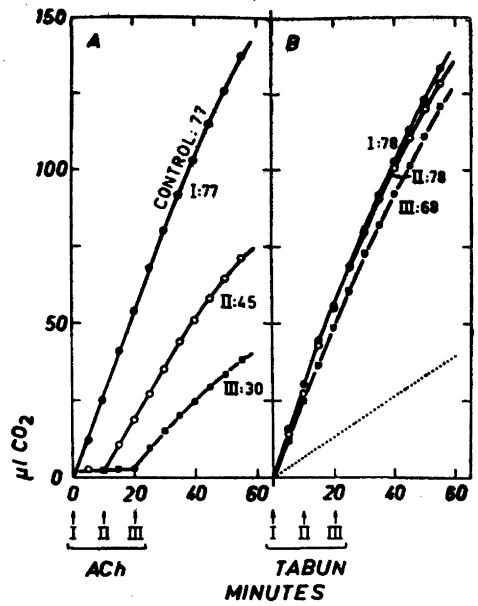

Fig. 3. The progressive nature of acetylcholinesterase inactivation by tabun. A) Esterase incubated with tabun from zero time; acetylcholine (ACh) added simultaneously with tabun (I), and after 10 (II) and 20 (III) minutes incubation. Arabic numbers refer to esterase activity (in b_{30} values). B) Acetylcholine present from zero time and tabun added simultaneously with ACh (I) and after 10 (II) and 20 (III) minutes.

taneous addition to the esterase of the phosphatase preparation and the acetylcholine (substrate). It was found that the activating effect of the phosphatase preparation on the esterase activity is not influenced by tabun. Furthermore, the low cholinesterase activity of the phosphatase preparation is reduced by

Table 1. Effect of phosphorylphosphatase (Fraction IV-1) on the inactivation of acetylcholinesterase (AChE, electric tissue) by tabun. AChE was incubated 45 minutes with tabun before the substrate (acetylcholine) or substrate + phosphatase was added. Phosphatase was added to AChE at the same time as the substrate, except in the last experiment where tabun and phosphatase were together 45 minutes before acetylcholine was added. Reaction mixture, 2.00 ml. In the two experiments (I and II) the concentration of tabun was different (appr. 2×10^{-8} M).

Enzyme system	Exp. I	Exp. II
AChE	91.5	154
AChE + Phosphatase	108.5	167
AChE + Tabun	20	76.5
(AChE + Tabun) + Phosphatase	31	89.5
Tabun + Phosphatase	8	10.5
(Tabun + Phosphatase)	1.5	6

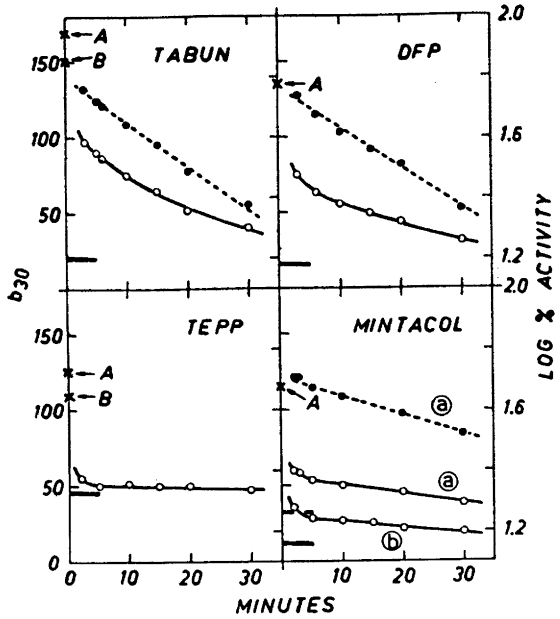

Fig. 4. Inactivation of acetylcholinesterase (AChE, electric tissue) by organophosphorus compounds. The reaction was stopped by adding phosphorylphosphatase (Fraction IV-1) after various periods of time. Esterase activity expressed in b_{30} values (left ordinate and full drawn lines). The logarithm of per cent activity (right ordinate and dotted lines) was calculated with the activity of the mixture AChE + phosphatase as control. Short and wide lines (on the ordinates) give the activity at maximum inactivation. A: activity of the AChE-phosphatase mixture; B: activity of the AChE preparation alone. Concentrations of the organopshophorus compounds: tabun, 4.16 × 10^{-8} M; DFP, 3.63 × 10^{-6} M; TEPP, 2.56 × 10^{-8} M; mintacol, a) 2.16 × 10^{-7} M; b) 4.32 × 10^{-7} M.

tabun. In the complex system, consisting of acetylcholinesterase + phosphatase + tabun + acetylcholine, we have to consider these two facts, *i. e.*, the activating effect on the esterase by phosphatase not influenced by tabun, and the inhibiting effect of tabun on the esterase activity of both acetylcholinesterase and the low one of the phosphatase preparation.

We have learned from the experiments described above that the inactivation of cholinesterases in most cases is progressive and it is surmised that it proceeds as a stepwise reaction (see further "Discussion" below). The effect of a phosphorylphosphatase preparation on the process of inactivation was therefore studied in more detail, especially the effects obtained by a certain concentration of the phosphorus compound before maximum inactivation was reached. The results of these experiments are shown in Figs. 4 and 5 and were obtained by employing the following experimental conditions. The phosphorus compound was added to the esterase and after various short periods of time (2 to 30 minutes) a phosphorylphosphatase preparation (Fraction IV—1) was added. The cholinesterase activity of that mixture was then determined with

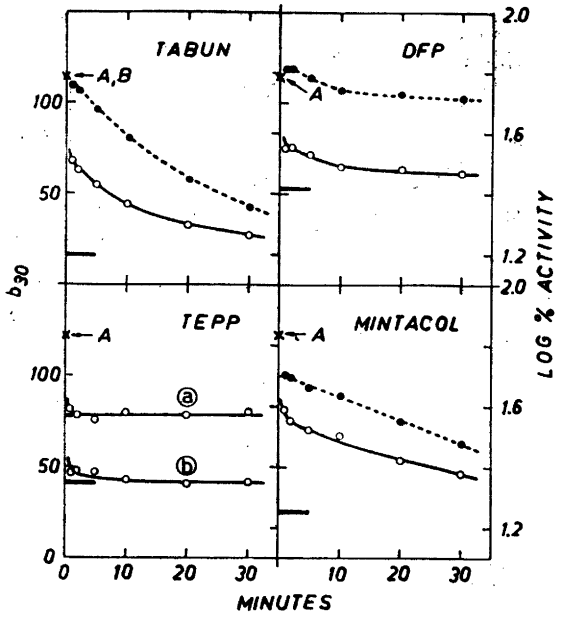

Fig. 5. Inactivation of cholinesterase (Fraction IV-6 of human serum) by organophosphorus compounds. See Fig. 4 for further explanations. Concentrations of the organophosphorus compounds: tabun, 1.66 × 10^{-5} M; DFP, 2.90 × 10^{-5} M; TEPP, a) 1.53 × 10^{-5} M; b) 3.07 × 10^{-5} M; mintacol, 1.15 × 10^{-5} M.

acetylcholine as substrate. It will be remembered (see Figs. 1 and 2) that the phosphatase has no effect on the esterase which beforehand was inactivated maximally by a specific concentration of a phosphorus compound.

For both acetylcholinesterase (Fig. 4) and serum cholinesterase (Fig. 5) the progressive enzyme inactivation by tabun, DFP and mintacol can be stopped by adding phosphorylphosphatase. Once the phosphatase is added there is no further decrease of esterase activity. It has been shown that all of the inactivator added reacts immediately with the esterase and this reaction can be reversed by phosphatase. In a second irreversible reaction the esterase is inactivated and this reaction is not influenced by the phosphatase. TEPP differs from the other three compounds studied in the very rapid reaching of maximum inactivation of the esterases. Even after one minute incubation with TEPP maximum inactivation is reached and therefore the addition of phosphatase after that period has no influence on esterase activity.

DISCUSSION

The mechanism of enzyme inhibition by organophosphorus compounds has been discussed in a variety of publications during the last few years. These compounds seem to be general inhibitors for enzymes having carboxylic esterase activity, *e. g.*, chymotrypsin, trypsin, liver esterase, acetylesterase, B-

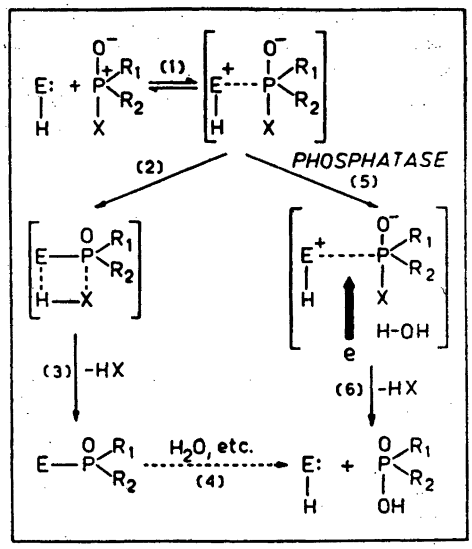

Fig. 6. Tentative scheme of the reaction mechanism for the inactivation of cholinesterases (E) by organophosphorus compounds, and the effect of phosphorylphosphatase (e) on that reaction.

esterase [10]. The inhibitory process for all these enzymes is a first order reaction and bimolecular. It has been demonstrated for some of these enzymes that the inhibitor phosphorylates the enzyme [11]. As far as cholinesterases are concerned most studies are consistent with the view that a similar reaction mechanism is valid for the inactivation of these enzymes by organophosphorus compounds. The analogy between this phosphorylating process and the reaction mechanism for the hydrolysis of acetylcholine by cholinesterases has been pointed out by Wilson *et al.*[12]

The reaction mechanism of the spontaneous hydrolysis of organophosphorus compounds was discussed by Larsson [13] and the similarity between the base-catalysed hydrolysis and the enzymic hydrolysis of these compounds was postulated by the present authors [3]. In some preliminary experiments carried out to study the effect of phosphorylphosphatase on phosphorylated cholinesterases the results were leading to the idea that the phosphatase is able to reactivate inactivated cholinesterases [14]. A more detailed study of this phenomenon, as made in the present paper, showed that there is no true enzymic reactivating effect, but that the phosphatase can stop the progressive inactivation when added before maximum inactivation is reached.

On the basis of investigations by Jansen, Aldridge, Wilson, Wagner-Jauregg, Myers, and others, and those from this laboratory, the following reaction mechanism is suggested (Fig. 6). The enzyme (E) combines reversibly (1) with the phosphorus compound by a one-point contact at the ester-bonding site (*i. e.*, the "esteric" site [7] or active group II [8] of the acetylcholinesterase molecule); then the acid group (X) of the phosphorus containing part (CN in

tabun) of the complex reacts (2, 3) with a hydrogen atom of the enzyme molecule releasing the corresponding acid. The dephosphorylating reaction (4) of the inhibited enzyme is, for most phosphorus compounds, very slow compared with reactions (1), (2) and (3), and therefore the enzyme remains inhibited (inactivated). Catalysis of reaction (4) by replacing water with hydroxylamine or derivatives of hydroxamic acid has recently been demonstrated by Wilson and Meislich [15].

On the basis of the results described in the present paper it is now suggested that phosphorylphosphatase (e) prevents the reactions (2) and (3) from taking place (see reaction 5). The phosphorus containing moiety of the loosely bound complex (reaction 1) is thereby hydrolytically split, acid (HCN in the case of tabun) and a phosphoric acid are released, and the cholinesterase becomes active (6). The degree of the effect of the phosphatase depends both on the time elapsing after cholinesterase and phosphorus compound have come in contact with each other, and on the various groups (alkyl, substituted amido) of the phosphate inhibitor.

The authors wish to express their sincere thanks to Professor Gustaf Ljunggren, Chief of the Research Institute of National Defence, Department 1, for his continual interest in these investigations. We are indebted to Ing. Henrik Björling of A/B Kabi, Stockholm, for the preparation of Fraction IV-1.

Estimation of Phenolic Hydroxyl Groups in Lignin

I. Periodate Oxidation of Guaiacol Compounds

ERICH ADLER and SVEN HERNESTAM

Organisk-kemiska Institutionen, Chalmers Tekniska Högskola, Göteborg, Sweden

A method for the estimation of free phenolic groups in softwood lignin has been developed. The method is based on the finding that the action of sodium periodate upon guaiacol results in rapid oxidative demethylation, methanol being liberated in a yield of about 0.9 mole per mole of guaiacol. A variety of substances containing one or two guaiacyl nuclei and representing the probable structural principles of lignin have been investigated with regard to their behaviour towards periodate. Substituents in the positions *para* and *ortho* to the phenolic hydroxyl group of guaiacol in general were found to be without influence upon the methanol formation. A few exceptions, which, however, are of minor importance to the lignin problem, are pointed out.

As a result of these model experiments, it is concluded that any amount of methanol (moles of methanol per methoxyl group) obtained on periodate oxidation of softwood lignin preparations, when multiplied by 1.1, will give the number of phenolic hydroxyl groups per methoxyl in the lignin preparation examined.

One of the main problems of lignin chemistry is to elucidate the way in which the guaiacyl propane monomers (in softwood lignin) or the guaiacyl and syringyl propane monomers (in hardwood lignin) are linked to each other to form the lignin molecules. Previous work (*cf.*[1]) suggests that different types of linkages are involved, *viz.*,

a) alkyl aryl ether linkages connecting the propane side-chain of one monomer with the aromatic nucleus of the following one. The alkyl carbon atom can be either the α-carbon (type a_1) or possibly the β-carbon (type a_2) of the side-chain;

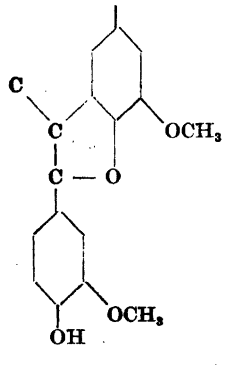
b) carbon-carbon linkages between the side-chain of one monomer and the aromatic nucleus of the following one;

c) alkyl ether linkages between two side-chains;

d) carbon-carbon linkages between two side-chains.

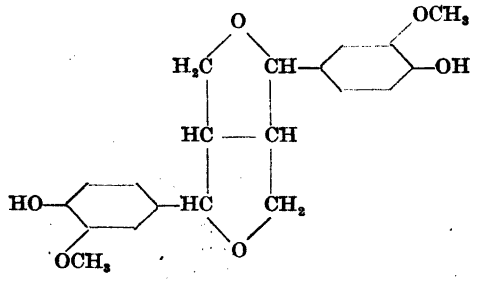
A combination of types a_1 and b is present in the coumaran ring structure (I), whereas a combination of types c and d is to be found in pinoresinol (II). Both structures have been shown to be formed as intermediates in the bio-

synthesis of lignin from coniferyl alcohol, and the coumaran structure at least is assumed to constitute an essential building element in the final lignin molecule [1] (*cf.*, however,[2]). It has been proposed that alkyl ether linkages (c) of the benzyl alkyl ether type are involved in sulphonation, alcoholysis, and other typical reactions of lignin [3,4]. Finally, the occurrence in lignin of alkyl aryl ether linkages of type a_2 (*iso*-propyl aryl ether linkage, III) has been discussed on the basis of model experiments [5,6].*



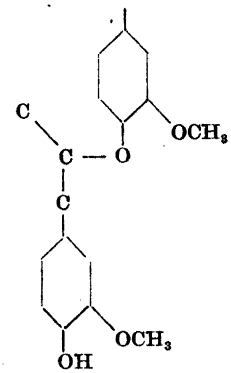
I

(linkages a_1 and b)



II

(linkages c and d)



III

(linkage a_2)

As yet, conclusive information regarding the relative amounts of the various kinds of linkages in lignin is missing. Obviously, for a further elucidation of this problem, a knowledge of the number of free phenolic groups in lignin must be of fundamental interest. If this number were known (*n* phenolic groups per phenylpropane monomer), the number of the alkyl aryl ether bonds (a_1 plus a_2) would also be known (1—*n*).

Moreover, a determination of any change in the number of phenolic groups taking place if lignin is subjected to reactions such as sulphonation and alcoholysis, would be of great value for the understanding of the mechanism of these reactions and the structure of the reacting groups.

The need of correct data concerning the phenol content of lignin was early realized, and a variety of methods for its estimation have been used in the past; they yielded, however, widely differing figures (*cf.* the summaries on lignin [7,8]). Conflicting values have also been reported very recently. Whereas Freudenberg [9,1], using the reaction of phenolic hydroxyl groups with 2,4-dinitrofluorobenzene and other methods, found 0.5—0.6 phenolic hydroxyls per methoxyl group (in lignosulphonic acid), Aulin-Erdtman [10,11], as a result of her extensive spectrophotometric investigations, concludes that lignosulphonic acid contains 0.17—0.25 phenolic groups per methoxyl. Values of 0.23—0.24, likewise obtained spectrographically, have been reported by Goldschmid [12].

* *Note added in proof:* The formation of linkages of type a_2 (III) on enzymatic dehydrogenation of coniferyl alcohol was recently demonstrated by K. Freudenberg, H. Schlüter and W. Eisenhut *Naturwiss.* **41** (1954) 576.

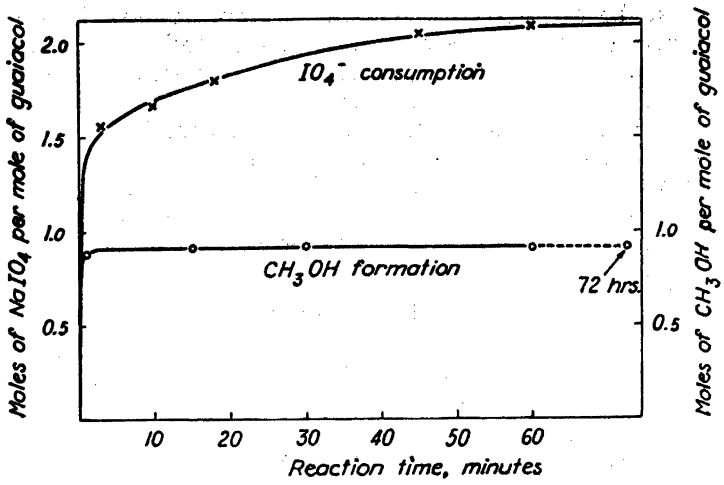


Fig. 1. Consumption of periodate and formation of methanol on periodate oxidation of guaiacol. (0.5 millimole of guaiacol and 3.5 millimoles of sodium metaperiodate in 50 ml of water, at 4°.)

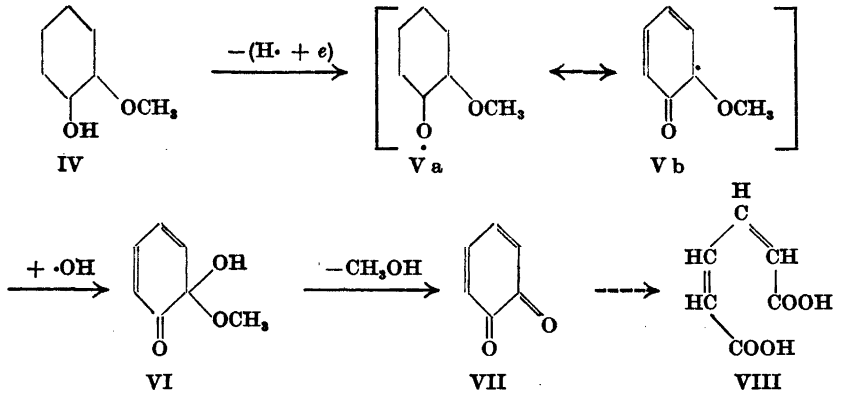
In this laboratory, a new method for the estimation of free phenolic groups in lignin has been developed. The present communication deals with an examination of the method using lignin model substances, and in following papers some results obtained with various lignin preparations will be reported. Preliminarly it may be stated that, with comparable lignin preparations (lignosulphonic acids), our method yielded values similar to those given by Aulin-Erdtman [11] and Goldschmid [12].

The new method is based upon the behaviour of phenols, especially guaiacol and substituted guaiacols, towards periodic acid. Whereas this reagent has been extensively used for many years in the cleavage of C—C linkages in α-glycols, α-ketols and related structures, very little attention has been paid to its action upon phenols. The only work covering the latter problem to be found in the literature is contained in two short communications by Pennington and Ritter [13,14]. These authors found that carbohydrate-free preparations of lignosulphonic acids consumed periodic acid, the products recovered after the oxidation containing less methoxyl than the original material. Methanol was detected in the reaction mixture. It was also shown that various phenols, including guaiacol and some substituted guaiacols such as vanillyl alcohol, vanillic acid, and ferulic acid, were attacked by periodic acid. In the two last-mentioned cases amorphous oxidation products were formed, the methoxyl contents of which were considerably lower than those of the original acids.

In connection with the synthesis of guaiacylglycerol, Adler and Yllner [15] investigated the periodate breakdown of the glycerol side-chain of this substance. As could be expected from the results of Pennington and Ritter, a simultaneous attack upon the guaiacyl nucleus occurred. A comparison with the behaviour of guaiacol revealed that in both cases a very rapid initial consumption of periodic acid, followed by a slower further oxidation, took place.

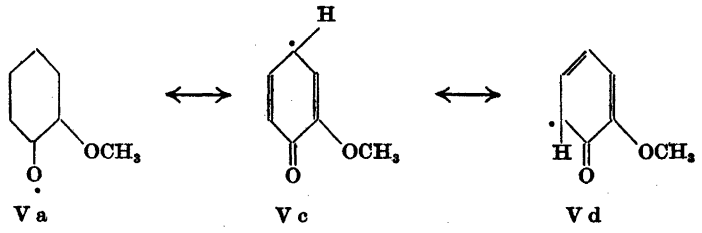
It seemed to be of interest to examine whether the periodate oxidation of these substances involved any formation of methanol, similar to that observed by Pennington and Ritter in the case of lignosulphonic acid. Surprisingly enough, it was found that no less than 90—92 % of the amount of methoxyl groups present were rapidly liberated as methanol, when guaiacol in aqueous solution was treated at 4° C with an excess of sodium periodate. The total amount of methanol was formed during the initial, rapid phase of periodate consumption (Fig. 1). Under the conditions used (4°, dark room), the methanol formed was stable against the excess periodate present during a period of several days (*cf.*[16]).

Regarding the mechanism of the oxidative methanol formation, the following sequence of reactions may be tentatively suggested:



The primary attack of periodate upon guaiacol will result in the formation of the mesomeric radical V. This view regarding the initial step in the oxidation of phenols by various oxidants has been put forward by Pummerer [17] and has been generally accepted (*cf*[18]). Recently, it has received further experimental support by the isolation of the comparatively stable 2,4,6-tri-*tert.*-butylphenoxyl radical [19] from the dehydrogenation of the corresponding phenol with lead dioxide and similar oxidants. In a second oxidation step, the radical V, in its mesomeric form V b, may react with an hydroxyl radical, yielding the hemiacetal VI. This will spontaneously lose one mol. of methanol, thus being converted into *o*-quinone (VII), which finally undergoes periodate oxidation to *cis-cis*-muconic acid (VIII). The last-mentioned product has been isolated from the reaction mixture.

Since the yield of methanol is 90—92 %, the reaction sequence proposed above appears to be the main pathway of the oxidation. Only 8—10 % of the guaiacol used is oxidized in a different way, obviously not including the hypothetical intermediate VI, which is supposed to be the immediate source of the methanol. These side-reactions might be explained by the assumption that the further oxidation of the aroxyl radical, to an extent of 8—10 %, arises from the mesomeric forms c and d:



As has been shown recently by Wessely [20], the action of lead tetraacetate upon guaiacol results in the formation of methoxy-*p*-quinone in a yield of 57 %. This oxidant thus seems to attack mainly the mesomeric form V c.

The scope and the mechanism of the oxidative cleavage of *o*- (and *p*-) hydroxyaryl ethers as well as the reaction of other types of phenols with periodic acid are being further studied in this laboratory.

In contrast with guaiacol, veratrol was found to be completely stable in the presence of sodium periodate under the experimental conditions used. It is interesting to note that, in this respect, periodic acid differs from other specific oxidants, like percarboxylic acids, which have been shown to oxidize not only pyrocatechol [21] — with the formation of muconic acid — but also veratrol [22], with the formation of dimethyl muconate.

These findings seemed to indicate that the determination of methanol formed on periodate oxidation of lignin might offer a possibility of estimating the amount of phenolic guaiacyl residues present in softwood lignin. It was obvious, however, that correct values would not be obtained unless the following conditions were fulfilled:

1) All types of phenolic guaiacyl groups in lignin, irrespective of their way of substitution, yield similar amounts of methanol;

2) Methanol is formed solely from the phenolic nuclei, and not from other structural elements in lignin.

The following experiments constitute an examination of point 1, *i.e.*, a study of the methanol formation from various guaiacol derivatives related to possible structural elements in lignin. The validity of point 2 will be discussed in a subsequent paper.

Table 1 gives the yields of methanol obtained from a series of guaiacol derivatives. The oxidation was carried out with an excess of sodium periodate either in aqueous solution or in 80 % acetic acid. After precipitation of iodate and unconsumed periodate with a lead nitrate solution, methanol was distilled off and determined by oxidation with permanganate and colorimetric measurement of the formaldehyde obtained (*cf.* exptl. part). Several (generally 3 to 6) samples of each substance were oxidized for various periods of time as shown for guaiacol in Fig. 1. The rate of methanol formation was slightly lower in 80 % acetic acid than in water. In the case of guaiacol, for instance, the maximum value was reached after a reaction time of 1—2 minutes in aqueous solution (*cf.* Fig. 1) and after 5—6 minutes in the acetic acid. The final methanol values, however, were practically equal in both types of experiments (*cf.* substances IV, XI, and XXIX, Table 1). The methanol figures given in Table 1 represent the average of the values obtained after various times of reaction, excluding values relating to the rapid initial phase (*cf.* Fig. 1). In some cases the periodate consumption was followed and found to procede in a generally similar way in both solvents, the total periodate consumption in the slower phase, however, being somewhat greater in acetic acid than in water.

The substances in Table 1 have been divided into four groups, A—D.

Group A comprises substances in which the guaiacol nucleus is substituted in the 4-position, with no double bond conjugated with the phenolic ring present. In addition to some guaiacyl carbinols (IX—XI, XVI), a guaiacyl

alkyl ether (XII), and a sulphonic acid (XIII), it includes the "dimeric" lignin models XVI (a guaiacyl-propane-β-aryl ether), XVII—XIX (coumarans), and *d*-pinoresinol (II).

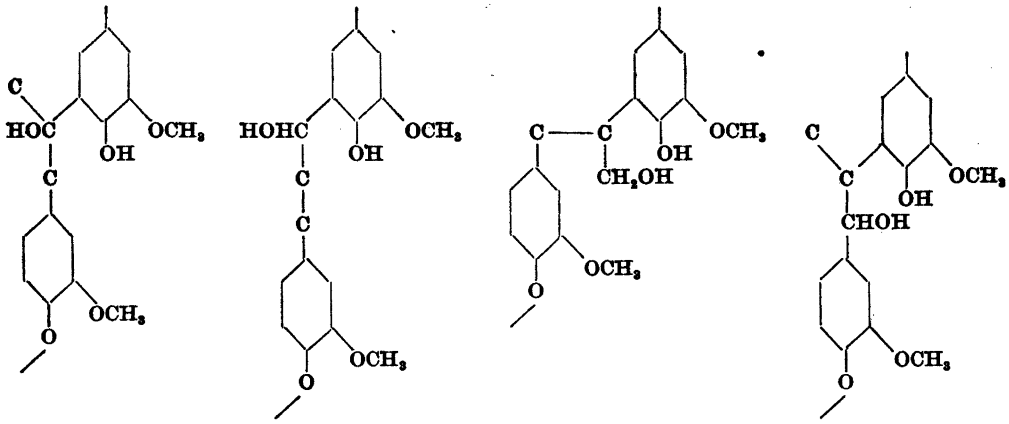
The behaviour of all these substances was very similar to that of guaiacol itself, the rates of methanol formation being practically the same as for guaiacol. The final amounts of methanol ranged from 0.88 to 0.94 moles per guaiacyl nucleus, with a mean value for all substances of 0.91.

It may be noted here that in the periodate oxidation of the carbinols IX, X, and XI the side-chains are partially split off yielding the corresponding aliphatic aldehydes in yields of 50—60 % of the theoretically possible amounts [36].

Group B. In addition to (phenolic or etherified) 4-propylguaiacol residues lignin contains 4,6-substituted guaiacol elements. Predominantly, the phenolic hydroxyl group and the 6-substituent will be joined by ring-closure, as in dehydro-diconiferyl alcohol (XIX), but there are also indications of the occurrence, in lignin, of minor amounts of phenolic structures like those represented by the upper ring of formula XXVI (*cf.* Richtzenhain [37], Aulin-Erdtman [11]). Furthermore, the presence of 6,6'-diguaiacyl structures, represented here by model substance XXV, has been discussed, although recent spectrophotometric evidence indicates [11] that their amount (in lignosulphonic acids) must be very low. Aulin-Erdtman [33] has shown that the two neighbouring phenolic groups in such substances have highly different ionization constants, and it could be supposed that this might influence their reactivity towards periodic acid.

Similarly, it appeared possible that the dehydrogenation of the phenolic hydroxyl group in *o*-vanillyl alcohol (XXIII) might be influenced by intramolecular hydrogen bonding. In lignin, the presence of *o*-guaiacyl carbinol groupings is, however, highly improbable. Tertiary carbinols of type XXXVI seem not to be present in lignin in appreciable amounts [1]. And also, the occurrence of carbinols of type XXXVII, represented by *o*-vanillyl alcohol (XXIII), would be hardly conceivable on the basis of the present views regarding the biosynthesis of lignin.

The main part of the aliphatic hydroxyl groups in lignin are probably primary carbinol groups [1]. Therefore, the presence of phenolic structures



XXXVI XXXVII XXXVIII XXXIX

like XXXVIII appears possible, although, as mentioned above, their frequency in lignin seems to be low [11]. Furthermore, structures like XXXIX cannot be excluded. In order to examine whether *ortho* side-chains with aliphatic hydroxyl groups in the β-position, such as in XXXVIII and XXXIX, may have any effect on the oxidation of the guaiacyl grouping, homo-*o*-vanillyl alcohol (XXIV) was synthesized as a model substance.

The periodate oxidation of the majority of the substances of group B exhibited no peculiarities. 6-*n*-Propylguaiacol (XX) yielded methanol at the same rate and in the same amounts as did guaiacol, and, similarly, the values obtained with substances XXI, XXII, XXIV, and XXVI were on the same level as those presented in group A. The oxidation of the diphenyl derivative XXV was slightly retarded, the final methanol value being reached shortly after a reaction time of five minutes. The extent of side-reactions was somewhat increased which is indicated by the comparatively low yield of methanol, *viz.*, 0.80 mole per guaiacyl nucleus. Possibly, the increased electron density at the *ortho*-linkage between the two phenolic nuclei favours attack of hydroxyl radicals upon the linked ring carbon atoms.

The behaviour of *o*-vanillyl alcohol (XXIII) was unlike that of all the other substances examined. The methanol value given for XXIII in Table 1 refers to a reaction time of only one minute. After a few further minutes of reaction a colourless crystalline solid began to deposit, the amount of which increased during the following hours. As the precipitate appeared, methanol determinations yielded values which were considerably lower (down to 0.4 moles of CH_3OH per mole of XXIII) than the initial value recorded in Table 1. It then was found that an aqueous suspension of the isolated precipitate, when boiled at pH 4.5, yielded a distillate which contained methanol.

The elementary composition of the crystalline solid, m. p. 171—172°, was $C_8H_8O_3$, which agrees to vanillyl alcohol minus two atoms of hydrogen. It contained 20.36 % OCH_3 (calc. OCH_3 20.40). Probably the substance is a dimerization product, $C_{16}H_{16}O_6$. Its structure as well as that of similar products obtained from other *o*-hydroxybenzyl alcohols is being further investigated.

The properties of the solid oxidation product of XXIII explain the observation mentioned above that the methanol values became lower when the amount of deposited

product increased. The deposited product containing the "loosely bound" methoxyl group was removed in the precipitation with lead nitrate, and, therefore, methanol was lost.

The behaviour of XXIII suggested the possibility that, in the periodate treatment, comparatively stable intermediates containing methoxyl groups in some "loosely bound" form might be similarly formed from other guaiacol compounds, although only in the case of XXIII was the intermediate sparingly water-soluble and therefore separated from the reaction mixture. If this were true, serious difficulties might arise in the application of the periodate method to the estimation of phenolic groups in lignin, especially in lignosulphonic acids. Oxidized material, carrying "loosely bound" methoxyl groups, might be totally or partially removed in the lead nitrate precipitation step, and methanol would thus be lost.

This possibility prompted experiments with the aim of examining whether or not the methanol which is obtained, when the filtrate from the lead precipitate is distilled, is generally present in a free state after completed periodate oxidation. Three representatives of group A were investigated in this respect. It was found that, after oxidation of guaiacol and carbinol XI in aqueous solution as well as of XVII in 80 % acetic acid the total methanol content could be distilled off from the reaction mixtures at 3 mm Hg (boiling temperature about 0°). This result, together with the fact that crystals of *cis-cis*-muconic acid deposit from an aqueous solution containing guaiacol and sodium periodate at 4°, constitute sufficient evidence in favour of the view that, generally, methanol is liberated from the guaiacyl nuclei in the oxidation step, and that the different behaviour of *o*-vanillyl alcohol is unusual. This question will be further discussed in a forthcoming publication.

Group C. It is well established that side-chains with a double-bond in conjugation with a phenolic nucleus are not present to any appreciable extent in lignin. This is obvious especially from spectrophotometric data [11], which indicate that mildly prepared lignin products contain less than 0.03—0.04 groups of this type per methoxyl group. On the basis of a specific colour reaction, Lindgren and Mikawa [2] state that small amounts of coniferyl alcohol groupings may be present in native lignin. As yet, however, there is no definite information as to whether such groups may be phenolic or etherified. The coniferyl aldehyde groups demonstrated in lignin [38,39] in an amount of one such group per 40—60 methoxyl groups, have been shown to occur predominantly in the etherified state [11]. Since lignin is devoid of carboxylic groups, the behaviour of the unsaturated substances XXVII—XXIX is of minor importance in the lignin problem.

*Iso*eugenol and coniferyl alcohol (XXVIII) reacted rapidly with periodate. Methanol formation, however, did not reach the normal level, the maximum values being about 0.7 mole of methanol per mole. This is obviously due to oxidative dimerization to dehydro-di*iso*eugenol (XVII) and dehydro-diconiferyl alcohol (XIX), respectively, taking place in competition with the oxidative demethylation and resulting in the blocking of phenolic groups. (*Cf.* the formation of XVII [30] and XIX[29] by ferric chloride oxidation of XXVII and XXVIII, respectively.

Coniferyl aldehyde (XXIX), in which the C=C bond is stabilized by further conjugation with a carbonyl group, probably will not undergo oxidative dimerization and yielded a normal methanol value. The same was true for ferulic acid (XXX).

Group D. As for the substances of group C, the carbonyl compounds collected in group D are of secondary importance as lignin models. It is true that lignin contains a certain number of carbonyl groups. In addition to the

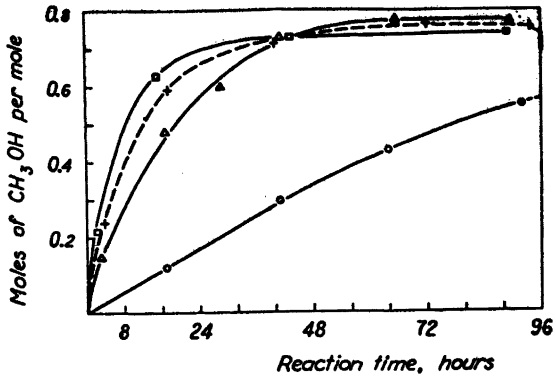


Fig. 2. Formation of methanol on periodate oxidation of O——O *vanillin,* △——△ *4-acetoguaiacone,* □——□ *4-propioguaiacone,* ×– – –× *vanillic acid. (0.5 millimole of substance and 3.5 millimoles of sodium metaperiodate in 50 ml of acetic acid-water (4 : 1), at 4°.)*

coniferyl aldehyde end groups (0.02—0.025 per OCH_3[38]), about 0.1 CO per OCH_3 has been shown to be present in Brauns' "native lignin" [40] and in lignosulphonic acid [41], both from spruce. These carbonyl groups, however, are mainly not in the α-position of the side-chains [42,40]. Consequently, neither vanillin nor the ketones XXXII and XXXIII are appropriate models for the majority of the carbonyl-containing phenolic elements in lignin. Their behaviour may be, however, of some interest, as it may illustrate the structural influences upon the course of the periodate oxidation of guaiacols.

The carbonyl compounds examined are oxidized at a much slower rate than the substances of groups A—C (Fig. 2). In the oxidation of vanillin, methanol was still being formed after one week's reaction, and in the case of the ketones XXXII and XXXIII the methanol values became constant only after about 48 hours. Vanillic acid (XXXIV) behaved in a similar way. It appears likely that this decreased activity towards periodate is due to the +I and +E effects exerted by the substituents and resulting in a diminished electron density at the phenolic hydroxyl group.

The final methanol values obtained in the case of the ketones and vanillic acid are definitely lower than those from the rapidly oxidized substances (except *iso*eugenol and coniferyl alcohol, see above). Since neither α-carbonyl groups nor carboxylic groups seem to be present in lignin in appreciable amounts, this fact is of practically no importance for the application of the method to lignin. In this connection, it may also be pointed out that a carbonyl group in the β-position of the side-chain, as in guaiacylacetone (XV), does not decrease the yield of methanol.

CONCLUSIONS

As an average for the yield of methanol from the various model substances in group A a value of 0.91 moles of methanol per mole is obtained. On the basis of this result and of the preceding discussion regarding the behaviour of

the other model substances, it appears justified to adopt this value as the yield of methanol per phenolic guaiacyl nucleus which can be expected on periodate oxidation of softwood lignin preparations. Consequently, any methanol value obtained (CH_3OH/OCH_3), when multiplied by 1.1, will give the number of phenolic hydroxyl groups per methoxyl in the lignin preparation examined.

In addition to the guaiacyl elements, softwood lignin contains very small amounts of syringyl and *p*-hydroxyphenyl elements [48]. Preliminary experiments have shown that pyrogallol-1,3-dimethylether is partially demethylated by periodate, the yield of methanol being slightly higher than that obtained from guaiacol. Phenolic elements of the *p*-hydroxyphenyl type, which may be present in lignin, are of course not determinable by the periodate demethylation method. The amount of such methoxyl-free elements, however, seems not to exceed 4 % of the total amount of phenyl propane units, and if it is assumed that one fourth of the *p*-hydroxyphenyl elements is phenolic, any figure obtained with the periodate method will be too low by an amount of, at most, 0.01 phenolic groups per methoxyl. In other words, the traces of syringyl and *p*-hydroxyphenyl groups present in softwood lignin will not have any appreciable influence on the estimation of phenolic groups.

EXPERIMENTAL

Periodate oxidation. 1. In aqueous solution. A solution of 0.5 millimole of the substance in 25 ml of water was kept for about 10 minutes at 4° in a dark-room. (Of substances containing two phenolic nuclei, 0.25 millimole was used.) A solution of 3.5 millimoles of sodium metaperiodate, $NaIO_4$, in 25 ml of water, cooled to 4°, was added. The reaction was stopped by the addition of 25 ml of 20 % lead nitrate solution. The precipitate (lead iodate and periodate) was filtered off and washed thoroughly with water.

From the filtrate (about 200 ml) about 100 ml were distilled off in a slow stream of nitrogen and the distillate was collected in an ice-cooled receiver containing about 50 ml of water. In order to remove traces of iodine, the distillate was passed through a column (13 × 200 mm) of an anion exchange resin (Dowex 2), which had been saturated with bisulphite ions. The column was washed with water, and the filtrate made up to a final volume of 300 ml.

Formaldehyde which is formed in the oxidation of vanillyl alcohol (IX) and which would interfere with the subsequent methanol determination, is completely retained by the bisulphite-saturated resin [44] in the same operation.

2. In 80 % acetic acid. Substances which were sparingly soluble in water, were oxidized in 80 % acetic acid. Glacial acetic acid *pro analysi*, 99—100 % (E. Merck, Darmstadt), which was shown to be free of methanol, was used.

The solution of the substance (0.5 millimole) in 25 ml of glacial acetic acid was mixed with 25 ml of a solution of sodium metaperiodate, prepared by dissolving 0.14 mole of periodate in 400 ml of water and adding acetic acid to a volume of 1 litre. The oxidation was carried out at 4° in a dark-room. At the end of the reaction time 25 ml of a 20 % aqueous lead nitrate solution was added, the mixture filtered and the precipitate washed with about 50 ml of acetic acid and subsequently with about 75 ml of water.

The combined filtrates were distilled as described above. As it was found that acetic acid, when oxidized with permanganate under the conditions used in the following oxidation step, gave rise to formaldehyde, acetic acid contained in the distillate had to be removed. For this purpose the distillate was made alkaline by the addition of an excess of 50 % sodium hydroxide solution, and redistilled. The final distillate was made up to a volume of 300 ml.

If formaldehyde was formed during the periodate oxidation, the final distillate was passed through a bisulphite-saturated anion exchange resin (see above), and the filtrate made up to a volume of 300 ml.

Determination of methanol. The procedure of Ahlén and Samuelson [44] was followed with slight modifications. To a mixture of 25 ml of the distillate, obtained according to procedure 1 or 2 above, and 5 ml of an aqueous solution of phosphoric acid (165 ml H_3PO_4, $d = 1.75$, per litre), 5 ml of potassium permanganate (40 g $KMnO_4$ per litre) were added at 25°. After exactly 10 minutes, 10 ml of a mixture of oxalic and sulphuric acid (40 g $H_2C_2O_4$, $2H_2O$ and 40 ml of conc. H_2SO_4 per litre) were added. The solution became colourless after about 10 minutes. The carbon dioxide evolved was removed by shaking, and 5 ml of the solution were mixed with 5 ml of a freshly prepared 2 % aqueous solution of chromotropic acid and 25 ml of conc. sulphuric acid. This mixture was heated in a loosely stoppered Erlenmeyer flask for 45 minutes in a boiling water bath. The extinction of the solution was measured at 570 mμ against a blank solution prepared in a similar way from 25 ml of distilled water.

A standard curve was obtained with aqueous solutions of methanol of known concentration, which were treated as described above. At least up to a concentration of 30 mg of methanol per 300 ml the amount of formaldehyde formed is a linear function of the methanol content.

The accuracy of the method may be illustrated by the following example (periodate oxidation of guaiacol, *cf.* Fig. 1).

Time of periodate oxidation, hrs	1/60	1/4	1/2	1	6	14	38	72
Moles of CH_3OH per mole of guaiacol	0.89	0.92	0.92	0.91	0.92	0.93	0.92	0.91

cis-cis-Muconic acid from guaiacol. From the red-brown aqueous solution obtained when guaiacol was oxidized with periodate under the conditions given above, a carboxylic acid could be isolated by extraction with ethyl acetate. The crystalline product, after recrystallization from water, had a wide melting point range and probably consisted of a mixture of the geometric isomers of muconic acid.

If the concentration of guaiacol was increased to 0.8 millimole per 25 ml of water and the amount of periodate kept unchanged, a small amount of nearly colourless prismatic needles deposited from the reaction mixture after some hours at 4°. The crystals were collected and washed with little water; m. p. 187°, no depression with *cis-cis*-muconic acid, m. p. 187—188°, prepared from phenol or pyrocatechol and peracetic acid [21].

α-(4-Hydroxy-3-methoxyphenyl)-ethanol (=Apocynol) (X). Sodium borohydride (0.45 g) was added to a solution of 4-acetoguaiacone (4 g) and sodium hydroxide (1.2 g) in water (60 ml). After three days at 60° a sample of the mixture no longer gave any precipitate with 2,4-dinitrophenylhydrazine. The solution was neutralized at room temperature with carbon dioxide, and extracted with ether. Evaporation of the dried ether solution yielded 3.7 g of a crystalline product, which was recrystallized by dissolving in ethylacetate (without heating!) and precipitation with hexane. M. p. 101—102° C (101° according to Finnemore [45]).

Vanillyl ethyl ether (XII). A 4 % solution of dry hydrogen chloride in abs. ethanol (521 g) was added dropwise during 3 hours to a stirred, ice-cooled solution of vanillyl alcohol (30 g) in abs. ethanol (500 g). After 16 hours at room temperature, somewhat less than the equivalent amount of sodium hydroxide (15 g NaOH in 50 ml H_2O) was added and the solution finally neutralized with a saturated sodium bicarbonate solution. Ethanol was distilled off and the residue extracted with chloroform. The chloroform solution was dried over Na_2SO_4, and the solvent removed by distillation. The residual oil was distilled, b. p. 124—125° at 4 mm; $n_D^{20} = 1.5297$. Yield 85 %. (Found: C 65.6; H 7.59; alkoxyl calc. as OCH_3 33.9. Calc. for $C_{10}H_{14}O_3$: C 65.9; H 7.74; alkoxyl calc. as OCH_3 34.1.)

Barium 1-(4-hydroxy-3-methoxyphenyl)-n-propane-1-sulphonate (XIII) *. Guaiacyl ethyl carbinol (XI) (1 g) was sulphonated with an aqueous solution (50 ml) containing 14.3 g NaOH and 50 g SO_2 per litre. The mixture (pH 1.4) was heated to 135° during 3 hours and kept at this temperature for a further 3 hours. Excess of SO_2 was removed *in vacuo*, the solution neutralized with barium carbonate and filtered. The filtrate was

* This preparation was carried out by Mr. E. Eriksoo.

passed through a cation exchange resin and sulphur dioxide removed *in vacuo*. The solution was reneutralized with calcium carbonate and the precipitate ($CaSO_3$) filtered off. Residual sulphite was precipitated by the addition of saturated calcium hydroxide solution to pH 8—9. The filtered solution was concentrated *in vacuo* in a carbon dioxide atmosphere to about 40 ml, the concentrate filtered and again passed through a cation exchange resin. Finally, the solution was neutralized with barium carbonate, filtered and concentrated *in vacuo* to a small volume. The barium salt (XIII) deposited and was recrystallized by dissolution in *iso*propanol-water (85 : 15) and addition of ethyl ether. Colourless needles. (Found: OCH_3 9.55; S 10.47; Ba 21.4. Calc. for $C_{10}H_{13}O_5SBa_{0.5}$: OCH_3 9.85; S 10.18; Ba 21.8.)

5-n-Propylvanillyl alcohol. 5-Allylvanillin [32] (5 g), dissolved in 96 % ethanol (25 ml) was shaken with platinum oxide catalyst (0.05 g) in a hydrogen atmosphere at a pressure of 4 kg/cm^2. One mole of hydrogen per mole of the substance was rapidly consumed. Since 2,4-dinitrophenylhydrazine produced a precipitate with a sample of the solution, only the allyl group had been hydrogenated. A further mole of hydrogen was consumed after the addition of 0.5 ml 1 *M* $FeCl_3$, and the dinitrophenylhydrazine test became negative. The catalyst was filtered off and the solvent removed *in vacuo*. The residual oil was dissolved in ether, the solution dried over Na_2SO_4 and the solvent evaporated. The product crystallized from benzene-hexane in needles, m. p. 45—47°. Yield 4.5 g (88 %). (Found: OCH_3 15.97; Calc. for $C_{11}H_{16}O_3$: OCH_3 15.81.)

The free phenol alcohol was unstable at room temperature; it turned slightly yellow and became liquid after a few days. After a few weeks the product had crystallized again. Recrystallization from ethanol-water yielded the diphenylmethane described below.

Bis-(4-hydroxy-3-methoxy-5-n-propylphenyl-)methane. Attempts to prepare 5-*n*-propylvanillyl alcohol from 6-*n*-propylguaiacol (XX) by the Lederer-Manasse reaction yielded the corresponding diphenylmethane. A mixture of 6-*n*-propylguaiacol (5 g), sodium hydroxide (6 g NaOH in 30 ml H_2O) and formalin (8 ml) was kept at 40—45° for one week. Neutralization with carbon dioxide yielded a white precipitate, which after washing with petroleum ether was recrystallized from ethanol-water. Needles, m.p. 124—125°; yield 1.4 g. (Found: C 73.3; H 8.26; OCH_3 18.22. Calc. for $C_{21}H_{28}O_4$: C 73.2; H 8.19; OCH_3 18.02.)

Barium 3-methoxy-4-hydroxy-5-n-propylbenzyl sulphonate (XXI). Freshly prepared 5-*n*-propylvanillyl alcohol was heated at 135° for three hours with an aqueous solution of sodium sulphite and sodium bisulphite of pH 6.6 and a total SO_2 content of 5 %. The sulphonic acid formed was isolated as described above for XIII. Needles from *iso*propanol-water (85 : 15)-ethyl ether. (Found: OCH_3 9.42; Ba 20.8. Calc. for $C_{11}H_{15}O_5SBa_{0.5}$: OCH_3 9.46; Ba 20.9.)

o-Vanillyl alcohol (XXIII). *o*-Vanillin was reduced catalytically as described by Carothers and Adams [33] for other hydroxybenzaldehydes. The oily product crystallized in needles from benzene-hexane. Yield 91 %, m. p. 60—61° (60—62° according to Eliel [46]).

o-Homovanillyl alcohol (XXIV). *o*-Eugenol (5.0 g) was treated in ethyl acetate solution with a stream of oxygen containing 0.8—1.0 % of ozone, as described by Hahn and Schales [47] for the ozonisation of safrol. Hydrogenation with Pd-$CaCO_3$ catalyst and bisulphite extraction yielded 4.0 g of a crystalline bisulphite addition product. This was dissolved in water and the solution extracted with ether to remove impurities. Sodium hydroxide (4 g) and sodium borohydride (1 g) were added to the aqueous phase. The mixture was kept over night at 50°, neutralized with carbon dioxide and extracted with ethyl ether. The ether solution was dried over Na_2SO_4 and the ether evaporated, yielding a colourless, viscous oil. Yield: 1.6 g. (Found: OCH_3 18.37; Calc. for $C_9H_{12}O_3$: OCH_3 18.45.)

Dehydrodi-vanillyl alcohol. Dehydrodi-vanillin (8.2 g), dissolved in sodium hydroxide (6.5 g NaOH in 60 ml H_2O) was reduced with sodium borohydride (1.0 g) at room temperature. After 16 hours, long needles of the sodium phenolate had deposited. These were collected, dissolved in water (200 ml), and the free phenol was precipitated with acetic acid. Recrystallization from ethyl acetate yielded 6.42 g (76 %) of a crude product, which was purified by recrystallization from acetone-ethanol (1:1). Prisms, m. p. 187—190° (rapid heating). (Found: C 62.7; H 6.11; OCH_3 20.6. Calc. for $C_{16}H_{18}O_6$: C 62.7; H 5.93; OCH_3 20.3.)

Barium dehydrodi-vanillyl disulphonate (XXV). The sulphonation of dehydrodi-vanillyl alcohol was carried out as described for the preparation of the sulphonate XIII.

The barium salt deposited from the final aqueous concentrate and was completely precipitated by the addition of ethanol and ether. Reprecipitated from aqueous *iso*propanol-ethyl ether. (Found: OCH_3 10.74; Ba 23.8. Calc. for $C_{16}H_{16}O_{10}S_2Ba$: OCH_3 10.89; Ba 24.1.)

Coniferyl aldehyde (XXIX) was prepared according to Pauly and Feuerstein [49] with a few modifications *. The condensation of methoxymethyl vanillin with acetaldehyde was carried out in a borate buffer solution at pH 11.5. Coniferyl aldehyde was obtained from its methoxymethyl ether by heating the latter in a solution of 0.1 % conc. H_2SO_4 in 50 % acetic acid for 1 hour at 80° in a nitrogen atmosphere.

4-Acetoguaiacone (XXXII) **. The substance was prepared from guaiacol, acetic acid, and boron fluoride, following the procedure used by Kästner [48] for the synthesis of *p*-hydroxyacetophenone. Its purification was carried out according to Reichstein [50]. Yield 50 %.

4-Propioguaiacone (XXXIII). From guaiacol, propionic acid, and boron fluoride. Yield 60 %, m. p. 58° (*cf.* Kratzl [51]).

Short Communications

The Distribution of Sulphur in Cytochrome c

SVEN PALÉUS

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

In connection with other investigations [1] we have found it necessary to reinvestigate the distribution of sulphur in cytochrome c. In a recent review [2] it was concluded that the cytochrome c molecule contains six sulphur atoms, two of which belong to methionine [3], two to the cysteine residues in the thioether bridges [4,5], and two to cystine. These conclusions were based on data obtained on cytochrome c preparations purified according to Theorell and Åkeson [6] with the use of electrophoresis at different pH levels. We have now redetermined the content of sulphur and methionine in cytochrome c prepared on ion exchangers [7,8] and tested the cytochrome c for the presence of sulfhydryl and disulphide groups.

Experimental and results. Cytochrome c preparation. Cytochrome c was prepared from beef hearts on ion exchangers according to the principles given by Paléus and Neilands [7] and Margoliash [8]. The preparation contained 0.429 % iron.

Sulphur analysis. Three different methods were used, namely those of Josephson [9], Kirsten [10] and Zimmermann [11]. The figures show that cytochrome c contains 4 atoms of sulphur per molecule. The values obtained with the methods of Kirsten and Zimmermann agree very well, while the method of Josephson seems to give too low values (Table 1).

Determination of methionine. Methionine was determined by a modification of the Baernstein method [12]. We have only determined the methyl iodide formed and not the homocysteine thiolactone, which is the other product of the digestion. The determination was carried out in a Pregl micromethoxyl apparatus according to Vieböck and Brecher [13]. The yield of methyl iodide for a pure sample of methionine was found to be 96 % and the corresponding factor was thus 1.04. When 40.6 mg of cytochrome c with the iron content of 0.429 % was digested with hydriodic acid for 12 hours 0.922 mg CH_3I was obtained, corresponding to 2.16 methionine residues per molecule cytochrome c. Cytochrome c thus contains two methionine residues in the molecule.

Sulfhydryl- and disulphide group determination. The sulfhydryl group determination in the intact cytochrome was carried out with the mercurimetric amperometric titration method as published by Kolthoff *et al.*[14]. No mercury consumption could be detected in up to 28.5 mg of preparation used (2.4×10^{-6} moles cytochrome c). As this method determines as little as 5×10^{-8} moles of cysteine, cysteine must be absent from cytochrome c. The native cytochrome and preparations hydrolyzed in 20 % HCl for up to 20 hrs were titrated in the presence of sulphite with mercury ions according to Stricks *et al.*[15]. Up to 35 mg hydrolyzed cytochrome (2.9×10^{-6} moles) was titrated but in none of the samples could mercury consumption be demonstrated. As the sensitivity in this case is about 2×10^{-7} moles cystine, less than 1/10 mole of cystine is present in 1 mole of cytochrome c.

In addition, the nitroprusside test for sulfhydryl groups was negative on the preparation used in this work. This confirms the results obtained by Theorell and Åkeson [16]. The nitroprusside test for disulphide groups [17] was also negative.

Åkeson [3] found two methionine residues and two cysteines involved in the thioether linkages to the heme prosthetic group and could thus account for the presence of four of the six S atoms/molecule. The methionine analysis in the present work only verifies the data of Åkeson. The sulphur analyses, however, have revealed only four

Table 1. Results of the sulphur analyses.

Preparation	% Sulphur	Methods	Atoms sulphur per mole cyt. c (calculated from the iron content)
0.429 % iron	0.87, 0.87	Josephson	3.52
0.429 » »	1.00, 0.95	Kirsten	3.97
0.429 » »	0.94	Zimmermann	3.81
0.409 » » *	0.98	»	4.17

* This preparation was kindly provided by Drs H. Tuppy and G. Bodo, II. chem. Laboratorium der Universität, Wien.

sulphur atoms/molecule, and we have therefore been able to account for all the sulphur occurring in this preparation of cytochrome c.

The discrepancy of the present work with the results of Carruthers [18] is difficult to explain. Using electrophoretically purified cytochrome c with an iron content of 0.411 % he found a catalytic double wave in an ammoniacal solution of hexamine cobalt ions, which he attributed to cysteine or cystine in the cytochrome. There is a possibility that the cobalt ions present in the experiments of Carruthers might split the thioether bond of cytochrome c in the same way as silver ions [19], the double catalytic wave thus being caused by the two heme-linked cysteine residues.

Paul [20] dissociated a specially purified preparation of cytochrome c (iron content = 0.424 %) with silver and found that the protein moiety combined with 3.5—3.6 atoms of silver, probably due to two thiol groups (derived from the thioether bridges) and one disulphide group.

There is still the difference of two sulphur atoms between the preparation of Theorell and Åkeson [16] and the preparation of the present work to be explained. Perhaps that difference might be due to the preparation method used in each case. Further investigations of this difference would be of great interest.

Acknowledgements. The author wants to express his sincere gratitude to Professor H. Theorell and Dr. B. Sörbo for kind advice and criticism in connection with the work.

It is a pleasure to thank Dr. G. Kainz and Mr. W. Silhan at the II. Chemical Laboratory of the University of Vienna for careful analyses.

Organic Hydroxylamine Compounds Formed from Nitrite in *Torulopsis utilis*

ARTTURI I. VIRTANEN and NILS-ERIK SARIS

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

For some twenty years the formation of hydroxylamine both in the reduction of nitrate and in the fixation of molecular nitrogen has often been dealt with [1]. Bound hydroxylamine has been found to be formed in connection with both processes ("bound hydroxylamine" = a substance released on acid hydrolysis, which on oxidation with iodine gives nitrite [2]). On the whole, the nature of the "bound hydroxylamine" has remained unknown. Only Virtanen and Laine [3] were once able to isolate an oxime compound from the "sterile" sand-substrate of pea inoculated with effective *Rhizobium*, which compound on reduction gave aspartic acid and accordingly was, or contained, the oxime of oxalacetic acid. Except oxime nitrogen "bound hydroxylamine" could also be hydroxamic acid, especially as the formation of hydroxamic acid from hydroxylamine and organic acids or their amides has been brought about with preparations made from plant- and animal organisms.

Chromatographic methods have rendered it possible to study the "bound hydroxylamine" fraction more closely. Work on this line is going on in our laboratory. The first results of these investigations are presented in this communication.

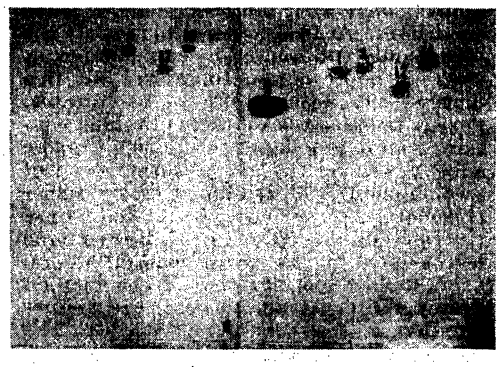
Virtanen and Csáky [4] observed that both low- and normal-nitrogen *Torulopsis utilis*, when suspended in a nitrate containing solution, which was vigorously aerated, forms "bound hydroxylamine" very rapidly. The amount of it decreased, however, as soon as after 15—20 min., probably indicating that the enzyme needed for its reduction had time to become effective enough through adaptation. We therefore used *Torulopsis*-yeast in our experiments. As the strain used now formed only a very small amount of "bound hydroxylamine" from nitrate as well as from nitrite in aerated solutions we performed our experiments in a low oxygen solution containing nitrite, the amount of "bound hydroxylamine" increasing noticeably under these conditions. At first we tried to identify the compounds containing hydroxylamine as such by paper chromatography, but this method did not turn out to be suitable, mostly because the extracts obtained contained large amounts of unknown organic substances. As the identification even of small amounts of amino acids by paper chromatography is easy we started to use the method of reducing hydroxylamine compounds to the corresponding amino acids and to identify these. The method presupposes that amino acids are beforehand removed as carefully as possibly. The method we used was briefly the following:

115 g of fresh low-nitrogen *Torulopsis utilis* (N-content 6.0 % of dry materia) was suspended in 1 150 ml of a mineral nutrient solution without combined nitrogen in a Kluyver flask placed in a waterbath at 30° C. Air was flushed through the suspension for 10 min., followed by nitrogen gas for 10 min. more before the addition of sodium nitrite in a concentration of 75 μg N/ml. This leads to the accumulation of about 3 μg NH_2OH-N/g fresh yeast. After 35 min. the suspension was centrifuged, the cells were washed with icecold distilled water, re-centrifuged and suspended in 96 % alcohol (3 ml/g yeast) freed from aldehydes. The whole operation after the addition of nitrite took 1 h. The suspension was kept in an icebox overnight and then centrifuged.

The clear supernatant was evaporated *in vacuo*, lipid material extracted by *iso*amylalcohol, and amino acids removed by cation exchange resin (Dowex 50) in the cold (0—3°C). The solution then contained 240 μg bound hydroxylamine-N, but no nitrite or free NH_2OH. Only traces of some amino acids could be found in the solution (*cf.* below). Half of the solution was subjected to reduction by 1.5 % sodium amalgam in the cold, the other half regarded as a control. Reduction time was 6 h whereby about 70 % of bound hydroxylamine was reduced.

Amino acids were absorbed on Dowex 50, displaced by ammonia and chromatographed on Whatman No. 4 paper using the solvent system butanol-acetic acid and phenol-NH_3. As a further control 73 g of *Torulopsis*-yeast were treated in the same way, but without addition of nitrite (Figs. 2A and 2B).

Figs. 1 and 2 show a two-dimensional paper chromatogram from the experiment in which nitrite had been added to the suspension of *Torulopsis*-yeast. Fig. 1 A shows the amounts of amino acids *before*

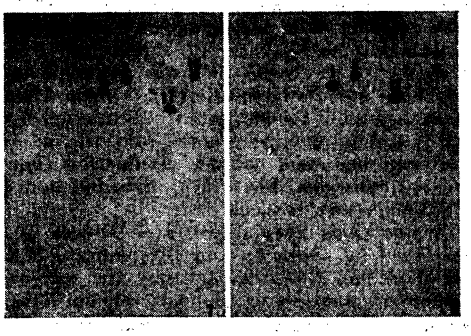


A B

Fig. 1 A. Two-dimensional paper chromatogram from the experiment with Torulopsis utilis suspension in a nitrite containing solution after removing of amino acids and before reduction. Only traces of 1 = gly, 16 = asp, 17 = glu, distinctly more of 8 = ser.

B. The same as A but after reduction with sodium amalgam. 2 = ala.

reduction, Fig. 1 B again *after* it. It appears from the chromatogram Fig. 1 A that we had succeeded fairly well in removing amino acids from the solution before reduction. Alanine was not found at all before reduction, of glutamic acid, aspartic acid, and glycine only traces were found. Of serine there was a somewhat larger amount. The reduction led to a profuse



A B

Fig. 2 A. Two-dimensional paper chromatogram from the experiment with Torulopsis utilis suspension in a solution without nitrite after removing of amino acids and before reduction. Only traces of 1, 8, 16, 17.

B. The same as A but after reduction.

formation of alanine, and increased the amount of glutamic acid more than tenfold. Similarly the amount of aspartic acid and glycine increased manifold. The amount of serine increased only slightly. It could thus be established that when *Torulopsis* reduces nitrite the oximes of pyruvic acid, ketoglutaric acid, oxalacetic acid, and glyoxalic acid are formed. The formation of the oxime of hydroxypyruvic acid was uncertain. As the keto acids corresponding to these oximes are of common appearance in cells, and hydroxylamine reacts with them with different velocities (Virtanen and Alfthan [5]), it is probable that in the cells hydroxylamine forms oximes with keto acids in amounts corresponding to their respective reaction velocities and concentrations.

The results related show that oximes of α-keto acids are formed in *Torulopsis*-yeasts on the reduction of nitrite. The identification of these have given conclusive evidence concerning the nature of the mysterious "bound hydroxylamine". The results give support to the idea (Virtanen *et al.* [3,5,6]) that when nitrate is the source of nitrogen the formation of amino acids in green plants as well as in micro-organisms may occur along two different pathways: *via* ammonia and *via* hydroxylamine. The reduction of oximino acids in organisms is still fairly unknown.

$$NO_3 \rightarrow NO_2 \rightarrow \rightarrow NH_2OH \rightarrow NH_3$$

$$\begin{array}{lll} & + & + \\ & \text{α-keto acid} & \text{α-keto acid} \\ & \downarrow & \downarrow \\ \text{oxime of α-keto acid} & \rightarrow & \text{α-amino acid} \end{array}$$

Even if the formation of the oximes in cells according to the foregoing obviously is a non-enzymatic reaction, the amino acid synthesis may, along this pathway, lead to a normal amino acid composition as amino acids through the action of transaminases can change into one another. How great a part of amino acids are formed *via* oximes is unknown.

A Diffusion-equilibration Method as a Stage in the Determination of the Deuterium Oxide Content in 1—2 Microlitres of Fluid

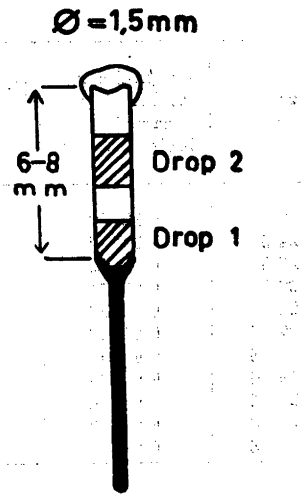
LARS GARBY

Institute of Physiology, University of Upsala, Sweden

Determination of the deuterium oxide content in fluids is generally performed utilizing the difference in density between pure water and deuterium oxide. Convenient methods have been described which allow an estimation of the deuterium oxide content in very small volumes with sufficient accuracy for most biological purposes. Thus the gradient tube method developed by Linderstrøm-Lang [1] (see also Linderstrøm-Lang, Jacobsen and Johansen [2]) requires only about 0.5 microlitre for an accurate determination. However, all methods based upon density determinations require that the fluid, the deuterium oxide content of which will be determined, contains only H_2O, HDO and D_2O, respectively. A distillation procedure is thus a necessary step before the actual measurements can be made. If the volume of the fluid to be analyzed is limited to a few microlitres, common distillation procedures become inconvenient.

The present work is a description of a simple method for "purification" of very small samples (1—2 μl) prior to the density determination in the gradient tube.

Theory. The principle of the method is shown in Fig. 1. Sample 1, a drop of volume V_1 containing an unknown concentration C_1° of deuterium oxide, is allowed to attain diffusion-equilibrium in a



small closed space with sample 2, a drop of volume V_2 containing distilled water. (It is assumed, for the sake of simplicity, that the distilled water used contains no deuterium oxide. This assumption introduces a negligible error.) The air space between the drops acts as a semipermeable membrane allowing only volatile substances to pass through. After equilibrium has been attained, any volatile substance has the same activity in both drops. It may be assumed that the activity coefficients of HDO (and D_2O) in water do not significantly differ from the activity coefficients of HDO (and D_2O) in water solutions of the molar and ionic strength present in biological fluids. Therefore

$$C_1^{eq} = C_2^{eq} \qquad (1)$$

where the superscripts denote that the concentrations are those at equilibrium.

Furthermore

$$C_1^\circ \, V_1 = (V_1 + V_2) \, C_2^{eq} \qquad (2)$$

and

$$C_2^{eq} = C_1^\circ \frac{V_1}{V_1 + V_2} \qquad (3)$$

If the only volatile substance present is deuterium oxide, a density determination of sample 2 at equilibrium will give the original concentration of deuterium oxide in sample 1. Equation (2) contains of course the assumption that the amount of deuterium oxide present in the air space

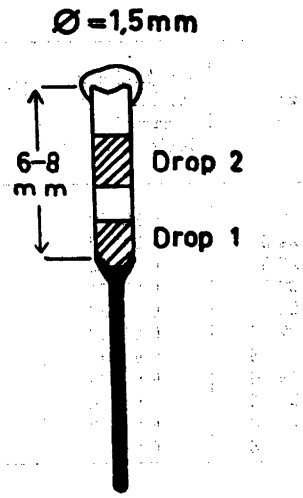
Institute of Physiology, University of Upsala, Sweden

Determination of the deuterium oxide content in fluids is generally performed utilizing the difference in density between pure water and deuterium oxide. Convenient methods have been described which allow an estimation of the deuterium oxide content in very small volumes with sufficient accuracy for most biological purposes. Thus the gradient tube method developed by Linderstrøm-Lang [1] (see also Linderstrøm-Lang, Jacobsen and Johansen [2]) requires only about 0.5 microlitre for an accurate determination. However, all methods based upon density determinations require that the fluid, the deuterium oxide content of which will be determined, contains only H_2O, HDO and D_2O, respectively. A distillation procedure is thus a necessary step before the actual measurements can be made. If the volume of the fluid to be analyzed is limited to a few microlitres, common distillation procedures become inconvenient.

The present work is a description of a simple method for "purification" of very small samples (1—2 μl) prior to the density determination in the gradient tube.

Theory. The principle of the method is shown in Fig. 1. Sample 1, a drop of volume V_1 containing an unknown concentration C_1° of deuterium oxide, is allowed to attain diffusion-equilibrium in a



small closed space with sample 2, a drop of volume V_2 containing distilled water. (It is assumed, for the sake of simplicity, that the distilled water used contains no deuterium oxide. This assumption introduces a negligible error.) The air space between the drops acts as a semipermeable membrane allowing only volatile substances to pass through. After equilibrium has been attained, any volatile substance has the same activity in both drops. It may be assumed that the activity coefficients of HDO (and D_2O) in water do not significantly differ from the activity coefficients of HDO (and D_2O) in water solutions of the molar and ionic strength present in biological fluids. Therefore

$$C_1^{eq} = C_2^{eq} \qquad (1)$$

where the superscripts denote that the concentrations are those at equilibrium.

Furthermore

$$C_1^\circ \, V_1 = (V_1 + V_2) \, C_2^{eq} \qquad (2)$$

and

$$C_2^{eq} = C_1^\circ \frac{V_1}{V_1 + V_2} \qquad (3)$$

If the only volatile substance present is deuterium oxide, a density determination of sample 2 at equilibrium will give the original concentration of deuterium oxide in sample 1. Equation (2) contains of course the assumption that the amount of deuterium oxide present in the air space

Table 1.

23.10	0.00912	160	0.004635	0.00927	101.6

is negligible in comparison with that present in V_1 and V_2.

The basic principle of this method has long been known (*cf.* Linderstrøm-Lang and Holter [3] and Conway [4]).

Method. Small glass tubes of the form and dimensions given in Fig. 1 are made from ordinary glass. They are thoroughly cleaned and treated on the inside with Desicote (Beckman) to make the surface non-wettable. After Desicoting they are again rinsed several times with distilled water. The rinsing after the Desicoting procedure is important as it removes traces of water-soluble matter in the Desicote film. The sample to be analyzed is then transferred into the bottom of the tube, preferably by means of a constriction pipette. Sample 2 is then immediately placed in the tube about 1 mm above the bottom drop (see Fig. 1). These operations are conveniently performed using the clamps and stands for pipettes and tubes described by Holter [5] for Cartesian diver manometry. Immediately after sample 2 has been delivered, the open end of the tube is dipped into melted paraffin which upon rapid cooling forms an effective seal. The tube is then allowed to stand in room temperature for equilibration. The time necessary for complete equilibration depends of course on the dimensions of the system. The dimensions used in the present investigation are seen in Fig. 1 and complete equilibrium is attained after about 100 minutes.

Results. The results from measurements on different standard solutions containing varying amounts of deuterium oxide is seen in Table 1. The concentrations are given as mole fractions HDO as if no D_2O molecules are present, an assumption which is nearly true in the dilutions used. The volume of the samples was 1.6 µl throughout, the same pipette used for both samples. The time for equilibration is also shown, it was always more than 125 minutes. In one instance it was as long as 1 110 minutes without affecting the recovery percentage. The mean recovery percentage from the 11 experiments shown in the table was 100.6 with a range between 99.1 and 101.9.

Discussion. As is seen from Table 1, recovery is obtained with an accuracy sufficient for most biological purposes. It seems therefore that the method described might be useful in those cases where the amount of fluid available for analyses is of the order of a few microlitres. Of course, any volatile substance present in addition to deuterium oxide is liable to affect the density of the recipient drop, and in certain cases this effect might be larger than otherwise tolerated.

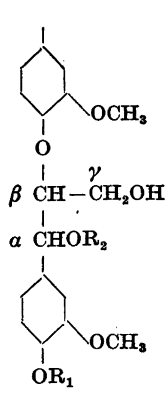
Note (added in proof): After this paper was submitted for publication the author's attention was drawn to a very recent paper by A. Hvidt, G. Johansen, K. Linderstrøm-Lang and F. Vaslow (*Compt. rend. trav. Lab. Carlsberg, Sér. chim.* **29** (1954) 129). The method used by these authors is essentially the same as that presented here, with the exception that it is used for larger volumes (~ 15 µl).

Guaiacylglycerol and its β-Guaiacyl Ether

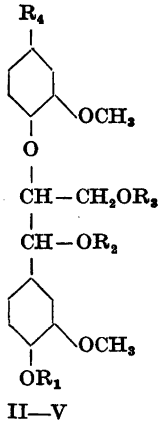
ERICH ADLER and EDGAR ERIKSOO

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

According to the views expressed by Erdtman [1,2] regarding the course of the dehydrogenative dimerization and polymerization of *p*-propenylphenols, guaiacylglycerol-β-aryl ether structures (I), in addition to other structures, can be expected to arise when coniferyl alcohol is subjected to dehydrogenation. The same author discussed the occurrence of such structures in lignin. On the basis of experimental results concerning the behaviour of lignin in sulphonation with sulphite solutions, alkylation with alcoholic hydrochloric acid, and similar reactions, Adler and Lindgren [3,4] and Adler and Yllner [5] also suggested the presence of structure I in lignin.



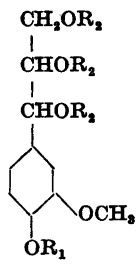
I



II—V

I. R_1 = H or the β-C-atom of a propane side-chain; R_2 = H or a C-atom of a propane side-chain
II. $R_1 = CH_3$; $R_2 = R_3 = R_4 = H$
III. $R_1 = R_2 = R_3 = R_4 = H$
IV. $R_1 = R_2 = R_3 = COCH_3$; $R_4 = H$
V. $R_1 = R_2 = R_3 = H$; $R_4 = CH{=}CH{-}CH_2OH$

The β-guaiacyl ether of α-(3,4-dimethoxyphenyl)-glycerol (II) was synthesized [3] and found to be a promising lignin model. It was sulphonated [3,4] and alkylated [3-6] in the expected manner, and also yielded formaldehyde on heating with strong sulphuric acid [3,4,7]. As in the case of α-(3,4-dimethoxyphenyl)-glycerol (VI) [5,7], the β-guaiacyl ether II yielded Hibbert's "ethanolysis" products on prolonged heating with ethanolic hydrochloric acid. This reaction cannot be given by other dimeric systems like those present in dehydro-diconiferyl alcohol or in pinoresinol which also are assumed to occur in lignin (*cf.* Ref.[5]).



VI. $R_1 = CH_3$; $R_2 = H$
VII. $R_1 = R_2 = H$
VIII. $R_1 = R_2 = COCH_3$

Only one phenolic guaiacylglycerol compound, *viz.*, "guaiacylglycerol" itself, *i. e.*, α-(3-methoxy-4-hydroxyphenyl)-glycerol (VII), has been available as yet. It had been obtained [8] as a syrupy mixture of the two possible pairs of optical antipodes, and yielded two crystalline tetraacetates (VIII), m.p. 84—85° and 113—114°, respectively. A sample of the syrupy product, which contained some water and had been kept in the refrigerator for several months, has now partly crystallized. Inoculation of other samples with the crystalline material induced rapid crystallization. Recrystallization from ethyl acetate, which was saturated with water, yielded needles, m. p. 82—84°. This compound contained one mole of water, which was removed at 60° (0.1 mm Hg). (Found: H_2O 7.71. Calc. for $C_{10}H_{14}O_5,H_2O$: H_2O 7.76.) The anhydrous product was a colourless glass. (Found: C 56.0; H 6.62; OCH_3 14.8. Calc.

VI. $R_1 = CH_3$; $R_2 = H$
VII. $R_1 = R_2 = H$
VIII. $R_1 = R_2 = COCH_3$

Only one phenolic guaiacylglycerol compound, *viz.*, "guaiacylglycerol" itself, *i. e.*, α-(3-methoxy-4-hydroxyphenyl)-glycerol (VII), has been available as yet. It had been obtained [8] as a syrupy mixture of the two possible pairs of optical antipodes, and yielded two crystalline tetraacetates (VIII), m.p. 84—85° and 113—114°, respectively. A sample of the syrupy product, which contained some water and had been kept in the refrigerator for several months, has now partly crystallized. Inoculation of other samples with the crystalline material induced rapid crystallization. Recrystallization from ethyl acetate, which was saturated with water, yielded needles, m. p. 82—84°. This compound contained one mole of water, which was removed at 60° (0.1 mm Hg). (Found: H_2O 7.71. Calc. for $C_{10}H_{14}O_5,H_2O$: H_2O 7.76.) The anhydrous product was a colourless glass. (Found: C 56.0; H 6.62; OCH_3 14.8. Calc.

for $C_{19}H_{14}O_8$: C 56.1; H 6.59; OCH_3 14.5.) Acetylation of the crystalline racemate or of the anhydrous product yielded a tetraacetate of m. p. 86–88°, identical with the previously [9] described acetate (VIII) of m. p. 84–85°, which obviously was not quite pure. Acetylation of the non-crystallizable residue obtained from the mother-liquors of the crystalline guaiacylglycerol furnished the second tetraacetate (VIII), m. p. 113–114°.

We further want to report the synthesis of the phenolic guaiacylglycerol-β-guaiacyl ether (III). It was carried out in a manner analogous to the preparation of the corresponding methyl ether (II). The reaction of ω-bromo-benzoyl-acetoguaiacone [1] with guaiacol in anhydrous methyl ethyl ketone in the presence of anhydrous potassium carbonate gave ω-(2-methoxy-phenoxy)-benzoyl-acetoguaiacone, which was treated in abs. ethanol with paraformaldehyde and potassium carbonate at room temperature. Reduction of the resulting α - (2-methoxy-phenoxy) - β - hydroxy-propioguaiacone with lithium aluminium hydride yielded the crude substance III as a syrup, from which a crystalline triacetate (IV), m. p. 106–108°, was obtained. (Found: C 62.0; H 6.08; OCH_3 14.06; CH_3CO 28.5. Calc. for $C_{22}H_{26}O_9$: C 61.8; H 5.86; OCH_3 13.90; CH_3CO 28.9.) The acetyl groups were removed from this triacetate by reduction with $LiAlH_4$. The guaiacylglycerol-β-guaiacyl ether (III) thus obtained was a practically colourless syrup. On re-acetylation the triacetate IV was again obtained.

Very recently, Freudenberg [10] has synthesized substance V by a similar procedure and has shown that one of the three dimeric products previously obtained on enzymatic dehydrogenation of coniferyl alcohol [11] is identical with this substance.

The view expressed by Adler and Lindgren [3-5] that guaiacylglycerol-β-aryl ether structures (I) may be essential elements in lignin has thus received further substantial support.

Details regarding the synthesis of III and of related compounds as well as their behaviour in typical lignin reactions, especially in ethanolysis, will be published later.

Expansion of Condensed Monolayers of Normal Long Chain Fatty Acids on Admixture of *Iso*-dextropimaric Acid

HENRIK H BRUUN

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Previous investigations [1,2] have shown that myristic and other long chain fatty acids, which give expanded monolayers in pure form, yield condensed monolayers when cholesterol and certain other bulky molecules are added to them. In the following an admixture-effect will be described which is the opposite of the above, *i. e.* an expansion of condensed fatty acid monolayers occurs on addition of a foreign substance, which alone forms a monolayer of the condensed type.

The study was conducted with a continuously recording surface balance of the Wilhelmy-Dervichian type [3]. The fatty acids investigated were palmitic, stearic, arachidic, behenic, lignoceric and myristic acids, of which the last-mentioned forms a monolayer of the expanded type. As the admixture-substance, *iso*dextropimaric acid *, a rosin acid, was employed.

* For a detailed investigation of the monolayer properties of this and other rosin acids, see references 4 and 5.

Expansion of Condensed Monolayers of Normal Long Chain Fatty Acids on Admixture of *Iso*-dextropimaric Acid

HENRIK H BRUUN

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Previous investigations [1,2] have shown that myristic and other long chain fatty acids, which give expanded monolayers in pure form, yield condensed monolayers when cholesterol and certain other bulky molecules are added to them. In the following an admixture-effect will be described which is the opposite of the above, *i. e.* an expansion of condensed fatty acid monolayers occurs on addition of a foreign substance, which alone forms a monolayer of the condensed type.

The study was conducted with a continuously recording surface balance of the Wilhelmy-Dervichian type [3]. The fatty acids investigated were palmitic, stearic, arachidic, behenic, lignoceric and myristic acids, of which the last-mentioned forms a monolayer of the expanded type. As the admixture-substance, *iso*dextropimaric acid *, a rosin acid, was employed.

* For a detailed investigation of the monolayer properties of this and other rosin acids, see references 4 and 5.

In Fig. 1 are plotted the areas per molecule of monolayers containing different contents of *iso*dextropimaric acid (IdP); these relate to a surface pressure of 1.5 dynes / cm *. The palmitic-IdP layers (Curve *16 C*) are seen to exhibit much higher area values than would be expected if the monolayer behaved as an ideal mixture, *i. e.* if the molecular area of the mixture were given by the expression $A_{mixt.} = x_1A_1 + x_2A_2$ (dotted line). The area increase is also considerable for the stearic-IdP layers (Curve *18 C*), but only relatively slight for the arachidic-IdP layers (Curve *20 C*), and very small for the behenic-IdP layers (curve *22 C*). The areas for the lignoceric-IdP layers follow the ideal curve,

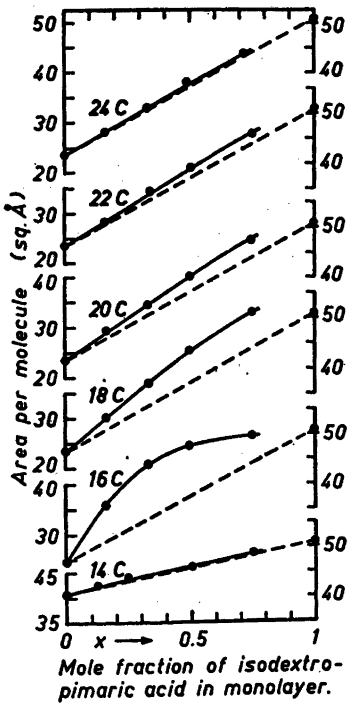

Fig. 1. Molecular areas of normal fatty acid monolayers (C_{14}—C_{24}) containing isodextropimaric acid. *Surface pressure, 1.5 dynes/cm. Dotted lines: calculated molecular areas corresponding to ideal behaviour. Substrate: dilute HCl (pH 3). 20° C.*

* This pressure is frequently employed when defining areas of monolayers of aliphatic long chain compounds.

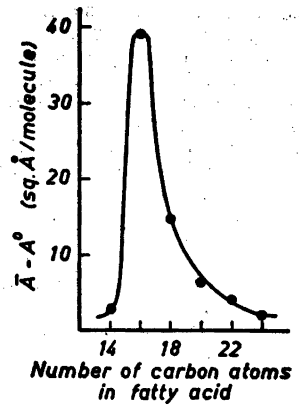

Fig. 2. Expansion of fatty acid monolayers containing isodextropimaric acid *(mole fraction x = 0.1). Ordinate: difference between partial molecular area for* isodextropimaric acid *in the fatty acid monolayer and the molecular area in the pure* isodextropimaric acid *monolayer. Surface pressure, 1.5 dynes/cm. Substrate: dilute HCl (pH 3). 20° C.*

as also do those for the myristic-IdP layers (Curve *14 C*). In Fig. 2 the difference between the actual partial molecular area $\bar{A}$ as determined by the tangent method and the molecular area $A°$ for the pure substance is plotted for *iso*-dextropimaric acid (mole fraction $x = 0.1$) against the number of carbon atoms of the fatty acid forming the other component of the mixture. The different degrees of expansion become clearly evident from the diagram.

Palmitic acid is the first fatty acid with increasing chain length that at room temperature forms a condensed monolayer. It possesses a hydrocarbon chain of sufficient length to give rise to a lateral attraction strong enough to overcome the thermal agitation of the flexible chains. When IdP molecules are added to its monolayer, they force apart the densely packed palmitic acid molecules and owing to their short length (IdP 16 Å, palmitic acid 24 Å) they are able to fill only the lowers parts of the openings formed. The lateral attraction, composed of the attraction between the palmitic and IdP molecules and between the upper ends of the former molecules becomes insufficient to maintain a condensed monolayer. With increasing chain length however, the lateral attraction gradually

increases, until in the case of lignoceric acid, for which the part of the chain projecting above the IdP molecules has a length of about 19 Å, it is sufficient to effect complete condensation even in the presence of IdP molecules.

It may be noted that also in other systems formed by flexible long chain molecules and rosin acid molecules, the relative lengths of the molecules play an important part. In solutions of binary mixtures of rosin acid soap and fatty acid soaps, mixed micelle formation occurs when the fatty acid soaps are sodium myristate and laurate, but not in the case of sodium palmitate and oleate [6].

I wish to express my gratitude to Professor Per Ekwall, Ph. D., the Head of the Institute, for allowing me to use the facilities of the Institute. I am grateful to Professor Einar Stenhagen of the Institute of Medical Chemistry of Uppsala University for samples of the three higher fatty acids and to Dr. C. G. Harris of Hercules Powder Company, Wilmington, USA, for the sample of *iso*dextropimaric acid.

Self-diffusion and Viscosity in Liquids

B. OTTAR

Norwegian Defence Research Establishment, Lilleström, Norway

In this preliminary communication some problems connected with self-diffusion and viscosity in liquids are treated using a modified kinetic theory. The molecules of a liquid are assumed to move in jumps between equilibrium positions by passing across a potential barrier, $\triangle F$. For a pure liquid in thermodynamic equilibrium, the mole flow from left to right through a unit area normal to the x-direction, is given by

$$\text{Flow}_{x\rightarrow} = v \cdot c/6 \qquad (1)$$

where c is the concentration in moles/cm³. The velocity of the molecules v is equal to $p \cdot \lambda$, where λ is the mean distance between successive equilibrium positions and p is the number of jumps per sec for which an exponential expression should be used. The mole flow may then be written

$$\text{Flow}_{x\rightarrow} = D \cdot c/\lambda \qquad (2)$$

where $D = p\lambda^2/6$ is the coefficient of self-diffusion. In equilibrium the same flow takes place in the opposite direction and the net flow is zero.

If there is a concentration gradient and D is independent of $c(x)$, the net rate of flow becomes

$$\text{net Flow} = \frac{\partial}{\partial c}\,\text{Flow}_{x\rightarrow} \cdot \triangle c = D \cdot \frac{dc}{dx} \qquad (3)$$

since $\triangle c = \lambda \cdot dc/dx$, and Ficks law is obtained.

The diffusion of a group of n arbitrary molecules in the liquid is then considered. The vectorial displacement of the group centroid, when each molecule in the group has made an independent jump, is given by

$$\bar{\lambda}_n = \frac{1}{n}\sum_1^n \bar{\lambda} \qquad (4)$$

The average numerical value of $\bar{\lambda}_n$ for a large group, or a large number of small groups, is

$$\lambda_n = \frac{1}{\sqrt{n}} \cdot \lambda \qquad (5)$$

The flow of such groups in equilibrium (*cf.* eqs. (1) and (2)) is then

$$\text{Flow}_{x\rightarrow} = D_n \cdot c_n/\lambda \text{ with } D_n = \frac{p \cdot \lambda^2}{6\cdot\sqrt{n}} \qquad (6,7)$$

The activation energy of a solute molecule (or ion) in water, is supposed to be due to the formation of hydrogen bonds between this and the water molecules, the solute molecule being able to establish a certain maximum number n_s of hydrogen bonds according to its molecular structure. Only a fraction of these hydrogen bonds are established at any time, and this fraction is continually changing. It is postulated that the diffusion coefficient of the solute molecule is equal to the diffusion coefficient of the surrounding group of n_s water molecules. If Eyring's expression for p is used, the diffusion coefficient becomes

increases, until in the case of lignoceric acid, for which the part of the chain projecting above the IdP molecules has a length of about 19 Å, it is sufficient to effect complete condensation even in the presence of IdP molecules.

It may be noted that also in other systems formed by flexible long chain molecules and rosin acid molecules, the relative lengths of the molecules play an important part. In solutions of binary mixtures of rosin acid soap and fatty acid soaps, mixed micelle formation occurs when the fatty acid soaps are sodium myristate and laurate, but not in the case of sodium palmitate and oleate [6].

I wish to express my gratitude to Professor Per Ekwall, Ph. D., the Head of the Institute, for allowing me to use the facilities of the Institute. I am grateful to Professor Einar Stenhagen of the Institute of Medical Chemistry of Uppsala University for samples of the three higher fatty acids and to Dr. C. G. Harris of Hercules Powder Company, Wilmington, USA, for the sample of *iso*dextropimaric acid.

Self-diffusion and Viscosity in Liquids

B. OTTAR

Norwegian Defence Research Establishment, Lilleström, Norway

In this preliminary communication some problems connected with self-diffusion and viscosity in liquids are treated using a modified kinetic theory. The molecules of a liquid are assumed to move in jumps between equilibrium positions by passing across a potential barrier, $\triangle F$. For a pure liquid in thermodynamic equilibrium, the mole flow from left to right through a unit area normal to the x-direction, is given by

$$\text{Flow}_{x\rightarrow} = v \cdot c/6 \qquad (1)$$

where c is the concentration in moles/cm³. The velocity of the molecules v is equal to $p \cdot \lambda$, where λ is the mean distance between successive equilibrium positions and p is the number of jumps per sec for which an exponential expression should be used. The mole flow may then be written

$$\text{Flow}_{x\rightarrow} = D \cdot c/\lambda \qquad (2)$$

where $D = p\lambda^2/6$ is the coefficient of self-diffusion. In equilibrium the same flow takes place in the opposite direction and the net flow is zero.

If there is a concentration gradient and D is independent of $c(x)$, the net rate of flow becomes

$$\text{net Flow} = \frac{\partial}{\partial c}\,\text{Flow}_{x\rightarrow} \cdot \triangle c = D \cdot \frac{dc}{dx} \qquad (3)$$

since $\triangle c = \lambda \cdot dc/dx$, and Ficks law is obtained.

The diffusion of a group of n arbitrary molecules in the liquid is then considered. The vectorial displacement of the group centroid, when each molecule in the group has made an independent jump, is given by

$$\bar{\lambda}_n = \frac{1}{n}\sum_1^n \bar{\lambda} \qquad (4)$$

The average numerical value of $\bar{\lambda}_n$ for a large group, or a large number of small groups, is

$$\lambda_n = \frac{1}{\sqrt{n}} \cdot \lambda \qquad (5)$$

The flow of such groups in equilibrium (*cf.* eqs. (1) and (2)) is then

$$\text{Flow}_{x\rightarrow} = D_n \cdot c_n/\lambda \text{ with } D_n = \frac{p \cdot \lambda^2}{6\cdot\sqrt{n}} \qquad (6,7)$$

The activation energy of a solute molecule (or ion) in water, is supposed to be due to the formation of hydrogen bonds between this and the water molecules, the solute molecule being able to establish a certain maximum number n_s of hydrogen bonds according to its molecular structure. Only a fraction of these hydrogen bonds are established at any time, and this fraction is continually changing. It is postulated that the diffusion coefficient of the solute molecule is equal to the diffusion coefficient of the surrounding group of n_s water molecules. If Eyring's expression for p is used, the diffusion coefficient becomes

$$D_{n_s} = \frac{\lambda^2}{6 \cdot \sqrt{n_s}} \cdot \frac{kT}{h} \exp(\triangle F_s/RT) \quad (8)$$

where n_s is the maximum number of hydrogen bonds for a solute molecule, and $\triangle F_s$ is the activation energy of these bonds.

In other liquids n_s may be the coordination number and $\triangle F_s$ the activation energy of exchange of one of the neighbouring solvent molecules. When the $\triangle F_s$ values of two ions are equal, the simpler equation

$$D_{n_1} \cdot \sqrt{n_1} = D_{n_2} \sqrt{n_2} \quad (9)$$

may be used to interpret experimental data.

Conductivity and viscosity. The conductivity of ions at infinite dilution is obtained from eq. (8) by partial differentiation with respect to $\triangle F_s$

$$\text{net Flow} = 2 \cdot \frac{\partial}{\partial \triangle F_s} \text{Flow}_{x \to} \cdot \triangle(\triangle F_s) \quad (10)$$

where

$$\triangle(\triangle F_s) = N \cdot z \cdot e \cdot V \cdot \lambda \quad (11)$$

and Nernst's law is obtained:

$$\Lambda_\infty^{\pm} = D_n \cdot \frac{F^2 \cdot z}{RT} \quad (12)$$

This derivation of Nernst's law assumes that the electric field causes only a differential change in the free energy of activation, this being the foundation of Ohm's law in the present model for a liquid. The importance of this argument lies in the possibility of deriving similar relationship for other properties of a liquid.

The laminar flow in a liquid is proportional to the applied tangential force

$$K = \eta \cdot dv/dz \quad (13)$$

where η is the coefficient of viscosity and dv/dz the velocity gradient normal to the moving layers. The unit of viscosity, the poise, is defined with reference to flow through a centimeter cube, when the top layer moves with a constant velocity v_0 of 1 cm/sec relative to the bottom layer. If this centimeter cube is considered as being divided into molecular layers, and the flow represented as a diffusion of these layers under the influence of an external force K, then the diffusion coefficient of a layer is given by eq. (8) with $n = \frac{1}{2} (N/V_M)^{2/3}$ as only one side of the layer resists the flow, *cf.* eq. (5). The net flow is given by eq. (10) with

$$\triangle(\triangle F) = N \cdot \eta \cdot \lambda \cdot dv/dz \quad (14)$$

From macroscopic considerations the flow is equal to

$$\frac{v_0}{2} \cdot c$$

and the equation

$$\frac{1}{\eta} = \frac{4 \cdot \sqrt{2} \cdot N^{2/3} \cdot V_M^{1/3}}{RT} \cdot D \quad (15)$$

is obtained, where D is the coefficient of self-diffusion for the liquid.

Applications. By assuming a common value of the entropy of activation, eq. (8) yields the following n-values of some simple ions based on $nH_2O = 4$, NH_4^+ 11.6; Cl^- 12.1; K^+ 11.9; Na^+ 15.0; Ag^+ 11.2; NO_3^- 21.7; Ac^- 18.8; Ox^{2-} 37.0; Ca^{2+} 33.9; Ba^{2+} 33.9; SO_4^{2-} 29.1;

Values of $\Lambda\infty$ taken from Handbook of Chem. and Physics. Log D/T plotted against $(1/RT)^2$ over the temp. range 50—156° C.

Possible ionic structures are $K^+ \cdot 4\,H_2O$, $NO_3^- \cdot 6\,H_2O$, $SO_4^{2-} \cdot 10\,H_2O$. Ca^{2+} appears to have a double layer of H_2O molecules.

Comparison of the diffusion coefficients of silicate [1], phosphate [2], vanadate [1] and chromate ions [3], with the corresponding Me_2O_7-ions gives n_3/n_1-values close to 1.50 which agrees well with a number of 4 or 6 oxygen-atoms, respectively, interacting with the solvent molecules. The corresponding values $n_3/n_1 = 1.99$ and $n_4/n_1 = 2.56$ for the more complex vanadate ions indicate the open tetrahedral structures V_3O_{10} and V_4O_{12}.

Coefficients of self-diffusion calculated from viscosity data using eq. (15) agree with experimental coefficients of self-diffusion for the following liquids, water [4], heavy water [4], mercury [5], ethyl bromide [6] and benzene [6]; the calculated values of alcohols [7] are lower due to the effect of deuterium on the hydrogen bonds in these liquids when an alcohol-d is used as tracer. This effect is large in methyl and ethyl alcohol, small in *n*- and *t*-propyl alcohol and almost disappears in *n*- and *t*-butyl alcohol.

A more detailed report on these matters will be given elsewhere.

Desoxypodophyllotoxin, Isolated from Podophyllin

HELMER KOFOD and CHR. JØRGENSEN

Danmarks farmaceutiske Højskole, organisk-kemisk Lab., Copenhagen, Denmark

In the course of a systematic re-investigation of the constituents of Podophyllin (the resin from *Podophyllum peltatum* L.) by means of chromatographic methods [1] a substance has been isolated as colourless needles, m. p. 170–172° C corr., yield approximately 0.1 %. It analyzed as $C_{22}H_{22}O_7$. (Found: C 65.7; H 5.58; OCH_3 23.3. Calc. C 66.3; H 5.57; 3 OCH_3 23.4.) The optical rotation in chloroform solution (c = 0.98) was $[\alpha]_D^{22} = -123° \pm 10°$. These data are close to those reported for desoxypodophyllotoxin (I), a compound which was prepared artificially by Hartwell, Schrecker and Johnson [2] by hydrogenolysis of podophyllotoxin chloride (III). These authors reported a melting point of 168–69° and $[\alpha]_D^{20} = -115°$ (chloroform, c = 0.50). The location of our natural substance on paper chromatograms (formamide-paper/benzene [1]) close to the solvent front and thus with a much higher R_F-value than podophyllotoxin (II) is consistent with the absence of the hydroxy-group (*cf.* Ref. [1], p. 950). Further evidence is provided by the ultra-violet spectrum, Fig. 1. It shows the essential features of the spectrum reported by Schrecker and Hartwell [2] for the synthetic desoxypodophyllotoxin. Although the minimum is slightly flattened, this and the maximum are identical with those of the synthetic substance with respect to the wave lengths. Finally on base-catalyzed epimerization the natural product yielded a substance identical with desoxypicropodophyllin (I, *cis*-2 : 3-*trans*-3 : 4) by melting point and optical rotation (Found m. p. 171–173°C, $[\alpha]_D^{21} = +33° \pm 10°$ (c = 0.25, chloroform); lit. m. p. 170.7–172.0°, $[\alpha]_D^{21} = +32°$ (c = 0.50, chloroform) [2]; m. p. 168–170°, $[\alpha]_D^{19} = +39°$ (c = 0.53, chloroform) [3, p. 5922]; m. p. 169.5–171°, $[\alpha]_D^{20} = +37°$ (c = 1.0, chloroform) [3, p. 5922].

To our knowledge this is the first time desoxypodophyllotoxin has been isolated from a *Podophyllum* species. It has previously been obtained from *Juniperus*

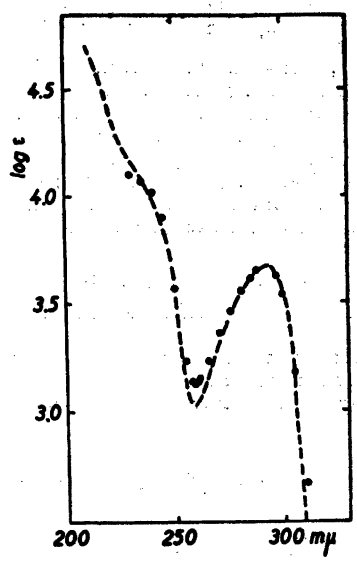

Fig. 1. Absorption in the ultra-violet of desoxypodophyllotoxin (I) in 95 % ethanol. ..... Curve given by Schrecker and Hartwell [2] for their synthetic product. O Natural product described in the present communication.

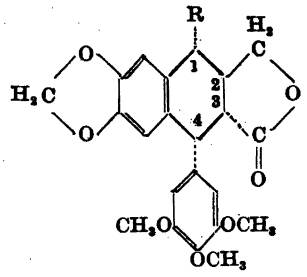
silicicola (Small) Bailey by Hartwell and co-workers [2,4], and was originally named silicicolin (m. p. 173.9–175.5° corr., $[\alpha]_D^{19} = -119$ (chloroform) (Ref.[4], *cf.* Ref.[2], footnote 15); m. p. 171–172° corr.[2]. The discoverers of silicicolin also demonstrated [7] that anthricin, isolated in 1940 (Noguchi and Kawanami [5]) from *Anthriscus silvestris* Hoffm. and hernandion, isolated in 1942 (Hata [6]) from *Hernandia ovigera* L. were in fact identical with desoxypodophyllotoxin.

A direct detection of desoxypodophyllotoxin in extracts of fresh plant material is impracticable even with the highly sensitive paper chromatographic technique [1]. It has not been definitely proved, therefore, whether the isolated desoxypodophyllotoxin is a genuine constituent in the plant or an artifact. However, a formation of the substance by dehydroxylation of podophyllotoxin, the principal constituent of podophyllin, or in fact of any other recorded constituent, must be regarded as extremely unlikely under the conditions normally applied during the preparation of

the commercial resin from the plant material.



I R = H desoxypodophyllotoxin $C_{22}H_{22}O_7$ (398.4) *trans*-2:3-*cis*-3:4

A Note on the Melting Point of Podophyllotoxin

HELMER KOFOD and CHR. JØRGENSEN

Danmarks farmaceutiske Højskole, organisk-kemisk Lab., Copenhagen, Denmark

The melting points previously reported in the literature for podophyllotoxin vary within the limits *ca.* 100—189° C, the majority falling in the ranges 110—118, 158—162 and 179—184° C. The explanation of this divergency is (1) that the substance is polymorphic, and occasionally (2) that investigators have overlooked [7], *cf.* [8] the fact that podophyllotoxin retains liquid of crystallization very strongly [5,8], so that some melting points actually refer to solvated products. In either case the experimental melting point will be dependent upon the type of apparatus, the rate of heating *etc.*

The melting point 188—189° C, recently communicated by us [1] is the highest ever obtained and it may need a few comments.

The general experience accumulated in this laboratory concerning the melting points of various podophyllotoxin preparations is summarized below. Unless otherwise stated the melting points — or rather melting intervals — were determined with the hot-stage microscope, essentially according to Kofler [8]. The apparatus was carefully calibrated against a series of pure standard substances. All podophyllotoxin samples were obtained in this laboratory by chromatographic fractionation of Podophyllin, *Pharmacopoia Danica Ed. IX*, on either alumina or formamide-impregnated silica-gel, benzene being the eluent.

Several preparations of podophyllotoxin, recrystallized from commercial wet benzene and dried in the atmosphere under an infra-lamp (*i. e.* exposed to a maximum temperature of 50° C) had a melting point of 110—115°. The same melting point was normally obtained in a closed capillary heated in a silicone bath. Elementary analysis and the percentage loss upon drying to constant weight at 0.01 mm Hg (continuous pumping) and 100° C (up to 18 hours) almost invariably indicated the composition 2 $C_{22}H_{22}O_8$, 2 H_2O, C_6H_6 of the original air-dried solvate, *cf.* Ref. [4,5].

The pure, unsolvated podophyllotoxin obtained by the above drying procedure in the first period of our work had a m. p. 183—84°. Later preparations, however, obtained without any deliberate alteration of procedure, melted completely at 111—118°. When heated at 150° for 1—2 hours on the microscope slide the substance resolidified and the crystals eventually melted at 183—184°. In a few cases, particularly with excessively slow heating it was possible to pass through the temperature range 111—118° without any visible phase-transition. Then the substance finally melted at 188—189°. Such was the case with the sample mentioned in our first paper [1].

A Note on the Melting Point of Podophyllotoxin

HELMER KOFOD and CHR. JØRGENSEN

Danmarks farmaceutiske Højskole, organisk-kemisk Lab., Copenhagen, Denmark

The melting points previously reported in the literature for podophyllotoxin vary within the limits *ca.* 100—189° C, the majority falling in the ranges 110—118, 158—162 and 179—184° C. The explanation of this divergency is (1) that the substance is polymorphic, and occasionally (2) that investigators have overlooked [7], *cf.* [8] the fact that podophyllotoxin retains liquid of crystallization very strongly [5,8], so that some melting points actually refer to solvated products. In either case the experimental melting point will be dependent upon the type of apparatus, the rate of heating *etc.*

The melting point 188—189° C, recently communicated by us [1] is the highest ever obtained and it may need a few comments.

The general experience accumulated in this laboratory concerning the melting points of various podophyllotoxin preparations is summarized below. Unless otherwise stated the melting points — or rather melting intervals — were determined with the hot-stage microscope, essentially according to Kofler [8]. The apparatus was carefully calibrated against a series of pure standard substances. All podophyllotoxin samples were obtained in this laboratory by chromatographic fractionation of Podophyllin, *Pharmacopoia Danica Ed. IX*, on either alumina or formamide-impregnated silica-gel, benzene being the eluent.

Several preparations of podophyllotoxin, recrystallized from commercial wet benzene and dried in the atmosphere under an infra-lamp (*i. e.* exposed to a maximum temperature of 50° C) had a melting point of 110—115°. The same melting point was normally obtained in a closed capillary heated in a silicone bath. Elementary analysis and the percentage loss upon drying to constant weight at 0.01 mm Hg (continuous pumping) and 100° C (up to 18 hours) almost invariably indicated the composition 2 $C_{22}H_{22}O_8$, 2 H_2O, C_6H_6 of the original air-dried solvate, *cf.* Ref. [4,5].

The pure, unsolvated podophyllotoxin obtained by the above drying procedure in the first period of our work had a m. p. 183—84°. Later preparations, however, obtained without any deliberate alteration of procedure, melted completely at 111—118°. When heated at 150° for 1—2 hours on the microscope slide the substance resolidified and the crystals eventually melted at 183—184°. In a few cases, particularly with excessively slow heating it was possible to pass through the temperature range 111—118° without any visible phase-transition. Then the substance finally melted at 188—189°. Such was the case with the sample mentioned in our first paper [1].

Recently we have obtained a product, which, recrystallized from benzene and dried to constant weight under the conditions specified above, had a single melting point at 188—189°, both with the Kofler apparatus and as determined by the capillary method (rate of heating in the melting region 2°/min). Only a very slight temporary moistening was noticeable at about 115° C, even when heating rapidly. When, beyond the melting point, the heating was discontinued and the hot-stage allowed to cool to 180° the substance crystallized, and repeated melting point determination now gave 187—188°.

The molecular identity of the new modification with podophyllotoxin m. p. 183—184° was proved by elementary analysis (Found: C 63.29; H 5.55). Calc. for $C_{22}H_{22}O_8$: C 63.75; H 5.35), by paper chromatography (*vide* Ref.[1]), by its ultraviolet absorption spectrum and by the optical rotation. Finally on epimerization with sodium acetate [5] it yielded picropodophyllin, m. p. 228—231° (lit.[6] 231.5—232.5°) which did not depress the melting point of an authentic sample.

Besides the modifications already mentioned a fourth one is known, melting at 158° (Ref.[5]). This modification has never been encountered in this laboratory. Its existence has, however, recently been confirmed by American investigators [8] who report a melting point of 161—162° C.

It appears, therefore, that according to circumstances, dried and unsolvated podophyllotoxin may come out in four different crystal modifications

I m. p. 114—118 (without foaming, Ref.[4]); 111—118 (this laboratory)
II m. p. 161—162 (Ref.[3]); 158 (without foaming, Ref.[5]); 157 (Ref.[10])
III m. p. 183—184 (Ref.[8], p. 2913 and the present authors); 179 (Ref.[11])
IV m. p. 188—189 (the present paper)

Various air-dried solvates have been described in the literature,

e. g., 2 PT, 2 H_2O, C_2H_5OH, m. p. 106—108 (Ref.[4])
2 PT, 2 H_2O, C_6H_6, m. p. 114—116, foaming (Ref.[9] and Ref.[6], footnote 32); m. p. 114—117 (Ref.[7], *cf.* Ref.[8]); 110—115 (this laboratory).

Since these solvates melt in much the same region as modification I, the postulated existence of I is open to the criticism that the experimental observations (*vide infra*) might as well be explained by assuming that the "modification" is a partially solvated podophyllotoxin melting around 115°, then loosing solvent of crystallization, the last trace of which disappears at about 150°, subsequently resolidifying as modification III or IV, which finally melts at the appropriate temperature. Evidence against this explanation is, however, that both Borsche and Niemann's and our own preparation of modification I was dried under carefully controlled conditions and analyzed as unsolvated podophyllotoxin. No loss of weight was observed on further drying at 125°, 0.01 mm Hg for two hours. It should also be mentioned that the melting process of I was not accompanied by the foaming, characteristic of the solvates.

Our thanks are due to Dr. A. W. Schrecker for discussion and for permission to publish the melting point of modification II. Analyses are by Mr. W. Egger, Chemical Laboratory, University of Copenhagen. This work is part of investigations supported by *Statens almindelige Videnskabsfond.*

The Determination of Oxime Nitrogen

TOSHIRO YAMADA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The acid hydrolysis method which is usually employed for oxime determination does not give quantitative results as reported by Novak and Wilson [1]. One cause of error is that the reaction is reversible and the hydroxylamine formed recombines with the keto compound. Moreover, this method does not give satisfactory results in the presence of ascorbic acid [2]. Yamafuji *et al.*[3] developed a quantitative method for oxime determination under alkaline conditions. This method is suitable for oximes of some keto compounds. It is, however, not applicable to acetoxime or glucosoxime. I, therefore, developed a modification of the acid hydrolysis method involving the addition of 2,4-dinitrophenylhydrazine and can confirm that this procedure gives good results with various oximes even in the presence of interfering substances.

The determinations were carried out according to the following procedure.

Reagents: 2 % 2,4-dinitrophenylhydrazine in 6 *N* H_2SO_4, 10 % (v/V) ethyl acetate in benzene and benzene and hydroxylamine reagents, prepared according to Csáky's method [4], *i. e.* 35 % Na-acetate, sulphanilic acid (30 % acetic acid solution), I_2 in glacial acetic acid, α-naphthylamine (30 % acetic acid solution) and Na-arsenate.

Conditions of hydrolysis: 1 ml of 2,4-dinitrophenylhydrazine in 6 *N* H_2SO_4 and 2 ml of the sample (containing 0.1 ~ 0.4 μmole of oxime) were mixed and boiled for 2 hours on a water bath.

Extraction of 2,4-dinitrophenylhydrazine and hydrazone: After cooling the appropriate amount of water was added to the hydrolyzed mixture *. Usually the total volume was 7 ml. Hydrazone together with hydrazine were extracted three times with 3 ml of 10 % ethyl acetate (in benzene) and then twice with 3 ml of benzene. After separating the water phase from the benzene 5 ml of the water phase was transferred to another test tube and mixed with 2 ml of Na-acetate solution to neutralize excess H_2SO_4 and then extracted again with 3 ml benzene three times. The 10 % ethyl acetate was used because it had a stronger extracting capacity than benzene only for 2,4-dinitrophenylhydrazine and especially the hydrazone. However, it also extracts free hydroxylamine in the absence of 2,4-dinitrophenylhydrazine as shown in Table 1. It is not, therefore, desirable to use this solvent more than is necessary.

Table 1. Effect of extraction with 10 % ethyl acetate in the absence of 2,4-dinitrohydrazine.

Number of extractions		Extinction

0	0	38.0
1	4	39.7
3	3	38.7
5	3	36.8

Colourimetry: 5 ml of the water phase thus obtained was taken out as the aliquot for hydroxylamine determination according to Csáky and measured with Fischer's photoelectric colourimeter using 525 mμ filter. A solution, treated similarly to the test solutions without oxime, was used as reference solution.

The experimental results obtained with several oximes are shown in Table 2. The standard solutions of pyruvic oxime and glucosoxime were prepared from solid samples and those of α-ketoglutaric oxime and acetoxime were obtained by diluting a mixture of 1 part of 4×10^{-4} *M* hydroxylamine and 1 part of the corresponding keto compounds (0.2 mg/ml) after a reaction time of 3 hours. The recovery in using this method was always more than 95 %. With the alkaline method, however, pyruvic oxime and α-ketoglutaric oxime are determined quantitatively. As the latter method is unsuitable for acetoxime and glucosoxime the new method may be said to have a wider application, being at the

* The suitable amount depends on the kind of colourimeter.

same time more accurate than the ordinary acidic methods.

When oximes of ketoacids were hydrolysed ordinarily in an acidic medium, the liberated hydroxylamine was decomposed by various substances, including the liberated ketoacids. This interfering effect was eliminated by addition of 2,4-dinitrophenylhydrazine as well as by using the alkaline method (Table 3).

As the coexisting nitrite tends to decompose hydroxylamine and is colourized simultaneously, it is desirable to remove the nitrite beforehand. This was achieved when the test solution containing nitrite was kept for 20 min. with urea in an acidic solution before addition of 2,4-dinitrophenylhydrazine. In this case, it was necessary to increase the amount of Na-acetate to neutralize excess of acid. The results are shown in Table 4. This method is more convenient because oxime can be determined independently.

Bernhauer *et al.* have recently isolated five different vitamin B_{12}-factors from digested sewage sludge [1,2]. One of these factors, provisionally called "Factor III", has practically the same microbiological activity towards *E. coli* and *Lb. leichmannii* in the tube-assay as cyanocobalamin (vitamin B_{12}) and has strong activity towards *Ochromonas malhamensis*. The antipernicious anemia activity of Factor III is similar to that of cyanocobalamin [3]. Factor III, however, differs from other vitamin B_{12}-factors with regard to R_F-values and distribution coefficients [3]. The absorption spectrum of Factor III closely resembles that of cyanocobalamin with the difference that the narrow band at 278 mμ is only faintly marked while a wide band at 295 mμ appears. Such a band has never been noticed before in any other vitamin B_{12}-factor. Factor III like cyanocobalamin itself is able to form aquo- and hydroxo-complexes as well as a cyano-complex containing more than one CN-group per molecule of Factor III.

A comparison between the effect of pH on the electrophoretic mobility of Factor III and of cyanocobalamin has been carried out in our laboratories.[4] It was concluded at first that the electrophoretic properties of Factor III closely resembled those of cyanocobalamin, except at pH values between 1 and 2. On reinvestigating thoroughly the electrophoretic mobility of cyanocobalamin in this pH-region, we found that the isoelectric point of this compound is somewhat lower than pH 1.9, as was first stated, and occurs at pH 1.5. Factor III has its isoelectric point at the same pH-value. The variation of

Study of a Peptic Degradation Product of Cytochrome c

I. Purification and Chemical Composition

HANS TUPPY and SVEN PALÉUS

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden and Zweites Chemisches Universitätslaboratorium, Vienna, Austria

A ferriporphyrin c-peptide obtained from *beef* cytochrome c by digestion with pepsin and previously described by Tsou [1,2] has been purified by a partition chromatographic method.

The peptide component of this haemopeptide has been shown to be composed of eleven amino acid residues arranged in the following sequence: Val-Glu(NH_2)-Lys-CySH-Ala-Glu(NH_2)-CySH-His-Thr-Val-Glu. The two cysteine residues occurring in this chain are linked to the side-chains 2 and 4 of the ferriporphyrin prosthetic group *via* two thioether bridges.

The sequence of amino acid residues in the ferriporphyrin c-peptide prepared by peptic degradation of *salmon* cytochrome c is identical with the one found in the split product of beef cytochrome c. The corresponding peptide derived from *chicken* cytochrome c, however, differs from the others by the replacement of the alanine residue by a serine residue.

Through digestion of horse cytochrome c with *pepsin*, Tsou [1] has obtained a brown-red coloured split product of relatively low molecular weight. This "pepsin-modified cytochrome c" contained the prosthetic group of the enzyme linked to a peptide component which represented a part of the original protein moiety of cytochrome c. The haemopeptide exhibited interesting enzymatic properties [2] different from those of native cytochrome c. Tsou's degradation method was recently applied to cytochromes of three different animal species [3]; the peptic split products of beef, chicken and salmon cytochromes c were prepared and found to show a high degree of similarity.

In another recent investigation[4] a *tryptic* degradation product of cytochrome c was purified and its chemical structure determined. The peptide component was shown to contain nine amino acid residues arranged in the following sequence *:

CySH—Ala—Glu(NH_2)—CySH—His—Thr—Val—Glu—Lys.

* Throughout this paper the abbreviations for the amino acid residues suggested by Brand and Edsall [5] will be used. The symbol for cysteic acid will be $CySO_3H$. The arrangement of amino acid residues in peptides will be described as suggested by Sanger [6].

The two cysteine residues occurring in this chain are linked to the side chains 2 and 4 of haematohaemin c[7] *via* two thio-ether bridges[8, 9]. The same sequence of nine amino acid residues could be demonstrated to occur in the ferriporphyrin c-peptides obtained by tryptic degradation of three different mammalian cytochromes[10].

In the present investigation the *peptic* degradation product, which Tsou had thought to be a pure substance, has been prepared free from contaminating peptides, and the chemical structure of the purified product has been established. By comparing the sequence of amino acid residues in the haemopeptides isolated from peptic digests of beef, chicken and salmon cytochromes c, an unexpected instance of species specificity of protein structure has been found.

MATERIAL

Cytochrome c. Beef, chicken * and salmon cytochromes were prepared from minced hearts by the method of Keilin and Hartree[11]. In the case of salmon, however, the initial extraction of the enzyme from the mince was carried out using dilute sulphuric acid[3] instead of trichloroacetic acid. After fractionation of the extracts with ammonium sulphate and precipitation of the enzyme with trichloroacetic acid, the cytochromes were dissolved in dilute ammonia, dialyzed against 0.05 *N* ammonia and finally against distilled water.

Beef cytochrome c was further purified as described by Paléus and Neilands[12]. For chicken and salmon cytochromes the method of Margoliash[13] was followed. In all three cases Amberlite XE-64 was the ion exchange resin used. The preparations of cytochrome c thus obtained had iron contents of 0.41 % (beef), 0.40 % (chicken) and 0.31 % (salmon).

Proteolytic enzymes. The samples of pepsin and of trypsin used in this work were crystallized products of the "Bios Laboratories". Their proteolytic activities were tested by Anson's haemoglobin method[14] and found to be, respectively, 0.0266 units/mg and 0.0065 units/mg. The crystallised *Bacillus subtilis* proteinase "subtilisin"[15, 16] was kindly made available to us by Professor K. Linderstrøm-Lang and Ing. M. Ottesen.

METHODS

Preparation of the peptic split product of beef cytochrome c. For the splitting of cytochrome c with pepsin the procedure of Tsou[1] was adopted. However, in contrast to his experience, after digestion in acid solution and neutralisation of the digest, the degraded pigment could not be precipitated quantitatively by making the solution 85 % saturated with ammonium sulphate. This indicated incomplete splitting. The incompletely digested material had to be subjected to another incubation with pepsin **. In the following a representative two-stage digestion experiment is described in detail.

A solution of 0.830 g beef cytochrome c in 83 ml distilled water was mixed with 20 ml 0.3 *N* HCl. To the acid solution (pH 1.55) was added 16.1 mg pepsin dissolved in a few ml of 0.01 *N* HCl. The mixture was incubated 28 h at 25° C and the digestion stopped by adding 20 ml 0.3 *N* NaOH. Solid ammonium sulphate was added to the slightly alkaline solution (pH 8.5) to make it 85 % saturated. Most of the pigment was precipitated, but on filtration the solution also proved to be somewhat coloured. The filtrate was discarded. The precipitate was dissolved from the filter using 0.01 *N* HCl and the pH of the

* We wish to thank AB. Findus, Hälsingborg, for kindly supplying frozen chicken hearts.

** The incomplete digestion of cytochrome samples appears to have been caused by the presence of some substance inhibiting the peptic proteolysis. The inhibitor is likely to have its origin in the ion exchange resin used for the purification of the cytochromes. The inhibitor can be removed from the cytochrome preparations by reprecipitating them with trichloroacetic acid from ammonium sulphate solution. Inhibitor-free cytochrome preparations do not require the two-step digestion with pepsin described above.

solution adjusted to pH 1.60 with 0.3 *N* HCl. To the acid solution (124 ml) 9.8 mg pepsin were added. After 20 h at 28° C the digestion mixture was neutralized by the addition of 0.3 *N* NaOH and made 85 % saturated with ammonium sulphate. Now the precipitation of the pigment was complete. The precipitate was collected by filtration and dissolved from the filter with 100 ml water containing a few drops of ammonia. The dark red solution was mixed with a solution of 280 g ammonium sulphate in 500 ml water and the pigment precipitated by the addition of 19 ml of 20 % aqueous trichloroacetic acid. The precipitate was centrifuged down and dissolved in the smallest possible amount of 0.05 *M* NH_3. The ammoniacal solution was dialyzed in the cold against 0.01 *M* phthalate buffer of pH 5.0 (three changes) and finally against distilled water (two changes). This resulted in an almost complete precipitation of the pigment. The brown-red powdery material was dissolved in 0.02 *M* NH_3 and the precipitations by ammonium sulphate and trichloroacetic acid repeated. Following dialysis against phthalate buffer and distilled water, the peptic degradation product of cytochrome c was collected by centrifugation and dried. Yield: 101 mg.

Purification of the ferriporphyrin c-peptide by partition chromatography. The final purification of the peptide was achieved using essentially the same method as that previously described for the tryptic split product of cytochrome c[4]. To 15 g of carefully washed and dried Hyflo Supercel was added 5.5 g of the lower layer of a freshly prepared mixture of *n*-butanol, glacial acetic acid and water (4 : 1 : 5). After thorough mixing, the Hyflo Supercel was suspended in a suitable volume of the upper phase of the solvent system so as to form a slurry and was poured into a chromatography tube 1.9 cm in diameter. After settling, the Hyflo Supercel formed a column 18.5 cm high. On the top of this column was placed 74.5 mg of the ferriporphyrin c-peptide dissolved in the smallest possible volume of the lighter phase. The chromatogram was developed with the help of larger amounts of the upper layer of the solvent mixture. In order to prevent the pigment from being partially destroyed, the ferriporphyrin c-peptide during chromatography had to be protected from direct illumination. The main component formed a dark brown band nicely moving down the column, the R_F value being approximately 0.9 in the beginning and somewhat decreasing in the course of the development. The main band was closely preceded by a lighter brown-coloured fraction and followed by a greenish band. Sometimes another brown-coloured band travelling slowly was observed. The effluent containing the main fraction was collected separately and evaporated to dryness *in vacuo* in a desiccator over conc. H_2SO_4 and solid KOH. The dried material was dissolved in as little 0.05 *M* ammonia as possible and dialysed in the cold against several changes of 0.01 *M* phthalate buffer pH 5 and subsequently against distilled water. The precipitated pure ferriporphyrin c-peptide was centrifuged down and dried. The final yield was 41 mg.

A: Amino acids determined by qualitative paper chromatography.
B: Moles of amino acid found, using the method of Moore and Stein [17, 18].

Determination of the constituent amino acids. For a qualitative determination 0.4 mg of the purified preparation were hydrolyzed overnight in a sealed capillary with 5.7 *N* HCl at 105° C, and the hydrolysate subjected to two-dimensional chromatography on Whatman No. 4 filter paper using phenol/NH_3/HCN in the first and collidine/lutidine/water in the second direction. For a quantitative determination 1 mg of the ferriporphyrin c-peptide was hydrolysed and the resulting amino acid mixture analysed by a modification [17] of the method of Moore and Stein [18]. The results of these determinations are summarised in Table 1.

Determination of the amino-terminal amino acid residues. The method used was Sanger's DNP technique [19]. 2.25 mg of the ferriporphyrin c-peptide were reacted with fluorodinitrobenzene in aqueous ethanol containing sodium bicarbonate. After 10 hrs. standing at room temperature with occasional shaking, the reaction mixture was diluted with water and extracted three times with peroxide-free ether. On acidification with HCl, the DNP derivative of the ferriporphyrin c-peptide precipitated quantitatively in the form of a brown powder. It was centrifuged down, washed with water, dried, and finally washed with ether.

0.5 mg of the DNP-derivative was hydrolysed with 5.7 *N* HCl at 105° in a sealed capillary. After 7 hrs. heating the yellow solution, in which black grainy material derived from the porphyrin moiety was floating, was diluted with water and extracted with ether. Paper chromatography of the aqueous solution with the butanol-acetic acid solvent of Partridge [20] revealed the presence of ε-DNP-lysine and im-DNP-histidine, besides free amino acids. In the ethereal extract DNP-valine was identified by the paper chromatographic methods of Biserte and Osteux [21] and of Blackburn and Lowther [22]. This DNP amino acid was further characterized by eluting it from the paper after chromatographic separation and heating it with concentrated ammonia solution [23] in a sealed capillary; after 12 hrs. at 108° a considerable part of the DNP-derivative had been split and free valine could be identified by paper chromatography.

On the paper chromatograms of the ether-soluble fraction a slow-moving and considerably weaker yellow spot (R_F 0.13 in phenol-*iso*amyl alcohol-water solvent [21]) was also found, besides the strong spot of DNP-valine (R_F 0.75). This substance was obtained as the main ether-soluble product, when the DNP-derivative of the ferriporphyrin c-peptide was dissolved in a mixture of equal parts of glacial acetic acid and concentrated HCl and hydrolysed at 108° for 1/2 h only. On further hydrolysis with 5.7 *N* HCl (12 hrs. at 108°) this yellow product gave rise to DNP-valine and free glutamic acid and was thus shown to be DNP-Val-Glu.

Splitting with trypsin. 1.0 mg of the peptic split product of bovine cytochrome c was dissolved in 0.50 ml of a 0.005 *M* ammonia solution, mixed with 0.05 ml 0.2% aqueous trypsin solution and incubated 23 hrs. at 36° C. The digest was then heated 5 minutes in a boiling water bath to inactivate the trypsin and was evaporated to dryness. The dry brown material was dissolved in a small volume of dilute ammonia and the solution placed on a strip of Whatman No. 4 paper in the form of a line 9 cm long. The chromatogram was developed one-dimensionally using butanol-acetic acid [20] as the solvent. The pigment moved down the paper in the form of a broad diffuse brown band (R_F 0.22—0.45). After drying of the chromatogram, a narrow strip was cut off from its long edge and sprayed with ninhydrin; on heating a strong violet colour developed at R_F 0.13. The ninhydrin-positive substance was eluted from the untreated part of the chromatogram.

One third of the eluted material was hydrolysed with 5.7 *N* HCl overnight at 105°. In the hydrolysate 3 amino acids were identified by paper chromatography: valine, glutamic acid and lysine. One third of the peptide was investigated using the DNP technique [6]; the dinitrophenylated peptide, on hydrolysis with 5.7 *N* HCl (10 hrs. at 105°), yielded DNP-valine, ε-DNP-lysine and glutamic acid. The remainder of the eluted peptide was subjected to electrophoresis using the method previously described by the senior author [24] ("Munktell 20, 150 g" filter paper; *M*/15 phosphate buffer pH 6.4; 75 volts; 2.5 mA; 5 hrs.) and it was found to migrate towards the cathode.

Preparation of the porphyrin-free peptide component of the peptic split product of cytochrome c. The thio-ether bridges were split by the method of Paul [25] following the procedure previously described for the removal of the pigment moiety from the tryptic degradation product of cytochrome c[4]. The thiol groups set free through the action of silver salts were oxidized to sulphonic acid groups by treatment with performic acid [26].

12 mg of the peptic split product of cytochrome c were dissolved in 5 ml of 60 % acetic acid, mixed with a warm solution of 80 mg silver sulphate in 10 ml water and heated at 50° for 9 hrs. Then the solution was evaporated to dryness *in vacuo* at low temperature. To the residue a mixture of 3 ml 87 % formic acid and 0.3 ml 30 % hydrogen peroxide was added. After 20 minutes standing at room temperature the reaction mixture, which had turned light yellow through oxidative degradation of the porphyrin, was diluted with water and evaporated to dryness *in vacuo* at a temperature not exceeding 30° C. Addition of water and evaporation to dryness was repeated twice in order to remove all the hydrogen peroxide. The residue was dissolved in 40 ml distilled water of 60°, 2 drops of 20 % H_2SO_4 added and H_2S passed into the warm solution. The precipitate of Ag_2S was removed by filtration and the clear filtrate reduced to a volume of about 10 ml by careful evaporation *in vacuo* at a temperature not higher than 25°. The sulphuric acid was removed by extracting three times with a solution of 0.25 ml tri-*n*-octylamine in 10 ml chloroform [27, 28], followed by chloroform and ether. The aqueous solution was evaporated to dryness leaving behind the porphyrin-free peptide.

A small amount of the peptide was heated 20 hrs. with 5.7 *N* HCl at 105°; in the hydrolysate the following amino acids were found by paper chromatography: $CySO_3H$, Glu, Thr, Ala, Val, His and Lys.

Partial acid hydrolysis of the porphyrin-free peptide. Separation and examination of the split products. The peptide prepared from 12 mg of bovine ferriporphyrin c-peptide as described above was hydrolysed 4 days at 37° C in concentrated HCl. After removal of excess HCl, the hydrolysate was adjusted to pH 5 and fractionated in the four-compartment ionophoresis cell described by Sanger and Tuppy [29]. The peptide and amino acid mixtures present in the acidic and neutral fractions were investigated by two-dimensional paper chromatography using essentially the same methods as those reported by Sanger and coworkers [29, 30].

Digestion of the porphyrin-free peptide with subtilisin. Porphyrin-free peptide obtained from 6 mg of ferriporphyrin c-peptide was dissolved in 0.5 ml water and adjusted to a pH of 7 to 8 by dropwise addition of 0.05 *M* ammonia. A solution of 0.2 mg subtilisin in 0.1 ml water was added and the mixture incubated at 37° for 23 hrs. After heating for 3 minutes in a boiling water-bath to inactivate the enzyme, the solution was evaporated to dryness *in vacuo*. No preliminary fractionation was necessary and the digest was investigated directly on paper chromatograms.

The peptic split products of salmon and chicken cytochromes. Salmon and *chicken* cytochromes c were digested with pepsin in the same way as has been described above for beef cytochrome. In the purification involving partition chromatography on Hyflo Supercel, the ferriporphyrin c-peptides obtained did not differ in their behaviour from the cor-

responding peptide of bovine origin. The amino acid composition and the iron contents of the three haemopeptides are compared in Tables 1 and 2. After splitting with silver salt in acetic acid, the porphyrin-free peptides were subjected to further digestion with subtilisin and the resulting mixtures of lower peptides investigated by paper chromatography.

RESULTS AND DISCUSSION

In the hydrolysate of the purified ferriporphyrin c-peptide of *bovine* origin, 6 amino acids were identified by paper chromatography: glutamic acid, threonine, alanine, histidine, valine and lysine (Table 1). For comparison, it may be noted that the peptic degradation product of cytochrome c as obtained by the isolation procedure of Tsou [1], which did not include a partition chromatographic purification, contained aspartic acid, glycine, leucine, phenylalanine, proline and serine [2,3] in addition to the six amino acids found in the purified preparation.

A quantitative analysis by the method of Moore and Stein [17] gave evidence that the peptide was composed of one residue of threonine, alanine, histidine and lysine, while valine occurred twice and glutamic acid three times (Table 1). Neither paper chromatography nor ion exchange chromatography revealed the presence of cysteine or cystine, but this is not inexplicable since it is known that the two sulphur containing amino acid residues linked to the prosthetic group of cytochrome c are not set free by mild acid hydrolysis, but remain combined with the pigment in the form of porphyrin c [31,9]. However, after fission of the thioether bridges by the silver salt method of Paul [25] and oxidation of the —SH groups to —SO_3H groups, the porphyrin-free peptide moiety, after hydrolysis with acid, yielded cysteic acid in addition to the other six amino acids. Since the cysteic acid found is derived from two porphyrin-bound cysteine residues, and since the six other amino acids account for nine amino acid residues, it can be concluded that the peptide component of the peptic degradation product of cytochrome c is composed of 11 amino acid residues.

In the ferriporphyrin c-peptide only one α-amino group was found free to react with fluorodinitrobenzene; after dinitrophenylation and hydrolysis, one of the two valine residues was recovered in the form of DNP-valine. After short hydrolysis, however, DNP-Val-Glu was found in high yield. This indicates that the 11 amino acid residues of the ferriporphyrin-c-peptide are arranged in one single peptide chain having the dipeptide sequence Val-Glu in the N-terminal position. In contrast, Tsou [2] had found that his "pepsin-modified cytochrome c" contained 3.4 α-amino nitrogen atoms per atom of iron.

On treatment of the ferriporphyrin c-peptide with trypsin, a small fragment was split off which, on acid hydrolysis, yielded valine, glutamic acid and lysine. DNP treatment showed valine to be the N-terminal residue. Lysine, on the other hand, could be assigned the C-terminal position since trypsin is known to split specifically peptide bonds involving the carboxyl groups of lysine and arginine residues [32-34,4]. A tripeptide containing one glutamic acid and one lysine residue would be expected to behave as a neutral substance at a pH of 6 to 7; the peptide under investigation, however, at a pH of 6.4, proved to be a basic substance. This suggests that the glutamic acid residue is not present as such, but is in the form of its amide, glutamine, and that the tripeptide is Val—Glu(NH_2)—Lys.

Further information about the amino acid sequence in the ferriporphyrin c-peptide was obtained by hydrolysis of its porphyrin-free peptide moiety and investigation of the split products. The results obtained with the acidic and neutral fractions of a partial acid hydrolysate are recorded in Figs. 1 and 2 and Tables 3 and 4. Fig. 3 and Table 5 give results obtained through the use of the proteolytic enzyme subtilisin.

Special attention must be given to peptides 3 and 4 in Fig. 3 and Table 5. These two dipeptides would seem to be identical with the dipeptides 7 and 8 (Ala—Glu and Val—Glu) found in the acid hydrolysate (Fig. 1 and Table 3), but they differ markedly in their R_F values. Whereas the peptides 7 and 8 (Fig. 1) show chromatographic properties previously found to be exhibited by Ala—Glu [4] and Val—Glu [29], the dipeptides 3 and 4 of the enzymic digest (Fig. 3) are travelling faster in phenol and slower in butanol-acetic acid. This behaviour appears to be characteristic of peptides containing glutamine rather than glutamic acid, and it may be mentioned that free glutamine shows the same difference in chromatographic properties with respect to free glutamic acid. The conclusion that peptides 3 and 4 of the enzymic digest are Ala—Glu(NH_2) and Val—Glu(NH_2) is strongly supported by the known

proteolytic specificity of subtilisin; this bacterial enzyme has previously been reported to attack peptide bonds involving the carboxyl groups of glutamine and asparagine residues [35, 36], whereas the amide groups are left intact. Mineral acid, on the contrary, readily breaks amide bonds.

In Table 6 all the peptides are listed which have been obtained from the peptic degradation product of bovine cytochrome c. From their structure the following sequence of amino acids can be deduced:

$$Val—Glu(NH_2)—Lys—CySO_3H—Ala—Glu(NH_2)—CySO_3H—His—Thr—[Val\ Glu].$$

In this sequence the order of the last two residues has not yet been established in a straightforward manner. It can be assumed, however, that the order is not different from that occurring in the corresponding porphyrin-free peptide derived from the *tryptic* degradation product of cytochrome c [4, 10],

$$CySO_3H—Ala—Glu(NH_2)—CySO_3H—His—Thr—Val—Glu—Lys,$$

since both peptides have their origin in the same part of the protein moiety of cytochrome c. The perfect agreement between the two enzymic degradation products as regards amino acid sequence is clear evidence that no rearrange-

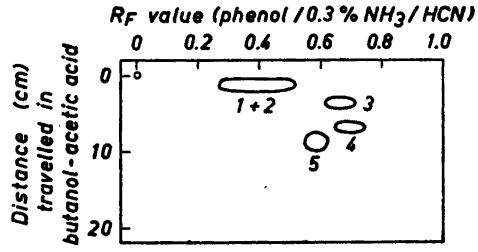

Fig. 3. Chromatogram of subtilisin hydrolysate of bovine "porphyrin-free peptide" (see Table 5).

ment has taken place within the peptide chain during enzymic digestion. Taking this for granted and remembering that the two cysteic acid residues of the porphyrin-free peptide are derived from two porphyrin-bound cysteine residues, the sequence of amino acids in the peptic degradation product of bovine cytochrome is concluded to be

$$\text{Val—Glu}(NH_2)\text{—Lys—CySH—Ala—Glu}(NH_2)\text{—}$$
$$\text{CySH—His—Thr—Val—Glu.}$$

On the basis of this peptide formula and of the known nature of the porphyrin component of cytochrome c[7], it is possible to calculate the iron and nitrogen contents of the peptic degradation product. In Table 2 the calculated figures are compared with the values actually found by analysis. The latter values prove to be considerably lower than expected although the iron content (2.76 %) is obviously far superior to that reported by Tsou (2.21 %) [2]. However, the molar ratio between the values found for nitrogen and iron is in excellent agreement with the theoretical figure of 20. This gives definite indication

that the haemopeptide preparation is free from contaminating nitrogenous substances such as peptide impurities, though not free from other substances which may increase the molecular weight and lower iron and nitrogen values, such, for instance, as inorganic or organic (*e.g.*, phthalate) ions.

In Tables 1 and 2 results are included which have been obtained with the peptic degradation products of *salmon* and *chicken* cytochromes. It can be seen

Table 6. Peptides obtained from the peptic degradation product of bovine cytochrome c.

DNP-technique	DNP-Val-Glu

Hydrolysis with HCl	Val-Glu $CySO_3H$-Ala $CySO_3H$-His Val-[Glu, Lys] Ala-Glu Thr-[Val, Glu] Lys-$CySO_3H$ Glu — $CySO_3H$ [$CySO_3H$, Ala, Glu] Glu — [$CySO_3H$-His]
Digestion with subtilisin	Val-Glu(NH_2) Ala, Glu(NH_2) Thr-[Val, Glu] [Lys, $CySO_3H$] [$CySO_3H$, His]
Structure of the "porphyrin-free peptide"	Val-Glu(NH_2)-Lys-$CySO_3H$-Ala-Glu(NH_2)-$CySO_3H$-His-Thr-[Val, Glu]

that the iron contents of these two ferriporphyrin c-peptide preparations were found to be virtually the same as those obtained for the bovine material. In the amino acid composition, the *salmon* haemopeptide did not differ at all from the bovine one, whereas *chicken* ferriporphyrin c-peptide did not contain alanine, and serine was found instead. In all three haemopeptide preparations, the same N-terminal dipeptide sequence, Val—Glu, was found to be present.

To get further information, the peptic degradation products of salmon and chicken cytochromes c were split with silver salt and oxidized with performic acid, using the same methods as described above for bovine preparations. The porphyrin-free peptides thus obtained were subjected to the proteolytic action of subtilisin. In the enzymic digest of the *salmon* peptide the following 5 split products were found to be present preeminently:

Val—Glu(NH_2), Lys—$CySO_3H$, Ala—Glu(NH_2), $CySO_3H$—His and Thr—[Val, Glu].

These peptides being identical with the ones identified in the subtilisin hydrolysate of the corresponding bovine peptide preparation (*cf.* Table 6), the sequence of amino acid residues in the peptic degradation product of salmon cytochrome c appears to be the same as in bovine cytochrome,

Val—Glu(NH_2)—Lys—CySH—Ala—Glu(NH_2)—CySH—His—Thr—Val—Glu.

Subtilisin treatment of the *chicken* peptide also yielded

Val—Glu(NH_2), Lys—$CySO_3H$ and Thr—[Val, Glu];

instead of Ala—Glu(NH_2), however, Ser—Glu(NH_2) was found. This is taken to indicate that the amino acid sequence in the peptic degradation product of chicken cytochrome c will be

Val – Glu(NH_2) – Lys – CySH – Ser – Glu(NH_2) – CySH – His – Thr – Val – Glu *.

The fact that an alanine residue occurring in beef and salmon cytochromes c and previously shown to be also present in horse and pig cytochromes [4], is replaced by a serine residue in a bird cytochrome, is rather surprising. It is the more interesting, since an amino acid residue with a side-chain devoid of a polar group appears to be substituted by another residue possessing a polar group in its side chain, and since the amino acid residue found to be replaceable is situated in the very neighbourhood of the prosthetic group. Certainly, this is a remarkable example of how the species specificity of protein structure may be explicable in terms of differences in amino acid sequence, and the question arises what the genetic implication of such differences may be.

* Further evidence for this sequence was adduced by subjecting the porphyrin-free peptide (obtained from the peptic degradation product of chicken cytochrome c) to partial hydrolysis with hydrochloric acid and investigating the split products present in the hydrolysate. The following peptides were found and characterised: Val-Glu, Val-[Glu,Lys], Val-[Glu, Lys, $CySO_3H$], Lys-$CySO_3H$, Ser-Glu, Ser-[Glu, $CySO_3H$], Ser-[Glu, $CySO_3H$, His], $CySO_3H$-His, Thr-[Val, Glu].

Acknowledgement. The authors' thanks are due to Professor H. Theorell for stimulating discussions during the course of this work, and to Professor F. Wessely for advice and encouragement. They also wish to thank Laborator K. G. Paul for valuable discussions and Dr. R. Bonnichsen and Miss A. C. Riiber for performing a quantitative amino acid analysis.

It is a pleasure to thank Miss G. Östensen for valuable technical assistance, and Miss B. Rolander for performing microanalytical determinations.

The work described in this paper was supported by grants from *Statens naturvetenskapliga forskningsråd*, for which the authors wish to express their thanks.

Study of a Peptic Degradation Product of Cytochrome c

II. Investigation of the Linkage between Peptide Moiety and Prosthetic Group

SVEN PALÉUS, ANDERS EHRENBERG and HANS TUPPY

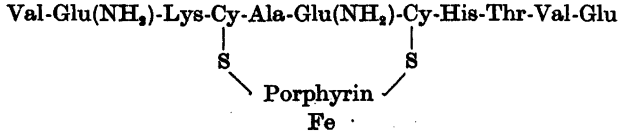
Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden and Zweites Chemisches Universitätslaboratorium, Vienna, Austria

The ferriporphyrin c-peptide obtained by peptic digestion of cytochrome c has been subjected to titrimetric, spectrophotometric and magnetic measurements. The results are compared with corresponding data for cytochrome c. In contradistinction to its parent protein, ferriporphyrin c-peptide is not altered spectrophotometrically by chloride ions at low pH values. Whereas the acid compound of ferricytochrome is transformed to the neutral form by a divalent dissociation with a pK of 2.12, it was found that the corresponding transformation of the peptide takes place in two separate steps with a pK of 3.4 and 5.8, respectively. The iron of the acid form has a susceptibility of 11 900 $\times$ 10^{-6} cgs emu and hence essentially ionic bonds. The alkaline form is covalent with a susceptibility of 2 100 $\times$ 10^{-6} cgs emu. The intermediate form (present between pH 3.4 and 5.8) has a tentative susceptibility of 8 800 $\times$ 10^{-6} cgs emu, and its structure is uncertain. The experimental data are related to structural differences between the peptide and cytochrome c, and the nature of the heme-linked groups is discussed. At pH 4.9 the ferriporphyrin c-peptide exhibits a peroxidatic activity more than 20 times stronger than that of cytochrome c.

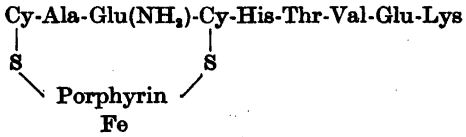
Attempts to understand the biological activity of a protein must be firmly based on considerations of the chemical structure of the molecule. Since many heme proteins have identical prosthetic groups [1], the activity associated with a particular heme protein must be a reflection of specific relationships existing between the prosthetic group and the protein moiety. Theorell and coworkers have for many years been concerned with the chemistry of heme proteins including cytochrome c. In 1939, Theorell [2] presented evidence suggesting two stable thioether bridges between the heme prosthetic group and the cytochrome c-protein. Data accumulated since that time strongly indicate the existence in fact of such bridges. In 1941, on the basis of titrimetric, spectrophotometric, and magnetic investigations, Theorell and Åkeson [3] proposed, in addition, two linkages between the iron atom of the prosthe-

tic group and imidazole groups of histidine residues in the protein moiety. Further investigations have substantiated this concept, and the nature of the iron-nitrogen linkages at various pH's has been clarified [4,5].

With the development of convenient methods for the preparation of relatively large amounts of pure cytochrome c[6] it has now become possible to study in greater detail certain structural aspects of the cytochrome c-protein itself. By controlled digestion with proteolytic enzymes [7], fragments of the protein firmly bound to the prosthetic group have been obtained. In the foregoing paper [8] the purification and structure of a peptic degradation product has been described:



Tuppy and Bodo [9] have also studied the structure of a tryptic degradation product:



The two fragments have certain important structural features in common. The porphyrin is bound *via* thioether bridges to two cysteine residues. In addition, a histidine residue is attached to one of the cysteine residues in the polypeptide sequence. The imidazole group of this histidine has been suggested by one of us to be one of the groups linked to the iron atom of the heme in the intact cytochrome c molecule [9].

This paper is concerned with an investigation of the peptic degradation product using the same physico-chemical methods which have been applied to the intact cytochrome c molecule.

MATERIAL AND METHODS

All the experiments were performed with the peptic degradation product of *cow* cytochrome c described in the foregoing paper [8]. The product is easily autoxidizable and is therefore obtained as a *ferriporphyrin* c-peptide. The iron content was determined by a modification of the method given by Lorber [10]. It was found to be 2.85 % in most of the preparations. All molarities are calculated on iron basis.

The titration apparatus described by Paléus was used [5]. N_2O or N_2 was passed through the titration vessel in order to diminish CO_2 errors. The pH of the solution was measured with a Radiometer Model 22 pH meter. The spectrophotometric experiments were carried out at 20° in a Beckman Model DU spectrophotometer. The absorption data are given as $\beta = d^{-1} \cdot c^{-1} \cdot \ln I_0/I$ cm²/mole, where natural logarithms are used, d is the optical path length in cm and c is the concentration in moles/cm³.

Especially when containing higher concentrations of salt and in certain pH regions the absorption values of the peptide solutions showed a tendency to decrease with time in an irreproducible manner. This troublesome behaviour of the peptide was eliminated to a large extent by carefully washing all vessels and absorption cuvettes with dilute ammonia and distilled water, and by rinsing them several times with the solution to be investigated.

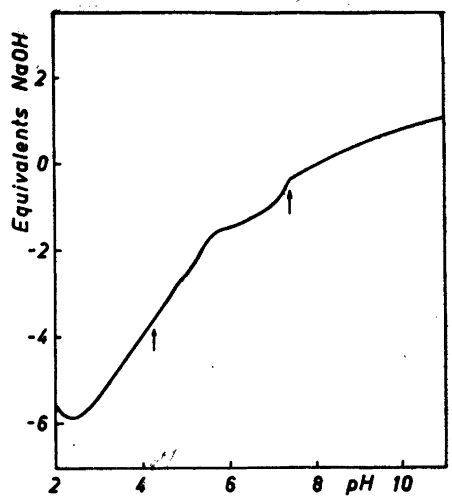


Fig. 1. Titration curve of the peptic degradation product of cow cytochrome c. The two arrows indicate the range of pH where the peptide precipitated.

The magnetic determinations were made in the apparatus constructed by Theorell and Ehrenberg[11]. A dilute solution of nickel chloride was used as a paramagnetic standard, $\chi_M = 4\,434 \times 10^{-6}$ cgs emu at 20° C, at which temperature all the measurements were made.

EXPERIMENTS AND RESULTS

Titrations

Approximately 3.5 mg of the peptide were suspended in 2.5 ml of water and dissolved by the addition of 1 *N* H_2SO_4 to obtain pH 2. The sample was then titrated with 1 *N* KOH. Under these conditions the peptide regularly precipitated at a pH of about 4.3 and did not redissolve until about pH 7.4. In this region the pH values, as measured immediately after each addition of alkali, were unstable but attained a constant value after longer waiting.

Several titrations were made with the same peptide preparation. It appeared difficult to reproduce the titration curve exactly, especially at the extreme pH values. One titration curve, corrected for blank, is shown in Fig. 1. The main shape of that curve was constantly reproduced and all the experiments indicated that about 7 equivalents were titrated between pH 2 and 11. This is in agreement with the structure of the peptide which has 7 titratable groups. Using the following tentative p*K* values: 3.1 and 4.4 for the carboxyls of glutamic acid, 4.6 for the two propionic acid residues, 6.3 for the imidazole of the histidine, 7.6 for the α-amino group of valine and 9.6 for the ε-amino group of lysine, a theoretical titration curve could be constructed which agreed nicely with the experimental observations except for the S-shaped part in the pH region 6—7.5. It has been suggested that the p*K* of the propionic acid residues in cytochrome c is about 5.5[2,5]. If this value is applied in our case, the p*K* of histidine must be shifted down to as far as 3.5, in order to obtain the same degree

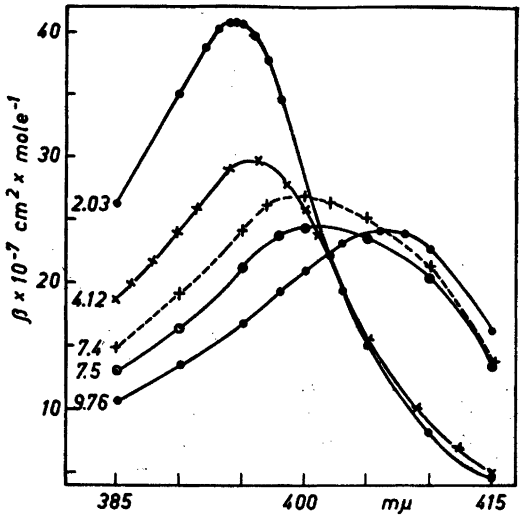

Fig. 2. Soret band of the peptide at different pH values. The pH is indicated at the beginning of every curve. The drawn curves are made from an acid stock solution, the dotted curve is from an alkaline stock solution. Cf text.

of coincidence with the experimental curve. The S-shaped part around neutrality remains unexplained, but might be a result of the precipitation and redissolution of the peptide.

Spectrophotometric investigations

The insolubility of the peptide made it difficult to obtain spectrophotometric data in the visible range of the spectrum. All the measurements were therefore made in the Soret band region.

a. The effect of the chloride ion concentration on the absorption spectrum in the Soret band region.

In order to determine the influence of anions on the absorption spectrum, aliquots of a 5 μM solution of the ferriporphyrin c-peptide in 0.001 N HCl (pH 3.03) were diluted with equal volumes of 0.001 N HCl containing varying concentrations of NaCl. In contrast to the findings of Boeri, Ehrenberg, Paul and Theorell [4] with intact cytochrome c, the position of the absorption maximum of the ferriporphyrin c-peptide at 395 mμ was not influenced by the Cl^- concentration. Furthermore, as shown in Fig. 4, the extinction at this wave length was not influenced by Cl^- concentrations between 0.001 and 0.3 M. At higher Cl^--concentrations a moderate decrease in absorption was observed. The same results were obtained in experiments at pH 2.00.

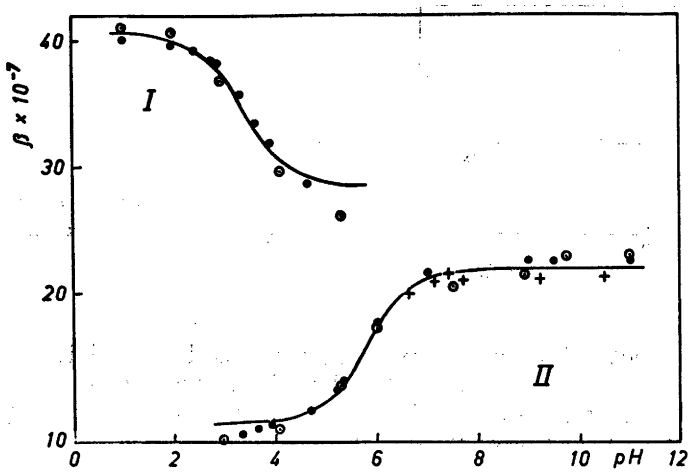

Fig. 3. Extinctions at 395 mμ (curve I) and 410 mμ (curve II) plotted versus pH. The different points are from different sets of experiments.

b. The effect of hydrogen ion concentration on the absorption spectrum in the Soret band region.

A 2.5 μM solution of peptide (2.85 % Fe) in 0.01 M HCl was prepared. To aliquots of this stock solution, either 3 N HCl or 1 N KOH was added from an "Agla" micrometer syringe, until the desired pH was obtained. Fig. 2 shows that in the strongly acid range the Soret band has a high maximum at 395 mμ. As the pH was increased towards 5.0, the extinction at 395 mμ decreased conspicuously, while the absorption maximum shifted only slightly towards the visible region. As the pH was increased above pH 5, however, the absorption maximum shifted markedly towards longer wavelengths, whereas the extinction changed only slightly.

Another set of curves were measured starting with a stock solution, 6.51 μM peptide (new preparation: 2.76 % iron) and 10^{-4} N NaOH. Aliquots of this stock solution were mixed with the double volume of acid, water or mixtures of water and NaOH to give different pH-values. At the most acid or alkaline pH's the new curves are almost identical with the corresponding ones of Fig. 2. One curve with an intermediate pH is included in that figure. It clearly shows the difficulty to obtain coinciding curves in this pH region where, however, the measured pH values of these unbuffered solutions are very unreliable.

In Fig. 3 the absorption values at 395 mμ and 410 mμ are plotted *versus* pH. The data at 395 mμ between pH 1 and 4.5 fit satisfactorily with a normal dissociation curve I with $n = 1$, $pK = 3.4$ and the asymptotic levels of $\beta_{395} = 40.5 \times 10^7$ cm²/mole at low pH and 28.5×10^7 cm²/mole at high pH. Also the data at 410 mμ are in fair agreement with a normal dissociation curve II: $n = 1$, $pK = 5.8$, $\beta_{410} = 9.5 \times 10^7$ cm²/mole and 21.9×10^7 cm²/mole at low and high pH, respectively.

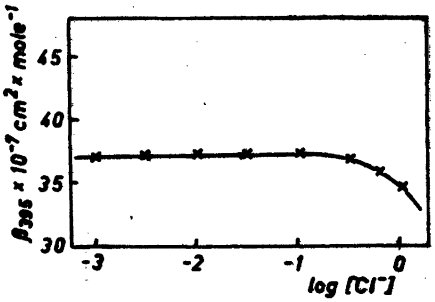

Fig. 4. The extinction at 395 mμ as a function of [Cl⁻] at pH 3.0.

From the spectrophotometric experiments just described it is clear that three forms of the polypeptide can be identified, one acid, one alkaline and one intermediate form. Because of the proximity between the two pK values the latter form is never present to 100 %.

Magnetic experiments

The following experiments were undertaken to determine the paramagnetic susceptibility of the three forms of the polypeptide described above.

About 2 mg of the dry polypeptide were accurately weighed in a small glass beaker, 1 ml of water was added and the sample was acidified by slow addition of 3 *N* HCl from a micrometer syringe, during rapid stirring by means of a magnetic stirrer. The pH was measured with a carefully cleaned and dried glass electrode and adjusted to about 1.5. The sample was immediately transferred from the open beaker to a closed tube. A large amount of a buffer with the same proportions of water and acid was prepared and measured as blank in the magnet. After that the sample was measured and then brought back to the closed tube. The blank was read again.

Largest possible amount was accurately pipetted over to the cleaned beaker and the pH of that sample was adjusted to between 3.7 and 4.0 by 3 *N* NaOH added from a micrometer syringe. Higher pH values must be avoided because of the risk of precipitation. The sample was transferred to a closed tube, a proper blank buffer was prepared from the old buffer and the magnetic measurements made.

Table 1. Paramagnetic susceptibilites of the iron of the ferri porphyrin peptide at different pH values in the presence of chloride or sulfate ions.

HCl			H_2SO_4		
pH	c_{Cl^-} m*M*	$\chi_{Fe} \times 10^6$ cgs emu	pH	$c_{SO_4^{2-}}$ mM	$\chi_{Fe} \times 10^6$ cgs emu

10.60	37	1 930	10.90	31	2 230
1.50	68	12 750	1.40	91	11 420

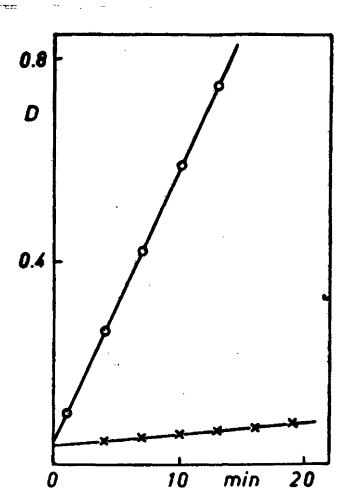

Fig. 5. The peroxidatic activity of the peptide (o) and cytochrome c (×).

A measurement was similarly made at pH 10.5—11.0 and finally the sample was again brought to pH 1.5 and remeasured. An iron determination was made on the rest of the sample.

The same procedure was repeated on a new sample but with hydrosulfuric acid instead of hydrochloric acid.

From the iron content of the dry peptide and the dilutions made, it is easy to calculate the concentration of iron in every magnetic determination. In both sets of experiments, however, the direct determination of iron in the sample after the last measurement in the magnet showed 4 % higher iron content than calculated. This is probably due to evaporation and an additive correction of 1 % per step in the treatment of the sample was introduced.

Because of the high iron content of the polypeptide the diamagnetic contribution is of comparatively small importance. A rough value for it, 100×10^{-6} cgs emu, was obtained by analogy with known figures of various heme proteins studied in this laboratory.

The susceptibilities determined are listed in Table 1. No definite influence by the anions can be seen at the low pH. According to the spectrophotometric investigation the acid form is present to practically 100 % at pH 1.5 and the alkaline form at pH above 10.5. We thus obtain $\chi_{acid} = 11\,900 \times 10^{-6}$ and $\chi_{alkaline} = 2\,100 \times 10^{-6}$ cgs emu. From these values, the data at pH 3.70 and 3.90 and the two pK values of 3.4 and 5.8, we calculate $\chi = 8\,800 \times 10^{-6}$ cgs emu as a tentative value of the susceptibility of the intermediate form.

Peroxidatic activity

The procedure designed by Paul and Avi-Dor [12] for the assay of horseradish peroxidase, in which mesidine serves as hydrogen donor, was used in a simplified form to compare the known slight peroxidatic activity of cytochrome c with that of its peptic degradation product.

Two flasks, each containing 35 ml 0.1 *M* acetate buffer pH 4.9, 3 ml of an aqueous 0.2 *M* mesidine hydrochloride solution, and 2 ml 0.1 *M* hydrogen peroxide, were cooled down to 0° in a bath containing crushed ice. Then 1.0 ml of 0.2 m*M* solutions of bovine cytochrome c (0.433 % Fe) and of the ferriporphyrin c-peptide in 0.05 *M* NH_3 were added. From the reaction mixtures kept at 0°, after different time intervals, aliquots were taken out and their extinctions at 490 mμ measured immediately in a Beckman spectrophotometer. In Fig. 5 the extinction readings are plotted *versus* time. The slope of the straight lines obtained is proportional to peroxidatic activity.

DISCUSSION

As a consequence of their investigations, Theorell and coworkers have suggested a conceptual picture of cytochrome c which reflects its observed properties. The prosthetic group can be imagined to be a hematin disc embedded in a crevice of the protein moiety. The iron in the prosthetic group is coordinated to two haemochromeforming groups in addition to the four porphyrin nitrogen atoms. Presumably because of the structural architecture, the iron atom is inaccessible to molecular oxygen and is therefore non-autoxidizable. At the same time, electron transfer is made possible.

At acid reactions, however, the covalent bonds between the iron and the hemochrome forming groups of ferri-cytochrome c are ruptured (p*K* 2.12) [4], and the bonds to the iron assume an essentially ionic character. Chloride ions can enter yielding a dichloride derivative of the acid ferri-cytochrome c which has a peculiar structure around the iron atom with covalent bonds to the four pyrrolic nitrogens and two ionic bonds perpendicular to the heme disc (Boeri, Ehrenberg, Paul and Theorell [4]). The unusual stability of this structure, and the fact that even at low pH values, the protein moiety and prosthetic group do not dissociate are presumably due to the stable thioether bridges.

This investigation reveals that there are some interesting similarities and dissimilarities between the native cytochrome c and its peptic degradation product.

The spectrum of the ferriporphyrin peptide in the Soret band region is at very low pH values quite similar to that of acid ferricytochrome c ("cyt-$2H^+$", Boeri *et al.*[4]). The absorption maximum of both compounds is situated at 395 mμ; the absorption coefficient ($\beta \times 10^{-7}$ cm^2/mole) is about 41 for the peptide whereas Boeri *et al.*, by extrapolation to $[Cl^-] = 0$, calculated it to be around 50 for "cyt - $2H^+$".

The magnetic susceptibility of the two compounds are not equal. For the peptide χ_{Fe} was measured to be 11 900 $\times 10^{-6}$ cgs emu, and the extrapolated value for "cyt - $2H^+$" was 16 200 $\times 10^{-6}$ cgs emu. Both values are, however, compatible with the presence of 5 odd electrons in the iron atom, and the bonds involved are essentially ionic. The difference in paramagnetic susceptibility might be reflected in heme-linked groups of different nature.

As shown here, contrary to the findings in the intact enzyme, the peptic degradation product of cytochrome c does not exhibit a "chloride effect", its spectrophotometric properties in the Soret band region remain unchanged on

increase of the chloride ion concentration up to a molarity of 0.3. The failure of chloride ion to be incorporated between iron and hemochrome forming groups of the peptide can be attributed to the lack of the firm architecture present in the undenatured cytochrome c molecule when the covalent bonds between them and the iron are broken.

An increase in pH leads to a simultaneous release of 2 protons from "Cyt $-2H^+$" (pK 2.12) and the formation of neutral cytochrome c. This behaviour has been interpreted as indicating that the two hemochrome-forming nitrogenous groups of the protein moiety of cytochrome c are identical, and are symmetrically attached and equally firmly bound to the iron. In the peptide investigated, only one histidine is present, and the protons are, as might be expected, not released simultaneously. The first is released at a pK of 3.4 and the second at 5.8.

No further spectral changes could be derived in the Soret band region at pH's below 11. The alkaline form of the peptide has its absorption maximum at 406 mμ with $\beta = 24.5 \times 10^{-7}$ cm^2/mole, which is nearly identical with the corresponding values of neutral cytochrome c, 407 mμ and $\beta = 26.0 \times 10^{-7}$ cm^2/mole. Also the paramagnetic susceptibilities are in close agreement, 2 080 (mean value) and 2 120 $\times 10^{-6}$ cgs emu, respectively. Our conclusion is that the iron in the alkaline form of the peptide is held by six octahedral covalent bonds. It is interesting to observe that the great similarity of paramagnetism and absorption properties in the Soret region do not correspond to identical groups coordinated to the iron. In cytochrome c two histidine residues are supposed to be bound but in the peptide only one histidine is present and could possibly be heme-linked.

The intermediate compound (appearing between pH 3.4 and 5.8) of the peptic degradation product has its Soret maximum at about 396 mμ with $\beta \sim 30 \times 10^{-7}$ cm^2/mole. The paramagnetic susceptibility of this compound is found to be about 8 800 $\times 10^{-6}$ cgs emu. In this case no close analogy could be drawn with any compound of native cytochrome c. It is true that the ferricytochrome dichloride (cyt. $- 2H^+ - 2Cl^-$) has a paramagnetism of comparable magnitude but it is somewhat lower, and its Soret band is situated at 401 mμ. Probably the most suitable assumption is nevertheless that the susceptibility 8 800 $\times 10^{-6}$ cgs emu is due to a structure with 3 odd electrons in the iron atom as in the ferricytochrome dichloride. This type of compound is rare and the types of bonds involved are but little known. The possibility of 5 odd electrons and essentially ionic bonds cannot, however, be totally excluded. In any case the transition with pK = 3.4 means that one heme-linked group is titrated and that the bonds to the iron are more or less profoundly changed.

The present investigations do not give any unambiguous indication of the nature of the heme-linked groups of the ferriporphyrin c-peptide. The structure of the peptide, however, limits the number of groups which can be involved. One of us (Tuppy [9]) has suggested that the histidine residue is heme-linked. From the titration curve it cannot be decided whether this group has a pK around 3.5 or 6.3. A heme-linked histidine group would be expected to have a pK lower than the "normal" value (5.5—8.0) but higher than that of ferricytochrome c (pK = 2.12) [4]. The pK of 3.4 is within that range. On the other hand it has been proposed that the imino groups of the two heme-linked

imidazoles in cytochrome c are titrated with pK's of about 9.5 [3]. The titration curve of the peptide shows that the imino group in this case cannot be titrated below pH 11. This means that either the imidazole group is heme-linked and the pK of its imino group is above 11 or the imidazole group is not heme-linked. The former possibility is in reasonable agreement with the experimental data if it is assumed that the amino group of either lysine or valine is also heme-linked with the pK shifted to 5.8. Such a shift would not distort the theoretical titration curve too much.

It is *a priori* also possible that an ionically bound carboxyl group is titrated with a pK of 3.4. The pK of 5.8 would then correspond to the titration of the imidazole or one of the amino groups. The "acidifying" effect of the heme linkage on the imidazole might be so much smaller in the peptide compared to cytochrome c as to justify the assumption that it is titrated at the lower limit of its normal region. The carboxyl group, however, does not necessarily need to be linked to the iron in the alkaline form as it could be competitively replaced by the already titrated amino group of valine without changing the titration curve. The possibility that one of the carboxyl groups of the C-terminal glutamic acid is heme-linked in the way just discussed seems much less likely than the former assumption that the imidazole of histidine and the ε-amino group of lysine or the α-amino group of valine are the heme-linked groups involved.

The configuration around the heme of the peptide might be somewhat similar to that of peroxidase. On account of this assumption the activity experiment was undertaken. It showed that the peroxidatic activity of the peptide is more than 20 times stronger than that of cytochrome c and thus about one per cent of the activity of peroxidase itself [12].

The authors want to express their sincere gratitude to Professor H. Theorell and to Professor F. Wessely for advice, encouragement and criticism during the work. We also want to thank Laborator K. G. Paul and Dr. W. J. Rutter for valuable discussions and Miss B. Rolander for careful and valuable assistance.

The work was supported by grants from *Statens Naturvetenskapliga Forskningsråd* for two of us (A. E. and H. T.) and from *Medicinska Prisgruppens särskilda fond* and *Medicinska Forskningsanslaget* for one of us (S. P.).

Investigations in the Retene Field

VI.* The Composition of the Mixture of Mononitroretenes Obtained by Nitration of Retene in the Presence of Boron Trifluoride

L. SIHLBOM

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

In a previous work it was shown that nitration of retene and subsequently chromatographic purification of the crude nitration product gave a mixture of mononitroretenes in a yield of 83 %. In the present investigation, the composition of the mixture has been determined by reducing the mononitroretenes and separating the mixed aminoretenes so obtained. By acetylation, 9-acetamidoretene (38 %) and 10-acetamidoretene (12 %) were isolated. The remaining part of the acetylation product was chromatographed and yielded 3- (4 %), 4- (16 %), 6- (2 %), 9- (4 %), and 10-acetamidoretene (4 %). Thus the mixture of nitroretenes contained 3- (4 %), 4- (16 %), 6- (2 %), 9- (42 %), and 10-nitroretene (16 %).

A simple method for the preparation of 9-acetamidoretene has been described. It includes only three operations, namely, nitration of retene, reduction of the crude nitration product, and acetylation of the mixture of aminoretenes so obtained, and gives the pure compound in a yield of 24 %.

In a previous investigation of this series [1] it was found that retene, when treated with slightly more than the theoretically required amount of nitric acid at 80—90° in a glacial acetic acid solution containing boron trifluoride, gave, after chromatographic purification of the crude product, a mixture of mononitroretenes in a yield of *ca.* 83 % (85 % if the amount of retene recovered is taken into account). In the present work attempts were made to determine the composition of the mixture.

Karrman and Bergkvist [2] nitrated retene in a mixture of glacial acetic and propionic acids at 7—10° with excess of concentrated nitric acid and obtained mixed mononitroretenes in a yield of *ca.* 60 %. By chromatography (Al_2O_3, light petroleum-benzene) they were able to separate 3-nitroretene (*ca.* 30 % of the mixture), and a mononitroretene of unknown structure ** (*ca.* 0.5 %), but

* Part V. *Acta Chem. Scand.* **6** (1952) 1528.

** Proved to be 8-nitroretene. K. J. Karrman *Private communication.*

not the other components of the mixture. However, by fractional crystallization carried out in light petroleum, the process being followed using a microscope, they succeeded in separating this part of the mixture into 4-nitroretene (*ca.* 20 %) and 9-nitroretene (*ca.* 50 %).

In view of these results, it was to be expected that the mixture of mononitroretenes obtained in the boron trifluoride nitration should also contain 3-, 4- and 9-nitroretene. Before the mixture was more closely investigated, some experiments were carried out in order to find a more convenient method for the separation of the two last mentioned isomers. These experiments showed that they could indeed be separated by chromatography (Al_2O_3, light petroleum) if a big column was used. However, the mixture of mononitroretenes obtained in the nitration could not be successfully chromatographed under these conditions. Only 9-nitroretene could be separated in a pure state (*ca.* 27 %); 3- and 4-nitroretene were also obtained but were contaminated with considerable amounts of isomers. As 3-, 4- and 9-nitroretene can be separated under these conditions, the above result indicates the presence of compounds other than these three isomers.

Apparently, it is rather difficult to achieve a clear separation of the mixed mononitroretenes obtained in the boron trifluoride nitration. Attempts were made, therefore, to determine the composition of the mixture by reducing the mononitroretenes and separating the corresponding amines. By catalytic reduction with Raney nickel, 4- and 9-nitroretene can easily be converted to aminoretenes in almost quantitative yields, and this method could also be successfully used for the reduction of the mixture of mononitroretenes. The theoretically required amount of hydrogen was taken up and the mixed aminoretenes were obtained as a straw-coloured, viscous product which gradually crystallized.

Two of the amines could be separated as their N-acetyl-derivatives by taking advantage of their different rates of acetylation. Acetic anhydride was added to an ether solution of the mixed aminoretenes and in about half an hour 9-acetamidoretene (*ca.* 38 %) had separated. It was removed, and after fifteen hours another acetamidoretene (*ca.* 12 %), hitherto unknown, could be collected. When oxidized with chromic acid it yielded retenequinone and its structure must, therefore, be 10-acetamidoretene.

The rest of the acetylation product did not separate from the solution. After removal of the solvents it was obtained as a light-brown material which was found to consist chiefly of acetamidoretenes. These were successfully chromatographed on alumina using a mixture of light petroleum and ethylacetate. For a satisfactory separation alumina with relatively weak adsorptive power must be used. It should be pointed out that the acetamidoretenes show blue fluorescence and most zones could be located, therefore, by inspection of the column in ultraviolet light (glass tube with a thickness of 1 mm was used). The result of the chromatographic investigation is displayed in Table 2 (p. 380). As can be seen, fractions of relatively pure 3-, 4-, 9- and 10-acetamidoretene were obtained. Fractions 24—26 were found to be a mixture of 3- and 6-acetamidoretene which, however, could be separated on alumina using a mixture of benzene and ethylacetate — the result appears in Table 3 (p. 381). In connexion with these separations, it was observed that an inversion of the

* Calculated on the mixture of aminoretenes.

chromatographic sequence on alumina for 3- and 9-acetamidoretene can be effected by changing the developer. Separations have been carried out with ethylacetate (8—16 % by volume) in light petroleum and with ethylacetate (0—6 %) in benzene. In the former cases 3-acetamidoretene was located above the 9-isomer while in the latter cases the inverse order was obtained.

The result of the investigation is summarized in Table 1. The yields of the acetamidoretenes obtained and thus also the composition of the mixture of mononitroretenes appear from the last column of the Table. The yields are, of course, rather approximate. This can already be seen from the fact that some of the fractions, from which the yields are calculated, were not quite pure whilst others consisted of mixtures of the separated compounds. As appears from the Table, the nitration of retene gave a mixture of mononitroretenes containing 9-, 10-, 4-, 3- and 6-nitroretene, approximately in the ratio 20 : 8 : 8 : 2 : 1. The nitration carried out by Karrman and Bergkvist [2] yielded 9-, 4- and 3-nitroretene in the ratio 20 : 12 : 8. As in the case of phenanthrene which gives 9-, 4-, 2- and 3-nitrophenanthrene [3-4] (ratio 20 : 11 : 11 : 7), 9 and 4 are the most reactive positions. From the nitration of phenanthrene, and from the theoretical calculations by Buu-Hoi, Royer, Daudel and Martin [5] according to which 2 is the most reactive position, it was to be expected that 2-nitroretene should also be formed. However, this isomer has not been detected in the nitration products of retene.

The 10-acetamidoretene isolated above was not more closely investigated but the following observations of interest may be mentioned:

1. In the acetylation experiment 10-acetamidoretene was formed much more slowly than the 9-isomer.

2. When refluxed in a mixture of ethanol and concentrated hydrochloric acid, 10-acetamidoretene was only slowly attacked and gave 10-ethoxyretene instead of the expected amine. For comparison, when treated in the same way,

the 9-isomer was hydrolysed to 9-aminoretene and 9-retenol was converted to its ethyl ether (similar etherifications are reported in the literature [6]).

These observations indicate an influence of the methyl-group of retene on a substituent in the 10-position, similar to that found by Fieser and Young [7] when retenequinone was condensed with *p*-nitrophenylhydrazine or reduced with zinc dust and acetic acid. In the former case, a reaction at the ketonic group closest to the methyl-group is retarded and only 10-hydroxy-9-(*p*-nitrophenylazo)retene is formed. In the latter case, the retenehydroquinone first formed easily splits off the hydroxy-group in the 10-position to give 9-retenol. From the fact that 1-methylphenanthrenequinone reacts in the same way, but phenanthrenequinone is reduced only to the hydroquinone under similar conditions, they concluded that it is the methyl-group which activates the bond holding the hydroxy-group.

As seen in the foregoing, 90 % of the 9-acetamidoretene separated on the acetylation of the mixed aminoretenes—the yield corresponds to 32 % calculated on retene. This method for the preparation of 9-acetamidoretene may be preferred to those reported in the literature [8,9] which include more operations and give lower yields. The mixture of mononitroretenes used as starting material in the catalytic reduction was isolated from the crude nitration product by chromatography (*cf.* Part IV [1]), this being a disadvantage of the method especially if large amounts of the 9-derivative should be prepared. The method can, however, be simplified by excluding the chromatographic purification. Certainly, a lower yield (24 % calculated on retene) is then obtained, but on the other hand only three operations are required, namely nitration of retene in the presence of boron trifluoride, catalytic reduction of the crude nitration product with Raney nickel, and acetylation with acetic anhydride of the reduction product dissolved in ether.

EXPERIMENTAL *

Separation of 4- and 9-nitroretene. A solution of 4- and 9- nitroretene (45 mg of each) in light petroleum (b.p. 40—60°) was introduced in a column of alumina (10 cm^2 × 30 cm). On passing light petroleum through the column, two faintly yellow zones were developed and successively eluted. Three fractions were collected, the first containing 9-nitroretene (38 mg, m.p. 126—27°), the second a mixture of 4- and 9-nitroretene (15 mg, m.p. 118—23°), and the third 4-nitroretene (31 mg, m.p. 135—36°).

Attempt to separate the mixed mononitroretenes obtained by the nitration of retene. The mixture (160 mg) was chromatographed on a column of alumina (10 cm^2 × 31 cm). The column was first washed with light petroleum (3.2 l) and then fifteen fractions, accounting for *ca.* 90 % of the amount adsorbed, were collected. Light petroleum was used for the elution of the first thirteen fractions but fractions 14—15 were eluted with a mixture of light petroleum (9 vol.) and benzene (1 vol.). Fractions 5—9 contained 9-nitroretene (44 mg, m.p. 122—24° to 126—27°) but all the other fractions were mixtures melting over wide ranges. However, after recrystallizations from ethanol and from

* All melting points are corrected.

light petroleum, fraction 12 (12 mg, m.p. 105—15°) gave 4-nitroretene, m.p. 136—37°, and fraction 14 (13 mg, m.p. 110—25°) 3-nitroretene, m.p. 152—53°. The isolated nitroretenes were identified by mixed melting point determinations.

4-Aminoretene was prepared by catalytic reduction of 4-nitroretene (0.28 g) in absolute ethanol (50 ml) over Raney nickel. The theoretically required amount of hydrogen was taken up, and, from the reaction solution, 4-aminoretene (0.21 g, m.p. 79—82°) was obtained. After one recrystallization from ligroin (b.p. 60—90°) it was obtained as colourless needles, m.p. 88—89°. (Found: C 87.1; H 7.59. Calc. for $C_{18}H_{19}N$ (249.3): C 86.9; H 7.69).

4-Acetamidoretene separated in a pure state when acetic anhydride was added to an ethereal solution of 4-aminoretene. It was collected after 4 hours and obtained as colourless flat needles, m.p. 201—02°. (Found: C 82.0; H 7.35. Calc. for $C_{20}H_{21}ON$ (291.4): C 82.4; H 7.26).

9-Aminoretene was prepared by reduction of 9-nitroretene (0.28 g) as described above for the 4-isomer. The crude product (0.22 g) melted at 124—25° undepressed on admixture with an authentic sample.

Reduction of the mixture of mononitroretenes. The mixture (5.6 g) was dissolved in absolute ethanol (250 ml) and reduced over Raney nickel (*ca.* 4.5 g). In 5 hours 1 370 ml (N.T.P.) of hydrogen were taken up. From the reaction solution the mixed aminoretenes were obtained as a straw-coloured viscous product (4.9 g, 99 %) which gradually crystallized. (Found: C 86.9; H 7.72. Calc. for $C_{18}H_{19}N$ (249.3): C 86.9; H 7.69).

Acetylation of the mixture of aminoretenes. The mixture (3.20 g) was dissolved in ether (100 ml) and the solution mixed with acetic anhydride (6.5 ml). Within 5 minutes crystals began to separate. After 35 minutes these were collected and washed with ether (yield: 1.42 g, 38 %, m.p. 205—06.5°). The product was recrystallized twice from toluene and melted then at 210—11°, undepressed on admixture with 9-acetamidoretene. After 15 hours another acetamidoretene which gradually separated from the acetylation solution was collected and washed with ether (yield: 0.45 g, 12 %, m.p. 216—17°). It was recrystallized from benzene and from *n*-propanol and obtained as colourless needles, m.p. 219—20°. (Found: C 82.6; H 7.42; N 4.72. Calc. for $C_{20}H_{21}ON$ (291.4): C 82.4; H 7.26; N 4.81). Its oxidation to retenequinone indicates its structure to be 10-acetamidoretene (see below).

The filtrate from the acetylation was shaken with a dilute sodium carbonate solution to remove acetic acid and acetic anhydride, washed with water and dried over sodium sulphate. After removal of the ether a light-brown friable product (1.86 g) was obtained. (Found: C 82.0; H 7.32. Calc. for acetamidoretene $C_{20}H_{21}ON$ (291.4): C 82.4; H 7.26).

In another experiment, a product (0.50 g), prepared by catalytic reduction of the crude material obtained by the nitration of retene, was dissolved in ether (10 ml) and treated with acetic anhydride (2 ml). After 1 hour the 9-acetamidoretene which had separated (0.15 g, *ca.* 24 % calculated on retene, m.p. 210—11°) could be collected. No other pure compounds separated from the reaction solution.

Separation of acetamidoretenes from the product obtained from the filtrate in the acetylation. The product (780 mg) was dissolved in a mixture of light petroleum (20 ml) and ethylacetate (10 ml) and the solution was introduced in

ethanol. The acetamidoretenes were identified by mixed melting point determinations with authentic samples.

Most (60 mg) of the material from fractions 24—26 was rechromatographed on alumina (the above mentioned commercial product). The column was washed with a mixture of benzene (19 vol.) and ethylacetate (1 vol.) and 100-ml fractions were collected. The result is given in Table 3.

Oxidation of the acetamidoretene (m.p. 219—20°) isolated from the acetylation. The compound (0.15 g) was oxidized with CrO_3 (0.35 g) in hot glacial acetic acid (3 ml). After cooling to room temperature the crystals which separated were collected, washed with 50 % acetic acid and recrystallized from glacial acetic acid giving retenequinone, m.p. 196—97°, undepressed on admixture with an authentic sample.

10-Ethoxyretene was obtained when 10-acetamidoretene (0.25 g) was refluxed for 9 hours in a mixture of ethanol (15 ml) and conc. hydrochloric acid (4 ml). On cooling colourless needles separated (0.18 g, m.p. 100—01°). These were collected and recrystallized from ethanol to give needles melting at 101—02°. (Found: C 86.3; H 8.03; C_2H_5O 16.0. Calc. for $C_{20}H_{22}O$ (278.4): C 86.4; H 7.96; C_2H_5O 16.2). When oxidized with chromic acid, as described above for 10-acetamidoretene, it yielded retenequinone.

A hydrolysis of 9-acetamidoretene was carried out under the above conditions. After 3 hours the reaction solution was cooled, diluted with water and neutraliz-

ed. The product which separated was collected, washed with water and dried. It melted at 122—24°, undepressed on admixture with 9-aminoretene.

9-Ethoxyretene. 9-Retenol (0.10 g) was refluxed for 5 hours in a mixture of ethanol (8 ml) and conc. hydrochloric acid (2 ml). The reaction solution was worked up as described for 10-ethoxyretene. The crude product (0.11 g) melted at 95—97° and the colourless needles obtained from ethanol at 98—99°. On admixture with 10-ethoxyretene it melted at 88—90°. (Found: C 86.4; H 8.00. Calc. for $C_{20}H_{22}O$ (278.4): C 86.4; H 7.96).

The author wishes to express his sincere thanks to Laborator K. J. Karrman, University of Lund, for a sample of 6-acetamidoretene.

Enzymatic Hydrolysis of Organophosphorus Compounds

VI. Effect of Metallic Ions on the Phosphorylphosphatases of Human Serum and Swine Kidney

KLAS-BERTIL AUGUSTINSSON and GUNILLA HEIMBÜRGER

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

The effects of metallic ions on the phosphorylphosphatases of purified preparations of human serum and swine kidney were studied with tabun as substrate.

The serum enzyme is activated by Sr^{2+} and Ba^{2+}, the kidney enzyme by Mn^{2+} and Co^{2+}. Both types of phosphorylphosphatases are strongly inhibited by the following ions: Ni^{+2}, Pd^{+2}, Cu^{+2}, Ag^{+}, Au^{3+}, Zn^{2+} and Hg^{2+}; the serum enzyme is also inhibited by Mn^{2+} and Co^{2+}. The most potent inhibiting ion of the kidney enzyme is Ag^{+} (pI_{50} 5.55).

Some of the metallic ions studied also catalyse the non-enzymic hydrolysis of tabun; the most active ones in this respect are: Cu^{2+}, $Pd^{2+} > Au^{3+} > Ag^{+} > Ni^{2+} > Co^{2+} > Zn^{2+}$.

Mn^{2+} has a similar effect on the enzymic reactions when DFP is used as substrate. Similarly, Ag^{+} is a strong inhibitor of the DFP hydrolysis by the kidney enzyme. Sr^{2+}, on the other hand, inhibits this enzymic hydrolysis of DFP by the serum enzyme, in sharp contrast to the activating effect of this ion on the tabun hydrolysis.

Activation (by Mn^{2+}) and inhibition (by Ag^{+}) of kidney phosphorylphosphatase are time reactions. The interaction between the serum enzyme and metallic ions, on the other hand, is independent of time.

Activating and inhibiting ions compete with each other for active groups of the enzyme molecules.

After incubation of the phosphorylphosphatases of serum and kidney with metallic ions and subsequent dialysis the two enzymes behave differently.

The effects of metallic ions on the enzyme activities have been discussed from a more general point of view.

Recent papers by the present authors reported the existence and properties of phosphorylphosphatases [1]. In most of these studies tabun (dimethylamido-ethoxy-phosphoryl cyanide) was used as substrate. Employing DFP (di*iso*propoxy-phosphoryl fluoride) as a substrate and kidney as a source for "dialkylfluorophosphatase" (DFPase) in similar studies, Mounter *et al.*[2] recently reported the effects of various cations on the enzymic hydrolysis. In a preliminary comparative study of the phosphorylphosphatases of human

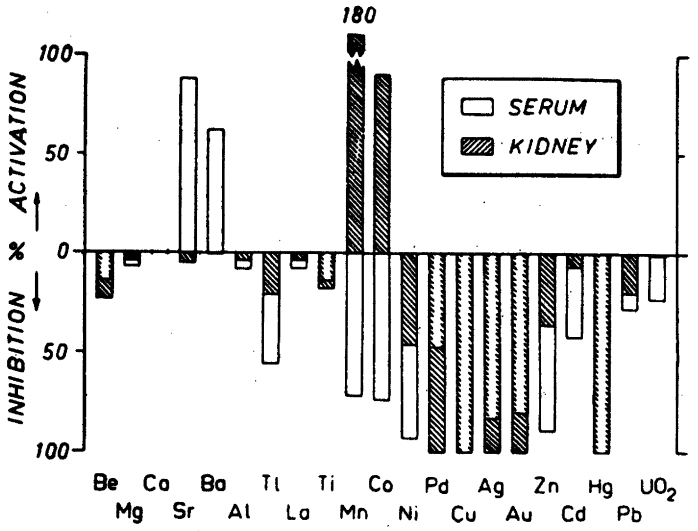

Fig. 1. Effect of various metallic ions on the phosphorylphosphatase activities of human serum and swine kidney (purified preparations). Substrate, 5.3 × 10^{-3} M tabun. Concentration of ions during activity determinations, 1.0 × 10^{-3} M. Time of incubation with ions, 60 minutes. serum and rabbit kidney we found, among other things, that the two enzymes behave differently, the serum not being activated by Mn^{2+}, but inhibited instead [3]. The activation of the "DFPase" of swine kidney by Mn^{2+} was reported earlier by Mounter *et al.*[2], who later [4] confirmed our observation that the two enzymes show differences in respect to Mn^{2+} and other cations. The effect of a variety of ions has been investigated in this laboratory, and the present report deals with the results obtained with metallic ions.

METHODS AND MATERIAL

The Warburg manometric technique was used in determining enzyme activity [1]. All measurements were made at 25° C in 0.040 *M* sodium bicarbonate. The enzyme activity was expressed in b_{30} values. Tabun was used as substrate in most experiments; its concentration in the reaction mixture (total volume, 2.00 ml) was 5.3 × 10^{-3} *M*. DFP of the same molar concentration was also employed in some comparative studies.

The enzyme preparations used were Fraction IV-1 of human postpartum serum and a purified preparation of swine kidney. The latter was prepared according to the method described by Mounter *et al.*[3] for "DFPase". Both these phosphorylphosphatase preparations were dialysed free of ions against distilled water and then diluted to a proper concentration for enzyme activity determinations with bicarbonate solution.

The chlorides of the metals were used, except $AgNO_3$, $Pb(NO_3)_2$, $TlNO_3$, and UO_2SO_4. In preliminary testing of the effects of the metallic ions, the salt concentration in the reaction mixture during activity determination was 1.0 × 10^{-3} *M*. The enzymes were incubated 60 minutes with the ions, unless otherwise stated, before the substrate was added.

RESULTS

Effects of various metallic ions on the enzymic hydrolysis of tabun. The effects of metallic ions, the concentration of which was 1.0×10^{-3} *M* during enzyme activity determination, were studied using purified preparations of phosphorylphosphatases of human serum and swine kidney. The results are shown in Fig. 1. The serum enzyme was activated by Sr^{2+}, and Ba^{2+}; these ions had practically no effect on the kidney phosphorylphosphatase. Mn^{2+} and Co^{2+} were strong activators of the kidney enzyme, the former being particularly effective; the serum enzyme, on the other hand, was inhibited by these cations. Strong inhibitors of both types of phosphorylphosphatases were Pd^{2+}, Cu^{2+}, Ag^{+}, and Hg^{2+}. In addition, Ni^{2+} and Zn^{2+} were strong inhibitors of the serum phosphatase and moderate inhibitors of the kidney enzyme. Fe^{2+} (not inserted in Fig. 1) is a weak inhibitor of the serum phosphatase; this ion, however, is not suitable to study in bicarbonate systems, and no further work has therefore been carried out with Fe^{2+}.

Activation and inhibition by certain metallic ions as function of ion concentration. Those ions, which were found to be strong activators or inhibitors of the phosphorylphosphatases, were used in more detailed studies of the effects as a function of ion concentration. The results are shown in Fig. 2 for the serum enzyme and in Fig. 3 for the kidney enzyme. The *activating* ions gave optimum effect when present in a concentration of 10^{-3} *M*. In the presence of still higher concentrations of these ions the enzyme activity was slightly decreased or remained constant. It was especially noticeable that Mg^{2+} and Ca^{2+} had practi-

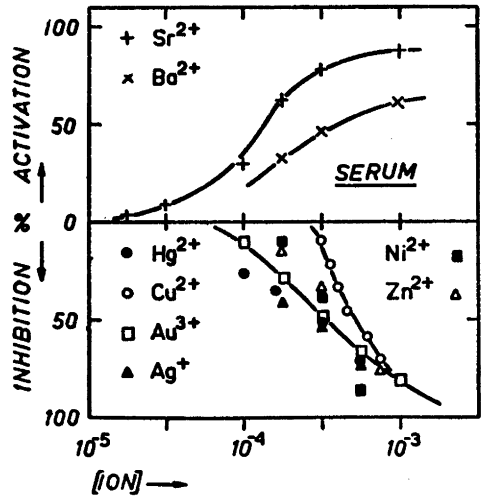

Fig. 2. Effect of metallic ions on the enzymic hydrolysis of tabun by human serum phosphorylphosphatase as function of molar ion concentration. Values corrected for non-enzymic hydrolysis (cf. text to Fig. 1). The values obtained for Mn^{2+} are found in Fig. 4. The pI_{50} values (— log molar ion concentration giving 50 % inhibition of enzyme activity) of the inhibiting ions are summarized in Table 1.

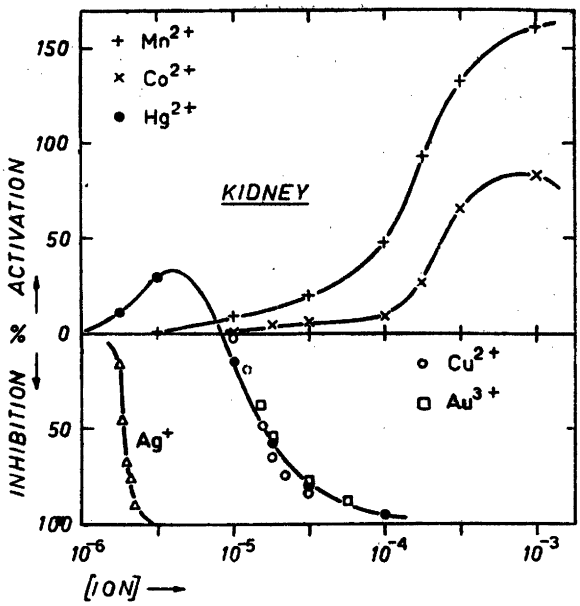

Fig. 3. Effect of metallic ions on the enzymic hydrolysis of tabun by swine kidney phosphorylphosphatase as function of molar ion concentration. Values corrected for non-enzymic hydrolysis (cf. text to Fig. 1). The pI_{50} values of the inhibiting ions are summarized in Table 1.

cally no effect on either of the two enzymes studied. This is in contrast to the observation made by Mazur [5] who recommended Mg^{2+} or Ca^{2+} as activators in the enzymic hydrolysis of DFP by liver extracts.

Those ions which are strong *inhibitors* of the phosphorylphosphatases were found to be equally active for each of the enzymes studied. That ion concentration which gives 50 % inhibition of the enzymic hydrolysis of tabun, expressed in pI_{50} values (— log molar ion concentration), is approximately the same for various ions: 3.2—3.4 for the serum enzyme and 4.7 for the kidney enzyme.

The effects of Hg^{2+} and Ag^{+} on the kidney phosphorylphosphatase are especially interesting. Mercuric ions, being equally active as inhibitors as, for instance, Cu^{2+} and Au^{3+}, increase the enzyme activity when present in low concentrations. Such a Hg^{2+}-activating effect was observed by Mazur [5] for the hydrolysis of DFP by liver, but could not be confirmed by Mounter *et al.*[2] with a purified preparation similar to that used in the present investigations. The inhibiting effect of Ag^{+} on the kidney phosphorylphosphatase is very striking; 50 % inhibition was obtained by 2.81×10^{-6} *M* Ag^{+} (pI_{50} 5.55), which is a concentration approximately ten times lower than those of Cu^{2+}, Au^{3+}, and Hg^{2+} giving the same degree (50 %) of inhibition. The pI_{50} values are summarized in Table 1.

Effects of metallic ions on the non-enzymic hydrolysis of tabun in the absence of phosphorylphosphatase. It was recently demonstrated by Wagner-Jauregg *et al.*[6] that certain metallic ions themselves catalyse the hydrolysis of DFP

Table 1. Effect of metallic ions (10^{-3} M) on the non-enzymic hydrolysis of tabun (expressed in b_{30} values), and molar ion concentration (in pI_{50} values) giving 50 % inhibition of the phosphorylphosphatase activities of purified preparations of human serum and swine kidney. a: activation. and other organophosphorus compounds. Cu^{2+} is particularly active in such reactions, especially when present as chelates with dipyridyl, histidine, *etc.* The metallic ions used in the present studies, were also investigated for their effects on the non-enzymic hydrolysis of tabun. Amongst the ions studied the following are the most active catalysts: Cu^{2+}, $Pd^{2+} > Au^{3+} > Ag^{+} > Ni^{2+} > Co^{2+} > Zn^{2+}$ (Table 1). It is interesting to note that Mn^{2+} is without any effect on the non-enzymic hydrolysis.

Comparison between the effects of ions on the enzymic hydrolysis of DFP and tabun. In the investigations reported by Mounter *et al.*[2] the enzymic hydrolysis of DFP by swine kidney was found to be activated by Mn^{2+}. In Fig. 4 the effects of Mn^{2+} on the DFP hydrolysis catalysed by the phosphorylphosphatases of serum and kidney are compared with the results obtained with tabun as substrate. As far as the kidney enzyme is concerned this ion increases the activity for both substrates. The percentage activation of the DFP hydrolysis, however, is much more striking than that of the tabun hydrolysis. For serum phosphorylphosphatase, Mn^{2+} is an inhibitor in both the DFP and tabun reactions. The strongest inhibitor of the cations, Ag^{+}, studied with tabun as substrate is also a very potent inhibitor of the DFP hydrolysis by the kidney enzyme.

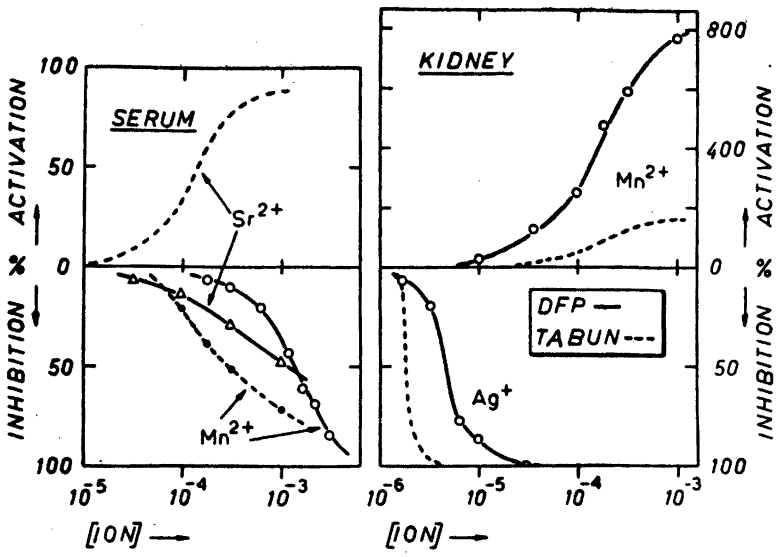

Fig. 4. Comparison between the effects of ions on the enzymic hydrolysis of tabun and DFP. Data referring to tabun (dotted lines) are taken from Figs. 2 and 3.

As mentioned above, Sr^{2+} is an activator of the enzymic hydrolysis of tabun by serum phosphorylphosphatase. However, when DFP is used as a substrate for this enzyme, Sr^{2+} acts as an inhibitor. In view of this observation one could surmise that two different enzymes are responsible for the hydrolysis of the two substrates. It was, however, demonstrated in a previous paper by the present authors [1] that DFP and tabun are hydrolysed by the same enzyme of the preparation of human serum used (Fraction IV—1) (see further "Discussion" below). As far as the kidney phosphorylphosphatase is concerned the results reported in the present paper are consistent with the view that DFP and tabun are hydrolysed by the same enzyme.

Activation and inhibition by metallic ions as time reactions. The enzyme activation by a metallic ion cannot be entirely electrostatic (there is no requirement for activation energy in such reactions) if the interaction between the metal and the protein is a time-reaction. Examples of such time-reactions, in which active enzymes are formed, have been described elsewhere [7]. In the present series of studies on the effects of ions on phosphorylphosphatases, the enzymes were incubated with certain metallic ions for various periods of time before the substrate (tabun) was added to the incubation mixture. The enzyme activity values obtained are shown in Fig. 5. It is clear from these results that there is a fundamental difference between the mechanism of the action of metallic ions on the two phosphorylphosphatases. Both the activation (by Mn^{2+}) and the inhibition (by Ag^+) of the kidney enzyme are time-reactions, in sharp contrast to the activation (by Sr^{2+}) and the inhibition (by Mn^{2+}) of the serum enzyme, which are independent of time. It will be noted that the

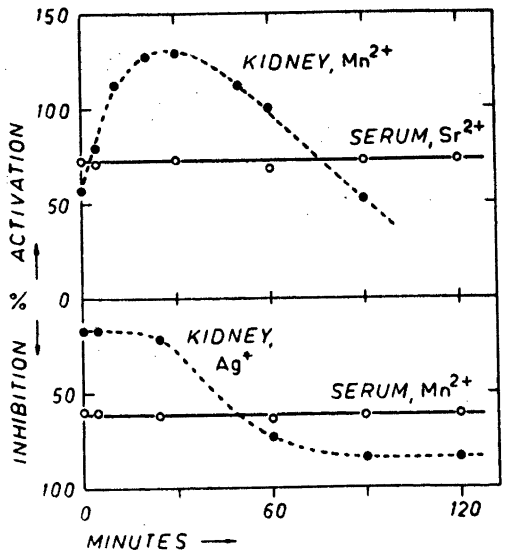

Fig. 5. Activation and inhibition of phosphorylphosphatases incubated for various periods of time with metallic ions. Molar concentrations of the metallic ions during incubation: 1.25 × 10⁻³ M Mn^{2+}, 1.25 × 10⁻³ M Sr^{2+}, and 3.75 × 10⁻³ M Ag^{+}; N.B. the ion concentration during activity determinations are 1.25 times less than those during incubation.

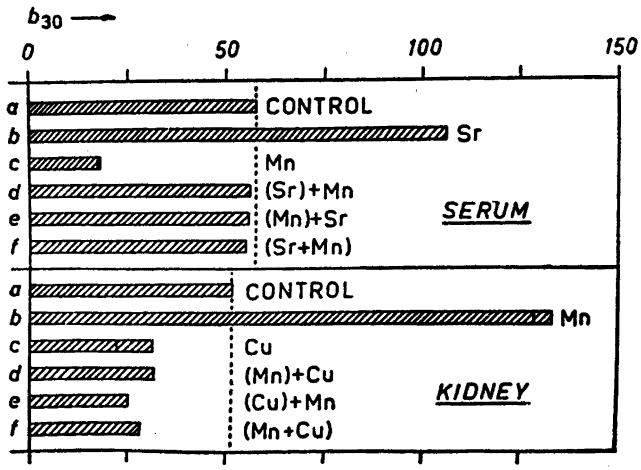

Fig. 6. Competition between activating and inhibiting metallic ions. The enzymes (activities: a) were incubated 30 and 60 minutes with either ion (b, activator; c, inhibitor), 30 minutes with the activator and then a further 30 minutes with the inhibitor (d), 30 minutes with the inhibitor and then a further 30 minutes with the activator (e), and 60 minutes with a mixture of activator and inhibitor.

"zero" values were obtained by adding the substrate a few seconds *before* the addition of the metallic ion.

Competition between activating and inhibiting metallic ions. Activating and inhibiting ions were found to compete with each other for active groups of the phosphorylphosphatase molecules. The results showing this phenomenon are demonstrated in Fig. 6 by a preliminary experiment. The activating effect of an ion is depressed by an inhibiting ion even if the enzyme was incubated with the activator 30 minutes before the inhibitor was added. This competition phenomenon will be studied in more detail before any discussion of its meaning is given.

Table 2. Effect of dialysis of enzyme preparations incubated with metallic ions. Enzyme activity was determined "before" and "after" dialysis and expressed in b_{30} values.

		Serum		Kidney	
		Metal	b_{30}	Metal	b_{30}
Control		—	85	—	48
Activator	Before	Sr^{2+}	145.5	Mn^{2+}	118
	After		85		32
Control		—	116.5	—	41
Inhibitor	Before	Mn^{2+}	52	Ag^{+}	4.5
	After		101		5

Effect of dialysis of enzyme preparations incubated with metallic ions. The enzyme preparations were incubated with activating and inhibiting metallic ions respectively and the mixtures dialysed against distilled water. The phosphorylphosphatase activities of the dialysed solutions were then determined and compared with those of the non-dialysed ones. The results obtained are recorded in Table 2. The effect of the activator (Sr^{2+}) as well as of the inhibitor (Mn^{2+}) of the serum enzyme is reversed by dialysis. The inhibition of the kidney enzyme, on the other hand, cannot be reversed by this procedure. The effect of dialysis on the Mn^{2+} activated is most interesting and unexpected. The activity of the activated enzyme is depressed markedly after dialysis and is even lower than the activity of the original non-treated enzyme. In one experiment (not demonstrated in Table 2) the enzyme, activated with Mn^{2+} to about 150 %, had lost after dialysis 67 % of its original activity. Before more experiments have been carried out, no explanation of this phenomenon will be attempted.

DISCUSSION

There are a number of ways in which a metal can be visualized as influencing the activity of an enzyme. Apart from the role of metals in the iron and copper oxidation-reduction enzymes, in which the usual function of the protein is to keep the metal in solution and to stabilize the state of lower valence, there may be a primary effect of the metal on the enzyme protein or co-operative effect

of metal and protein. These mechanisms of the action of metals can be exemplified by several well-known enzyme systems [7-10].

Let us first consider the mode of action of a metallic ion on the enzyme. By combining with an enzyme molecule, the metallic ion gives the complex a net charge which is obviously different from the original charge of the protein. At the same time the affinity of the enzyme for the substrate may be changed. This effect can be entirely electrostatic; there is no requirement of activation energy in such reactions and the effect is independent of the time of interaction between metal and protein. In addition to modifying the charge, the metal can change the configuration of the enzyme protein, *e.g.*, by reacting with —SH groups when these groups are necessary for enzyme activity. It may be pointed out that in these instances of metal-enzyme interaction the change in enzyme activity (it may be activation or inhibition) does not necessarily imply that the metal is involved directly in the formation of an enzyme-substrate complex. In the present study on the effects of metallic ions on the human serum phosphorylphosphatase, the activation by Sr^{2+} (tabun as substrate) and the inhibition by Mn^{2+} (and other ions as well) might be explained by this latter idea. The interaction between metallic ion and enzyme in these cases is independent of time (Fig. 5) and the metal most probably does not act as a mediator (Sr^{2+}) nor does it prevent the formation of an intermediate complex (Mn^{2+}, *etc.*). In fact, the observation made that the DFP hydrolysis by this enzyme is inhibited instead of being activated by Sr^{2+} makes it likely that the metal does not act as a mediator, but reacts at a site of the enzyme molecule which is responsible for the splitting of the P—CN (in tabun) and P—F linkages in the substrate molecules. The Sr^{2+}-protein complex favours this reaction for tabun but inhibits it for DFP.

For many metal-activated enzyme reactions the mechanism of activation postulated is that the metal acts as a mediator (bridge) between enzyme and substrate. It has been suggested that in this type of metal activation a chelate is formed between the metallic ion and the substrate, this chelate-formation being necessary for the enzyme activity. One of the arguments against this hypothesis is that those metals (*e.g.*, Mn^{2+} and Mg^{2+}) which possess weak chelating activity are commonly occurring activators of hydrolytic enzyme reactions. An alternative role for the metallic ion in such reactions was recently postulated by Klotz and LohMing [11]. According to this idea, the metallic ion favours the formation of the activated enzyme-substrate complex by co-ordinating with both enzyme and substrate and by increasing the local concentration of OH^- thus speeding up the hydrolysis. This idea seems to be applicable to Mn^{2+} and Co^{2+} activation of the hydrolysis of tabun by the kidney phosphorylphosphatase. The substituents [$(CH_3)_2N$—, C_2H_5O—, and CN—] of tabun, determining the specificity of the enzyme, are assumed to be bound directly to the enzyme (not to the metal in form of a chelate). The inhibiting ions (Cu^{2+}, Au^{3+}, Hg^{2+}, *etc.*) also form complexes with the enzyme protein, but these complexes prevent the substrate from reacting with the enzyme. In this respect, Ag^+ is particularly active.

Various opinions have been formed to explain the fact that metals have different (activating as well as inhibiting) effects on one particular enzyme activity and also that one metal can activate one enzyme and inhibit another.

As demonstrated in the present paper Mn^{2+} is an example of a metallic ion which can activate one enzyme and inhibit another and the explanation might be that there are two different mechanisms for enzyme activity which are influenced in different ways by the metallic ion. As far as the Mn^{2+} activation of the kidney phosphorylphosphatase and other enzymes is concerned and taking into account the fact that Mg^{2+} is without any effect on the enzymes studied by us, in contrast to the similar effect of Mg^{2+} and Mn^{2+} on other enzym systems, it may be useful to compare the electron configuration of Mn with that of Mg. Magnesium has a filled outer shell (3 *s*) and manganese a half-filled 3 *d* shell (5 electrons instead of 10). Manganese is the only divalent ion with this electron structure which may explain the different effects of Mn^{2+} and Mg^{2+}. It may also explain the instances when Mn^{2+} behaves like Co^{2+} which has a partly filled 3*d* shell (7 electrons).

Such an explanation does not seem to be valid for the effect of metallic ions on the serum phosphorylphosphatase. This is particularly true for the Sr^{2+} activation of this enzyme which to the authors' knowledge is the only known enzyme activation by this ion. Whatever the explanations of the effects studied may be, it is obvious that the activating effect of Sr^{2+} on the serum phosphorylphosphatase depends on a different mechanism to that for the Mn^{2+} activation of the kidney enzyme. From this we can conclude that the mechanisms of enzyme action of the serum phosphorylphosphatase and the kidney phosphorylphosphatase differ fundamentally.

The authors wish to express their sincere thanks to Professor Gustaf Ljunggren, Chief of the Research Institute of National Defence, Department 1, for his continual interest in these investigations. Our grateful thanks are also due to Professor Hugo Theorell and Ing. Åke Åkesson of the Medicinska Nobelinstitutet, Biokemiska Avdelningen, for the provision of laboratory facilities. We are indebted to Ing. Henrik Björling of A/B Kabi, Stockholm, for the preparation of Fraction IV-1.

The Synthesis of D-Arabinose-1-^{14}C and D-Ribose-1-^{14}C

S. G. LALAND and I. SMITH-KIELLAND

Institutt for Ernæringsforsking, Universitetet, Oslo, Norway

A method for the synthesis of D-ribose-1-^{14}C and D-arabinose-1-^{14}C is described.

For certain biochemical investigations, we required some of the aldopentoses labelled with ^{14}C in the $C_{(1)}$ position, particularly D-ribose-1-^{14}C. To prepare these sugars we decided upon the cyanohydrin method, using D-erythrose as the starting material. When this work was undertaken Isbell *et al.*[1] had published methods for the synthesis of D-glucose-1-^{14}C and D-mannose-1-^{14}C from D-arabinose by the above method. Later when the present work was approaching completion they reported the synthesis of D-ribose-1-^{14}C and D-arabinose-1-^{14}C from D-erythrose [2]. Experimental details of their work has not yet been available to us.

The cyanohydrin synthesis of aldoses involves the addition of KCN to the one lower member of the homologous sugar series. The mixture of the two epimeric aldonic acids produced by hydrolysis of the nitriles is usually separated before the reduction of the lactones of the aldonic acids to the aldoses. Isbell *et al.*[1] separated the mixture of the D-gluconic and D-mannonic acids by fractional crystallization using the lactones and the barium salts. In the present case the reduction has been carried out with the mixture of the two epimers, and D-ribose and D-arabinose were finally separated by paper chromatography. For practical reasons, it was necessary to carry out the synthesis on a sufficiently small scale to enable the separation of the sugars on a few sheets of filter paper. For the sake of convenience no purification of the intermediates was attempted, although this resulted in a lower over all yield. Approx. 0.3 millimole K^{14}CN with an activity of 1 mC was used in the present synthesis. The high specific activity of the cyanide made it possible to dilute considerably the radioactive sugars with inactive material since only a specific activity of approx. 1 μC per milligram was desired.

Isbell *et al.* discovered, when synthesising labelled glucose and mannose from D-arabinose, that the ratio of the epimeric aldonic acids depended upon whether the cyanohydrin reaction was acid catalyzed (predominantly mannonic acid) or base catalyzed (predominantly gluconic acid). We attempted similar conditions in the cyanohydrin synthesis starting from D-erythrose, but in both

cases arabonic acid was formed in a high proportion. To obtain a mixture with a higher proportion of the ribonic acid we decided to induce epimerization of the arabonic acid by the method of Fischer [3,4] which involves heating of the latter with pyridine. Unfortunately the degree of epimerization was not as high as hoped for, only approx. 20 %.

EXPERIMENTAL

Preparation of D-*erythrose.* The D-erythrose employed was prepared from 4,6-diethylidene-D-glucose by the method of Rappaport and Hassid [5]. The product was a slightly yellow syrup and had $[\alpha]_D^{20} -19.8°$ (water, *c* 6.86).

Addition of $K^{14}CN$ *to* D-*erythrose.* The method used was a modification of that reported by Isbell *et al.*[1] Potassium hydroxide (11 mg) and $K^{14}CN$ (20.6 mg, 1 mC, containing 9 mg potassium hydroxide) were dissolved in water (3 ml) in a 50 ml flask fitted with a long neck and a quick fit stopper. The mixture was frozen in a mixture of acetone and solid carbon dioxide. D-Erythrose (80 mg) dissolved in water (1 ml) was added and subsequently solid carbon dioxide (160 mg). The stopper was kept in position and the mixture allowed to thaw. When melted the stopper was removed for a moment to release the pressure. The flask was kept at 0° C for 20 hours and then at room temperature for two days. The mixture was then heated to 50° C while bubbling air through the solution. To trap any radioactive HCN, the escaping air was passed through a solution of KOH. The reaction mixture was then concentrated to dryness *in vacuo* in the solid state. The residue was dissolved in water (1 ml) and ethanol (15 ml) added and the mixture put aside at 0° C for 4 days. Crystalline plates of the potassium salts of the aldonic acids together with a small amount of syrupy material had precipitated. The supernatant was easily decanted off and the crystals washed three times with alcohol (10 ml each time) and finally three times with ether (10 ml each time). The last traces of ether were removed in a desiccator.

Epimerization of arabonic acid. The crystalline mixture of the potassium salts of the aldonic acids was dissolved in water (30 ml) and passed slowly through a column of Amberlite IR-120(H) (7 ml wet resin, hydrogen form) to convert the salt to the free acids. The column was washed with water until negligible activity appeared in the eluate. The solution was concentrated to dryness in the solid state *in vacuo*. The residual syrup was dissolved in a small volume of pyridine (0.07 ml) and transferred to a pyrex tube (diameter 1.5 cm, length 10 cm). The flask was washed out four times with water (0.25 ml each time). The tube was sealed and heated at 130° C for two days. The dark content of the tube was diluted with water (10 ml), passed through a column of Amberlite IR-120(H) (4 ml wet resin, hydrogen form) and the column washed until negligible activity appeared in the eluate. The slight colour of the eluate was removed by treatment with charcoal. The filtrate was evaporated to dryness in the solid state *in vacuo* to yield a straw coloured syrup.

Lactonization of the aldonic acids. To induce lactonization the mixture of the aldonic acids was heated at 90° C for one hour *in vacuo* (0.01 – 0.001 mm Hg).

Reduction of the lactones with sodium amalgam. To ensure a suitable pH during the reduction we have used the mixture of oxalic acid and sodium oxalate introduced by Isbell and collaborators [1] for the reduction of the lactones of gluconic and mannonic acids. As suggested by these workers we also used a 5 % sodium amalgam. We encountered, however, difficulties in preparing a sodium amalgam which would give us a constant yield of the pentoses. Judging from trial experiments using inactive material the yield of the pentoses seemed to depend upon the quality of the amalgam. In one reduction we would obtain the usual yield of the sugars and with a new batch of sodium amalgam practically nothing. It seems to us that an amalgam with poor quality is obtained if the temperature during its preparation is too high. In our experience the temperature must not be so high as to give a dark surface on the amalgam. Thus when preparing 5 % sodium amalgam we proceeded as follows*: A 3 % amalgam was prepared by adding

* We thank Professor M. Stacey F.R.S. for helpful discussions on this point.

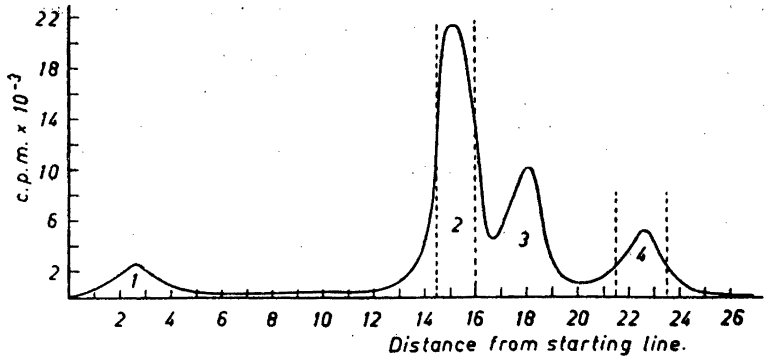

Fig. 1. The distribution of radioactivity along the paper chromatogram. Peak 2 and 4 are arabinose and ribose respectively.

sodium to the pure mercury, the amalgam was subsequently slightly heated and further sodium added. The mixture was then heated under stirring until just melted and poured into oil.

The reduction was carried out in a tube (diameter 2 cm, length 10 cm) fitted with a glass stopper which contained a small hole for the hydrogen to escape. The tube was immersed in a mixture of ice and water. The mixture of the lactones was dissolved in icecold water (3.5 ml) and transferred to the tube. Oxalic acid (117 mg) and sodium oxalate (133 mg) were added. Sodium amalgam (800 mg, 5 %) was then added and the mixture shaken for three hours in the cooling mixture, and left at room temperature over night. To remove all ions the reaction mixture was passed through a small coloumn of Amberlite IR-120(H) (2.5 ml wet resin) and subsequently through a column of Amberlite IR-4B (OH) (2.5 ml wet resin). The coloumns were washed with water until negligible activity was present in the eluate. The amounts of pentoses was determined in the eluate using the colourimetric method of Euler and Hahn [6]. The eluate contained 11.4 mg and 9.5 mg when calculated as arabinose and ribose respectively. This corresponded to a yield of approx. 25 % when calculated from the amount of K^{14}CN used.

Chromatographic isolation of D-*ribose-1-*^{14}*C and* D-*arabinose-1-*^{14}*C.* The eluate containing the two pentoses was concentrated to dryness *in vacuo* in the frozen state. The residue was dissolved in a small volume of water (0.4 ml). An aliquot (0.1 ml) was put on a sheet (25 cm × 55 cm) of Whatman paper No. 3 in a band of length 15 cm and width 2 mm. On both sides of the band was put a mixture of inactive ribose and arabinose as reference compounds. The paper chromatogram was run for three days in the top layer of a mixture of water-butanol-ethanol-ammonia (49:45:5:1, v/v/v/v). The reference runs were developed with aniline hydrogene phthalate and used as a guide when locating the positions of the radioactive sugars. A very narrow strip (0.5 cm) was cut out of that part of the paper which contained the radioactive run, cut transversely in small segments (0.5 cm width) and the activity of the segments determined using a thin window Geiger Müller tube. The distribution of the activity along the chromatogram is seen on Fig. 1. Peak 2 is arabinose and peak 4 is ribose. The other two peaks are unidentified. The areas on the chromatograms containing the radioactive sugars were cut out, these are indicated between the dotted lines in Fig. 1. It was necessary to run three more chromatograms to separate the remaining of the mixtures of the pentoses. The radioactive sugar strips were eluted with water and the solutions concentrated to dryness in vacuum in the frozen state, yielding small amounts of white material. The amounts of the pentoses were determined according to the method of Euler and Hahn [6]. The yields were:

D-arabinose-1-^{14}C 6 mg and D-ribose-1-^{14}C 1.8 mg.

The purity of the sugars was tested by running paper chromatograms in different solvent mixtures and examining the radioactivity along the chromatograms as described

above. The arabinose was homogeneous in the following solvent systems: butanol-acetic acid-water (4:1:5, v/v/v) and phenol saturated with water. It had an activity of 3.24×10^6 c.p.m. per milligram. Ribose when examined in the butanol acetic acid solvent contained 5—6 % of impurities. The radioactive ribose was therefore further purified by paper chromatography in this solvent system and the ribose eluted again from the chromatogram. It was only necessary to run one chromatogram to achieve this. The purified ribose-1-^{14}C was homogeneous in the phenol water solvent system. It had an activity of 3.07×10^6 c. p. m. per milligram. The sugars were plated directly and counted using the thin window Geiger Müller tube.

The authors wishes to thank *Freias fond for Ernæringsforsking* for a fellowship (S.G.L.) and *Norges Almenvitenskapelige Forskningsråd* for financial support.

Studies of Absorption Spectra

IX. The Spectra of Cobalt(II) Complexes

C. J. BALLHAUSEN and CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The spectra of hexammine and tris(ethylenediamine) cobalt(II) ions were measured taking special precaution against the formation of the highly coloured oxidation products. The mono- and diammine spectra were found by use of Bjerrum's equilibrium data. The spectra of several octahedral cobalt(II) complexes are compared, and the displacements of band maxima discussed. The spectrum of the tetrachloro complex is shown to agree with the crystal field theory if a tetrahedral configuration is assumed. All the cobalt(II) complexes which have been considered here are magnetically normal, *i. e.* $S = 3/2$ in the ground state. The strong bands are then attributed to transitions $S = 3/2 \rightarrow 3/2$ while the weak bands originate from transitions $S = 3/2 \rightarrow 1/2$. Further the spectra of complexes with two different ligands are discussed and connected with the configuration and existence of geometrical isomers.

The crystal field theory, primarily set forth in the papers of Bethe [1] and van Vleck and his co-workers [2-4] has been successfully applied [5-9] to the spectra of the transition elements. The present paper compares the measured spectra of different cobalt(II) compounds with the theoretical predictions offered by the crystal field theory. Regular octahedral complexes with cubic symmetry such as the hexaaquo ion $[Co(H_2O)_6]^{++}$, the hexammine ion $[Co(NH_3)_6]^{++}$ and the tris(ethylenediamine) ion $[Co\ en_3]^{++}$ are of particular interest.

The two latter complexes were investigated by Roberts and Field [10]. The absorption spectrum they report for $[Co\ en_3]^{++}$ does not lend itself to a closer identification of the absorption bands. Thus it was observed that the steep absorption below 400 mμ can be reduced much below what is found by Roberts and Field when air oxidation is completely prevented. The operations were carried out in an atmosphere of nitrogen, and the technique used was to dissolve solid $CoSO_4$, $7H_2O$ in an oxygen free aqueous solution of the amine. Fig. 1 shows the spectra of 0.005 *M* $CoSO_4$ in 12 *M* NH_3 and in 0.5 *M* en, containing thus the nearly pure hexammine complexes, according to the equilibrium measurements by Bjerrum [11]. It is apparent from the curves that there is practically no absorption in the near ultraviolet.

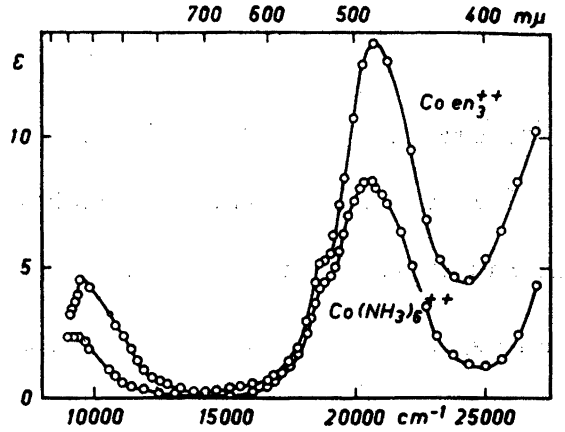

Fig. 1. Absorption spectra of hexaammine and tris(ethylenediamine)cobalt(II) ions. 0.005 M $CoSO_4$ (AnalaR) in 12 M NH_3 and 0.5 M en, respectively, at 25° C.

The strongly absorbing oxidation products seem to be one individual compound in each case, since the spectra of the solutions with different degrees of slight oxidation deviate linearly from the spectra of the hexa-complexes. The compounds formed are probably bi-nuclear peroxo complexes which in the course of some hours undergo changes to mono-nuclear cobalt(III) complexes. These latter complexes are known to be much less absorbing than the intermediate peroxo complexes. The reaction mechanism for the oxidation of Co(II) amine complexes is now being investigated in this laboratory.

The method for determining the spectra of the individual nickel (II) ammonia complexes [11] has here been applied to the two first complexes of cobalt(II), $[Co(NH_3)(H_2O)_5]^{++}$ and $[Co(NH_3)_2(H_2O)_4]^{++}$, respectively. Fig. 2 gives the two spectra, measured in 2 *M* NH_4NO_3 as well as the spectrum of $[Co(H_2O)_6]^{++}$ in the same salt solution.

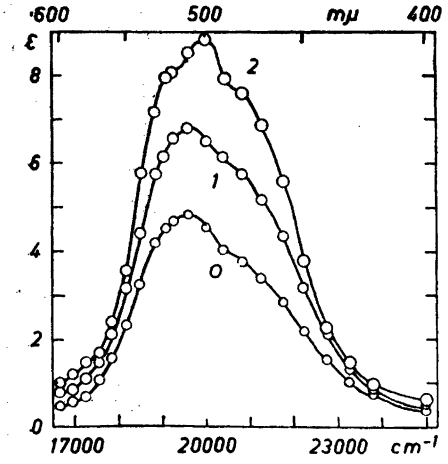

Fig. 2. Resolved absorption spectra of $Co(NH_3)_n^{++}$ in 2 M NH_4NO_3 at t = 25° C for n = 0, 1 and 2. Determined from the equilibria constants given by Bjerrum [11] for this salt medium and temperature.

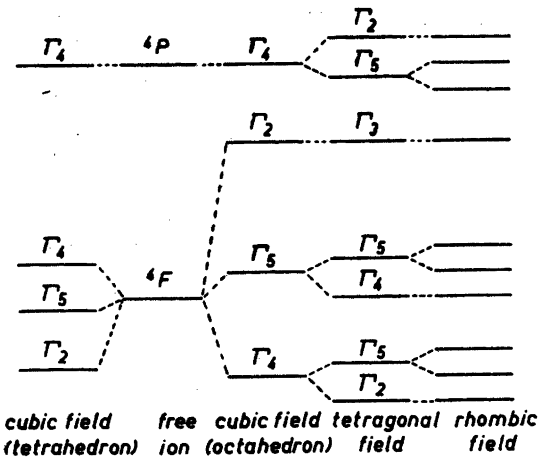

Fig. 3. Energy levels of ^4P *and* ^4F (d^7) *in crystal fields of different symmetry.*

The Co(II) ion has the electron configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^7$. Thus two terms with $S = 3/2$ are possible, *viz.* the ground state ^4F and the ^4P term which is placed 15 400 cm^{-1} above the ^4F level [12]. The splittings of these two terms in crystal fields of various symmetry are shown schematically in Fig. 3. The notation is the nomenclature of Bethe [1].

The orbital degeneracy is

	Γ_1	Γ_2	Γ_3	Γ_4	Γ_5
cubic	1	1	2	3	3
tetragonal	1	1	1	1	2

It is seen that a tetragonal field removes nearly all the orbital degeneracy. The effect of a rhombic field is to do away with all the orbital degeneracy.

For Co(II) complexes with cubic symmetry the theory then predicts three bands, originating from transitions between the ground level and the three excited states all with $S = 3/2$. Further it is seen that the absorption spectrum for a regular octahedral complex is different from that of a regular tetrahedral Co(II) complex. The crystal symmetry is the same, but the energies of the states are different in the two cases.

An important theorem set forth by Jahn and Teller [13] states that in a stable molecule all orbit degeneracy is removed from the ground state. This rule can be applied to complex ions as follows: Consider a cubic configuration of the ligands around the metal ion. The energy then required to move the ligands a little from their equilibrium positions in the potential holes is of second order in the displacement and therefore small compared to the first

order energy gain produced by a possible accompanying splitting of the ground level. This continues until the ligands have arranged themselves in such a way that the ground state is unable to split up any further; the orbit degeneration of this level is then one. This rule predicts nothing about the order of magnitude of the distortion of the ligands from cubic symmetry, it merely states that there is a distortion. In some cases, however, the effect may perhaps be clearly seen as for example in the complexes of Cu(II). A regular octahedral Cu(II) complex with cubic symmetry has the ground state Γ_3. In a tetragonal field this level will split up into two new states [6], both once degenerated. The Jahn-Teller rule thus predicts that it is a tetragonal structure which is stable for Cu(II) complexes, as in fact demonstrated [5].

Fig. 3 shows that if the Jahn-Teller rule is to be obeyed octahedral Co(II) complexes must necessarily be of a tetragonal or of a rhombic structure. That this is the case is strongly supported by magnetic evidence [3]. However, the splittings of the states due to the superimposed rhombic field is only a few hundred cm^{-1}, and consequently these splittings only affect the absorption spectra to a very slight extent. It is therefore sufficient to consider the splittings due to the predominant cubic field in order to explain the absorption spectrum. On the other hand it is seen that it is possible to have regular tetrahedral Co(II) complexes, as the ground state here is a cubic Γ_2 level which is once degenerated.

OCTAHEDRAL Co(II) COMPLEXES

The level order is here $^4F(\Gamma_4)$, $^4F(\Gamma_5)$, $^4F(\Gamma_2)$ and $^4P(\Gamma_4)$. The infrared band of $[Co(H_2O)_6]^{++}$ measured by Dreisch and Trommer [14] at 8 000 cm^{-1} has been identified [7] as the first transition $^4F(\Gamma_4)$—$^4F(\Gamma_5)$. Similar bands were found for $[Co(NH_3)_6]^{++}$ at 9 000 cm^{-1} and for [Co en_3]$^{++}$ at 9 800 cm^{-1} (Fig. 1).

The theory [9] predicts three bands placed at $\nu_1 = 4/5\ (E_1—E_2)$ cm^{-1} $\nu_2 = 9/5\ (E_1—E_2)$ cm^{-1} and $\nu_3 = 3/5\ (E_1—E_2) + 15\,400$ cm^{-1} respectively. The parameter $(E_1—E_2)$ is the energy difference between the two possible levels of a single d electron in a crystal field of cubic symmetry.

To obtain the best agreement between the calculated and found absorption maxima we place $(E_1—E_2) = 9\,000$ cm^{-1} for the aquo-ion, $(E_1—E_2) = 10\,500$ cm^{-1} for the ammonia complex and $(E_1—E_2) = 11\,000$ cm^{-1} for the ethylenediamine complex (Table 1). This is in good agreement with the corresponding values for $(E_1—E_2)$ in Ni(II) complexes [8].

The two visible bands in $[Co(H_2O)_6]^{++}$ are then predicted to be situated at 16 200 cm^{-1} and 20 800 cm^{-1}, as seen in Table 1. The strongest band observed in the spectrum is a double band [15] with the centre of gravity at 20 200 cm^{-1}. This band is undoubtedly due to the transition $^4F(\Gamma_4) \rightarrow {}^4P(\Gamma_4)$, and is split up for similar reasons as the second band [8] of $[Ni(H_2O)_6]^{++}$. That the origin of this band is due to such a transition is further supported by the splitting found in the mono- and diammine cobalt(II) complexes, which have tetragonal symmetry. The low bands found [7] at 16 000 cm^{-1} in $[Co(H_2O)_6]^{++}$ and as shown above at 18 500 cm^{-1} in $[Co(NH_3)_6]^{++}$ and 18 700 cm^{-1} in [Co en_3]$^{++}$ are then identified as $^4F(\Gamma_4) \rightarrow {}^4F(\Gamma_2)$. The low intensity observed in these bands is probably connected with the fact that the state $^4F(\Gamma_2)$

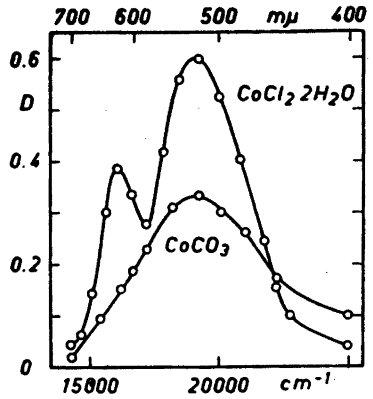

Fig. 4. Reflection spectra of cobalt(II) carbonate and cobalt(II) chloride dihydrate, measured on a Beckman DU spectrophotometer. t = 25° C.

has the orbital degeneracy = 1, while the much stronger combining state $^4P(\Gamma_4)$ is three times degenerate.

It may be shown that the symmetry and strength of the crystal field of an octahedral complex can be described in the following way: The sum of the contributions of the two ligands on each axis, we will call respectively $\sum(x)$, $\sum(y)$ and $\sum(z)$. The complex is said to have cubic symmetry when $\sum(x) = \sum(y) = \sum(z)$, and tetragonal symmetry when $\sum(x) = \sum(y) \neq \sum(z)$. Finally rhombic symmetry occurs when all three functions are different.

The crystal field states are alone determined by the set ($\sum(x)$, $\sum(y)$, $\sum(z)$). Thus all the complexes MA_5B, MA_4B_2 have tetragonal symmetry. The lowest possible symmetry, the rhombic, is represented by one of the geometrical isomers of MA_3B_3 (and of course in most complexes with three different ligands), while the other isomer of MA_3B_3 has cubic symmetry.

The influence on the metal ion of other crystal fields than cubic ones are considered by the authors [5,6,8,17] and by Orgel [16]. It turns out that the monoammine and the *cis*- and *trans*-diammine of Co(II) are each expected to exhibit two bands instead of the pure cubic band $^4F(\Gamma_4) \rightarrow {}^4P(\Gamma_4)$. The band $^4F(\Gamma_4) \rightarrow {}^4F(\Gamma_2)$ cannot be split up by fields of lower symmetry, except when the excited levels of the ground state begin to be populated but this can only account for a few hundred cm^{-1} at room temperature. The splitting in *cis*-complexes is generally — ½ times the corresponding splitting in *trans*-complexes [17]. Thus in most cases the *cis*-complexes have only broad bands, in contrast to the *trans*-complexes where there is a distinct separation into two bands.

Table 1. Comparison of calculated and found absorption maxima for $[Co(H_2O)_6]^{++}$, $[Co(NH_3)_6]^{++}$ *and* $[Co\ en_3]^{++}$ *in* cm^{-1}.

$[Co(H_2O)_6]^{++}$	obs.	8 000	~16 000	20 200
	calc.	7 200	16 200	20 300
$[Co(NH_3)_6]^{++}$	obs.	9 000	18 500	21 100
	calc.	8 400	18 900	21 700
$[Co\ en_3]^{++}$	obs.	9 800	18 700	21 700
	calc.	8 800	19 800	22 000

The vivid colour changes of certain cobalt(II) salts from red to blue forms may be due to one of two different reasons. Either the bands of the hexaaquo ion are only slightly shifted, and can still be recognized, or the configuration of the complex is totally changed with the appropriate consequences for the bands. This difference in spectral change was empirically pointed out by Feitknecht [18] and Katzin and Gebert [19] and rationalized on the basis of crystal fields by Orgel [16].

The first case, the small changes of octahedral energy levels, is exemplified by many complexes with oxy-anions. Fig. 4 shows the reflection spectrum of cobalt(II) carbonate, measured on the Beckman D.U. The only maximum found is at 530 mμ, and the usual structure of the band with a shoulder towards blue is still observed. The maximum at 512 mμ of $[Co(H_2O)_6]^{++}$ is shifted to 540 mμ in concentrated sulphuric acid.[23] Solutions in phosphoric acid give similar changes especially at elevated temperatures, and Dr. N. Hofman-Bang has kindly pointed out to us that cobalt(II) salts in formamide show reversible changes of colour with temperature. In a spectroscope the blue colour is seen to be due to a broadening of the usual band and a continuous displacement towards the red. Similar observations can be made on solutions of cobalt(II) nitrate in glycerol.

The temperature effects mentioned above are due to shifts of equilibria as the weaker anion and organic solvate complexes are generally formed with absorption of heat. However, the spectrum of a definite complex, *e. g.* $[Co(H_2O)_6]^{++}$ undoubtedly changes with temperature. These changes correspond to stronger crystal fields at lower temperatures resulting in spectral shifts in the same direction as substitution of, *e. g.*, ammonia for water. This hypsochromic effect at low temperature can be demonstrated by pouring liquid air on solid cobalt(II) salts of the usual red colour, which changes to yellow-orange.

Analogous to this effect, the green nickel(II) salts turn sky-blue at liquid air temperature. The observed increased crystal field is probably due to the greater orientation of the ligands at the lower temperature.

TETRAHEDRAL Co(II) COMPLEXES

The absorption spectrum of cobalt(II) in concentrated hydrochloric acid has been measured by many authors, *e. g.* Formanek [20], Jones [21], Brode [22], Kiss and Gerendás [23], Dreisch and Trommer [14] and Katzin [24]. The spectrum as recorded on a Cary spectrophotometer is shown in Fig. 5. If the complex formed was octahedral with two molecules of water, the spectrum would show bathochromic effects and slightly tetragonal splitting, but would otherwise resemble the spectrum of the aquo ion. The purple solid $CoCl_2, 2H_2O$ has the environment two water in the *trans*-position and four chloride ions in the plane around the cobalt(II) ion according to X-ray measurements by Vajnstejn [25]. Here the reflection spectrum (Fig. 4) is also seen to resemble other octahedral Co(II) complexes. Contrary to this, the spectrum of a tetrahedral $CoCl_4^{--}$ can be described by a cubic crystal field with $(E_1—E_2)$ equal to $-4/9$ $(E_1—E_2)$ of an octahedral $CoCl_6^{-4}$ with the same distances. The inversion of the levels is indicated by the minus sign, the numerical factor 4/9 is given by one of the

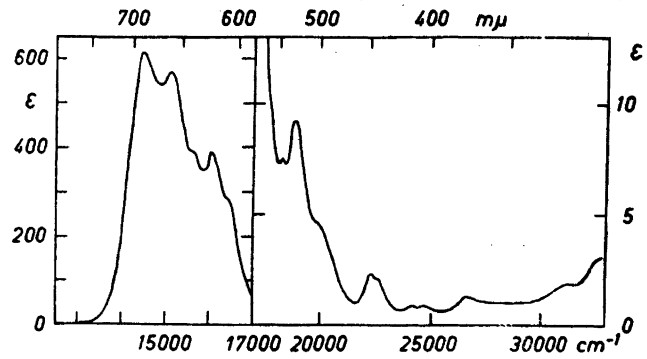

Fig. 5. Absorption spectrum of tetrachloro cobalt(II) ions (0.002 M *and 0.05* M $CoSO_4$ *in 12* M *HCl) measured on a Cary spectrophotometer.* t = 30° C.

authors[6]. Since $(E_1—E_2)$ in chloro-complexes is generally smaller than in aquo ions (compare Ti(III), V(III), Cr(III), Cu(II), *etc.*) one would expect $(E_2—E_1)$ to be somewhat smaller than 4 400 cm^{-1} in $CoCl_4^{--}$.

The band[15] at 6 300 cm^{-1} can be identified as a transition from the ground state $^4F(\Gamma_2)$ to $^4F(\Gamma_4)$ [see Fig. 3], giving 9/5 $(E_2—E_1)$ = 6 300 cm^{-1} or $(E_2—E_1)$ = 3 500 cm^{-1} in good accordance with the arguments given above. The other internal ^4F transition to Γ_5 must then be placed far in the infrared at ~ 3 500 cm^{-1}. The very intense band with a complex structure (five or six maxima) between 14 300 and 16 400 cm^{-1} is then due to $^4F(\Gamma_2) \rightarrow {}^4P(\Gamma_4)$ transitions which should be placed at 15 400 + 6/5 · 3 500 = 19 600 cm^{-1}, supporting the idea that $(E_2—E_1)$ is even smaller than 3 500 cm^{-1}.

Except in the lanthanides and actinides this is the weakest crystal field ever observed. The spectrum must therefore reproduce the atomic energy levels[12] quite exactly. The ^2G level which is placed at 17 300 cm^{-1} in the free ion has the crystal field splittings[9] in cubic fields amounting to + 1/5, +1/35, + 1/10 and —13/70 $(E_1—E_2)$, around the centre of gravity. This corresponds to a total splitting of 27/70 $(E_1—E_2)$ of the term. In $CoCl_4^{--}$ this is below 1 500 cm^{-1}. The bands at 18 300 and 18 800 cm^{-1} and probably also 19 800 cm^{-1} are due to ^2G, while the predicted centre of gravity is 17 300 + 6/5 $(E_2—E_1)$ = 21 500 cm^{-1}. The other weak bands are presumably due to the other doublet levels of Co^{++}, ^2H, ^2F, ^2D, *etc.* They continue down in the ultraviolet (Kiss and Gerendás[23] give the last at 34 700 cm^{-1}) corresponding to the latter doublets which are not known from atomic spectroscopy.

The bands are very narrow which is probably connected with the occurring weak crystal field, just as in the lanthanide and actinide spectra. The splitting of the $^4P(\Gamma_4)$ state is due to (L,S)-coupling effects, which are also quite large in the free ion[12]. Of the $(2S+1)(2L+1) = 4 \times 3 = 12$ independent states of ^4P the crystal field can only form six different levels, since the Kramers degeneracy cannot be removed. Of these six levels a pure cubic field should furthermore only present four, since two of the levels are four times degenerate on the basis of $(2S + 1)(2L + 1)$. It is highly improb-

able that the fine structure of the weak bands is due only to vibrational states (as in MnO_4^- or UO_2^{++}), as postulated by Brode [22] or Yamada and Tsuchida [26] since the intensities are so irregular, and no constant frequency difference can be found with certainty.

The intensity of the bands in $CoCl_4^{--}$ is anomalously large, compared with the other cobalt(II) complexes. While the transitions between states with $S = 3/2$ in most of the complexes have maximal molar extinction coefficients $\varepsilon_n \sim 10$ and the spin-forbidden transitions $S = 3/2 \rightarrow 1/2$ have $\varepsilon_n \sim 0.1$, the two different types of bands in $CoCl_4^{--}$ have $\varepsilon_n \sim 500$ and 5. This phenomenon is also encountered in chloro- and bromo-complexes of copper(II).

Simple crystal field considerations seem to be able to account reasonably for the experimental evidence, and it is possible to find some indications concerning the configuration of the various cobalt(II) complexes from their spectra. This again depends upon the perturbations from the ligands being strongly dependent on distances. The absorption spectrum of a given complex will then be determined mostly by the ligands in the first sphere, *i. e.*, the nearest environment of the metal ion.

We want to express our gratitude to Professor J. Bjerrum for his great interest in the work and for many valuable discussions. Further the *Ole Rømer Foundation* is thanked for financial support.

Some Problems of Intensity of Absorption Bands and Chemical Bonding

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The influences of different ligands on the wavenumber and intensity of the absorption bands of a given metal ion are compared. The intensities are connected with the intermixing of about one per cent odd functions in the even wavefunctions $[A]3d^n$. The other types of absorption bands in inorganic salts are classified. The difference between one and more times orbitally degenerate ground states in the cubic fields is shown to be relevant to complexity constants, activation energies and relative displacement of spectra of unsymmetrical complexes towards higher wavenumbers.

The crystal field theory of Bethe [1] has been applied to the absorption spectra of all the ions of the first transition group, first by Hartmann and Ilse [2,3], Orgel [4], and later by J. Bjerrum, Ballhausen and the author [5–11]. The agreement with the observed wavenumbers of the absorption band maxima is good, when reasonable values are assumed for the distances within the complex ions and the dipole moments or charges of the ligands. While the energy states are thus determined, the explanation of the transitions between the states has as yet not been fully given (the transition between states of the same electron configuration $[A]3d^n$ is forbidden by Laporte's rule and should have the probability 0). In the following discussion of this problem, some general remarks are first made on the energy states in different complexes of the same metal ion.

Already Fajans [12] developed the "spectrochemical series" of hypsochromic influence of different ligands *inter alia*, and Tsuchida [13] extended this concept further:

$$Br^- < Cl^- \lesssim OH^- < RCOO^- < F^- \lesssim H_2O < SCN^- < NH_3 < en \lesssim NO_2^- < o\text{-phen} < CN^- \quad (1)$$

When all six ligands are equal and placed at the same distances in an octahedral complex, the spectrochemical series (1) is easily explained as corresponding to increasing value of $(E_1—E_2)$ in a crystal field of cubic symmetry, where E_1

is the energy of a γ_3-electron and E_2 of a γ_5-electron [2,3,7]. It might seem curious that anions and neutral molecules all find their fixed places in (1), but it must be remembered that the point-dipoles used in calculations [2,5,6] are fictious quantities, only electrical charges occur in reality. In the neutral ligands, the negative part (distributed by polarization) is much nearer to the metal ion than the positive part, which thus has only a very small opposite influence on the crystal field perturbation, since it depends on R^{-5} or R^{-6} in most cases. R is the distance from the centre of the metal ion [2,6]. The real dipole moments of neutral ligands are undoubtedly somewhat smaller than the crystal field parameter μ caused by the strongly increased effects of the negative end of the dipole. The spectrochemical series (1) is not a direct measure of the affinity to the ligands, since the free energy changes depend on R^{-1} and R^{-2} potentials, which are much less dependent on distance. Therefore, anions, which are not strongly polarizable (as are CN^- and NO_2^-) have an anomalously early position in the series. But a quite paradoxical fact is the lower (E_1—E_2) value of OH^- than of H_2O. Probably, the three lone-pairs of electrons found in OH^- are not so effectively perturbing as the two lone-pairs of H_2O. Analogously, the latter molecule is not as effective as NH_3 with one lone-pair.

If a similar series as (1) is constructed of the intensities of the crystal field spectra, the anions will undoubtedly be placed at very late positions. Chloro- and bromo-complexes of copper(II) complexes have maximum molar extinction coefficients $\varepsilon_n = 100$ to 200 at $\sim 10\,000$ cm^{-1}, while $[Cu(H_2O)_6]^{++}$ has maximum at 12 600 cm^{-1} with $\varepsilon_n = 12$. Nitro-complexes of copper(II) measured by Fronæus [15], and cobalt(III) complexes among others by Basolo [16], show relatively very high intensities. In the preceding paper of this series [10], $CoCl_4^{--}$ was shown to have $\varepsilon_n \sim 500$ in ordinary and $\varepsilon_n \sim 5$ in ΔS-forbidden [7] bands, while in cobalt(II) complexes with neutral ligands the corresponding values are $\varepsilon_n \sim 5$ and $\varepsilon_n \sim 0.1$. In a paper to be later published, the dark-coloured bi-nuclear complex of titanium(III) and titanium(IV) in concentrated HCl will be discussed. It deceived Hartmann and Schläfer [14] to assume titanium(III) chloro-complexes alone to be ~ 10 times more absorbing than $[Ti(H_2O)_6]^{+++}$, while the real $[Ti(H_2O)_5Cl]^{++}$ is sky-blue. Since amine complexes are well known to be more absorbing than aquo ions, the intensity series can be written

$$H_2O < NH_3 < en \lesssim Cl^- < NO_2^- \lesssim Br^- \qquad (2)$$

with aquo ions being the least coloured complex of a given metal ion. Organic ligands give generally also increasing intensity, *viz.* alcohols and aliphatic amines, compared with H_2O and NH_3 respectively.

The theoretical explanation of intensity can in the author's opinion be found along the lines drawn by Broer, Gorter and Hoogschagen [17], who investigated the weak bands of lanthanide ions. The fundamental difficulty of providing internal d^n- or f^n-transitions with any positive probability is the following: Analogous to departure [18] from Russell-Saunders coupling, which intermix states of different L and S in such a way that only the vector sum J is preserved, the configuration interaction [18] may in the free ion intermix states of different electron configuration, but with the restriction that the

parity is the same. The parity, which thus is one of the most strictly defined quantum numbers of the free ion, is "even" or "odd", according to the sum of the values of l of the individual electrons in the system being even or odd. Laporte's rule for electric dipole radiation is: the transitions shall occur between states of opposite parity. Other radiation types, as electric quadrupole or magnetic dipole, give too small oscillator strengths [17] ($P \sim 10^{-8}$) for most lanthanide and all first-transition group bands, even though they allow transitions between states of the same parity. The oscillator strengths P can be found from the observed absorption spectra [19]

$$P = 4.32 \cdot 10^{-9} \int \varepsilon d\nu \simeq 4.6 \cdot 10^{-9} \; \varepsilon_0[\delta(+) + \delta(-)] \qquad (3)$$

ε_0 is the maximum extinction coefficient and δ (+) and δ (—) the two half-widths towards higher and lower wavenumbers. It is seen that for most normal bands [19] of the first transition group aquo ions, $P \sim 10^{-4}$. For the weak bands, where the total spin quantum number S changes 1 under the transition [7], $P \sim 10^{-6}$. The factor 10^{-2} is determined from the (L, S) coupling effects with intermixing of states with different S, but the same J as mentioned above.

Now, Broer, Gorter and Hoogschagen [17] pointed out that even the parity can be slightly intermixed by perturbations of crystal fields with no centre of symmetry. Also vibrations of the ligands can provide such an intermixing. In the lanthanides, the statically hemiedric perturbations are presumed [17] to be slightly more important than the vibrational. The intermixing of the wavefunctions can be formally expressed for the groundstate Ψ_1 and the excited state Ψ_2:

$$\begin{aligned} \Psi_1 &= a_1 \Psi_{even} + b_1 \Psi_{odd} \qquad (a_1^2 + b_1^2 = 1) \\ \Psi_2 &= a_2 \Psi_{even} + b_2 \Psi_{odd} \qquad (a_2^2 + b_2^2 = 1) \end{aligned} \qquad (4)$$

In the first transition group Ψ_{even} is represented by [A]$3d^n$ and Ψ_{odd} by [A]$3d^{n-1}4p$, while in the actinide ions the two types of Ψ are [Em]$5f^n$ and [Em]$5f^{n-1}6d$. In the latter case this treatment has given good agreement with the trend of observed intensities of the absorption bands in different actinides.

It must be remarked that the intermixing coefficients b_1^2 and b_2^2 are very small in most transition group complexes and that the meaning of "even" and "odd" is weakened, if this is not the case. Only the part $(a_1b_2 + a_2b_1)^2 \simeq (b_1 + b_2)^2$ will contribute to the oscillator strength of electric dipole radiation:

$$P \simeq \frac{1}{30} (b_1 + b_2)^2 \qquad (5)$$

The proportionality factor between 10^{-1} and 10^{-2} consists of the following factors: The wavenumber ν divided by the Rydberg constant 109 740 cm^{-1}; the "strength" of the transition, as defined by Condon and Shortley [18], divided by $e^2a_0^2$ (e is the electronic charge and a_0 the Bohr radius), and finally some statistical weights.

Since $P \sim 10^{-4}$, either the groundstate or the excited state or both (which is more reasonable) must be intermixed with odd functions to the extent of

$\sim 10^{-3}$. In the chloro- or ethylenediamine-complexes (see the series (2)), P has mostly increased to $\sim 10^{-3}$, and in the special case of $CoCl_4^{--}$ (where the tetrahedral configuration perhaps provides a stronger hemiedric perturbation than in octahedral complexes), $P \sim 10^{-2}$.

The intermixing of about one per cent odd functions in the complex ion states [A]$3d^n$ cannot be directly connected with the electron overlap from the ligands, which according to calculations of Craig, Maccoll, Nyholm, Orgel and Sutton [20] is recognized also to be $\sim 10^{-2}$. However, the assumption of one per cent covalency * may very well result in the same effects on intensity as the more atomic-spectroscopical picture given above. The most divergent point between the current theories of covalency in coordination chemistry and the crystal field theory is the assumption of the magnetic criterion. It seems unreasonable from the latter point of view to assume discontinuous appearance of considerable covalency in cobalt(III) complexes, whose two ordinary bands have $P \sim 10^{-3}$ as do magnetically normal complexes. Below, another criterion, the "robustness" of the complexes is discussed on the basis of the crystal field theory.

Empirically, it can be shown that the intensities of different bands of the same metal ion develop in slightly different ways. Let us consider [19] $Ni(H_2O)_6^{++}$ and Ni en_3^{++}. They give values of $(E_1—E_2) = 7\,600$ cm^{-1} and 10 500 cm^{-1} respectively, and their second and third bands have the transition probabilities:

		$Ni(H_2O)_6^{++}$	Ni en_3^{++}
$^3\Gamma_2 \rightarrow {}^3\Gamma_4(F)$	**	$P = 3.5 \cdot 10^{-5}$	$P = 10.2 \cdot 10^{-5}$
$^3\Gamma_2 \rightarrow {}^3\Gamma_4(P)$		$P = 7.2 \cdot 10^{-5}$	$P = 14.3 \cdot 10^{-5}$

If a similar calculation is performed with $Cr(H_2O)_6^{+++}$ and *** Cr en_3^{+++} which have respectively $(E_1—E_2) = 17\,400$ cm^{-1} and 21 600 cm^{-1}, one obtains:

	$Cr(H_2O)_6^{+++}$	Cr en_3^{+++}
$^4\Gamma_2 \rightarrow {}^4\Gamma_5(F)$	$P = 2.0 \cdot 10^{-4}$	$P = 11.1 \cdot 10^{-4}$
$^4\Gamma_2 \rightarrow {}^4\Gamma_4(F)$	$P = 3.0 \cdot 10^{-4}$	$P = 11.5 \cdot 10^{-4}$

Just as the series (1) is quantitatively expressed with the ratio between $(E_1—E_2)$ in the considered complex and in the aquo ion $((E_1—E_2)_{en}/)E_1—E_2)_{aq} = 1.38$ in nickel(II) and 1.24 in chromium(III) systems), the intensity series (2) seems to determine the intensity changes of the individual absorption band by change of ligand. For example in the two cases cited above P of the first band increases more than P of the second band. Generally, all chromium(III) complexes with relatively intense absorption have their first band highest contrary to the aquo ion.

* Intermixing with electron transfer states is supported by the higher intensities [7] of d^n-transitions in iron (III) compared to the isoelectronic manganese (II), or by copper(II) compared to nickel(II). The high intensity in anion complexes may be connected with the relatively low energy of the excited states with an extra electron in the metal ion.

** This band of the nickel(II)hexaaquo ion is presumably double, because the two states with $J = 2$ in ^3F and ^1D give an extraordinarily large intermediate coupling effect [18]. This causes intermixing of the state $^1\Gamma_3(D)$ predicted [11] at about 17 000 cm^{-1}.

*** Measurements by Mr. F. Woldbye in this laboratory.

These features cannot support the unfortunate distinction between the origin of the first and the second band, which confused Tsuchida's otherwise very useful classification [13]. Rather, Rabinowitch [21], Lindhard and Weigel [22] are correct in distinguishing between bands with $\varepsilon_n \sim 10$ due to energy states of the metal ion and bands with $\varepsilon_n \sim 10\,000$ due to electron transfer from the ligands to the metal ion. According to the modern theories, all the absorption bands of inorganic salts in the range between the vibrational bands in the infrared and the ionization bands in the far ultraviolet can be classified according to increasing perturbations of the environment:

f^n-transitions with nearly no chemical influence
($P \sim 10^{-6}$ in lanthanides and $\sim 10^{-4}$ in actinides)
$f^n \rightarrow f^{n-1}d$, broad bands with $P \sim 10^{-1}$ (see ref. 23, 24, 25)
d^n-transitions with strong influence of crystal fields
($P \sim 10^{-4}$ for $\Delta S = 0$, $P \sim 10^{-6}$ for $\Delta S = 1$ in the first transition group)
electron transfer spectra ($P \sim 10^{-1}$)
Electron transfer from ligands to metal ion or between different metal ions (*e. g.* some element in different oxidation states or with metallic bonding).

But the value $P \sim 10^{-4}$ assigned in this table to internal d^n-transitions is no absolute upper limit. In metal ions, strongly perturbed by the environments, it is possible to have $P \sim 10^{-1}$. Thus, it can be difficult to distinguish such bands from the electron transfer spectrum, as in the tris(*o*-phenanthroline) and tris(α,α'-dipyridyl) iron(II) complexes. The electron transfer spectrum may also have structure due to crystal fields, *e. g.* the tetrahedral CrO_4^{--} or MnO_4^- show two extremely strong bands. The groundstate contains only a very little of a 3d-electron wavefunction (perhaps causing the temperature-independent paramagnetism) while the excited state contains one 3d-electron, captured from the oxygen atoms, which can be either in the state γ_3 or γ_5. Recently, these ions were investigated by Wolfsberg and Helmholz [26] by the method of molecular orbitals. Empirically, it is known [27] that tetrahedral configurations give spectra with much more vibrational fine structure than complexes with octahedral configuration. The rare case of a weak electron transfer spectrum ($P \sim 10^{-4}$) is found in the bands of UO_2^{++} at 22 000 cm^{-1}, where the hexavalent uranium takes up a 5f-electron [25], while the strong ($P \sim 10^{-1}$) bands $\sim 40\,000$ cm^{-1} are due to formation of [Em]6d.

In the theory of chemical bonding, covalency has often been connected with the criterion of robustness, *i. e.* high activation energy (or extraordinarily low frequency factor). In the crystal field theory the standard state of reactivity is represented by ions with closed shells (Ca^{++}, Zn^{++}) whose ^1S-states are not influenced by crystal field perturbations. Magnetically normal d^5-systems (Mn^{++}, Fe^{+++}) have similar properties in their ^6S-states. Of the other d^n-systems in octahedral complexes, some have groundstates, which in crystal fields of cubic symmetry would be several times orbitally degenerate, *viz.* magnetically normal d^2, d^4, d^6, d^7 and d^9-systems, while the others have non-degenerate cubic groundstates, *viz.* d^3, d^8 and diamagnetic d^6-systems. It was

pointed out by Van Vleck [28] that the former type of complex with six equal ligands is not stable with cubic symmetry, but due to the Jahn-Teller effect must distort to a field of tetragonal (d^4, d^9) or even rhombic symmetry (d^1 can show "compressed" tetragonality [11] in the place of rhombic symmetry, having [10] $\Sigma(x) = \Sigma(y) < \Sigma(z)$). The two types of complex ion are referred to here as "distorted" and "regular" octahedral complexes.

The distorted complexes are seen to have low activation energies [29], sometimes even lower than the closed shell-configurations. In these cases, the distortion during the chemical exchange reaction is promoted by the tetragonal or rhombic splitting of the groundstate. However, in the regular complexes, the crystal field energy decrease is weakened during the distortion, because five (or seven loosely bound) ligands cannot produce as much perturbation as six ligands. The robust complexes with activation energy over 20 kcal/mole are all found in the regular group (*e. g.* nickel(II), cobalt(III), rhodium(III) and platinum(IV) complexes). Homogeneous reaction rates with cobalt(III) ammines and neutral ligands have as yet not been determined, but they probably all correspond to activation energies over 30 kcal/mole, while the cubic crystal field energy decrease [11] is $\sim$60 000 cm^{-1} = 85 kcal/mole. Electron transfer agents as carbon or palladium [30] catalyze the cobalt(III) reactions, probably because the labile cobalt(II) complexes are intermediately formed.

The consecutive formation constants of complexes $MA_{6-n}B_n$ and their absorption spectra are also widely different in the "distorted" and "regular" octahedral group. In the former group, characteristic [30] coordination numbers 2 and 4 can occur. While the latter is quantitatively supported [30] by copper(II) ammines, and qualitatively observed for chromium(II) complexes, evidence for the characteristic coordination number 2 is also indicated in the irregular behaviour of cobalt(II) ammines, where the existence range of the tri-ammine complex is anamalously narrow (Ref.[30], p. 287). In the regular group, the rest effects [30] are small except due to steric influences. Here, the absorption spectra are linear combinations [11] of $(1-\frac{n}{6})\,[MA_6] + \frac{n}{6}\,[MB_6]$, when the centre of gravity of tetragonal and rhombic split bands are considered. Contrary to this, the distorted group exhibits tetragonal splitting also of the groundstate and thus shows systematic displacement of the absorption spectrum towards higher wavenumbers by decreasing symmetry of the complex. This is exemplified in $[Cu(NH_3)_5H_2O]^{++}$, which is less pronounced tetragonal than $[Cu(NH_3)_4(H_2O)_2]^{++}$ and thus gives rise to the pentammine effect [5].

Hellwege [31] has investigated the selection rules in crystal fields and concluded that for octahedral complexes the transitions from Γ_4 to $\Gamma_1, \Gamma_3, \Gamma_4$ and Γ_5 and from Γ_5 to $\Gamma_2, \Gamma_3, \Gamma_4$ and Γ_5 and the reverse are the only possible ones for dipole radiation. Hellwege agrees with the present author that Laporte's rule is exactly valid in crystal fields, having a centre of symmetry (as have octahedral (O_h), but not tetrahedral (T_d) complexes). These selection rules are not entirely fulfilled by the the relative intensities of different transitions arising from the hemiedric potential. Thus, transitions from Γ_1 in diamagnetic cobalt(III) and from Γ_2 in nickel(II) and chromium(III) to both Γ_4 and Γ_5 have nearly the same probability. Therefore, only a rough proportionality to the orbital degeneracy number can be expected. Since the transi-

tion probabilities in fields of lower symmetry are not much higher than in the octahedral complexes, these cannot alone be important in determining the intensity of the bands. However, an increased intensity in tetrahedral and *cis*-MA_4B_2 complexes, due to hemiedric potentials, is observed in some cases.

Acknowledgments. I am very much indebted to Professor Jannik Bjerrum for his continued interest in the investigation, and to Mr. C. J. Ballhausen for valuable criticism. Mr. C. J. Ballhausen plans to publish a paper on selection rules in which the viewpoint is quite different from that presented here.

Surface-Chemical Studies on the Formation of Aluminium Soaps

I. The Interaction between Aluminium Ions and Rosin Acid Monolayers

PER EKWALL and HENRIK BRUUN

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

A continuously recording surface balance has been employed to study monomolecular layers of purified tall oil rosin acid on substrates of varying acidity and containing different amounts of potassium aluminium sulphate. The conditions promoting interaction between the monolayer substance and aluminium ions in the substrate have been investigated in detail in the presence of 2 *M* sodium chloride and without added salt. The monolayer properties of the aluminium rosinate formed by the interaction have been examined.

The conditions in which the interaction begins, in which it attains a wider scope and in which it leads to a definite endpoint are well-defined and reproducible. The aluminium rosinate formed has characteristic and constant monolayer properties.

In the year 1948 the present authors began a series of investigations with the object of defining the conditions which promote interaction between aluminium ions in aqueous solution and rosin acid spread in a monolayer on the surface of the solution. Up to the year mentioned most of the numerous investigations that had dealt with the formation of aluminium soaps had involved reactions in three-dimensional systems [1–11]. Only a few observations in this respect had been made using surface-chemical methods [12–14].

In our investigations we established [15] that by means of the surface balance technique it is possible to determine rapidly and in an elegant manner the conditions favouring such interactions. The same technique was then employed in a study of the interactions between aluminium ions and fatty acid monolayers [16,17]. These studies have later been extended to reactions between aluminium ions and the surfaces of solid rosin acid and solid fatty acids which were examined by another surface-chemical method, the measurement of contact angles [16,17]. This latter work confirmed, for instance, that the results obtained with the aid of the monolayer technique are of general significance. At approximately the same time as our first results were reported, Schulman

and coworkers published the results of their work on metal-monolayer interactions in aqueous systems in which they employed a similar technique to solve problems of a similar nature [18–21].

It is our intention to describe our investigations in a series of articles under the main title of this paper.

MATERIALS AND METHODS

The investigations described below were made with tall oil rosin acid because of the great technical importance of this material.

The rosin acid was prepared from crystalline tall oil rosin from Enso-Gutzeit Oy., Kotka, Finland. According to Juvonen [22], this product comprises 94.7 % rosin acids, 4.8 % unsaponifiables and 0.07 % ash; its melting range is 160—165° C. At Oy Keskuslaboratorio — Centrallaboratorium Ab, Helsingfors, the unsaponifiables and fatty acids were removed by extraction, the latter after esterification, and remaining rosin acids were recrystallized from ethanol. The melting point of this product was 166—169° and the mean equivalent weight 301. We then purified this product by the method of Aschan [3]. The substance was ground to a powder and allowed to remain for 20 hours under 80 % ethanol. The undissolved rosin acids were recrystallized twice from pure methanol and once from acetone. The rosin acid remaining melted in the range 168—174° C (corr.). The optical rotation $[\alpha]_D^{20}$ in absolute ethanol varied from −33° to −43° for different samples (measured with a Lippich polarimeter using a 2 dm tube, the concentration being about 0.01 g/ml).

Tall oil rosin acid is a mixture of different rosin acids [24]. According to Sanderman [25] it comprises about 50 % abietic acid, about 25 % dehydro-, dihydro- and tetrahydroabietic acids and about 25 % dextropimaric acid. Harva [26] has spectrophotometrically followed the purification of the Enso-Gutzeit tall oil rosin acid by recrystallization in the above-mentioned manner and found that the abietic acid content first rises to a level of 43 % but then remains fairly constant on further recrystallization.

Aschan and coworkers [27–29] established that the tall oil rosin acid mixture prepared in the above-mentioned manner behaves in many respects as a single rosin acid. This was to some extent confirmed by Harva [30] in respect of the physico-chemical properties of tall oil rosin soap in aqueous solution. Later studies in this laboratory with synthetic mixtures of pure rosin acids have shown that this is also the case in respect of the surface-chemical properties [31] and that the properties of the individual acids greatly resemble those of the tall oil rosin acid [32].

The rosin acid was dissolved in benzene (concentration, $2 \cdot 10^{18}$ molecules per ml). In order to prevent the oxidation of the abietic acid, the solution was stored in a glass-stoppered flask in a benzene atmosphere; fresh solutions were frequently prepared.

The rosin acid-benzene solution was added from an Agla micrometer syringe to the surface of the aqueous substrate in a Langmuir trough and the properties of the rosin acid monolayer formed investigated by the aid of an automatic, self-recording surface balance of Wilhelmy-Dervichian type [33,34] (improved by Anderson-Groth, Ställberg-Stenhagen and Stenhagen [35]). Compression of the monolayer was begun 2—3 minutes after the rosin acid had been spread on the surface; the rate of compression was 7—12 cm per minute.

When the effect of hydrogen ion concentration on the monolayer was studied, the pH values of the substrates were measured with a glass electrode and a saturated calomel reference electrode. The standard EMF was checked against phosphate buffer solutions.

TALL OIL ROSIN ACID MONOLAYERS AT DIFFERENT pH VALUES

Tall oil rosin acid monolayers give surface pressure-area curves (Fig. 1) that are of the same type as those obtained for the dextropimaric acids and tetrahydrodextropimaric acid by Harkins, Ries and Carman [36,37]. Both

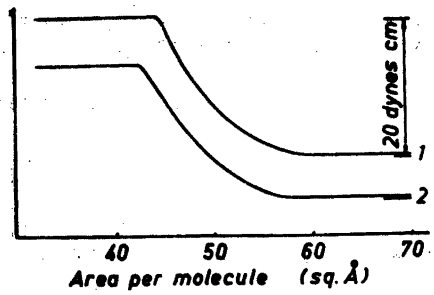

Fig. 1. π—A curves of tall oil rosin acid recorded on dilute hydrochloric acid (pH 3). 20° C. 1 The substrate contains no sodium chloride. 2 The substrate contains 2 moles of sodium chloride and 5 · 10⁻³ moles of acetic acid-acetate buffer per litre.

on pure water and on 2 *M* aqueous sodium chloride solution, the monolayers are of the liquid condensed type.

Fig. 2 shows the variation of certain characteristic points on the surface pressure-area curves with the pH of the substrate. A_0 denotes the area per molecule in the monolayer when the pressure first begins to rise, A_K the area per molecule at the point where the monolayer collapses and π_K the surface pressure at this point. (The collapse point is determined by extrapolation.) The mentioned quantities remain practically unaltered on acid substrates up to pH 4.2—4.6. Above this pH, the areas per molecule begin to decrease and the pressure to increase. It is obvious that at pH values below this limit, the rosin acid molecules are undissociated. The changes in the monolayer properties observed above this pH limit are evidently due to the inception of ionization in the monolayer. In Table 1 data characteristic of undissociated tall oil rosin acid monolayers are given.

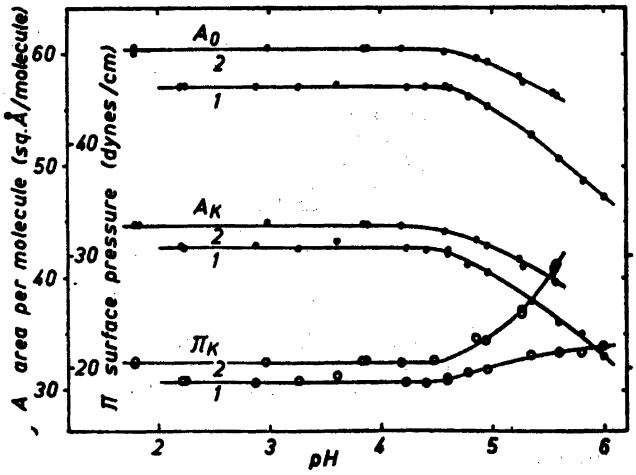

Fig. 2. The values of A_0, A_K and π_K for different pH values of the substrate. 20° C. 1 The substrate contains no sodium chloride. 2 The substrate contains 2 moles of sodium chloride and 5 · 10⁻³ moles of acetic acid-acetate buffer per litre.

Table 1. Characteristic data for undissociated tall oil rosin acid monolayers (below pH 4.2—4.6).

Substrate	A_0 Å² per molecule	A_K Å² per molecule	π_K dynes/cm
Water; pH adjusted with dilute HCl	57.1	42.7	19.4
2 *M* NaCl, buffered with $5 \cdot 10^{-2}$ *M* acetic acid-acetate	60.2	44.6	20.4

On the 2 *M* sodium chloride solution the molecules in a rosin acid monolayer take up an area about 2—3 Å² larger than on pure water. The pressure that the monolayer can withstand before it collapses is about 1 dyne/cm larger in the former case.

On pure water the ionization becomes evident in the monolayer properties in the pH range 4.4 to 4.6 and on 2 *M* sodium chloride in a slightly lower pH range between 4.2 and 4.5. The ionization results in an increase of the solubility of the rosin acid. It is, however, difficult to determine to what extent this increase of the solubility leads to a transfer of rosin acid ions from the monolayer into the substrate. It is also difficult to determine if the observed decrease in the area per molecule is caused only by this dissolving process. The fact that the collapse pressure increases slightly in this pH range shows that the mentioned area decrease is not solely attributable to the dissolution of the monolayer substance even in the case of pure water. On the 2 *M* sodium chloride substrate, in which the solubility of the monolayer substance is lower than in water, the decrease of the area per molecule is less and the increase in collapse pressure considerably larger than on pure water.

THE INTERACTION BETWEEN ALUMINIUM IONS AND TALL OIL ROSIN ACID MONOLAYERS ON 2 *M* SODIUM CHLORIDE

The surface balance method can be employed to define those conditions in which interaction between aluminium ions and rosin acid monolayers can and cannot take place. An interaction will lead to changes in the properties of the monolayer which will become evident in the form of the surface pressure-area curve [15]. This is shown by the curves in Fig. 3 which refer to tall oil rosin monolayers spread on substrates 2 *M* in sodium chloride and containing different concentrations of aluminium ions. In all cases the hydrogen ion concentration was regulated to pH 4.00 by means of an acetic acid-acetate buffer. Curve 3,0 is a recording taken when the substrate contained no aluminium ions, and curve 3,1 refers to a substrate containing $4.92 \cdot 10^{-5}$ mole of potassium aluminium sulphate per litre. No effect of aluminium ions is evident in the latter curve. As soon as the aluminium concentration is increased to $1.17 \cdot 10^{-4}$ *M* (curve 3,2), however, the curve undergoes a slight change; both A_0 and A_K decrease. These changes become more marked with increasing aluminium ion

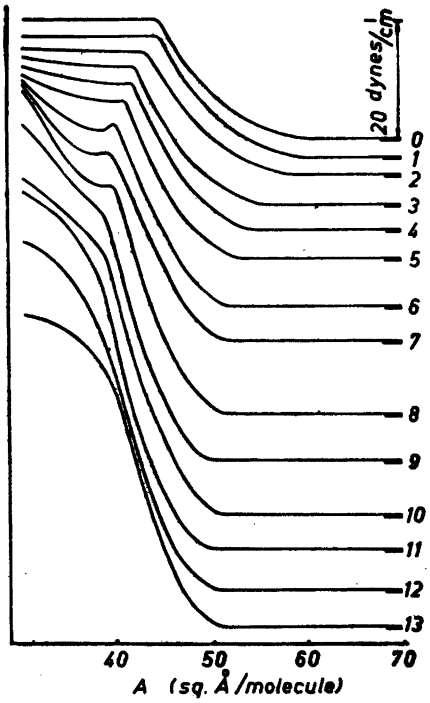

Fig. 3. π—A curves of tall oil rosin acid recorded on substrates of pH 4.00 containing 2 moles/l sodium chloride, 5 · 10⁻² moles/l acetic acid-acetate buffer and different potassium aluminium sulphate concentrations.

Curve No.	Al conc. moles/litre	Curve No.	Al conc. moles/litre
0	—	7	$5.00 \cdot 10^{-4}$
1	$4.92 \cdot 10^{-5}$	8	$6.14 \cdot 10^{-4}$
2	$1.17 \cdot 10^{-4}$	9	$9.22 \cdot 10^{-4}$
3	$1.78 \cdot 10^{-4}$	10	$1.05 \cdot 10^{-4}$
4	$2.21 \cdot 10^{-4}$	11	$1.17 \cdot 10^{-4}$
5	$3.08 \cdot 10^{-4}$	12	$1.86 \cdot 10^{-4}$
6	$4.32 \cdot 10^{-4}$	13	$5.02 \cdot 10^{-3}$

concentration; at the same time the curve shifts upwards and the collapse pressure π_K attains a higher value. The curve type passes through several intermediate stages from the original type to an altogether new type. This new type is fully developed in curve 3,12. When the aluminium ion concentration is increased further, this type remains constant; only the height of the curve diminishes slightly.

Values of A_0, A_K and π_K have been measured from a larger series of recorded curves of which those shown in Fig. 3 are representative. The variation

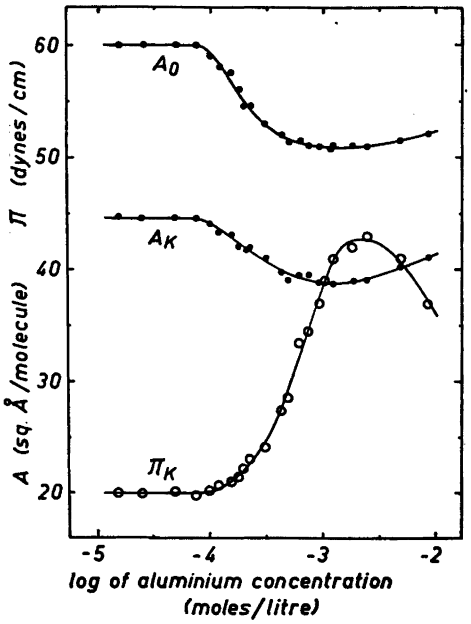

Fig. 4. The dependence of A_0, A_K *and* π_K *on the potassium aluminium sulphate concentration of the substrate at constant pH 4.00 · 20° C. The substrate contains 2 moles of sodium chloride and* $5 \cdot 10^{-2}$ *moles of acetic acid-acetate buffer per litre.*

of these quantities with the aluminium concentration is shown in Fig. 4. It is seen that when the pH of the substrate is held at 4.00, the tall oil rosin acid monolayer is unaffected by aluminium ions until the concentration of the latter exceeds $8.9 \cdot 10^{-5}$ *M*. Higher aluminium ion concentrations bring forth changes in the curves and hence in the structure of the monolayer itself. Each variation in the aluminium ion concentration effects definite reproducible changes in the monolayer properties. The previously mentioned new curve type is fully developed when the aluminium ion concentration is about $1.8 \cdot 10^{-3}$ *M*. The collapse pressure has increased from 20.4 dynes per cm to more than double this value, 42.6 dynes per cm. The interaction between the rosin acid molecules in the monolayer and the aluminium ions in the substrate gradually leads to an exchange of the monolayer substance from one of pure rosin acid to one composed of an aluminium rosinate, and this exchange seems to be complete at the aluminium ion concentration $1.8 \cdot 10^{-3}$ *M*. The new curve type is characteristic for monolayers composed of this aluminium rosinate. When the aluminium ion concentration is increased above the last-mentioned value, the aluminium rosinate layer undergoes further changes which become evident in the pressure-area curves: the collapse pressure π_K decreases again slowly and the areas per molecule, A_0 and A_K, increase gradually.

We have conducted a similar series of experiments in order to determine the effect of increasing the aluminium concentration at several pH-values. Some of the results are illustrated in the form of curves of the same type as in Fig. 4. Fig. 5 thus shows the effect on A_0, A_K and π_K of increasing aluminium ion concentration at pH 3.77, Fig. 6 at pH 4.32, Fig. 7 at pH 4.54, Fig. 8 at pH 5.00 and Fig. 9 at pH 5.60. In all cases the interaction between the

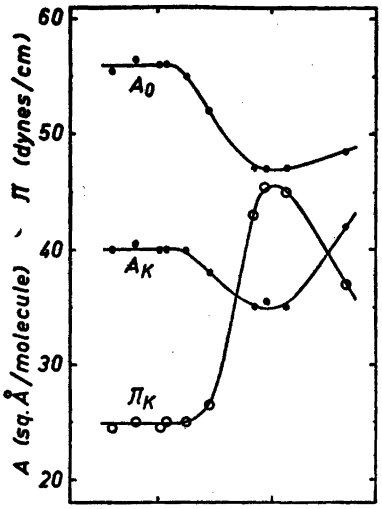

Fig. 9.

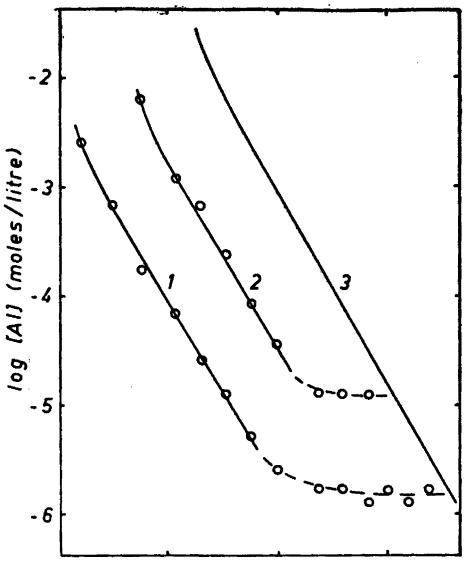

Fig. 10.

Fig. 10. The potassium aluminium sulphate concentrations and corresponding pH values of the substrate when the first signs of interaction between aluminium ions and the rosin acid (Curve 1) and when maximum interaction (Curve 2) is noted. Curve 3 gives the aluminium concentrations and pH values at which aluminium hydroxide precipitates in equilibrium conditions. 20° C. The $KAl(SO_4)_2$ solutions contained 2 moles of sodium chloride and $5 \cdot 10^{-2}$ moles of acetic acid-acetate buffer per litre.

aluminium ions of the substrate and the rosin acid molecules of the monolayer becomes evident in a similar manner. The lowest aluminium ion concentration at which this interaction occurs shifts, however, to lower values with increasing pH. The same applies to the lowest aluminium ion concentration at which the new curve type, the aluminium rosinate type, is fully developed. In all cases this curve type is fully developed at about the same aluminium concentration at which the value of collapse pressure attains its maximum and just before the area per molecule in the monolayer again begins to increase. By means of monolayer studies it thus is possible to determine the end-point of the reaction between aluminium ions and rosin acid which leads to the formation of a uniform monolayer of aluminium rosinate.

The results of the above-mentioned studies on the reaction between rosin acid and aluminium ions are summarized in the diagram of Fig. 10. Curve 1 gives the aluminium concentrations and corresponding pH values at which the interaction begins. Under the conditions to the left of this curve no effect of aluminium ions on the rosin acid monolayer is observed; to the right of the curve the interaction grows in scope until curve 2 is reached. In the conditions given by curve 2 the end point of the reaction is reached. The fully drawn curves give the conditions in which the reaction is independent of the time

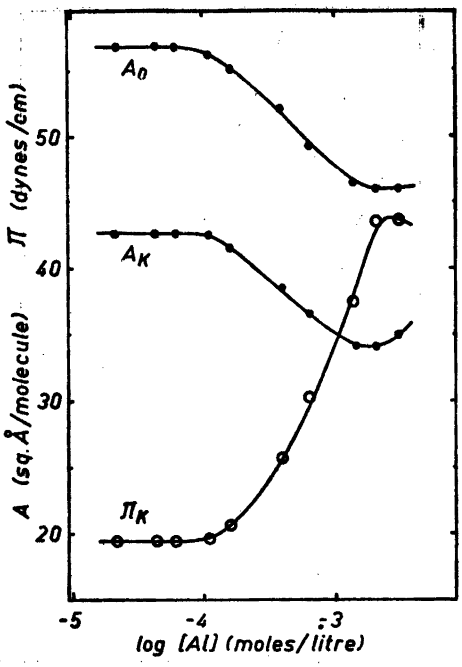

Fig. 11.

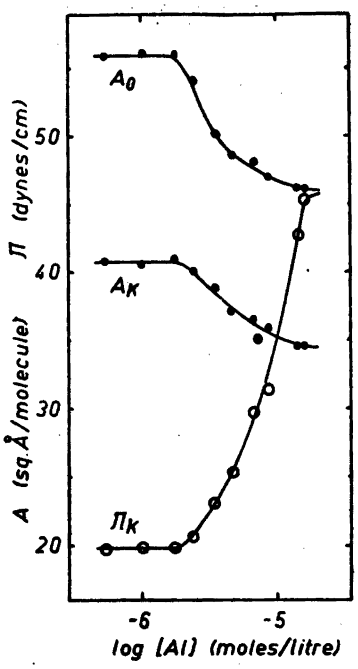

Fig. 12.

Figs. 11—12. The dependence of A_0, A_K and π_K on the potassium aluminium sulphate concentration at constant pH. 20° C. The substrate contained no added salts. Fig. 11 pH 4.00, Fig. 12 pH 5.00.

before compression is begun. At low aluminium concentrations, however, the interaction requires some time to attain equilibrium; the dotted parts of curves 1 and 2 apply to the time of reaction allowed in our experiments, *i.e.* a total reaction period of five minutes. If the aluminium ions are given a longer time to diffuse to the rosin acid monolayer, the first signs of an interaction will occur at somewhat lower aluminium ion concentrations and lower pH values. (This phenomenon will be discussed in more detail in a later publication of this series.)

The curve 3 in Fig. 10 gives the pH and aluminium concentration values at which aluminium hydroxide begins to precipitate under equilibrium conditions. This curve is based on investigations of potassium aluminium sulphate solutions of different pH values containing precipitated aluminium hydroxide. After 1—2 days the solution was separated from the precipitate by decantation and analysed for aluminium.

THE INTERACTION BETWEEN ALUMINIUM IONS AND TALL OIL ROSIN ACID MONOLAYERS ON WATER

The conditions promoting interaction between tall oil rosin acid monolayers spread on a substrate containing aluminium ions but no added sodium chloride

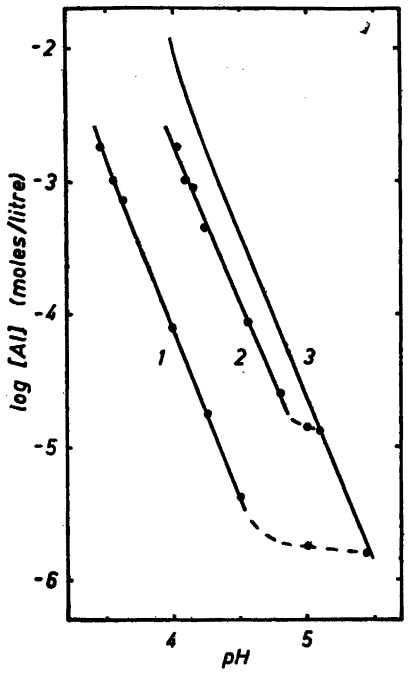

Fig. 13. The potassium aluminium sulphate concentrations and corresponding pH values of the substrate when the first signs of interaction between aluminium ions and the rosin acid (Curve 1) and when maximum interaction (Curve 2) is noted. Curve 3 gives the aluminium concentrations and pH values at which aluminium hydroxide precipitates in equilibrium conditions. 20° C. The $KAl(SO_4)_2$ solutions contained no added salts.

have been studied in a similar manner as above. The ionic strength of the substrate was only *ca.* 0.0001 in these experiments, compared with *ca.* 2.1 in the preceding experiments. The pH was adjusted with dilute HCl or NaOH.

The effect of the aluminium ions on the monolayer becomes evident in changes in the surface pressure-area curves similar to those described above. Figs. 11 and 12 show curves based on the observed changes which refer to the pH values 4.00 and 5.00, respectively.

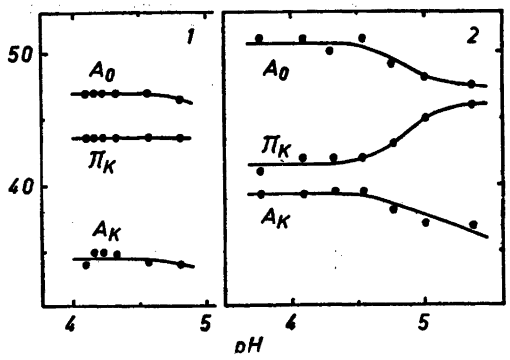

Fig. 14. The values of A_0, A_K and π_K of dibasic aluminium monorosinate monolayer at different pH values of the substrate. 20° C. 1 The substrate contains no added salts. 2 The substrate contains 2 moles/l sodium chloride and $5 \cdot 10^{-2}$ moles/l acetic acid-acetate buffer.

The experimental results can also in this case be summarized in a similar diagram as in Fig. 10. In this new diagram, Fig. 13, curve 1 shows the pH and aluminium concentration values up to which the properties of an rosin acid monolayer on water remain unchanged, curve 2 shows the conditions in which the end-point of the reaction between the aluminium ions and the rosin acid occurs and an uniform aluminium rosinate monolayer is formed. Curve 3 again gives the conditions where precipitation of aluminium hydroxide occurs. On water, especially when the aluminium concentration is low, the interaction begins and ends at lower pH values than when sodium chloride is present in the substrate. Also the precipitation of aluminium hydroxide takes place at lower aluminium concentrations and pH values. Owing to this, the curve 3 is situated at pH values only 0.2 unit higher than curve 2.

THE PROPERTIES OF THE ALUMINIUM ROSINATE MONOLAYER AT DIFFERENT pH VALUES

It has been possible to determine that when the new curve type, *i.e.* the curve for the aluminium rosinate monolayer, is fully developed, the monolayer is composed solely of dibasic aluminium monorosinate. The evidence proving this will be given in the following paper of this series.

The experimental data given in the preceding sections can be employed to determine how the properties of these aluminium monorosinate monolayers vary with the pH of the substrate (Fig. 14). On water the characteristic properties of the monorosinate monolayer remain unchanged up to a pH of about 4.7, but above this value the area per molecule decreases slowly. On 2 *M* sodium chloride, similar changes occur slightly earlier, at pH 4.5—4.6; also the collapse pressure increases. The data become erratic at pH 4.9 in the former case (water) and at pH 5.5 in the latter case (2 *M* NaCl); in this range the interaction with aluminium ions begins to depend on the time of reaction. Above pH 5.1 and 6.0, in the respective cases, it was not possible to obtain aluminium monorosinate monolayers giving well-defined pressure-area curves.

Table 2. Characteristic data for dibasic aluminium monorosinate monolayers (below pH 4.5).

Substrate	A_0 Å² per molecule	A_K Å² per molecule	π_K dynes/cm
Water; pH adjusted with dilute HCl	46.0	34.8	43.6
2 *M* NaCl, buffered with $5 \cdot 10^{-2}$ *M* acetic acid-acetate	50.7	39.3	41.6

Table 2 gives data which characterize the monolayers of dibasic aluminium monorosinate. These data have been obtained for monolayers formed on substrates with very different aluminium ion concentrations, from 10^{-5} *M*

up to 10^{-2} *M*. An increase in the sodium chloride content of the substrate leads to larger areas per molecule of the monolayer substance and causes the collapse pressure to fall slightly.

The deviations from the characteristic values given in Table 2 at higher pH values are observed at the same pH values at which a pure rosin acid monolayer begins to undergo ionization.

II. The Product of the Reaction between Aluminium Ions and Monolayers of Tall Oil Rosin Acid

PER EKWALL and HENRIK BRUUN

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Monomolecular layers of purified tall oil rosin acid have been spread on substrates containing potassium aluminium sulphate under conditions in which interaction takes place between aluminium ions and the monolayer. The interacted layers have been skimmed from the surface and the content of aluminium, carbon and hydrogen in the collected substances has been determined.

The interaction leads to the formation of dibasic aluminium monorosinate. The existence of other aluminium rosinates in the monolayer has not been observed.

In the foregoing paper (Part I)[1] we described a series of surface balance measurements that were planned to define the conditions in which reaction takes place between a tall oil rosin acid monolayer and aluminium ions in the supporting substrate. The lowest aluminium concentration at which the reaction begins varies with the pH of the substrate and the reaction attains a definite end-point at a higher aluminium concentration which also depends on the substrate pH. This end-point is signalized by the fact that the changes in the monolayer properties effected by the reaction attain their maximum extent. In the following we shall describe the results of our investigation of the constitution of the monolayer substance.

EXPERIMENTAL

The isolation of the monolayer substance. In order to be able to conduct an analysis of the substance formed by the reaction between the tall oil rosin acid monolayer and aluminium ions it was necessary to collect a sufficient quantity of it. A monolayer of rosin acid was spread in the usual manner on an aqueous potassium aluminium sulphate solution of known concentration and pH. The monolayer substance was compressed to a very small area and removed with suction together with the smallest possible volume of the substrate. New rosin acid was again spread on the substrate and the monolayer substance compressed and removed; this procedure was repeated 200 to 500 times (for different

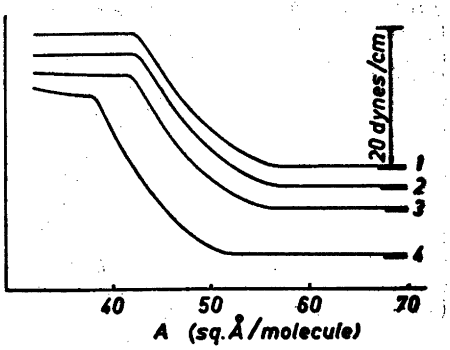

Fig. 1. π-A curves of tall oil rosin taken at different pH values for the determination of the aluminium ion concentration of the substrate. Curve 1 pH 4.12, 2 pH 4.20, 3 pH 4.28, 4 pH 4.39.

samples). After the monolayer substance had been skimmed off, it consisted of a white flocculent precipitate dispersed in some of the substrate solution. The precipitate was filtered, washed with a few millilitres of water and dried. The quantities of substance obtained in this way varied from 10 to 15 mg.

As the monolayer substance comprised an aluminium rosinate, the concentration of aluminium ions in the substrate was gradually reduced by the above-mentioned skimming procedure. This reduction was especially marked when the aluminium ion concentration was initially low. (In order to maintain the conditions as constant as possible, the substrate was renewed after several skimmings.)

It was established that also the pH of the substrate was altered when the surface layer was removed. In experiments in which the initial aluminium ion concentration was 1.4×10^{-5} *M*, the pH decreased from the value 5.20 to 5.08. In other experiments in which the aluminium ion concentration was 4×10^{-5} *M*, the pH diminished during 120 skimmings from 4.80 to 4.60 and 4.50 and in an experiment with the initial aluminium concentration 5.20×10^{-4} *M*, 240 skimmings lowered the pH from 4.25 to 4.18.

As we wished to know the constitution of the monolayer substance formed under definite conditions, the pH was checked and adjusted from time to time or the substrate was renewed after several skimmings. Since the changes were less marked when the aluminium content of the substrate was not too low, the aluminium concentration was held at 1×10^{-3} *M* in most of the experiments.

The analytical methods. Carbon and hydrogen in the isolated aluminium rosinate were determined by micro combustion analysis. (These analyses were performed by Mr. K. Salo at the Chemical Institute of the University of Helsingfors.)

The aluminium content was determined by a surface-chemical method developed for the purpose. The principle of the method is the following. 4—6 milligrams of the aluminium rosinate were ashed carefully in a platinum dish and the ash treated with 1—2 drops of concentrated sulfuric acid and some nitric acid. The dried aluminium sulphate was dissolved in water and diluted to a volume (about 1.3 litres) sufficient to fill the surface balance trough. A rosin acid monolayer was spread on this substrate and its pressure-area curve was recorded in the usual manner with the surface balance. The pH of the substrate was adjusted to known values and new pressure-area curves recorded for rosin acid at each pH value. It was found suitable to begin at a low pH value and increase it gradually. The recordings were continued until a definite change in the pressure-area curve revealed that the aluminium ions had begun to interact with the rosin acid monolayer. The data were employed to evaluate accurately the lowest pH value at which the interaction could be detected. Knowing this value of the pH, it was possible to read from curve 1 in Fig. 13 (in Part I of this series) the aluminium ion concentration of the substrate. This procedure could be repeated as many times as desired. The pH of the substrate was altered by adding sodium hydroxide or hydrochloric acid and measured with a valve potentiometer (Radiometer PHM 3) using glass and saturated calomel electrodes.

A number of pressure-area curves recorded during the course of our analyses are reproduced in Fig. 1. No effect of aluminium ions is noted in curve 1 (pH 4.12) and curve

2 (pH 4.20). In curve 3 (pH 4.28), the interaction with the aluminium ions has already become clearly evident; the area A_o has diminished from 57.0 to 56.2 Å^2 per molecule and the collapse pressure π_K has increased from 19.3 to 19.6 dynes per cm. In general, the pH range in which the effect of aluminium ions was first observed could be determined within ± 0.02 pH units. This permits the determination of the aluminium content of the solution with an accuracy of ± 0.038 units of the logarithm of the aluminium concentration, which corresponds to an accuracy of the analysis of ± 9 %. At first the analyses were conducted using tall oil rosin acid monolayers. Later one of us (Bruun) has employed tetrahydroabietic acid for the purpose, with an increase in accuracy (± 6 %).

Our aluminium analyses were usually conducted in the aluminium concentration range $3 \times 10^{-6} - 3 \times 10^{-5}$ *M*. The method of analysis cannot be employed with aluminium concentrations under 2×10^{-6} *M* (See Fig. 13 in part I of this series). It is hence necessary to have at least 0.07 mg aluminium for each analysis when our present surface balance (trough volume 1.3 litres) is used for recordings.

RESULTS

We were particularly interested to determine the constitution of the monolayer formed in the conditions where the surface balance studies indicated that the interaction of aluminium ions and the rosin acid monolayer attained a definite limit, *i.e.* under those conditions defined by curve 2 in Fig. 13 of the first paper of this series. The analyses 1—4 (see Table 1) relate to monolayer substance collected under conditions close to this curve. The material used in analyses 5 and 6 was collected under conditions to the right of this curve, but under conditions where no precipitation of aluminium hydroxide was yet possible. The conditions in which material for analyses 7, 8 and 9 was collected are represented by points in the region between curves 2 and 1, *i.e.* in the region where the monolayer has not yet been completely transformed into aluminium rosinate according to our surface balance studies in Part I. In Fig. 2 the mentioned diagram is reproduced and the conditions under which the different samples were collected are marked with circles.

The analyses of all samples of monolayer substance collected when the typical aluminium rosinate pressure-area curve had fully developed gave an

aluminium content exceeding 7 %. The monolayer must hence have been converted into an aluminium monorosinate. The mean aluminium content, 7.5 %, corresponds closely to that calculated for a dibasic aluminium monorosinate, 7.44 % (Table 2). Also the carbon content is in agreement with that

Table 2. Theoretical aluminium, carbon and hydrogen contents for different aluminium rosinates (%).

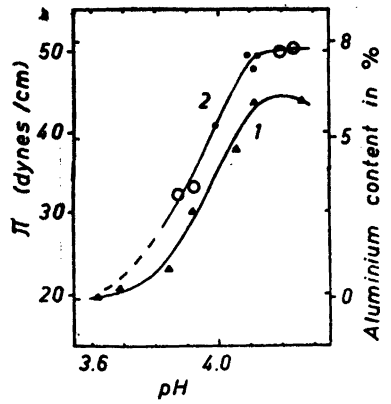

Fig. 3. The collapse pressure π_K (Curve 1) and the aluminium content (Curve 2) of tall oil rosin acid monolayers on substrates of different pH values containing $1 \cdot 10^{-3}$ mole/l of $KAl(SO_4)_2$. 20° C. (The pH values of the points on curve 2 were found by interpolation).

of aluminium monorosinate, but the hydrogen values deviate somewhat more and are between the values for the mono- and dirosinate.

Analyses 7—9 have given results which show that the monolayer substance in question corresponds to an aluminium rosinate of low aluminium content. The aluminium content decreases with the pH of the substrate on which the monolayer was formed *i.e.* the more the conditions differ from those yielding the aluminium rosinate pressure-area curve. It falls down to and below the aluminium content of monobasic aluminium dirosinate.

In order to give a clear picture of how the properties of the monolayer vary with its constitution, the curves in Fig. 3 are reproduced. Curve 1 in Fig. 3 shows the changes of the collapse pressure with pH on substrates containing 1×10^{-3} mole aluminium per litre. Curve 2 gives the aluminium content of the monolayer substance formed on solutions of the same composition. (The circles give experimentally determined aluminium values. In those cases where the monolayer substance has been collected on solutions of lower aluminium content than 1×10^{-3} *M*, the corresponding pH value on the substrate mentioned has been interpolated from the curve 2 of Fig. 13 in Part I.) The point

The dotted lines give theoretical aluminium content for different aluminium rosinates. 1 aluminium trirosinate, 2 monobasic aluminium dirosinate, 3 dibasic aluminium monorosinate.

where the properties of a typical aluminium rosinate curve are fully developed and the aluminium content of the monolayer substance is that of the dibasic aluminium monorosinate becomes clearly evident. Up to this pH value, both curves run continuously.

Fig. 4 shows directly the variations of the collapse pressure of the monolayer with its aluminium content. There are no break points in the curve up to the aluminium content of the dibasic aluminium monorosinate. The conclusion thus seems justified that the reaction between aluminium ions and the rosin acid monolayer takes place without intermediate stages until the formation of aluminium monorosinate is complete and that the latter compound is the final product of the primary interaction. Before this end-point is reached, the monolayer is evidently a mixture of unreacted rosin acid and aluminium monorosinate.

Kinetics of the Autoxidation of Cuprous Chloride in Hydrochloric Acid Solution

HAKON NORD

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

It is shown that the velocity of the autoxidation of cuprous ion in hydrochloric acid solution is proportional to the concentrations of oxygen and cuprous ion. The velocity increases with increasing hydrogen ion concentration, the reciprocal velocity being a linear function of the reciprocal hydrogen ion concentration, provided $cH^+ \geq 0.1$. As the rate of reaction was high, it proved impossible to saturate the reacting solutions with oxygen, so that the oxygen concentration had to be determined by calculations assuming a steady state.

The kinetic expression found suggests the following mechanism:

$(O_2)_{gas}$	$\rightleftharpoons$	$(O_2)_{liquid}$	(± 1)
$O_2 + Cu^+$	$\rightleftharpoons$	CuO_2^+	(± 2)
$CuO_2^+ + H^+$	$\rightarrow$	$Cu^{++} + HO_2$	$(+3)$

followed by a sequence of fast steps in which three more cuprous ions per oxygen molecule are oxidised. The values of the rate constants for the individual steps are discussed.

It is well known that copper ions play an important part as a catalyst in many oxidations. The mechanism of this behaviour is generally associated with the ability of copper to exist in two oxidation states in solution [1]. To solve the kinetic problems of such reactions adequately it is necessary to know the kinetics of the oxidation of cuprous ion. The present investigation is of preliminary character as various factors which influence the rate have been varied within rather narrow limits only. The results have been used in evaluation of the kinetics and mechanism of the copper catalysed autoxidation of ascorbic acid, which is treated in a following paper.

The autoxidation of cuprous chloride in mixed solution of sodium chloride and hydrogen chloride was investigated. The chloride concentration was kept throughout at 1.000 *M*. The hydrogen ion concentration varied from 0.400 to 0.020 *M* and the sodium ion concentration correspondingly from 0.600 to 0.980 *M*. The initial concentration of chlorocuprous ion was generally about 0.008 *M*. It has been shown in this laboratory[2] that cuprous ions in such solutions exist essentially as $CuCl_2^-$.

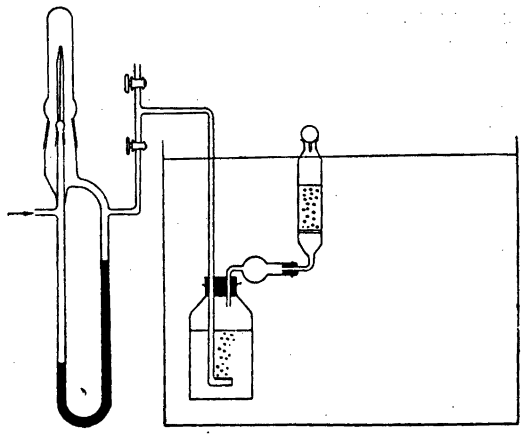

Fig. 1. Experimental set up (see text).

All reagents used were "Baker's analyzed". The cuprous chloride was washed with dilute hydrochloric acid to remove oxidised products, otherwise the chemicals were used as delivered. The solutions were made up under anaerobic conditions. 225 ml of suitable mixtures of 1.000 *M* hydrochloric acid and 1.000 *M* sodium chloride were deaerated in a two necked bottle by a stream of carbon dioxide. To this solution was added a saturated solution of cuprous chloride in 1 *M* sodium chloride, generally 25 ml.

As discussed below it was impossible to saturate the solutions with oxygen because of the high rate of the reaction. Therefore it was necessary to determine the progress of the reaction in separate runs each of which gave one interrelation between time and degree of reaction only. The reaction was carried out in a small reaction vessel (Fig. 1), a vertical glass cylinder with a sintered glass disc as a gas inlet in the bottom. The volume of the reaction vessel was about 25 ml.

In each run 15 ml of the reaction mixture was transferred from the stock solution in the two necked bottle by a pipette, the tip of which was somewhat enlarged to ensure quick delivery. The gas, a mixture of oxygen and nitrogen, generally with 4.05 % oxygen, was taken from a small steel cylinder and passed through a wash bottle with 1 *M* sodium chloride, submerged in the thermostat, to ensure proper temperature and humidity. The rate of the gas flow was carefully controlled by a flow meter. No temperature difference was detectable between the contents of the reaction vessel and the thermostat water.

At the end of the time scheduled for the individual runs the gas flow was discontinued by releasing the pressure below the glass disc. The amount of oxygen in the solution was generally so small compared with the cuprous ion concentration that no great error was introduced by further reaction. 10.00 ml of the reacted solution was transferred by means of a Krogh syringe to a sulphuric acid and ferric chloride solution, and the ferrous ion formed titrated with 0.01 *N* potassium permanganate with ferroin as an indicator. A small blank was subtracted.

Ferric salt was used as oxidant because cuprous ions do not react stoichiometrically with permanganate or with ceric sulphate [3]. When cuprous salt was titrated directly, *i.e.*, without addition of ferric ion, the results were found to depend on such things as acidity, rate of titration, and rate of carbon dioxide current. The method here described was tested on solid cuprous chloride purified in the following way: dissolution in concentrated hydrochloric acid, reprecipitation by dilution, washing with glacial acetic acid and drying at 130° C. The results were in agreement with stoichiometry within 0.5 %.

The first runs showed that the velocity of the reaction does not depend on illumination or on added cupric chloride. It was further shown that although hydrogen peroxide could be detected by the spot test with lead sulphide it was only formed in negligible amount and could not be determined by the usual quantitative methods. The stoichiometry of the reaction is therefore:

$$4\ Cu^{+} + 4\ H^{+} + O_2 \rightarrow 4\ Cu^{++} + 2\ H_2O$$

The reaction vessel described above ensures a very intimate contact between gas phase and solution. Even so it was impossible to approach a state of saturation with oxygen, so that the concentration of oxygen in the reacting solution had to be determined by a steady state method, *i.e.*, by calculations assuming the rate of flow of oxygen from the gas phase into the liquid to be equal to the flow of oxygen in the opposite direction plus the rate of oxygen consumption:

$$k_1\ pO_2 = k_{-1}cO_2 + s \qquad (I)$$

Here s is the experimentally determined speed of the reaction: $\left(-\frac{dcCu^{+}}{dt}\right)$, and k_1 and k_{-1} the first order constants of forward and backward reaction according to the scheme

$$(O_2)_{gas} \rightleftharpoons (O_2)_{liquid} \qquad (\pm 1)$$

The exact values of these constants are determined by the conditions of experiment but the ratio between them is of course the solubility of oxygen in the liquid according to Henry's law. Whenever s is small compared with the two other terms the oxygen concentration of the reacting solution will approach saturation. An early attempt to determine the kinetics of the autoxidation of cuprous ion was unsuccessful because s was very nearly equal to k_1pO_2, so that the oxygen transference apparently was the sole rate determining factor [4]. In the present investigation the upper limit for s was about semisaturation upwards. It is evident that a necessary condition for success was a careful control of the factors which determine the rate of diffusion of oxygen into the solution.

Fig. 2 demonstrates the proportionality between velocity and oxygen concentration in the liquid phase. We may write:

$$s = cO_2 f(c,h) \qquad (II)$$

where c is the cuprous ion concentration and h the hydrogen ion concentration. The elimination of cO_2 between I and II gives:

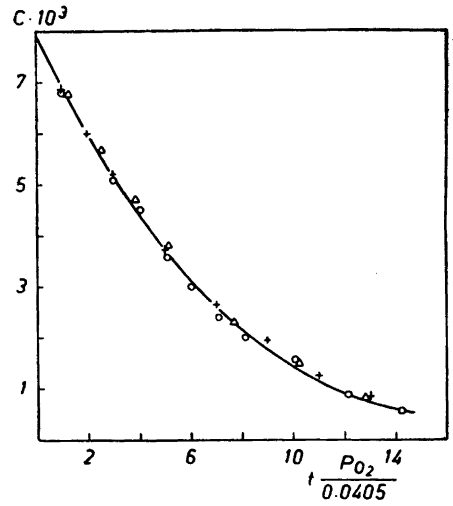

Fig. 2. Demonstration of the proportionality between rate and oxygen pressure in gas phase.

Ordinate: Cuprous ion concentration.

Abscissa: Time multiplied by oxygen pressure, divided by 0.0405. All times are hence referred to $pO_2 = 0.0405$.

△ ○ × denote values from experiments with [H+] = 0.100 and with oxygen pressures 0.208, 0.082, 0.0405

$$s = -\frac{dc}{dt} = \frac{k_1 pO_2 \cdot f(c,h)}{k_{-1} + f(c,h)}$$

or

$$\frac{1}{s} = -\frac{dt}{dc} = \frac{1}{k_1 \cdot pO_2} + \frac{k_1}{k_1 \cdot pO_2 \cdot f(c,h)} \qquad \text{(III)}$$

The integral form is:

$$t = \frac{c_o - c}{k_1 \cdot pO_2} + \frac{k_{-1}}{k_1 \cdot pO_2} \cdot \int_c^{c_o} \frac{dc}{f(c,h)} \qquad \text{(IV)}$$

The first term on the right hand side of (IV) can be determined in two ways, either by direct experiments or indirectly by analysis of the experimental material from the main experiments. The accuracy of this investigation being rather low, it was considered unfavourable to use the latter method. Inspection of (I) shows that k_1 may be easily determined if it is possible to design experiments in which the steady state concentration of oxygen in the liquid phase is nearly zero. Therefore s was determined in experiments with solutions of sodium sulphite or with higher concentrations of cuprous chloride. Using sulphite it was found that the velocity of reaction was independent of sulphite

concentration and proportional to the oxygen pressure of the gas phase. For the experimental conditions used in the investigation was found:

$$s = 0.0483 pO_2 \text{ equivalent/liter} \cdot \text{minute}$$

The initial velocity of oxidation of concentrated solutions of cuprous chloride was nearly zero order in cuprous ion and proportional to the oxygen pressure. This velocity was almost identical with the velocity from the sodium sulphite experiments, so no doubt these velocities are actually the rate at which oxygen is transferred from gas to liquid.

Knowing k_1 we can determine the first term on the right hand side of (IV) and define a new parameter:

$$t' = t - \frac{c_o - c}{k_1 \cdot pO_2} = \frac{k_{-1}}{k_1 \cdot pO_2} \int_c^{c_o} \frac{dc}{f(c,h)} \qquad (V)$$

Here t' is the time the reaction from c_o to c would have taken had the solution been saturated with oxygen. The influence of the oxygen deficiency is thus eliminated.

It was now found that ln c is nearly a linear function of t'. This indicates linearity between velocity and c. Strict linearity of the logarithmic plot cannot be expected as the velocity increases with acidity, which again falls as the reaction proceeds. The relation between reciprocal velocity and reciprocal hydrogen ion concentration is nearly linear when $h \geq 0.1$. In less acid solution the rate is higher than corresponding to this relationship. We shall confine the attention to the acidity region in which the simple relation holds.

Analysis of the available experimental material gives the expression

$$\frac{1}{s} = -\frac{dt}{dc} = \frac{20.7}{pO_2} + \frac{1.62 \cdot 10^{-2}}{pO_2 \cdot c} + \frac{1.40 \cdot 10^{-2}}{pO_2 \cdot c \cdot h} \qquad (VI)$$

Introducing $h = h_o - c_o + c$, h_o and c_o being initial values of h and c, the integration gives:

$$t = \frac{(c_o - c) \cdot 20.7}{pO_2} + \frac{1.62 \cdot 10^{-2}}{pO_2} \cdot \ln \frac{c_o}{c} + \frac{1.40 \cdot 10^{-2}}{pO_2 (h_o - c_o)} \ln \frac{(h_o - c_o + c) \cdot c_o}{h_o \cdot c} \qquad (VII)$$

The acidity change during the experiments was so small that the following approximation is useful

$$\ln \frac{h_o - c_o + c}{h_o} = -\frac{c_o - c}{h_o}$$

Therefore

$$t = \left[\frac{20.7}{pO_2} + \frac{1.40 \cdot 10^{-2}}{pO_2 \cdot (h_o - c_o) h_o}\right](c_o - c) + \left[\frac{1.62 \cdot 10^{-2}}{pO_2} + \frac{1.40 \cdot 10^{-2}}{pO_2 \cdot (h_o - c_o)}\right] \ln \frac{c_o}{c} \qquad (VIII)$$

Table 1. I and II mean zero- and first order terms respectively. pO_2 was 0.208, initial hydrogen ion concentration 0.100. Hence the zero order factor was 92.5 and the first order factor 0.808.

The agreement between (VIII) and experiment is demonstrated in the Tables 1 and 2. The coefficients of the two terms are calculated from the experimental conditions. The expression is then used to calculate t, and the agreement between theory and experiment is illustrated by the concordance between experimental and calculated values of t.

The experimental expression, *e.g.* equation (VI), suggests the following mechanism:

$$(O_2)_{gas} \rightleftharpoons (O_2)_{solution} \qquad (\pm 1)$$

$$Cu^+ + O_2 \rightleftharpoons CuO_2^+ \qquad (\pm 2)$$

$$CuO_2^+ + H^+ \rightarrow Cu^{++} + HO_2 \qquad (\pm 3)\ *$$

The corresponding expression for the reciprocal rate, as derived by a steady treatment, is [5]:

$$\frac{1}{s} = \frac{1}{k_1 pO_2} + \frac{k_{-1}}{k_1 k_2 \cdot pO_2 \cdot c} + \frac{k_{-1}k_{-2}}{k_1 k_2 k_3 pO_2 \cdot c \cdot h} \qquad (IX)$$

* Strictly speaking nothing is known about the products of reaction (+ 3).

which is identical with (VI). The third step must be irreversible, otherwise the rate would depend on the cupric ion concentration. Almost certainly three more cuprous ions are oxidised by the HO_2 radical in a sequence of fast reactions, but these steps are not kinetically perceptible as the terms after the third must be small when the rate is uninfluenced by cupric ion concentration. The only alternative to this mechanism is reformation of oxygen by reactions between the partly reduced oxygen molecules (HO_2, H_2O_2, HO), which is clearly improbable because such molecules would be rare.

It should now be emphasized that this expression is valid only when $cH^+ \geq 0.1$. At lower hydrogen ion concentrations the rate is somewhat higher than corresponding to the expression. The reason for this complex relationship is probably that the cuprous-oxygen complex formed in the second step may react further in two ways, one of which is reaction (+ 3) in the mechanism given above. It may be assumed that (+ 3) has a dominating probability compared with an alternative mechanism (which does not involve hydrogen ions) when hydrogen ion concentration is 0.1 or greater, but that the other mechanism gains significance when the hydrogen ion concentration is essentially lower. The deviation between (VII) and experiment is about 15 % at $cH^+ = 0.05$ and about 40 % at $cH^+ = 0.02$. Universal agreement would imply that cuprous ions are not oxidised in neutral solution.

We shall now investigate what information we can get from the absolute values of the constants. Comparison of (VI) and (IX) gives:

$$k_1 = 0.048; \qquad \frac{k_1 k_2}{k_{-1}'} = 62; \qquad \frac{k_1 k_2 k_3}{k_{-1} k_{-2}} = 71$$

The solubility of oxygen in water at 25° C is about 10^3 mole/atmosphere, so $k_{-1}k_{-1} = 10^{-3}$. Therefore k_2 is about $60 \cdot 10^3$ $mole^{-1} \cdot minute^{-1}$, or 10^3 $mole^{-1} \cdot sec^{-1}$. The kinetic expressions derived above do not take into account that presumably four cuprous ions are oxidised every time one passes through the rate determining steps, so k_2 is actually about 250. The Arrhenius equation

$$k = Z \cdot \exp(-E/RT) \qquad (X)$$

where Z is the frequency factor and E the energy of activation would with "normal" Z value, 10^{11}, suggest an energy of activation of roughly 12 000 calories per mole.

k_{-2}/k_3 is nearly one. This means that a CuO_2^+ complex when formed has about equal prabability to react according to (+3) and (—2) in a solution which is 1 M in hydrogen ions. Christiansen [6] has pointed out that at least one of the two reactions in an element of a sequence of reactions has zero energy of activation. As now both (+ 2) and (— 3) are slow we would expect (—2) and (+ 3) to be fast reactions where the exponential factor of (X) are unity. The closeness to unity of k_{-2}/k_{+3} indicates that this condition is fulfilled, although the value should rather have been 10^2, as the most probable value (according to the mechanism suggested) of the frequency factor would be 10^{13} for k_{-2}, corresponding to a monomolecular reaction, and 10^{11} for k_3, as (+ 3) is bimolecular. The value 1 might suggest that (—2) actually is bimolecular, *e.g.* a reaction between CuO_2^+ and chloride ion, which was present at molar con-

centration in all experiments. As a matter of fact it was found that the reaction proceeds much faster when the chloride concentration was reduced.

A result of this investigation, the indication of the existence of a complex between cuprous ion and oxygen, is an extention of the analogy between cuprous ion and haemoglobine, shown by their similar behaviour towards carbon monoxide.

Applicability of the Steady State Principle to the Autoxidation of Cuprous Chloride

HAKON NORD

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The *steady state equation* for determination of oxygen in a solution through which an oxygen containing gasphase is blown, and in which oxygen is being consumed by a chemical reaction, is compared with the *differential equation* for the oxygen concentration. The error introduced by determination of the oxygen concentration by using the simpler equation is calculated, and is negligible.

It is customary in chemical kinetics to base the treatment of the overall rate problem for a sequence of reactions on the assumption that the system will quickly settle down to a state in which the rates of appearance and disappearance of molecular species, which do not occur in the stoichiometric reaction scheme, are equal. This method is only strictly valid for systems which are invariant in time, but the difference for other systems between treatments based on this principle and rigorous solutions of the system of simultaneous differential equations for all species in the given problem is very often far below the limits of experimental accuracy. The steady state principle is always applicable in cases where the intermediates are so shortlived that they only represent a negligible amount of the reaction system in comparison with the concentrations of the stoichiometric components. Sometimes it is, however, convenient to apply steady state treatment to systems where this condition is not strictly fulfilled, and in such cases it is desirable to have a method to test the reliability of the method.

A problem of this kind is found in the preceding paper[1]. There it was found that the rate with which oxygen was used in a certain reaction was so high that the oxygen concentration in the reacting solution was essentially below saturation when a mixture of oxygen and nitrogen was blown through the reaction vessel. The oxygen concentration was in this case determined by the steady state principle, *i.e.*, by the equation

$$k_1 pO_2 - k_{-1} cO_2 - s = 0$$

(equation (I) in the preceding paper)

where everything except cO_2 was known. The problem should strictly have been solved by integration of the differential equation

$$\frac{dcO_2}{dt} = k_1 pO_2 - k_{-1} cO_2 - s$$

with appropiate boundary conditions. The objections against the use of the steady state principle in kinetics originate in the difference between these two equations, the apparent paradox introduced by equating to zero the rate of change of something which actually does change.

In the present problem the first term on the right hand side of the differential equation is a constant, and the next two terms are proportional to the oxygen concentration, s being a function of time. The problem is now to determine the difference between a determined by the equation

$$a - a(b + y) = 0 \qquad \text{(I)}$$

and by integration of the differential equation

$$\frac{da}{dt} = a - a(b + y) \qquad \text{(II)}$$

the boundary condition being that $a = 0$ for $t = 0$.

The general solution of the differential equation is

$$a = a \cdot e^{-\int_0^t (b+y)\,dt} \int_0^t e^{\int_0^\tau (b+y)\,d\tau} dt \qquad \text{(III)}$$

This expression can be transformed in a convenient way by means of the following relations:

$$\int e^{F(x)} dx = \int \frac{1}{f(x)} \cdot e^{F(x)} dF(x) = \frac{1}{f(x)} \cdot e^{F(x)} - \int \frac{d1/f(x)}{dF(x)} e^{F(x)} dF(x) =$$

$$= \frac{1}{f(x)} e^{F(x)} - \int \frac{d1/f(x)}{dx} e^{F(x)} dx = \frac{1}{f(x)} e^{F(x)} + \int \frac{f'(x)}{f(x)^2} e^{F(x)} dx;$$

$$f(x) \equiv F'(x)$$

The boundary condition given above is satisfied when the integration constant

$$\frac{1}{f(0)}$$

is subtracted. Introduction into the general solution for the differential equation gives:

$$a = a \cdot e^{-\int_0^t (a+y)dt} \left\{ \frac{1}{b+y} e^{\int_0^t (a+y)dt} - \frac{1}{b+y_0} - \int_0^t \frac{y}{(b+y)^2} e^{\int_0^\tau (b+y)\,d\tau} dt \right\}$$

$$a = \frac{a}{b+y} - \frac{a}{b+y_0} e^{\int_0^t (a+y)dt} - a\, e^{-\int_0^t (a+y)dt} \int_0^t \frac{y'}{(b+y)^2} e^{\int_0^\tau (b+y)d\tau} dt \qquad \text{(IV)}$$

This expression is identical with the general solution above. The first term is identical with the solution of the steady state equation (I). The second term is the initial value of the steady state solution multiplied by an exponential factor. It is easy to investigate how quickly this term vanishes in a given problem. The third term is identical with (III) apart from the factor immediately after the big sign of integration. The contribution from this term is determined by calculation of this factor, and is negligible if

$$\frac{y'}{(b+y)^2} << 1.$$

In the preceding paper it was found that k_1 for the applied experimental conditions has the value

0.0483 equivalent/liter · minute · atmosphere

In the state of saturation we have:

or $$a = b \cdot \alpha$$

$$k_1 pO_2 = k_{-1} \cdot cO_2$$

As now $$\frac{pO}{cO} \sim 800 \text{ atmospheres/mole}$$

we have $$k_{-1} = 60$$

y is the function, which by multiplication with cO_2 (α) gives s, so we have

$$y \cdot cO_2 = \frac{62.6 \cdot c \cdot h}{0.875 + h} \cdot pO_2 = \frac{50\,000 \cdot c \cdot h}{0.875 + h} \cdot cO_2$$

Introduction of $c = 0.01$ and $h = 0.1$ gives

$$y = 50$$

so the exponential factor has the value

$$e^{-110t}$$

which reaches the value 0.01 in less than three seconds.

Under the chosen experimental conditions we have:

$$y \sim 5\,000 \cdot c$$

or

$$y' \sim 5\,000 \cdot \frac{dc}{dt}$$

We were (preceding paper equation (VI)) able to express the variation of c in time by the empirical formula

$$-\frac{dt}{dc} = \frac{20.7}{pO_2} + \frac{1.62 \cdot 10^{-2}}{pO_2 \cdot c} + \frac{1.40 \cdot 10^{-2}}{pO_2 \cdot c \cdot h}$$

Introduction of the values for c and h above and $pO_2 = 0.2$ gives

$$-\frac{dt}{dc} \sim 100 + 30 + 300 = 430$$

or

$$-\frac{dc}{dt} \sim 0.002$$

This gives $y' = -5\,000 \cdot 0.002 = -10$
We therefore have

$$-\frac{y'}{(k_{-1} + y)^2} \sim \frac{10}{110^2} \sim 0.0008 << 1$$

Thus also the third term of (IV) is small and it is seen that the special application of the steady state principle in the preceding paper is fully justified.

Kinetics and Mechanism of the Copper Catalysed Autoxidation of Ascorbic Acid

HAKON NORD

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Based on a discussion of earlier investigations of the copper catalysed reaction between oxygen and ascorbic acid the following mechanism is suggested

$$\begin{aligned} H_2A &\rightleftharpoons HA^- + H^+ \\ HA^- + Cu^{++} &\rightleftharpoons HA + Cu^+ \\ HA &\rightleftharpoons A^- + H^+ \\ A^- + Cu^{++} &\rightarrow A + Cu^+ \\ 2\,Cu^+ + 2\,H^+ + \tfrac{1}{2}O_2 &\rightarrow 2\,Cu^{++} + H_2O \\ \hline H_2A + \tfrac{1}{2}O_2 &\rightarrow A + H_2O \end{aligned}$$

The corresponding kinetic expression is derived, certain justified approximations being introduced. It is shown that there is complete agreement between the integrated velocity expression and the course of the reaction as determined by experiment. From the kinetic expression the steady state distribution of copper in the two oxidation states is calculated for the conditions of a special experiment, and the values calculated are compared with the result of a spectrophotometric determination of cupric ion as a function of time in an identical experiment. The values of the velocity constants for the single steps are derived from the experiments, and a discussion proves them to be reasonable. It is therefore evident that the above mechanism is correct.

The most remarkable feature in the chemistry of ascorbic acid is its reaction with oxygen, strongly and specifically catalysed by copper ions. In view of the physiological importance of ascorbic acid it is understandable that most of the available investigations of the kinetics of this reaction have been carried out in solution near the physiological pH region. However, the protolytic properties of ascorbic acid, and the ability of copper ions to form complexes with various components of buffered solutions, introduce unnecessary complications, the result being that none of the earlier investigators have been able to provide experimental material from which an established mechanism can be derived. In the present investigation an attempt is made to overcome these difficulties by a choice of conditions much more convenient from the point of

view of physical chemistry. In this way it proves possible to remove the uncertainty completely, and thence to derive a mechanism.

In previous investigations it is almost universally maintained that the autoxidation of ascorbic acid in the presence of copper ion is a transference catalysis:

$$\begin{array}{rcl} H_2A + 2Cu^{++} & \rightarrow & A + 2Cu^{+} + 2H^{+} \\ 2Cu^{+} + 2H^{+} + O_2 & \rightarrow & 2Cu + H_2O \\ \hline H_2A + O_2 & \rightarrow & A + H_2O \end{array}$$

(H_2A = ascorbic acid; A = dehydro ascorbic acid).

The most careful investigations of the kinetics of this reaction are due to Barron, de Meio and Klemperer [1], Weissberger and LuValle [2] and Lyman *et al.*[3] Barron *et al.*[1] found in 1936 that the rate of the uncatalysed reaction is negligible at pH < 7.6. In alkaline solution ascorbic acid reacts with one molecule of oxygen, even without a catalyst, forming oxalic acid and L-treonic acid. This reaction is, as opposed to the catalytic reaction in neutral or acid solution, irreversible and uninhibited by cyanide ion. At pH values lower than 6.6, in the presence of copper, one molecule of ascorbic acid reacts with one atom of oxygen only, forming dehydro ascorbic acid as by the oxidations with iodine or 2,6-dichlorophenoleindophenole. Accordingly the ascorbic acid is recovered quantitatively by reduction with hydrogen sulphide. The velocity of the reaction, according to Barron *et al.*, increases with increasing copper concentration, but less than corresponding to a simple proportionality law. The rate decreases with increasing acidity, but is still measurable in 0.1 *M* hydrochloric acid. The rate increases with oxygen concentration, but less than according to proportionality. These are the facts on which Barron *et al.* based the undetailed transference mechanism. They are all confirmed by the present investigation.

Weissenberger and LuValle [2] suggest that the rate determining step in the copper catalysed autoxidation of ascorbic acid is

$$HA^{-} + Cu^{++} \rightarrow HA + Cu^{+}$$

the semiquinone (HA) and the cuprous ion formed both reacting further with oxygen. All steps except this one are considered fast. This is hardly in accordance with an experimental finding by the same authors: that the velocity is proportional to the oxygen concentration. The complex relationship between velocity and copper concentration is, according to Weissberger and LuValle, associated with the ability of copper to form complexes with buffer components.

Ball [4] has determined the redox potential of the reaction

$$H_2A \rightleftharpoons A + 2\ H^{+} + 2\ e^{-}$$

to be 0.390 volt. This potential has been verified by various investigators. Fenwick [5] has determined the potential for the reaction

$$Cu^{+} \rightleftharpoons Cu^{++} + e$$

to be 0.167 volt. These figures mean that the equilibrium

$$H_2A + 2\ Cu^{++} \rightleftharpoons A + 2\ Cu^{+} + 2\ H^{+}$$

in acid solution is displaced to the left hand side. The solutions used in the present investigation was 1.000 *M* in chloride ion throughout. Therefore the formation of dichloro cuprous ion was significant for the distribution of copper on the two oxidation states:

$$H_2A + 2\ Cu^{++} + 4\ Cl \rightleftharpoons A + 2\ CuCl_2^- + 2\ H^+$$

The dissociation constant of the dichloro cuprous ion is estimated by Latimer [6] as 2.9×10^{-6} and by Bjerrum [7] as about 3.0×10^{-6}. These values combined with the redox potential for the free cuprous ion gives about 0.487 volt for the reaction

$$CuCl_2 \rightleftharpoons Cu^{++} + 2\ Cl^- + e^-$$

Handbook of Physics and Chemistry (1947) p. 1418, quotes 0.455 volt. The writer has been unable to trace the origin of this value, but has confirmed it by his own measurements. Cupric ion is thus almost completely reduced by ascorbic acid in acid chloride solution.

Lyman *et al.*[3] have shown that the velocity of the copper catalysed autoxidation in 0.1 *N* sulphuric acid solution is vanishingly small, but quite measurable in 0.1 *M* hydrochloric acid solution, where the rate as a function of the hydrochloric acid concentration has a minimum. In the present investigation it was found that the velocity of the reaction is zero in 0.1 *M* perchloric acid and conveniently measurable in a solution which is 0.1 *M* in hydrochloric acid and 0.9 *M* in sodium chloride.

The first two steps in the mechanism suggested by Weissberger and LuValle were

$$H_2A \rightarrow HA^- + H^+ \qquad (+1)$$

$$HA^- + Cu^{++} \rightarrow HA + Cu^+ \qquad (+2)$$

These steps are essentially uninfluenced by chloride ions, so apparently they are not sole rate-determining. Chloride ion will trap the cuprous ion formed by (+ 2) and therefore prevent or at least grossly inhibit the reaction

$$HA + Cu^+ \rightarrow HA^- + Cu^{++} \qquad (-2)$$

The third step in the Weissberger and LuValle mechanism is

$$HA \rightarrow H^+ + A^- \qquad (+3)$$

which we shall accept. The fourth step suggested is

$$A^- + O_2 \rightarrow A + O_2^-$$

which seems very unlikely as the concentrations of copper and oxygen are comparable. There is no obvious reason to assume that A^- should prefer to react with oxygen when HA^- prefers the cupric ion. The fourth step is rather

$$A^- + Cu^{++} \rightleftharpoons A + Cu^+ \qquad (\pm 4)$$

In a preceding paper it was suggested that the oxygen molecule is reduced stepwise by four cuprous ions, the final product being water. Therefore a solution in which oxidation of cuprous ion is going on must contain partly reduced oxygen molecules such as H_2O, H_2O_2 and HO. Experiments in which cuprous ion was oxidised in the presence of oxalic acid, formic acid or pyrogallol showed that these organic compounds are not subject to "induced oxidation",

the organic compounds being present quantitatively after the experiments, and the rate of oxidation of cuprous ion being unimpaired by their presence. It is therefore suggested that the following reactions are insignificant:

$$H_2A + HO_2 \rightarrow ?$$
$$H_2A + H_2O_2 \rightarrow ?$$
$$H_2A + HO \rightarrow ?$$

We shall also neglect

$$HA^- + HO_2 \rightarrow ?$$
$$HA + HO_2 \rightarrow ?$$
$$A^- + HO_2 \rightarrow ?$$

etc. as the ascorbic acid derivatives are rare in the reacting solutions compared with the cuprous ions with which the oxygen derivates are supposed to react fast. Also the possibility that the complexes $CuHA^+$ and CuA^+ have a significant lifetime is disregarded. It is well known that copper complexes with polyalcohols and similar compounds do not exist in acid solution.

As a result of the introductory discussion, the following mechanism is suggested:

$$H_2A \rightleftharpoons H^+ + HA^- \qquad (\pm 1)$$
$$HA^- + Cu^{++} \rightleftharpoons HA + Cu^+ \qquad (\pm 2)$$
$$HA \rightleftharpoons A^- + H^+ \qquad (\pm 3)$$
$$A^- + Cu^{++} \rightarrow A + Cu^+ \qquad (+ 4)$$
$$2\ Cu^+ + 2\ H^+ + \tfrac{1}{2}O_2 \rightarrow 2\ Cu^{++} + H_2O \qquad (5)$$
$$H_2A + \tfrac{1}{2}O_2 \rightarrow A + H_2O$$

The overall velocity of this reaction will be a function of the concentrations of ascorbic acid, hydrogen ion, copper ion and oxygen. It is also influenced by temperature and chloride ion concentration, but these two factors were kept constant, their variation not being necessary to solve the problem set, to establish a mechanism of the reaction. In the individual runs all factors except the ascorbic acid concentration (and of course the concentration of dehydro ascorbic acid) were constant. It is our task to calculate what kind of function of time the ascorbic acid concentration should be in an experiment were the above mechanism right. The method used is that of steady state calculations, *i.e.*, writing down of equations assuming the rates of appearance and disappearance of the intermediate molecular species to be equal. From these equations the concentrations of the intermediates are then eliminated.

The system of equations would have been linear in the ascorbic acid concentration, c, had each step involved formation and disappearance of not more than one intermediate. Whenever two intermediates appear on the same side of an element of the sequence the degree of the kinetic expression is raised by one. As both the ascorbic acid derivatives (except dehydro ascorbic acid) and the two oxidation steps of copper are intermediates in the reaction-kinetic sense of the word, this occurs three times: in the reactions (+ 2), (— 2) and (+ 4). Therefore our expression will be strictly one of the fourth degree in c. Obviously certain approximations are necessary to solve the system of equations.

One simplification is justified by the following: When an ascorbic acid ion (HA^-) is formed it may either react with a cupric ion, (+2), or it may recombine with a hydrogen ion, (—1). Hydrogen ions are much more abundant than cupric ions, so the probability of (—1) is therefore likely to be much higher than that of (+2). The final result of the present investigation is that only few of the encounters between cupric ion and ascorbic acid ion lead to reaction according to (+2), so (—1) is definitely the fate of the great majority of ascorbic acid ions. Therefore the concentration of ascorbic acid ion (HA^-) can be calculated simply by using the mass action law on the dissociation according to (1). This simplication reduces the degree of our system of equations to three.

A great simplification is introduced by the experimental finding that the velocity of the reaction is uninfluenced by the concentration of dehydro ascorbic acid, *i. e.*, the velocity of (—4) is almost zero. This is only true when the system investigated contains chloride ions to trap the cuprous ions formed by (+2) and by (+4). Otherwise (—4) is so dominating that the overall rate of the reaction is negligible.

It is an important assumption that the state of the cuprous chloride system is the same as in the solutions used in a previous investigation [8] of the cuprous ion autoxidation.

We are now able to write down the equations necessary to derive the overall kinetics according to the mechanism suggested:

$$0 = [\dot{HA}] = k_2[HA^-][Cu^{++}] - k_{-2}[HA][Cu^+] - k_3[HA] + k_{-3}[A^-][H^+] \quad (I)$$

$$0 = [\dot{A}^-] = k_3[HA] - k_{-3}[A^-][H^+] - k_4[A^-][Cu^{++}] \quad (II)$$

$$0 = [\dot{Cu}^+] = -[\dot{Cu}^{++}] = k_2[HA^-][Cu^{++}] - k_{-2}[HA][Cu^+] + k_4[A^-][Cu] - 2s \quad (III)$$

where the dots denote differentiation with respect to time.

s is the rate of disappearance of ascorbic acid, $-\frac{dc}{dt}$, and two cuprous ions are oxidised in each cycle of the reaction. We thus have three equations with five unknowns. The distribution of copper on two oxidation states gives a fourth equation:

$$[Cu^+] + [Cu^{++}] = (Cu) \quad (IV)$$

where complex formation between copper and chloride is disregarded, and (Cu) is the total copper concentration. The remaining equation is

$$s = f([Cu^+]\, pO_2\, [H^+]) \quad (V)$$

as found in the preceding investigation [8].

Elimination of [HA] and [A^-] from the first three equations gives:

$$s = \frac{k_2k_3k_4[HA^-][Cu^{++}]^2}{k_3k_4[Cu^{++}] + k_{-2}k_4[Cu^+][Cu^{++}] + k_{-2}k_{-3}[Cu^+][H^+]}$$

$$\text{or } \frac{1}{s} = \frac{1}{k_2[HA^-][Cu^{++}]} + \frac{k_{-2}[Cu^+]}{k_2k_3[HA^-][Cu^{++}]} + \frac{k_{-2}k_{-3}[H^+][Cu^+]}{k_2k_3k_4[HA^-][Cu^{++}]^2} \quad (VI)$$

In the preceding paper it was found that the velocity of the oxidation of cuprous ion at 25° C in a medium which is 1.000 *M* in chloride ion and at least 0.1 *M* in hydrogen ion is

$$s' = \frac{61.8 \cdot pO_2 \cdot [Cu^+][H^+]}{0.863 + [H^+]}$$

where pO_2 is the partial pressure of oxygen in a gas phase with which the solution is in equilibrium. The velocity with which ascorbic acid is oxidised is, according to the mechanism suggested, equal to the velocity of oxidation of two cuprous ions:

$$s = \frac{30.9\ pO_2[Cu^+][H^+]}{0.863 + [H^+]} = H[Cu^+] \qquad \text{(VII)}$$

where H is a known function of experimental conditions.

Introduction of K_s, the acid dissociation constant of ascorbic acid, gives

$$[HA^-] = \frac{[H_2A]}{[H^+]} K_s = \frac{c}{[H^+]} K_s$$

We further define:

$$[Cu^+] = \alpha\,(Cu) \text{ and } [Cu^{++}] = (1-\alpha)\,(Cu) \qquad \text{(VIII)}$$

We can therefore rewrite (VI):

$$\frac{1}{s} = \frac{1}{H\alpha\,(Cu)} \frac{[H^+]}{K_s k_2 \cdot c(1-\alpha)(Cu)} + \frac{k_{-2}[H^+]\alpha\,(Cu)}{K_s k_2 k_3\, c\,(1-\alpha)(Cu)} + \frac{k_{-2}k_{-3}[H^+]^2\alpha\,(Cu)}{K_s k_2 k_3 k_4\, c\,(1-\alpha)^2\,(Cu)^2}$$

Introducing simpler symbols for constants and concentrations not changed in individual experiments gives:

$$\frac{1}{\alpha} = \frac{H}{L\,c\,(1-\alpha)} \left\{ 1 + \frac{(Cu)}{M}\alpha + \frac{1}{N}\frac{\alpha}{1-\alpha} \right\} \qquad \text{(IX)}$$

where $L = \frac{K_s k_2}{[H^+]}, M = \frac{k_3}{k_{-2}}$ and $N = \frac{k_3 k_4}{k_{-2}k_{-3}[H^+]}$.

(IX) is an equation between c and α. (VII) and (VIII) define a simple relationship between s and α. From this is seen that were the second term in the bracket of equation (IX) vanishingly small compared with the other terms. the velocity of the reaction would be proportional to (Cu). Without this term (IX) is a second degree equation. As it turns out that the velocity of the reaction is nearly, but not quite, proportional to (Cu) it proves useful to solve (IX) as a quadratic equation, *i. e.*, without considering the variation of the term in question:

$$\frac{Lc}{H}\left(\frac{1-\alpha}{\alpha}\right)^2 - \frac{1-\alpha}{\alpha} - \left\{ \frac{(Cu)\,(1-\alpha)}{M} + \frac{1}{N} \right\} = 0$$

$$\frac{1-\alpha}{\alpha} = \frac{1 + \sqrt{1 + \frac{4Lc}{H}\left(\frac{(Cu)\,(1-\alpha)}{M} + \frac{1}{N}\right)}}{2\frac{Lc}{H}}$$

$$\frac{1}{\alpha} = 1 + \frac{H}{2Lc}(1 + \sqrt{1 + Rc}) \qquad \text{(X)}$$

where $$R = \frac{4L}{H}\left(\frac{(Cu)\ (1-\alpha)}{M} + \frac{1}{N}\right) \qquad (XI)$$

Introduction of $\frac{1}{s} = -\frac{dt}{dc} = \frac{1}{H\alpha\,(Cu)}$ gives

$$\frac{1}{s} = \frac{1}{H(Cu)} + \frac{1}{2L\,(Cu)}\left(\frac{1}{c} + \frac{1}{c}\sqrt{1+Rc}\right)$$

or

$$t = \int_{c}^{c_o}\left[\frac{1}{H\,(Cu)} + \frac{1}{2L\,(Cu)}\left(\frac{1}{c} + \frac{1}{c}\sqrt{1+Rc}\right)\right] dc$$

c_o being the initial concentration of ascorbic acid. Considering R constant we have

$$t = \frac{c_o - c}{H\cdot\,(Cu)} + \frac{1}{2L\,(Cu)}\left[\ln c + 2\sqrt{1+Rc} - 2\,\coth^{-1}\sqrt{1+Rc}\right]_{c}^{c_o}$$

which is not changed when $\ln x = \ln Rc$ is substituted for $\ln c$, so we have:

$$t = \frac{c_o - c}{H\,(Cu)} + \frac{1}{2L\,(Cu)}\left[\ln x + 2\sqrt{1+x} - 2\,\coth^{-1}\sqrt{1+x}\right]_{c}^{c_o} \qquad (XII)$$

As H is known from the preceding investigation we can calculate the zero order term, and so define:

$$t' = t - \frac{c_o - c}{H\,(Cu)}$$

The ascorbic acid used in the present investigation was a synthetic product from Hoffmann-La Roche. The experimental set up was the same as in the previous paper. As the absolute rate of the reaction is low compared with the rate of dissolution of oxygen, the reacting solution was nearly saturated with oxygen at the partial pressure of the oxygen-nitrogen mixture blown through the solution. The course of the reaction was followed by extraction of 1.000 ml samples from the solutions in the reaction vessel at suitable intervals by means of a Krogh syringe. The samples were transferred to a small titration vessel in which they were diluted to about 4 ml by the washing of the syringe with oxygenfree water, and they were stirred and de-oxygenated by a fast stream of carbon dioxide during the titration. The titrations were performed with 0.1 N I^-_3 solution with starch as an indicator. The burette was a 100 μl calibrated Rehberg micro burette.

The nature of the course of the reaction is shown on Fig. 1. It is seen that "the order of the reaction" is between zero and one. It is further seen that the velocity falls off as the acidity is increased. The velocity increases with oxygen concentration, but less than according to a proportionality law. The velocity is most sensitive to change of oxygen concentration at the lower acidity.

In chemical kinetics it is usual to investigate a first order reaction by plotting $\ln c$ against t, the proof of the first order character being that the plot is a straight line. In the present case (see XII) a plot of the function

$$y = \ln x + 2\sqrt{1+x} - 2\,\coth^{-1}\sqrt{1+x}$$

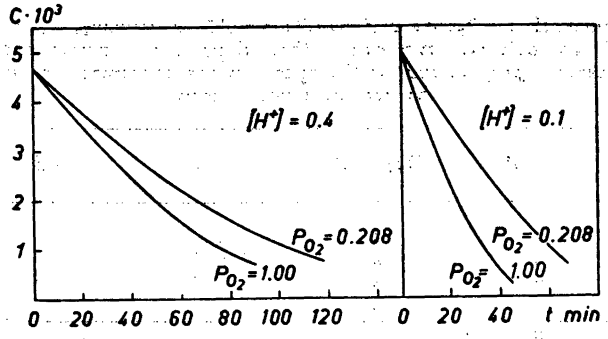

Fig. 1. Ordinate: Concentration of ascorbic acid. Abscissa: Time. It is seen that the rate is higher at the lower hydrogen ion concentration. Further that the rate is more sensitive to change of oxygen concentration at the lower hydrogen ion concentration.

against t' should be linear. Furthermore, when the conditions of experiment are changed, the variation of the reciprocal slopes from plots corresponding to individual experiments should vary in agreement with the coefficient 1/2L(Cu), *i. e.*, the slopes should be proportional to the concentration of copper and to the reciprocal hydrogen ion concentration, but should be independent of the oxygen concentration. The problem is therefore to investigate whether it is possible to assign such values to R, defined by (XI), that these conditions are fulfilled. We reintroduce the original meanings of the symbols L, M and N into R and have:

$$\ln x = \ln c + \ln \frac{4K_3k_2}{[H^+]H} \left\{ \frac{k_{-2}k_{-3}}{k_3k_4}[H^+] + \frac{k_{-2}}{k_3}(Cu)\,(1-\alpha) \right\}$$

Further introducing

$$H = F\ pO_2;\ F = \frac{30.9\ (H^+)}{0.863 + [H^+]}$$

we have:

$$\ln x = \ln c + \ln \frac{4K_3k_2k_{-2}k_{-3}}{k_3k_4} - \ln F - \ln pO_2 + \ln\left\{1 + \frac{k_4(Cu)}{k_{-3}[H^+]}\right\}(1-\alpha) \quad \text{(XIII)}$$

The second term on the left hand side is a constant, common to all experiments, the third and fourth terms are known functions of the experimental conditions. The fifth term is regarded a constant; that was one of the assumptions necessary to solve the mathematical problem. From the definition of t' it is seen that $t - t'$ is the time the reaction from c_0 to c would have taken, had all the copper been in the cuprous state. Therefore, $1-\alpha = \frac{dt'}{dt}$ or, as long as the order of the reaction is regarded zero, $1-\alpha = \frac{t'}{t}$. The procedure has been to use the value t'/t from the initial part of individual runs to calculate $1-\alpha$, and to use this value for the whole run. This is an approximation, but special calculations have shown that the value of y as a function of $\ln x$ is not

Table 1. Experimental conditions and results for 21 experiments. β is the slope of the (y, t') plots. The last column confirms that these slopes are proportional to the total copper concentration, inversely proportional to the hydrogen ion concentration and independent of the oxygen concentration.

[H+]	$c_0 \cdot 10^3$	(Cu) · 10^4	pO_2	$-\beta$	$-\beta \cdot \frac{[H^+]}{(Cu)}$

seriously sensitive to the variations of $1-\alpha$ during an experiment, so the credibility of the investigation is not influenced.

The method was to determine a set of values of lnR which gave oxygen independent slopes for the last three runs in Table 1. Afterwards these values were slightly adjusted to give proper copper concentration dependence of the slopes of the four experiments with hydrogen ion concentration 0.1 *M* and oxygen pressure of 1.00 atmosphere. As independent checks (apart from the linearity of the y, t' plots), consistency was found in the determination of the term $k_4(Cu)(1-\alpha)/k_{-3}[H^+]$ from the four experiments mentioned, and universal agreement between theory and experiment as far as dependences on concentrations of hydrogen ion and copper ion of the y, t' slopes are concerned, as demonstrated in Table 1. A further decisive test is reported at the end of the present paper.

The equation for determination of ln$x$ derived was:

$$\ln x = \ln\ 10^3\ c + 0.72 - \ln F - \ln pO_2 + \ln\left\{1 + 330\ \frac{(Cu)}{[H^+]}\ (1-\alpha)\right\} \qquad \text{(XIV)}$$

Table 2 gives the details of the calculation of an experiment, and the linearity of the corresponding y, t' plot is demonstrated on Fig. 2.

Table 2. Details of the first experiment in Table 1. By introduction of the values for concentrations it is found that $H = 3.21$, and by application of the value $(1-a) = 0.78$ further that $\ln x = \ln c \cdot 10^3 - 0.04$ (XIV).

t	$10^3 \cdot c$	$(c_0 - c) \cdot 10^3$	$\frac{c_0 - c}{H\ (Cu)}$	t'	$\ln c \cdot 10^3$	$\ln x$	y	$1-a$

39	0.58	4.33	6.74	32.26	−0.54	−0.58	−0.26	
42	0.40	4.44	6.92	35.08	−0.75	−0.79	−0.71	
45	0.35	4.56	7.10	37.90	−1.05	−1.09	−1.38	

From (XIII) and (XIV) we derive the following equations:

$$\frac{4K_s \cdot k_2 \cdot k_{-2} \cdot k_{-3}}{k_3 \cdot k_4} = 10^3 \cdot e^{0.72} = 2.05 \cdot 10^3$$

$$\frac{k_4}{k_{-3}} = 330 \qquad \text{(XV)}$$

Table 1 shows:

$$-\beta \frac{[H^+]}{(Cu)} = 2 \cdot K_s \cdot k_2 = 88$$

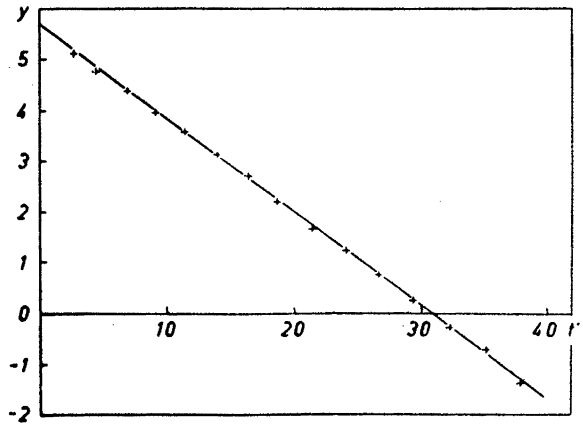

Fig. 2. Demonstration of the linearity of y as a function of t' (see text and Table 2).

The first dissociation constant for ascorbic acid, K_s, is about $6.2 \cdot 10^{-5}$, so we have

$$k_2 \sim 7 \cdot 10^5 \text{ liter mole}^{-1}\text{min}^{-1} \text{ or } k_2 \sim 10^4 \text{ liter mole}^{-1} \text{ sec}^{-1} \quad \text{(XVI)}$$

and $$\frac{k_{-2}}{k_3} \sim 4 \cdot 10^3.$$

(XVI) shows that (+2) is slow compared with (—1) (probable value 10^{11}), so no error was introduced by the simplified calculation of the ascorbic acid ion concentration.

According to a principle pointed out by Christiansen [9] (—2) should be fast. The direct reaction

$$CuCl^-_2 + HA \rightarrow HA^- + Cu^{++} + 2\ Cl^-$$

is probably impossible. To determine the proportion between the genuine constants for (—2) and (+3) we must (the medium being 1 *M* in sodium chloride) divide the value from (XVI) by the mass action constant for the reaction

$$CuCl^-_2 \rightleftharpoons Cu^+ + 2\ Cl^-$$

which is given as $3 \cdot 10^{-6}$,

$$\frac{k_{-2}}{k_3} = \frac{4 \cdot 10^3}{3 \cdot 10^{-6}} \sim 1.3 \cdot 10^9$$

The assumption of low energy of activation for (—2) is justified. It is therefore understandable that the reactions

$$HA \rightarrow H^+ + A^- \qquad (-3)$$

and $$Cu^+ + O_2 \rightarrow CuO_2^+ \qquad (+5)$$

can hardly compete with

$$Cu^+ + HA \rightarrow Cu^{++} + HA^- \qquad (-2)$$

in chloride free medium.

As (+3) is slow (—3) should be fast, which means that HA is a weak acid. The independence of velocity on dehydro ascorbic acid concentration shows that (—4) is slow, so (+4) should also be fast. Therefore k_{-5}/k_4 should not be far from unity. The value 330 is in fair agreement with the difference expected for electrostatic reasons, as an ion with one negative charge should encounter a double charged positive ion more frequently than a single charged ion, other conditions being equal.

The mathematical problem of the present investigation was solved by derivation of the distribution of copper on the two oxidation states. The absorption of cupric ion at 800 mμ is just sufficient to allow a reasonable estimate at concentrations around 10^{-4} when 10 cm cells are used in a Beckman DU spectrophotometer. It must however be emphasised that the determination is rather coarse as the extinctions measured are from about 0.06 downwards.

Table 3. D means the extinction of the reacting solution at 800 mμ in 10 cm cells. The value for a corresponding solution without ascorbic acid was 0.076.

t	H_2A	pO_2	α calc.	D	α obs.
0	4.93	1.00			
5	4.25	1.00			
10	3.45	1.00			
13	3.03	0.80	0.25	0.058	0.24
16	2.71	0.59	0.27	0.055	0.28
19	2.41	0.49	0.30	0.054	0.29
22	2.14	0.35	0.32	0.051	0.33
25	1.93	0.25	0.36	0.047	0.38
28	1.76	0.17	0.41	0.042	0.45
31	1.66	0.12	0.46	0.037	0.52
34	1.58	0.08	0.52	0.032	0.58
37	1.50	0.04	0.61	0.027	0.64
40	1.45	0.02	0.74	0.021	0.72
43	1.42	0.01	0.78	0.017	0.78

An experiment was performed as follows: 25 ml of a solution of ascorbic acid (Co = $5 \cdot 10^{-3}$, (Cu) = $2 \cdot 10^{-4}$, $[H^+] = 0.1$) was placed in the reaction vessel, and oxygen was bubbled through for 10 minutes. Then the solution was quickly transferred to the absorption cell which was filled up into the neck so that there was no gas phase when the glass stopper was inserted. The extinction at 25° C was measured every third minute. From the extinctions the concentrations of cupric copper was determined, and α computed. In a similar kinetic run the bubbling through of oxygen was discontinued after 10 minutes, and the solution was left in the reaction vessel so that dissolved oxygen was allowed to react with the ascorbic acid. The course of the reaction was followed in the usual way (see the experimental section). Stirring of the solution by extraction of samples was carefully avoided.

Introduction of the numerical values for concentrations and constants into (X) gives:

$$\frac{1}{\alpha} = 1 + 3.67 \cdot \frac{pO_2}{c \cdot 10^3}\left\{1 + \sqrt{1 + 0.64 \cdot \frac{c \cdot 10^3}{pO_2}\,[1+0.66(1-\alpha)]}\right\}$$

c was determined by experiment, pO_2 was calculated from stoichiometry. Hence
α could be calculated by iteration. Table 3 demonstrates the accordance between
α calculated in this way and determined by spectrophotometry.

On the Isomerism of Hydroxyurea

V. Polarographic Behaviour of the Lower-Melting Isomer

HELMER KOFOD

Danmarks farmaceutiske Højskole, Org.-kem. lab., København, Danmark

The lower-melting hydroxyurea (m.p. 72 °C) has been found to produce a single, well-developed and reproducible diffusion-controlled cathodic wave at approximately −1.5 V (S.C.E., 25° C) in neutral, buffered and unbuffered solutions, 0.1 to 0.2 *N* in potassium ion. In acidic buffers the hydrogen wave interferes, in alkaline solution, pH> 9, the wave is independently developed, but it decreases rapidly with time due to instability of the substance. The variation of wave height with concentration is linear over the range 0.5 to 5 millimoles/l. The observed influence of the pH upon the half-wave potential together with the shape and the height of the wave seem to indicate that hydroxyurea (m.p. 72°) is reduced according to two distinctly different mechanisms, a pH-dependent one in acid solution and a pH-independent one in neutral and alkaline solution, both being irreversible two-electron processes.

A concurrent polarographic examination of the hydroxylammonium ion confirmed that the lower melting hydroxyurea is not identical with hydroxylammonium cyanate.

Since the higher melting isomer (140° C) proved to be polarographically inactive in the same voltage region, the method developed in this paper is an adequate analytical tool for a study of the formation and interconversion of the isomerides.

The polarographic method, when applicable to an organic compound, not only constitutes an analytical tool of high sensitivity, but very often valuable structural inferences may be drawn from the experimental data. Both potentialities are relevant to the studies dealt with in the present series, the former with a view to a kinetic examination of interconversions of the isomers. This will be the subject of a separate paper. In the following a general polarographic examination of the hydroxyureas is presented and the requisite analytical conditions are reported.

Introductory experiments revealed that in neutral unbuffered electrolyte solution (0.5 *M* lithium chloride) the lower melting isomer (m.p. 72°C) produced a cathodic wave at approximately —1.5 V *vs* S.C.E. ("saturated calomel electrode"), whereas the higher melting isomer (m.p. 140° C) gave neither a

Wave-height (1 unit = 2.33 microamp.) against minutes from dissolution of the solid. △ 10.0 mM *stock solution (diluted with 4 volumes of buffer at pH 7.2 immediately before recording of the polarogram). 2.0* mM *solutions in buffer pH 7.2 (□), 8.1 (▽), 9.2 (+) and in 0.1* N *potassium hydroxide (○) respectively.*

cathodic nor an anodic wave in the voltage region + 0.2 to —2.0 V (S.C.E.) covered by the experiments. A typical polarographic wave of the lower melting hydroxyurea is given in Fig. 2, pH 7.2, upper curve. The current-voltage curve produced by the higher melting isomer under similar conditions was identical with that of the supporting electrolyte (lower curve) even at high galvanometer sensitivities. This proves the polarographic inactivity of the higher melting isomer and also indicates that it does not contain detectible amounts of the lower melting isomer, when prepared according to the previously reported directions [1].

EXPERIMENTS ON THE STABILITY OF THE LOWER-MELTING HYDROXYUREA IN SOLUTION

Although no quantitative information is available, the lower melting isomer is known to be relatively labile [2, 3, 4] and at the same time the polarographic method of analysis is a rather slow one, the recording of a polarographic wave requiring 2—3 minutes at least. It was therefore imperative to ensure that the error due to the drop in concentration during the time of recording did not seriously exceed the normal error in quantitative polarographic analysis.

Some important results are summarized in Fig. 1, giving the wave height against a time basis. A freshly prepared 0.01 *M* aqueous stock solution was kept at room temperature (20° ± 1°). 1 ml samples were withdrawn at intervals, mixed with 4 ml buffer solution at pH 7.2 (see the last section) and polarographed after appropriate deaeration. The experimental points (△) indicate a drop of approximately 1 % during the first hour from the preparation of the stock solution. This is within the probable error in wave heights (2—4 %).

The first analytical dilution in the above experiment was set aside at room temperature and measured from time to time, Fig. 1, □. It is seen that the stability of this 2.0 m*M* solution in buffer at pH 7.2 is very nearly the same as that of the unbuffered stock solution. Similar orienting experiments were carried out at pH 8.1 (▽) and 9.2 (+) with similar results. The deviations between these curves are probably not significant.

In strongly alkaline medium the situation is different. If a freshly prepared 2.0 m*M* solution in 0.1 *M* potassium hydroxide (pH *ca.* 13) is kept at room temperature, the wave height (Fig. 1, ○) is reduced to approximately half the initial value in the course of the first hour.

In acid solution the lower melting hydroxyurea is perfectly stable. A 10.0 m*M* solution in 0.52 *N* hydrochloric acid was stored in a closed vessel at room temperature. 0.2 ml samples were withdrawn at intervals, diluted with 5 ml buffer to give a final pH of ca. 7 and polarographed under the standard conditions specified in the last section ($s = 150$, $t = 3.2$ sec.). The results are given in Table 1, τ being the time elapsed from the dissolution of hydroxyurea in the hydrochloric acid and until the recording of the polarogram. There is no detectible drop in wave height i_d over a period of 72 hours, on the contrary there appears to be a slight increase. A satisfactory explanation of this phenomenon has not so far been found.

A rough test was made of the lability of neutral solutions at higher temperatures. 5 ml samples of a 10.0 m*M* solution in 0.5 *M* lithium chloride were exposed to heat as indicated in Table 2 and subsequently polarographed at room temperature. *H* is the wave height in arbitrary units.

Table 1.

Stability of hydroxyurea (m.p. 72°) in acidic medium

τ min.	i_d μamp.
5	3.0
13	3.0
25	3.0
37	3.0
79	3.1
96	3.1
116	3.1
153	3.1
205	3.1
280	3.1
365	3.3
4 320 (72 h)	3.2

Table 2.

Thermolability of hydroxyurea (m.p. 72° C) in aqueous solution

	H
not heated	34
heated to the boiling point, quickly cooled	32
boiled for 2 minutes	17
boiled for 5 minutes	5
boiled for 10 minutes	0

The hydroxyurea wave rapidly decreases. After 10 minutes boiling no trace of the original substance is detectible even when applying high galvanometer sensitivity.

To summarize the above results it has been shown that acidic aqueous solutions of the lower melting hydroxyurea are perfectly stable at room

temperature. In neutral and slightly alkaline, buffered and unbuffered solutions it is reasonably stable for experimental work carried out within a few hours from the dissolution, but freshly prepared solutions should always be used. Satisfactory stability was also found under conditions extant in polarographic work, *i.e.* in the presence of mercury and maximum suppressor (methylcellulose). Strongly alkaline solutions, pH > *ca.* 11, are very unstable at room temperature and at higher temperatures this also applies to neutral solutions.

The actual process responsible for the deterioration of hydroxyurea (m.p. 72° C) in neutral and alkaline solutions and the kinetics of this reaction from more exact data will be considered in a subsequent paper.

THE INFLUENCE OF THE pH ON THE WAVE OF HYDROXYUREA (m.p. 72° C)

A 10.0 m*M* solution of hydroxyurea in redistilled water was freshly prepared and kept at room temperature. 1 ml samples of this stock solution were mixed with 4 ml of buffer solution and polarographed at 25.0° C after appropriate deaeration. The general technique and the composition of the buffers are given in the last section.

The appearance of the hydroxyurea wave at various pH-values is illustrated in Fig. 2. The lower curve in each graph is that of the supporting buffer solution, polarographed under identical conditions immediately before the hydroxyurea was added. The rise of these blank curves represents the hydrogen discharge in the acidic buffers and the reduction of the supporting potassium ion in the neutral and alkaline buffers.

On the acid side the hydroxyurea wave is poorly developed, it is more or less masked by the hydrogen wave. Measurements of the independent wave can be undertaken with fair accuracy from pH 5.6 onwards, more accurately still from pH 7 and far into the alkaline region. However, in view of the notable instability of hydroxyurea in alkaline solutions, demonstrated in the preceding section, pH 7—8 should be preferred for analytical work.

It should be noted that the wave height is essentially the same over the pH-range investigated and that only one wave appears.

In neutral unbuffered solution with potassium chloride as a supporting electrolyte, last graph in Fig. 2, the wave is of a similar shape and appears to be equally reproducible.

The variation of the half wave potential $E_{0.5}$ with the pH is demonstrated in Fig. 3, curve d (the experimental data are taken from a series different from the one illustrated in Fig. 2). $E_{0.5}$ is shifted to more negative values with rising pH until at pH 5.5 it becomes constant. The implications of this result is discussed later in this paper.

THE INFLUENCE OF CONCENTRATION ON THE WAVE OF HYDROXYUREA

As a consequence of the results reported in the preceding section the buffer having pH 7.2 was chosen for a detailed investigation of the concentration influence. From a 2.0 mM stock solution in the buffer a series of dilutions were prepared as indicated in Table 3 column 2, using the buffer as a diluent. Each

* wave poorly developed.

dilution was deaerated by passing a nitrogen stream through it for 6 minutes, whilst at the same time the following dilution was being prepared and the foregoing one was being recorded. In that way the error due to the lability was reduced to a minimum. Polarogram No. 39 served as a control. It was recorded with the same cell-solution as No. 19 at the end of the series, 2 hours after the preparation of the stock solution. Comparison of the diffusion currents shows that the error due to the lability of hydroxyurea is less than 1.5 % in all the i_d-values.

The higher concentrations were investigated in a separate series, polarograms Nos. 40 to 47. The dilutions were prepared from a fresh 10.0 mM stock solution of hydroxyurea and the operations were carried out exactly as above. The last polarogram in this series was recorded less than one hour from the dissolution of the solid.

In the table s is the current multiplier, H is the wave-height actually measured at the applied galvanometer sensitivity (full sensitivity divided by s), i_d is the diffusion current calculated from the wave-height by means of the expression $i_d = Hs/300$ and $E_{0.5}$ is the half-wave potential in volts *vs* S.C.E., corrected for the iR drop across the polarographic cell, as indicated in the last section.

Apart from the most dilute solutions in which the wave was poorly developed and the experimental error abnormally large, the half-wave potential is virtually independent of concentration. The best value is probably 1.46 ± 0.02 V.

The relation between wave-height (diffusion current) and concentration is graphically represented in Fig. 4. It is perfectly linear up to 5 millimoles/l but shows a slight deviation from linearity above this concentration. The optimal concentration region for analytical work is from 0.5 to 2 millimoles/l, provided the supporting electrolyte is approximately 0.1 M. At higher concentrations the buffering capacity is inadequate, and this cannot be improved by increasing the buffer concentration because the hydrogen wave and potassium wave would then start at a more positive voltage and interfere with the hydroxyurea wave. Concentrations below 0.5 millimoles/l are inconvenient because much greater attention must then be given to the removal of oxygen from the solution.

The slope of the straight line in the optimal concentration region is 8.0. Concentrations may therefore — under standard conditions, see Fig. 4 — be calculated from the experimental diffusion currents i_d by means of the equation $i_d = 8.0\ c$, in which c is given in millimoles/l and i_d in units of microamperes (10^{-6} amp.).

Fig. 5 illustrates the variation of wave-height with concentration in unbuffered solution. 0.5 M lithium chloride was used as a supporting electrolyte. There is strict linearity over the concentration range 0.4 to 10 millimoles/l. The ordinate is the wave-height in cm for a galvanometer sensitivity reduced 1 : 30, but these data were measured some years ago with an older polarographic instrument about 20 times less sensitive, and the results are therefore not directly comparable with other ones reported in this paper. They do, however, support the view that buffering of the cell solution is not strictly necessary in analytical work with hydroxyurea in the neutral region.

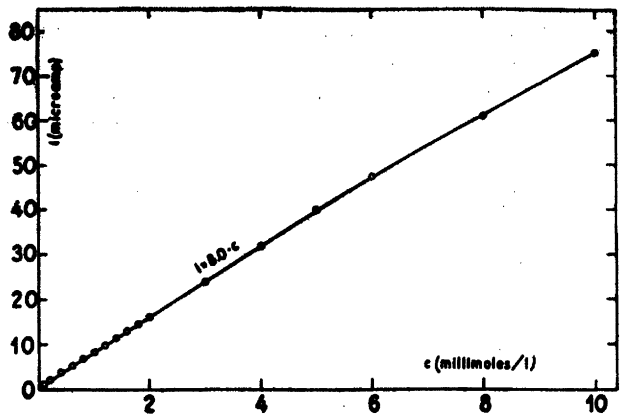

Fig. 4. Hydroxyurea, m. p. 72°. Relation of diffusion current to concentration. Supporting electrolyte 0.1 M *potassium phosphate buffer at pH 7.2. Temp. 25.0° C, drop time* t = *3.33 sec, height of mercury column* h = *45 cm, rate of mercury outflow* m = *2.66 mgsec*$^{-1}$.

THE ELECTRODE PROCESS

The conventional logarithmic analysis of the current-voltage curve of the lower melting hydroxyurea clearly indicates an irreversible electrode process. The general equation of a wave due to a cathodic, *reversible* electrode reaction in a well buffered solution is [6]

$$E = E_{0.5} - \frac{0.0591}{n} \log \frac{i}{i_d - i}$$

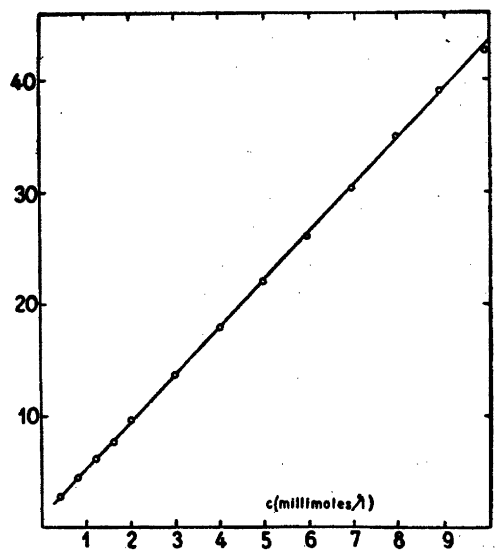

Fig. 5. Hydroxyurea, m. p. 72°. Relation of diffusion current to concentration. Supporting electrolyte 0.5 N *lithium chloride. 20° C.*

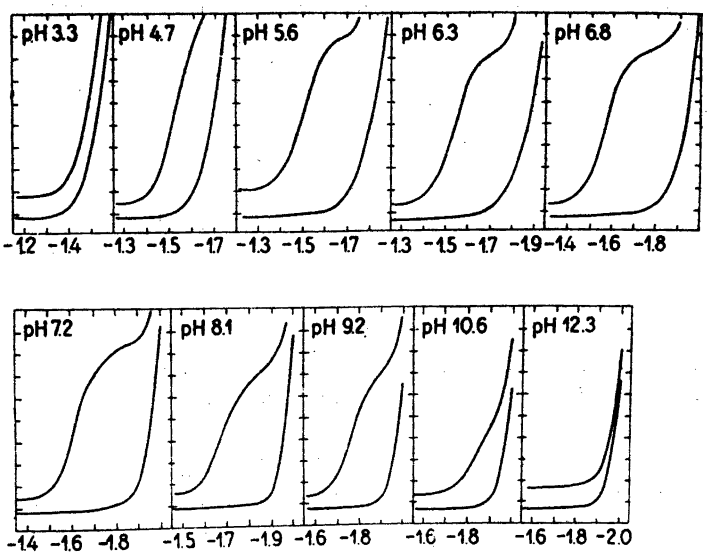

Fig. 6. Polarographic wave of hydroxylammonium chloride at various pH values. 2.0 mM *solutions in buffers approximately 0.1* N *in potassium ion (upper curve). Blank polarograms of the supporting buffers (lower curve). Units and experimental conditions as in Fig. 2.*

i being the diffusion current at any time during the reduction, i_d the limiting diffusion current and n the number of electrons. It follows that a plot of log $\frac{i}{i_d - i}$ against the potential E of the dropping electrode should be linear.

Since n has been estimated to 2 (see below) the theoretical slope would be approximately —30 mV. The actual plot (Fig. 2, last graph) is not linear and the slope in the half-wave point is approximately —190 mV, and thus considerably at variance with the theoretical value. This indicates the irreproducibility of the process.

Since the diffusion coefficient of the lower-melting hydroxyurea is unknown, the number of electrons involved in the cathodic reduction can only be estimated by comparison of the wave height with that produced by some suitable substance, for which the electrode process is established. Hydroxylammonium chloride was chosen for this purpose, firstly because it has a similar molecular size, secondly because it is one of the starting materials in the preparation [1] of hydroxyurea and hence may possibly occur as an impurity, and thirdly because a comparison with the hydroxylammonium wave might provide additional evidence as to whether the lower-melting hydroxyurea is identical with hydroxylammonium cyanate or not.

Although some previous information on the polarographic behaviour of hydroxylammonium chloride is available [5] it was deemed necessary to reinvestigate the substance under conditions strictly identical with those applied to hydroxyurea in Fig. 2.

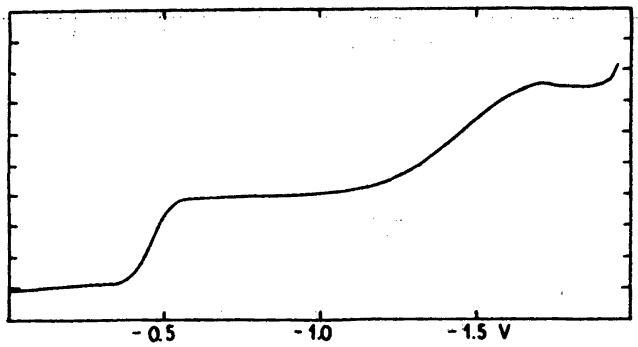

Fig. 7. Polarogram of a solution 1.0 mM *in hydroxyurea, 1.0* mM *in thallous ion and 0.1* M *in potassium chloride. 0.02 % methylcellulose added as a maximum suppressor.*

Freshly prepared 2.0 m*M* solutions of hydroxylammonium chloride in a series of buffers (*cf.* p. 469) were polarographed with the standard technique described in the last section. The results, which on the whole confirm those of Petru [5], are reproduced in Fig. 6. There is a relatively well developed wave in the pH-range from about 6 to 7; in acid solution the wave is masked by the hydrogen wave, in alkaline medium the wave due to the discharge of the supporting potassium ion interferes, in contradistinction to the hydroxyurea wave, which is independently developed far into the alkaline region (*cf.* Fig. 2). In neutral solution, where the wave is well developed, its height is very nearly identical with that of the hydroxyurea wave under equal conditions, *cf.* Fig. 2. Since, according to Petru [5] hydroxylamine is reduced by a two-electron process, it is a reasonable assumption that the cathodic reduction of hydroxyurea also involves two electrons per molecule and this seems to apply over the entire pH-range investigated.

A calculation of n from the Ilkovic equation, using an estimated value of the diffusion coefficient also gave a result close to 2. From polarogram No. 43 (Table 3) the following set of experimental data were drawn; diffusion current $i_d = 40.0$ microamperes, concentration $c = 5.0$ millimoles/l, mercury flow rate $m = 2.66$ mg/sec and drop time $t = 3.33$ sec, temperature 25° C. By inserting these figures in the Ilkovic equation $i_d = 607 \cdot n \cdot D^{1/2} \cdot c \cdot m^{2/3} \cdot t^{1/6}$ we get at 25° C $nD^{1/2} = 0.0056$. The diffusion coefficient D of most organic compounds is of the order of magnitude 1×10^{-5} cm^2 sec^{-1} which gives a value $n = 1.75$.

Finally the wave height of hydroxyurea has been compared with that produced by thallous ion, which is known to react according to a one-electron process. Fig. 7 shows a polarogram of a solution containing equimolar amounts of hydroxyurea and thallous ion. The limiting diffusion currents are 8.4 and 6.3 microamperes, respectively. Since the two species are polarographed under strictly identical conditions we get from the Ilkovic equation

$$\frac{(i_d)_{hy}}{(i_d)_{Tl^+}} = \frac{n_{hy} D_{hy}^{1/2}}{n_{Tl^+} D_{Tl^+}^{1/2}}$$

the index hy standing for hydroxyurea. The diffusion coefficient of thallous ion is $D_{Tl^+} = 2 \times 10^{-5}$ cm^2 sec^{-1}. Introducing this, as well as $n = 1$, the above experimental diffusion currents and the assumed diffusion coefficient $D_{hy} = 1 \times 10^{-5}$ cm^2 sec^{-1} we get $n_{hy} = 1.7$. There seems to be every reason to believe, therefore, that the reduction of hydroxyurea, m.p. 72°, involves two electrons per molecule.

In the dependency of the half wave potential upon the pH hydroxylamine and hydroxyurea show a remarkable difference (Fig. 3, b and d). Whereas $E_{0.5}$ of the former is strongly dependent upon the pH in the region pH 5—10 that of the latter is constant in the same region. The $E_{0.5}$ values for hydroxylamine are somewhat larger than those reported by Petru [5] (Fig. 3 c) but it should be remembered that the absolute values can only be roughly estimated because the wave is more or less masked by the hydrogen wave in all the buffer solutions.

For hydroxyurea the relation between the half-wave potential and the pH has the form of two straight lines intersecting at pH 5.5. The linear dependency in acid solution is substantiated by supplementary measurements (e) of the tangent potential (45°) (Ref.[6], p. 623) in strongly acidic medium, where the half-wave potential cannot be determined with any great accuracy. The general relation between $E_{0.5}$ and pH for a *reversible* reduction $R + nH^+ + ne^- \rightleftharpoons RH_n$ is given by [6]

$$E_{0.5} = E^\circ_{0.5} - \frac{0.0591}{n} \log \frac{k_R}{k_{RH_n}} - 0.0591 \text{ pH} \qquad (1)$$

in which $E^\circ_{0.5}$ is the standard potential of the reaction and k a constant characteristic of the species. The second term on the right is usually negligibly small. It follows that the theoretical shift of the half-wave potential due to one pH-unit is —59 millivolts for the above *reversible* reaction. The acidic branch of the curve Fig. 3 d is strictly linear as required, but its slope is —87 millivolts.

The slope —87 millivolts is so close to the average slope found for the discharge of the hydrogen ion (Ref.[12], p. 123; *cf.* Fig. 3 a) that the possibility should be considered whether the hydroxyurea wave in acid medium be due to hydrogen discharge from the hydroxyuronium ion functioning as a weak acid, the discharge for some reason taking place slightly before the hydrogen wave of the buffer starts. This explanation is, however, unlikely, because the hydrogen wave is much higher than that due to normal organic compounds. Consequently a considerable change in wave height should have been observed for hydroxyurea when shifting from acid to alkaline medium. As reported above (*cf.* Fig. 2) no such change was observed, the wave height is constant over the entire pH-range.

The deviation of the slope from the theoretical value may then be explained either as a result of the irreproducibility of the process or by assuming an anomalous number of hydrogen ions to take part in the electrode process [12]. Equation (1) is valid only for a process involving the same number (usually $n = 2$) of electrons and hydrogen ions. If the numbers were n and m respectively, the constant in the last term in eq. 1 would be $\frac{m}{n}$ (—59) mV. It is seen that

an electrode process involving two electrons and three hydrogen ions per molecule

$$R + 2e^- + 3H^+ \rightarrow RH_3^+ \qquad (2)$$

would give a shift of $3/2 \cdot (-59) = -88$ mV in close agreement with the experimental value.

In neutral and alkaline solution the half-wave potential of hydroxyurea is completely independent of the pH. The distinct break at pH 5.5 suggests that hydroxyurea is reduced at the dropping mercury-electrode by two distinctly different mechanisms. A pH-dependent one, in which hydrogen ions take part in the potential-determining step, operates in acid solution. As the hydrogen ion activity decreases, the reduction by this mechanism finally becomes so difficult (*cf.* the rising $E_{0.5}$) that a different, pH-*in*dependent mechanism is favoured. That hydrogen ions do not take part in the second mechanism seems to be substantiated by the fact that hydroxyurea produces a well-defined wave of exactly the same height in neutral *unbuffered* solutions (*cf.* Fig. 2, last graph) in distinct contrast to hydroxylamine, which gives ill-defined double waves under such conditions, as expected with the mechanism suggested by Petru [5] involving hydrogen ions. It is quite certain, therefore, that in neutral and alkaline medium hydroxyurea and hydroxylamine are reduced by entirely different mechanisms and the question as to whether the lower-melting hydroxyurea is simply hydroxylammonium cyanate has at the same time received a clear negative answer. Whether the pH-dependent mechanisms are of a similar type remains to be settled.

The regions of pH-dependency fall in the vicinity of the dissociation constants, $pK_a = 8.0$ for hydroxylammonium ion [10] and ca. 2.3 for the hydroxyuronium ion [11]. It seems probable that the species, which is reduced at the dropping electrode in the case of hydroxyurea is the uncharged basic molecule (B) in neutral and alkaline medium and the conjugate acid, hydroxyuronium ion (BH^+) in acid solution. The fact that only a single wave of constant height is obtained over the whole pH-range indicates that the protolytic reaction $BH^+ \rightleftharpoons B + H^+$ proceeds with infinite velocity (*cf.* Ref.[7]) so that the hydroxyuronium ions consumed by the electrode process are immediately replaced by newly formed ones. Under these circumstances (*cf.* Ref.[8]) no separate reduction of the basic form takes place until at about pH 5.5 the pH-dependent mechanism has become so difficult that the pH-*in*dependent reduction of the uncharged molecule, taking place at a slightly more negative potential, is favoured. As a result of these combined mechanisms the limiting current (wave height) would be independent of pH and proportional to the total analytical concentration of hydroxyurea, as indeed we find.

The possibilities that the limiting current is either kinetically controlled or of a catalytic nature have been ruled out since the relation $i_d = k \cdot h^{1/2}$ (Ref.[6], p. 85) characteristic of a purely diffusion-controlled current has been found to hold for hydroxyurea. Table 4 contains the experimental material. h_{corr} is the height of the mercury column, corrected for the back-pressure $-\frac{3.1}{(mt)^{1/3}}$ due to interfacial tension (Ref.[6], p. 79) which for the employed capillary ($mt = 7.68$ mg) amounted to -1.6 cm Hg.

Table 4. Variation of i_d *with the height* $h_{corr.}$ *of the mercury column. 2.0* mM *hydroxyurea in 0.1* N *potassium chloride, 0.02* % *methylcellulose.*

$h_{corr.}$ cm	t sec	i_d μamp	$i_d / h_{corr}^{1/2}$
28.4	3.7	14.5	2.72
38.4	2.8	16.6	2.68
43.4	2.5	17.8	2.70
48.4	2.2	18.7	2.69
58.4	1.9	20.3	2.67
68.4	1.6	22.0	2.66

The values in the last column are virtually constant. The apparent decrease is due partly to the approximative nature of the equation $i_d = k \cdot h^{1/2}$ (Ref.[5], p. 85) and partly to the lability of the substance in aqueous solution. The last polarogram in Table 4 was recorded 1 ½ hour after the first one. According to previous results a drop of 1—2 % in the "constant" is to be expected in this period, due to the lability of hydroxyurea. Much larger deviations in $i_d/h_{corr}^{1/2}$ would have been found if the limiting current were kinetically controlled. Frequently the current is quite independent of the height of the mercury column (Ref.[5], p. 274). Adsorption waves usually show a linear relationship between the limiting current and h.

No attempt will be made at the present time to formulate definite electrode processes. When dealing with irreversible reductions of organic molecules this cannot normally be achieved on the basis of polarographic data alone.

It seems likely, however, that urea must be taken into account as a possible reduction product. This would be compatible with a two-electron process and, since urea has been found to be inactive towards the dropping mercury electrode, also with the apparent irreversibility of the electrode process. It should be added that the reaction scheme (2), p. 466, must be discarded, if the reduction product is shown to to be urea, because this substance is a *weaker* base than hydroxyurea, whereas the hypothetical process

$$O = C\begin{matrix}\diagup NHOH \\ \diagdown NH_2\end{matrix} + 2e^- + 3H^+ \rightarrow O = C\begin{matrix}\diagup NH_3^+ \\ \diagdown NH_2\end{matrix} + H_2O$$

corresponding to (2), requires that the reduction product be a stronger base than hydroxyurea. Isolation of urea from a large scale controlled-potential electrolysis is being attempted.

The higher-melting hydroxyurea (140°) produces neither a cathodic nor an anodic wave in the usual voltage region + 0.2 to —2.0 V *vs* S.C.E. It may be assumed that a much more negative potential is required for the reduction of the higher melting isomer; this would be parallelled by the greater robustness of that isomer. Alternatively the reducible group in the lower melting isomer may be absent in the higher melting one.

Methoxyurea, which only exists in one form, is not reduced at the dropping mercury electrode. This is compatible with the view that the —NHOH group is engaged in the polarographic reduction of the lower melting isomer.

MATERIALS, APPARATUS, AND GENERAL TECHNIQUE

The preparation and characterization of the isomeric hydroxyureas have been reported in a previous paper [1].

The lower melting hydroxyurea was stored at 0° C in a dry atmosphere, and all measurements reported in this paper were carried out within 2 weeks from the preparation. Comparison of the wave-height produced under standard conditions at various instants indicated a satisfactory stability under these circumstances.

Hydroxylammonium chloride as well as all chemicals used for the preparation of the supporting solutions were analytical grade products. The solvent was water, carefully redistilled in a Pyrex apparatus. The composition of the various stock solutions used for preparing the buffers are indicated in Table 5.

Table 5. Composition of buffer stock-solutions.

A	1 *M* phosphoric acid 1 *M* potassium chloride
B	1 *M* citric acid 1 *M* potassium chloride
C	1 *M* acetic acid 1 *M* potassium chloride
D	1 *M* potassium hydrogen carbonate
E	1 *M* boric acid 1 *M* potassium chloride
F	1 *M* potassium di-hydrogen phosphate
G	1 *M* potassium mono-hydrogen phosphate
H	1 *M* potassium di-hydrogen borate
I	1 *M* potassium hydroxide

The set of stock solutions used for each individual buffer is indicated in Table 6. Appropriate volumes were mixed and diluted to the tenfold volume with water containing 0.05 % methylcellulose as a maximum suppressor. In most experiments 4 to 4.5 ml of the buffer were mixed with 1 to 0.5 ml of a stock solution of the depolarizer, so that the final volume of cell solution was 5 ml, and the final concentration of potassium ion was approximately 0.1 to 0.2 *M*. By employing a relatively large number of buffer types (Table 6, col. 4) and using each system only in the immediate neighbourhood of the relevant p*K*-value a sufficient buffer capacity was secured in all solutions. This is a point of great importance often neglected in polarographic work [9]. The final pH of each cell-solution was measured after the polarographic recording by means of a "Radiometer" pH-meter, type PHM 221, against a standard phosphate buffer of pH 6.78.

The polarographic cell was a cylindrical glass tube, 17 by 50 mm, fitting into a brass water-jacket through which water at 25.0 ± 0.1 was circulated from a Höppler ultra-thermostat. The anode was a saturated potassium chloride-calomel electrode with a saturated potassium chloride liquid junction. Unless otherwise stated the capillary characteristics of the dropping mercury electrode were as follows, height of mercury column h = 45 cm, rate of mercury outflow into distilled water m = 2.66 mg sec^{-1}, drop time 3.0 to 3.3 sec.

Table 6.

Final pH	Stock solutions		Buffer type
	acid	base	
1.0	A	F	phosphate
1.6	A	F	
2.2	A	F	
2.4	A	F	
2.9	B	I	citrate
3.6	B	I	
4.0	C	I	acetate
4.7	C	I	
5.6	F	G	phosphate
6.3	F	G	
6.8	F	G	
7.2	F	G	
8.1	F	G	
9.2	E	H	borate
9.7	D	I	carbonate
10.5	D	I	
11.9	G	I	phosphate

Oxygen was removed from the cell-solution prior to any polarographic recording by passing a stream of oxygen-free nitrogen through the cell. 6 to 10 minutes were required to reduce the oxygen wave to a negligible height, depending upon the applied galvanometer sensitivity. The absence of the oxygen wave and of waves due to other impurities was checked by running a blank polarogram of the supporting electrolyte solution before the addition of the depolarizer.

The polarographic instrument was a "Radiometer" PO 3e. The voltage scale was checked against thallous ion, the half-wave potential of which was taken as -0.46 V *vs* S.C.E. Half-wave potentials were corrected for the iR-drop across the cell, when necessary. The resistance of the polarographic cell under average experimental conditions was determined by measurement of a series of widely different concentrations of thallous ion. The plot of the apparent half-wave potentials against the diffusion current in the half-wave point was linear with the slope $\triangle E_{0.5} / \triangle i_{0.5} = 2.0 \times 10^3$, which is equal to R. The correction thus amounts to $+0.002\ i_{0.5}$ volts, $i_{0.5}$ being in units of microamperes. It is seen that the correction is significant only for diffusion currents $i_d > 20$ microamperes ($i_{0.5} > 10$), since the probable error in polarographic half-wave potentials with the employed technique is estimated to $\pm$ 0.02 V.

The full galvanometer sensitivity was maintained at a constant value of 7.8 cm deflection for a current of 2.6×10^{-8} amperes by frequent adjustment. In most measurements this sensitivity was reduced to 1/300 to 1/500 (current multiplyer s = 300 to 500). The diffusion currents i_d were calculated from $i_d = H \cdot s/300$, H being the wave height in cm and i_d the current in microamperes (10^{-6} amperes). The wave-height H was measured as the vertical distance between the tangent intersection points and has thus been corrected for the residual current.

ACTA CHEMICA SCANDINAVICA 9 (1955) 471—474

On the Thermal Decomposition of Molybdenum Trioxide *in vacuo*

LARS KIHLBORG and ARNE MAGNÉLI

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

When heated in evacuated, sealed silica tubes at temperatures between 550° and 800° C molybdenum trioxide has been found to undergo partial decomposition forming various lower molybdenum oxides. Among the latter are two previously unknown compounds, ζ- and η-molybdenum oxide, which have been characterized by their X-ray powder patterns.

In connection with studies on various molybdenum oxides carried out at this Institute it was observed that molybdenum trioxide decomposes when heated in evacuated, sealed silica tubes at red heat. After the heat treatment the trioxide crystals were slightly contaminated by dark blue or bluish-violet particles. Previous authors have also reported that molybdenum trioxide is unstable at reduced pressures of oxygen. Thus Nydahl [1] observed that molybdenum trioxide, when sublimed in a stream of air at about 800° C, gives partly reduced bluish products, while preparations obtained at the same temperature by sublimation in oxygen are colourless or faintly yellow. Decomposition of molybdenum trioxide in the electron microscope has been reported by König [2,3], who observed the formation of dioxide during this process, and by Glemser and Lutz [4], who found the decomposition products to contain the oxides Mo_4O_{11}, Mo_8O_{23}, Mo_9O_{26}, and probably MoO_2. Studies on the thermal decomposition of tungsten trioxide have previously been carried out at this Institute [5].

In order to make sure that no reducing material was present, our experiments were carried out using molybdenum trioxide which had been sublimed in a stream of oxygen at about 800° C*. The heat treatment was performed in silica tubes which had been preheated in a stream of oxygen for several hours at 900° C. The reaction tubes containing the molybdenum trioxide samples were evacuated by means of a rotary oil pump, a cold trap with liquid air being attached to the pump, and sealed in a gas oxygen flame.

* A finely ground specimen of this preparation was found to have grown appreciably darker than a freshly powdered sample after preservation for a few months in a covered weighing bottle kept in the laboratory.

The heat treatment was carried out in an electric furnace. In order to reduce the temperature gradient within the reaction tubes they were kept in holes bored in a heavy cylindrical block of fire-resisting steel. This block was covered with a steel lid and vertically inserted in the furnace. A platinum-platinum rhodium thermocouple was introduced in one of the holes of the cylinder through a narrow opening in the lid. The variation of the temperature during an experiment did not exceed $\pm$ 5° C. The samples were quenched in water from the reaction temperature.

The preparations were investigated under the microscope. Concentrated samples of the reduced material were obtained by picking out the dark particles. The phases forming relatively large crystals, *viz.* Mo_8O_{23} and Mo_9O_{26}, were readily isolated in this way, while the enrichment of those occurring in very small crystals offered some difficulties. Attempts to perform the separation of the phases chemically, *e.g.* by means of ammonia, were less successful. The various phases were identified by means of X-ray powder photographs taken in a Guinier focusing camera using Cu-$K\alpha$ radiation. Sodium chloride was always added to the powder specimens as an internal standard ($a_{NaCl} = 5.6398$ Å). A survey of the results of the phase analyses of several preparations is given in Table 1.

Table 1. Phase analysis of preparations obtained by heating molybdenum trioxide in evacuated, sealed silica tubes.

Heating temperature	Heating time	Phases identified by microscopical examination	Phases identified by powder photographs
549° C	87 hours	MoO_3 crystals + small amount of irregular bluish-black aggregates, consisting of extremely thin, fragile plates	MoO_3 + η-oxide
608° C	46 hours	MoO_3 crystals + aggregates of dark crystals	MoO_3 + η-oxide
650° C	44 hours	MoO_3 crystals + prismatic, blue-violet crystals or crystal aggregates of high brilliance	MoO_3 + Mo_8O_{23}
700° C	46 hours	—"— —"— —"—	MoO_3 + Mo_8O_{23}
722° C	42 hours	—"— —"— —"—	MoO_3 + Mo_9O_{26}
803° C	42 hours	Highly discoloured, greyish-black MoO_3. (An extremely small amount of a bluish-black phase isolated by treatment with ammonia)	MoO_3

In all cases the quantity of reduced material in the samples was very small in comparison with the amount of undecomposed trioxide, but generally seemed to increase with increasing heating temperature as long as the melting point of the preparations was not exceeded. The main portion of the reduced substance generally appeared in the top layer of the trioxide samples.

After heating at high temperatures (below the melting temperature) the molybdenum trioxide appeared in discoloured, greyish-blue or green crystals which, however, gave powder patterns very similar to those obtained from trioxide crystals of normal appearance. Thus only some minor variations of the intensities of the lines could be observed which may be attributed to

Table 2. Powder pattern of ζ-molybdenum oxide. ($MoO_{2.88}$ heated at about 600° C for 2 days.)

orientation effects. At present it is not possible to conclude whether the reason for this change of colour is the existence of an extended homogeneity range of the trioxide structure or the formation of another phase (*cf.* the discussion of the thermal decomposition of tungsten trioxide [5]).

Samples heated above the melting temperature formed a greyish-black mass from which it was not possible to separate the constituents by picking out crystals. By treating with dilute ammonia the molybdenum trioxide was dissolved, leaving an extremely small residue of a bluish-black substance. However, the quantity of this material was too small to allow a powder photograph to be taken.

In spite of the care given to the experimental conditions it was very difficult to obtain reproducible results in some cases. Thus some of the preparations obtained definitely did not correspond to a state of equilibrium. A sample heated at 680° C for 72 hours was found to contain MoO_3, Mo_8O_{23} and another oxide phase (ζ-molybdenum oxide) which has also been prepared by heating a mixture of molybdenum and molybdenum trioxide of the gross composition $MoO_{2.88}$ at about 600° C *in vacuo*. In a molybdenum trioxide sample heated at 753° C for 45 hours Mo_9O_{26} as well as Mo_4O_{11} could be identified in the powder

Table 3. Powder pattern of η-molybdenum oxide, obtained by heating molybdenum trioxide in vacuo at 608° C.

patterns in addition to the trioxide. Similar difficulties in reaching a state of equilibrium have also been observed previously in connection with attempts to prepare the oxides Mo_8O_{23} and Mo_9O_{26} in a pure state by heating molybdenum metal and trioxide *in vacuo*[6]. Due to the difficulties in performing the phase analyses it cannot at present be definitely concluded whether or not the samples listed in Table 1 correspond to states of equilibrium.

However, the experiments show that molybdenum trioxide undergoes a partial decomposition under the conditions applied. As the presence of reducing material was carefully avoided it seems most likely that the trioxide is unstable in the temperature interval 550°—800° C at a reduced pressure of oxygen. Two previously unknown molybdenum oxides have been observed during the experiments and preliminarily designated with the symbols ζ-molybdenum oxide and η-molybdenum oxide. Powder patterns which are likely to represent fairly pure samples of these two oxides are listed in Table 2 and 3. These serve to complement the powder data on molybdenum oxides previously reported from this Institute[7].

The molybdenum oxides known at present are thus MoO_3[8–10], Mo_9O_{26}[11], Mo_8O_{23}[11], Mo_4O_{11}[12], MoO_2[13], and Mo_3O[14], the crystal structures of which have been determined, and the ε-[5], ζ-, and η-oxides of unknown compositions and structures. Further studies on the molybdenum-oxygen system are in progress.

This investigation forms part of a research program on oxides and oxide systems financially supported by the *Swedish Natural Science Research Council.*

Reaction of Furfuryl Alcohol, Furfuryl Methyl Ether and 2,5-Dimethoxy-2,5-dihydrosilvan with Methanolic Hydrogen Chloride

NIELS CLAUSON-KAAS and JØRGEN TORMOD NIELSEN

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

The products formed by interaction of methanolic hydrogen chloride and furfuryl alcohol, furfuryl methyl ether and 2,5-dimethoxy-2,5-dihydrosilvan, respectively, have been analyzed by fractional distillation. Four new compounds, *viz.* 2,3 (or 4), 5-trimethoxytetrahydrosilvan, methyl levulinate dimethyl ketal, α(or β)-methoxylevulinaldehyde dimethyl acetal and 1,1,2 (or 3), 4,4-pentamethoxypentane were identified and at least three unknown compounds were shown to be present. Earlier experiments in this field, in particular by Pummerer *et al.*, *Ber.* **56** (1923) 999; **68** (1935) 480, are discussed.

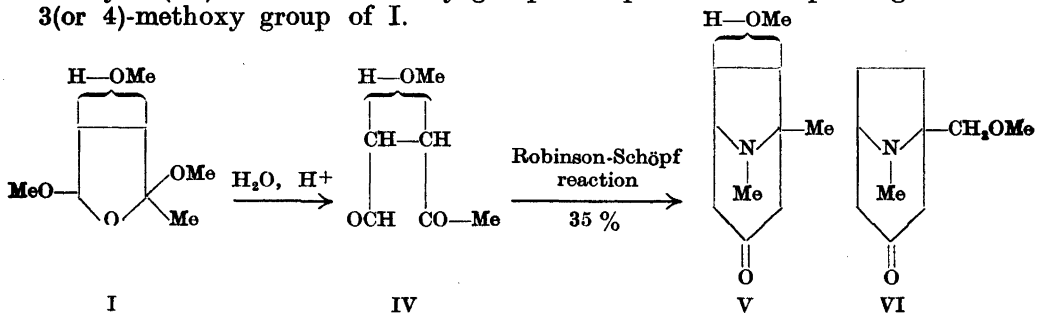
By heating furfuryl alcohol, furfuryl methyl ether and 2,5-dimethoxy-2,5-dihydrosilvan, respectively, under reflux with methanolic hydrogen chloride, distillable mixtures of liquid compounds were obtained and separated by fractional distillation under 21 mm through a 25 cm column (distillation time 8—10 days). The results of the distillations are shown in Fig. 1. The fractions were mainly identified by measuring the refractive index and the infrared absorption, and by analyses. Three new compounds, *viz.* 2,3 (or 4),5-trimethoxytetrahydrosilvan (I), methyl levulinate dimethyl ketal (II) and α(or β)-methoxylevulinaldehyde dimethyl acetal (III) were identified, and at least 3 unknown compounds were shown to be present. The yields of the various compounds are given in Table 1.

I is stable towards alkali and shows no absorption band around 5.8 mμ. Hydrolysis with 0.025 *N* hydrochloric acid gives a reaction product, which condenses with methylamine and acetonedicarboxylic acid (Robinson-Schöpf reaction) to a tropinone $C_9H_{14}ON(OMe)$, which is different from the known 1-methoxymethyltropinone (VI) and therefore is 1-methyl-6(or 7)-methoxytropinone (V). From this, and from the fact that I not only is formed from furfuryl alcohol and furfuryl methyl ether, but also from dimethoxydihydrosilvan, it is inferred that the compound is either a 2,3,5- or a 2,4,5-trimethoxy-

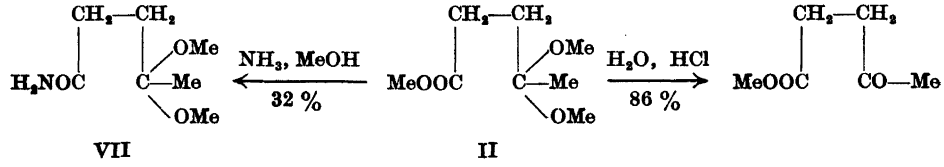
Table 1. Yields of compounds present in the reaction mixtures prepared from furfuryl alcohol, furfuryl methyl ether and dimethoxydihydrosilvan.

Compound	Yield, % based upon			Yield, % of distillable product from		
	Furfuryl alcohol	Furfuryl methyl ether	Dimeth-oxy-dihydro-silvan	Furfuryl alcohol	Furfuryl methyl ether	Dimeth-oxy-dihydro-silvan
I. [2,3 (or 4), 5-Tri-methoxytetrahydro-silvan]	3.0	1.8	2.8	7	5	4
Methyl levulinate	27.7	11.2	15.2	65	32	22
II. (Methyl levulinate dimethyl ketal)	1.2	15.3	33.8	3	44	49
III. [α (or β)-Methoxy-levulinaldehyde dimethyl acetal]	10.1	0.0	0.0	24	0	0
Unknown compounds	0.3	6.2	17.3	1	18	25
Total yield of distillable compounds	42.3	34.5	69.1	100	100	100

tetrahydrosilvan and that the product of hydrolysis is α- or β-methoxylevulinaldehyde (IV) with the methoxy group in a position corresponding to the 3(or 4)-methoxy group of I.



II is transformed into methyl levulinate by heating under reflux with methanolic hydrogen chloride containing 1.07 mole of water. Reaction with ammonia gives a crystalline compound with the formula $C_5H_9ON(OMe)_2$. From this it is inferred that II is methyl levulinate dimethyl ketal and that the nitrogen containing compound is the corresponding amide (VII).



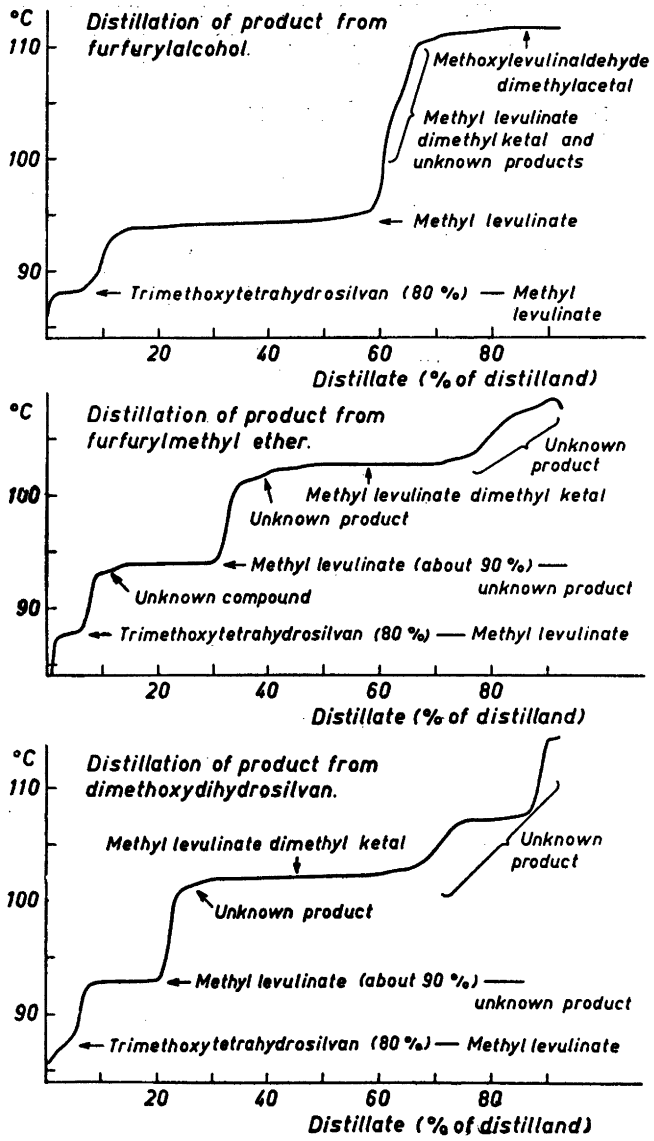


Fig. 1. Curves for the distillations of the reaction mixtures prepared from furfuryl alcohol, furfuryl methyl ether and dimethoxydihydrosilvan.

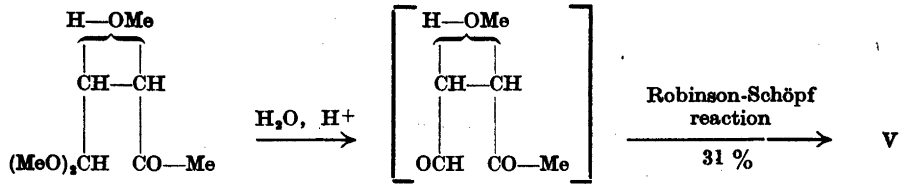
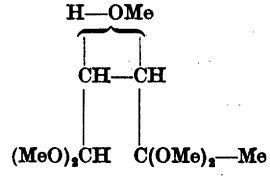
III is unstable towards alkali. Hydrolysis with hydrochloric acid and condensation of the reaction product with methylamine and acetonedicarboxylic acid give a tropinone, which is identical with V. From this it is inferred that the product of hydrolysis is either α- or β-methoxylevulinaldehyde (IV)

and that III is α- or β-methoxylevulinaldehyde dimethyl acetal with the methoxy group in a position corresponding to the position of the 3(or 4)-methoxy group of I.



III IV

The percentage of unknown compounds in the distillate from furfuryl alcohol is small compared to the percentage in the distillates from furfuryl methyl ether and dimethoxydihydrosilvan, respectively. As about 4 % (by weight) of methanol is slowly split off during the distillation of the reaction products from furfuryl methyl ether and dimethoxydihydrosilvan we assumed that a number of the unknown compounds are formed from 1,1,2(or 3),4,4-pentamethoxypentane (VIII) by loss of one or two moles of methanol.



VIII

In order to test this hypothesis, the reaction mixture from furfuryl methyl ether was heated under reflux with a solution of potassium hydroxide in methanol. This should remove all esters and all compounds containing free carbonyl groups. The resulting product was then distilled rapidly under 12 mm through a 12 cm column (distillation time 12 hours). The result of the distillation is shown in Fig. 2 and the yields of the products, based upon furfuryl methyl ether, are given in Table 2.

VIII is stable towards alkali and shows no absorption band around 5.8 mμ. Acid hydrolysis followed by a Robinson-Schöpf reaction gives the tropinone V.

Table 2. Yields of alkali-resistant compounds from furfuryl methyl ether.

Compound	Yield, % based upon furfuryl methyl ether
2,3 (or 4)-Trimethoxytetrahydrosilvan (I)	1.1
Unknown compounds	about 2.5
1,1,2 (or 3), 4,4-Pentamethoxypentane (VIII)	0.7

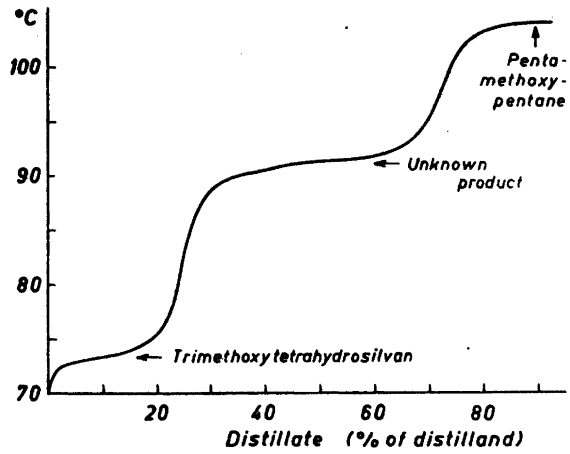


Fig. 2. Curve for the distillation of alkali-treated reaction product from furfuryl methyl ether.

From this it is inferred that the product of hydrolysis is α- or β-methoxylevulinaldehyde (IV) and that VIII is 1,1,2 (or 3),4,4-pentamethoxypentane with the 2(or 3)-methoxy group in a position corresponding to the position of the 3(or 4)-methoxy group of I.

Although the pentamethoxypentane VIII has thus been isolated, the yield is much lower than the yields of unknown compounds from the distillations of the reaction mixtures from furfuryl methyl ether and dimethoxydihydrosilvan. However, we still think that VIII is the progenitor of the major portion of the unknown compounds and that the yield of VIII in the isolation experiment is low, because most of the compound has been hydrolyzed or transformed in other ways during the alkaline treatment and the isolation.

The formation of acetals of α(or β)-methoxylevulinaldehyde (IV) in the reaction of dimethoxydihydrosilvan with methanolic hydrogen chloride is just another example of the known addition of an alcohol to the 3,4-double bond of 2,5-dimethoxy-2,5-dihydrofurans by the action of the alcohol and a catalytic amount of a strong acid [1]. The formation of derivatives of IV from furfuryl alcohol and furfuryl methyl ether may, on the other hand, be taken as proof of the initial formation of dimethoxydihydrosilvan or its equivalent during the fission of furfuryl alcohol and furfuryl methyl ether, respectively. This is consistent with experiments with similar compounds as well as with theoretical considerations [2, 3, 4].

The distillable reaction product from furfuryl methyl ether has by and large the same composition as the product from dimethoxydihydrosilvan. The composition of the product from furfuryl alcohol is somewhat different, but this becomes understandable if one takes into account that in any reaction between furfuryl alcohol and methanol there is an excess of one mole of water over similar reactions with furfuryl methyl ether and dimethoxydihydrosilvan, respectively.

In spite of the similarity in composition, the yield of distillable product from dimethoxydihydrosilvan is almost twice as large as from furfuryl alcohol and furfuryl methyl ether, respectively. This can be understood by assuming that the fission reactions of furfuryl alcohol and furfuryl methyl ether to distillable products compete with other reactions leading to non-distillable products (polymerisation reactions), while the reactions of all the compounds roughly speaking follow the same path after the furans have been rearranged to dimethoxydihydrosilvan or its equivalent.

Pummerer *et al.*[5,6] (*cf.* also [7]) have previously investigated the action of methanolic hydrogen chloride on furfuryl alcohol and furfuryl methyl ether and the reaction conditions given by these authors have been followed here. From the reaction product from furfuryl alcohol they isolated 2 % of impure methyl levulinate and 19 % of a product, which, judging from their experimental data, was a mixture of two or more compounds, but which was claimed to be 5-methoxylevulinaldehyde dimethyl acetal.

The correctness of the experimental data of Pummerer *et al.*, as well as the deductions based thereon, have previously been questioned [2,3]. The experiments presented here are on the whole consistent with the main findings of Pummerer *et al.* (*cf.* also [7]), but their claim to have identified 5-methoxylevulinaldehyde, as well as all deductions based on this claim [5-8], cannot be accepted.

EXPERIMENTAL

Microanalyses by Ernst Boss and Kirsten Glens

Reaction of furfuryl alcohol with methanolic hydrogen choride (*cf.*[5,6]). Furfuryl alcohol (161 g, 1.64 mole), methanol (dried with magnesium, 1840 ml) and acetyl chloride (17.0 ml) were mixed and heated under reflux (3 h) [6]. After cooling a solution of sodium methoxide [from sodium (5.70 g) and methanol (70 ml)] was added and the mixture brought to pH 7 (test with wet indicator paper) by addition of small amounts of glacial acetic acid or sodium methoxide. The methanol was evaporated in a vacuum from a water-bath, a precipitate removed by filtration and washed with ether, and the filtrate distilled. The yield was 110.8 g of a slightly yellow liquid ($b.p._{0.3}$ 43—75°).

110.3 g of this product was fractionally distilled through a 25 cm packed column [9] into 26 fractions of approximately the same size (distillation pressure 21 mm, heat input 3.7 watt, take-off every 6.9 minutes, change of fraction every 8 hours, total distillation time 9 days) (Fig. 1). The refractive index and the infrared absorption of all fractions were measured. The yield of distillate was 102.7 g (93 % of distilland).

(a) The distillate boiling at about 88° (n_D^{25} 1.4235) (2.48 g) was heated under reflux (40 min) with sodium hydroxide (8 %, 10 ml) and the reaction mixture continuously extracted with ether. Distillation of the etheral extract gave 1.61 g of 2,3(or 4),5-trimethoxytetrahydrosilvan (I) (colorless liquid, $b.p._{10}$ 75°, n_D^{25} 1.4239). The compound showed no absorption band around 5.8 mμ. (Found: C 54.7; H 9.1; OCH_3 51.6. Calc. for $C_5H_7O(OCH_3)_3$ (176.2): C 54.5; H 9.2; OCH_3 52.8).

I (0.700 g, 0.0040 mole) was heated under reflux (10 min) with 0.025 *N* hydrochloric acid (4.0 ml). After cooling, the light-yellow reaction mixture was added to a solution of acetonedicarboxylic acid (1.80 g), methylamine hydrochloride (0.84 g), citric acid (3.00 g) and sodium hydroxide (2.36 g) in water (68 ml). The resulting solution (pH 5.0) was left standing (48 h) at room temperature. Potassium carbonate (anhydrous, 35 g) was added and dissolved, and the solution continuously extracted with ether. The ether was removed from the etheral extract by distillation. The oily residue was dissolved in ethanol (5 ml) and added to a solution of picric acid (1.20 g) in hot ethanol (10 ml). Hereby 0.570 g (35 %) of methylmethoxytropinone picrate was obtained [m. p. 129—131° (Hershberg

apparatus, corr.)]. Crystallization from ethanol gave 0.374 g (m. p. 135—136°; further crystallization did not change the m. p.). (Found: C 46.8; H 5.0; N 13.1; OCH_3 6.6. Calc. for $C_{15}H_{17}O_8N_4$ (OCH_3) (412.4): C 46.6; H 4.9; N 13.6; OCH_3 7.5).

The picrate was further characterized by its infrared spectrum (in potassium bromide), which was found to be different from the spectrum of 1-methoxymethyltropinone picrate (m. p. 164—170°), prepared from 2,5-dimethoxytetrahydrofurfuryl methyl ether [10].

The aqueous layer from the etheral extraction of trimethoxytetrahydrosilvan was acidified to Congo red with concentrated hydrochloric acid and extracted further with ether. The ether was removed by distillation and the oily residue dissolved in water (5 ml). Semicarbazide hydrochloride (0.5 g) and sodium acetate (0.75 g) were added and dissolved. After standing for 30 minutes a precipitate of levulinic acid semicarbazone was removed by filtration. The yield was 361 mg [m. p. 187° (dec.) (Hershberg apparatus, corr.)]. Crystallization from ethanol gave 296 mg [m. p. 187° (dec.)]. (Found: C 41.5; H 6.3; N 24.6. Calc. for $C_6H_{11}O_3N_3$ (173.2): C 41.6; H 6.4; N 24.3).

From the above data, analyses and infrared spectra, it is inferred that the distillate boiling at 88° is an azeotrope of 80 % of trimethoxytetrahydrosilvan and 20 % of methyl levulinate. In the separation experiment the yield of trimethoxytetrahydrosilvan (1.61 g) thus corresponds to 81 % and of levulinic acid semicarbazone (361 mg) to 55 %. (Found: C 55.1; H 8.8; OCH_3 47.5. Calc. for 80 % $C_5H_7O(OCH_3)_3$ + 20 % $C_5H_7O_2$ (OCH_3): C 54.7; H 8.9; OCH_3 47.0).

From the distillation curve (Fig. 1) the yield of trimethoxytetrahydrosilvan is estimated to 8.6 g (3.0 % based upon furfuryl alcohol) and of methyl levulinate to 2.2 g.

(b). The distillate boiling at about 94° (n_D^{25} 1.4201, n_D^{20} 1.4223, d_4^{20} 1.0490) is methyl levulinate, which previously has been prepared pure by Langlois and Wolff [11] (b. $p._{15}$ 89—91°, n_D^{20} 1.4225, d_4^{20} 1.0495). (Found: C 55.4; H 7.9; OCH_3 24.0. Calc. for $C_5H_7O_2$ (OCH_3) (130.1): C 55.4; H 7.8; OCH_3 23.8).

The yield of methyl levulinate is 57.0 g. This brings the total yield of methyl levulinate up to 59.2 g (27.7 %).

(c). The distillate boiling at about 112° (n_D^{25} 1.4229) is *a*(or *β*)-methoxylevulinaldehyde dimethyl acetal (III) [yield 29.2 g (10.1 %)]. (Found: C 54.8; H 9.2; OCH_3 52.6. Calc. for $C_5H_7O(OCH_3)_3$ (176.2): C 54.5; H 9.2; OCH_3 52.8).

III (2.56 g) was shaken (20 h) with a solution of sodium hydroxide (8 %, 50 ml) and the reaction mixture continuously extracted with ether and distilled under 11 mm. The distilland was dark-red and only 0.3 g of distillate, b. p. 115—162°, could be collected. III is thus transformed into undistillable material under the influence of alkali.

III (0.700 g, 0.040 mole) was hydrolyzed and the hydrolysate treated with acetonedicarboxylic acid and methylamine as described above. The yield of methylmethoxytropinone picrate was 0.504 g (31 %) (m. p. 135—136°). (Found: C 46.5; H 4.6; N 13.5; OCH_3 6.6).

The infrared spectrum was identical with that of the picrate of the tropinone from trimethoxytetrahydrosilvan.

(d). The distillate boiling between 94° and 112° contains

(1) a product (yield about 0.5 g), which has a larger refractive index than either methyl levulinate or methoxylevulinaldehyde dimethyl acetal. Of the fractions collected by us, the largest index (1.4258) was shown by the fraction (3.88 g) boiling from 103.1° to 108.2°. The product was not identified.

(2) Methyl levulinate dimethyl ketal [yield about 3.6 g (1.2 %)], which was identified by its spectrum. The fraction boiling from 103.1° to 108.2° was richest on ketal.

(3) A compound which turns yellow on standing. The compound, which is present in the fractions boiling above 103°, and in particular in the fraction boiling from 103.1° to 108.2°, was not identified. The yield of the compound is about 0.3 g. This brings the total yield of unknown compounds up to 0.8 g. Assuming an average molecular weight of 175, this corresponds to 0.3 %.

The yield of all distillable products from furfuryl alcohol is thus 42.3 %.

Reaction of furfuryl methyl ether with methanolic hydrogen chloride. Furfuryl methyl ether (184.0 g, 1.64 mole) was treated as described for furfuryl alcohol. The yield of distillable product was 101.9 g ($b.p._{0.5}$ 57—79°), 100.9 g of which was fractionated (Fig. 1) into 24 fractions. During the later half of the distillation methanol was conti-

nuously split off from the distilland. This was indicated by the accumulation of methanol in the cooling trap (3.8 g in all, n_D^{25} 1.3327). The yield of distillate, including the methanol, was 96.7 g (96 % of distilland).

(a). The distillate boiling at about 88° is identical with the 88° – distillate from furfuryl alcohol (inferred from the spectrum). The yield of trimethoxytetrahydrosilvan is 5.2 g (1.8 % based upon furfuryl methyl ether) and of methyl levulinate 1.3 g.

(b). The distillate boiling at about 94° (n_D^{25} 1.4218) is, as inferred from the spectrum and from analyses, an azeotrope of about 90 % of methyl levulinate and about 10 % of an unknown product, which has a considerably higher refractive index and a high content of methoxy groups. The yield of methyl levulinate is about 22.5 g and of the unknown product about 2.5 g. This brings the total yield of methyl levulinate up to 23.8 g (11.2 %). (Found: C 56.2; H 8.2; OCH_3 26.2).

(c). The distillate boiling between 88° and 94° and in particular the fraction (4.35 g) boiling from 89.8° to 93.2°, turns yellow on standing. The compound responsible for the coloration was not identified (yield about 0.5 g), but is probably identical with the above mentioned compound from furfuryl alcohol having the same property.

(d). The distillate boiling at about 103° (n_D^{25} 1.4239) is methyl levulinate dimethyl ketal (II) [yield about 44.3 g (15.3 %)]. The compound showed no absorption band around 5.8 mμ. (Found: C 54.9; H 9.4; OCH_3 51.6. Calc. for $C_5H_7O(OCH_3)_3$ (176.2): C 54.5; H 9.2; OCH_3 52.8).

II (3.00 g) was heated under reflux (3 h) with methanol (dried with magnesium, 3.0 ml) to which had been added water (310 mg) and concentrated hydrochloric acid (50 mg). Sodium (12 mg) was added and the mixture distilled. Hereby 1.90 g (86 %) of almost pure methyl levulinate was obtained (b. $p._{13}$ 83–86°, n_D^{25} 1.4208). (Found: C 55.6; H 8.6; OCH_3 25.5. Calc. for $C_7H_7O_3(OCH_3)$ (130.1): C 55.4; H 7.8; OCH_3 23.8).

II (3.80 g) was dissolved in a solution of methanol (10.0 ml), water (0.50 ml) and ammonia (2.3 g) and the resulting light-yellow solution left standing for 3 days. The solution was evaporated in a vacuum from a water-bath and the oily residue crystallized from benzene-petroleum ether. The resulting light-brown crystals were washed twice with benzene-petroleum ether and dried under 0.1 mm over sulfuric acid (3 h). The yield of impure levulinamide dimethyl ketal (VII) was 1.41 g (41 %) (m. p. 64–68°). Recrystallization from benzene-petroleum ether gave 1.10 g (32 %) of pure VII (slightly yellow crystals, m. p. 67–70°; further crystallization did not change the m. p.). (Found: C 52.1; H 9.5; N 9.1; OCH_3 38.0. Calc. for $C_5H_9ON(OCH_3)_2$ (161.2): C 52.2; H 9.4; N 8.7; OCH_3 38.5).

As explained in the following, only the intermediate fractions of the distillate boiling at about 103° are pure methyl levulinate ketal, while the first and the last fractions are contaminated with other compounds.

(e). The distillate boiling between 94° and 103° contains a product (yield about 1.4 g), which has a larger refractive index than either the 94°-azeotrope or methyl levulinate dimethyl ketal. Of the fractions collected by us, the largest index (1.4289) was shown by the fraction (3.88 g) boiling from 98.2° to 101.3°. The product which contaminates the first fractions of methyl levulinate dimethyl ketal was not identified, but is possibly identical with the above mentioned product from furfuryl alcohol having the same property.

(f). The distillate boiling above 103°. In this range at least one compound, which was not identified, was shown to be present as judged by the spectra. The compound contaminates the later fractions of the ketal. The data for the last 8 fractions of the distillation are given in Table 3.

The yield of unknown compounds boiling above 103° is about 15.0 g. This brings the total yield of unknown compounds up to 19.4 g. Assuming an average molecular weight of 190, this corresponds to 6.2 %.

The yield of all distillable compounds from furfuryl methyl ether is thus 34.5 %.

Reaction of dimethoxydihydrosilvan with methanolic hydrogen chloride. Dimethoxydihydrosilvan (237.0 g, 1.64 mole) was treated as described for furfuryl alcohol. The yield of distillable product was 209.0 g (b. $p._{0.6}$ 53–74°), 121.8 g of which was fractionated into 32 fractions (Fig. 1). Methanol was split off from the distilland as in the furfuryl methyl

Table 3. Data for the last 8 fractions of the distillation of the reaction product from furfuryl methyl ether.

Fraction (g)	B. p. °C	n_D^{25}	C	H	OCH_3
17 (3.69)	103.7	1.4239			
18 (3.73)	103.7—103.8	1.4239	55.7	9.4	51.1
19 (3.56)	103.8—104.2	1.4241			
20 (3.74)	104.2—104.8	1.4252	55.6	9.3	53.4
21 (3.92)	104.8—107.2	1.4278	55.6	9.3	56.7
22 (3.65)	107.2—108.4	1.4301	56.4	9.3	57.3
23 (3.80)	108.4—109.0	1.4291			56.4
24 (3.97)	109.0—109.8	1.4267			

ether experiment (yield 3.5 g, n_D^{25} 1.3397). The yield of distillate, including the methanol, was 115.4 g (95 % of distilland).

(a). The distillate boiling at about 87° is identical with the 88°-distillate from furfuryl alcohol. The yield of trimethoxytetrahydrosilvan is 4.7 g (2.8 % based upon dimethoxydihydrosilvan) and of methyl levulinate 1.2 g.

(b). The distillate boiling at about 93° (n_D^{25} 1.4212) is identical with the 94°-distillate from furfuryl methyl ether. The yield of methyl levulinate is about 17.7 g and of the unknown product about 2.0 g. This brings the total yield of methyl levulinate up to 18.9 g (15.2 %). (Found: C 55.7; H 8.1; OCH_3 26.3).

(c). The distillate boiling at about 102° (n_D^{25} 1.4229) is methyl levulinate dimethyl ketal. The yield is about 56.9 g (33.8 %). (Found: C 54.5; H 9.4; OCH_3 52.6).

(d). The distillate boiling between 93° and 102° contains a product (yield about 1.2 g), which has a larger refractive index than either the 93°-azeotrope or methyl levulinate dimethyl ketal. Of the fractions collected by us, the largest index (1.4249) was shown by the fraction (4.1 g) boiling from 101.0° to 101.6°. The product, which contaminates the first fractions of methyl levulinate dimethyl ketal, was not identified, but is possibly identical with the above mentioned product from furfuryl alcohol and furfuryl methyl ether having the same property.

(e). The distillate boiling above 102°. In this range at least 2 different compounds, which were not identified, were shown to be present as judged by the spectra. The lowest boiling of these, which is identical with the unknown compound boiling in the same range in the furfuryl methyl ether experiment, contaminates the later fractions of methyl levulinate dimethyl ketal. The data for the last 12 fractions of the distillation are given in Table 4.

The yield of unknown compounds boiling above 102° is about 28.0 g. This brings the total yield of unknown compounds up to 31.2 g. Assuming an average molecular weight of 190, this corresponds to 17.3 %.

The yield of all distillable products from dimethoxydihydrosilvan is thus 69.1 %.

Treatment of the reaction mixture from furfuryl methyl ether with methanolic potassium hydroxide. Furfuryl methyl ether (350.0 g) was heated under reflux with methanolic hydrogen chloride as described above. Potassium hydroxide pellets (250 g) were added and the mixture heated further under reflux (18 h). The major part of the methanol was removed from the black reaction mixture by distillation in a vacuum. Water (150 ml) was added and the remainder of the methanol was removed by distillation under 200 mm through a Vigreux type column. Another 150 ml of water was added and the mixture

Table 4. Data for the last 12 fractions of the distillation of the reaction product from dimethoxydihydrosilvan.

Fraction (g)	B. p. °C	n_D^{25}	C	H	OCH_3
21 (4.13)	102.2—102.3	1.4230

32 (0.41)	114.8—116.1	1.4485	56.1	9.3	54.6

continuously extracted with ether in a Kutscher-Steudel apparatus for 2 days. The black liquid in the boiling flask (2 layers) was shaken with anhydrous magnesium sulfate (100 g), filtered, and the magnesium sulfate washed with ether. The combined etheral solutions (0.5 l) were shaken with a saturated solution of calcium chloride (0.5 l), dried with potassium carbonate and distilled under 0.2 mm. The yield of distillate was 25.3 g (colorless liquid, b. p. 65—71°, n_D^{25} 1.4254), a portion of which (23.2 g) was fractionated through a 12 cm column [9] into 12 fractions (distillation pressure 12 mm, heat input 3.6 watt, take-off every 2.4 minutes, change of fraction every hour, total distillation time 12 hours) (Fig. 2 and Table 5). The infrared absorption of all fractions was measured. The yield of distillate was 21.5 g (93 % of distilland).

(a). The distillate boiling at about 73° is the same trimethoxytetrahydrosilvan as isolated above (inferred from the spectrum).

(b). The distillate boiling at about 91° consists of a main product (inferred from the spectrum) and another product, which turns yellow on standing. Fractions 4 and 5 turn strongly yellow, and fractions 6—9 weekly yellow. None of the compounds were identified, but the compound responsible for the coloration is probably identical with the above mentioned compound from furfuryl alcohol and furfuryl methyl ether having the same property. Since the compound is alkali stable, and is not found in the reaction product from dimethoxydihydrosilvan, we believe it to be a furan compound, which is autoxidized on standing.

(c). The distillate boiling at 104° is 1,1,2(or 3),4,4-pentamethoxypentane (VIII). [Calc. for $C_5H_7(OCH_3)_5$ (222.3): C 54.0; H 10.0; OCH_3 69.8]. The compound showed no absorption band around 5.8 mμ.

0.900 g of pentamethoxypentane (0.040 mole) was hydrolyzed and the hydrolysate treated with acetonedicarboxylic acid and methylamine hydrochloride as described above. The yield of methylmethoxytropinone picrate was 0.600 g (36 %) (m. p. 132—136°). Crystallization from ethanol gave 0.500 g (m. p. 133—134°). (Found: C 46.6; H 4.6; N 13.6; OCH_3 7.2).

Table 5. Data for the distillation of alkali-resistent compounds from furfuryl methyl ether.

Fraction (g)	B. p. °C	n_D^{25}	C	H	OCH_3
1 (1.35)	70.5— 73.0	1.4242	55.4	9.3	52.4
2 (1.52)	73.0— 73.6	1.4236	55.0	9.6	51.5
3 (1.97)	73.6— 76.0	1.4239	54.9	9.4	51.5
4 (2.02)	76.0— 88.5	1.4256	54.8	10.1	54.4
5 (2.02)	88.5— 90.3	1.4268	55.2	9.5	53.8
6 (2.06)	90.3— 91.0	1.4262	55.1	9.6	55.3
7 (2.04)	91.0— 91.5	1.4261	55.4	9.6	53.5
8 (1.99)	91.5— 92.4	1.4258	55.1	9.4	53.7
9 (1.98)	92.4— 98.6	1.4258	55.3	9.5	56.6
10 (1.89)	98.6—103.2	1.4243	54.8	9.9	65.4
11 (1.71)	103.2—104.0	1.4232	54.2	9.8	70.6
12 (0.91)	104.0	1.4231	54.6	10.4	68.5

The infrared spectrum of the picrate was identical with that of the picrate of the tropinone from trimethoxytetrahydrosilvan.

The yield of trimethoxytetrahydrosilvan, as estimated by the distillation curve, is 5.5 g (1.1 %), of pentamethoxypentane 4.7 g (0.7 %) and of unknown compounds 11.1 g (about 2.5 %).

Studies on Carbamates

XI. The Carbamate of Ethylenediamine

ARNE JENSEN and RUTH CHRISTENSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

The velocity constants of the reaction $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2 + CO_2 \rightleftharpoons {}^+H_3N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-$ and the equilibrium constant for the reaction $H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^- + H_2O \rightleftharpoons H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2 + HCO_3^-$ have been determined. The velocity of the decomposition of $H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-$ in basic medium was investigated and may be explained in assuming that the decomposition is a two stage reaction, *viz.* 1) carbamate $\rightleftharpoons$ amine + carbon dioxide, 2) carbon dioxide $\rightleftharpoons$ carbonate.

It is to be noticed that the carbamate has been prepared not only in solution by leading CO_2 into a diluted solution of $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2$ but also as a solid. This substance consists of equal moles of $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2$ and CO_2 so that the gross composition corresponds with both monocarbamate, $^+H_3N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-$, and dicarbamate, $^+H_3N \cdot CH_2 \cdot CH_2 \cdot NH_2^+$, $^-OOCHN \cdot CH_2 \cdot CH_2 \cdot NHCOO^-$. The carbamate showed by analysis that it did not contain monocarbamate exclusively, approx. 20 % CO_2 being present as dicarbamate. The experiments on equilibrium and velocity have been calculated as if all the carbamate was present as monocarbamate.

1. The equilibrium conditions and reaction mechanism of the formation and decomposition in aqueous medium of the carbamate formed by ethylenediamine have been studied. As the experimental and theoretical conditions are practically analogous to those of the carbamates previously investigated, we confine ourselves, with some exceptions, to refer to an earlier paper [1,2] for the detailed information concerning method, theory, significance of constants, *etc.* It should be noted, though, that "Am" means $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2$ and "AmH^+" $^+H_3N \cdot CH_2 \cdot CH_2 \cdot NH_2$.

2. Two different preparations of ethylenediamine were used in the experiments. One preparation was purified through the acid oxalate by recrystallization, until constant molecular weight was obtained. The molecular weight of the acid oxalate, crystallizing with one molecule of crystal water, is theoretically 258.20. The preparation obtained showed the following molecular weight: By titration with permanganate it was found to be 256.8, and by a Kjeldahl

analysis it was found to be 262.1; the melting point was about 210°C. From the acid oxalate was prepared an aqueous solution of ethylenediamine by distilling it off with sodium hydroxide.

The other preparation was purified by distillation in an ordinary distiller at atmospheric pressure after drying with metallic sodium; the fraction used had a boiling point of 117.3—117.7° C (768 mm Hg), $n_D^{25.0°} = 1.4548$, and by titration with 1.0 *N* HCl a molecular weight of 61.7 (theoretically 60.1) was found. Presumably this difference in the molecular weight is due to small contents of water.

The two preparations gave the same results in the experiments concerning the formation and decomposition of carbamate.

3. The carbamate of ethylenediamine was prepared partly in solution by leading a deficit of carbon dioxide to aqueous solutions of the amine, practically all of the carbon dioxide thus being converted to carbamate, and partly as a solid.

The solid substance, the gross composition of which corresponds with equal moles of $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2$ and CO_2 was prepared in the following way. Carbon dioxide was lead through a mixture of 80 g amine and 20 g water, cooled to 0° C, for an hour; after ten hours at 0° C a microcrystalline precipitate was formed, which increased for the following fifty hours at 20° C. It was dried and stored over concentrated sulphuric acid in an exsiccator, in which it, at least for some time, showed no sign of decomposition. 58.0 % of amine (theoretically 57.73 %) was found by titration of the carbamate with 0.1 *N* HCl, and by the method of analysis, stated under 4, 42.0 % of carbon dioxide (theoretically 42.27 %) in the form of carbamate was found.

The gross composition corresponds with two compounds, *viz.* $^+H_3N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-$ and $^+H_3N \cdot CH_2 \cdot CH_2 \cdot NH_3^+$,$^-OOCHN \cdot CH_2 \cdot CH_2 \cdot NHCOO^-$. Katchalski, Berliner-Klibanski and Berger [3-5] have recently shown that a carbamate they prepared as a solid substance was a mixture of approx. equal parts by weight of monocarbamate and dicarbamate.

We have examined the same problem but after quite another method than the one used by the above-mentioned authors. Our principle has been to dissolve the preparation of carbamate in excess of 1.0 *N* NaOH. By this method 1 mole of amine was liberated from 1 mole of dicarbamate but no amine was liberated from monocarbamate. The solution was immediately shaken with *n*-amyl alcohol whereupon the concentration of $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2$ in the layer of *n*-amyl alcohol was determined by titration. Approximately, the partition coefficient of $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2$ between *n*-amyl alcohol and 1.0 *N* NaOH was found equal to 0.10. By means of the titration results and the partition coefficient the concentration of liberated amine was calculated. The indicator was bromophenol blue, and the layer of *n*-amyl alcohol was dissolved in enough *iso*-propyl alcohol to ensure homogeneity after titration. The examination showed that approx. 20 % CO_2 was present as a dicarbamate, *i.e.* approx. 80 % CO_2 was present as a monocarbamate.

4. The method of analysis was as in previous investigations precipitation with barium chloride, causing the precipitation of carbonate, but not of carbamate. All of the data presented in the later tables are corrected for blank values, *viz.* 3—5 units of the percentage.

5. All of the experiments were performed at 18° C, and the velocity constants were calculated by means of Briggs' logarithms, the unit of time being the minute. As in previous investigations the activity coefficient f for a monovalent ion was calculated from the expression of Bjerrum $-\log f = 0.3 \sqrt[3]{c_{ion}}$.

6. For the calculation of certain experiments we have needed the value of the equilibrium constant of $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_3^+ \rightleftharpoons H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2 + H^+$. Since the values of K_{AmH^+} stated in the literature [6-8] not agree very well, we have used a value determined by us. This constant was calculated (Table 1) on the basis of determinations of the hydrogen ion activity in solutions containing equal moles of corresponding acid and base, prepared by the mixing of ethylene diamine with half the number of moles of hydrochloric acid. The investigations were carried out both by means of a hydrogen electrode against a 0.1 N calomel electrode and by means of a glass electrode. By the hydrogen electrode the hydrogen ion activity was calculated from the expression $pa_H = -\log a_H{}^+ = (E - E_o) \frac{F \log e}{RT}$, E_o being fixed at 0.3360 [9], and the adjustment of the glass electrode was carried out by means of buffer solutions of phosphate, borate and sodium hydroxide, according to Sørensen. No corrections were made for the diffusion potentials, these being insignificant.

Table 1. Determination of the second acidic dissociation constant of ethylenediamine 18°.

c_{acid}	c_{base}	pa_H	
		Glass electrode	Hydrogen electrode
0.198	0.198	10.19	10.22
0.148	0.148	10.17	10.21
0.099	0.099	10.16	10.19
0.079	0.079	10.14	10.18
0.060	0.060	10.21	10.18
0.049	0.049	10.13	10.16
0.039	0.039	10.19	10.17

The results are found in Table 1, from which it appears that the expression

$$\frac{a_H{}^+ \times c_{H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2}}{c_{H_3N \cdot CH_2 \cdot CH_2 \cdot NH_2{}^+}} = K'_{AmH^+}$$

has a practically constant value independent of the ion concentration. We have used $K_{AmH^+} = 10^{-10.17}$ in the calculations.

The acidic dissociation constant for $^+H_3N \cdot CH_2 \cdot CH_2 \cdot NH_3^+ \rightleftharpoons H_2N \cdot CH_2 \cdot CH_2 \cdot NH_3^+ + H^+$ was calculated by us on the basis of similar determinations as mentioned before and was found to be about $10^{-7.2}$. In the calculations of our experiments we have only used K'_{AmH^+}, since the solutions are so basic, that they contain practically nothing of the ion $^+H_3N \cdot CH_2 \cdot CH_2 \cdot NH_3^+$.

7. The acidic dissociation constant

$$K'_{amate} = \frac{c_{H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-} \times a_H{}^+}{c^+_{H_3N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-}}$$

for the process: $^{+}H_3N \cdot CH_2 \cdot CH_2 \cdot NHCOO^- \rightleftharpoons H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^- + H^+$ has been determined in the following way. By dissolving the carbamate, $^{+}H_3N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-$, as quickly as possible in a deficit of sodium hydroxide solution, we made solutions containing acid and corresponding base, and in these solutions we determined pa_H by means of a glass electrode in the course of a few minutes. It should be noted, that we, during this short time, took the liberty of ignoring the decomposition of the carbamate. The results are found in Table 2, from which it appears, that

$$K'_{amate} = \frac{c_{H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-} \times a_{H^+}}{c^+_{H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-}}$$

is independent of the ion concentration analogous to the conditions of the alanines [1].

Table 2. Determination of the acidic dissociation constant of the carbamate 18°.[1]

c_{acid}	c_{base}	pa_H	pK'_{amate}
0.0025	0.0025	10.09	10.09
0.005	0.005	10.10	10.10

On the reaction "amine + carbon dioxide → carbamic acid"

500 ml of an aqueous solution containing both amine and sodium hydroxide were shaken vigorously for two minutes with a deficit of a gaseous mixture of 15 % carbon dioxide and 85 % atmospheric air. We also tried in the course of approx. 15 minutes to lead atmospheric air containing about 1 % carbon dioxide into the solution of both amine and sodium hydroxide, the decomposition of the carbamate going so slowly, that we can disregard it. The mixture was immediately analysed, and the two methods gave practically the same results. The analytical data obtained in the experiments are listed in Table 3, where "% carbamate" indicates how many per cent of the carbon

dioxide absorbed have been converted to carbamate. Furthermore, the velocity constant $k_{CO_2 \cdot Am}$ for the reaction $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2 + CO_2 \rightarrow H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOOH$ was calculated.

The equilibrium "carbamate ⇌ carbonate"

Experiments with ethylenediamine have been done from the carbonate side as well as from the carbamate. In Table 4 are listed the compositions of the solutions and the equilibrium constant K_{Eq} for the reaction $H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^- + H_2O \rightleftharpoons H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2 + HCO_3^-$.

It should be noted that in the experiments

$c_{Am} = c_{H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2}$, $c_{AmH^+} = c_{H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2^+}$ and $c_{amate} = c_{H_2N \cdot CH_2 \cdot CH_2 \cdot NHCOO^-}$, c_{amate} being calculated on the basis of $c_{+H_2N \cdot (CH_2)_2 \cdot NHCOO^-}$, a_{H^+} and K'_{amate}.

Table 5. Velocity constants for the process "carbamate ⇌ carbonate"; pa_H = approx. 10—11; 18°.

The velocity of the conversion "carbamate ⇌ carbonate"

In Table 5 are presented the experiments on velocity, which have been carried out in a buffer solution consisting of $^{+}H_3N \cdot CH_2 \cdot CH_2 \cdot NH_2$ / $H_2N \cdot CH_2 \cdot CH_2 \cdot NH_2$, where a measurable equilibrium is established between carbamate and carbonate. In Table 6 are presented those experiments which have been carried out in a medium containing sodium hydroxide, where carbamate is converted almost completely to carbonate.

The velocity constants calculated from the experiments are listed in Table 5 and 6. These velocity constants may be calculated in advance, provided the decomposition takes place through the reactions

$$\text{carbamate} \rightleftharpoons \text{amine} + CO_2$$
$$CO_2 \rightleftharpoons \text{carbonate}.$$

Table 6. Velocity constants for the process "carbamate → carbonate"; pa_H = approx. 13; 18°.

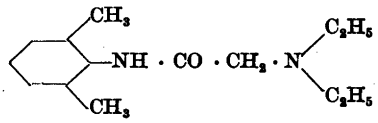
Studies on Local Anesthetics XI *

NILS LÖFGREN and CLAËS TEGNÉR

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden, and School of Pharmacy, University of Lausanne, Lausanne, Switzerland

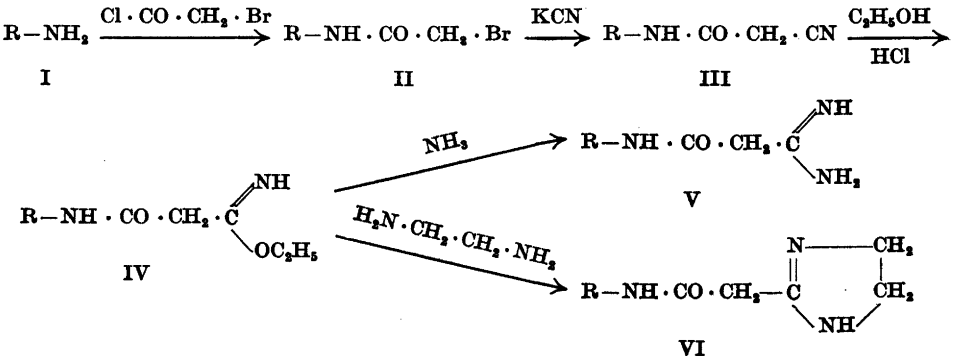
Three new compounds, related to xylocaine(α-diethylamino-2,6-dimethylacetanilide), *viz.* β-imino-β-ethoxy-2,6-dimethylpropionanilide, α-guanyl-2,6-dimethylacetanilide and α-(2-imidazolin-2-yl)-2,6-dimethylacetanilide have been synthesized and tested pharmacologically. In comparison with xylocaine the imido-ester and the imidazoline have very slight anesthetic activities on the rabbit cornea. The amidine is inactive. On the blood pressure the amidine and the imidazoline, like xylocaine, have a weak depressant action.

The syntheses of three compounds in which the diethylamino group of xylocaine



Xylocaine

is replaced by an imidocarbethoxy, a guanyl or a 2-imidazolin-2-yl group were carried out according to the following scheme:



R = 2,6-$(CH_3)_2C_6H_3$

* For paper X of this series see Löfgren and Tegnér [1].

The bromoacetylation of 2,6-dimethylaniline (I) yielding α-bromo-2,6-dimethylacetanilide (II) was carried out according to the aqueous acetate buffer method described by Löfgren [2,3]. Heating of II with KCN in ethanol gave α-cyano-2,6-dimethylacetanilide (III). This derivative was converted into β-imino-β-ethoxy-2,6-dimethylpropionanilide (IV) by reaction with ethanol and dry hydrogen chloride in dioxan solution, the procedure being a modification of that used by Cook and Reed [4] for the preparation of 1,4-bis(3-ethoxy-3-iminopropoxy)benzene. The ammonolysis of the imido-ester IV forming α-guanyl-2,6-dimethylacetanilide (V) was carried out in absolute ethanol during 5 days at 0°, and then for 2 days at room temperature. When condensing IV with ethylene diamine to give α-(2-imidazolin-2-yl)-2,6-dimethylacetanilide (VI) we followed the directions given by Klarer and Urech [5] who synthesized 2-(hydroxymethyl)-2-imidazoline by reaction between ethyl glycolimidate and ethylene diamine in absolute ethanol. To get a satisfactory yield of VI we had to perform the reaction at a lower temperature and over a longer period than is described in the synthesis of Klarer and Urech who obtained a high yield of their compound.

The compounds IV, V and VI were tested for their local anesthetic activity on the rabbit cornea and compared with xylocaine, the method given by Wiedling being followed [6]. In these experiments the imido-ester IV and the imidazoline VI gave very slight anesthetic activities. The amidine V was found to be inactive *.

In common with local anesthetics in general xylocaine exercises a weak hypotensive action [6,7]. The effect on blood pressure of IV, V, VI and xylocaine were compared in the rabbit **. It was found that the imido-ester IV was devoid of action whereas the amidine V and the imidazoline VI, like xylocaine, gave a weak depressant action according to the following order of magnitude: V > VI > xylocaine.

As shown previously by Wiedling [6] in experiments on isolated guinea pig intestine xylocaine is devoid of histaminolytic action but has a slight cholinolytic activity, *i.e.* about 1 % of that of diphenhydramine. For an estimation of the histaminolytic and cholinolytic effects of compounds IV, V and VI the above mentioned method of Wiedling was used. No appreciable effects were found.

By subcutaneous injections in white mice the toxicities were determined for V and VI. The toxicity of IV was not investigated since its solubility in acids was too low to allow a proper determination. The LD_{50} values of the amidine V and the imidazoline VI, calculated as grams of the base per kilogram of body weight were found to be 0.45 and 0.24, respectively. The corresponding value for xylocaine [6] is 0.34. In terms of *molar toxicity*, *i.e.* the toxicity expressed in moles per kilogram of body weight, the LD_{50} values of V, VI and xylocaine are $2.2 \cdot 10^{-3}$, $1.0 \cdot 10^{-3}$ and $1.4 \cdot 10^{-3}$, respectively.

* No action of 0.25 ml of a 2 % hydrochloride solution of pH 7.3 even after 4 minutes' exposure to the eye.

** Intravenous supply to amytal anesthetized rabbits.

EXPERIMENTAL *

α-Bromo-2,6-dimethylacetanilide (II). This compound was prepared by reaction between 2,6-dimethylaniline and bromoacetyl chloride in an acetate buffer, the general directions of Löfgren [2,3] for this type of reaction being followed. The yield of the crude α-bromo-2,6-dimethylacetanilide melting at 145—150° was 91 %. On recrystallization from absolute ethanol the compound was obtained as colourless needles. M. p. 155—156° (corr.). (Found: C 49.7; H 4.99. Calc. for $C_{10}H_{12}BrNO$ (242.1): C 49.6; H 5.00).

α-Cyano-2,6-dimethylacetanilide (III). In a round-bottomed flask equipped with a stirrer and a reflux condenser a solution of 20 g (0.083 mole) of α-bromo-2,6-dimethylacetanilide in 140 ml of absolute ethanol was heated to 60°. To the hot solution were added in small portions and during a period of 45 minutes 7.2 g (0.11 mole) of potassium cyanide, dissolved in 9 ml of water. On the addition a precipitate formed. The mixture was then diluted with 20 ml of absolute ethanol and under continued stirring the temperature was maintained at 60° for another 2 hours. Finally, the mixture was heated to 80° and filtered by suction through a pre-heated glass filter. After dilution with a large quantity of water the precipitate was filtered off, washed with water and dried in a vacuum desiccator over silica gel. On recrystallization from 96 % ethanol pale yellow needles were obtained. M. p. 210—212° (corr.); yield 6.4 g (0.034 mole), *i. e.* 41 %. (Found: C 70.4; H 6.43. Calc. for $C_{11}H_{12}N_2O$ (188.2): C 70.2; H 6.43.)

β-Imino-β-ethoxy-2,6-dimethylpropionanilide (IV). A mixture of 5.1 g (0.027 mole) of finely ground α-cyano-2,6-dimethylacetanilide, 1.3 g (0.027 mole) of absolute ethanol and 60 ml of highly purified dioxan was placed in a 250-ml round-bottomed flask fitted with a gas inlet tube, a thermometer and an ascending reflux condenser with a calcium chloride tube. Through the gas inlet tube a moderate stream of hydrogen chloride, carefully dried by passage through a mixture of phosphorus pentoxide and asbestos, was introduced. The temperature of the reaction mixture was not allowed to rise above 40°. After 4—5 hours the solution was cooled to 5° and the introduction of gas was continued until saturation. The reaction vessel was then closed and kept at a temperature of 4—5° for two days. After that time the expected *hydrochloride* of the imido-ester had partly precipitated. The precipitation was completed by dilution with absolute ether. The substance was filtered off, washed with absolute ether and dried in a vacuum desiccator over potassium hydroxide and silica gel. M. p. 128—129°; yield 6.7 g (0.025 mole), *i. e.* 91 %. (Found: Cl 13.16 (Mohr). Calc. for $C_{13}H_{19}ClN_2O_2$ (270.8): Cl 13.10.)

In some runs a less pure product was obtained since a small quantity of ammonium chloride contaminated the imido-ester hydrochloride. Satisfactory purification could be obtained by dissolving the substance in cold ethanol followed by fractional precipitation with dry ether. However, a more convenient purification was obtained by preparing the free base followed by recrystallization. For this purpose the salt preparation was dissolved in cold water and the imido-ester base liberated by the addition of dilute ammonia. The base was taken up in ether and after washing with water and drying with sodium sulphate the ether was driven off, leaving the imido-ester as needles. The base was dissolved at room temperature in a little more than the required amount of xylene (commercial mixture of isomers) and after addition of some light petroleum the compound was recrystallized by cooling to about −10°. M. p. 87—89°. (Found: C 66.9; H 7.48. Calc. for $C_{13}H_{18}N_2O_2$ (234.4): C 66.6; H 7.74.)

α-Guanyl-2,6-dimethylacetanilide hydrochloride (V). An alcoholic ammonia solution was prepared by saturating 10 ml of absolute ethanol at 0° with dry ammonia gas and diluting with 10 ml of alcohol. To this solution, 5.0 g (0.018 mole) of β-imino-β-ethoxy-2,6-dimethylpropionanilide · HCl were added. The mixture which was kept in a glass stoppered bottle was well shaken and allowed to stand for 5 days at 0° and for another 2 days at room temperature. After that time the mixture was filtered to remove the ammonium chloride which had precipitated. The red-violet filtrate was diluted with absolute ether until no more precipitate was formed. The precipitate was filtered off and washed with dry ether. This product in the form of a fine white crystalline powder was the desired amidine hydrochloride and did not need any further purification. M. p.

* All melting points are uncorrected unless otherwise stated.

230°; yield 3.1 g (0.013 mole), *i. e.* 72 %. (Found: C 54.4; H 6.63; Cl 14.93 (Mohr). Calc. for $C_{11}H_{16}ClN_3O$ (241.7): C 54.7; H 6.76; Cl 14.67).

α-(2-Imidazolin-2-yl)-2,6-dimethylacetanilide hydrochloride (VI). A solution of 1.1 g (0.019 mole) of ethylene diamine in 15 ml absolute ethanol was placed in a 100-ml two-necked flat-bottomed flask equipped with a magnetic stirrer and an ascending reflux condenser with a drierite tube. The solution was cooled to −15° and 5.2 g (0.019 mole) of β-imino-β-ethoxy-2,6-dimethylpropionanilide · HCl were added under vigorous stirring. The mixture was kept at −15° for half an hour and then at 0° for two hours after which time 11 ml of 1.74 *N* alcoholic hydrogen chloride (0.019 mole of HCl) were added under continued stirring. The flask was now allowed to assume room temperature and to remain at that temperature for 2 hours. The mixture was then heated at 40° for 2 hours, stirring being continued. After that time the mixture was filtered by suction through a pre-heated glass filter. On cooling, the hydrochloride of α-(2-imidazolin-2-yl)-2,6-dimethylacetanilide separated as colourless crystals. They were collected and washed with dry ether. The product did not need further purification. M. p. 238−240°; yield 2.7 g (0.010 mole), *i. e.* 53 %. (Found: C 57.9; H 6.70. Calc. for $C_{13}H_{18}ClN_3O$ (267.8): C 58.3; H 6.77.)

We are indebted to A.-B. Astra, Södertälje, Sweden, for financial support and to Dr. S. Wiedling of the Biological Department of Astra for performing the pharmacological tests. Our sincere thanks are also due to Professor A. Girardet of the University of Lausanne who read through the manuscript.

Studies on Methods for the Determination of Lipoperoxides

J. GLAVIND and S. HARTMANN

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

1. Various improvements and modifications of the colorimetric indophenol method for peroxide determinations are described. The method can be carried out as a "cold" method when a small amount of ferric chloride is added. The extinction produced by 0.001 milliequivalent of peroxide in 5 ml volume using benzene-ethanol or chloroform-ethanol as a solvent is about 1.00 at 520 mμ.

2. The bleaching effect of phospholipids in the thiocyanate method for peroxide determination is caused by the complex-binding of iron to the phosphoric acid groups of the phospholipids. It can be overcome by increasing the thiocyanate concentration.

3. Methods for the determination of peroxide groups in phospholipids and triglycerides containing high amounts of phospholipids are described.

4. The iodometric, the indophenol, and the thiocyanate methods for peroxide determination were compared. The latter method, carried out in the absence of oxygen, was found to be most suitable.

In a previous paper from this laboratory a new method, the colorimetric indophenol method, for the determination of the peroxides of fats and fatty acids (lipoperoxides) was described [1]. The method consists of heating the lipoperoxide-containing fat in a xylene-acetic acid solution with dichlorodihydroxydiphenylamine, the leuco-compound corresponding to the well-known redox indicator dichlorophenolindophenol. By oxidation of the leuco-compound, an amount of the indophenol equivalent to the quantity of lipoperoxide is formed. From the intensity of the red color of the indophenol the peroxide content is calculated.

The method has been used in this laboratory for several years and has been found sensitive and reproducible for the determination of lipoperoxides in several kinds of material. In the course of this work a number of improvements have been introduced in the method. The first part of this paper deals with our experiences with the colorimetric indophenol method, and at the same time two publications from other investigators [2,3], who have criticized the method, are discussed. Later parts of the paper contain a comparison of our method with other methods for the determination of peroxides as well as a study of the influence of phospholipids on the determination of peroxides.

A. THE COLORIMETRIC INDOPHENOL METHOD

Purification of solvents. All solvents used in work with lipoperoxides must be of a high degree of purity and free of peróxides as well as reducing substances and of heavy metal contamination. Peroxide-containing solvents can be purified by distillation under suitable conditions, for instance, water vapor distillation (toluene), or by filtering through a column of alumina (petroleum ether, benzene, toluene).

Several solvents (*e. g.*, petroleum ether and xylene) only remain peroxide-free for a very short time after they have been purified. On the other hand, benzene, chloroform, methanol and ethanol remain peroxide-free almost indefinitely, and good commercial qualities can be used without purification.

Preparation of color reagent. Dichlorodihydroxydiphenylamine, the leuco compound corresponding to dichlorophenolindophenol, is prepared by reduction of the latter by the following simplified method.

Two grams of 2,6-dichlorophenolindophenol (the product from British Drug House Company was found to be of a superior quality) are dissolved in 200 ml of hot distilled water. After filtration, the dye is reduced by the addition of about 1 g ascorbic acid. The precipitate of dichlorodihydroxydiphenylamine (in the following abbreviated "leuco") is filtered off on a glass filter and washed with redistilled water. When dissolved in a small quantity of absolute ethanol, some dark colored impurities are left on the filter. Further quantities of brownish impurities are removed by shaking the alcoholic solution with a small amount of activated carbon, followed by filtration. The leuco is precipitated again by the addition of redistilled water, filtered off, washed with redistilled water, and stored *in vacuo* over silica gel desiccant.

The leuco forms needles that are snow-white when freshly prepared but assume a bluish metallic appearance due to oxidation when stored for a long time. The use of redistilled water is essential, since the presence of small amounts of heavy metals generally occurring in ordinary distilled water markedly reduces the stability of leuco, especially in solution.

The color reagent is a 2 % solution of leuco in absolute ethanol. It keeps for several days when stored in a brown bottle, preferably in the ice-box. Two drops of the solution taken with a dropping pipette are used for an analysis. A blank containing 2 drops of leuco in 5 ml solvent should not produce an extinction exceeding 0.05 at 530 mμ (1 cm cuvette).

Determination of the extinction coefficient

In our first paper we reported that 0.001 milliequivalent of peroxide would give an extinction in 5 ml about 1.17. Hartmann and White [2], however, reported an extinction of 0.73, while Lea [3] recorded 0.83—0.84.

The extinction depends on the nature of the solvent. In the solvent mixture used in most of our experiments (benzene-ethanol-acetic acid, 45 : 50 : 5), careful determinations using several methods, as did Hartmann and White, gave an extinction of 1.00 at 520 mμ, and 1.02—1.03 at 530 mμ.

About the influence of the solvent the following can be said. If the extinction at the absorption maximum of a given concentration in ethanol is taken as unity, an extinction about 1.00 is also found with methanol, butanol, amyl alcohol, acetone, and ethyl acetate, but in solvents such as chloroform, benzene, and xylene, only about 0.60 is found (all solvents containing 2—5 % acetic acid). The presence of about 5 % ethanol in the nonpolar solvent will increase the extinction to about 0.8, and 15—30 % ethanol will bring it to about the same value as in ethanol. At the same time the addition of alcohol brings about a shift of the absorption maximum from about 500 mμ in xylene-acetic acid, to about 520 mμ, in the presence of 4 % ethanol, and to about 535 mμ at still higher alcohol concentrations. In our experiments we generally used absolute

ethanol for diluting our xylene-solutions to the mark in order to clarify them. This is the probable explanation of most of the discrepancy between our value and those found by the other workers, who use only 4 % butanol (0.2 ml color reagent) in their trials.

The presence of salts also may influence the extinction. When determinations are carried out in the presence of 10 % magnesium chloride, 0.001 milliequivalent peroxide will give an extinction of about 1.35.

The benzene-ethanol modification of the indophenol method

In our first paper we heated the xylene-acetic acid solution of leuco and fat in a boiling water bath for 10 minutes. Heating at 70° for 20 minutes is, however, sufficient to complete the oxidation of leuco by lipoperoxides. The greater part of the peroxide determinations in biological materials published by us were carried out using such a temperature and a solvent mixture consisting of ethanol-benzene-acetic acid 50 : 45 : 5.

The iron-catalyzed indophenol method

It is possible to carry out determinations at room temperature when a small amount of certain metals, for instance, iron or vanadium, is added. The determination can be carried out in the following way. The fat is dissolved in a mixture of equal parts of chloroform and alcohol to 5 ml volume. Two drops of the leuco reagent and one drop of a solution of 100 mg $FeCl_3$ in 100 ml of absolute alcohol are added, and the color compared with the blank after 10 minutes.

The indophenol method will give too high results when carried out in the presence of atmospheric oxygen. By the methods described above reproducible comparative results are obtained. In order to obtain correct values, however, it is necessary to carry out the determinations with the exclusion of oxygen. The iron-catalyzed indophenol method is especially easily carried out "anaerobically": The solution of fat + leuco is bubbled through with nitrogen for 10 minutes, a drop of ferric chloride is added, and the bubbling continued for 10 minutes more, after which the volume is adjusted and the colors are read in the photometer.

The presence of phospholipids causes an inhibition of the indophenol method. The inhibition can, in the case of the iron-catalyzed method, be overcome by the addition of magnesium chloride. Elevating its concentration results in acceleration of the color development. A method for the determination of peroxide groups in phospholipids by the indophenol method using the addition of 10 % magnesium chloride is reported in part C of this paper. The phospholipid inhibition of the iron-catalyzed indophenol method is probably due to complex-binding of iron to the phosphoric acid groups. A similar inhibition by phospholipids in the thiocyanate method for peroxide determination is probably also explained by complex-binding of the iron as will be reported in the following.

B. THE INFLUENCE OF PHOSPHATIDES ON THE THIOCYANATE METHOD

In a short communication Loftus Hills and Wilkinson [4] gave some observations on the influence of phosphatides on the determination of peroxide groups in fats by the ferric thiocyanate test. They added phosphatide in graded amounts to a series of solutions of 0.1 g of a slightly oxidized butterfat in 10 ml benzene-methanol. Milk phosphatide at a concentration of 0.05 % was found to interfere with the test, and in one of the experiments an amount of 0.5 % phosphatide completely inhibited color development.

These authors relate the effect of the phosphatides to the phosphoric acid group, pointing to the known interference by phosphoric acid in the thiocyanate test for ferric ions in aqueous solution. If this be true, *i.e.*, if complex formation between iron and the phosphoric acid groups of the phospholipids reduces the amount of red ferric thiocyanate compound, it is to be expected that the bleaching effect of phosphatide can be overcome by adding more thiocyanate or iron. This we found to be the case.

The first experiment, shown in Table 1, was carried out as described by Loftus Hills and Wilkinson. Graded amounts of phosphatide, freshly prepared from eggs, were added to a series of solutions of lard in 5 ml benzene-methanol (7 : 3). One drop of each of an ammonium thiocyanate and a ferric chloride solution, both prepared as described by Loftus Hills and Thiel [5], were added. The colors were read in the Beckman spectrophotometer at 500 mμ. As can be seen (Table 1), results almost identical with Loftus Hills and Wilkinson's with respect to the influence of phosphatide were observed. Next, 5 ml of a 6 % solution of ammonium thiocyanate in benzene-methanol was added to each test tube, and the colors read gain. The results as given in Table 1 are corrected for phosphatide blanks and adjusted to original volume of 5 ml. It is noted that even in the presence of 100 mg phosphatide, a large amount of ammonium thiocyanate could overcome most of the inhibition.

Table 2 shows the results of another experiment illustrating the effect of graded amounts of thiocyanate in overcoming the influence of a constant, high amount of phosphatide. A series of test-tubes were prepared containing

the same amount of a peroxide-containing lard as used in the previous experiment, 100 mg egg phosphatide, and the amount of ammonium thiocyanate given in the table, all in 5 ml benzene-methanol. One drop of the Loftus Hills-Thiel ferrous chloride solution was added, and the color read in the spectrophotometer.

Finally, an experiment is recorded in which the effect of increasing the iron concentration is demonstrated. The same solutions as in the first experiment — containing a constant amount of lard and graded amounts of phosphatide — were prepared in two series. One drop of the Loftus Hills ferrous chloride reagent per 10 ml solution was added to one series. One drop of a solution prepared in the same way and containing the same amount of hydrochloric acid, but twenty times as much iron, was added to the other series. The solutions were compared in the photometer with the corresponding blanks (Table 3).

The experiments recorded in Tables 1—3 quite well support the theory that the reason for the inhibiting effect of phosphatides in the thiocyanate test for peroxides is a complex-binding of ferric iron to phosphatides. This effect can be partly overcome by increasing the concentration of ferrous chloride added, or, more effectively, by increasing the thiocyanate concentration. In the Loftus Hills-Thiel method, the presence of phosphatide decreases the light absorption and also produces a shift in color from bright red to yellowish. This is possibly

Table 3. The effect on the peroxide test of low and high ferrous chloride concentration in the presence of varying amounts of phosphatides.

the reason that a still more complete inhibition is found when the colors are measured with a visual colorimeter of the type mostly used by Loftus Hills and his coworkers.

The experiments recorded in the tables were carried out in the same way as did Loftus Hills and Wilkinson, *i.e.*, without deaeration, but of course similar results are obtained when oxygen is excluded. The question whether the addition of high concentrations of ammonium thiocyanate can completely overcome the inhibiting effect of the phospholipids is discussed in the following part of this paper, which describes methods for the determination of peroxide groups in the presence of phospholipids.

C. THE DETERMINATION OF PEROXIDE GROUPS IN PHOSPHOLIPIDS AND PHOSPHOLIPID-CONTAINING FATS

Although it is well known that phospholipids usually contain a high amount of unsaturated fatty acids and are easily oxidized in the presence of atmospheric oxygen, it seems that the presence of peroxide groups in phospholipids has never been studied. Oxidation of the phospholipid has frequently been expressed simply by the decrease in iodine value.

Above we have reported our observations on the overcoming of the phospholipid inhibition in peroxide determination methods. The addition of magnesium chloride in the indophenol method, and of ammonium thiocyanate in the thiocyanate method, not only permit the determination of peroxide groups in triglycerides when phospholipids are present in large amounts, but also give reactions on oxidized samples of phospholipids containing very little triglyceride fat. The results obtained when the methods are employed on samples of phospholipids purified by repeated precipitation with acetone must be considered as indicative of the presence of peroxide groups in the phospholipids themselves.

Methods developed for the determination of peroxide in phospholipids and phospholipid-containing fats are outlined below.

Determination of peroxide groups in phospholipids by the indophenol method

A suitable amount of the lipid is dissolved in 5 ml of a mixture of equal parts of chloroform and 20 % $MgCl_2$, 6 H_2O in absolute ethanol. Two drops of leuco reagent and 1 drop of 0.1 % ferric chloride in ethanol are added. At the same time a blank containing 2 drops of leuco and 1 drop of ferric chloride solution in 5 ml chloroform-magnesium chloride-ethanol is prepared. After 10 minutes the colors are compared in the Beckman spectrophotometer at 530 mμ. The results are calculated on the basis of a linear relation between peroxide content and extinction of the amount of indophenol formed; 0.001 milliequivalent in 5 ml solution is assumed to give an extinction of about 1.35.

The test should preferably be carried out in the absence of oxygen. This can be done by passing oxygen-free nitrogen through the solution of lipid in magnesium chloride-containing solvent, and the corresponding blank for 10 minutes, then adding leuco and ferric chloride, and continuing to bubble with N_2 for 10 minutes. The deaeration can be carried out in the Beckman cuvettes using a volume of 3 ml and a glass capillary for the introduction of N_2.

Determination of peroxide groups in phospholipids by the thiocyanate method

A suitable amount of the lipid is dissolved in 5 ml of a solvent mixture containing 6 % ammonium thiocyanate in chloroform-ethanol (1 : 1). One drop of 0.22 % $FeCl_2$ prepared by Loftus Hills and Thiel's method is added. After a few minutes the solution is compared with a blank in the spectrophotometer at 500 mμ. The results are calculated on the supposition that 0.0003 milliequivalent peroxide in 5 ml solution gives an extinction about 1.0.

The test should be carried out in the absence of oxygen by passing purified N_2 through the solution for 10 minutes before ferrous chloride is added.

Results

A few typical results obtained by the two methods given above are presented in Table 4 which also contains the results found with the iodometric method. All methods were carried out in the absence of oxygen. The iodometric method used was the "cold" Lea modification [6], although this method has been worked out for triglycerides. The method is very unsuitable for phospholipids, since emulsions are formed when water is added before the titration, and at the same time a dark coloration of the oxidized phospholipids interferes with the exact observation of the disappearance of the iodine color. The results are, however, shown for comparison.

Table 4. Comparison of different methods for the determination of peroxide groups in phospholipids.

Discussion

From the reasons mentioned above, the iodometric method only permits very rough estimations. The results are probably too low, at least in freshly prepared phospholipids. On the other hand, with the two other methods, rather reproducible results are obtained that are almost identical, irrespective of the method.

In freshly prepared phospholipids generally higher values are found by the indophenol than by the thiocyanate method. The reason for this fact is not quite understood as yet. It might be that while in the indophenol method iron acts only as a catalyst, and so the final color development is independent of possible complex-binding of part of it to phosphoric acid groups, in the thio-

cyanate method partial binding of iron to phosphatides will lead to a decrease in color intensity. Such a difference between the functions of iron in the two methods could give a simple explanation of why too low values are found by the thiocyanate method in comparison with the, presumably, more stoichiometric values found by the indophenol method, when only small amounts of peroxide are present together with relatively much phospholipid. However, more work is needed to establish by which method the true peroxide content in the first stage of the oxidation of phospholipids is found. Until this problem is solved it cannot be definitely settled whether an upper limit exists for the amount of phosphatide that may safely be present in the thiocyanate method.

By means of the methods described we have been able to follow the formation of peroxides in freshly prepared phospholipids, and to demonstrate the presence of peroxides in certain phosphatides prepared from natural products. In a later paper methods for the separation of peroxides of phospholipids from peroxides of triglycerides will be described.

Since many fats and oils contain considerable amounts of phospholipids, Loftus Hills' modification of the thiocyanate method will yield too low values. When analyzing products like butter or soy-bean oil a higher concentration of thiocyanate should therefore be used, although perhaps not as high as in the case of products consisting almost exclusively of phospholipids.

Increasing the thiocyanate concentration up to a certain point gives a slightly higher light absorption of the ferric thiocyanate complex. A concentration of 2—5 % ammonium thiocyanate in the final solution will, in most cases, give maximal extinction.

As a solvent mixture we prefer a chloroform-ethanol solution. Although Loftus Hills and Thiel state that water has the same solubility in benzene-methanol as in chloroform-ethanol, we find that chloroform-ethanol (73 : 27) or chloroform-methanol will dissolve more water than the corresponding benzene-mixtures. Ethanol and, especially, methanol are good solvents for ammonium thiocyanate. Therefore, the use of aqueous solutions of this substance is not necessary.

As a result of these considerations we have arrived at the following modification of the thiocyanate method for fats containing moderate amounts of phospholipids. This modification can, of course, also be used for fats with low phospholipid content.

The fat is dissolved in chloroform-absolute ethanol (5 : 3) and brought to a volume of 8 ml. Two ml 30 % ammonium thiocyanate (analytical grade) in absolute methanol are added. After daeration for 10 minutes with purified nitrogen, 1 drop of the Loftus Hills-Thiel ferrous chloride reagent (or a reagent prepared in the same way but of double strength [7]) is added, and the colors are measured after a few minutes. In our hands, heating at 50° C was not necessary. Loftus Hills has come to the same conclusion (personal communication).

D. COMPARISON OF METHODS. GENERAL DISCUSSION

In this part of our paper we shall report typical results from experiments carried out in order to compare different methods for the determination of peroxides.

The iodometric method was carried out by the "cold" Lea method [6]. At the same time the substances were tested by the same method carried out "aerobically", that is, in exactly the same way but without bubbling through with nitrogen.

The thiocyanate method was used in the Loftus Hills and Thiel modification [5]. However, a double strength ferrous chloride solution was used [7], and the heating at 50° C was omitted. Also in this case two series of tests were carried out. In one series the solutions were deaerated with nitrogen for 15 minutes before the iron solution was added. In the case of benzoyl peroxide a higher concentration of ammonium thiocyanate (5 %) was used, since the concentration used by Hills and Thiel resulted in a very low reaction velocity.

Similarly, the same substances were tested with and without deaeration before the addition of ferric chloride, by the iron catalyzed indophenol method. The results are summarized in Table 5.

Table 5. Comparison of different methods for the determination of peroxide groups in fat, with and without the exclusion of atmospheric oxygen.

	Milliequivalents of peroxide per kg fat					
	Iodometric method		Thiocyanate method		Indophenol method	
	O_2 absent	O_2 present	O_2 absent	O_2 present	O_2 absent	O_2 present
Butterfat	0	0	0.2	0.25	0.3	0.46
»	0.6	1.2	1.25	1.45	1.1	1.75
»	1.07	2.2	1.85	2.1	1.75	2.45
Lard	4.3	4.7	5.8	7.6	4.0	7.4
»	280	344	395	450	320	570
Cod liver oil	5.4	6.4	6.6	7.1	4.8	9.6
» » »	28.5	36	42.5	49	39	52
Ethyl oleate hydroperoxide	840	940	970	1 230	840	1 140

It will be seen from Table 5 that all the methods give higher values in the presence of dissolved oxygen. In most cases the indophenol method showed the highest and the thiocyanate method the lowest degree of oxygen sensitivity.

The oxygen sensitivity of various methods has been studied by other investigators, *e.g.* Lea [3, 6, 9], who finds the iodometric method to be by far the least sensitive to oxygen. The reason for this discrepancy is, probably, smaller or larger differences in methods and purity of the chemicals. For example, Lea's studies on the influence of oxygen on the thiocyanate method were mainly carried out with a modification [9] rather different from ours.

It should be pointed out that we have found no considerable oxygen sensitivity in any of the methods when they were carried out on benzoyl or hydrogen peroxide. This also holds true for the original modification of the indophenol method first published [1]. Contrary to the criticism of Hartmann and White [2], our results suggest that atmospheric oxygen only interferes in the methods when a free radical is formed in the reaction which is stable enough to function as a carrier in a chain reaction.

When comparing the anaerobic results presented in Table 5, it is seen that, although in most cases the thiocyanate method gives the highest, the iodometric the lowest values, almost identical results are found, irrespective of the method.

The literature in this field is quite confusing, and direct comparisons between anaerobic methods for the determinations of peroxides in fats and oils are scarce. Lea [3], for instance, presents several tables comparing the aerobic colorimetric methods with the anaerobic iodometric method, but no figures concerning a direct comparison between the different anaerobic methods. He observed that ferric thiocyanate determinations with exclusion of atmospheric oxygen gave much too low results, but he presented no details that make it possible to find out why he was unable to obtain quantitative results with the thiocyanate method.

Kolthoff and Medalia [8] found lower results in certain oxidized fatty substances by the anaerobic thiocyanate method than by the iodometric method. However, they used a thiocyanate method very different from ours, with acetone as solvent.

Kolthoff and Medalia have proposed a mechanism for the thiocyanate reaction and possible by-reactions which explains the high results found by the influence of an organic solvent in the presence of oxygen, and low results due to decomposition by the solvent. They assume that the reaction between hydroperoxide and ferrous ions takes place through two one-electron transfers

$$ROOH + Fe^{++} \rightarrow RO^{\cdot} + OH^{-} + Fe^{+++};$$
$$RO^{\cdot} + Fe^{++} + H^{+} \rightarrow ROH + Fe^{+++}.$$

The free alkoxy radical RO $^{\cdot}$ is very reactive and may react with solvent molecules *etc.*, whereby the by-reactions are initiated.

The reactions are quite complex. Lea [3] can, however, scarcely be right in his rather pessimistic view that the complicated character *per se* of the reaction can prevent it from being made truly stoichiometric. The complicated character of the reaction so far cannot be used as an argument for the superiority of the iodometric method, especially since the chemical reactions involved in the iodometric method are probably equally complicated or quite analogous, with the intermediate formation of reactive alkoxy radicals.

Lea thinks that there is no advantage in carrying out the ferric thiocyanate determination with exclusion of atmospheric oxygen, since the method then loses much of its desirable simplicity, and also that the results with oxidized fats become much too low [3]. However, it seems that the thiocyanate method remains much simpler than the iodometric even though in both cases atmospheric oxygen is removed by bubbling with nitrogen. Lea [3] and G. Howard Smith [7] recommend the thiocyanate method in the presence of oxygen as a micromethod and think that by division with a conversion factor about 2, but slightly different for different fats, the values can be converted into the true values. Aerobic determinations carried out under uniform circumstance have proved to give relative values that are useful for many practical purposes. However, the physical foundation of the conversion factors involves so many single factors which can deviate from laboratory to laboratory and from trial to trial that their use becomes rather unsafe. Kolthoff and Medalia have

concluded, more justifiably, that the only sound basis for the development of satisfactory procedures for the thiocyanate reaction is complete exclusion of oxygen and the use of a solvent which entirely suppresses the induced decomposition of the peroxide.

When comparing the methods it should be borne in mind that the iodometric method is unsatisfactory for substances having a low peroxide content. The limit of sensitivity is about 0.05 ml 0.002 *N* thiosulfate, corresponding to 10^{-4} milliequivalent peroxide, probably a still higher value since a blank titration has to be subtracted. On the other hand, by the thiocyanate method, a difference in extinction of 0.05 can easily be observed, corresponding, in a 5 ml volume, to about 0.15×10^{-4} milliequivalent. For practical application, especially in work with foods, a high degree of sensitivity is the most important problem. In a product like butter, oxidative changes, giving a distinct off-flavor, are often observed by a peroxide content of about 0.2 milliequivalent per kg. Such a small quantity of peroxide can scarcely be determined by the iodometric method, whereas still lower values can quite well be determined by the colorimetric methods.

In nutritional work, *e.g.*, it is generally of little importance to know exactly the peroxide content of a product which has been definitely rancid for a long time, and there is thus little reason to use the rather troublesome iodometric method. Even though the colorimetric methods are only carried out with an error of about 5—10 %, this is, as a rule, sufficiently accurate for work with foods.

On the other hand, since a titration can be carried out very exactly, the iodometric method will allow much more exact determinations of higher peroxide contents. This is very important *e.g.*, in chemical work with peroxides, and the iodometric method must be preferred in such work.

A very sensitive method, based on the iodometric, is the thiofluorescein method, given by Dubouloz *et al.*[10]. However, while in the thiocyanate and the indophenol colorimetric methods, colors are measured that are proportional to the peroxide content, in the thiofluorescein method a decrease in color intensity is measured, so that the lowest contents of peroxide are least exactly determined. Furthermore, the thiofluorescein method is quite complicated in comparison with the other colorimetric methods.

Regarding the two colorimetric procedures, it must be concluded that the thiocyanate method is preferable to the indophenol method for general use. The reason for this conclusion is that although the very saturated indophenol color seems as intensive to the eye as the thiocyanate color, nevertheless a given amount of peroxide in the same volume will give a color intensity of only 30 % of the color intensity produced by the thiocyanate method with correspondingly lower sensitivity. For special purposes the indophenol method may still be useful, *e.g.*, in work with phospholipids, since in the first stage of the oxidation of such substances the indophenol method is possibly more truly stoichiometric.

Effect of Irradiation on Hemin Formation

R. BONNICHSEN and G. HEVESY

Nobel Institute for Biochemistry and Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

Irradiation with Röntgen rays was found to depress very appreciably the rate of extrusion of ^{59}Fe bound to β_1-globulin in the circulation of the rabbit, the depression being much more pronounced 2 days after irradiation than shortly after exposure. It is suggested that erythrocytes of the bone marrow which have not yet completed their hemoglobin content are radioresistant and continue to incorporate ^{59}Fe in the bone marrow of the irradiated animal. Correspondingly, the effect of exposure to radiation on the rate of extrusion of ^{59}Fe from the plasma gets strongly pronounced only after the lapse of several hours.

A radiation dose which reduces the incorporation of ^{59}Fe into the hemoglobin to 30 % of that of controls does not diminish the rate of incorporation of ^{59}Fe into cytochrom b of the liver of guinea-pigs.

The rate of incorporation of ^{59}Fe into myoglobin of the muscles of guinea-pigs was found to be reduced in the exposed animals. The interpretation of this finding are discussed.

The study of iron metabolism can be approached in different ways, a very profitable one being the study of the fate of plasma iron. Iron utilized for hemoglobin formation has to pass the plasma, so iron coming from and going to the various organs in which it is present as a constituent of ferritin, hemosiderin, myoglobin, cytochrom, catalase or other compounds.

Flexner *et al.*[1] injecting labelled ferric chloride into the circulation of guinea-pigs observed a rapid initial disappearance of the radioactive iron from the circulation followed by a slower process. They interpreted the first process to be due to the disappearance of inorganic iron, the second to iron bound to proteins. These early experiments brought thus already out the difference between the circulating "physiological" iron and the plasma foreign iron injected into the circulation. The physiological plasma iron is bound to the β_1-globuline of the plasma which amounts to 3 % of the plasma proteins. This protein fraction, the transferrin, is identical with Cohn's fraction IV—7 as shown by Holmberg and Laurell [9], by Laurell [3] and others. That the albumine fraction of the plasma proteins does not fix iron was recently demonstrated by Wuhrmann and Jasinski [4] by combining paper chromatographic

with radioactive measurements. From the spots of the paper diagram of the plasma proteins from a rabbit 10 minutes previously injected with labelled ferric chloride only that due to β_1-globulin was found to be radioactive.

How the turnover rate of the circulating plasma iron is influenced by interference with hemeoipoetic processes going on in the human and animal organism was investigated in numerous cases by John Lawrence and his colleagues and several others.

Being interested in the problem of radiation anemia we determined the rate of disappearance of labelled plasma globulin from the circulation of rabbits exposed to Röntgen rays and the incorporation of ^{59}Fe into the circulating hemoglobin and into marrow hemin of guinea-pigs and rabbits. The effect of irradiation on the incorporation of ^{59}Fe into the red corpuscles of the rabbit and of the rat was previously investigated by Huff, Henessy and their associates [5,6].

In view of the marked effect of irradiation on the incorporation of ^{59}Fe into hemoglobin we wished to know if hemins formed in another *milieu* than the bone marrow are affected by irradiation as well. We investigated therefore the effect of exposure to radiation on the incorporation of ^{59}Fe into the iron containing enzymes of the liver and into cytochrome c and myoglobin of the muscles. In this note results obtained in the investigation of cytochrom b (Strittmatter [26]) of the liver and that of myoglobin are communicated.

EXPERIMENTAL

In 21 experiments with guinea-pigs an aggregate number of 220 animals, weighing 450—700 g, were injected intraperitoneally with 0.2—0.4 ml of saline containing 2 to 7 μg of with ^{59}Fe labelled iron of 1/2—1/4 μCurie activity. Half of the guinea-pigs was exposed to X-rays (160 kV, 43 r per min. for 10 to 33 minutes). Injection took place 15 to 300 min. following exposure. No food was administered during the experiment.

The animals were killed 4 to 48 hrs later, their livers homogenized in sucrose and fractionated as described by Hogbein and Schneider. Ferritin was extracted both from microsomes and from the supernatant, cytochrom b hemin from microsomes (Loftfield [7]) and catalase from the supernatant. Total iron, cytochrom c and myoglobin iron were furthermore isolated from the muscles making use of the method of Theorell and Åkeson [8].

Ferritin was precipitated from the supernatant by addition of half volume of ammoniumsulfate. The precipitate was taken up in water and repeatedly fractionated with ammoniumsulfate. The precipitate was then taken up in water, heated to 70° C for a few minutes and centrifuged after cooling. The supernatant ferritin was found to contain 17 to 20 % iron.

The microsomes were homogenized in water, the pH adjusted to 5 and centrifuged after the lapse of 30 minutes. The precipitate was once more homogenized and washed with water. All the microsome ferritin was found to be in the water phase. The insoluble particles contained the cytochrom b and some proteinbound iron. The cytochrom b hemin was extracted from this fraction with a mixture of acetone and HCl (10 ml 20 % HCl in 1 liter of acetone). The acetone was evaporated *in vacuo*, the precipitated hemin washed with 1 *N* HCl and dissolved in ether. The ether was evaporated and the hemin combusted with sulfuric acid and hydrogen peroxide. The determination of iron was carried out by a colorimetric method using the sulfosalicylic acid complex.

An aliquot of the solution was used for colorimetric determination of the iron content, to another aliquot iron chloride was added bringing its iron content up to 500 μg. The iron was precipitated as FeS and filtered through a perforated aluminium dish covered with filter paper as described by Agner *et al.*[9]. The aluminium dish was then placed under the window of a Geiger counter. An aliquot of the solution which was injected was trea-

ted in the same way. The data obtained permitted to calculate the relative specific activity of the iron fraction (activity per mg iron in arbitrary units) and also the absolute specific activity (percentage of injected ^{59}Fe present in 1 mg of iron).

In our experiments on the iron turnover of the plasma 5—10 μg of iron having an activity of about 2 μCurie were injected into the ear vein of a rabbit. After the lapse of about 1 h a few ml of the plasma of this rabbit, which now contained all ^{59}Fe present in the plasma as β_1-globulin, was injected into the jugular vein of a sister rabbit. At intervals blood samples were taken from the carotic vein of this rabbit, the heparinized blood centrifuged, the plasma combusted as described above, 500 μg carrier iron added and the iron precipitated as sulphide as described above. 2—3 kg rabbits were applied in these experiments, in which the effect of irradiation on the formation of labelled hemoglobin and labelled hemin of the bonemarrow was investigated.

RESULTS

a) Cytochrom b

The data obtained for the ratio of the specific activities of cytochrom b iron (Strittmatter [26]) and also of microsome ferritin iron of irradiated and control guinea-pigs are listed in Table 1. Out of 13 ratios listed in Table 1 one is as low as 0.77, but even this ratio is by about 250 % higher than that obtained for hemoglobin iron, which was found to be 0.3, corresponding to a depression of ^{59}Fe incorporation into hemoglobin in the irradiated guinea-pig to 1/3 of that into the hemoglobin of controls.

Table 1. Effect of exposure to 500—1 400 r on the incorporation of ^{59}Fe into the cytochrom b of the liver of guinea-pigs. Each figure is obtained by pooling 5 livers.

Mean value	1.25 ± 0.036	1.32 ± 0.010

Not only does exposure of guinea-pigs to large doses of Röntgen rays not diminish the rate of incorporation of the ^{59}Fe into cytochrome b but as seen in Table 1 promotes it. The increased incorporation of ^{59}Fe does, however, not or not mainly indicate an increased rate of formation of cytochrome b. It is, at least to a large extent, due to the change in sensitivity of the radio-

active indicator. About half of the plasma iron takes its way into the bone marrow and is applied to hemoglobin synthesis, the other half into the liver and other organs. The labelled iron atoms which leave the plasma are replaced by inactive ones coming from the organ depots and to a minor extent from the intestine. Irradiation upsets this distribution. Incorporation into hemoglobin is strongly reduced which results in an increased life time of ^{59}Fe in the plasma which in turn leads to a change in the sensitivity of the radioactive indicator. The increase in the iron content of the plasma of the irradiated animals (Schuck [10], Ludewig [11]) remains behind the increase of its ^{59}Fe content and correspondingly the sensitivity of the radioactive indicator decreases. Thus we can expect more ^{59}Fe to reach the liver in the exposed animals than in the controls. If this line of thought is correct we must expect the ratio of the specific activity of the iron of exposed and control animals, which for cytochrom b was found to be 1.3, to be about 1.3 for other liver fractions as well (as far as their rate of formation is not influenced by irradiation). As seen from Table 1 this is almost the case for microsome ferritin, 1.32 being found for the corresponding ratio.

Elmlinger *et al.*[12] found in normal humans about 55 % of the iron which passed the plasma to be utilized in red corpuscle formation. The rest takes its way into the other organs. Should the last mentioned inflow be unilateral the iron content of these organs would increase already in the course of 120 days with about 2 g which is more than the total iron depot of a man which amounts to about 1.6 g (Haskins [13]). We have therefore to conclude that the flow or iron from the plasma into the depot organs goes hand in hand with an outflow of an even larger amount of iron from the depots into the plasma.

A different line of thought supports this view. Hemoglobin iron is almost quantitatively reutilized for hemoglobin formation as shown by Hahn *et al.*[29]. We injected labelled red corpuscles of a donor rabbit to an acceptor rabbit and after the short interval of only 5 hours found 90 times more ^{59}Fe in the liver than in the spleen of the thoroughly perfused animals, the gall containing 2/3 of that of the last mentioned organ. The reutilization of this iron for hemoglobin formation necessitates its passage through the plasma to the marrow. Thus a continuous flow of iron from the liver (and presumably other organs responsible for the phagocytosis of red corpuscles) to plasma has to take place. In the course of 120 days (the time necessary to replace the circulating human red corpuscles) about 2 g of iron has to pass from the depot organs to the bone marrow. The corresponding figure in the rabbit in the course of 50 days is about 0.1.

Effect of irradiation on ^{59}Fe incorporation into hemoglobin. As to be expected and also shown by Huff [5], Hennessy [6] and their associates irradiation strongly depresses the incorporation of ^{59}Fe into hemoglobin. Our results obtained with guinea-pigs injected within 6 hours after exposure and killed 17 hours later are seen in Table 2.

In each of the experiments Nos. 9 to 16 the blood of 10 guinea-pigs, in Nos. 21 and 22 of 20 animals was pooled.

Incorporation of ^{59}Fe into hemoglobin was thus reduced by irradiation in these experiments to 30 % of that of controls.

Delay of the effect of irradiation on the incorporation of labelled iron into hemoglobin. Red corpuscles are very radioresistant. We need very massive doses to achieve hemolysis and a dose of 4 000 r for example as shown by Sheppard [14] does not influence the rate of intrusion of ^{42}K in the red corpuscle though it does to some extent weaken the mechanism responsible for the concentration of potassium in the red corpuscles. Dog blood exposed to a dose of 200 000 r does not hemolyse as observed by Nizet *et al.*[24].

The radioresistance of circulating red corpuscles suggests that the not fully completed red corpuscles in the bone marrow are radiation resistant as well and continue even in the exposed animal to complete their hemoglobin content. In the bone marrow of swine exposed to radiation of the Bikini explosion often only fat cells and a few clumps of erythrocytes were found [25].

The above conclusion is supported by the observation that the uptake of ^{59}Fe or ^{14}C by the hemoglobin of red corpuscles *in vitro* is not reduced by irradiating the animal before securing the blood sample. Reticulocytes and other types of incomplete red corpuscles can complete their hemoglobin content *in vitro*. Not only is the ^{14}C incorporation *in vitro* not smaller into the blood corpuscles of irradiated animals than into those of controls, it is even markedly enhanced as shown by Nizet *et al.*[15] who investigated the uptake of ^{14}C by the dog. Rauntanan and one of us made similar observations when studying incorporation of ^{59}Fe *in vitro* into the red corpuscles of the hen which was found to be increased in extreme cases up to 300 % if the hen was 18 hours previously exposed to a dose of 1 000 r. Irradiation induces presumably the bone marrow to release some of the red corpuscles in an earlier stage of their maturation. Nizet *et al.* have furthermore shown that irradiation *in vitro* produces changes in the plasma which are favourable to ^{59}Fe incorporation into the red corpuscles.

These considerations support the conclusion that as far as red corpuscles in the advanced stage of their maturation are present in the bone marrow a completion of their hemoglobin content takes place even in the exposed organism

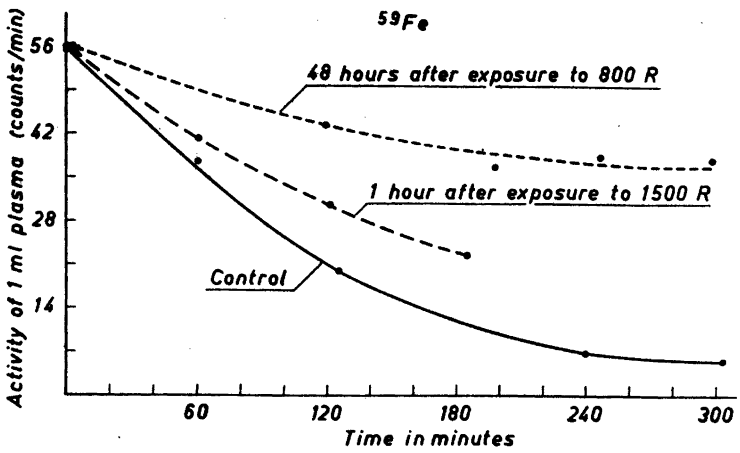

Fig. 1. Effects of exposure to Röntgen rays on the rate of extrusion of circulating labelled plasma iron from the circulation of rabbits.

and that some of the ^{59}Fe administered shortly after irradiation will be utilized by the bone marrow. With increasing time the completed red corpuscles being discharged into the circulation or wiped out in the exposed organism the utilization of ^{59}Fe by the bone marrow will diminish and after the lapse of about 1 day may almost cease. As the non-utilization of labelled plasma iron by the bone-marrow leads to a depressed turnover rate of the plasma iron this depression is to be expected not to be shown to its full extent already shortly after irradiation but only at a later date. That this is the case is demonstrated by Fig. 1 and the data of Table 2.

As seen in Fig. 1 the effect of irradiation with such a high dose as 1 700 r influences the rate of extrusion of ^{59}Fe from the plasma, when measured 1/2 hour only after exposure, is much less than an irradiation with 800 r only, when the rate of extrusion is measured 2 days after irradiation.

When injecting rabbits weighing 600 g intraperitoneally with labelled $FeCl_3$ 48 hours after exposure to 500 r we observed 5 hours after injection the ^{59}Fe content of the plasma to be 120 % higher than that of the control. In experiments in which 500—900 g rabbits were injected intraperitoneally within 1/2 hour after irradiation with 5 μg labelled iron as $FeCl_3$ and killed 3 hours later the ^{59}Fe content of the plasma was increased with 6 % only. Further data on the effect of time which elapsed after exposure to irradiation on the ^{59}Fe content of the plasma is seen from Table 3. This table also contains data on the incorporation of ^{59}Fe into hemoglobin, which is much more markedly depressed under the effect of irradiation after the lapse of 48 hours than after that of 1/2 hour. In these experiments 5 μg of iron as $FeCl_3$ were interperitoneally injected to each rabbit. Similar observations on the effect of irradiation on the incorporation of ^{59}Fe into the red corpuscles were made by Hennessy and Huff[6].

These results support the conclusion arrived at that for some time after irradiation the completion of the hemoglobin content of the red corpuscles is still going on in the marrow and supports indirectly also the result arrived at by Thorell that hemoglobin is layed down in the later phase of the maturation of erythropoeitic cells of the bone marrow.

Table 3. Incorporation of interperitoneally injected ^{59}Fe in the course of 5 hours into the hemoglobin of controls and with 500 r irradiated rabbits. C = control. R = exposed.

Time in hours between exposure and injecting of ^{59}Fe	Relative ^{59}Fe content			
	Plasma		Hemoglobin	
	C	R	C	R
0	100	100	100	100
0.5	100	118	100	68 *
17	100	124	100	56
48	100	223	100	3.2
72 **	100	447	100	17.3

* For the bone marrow hemin the corresponding figure was 43.

b) Muscle myoglobin

In view of the fact that the chemical composition of myoglobin closely resembles that of hemoglobin — they are differing only as to their degree of polymerisation — it was of great interest to investigate the effect of exposure to irradiation on the incorporation of ^{59}Fe into the myoglobin of guinea-pigs extracted from their muscles. The method of purification was that described by Theorell and Åkeson [8]. The myoglobin obtained was practically free from hemoglobin as revealed by a spectroscopic investigation of the CO-myoglobin. In 4 experiments in each of which 10 female guinea-pigs having a weight of 450—550 g were injected 6 hours after exposure to 1 400 r with 3 μg of labelled iron as sodium iron citrate and killed 18 hours later and 10 controls were treated in the same way the following rel. specific activity figures were obtained for the myoglobin and hemoglobin iron of controls and exposed animals.

Table 4. Effect of irradiation on the incorporation of ^{59}Fe into myoglobin and hemoglobin of guinea-pigs. Control = C, exposed = R.

No. of expt.	Rel. spec. activity * of myoglobin		Ratio $\frac{C}{R}$	Rel. spec. activity of hemoglobin		Ratio $\frac{C}{R}$
	C	R		C	R	
1	0.098	0.042	2.3	0.236	0.047	5.0
2	0.034	0.026	1.3	—	—	—
3	0.476	0.215	2.2	2.19	0.48	4.6
4	0.415	0.164	2.6	2.44	0.68	3.6

* count per μg Fe.

Under effect of exposure the ^{59}Fe incorporation into myoglobin was thus reduced to 1/2, that into hemoglobin to 1/4 of that of the controls. In the 2 last experiments we determined the effect of exposure on the specific activity of the total iron present in the muscles as well and found it, as to be expected (*cf.* p. 511), increased under the effect of exposure, in the third experiment from 0.714 to 0.810, in the fourth one from 0.687 to 1.04.

DISCUSSION

Hemoglobin is one of the comparatively few molecular constituents of the adult organism that is formed in close connection with cell division. The latter being very susceptible to the effect of ionising radiation, exposure to radiation is bound to interfere with hemoglobin formation as well. Furthermore marrow cells are radiosensitive and exposure to radiation may lead to destruction of marrow cells. Irradiation of rats with 400 r was found to lead to a decrease in the total number of marrow cells to almost one half of its normal value in the course of the first day following exposure (Brecher [15]) and the chemical composition of the bone marrow was found markedly influenced. Lutwak-Mann [17] found 3 hours only after total body exposure to a dose of 1 500 r the labile acid-soluble P of the bone marrow of rabbits to be reduced by 30 %, that of DNA and RNA phosphorus by 20 and 16 %. The total nucleic acid P of the marrow of the to 500 r exposed rat amounted to only half of that of controls. Mandel *et al.*[18] report the bone-marrow of rats exposed to 500 r to show after the lapse of 26 hours a by 50 % reduced PNA content, the DNA being reduced to 30 % of that of the controls after the lapse of 2 days. Thus radiation anemia is at least partly due to the fact that hemoglobin is formed in close connection with the cell division and also that it takes place in the radiosensitive marrow cells.

Altmann *et al.* (Richmond [19], Stokinger [20]) in their very extended studies found incorporation of ^{14}C into globin and hemin to be influenced at a very different rate by irradiation. Incorporation of ^{14}C into hemin of the exposed animals was greatly depressed, whereas globin was affected to a considerably smaller extent. From this finding it does not necessarily follow that it is not the *milieu* of its formation, the bone marrow, which is responsible for the radiation sensitivity of the formation of hemoglobin.

We found no interference with the formation of cytochrom b in the liver of the strongly irradiated guinea-pig. In this case heme formation is thus not radiosensitive. We found, however, interference with formation of myoglobin. We are reluctant to make any definite conclusion from this finding. The possibility must not be excluded that myoglobin formation in the muscles of the 450—550 g guinea-pig takes place in connection with mitotic processes. Histologic evidence proves cell division in muscle tissue to be a very rare process. A very few mitoses would however be sufficient to account for the formation of much of the myoglobin of the muscles as a process preceded by cell division. This is shown by the following calculation.

The maintenance of a hemoglobin level of 6 g per kg guinea-pig requires a mitotic figure of 1—2 % in the hemopoietic bone marrow weighing about 10 g. The amount of myoglobin present in the guinea pig is not known. Assuming

the hemoglobin content of the guinea-pig to be 32 times its myoglobin content as found for the rat by Drabkin [27] and furthermore that the muscle tissue of the guinea-pig amounts to 40 % of its body weight, *i.e.* its myoglobin being formed in a 40 times larger amount of tissue than its hemoglobin, then the mitotic figure to maintain the production of myoglobin should be 32 × 40 times less than that permitting the production of hemoglobin. We have further to consider that the life cycle of myoglobin is longer than that of hemoglobin. No exact data are available on the life cycle of myoglobin. Theorell *et al.*[28] estimate hemoglobin to have an about 4 times longer life time than hemoglobin and from the finding of Helwig and Greenberg [21] a ratio of 2—3 follows for the life time of the protohemin part of myoglobin and hemoglobin; our figures suggest a ratio of about 3. We have thus to multiply the above mentioned 32 × 40 by at least 3 to arrive at the ratio of mitotic figures in the hemopietic bone marrow and the muscle tissue assuming the formation of myoglobin being preceded by cell division. This ratio works out to be about 4 000. If out of 200 000 cells one would show division it would suffice to interpret myoglobin formation to be in close connection with cell division.

It is often assumed that amiotic division of muscle cells is less rare than a miotic one. As irradiation can be expected to interfere with this type of cell division as well it is bound to depress myoglobin formation if myoglobin is laid down as we are inclined to assume in the course of maturation of muscle cells. We are engaged in determining the effect of irradiation on the incorporation of ^{59}Fe into myoglobin of both fully grown and growing rats in the hope of getting more information on the radiation sensitivity of myoglobin formation.

Our thanks are due for valuable assistance to Mr. Åke Åkeson, Mrs. Ingegerd Björkman and Miss Jutta Schliack, to the *Knut och Alice Wallenbergs Stiftelse* and to the *Riksföreningen för kräftsjukdomarnas bekämpande, Cancernämnden*, for their generous support of this investigation.

Synthesis of Ureidosuccinic Acid with Soluble Enzymes from Liver Mitochondria and *Escherichia coli* *

PETER REICHARD and GUNNAR HANSHOFF

Department of Biochemistry, Karolinska Institutet, Stockholm, Sweden

An extract from rat liver mitochondria catalyzed the enzymatic formation of ureidosuccinic acid from aspartic acid, NH_3 and CO_2 in the presence of acetylglutamate, Mg^{++}, ATP and an ATP regenerating system. It was shown that the reaction proceeded in two enzymatic steps. The first involved the formation of compound X from acetylglutamate, NH_3, CO_2 and ATP in the presence of Mg^{++}. In the second step compound X was condensed with aspartate to form ureidosuccinate.

The enzyme catalyzing the second step was also present in rat spleen, kidney and heart and in an extract of *E. coli*.

The enzyme from *E. coli* was purified about tenfold and found to catalyze the following reaction:

L-aspartate + compound X → L-ureidosuccinate (+ acetylglutamate + phosphate).

The enzymatic synthesis of ureidosuccinic acid (USA **) has been demonstrated with isolated mitochondria from rat liver. [1] It was found that USA was synthesized from NH_3, CO_2 and L-aspartate in the presence of Mg^{++}, ATP and carbamyglutamate under conditions where ATP was regenerated by oxidation of glutamate or succinate.

The requirement of a substituted glutamate derivative suggested a similarity between USA synthesis and the enzymatic synthesis of citrulline, which is also localized in rat liver mitochondria. The work of Grisolia and Cohen (see *e.g.* Grisolia [3]) has demonstrated that the enzymatic synthesis of citrulline requires at least two steps. The first involves an "activation" of CO_2 and NH_3 with a substituted glutamate derivative (*e.g.* carbamylglutamate or acetylglutamate) and ATP in the presence of Mg^{++} to form an unstable "compound X" whose exact structure has not yet been elucidated:

* A preliminary report of part of this work was given at a meeting of the Swedish Biochemical Society (*Acta Chem. Scand.* 8 (1954) 1102).

** The following abbrevations are used in this paper: USA, ureidosuccinic acid; ATP, adenosine triphosphate; PGA, 3-phosphoglyceric acid; PCA, perchloric acid; MP, muscle protein fraction, prepared according to Ratner and Pappas [2].

$$NH_3 + CO_2 + ATP + \text{acetylglutamate} \rightarrow \text{compound X} + ADP \quad (1)$$

In the second reaction citrulline is formed by condensation of compound X with ornithine:

$$\text{Compound X} + \text{ornithine} \rightarrow \text{citrulline} + \text{acetylglutamate} + P_i \quad (2)$$

USA synthesis also involves a fixation of ammonia and carbon dioxide on an amino group which is carried out with the aid of carbamyl- or acetylglutamate and ATP [1]. It seemed rather probable, therefore, that reaction (1) was the first step in USA synthesis also, followed in sequence by the final reaction:

$$\text{Compound X} + \text{L-aspartate} \rightarrow \text{L-ureidosuccinate} + \text{acetylglutamate} + P_i \quad (3)$$

The present paper describes evidence obtained for reactions (1) + (3) in extracts from rat liver mitochondria. Reaction (3) has furthermore been studied with a partially purified enzyme from *E. coli*.

After the completion of this work Lowenstein and Cohen [4] have briefly described the formation of labeled USA from ^{14}C-compound X in rat liver supernatant.

MATERIALS AND METHODS

L-Acetylglutamic acid was synthesized according to Karrer *et al.*[5], *D,L-ureidosuccinic acid* according to Nyc and Mitchell [6]. *ATP* and *PGA* were purchased as barium salts from Sigma company. The sodium salts were prepared as described earlier for ATP [1].

L-Aspartic acid-^{15}N and *L-aspartic acid-2,3-*^{14}C have been synthesized earlier [7].

Acetone powder of rat liver residue and *enzyme B* (obtained by alcohol fractionation of the acetone powder extract) were prepared as described by Grisolia and Cohen [8].

Compound X was prepared enzymatically and purified according to an unpublished method of Grisolia *. It was found that optimal time conditions for obtaining compound X synthesis had to be determined for each preparation of enzyme B. As already demonstrated by Grisolia and Cohen [8] the amount of compound X formed reached a maximum after some time and then rapidly decreased. Increasing enzyme concentration produced compound X in maximal yields of 40—50 % (based on acetylglutamate). Further increases in enzyme concentration served only to produce a more rapid formation of about the same amount of compound X. These interrelationships are demonstrated by Fig. 1.

For each new enzyme preparation a time curve of optimal compound X synthesis was determined with an enzyme concentration of 10 mg/ml. The same enzyme preparation gave then very reproducible results.

Purification of compound X was carried to the "20 % pure" stage according to Grisolia's description with isolation as the calcium salt. According to the enzymatic assay (formation of citrulline with heat denatured enzyme B and ornithine [8]) different preparations contained between 16.5—21 % compound X. A nitrogen analysis in one case showed that 62 % of the nitrogen in the calcium precipitate corresponded to compound X. When $^{15}NH_4Cl$ was used for the preparation of compound X, isotope analysis of the "20 % pure" precipitate showed that 42 % of all nitrogen originated from the isotopic ammonia. Pure compound X would give a value of 50 %, since only one out of two nitrogen atoms stems from ammonia. The data thus indicate that a greater part of the impurities in the "20 % pure" precipitate do not contain nitrogen. Light absorption measurements of an extract of compound X showed only negligable absorption at 2 600 Å (corresponding to less than one molecule of adenine derivative per 100 molecules of compound X).

* We wish to express our great appreciation to Dr. Grisolia who gave us the details of the method for preparation of compound X before publication.

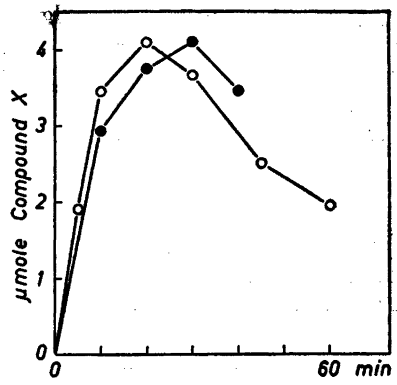

Fig. 1. Synthesis of compound X. Each vessel contained per ml: 2 µmole ATP, 25 µmole PGA, 20 µmole $MgSO_4$, 10 µmole acetylglutamate, 15 µmole $NaHCO_3$, 20 µmole NH_4Cl, 2 mg MP. pH = 7.3. ○ = 15 mg enzyme B, ● = 10 mg enzyme B. The values for the formation of compound X are given for 1 ml.

Quantitative analysis for compound X was carried out with heat treated enzyme B[8]. Analysis for citrulline was made according to Koritz and Cohen [9].

Determination of ureidosuccinate. The experiments were carried out with isotopic substrates. In the study of the liver enzyme $^{15}NH_4Cl$ and L-aspartate-^{15}N were used. The amount of USA formed was then determined by the isotope dilution method as described earlier [1]. In experiments with the enzyme from *E. coli* L-aspartate-2,3-^{14}C was the substrate together with nonlabeled ammonia and CO_2, or compound X. At the end of each experiment carrier nonlabeled USA (usually 200 µmoles) was added and the amount of enzymatically formed USA was calculated from the radioactivity in the reisolated substance. Radioactivity determinations were carried out on infinitely thin samples in a windowless gas flow counter. Since the aspartic acid used as substrate contained 12 000 ct/min./µmole (infinite thin sample) the amount of enzymatically formed USA could be calculated according to:

$$\mu\text{moles USA formed} = 200 \cdot a/12\,000 = a/60$$

where a = ct/min/µmole in the reisolated USA.

RESULTS

USA synthesis in mitochondrial extracts

Preparation of enzyme. Rat or rabbit liver mitochondria were prepared as described earlier [1] by differential centrifugation according to the principles worked out by Schneider and Hogeboom [10]. The enzymes synthesizing USA could be obtained in solution after rupture of the mitochondrial membrane. This could be done by suspension of the washed mitochondria in distilled water or by sonic vibration. The latter treatment, however, rapidly inactivated the enzymes, while following osmotic rupture more than 50 % of the enzymatic activity remained in the sediment after centrifugation of the lysed mitochondria. The best yield of soluble enzymes was obtained by a quick freezing and thawing of a mitochondrial suspension in 0.1 *M* $NaHCO_3$ (10—20 ml solution per 10 g of liver). When the resulting suspension of broken mitochondria was centrifuged at 20 000—100 000 g for 20 minutes at 0° most of the activity was located in the supernatant. Not quite as good results were obtained using 0.1 *M* potassium phosphate buffer, pH 7.5, or isotonic KCl as the suspending solution. Freezing in distilled water destroyed most of the activity. Repeated freezing and thawing in bicarbonate also decreased the activity.

Routinely the enzyme was prepared in 0.1 *M* $NaHCO_3$. The clear supernatant was filtered through cotton wool to remove fat particles and could then be lyophilized and stored as a dry powder in a dessicator at —10°. Enzymatic activity invariably decreased during storage, although there was considerable variation in the rate of decline of activity with different preparations. More than 50 % of the initial activity was usually retained for 2 weeks.

Most of the experiments were carried out with rat liver mitochondrial extracts, which contained the highest enzymatic acitivities (per amount of nitrogen). Some experiments with rabbit liver mitochondrial preparations were included, although here more variation in activity among preparations was encountered.

Table 1. Requirements for USA synthesis in mitochondrial extract.

	μmole ureidosuccinate formed
complete substrate	0.70
— aspartate	0.01
— ammonia	0.07
— $MgCl_2$	0.02
— ATP, PGA, MP	0.00
— PGA, MP	0.15
— acetylglutamate	0.04

Complete substrate: 30 μmole L-aspartate-^{15}N, 30 μmole $^{15}NH_4Cl$, 25 μmole $MgCl_2$, 10 μmole ATP, 50 μmole PGA, 15 μmole acetylglutamate, 100 μmole phosphate buffer pH 7.2, 3 mg MP. Volume = 3 ml. All acids neutralized with KOH. Incubation for 90 minutes at 37° with 1 mg enzyme nitrogen.

Overall requirements for USA synthesis. USA was synthesized from the same substrates by the extracts as by the intact mitochondria and also required the presence of acetylglutamate (or carbamylglutamate), Mg^{++} and ATP (Table 1). Acetylglutamate was used throughout the present investigation rather than carbamylglutamate, which had been used with intact mitochondria [1], since it was found that smaller concentrations of acetylglutamate gave optimal USA synthesis with intact mitochondria. This is in accordance with the results obtained by Grisolia and Cohen [11] on citrulline synthesis.

In the absence of acetylglutamate USA synthesis was reduced from 0.70 μmole to 0.04 μmole under the experimental conditions of Table 1. The catalytic nature of acetylglutamate requirement in the overall reaction could be demonstrated in an experiment, in which only 0.5 μmole of acetylglutamate was present in the substrate. During 6 hours incubation 2.1 μmole of USA was formed. Except for acetylglutamate conditions were as in Table 1. Another 50 μmole of PGA was added after 3 hours.

In the absence of ATP no USA synthesis was obtained with rat liver mitochondrial extracts and an otherwise complete substrate (Table 1). ATP was broken down during the reaction by ATP-ases in the extract. For optimal synthesis of USA, 3-phospho-glyceric acid and a muscle protein fraction had to

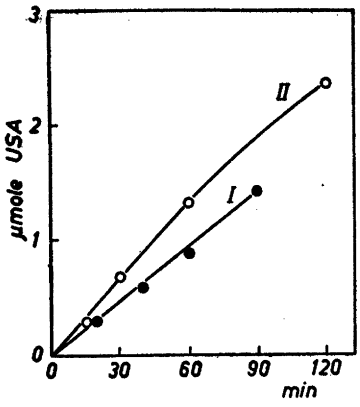

Fig. 2. Time curve for USA formation in mitochondrial extract. Curve I = overall reaction, curve II = formation from purified compound X.
*Substrates: Curve I: 60 µmole L-aspartate-^{15}N, 60 µmole $^{15}NH_4Cl$, 40 µmole acetylglutamate, 40 µmole ATP, 200 µmole PGA, 12 mg MP, 100 µmole $MgCl_2$, 120 µmole phosphate buffer, pH 7.2. Volume = 12 ml. 4.1 mg enzyme nitrogen. Curve II: 25 µmole L-aspartate-^{14}C, 22 µmole compound X *, 500 µmole phosphate buffer, pH = 7.0. Volume = 15 ml. 4.8 mg enzyme nitrogen.*

be added in order to regenerate ATP. The same general type of behaviour has been found first by Ratner in arginine synthesis [2] and also by Grisolia and Cohen [8] in citrulline synthesis. In both cases the accumulation of ADP formed by ATP breakdown inhibited the reaction. Ratner showed that this difficulty could be overcome by the addition of PGA which in the presence of a suitable ammonium sulfate fraction from a muscle extract regenerates ATP from ADP.

The *time curve* of the overall reaction is given by Fig. 2, curve I. The influence of *enzyme concentration* is demonstrated by Fig. 3.

Stepwise synthesis of USA. An extract from acetone powder of liver residue [8] which showed good activity for citrulline synthesis formed very little USA under the present conditions. The mitochondrial extract, on the other hand, could synthesize either citrulline or USA. This marked difference between the two preparations in the relative ability to synthesize citrulline and USA (summarized in Table 2) demonstrates that at least one enzyme in USA synthesis is different from the enzymes in citrulline synthesis.

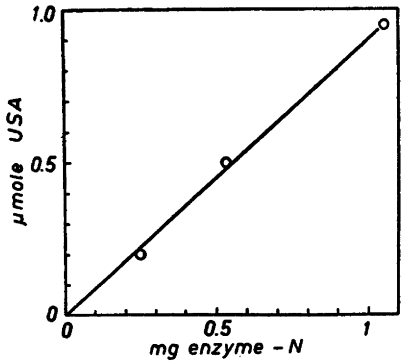

Fig. 3. Overall formation of ureidosuccinate with different amounts of enzyme. Substrate as in Table 1. Incubation for 90 min. at 37°.

* *The finely divided Ca-salt of compound X was extracted for two minutes with ice cold water (2—8 ml of water/50 mg Ca-salt), a slight excess of potassium oxalate (M solution) was added and the suspension centrifuged in the cold. Aliquots of the solution were immediately used for a serie of experiments*

Table 2. Non identity of enzymes for citrulline and ureidosuccinate synthesis.

	Synthesized per mg enzyme nitrogen	
	μmole of citrulline	μmole of ureidosuccinate
Acetone powder extract:		
30 min. incubation	0.97	0.05
90 min. incubation	1.92	0.04
Mitochondrial extract:		
30 min. incubation	1.03	0.40
90 min. incubation	1.53	0.89

Substrates as in Table 1 for ureidosuccinate synthesis. In the citrulline experiments 20 μmole of $NaHCO_3$ was added to each medium and 20 μmole ornithine was substituted for L-aspartate.

Table 3 demonstrates that more than one enzyme is involved in USA synthesis. When the mitochondrial enzyme was heated at 54° for 3 minutes (pH 7.4) its ability to synthesize USA was almost completely destroyed. This treatment has been shown to inactivate the first step in citrulline synthesis [8]. The combination of this heated mitochondrial enzyme and acetone powder extract, each of which was virtually inactive alone, synthesized USA actively (Table 3). The addition of heated mitochondrial enzyme to a non heat-treated mitochondrial enzyme increased USA formation somewhat. Addition of acetone powder extract did not show this effect.

The results fit the following interpretations: (1) The first step of USA synthesis is present in the acetone powder and is heat labile. (2) The second step is contained in mitochondrial extract and is more heat stable (although a considerable part of the activity is also destroyed by heating at 54° for 3 minutes). (3) The second step seems to be limiting in the untreated mitochondrial extract, since addition of the heated mitochondrial enzyme increased USA formation, while addition of acetone powder extract had no effect.

Table 3. Involvement of several enzymes in ureidosuccinate synthesis. Substrate and conditions as in Table 1.

Enzyme preparation	μmole of ureidosuccinate formed
Mitochondrial extract (ME), 1 mg enzyme-N	1.45
Mitochondrial extract, 3 min. at 54° (MEH) (1.5 mg enzyme-N)	0.10
Acetone powder extract (AP), 0.5 mg enzyme-N	0.07
ME + MEH	1.90
ME + AP	1.38
MEH + AP	0.42

Table 4. Stepwise synthesis of ureidosuccinate.

	Experiment No.

Enzyme source:														
Acetone powder extract (0.5 mg N)	+		+				+			+	+			+
Mitochondrial extract, 3 min. at 54° (2.0 mg N)	+				+			+	+			+	+	
μmole ureidosuccinate formed	0.16		0.02		0.05		0.21		0.06		0.05		0.00	

Substrate 1: 30 μmole $^{15}NH_4Cl$, 20 μmole $NaHCO_3$, 10 μmole ATP, 50 μmole PGA, 15 μmole acetylglutamate, 25 μmole $MgCl_2$, 100 μmole phosphate buffer, pH 7.2, 2 mg MP. Volume = 3 ml.
Substrate 2: 30 μmole L-aspartate-^{15}N, 100 μmole phosphate buffer, pH 7.2. Volume = 3 ml. 60 minutes incubation at 37° for each step.

A more direct demonstration of this reaction sequence is given by the experiments summarized in Table 4. Experiments 1—3 demonstrate again that the presence of both the heated mitochondrial enzyme and the acetone powder is required for USA synthesis. In experiments 4—7 the study of USA formation was carried out in stepwise sequence. The substrate was divided into two parts: substrate 1 containing everything necessary for reaction (1), *i.e.* the formation of compound X; substrate 2 containing only aspartate (and buffer). In the first step an enzyme preparation was incubated with one substrate for 60 minutes at 37°. The reaction was then stopped by addition of 0.5 ml *N* PCA to the cooled solution. After 5 minutes in an ice bath the solution was neutralized to pH 7 with *N* $NaHCO_3$. The second step was then studied by the addition of the other enzyme and substrate, and incubation for an additional 60 minutes at 37°. Using the four possible combinations of substrates and enzymes it could be shown that the first step required the enzyme from the acetone powder extract and the substrate necessary for the formation of compound X, while the second step involved the participation of aspartate and the enzyme from the heated mitochondrial extract.

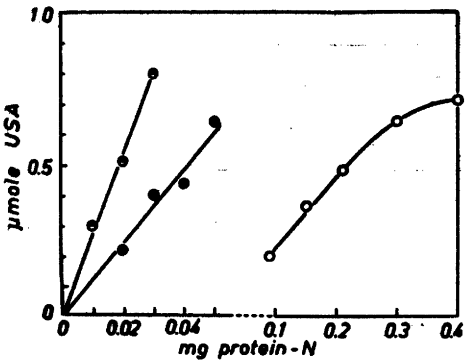

Fig. 4. Formation of ureidosuccinate by enzyme from E. coli. ○ = *unfractionated extract,* ● = *protamine fraction,* ◒ = *ammoniumsulfate fraction. The abscissa gives the amount of enzyme nitrogen per experiment for each point. Incubation at 37°, 15 min.*
Substrate: 10 µmole L-*aspartate-*^{14}C*, 2.6 µmole compound X, 100 µmole phosphate buffer, pH 6.5. Volume 1.3 ml.*

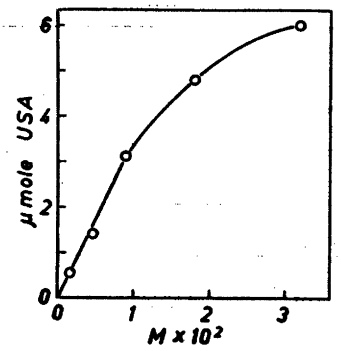

Fig. 5. Dependence of USA synthesis on L-*aspartate.*
Substrate: 7.7 µmole compound X, 150 µmole phosphate buffer, pH = 6.5, and L-*aspartate-*^{14}C *as indicated on abscissa. Volume 3.7 ml. Incubation 15 min. at 37° with 0.07 mg enzyme-N (ammonium sulfate fraction).*

A direct demonstration of reaction (3) was obtained by incubation of mitochondrial enzyme with aspartic acid and compound X. In this experiment L-aspartate-^{14}C was used. The resulting time curve of USA formation is shown in curve II of Fig. 2.

Experiments with enzyme from *E. coli.*

Studies of the condensing enzyme from liver which catalyzes reaction (3) were greatly hampered by the instability of the enzyme. The enzyme was also found to be present in rat kidney, spleen and heart, yeast autolysate and an extract of lyophilized *E. coli*. By far the highest activity was observed in the bacterial extract and further investigations were therefore carried out with the enzyme from this source.

Assay system. The bacterial extract showed no ability to synthesize USA from ammonia, bicarbonate and aspartic acid and thus contained little or no enzyme activity for reaction (1). Since the bacterial enzyme formed no compound X, it was not necessary to use purified compound X for the assay. It was instead prepared in solution by incubation of ammonia, $NaHCO_3$, ATP and acetylglutamate together with "enzyme B" [8], as described in the experimental part. The reaction was stopped by addition of 0.2 volumes of 0.5 *M* PCA to the cooled solution. After centrifugation and neutralization to pH 6.5 with *N* KOH an aliquot of the solution containing 2.6 µmole of compound X was added to 10 µmole of aspartate-^{14}C and 100 µmole of phosphate buffer pH 6.5. The bacterial enzyme was added and incubation (final volume 1.3 ml) carried

out for 15 minutes at 37°. Under these conditions USA formation (in the range 0.2—0.5 μmole) was proportional to the amount of enzyme added (see Fig. 4).

Quite large amounts of substrate are needed to saturate the enzyme (see below) and the conditions described do not permit maximal USA synthesis. Lack of sufficient substrate did not allow work with substrate-saturated enzymes. When an exact assay of the enzyme activity was desired several experiments at different enzyme concentrations were carried out and satisfactory results were obtained.

Purification of the enzyme. The lyophilized *E. coli* preparation was obtained through the courtesy of Dr. G. Hedén of the Bacteriological Department of the Karolinska Institutet. The cells had been grown on a synthetic liquid medium [12] for 18 hours. After this time the cells were harvested in a Sharples centrifuge, washed once with 0.9 % NaCl and lyophilized. At this stage the preparation, when stored in a desiccator in the cold room, retained enzymatic activity for at least one year.

Extraction of the cells was carried out by sonic vibration with glass beads (0.28 mm diameter). Five g of the lyophilized powder was homogenized in 50 ml of 0.1 *M* $NaHCO_3$. 40 ml of glass beads were added and vibration carried out by a "microid flask shaker" (Griffin and Tatlock, Ltd) at room temperature for 90 minutes. The very viscous solution was separated from the glass beads by filtration. The beads were washed with 50 ml of 0.1 *M* $NaHCO_3$. The combined filtrate and washings were centrifuged at 20 000 g at 20° for 30 minutes. 65 ml of slightly turbid supernatant was obtained.

To the supernatant was added 32.5 ml of a 2 % solution of protamine sulfate (neutralized to pH 8 with 0.5 *N* NaOH). The resulting stringy precipitate was centrifuged and the supernatant discarded. The precipitate was finely homogenized in 15 ml of 0.1 *M* potassium phosphate buffer, pH 7. After centrifugation the precipitate was once more extracted in the same way and centrifuged. All operations up to this step were carried out at room temperature.

The combined supernatants (30 ml) were cooled in an ice bath. Solid ammonium sulfate (6.35 g) was added to bring the solution to 30 % saturation. After standing for 10 minutes the precipitate was centrifuged off and discarded. More ammonium sulfate (3.1 g) was added to the supernatant and the solution centrifuged after 10 minutes. The resulting precipitate contained most of the enzymatic activity. It was dissolved in 5 ml of 0.1 *M* phosphate buffer, pH 6.5, and could be stored in the deep freeze. Most experiments were carried out

Table 5. Purification of condensing enzyme from E. coli.

	mg protein nitrogen	total units	units / mg N
Extract	259	1 220	4.7
Protamine precipitate	37	870	23
Ammonium sulfate, 30—45 % sat.	11.5	620	54

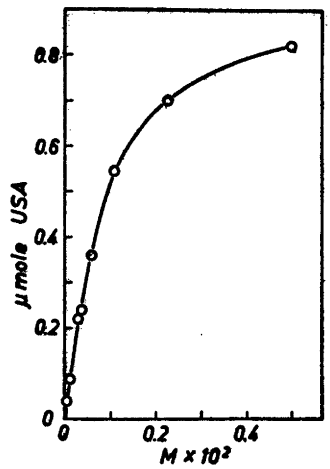

Fig. 6. Dependence of USA synthesis on compound X. Substrate: 5 µmole L-aspartate-^{14}C, 150 µmole phosphate buffer, pH 6.5, compound X as indicated on abscissa. Volume 3.7 ml. Incubation at 37° for 15 min. with 0.07 mg enzyme nitrogen (ammonium sulfate fraction).

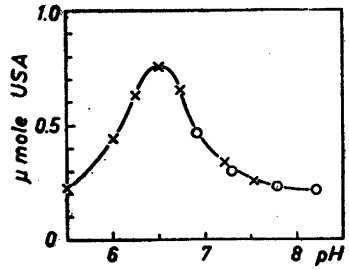

Fig. 7. pH curve of USA synthesis. Substrate: 4.5 µmole compound X, 5 µmole L-aspartate-^{14}C, 250 µmole buffer (× = phosphate, ○ = glycylglycine). Incubation at 37° for 15 min. with 0.07 mg enzyme nitrogen (ammonium sulfate fraction). Volume 3.7 ml.

with this fraction. Dialysis of the solution for 18 hours at + 2° against 0.01 *M* phosphate buffer resulted in the loss of ca 30 % of the activity. The dialyzed solution could be lyophilized without further loss of activity. A summary of the purification procedure is given in Table 5.

Some properties of the reaction. The dependence of the reaction on the simultaneous presence of L-aspartate and compound X is demonstrated by Figs. 5 and 6. All experiments subsequently described were carried out with purified compound X. Although it was not possible to effect enzyme saturation under the present experimental conditions, the results are sufficient to indicate that high concentrations of compound X and especially aspartate would be necessary for optimal synthesis*. The pH optimum of the reaction was at 6.5. Phosphate was without influence on the reaction (Fig. 7).

Mg^{++}, Zn^{++}, Mn^{++}, Ca^{++} and Fe^{++} did not stimulate USA formation by lyophilized, dialyzed bacterial enzyme under the following experimental conditions. In each experiment 1.0 mg of enzyme was incubated with 5 µmole of L-aspartate-^{14}C and 4 µmole compound X in a final volume of 2.8 ml, pH 7.2. In the presence of 10 µmole of either $MnCl_2$, $ZnCl_2$, $CaCl_2$, or $FeSO_4$ the following amounts of USA (in µmoles) were synthesized during 30 minutes at 37°: 1.11; 1.00; 1.09; 1.09. In the control experiment without addition of divalent ions, 1.01 µmole of USA was formed. In another similar experiment 0.81 µmole

* The experiments were complicated by the fact that at high concentrations of the reactants a non-enzymatic formation of USA took place. This was negligible under the conditions for enzyme assay. However, under the conditions of Fig. 5 an increasing part of the USA synthesis observed at aspartate concentrations above 0.5×10^{-2} *M* was non-enzymatic.

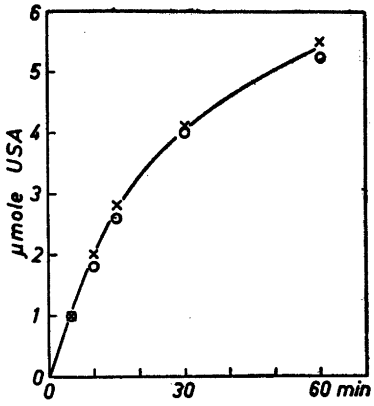

Fig. 8. Time curve and stoichiometry of USA formation.
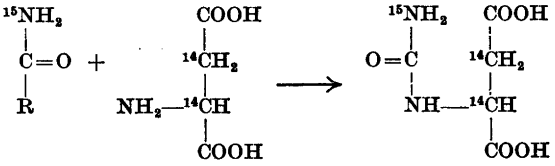
Substrate: 25 µmole L-aspartate-^{14}C, 22 µmole compound X-^{15}N, 1 250 µmole glycyl-glycine buffer, pH 7.0. × = values calc. from ^{14}C; o = values calc. from ^{15}N. Volyme = 15 ml. For further explanation see text.

of USA was formed in the presence of 30 µmole of $MgSO_4$, while 0.85 µmole was formed in the control.

Stoichiometry of the reaction. The formation of one molecule of USA per one molecule of aspartate and compound X each was demonstrated by the simultaneous use of ^{15}N-labeled compound X and L-aspartate-^{14}C in one experiment. The USA formed stoichiometrically under these experimental conditions should be doubly labeled according to:



compound X + aspartate → ureidosuccinate

Compound X was enzymatically synthesized from $^{15}NH_4Cl$ (32 % excess ^{15}N). The carbamino group of USA therefore contained the same excess of ^{15}N. The succinate moiety of USA contained the same specific activity of ^{14}C as the precursor aspartate. The experiment summarized in Fig. 8 demonstrates the stoichiometric relation. The figure represents a time curve of USA formation. At each time point the amount USA formed was calculated independently from both the ^{15}N and the ^{14}C, respectively, of the reisolated USA. Within experimental error identical values were obtained for each time point.

DISCUSSION

The experiments described here demonstrate the occurrence in rat organs and *E. coli* of an enzymatic reaction by which ureidosuccinic acid, an intermediate in pyrimidine biogenesis, is formed from aspartic acid and compound X. Compound X has earlier been described as an intermediate in citrulline synthesis by Grisolia and Cohen [8]. The formation of compound X from CO_2,

NH_3, ATP and a substituted glutamate derivative seems therefore to represent one common step for both citrulline and USA biosynthesis. It is interesting that we were not able to demonstrate the occurrence of this enzymatic reaction in the bacterial extract. The possibility exists that the enzyme responsible for compound X formation had been destroyed during the preparation of the extract. On the other hand it was not possible to demonstrate this reaction in homogenates from most rat organs, which contained the enzyme forming USA from compound X. In the rat, with the exception of liver, only kidney preparations were found to form compound X, and here only minimal synthesis was obtained.

It seems unlikely that liver and possibly kidney are the only mammalian organs capable of synthesizing pyrimidines. The widespread existence of the enzyme capable of forming USA from compound X and aspartate also argues against this. The possibility arises, therefore, that compound X is synthesized by another mechanism than reaction (1). An example for such a reaction is the recently demonstrated conversion of citrulline-ureido-^{14}C to labeled USA, which probably proceeds *via* compound X as an intermediate [13].

Short Communications

The Occurrence of Free Ornithine and its N-Acetyl Derivative in Plants

ARTTURI I. VIRTANEN and P. LINKO

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

When investigating the free amino acids in plants it was found in this laboratory that *Asplenium* species surprisingly contained many unknown ninhydrin-positive substances. Virtanen *et al.*[1,2] have recently isolated α-aminopimelic acid, γ-hydroxy-α-aminopimelic acid and its lactone from *Asplenium septentrionale*. We noticed that on hydrolysis of the free amino acid fraction of *Aspl. nidus*, even with 1 *N* HCl a large amount of ornithine was formed while the unknown spot 72 disappeared entirely (Fig. 1). A smaller amount of free ornithine was also present before hydrolysis. This was identified both chromatographically and by vanillin[3] spraying.

Ornithine is known to be a part of some cyclic peptides, tyrocidin[4], gramicidin[5] and bacitracin[6]. The free amino acid has only twice been chromatographically identified in plants[7,8]. Manske[9] found, however, in 1937, that the roots of *Corydalis ochotensis* contained 10 % of mono-N-acetylornithine based on the weight of air-dried material. We therefore examined the Finnish specimen *Corydalis bulbosa* and found a spot on the chromatograms, which was identical with that of our unknown substance. We have now been able to isolate this substance from the leaves of *Asplenium nidus*.

The 70 % ethanol extract (380 g fresh wt., 55 g dry wt.) was first purified with Amberlite IR-120 resin. However, only the basic amino acids, arginine, ornithine and lysine remained on the column. This was presumably due to the high content of slimy material, which filled the column, because the second treatment with the same resin gave only a mixture of neutral and acidic amino acids. Acidic amino acids were removed with Amberlite IR-4 B resin and the remaining solution of neutral amino acids was then fractionated by means of Dowex 50 resin (column 26 × 520 mm). 100 fractions of 20 ml each with 1.5 *N* HCl and 120 fractions af 15 ml each with 2.5 *N* HCl were taken. Fractions 25—60 contained serine and threonine, 40—45 glycin and alanine, 40—60 the lactone of γ-hydroxy-α-aminopimelic acid, 60—65 valine *etc.* and 160—190 only the unknown amino acid in question. The eluate was evaporated *in vacuo* at 33° C to a syrup (126.2 mg). After drying in a vacuum desiccator a crystalline mass (105.4 mg) was obtained on the addition of a small amount of absolute ethanol. It was found chromatographically that during concentration 3—5 % of the compound was decomposed to ornithine, but crystallization from ethanol-ether gave 20.8 mg of pure product. The substance decomposed at 200° C. (Found: C 34.62; H 6.54. Calc. for $C_7H_{14}N_2O_3 \cdot 2$ HCl: C 34.02; H 6.53. On titration 0.919 mg required 0.80 ml 0.00917 *N* NaOH in water and 1.19 ml in 80 % ethanolic solution. Found equivalent weights 125.14 and 84.13. Calc. for $C_7H_{14}N_2O_3 \cdot 2$ HCl: 123.57 and 82.38, respectively). By the method of Virtanen and Pulkki[10] 6.22 mg acetic acid was found from 26.2 mg substance (97.0 % of theor.). Acetate was qualitatively identified by means of $FeCl_3$, iodine and $La(NO_3)_3$, by As_2O_3 as cacodyl oxide and dry distillation with $Ca(CO_2)_2$ to acetone, which reacts with *o*-nitrobenzaldehyde to form indigo.

The unknown amino compound was chromatographically identical with acetylornithine isolated by Manske. It was unstable in the presence of nitrogen oxides (from $NaNO_2$ and HCl) and gave negative results with *p*-dimethyl-aminobenzaldehyde, isatin, iodine, vanillin and $KMnO_4$ when the

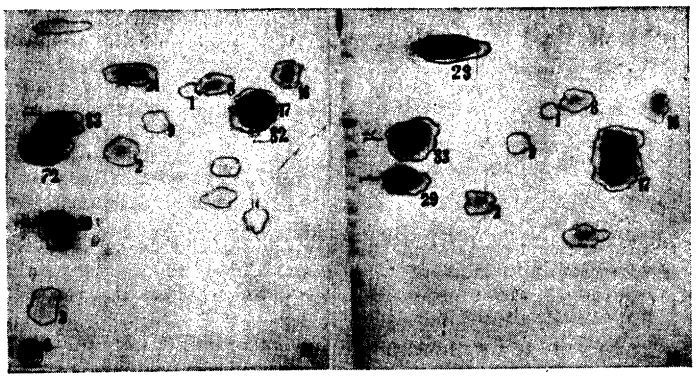

Fig. 1. Two-dimensional paper chromatograms of purified 70 % ethanol extract containing free neutral and acidic amino acids of Asplenium nidus; before hydrolysis (left) and after hydrolysis (right). 1 = gly, 2 = ala, 3 = val, 6 = phen.ala, 8 = ser, 9 = threo, 16 = asp, 17 = glu, 23 = orn, 24 = glutamine, 29 = γ-aminobutyric, 72 = acetylorn, 82 = γ-hydroxy-α-aminopim, 83 = lactone of 82.

reagents were sprayed on the chromatograms. Negative results using the methods of Hanes and Isherwood [11] and Chargaff, Levine and Green [12] indicated that the substance did not contain any phosphorus or sulphur. On paper electrophoresis it proved to be neutral, but after hydrolysis strongly basic ornithine appeared. From all these data it is clear that the substance in question is mono-N-acetyl-ornithine.

No chromatographical data about this substance are to be found in the literature. We obtained the following R_F-values:

	Butanol-acetic acid-water	Phenol-NH_3-water
Proline	0.32	0.91
Alanine	0.27	0.62
Acetylornithine	0.28	0.84
Ornithine	0.07	

In the protein hydrolysate no ornithine could be found. In addition to *Aspl. nidus* and *Corydalis bulbosa*, *Aspl. septentrionale*, *Aspl. viviparum* and *Aspl. trichomanes* also contained acetylornithine. *Dryopteris linnaeana*, *D. filix mas*, *Woodsia ilvensis*, *Eupteris aquilina*, *Struthiopteris filicastrum* and *Athyrium filix femina* were investigated, but no acetylornithine could be found.

Acetylornithine-N in *Aspl. nidus* was about 10 % of the free amino acid nitrogen and 1.14 % of the total nitrogen.

We wish to thank professor A. Kalela for *Asplenium* species obtained from the University of Helsinki Botanical Gardens and Dr. H. F. Manske for a sample of acetylornithine.

On the Content of Hexosamines in Cell Nuclei of Calf Thymus and Calf Liver

SVEN GARDELL and STAFFAN MAGNUSSON

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

In 1951 Bychkov *et al.*[1] claimed that mucopolysaccharides and mucoproteins are regular constituents of the cell nuclei. They based this conclusion on hexosamine determinations made on dried tissues and on nuclear preparations.

However, the method of Elson and Morgan [2] used by them is known to give too high values in the presence of basic amino acids and neutral sugars [3]. This combination is present in the cell nuclei, where basic proteins and pentoses from the nucleic acids make up a considerable part of the dry matter.

The application of a chromatographic step [4] before applying the Elson and Morgan reaction offers a possibility for the determination of hexosamines without any interference of foreign substances.

Bychkov *et al.*[1] used dilute citric acid for the isolation of the cell nuclei [5]. Data presented by Mirsky *et al.*[6] indicate that dilute citric acid may remove from 18 to 55 % of the proteins of the nucleus as compared with the results obtained in using anhydrous lipid solvents for the isolation of the nuclei. It thus seemed necessary to reinvestigate the possible content of hexosamines in cell nuclei.

We used the method of Mirsky *et al.*[6] for the isolation of cell nuclei from calf thymus and calf liver. The final purity of the preparations was judged by staining with crystal violet.

The hexosamine content was determined according to Gardell [4] on hydrochloric acid hydrolysates of the preparations.

From calf thymus we obtained 4.38 g of nuclei from 100 g of dried tissue. Mirsky *et al.*[6] obtained 20—25 g/100 g. Our preparation looked very pure on microscopical examination, and seemed to be practically free from cytoplasmic contamination.

The liver preparation, on the contrary, was not so pure. Our yield of 7.9 g of nuclei out of 200 g of dried tissue is even more than double the yield of Mirsky *et al.*[6]

The analytical results are shown in Table 1.

The figures for the hexosamine content in whole thymus tissue are derived from six chromatographic runs on three different hydrolysates. In five of them two peaks were obtained, one for glucosamine, and one for galactosamine. The galactosamine peak contained some 10—15 % of the total hexosamine content, the glucosamine peak the remaining 85—90 %. The sixth chromatogram showed only a glucosamine peak.

The figures for the hexosamine content in thymus cell nuclei are also derived from six chromatographic runs on three different hydrolysates. Only in three of them there was a trace of galactosamine.

The same results were obtained in analyzing another preparation of cell nuclei from calf thymus.

As the purity test of the nuclear preparations is entirely subjective, one cannot draw extensive conclusions from our results. We cannot exclude the possibility that the amount of hexosamines in our nuclear preparations is due to cytoplasmic contamination. One can state anyhow, that the amount of hexosamine found by Bychkov *et al.*[1] is at least five times too large. If the cell nuclei really contain hexosamines, the amount is of the order of

Table 1.

Percentage of	Thymus		Liver	
	Whole tissue	Nuclei	Whole tissue	Nuclei
Nitrogen (micro-Kjeldahl)	15.65	16.60	10.40	10.87
Ash	12.20	12.2	4.98	5.06
Moisture	5.1	7.1	7.1	6.8
Hexosamine	0.24	0.09	0.23	0.13

magnitude of 0.1 % of the dry substance or less. Mucopolysaccharides containing galactosamine are not present in the cell nuclei of calf thymus.

Uptake of ^{35}S-labelled Sulfate in the Heparin of a Dog Mastocytoma

STAFFAN MAGNUSSON and BENGT LARSSON

Chemistry Department II, Karolinska Institutet; Department of Surgery and Department of Clinical Biochemistry, Royal Veterinary College, Stockholm, Sweden

Oliver, Bloom and Mangieri [1] in 1947 found dog mast cell tumors to be very rich in heparin. The heparin content of a highly differentiated tumor was some fifty times that of the dog liver. This finding has been confirmed by Riley and co-workers [2] in 1954. In 1953 Jorpes, Odeblad and Boström [3], by means of an autoradiographic technique, observed that ^{35}S-labelled sulfate is taken up by the mast cells in the subcutaneous tissue of the rat. They could not, however, determine whether the exchange observed occurred in heparin, in any of its precursors or in chondroitin sulfuric acid.

It was therefore considered of interest to know if the sulfate groups of heparin can be labelled with ^{35}S. The large content of heparin in mast cell tumors makes them a suitable material for the study of this question. At the suggestion of Dr. B. Åberg the following experiment was therefore performed.

Experimental. To a dog suffering from a rather highly differentiated mastocytoma was given 1 mC of carrier free sodium sulfate intravenously. After 24 hours the tumor, weighing 16.7 g, was removed and frozen to —20° C. After mincing in the Latapie mill, the material was digested for three weeks with proteolytic enzymes according to the technique of Gardell [4]. After digestion the suspension was treated with several volumes of 96 % ethanol at pH 8.8. The precipitate formed was suspended in water at pH 8—9 and after centrifugation the solution was passed through an anion exchange column, Dowex 2, (Boström and Månsson [5]) in order to remove inorganic sulfate. In a control test with a mixture of heparin and radioactive sulfate it was found that the radioactivity was retained, while the heparin passed through.

The sulfate free solution was evaporated *in vacuo* to dryness and dissolved in water to a concentration of 5 %. The pH was adjusted to 7—8. Then 0.2 volumes of 20 % barium chloride were added. The precipitate was separated by centrifugation. The supernatant was precipitated by adding a third of its volume of glacial acetic acid. The precipitate weighed 3.060 mg. To the mother liquor three volumes of 96 % ethanol were added. This precipitate weighed 9.795 mg. The former precipitate should contain heparin and the latter chondroitin sulfuric acid or the heparin monosulfuric acid found by Jorpes, Werner and Åberg [6] to occur in the normal mast cells. These compounds can easily be separated by

Table 1.

	Weight in mg	Counts/min./cm² of 3 mg	I. U. of heparin / mg	
			Whole blood method	Thrombin method

Uptake of ^{35}S-labelled Sulfate in the Heparin of a Dog Mastocytoma

STAFFAN MAGNUSSON and BENGT LARSSON

Chemistry Department II, Karolinska Institutet; Department of Surgery and Department of Clinical Biochemistry, Royal Veterinary College, Stockholm, Sweden

Oliver, Bloom and Mangieri [1] in 1947 found dog mast cell tumors to be very rich in heparin. The heparin content of a highly differentiated tumor was some fifty times that of the dog liver. This finding has been confirmed by Riley and co-workers [2] in 1954. In 1953 Jorpes, Odeblad and Boström [3], by means of an autoradiographic technique, observed that ^{35}S-labelled sulfate is taken up by the mast cells in the subcutaneous tissue of the rat. They could not, however, determine whether the exchange observed occurred in heparin, in any of its precursors or in chondroitin sulfuric acid.

It was therefore considered of interest to know if the sulfate groups of heparin can be labelled with ^{35}S. The large content of heparin in mast cell tumors makes them a suitable material for the study of this question. At the suggestion of Dr. B. Åberg the following experiment was therefore performed.

Experimental. To a dog suffering from a rather highly differentiated mastocytoma was given 1 mC of carrier free sodium sulfate intravenously. After 24 hours the tumor, weighing 16.7 g, was removed and frozen to —20° C. After mincing in the Latapie mill, the material was digested for three weeks with proteolytic enzymes according to the technique of Gardell [4]. After digestion the suspension was treated with several volumes of 96 % ethanol at pH 8.8. The precipitate formed was suspended in water at pH 8—9 and after centrifugation the solution was passed through an anion exchange column, Dowex 2, (Boström and Månsson [5]) in order to remove inorganic sulfate. In a control test with a mixture of heparin and radioactive sulfate it was found that the radioactivity was retained, while the heparin passed through.

The sulfate free solution was evaporated *in vacuo* to dryness and dissolved in water to a concentration of 5 %. The pH was adjusted to 7—8. Then 0.2 volumes of 20 % barium chloride were added. The precipitate was separated by centrifugation. The supernatant was precipitated by adding a third of its volume of glacial acetic acid. The precipitate weighed 3.060 mg. To the mother liquor three volumes of 96 % ethanol were added. This precipitate weighed 9.795 mg. The former precipitate should contain heparin and the latter chondroitin sulfuric acid or the heparin monosulfuric acid found by Jorpes, Werner and Åberg [6] to occur in the normal mast cells. These compounds can easily be separated by

Table 1.

	Weight in mg	Counts/min./cm² of 3 mg	I. U. of heparin / mg	
			Whole blood method	Thrombin method
Barium chloride-acetic acid precipitate	3.060	6 690	61	96
Ethanol precipitate from the mother liquor	9.795	1 750	8.5	12

means of the solubility of their barium salts (Jorpes and Gardell [7]).

The anticoagulant activity was assayed by the whole blood method of Jalling, Jorpes and Lindén [8] and by a thrombin titration method described by Quick [9]. The radioactivity was measured in a Geiger-Müller counter. The condition of infinite thickness of the preparation is not reached for the 0.1 MeV beta-radiation of ^{35}S until it has a thickness of some 30 mg/cm^2. As this condition could not be fulfilled with our preparation, we decided to measure the activities of 3 mg/cm^2. For that reason the counts of the two preparations are not quite comparable.

The amino sugar content of the two precipitates was determined according to Gardell [10]. Results in Table 1.

As is evident from the table a highly active barium salt of heparin was obtained. In accordance herewith it was found that the substance contained 13.2 % of glucosamine and 0.45 % of galactosamine. The ethanol precipitate contained 3.35 % glucosamine and 2.17 % galactosamine. It is not conceivable that anything but heparin could account for the radioactivity of the barium chloride — acetic acid precipitate. Consequently this infers that sulfuric acid groups of heparin can be labelled with ^{35}S.

This investigation was aided by a grant to B. Åberg and B. Larsson from *The Swedish Cancer Society*.

Note on the Rheology of Polyacrylonitrile Solutions

SVEN SONNERSKOG

Stockholms Superfosfat Fabriks AB, Ljungaverk, Sweden *

Suspension polymers of acrylonitrile, prepared by the *azo* activator technique [1], show apparent deviations from the ordinary behaviour of *redox* (emulsion or solution) polymers that calls for further attention. As earlier pointed out [1] suspension polymers do not dissolve at room temperature in dimethyl formamide even in a very broad range of molecular weight. At said temperature redox polymers may show complete solubility, and solutions containing more than 15 % by weight of polymer can ordinarily be prepared. Even if the different end groups in the two types of polymers may be one reason for this anomaly, it seems to be an undue simplification to ascribe the effect entirely to the interaction between solvent and terminating groups. The final step in the kinetic scheme of polymerization is generally shared between chain coupling and disproportionation [2], which would mean that other end groups than those derived from the activator would be present.

Some peculiarities, connected with suspension polymerization of acrylonitrile, should be shortly emphasized. Even at low degrees of conversion the monomer droplets are converted into a porous (spongy) particle. This polymer is insoluble in its monomer, and a two-phase system is obtained, where the reaction mainly proceeds on the large interphase. The supply of monomer at the reaction centres is secured by the action of capillary forces and by diffusion. As the particle grows acrylonitrile is consumed, why the propagation rate gradually decreases. The reaction ceases asymptotically by deficit of monomer and evidently shows a fairly long step gradually retarded due to a decreasing supply of acrylonitrile. Just as in the case of polyvinyl chloride [3] an excessive branching, chain transfer and an abnormal molecular size distribution should be expected at said reaction step. If sufficient activator is present, it is permitted to ask if even a slight crosslinking takes

Note on the Rheology of Polyacrylonitrile Solutions

SVEN SONNERSKOG

Stockholms Superfosfat Fabriks AB, Ljungaverk, Sweden *

Suspension polymers of acrylonitrile, prepared by the *azo* activator technique [1], show apparent deviations from the ordinary behaviour of *redox* (emulsion or solution) polymers that calls for further attention. As earlier pointed out [1] suspension polymers do not dissolve at room temperature in dimethyl formamide even in a very broad range of molecular weight. At said temperature redox polymers may show complete solubility, and solutions containing more than 15 % by weight of polymer can ordinarily be prepared. Even if the different end groups in the two types of polymers may be one reason for this anomaly, it seems to be an undue simplification to ascribe the effect entirely to the interaction between solvent and terminating groups. The final step in the kinetic scheme of polymerization is generally shared between chain coupling and disproportionation [2], which would mean that other end groups than those derived from the activator would be present.

Some peculiarities, connected with suspension polymerization of acrylonitrile, should be shortly emphasized. Even at low degrees of conversion the monomer droplets are converted into a porous (spongy) particle. This polymer is insoluble in its monomer, and a two-phase system is obtained, where the reaction mainly proceeds on the large interphase. The supply of monomer at the reaction centres is secured by the action of capillary forces and by diffusion. As the particle grows acrylonitrile is consumed, why the propagation rate gradually decreases. The reaction ceases asymptotically by deficit of monomer and evidently shows a fairly long step gradually retarded due to a decreasing supply of acrylonitrile. Just as in the case of polyvinyl chloride [3] an excessive branching, chain transfer and an abnormal molecular size distribution should be expected at said reaction step. If sufficient activator is present, it is permitted to ask if even a slight crosslinking takes

place by an initiating action on traces of bifunctional impurities (*e. g.* divinyl acetylene) generally present in the technical grade of acrylonitrile, prepared from acetylene.

The mentioned features of the polymerization mechanism ought to influence on the physical properties of the polymer in general, but particularly on its behaviour in solution. Even low degrees of branching and crosslinking act as steric hindrances, causing deviations from the *random flight* type of molecular configuration in dilute solutions. A look upon the general theory on the properties of macromolecular substances in solution, developed by Kirkwood [4,5], Riseman [4], and Flory [6], seems to be appropriate here. The intrinsic viscosity, $[\eta]$, of a polymer is stated to be a linear function of the effective volume of the separate molecular coils in dilute solution. Thus, if $\bar{r}^2$ is the mean-square end-to-end distance of the coil, the following relation applies:

$$[\eta] = \Phi \cdot (\bar{r}^2)^{3/2}/M \qquad (1)$$

where M is a measure of the molecular weight of the polymer, Φ a universal parameter (approximative value $2 \cdot 10^{21}$, r beeing expressed in cm and $[\eta]$ in decilitres per gram), Apparently $(\bar{r}^2)^{3/2}$ indicates the effective volume of the molecular coil in solution. In the actual case it is preferably split into its component factors, referring to the unpertubated mean end-to-end distance r_0 and the coefficient of deformation α. This gives the key equations

$$[\eta] = \Phi \cdot (\bar{r}_0^2/M)^{3/2} \cdot M^{\frac{1}{2}} \cdot \alpha^3 \qquad (2)$$

Table 1. Viscosity gradient of a polymer of acrylonitrile, prepared in a redox system. Activator: ammonia persulphate-sodium sulphite. Average visc. mol. weight = 57 000. Solid content of solution: 18.0 %.

Activation energy of flow, cals. mole^{-1}	6.1×10^3

or

$$[\eta] = K \cdot M^{\frac{1}{2}} \cdot \alpha^3 \qquad (3)$$

where $K = \Phi \cdot (\bar{r}_0^2/M)^{3/2}$. The magnitudes K and α are in general dependent of the temperature. By differentiating the logarithms of eq. (3) we obtain

$$\mathrm{d}\ln [\eta]/\mathrm{d}T = 3\,\mathrm{d}\ln \alpha/\mathrm{d}T + \mathrm{d}\ln K/\mathrm{d}T \qquad (4)$$

which reveals that the intrinsic viscosity gradient is mainly determined by the change of the factor of expansion α with temperature. If steric hindrances are present, we should expect an abnormal increase in the value of α, as all effects implying hindrances to free rotation expand the chain to a larger configuration [6]. The

90	38	49	77	90	59	106	18	34
110	19	28	42	57	36	71	11	17
130	15	19	26	34	23	45	8	10
Act. energy, cals. mole$^{-1} \times 10^{-3}$	6.8	7.2	7.3	6.5	6.5	6.4	6.8	7.0

corresponding influence on the magnitude $[\eta]$ was earlier implicitely formulated $[\eta] = K'M^a$, where the exponent is to regard as a comprehensive parameter, including deviations from "ideal" behaviour. Only at the *Flory point* [7], Θ °K, intramolecular effects disappear and the relation (3) reduces to $[\eta]\Theta = KM^{\frac{1}{2}}$, a formula showing a large similarity to the preceding expression.

What has been said about the intrinsic viscosity should also be valid in a qualitative sense for viscosity at higher concentrations as far as the dependence of the volume expansion factor is concerned. At a fixed concentration of the polymer in a good solvent, the viscosity gradient (or its computed equivalent, the activation energy of flow) is expected to show different values for various types of polymers where irregularities in structure cause deviations from the standard state (straight addition chains).

In accordance with the considerations above a series of suspension polymers was prepared and their viscosity-temperature gradients measured in the range 50—130° C. The activation energy of flow was computed from the Andrade [8] formula

$$\eta = Ae^{E/RT} \qquad (7)$$

giving the value of E as the slope of the straight line

$$2.3 \log \eta = \log A + E/R \cdot (1/T)$$

where the viscosity value may be expressed in arbitrary units. The explicit value of the activation energy is preferably written

$$E = 4.6\ \Delta \log \eta/\Delta 1/T \text{ cals.mole}^{-1} \qquad (8)$$

Experimental. Eight polymers were prepared in accordance with the method earlier described [1], using azo-*bis* (*iso*butyronitrile) as an activator and tertiary dodecylmercaptan as a modifier *. The average viscosity molecular weight was varied in the desired range ($44—75 \cdot 10^3$) by using different amounts of the modifier. Solutions of the polymers were prepared by wetting the granules at 20° C with the required amount of dimethyl formamide for at least ten minutes. On slow agitation the slurry was gradually heated to 80° C, where dissolution is complete within 60 minutes. Dilute solutions can be prepared already at 40—45° C, but practical difficulties (high viscosity, slow rate of swelling) makes dissolution at higher temperatures more attractive in the actual case. A concentration of 18.0 % was chosen. This value seems roughly to be comparable with the value 17.8 %, used in a recent investigation [9], as the suspension polymer contains residues of activator and modifier, which are more difficult to remove by washing than water soluble catalysts. In the cited study [9] an activation energy of flow of 5 700 cals.mole^{-1} was found, measurements beeing made in the *Jullander* consistometer at small angles of shear. In the present case some direct reference measurements were carried out on a *redox* (emulsion) polymer, synthesised in the laboratory. The general features of redox polymerization are described elsewhere [1,3]; the most important point in this connection is to observe that the reaction is terminated (interrupted) as soon as the amount of monomer present is insufficient to maintain saturation in the aqueous phase.

The viscosity gradients of the redox polymer and the suspension polymers are found in Tables 1 and 2, respectively. All measurements of viscosity were carried out in test tubes of 200 mm measuring range (diametre 20 mm, falling ball method). A lot of 15 balls (stainless steel, diametre 2.0 mm) were selected from a larger assortment and calibrated in a filtered dope of polyacrylonitrile at room temperature. Heating of the test tubes was arranged in a thin, light lubricating oil and the temperature measured at the centrum line of the tubes.

* In the present investigation acrylonitrile from acetylene was used throughout all polymerizations. Average content of divinyl acetylene: 260 p. p. m.

Sedimentation Studies of Cytochrome c

ANDERS EHRENBERG and SVEN PALÉUS

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

Pedersen [1] more than 15 years ago determined the sedimentation constant ($S°_{20} = 1.83 \times 10^{-13}$ *s*) and the diffusion coefficient ($D°_{20} = 11.3 \times 10^{-7}$ $cm^2 \cdot s^{-1}$) of the purified cytochrome c obtained by Theorell and Åkeson [2] from beef heart. Recently, Atlas *et al.*[3] reported that they had determined corresponding data of cytochrome c from different sources. Their values have been quoted by Edsall [4] as $S°_{20}$ about 2.3×10^{-13} *s* and $D°_{20}$ about 13×10^{-7} $cm^2 \times s^{-1}$ for cytochrome c from beef, horse and pig. Because of these discrepancies and the modified preparation methods developed [5,6], we found that a more systematic investigation would be of interest.

The sedimentation studies were made with a Spinco analytical ultracentrifuge model E, using a synthetic boundary cell, which is especially suited for work on slowly sedimenting molecules. The reliability of the method was controlled by running bovine albumin (Armour fraction V) both in the common and the synthetic boundary cell. This substance has previously been used in a comparative study of values obtained by a Spinco centrifuge and an oil turbin centrifuge [7]. The values thus obtained agreed fully with these data with a discrepancy less than 1 %. All our runs on cytochrome preparations were made at 260 000 g, and 0.05 *M* phosphate buffer of pH 6.8 with 1 % sodium chloride added was consequently used. Protein concentrations between 1 and 5 mg/ml were used, and in none of the cases could any concentration dependence of $S°_{20}$ be seen.

In a few cases we tried to determine the diffusion coefficient at 23°, using a Tiselius apparatus with the Philpot-Svensson optical system, and a cell 15 mm long and 2 mm broad. An interference filter (Bausch & Lomb) after the lamp allowed a red light of 639 mμ so that the image on the plate was homogeneously illuminated. Because of the low illumination, exposures of several minutes were necessary. The diffusion coefficients were calculated according to the "height-area" method. The percentage of error of our data appeared to be as high as ±10 %, mostly due to an imperfect initial boundary and disturbances during the compensation procedure in the narrow cell.

For salmon and chicken cytochrome the apparent partial specific volume was determined both in water and in the buffer, by means of a common pycnometer. No significant influence of the buffer could be

* Some denaturation might have occurred in this preparation.

seen. Our results are summarized in Table 1. The errors given for $S°_{20}$ are the calculated standard deviations of the mean of each preparation.

It is seen that $S°_{20}$ varies both between the different species and between the two preparation methods for the same species. In spite of their lower iron content, the preparations according to Loftfield and Bonnichsen give lower $S°_{20}$ values than those according to Paléus and Neilands. This indicates that the former preparations might contain impurities with slightly lower sedimentation constant than cytochrome c itself. The two components cannot be resolved but should give rise to a higher apparent diffusion constant which, however, could not be detected in the ultracentrifuge. The high value of V_p for salmon cytochrome c according to Loftfield and Bonnichsen might also be due to this impurity.

In only two cases we got sedimentation constants comparable to those of Atlas *et al.*[3], but one of them might have been modified by partly denaturation.

Our value for beef cytochrome c is 10 % lower than the cited value of Pedersen. This is in accord with the known difference of 5 to 10 % between the oil turbin and the Spinco centrifuge [7, 8].

The calculated frictional ratios also agree quite well with the older value 1.29 of beef cytochrome but not with the data of Atlas *et al.* close to 1.0. The rather high values of f/f_0 for horse cytochrome c might reflect that the diffusion constant of 9.5×10^{-7} cm^2 $\times$ s^{-1} is somewhat too low.

Effects of X-rays and Water Content on Sugars in Barley Seeds

L. EHRENBERG and M. JAARMA

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

An investigation of the influence of ionizing radiations on biochemical systems demonstrated that the relative concentrations of simple sugars in growing *Vicia faba* plants were strongly affected by chronic γ-irradiation [1]. When resting (*i. e.*, ripe) barley seeds are irradiated, their radiosensitivity was found to decrease with increasing water content [2]. Since the concentration of reducing sugars has been shown [3,4] to increase with increasing moisture content, we found it important to investigate possible relations between sugar content and radiation sensitivity. Under certain conditions glucose may act as a protective agent [5].

Methods. Seeds of the two-rowed barley strain, Bonus, were treated for 6 days with streaming air of the relative humidities 0 % and 90 %. This treatment gave samples containing 7.5 % and 17 % H_2O, respectively. The seeds were irradiated with 175 kV unfiltered X-rays at an intensity of 4 000 r min.$^{-1}$. Analysis of reducing sugars was made 15 hours after irradiation, and again after 2—4 weeks' storage at a constant water content and at 20° C.

For the analysis the material was ground twice in a Wiley mill, using first a 20-mesh, then a 40-mesh sieve. The grist was boiled for 3 min. in 80% ethanol, and thereafter extracted, with the same solvent, for 3 hours in a micro-Soxhlet apparatus. (Using 96 % ethanol instead, only about two thirds of the sugars were extracted by the same procedure.) After deproteinizing [6], reducing sugars were titrated, with an accuracy of 2 %, according to Somogyi [7]. The maximum variation between individual extractions amounted to 5 %.

Results. It was demonstrated (Table 1) that in the unirradiated material the in-

seen. Our results are summarized in Table 1. The errors given for $S°_{20}$ are the calculated standard deviations of the mean of each preparation.

It is seen that $S°_{20}$ varies both between the different species and between the two preparation methods for the same species. In spite of their lower iron content, the preparations according to Loftfield and Bonnichsen give lower $S°_{20}$ values than those according to Paléus and Neilands. This indicates that the former preparations might contain impurities with slightly lower sedimentation constant than cytochrome c itself. The two components cannot be resolved but should give rise to a higher apparent diffusion constant which, however, could not be detected in the ultracentrifuge. The high value of V_p for salmon cytochrome c according to Loftfield and Bonnichsen might also be due to this impurity.

In only two cases we got sedimentation constants comparable to those of Atlas *et al.*[3], but one of them might have been modified by partly denaturation.

Our value for beef cytochrome c is 10 % lower than the cited value of Pedersen. This is in accord with the known difference of 5 to 10 % between the oil turbin and the Spinco centrifuge [7, 8].

The calculated frictional ratios also agree quite well with the older value 1.29 of beef cytochrome but not with the data of Atlas *et al.* close to 1.0. The rather high values of f/f_0 for horse cytochrome c might reflect that the diffusion constant of 9.5×10^{-7} cm^2 $\times$ s^{-1} is somewhat too low.

Effects of X-rays and Water Content on Sugars in Barley Seeds

L. EHRENBERG and M. JAARMA

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

An investigation of the influence of ionizing radiations on biochemical systems demonstrated that the relative concentrations of simple sugars in growing *Vicia faba* plants were strongly affected by chronic γ-irradiation [1]. When resting (*i. e.*, ripe) barley seeds are irradiated, their radiosensitivity was found to decrease with increasing water content [2]. Since the concentration of reducing sugars has been shown [3,4] to increase with increasing moisture content, we found it important to investigate possible relations between sugar content and radiation sensitivity. Under certain conditions glucose may act as a protective agent [5].

Methods. Seeds of the two-rowed barley strain, Bonus, were treated for 6 days with streaming air of the relative humidities 0 % and 90 %. This treatment gave samples containing 7.5 % and 17 % H_2O, respectively. The seeds were irradiated with 175 kV unfiltered X-rays at an intensity of 4 000 r min.$^{-1}$. Analysis of reducing sugars was made 15 hours after irradiation, and again after 2—4 weeks' storage at a constant water content and at 20° C.

For the analysis the material was ground twice in a Wiley mill, using first a 20-mesh, then a 40-mesh sieve. The grist was boiled for 3 min. in 80% ethanol, and thereafter extracted, with the same solvent, for 3 hours in a micro-Soxhlet apparatus. (Using 96 % ethanol instead, only about two thirds of the sugars were extracted by the same procedure.) After deproteinizing [6], reducing sugars were titrated, with an accuracy of 2 %, according to Somogyi [7]. The maximum variation between individual extractions amounted to 5 %.

Results. It was demonstrated (Table 1) that in the unirradiated material the in-

Table 1. Content of reducing sugars (mg glucose/g dry weight) after irradiation and storage at different water contents.

Water content %	Analysis after	Seeds irradiated with, r		
		0	5×10^5	10×10^5
7.5	15 hours	1.46	1.53	1.46
	4 weeks	1.51	1.61	1.64
17	15 hours	1.15	1.33	1.21
	4 weeks	1.92	2.21	2.05
17 *	2 weeks	1.98	2.55	—

* Experiment not simultaneous with those above.

crease of the water content first caused a fall in reducing sugars, possibly a consequence of the increased respiration [3, 4]. During 2—4 weeks storage, at unchanged water content, the value increases, possibly becoming slightly higher at the higher water content.

Irradiation with 5×10^5 r increases the content of reducing sugars, especially at the higher water content. (10×10^5 r gives a somewhat lesser chemical change. After treatment with this high dose, a fraction of the seeds do not germinate; and death of seeds might therefore be responsible for any disturbed values.) As this increase is already observed immediately after irradiation, it is probably not an effect of a changed metabolic rate (*e. g.*, decrease of respiration rate [9]). It might be ascribed to a radiation induced disintegration of, *e. g.*, starch. If this is so, intermediates originating from cellular constituents other than carbohydrates and water, obviously play a role, as the disintegration of starch, irradiated at 8—23 % H_2O, was only measurable as viscosity decrease.

It can be concluded that irradiation causes a greater chemical change in sugars when the seeds have a higher moisture content, and consequently are protected against biological damage. The significance of this result, for the interpretation of the mechanism of action of radiations, will be discussed elsewhere [10].

The States ^1I of Trivalent Praseodymium and Thulium

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The identification by Spedding [1] of the states of Pr^{+3} has for many years been assumed to be complete. But the proposal of Ellis [2] that the band in the orange is due to a transition to $^1D_2$ rather than to $^1I_6$ was recently supported by the crystal field studies of Hellwege [3]. The Condon-Shortley theory [4] was applied to this f^2-system by Trefftz [5]. This author calculated the electrostatic interaction parameters F_2, F_4, and F_6 for a hydrogen-like 4f-wave function with an effective charge $Z_0 = 9.48$ (this seems very reasonable, because the ionization energy of Ce^{+3} corresponds to $Z_0 = 6.56$). However, the value of F_6 calculated by Trefftz is 64 times too small due to a misinterpretation of Condon and Shortley's decimal point as a multiplication operator. This led Trefftz to accept Spedding's very small value of F_6.

In the author's opinion*, F_6 is not necessarily negligible [6-8]. The position of ^1D, relatively to ^3P, can easily be accounted for by the set of ratios [6] $F_4 = 0.2\,F_2$ and $F_6 = \frac{1}{7}\,F_2$, given in Ref. 8, p. 19.

* *Note added in proof:* Judd [15] has recently drawn the same conclusion from Eu^{+3}. The present author must here correct the highest value among the three diagonal elements of energy of the ^5D-states to $9E^1 - 11E^3$ rather than $9E^1 + \frac{143}{7}\,E^3$,

The States ^1I of Trivalent Praseodymium and Thulium

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The identification by Spedding [1] of the states of Pr^{+3} has for many years been assumed to be complete. But the proposal of Ellis [2] that the band in the orange is due to a transition to $^1D_2$ rather than to $^1I_6$ was recently supported by the crystal field studies of Hellwege [3]. The Condon-Shortley theory [4] was applied to this f^2-system by Trefftz [5]. This author calculated the electrostatic interaction parameters F_2, F_4, and F_6 for a hydrogen-like 4f-wave function with an effective charge $Z_0 = 9.48$ (this seems very reasonable, because the ionization energy of Ce^{+3} corresponds to $Z_0 = 6.56$). However, the value of F_6 calculated by Trefftz is 64 times too small due to a misinterpretation of Condon and Shortley's decimal point as a multiplication operator. This led Trefftz to accept Spedding's very small value of F_6.

In the author's opinion*, F_6 is not necessarily negligible [6-8]. The position of ^1D, relatively to ^3P, can easily be accounted for by the set of ratios [6] $F_4 = 0.2\,F_2$ and $F_6 = \frac{1}{7}\,F_2$, given in Ref. 8, p. 19.

* *Note added in proof:* Judd [15] has recently drawn the same conclusion from Eu^{+3}. The present author must here correct the highest value among the three diagonal elements of energy of the ^5D-states to $9E^1 - 11E^3$ rather than $9E^1 + \frac{143}{7}\,E^3$,

0.02 F_2 just as well as by Trefftz's values, $F_4 = 0.138\ F_2$ and $F_6 = 0.0152\ F_2$ (if F_6 multiplied by 64). Also Racah's values [9] for Th^{++} suggest a similar decrease in the F^k integrals: $F_4 = 0.19\ F_2$ and $F_6 = 0.018\ F_2$. Both Trefftz's revised and the other proposals give ^1I at nearly the same place as the triplet ^3P. Thus, it will probably be masked by the three strong bands in the blue. Broer, Gorter and Hoogschagen, in their investigation of band intensities [10], could not explain the anomalously high intensity of the ^1I-band of Pr^{+3}. Hellwege's identification of the band as $^1D_2$ removes this difficulty, and one must consider the ^1I as not yet observed. The triplet character [10] expressed in squares of the wave function will only be of the magnitude [1].

$$[S = 1] = \frac{6\,\zeta^2}{(^1I_6 - {}^3H_6)^2}$$

Since $\zeta = 400$ cm^{-1} and the distance $^1I_6 - {}^3H_6$ between the two perturbing levels is $\sim 15\,000$ cm^{-1}, the quantity $[S = 1]$ will only be ~ 0.005. Even if the molar extinction coefficient ε_0 of the band $^3H_4 - {}^1I_6$ were 20 for the pure triplet transition, the actual ε_0 would only be 0.1. Nevertheless, this should be observable. The author has tried in vain in the wavelength range 550—270 mμ for 0.2 M $Pr(ClO_4)_3$ in 5 cm cells. However, the spectrum does show a conspicuous broadening towards shorter wavelengths of the band $^3P_1$, but no definite conclusion can be drawn.

According to Pauli's equivalence theorem of holes, f^{12} in Tm^{+3} and f^2 in Pr^{+3} have the same set of terms. The band at 350 mμ of Tm^{+3}, supposed to be due to $^3H_6 - {}^1I_6$, is cited above [10] as the only other known example of anomalously high intensity. But an aqueous solution of thulium(III) perchlorate in 1 M $HClO_4$ shows this band as not having any larger oscillator strength P (which is proportional to the area of the band as a function of wave number [10]) than the other bands, while Hoogschagen, Scholte and Kruyer [11] give $P \sim 30 \cdot 10^{-6}$, contrary to usual lanthanide bands with $P \sim 10^{-6}$. The materials used by these authors seem to contain strongly ultraviolet-absorbing impurities (iron?) as was true in the case of their holmium [11]. Measurements on a Cary spectrophotometer of 0.1 M $Tm(ClO_4)_3$ in 2 cm cells give the following maximum values ε_0 and oscillator strengths P (uncertainty $\sim$20 %):

Maxima observed	ε_0	P	P (Ref. [11])
780 mμ	1.0	$1.9 \cdot 10^{-6}$	$1.98 \cdot 10^{-6}$
695,682,655	0.9; 1.5; 0.3	3.0	3.18
462	0.4	0.4	$\sim$0.45
358,355	0.8; 0.8	2.4	$\sim$30
290,284	0.1; 0.2	0.4	
276,274	0.1; 0.2	0.3	
263,260	1.4; 1.2	5	

Qualitative agreement is found with the measurements by Rodden [12] for wavelengths over 350 mμ. Besides the bands of the table, weak and narrow bands at 520, 378 and 255 mμ (with $\varepsilon_0 \sim 0.1$) may be ascribed to an impurity of $\sim$ 3 % erbium, whose strong bands occur at these wavelengths [8]. Below 300 mμ the background rises appreciably, and below 230 mμ a steep absorption limit appears. The latter

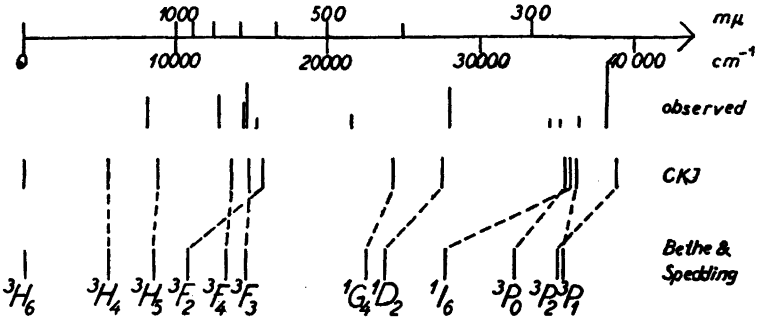

Fig. 1. Observed bands of Tm^{+3} (except that at 8 100 cm^{-1}) represented by peaks proportional to the oscillator strength P. Calculated positions with intermediate coupling from the parameters, given in the text.

is not due to ClO_4^- and is perhaps due to $4f^{13}-4f^{11}5d$ transitions in Tm^{+3}. The three band groups in the range 290–260 mμ are equivalent to those found by Gobrecht [13] in solid $Tm_2(SO_4)_3$, $8H_2O$. The multiplet ^3P is somewhat perturbed, the most intense band group 263–260 mμ presumably being due to $^3H_6-{}^3P_2$.

Since $[S = 1] = 0.02$ for $^1I_6$ in Tm^{+3}, the transition to this state is still of unusually high probability, if it corresponds to the 358–355 mμ band group. This is not certain, since the strong intermixing of the states with $J = 4$, *viz.* $^3H_4$, $^3F_4$ and $^1G_4$, may distribute two of the states to 685 and 355 mμ. Bethe and Spedding [1,14] choose the set of parameters $F_2 = 308$ cm^{-1}, $F_4 = 71$ cm^{-1}, and $F_6 = 0.86$ cm^{-1} by extrapolation from [3] La^+. If the possibility [6] $F_2 = 450$ cm^{-1}, $F_4 = 90$ cm^{-1}, and $F_6 = 9$ cm^{-1} is applied to Tm^{+3} with $\zeta = -1\,400$ cm^{-1}, the identifications are changed somewhat. Fig. 1 gives the two sets of calculated wave numbers and the observed. But the question cannot be settled, before J can be determined from crystal field studies. The low intensity of the band at 462 mμ might support the identification with $^1D_2$.

I am much indebted to Professor Jannik Bjerrum for his interest in the work. Further, I thank *Universitetets Institut for Teoretisk Fysik* for putting at my disposal a sample of thulium oxide.

4-Methylthiobutyl *iso*Thiocyanate, a New Naturally Occurring Mustard Oil

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark *

In a previous communication of this series [1] it was observed that seeds of *Eruca sativa* Mill. contain a volatile mustard oil which is paperchromatographically different from the known, naturally occurring *iso*thiocyanates. We now wish to report on the identity of this mustard oil as 4-methylthiobutyl *iso*thiocyanate (I), a compound first synthesized by Schmid and Karrer [2].

$$CH_3SCH_2CH_2CH_2CH_2-N=C=S$$

I

$$CH_3SCH_2CH_2CH_2CH_2-NHCSNH-R$$

II R = H

III R = $CH_2C_6H_5$

From a larger seed sample, made available to us during the summer of 1954, we isolated the thiourea derivative (II) of the volatile *iso*thiocyanate. The chemical structure was established by analysis and by comparison with a synthetic specimen of (II). Mixed melting point, paper chromatography in various solvents and infrared spectra left no doubt as to the identity of the two preparations.

In Nature (I) occurs as a yet uncharacterized glycoside for which we suggest the name *glucoerucin*. Its presence is disclosed upon paper chromatography according to Schultz and Gmelin [3]. These authors noticed in seeds of *Eruca sativa*

* Part of the present work was carried out during a visit by one of us (A.K.) to the Department of Physiological Chemistry of the University of Lund, Sweden.

is not due to ClO_4^- and is perhaps due to $4f^{13}-4f^{11}5d$ transitions in Tm^{+3}. The three band groups in the range 290–260 mμ are equivalent to those found by Gobrecht [13] in solid $Tm_2(SO_4)_3$, $8H_2O$. 4-Methylthiobutyl *iso*Thiocyanate, a New Naturally Occurring Mustard Oil

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark *

In a previous communication of this series [1] it was observed that seeds of *Eruca sativa* Mill. contain a volatile mustard oil which is paperchromatographically different from the known, naturally occurring *iso*thiocyanates. We now wish to report on the identity of this mustard oil as 4-methylthiobutyl *iso*thiocyanate (I), a compound first synthesized by Schmid and Karrer [2].

$$CH_3SCH_2CH_2CH_2CH_2-N=C=S$$

I

$$CH_3SCH_2CH_2CH_2CH_2-NHCSNH-R$$

II R = H

III R = $CH_2C_6H_5$

From a larger seed sample, made available to us during the summer of 1954, we isolated the thiourea derivative (II) of the volatile *iso*thiocyanate. The chemical structure was established by analysis and by comparison with a synthetic specimen of (II). Mixed melting point, paper chromatography in various solvents and infrared spectra left no doubt as to the identity of the two preparations.

In Nature (I) occurs as a yet uncharacterized glycoside for which we suggest the name *glucoerucin*. Its presence is disclosed upon paper chromatography according to Schultz and Gmelin [3]. These authors noticed in seeds of *Eruca sativa*

* Part of the present work was carried out during a visit by one of us (A.K.) to the Department of Physiological Chemistry of the University of Lund, Sweden.

two glucosides one of which was interpreted as belonging to their "SO-group" whereas the higher spot was attributed to glucotropaeolin. Upon paper chromatography of our crude thiourea we could exclude the presence of N-benzylthiourea. Consequently, the spot of presumed glucotropaeolin undoubtedly represented glucoerucin, the two being hardly distinguishable in the usual glucoside chromatography.

In older literature seeds of *Eruca sativa* are reported to contain an unidentified mustard oil [4] whereas Mohammad and Ahmad [5] tacitly assumed allyl *iso*thiocyanate to be present in the seeds, known in India as "taramira" and of importance for the local oil production (jamba oil). Sudborough *et al.*[6] isolated and purified the volatile mustard oil from *Eruca sativa* seeds and transformed it into a derivative, m. p. 83—84°, upon reaction with benzylamine. The composition $C_{19}H_{25}N_3S_3$ was reported for this derivative, apparently without suggestions as to its chemical structure. Therefore, we submitted authentic 4-methylthiobutyl *iso*thiocyanate to reaction with benzylamine and obtained in good yield the expected N-(4-methylthiobutyl)-N′-benzylthiourea (III), $C_{13}H_{20}N_2S_2$, with m. p. 77—78°. We are inclined to believe that the Indian authors have been mislead by inaccurate analyses inasmuch as the calculated figures for the two formulae do not deviate very much (see Experimental).

The characteristic radish-like smell and taste of (I) proved of much diagnostic value in our search for the new mustard oil in various species. The taste, in conjunction with paperchromatographic results, points to (I) as being widely distributed in the plant kingdom. So far, we consider 4-methylthiobutyl *iso*thiocyanate to be present in seeds of *Iberis sempervirens* L., *Vesicaria utriculata* L. and *V. sinuata* Poir. *Matthiola annua* R.Br. and various species of *Cheiranthus* and *Brassica oleracea* L., as well as root materials of *Hesperis matronalis* L. and *Farsetia clypeata* R.Br. seem to contain (I) or closely related *iso*thiocyanates.

It is pertinent here to refer to two previously recorded, naturally occurring *iso*thiocyanates with the same carbon skeleton as that of (I). From seeds of *Erysimum Perofskianum* Fisch. et M., Schneider and Kaufmann [7] isolated erysolin (IV), representing the sulphone corresponding to (I).

$$CH_3SO_2CH_2CH_2CH_2CH_2-N=C=S$$

IV

$$CH_3SOCH=CHCH_2CH_2-N=C=S$$

V

Sulphoraphen, the characteristic *iso*thiocyanate of radish seed (*Raphanus sativus* L.), was shown by Schmid and Karrer [8] to possess the structure (V), differing from (I) in being unsaturated and containing a sulphoxide-grouping. It is interesting in this connection that Lavine [9] demonstrated the intermediate formation of a "dehydro"-derivative in the oxidation of methionine to its sulphoxide.

The isolation and characterization of further *iso*thiocyanates, structurally related to (I), will form the subject of future communications.

Experimental. Isolation and structure proof of (II). A preliminary argentometric analysis of the air-dried, fatty seeds of *Eruca sativa* Mill. showed a content of 1.4 % of volatile mustard oil, calculated as methylthiobutyl *iso*thiocyanate.

A homogenized mixture of 25 g of seeds of *Eruca sativa* (fat-containing) and 500 ml of water was placed at 35° for 3 hours. The volatile constituents were removed by steam distillation, 500 ml of distillate being collected and transformed into thiourea upon standing for 24 hours with 100 ml of conc. ammonia. Evaporation *in vacuo* left a brownish, crystalline residue which was taken up in hot water, treated with a little charcoal, filtered and cooled. Colourless, nacreous plates separated and were recrystallized twice from water and once from ethyl acetate and petroleum ether before analysis. The yield was 0.25 g, m. p. 53° (Fisher-John's block), undepressed on admixture with an authentic specimen of N-(4-methylthiobutyl)-thiourea (II). (Found: C 40.71; H 7.87; N 15.62. Calc. for $C_6H_{14}N_2S_2$: C 40.42; H 7.91; N 15.72). Paper chromatography with chloroform as the solvent [10] gave the R_{Ph}-value 0.97, whereas in the following systems: 1) pyridine : amyl alcohol : water (35:35:30); 2) heptane : 90 % formic acid: *n*-butanol (20:20:15)[12]; 3) heptane : 90% formic acid : *n*-butanol (20:10:22)[12], R_F-values of 0.82, 0.13 and 0.76 were found, respectively, for both the natural and the synthetic specimen. The infra-red spectra were determined in potassium bromide discs and proved to be completely identical.

Synthesis of (I) and (II). 4-Methylthiobutylamine (6.3 g), prepared by our previously

recorded method [11], was dissolved in water (45 ml), and a solution of thiocarbonyl chloride (6.1 g) in chloroform (50 ml) was added. To the vigorously shaken mixture 1.4 *N* NaOH (76 ml) was slowly added. After 0.5 hour, the chloroform layer was separated, dried and evaporated. Distillation *in vacuo* of the residue afforded 5.1 g (60 %) of the *iso*thiocyanate, b.p. 136° at 12 mm, with a characteristic smell of radish. Ref.[3] lists b. p. 130—140° at 9 mm.

The mustard oil was dissolved in ethanol, previously saturated with ammonia at 0°, and left at room temperature for 3 days. The solvent was removed and the residue recrystallized twice from water and once from chloroform and petroleum ether before analysis. M. p. 53° (Fisher-John's block). Ref.[3] reports m. p. 55—56°. (Found: N 15.80; S 36.07. Calc. for $C_6H_{14}N_2S_2$: N 15.72; S 35.96).

N-(4-Methylthiobutyl) - N' - benzylthiourea (III). A solution of (I) (615 mg) and benzylamine (735 mg) in ethanol (3 ml) was kept at 40° for 18 hours. The solvent was then removed and the residue taken up in ether. The solution was shaken with small portions of 0.5 *N* HCl and water in order to remove the excess amine. During these operations the separation of the crystalline thiourea started (900 mg). Before analysis, the sample was recrystallized twice from 70 % ethanol and once from ethyl acetate and petroleum ether, m. p. 77—78° (water bath). (Found: C 58.25; H 7.55; N 10.45. Calc. for $C_{13}H_{20}N_2S_2$: C 58.15; H 7.51; N 10.44. Calc. for $C_{19}H_{25}N_3S_3$: C 58.28; H 6.44; N 10.81).

Microanalyses by Mr. W. Egger. We wish to thank the *Botanical Garden of Copenhagen* for cultivating *Eruca sativa* Mill. for our use. Thanks are also due to Dr. Nuding of the *Landwirtschaftl. Hochschule, Stuttgart-Hohenheim* and Mr. R. von Hösslin of the *Staatl. Lehr- und Forschungsanstalt für Gartenbau, Weihenstephan b. München*, for furnishing us with further samples of the same seeds.

The Calculation of Sedimentation Velocity from Experiments with Concentrated Mixtures

OLE LAMM

Department of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

A sedimenting boundary in the ultracentrifuge is by no means mathematically simple even in the case of a dilute solution of an ideal solute, as is seen from Faxéns [1] solution of the concentration function in a centrifuge cell. Additional complications, to which considerable attention has been paid, arise from thermodynamic and frictional effects, and from polydispersity. Thus the situation may be very complicated and is still more accentuated if the solution is concentrated *in a more hydrodynamic sense* [2], in which case the general form of the differential equation describing the course of the concentration change in the cell is intricate, even apart from effects of the non-constancy of the thermodynamical and frictional coefficients.

In such a situation it may sometimes seem more natural to use the concentration decrease in the middle of the sectorshaped cell than to use an analytical property of the boundary. This well-known possibility is evident from the considerations of Rinde [3, 4], of Trautman and Schumaker [5] and others.

In a part of the cell, not reached by the diffusion gradient regions at the top and bottom, the determination of the actual sedimentation coefficients of a two-com-

recorded method [11], was dissolved in water (45 ml), and a solution of thiocarbonyl chloride (6.1 g) in chloroform (50 ml) was added. To the vigorously shaken mixture 1.4 *N* NaOH (76 ml) was slowly added. After 0.5 hour, the chloroform layer was separated, dried and evaporated. The Calculation of Sedimentation Velocity from Experiments with Concentrated Mixtures

OLE LAMM

Department of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

A sedimenting boundary in the ultracentrifuge is by no means mathematically simple even in the case of a dilute solution of an ideal solute, as is seen from Faxéns [1] solution of the concentration function in a centrifuge cell. Additional complications, to which considerable attention has been paid, arise from thermodynamic and frictional effects, and from polydispersity. Thus the situation may be very complicated and is still more accentuated if the solution is concentrated *in a more hydrodynamic sense* [2], in which case the general form of the differential equation describing the course of the concentration change in the cell is intricate, even apart from effects of the non-constancy of the thermodynamical and frictional coefficients.

In such a situation it may sometimes seem more natural to use the concentration decrease in the middle of the sectorshaped cell than to use an analytical property of the boundary. This well-known possibility is evident from the considerations of Rinde [3, 4], of Trautman and Schumaker [5] and others.

In a part of the cell, not reached by the diffusion gradient regions at the top and bottom, the determination of the actual sedimentation coefficients of a two-com-

ponent system is quite simple even in the cases of the most complicated boundaries indicated above.

Disregarding the diffusion term, the two-component case is described by (*cf.* Ref.[2], eq. (11); V is the partial specific volume)

$$\frac{\partial m_2}{\partial t} = -\frac{1}{x}\frac{\partial}{\partial x}\left(\frac{m_1^2 m_2^2 (V_1 - V_2) V_1 \omega^2 x^2}{\varphi_{12}}\right) \quad (1)$$

Rinde showed for this non-diffusion case that the concentration decrease during the process is uniform over the cell and is thus the same at different levels. This statement is a consequence of the condition of continuity and does not assume a dilute system. However, it assumes that we start from a constant composition in the cell. Such being the case, we have the advantage that the concentrations m_1, m_2 g/cm³ and the friction per cm³ φ_{12} are independent of x, which reduces equation (1) to

$$\frac{\partial m_2}{\partial t} = -2m_1^2 m_2^2 (V_1 - V_2) V_1 \omega^2 / \varphi_{12} \quad (2)$$

The sedimentation coefficient of component 2 is [2]

$$s_2 = m_1^2 m_2 (V_1 - V_2) V_1 / \varphi_{12} \quad (3)$$

which, by substituting equation (2), can be consequently determined from

$$s_2 = -\frac{1}{2m_2\omega^2}\frac{\partial m_2}{\partial t} \quad (4)$$

by an experimental determination of $\partial \ln m_2/\partial t$ somewhere in the middle of the cell.

Equation (4) is the same here as in the theory of the sedimentation of a dilute substance. As already mentioned, the equation assumes a uniform concentration over the cell. We will stick to this restriction but will drop now the restriction to two components. For the ith component, the continuity equation for the "cylindrical" flow in the cell of sector shape is

$$\frac{\partial m_i}{\partial t} = -\frac{1}{x}\frac{\partial}{\partial x}(s_i m_i \omega^2 x^2) = -2s_i m_i \omega^2 \quad (5)$$

where $s_i\,\omega^2 x$ is, by definition, the sedimentation velocity in cm/sec. For any partial quantity, in this case the partial volume V_i, $\Sigma V_i dm_i = 0$. Combined with equation (5) this gives an equation previously proved for two components

$$\Sigma s_i m_i V_i = 0 \quad (6)$$

The deduction shows that this special relation is not restricted to constant partial volumes, as distinct from the special relations which connect sedimentation coefficients with frictions, which were reported elsewhere [2].

It is often more practical to measure the change of refractive index n. Applying the approximation introduced previously [2] in writing the refractive index n of the mixture

$$n = n_1^\circ m_1 V_1^\circ + n_2^\circ m_2 V_2^\circ \quad (7)$$

(where the index ° refers to the pure component) and, in addition, assuming $V_1 = V_1^\circ$ and $V_2 = V_2^\circ$ as in the case of an ideal mixture, s_2 may be calculated according to

$$s_2 = \frac{\partial n/\partial t}{2(n_1^\circ - n)\omega^2} \quad (8)$$

n_1° is the refractive index of the medium, n that of the solution as measured in the cell during the experiment. The general expression $m_1 V_1 + m_2 V_2 = 1$ has been used in the deduction. As symmetry has been preserved, a corresponding approximate expression is valid also for s_1. Equations other than (7) are not considered here.

Owing to its simplicity, expression (8) seems to be worth notice even if more exact expressions may prove necessary in many instances. Several-component cases must be specially considered. When using this procedure of measuring s for low-molecular mixtures, much will depend on the control of temperature, the sensitivity being excellent in itself if interference methods of observation are employed.

Conclusions. Owing to the complicated nature of a sedimentation boundary, it may sometimes be of value to use the general concentration change in the middle of the cell, the theory of which remains simple also in experiments with concentration effects. Some remarks are made on this procedure, which possesses a practical applicability also for the non-dilute system, the theory of which was treated in an earlier communication without mentioning any mode of practical calculation.

Eine praktische Vereinfachung bei der Skalenmethode zur Messung von Brechungsindexgradienten

OLE LAMM

Physikalisch-Chemisches Institut der technischen Hochschule, Stockholm, Schweden

Bei der bisher benutzten Anordnung z.B. für Diffusionsmessung [1,2] müssen die Skalenstrichverschiebungen nicht über eine gleichförmige Skala sondern über die Linien des Skalenphotogrammes, d.h. über die verschobenen Linienlagen aufgetragen werden, damit die Brechungsindexgradienten als Funktion der Höhenkoordinaten in der Diffusionszelle richtig herauskommen sollen. Es ist dies nachteilig an und für sich, führt aber ausserdem eine Korrektur mit sich, die von der Art der einfachsten Benutzung einer Referenzskala herrührt. Diese letztere ist ein Skalenphotogramm, dass ohne Konzentrationsgradient aufgenommen wird (jedoch mit Beibehaltung der übrigen Bedingungen), und dessen Linienlagen bei Berechnung der Skalenstrichverschiebungen des Hauptphotogrammes als Referenzwerte dienen. Dieses Verfahren dient zur Eliminierung optischer Unvollkommenheiten besonders der Diffusionszelle. Es setzt voraus, dass Referenzlinie und Linie der Hauptaufnahme derselben Lage in der Zelle entsprechen, was bei der bisherigen Anordnung nur ungefähr zutrifft. Die dafür zu berechnende Korrektur [2] kann nun in einfacher Weise vermieden werden.

Die Vereinfachung besteht in einem Platzwechsel von Skala und photographischer Platte. Bei der gebräuchlichen Apparatur, wo die Zelle zwischen Skala und Objektiv steht, ist die abbildende Projektion geradlinig von der photographischen Platte bis zum Objektiv und weiter zu der Zelle (wo sie durch die Lichtkrümmung gestört wird). Deshalb korrespondieren die (lichtkrümmenden) Zellenlagen mit den Lagen auf der Platte, d.h. mit den durch die Krümmung verzerrten veränderlichen Lagen. Bei dem entgegengesetzten Verfahren herrscht Geradlinigheit von der Skala zum Objektiv und bis zu der Zelle. Dadurch werden die Zellenlagen durch die Originalskala geregelt. Der Vorteil liegt teils darin, dass letztere gleichförmig ist, teils darin, dass die Zellenlagen einmalig definiert und von der Lichtkrümmung oder Brechung in der Zelle zunächst unabhängig werden.

Diese Beobachtung ist allgemeiner Art und gilt damit auch bei den modifizierten Verfahren mit zweimaliger Abbildung, sei es dass diese durch die Raumverhältnisse bedingt ist wie bei gewissen Ultrazentrifugen, oder aus anderen Gründen durchgeführt wird, wie bei der von Svensson [3] vorgeschlagenen verkürzten Anordnung. Massgebend ist ob die Aperturblende (das Projektionszentrum), zwischen Zelle und Platte (die alte Anordnung) oder zwischen Skala und Zelle steht.

Die Rolle der Aperturblende wird besonders klar im Falle zweimaliger reeller Abbildung, wobei wir der Reihe nach Skala, erstes Objektiv, erstes Skalenbild, zweites Objektiv und schliesslich zweites Skalenbild haben, wo die photographische Schicht angebracht ist. Ob die Zelle zwischen Objektiv I und Skalenbild I ("negativer Skalenabstand"), oder zwischen letzterem und Objektiv II steht, ist für unser Problem zunächst gleichgültig. Um scharfe Linien zu erzielen muss, je nach der Steilheit der Gradienten in der Zelle, die Apertur mehr oder weniger klein gewählt werden. Wird die diesbezügliche Blende am Objektiv II angebracht, so liegt die alte Anordnung vor, während eine Anbringung am Objektiv I die neu vorgeschlagene Anordnung liefert.

Die Messgeräte zur Answertung der Skalendiagramme wie sie von Schumacher [4] und von Claesson [5] konstruiert und ausgeführt worden sind, werden durch die Umänderung nur unbedeutend berührt und jedenfalls nicht in unvorteilhafter Richtung.

Spaltung von D,L-Histidin bei Papierchromatographie

RUTH WEICHERT

Institutet för organisk kemi och biokemi, Stockholms Högskola, Stockholm, Schweden

Seit 1951 wurde mehrfach über razemische Aminosäuren berichtet, die bei Papierchromatographie mit optisch inaktiven Lösungsmittelsystemen in optische Antipoden gespalten werden. Der Grund hierfür muss in einer Adsorption an der optisch aktiven Cellulose liegen, wobei die eine Antipode stärker adsorbiert wird als die andere.

Zu diesen Aminosäuren gehören verschiedene Dioxyphenylalanine [1,2]. Die Rolle der Hydroxylgruppen dieser Aminosäuren könnte in der Bildung von Wasserstoffbrücken zur Cellulose liegen; eine Gesetzmässigkeit in der Stellung dieser Hydroxylgruppen im Benzolkern kann noch nicht festgestellt werden. Bei 2,5-Dioxyphenylalanin ist gezeigt worden [1], dass die L-Form die kürzere Wanderungsstrecke hat, d.h. vom Papier stärker adsorbiert wird; ob bei den anderen spaltbaren Dioxyphenylalaninen dieses auch der Fall ist, ist nicht bekannt, da nur die Razemate untersucht wurden [1,2].

Closs und *Haug* [3] berichteten über die Spaltung von D,L-Tryptophan bei Papierchromatographie und zeigten, dass die L-Form am stärksten auf dem Papier festgehalten wird. Mehrfach wurde die papierchromatographische Spaltbarkeit von D,L-Kynurenin mitgeteilt [4,5]. Bei Kynurenin scheint die Wasserstoffbrücke zwischen der aromatischen Aminogruppe und der Carbonylgruppe für die Spaltung notwendig zu sein, da eine Veränderung der Carbonylgruppe zur CH(OH)- oder CH_2-Gruppe diese Spaltbarkeit aufhebt [6]. Kynurenin würde somit aus zwei kondensierten Ringen bestehen und Ähnlichkeit mit Tryptophan aufweisen; bei Kynurenin wird aber die D-Form am stärksten adsorbiert.

D- und L-Phenylalanin zeigen keinen Unterschied in den R_F-Werten [4]. Es war von Interesse zu untersuchen, wie sich ein Austausch des Benzolringes in Phenylalanin gegen einen heterocyclischen Ring auf die Spaltbarkeit auswirkte. Aus diesem Grunde wurden papierchromatographische Versuche mit D,L-, D- und L-Histidin-mono-hydrochlorid ausgeführt. Es zeigte sich, dass razemisches Histidin in optische Antipoden gespalten wird und die D-Form die kürzeste Strecke wandert.

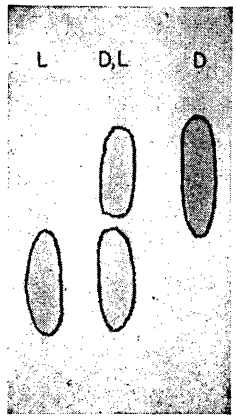

Abb. 1. Durchlaufchromatogramm von L-, D,L- *und* D-*Histidin-mono-hydrochlorid mit Methanol-Wasser (3:1) auf Whatman Nr. 4-Papier. Zeit: 23 ½ Std. Wanderungsstrecken der Antipoden:* D *26,3 cm,* L *29,7 cm. Wanderungsstrecken des gespaltenen Razemats:* D *26,2 cm,* L *29,7 cm.*

Microestimation of Cyanide with a Modified Epstein Procedure

KJELD JØRGENSEN

Institute of Physical Chemistry, University of Copenhagen, Denmark

For microestimation of cyanide the methods of Alridge [1] and Epstein [2] seem to be the most sensitive and accurate [3]. Both of them use a preliminary formation of cyanohalogenide, which is then reacting with pyridine and benzidine (Alridge) or phenyl-methyl-pyrazolone (Epstein), thus giving a coloured compound for colorimetry. For further increase of sensitivity two principles can be applied: A preliminary concentration of the sample by distillation or aeration [4] or concentration of the final coloured substance by extraction in *e. g.* butanol [5].

In our work with the hemiglobin-cyanide complex we had some experience with the Epstein procedure, which we modified by altering the preparation of reagents. In this way we increased the sensitivity 5 to 6 times, and the method became more convenient to handle. Using 4 ml of sample with a cyanide concentration from 10^{-5} *M* to 10^{-6} *M*, the cyanide content could be determined with a standard deviation of $\pm$ 3 %. The final extinction, read at 632 mμ, would vary from 1.0 to 0.1. Under these conditions Beers law is obeyed. The modification will be described here with a few comments.

Reagents. Chloramin-T, 0.5 % in water. Stable in the refrigerator for months. The concentration may vary from 0.25 to 1.0 %.

Pyridine. A. R. Stored in the refrigerator.

3-Methyl-1-phenyl-5-pyrazolone. Commercial product recrystallized to m. p. 127—128° C.

Bis-3-methyl-1-phenyl-5-pyrazolone. Can be prepared by boiling the monopyrazolone for several hours with phenylhydrazine but is more easily synthesized by gently refluxing 1 mole ethylacetoacetate with 3 mole phenylhydrazine for less than 0.5 h. The mixture will suddenly solidify. The solid bispyrazolone is boiled out three times with alcohol.

Mixed pyrazolone powder. A stock is made by mixing 5 parts mono- and 1 part bispyrazolone.

Pyridine-pyrazolone reagent. 150 mg mixed pyrazolone powder is dissolved in 25 ml pyridine. This reagent is stable for one week when kept in the refrigerator. The solution of bispyrazolone alone in pyridine [3] is only stable for 2 days. The ratios of mono- to bispyrazolone and of pyrazolone to pyridine are chosen so that the final colour will be maximal. Small variations will cause no influence on the final result, so the preparation of reagents can be made easily. The chosen amount of powder is easily dissolved in the cold pyridine.

Standard cyanide solution.

Procedure. A 4 ml sample, with pH between 4 and 8, is chilled. 0.2 ml chilled chloramine solution is added and mixed by swirling. After 5 minutes in an ice bath 0.8 ml chilled pyridine-pyrazolone reagent is added. The mixture is left at room temperature for 80-90 minutes. The blue colour is read in a colorimeter or in a spectrophotometer at 632 mμ. A known standard is always run simultanously.

5 minutes was found nesessary for quantitative chlorination. As the reagent was stored cold, it was preferred to add it chilled. It was found of no advantage to control temperature with a thermostate during colour development. The final colour was only little influenced by the temperature used. Using room temperature, maximum intensity of colour is obtained after 75 min. and the colour is stable for at least 0.5 h.

If the sample contains other substances than cyanide, these of course may interfere and make it necessary to run blinds.

Many attemps to increase the sensitivity further by previous aeration with the technique of Boxer and Rickards [4] and with modifications always failed to give satisfactory recoveries or reproducible results. On the other hand it was shown that extraction of the fully developed colour by butanol could increase the sensitivity at least 5 times, but as our experience with that method is only limited, a detailed description is omitted.

Enzymatic Decarboxylation of γ-Hydroxyglutamic Acid to α-Hydroxy-γ-amino-*n*-butyric Acid

ARTTURI I. VIRTANEN and PENTTI K. HIETALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

We have recently isolated γ-hydroxyglutamic acid from *Phlox decussata* [1]. Attempts to decarboxylate this acid with homogenates of *Phlox* led to negative results, whereas L-glutamic acid was easily decarboxylated with the same homogenates. Accordingly, *Phlox* did not contain the specific γ-hydroxyglutamic acid decarboxylase. The same result was obtained with homogenates of pea.

After fruitless experiments with green plants we found decarboxylase activity also with γ-hydroxyglutamic acid by using as enzyme material *Escherichia coli*, a B_{12}-vitamin requiring mutant. α-Hydroxy-γ-aminobutyric acid was hereby formed as the decarboxylation product (Fig. 1) which could be isolated and characterized (*cf.* below). This amino acid could not be detected in *E. coli* without addition of γ-hydroxyglutamic acid (70 % alcohol extract of bacteria, two-dimensional paper chromatography).

According to Umbreit and Heneage [2] *E. coli* decarboxylates *allo*-β-hydroxy-DL-glutamic acid (synth.). All strains of *E. coli* capable of decarboxylating this acid contained glutamic acid decarboxylase too, but the results suggested that the two enzymes are different. We have compared the velocities of the decarboxylation of L-glutamic acid, our γ-hydroxyglutamic acid, *allo*-β-hydroxy-DL-glutamic acid and β-hydroxy-DL-glutamic acid using *E. coli*. The CO_2 evolution was measured in a Warburg apparatus in N_2-atmosphere according to Schales *et al.*[3]. The results are presented in Table 1.

Isolation of the decarboxylation product. 27 mg of γ-hydroxyglutamic acid in 10 ml of 0.1 *M* acetate buffer (pH 4.9) + 1 g of fresh *E. coli* (178 mg dry subst.) was kept for 24 h at 38° C with occasional shaking. The bacteria were separated and washed with the buffer. The solution + washwater was passed through an Amberlite IR-120 column. The amino acids remained in the column and were eluted with 1 *N* ammonia. After evaporation *in vacuo*

Fig. 1b. Control experiment without any substrate.

Table 1. Decarboxylation rates of hydroxyglutamic acids. Measurements were made with E. coli at pH 4.9 in a 0.1 M acetate buffer at 37° C and with Phlox and Pisum at pH 6.2 in a 0.1 M phosphate buffer at 30° C with a final substrate concentration of about 5.5 μmoles/ml in each case.

Agent	Q_{CO_2} (μl CO_2/hour/g dry weight)			
	L-Glutamic acid	γ-Hydroxy-glutamic acid	Allo-β-hydroxy-DL-glutamic acid	β-Hydroxy-DL-glutamic acid
E. coli	34 900	3 400	8 200	650
Phlox decussata	730	0		
Pisum sativum	3 000	0		

the solid rest was dissolved in 1 ml of phenol-water-solvent (500:184) and fractionated in a cellulose powder column (1.2 × 37 cm) on the top of which 1 mg methylorange was placed. 17 fractions of 1.5 ml were collected. The indicator came out in fractions 2—5, γ-aminobutyric acid in fractions 6—11, and the decarboxylation product of γ-hydroxyglutamic acid in fractions 11—17. The combined fractions 12—17 (9 ml) were diluted with alcohol and water, the amino acid separated in an Amberlite IR-120 column, eluted with ammonia and evaporated to dryness. After recrystallization from water the mp. was 199° C.

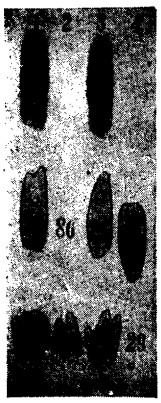

Fig. 2. Paper chromatogram of the pure decarboxylation product after reduction with HI and red P. 1 = reduction products + γ-aminobutyric acid (29), 2 = γ-aminobutyric acid alone, 3 = reduction products, 4 = decarboxylation product alone (86). Solvent phenol-NH_3. The slow moving spots are probably iodine-containing compounds.

Characterization of the decarboxylation product.

1. By reduction with HI (*d* 1.96) and red P at 140° C for 4 h. (1 mg substance + 1 mg P + 6 μl HI) γ-aminobutyric acid was formed (Fig. 2). Accordingly the decarboxylation product was a hydroxyderivative of γ-aminobutyric acid.

2. Analysis: N 11.55. Calc. for a monohydroxyaminobutyric acid N 11.75.

3. The decarboxylation product is not homoserine, and does not contain the α-amino group. Accordingly, the α-carboxyl group is split off by decarboxylation, and the decarboxylation product is α-hydroxy-γ-amino-*n*-butyric acid.

$$HOOC \cdot CHOH \cdot CH_2 \cdot CHNH_2 \cdot COOH \xrightarrow{-CO_2} HOOC \cdot CHOH \cdot CH_2 \cdot CH_2NH_2$$

Transamination: α-ketoglutaric acid + γ-hydroxyglutamic acid ⟶ glutamic acid + γ-hydroxy-α-ketoglutaric acid, could be found with homogenates of *Phlox*.

As far as we know α-hydroxy-γ-amino-*n*-butyric acid has not earlier been found in any biological material.

We are very grateful to Dr. Karl Pfister, Rahway, New Jersey, for preparations of synthetic β-hydroxy-DL-glutamic acid and *allo*-β-hydroxy-DL-glutamic acid.

A New Type of Nitrogen Compound in Green Plants. A Cyclic Homoserine Derivative in Some *Liliaceae* Plants

ARTTURI I. VIRTANEN and P. LINKO

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Species of *Convallaria* and related plants have been widely investigated because of the high content of many important alkaloids. We have, however, found no report in the literature confirming the free amino acid composition of these plants.

It was found by paper chromatography that *Polygonatum officinale* contained large amounts of an unknown ninhydrin-positive substance (I; spot 0 on Fig. 1). After ninhydrin spraying the color of the spot was brownish violet. A strong red color developed by treatment with sodium 1,2-naphthoquinone-4-sulfonate and alkali [1]. *p*-Dimethylaminobenzaldehyde gave a positive reaction, too, somewhat weaker only than with citrulline. When hydrolysed with 1 *N* HCl, substance I either disappeared totally or at least diminished very much and two other spots were formed. One of them (spot 51 on Fig. 2) had a typical violet color reaction with ninhydrin and was identified as homoserine. The other one (II; spot 00 on Fig. 2) appeared as a very intensive deep-yellow spot on chromatograms sprayed with ninhydrin. The color of this spot changed, however, rather rapidly to violet. Both I and II were quite stable against deamination with nitrogen oxides (from $NaNO_2$ and HCl). As will appear from the following, I is built up exclusively from homoserine though, in acid hydrolysis, it also gives substance II.

The unknown substance I was isolated by using Dowex 50 ion exchange resin, and HCl from the hydrochloride was removed with Amberlite IR-120. 4 g of a white crystalline product was obtained from 2.9 kg material (1.6 kg roots and 1.3 kg leaves; fresh wt.). Its elementary composition corresponded to the formula $C_4H_7O_2N$, hence the lactone of homoserine. (Found: C 47.22; H 6.83; N 13.94; equiv. wt. 101.9. Calc. for $C_4H_7O_2N$: C 47.51; H 6.98; N 13.87; Equiv. wt. 101.1). However, no lactone reaction could be detected. In the infrared spectra no typical absorptions either for lactones or for dioxopiperazines could be found. By

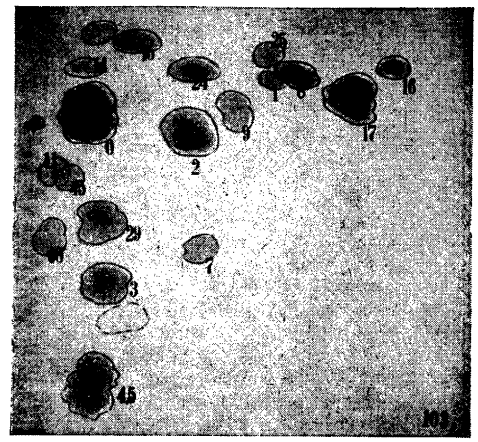

Fig. 1. Two-dimensional paper chromatogram (butanol-acetic acid and phenol-NH_3) of the free amino acids of Polygonatum officinale. O = unknown I, 1 = gly, 2 = ala, 3 = val, 4 = ileu, 5 = leu, 7 = tyr, 8 = ser, 9 = threo, 11 = pro, 14 = arg, 15 = lys, 16 = asp, 17 = glu, 24 = glu-NH_2, 25 = asp-NH_2, 29 = γ-NH_2-butyric, 45 = ethanolamine, 60 = piperidine-2-carboxylic acid.

Fig. 2. Partial hydrolysis (with HCl) of the unknown I. Alanine is added to the chromatogram. 00 = unknown II, 51 = homoserine, 81 = lactone of homoserine.

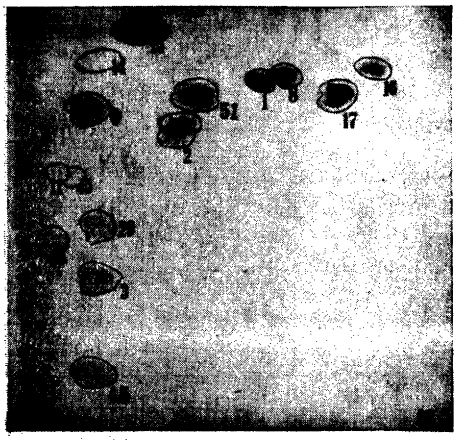

Fig. 3. Treatment of the free amino acid fraction of P. officinale with 4 N NaOH.

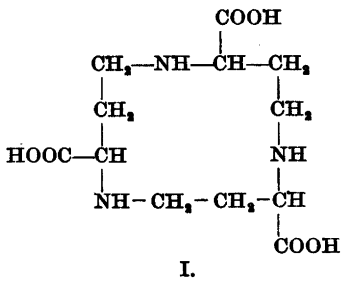
using the method of Wendt [2] a molecular weight approximately = 303 was found (Calc. for $(C_4H_7O_3N)_3$: 303.32).

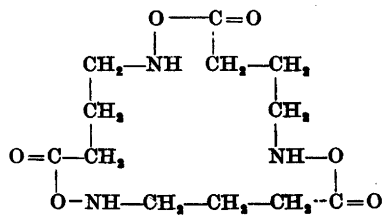
Substance II was prepared and purified in the following way. 926 mg of I were hydrolysed with 6 *N* HCl in a sealed tube for 20.5 hours at 95° C. The reaction products were fractionated on a Dowex 50 column (2 × 42 cm) and the fractions containing mainly II were again hydrolysed to remove traces of I and then deaminated to remove small amounts of homoserine and its lactone. After purification with Amberlite IR-120 some conc. HCl was added and the solution was evaporated to a small volume on a water bath. On precipitation with absolute ethanol 27.8 mg pure hydrochloride of II was obtained. (Found: C 34.23; H 5.84; N 9.93; equiv. wt. 136.0. Calc. for $C_4H_7O_3N$. HCl: C 34.92; H 5.86; N 10.18; equiv. wt. 137.6). Accordingly, II had the same empirical formula as I.

When treated with a saturated solution of $Ba(OH)_2$ II can be changed to I, which then is decomposed to homoserine. Substance I thus gives only homoserine on treatment with alkalies (Fig. 3). It is therefore probable that II, which is formed by acid hydrolysis of I as a byproduct besides the main hydrolysis product homoserine, is some rearrangement product of I. Hence the relationships between I, II and homoserine and its lactone can be shown as depicted below.

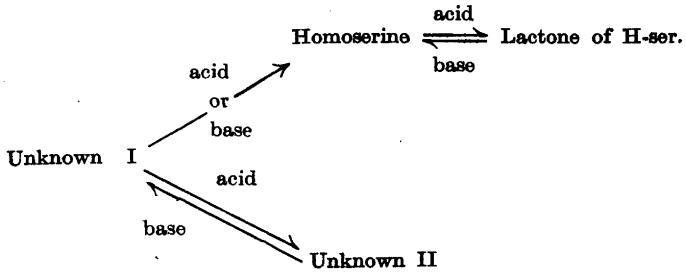
Unknown I has all its carboxyl groups free, but containes no primary or tertiary amino groups. With ninhydrin it liberates the theoretical amount of CO_2 and 55 % of total N as ammonia. It gives a strongly positive reaction for the secondary amino group with sodium nitroprusside and acetaldehyde. Ninhydrin liberates neither



I.



II.



CO_2 nor NH_3 from II, the latter being ninhydrin-positive only on paper, which may be due to some kind of decomposition. However, substance II gives no positive reaction for the secondary amino group as does I. Both I and II are neutral on paper electrophoresis.

The study of these compounds is continued and the experiments and results will be published in detail elsewere. There is, however, now evidence for the structures proposed for I and II.

The following R_F-values were found:

	Phenol-H_2O-NH_3	BuOH-AcOH-H_2O
Lactone of homoserine	0.95	0.35
Unknown I	0.82	0.24
Unknown II	0.66	0.33
Alanine	0.62	0.27
Homoserine	0.57	0.23

When investigating other specimens of the family *Liliaceae*, substance I could be found only in *Convallaria majalis*, *Polygonatum giganteum*, *P. multiflorum*, *Smilacina stellata* and *Majanthemum bifolium*, but not *e. g.* in *Paris quadrifolia*. From a taxonomical point of view this result is very interesting.

We wish to express our deeply felt gratitude to Mr. Andreas Rosenberg, Uppsala for taking the infrared spectra.

New Aminodicarboxylic Acids and Corresponding α-Keto Acids in *Phyllitis scolopendrium*

ARTTURI I. VIRTANEN and ANN-MARIE BERG

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In a paper by Virtanen and Alfthan [1] the appearance of two new α-keto acids and the corresponding α-amino acids in a fern (*Phyllitis scolopendrium*) was reported. These amino acids formed the spots V and P on a two-dimensional paper chromatogram (butanol-acetic acid and phenol-NH_3). Both acids were found to be acidic. We have isolated these amino acids and established their chemical nature. At

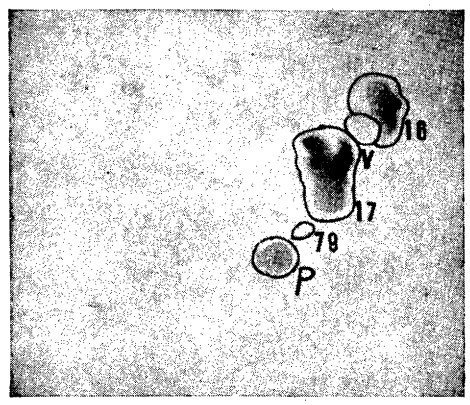

Fig. 1. Two-dimensional paper chromatogram (butanol-acetic acid and phenol-NH_3) of acidic amino acids in Phyllitis scolopendrium. 16 = asp. V = unknown amino acid, 17 = glu, 79 = γ-methyleneglutamic acid, P = unknown amino acid.

New Aminodicarboxylic Acids and Corresponding α-Keto Acids in *Phyllitis scolopendrium*

ARTTURI I. VIRTANEN and ANN-MARIE BERG

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In a paper by Virtanen and Alfthan [1] the appearance of two new α-keto acids and the corresponding α-amino acids in a fern (*Phyllitis scolopendrium*) was reported. These amino acids formed the spots V and P on a two-dimensional paper chromatogram (butanol-acetic acid and phenol-NH_3). Both acids were found to be acidic. We have isolated these amino acids and established their chemical nature. At

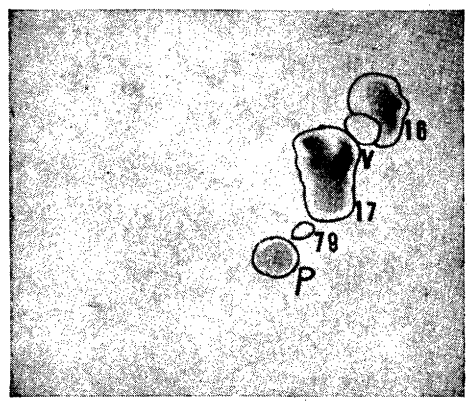

Fig. 1. Two-dimensional paper chromatogram (butanol-acetic acid and phenol-NH_3) of acidic amino acids in Phyllitis scolopendrium. 16 = asp. V = unknown amino acid, 17 = glu, 79 = γ-methyleneglutamic acid, P = unknown amino acid.

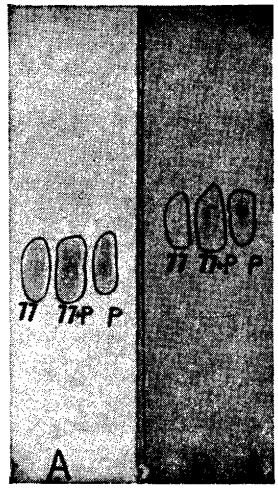

Fig. 2. One-dimensional paper chromatograms of P, synth. γ-methylglutamic acid (77), and a mixture of both. A: butanol-acetic acid, B: phenol-NH_3.

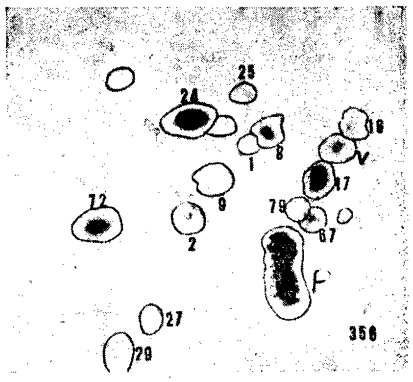

Fig. 3. Two-dimensional paper chromatogram of free amino acids in Phyllitis. 67 = α-aminoadipic acid (added), 79 = methyleneglutamic acid, P = unknown amino acid.

the same time the structure of the corresponding keto acids has been established.

The amino acids were isolated using our earlier method. A 70 % ethanol extract of the plants was run through an Amberlite IR-120 column, and the amino acids remaining in the column were eluted with 1 *N* ammonia. Acidic amino acids were separated from the neutral and basic ones in an Amberlite IR-45 column. The acidic amino acids were eluted from the column with 0.4 *N* hydrochloric acid. The solution was evaporated *in vacuo* to a very small volume. This solution contained aspartic acid, the amino acid V, glutamic acid, γ-methyleneglutamic acid, and the amino acid P (Fig. 1). The acids were separated from each other on the paper chromatogram using butanol-acetic acid as solvent. The separation of P from other amino acids was relatively easy, but the separation of V from aspartic acid and glutamic acid proved to be difficult.

The amino acid P travels with the same velocity as γ-methylglutamic acid (synthetic preparation) when either butanol-acetic acid or phenol-NH_3 are used as solvents (Fig. 2). Analysis of the amino acid P: C 44.88; H 6.87. Calc. for $C_6H_{11}O_4N$: C 44.72; H 6.83; N 8.69. The substance did not contain any OH group. α-Aminoadipic acid travels both with butanol-acetic acid and phenol-NH_3 more slowly than its isomer γ-methylglutamic acid or P (Fig. 3). On the basis of both chromatographic and elementary analysis the amino acid P is γ-methylglutamic acid, $HOOC-CH(CH_3)-CH_2-CHNH_2-COOH$.

When still working on the purification and structure of the amino acid V, we were informed by Dr. F. C. Steward that from the *Adiantum* fern he had isolated a small amount of an amino acid which proved to be identical with synthetic γ-methyl-γ-hydroxyglutamic acid. A small amount of this synthetic acid which Dr. Steward sent in his letter was, according to paper chromatographic analysis, found to be identical also with our amino acid. For the present we have not investigated our acid V more closely chemically. As it is probable that hydroxy-α-aminoadipic acid should travel with the solvents used with about the same velocity as its isomer γ-methyl-γ-hydroxyglutamic acid a later control of the amino acid V is still needed.

On the basis of the results related above the α-keto acids which Virtanen and Alfthan reduced to the corresponding amino acids seem to have the following structure: γ-methyl-α-ketoglutaric acid, $HOOC-CH(CH_3)-CH_2-CO-COOH$, and γ-methyl-γ-hydroxy-α-ketoglutaric acid, $HOOC-C(CH_3)(OH)-CH_2-CO-COOH$.

Correction: In the paper by Virtanen and Alfthan [1], p. 189, "acidic OH-containing amino acid P and — — — of another amino acid V" should according to the manuscript be: acidic amino acid P and ——— of another OH-containing amino acid V.

We are indebted to Dr. L. Fowden, London, for a sample of synthetic γ-methylglutamic acid, and to Dr. F. C. Steward, New York, for γ-methyl-γ-hydroxyglutamic acid.

ACTA CHEMICA SCANDINAVICA 9 (1955) 555—561

The Anomalous Reactivity of *o*-Methoxyphenylmagnesium Bromides

GUST.-AD. HOLMBERG

Institutet för Organisk Kemi, Åbo Akademi, Åbo, Finland

In the reactions between carbon dioxide and the Grignard reagents prepared from *o*-methoxybenzyl chloride, *o*-bromodimethylaminobenzene, and *o*-bromomethylthiobenzene, both the corresponding acids and the corresponding ketones are formed. The Grignard reagents prepared from β-(*o*-methoxyphenyl)ethyl chloride and γ-methoxypropyl bromide yield only the corresponding acids under the same conditions. The anomalous reactivity leading to ketone formation is associated with the formation of strained planar rings through a complex bond between the magnesium atom and the nitrogen, oxygen, or sulphur atoms. Such rings are not likely to be formed by the molecules of the above-mentioned two Grignard reagents which react normally. Steric hindrances of different kinds seem to be involved in other previously described cases in which the anomalous reactivity is cancelled.

Some time ago, the author showed that in the reaction between *o*-methoxyphenylmagnesium bromide and carbon dioxide 2,2′-dimethoxybenzophenone is formed in addition to *o*-methoxybenzoic acid, and that a similar ketone formation occurs when a methyl or methoxy substituted *o*-methoxyphenylmagnesium bromide reacts with carbon dioxide unless the second substituent is in the ortho position relative to the original methoxy group or to the magnesium atom [1,2]. It was concluded that the ketone formation is an exceptional reaction of the Grignard reagent.

When the investigations were extended to *o*-methoxybenzylmagnesium chloride and β-(*o*-methoxyphenyl)ethylmagnesium chloride, it was found that the former gave the corresponding ketone (isolated only as its 2,4-dinitrophenylhydrazone) and the corresponding acid, whereas the latter gave β-(*o*-methoxyphenyl)propionic acid as the only product of the reaction. These reaction products seem to indicate that the exceptional reactivity is connected with ring formation in such a way that one of the two "etherate" ether molecules of the Grignard reagent has been displaced by the methoxy group, *i.e.* *o*-methoxybenzylmagnesium chloride and *o*-methoxyphenylmagnesium bromide have the constitutions shown by formulae I and II.

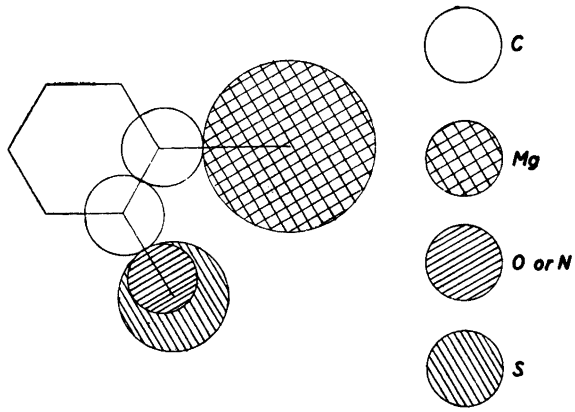

Fig. 1. The theoretical positions of the atoms in o-*methoxyphenylmagnesium bromide,* o-*dimethylaminophenylmagnesium bromide, and* o-*methylthiophenylmagnesium bromide as based on the assumption that the bond lengths and the valence angles have the usual values and that attractive forces do not exist between the Mg atom on one side and the O, N, and S atoms on the other. The radii of the circles are proportional to the bond lengths of the atoms. Atoms not participating in the reaction have been omitted.*

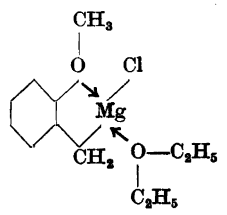
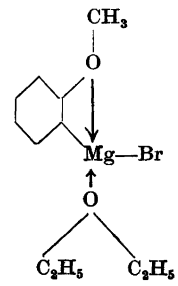
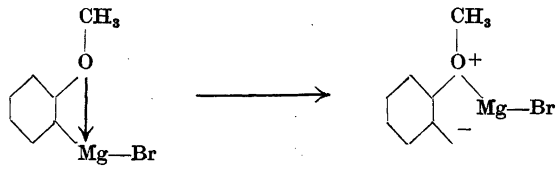


I



II

That these ring formations are possible with all atoms in one plane is shown in Figs. 1 and 2. From these figures it will also be seen that the rings must be under strain, at least with respect to the valence angles. In the case of β-(*o*-methoxyphenyl)-ethylmagnesium chloride the ring would contain too many atoms. The intramolecular strained ring may be expected to favour the polarization of the carbon-to-magnesium bond and thus to increase the reactivity of the compound.



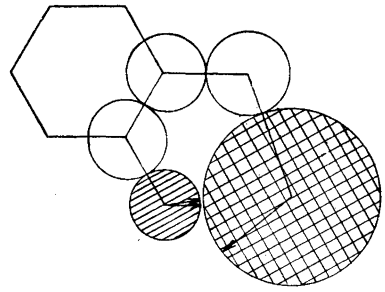


Fig. 2. The theoretical positions of the atoms in o-methoxybenzylmagnesium chloride when the distance between Mg and O atoms is a minimum as based on the assumptions stated in Fig. 1. The arrows indicate possible directions of the complex bonds.

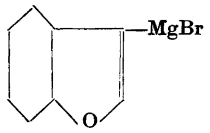
If this hypothesis is correct, one may expect that β-methoxyethylmagnesium bromide and other non-aromatic Grignard reagents with an alkoxy group in the β position relative to the magnesium atom would possess an exceptional reactivity of the type in question, provided that the magnesium atom and the ether group are in the "*cis*" position relative each other. Unfortunately such Grignard reagents cannot be prepared since any attempt in this direction leads to the formation of unsaturated compounds [3-5]. Mann and Steward [6] have recently discussed reactions of this type and proposed the following mechanism for β-alkoxyethylmagnesium bromide:

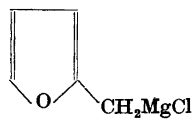
$$RO{-}CH_2{-}CH_2{-}Br + Mg \rightarrow RO{-}CH_2{-}CH_2{-}MgBr \rightarrow CH_2{=}CH_2 + RO{-}MgBr$$

The hypothesis proposed above for the exceptional reactivity of *o*-methoxyphenylmagnesium bromide and related compounds requires that β ether Grignard reagents with the oxygen atom and the magnesium atom in the "*trans*" position relative to each other should give acids but no ketones in the reaction with carbon dioxide. Compounds of this kind are not generally stable but decompose according to the mechanism of Mann and Steward. The only Grignard reagent of this type that appears to have been synthesized (although in poor yield) is 3-bromobenzofurylmagnesium bromide (III). Reichstein and Baud [7] isolated from the products of the reaction between this Grignard reagent and carbon dioxide chiefly *o*-hydroxyphenylacetylene (formed according to the mechanism of Mann and Steward) and a small amount of 3-benzofuroic acid. No ketone seems to have been formed, which supports the above hypothesis.

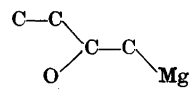
The fact that aromatic Grignard reagents do not decompose according to the mechanism of Mann and Steward is, of course, due to the stabilization of



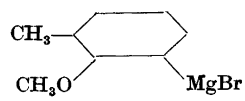
III



IV



V



VI

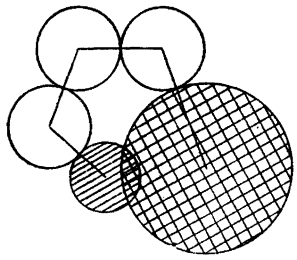


Fig. 3. The structure of an alkoxyethylmagnesium halide computed as for the Grignard reagents in Fig. 1 and 2.

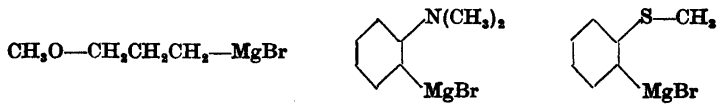
the bonds in the aromatic nucleus. A similar stabilization might be expected in furfurylmagnesium chloride (IV). This compound is not, however, well adapted for an investigation of the present type, because a Wurtz' type of reaction seems to predominate in the reaction between magnesium and furfuryl chloride[8]. Further, even if the corresponding ketone would not be formed in the reaction between this Grignard reagent and carbon dioxide, this could be explained by noting that the compound in question has a constitution that in certain respects resembles that of 3-methyl-2-methoxyphenylmagnesium bromide (VI), which does not give the corresponding ketone in the reaction with carbon dioxide. An examination of the constitutions of the two substances (IV and VI) and formula V, which gives the part that is common to both, shows that the carbon atom in position 4 of the furyl derivative corresponds to the carbon atom in the methyl group of the benzene derivative. Introduction of this latter methyl group cancelled the anomalous reactivity of *o*-methoxyphenylmagnesium bromide, and one might expect that the carbon atom in position 4 would also cancel a potential anomalous reactivity of the furan derivative.

A chelate formation of the type in question is not likely in γ-methoxypropylmagnesium bromide (VII; *cf.* Fig. 3). It may thus be expected that this Grignard reagent will give only the corresponding acid in the reaction with carbon dioxide. This prediction was experimentally confirmed.

Finally, if the hypothesis proposed above is correct the exceptional reactivity of the type in question should be possible also in cases in which the methoxy



VII VIII IX

group is replaced by other groups with unshared electrons on the central atom, which are able to form a complex bond with the magnesium atom similar to that formed between magnesium and the oxygen in the methoxy group. Compounds of this type, *o*-dimethylaminophenylmagnesium bromide (VIII) and *o*-methylthiophenylmagnesium bromide (IX) were studied. Both gave the corresponding acids and the corresponding ketones in accordance with the hypothesis.

On the basis of the above it seems justified to suppose that the ring formation is the explanation for the exceptional reactivity of *o*-methoxyphenylmagnesium bromide and other Grignard reagents with unshared electron pairs which are able to form a bond with magnesium, which leads to the formation of a strained planar ring.

As mentioned above, *o*-methoxyphenylmagnesium bromides do not give the corresponding ketones in the reaction with carbon dioxide if there is a methyl or methoxy group in the *ortho* position relative to the methoxy group or to the magnesium atom. A molecular model study shows that in the first case the methoxy group is not able to rotate freely. In the second case, a steric hindrance similar to that existing in mesityl compounds is probable.

EXPERIMENTAL

o-Methoxybenzyl chloride was obtained from *o*-methoxybenzyl alcohol which was prepared from ethyl *o*-methoxybenzoate.

Lithium aluminium hydride (7.5 g; technical grade) and dry ether (500 ml) were placed in a flask (1 l), which was equipped with a mercury-sealed stirrer, a reflux condenser, and a dropping funnel. The stirrer was started and after five hours a solution of ethyl *o*-methoxybenzoate [9] (57.8 g) in dry ether (200 ml) was added through the dropping funnel at such a rate that the ether refluxed gently. When the addition was complete, the reaction mixture was warmed on a water bath for three quarters of an hour. The excess of lithium aluminium hydride was destroyed by adding ethyl acetate and the reaction products were hydrolyzed by adding water. The reaction mixture was then poured into a solution of concentrated hydrochloric acid (100 ml) in water (1 l) in order to dissolve the precipitated aluminium hydroxide. The ether phase was removed and the aqueous phase was extracted with a second portion of ether. The ether solutions were combined and dried with anhydrous sodium sulphate. When the solvent had been evaporated, *o*-methoxybenzyl alcohol, b. p. 126—127°/15 mm, was obtained by distillation. The yield was 77.5 % (34.5 g).

A small amount of this alcohol was converted into the corresponding *p*-nitrobenzoate. The melting point of the ester was 81—82°, as reported by Mozingo and Folkers [10].

o-Methoxybenzyl alcohol (33.2 g) was dissolved in chloroform (50 ml) and added to a flask (250 ml) equipped with a reflux condenser and a dropping funnel, through which a solution of thionyl chloride (30 g) in chloroform (50 ml) was gradually added. When addition was complete, the reaction mixture was heated to boiling until evolution of gas ceased. The solvent was distilled off under normal pressure and the residue under reduced pressure. The yield of *o*-methoxybenzyl chloride, b. p. 108—109°/15 mm, was 35.5 % (13.7 g).

β-(o-Methoxyphenyl)ethyl chloride was prepared according to Hill, Short, and Stromberg [11] from β-(*o*-methoxyphenyl)ethyl alcohol, which was obtained from *o*-methoxyphenylmagnesium bromide and ethylene oxide according to Bogert and Hamann [12].

A small amount of the alcohol was converted into the corresponding *p*-nitrobenzoate. This latter substance melted at 58—59°. (Found: N 4.77. Calc. for $C_{16}H_{15}O_5N$: N 4.65).

γ-Methoxypropyl bromide. γ-Methoxypropyl alcohol was prepared from trimethylene glycol and methyl iodide according to Smith and Sprung [13]. The alcohol was then converted into the chloride according to Pummerer and Schönamsgruber [14].

o-Bromodimethylaniline was prepared according to Gilman and Banner [15] from *o*-bromoaniline in 78.2 % yield. *o*-Bromoaniline was obtained by the reduction of *o*-bromonitrobenzene with stannous chloride in the way previously described for 5-amino-3-bromoveratrole [3]. After distillation under reduced pressure, the yield of *o*-bromoaniline, b. p. 98°/11 mm, was 78.2 %.

o-Bromomethylthiobenzene. o-Bromothiophenol (48 g), prepared according to Schwarzenbach and Egli [16] from *o*-bromoaniline, was dissolved in an aqueous solution (100 ml) of sodium hydroxide (10.5 g) and the mixture was shaken with dimethyl sulphate (32 g). When the mixture had cooled, dimethyl sulphate (16 g) and a dilute solution of sodium

hydroxide (5.3 g) in water (50 ml) were added and shaking was continued until the mixture had cooled again. A solution of sodium hydroxide (12 g) in water (50 ml) was now added and the mixture was heated for half an hour on the boiling water bath. After cooling, the oil was taken up into ether and the water solution was extracted once more with ether. The combined ether solutions were dried with anhydrous sodium sulphate and gave after distillation under reduced pressure a 88.5 % yield (48 g) of pure *o*-bromomethylthiobenzene, b. p. 145—146°/27 mm.

The reactions between Grignard reagents and carbon dioxide were examined as has been described previously [1]. The results are given below.

o-Methoxybenzylmagnesium chloride (prepared from 5 g of the corresponding halide) gave 0.91 g of *o*-methoxyphenylacetic acid, m. p. 124—125°, and 2.19 g of neutral substances. When the latter were treated with alcohol, 0.80 g of 2,2′-dimethoxydibenzyl (m. p. after recrystallization from alcohol 85—86°) were obtained. The filtrate was evaporated to dryness and the residue (1.20 g) treated with 2,4-dinitrophenylhydrazine. From the mixture the hydrazone (1.02 g) of 1,3-di-(*o*-methoxyphenyl)acetone was isolated. After recrystallization from alcohol, the substance melted at 157.5—158°. (Found: N 12.32. Calc. for $C_{23}H_{22}O_6N_4$: N 12.44.)

A small amount of the *o*-methoxyphenylacetic acid was converted into its *p*-nitrobenzyl ester. This substance melted at 64.5—65°. (Found: N 4.51. Calc. for $C_{16}H_{15}O_5N$: N 4.65.)

β-(*o*-Methoxyphenyl)ethylmagnesium chloride (prepared from 5 g of the corresponding halide) gave 1.55 g of *β*-(*o*-methoxyphenyl)-propionic acid, m.p. 88—89°. The *p*-nitrobenzyl ester of the latter melted at 45—46°. (Found: N 4.41. Calc. for $C_{17}H_{17}ON$: N 4.44.) No ketone could be isolated.

γ-Methoxypropylmagnesium bromide (prepared from 5 g of the corresponding halide) gave 0.89 g of *γ*-methoxybutyric acid. Its *p*-phenylphenacyl ester melted at 79—81°, in agreement with the value found by Owen and Sultanbawa [17]. No ketone was detected.

o-Dimethylaminophenylmagnesium bromide (prepared from 5 g of the corresponding halide) was treated with carbon dioxide in the usual manner. The reaction mixture was treated with dilute hydrochloric acid and the ether was separated (residue of neutral substances 0.04 g). The aqueous layer was made alkaline with aqueous ammonia, ether was added, and the mixture was filtered. The layers in the filtrate were separated. When the solvent had been evaporated from the ether phase, 1.94 g of 2,2′-di-(dimethylamino) benzophenone were isolated. After recrystallization from ligroin, it melted at 120—121°. With picric acid it formed an addition compound that melted at 150—151°. The aqueous solution was acidified with acetic acid and extracted with ether in an extractor for several hours. When the residue from the ether solution was treated with ether 0.70 g of dimethylanthranilic acid was obtained.

o-Methylthiophenylmagnesium bromide (prepared from 5 g of the corresponding halide gave 1.10 g of *o*-methylthiobenzoic acid, m.p. 168—169°, and 1.43 g of neutral substances. When the latter were treated with benzene 2,2′-dimethylthiobenzophenone separated. After recrystallization from ethyl alcohol, the latter melted at 105—106°. (Found: S 23.55. Calc. for $C_{15}H_{14}OS_2$: S 23.37.) The same substance was obtained by hydrolyzing the reaction product from the reaction between *o*-methylthiophenylmagnesium bromide and *o*-methylthiobenzonitrile but not by decomposing *o*-methylthiophenylmagnesium bromide with water.

A small amount of the *o*-methylthiobenzoic acid was converted into its *p*-nitrobenzyl ester. The melting point of this ester was 122—123°. (Found: N 4.71. Calc. for $C_{15}H_{13}O_4NS$: N 4.62.)

A Microbiological Assay of Vitamin B_1

E. HOFF-JØRGENSEN and BODIL HANSEN

Universitetets Biokemiske Institut, Copenhagen, Denmark

A microbiological assay for thiamine, using the yeast *Kloeckera brevis* is described. The method is simple and specific. The sensitivity is high enough to allow the determination of 0.001 μg of thiamine per ml of extract with a standard deviation of less than 10 %.

Although a large number of methods for the determination of thiamine (vit. B_1) has been described, each has certain limitations.

Modifications of Jansens [1] fluorometric thiochrome method seems to be preferred in most laboratories, although this method is neither as specific nor as sensitive as the microbiological methods.

The only microbiological assay which seems to have been generally used is modifications [2] of the *Lactobacillus fermentum* method, originally described by Sarett and Cheldelin [3]. *L. fermentum*, however, is very exacting and some laboratories including our own have been unable to obtain consistent satisfactory results with this organism.

We have therefore investigated a number of thiamine requiring microorganisms in search of a less exacting strain which could be used both for the routine analysis of thiamine in natural products and in an investigation of the effect of various factors on the destruction of this vitamin. Of the organisms tested *Kloeckera brevis* gave the most promising results. Burkholder [4] has shown that this yeast strain requires six members of the B-vitamin group for optimal growth and he has recommended this organism for the assay of inositol. Our preliminary tests, however, showed that none of the media described for *Kloeckera brevis* allow maximum growth in a thiamine assay. The main problem therefore was to devise assay conditions under which thiamine is the only limiting factor for growth.

METHOD

a. *Organism.* *Kloeckera brevis* B 768, obtained from *The National Collection of Industrial Bacteria*, Teddington, Middlesex, U.K.

b. *Agar medium.* Dissolve 20 g of malt extract, to which no preservative has been added, in 200 ml of water. Adjust the pH to 5.0 and dissolve 5.0 g of agar in the mixture at about 100° C. Dispense the medium in 5 ml quantities to test tubes. Plug

the tubes with cotton, autoclave at 120° C for 15 min., slope, and store in a refrigerator. After transfer incubate the cultures at 30° C for 16—24 h and keep them in a refrigerator until the next transfer. Transfer the stock cultures at monthly intervals.

c. *Inoculum.* Remove about 2 mg of wet yeast cells with a bacteriological loop from a 16—24 h old culture and suspend in 10 ml of sterile tap water. Dilute 1 ml of this suspension with 10 ml of sterile tap water. Use 0.05 ml of this diluted cellsuspension for the inoculation of each tube.

d. *Basal medium.*

0.5	g	casamino acids (Difco)
4.0	g	glucose
10	ml	salt E
5	»	trisodium citrate · 5 H_2O solution, 15 % w/v
2	»	L-asparagine solution, 2 % w/v
5	»	yeast extract solution
1	»	vitamin solution

Mix the solutions, add 50 ml of water and dissolve the glucose and the casamino acids in the mixture. Adjust the pH to 4.7 with 1 *N* HCl and add water to make 100 ml.

Prepare the solutions as follows:

Salt E. Dissolve 22 g KH_2PO_4, 17 g KCl, 10 g $(NH_4)_2SO_4$, 4 g $CaCl_2$, 4 g $MgSO_4 \cdot 7\ H_2O$, 0.1 g $FeCl_3$, 0.1 g $MnSO_4 \cdot 4\ H_2O$ and 10 ml conc. HCl in water to make 1 000 ml.

Vitamin solution. Dissolve 100 mg *meso*-inositol, 20 mg choline chloride, 50 μg (+) biotin and 5 mg each of nicotinic acid; pyridoxine chloride and calcium pantothenate in water to make 50 ml. Store under a preservative in a refrigerator. Prepare a fresh solution every month.

Yeast extract solution. Dissolve 5 g of yeast extract (Difco) and 0.25 g of $Na_2S_2O_3 \cdot 7\ H_2O$ in 50 ml of water, adjust the pH to 5.4 and autoclave the mixture at 120° C for 30 min. Cool the solution and add an exact amount of 2 % H_2O_2 solution (about 6 ml) to oxidize excess sulfite. A freshly mixed solution of equal parts of 5 % KI solution, 1 % starch solution and 50 % w/v sulfuric acid solution is used as an external indicator. Dilute the yeast extract solution with water to make 100 ml. Store under a preservative in a refrigerator. Prepare a fresh solution every month.

Standard thiamine solution, 0.0025 μg per ml. Dry thiamine dichloride (M 337.3) over H_2SO_4 in vacuum to constant weight.

Stock solution: Dissolve 100 mg of the dried vitamin in 50 ml of 0.1 *N* HCl and add water to make 100 ml. Store in a refrigerator. Prepare a fresh solution every month. The standard solution is prepared fresh every day by diluting 250 μl (constriction pipette) of the stock solution with water to make 100 ml.

e. *Assay procedure.* The assay is carried out in lipless uniform test tubes (100 × 16 mm. i.d.). To each series the standard thiamine solution (2.5 mμg per ml) is added in the following amounts: 0, 0, 0.1, 0.2, 0.4, 0.6, 0.8, and 1.0 ml, each with an error of not more than 2 %. Each level is set up in triplicate. The sample to be assayed is similarly added to a series of tubes in the following amounts: 0.3, 0.5, and 0.8 ml in duplicate. Water is added to the tubes to make a total volume of 1 ml, and 0.95 ml of the basal medium is added. The tubes are shaken to mix the content, covered with a cloth, steamed at 100° C for 10 min., cooled and inoculated. In each set of standard tubes one of the tubes containing 0 ml of standard solution is left uninoculated. These tubes are used as blanks in the turbidimetric determination of growth. The tubes are incubated at 30° ± 0.5° C for 18—24 h in a *shaking machine* to guarantee sufficient aeration and uniform growth.

f. *Determination of response.* The tubes are shaken and the cultures transferred to a microcuvette. The turbidity is read at λ = *ca.* 650 mμ in a suitable photometer (*e.g.* Lumetron 402 E).

g. *Calculation of results.* A standard dose-response curve is prepared by plotting the average of the turbidity values found at each level of the thiamine standard against the amount of thiamine present (*Cf.* Table 1 and Fig. 1). The vitamin content of a sample is determined by interpolating the response to the known amounts of the test solution onto this standard curve. The thiamine content per ml of the test solution is now calculated for each duplicate sets of tubes, and the thiamine content of the sample is calculated from the average of the values.

h. *Preparation of samples for assay.* Enough of the material to give a representative sample is suspended in at least 25 ml of 0.1 *N* sulfuric acid per g dry matter. The mixture is steamed for 30 min. at 100° C and the pH adjusted to 4.7 with 2.5 *M* sodium acetate. 100 mg of mylase P (Wallerstein Lab., N.Y.) or another suitable enzyme preparation is added per g of dry matter. The mixture is covered with a preservative and incubated at 37° C for 18—24 h. The digest is then steamed for 10 min. at 100° C and diluted with water to a suitable volume. After filtering through filterpaper the clear filtrate is diluted to contain 1—2 mμg of thiamine per ml. The content of thiamine in each batch of enzyme preparation must be determined and if significant taken into account.

i. *Reproducibility of the assay.* The standard deviation of repeated independent assays of several crude materials has been 5—8 %.

RESULTS

a. *Effect of yeast extract on growth.* For some time we used the basal medium described without the addition of the sulfite treated yeast extract after having convinced ourselves that neither the addition of other substances known to be growth factors for microorganisms (vitamins, purines, pyrimidines, nucleotides, deoxynucleotides, salts, amino acids *etc.*) nor the addition of alkalitreated peptone, malt extract and yeast extract enhanced the growth. Sometimes, however, assays of crude material showed positive "drift" and occasionally results seem to be too high. As shown by Williams [5] sulfite under rather mild conditions destroys the thiamine activity by splitting the thiamine molecule. We therefore tested the growth effect of some sulfitetreated natural products and found that yeast extract and malt extract in which the thiamine was destroyed by sulfite did actually enhance the growth (Fig. 1). After the addition of an optimal amount of sulfitetreated yeast extract thiamine seems to be the only limiting factor for growth as no "drift" occurred in the assay of natural products as exemplified in Table 1.

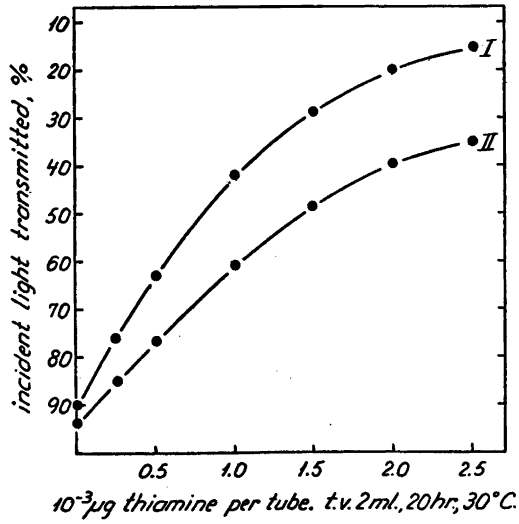

Fig. 1. Growth curves for Kloeckera brevis. I Medium as described. II Medium as described without yeast extract.

Table 1. Determination of thiamine in beef. 5 g of minced beef extracted as described. Final solution ~ 1.25 mg beef per ml. Total volume: 2 ml per tube.

Standard					Beef extract				
Thiamine	Turbidity				Beef	Turbidity			Thiamine
mμg per tube	ser. 1	ser. 2	ser. 3	mean	mg per tube	ser. 1	ser. 2	mean	mμg/mg beef
0	90	89	90	90	0.125	82	80	81	1.12
0.25	75	77	76	76	0.25	72	71	72	1.20
0.5	63	64	62	63	0.50	63	61	62	1.02
1.0	42	(90)	42	42	0.75	44	44	44	1.22
1.5	29	30	28	29	1.00	39	37	38	1.12
2.0	21	19	20	20	1.25	32	(12)	31	1.05
2.5	(21)	14	15	15					
							mean:		*1.12*

b. *Response to cocarboxylase and to the pyrimidine and thiazole moities of thiamine.* On a molar basis cocarboxylase (thiaminepyrophosphate) has about 30 % less growth promoting activity as thiamine. After treatment with mylase, as described for the preparation of samples for assay, the response to cocarboxylase is the same as to thiamine.

For several microorganisms the growth effect of thiamine can be substituted by either both or one of the two main fission products of thiamine namely, 2-methyl-4-amino-5-aminomethyl-pyrimidinedichloride and 4-methyl-5-(β-hydroxyethyl)thiazole. For mammals these two naturally occurring substances are without vitamin activity. The same holds true for *Kloeckera brevis*. Even after incubation for 72 h neither of the two substances nor a mixture of both can substitute thiamine for growth. At least up to concentrations 10 times the maximum concentration of thiamine used in the assay, they have no inhibitory effect either.

Table 2. Results of analysis of some products for their thiamine content by two methods.

Product	Thiamine μg/g	
	Kloeckera brevis method	Thiochrome method
Wheat flour	1.85	1.65
» » vitaminized	5.60	5.25
Rye bread	2.20	2.30
Fodder additive A	58.5	58.0
Liquor B-vitaminorum	48.0	45.5
Fodder yeast 1.	1.90	1.75
» » 2.	2.70	2.45
» » 3.	11.5	12.0
Fodder additive B	110	115

c. *Comparison of results obtained by the Kloeckera brevis method and the thiochrome method.*
As seen from Table 2 the results of the two methods agree resonably well.

The authors wish to express their thanks to Dr. W. Hjarde, Statens Vitaminlaboratorium, Copenhagen, for the fluorometric analysis.

On Adsorption of Alkaloids

C. O. BJÖRLING and A. BERGGREN

Laboratories of Pharmacia Ltd., Uppsala, Sweden

Experiments on the behaviour of alkaloidal salts on columns of the artificial permutit Decalso F have given the following results:

1. In alkaloidal and similar salts in aqueous solution the cations are exchanged for potassium, and monovalent anions go straight through. Multivalent anions are retained stronger.
2. Alkaloidal salts soluble in organic solvents, *e.g.* chloroform, are most often retained as a whole.
3. Subsequent elution with water releases the anion.
4. Free alkaloidal bases dissolved in *e.g.* chloroform are adsorbed to the Decalso.

Decalso and other permutoid compounds have frequently been used for water softening by ion exchange, calcium and magnesium being exchanged for sodium or potassium. It seems likely that alkaloidal salts in aqueous solution will behave in a similar way. In recent papers [1,2] it has been established that the cations of such salts are adsorbed by the Decalso and in the present paper evidence is given that both ions follow the general rules valid for ion exchange processes.

Hyoscine hydrobromide, atropine sulphate, and codeine phosphate were adsorbed on Decalso columns from aqueous solutions [1,2]. The recoveries of the anions are shown in Table 1.

The bromide is very easily eluted, the sulphate requires much more water and some losses appear. The phosphate is most strongly adsorbed and could only be recovered in 83 % yield with twenty times as much water as for the bromide. Subsequent elution with 0.2 *N* hydrochloric acid did only add 7 % to the yield of phosphate in the eluate, and 0.2 *N* acetic acid nothing. For alkaloidal cations these acids are very effective eluants [1,2]. These findings concord with the general ion exchange experience.

As cation only potassium could be detected in the water effluent from columns charged with hyoscine hydrobromide. The recoveries were between 121 and 129 % calculated on the amount equivalent to the alkaloid. The values are difficult to explain but might be due to a slight decomposition of the Decalso lattice. We are, however, sure that the discrepancy is not due to experimental errors.

Previously we have shown [1] that the free bases of atropine and hyoscine extracted from their salts could be adsorbed by Decalso from ethereal solutions. The bases were in those cases liberated with ammonia or sodium carbonate. Now, a similar technique has been applied to a number of other bases. Most bases investigated were quantitatively retained by the Decalso from solutions in chloroform or ethyl ether and could be eluted in excellent yields with acids as before (Table 2). It did not matter whether the organic solvents were dry or saturated with water or whether the Decalso column was prepared with the exclusion of water or not. If, however, the organic solvent contained too much ammonia the alkaloid leaked through: the more ammonia the more leakage.

Some organic salts, *e.g.* some alkaloidal salts of inorganic acids, are soluble in organic solvents such as chloroform and ether. Such solutions were applied to Decalso columns and the effluents were tested for cations and anions. Most of the salts investigated were retained by the Decalso, *i.e.* not only the cation but also the anion. This is a most interesting fact which indicates that the process involved is hardly a common ion exchange.

If the column charged with the salt is washed with water the anion is eluted as before. The cation sticks to the Decalso but can as usual be eluted with acids.

An inspection of the Tables 2 and 3 and the previous paper [1] reveals that some bases and some salts do not behave in the same way as the majority of the compounds tested. Bases as atropine [1], hyoscine [1], codeine, quinine, strychnine, and even 2-aminopyridine (pK_b in water ranging from 3.3 to 6.9) were adsorbed by the Decalso both as free bases and salts from chloroform, ether, or water. Weaker bases, however, as N-diethylaniline, pyridine, and 1-naphthylamine (pK_b in water 7.4—10.0) leaked through, the weaker the more. Thus, there seems to be a certain limit as to the strength of the bases which can be taken up by the Decalso.

EXPERIMENTAL

Table 1. Desorption of anions.

Alkaloidal salt	Elution with water ml	Recovery of anion %
Hyoscine hydrobromide	15	99.1; 98.7
Atropine sulphate	40	95.0; 98.7
Codeine phosphate	50—300	45—83

10—15 mg of the alkaloidal salt was adsorbed on 2.0—2.5 g of Decalso * in a column 1 cm wide [1]. The column was washed with varied amounts of water and the anion determined in the effluents. Blanks were always run.

Bromide. The eluate was evaporated to near dryness after the addition of 0.50 ml of 0.1 *M* sodium bicarbonate solution and titrated with 0.1 *N* silver nitrate according to Volhard in the presence of nitrobenzene.

* Decalso F, obtained from the Permutit Company, Gunnersbury Av., London, W. 4. through Rudolph Grave, Stockholm.

Sulphate. The eluate was acidified with 1.0 ml of 2 *M* hydrochloric acid and the sulphate precipitated with 5.00 ml of 0.2001 % barium chloride solution. The mixture was evaporated to dryness on the waterbath, 5.00 ml of 0.1316 % potassium dichromate solution and 3.0 ml of 5 % sodium acetate solution were added. After evaporation to dryness on the waterbath the residue was stirred with 25.00 ml of water, centrifuged and 10.00 ml of the supernatant liquid withdrawn and after evaporation to about 2 ml the excess of potassium dichromate was titrated iodometrically with 0.1 *N* sodium thiosulphate.

Phosphate. The phosphate was determined both colourimetrically [4] and acidimetrically [5]. As the values obtained were very irregular and low we tried wet ashing with a mixture of nitric and sulphuric acids and dry ashing with sodium carbonate and potassium chlorate. These attempts did not improve the results on the effluents. When the various techniques were applied on plain codeine phosphate or potassium phosphate however good results were obtained.

Potassium was determined with a Zeiss flame spectrophotometer. Standard curves were made with solutions of potassium bromide. To all solutions lithium chloride was added to a final concentration of 0.1 mg per ml, *i.e.* about 10—20 times the amount of potassium.

During determinations frequent standards were run and in each sample also the sodium content was determined. In no case, however, measurable amounts of sodium were detected.

Preliminary experiments showed that it was impossible to obtain a potassium-free effluent from plain Decalso with water. However, after copious washing the potassium leakage became constant under the conditions of each experiment. Hence, the Decalso (2.50 g) was soaked overnight in water, and then washed in the column with 3—4 50 ml portions of water until the potassium content of the effluent had become constant. About 15.00 mg of hyoscine hydrobromide dissolved in 10 ml of water was adsorbed on the Decalso. The column was washed with water, the effluent being collected in 50.0 ml volumetric flasks. The potassium concentration was high in the first 50 ml eluate, but dropped in the second to the same value as before the adsorption. As checks blank columns were run parallel.

Example:	Uncorrected recovery	39.5	μg K/ml
	Constant leakage	1.5	»
	Corrected value	38.0	»
	Theory	32.45	»

As the values were always 20—30 % high wet ashing with perchloric and nitric acids was tried, but the same results were obtained.

The substance was dissolved in some ml of the solvent in question and the solution passed through the decalso column [1,2]. The column was washed, first with 10—15 ml of the solvent, then with 10—15 ml of water. If an organic solvent was used it was displaced

Table 2. Adsorption of bases on Decalso, 0.5 or 0.6 g.

Alkaloid	pK_b (water)	Amount mg	Solvent	Recovery (%) after elution with 0.2 *N* acetic or hydrochloric acid	
Codeine	6.05	4.8	Ether	100.2	99.2
»		5	Chloroform	99.5	100.3
Quinine	5.9	1.3	Ether	100.3	99.7

by some alcohol prior to the water. If the solvent was water the first 10—15 ml of effluent was examined separately. When chloroform or ether were used the organic phase and the alcoholic-aqueous phases were separately examined. The organic effluents were evaporated together with some water and the aqueous residue was investigated.

The cations were eluted from the columns with acids [1,2] and determined in the acid solution with the aid of their ultraviolet absorption. Diethylaniline was extracted with 2,2,4-trimethylpentane from the alkalinized effluent and measured in the hydrocarbon. Dimethylamine was determined by a micro-Kjeldahl procedure.

In addition to the quantitative experiments listed in Table 3 qualitative tests were made on chloroform solutions of the following salts:

Hyoscine hydrobromide	pK_b for the base in water	6.2
Papaverine hydrochloride		8.1
Narcotine hydrochloride		7.8
Atropine sulphate		4.4
Dimethylammonium chloride		3.3
Physostigmine salicylate		6.1
Alypine hydrochloride		4.5
Homatropine hydrobromide		~ 4.7

The chloroform effluents were evaporated with some water and the water tested for the anion in question, in each case with a negative result. On the other hand the anions were present in the subsequent aqueous eluates.

In one case, hyoscine hydrobromide, the anion was quantitatively determined in the aqueous eluate as previously described. The recoveries were: 100.6, 99.1, and 99.3 %.

We are indebted to Messrs. Pharmacia Ltd. for permission to publish this paper and to Mr. L. Magnusson who carried out most of the experimental work.

Countercurrent Fractionation of Cellulose Acetate by Preferential Diffusion into Porous Charcoal

HAROLD A. SWENSON*

Department of Paper Technology, Swedish Forest Products Research Laboratory, Stockholm, Sweden

A multi stage countercurrent apparatus is described with which porous charcoal is used as the stationary phase. The apparatus is used to fractionate secondary cellulose acetates with weight average molecular weights of *ca.* 35 000 and 60 000. Fifty fractions were isolated which increase in intrinsic viscosity with fraction number. The steady increase of intrinsic viscosity with fraction number appears to preclude effects from variations in acetyl substitution on the fractionation. Recoveries above 90 % representative of the entire sample, are demonstrated.

The effect of molecular weight, shaking time and concentration on the diffusion of cellulose acetate from acetone solutions into charcoal is illustrated by means of single batch experiments. A molecular weight gradient is demonstrated in the capillaries of the charcoal. Preliminary intrinsic viscosity weight distribution diagrams are presented.

A method for determining the intrinsic viscosity of cellulose acetate in acetone by single measurements is given. Graphs of $c\,[\eta]$ *vs.* t, where c is concentration, $[\eta]$ the intrinsic viscosity and t the efflux time of the solution in seconds, were obtained on several Ostwald pipettes [11] of low kinetic energy error. The graphs are based on Martins [12] equation $\log(\eta_{sp}/c) = \log[\eta] + K[\eta]\,c$, rearranged to the form $\eta_{sp} = c\,[\eta] \cdot 10^{Kc[\eta]} = \frac{t-t_0}{t_0}$ where t_0 is efflux time of the solvent. The K value was found to be 0.21 on secondary cellulose acetates ranging in intrinsic viscosity from 0.95 to 2.24, in concentrations up to 0.35 %.

Diffusion methods for the preparative fractionation of high molecular weight compounds have not been successfully used. Suitable membranes have not been found and when columns of porous media are used, selective migration is difficult to realize. As far as is known, capillary systems which take advantage of the variation in diffusion constant with molecular weight have not been employed for preparative polymer fractionation.

* American-Scandinavian Foundation Fellow 1953.

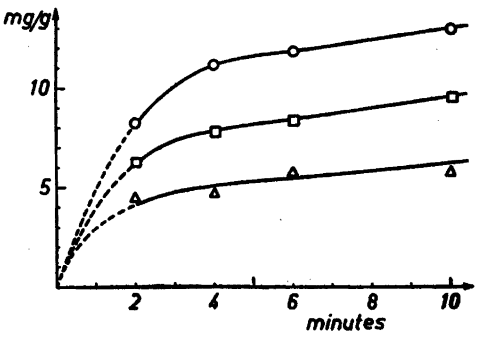

Fig. 1. The uptake versus time of cellulose acetate samples of varying molecular weight by charcoal. Circles: sample 0.95, squares: sample 1.62, triangles: sample 2.24.

When charcoal has been used for the chromatography of cellulose derivatives [1-4] equilibrium conditions have been sought but were difficult to obtain although slow flow rates were used. Nonquantitative elution has been the main difficulty hindering the use of chromatography as a practical fractionation method for high polymers.

The effect of diffusion upon the chromatography of cellulose derivatives and other polymers with charcoal has been noted by Claesson [5] who found that above a molecular weight of about 10 000, decreased amounts were taken up by the charcoal with increasing molecular weight, reflecting the decrease in diffusion constant.

Diffusion effects were not evident when starch was used by Brooks and Badger [6] for separations of cellulose nitrate. The rapid equilibrium observed, the preferential uptake of the larger molecules and the marked dependence of the separation on the degree of nitrate substitution indicate that adsorption was the single affecting factor.

The fractionation of polymethyl-siloxanes by gradient elution from charcoal has recently been reported [7]. An increase in molecular weight with increasing eluent was found.

In the method described in this paper, the preferential diffusion of lower weight molecules into porous charcoal is used to effect cellulose acetate fractionation. Adsorption influences the separation by retaining the more deeply diffused material.

The effect of time and of varying molecular weights on the diffusion into charcoal

Three secondary cellulose acetate samples with intrinsic viscosities of 2.24, 1.62 and 0.95 were used which are identified in the following text by their intrinsic viscosity values. Information about the materials used and further experimental details are found in the Experimental part.

Solutions containing 300 mg of the 2.24, 1.62 and 0.95 samples in 15 ml acetone were shaken for 2, 4, 6 and 10 minutes with six grams of acetone-saturated charcoal.

After decantation the charcoal was first washed for 30 seconds and then for ten minutes successively with 25 ml portions of acetone. The total material recovered in this way was then subtracted from the original sample weight to obtain the uptake per gram charcoal. The results are shown in Fig. 1.

The rapidity of the diffusion into charcoal and the pronounced dependence of the uptake on molecular weight is seen. The decreased rate of uptake after about four minutes followed by a nearly linear uptake by the charcoal during extended shaking periods is generally found in all experiments.

The preferential removal of lower weight molecules by charcoal

Solutions of the three samples of cellulose acetate, each in 25 ml acetone, 750 mg in four cases and 500 mg in another, were shaken for five minutes with ten grams of acetone saturated charcoal. After decanting the original solution the charcoal was shaken with successive 25 ml portions of acetone for five minutes until measurable acetate was no longer found. The charcoal was then shaken further with successive 25 ml volumes of dioxan. The amounts and intrinsic viscosities of the acetate first decanted and of that obtained from each of the successive washings and elutions were then measured.

The analytical data, given in Table 1, show the removal of successively lower molecular weight portions of the sample distribution by the repeated washings, evidence of a molecular weight gradient in the capillaries of the charcoal, the smallest molecules having penetrated most deeply. The intrinsic viscosities of the material obtained after prolonged shaking with dioxan evidently represent an average of the cellulose acetate remaining in the charcoal after no more material could be removed by the acetone washings.

That a gradient exists as well in the lower molecular weight material left in the charcoal after the acetone washings, is indicated in one column in Table 1 where the charcoal was shaken with dioxan for successive five minute periods.

The intrinsic viscosity weight average of the recovered fractions is lower than that of the original sample. This appeared to be due to analytical difficulties rather than to the holdup of high molecular weight material.

The effect of prolonged shakings and varying concentrations of cellulose acetate on the uptake

The results are shown in Table 2 which gives analyses of the solutions decanted after shaking solutions of sample 1.62 with the charcoal. Increased uptake with increased concentration is found as predicted by diffusion theory.

The increased uptake with time is reflected by the increasing intrinsic viscosity values.

THE SOLID PHASE COUNTERCURRENT APPARATUS

Although a machine was not developed for its use, Craig and co-workers [8] suggested that a solid could be used in countercurrent separations. To con-

the motor shaft to adjustable micro switches. Effective, though gentle shaking is obtained by this arrangement. The shaking time is controlled by a timer wired into the relay. Decanting, transfer and additions of solvent are done by hand.

Five tube countercurrent run

Five grams of charcoal, put into each of the first five tubes of the apparatus, were washed twice with acetone. Fifty ml of acetone containing 2.5 g of the 1.62 cellulose acetate was introduced into the first tube. After four minutes shaking and decantation, 25 ml acetone was added from the first reservoir to the first tube, while the decanted solution automatically transferred to the second tube. Acetone was added in this way four times following each four minute shaking period. At the end of twenty minutes the remainder of the original solution was thus decanted from the fifth mixing tube. Elution was done by shaking the charcoal with 25, 15 and 10 ml volumes successively, of dioxan, for one hour or more. Ten fractions resulted; five decanted to the reservoirs and five obtained by the subsequent elution of the charcoal. For clarity "decanted fractions" will refer to the solutions decanted before the dioxan elution.

Concentrations were determined on all the fractions and intrinsic viscosities on the first elution and on the decanted fractions. 97 % of the acetate was recovered, 20 % by elution from the charcoal.

The degree of separation obtained is shown by the intrinsic viscosity values in Fig. 4. The intrinsic viscosity range, from 0.9 to 1.8, after the short run, illustrates how rapidly the separation is initiated.

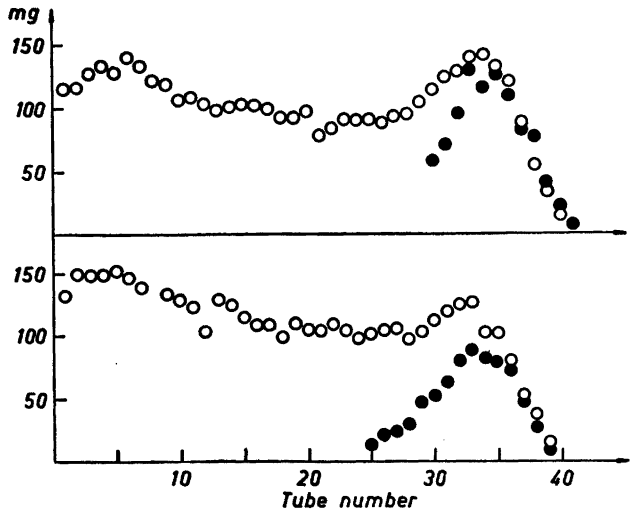

Fig. 5. Fraction weight versus tube number. Upper: from fifty tube run with cellulose acetate sample 1.62. Lower: from fifty tube run with sample 0.95. The solid symbols indicate the decanted acetone fractions.

Fifty tube countercurrent run with low molecular weight cellulose acetate

Nine grams of charcoal used per tube was first washed with acetone. Five grams of the 0.95 acetate sample in 70 ml acetone was introduced in two 35 ml portions to the first two tubes as the high viscosity of the full charge when used in the limited volume available in the one tube resulted in poor mixing. The cellulose acetate solution was followed by 25 ml additions of acetone to the first charcoal stage. Five minute shaking periods were used between the successive additions of solvent.

Elution was first done by shaking the charcoal successively with 25 and 15 ml dioxan for two hours or more. 15 % of the original material was in the decanted fractions which, with the eluted material from the two shakings with dioxan, accounted for 66 % of the original sample. The intrinsic viscosities, determined on every second fraction, are shown in Fig. 4.

A third elution was done with 25 ml dioxan. When this material was added to that already obtained, 92 % had been recovered. The viscosities determined on combined, contiguous pairs from this final elution are indicated by crosses on the curve in Fig. 4. They coincide well with the viscosity curve resulting from the previous elutions, showing that after the prolonged shaking with dioxan no molecular weight gradient has been detected. It was also found that the last elution removed nearly like proportions of material regardless of DP, attesting to the effectiveness of the elution.

The weight of each fraction is shown in the lower portion of Fig. 5. It can be seen from the figure that the higher viscosity decanted material

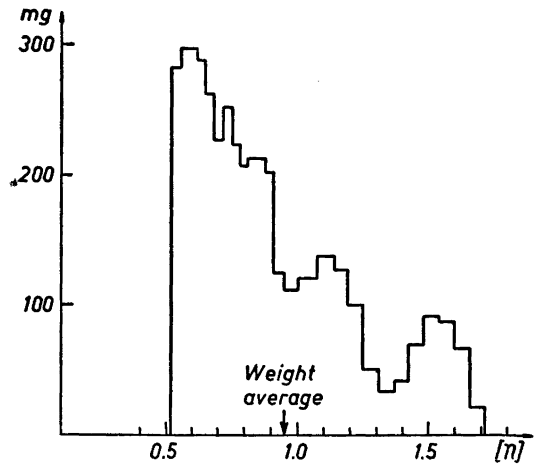

Fig. 6. The intrinsic viscosity weight distribution of the fractions from fifty tube run with acetate sample 0.95.

appears at tube 25, while beyond tube 40, extending to tube 50, acetate is found neither in the charcoal nor in the decanted acetone, illustrating the countercurrent effect.

The intrinsic viscosity weight distribution is given in Fig. 6. It is based on 100 % recovery, assuming that the material eluted was representative of that remaining in the charcoal. To prepare the diagram, the fraction weights were used directly. The intrinsic viscosity values however, were taken from a curve drawn by eye through the viscosity points in Fig. 4. The weight average intrinsic viscosity is the same as that of the original sample, confirming the reliability of the viscosity method used and the effectiveness of the recovery.

Countercurrent run with higher DP cellulose acetate

5 g of the 1.62 acetate in 70 ml acetone were introduced to the first two tubes of the apparatus. Other conditions were the same as those used with the lower DP sample.

25 % was found in the decanted fractions in comparison to 15 % when the lower DP acetate was run under like conditions. When this material was added to that obtained in the elutions with dioxan, 60 % was recovered. No further elution was done. The intrinsic viscositiy of each second fraction is shown in Fig. 4 and the amounts recovered, in Fig. 5.

The intrinsic viscosity weight distribution, shown in Fig. 7 is based on 100 % recovery. The intrinsic viscosity weight average, 1.53, is lower than that of the original sample. This may be due to unrepresentative elution or analytical errors.

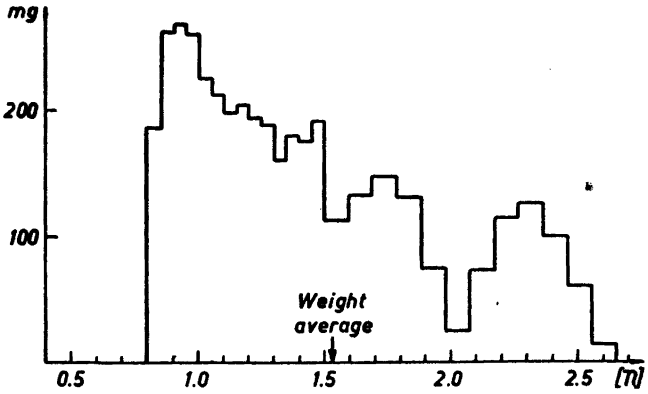

Fig. 7. The intrinsic viscosity weight distribution of the fractions from fifty tube run with acetate sample 1.62.

EXPERIMENTAL

Materials. The cellulose acetates are Hercules Powder Company products. The samples which have intrinsic viscosities of 2.24, 1.62 and 0.95 — weight average molecular weights of *ca.* 83 000, 60 000 and 35 000 — are substituted to the extent of 2.45, 2.39 and 2.48, respectively.

The charcoal, a Norit Company product, is a rather soft, activated carbon with a particle diameter of 0.7 mm. Acetone of analytical purity was used throughout. The dioxan used had 99 % purity and was used without further treatment.

Experimental details. To wash the charcoal, 25 ml portions of acetone were added simultaneously from the reservoirs and shaken with the charcoal for fifteen minutes. This was done twice. In addition to removing excessive charcoal fines, the acetone remaining on the charcoal after washing, served to dilute the cellulose acetate solution making it possible to transfer the original charge through the apparatus. Similar diffusion effects were found whether the cellulose acetate solution was shaken with dry charcoal or with acetone-saturated charcoal.

After the run the decanted acetone fractions in the reservoirs were removed with a syringe and centrifuged to remove charcoal fines. To determine concentrations, aliquots were precipitated in water on a steam bath in small, thin drying phials. The phials were hung in a vertical rack in an electrically heated drying column [10] under vacuum for twenty minutes. During the last ten minutes of this period 105—108° C was maintained. Viscosities were determined directly on the decanted acetone fractions after adjustment of concentrations.

For elution, the dioxan was added simultaneously to the charcoal from all the reservoirs and generally shaken two hours or more. Aliquots of the dioxan solutions were precipitated and dried in the same manner as the acetone fractions. The dried samples were dispersed in acetone for the viscosity determination.

Viscosity Measurements. Intrinsic viscosity analyses are laborious and since small quantities were analyzed, measurements at several concentrations would have been very difficult. In consequence means were sought to obtain the value from one efflux time at any single concentration in a low concentration range.

Ostwald pipettes [11] recommended for a range between 0.3 and 5.0 centipoises were used at 25° C ± 0.02. 2 ml solution was required. Conventional semi-log plots of spec. viscosity / conc. *vs.* conc. were made on several secondary cellulose acetates and on mixtures of these.

The finding of Martin [12] that the slopes obtained have a linear relation to their limiting viscosity values at zero concentrations was confirmed in concentrations up to 0.35 %

on samples ranging in intrinsic viscosity between 0.95 and 2.24. The low kinetic energy error of the pipettes was found to be a necessary condition in determining the relation.

A K value of 0.21 was obtained by plotting the slopes against the corresponding intrinsic viscosities. This was then used in Martins expression

$$\log \left(\frac{\eta_{sp}}{c}\right) = \log [\eta] + K [\eta] \cdot c$$

rearranged to the form

$$\eta_{sp} = c \cdot [\eta] \ 10^{Kc[\eta]} = \frac{t - t_0}{t_0}$$

where t, is efflux time of the solution, t_0, that of the solvent, c, the concentration and $[\eta]$, the intrinsic viscosity.

By using the equation in this form, graphs of $c \cdot [\eta]$ *vs.* t were obtained for several pipettes. One efflux time in the appropriate concentration range is thus sufficient. The $c \cdot [\eta]$ value found on the other axis need only be read off and divided by the concentration used.

DISCUSSION

An important aspect of the countercurrent method is the ease with which larger capacities and quantities can be employed. The rapidity of the fractionation is an obvious advantage.

It appears that a single batch separation method could be refined and used to partially characterize the distribution. It is also a convenient means to obtain a preliminary partition of the sample which can then be followed by the countercurrent fractionation of the upper or lower molecular weight segment.

In the countercurrent runs, the smaller molecules, continually pressing into the capillaries of the charcoal at each stage of the moving system, had an opportunity to be adsorbed. The decanted fractions of higher DP, were selectively refused by the charcoal stages, resulting in the progressively increasing intrinsic viscosity of the decanted, as well as the eluted, fractions.

When extended shaking times were used in a run with acetate 1.62, a small percentage of the sample, above viscosity 2.5, failed to diffuse into the charcoal. There was also some evidence that representative elution was more difficult after the extended contact between the charcoal and the cellulose acetate solution.

The steady increase of intrinsic viscosity with fraction number seems to preclude much effect from variations in the degree of substitution on the fractionation. Acetyl analyses are planned on the fractions.

The distributions obtained are asymmetrical with positive skewness conforming with the preponderance of theoretical and experimental evidence[13,14]. The presence of more than one maximum in the weight distribution diagrams is believed to have resulted from the experimental conditions. Homogeneity measurements of the fractions are planned.

It appears likely that other polymers may be separated with the demonstrated countercurrent method and such experiments are in progress.

Acknowledgments. The writer wishes to thank the *American-Scandinavian Foundation* for the Berquist fellowship grant and the *Sweden-America Foundation* for their hospitality.

The author is particularly indebted to Professor Börje Steenberg for proposing the project, his enthusiastic interest, the generous provision of facilities and for editing the

manuscript. He is also happy to be able to express his appreciation to Jan Bergström for his contribution to the viscosity method and for many enjoyable discussions.

The assistance of Miss Inger Almsäter and Miss Elizabeth Johansson has been invaluable. Dr. A. F. Martin, Hercules Powder Company, kindly provided the cellulose acetate samples with accompanying analytical data.

Determination of Mercury in Urine

AXEL JOHANSSON and HANS UHRNELL

Analytical Laboratory, Royal Institute of Technology, Stockholm, Sweden

Existing methods for the determination of mercury in urine are rather time-consuming. A more rapid method has therefore been elaborated, involving a wet combustion with sulphuric acid and potassium permanganate. After reduction of the excess of permanganate with hydrogen peroxide and oxalic acid the mercury is extracted with dithizone solution at a pH value of between 0 and 1, where other metals do not interfere. The dithizone-mercury dithizonate solution formed is divided in two parts, one of which is extracted with sodium thiosulphate solution and then used as blank solution in the spectrophotometric determination of the dithizonate in the other part. The method has been used for some years as routine control for persons employed in the manufacture of methyl mercuric hydroxide and in steeping seed with mercury containing material.

The method most frequently used in Sweden for the determination of mercury in urine and biological material is that of Vesterberg and Sjöholm[1]. According to this method the sample is subjected to wet combustion in an acidic solution of chlorine and, after evaporation of the chlorine, mercury is precipitated as sulphide with cadmium sulphide as collector. The mixture of sulphides is filtered off, dissolved in a solution of potassium chlorate and hydrochloric acid and reprecipitated. After treatment again with chlorine and hydrochloric acid, followed by evaporation of the chlorine, the mercury is extracted with a solution of dithizone and the excess of the reagent titrated with a silver nitrate solution. This method is time consuming and therefore not suited for routine analysis; the result of an analysis is only obtained after 4—5 days. For some years another more rapid method of analysis has been used in this laboratory with good results. It is much less laborious and the results are available after about 12 hours. In this method also the sample is subjected to wet combustion and the mercury determined by means of dithizone. The method does not contain anything essentially new but is the result of a critical review of available procedures. It has been used only for the routine control of persons, employed in the manufacture of methyl mercuric hydroxide and in steeping seed with mercury containing material. The method may possibly be useful in other cases and is published for that reason.

The determination of mercury in organic material involves mainly three problems, namely the oxidation of the organic material without the loss of mercury, reduction of the oxidising agents used and finally the actual determination of mercury. According to the proposed method the sample is oxidised in an acid potassium permanganate solution[2], which was found to be the most rapid method. No loss of mercury has been observed in any case with the types of mercury compounds used. For destruction of the excess permanganate many reducing agents have been proposed such as hydroxylamine and hydrazine. However when these substances are used, the mercury can not be extracted quantitatively with dithizone and the results of the analyses vary [3]. The best results have been obtained by reduction of the permanganate with a slight excess of hydrogen peroxide followed by the addition of a small amount of permanganate and finally decolourising with oxalic acid. Using this procedure it very occasionally happens that the dithizone is destroyed, probably by oxidation. If the sample solution after oxidation is left until the next day this phenomenon usually disappears. In order to avoid the loss of the whole analysis a test extraction is made with a small part of the sample solution with dithizone solution. If this solution turns a pale green or yellow green colour distinctly different from the usual green to olive green colour of the dithizone-dithizonate mixture or if the dithizone solution fades completely, the sample solution is boiled with some hydrogen peroxide after oxidation of the excess oxalic acid by the addition of permanganate. The oxalic acid must be destroyed to avoid the loss of mercury during boiling.

The solution of inorganic mercury thus obtained is extracted with a solution of dithizone in chloroform. To avoid interference from other metals that may be present, the extraction is carried out at a pH-value of between 0 and 1 [4,5], which is most easily obtained by diluting the solution of the sample. The spectrophotometric determination of the mercury may be done in two ways, either by determining the decrease in the extinction of the dithizone-solution at 520 mμ, the highest absorption maximum of the dithizone, or by determining the increase of the extinction at 490 mμ, the absorption maximum of the mercury dithizonate. The latter method seems to be the best for the small quantities of mercury usually occurring in urine. The original dithizone solution may be used as reference solution. A slightly more exact result will be obtained by extracting the mercury from part of the solution to be determined, and using the dithizone solution thus obtained as a reference solution. In this way an automatic correction for the eventual fading of the dithizone will be obtained and as well for other heavy metals that may occasionally be present.

Solutions of potassium iodide [5] or of sodium thiosulphate [2], both giving good results, have been suggested for the extraction of mercury.

PROCEDURE

Reagents

1) Concentrated sulphuric acid
2) Potassium permanganate
3) Hydrogen peroxide 15 % (1 volume hydrogen peroxide 30 % + 1 volume water).
4) Potassium permanganate solution in water (4 %).
5) Oxalic acid solution 0.5 *M*.

Table 1. Recovery of added amounts of mercury. A comparison of the amount (in μg) of mercury added with that found by analysis.

a) *Methyl mercuric hydroxide*		
Added	Found	Difference

6) Hydrogen peroxide 5 % (1 volume hydrogen peroxide 30 % + 5 volumes water).
7) Dithizone solution (10 mg of dithizone are dissolved in chloroform and diluted to 1 000 ml).
8) Sulphuric acid 0.1 *N*.
9) Sodium thiosulphate solution in water (1.5 %).
10) Mercury standard solution I (100 μg Hg^{2+} per ml). Mercuric chloride (135.7 mg) is dissolved in water and diluted to 1 000 ml.
11) Mercury standard solution II (2 μg Hg^{2+} per ml). Mercury standard solution I (5.00 ml) is diluted with water to 250 ml. This must be made immediately before use.

Destruction of organic matter. Shake the sample of urine vigorously in order to disperse any sediment and pour 500 ml into a 2 000 ml flask. Add 50 ml of conc. sulphuric acid in portions and then 25 g of solid potassium permanganate and shake the flask gently a couple of times. Heat over a flame under reflux, until boiling, and continue boiling for 8 hrs. If all the potassium permanganate is consumed during this period, cool the sample to room temperature and add about 10 g of solid potassium permanganate. Continue the boiling for a total time of 8 hrs. Cool to about 20° C. Wash the condenser down into the flask with about 15 ml of dist. water. Add hydrogen peroxide, 15 % in portions of 2—3 ml, each time shaking the flask several times rather vigorously until the sample is decolourised. Add a small excess of potassium permanganate solution and decolourise again, but this time with oxalic acid solution, and then add an excess of 2—3 ml of the oxalic acid solution.

Preliminary test extraction. Measure the volume of the decolourised sample in a cylinder and then transfer 20 ml to a 50 ml separating funnel. Add 1 ml dithizone solution and shake vigorously several times. Examine the dithizone layer by a diffuse light. If the dithizone solution fades, pour the main solution back into the flask and add a small excess of potassium permanganate solution and then decolourise with hydrogen peroxide solution, 5 %. After addition of an excess (2 ml) of hydrogen peroxide, reflux the sample for an hour and it will after cooling, be ready for further treatment. If the dithizone did not fade in the preliminary test extraction, this reheating is unnecessary.

Extraction of the mercury. After dilution of the sample solution to 1.6 l, pour it into a 2 l separating funnel and add 25 ml dithizone solution with a pipette. Shake the separating funnel vigorously 100 times, and separate the chloroform layer and filter it through glass wool into a 50 ml flask. Use part of this solution as the sample for the measurement of the extinction while the rest is poured into a 100 ml separating funnel and shaken with a mixture of 50 ml 0.1 *N* sulphuric acid and 10 ml 1.5 % sodium thiosulphate. This mixture is previously saturated by shaking with some chloroform which is then carefully separated. After shaking with the thiosulphate solution the dithizone solution should have a clearly bluish green colour and after filtration through glass wool it is used as the blank solution for the absorption measurement. This is made at a wave length of 490 mμ and the value obtained is compared with a standard curve, made using solutions of known concentration. In the calculation of the quantity of mercury in the sample correction must be made for traces of mercury in the chemicals used and for the quantity of the sample consumed by the preliminary test extraction.

Standard curve. A standard curve is made by mixing 1.6 l water and 50 ml conc. sulphuric acid with different known quantities of mercury standard II. It is convenient to use 0, 5, 10, 15, 20 and 25 ml equivalent to 0, 10, 20, 30, 40 and 50 micrograms of mercury. The samples are shaken with 25 ml dithizone solution which is then treated in the same way as before, and the standard curve is made with the extinction values obtained.

Test analyses. As well as the analyses done during the elaboration of this method, check analyses have also been carried out later while the method has been in use. To urine or in some cases to water has been added known quantities of mercuric chloride, methyl mercuric hydroxide or phenyl mercuric acetate and these samples have been mixed with the routine analyses. In Table 1 all the samples are collected that have been analysed during one period of time. As is clear from the table the difference between the mercury added and that found amounts to only a few micrograms, a fact that must be considered satisfying.

21-Derivatives of Compound S, Cortisone and Hydrocortisone

POUL BORREVANG

Leo Pharmaceutical Products, Copenhagen, Denmark

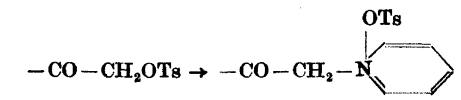
Treatment of compound S, cortisone and hydrocortisone with tosyl chloride and pyridine at low temperature (+ 2° and − 18°) affords the corresponding 21-tosylates. By means of tosyl anhydride and pyridine the 21-tosylate of compound S and cortisone have been prepared at higher temperature (*e. g.* room temperature). Cortisone tosylate has been prepared at room temperature by treatment with tosyl chloride and NaOH-solution. By reaction with salts of halide acids (NaI, NaBr, $CaCl_2$ and NH_4Cl) the corresponding halogen compounds have been prepared from the 21-tosylates. Treatment of the 21-iodo compounds with KCN affords the 21-cyano compounds. From the 21-tosylates and the 21-iodo compounds the 21-thiocyanates and the 21-thiolacetates have been prepared by reaction with KSCN and potassium thiolacetate, respectively.

For the purpose of investigating the biological effect of steroids of the cortisone (II) and hydrocortisone (III) type in which the primary hydroxyl group in the 21-position has been replaced by other groups, in particular groups containing S or N atoms, it would be desirable from II or III to prepare the corresponding steroids in which a halogen atom has been substituted for the hydroxyl group in the 21-position.

One of the generally known methods of substituting a halogen atom for a primary OH group is to prepare the *p*-toluenesulphonic acid ester (the tosylate) and subsequently treat the tosylate with a salt of a halide acid [1].

The attempts hitherto made to obtain the tosylate in the 21-position in pure condition and in good yield by treating steroids with the side chain —CO—CH_2OH with tosyl chloride in the presence of pyridine have not succeeded.

Reichstein and Schindler [2] recommend the preparation of such tosylates from the corresponding diazo-ketone, —$COCHN_2$, by treatment with anhydrous *p*-toluenesulphonic acid, as the tosylate formed primarily through the interaction of the 21-OH group with tosyl chloride in pyridine will readily react with pyridine to form the pyridinium salt:



Reichstein and Fuchs[3] have treated desoxycorticosterone and corticosterone in pyridine/chloroform solution with tosyl chloride at room temperature and have obtained a mixture of tosylate and 21-chloro compound and a small amount of pyridinium compound. A considerable excess of pyridine was avoided so that only a small amount of pyridinium compound was formed, but the tosylate formed primarily will react to some extent with pyridine hydrochloride to form the 21-chloro compound:

$$—CO—CH_2OTs \rightarrow —CO—CH_2Cl$$

Djerassi and Nussbaum[4] have treated compound S (I) and cortisone, respectively, in pyridine/chloroform solution at 0° C with tosyl chloride allowing the solution to stand at room temperature for 14 and 17 hours. From compound S a yield of 45 % of a substance which consists chiefly of the 21-chloro compound is obtained. From cortisone a yield of 65 % is obtained of a substance which probably contains pyridinium salt, 21-chloro compound, and tosylate.

Leanza and coworkers[5] have treated cortisone in pure pyridine solution with tosyl chloride heating gently for a few minutes and then allowing the solution to stand overnight at room temperature. In one case they have obtained 78.5 % 21-pyridinium chloride and in another 56 % 21-pyridinium tosylate. In a third case the cortisone solution was cooled to 15° C, tosyl chloride was added, the mixture was kept at a temperature of 10—15° C for one hour and allowed to stand overnight at room temperature. This resulted in a yield of 46 % of 21-chloro compound.

If the side reactions are taken to be the result of reactions between the tosylate formed primarily and the other components in the solution, tosylation must be assumed to be a reaction which takes place very readily. None of the authors mentioned apply temperatures below 0° C, and the possibility therefore existed that at very low temperatures tosylation would occur while the side reactions would take place less readily.

It proved possible to prepare the 21-tosylates of compound S (IV), cortisone (V), and hydrocortisone (VI) in pure condition and in good yields (in the case of cortisone tosylate (V) the yield was, *e. g.*, 73 %) by dissolving the steroid in pure, dry pyridine, cooling the solution in dry ice-acetone, adding tosyl chloride dissolved in dry methylene chloride and cooled to such an extent that the tosyl chloride just remained in solution, allowing the mixture to stand in dry ice-acetone for about two hours while occasionally shaking the flask, and finally setting aside the solution for 16—17 hours at +2° C and —18° C, respectively.

The preparation of cortisone tosylate (V) requires cooling to a lower temperature than does the preparation of compound S tosylate (IV). If the same temperature is used as in the preparation of compound S tosylate (IV), a substance is formed which has a melting point of 230—232° C and contains 7.1 % chlorine. As the Lassaigne test for N is negative (*i. e.* it is not a pyridinium compound), the substance must be assumed to consist of about 75 % 21-chloro compound (the theoretical content of chlorine in the 21-chloro compound is 9.36 %).

To eliminate this formation of 21-chloro compound completely it was tried to use *p*-toluenesulphonic acid anhydride (tosyl anhydride) [6] instead of tosyl chloride. Compound S tosylate (IV) was prepared by means of tosyl anhydride in pyridine and methylene chloride at low temperature, room temperature and with refluxing. The yields obtained at low temperature and at room temperature were the same, although somewhat lower than those obtained by the tosyl chloride method. When refluxing, the yields obtained were very low, as the formation of pyridinium salt is of course facilitated in this case, but in spite of this it is possible to isolate the tosylate in pure condition. As regards the preparation of cortisone tosylate (V) the same conditions apply when using tosyl anhydride as when using tosyl chloride. Already at room temperature the yield is low, the formation of side products occurring more readily than in the case of the compound S tosylate (IV) preparation.

To eliminate the formation of pyridinium salts and 21-chloro compound an attempt was made to replace pyridine with aqueous NaOH solution; cortisone tosylate (V) was obtained in good yield at a temperature of 25° C when using dioxan as the solvent, adding tosyl chloride and adding NaOH solution dropwise.

The tosylates tend to crystallize with 1 mole methanol, benzene, or ethanol which cannot be removed readily by drying. In case of cortisone tosylate (V) the benzene does not disappear when subjected to vacuum drying (about 10^{-1} mm) at room temperature for 20 hours. For this reason the melting points are often somewhat indefinite, and the melting is accompanied by vesiculation.

By means of NaI in acetone the corresponding 21-iodo compounds Δ^4-21-iodopregnene-3,20-dione-17α-ol (VII), Δ^4-21-iodopregnene-3,11,20-trione-17α-ol (VIII), and Δ^4-21-iodopregnene-3,20-dione-11β,17α-diol (IX) were prepared from compound S tosylate (IV), cortisone tosylate (V), and hydrocortisone tosylate (VI). These iodo compounds are white crystalline substances, which are fairly stable. After storage for about one month without exposure to light they tend to turn dark.

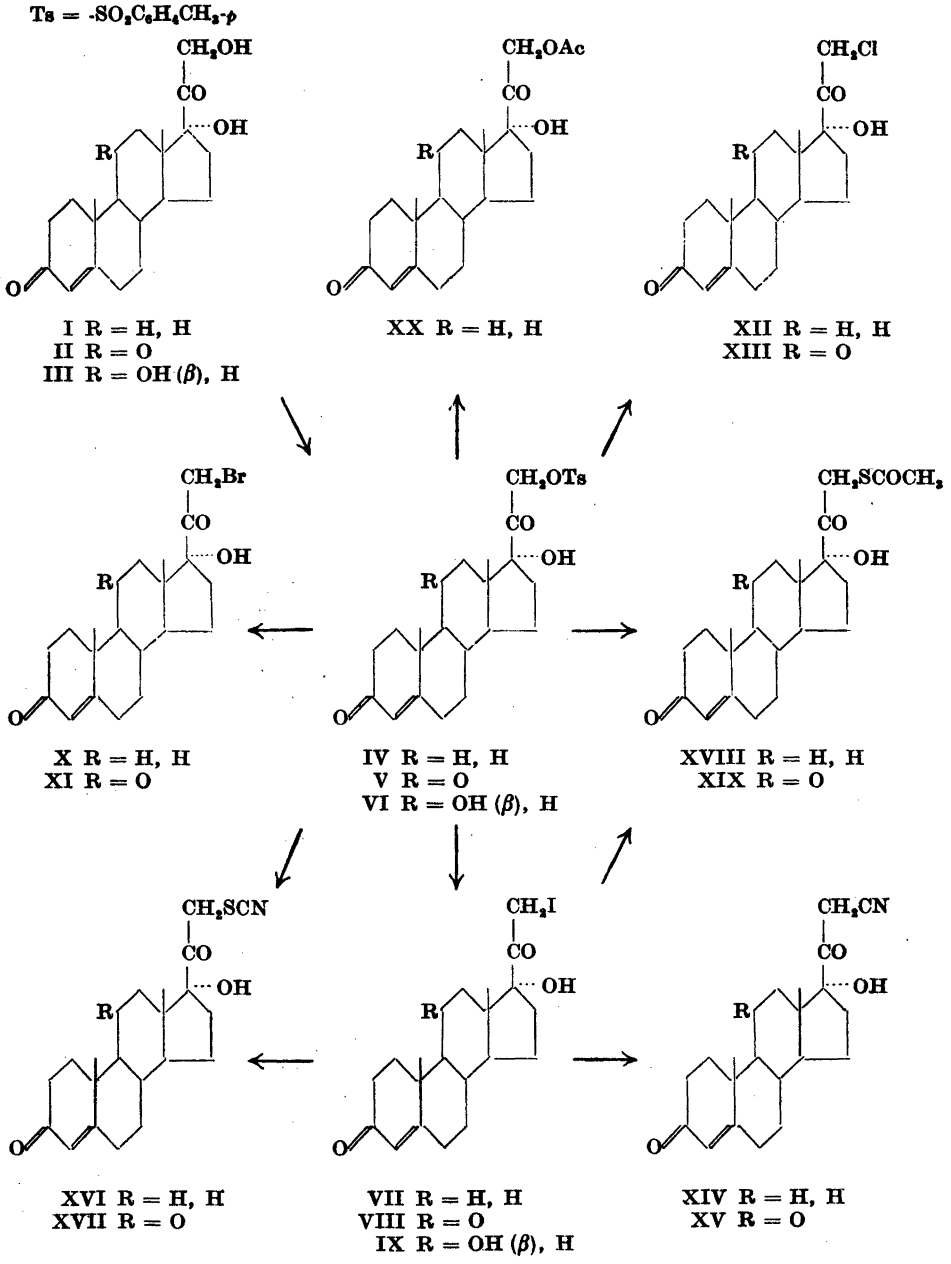
By the action of NaBr in methanol the 21-bromo compounds Δ^4-21-bromopregnene-3,20-dione-17α-ol (X) and Δ^4-21-bromopregnene-3,11,20-trione-17α-ol (XI) were prepared from IV and V.

According to Reichstein and Schindler [2] NaCl cannot be used for the preparation of 21-chloro compounds from tosylates on account of too low solubility in acetone and methanol, for which reason these authors use tetramethylammonium chloride.

Since $CaCl_2$ and NH_4Cl are soluble in ethanol, these substances were used for the preparation of the 21-chloro compounds Δ^4-21-chloropregnene-3,20-dione-17α-ol (XII) and Δ^4-21-chloropregnene-3,11,20-trione-17α-ol (XIII) from compound S tosylate (IV) and cortisone tosylate (V).

From the 21-iodo compounds (VII) and (VIII) the 21-cyano compounds, Δ^4-21-cyanopregnene-3,20-dione-17α-ol (XIV) and Δ^4-21-cyanopregnene-3,11,20-trione-17α-ol (XV), were prepared by means of KCN in methanol. By means of KSCN in acetone the 21-thiocyano compounds, Δ^4-21-thiocyanopregnene-3,20-dione-17α-ol (XVI) and Δ^4-21-thiocyanopregnene-3,11,20-trione-17α-ol (XVII), were prepared. XVII was also prepared from cortisone tosylate (V) by reaction with KSCN in acetone.

For the identification of the 21-halogen compounds and the 21-tosylates, the thiolacetates, compound S-thiolacetate (Δ^4-pregnene-3,20-dione-17α-ol-21-thiol-21-acetate, XVIII) and cortisone thiolacetate (Δ^4-pregnene-3,11,20-



trione-17α-ol-21-thiol-21-acetate, XIX) were prepared by reaction with potassium thiolacetate in acetone from the corresponding iodides and tosylates. The substances proved to be identical with the substances prepared by Djerassi and Nussbaum [4]. Finally compound S acetate (XX) was obtained from compound S tosylate (IV) by reaction with potassium acetate in acetone.

EXPERIMENTAL

Microanalyses by G. Cornali. All melting points are uncorrected.

Δ^4-pregnene-3,20-dione-17α,21-diol-21-tosylate (IV)

A. *With tosyl chloride and pyridine at low temperature.* A solution of 1.0 g (0.00289 mole) of compound S (I) in 10 ml of dry pyridine was placed in a bath of dry ice and acetone. 600 mg (0.00315 mole) of tosyl chloride (which had been dried by solution in a little benzene and subsequent evaporation of the benzene) was dissolved in 6 ml of dry methylene chloride, and the solution was cooled to such an extent that the tosyl chloride just remained in solution. This solution was poured rapidly into the solidified solution of I. By removing the flask at intervals from the bath and rotating the flask a clear solution was obtained. This solution was allowed to stand in the bath for 2 hours and subsequently at +2° C for 18 hours. The solution was now diluted with ether and washed twice with water, three times with dilute hydrochloric acid, four times with dilute sodium carbonate solution and twice with water. After drying over sodium sulphate the solution was evaporated to dryness. The residue was dissolved in 5 ml of methanol. This solution was filtered and allowed to stand. The crystals which separated were collected and air-dried to yield 1.0 g (69.2 %) with m. p. 159–160° C. (Found: C 66.95; H 7.34; S 6.34. Calc. for $C_{28}H_{36}O_6S$: C 67.17; H 7.25; S 6.40.) In some cases the m. p. was found to be 97–98° C with vesiculation. (Found: C 65.42; H 7.50; S 6.30. Calc. for $C_{28}H_{36}O_6S$, 1 mole CH_3OH: C 65.38; H 7.57; S 6.02.) Following recrystallization from 96 % ethanol the substance with m. p. 159–160° C melted at 160–161° C. (Found: C 65.20; H 7.72; S 5.81. Calc. for $C_{28}H_{36}O_6S$, 1 mole C_2H_5OH: C 65.90; H 7.75; S 5.86.)

B. *With tosyl anhydride and pyridine at low temperature.* Compound S (1 g) was treated as described under A with the exception that a cooled suspension of 1.1 g (0.00337 mole) of tosyl anhydride in 30 ml of dry methylene chloride was added. The solution was allowed to stand for 18 hours at +2° C and subsequently treated as described under A. The yield was 600 mg (41.5 %) of IV.

C. *With tosyl anhydride and pyridine at room temperature.* To a solution of 1 g of compound S in 10 ml of dry pyridine was added a suspension of 1.1 g of tosyl anhydride in dry methylene chloride. The resulting clear solution was allowed to stand at room temperature for 18 hours and subsequently treated as described under A. The yield was 600 mg (41.5 %) of IV.

D. *With tosyl anhydride and pyridine under reflux.* To a solution of 1 g of compound S in 10 ml of dry pyridine was added a suspension of 1.1 g of tosyl anhydride in 30 ml of dry methylene chloride. The solution was refluxed for 2.5 hours and cooled to room temperature, ether was added, and the treatment proceeded as described under A. The yield was 250 mg (17.3 %) of IV.

Δ^4-pregnene-3,11,20-trione-17α,21-diol-21-tosylate (V)

A. *With tosyl chloride and pyridine at low temperature.* Cortisone (II) (1 g; 0.00277 mole) was treated as described in the case of IV A with the exception that the mixture was allowed to stand for 18 hours at a temperature of −18° C. When the ether had been evaporated, the residue was dissolved in 5 ml of benzene and set aside for a short time. The crystals which formed were collected and air-dried to yield 1.2 g (73.0 %). M. p. 108–109° C with vesiculation. (Found: C 68.87; H 6.89; S 5.37. Calc. for $C_{28}H_{34}O_7S$, 1 mole C_6H_6: C 68.89; H 6.80; S 5.41.) A small sample was dissolved in methanol, the solution was filtered and set aside for a short time. The crystals which formed were collected. M. p. 141–143° C (sinters at about 100° C). (Found: C 64.27; H 7.00; S 5.86. Calc. for $C_{28}H_{34}O_7S$, 1 mole CH_3OH: C 63.71; H 7.01; S 5.86.)

In all calculations in which this substance occurs the molecular weight of cortisone tosylate has been taken to be 592.72 corresponding to $C_{28}H_{34}O_7S$, 1 mole C_6H_6.

B. *With tosyl anhydride and pyridine at room temperature.* Cortisone (1 g) was treated as described in the case of IV C. The residue obtained following the removal of the ether was dissolved in benzene, the crystals formed were collected and air-dried to yield 250 mg (15.2 %) of V.

C. *With tosyl chloride and NaOH solution (Schotten-Baumann).* To a solution of 1 g (0.00277 mole) of cortisone in 30 ml of dioxan was added 300 mg (0.00158 mole) of tosyl chloride. 10 ml (0.00158 mole) of aqueous NaOH solution (6.3 g—1 000 ml) was then added dropwise while stirring in the course of 30 min. Another 300 mg of tosyl chloride was now added followed by 10 ml of the abovementioned NaOH solution in the course of 3/4 hour. Ether was added, and the mixture was washed four times with dilute sodium carbonate solution and three times with water. After drying over sodium sulphate and filtration the solution was evaporated to dryness. The residue was dissolved in a little benzene and set aside for a short time. The crystals which formed were collected and air-dried to yield 800 mg (48.6 %) of V.

Δ^4-pregnene-3,20-dione-11β,17α,21-triol-21-tosylate (VI)

Compound F (III) (1 g; 0.00276 mole) was treated as described in the case of V A. The residue obtained after the evaporation of the ether crystallized by the addition of methanol. The solid was collected, washed with methanol and air-dried to yield 800 mg (52.8 %). M. p. 119—121° C with vesiculation. (Found: C 63.37; H 7.20; S 5.67. Calc. for $C_{28}H_{36}O_7S$, 1 mole CH_3OH: C 63.48; H 7.35; S 5.84.)

Δ^4-21-iodopregnene-3,20-dione-17α-ol (VII)

To a solution of 1 g (0.0020 mole) of IV in 5 ml of acetone was added a solution of 1 g (0.0067 mole) of sodium iodide in 7 ml of acetone. In the course of a few minutes separation of sodium tosylate started. The mixture was refluxed for 7—8 minutes, most of the acetone was distilled off, and the solution was cooled to room temperature. On the addition of dilute sodium thiosulphate solution and water a white precipitate was formed. This precipitate was collected, washed thoroughly with water and air-dried to yield 870 mg (95.4 %) of analytically pure VII. M. p. 135—136° C dec. (the substance turns dark at about 125° C). (Found: C 55.06; H 6.59; I 27.70. Calc. for $C_{21}H_{29}IO_3$: C 55.26; H 6.41; I 27.81.)

Δ^4-21-iodopregnene-3,11,20-trione-17α-ol (VIII)

Cortisone tosylate (V) (1 g; 0.0017 mole) was treated as described in the case of VII. The substance obtained was dried to yield 780 mg (98.3 %) of VIII, decomposition of which starts at about 140° C. Following recrystallization from dioxan of a small sample, it was found to have m. p. 155—156° C dec. (Found: C 53.71; H 5.99; I 26.79. Calc. for $C_{21}H_{27}IO_4$: C 53.62; H 5.79; I 26.98.)

Δ^4-21-iodopregnene-3,20-dione-11β,17α-diol (IX)

Compound F tosylate (VI) (1 g; 0.0018 mole) was treated as described in the case of VII. The substance obtained was dried to yield 750 mg (87.1 %) of IX. M. p. 148—149° C dec. (Found: C 53.57; H 6.30; I 26.60. Calc. for $C_{21}H_{29}IO_4$: C 53.39; H 6.19; I 26.87.)

Δ^4-21-bromopregnene-3,20-dione-17α-ol (X)

A solution of 0.5 g (0.0010 mole) of IV in 5 ml of dry methanol was prepared by heating on a steam bath, and a solution of 350 mg (0.0034 mole) of NaBr in 10 ml of dry methanol was added. The resulting solution was refluxed for 3 hours. Half of the methanol added was distilled off and the residue cooled in running water. The precipitate which formed was collected, washed thoroughly with water and dried to yield 300 mg (73.4 %) of X. M. p. 223—224° C dec. (Found: C 61.73; H 7.25; Br 19.55. Calc. for $C_{21}H_{29}BrO_3$: C 61.61; H 7.14; Br 19.52.)

Δ^4-21-bromopregnene-3,11,20-trione-17α-ol (XI)

Cortisone tosylate (V) (0.5 g; 0.0008 mole) was treated as described in the case of X. The 21-bromo compound started to crystallize during the boiling. After refluxing for three hours and cooling in running water, the solid was collected, washed thoroughly with water and dried to yield 300 mg (85.0 %) of XI with m. p. 249—250° dec.*. (Found: C 59.54; H 6.58; Br 18.75. Calc. for $C_{21}H_{27}BrO_4$: C 59.57; H 6.43; Br 18.88.)

Δ^4-21-chloropregnene-3,20-dione-17α-ol (XII)

To a solution of 0.5 g (0.0010 mole) of IV in 25 ml of dry ethanol was added a filtered solution of 1 g (0.0090 mole) of dried $CaCl_2$ in 25 ml of dry ethanol. The solution was refluxed for 5 hours. Most of the ethanol was distilled off and water was added. The precipitate was collected, washed with water and dried to yield 350 mg (96.0 %) of XII. M. p. 234—235° C dec. (Found: C 68.90; H 7.88; Cl 9.59. Calc. for $C_{21}H_{29}ClO_3$: C 69.12; H 8.01; Cl 9.72.)

Δ^4-21-chloropregnene-3,11,20-trione-17α-ol (XIII)

Cortisone tosylate (V) (0.5 g; 0.0008 mole) was treated as described in the case of XII. The precipitate was collected, washed with water and air-dried to yield 300 mg (93.9 %) of analytically pure XIII. M. p. 282—284° C dec.**. (Found: C 66.48; H 7.45; Cl 9.40. Calc. for $C_{21}H_{27}ClO_4$: C 66.57; H 7.18; Cl 9.36.)

To a solution of 0.5 g (0.0093 mole) of NH_4Cl in 150 ml of dry ethanol prepared by heating was added 0.5 g of V and the solution was refluxed for 5 hours. Most of the ethanol was distilled off and water was added. The precipitate was collected, washed with water, dried and recrystallized from 99 % C_2H_5OH to yield 275 mg (86.0 %) of XIII. M. p. 282—284° C dec. Identity with a sample prepared with $CaCl_2$ was established by a mixed melting point.

Δ^4-21-cyanopregnene-3,20-dione-17α-ol (XIV)

To a solution of 0.5 g (0.0011 mole) of VII in 70 ml of methanol was added 0.5 g (0.0077 mole) of KCN. The solution was refluxed for 10 min. and most of the methanol was then distilled off in vacuum. Water was added and the precipitate collected, washed with water and dried to yield 300 mg of a crude product, m. p. 210—225° C. After recrystallization from methanol the yield was 150 mg (38.5 %), m. p. 249—251° C. (Found: C 74.13; H 8.45; N 3.90. Calc. for $C_{22}H_{29}NO_3$: C 74.33; H 8.22; N 3.94.)

Δ^4-21-cyanopregnene-3,11,20-trione-17α-ol (XV)

To a solution of 0.5 g (0.0011 mole) of VIII in 80 ml of methanol was added 200 mg (0.0031 mole) of KCN dissolved in 4 ml of water. The solution was refluxed for 10 min. Most of the methanol was then distilled off in vacuum and a solution of sodium chloride was added. The precipitate was collected, washed with water and dried to yield 175 mg of a crude product with m. p. 210—220° C. Recrystallization from 96 % C_2H_5OH yielded 75 mg (19.1 %) with m. p. 236—237° C. (Found: C 71.53; H 7.63; N 3.82. Calc. for $C_{22}H_{27}NO_4$: C 71.52; H 7.37; N 3.79.)

Δ^4-21-thiocyanopregnene-3,20-dione-17α-ol (XVI)

To a solution of 0.5 g (0.0011 mole) of VII in 40 ml of dry acetone was added 0.5 g (0.0052 mole) of dried KSCN (benzene was poured over KSCN and then distilled off). The solution was refluxed for 3.5 hours and most of the acetone subsequently distilled off. Water was added, and the precipitate collected, washed with water and dried to yield 400 mg (94.2 %) of XVI with m. p. 188—189° C. Recrystallization from methanol did not raise the melting point. (Found: C 68.14; H 8.00; S 8.17; N 3.55. Calc. for $C_{22}H_{29}NO_3S$: C 68.18; H 7.54; S 8.27; N 3.62.)

* Velluz, L., Warnandt, J., Nominé, G., Joly, R. and Petit, A. *(Bull. soc. chim. France* (5) **20** (1953) 906) found m. p. 297—300° C.

** J. Leanza and coworkers [5] found m. p. 243—245° C dec.

Δ^4-21-thiocyanopregnene-3,11,20-trione-17α-ol (XVII)

The 21-iodo compound (VIII) (0.5 g; 0.0011 mole) was treated as described in the case of XVI. The yield obtained was 420 mg (98.4 %) of XVII with m. p. 193—194° C. Recrystallization from benzene did not raise the melting point. (Found: C 66.05; H 6.86; N 3.46; S 7.98. Calc. for $C_{23}H_{27}NO_4S$: C 65.81; H 6.78; N 3.49; S 7.98.)

To a solution of 0.5 g (0.0008 mole) of V in 40 ml of dry acetone was added 0.5 g of dried KSCN. The solution was refluxed for 3.5 hours and most of the acetone was subsequently distilled off. Water was added and the precipitate collected, washed with water and dried to yield 300 mg (88.6 %) of XVII with m. p. 192—193° C. The melting point was not depressed on admixture with the substance prepared from VIII.

Δ^4-pregnene-3,20-dione-17α-ol-21-thiol-21-acetate (XVIII)

To a solution of 1 g (0.0022 mole) of VII in 50 ml of dry acetone was added 650 mg (0.0057 mole) of potassium thiolacetate, and the mixture was refluxed for 2.5 hours and most of the acetone was subsequently distilled off. Water was added and the precipitate collected, washed with water and dried to yield 750 mg (84.6 %) of XVIII with m. p. 214—217° C. Recrystallization from 99% ethanol raised the m. p. to 219—222° C. (Found: C 68.22; H 7.88; S 7.72. Calc. for $C_{23}H_{32}O_4S$: C 68.28; H 7.97; S 7.93.)

Δ^4-pregnene-3,11,20-trione-17α-ol-21-thiol-21-acetate (XIX)

To a solution of 1 g (0.0021 mole) of VIII in 50 ml of dry acetone was added 650 mg of potassium thiolacetate, and the mixture was refluxed for 2.5 hours. Most of the acetone was then distilled off, and after addition of water the precipitate was collected, washed with water and dried to yield 650 mg (73.0 %) analytically pure XIX with m. p. 224—226° C. Recrystallization from methanol did not raise the melting point. (Found: C 65.83; H 7.30; S 7.36. Calc. for $C_{23}H_{30}O_5S$: C 66.00; H 7.23; S 7.66.)

To a solution of 1 g (0.0017 mole) of V in 50 ml of dry acetone was added 600 mg of potassium thiolacetate, and the mixture was refluxed for 2.5 hours. Most of the acetone was then distilled off, and after addition of water the precipitate was collected, washed with water and dried to yield 500 mg (70.8 %) of XIX with m. p. 224—226° C. Identity with a sample prepared from VIII was established by a mixed melting point.

Δ^4-pregnene-3,20-dione-17α,21-diol-21-acetate (XX)

To a solution of 0.5 g (0.0010 mole) of IV in 50 ml of dry acetone was added 250 mg (0.0025 mole) fused potassium acetate, and the mixture was refluxed for 4.5 hours. Most of the acetone was then distilled off, water was added and the precipitate was collected, washed with water and air-dried to yield 300 mg (77.3 %) of XX with m. p. 228—231° C. Identity with a sample of compound S acetate was established by a mixed melting point.

On the Alkaline Error of the Glass Electrode *

NILS LANDQVIST

Rydboholms A.B., Rydboholm, Sweden

A theoretical treatment is given to the glass electrode alkaline behaviour, considering the influence of the state of adsorption on the adsorption energies. By expanding in series and approximating, the equation deduced has been transformed into earlier known, empirical expressions. Experimental results confirm the theoretical treatment. Finally a differential measuring method has been described, to be applied for correcting the alkaline error in glass electrode measurements when the activity of the sodium ion (or other) is unknown, comprising the use of two glass electrodes of different, but known, alkaline error functions.

Since Hughes [1] discovered the alkaline error of glass electrodes in 1922, several theories have been applied to the quantitative treatment of the difference between hydrogen and glass electrode behaviour. Important contributions in this field have been made by Dole *et al.*[2–7], and also by Nicolsky [8], Gross and Halpern [9] and Tendeloo and Voorspuij [10, 11]. For a more general review of the different theories, reference may be made to Kratz [12].

The theories of Dole and of Nicolsky give the same final equation, which can be written:

$$\log[\exp\ (F\triangle E/RT) - 1] = \mathrm{pH} + \log\ C_{Na+} + \text{constant} \qquad (1)$$

($\triangle E$ is the alkaline error, pH and C_{Na+} refer to the solution surrounding the glass electrode.) If log [exp $(F\triangle E/RT) - 1$] is plotted as a function of pH from experimental data, the linear agreement is good, except that the slopes of the lines are not unity, as demanded by eq. (1). Thus, for an electrode made of Corning 015 glass, a slope of 0.57 for 1 M Na^+ at 25° C was found by Dole [13]. (It was also stated in the same paper that no quantitative explanation of the deviation of the slope from unity had been advanced at that time.)

The validity of the Gross and Halpern treatment has been discussed and criticised by Dole [7], who concludes that their final equation is not as good as eq. (1) for explaining glass electrode behaviour in alkaline solutions.

* This paper is based on a lecture given by the author at the 8:th Congress of Scandinavian Chemists in Oslo, June 14—17, 1953.

The treatment by Tendeloo and Voorspuij gives the equation:

$$\log [\exp (F\triangle E/RT)-1] = \mathrm{pH} + \log [(1 + K_2' \cdot C_{Na+})/K'_1] \quad (2)$$

($\triangle E$ is the alkaline error, pH and C_{Na+} refer to the surrounding solution, K_1' and K_2' are electrode constants.) The equation is very similar to eq. (1), and for ordinary glass electrodes it fails as does eq. (1) in predicting a slope of unity. However, these authors used an electrode made of Al_2O_3-containing glass with a very high alkaline error. At pH 11 and $C_{Na+} = 0.1$ the error was about 50 times greater than that of an electrode made of Corning 015 glass. In this case eq. (2) is in good agreement with experimental results, but the lack of agreement occurs at low $\triangle E$, which can be expected from the behaviour of said Corning 015 glass. This is also stated by the authors.

The basic ideas of the four different treatments refered to above, have been:

Dole: Ion exchange reactions take place between the glass electrode surface and the surrounding solution, and the equilibrium is treated mathematically by a statistical method used earlier by Gurney [14,15] in studies on other electrode reactions.

Nicolsky: The ion distribution on the glass surface and in the surrounding solution is treated by the law of mass action.

Gross and Halpern: "It is assumed that the electrode glass may be treated as a difficulty soluble salt, which forms with water a saturated solution, so that the water dissolves in the glass until the glass becomes saturated with water. It is also assumed that the mass action law holds for such strong electrolytes as sodium hydroxide and sodium acetate both in water and glass phases, that water, glass, acids, bases *etc.* distribute themselves between the glass and the aqueous phase in accordance with the well-known distribution law, and that the activity coefficients of all ions are the same." (Dole [7]).

Tendeloo and Voorspuij: Dissociation equilibria between the swollen glass surface and the surrounding solution are controlled by real constants of dissociation for the silicic acid in that surface.

In the following discussion a refined treatment of the glass electrode alkaline error will be given, and the influence of the state of adsorption on the adsorption energies will also be considered. This has not been made in the treatments mentioned above.

The *physical model* used for the mathematical treatment is in accordance with the ideas of Tendeloo and Voorspuij [11], the SiO_4-network of the electrode glass being regarded as containing three dimentional interstices, offering room for metal ions such as Na^+ and Ca^{2+}. When the electrode surface is brought in contact with water the network on the surface and to some depth into the glass will pass into a swollen state, the aforesaid metal ions will be dissolved to a great extent and replaced by H^+ or H_3O^+ ions. In this way the *surface layer* is substantially free from other cations, and consists of silicic acid. The silicic acid is then able to take part in ion exchange reactions, so that all states from complete H^+ saturation to a more or less mixed composition of H^+ and other cations are possible. Under these conditions it may be anticipated that the adsorption energies, *i.e.* the forces between adsorbed ions and the adsorption sites, will be dependent on the state of adsorption, so that the energy will not be the same if an adsorbed ion has identical or dissimilar ions as neighbours

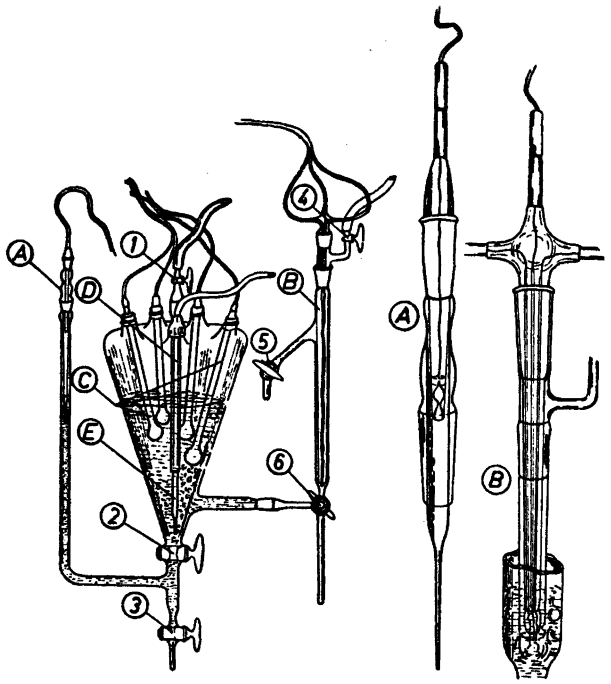

Fig. 1. Apparatus for hydrogen and glass electrode measurements.

on the surrounding adsorption sites. This seems to be reasonable, as the degree of "energy saturation" of each adsorption site may influence the surrounding sites, with regared to their available adsorption forces. As we are dealing with a network, *i.e.* a kind of a large molecule, the state of the internal resonance energies can to some extent be compared with that of a polybasic acid. However, in the case of glass the effect is more complex, as the glass is a solid acid, where the electrical forces outside the molecule have a large influence on the activity of the adsorbed ions.

EXPERIMENTAL

In the experiments a glass apparatus, Fig. 1, was used, with spaces for four glass electrodes C, a reference electrode A, a hydrogen electrode B and a temperature compensator D, used when measurements were made with instruments having an automatic temperature compensation device. During the measurements the whole system was enclosed in a Faraday cage, and the temperature of the surrounding room, 25° C, controlled by means of a radiant heating device to within 0.1° C, with a temperature change less than 0.1° C per hour. When hydrogen electrodes are used in alkaline solutions, it is of greatest importance that the hydrogen should be of a very high purity. An amount of oxygen exceeding 300 μg per litre can give mixed hydrogen-hydrogen ion and oxygen-hydroxyl ion potentials, disturbing the response of the electrode. The cylinder hydrogen used in this work was purified in the following manner, which gave excellent results. The gas was passed through a tube of stainless steel, with a diameter of 20 millimeters, con-

taining one layer of cut copper wires, and another of platinum deposited on porcelain. The height of each layer was 300 millimeters. The tube was heated by a 1 000 watt heating coil, controlled by an energy regulating device to maintain the temperature of the catalyst at 650 ± 25° C. The gas was in contact with the catalyst for about 5 minutes. It was then passed through a copper pipe for air cooling and bubbled through concentrated sulphuric acid and then through a solution of sodium hydroxide (400 g per litre). Before entering the hydrogen electrode, the gas was passed through a large quantity of thermostated distilled water, in order to avoid temperature changes at the electrode and to attain approximate equilibrium with the vapor pressure of the solution to be investigated. This eliminated changes in concentration, caused by evaporation from the electrode solution. The efficiency of the purification was examined from time to time. The purified hydrogen was bubbled through a small volume of 0.1 *M* KCl, and after one hour of bubbling the oxygen was determined polarographically. The amount of oxygen was always found to be less than a few μg per litre, which was below the limit for side reactions. Anodic polarographic investigations in 0.1 *M* Na_2HPO_4 gave no detectable wave of H_2S, arising from the sulphuric acid and not completely removed by the sodium hydroxide solution. From this it can be concluded that the amount of hydrogen sulphide was less than a few μg per litre of solution.

The hydrogen electrode B was designed as a triple electrode with three separate platinum wires for measuring the response of the electrode. In every pH measurement the three electrodes were measured individually several times, and the agreement of the three potentials had to be within the accuracy of the instruments used for the determination, before the measurements were accepted. Experience has shown that oxygen impurities, bad platinum plating and other electrode errors do not give identical potentials. The platinum plating was prepared by electrolysis, using a Pt anode, area 200 mm^2, at a distance from the cathodes of 20—30 mm, in 20 % $PtCl_4$ at 4 volts for 15 sec. and at a temperature of 20° C. The cathodes, *i. e.* the three platinum wires of the hydrogen electrode, were each 0.5 mm in diameter and 7 mm in length. The platinum deposit was renewed when necessary, but at least every day. The old deposit was carefully removed and the electrode cleaned by means of sodium chromate in sulphuric acid and rinsed in distilled water before replating. The reference electrode was a 0.1 *M* calomel electrode, this concentration being used as it has a low temperature coefficient and seems, with the electrode design used here to be practically free from variations in diffusion potentials. The electrode was similar to the type introduced by Perley [16].

The apparatus was operated in the following manner: With the cocks 2 and 6 (without grease) and 5 open, the test solution, buffer I or II, was introduced into the apparatus to cover the electrodes. (The reference electrode has a little hole, not shown, to allow the air to escape.) After closing the cocks 2 and 6 and opening 1 and 4, the hydrogen bubbling was started. As the hydrogen electrode space has a small volume, the oxygen in the solution was removed and hydrogen saturation quickly obtained. The minimum time of bubbling was of the order 10—15 minutes. The glass electrode potentials were measured at 5 minute intervals over a period of 30 minutes, thus giving 6 different determinations on each solution. The solution around the glass electrodes was stirred continously by means of the bubbling hydrogen, introduced by means of the pipe E. After 30 minutes the hydrogen electrode potential was determined, and during this measurement, cock 5 was closed, and all the three electrodes tested for coincidence. In order to investigate if any liquid junction potentials arise at the cocks 2 and 6, these cocks were opened and the potential difference determined. To change the pH of the solution, the cocks 1 and 5 were opened and the hydrogen electrode tube and that containing the reference electrode drained by means of cocks 2, 3 and 6. A desired amount of "contrabuffer" II or I was added to the solution around the glass electrodes, which was then stirred violently by means of the hydrogen, and by using the cocks 2, 3 and 6 the hydrogen and reference electrodes were rinsed several times, and finally as much solution removed as was necessary to maintain constant liquid level. The next measurements could then be made. Before and after each series of measurements the apparatus was filled with a control buffer and hydrogen and reference electrodes and asymmetry potential changes checked. As a rule identical values were found, but if this was not the case, the whole series of measurements were rejected and repeated after careful checking of the electrode system. The average accuracy was ± 0.25 mV.

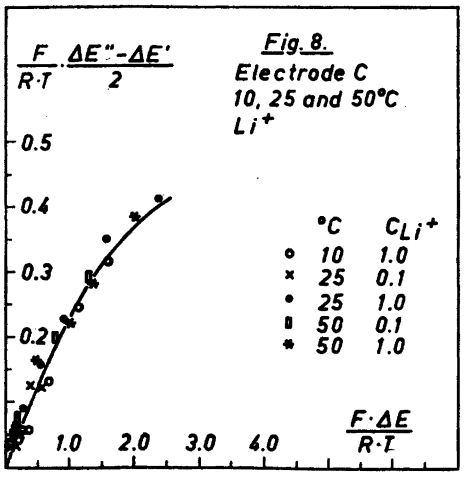
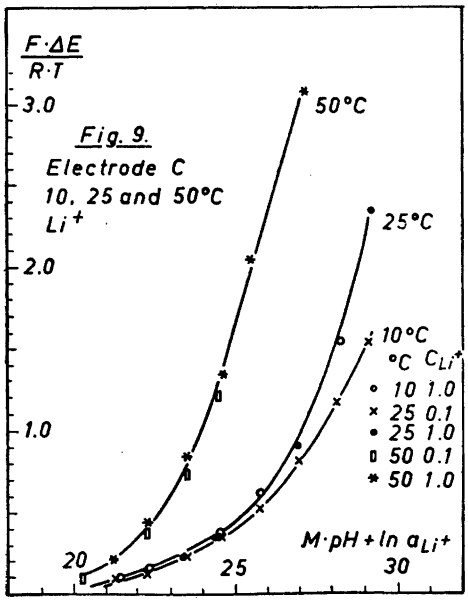
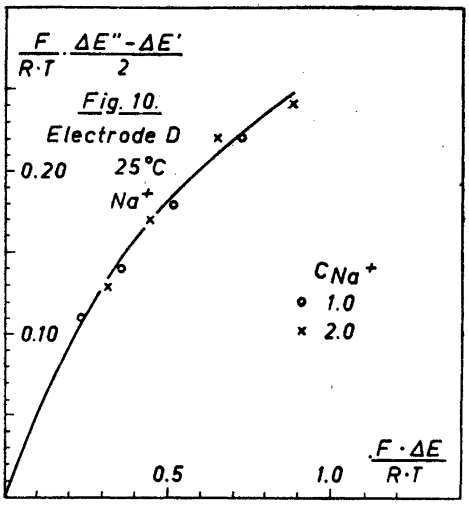
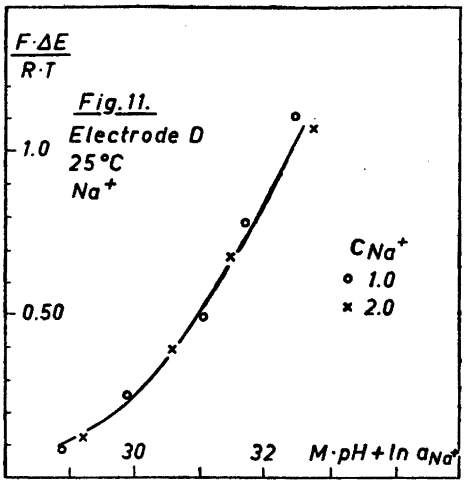
The buffer solutions used were: I. 0.010 *M* Na_3PO_4 + 0.010 *M* Na_2CO_3 + 0.050 *M* NaOH + NaCl to C_{Na+} = 0.10, 0.50, 1.00, 2.00 and 4.00. II. The same as I, but with 10 ml per litre 10 *M* HCl added. Control buffer: 0.025 *M* KH_2PO_4 + 0.025 *M* Na_2HPO_4; pH 6.86.

The instruments used for the potential determinations were a Radiometer PHM 3g and two different Leeds & Northrup instruments as secondary controls.

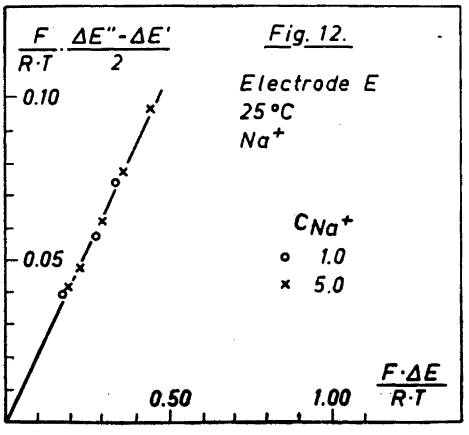


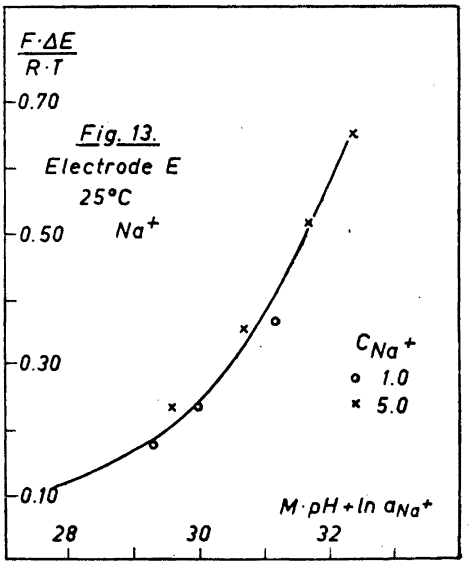






Measurements were made on two commercial glass electrodes, one of type A, and one of another type B, using the method described above. The investigated ranges were: pH 9—11.5 and C_{Na+} 0.10—4.00 at a temperature of 25° C. The electrodes A and B have different, but unknown glass composition. For calculations in accordance with the theory presented later in this paper, data obtained by Dole *et al.*[2-7, 12] have also been used. The object of this has been to include still another composition of glass, and also to include the effect of different temperatures, 10, 25 and 50° C, and of different ions, Na+ and Li+. (As the other ions investigated by Dole give a very low alkaline error, the accuracy is not sufficient for these calculations. Hence only the Na+ and Li+ results have been examined.)





In the present paper, the electrode used by Dole has been denoted by C. Figures for Na^+ at 25° C from the manufacturers' bulletins concerning two different electrodes D and E, having a very low alkaline error, were also used as a basis for mathematical calculations. In this case the data are of doubtful value, as nothing is known of the measuring technique and accuracy, the test solution composition and the activity changes at high pH values. The assumption has been made that NaCl was present in the solution and that the amount of buffer was low. The values have been included since they do give some additional indication of the low alkaline error electrode behaviour.

For the electrodes mentioned above, two functions have been plotted for all of them from experimental data, to be used in the theoretical treatment, namely:

$$F(\triangle E'' - \triangle E')/2\ RT = f(F\triangle E/RT) \tag{3}$$

$$F\triangle E/RT = g(\mathrm{M.pH} + \ln a_{Na+}) \tag{4}$$

In these functions $\triangle E$ is the alkaline error at an activity of hydrogen ions corresponding to pH and a sodium activity of a_{Na+}. $\triangle E''$ is the alkaline error at a pH 0.25 units above the pH value at $\triangle E$, and $\triangle E'$ is that at a pH 0.25 below. M is the logarithm conversion figure. In the case of eq. (4) the sodium ion activity has to be estimated. This is, of cause, a difficult task. In the measurements made by the author, the buffer concentration was kept low and most of the sodium ions are due to NaCl. This gives a simpler solution from the point of view of activity calculations. In all cases the mean activity coefficient of the electrolyte has been applied to Na^+, and has been taken from different papers [17-19]. However, even if the accuracy of the activity figures is moderate, they are to be preferred to the concentration figures used in other treatments. In Figs. 2—13 plots of the functions (3) and (4) are shown, and the mean curve from them will be used later for further calculations.

THEORETICAL

Applied to a system where ions are distributed between different phases, the Boltzmann energy distribution law can be written:

$$_iC_j = \exp(-{}_i\varepsilon_j/RT) \tag{5}$$

where $_iC_j$ = concentration of an ion i in a phase j; $_i\varepsilon_j$ = total energy for an ion i in a phase j. If considering the physical model, and eq. (5) is applied to one of the two glass electrode surfaces, *i.e.* to the system solution — surface layer, then:

$$_iC_s = \exp(-{}_i\varepsilon_s/RT) \tag{5a}$$

$$_iC_g = \exp(-{}_i\varepsilon_g/RT) \tag{5b}$$

$$_iC_g = {}_iC_s \cdot \exp[-({}_i\varepsilon_g - {}_i\varepsilon_s)/RT] \tag{6}$$

where: $_iC_s$ = concentration in the solution of an ion i, $_iC_g$ = concentration of an ion i in the *surface layer* of the glass, defined in accordance with the *physical model*, $_i\varepsilon_s$ = total energy in the solution for an ion i, $_i\varepsilon_g$ = total energy in the surface layer for an ion i.

Let: $_iU_s$ = equilibrium energy in the solution for an ion i, $_iU_g$ = equilibrium energy in the surface layer for an ion i.

Then:

$$_i\varepsilon_s = {}_iU_s + \text{constant}$$

$$_i\varepsilon_g = {}_iU_g + zFE + \text{constant}$$

where E is the difference in electrical potential between solution and surface layer, and z is the valency of i.

From this:

$$ {}_iC_g = {}_iC_s \cdot \exp\left[-({}_iU_g + zFE - {}_iU_s)/RT\right] \quad (6b) $$

As the logarithm of the activity coefficient gives the difference between actual and ideal energies in the solution, then if the ideal energy is written ${}_iU_{os}$:

$$ {}_iC_g = {}_ia_s \cdot \exp\left[-({}_iU_g + zFE - {}_iU_{os})/RT\right] \quad (7) $$

where ${}_ia_s$ is the activity of the ion in the solution.

If we define: ${}_iU_{os} - {}_iU_g = Q_i$
then

$$ \Sigma\, {}_ia_s \cdot \exp\left[(Q_i - zFE)/RT\right] = \Sigma\, {}_iC_g \quad (8) $$

This can be regarded as the fundamental equation of the glass electrode.

In the following treatment we shall for simplicity select the ions H_3O^+ and Na^+. In this case eq. (8) can be written:

$$ E = \frac{RT}{F} \ln\left[a_{H_3O+} \cdot \exp\left(Q_{H_3O+}/RT\right) + a_{Na+} \cdot \exp\left(Q_{Na+}/RT\right)\right] - \frac{RT}{F} \ln \Sigma\, {}_iC_g \quad (9) $$

Let $X_i = {}_iC_g/\Sigma_i C_g$, and define $Q_i \to Q_{oi}$ ${}_iC_g \to {}_iC_{og}$ when $X_i \to 1$.
If $a_{Na+} \cdot \exp\left(Q_{Na+}/RT\right) \ll a_{H_3O+} \cdot \exp\left(Q_{H_3O+}/RT\right)$ eq. (9) can be written:

$$ E' = Q_{oH_3O+}/F - \frac{RT}{F} \ln \Sigma\, {}_iC_{og} - \frac{MRT}{F}\,\mathrm{pH} \quad (10) $$

Let

$$ Q_{oH_3O+}/F - \frac{RT}{F} \ln \Sigma\, {}_iC_{og} = e_o $$

then

$$ E' = e_o - \frac{MRT}{F}\,\mathrm{pH} \quad (10a) $$

This is, except e_o, the equation for the hydrogen electrode. The differences in e_o for the two active surfaces of the glass electrode:

$$ e_o'' - e_o' = \varphi \quad (11) $$

is an expression of the *asymmetry potential, i.e.* the deviation in E_o in comparison with the hydrogen electrode. If the electrode surfaces change their properties in different ways, this will cause a variation in φ. However, for short periods (of the order 100 hours) φ is a constant.

If it is not possible to neglect the Na^+-term, and if we define:

$$ \Delta E = E - E' \quad (12) $$

then, since

$$ \Sigma\, {}_iC_g/\Sigma\, {}_iC_{og} = X_{H_3O+} + X_{Na+} $$

$$ (X_{H_3O+} + X_{Na+}) \cdot \exp\left[(Q_{oH_3O+} - Q_{H_3O+})/RT\right] \cdot \exp\left(F\Delta F/RT\right) = $$

$$ \frac{a_{Na+}}{a_{H_3O+}} \exp\left[(Q_{Na+} - Q_{H_3O+})/RT\right] + 1 \quad (13) $$

Applying the distribution law once more:

$$\frac{X_{Na+}}{X_{H_3O+}} = \frac{a_{Na+}}{a_{H_3O+}} \exp\ [(Q_{Na+} - Q_{H_3O+})/RT]$$

and $$\frac{a_{Na+}}{a_{H_3O+}} \exp\ [(Q_{Na+} - Q_{H_3O+})/RT] + 1 = \frac{X_{Na+} + X_{H_3O+}}{X_{H_3O+}}$$

Combining this with eq. (13) gives:

$$F \cdot \Delta E/RT = (Q_{H_3O+} - Q_{oH_3O+})/RT - \ln\ X_{H_3O+} \qquad (14)$$

So far nothing has been assumed concerning the *number* of points for cationic adsorption in the surface layer. Here the assumption will be made that *the number of points is constant.* The reason for this is that only a destruction of the surface layer will change that number, and the possibility of such a destruction seems to be remote. This can be concluded from the fact that the asymmetry potential remains constant, even if the electrode is alternately brought in contact with acid and alkaline solutions, and also from the reproducible alkaline behaviour.

From this assumption we get:

$$\Sigma_i C_g = \Sigma_i C_{og} = \text{constant} \qquad (15)$$

and $$X_{H_3O+} + X_{Na+} = 1 \qquad (16)$$

It may be pointed out that eq. (16) contains *concentrations, i.e. numbers* of ions. However, the *activity* of the adsorbed ions may change with the state of adsorption, and this will be revealed by variations in U_g and Q_i.
By applying eq. (16), eq. (13) is reduced to:

$$\exp\,[(Q_{oH_3O+} - Q_{H_3O+})/RT] \cdot \exp\,(F\Delta E/RT) = \frac{a_{Na+}}{a_{H_3O+}} \exp[(Q_{Na+} - Q_{H_3O+})/RT] + 1 \qquad (17)$$

From the treatment given above it is possible to calculate X_{H_3O+}, X_{Na+}, $(Q_{H_3O+} - Q_{oH_3O+})/RT$ and $(Q_{oH_3O+} - Q_{Na+})/RT$ from experimental data on the alkaline error under different conditions. This can be done from two separate values of both ΔE and a_{Na+}/a_{H_3O+} by means of eq. (14) and eq. (17). The first step is to determine $\exp\,[(Q_{oH_3O+} - Q_{H_3O+})/RT]$, keeping a_{Na+} constant.

In practice it is not possible to attain these conditions, as the sodium ion activity changes with the ionic strength when pH is altered. However, errors from this source can be kept low if a suitable solution is used, containing a small amount of buffer with most of the sodium ions present as NaCl. We write:

$$\exp\ [(Q_{oH_3O+} - Q_{H_3O+})/RT] = \gamma$$

$$\exp\ [(Q_{Na+} - Q_{H_3O+})/RT] = \delta$$

From eq. (17) $$\gamma \cdot \exp\ (F\Delta E/RT) = \delta \frac{a_{Na+}}{a_{H_3O+}} + 1$$

and for $\triangle E''$ and $\triangle E'$

$$\gamma \cdot \exp\ (F\triangle E''/RT) = \delta \frac{a_{Na+}}{a''_{H_3O+}} + 1$$

$$\gamma \cdot \exp\ (F\triangle E'/RT) = \delta \frac{a_{Na+}}{a'_{H_3O+}} + 1$$

i.e.

$$\frac{\gamma \cdot \exp\ (F\triangle E'/RT) - 1}{\gamma \cdot \exp\ (F\triangle E''/RT) - 1} = \frac{a''_{H_3O+}}{a'_{H_3O+}}$$

($\triangle E' < \triangle E''$ and correspondingly $a'_{H_3O+} > a''_{H_3O+}$)

With a pH difference of 0.50, which is adequate for over all accuracy in the measurements, we have: $a''_{H_3O+}/a'_{H_3O+} = 1/\sqrt{10}$ and

$$\frac{1}{\gamma} = \exp\left[(Q_{H_3O+} - Q_{oH_3O+})/RT\right] = \frac{3.16\ \exp(F\triangle E'/RT) - \exp\ (F\triangle E''/RT)}{2.16} \quad (18)$$

Putting as a first approximation $\triangle E = (\triangle E' + \triangle E'')/2$, which is equivalent to assuming that the alkaline error function is a straight line in the small interval between $\triangle E'$ and $\triangle E''$, and combining eq. (14) and eq. (18):

$$X_{H_3O+} = \frac{1.46}{\exp\ (F(\triangle E'' - \triangle E')/2RT]} - 0.462 \cdot \exp\ [F(\triangle E'' - \triangle E')/2RT] \quad (19)$$

From the earlier equation:

$$\frac{X_{Na+}}{X_{H_3O+}} = \frac{a_{Na+}}{a_{H_3O+}} \exp\ [(Q_{Na+} - Q_{H_3O+})/RT]$$

and eq. (14) we get:

$$\ln\ X_{Na+} + (Q_{oH_3O+} - Q_{Na+})/RT = \ln a_{Na+} + M \cdot pH - F\triangle E/RT \quad (20)$$

As $X_{H_3O+} + X_{Na+} = 1$ we can derive X_{Na+} and $(Q_{oH_3O+} - Q_{Na+})/RT$ from eq. (19) and eq. (20). As can be seen from above, it is convenient to plot the functions (3) and (4) from the experimental data, as this considerably reduces the calculation required.

In order to deduce an alkaline error equation, it is necessary to find the dependence of $(Q_i - Q_{oi})/RT$ on X_i. We will here start with the assumption earlier used for localized adsorption layers, *e.g.* by Fowler [20], that the energy of interaction can be expressed as the sum of contributions of pairs of nearest neighbours. If every adsorption point has n neighbours, and an ideal distribution is assumed, every site has a possibility X_i of being occupied by an ion i; the number of pairs will be $\frac{n}{2} \cdot X_i$. As it is assumed that the change in interaction energy, for the whole system given as $X_i \cdot d_i U_g$, is proportional to the change in number of pairs, we get:

$$X_i \cdot d_i U_g = k_2 \cdot \frac{n}{2} dX_i \quad (21)$$

Or, if we write $\frac{2}{n k_2} = k_3$,

$$\frac{dX_i}{X_i} = k_3 \cdot d_i U_g \tag{22}$$

and $$\ln X_i = k_3 \cdot d_i U_g + \text{constant} \tag{23}$$

As we defined ${}_iU_g \rightarrow {}_iU_{og}$ when $X_i \rightarrow 1$, the value of the constant is $-{}_iU_{og}$.

and $$\ln X_i = k_3({}_iU_g - {}_iU_{og}) \tag{23a}$$

Regarding the significance of Q_i and Q_{oi} and writing $k_3 \cdot RT = k_4$:

$$\ln X_i = k_4(Q_{oi} - Q_i)/RT \tag{24}$$

From the different experimental figures, plotted in accordance with eq. (3) and eq. (4), and by means of eq. (16), (18), (19) and (20) the functions

$$-\ln X_{H_3O+} = f\left(\frac{Q_{H_3O+} - Q_{oH_3O+}}{RT}\right)$$

$$-\ln X_{Na+} = f\left(\frac{Q_{oH_3O+} - Q_{Na+}}{RT}\right)$$

have been calculated for the different electrodes at different conditions. As can be seen from the diagrams, Figs. 14—17, the requirements of eq. (24) are fullfilled, *i.e.* the experimental results are in agreement with the theoretical equation:

From the distribution law we have:

$$X_i = \frac{a_i}{\Sigma_i C_{og}} \exp\ [(Q_i - EF)/RT]$$

and from this and eq. (24):

$$X_i^{(1 + k_4)/k_4} = \frac{a_i}{\Sigma_i C_{og}} \cdot \frac{\exp\ (Q_{oi}/RT)}{\exp\ (FE/RT)} \tag{25}$$

and $$X_{H_3O+} = \left(\frac{a_{H_3O+}}{\Sigma_i C_{og}} \cdot \frac{\exp\ (Q_{oH_3O+}/RT)}{\exp\ (FE/RT)}\right)^{k_{4H_3O+}/(1 + k_{4H_3O+})} \tag{25a}$$

$$X_{Na+} = \left(\frac{a_{Na+}}{\Sigma_i C_{og}} \cdot \frac{\exp\ (Q_{oNa+}/RT)}{\exp\ (FE/RT)}\right)^{k_{4Na+}/(1 + k_{4Na+})} \tag{25b}$$

Let $(1 + k_{4H_3O+})/k_{4H_3O+} = \vartheta$ and $(1 + k_{4Na+})/k_{4Na+} = \tau$; and we get from eq. (25a) and eq. (25b):

$$\frac{X_{H_3O+}^{\vartheta}}{X_{Na+}^{\tau}} = \varkappa \cdot \frac{a_{H_3O+}}{a_{Na+}} \tag{26}$$

In this treatment eq. [26) is therefore the adsorption isotherm of the glass electrode. As $\Sigma\ X_i = 1$, the general equation for a system containing two different univalent ions can be written:

$$\Sigma \left(\frac{\exp\ (Q_{oi}/RT)}{\Sigma_i C_{og}} \cdot \frac{a_i}{\exp\ (FE/RT)}\right)^{k_{4i}/(1 + k_{4i})} = 1 \tag{27}$$

(This treatment probably cannot be applied in its simple form to multi-ion systems, as the adsorption sites not occupied by the ion i can be occupied by more than one kind of ion. This makes the treatment of the interaction energies more complicated. However, in practice the case of two univalent ions is of most interest.)

Applied to H_3O^+ and Na^+ eq. (27) will be, if $p = 1/\vartheta$ and $q = 1/\tau$:

$$\left(\frac{\exp(Q_{oH_3O+}/RT)}{\Sigma_i C_{og}} \cdot \frac{a_{H_3O+}}{\exp(FE/RT)}\right)^p + \left(\frac{\exp(Q_{oNa+}/RT)}{\Sigma_i C_{og}} \cdot \frac{a_{Na+}}{\exp(FE/RT)}\right)^q = 1 \quad (28)$$

This equation can be transformed:

$$-p \cdot pH + p \cdot Q_{oH_3O+}/M \cdot RT - p \cdot F \cdot E/M \cdot RT - p \cdot \log \Sigma_i C_{og} =$$
$$\log\left[1 - K\left(\frac{a_{Na+}}{\exp(FE/RT)}\right)^q\right] \text{ where } K = \left(\frac{\exp(Q_{oNa+}/RT)}{\Sigma_i C_{og}}\right)^q.$$

Since $-pH = FE'/MRT - Q_{oH_3O+}/MRT + \log \Sigma_i C_{og}$; and as $\Delta E = E - E'$ therefore

$$\Delta E = -\frac{MRT}{pF} \cdot \log\left[1 - K\left(\frac{a_{Na+}}{\exp(FE/RT)}\right)^q\right] \quad (29)$$

or

$$\Delta pH = -\frac{1}{p} \cdot \log\left[1 - K\left(\frac{a_{Na+}}{\exp(FE/RT)}\right)^q\right] \quad (30)$$

It is interesting to see that by expanding eq. (30) in

$$\log(1-x) \sim -x \ldots\ldots\ldots$$

we obtain

$$\Delta pH \sim \frac{K}{p}\left(\frac{a_{Na+}}{\exp(FE/RT)}\right)^q$$

and from this:

$$\log \Delta pH = q \cdot (pH_{measured} + \log a_{Na+}) + \text{constant} \quad (31)$$

and, with the approximation $a_{Na+} = \text{constant} \cdot C^a_{Na+}$:

$$\log \Delta pH = a \cdot pH_{measured} + b \cdot \log C_{Na+} + \text{constant} \quad (32)$$

This is the same as Jordan's empirical equation [21, 22].

Eq. (29) can also be written:

$$\frac{1}{\exp(pF\Delta E/RT)} = 1 - \left[\frac{\exp[(Q_{oNa+} - Q_{oH_3O+})/RT]}{\exp(F\Delta E/RT)} \cdot \frac{a_{Na+}}{a_{H_3O+}}\right]^q \quad (33)$$

As, in accordance with eq. (24)

$$k_4 = \frac{\ln X_i}{(Q_{oi} - Q_i)/RT}$$

is $k_4 = \infty$ if not the interaction is considered. In such a case $p = q = 1$, and from eq. (33):

$$\log\,[\exp(F\triangle E/RT) - 1] = \mathrm{pH} + \log\, a_{Na+} \cdot \exp[(Q_{oNa+} - Q_{oH_3O+})/RT] \quad (34)$$

This is the same as eq. (1) derived by Dole, neglecting interaction. (Eq. (1) contains C_{Na+} as Dole starts from what has been defined as ${}_iU_s$ in this paper, instead of the constant value ${}_iU_{os}$.) As mentioned earlier, the lack of agreement is that the experimental alkaline error figures do not give the slope of unity, as the equation requires.

As, in accordance with the following

$$\exp\,[(Q_{oNa+} - Q_{oH_3O+})/RT] \cdot \frac{a_{Na+}}{a_{H_3O+}} = \beta$$

$$F \cdot \triangle E/RT = x$$

eq. (33) can be written:

$$\frac{1}{e^{px}} = 1 - \frac{\beta^q}{e^{qx}} \text{ or } e^{qx} - e^{(q-p)x} = \beta^q$$

and after expanding in series and approximating, we get:

$$e^{qx} - e^{(q-p)x} \sim p \cdot x$$

However, this is also the first member of the expression for $p(e^x - 1)$, and we get:

$$p(e^x - 1) \sim \beta^q$$

And from this

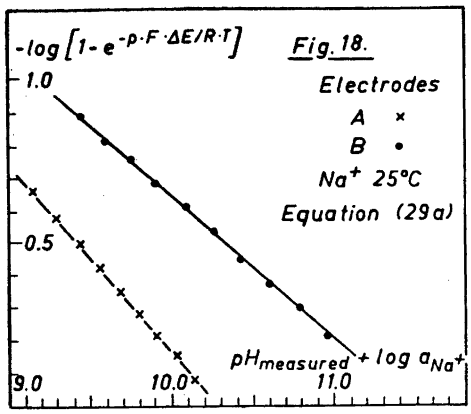
$$\frac{1}{q} \cdot \log[\exp(F\triangle E/RT) - 1] = \mathrm{pH} + \log\, a_{Na+} \cdot \exp[(Q_{oNa+} - Q_{oH_3O+})/RT] + \frac{1}{q} \cdot \log\, p \quad (35)$$

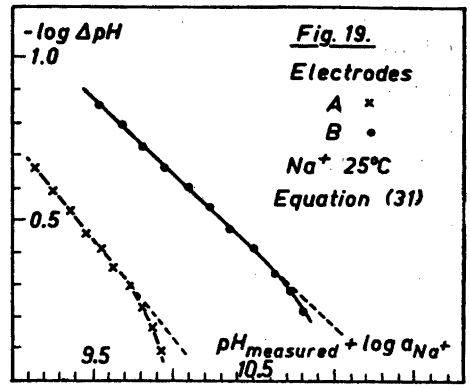
This equation is the same as eq. (1), except that it does not demand a slope of unity, and so can be brought into agreement with the experimental results.

Eq. (29) can also be written:

$$\frac{1}{q} \cdot \log[1 - \exp(-pF\triangle E/RT)] = \mathrm{pH} + \log\, a_{Na+} + \log\, K \quad (29a)$$

From the results obtained for the electrodes A and B, a check on the validity of eq. (29a), (31) and (35) can be obtained from Figs. 18—20. (The values of p are calculated from Fig. 14.) As can be expected from the approximations introduced, the agreement is good for low and moderate alkaline errors, but deviations appear at higher values. Deviations of the same kind can also be found in Dole's investigations, *e.g.* Dole [12], p. 271, Fig. 16.8. In the case of eq. (29a), where no mathematical approximations are introduced, it can be found that the equation is valid also at high alkaline errors, so that it describes the experimental behaviour of the glass electrodes in alkaline solutions.

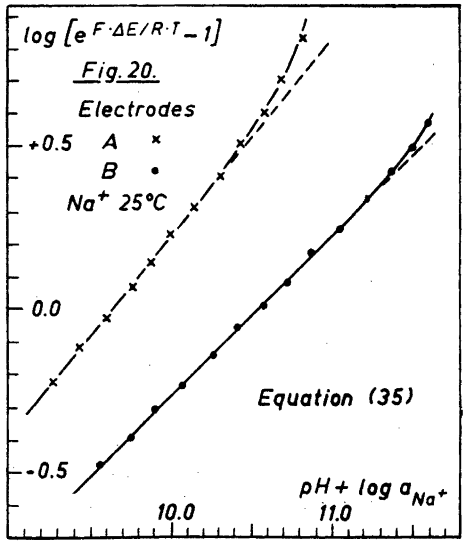


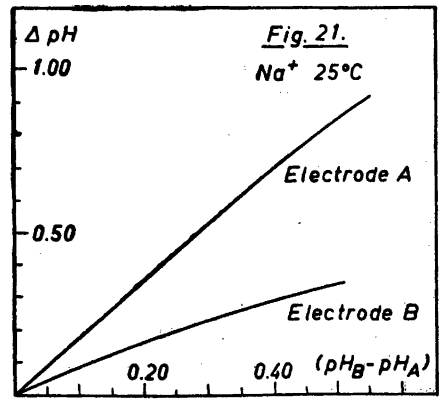


DISCUSSION

In the treatment given above, it has been shown that when the interaction in the surface layer is taken into account, an alkaline error equation can be derived, which is in good agreement with experimental results. The equation can also be approximated to the empirical equation suggested by Jordan, and to an equation of the Dole type, but with a slope in accordance with experimental data. It has also been shown that the interaction can be expressed as the sum of contributions of nearest neighbours. An adsorption isotherm for the glass electrode has been deduced, and the asymmetry potential given thermodynamic significance.

A more exact treatment of the significance of "contributions of nearest neighbours" would of cause be of great interest, but at present there is in-





sufficient theoretical and experimental background. The adsorption isotherm derived is probably of interest for ion exchange resins, where studies on different resins could give an indication of the interaction on a more general basis.

In the case of the glass electrode it would be of interest to determine the absolute amount of adsorbed ions, for example by means of radioactive isotopes. However, this approch is also difficult since it cannot be assumed that *e.g.* tritium is adsorbed to the same extent as protium, and furthermore the determination of tritium is very complicated. Other difficulties arise from the probable isotope equilibrium with water and the fact that the removal of excess solution from the glass will probably disturb the adsorption equilibrium.

However, some interesting figures can be obtained from the potential measurements. If in Figs. 15—17 an extrapolation is made to $-\ln X_{Na+} = 0$, *i.e.* $X_{Na+} = 1$, it is possible to determine:

$$(Q_{oH_3O+} - Q_{oNa+})/RT$$

This quantity is essentially the energy involved in the dissociation, so that a kind of dissociation constant, K_o, can be found from the formula:

$$(Q_{oH_3O+} - Q_{oNa+})/RT = -\ln K_o$$

or

$$pK_o = (Q_{oH_3O+} - Q_{oNa+})/M \cdot RT \qquad (36)$$

It may be expected that pK_o will be of the same order as the pH at which the alkaline error appears. pK_o can be considered as a characteristic of the glass electrode. Other characteristics are the interaction constants k_{4H_3O+} and k_{4Na+} in eq. (24) and these and pK_o will completely define the alkaline behaviour of the electrode. In Table 1 the values in question can be found for the electrodes studied. It would be of a great interest to determine these characteristics as functions of the electrode glass composition, and so facilitate the search for suitable glass electrode glasses.

A DIFFERENTIAL MEASURING METHOD

In the Swedish Patent 129833 a method is described for correcting the alkaline error in pH measurements when the activity of the sodium ion (or other) is unknown. The principle is that the measurements are made with two glass electrodes of different, but known, alkaline error functions. From the

Table 1. Characteristic constants of some glass electrodes.

Electrode and ion.	Temperature C°	pK_o	k_{4H_3O+}	k_{4Na+}
A Na+	25	10.4	1.08	0.36
B Na+	25	11.3	1.00	0.24
C Na+	10	11.6	1.00	0.32
C Na+	25	11.3	1.00	0.44
C Na+	50	10.1	1.00	2.00
C Li+	10	12.6	1.25	0.27
C Li+	25	12.2	1.25	0.32
C Li+	50	10.5	1.25	0.42
D Na+	25	14.3	0.41	1.00
E Na+	25	15.5	0.32	0.48

difference in measured pH for the two electrodes, pH_1—pH_2, the alkaline error for each can be found from a predetermined diagram. If curves similar to Fig. 2 are plotted from experimental data for the electrodes, each value of $M \cdot pH + \ln a_{Na+}$ corresponds to the alkaline errors ΔpH_1 and ΔpH_2, and as pH_1—$pH_2 = \Delta pH_2 - \Delta pH_1$ the required functions

$$pH_1 - pH_2 = f(\Delta pH_1) = g(\Delta pH_2)$$

can be determined. Such functions for the electrodes A and B are shown in Fig. 21.

The method seems to be valuable as highly stable low alkaline error electrodes seems to be rare, and for high temperature measurements, where even low alkaline error electrodes show a considerable deviation from ideal behaviour, and also when such electrodes are used for pH determinations in a range of high alkalinity. The method is also of interest when measuring at low temperatures, where the electrical resistance of some of said electrodes is rather high.

The author wishes to thank the board of *Rydboholms A. B.* for permission to publish this paper and Mr. A. Lindberg for his valuable assistance in the experimental work, and is also indebted to Professor N. Gralén, Dr. J. O'M. Bockris, Dr. T. Vickerstaff, Mr. E. Blomgren and Mr. A. Olofson for their kind interest.

Equilibria in Systems with Polynuclear Complex Formation

III. Derivation of a Generalized Bodländer Formula and a General Method of Calculating Equilibrium Constants

BENGT HEDSTRÖM

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden *

A number of relationships have been derived which apply to equilibrium mixtures of two reactants, A and B, and their condensation products, of the general type A_pB_q. Denoting total, stoichiometric concentrations with capital letters, and equilibrium concentrations with small letters, the following relationship, concisely stated in Jacobian notation, is found to be universally valid:

$$J(B,\ \ln\ b/\ln\ a,\ A) \equiv \frac{\partial(B,\ \ln\ b)}{\partial(\ln\ a,\ A)} = 1$$

Solving for $\alpha = a/A$, the following equation results

$$\log\ \alpha = \left[\int_0^B (\partial\ \log\ \beta/\partial A)_B dB\right]_A$$

From this equation, α and hence a, can be calculated graphically from a set of known values of A, B and $\beta = b/B$. The equations presuppose constant activity factors, an assumption which is approximately correct for solutions of high, and constant ionic strength.

In the latter part of the paper a straightforward method is presented which can be used to find the composition of poly- and mononuclear complexes and the corresponding equilibrium constants from experimental data on any set of equilibria between two reactants.

The methods presented in this paper have been successfully applied by the author in a study on the hydrolysis of the iron(III) ion, Fe^{3+}.

This paper is number three in a series dealing with the problem of interpreting experimental data on polynuclear complex formation. In the two previous papers (AB I[1], AB II[2]) Sillén has worked out in detail the mathematics of so-called "core and links" mechanisms. He derived very useful and simple criteria by means of which data on polynuclear complex formation can be tested. Although the methods developed in AB I and AB II seem to be of far-

* Present address: Mo och Domsjö AB, Husums Sulfatfabrik, Husum, Sweden.

reaching applicability, they do not cover all possible types of complex formation. Sillén purposely restricted his investigation to the "core and links" type of complex, which he has found to be rather common.

The field of polynuclear complex chemistry is in its infancy and it is, therefore, difficult to know which of several possible methods of interpreting experimental data will be the most useful in the majority of cases met with in practice. The accuracy of experimental data is, indeed, limited. One may therefore question if it is at all possible, at the present time, to prove the existence of more than a very limited number of species in a complex forming system, or, to put it another way, one may ask if experimental data, even in a favorable case, can supply more information than that represented by numerical values of, say three or four equilibrium constants. If this is so, it might, in an actual case, by very difficult to know exactly what is proof of the existence of the different possible complexes and what is merely a convenient method of correlating the experimental data in terms of the law of mass action. The methods in AB I and AB II should in many cases be useful for rejecting faulty hypotheses and also in choosing the one which is likely to be most consistent with the measurements.

In this paper a somewhat different method of attack is used in an effort to develop, in principle, a generally valid method of interpreting data on the formation of polynuclear complexes of the general type A_pB_q. The leading principle in the present work can be stated in the following way: No *a priori* assumption, whatsoever, is made as to the compositions or abundance of the complexes formed. This implies that the compositions of the complexes and the corresponding equilibrium constants will be obtained directly from a straight-forward method of calculation. In the author's opinion, the methods here presented should be of value as a supplement or an alternative to the methods in AB I and AB II.

The first part of the paper is devoted to the problem of calculating the equilibrium concentration of one of the reactants from a series of known values of the equilibrium concentration of the other and the total concentrations of the two reactants. Very often it is not possible to measure the equilibrium concentrations of both reactants directly. It is obvious that in such a case the interpretation of the data is made simpler if the unknown concentration can first be calculated, without presupposing any particular reaction mechanism.

In the second part of the paper, a method of interpretation of equilibrium data is presented which should be applicable to any type of mono- or polynuclear complex system, *provided data of sufficient accuracy are available.*

This paper is mathematical in character. The author has purposely omitted detailed discussions or examples of applications in order that the style should be as concise and as simple as possible. The methods presented here have been successfully applied in the author's investigation on the hydrolysis of the iron(III) ion, Fe^{3+}. The reader is referred to this work [3] for a detailed example of the application of the methods given in this paper.

List of symbols

b = equilibrium concentration of B
$F_{q+1} = (F_q - I_q)/ab$
$I_q = q \sum_p \varkappa_{pq} a^{p-1}$
p = number of A atoms in the complex A_pB_q
q = number of B atoms in the complex A_pB_q
S = complexity sum (4)
x, y = arbitrary, independent variables, used in equations 10 and 10 a (see text)
$\alpha = a/A$
$\beta = b/B$
$\varkappa_{pq}$ = equilibrium constant for the reaction $pA + qB = A_pB_q$

DERIVATION OF A GENERALIZED BODLÄNDER'S FORMULA

If possible, emf-methods are generally preferred in the study of complex formation. The reasons are that they are accurate and relatively simple from the experimental point of view. A few recent modifications of the emf-method for studying complex equilibria have been of great importance in simplifying both the experimental technique and the interpretation of the data obtained.

These modifications are: Activity factors are kept constant by working with solutions of high, constant ionic strength. The equilibrium solutions under study are prepared by a titration technique [4]. In this way a large amount of experimental data can be obtained in a relatively short time and with a minimum of manipulation. By using two (in some cases three) burets during an emf-titration, the total, stoichiometric concentration of one of the reactants can be kept constant, while the other is varied. A series of such titrations at different total, stoichiometric concentrations of one of the reactants often covers the whole range of complexes of the two reactants, and is very convenient for the mathematical interpretation of the data.

The aim of the following reasoning and deductions is to show how the equilibrium concentration of one of the reactants is fixed by the other in all circumstances, and how it can be calculated from data of the kind mentioned above, without presupposing any particular reaction mechanism.

In the case of a *mono*nuclear process the solution of this problem is the well-known Bodländer formula [4] (see eq. 14 below).

The formulas derived below may be considered as extensions of this formula. In contrast to Bodländer's formula they are, however, applicable to any set of mono- and *poly*nuclear complexes.

Consider an equilibrium involving two reactants A and B, forming a condensation product A_pB_q:

$$pA + qB \rightleftharpoons A_pB_q$$

In the special case of an equilibrium between a metal ion and a complex forming substance, B may symbolize the metal ion and A the ligand. A set

of equilibria of this kind may exist simultaneously, since p and q may, in general, have any positive, integral values.

On applying the law of mass action to these equilibria, equations of the following general type are obtained:

$$\frac{[A_pB_q]}{a^p b^q} = \varkappa_{pq} \tag{1}$$

where $\varkappa_{pq}$ denotes the equilibrium constant, and a and b the equilibrium concentrations of A and B, respectively. Activity coefficients are assumed to be constant, as a consequence of working in a medium of high, and constant ionic strength; the law of mass action will therefore apply to concentrations as well as to activities. From stoichiometric considerations

$$A = a + \Sigma\, p\varkappa_{pq}\, a^p b^q \tag{2}$$

$$B = b + \Sigma\, q\varkappa_{pq}\, a^p b^q \tag{3}$$

where A and B denote total, stoichiometric concentrations. The summations have been carried out over all pairs of values of p and q except (1;0) and (0;1). The absence of competitive complex-formation with any third reagent C is assumed.

From now on the problem is a purely mathematical one. The method adopted by the author in order to find the universal relationship between a and b, consists of an elimination of the unknowns p, q, and $\varkappa_{pq}$ by successive, partial differentiation.

Let us first define the function S

$$S = \Sigma\, \varkappa_{pq}\, a^p b^q \tag{4}$$

Sillén [1] introduced the term "complexity sum" for this expression. Partial differentiation of (4) with respect to ln a and ln b gives

$$\left(\frac{\partial S}{\partial \ln a}\right)_b = a\left(\frac{\partial S}{\partial a}\right)_b = \Sigma\, p\varkappa_{pq}\, a^p b^q \tag{5}$$

$$\left(\frac{\partial S}{\partial \ln b}\right)_a = b\left(\frac{\partial S}{\partial b}\right)_a = \Sigma\, q\varkappa_{pq}\, a^p b^q \tag{6}$$

Substituting into equations (2) and (3)

$$\left(\frac{\partial S}{\partial \ln a}\right)_b = A - a \tag{7}$$

$$\left(\frac{\partial S}{\partial \ln b}\right)_a = B - b \tag{8}$$

A second differentiation of (7) with respect to ln b and of (8) with respect to ln a, and application of the identity

$$\left(\frac{\partial^2 S}{\partial \ln a\ \partial \ln b}\right) = \left(\frac{\partial^2 S}{\partial \ln b\ \partial \ln a}\right)$$

finally gives

$$\left(\frac{\partial B}{\partial \ln a}\right)_b = \left(\frac{\partial A}{\partial \ln b}\right)_a \tag{9}$$

At this point the unknowns p, q, and $\varkappa_{pq}$ have been eliminated.

Equation (9) is not yet very useful in the calculation of a from b, or *vice versa*, since a and b cannot be expressed explicitly. It may, however, be transformed to useful relationships by a transformation of variables. As in the case of the usual thermodynamic functions, the most convenient way of performing this transformation is by means of the Jacobian (functional) determinant [5,6]. In terms of Jacobians, equation (9) can be written

$$\frac{\partial(\mathrm{B}, \ln b)}{\partial(\ln a,\ \ln b)} = \frac{\partial(A, \ln a)}{\partial(\ln b,\ \ln a)} \tag{9a}$$

from which we get the most concise, basic form of the universal relationship between the variables involved

$$J(B,\ \ln\ b/\ln\ a,\ A) \equiv \frac{\partial(B,\ \ln\ b)}{\partial(\ln\ a,\ A)} = 1 \tag{9b}$$

If two arbitrary quantities x and y are chosen as independent variables, it follows from (9b)

$$\frac{\partial(B,\ \ln\ b)}{\partial(x,\ y)} = \frac{\partial(\ln\ a,\ A)}{\partial(x,\ y)} \tag{10}$$

or in determinant notation

$$\begin{vmatrix} \left(\frac{\partial B}{\partial x}\right)_y & \left(\frac{\partial B}{\partial y}\right)_x \\ \left(\frac{\partial \ln b}{\partial x}\right)_y & \left(\frac{\partial \ln b}{\partial y}\right)_x \end{vmatrix} = \begin{vmatrix} \left(\frac{\partial \ln a}{\partial x}\right)_y & \left(\frac{\partial \ln a}{\partial y}\right)_x \\ \left(\frac{\partial A}{\partial x}\right)_y & \left(\frac{\partial A}{\partial y}\right)_x \end{vmatrix} \tag{10a}$$

As an illustration, let $x = \ln a$ and $y = \ln b$. We then get from equation (10)

$$\left(\frac{\partial B}{\partial \ln a}\right)_b = \left(\frac{\partial A}{\partial \ln b}\right)_a$$

which is identical with equation (9). If we focus attention on the five quantities A, B, $\ln a$, $\ln b$, and $\beta = b/B$, ten pairs of independent variables are possible. For illustrative purposes a few of these cases have been worked out below. It is a simple matter to derive formulas based upon other sets of independent variables.

Special choices of independent variables

With A *and* B as independent variables, (10) takes the form

$$\left(\frac{\partial \ln b}{\partial A}\right)_B = \left(\frac{\partial \ln a}{\partial B}\right)_A \tag{11}$$

On introducing $\alpha = a/A$, and $\beta = b/B$, instead of a and b, we get from (11)

$$\left(\frac{\partial \ln \beta}{\partial A}\right)_B = \left(\frac{\partial \ln \alpha}{\partial B}\right)_A \tag{11a}$$

With *B and ln a* as independent variables (10) gives

$$\left(\frac{\partial \ln b}{\partial \ln a}\right)_B = -\left(\frac{\partial A}{\partial B}\right)_a \tag{12}$$

If we assume that all complexes are *mononuclear in* B, thus can be written as BA_n, then

$$S = b\ \Sigma \varkappa_n a^n = b \cdot f(a) \tag{13}$$

and from (7) and (8)

$$A = a + baf'(a); \qquad B = b + bf(a)$$

$$\left(\frac{\partial A}{\partial B}\right)_a = \frac{af'(a)}{1 + f(a)} = \frac{A - a}{B} \tag{13a}$$

For complexes mononuclear in B, (12) thus takes the form

$$\left(\frac{\partial \ln b}{\partial \ln a}\right)_B = -\frac{A - a}{B} \tag{14}$$

which is identical with Bodländer's well-known formula; $\frac{A - a}{B}$ is the average ligand number, which is often denoted by $\bar{n}$; in AB I and AB II it was denoted Z.

Choosing *A and ln b* as independent variables (10) gives an equation of the same form as (12)

$$\left(\frac{\partial \ln a}{\partial \ln b}\right)_A = -\left(\frac{\partial B}{\partial A}\right)_b \tag{15}$$

With *B and ln b*, we find

$$\left(\frac{\partial \ln a}{\partial B}\right)_b \left(\frac{\partial A}{\partial \ln b}\right)_B - \left(\frac{\partial A}{\partial B}\right)_b \left(\frac{\partial \ln a}{\partial \ln b}\right)_B = 1 \tag{16}$$

With *B and β* as independent variables, (10a) yields

$$\left(\frac{\partial A}{\partial \ln \beta}\right)_B \left(\frac{\partial \ln a}{\partial B}\right)_\beta - \left(\frac{\partial \ln a}{\partial \ln \beta}\right)_B \left(\frac{\partial A}{\partial B}\right)_\beta = 1 \tag{17}$$

Choosing *ln a and β* as independent variables, one gets

$$\left(\frac{\partial A}{\partial \beta}\right)_a + \left(\frac{\partial \ln b}{\partial \ln a}\right)_\beta \left(\frac{\partial B}{\partial \beta}\right)_a - \left(\frac{\partial B}{\partial \ln a}\right)_\beta \left(\frac{\partial \ln b}{\partial \beta}\right)_a = 0 \tag{18}$$

Finally with *ln b and β* as independent variables, one gets from (10a)

$$\left(\frac{\partial B}{\partial \beta}\right)_b - \left(\frac{\partial \ln a}{\partial \beta}\right)_b \left(\frac{\partial A}{\partial \ln b}\right)_\beta + \left(\frac{\partial A}{\partial B}\right)_b \left(\frac{\partial \ln a}{\partial \ln b}\right)_\beta = 0 \tag{19}$$

DISCUSSION

It should be pointed out that the equations derived in the preceeding paragraph apply to any equilibrium mixture of the two reactants A and B, forming one or more condensation products of the general type A_pB_q. A and B may, for instance, be two organic compounds, or hydroxyl ion and a metal ion, forming a series of mono- and polynuclear complexes.

Usually one knows from experiments at least three of the four variables involved, for instance A, B, and b. One may then wish to find a also, before proceeding to interpret the data in terms of equilibrium constants for the a priori unknown equilibria.

Equation (11), or its equivalent (11a), seems to be most suitable to the calculation of a, since it can be expressed explicitly in terms of the other variables by this equation.

As equation (11) is a partial differential equation, it is satisfied by an infinite number of functions b (A, B, a) or a (A, B, b). The function a sought is the one which satisfies both (11) and the boundary conditions, as given by the experimental data. There are at least two generally valid boundary conditions

$$\ln \alpha = 0, \text{ for } B = 0 \tag{20a}$$

and

$$\ln \beta = 0, \text{ for } A = 0 \tag{20b}$$

which are independent of the actual reaction mechanism. On account of the symmetrical nature of (11), we shall consider only the first one. Solving equation (11a) for $\log \alpha$ gives

$$\log \alpha = \left[\int_0^B \left(\frac{\partial \log \beta}{\partial A} \right)_B \mathrm{d}B \right]_A \quad \text{or} \quad \log \frac{a}{A} = \left[\int_0^B \left(\frac{\partial \log \frac{b}{B}}{\partial A} \right)_B \mathrm{d}B \right]_A \tag{21a}$$

This relation suggests a relatively simple and straightforward method of calculating $\log \alpha$. For each series of experiments, at constant B, one plots $\log \beta$ against A, determines the derivatives of these curves at a certain A value, and finally the corresponding value of $\log \alpha$ from the area under $(\partial \log \beta / \partial A)_B$, when plotted against B.

Conversely, one may also calculate b from data of the form (A, B, a), applying the equation

$$\log \beta = \left[\int_0^A \left(\frac{\partial \log \alpha}{\partial B} \right)_A \mathrm{d}A \right]_B \tag{21b}$$

The graphical method discussed here suggests that measurements at a relatively large number of different values of B (or of A, respectively), including low values, are desirable in the calculation of a from b (or *vice versa*). This is one reason for trying to extend the range of concentrations as much as possible in investigating polynuclear equilibria.

For further details on the use of (21), the reader is referred to the author's paper on the hydrolysis of the iron(III) ion [3].

EVALUATION OF EQUILIBRIUM CONSTANTS OF A POLYNUCLEAR COMPLEX FORMATION PROCESS

In the evaluation of the equilibrium constants of a polynuclear process a knowledge of both a and b is highly desirable. If, therefore, only one of the two equilibrium concentrations can be measured directly, the other may be calculated by the methods developed in the preceeding section, which presupposes no particular reaction mechanism. When both a and b are known, the equilibrium constants may be calculated in a rather straightforward manner, as will now be shown.

Equation (3) may be written in the following way

$$F_1 = \frac{(B - b)}{ab} = \sum_{p,q} q\varkappa_{pq}\, a^{p-1}\, b^{q-1}$$

When $q = 1$, then F_1 will be a function of a only, independent of b. Bjerrum [7], Leden [4] and others have already given detailed accounts of the problem of dealing with mononuclear processes.

In order to evaluate the "degree" (q_{max}) of the polynuclear process, we may plot F_1 against b at a certain constant value of a. If a straight line with an intercept, I_1, and a finite slope is obtained, then only mono- and dinuclear complexes are present; if a parabola, trinuclear complexes are also present, and so on. It may be difficult to decide between curves of higher degrees than the first, but this problem can be solved in the following way.

From the plot of F_1 against b the intercept

$$I_1 = \sum_p \varkappa_{p\,1} a^{p-1}$$

is obtained. If then

$$F_2 = \frac{(F_1 - I_1)}{ab}$$

is plotted against b, the new intercept is given by

$$I_2 = 2 \sum_p \varkappa_{p\,2} a^{p-2}$$

This same procedure is repeated until a straight line is obtained. The "steps" ($q = 1,2,3 \ldots.$) of the process will be successively separated as intercepts:

$$I_q = q \sum_p \varkappa_{pq}\, a^{p-q}$$

$$F_{q+1} = \frac{F_q - I_q}{ab}$$

For each value of q, p can, in the general case, assume more than one value. In order to find all equilibrium constants, one must compare the F-curves obtained at different, constant values of a. From the resulting system of equations all $\varkappa_{pq}$'s may be calculated.

This method is laborious, but it appears to be the best method available, that does not involve any presuppositions as to the actual mechanism. In practice, the accuracy of the measurements is limited, and the data will probably be exhausted after the introduction of but a few constants. The calculations may therefore in reality become relatively simple. As an example, it may be mentioned that in the application of this method of calculation to the hydrolysis of Fe^{3+}, the data could be explained, within the limits of experimental error, by introducing only three constants, $\varkappa_{11}$, $\varkappa_{12}$ and $\varkappa_{22}$, corresponding to the formation of $FeOH^{2+}$, $Fe(OH)_2^{+}$ and $Fe_2(OH)_2^{4+}$, respectively.

On the other hand, it might happen that the actual reaction mechanism consists of a very large or even infinite number of steps ($q = 1 \ldots \infty$), as has been suggested [8] for the hydrolysis of Bi^{3+} and, more recently [9, 10], for Th^{4+} and UO_2^{2+}. This should be indicated by the fact that in such a case the data will not yield a straight line even for high orders (high q-values) of F_q, when plotted against a.

Acknowledgement. The author is much indebted to Professor L. G. Sillén for his advice and inspiring interest in the work.

Thanks are also due to Dr F. Rossotti, Oxford, for his valuable criticism of the paper.

ACTA CHEMICA SCANDINAVICA 9 (1955) 622—630

On Vitamins in Sewage Sludge

II *. Formation of Vitamin B_{12}-, Folic Acid-, and Folinic Acid Factors in Municipal Sludge

HALINA Y. NEUJAHR

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The decomposition of municipal sewage sludge by means of anaerobic and aerobic fermentation was studied with respect to the content and distribution of vitamin B_{12}-, folic- and folinic acid factors.

Factor B was found to represent an intermediate step in the decomposition as well as in the synthesis of other vitamin B_{12} factors.

Factor C_2 seems to occur only during the early stages of the microbial decomposition of the sludge.

The quantitative estimation of vitamin B_{12} activity by different methods and test organisms is discussed in connection with the experiments performed.

A new factor active towards *Streptococcus faecalis* was shown to be present during early stages of the anaerobic fermentation of sludge and was found to be chromatographically identical with a synthetic factor.

The mechanism of the formation of the different vitamin B_{12}-factors during decomposition of sewage sludge is discussed.

It has been previously reported from this laboratory [1] and by other authors [2,2a] that digested sewage sludge contains considerable amounts of 4—6 different vitamin B_{12}-factors. Several folic acid and folinic acid factors have also been found in the sludge [1].

In order to ascertain the necessary statistical basis for the estimation of the quantitative distribution of vitamin B_{12}-activity amongst these factors [3], data have been collected from assays during the last three years. Though the values obtained in this way were fairly constant over long periods of time, considerable deviations could however be noted in a few cases. It happened for instance that in some sludge samples almost all of the vitamin B_{12}-activity was due to the factors B and C, or to the factors A and pseudovitamin B_{12}, and only to a small degree to cyanocobalamin. In order to find some explanation for these phenomenona an attempt was made to investigate in what way the

* The first paper in this series was published by Sjöström, A.G.M., Neujahr, Halina Y. and Lundin, H. *Acta Chem. Scand.* 7 (1953) 1036.

different vitamin B_{12}-factors are formed in the sewage sludge when it is fermented in different manners. For this purpose primary sludge from a settling tank was fermented both aerobically and anaerobically in the laboratory, samples being taken during the fermentation and analyzed for vitamin B_{12}-, folic acid-, and folinic acid-activities in both quantitative and qualitative respects.

Anaerobic digestion of sewage sludge is a very slow process when allowed to develop spontaneously without seeding with previously digested sludge. According to Imhoff and Fair [4] the digestion proceeds in three stages:

1) "Acid fermentation", characterized by intensive acid production (pH drops below 6.0) and putrefactive odours. This stage lasts about 2—3 weeks, large volumes of gas (chiefly CO_2 with some H_2S) being produced.

2) "Acid regression" — a lengthy period (about 3—4 months) with small volumes of gas produced (CO_2 + H_2) and slow rise of pH to about 6.8.

3) "Alkaline fermentation" — large volumes of gas (chiefly CH_4 + CO_2) are liberated. The pH-value may rise above 7.0 and the sludge becomes well buffered.

"Acid fermentation" and "acid regression" constitute a "breaking in" or "ripening" period through which all primary sludge which is not seeded must pass when fermented anaerobically. Once alkaline fermentation is established the well buffered sludge rich in enzymes and possesing proper bacterial flora exerts a controlling influence over the course of digestion of incoming fresh sludge.

In technical practice, therefore, digestion tanks already containing well-digested sludge are charged daily with fresh sludge in amounts that cannot upset the alkaline fermentation. At the sewage plants of Stockholm, for instance, only 1/30 of the digested sludge in the digestion tanks is daily replaced by fresh solids, the total time for sludge digestion being 60 days. Obviously, this method could not be used in our laboratory digestion experiments since the microbiological methods for the determination of vitamin B_{12} have limits of error of ± 20 %. These limits are probably still wider in the experiments where the vitamin B_{12}-activity is due to several different factors. Consequently we limited the amount of "seed sludge" to only 10 % in two experiments and in other experiments no seeding at all was used. The total time of fermentation was thus extremely prolonged.

EXPERIMENTAL

Fresh sludge from a settling tank of the municipal sewage plant of Stockholm was disintegrated in a "Turmix" blendor and placed in glass fermentors each of 10 liters capacity, provided with stirrers, heating coils, arrangements for inlet of gas and for removal of samples. The appropriate temperature (33° C or 55° C) was obtained by circulating warm water from constant temperature baths through the coils of the fermentors with simultaneous stirring. In anaerobic digestions, nitrogen gas was blown through the sludge until all air was removed, this procedure being used every time the sludge came in contact with air, *e. g.* after removing a sample. In the aerobic fermentation, air was blown through the sludge continously. The gas evolved in anaerobic digestions was collected and measured. Four parallel experiments were performed according to the scheme shown in Table 1.

Samples of about 100 ml were taken off at regular time intervals (3—4 days) and the pH and content of dry solids were determined. 30 ml of each sample was treated as follows:

100 μg NaCN for each ml sludge was added, pH adjusted with sulphuric acid to 5.5, the sample autoclaved at 120° C for 10 min. and centrifuged. The centrifugate was used for the following estimations:

1) vitamin B_{12}-activity with the cup plate, the tube, and the bioautographic methods using *Escherichia coli* 113-3 and *Lactobacillus leichmannii* 313 and 4797, respectively.

2) "folic acid" and "folinic acid" activities with the cup plate and bioautographic methods using *Streptococcus faecalis* and *Leuconostoc citrovorum*, respectively.

Table 1.

Experiment No.	Type of treatment	Temp.	Seeding	pH adjustment	Additions
1	anaerobic	33° C	with digested sludge, 10 % v/v ,at the start	with $Ca(OH)_2$ to 7.0, at the start	crystalline cyanocobalamin after 80 days in an amount corresponding to0.08 μg B_{12}/ml sludge *
2	anaerobic	33° C	none	with $(NH_4)_2CO_3$ to 7.0, after the period of acid fermentation,	no
3	anaerobic	55° C	with digested sludge, 10 % v/v, after 10 days	with $Ca(OH)_2$ to 7.0	no
4	aerobic	33° C	none	no	no

* The reason for this addition is explained on p. 626.

RESULTS AND DISCUSSION

Vitamin B_{12}-factors

In experiments 1, 2 and 4 considerable amounts of cyanocobalamin were formed during the later stages of fermentation. In experiment 3, on the contrary, a destruction of all vitamin B_{12}-factors after about 100 days could be noted. This was probably caused by the relatively high temperature in connection with the prolonged time of the experiment (*cf.* p. 626). In practice where seeding with a sufficient amount of well-digested sludge can be made, such a thermophilic digestion of sewage sludge is performed in only 10—15 days. The course of formation of vitamin B_{12}-factors in the four experiments is represented in Figs. 1 a, b, c, d, respectively, by means of bioautograms with *E. coli* 113-3.

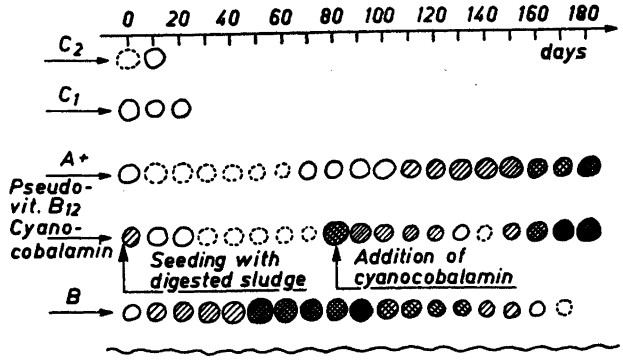

Fig. 1 a. Formation of vitamin B_{12}-factors during microbial decomposition of sewage sludge. Bioautogram. Anaerobic fermentation at 33° C (with seeding).

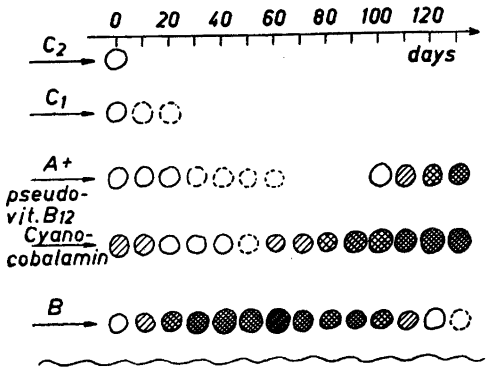

Fig. 1 b. Formation of vitamin B_{12}-factors during microbial decomposition of sewage sludge. Bioautogram. Anaerobic fermentation at 33° C (without seeding).

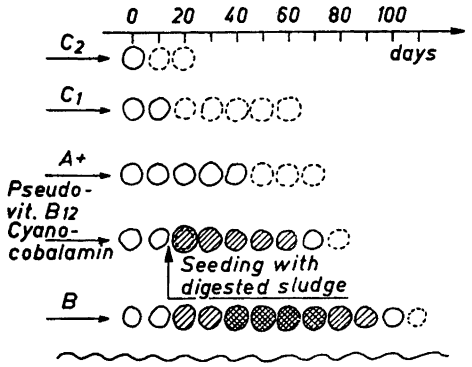

Fig. 1 c. Formation of vitamin B_{12}-factors during microbial decomposition of sewage sludge. Bioautogram. Anaerobic fermentation at 55° C (with seeding).

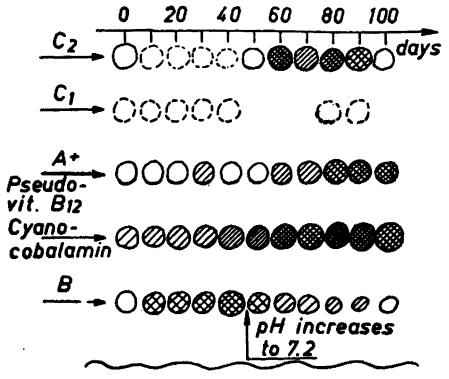

Fig. 1 d. Formation of vitamin B_{12}-factors during microbial decomposition of sewage sludge. Bioautogram. Aerobic fermentation at 33° C (without seeding).

It can be seen in Figs. 1 a and 1 b that in anaerobic fermentation the amounts of cyanocobalamin and of factors A + pseudovitamin B_{12} — present in the fresh sludge and the seeding — are usually destroyed during the first stage of digestion whilst factor B is simultaneously formed. To confirm this surprising observation, that cyanocobalamin is destroyed instead of being formed, crystalline cyanocobalamin was added after 80 days to the digestion tank of experiment 1 (Fig. 1 a). This amount of cyanocobalamin was also slowly destroyed. In the last stage of the digestion (after about 5—6 months) cyanocobalamin and factors A + pseudovitamin B_{12} were reformed while factor B disappeared. Factor C_1 and factor C_2 were present only at very early stages of the digestion.

Anaerobic digestion at 55° C (Fig. 1 c) had a similar course with initial destruction of cyanocobalamin and formation of factor B. At the later stage of this digestion, all vitamin B_{12}-factors were destroyed, probably due to the high temperature in connection with the prolonged time of the experiment as already mentioned. It can be seen in Fig. 1 c that factor B is comparatively more resistant to this destruction than the other factors which is in good agreement with the observation made above and by other authors[5,6] that this factor is a decomposition product of cyanocobalamin and factors A + pseudovitamin B_{12}.

In the aerobic fermentation of sludge (Fig. 1 d), no destruction of cyanocobalamin could be noted. This factor was instead formed continuously and, after 70 days, became the dominant form of vitamin B_{12}. Notable amounts of factor B were formed during the first 30 days, but after 40 days, when the pH-value increased to 7.0—7.5 (Figs. 1 d and 2 b), this factor slowly disappeared while considerable amounts of cyanocobalamin were formed, and also of factors A + pseudovitamin B_{12} and of factor C_2.

Quantitative estimation of vitamin B_{12}-activity. The quantitative estimation of vitamin B_{12} activity formed during the anaerobic and aerobic fermentation as performed by two different methods with *E. coli* 113-3, revealed a striking discrepancy between the values obtained (Figs. 2 a and 2 b).

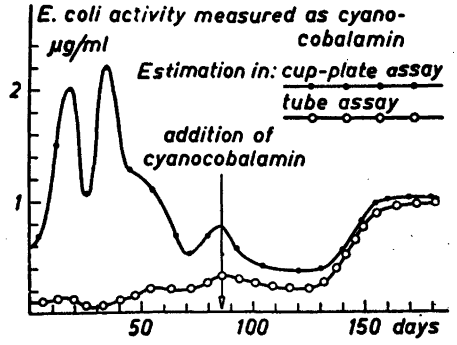

Fig. 2 a. Variations in vitamin B_{12}-activity during microbial decomposition of sewage sludge. Anaerobic fermentation at 33° C.

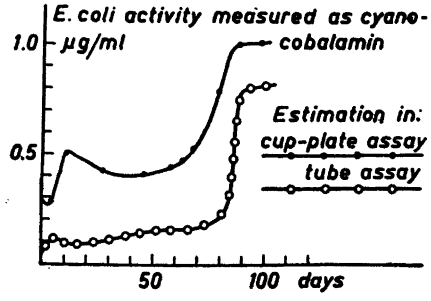

Fig. 2 b. Variations in vitamin B_{12}-activity during microbial decomposition of sewage sludge. Aerobic fermentation at 33° C.

Figs. 2 a and 2 b show that, in the determination of the vitamin B_{12} activity of sewage sludge, the cup-plate method gives much higher values than the turbidimetric method. This is due to the fact that the sludge contains not only cyanocobalamin but also other vitamin B_{12}-factors, many of which in the cup plate method exert a greater activity towards the test organism than in the tube method. The discrepancy in the values is especially pronounced when factors B and C are present in considerable amounts (*cf. e.g.* Figs 1a and 2a). Gregory and Holdsworth [7] have determined the activities of different vitamin B_{12}-factors towards *E. coli* in the tube assay and found them to be 34—92 % lower than that of cyanocobalamin. The corresponding activities in the cup-plate assay as found by Ford [8] are much higher than the activity of cyanocobalamin with differences varying between 274 and 1 000 %. This may account for the fact that the cup-plate method proved to be much less reliable than the turbidimetric method in the estimation of vitamin B_{12}-activity of sewage sludge, which often contains relatively large amounts of factors B, C and pseudovitamin B_{12}. However as soon as cyanocobalamin becomes the main vitamin B_{12}-factor in the sample analyzed, both methods may be of the same degree of reliability, as can be seen, for instance, in Fig. 2 a (activity values after 150 days of digestion) and in Fig. 1 a which shows that after 150 days cyanocobalamin and factors A + pseudovitamin B_{12} dominate.

A large discrepancy has also been found between the values for vitamin B_{12} activity obtained by assaying with *E. coli* 113-3 and *L. leichmannii*, the latter values being much lower. This is in agreement with the findings of Ford [9] that the "vitamin B_{12}-like" factors are much less active towards *L. leichmannii* than towards *E. coli* 113-3, factor B not being active at all towards the first mentioned organism.

Discussion. The formation of cyanocobalamin and other vitamin B_{12}-factors in sewage sludge is apparently a complicated process, proceeding in several stages and being caused by several different microorganisms, anaerobic as well as aerobic. Some of the anaerobic organisms probably consume cyanocobalamin and produce factor B which is then transformed by other organisms to cyanocobalamin and to factors A + pseudovitamin B_{12}. Factor C_2 seems to occur only during the growth period of the microorganisms. It was present during the early stages of both the anaerobic and the aerobic fermentations. In the aerobic fermentation it was also found at a later stage where the pH increases from about 5.0 to about 7.2 probably allowing a new microflora to grow.

However the results obtained until now do not exclude the possibility that during anaerobic fermentation the destruction of factors $C_1 + C_2$ at an early stage and the more slowly proceeding destruction of cyanocobalamin and factors A + pseudovitamin B_{12} during formation of factor B, and the disappearance of factor B under reformation of cyanocobalamin and factors A + pseudovitamin B_{12} during a later stage are independent processes, caused by different microorganisms. The formation of these factors during the different stages of fermentation could thus be caused by successive changes in the sludge, allowing different microorganisms to grow and to produce their characteristic growth factors.

In view of the findings of Armitage *et al.*[5] and of Gant *et al.*[6] that factor B is cyanocobalamin, factor A, or pseudovitamin B_{12} lacking their respective nucleotides, it seems possible that factor B formed during the digestion of sludge may derive from the decomposition of these three factors, or some of them. It is, however, probable that at least some of the organisms active in sludge digestion may be able to directly synthesize factor B. This seems to hold especially for organisms active in the aerobic decomposition of sludge since in this case no destruction of cyanocobalamin occurred during the formation of factor B. The mechanism of formation of factors A + pseudovitamin B_{12} could not be explained with any degree of probability. For the formation of these two factors * the presence of both factor B and cyanocobalamin may be necessary; cf. Fig. 1 a and 1 b.

Probably, the best solution of these problems could be obtained by isolation of the different organisms active in sludge decomposition and by investigating their ability to synthesise the different vitamin B_{12}-factors. This task, however, has proved so difficult and time consuming that we had to postpone it for the time being, especially as we have some reason to suspect that complicated symbiotic and synenergistic phenomenona are involved in the mechanism of vitamin B_{12} formation in the sludge.

Folic acid- and folinic acid-factors.

The course of formation of these factors in the anaerobic fermentation of sewage sludge carried out at 33° C is represented in Fig. 3 a and 3 b.

Fig. 3 a shows that during the digestion the "folinic acid activity" diminishes much quicker than the "folic acid activity" does. Fig. 3 b shows a chromatographic picture of different factors present and active towards *S. faecalis*. At early stages of the digestion the formation of a *new S. faecalis*-factor — PFH — with R_F-value = 0.75 could be noted (see Fig. 3 b). This factor has been chromatographically identified with a synthetic factor obtained by Ericson[9] in this laboratory by formylation and reduction of pteroic acid. This factor could not be found in a wort fermented by an anaerob, *Clostridium thermocellulaseum*[10].

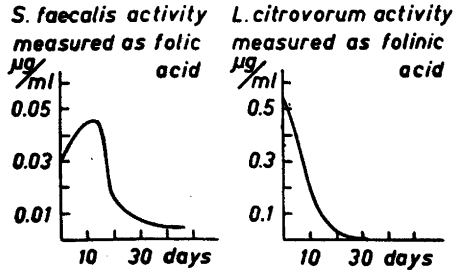

Fig. 3 a. Variations in S. faecalis- and L. citrovorum-activities during microbial decomposition of sewage sludge. Anaerobic fermentation at 33° C.

* After this paper had been prepared for publication, the latest papers of Ford and Holdsworth[9] came to our knowledge. In view of the synthesis of factor A, pseudovitamin B_{12} and cyanocobalamin, performed by these authors from factor B and precursors of different nucleotides, it seems likely that the formation of these three factors at a later stage of sludge decomposition depends on the appearance of the corresponding precursors in the medium.

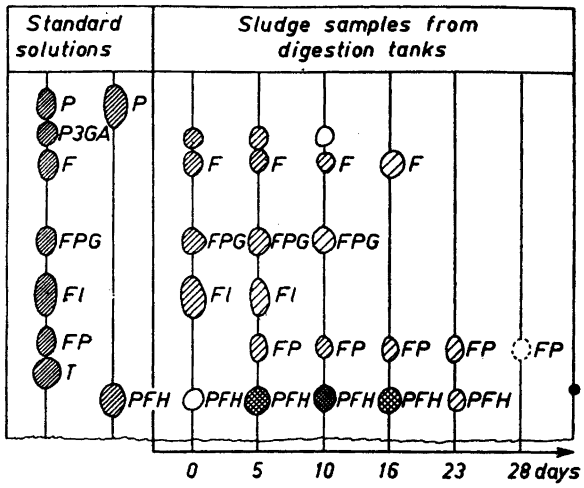

Fig. 3 b. Formation (destruction) of S. faecalis-factors during microbial decomposition of sewage sludge. Bioautogram. Anaerobic fermentation at 33° C.

P = *pteroic acid*
P3GA = *pteroyltriglutamic acid*
F = *folic acid*
FPG = *formylpteroylglutamic acid*
Fl = *folinic acid (Leucovorin)*
PF = *formylpteroic acid (Rhizopterin)*
PFH = *pteroic acid, formylated, hydrated.*

The appearance of this factor between the 5th and the 23rd day of digestion (Fig. 3 b) may explain the maximum of the *S. faecalis*-activity curve occurring on the 14—15th day of digestion (Fig. 3 a).

Bioautograms with *L. citrovorum* revealed activity mainly due to folinic acid (Leucovorin Lederle) and only to a less degree due to two unidentified factors with R_F-values 0.18 and 0.22. The presence of these factors in sludge has already been reported in a previous work [1]. Nothing of special interest concerning the course of formation or disappearance of these factors could be noted.

Acknowledgements. The author wishes to express her thanks to Prof. C. A. Elvehjem and to Dr. U. J. Lewis, Department of Biochemistry, University of Wisconsin, Madison, Wis., for samples of vitamin B_{12} and pseudo-vitamin B_{12}, to Dr. J. W. G. Porter, The National Institute for Research in Dairying, Shinfield, Reading, for a solution containing factor A and factor B, and to the Lederle Laboratories Inc., New York, for samples of the different folic acid and folinic acid factors.

We are greatly indebted to Mr. H. Johansson of Henriksdal for the sludge samples and for useful informations. We also wish to thank Mrs. G. Grömmer, Miss M. Knappe, Mr. Th. Kirsipuu and Mr. H. Flodström of this laboratory for valuable technical assistance.

The Kinetics of the Decarboxylation of *tert.*-Butylpropiolic Acid and its Sodium Salt in Water

EERO A. HALONEN

Institute of Chemistry, University of Helsinki, Helsinki Finland

In order to determine to what extent the rates of decarboxylation of α,β-acetylenic acids are influenced by various structural effects, a kinetic study has been made of the decomposition of *tert.*-butylpropiolic acid and its sodium salt in water at six temperatures. The data obtained have been used to calculate values of the activation energy, frequency factor, free energy of activation, heat of activation and the entropy of activation. The rates of decomposition of *tert.*-butylpropiolic acid and its salt are approximately equal to those of tetrolic acid and its salt, but the activation energies for the former are of the same magnitude as those found for propiolic acid and its sodium salt. It has been concluded that the low rates of decomposition of tetrolic acid and its salt compared to those of propiolic acid and its salt are due to the occurrence of hyperconjugation in the former.

In previous work [1] on the decarboxylation of some α,β-acetylenic acids and their salts, it was established that the decompositions reactions of tetrolic acid ($CH_3—C\equiv C—COOH$) and its sodium salt are much slower than those of propiolic acid ($HC\equiv C—COOH$) and its salt. It seemed that this could be attributed to hyperconjugation in tetrolic acid. To determine the validity of this assumption, the decarboxylation of *tert.*-butylpropiolic acid and its sodium salt in aqueous solution has been studied. The reactions involved are the following:

$$(CH_3)_3C—C\equiv C—COOH \rightarrow (CH_3)_3C—C\equiv CH + CO_2$$

$$2\ (CH_3)_3C—C\equiv C—COONa + H_2O \rightarrow 2\ (CH_3)_3C—C\equiv CH + CO_2 + Na_2CO_3$$

EXPERIMENTAL

Pinacone hydrate and pinacolin. Pinacone hydrate was first synthesized according to the method given in the Organic Syntheses [2]. The product was then transformed into pinacolin by a method also given in Organic Syntheses [2].

Chlorination of pinacolin with phosphorus pentachloride [3]. 140 g of pinacolin was slowly added to 300 g of phosphorus pentachloride in a flask immersed in a mixture of

ice and water. The reaction mixture was then allowed to stand 4 hours at room temperature, after which it was gradually added to a mixture of water and ice. The precipitate formed was separated by filtration, washed with water and dried by suction. The liquid reaction product in the filtrate was separated from the water in a separating funnel and dried with calcium chloride. The yield of the solid product was 92 g, that of the liquid product 84 g.

Tert.-*butylacetylene* [4]. The chlorinated products of the preceding synthesis were heated six hours with 500 g of potassium hydroxide and 40 ml of ethanol in a graphite bath at 150—270° C. The liquid distilling from the mixture below 50° C was collected, washed with water, dried over potassium hydroxide and subjected to fractional distillation in a Widmer column. The yield of *tert.*-butylacetylene boiling at 37.5—38.5° was 55 g.

Sodium tert.-*butylacetylide* [5]. 23.8 g of the *tert.*-butylacetylene was dissolved in 150 ml of anhydrous ether in a flask fitted with an efficient reflux condenser to which a calcium chloride tube was attached. 6.5 g of thin sodium wire were added. The reaction was allowed to continue 24 hours at room temperature, the flask being shaken at intervals. The mixture was then boiled 18 hours until a sample no longer gave a precipitate on adding ammoniacal silver nitrate solution.

Tert.-*butylpropiolic acid* [5]. Carbon dioxide gas dried by passing it through concentrated sulphuric acid was led into the flask containing the ether solution of *tert.*-butylacetylide during 26 hours at room temperature with intermittent shaking, after which the mixture was boiled for six hours. During this time the grey precipitate of sodium *tert.*-butylacetylide turned white and a sample no longer gave off *tert.*-butylacetylene when water was added to it. The contents of the flask were carefully added to ice-water and the solution was extracted with ether after acidification with sulphuric acid. The combined ether solutions were dried with anhydrous sodium sulphate, and the ether removed by distillation. The rest of the *tert.*-butylacetylene was treated in a similar manner. The products were combined and distilled by fractionation. The yield of product boiling at 112.5—113.0° at 14 mm Hg was 42.7 g. Its melting point was 47.9—48.0°. Analysis by titration: 30.0 mg of the acid consumed 11.65 ml of 0.0202 *N* barium hydroxide, which corresponds to an equivalent weight of 127.48 (calc. 126.15). The odour of the acid resembled those of propiolic and tetrolic acids and the acid was very hygroscopic.

Tetrolic acid. The tetrolic acid was the same as that used in the previous work [1].

Methods. The apparatus and the methods used in the measurement of the rates of decomposition were the same as in the earlier investigation [1].

RESULTS

The rates of decomposition of *tert.*-butylpropiolic acid and its sodium salt were measured in aqueous solution at six temperatures. The rate of decomposition of sodium tetrolate was measured in aqueous solution at three temperatures to extend the temperature range of the earlier measurements [1]. Similarly as in the earlier work, the initial concentrations of the acids were 0.01 *M*, those of the salts 0.02 *M*.

The reactions studied were all of the first order. The specific rates of the salts showed a good constancy over the range 20—70 % reaction, as seen from the example in Table 1. The rate constants were computed from the equations employed earlier [1].

Table 1. The decarboxylation of sodium tert.-*butylpropiolate in aqueous solution at 130.19° C.*

Time in sec.	7 260	10 620	13 200	15 660	21 060	26 400	35 640
% reaction	22.8	31.4	38.0	42.8	52.8	61.0	72.0
$10^5 k$ sec.$^{-1}$	3.565	3.549	3.621	3.567	3.565	3.567	3.572

The plots of log k against $1/T$ gave excellent straight lines for both sodium *tert.*-butylpropiolate and sodium tetrolate, the relative maximum deviations of the experimental points from the line calculated by the method of least squares being approximately 1 %.

The rate constants for the decarboxylation of *tert.*-butylpropiolic acid were satisfactorily constant at the higher temperatures; at the lower temperatures the values tended to increase towards the end of the reaction. Also the plots of log k against $1/T$ deviated from the linear course at the lower temperatures, whereas the values for the four higher temperatures were situated close to the same straight line. For this reason, only the latter four values were employed in the calculation of the activation energy, and thus the value obtained is a maximum value. A similar deviation from the Arrhenius plot has not been observed for the decarboxylation reactions of other acetylenic acids that have been studied.

The values of the rate constants are collected in Table 2 and the values of derived kinetic quantities in Table 3. The values of E and A, the energy of activation and the frequency factor, have been computed by the method of least squares. The values of the free energy of activation ΔG^*, the heat of activation ΔH^* and the entropy of activation ΔS^* refer to 100° C.

DISCUSSION

For comparison, the rate constants at 90° C, the activation energies, frequency factors and entropies of activation at 100° C for the decomposition of propiolic, tetrolic and *tert.*-butylpropiolic acids and their sodium salts are given in Table 4. It is seen that whereas sodium propiolate decomposes 25 times as rapidly as sodium tetrolate, sodium *tert.*-butylpropiolate decomposes at approximately the same rate as sodium tetrolate. The difference in the rates

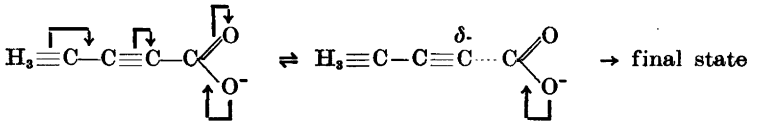
* Calculated by the Arrhenius equation.

of the salts of propiolic and tetrolic acids is primarily due to a difference in the activation energies, while that between the rates of the salts of propiolic and *tert.*-butylpropiolic acids can be attributed to a difference in the value of the frequency factor. The relationships between the acids are approximately similar to those found for the salts. The difference in the rates of *tert.*-butylpropiolic and propiolic acid is determined primarily by the (+ I) inductive effect of the *tert.*-butyl group. If the rate of decomposition of sodium tetrolate were solely determined by the inductive effect of the methyl group, one would expect sodium tetrolate to decompose with approximately the same rate as sodium propiolate, and also the other kinetic quantities should have approximately the same values for these two salts, since the inductive effect of the methyl group is small compared to that of the *tert.*-butyl group. The fact that sodium tetrolate decomposes 25 times slower than sodium propiolate and at approximately the same rate as sodium *tert.*-butylpropiolate can readily be explained by the hyperconjugation in sodium tetrolate in the initial state (see below). As in methylacetylene, π_y- and π_z-hyperconjugation can be postulated in sodium tetrolate. This implies a lower energy of the compound



initial state transition state

in the initial state. As the decomposing molecule enters the transition state, a partial negative charge develops at one end of the triple bond (transition state above). This charge, whose separation is opposed by the hyperconjugation, counteracts the hyperconjugative transfer of electrons and consequently hyperconjugation does not exist in the transition state. A similar explanation has been proposed by Ingold [6] for the differences observed between the dipole moments of *iso*cyanides and those of nitromethane and nitrobenzene, in which both conjugation and hyperconjugation are possible.

The difference, 1 310 cal., between the activation energies of sodium propiolate and sodium tetrolate is not as large as the energy of hyperconjugation for sodium tetrolate owing to solvation effects in aqueous solution.

The Energy of the Methyl Group-Triple Bond Hyperconjugation

EERO A. HALONEN

Institute of Chemistry, University of Helsinki, Helsinki, Finland

It has been qualitatively shown previously that the difference in the rates of decarboxylation of sodium tetrolate and sodium propiolate is mainly determined by hyperconjugation. In the present paper a quantitative study of the phenomenon is presented which is based on the assumption that under ideal conditions the difference in the activation energies for the decarboxylation of these compounds is equal to the experimentally determined energy of hyperconjugation between a methyl group and the triple bond. By determining the rates of decomposition of the above salts under conditions where solvation is a minimum, a limiting value, 3 440 ± 200 cal., has been calculated for the activation energy difference. By adding 1 100 cal. to this value as proposed by R. S. Mulliken, the value of the theoretical energy of hyperconjugation comes out to 4 540 cal., which is practically the same as the value computed by R. S. Mulliken and coworkers for the energy of hyperconjugation in methylacetylene by the molecular orbital method.

In a previous work [1] it was concluded the difference in the rates of decomposition of sodium propiolate and sodium tetrolate is primarily due to hyperconjugation in the latter compound. In the present study, this conclusion is considered on the basis of additional kinetic data.

EXPERIMENTAL

Materials. The propiolic, tetrolic and *tert.* butylpropiolic acids employed were those used in the previous studies [1,2]. The sodium salts of these acids were prepared as described earlier [2]. Dioxan (Merck) was purified by the method of Hess and Frahm [3], after which its melting point was 11.8° C. Ethanol (absolute ethanol, Oy Alkoholiliike, Rajamäki) was dried with aluminium using $HgCl_2$ as activator. Benzene (Merck, benzene free from tiophene) was refluxed over sodium wire and then distilled. The water was ordinary distilled water.

Measurements. The kinetic measurements were performed as described previously [2] using the same calibrated apparatus.

RESULTS

The decomposition of sodium propiolate was studied in an ethanol-dioxan mixture, that of sodium tetrolate in absolute ethanol, in two ethanol-benzene mixtures and in a dioxan-water mixture, and the decomposition of sodium *tert.* butylpropiolate in a dioxan-water mixture. In all experiments the initial concentration of the salt was 0.02 *M*. In the case of the above solvent mixtures, an attempt was made to increase the proportion of the non-polar component as far as possible without exceeding the precipitation limit of the salt at room temperature. This did not succeed for sodium tetrolate and sodium *tert.* butylpropiolate in the case of the dioxan-water mixtures, since these salts give 0.02 *M* solutions even in the 95 % dioxan-water mixture, which latter mixture, however, appeared to be unstable at the temperatures at which the experiments were performed. For this reason, sodium tetrolate was studied only in the approximately 80 % dioxan-water mixture and sodium *tert.* butylpropiolate in the approximately 60 % dioxan-water mixture. All the reactions were conducted in a nitrogen atmosphere.

The decompositions followed the first-order law in all solvents studied and the maximum deviations of the log k—$1/T$ points from the Arrhenius plots did not exceed 1 % except for sodium *tert.* butylpropiolate, for which the maximum deviation was approximately 2 %. The calculations were carried out using the same equations as previously [2].

The rate constants are given in Table 1 and the values of the derived kinetic quantities in Table 2. The activation energies E and frequency factors A have been calculated by the method of least squares. The values of the free energy of activation ΔG^*, heat of activation ΔH^* and the entropy of activation ΔS^* refer to 100° C.

DISCUSSION

When a molecule decomposes unimolecularly in the gaseous state to give radicals or atoms, the activation energy of the decomposition is equal to the energy of dissociation of the bond that is broken, provided the activation energy of the reverse reaction is zero [4].

As has been proposed previously [1], the initial state of sodium tetrolate is characterized by a π_y- and π_z-hyperconjugation between the methyl group and the triple bond, which decreases the potential energy of sodium tetrolate and at the same time retards its decarboxylation. The hyperconjugation is presumably of the same degree as in methylacetylene, *i. e.* a true hyperconjugation between the methyl group and the triple bond, since evidently conjugation does not occur between the triple bond and the carboxylate ion group in sodium tetrolate [2]. As the decomposing molecule enters the transition state, a partial negative charge develops at one end of the triple bond and prevents hyperconjugation to occur in the tetrolate ion. In order that the tetrolate ion can attain the same transition state structure as the propiolate ion, additional energy corresponding at least to the energy of hyperconjugation between the methyl group and triple bond is required in the case of the former in the gaseous state [1]. This is schematically shown in Fig. 1.

It is impossible to make measurements on the behaviour of ions in the gaseous state or even in non-polar solvents. An attempt has been made to approach the ideal conditions by conducting the decomposition reactions of the salts in aqueous and alcoholic solvents containing such proportions of non-polar components that the limits of precipitation of the salts are almost attained. Measurements on unimolecular reactions conducted in non-polar solvents are comparable with measurements conducted on such reactions in the gaseous state only if the initial state and the transition complex do not greatly differ from each other in structure. This condition appears to be fulfilled by the reactants under study, but since the purpose has been only to determine the activation energy difference, it is sufficient that the structures of the transition states of both the propiolate and tetrolate ions do not differ greatly. This appears to be true since the entropies of activation for the decompositions of these two compounds are only slightly different (Table 2). In fact the value of ΔS^* for sodium tetrolate is greater than that calculated for sodium propiolate,

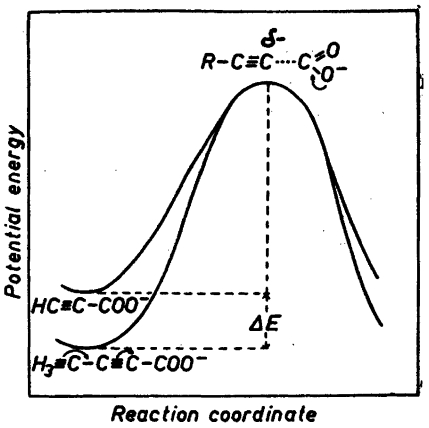

Fig. 1. A schematic diagram showing Potential-Energy-Reaction-Coordinate curves for the decomposition of sodium propiolate and sodium tetrolate. The zero levels for the two compounds do not coincide.

which is explained by the hyperconjugation in the former. According to the view of solvation outlined previously [2], an ideal solvent for these compounds would be one that is unable to release and form hydrogen bonds at different solvation sites on the reacting molecule. On the other hand, observations made during the course of this study which are being studied in more detail, indicate that the solvent cannot be a hydrocarbon owing to the presence of the hydrocarbon chain in the decomposing compounds. Since carbon tetrachloride is unstable to alkalis, dioxan has been chosen as the non-polar solvent, particularly as it was found to conform with the requirements for an ideal solvent.

The variation of the activation energy for the decomposition reactions of sodium propiolate and sodium tetrolate with the composition of the solvent is shown in Fig. 2. It will be seen from the figure that the activation energy for sodium propiolate increases at first as the proportion of the non-polar solvent increases but, later on, decreases fairly steeply. The activation energy for sodium tetrolate, however, remains fairly constant with only a slight gradual rise over the solvent range. In the case of sodium propiolate an ideal limiting

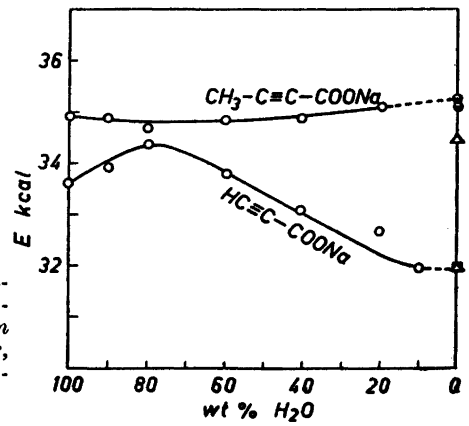

Fig. 2. The variation of the activation energy with solvent composition for the decomposition of propiolate and tetrolate ions in various solvent mixtures. ○ *dioxan-water,* △ *ethanol,* □ *dioxan-ethanol,* ◒ *benzene-ethanol.*

value appears to be attained when the limit of precipitation is approached, since the same value for the activation energy is found for the dioxan-water, ethanol-water and ethanol solutions. In the case of pure ethanol, sodium propiolate dissolves only with difficulty in this solvent to give a 0.02 *M* solution. As already mentioned, this precipitation limit could not be attained for sodium tetrolate in the case of the dioxan-water mixtures. However, the value found for the activation energy near the precipitation limit in the benzene-ethanol mixture appears to be the same as that which would be obtained by extrapolating the activation energy curve plotted for the reaction in the dioxan-water mixtures.

By subtracting the limiting value, 31 850 cal., of the activation energy for sodium propiolate from the corresponding value for sodium tetrolate, 35 290 cal., we obtain 3 440 cal. which is thus assumed to be the value of the hyperconjugation energy between a methyl group and a triple bond. This difference is believed to be accurate to $\pm$ 200 calories. To this experimental value, a further 1 100 cal. must be added as proposed by R. S. Mulliken and co-workers [5] to take into account the fact that work must be done when the acceptor bond decreases and the donor bond increases in length in hyperconjugation against the forces which tend to maintain the normal lengths of the bonds. The resulting value for the theoretical hyperconjugation energy is thus 4 540 cal. Using the molecular orbital method, Mulliken and co-workers [5] have theoretically calculated for the hyperconjugation energy in methylacetylene the value 4 520 cal. and on the basis of heats of combustion have obtained the experimental value 3 600 $\pm$ 200 cal. which by adding the correction 1 100 cal. gives 4 700 cal. as the theoretical value. The accordance between these values and the value found in the present study is very satisfactory.

Accurate Determination of Thermal Conductivities

D. G. GILLAM, LARS ROMBÉN, HANS-ERIK NISSEN and OLE LAMM

Division of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

The electrical method for measuring thermal conductivities, introduced by Stålhane and Pyk [1] and Eucken and Englert [2], has been put on a sound basis and the accuracy increased, for both solids and liquids, up to about ± 0.3 %. The principle is that of the classical methods for gases in which the temperature of an electrically heated wire, immersed in the medium, is measured over a suitable time interval. The temperature of the wire is determined continuously by a resistance measurement, not over the whole length of the wire but only over a central section. In this way undesired conduction effects at the ends of the cell and the corrections for them can be neglected. Also, because unsteady state conditions are used, no correction is required for the temperature discontinuity at the wire-medium interface. A number of precautions and arrangements, necessary for accurate work, have been examined in detail, in order to adapt the method for precision routine measurements.

The method can be used for solids, whose melting points are not too high, by pouring the liquified substance directly into the cell, care being taken to see that no gas bubbles settle out on the wire due to incomplete degasification. In the case of liquids, high accuracy is obtained for fluids of sufficiently high viscosity or sufficiently low thermal dilatation, as will be described in a following paper.

THE HOT WIRE PRECISION METHOD

1. General principles

Thermal conductivities, apart from their undoubted industrial importance, can also be used to throw light upon the structure of the substances studied and the mechanism by which heat is transmitted through them. The two main difficulties of this work are, first, to insulate the substance in such a way that heat will flow only in the desired direction and, second, to avoid errors in the temperature measurements due to the temperature jump which exists between the substance under investigation and the temperature measuring device. Accurate methods fall into two groups — those in which uni-dimensional heat conduction is investigated (generally steady state), proper care being taken with the insulation of the substance to ensure correct

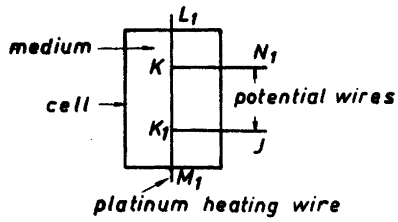

Fig. 1. Principle of the hot wire method.

boundary conditions, and those in which two-dimensional heat conduction is studied (both steady and unsteady state). With the former group and likewise with the steady state methods in the latter group, the insulation and temperature jump errors are likely to be appreciably large. Both of these errors can be avoided by using instead a certain two-dimensional unsteady state method. The principles of this method were first laid down by Stålhane and Pyk [1]. It was first used for accurate measurements by Eucken and Englert [2] but the cell and electrical system used by them were inconvenient and have been considerably simplified in the present work. Heat was provided by passing an electrical current through a thin platinum wire immersed in the medium and situated in the axis of the cylindrical glass containing vessel (Fig. 1).

As soon as current passed through the wire, the temperature of the wire increased but the rate of increase decreased as heat was conducted away by the medium. From a resistance determination on the platinum wire (*i.e.* a temperature determination at the axis) at various times during the passage of the current, the thermal conductivity could be calculated. Moreover by measuring the resistance of the section KK_1 only, using the potential wires shown in the diagram, it was possible to assume strictly two-dimensional heat conductivity and thus there was no necessity for applying a correction for the three-dimensional heat flow at the ends as is usual in methods of this type. Platinum, because of its superior resistance qualities, *e.g.* resistance stability over long time periods and freedom from corrosion, can be considered to be the most suitable material for the wire.

The mechanical design of Eucken and Englert's cell [2] was felt to be unnecessarily complicated and it was thought preferable to construct a simpler cell (Fig. 2) which could be easily filled with liquids and also solids whose melting points were not too high.

The diameter of this simpler cell was 3 cm, the length of the KK_1 section was 10 cm and the distances from the points K and K_1 to the ends of the cell were 4 cm. The lengths of the platinum sections of the potential wires were about 4 cm. Thermo-pure platinum was used for the central wire and chemical pure platinum for the potential wires.

The difficulty of making a neat join between the platinum wires was overcome by the use of a small spot welder. The welding current is rather critical; too small currents will not give sufficient heat for welding whilst too high currents will completely burn away the wires at the welding point. With practice, a strong, right-angle join could be made between the potential wires and the central wire without any bead formation at the point of union. The four ends of the platinum wire system were then each sealed into short copper wires, using a small reducing gas-oxygen flame and pushing the platinum wire into the molten

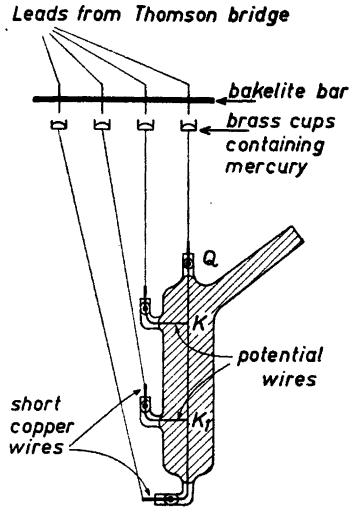

Fig. 2. Pyrex cell designed for the method.

copper bead. The wires were carefully moved into the cell by attaching cotton threads to the copper wires and pulling each section into the correct side arm. Both the copper and the platinum wires were sealed into the side arms — a small cavity containing the copper-platinum join being left unsealed. Thus the cell was made vacuum tight and the platinum wire system protected from mechanical breakage. The final operation was to straighten the central platinum wire in order to get a true cylindrical heat flow during the experiment. This was accomplished by inverting the cell and attaching a 50 g weight to the lower end of the side arm Q (*cf.* Fig. 2) and heating very gently in the middle of this side arm. As the glass began to melt, the weight brought the platinum wire straight. To each of the four short copper wires were soldered long copper wires to the other ends of which were soldered brass cups containing mercury. The cell was connected into the bridge by lowering the bakelite bar. This convenient method also gave freedom from variable contact potentials and resistances at the connection points. The cell was placed in a thermostat bath ($\pm$ 0.005° C) which was filled with transformer oil in order to insulate the cell leads.

With solids, the filling of the cells required care because of the ability of solid organic compounds to dissolve large amounts of air — both in the solid and fluid states. Moreover the difficulty is that many of them dissolve more air in the liquid state and thus on solidification air bubbles are formed in the solid which tend to become attached to the central platinum wire and thus alter completely the heat flow properties of the medium. To overcome this, the solid was alternately melted and frozen several times under vacuum in a large container until all the air bubbles had escaped — it was then melted again and poured carefully into the cell.

2. Electrical circuit

A Kelvin bridge was used to determine the resistance of the KK_1 section and thus the temperature of this platinum wire section (Fig. 3). The Kelvin bridge is usually used for measuring constant resistances and therefore, since the resistance of the platinum wire is continuously changing when the heating

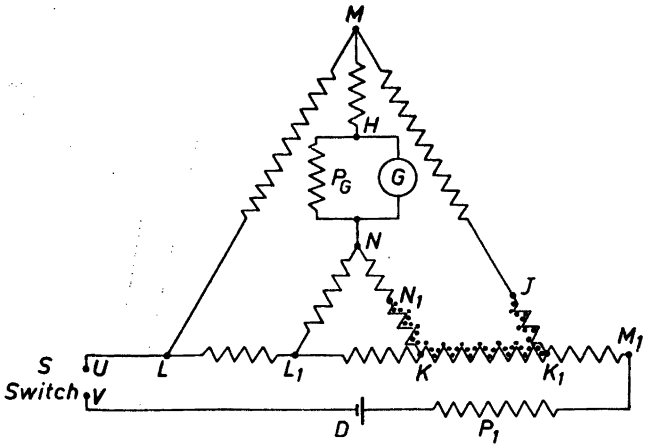

Fig. 3. Kelvin bridge used for the resistance measurements. G: galvanometer. The resistances of the platinum wire sections situated inside the cell are represented by L_1K, KK_1, K_1M_1, N_1K and JK_1 (cf. Figs. 1 and 2).

current is passing through it, the bridge method must be modified in order to determine a continuously varying resistance.

The battery D was used to supply current to the bridge and also to pass the heating current through the axial platinum wire during the experiment. The section KK_1 was that part of the platinum wire which was used to measure the temperature at the centre of the conductivity cell whilst N_1K and JK_1 correspond to the potential wires which were connected to the end points of this section. The two end sections of the central platinum wire are included in the parts of the bridge denoted by L_1K and K_1M_1.

It is necessary to make the central wire as thin as possible to make the heating effect large. Thus the resistance change will be large and hence an increase in accuracy will result. From the practical point of view, *e.g.* mechanical strength and possibility of manipulating the wire *etc.*, 0.1 mm diameter platinum wire was the thinnest possible to use. It was necessary that the potential wires should also be thin so that there would be a negligible disturbance of the two-dimensional heat flow from the central wire. The practical limit to the diameter was about 0.05 mm and it was proved that the disturbance of the heat flow from the axial wire into the medium was small with such a diameter. Because the potential wires were so thin, it was necessary to ensure that only small currents were passed through them. For this reason, ML consisted of a fixed resistance of 100 ohm whilst NK was made up of a fixed resistance of 50 ohm (NN_1) in series with the upper platinum potential wire (N_1K) in Fig. 1. Because the conditions for bridge balancing are:

$$\frac{MK_1}{ML} = \frac{NK}{NL_1} = \frac{KK_1}{LL_1}$$

and $KK_1/LL_1 = 1.25$ (LL_1 consisted of a fixed resistance of 1 ohm), it is seen that NL_1 will be about 40 ohm and MK_1 about 125 ohm. This also guaranteed that the maximum possible changes in the resistances of the potential wires during the experiment due to the temperature alterations were not sufficient to disturb the balance of the bridge. A Leeds and Northrup potentiometer was set up so that the potential differences across LL_1 and KK_1 could be measured. Using these potential differences, the values of the heating current and the KK_1 resistance at the start of the experiment (both required for the calculation of the thermal conductivity) could be computed.

Since the bridge galvanometer deflection can vary continuously, this gives the idea for the measurement of a resistance varying with time. Assuming first that the bridge has been balanced, then, if one of the resistances, say KK_1, is altered, the galvanometer will be deflected from its zero position and for each value of the resistance there will be a corresponding value of the galvanometer scale reading. Thus from a calibration curve of the galvanometer scale against the cell resistance KK_1, the resistance and thus the temperature of the central platinum wire can be determined during the whole of the experiment. However, it would be clearly impossible to use the cell resistance KK_1 for this calibration because of its variation with the passage of current and therefore it was necessary to use instead a continuously adjustable resistance whose value was independent of the current and could also be altered by previously determined small steps. This resistance will be referred to as the "calibration resistance". It is also clear that the initial value of this calibration resistance should be equal to the cell resistance KK_1 (at $t = 0$, *i.e.* before it is altered by the passage of current) and that, for the calibration using the calibration resistance to correspond to the cell resistance, it is necessary that the other elements in the bridge circuit should be the same in both cases. Now ML, NL_1 and LL_1 can be kept the same but this is not possible for MK_1 and NK since parts of these resistances lie within the cell itself (*i.e.* the two potential wires form part of MK_1 and NK). This difficulty can be overcome by placing switches in the circuit so that the parts N_1K, KK_1 and JK_1 (*i.e.* the cell resistance and its potential wires) can be replaced by the calibration resistance and new N_1K, JK_1 resistances (represented by the dotted lines, see Fig. 3). If this new system is balanced by adjusting the new N_1K and JK_1 resistances and using the same values for ML, NL_1, MJ and LL_1 as before, then, because of the balance conditions, the values obtained for the new N_1K and JK_1 will be identical with those obtained previously for N_1K and JK_1 when the cell resistances were contained in the circuit. Thus the bridge circuit containing the calibration resistance can be made identical with that containing the cell and therefore the calibration curve of KK_1 resistance against scale reading, obtained with the calibration resistance, will also apply for the cell.

3. Bridge adjustments performed during an actual experiment

When current flows through the central platinum wire, its temperature rises as a logarithmic function of the time. Thus its resistance rises logarithmically and hence also the galvanometer scale deflection (Fig. 4).

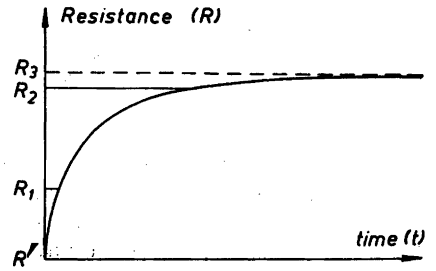

Fig. 4. Resistance versus time for a wire surrounded by a conducting medium and heated by a constant electric current.

The time taken for the resistance increase from the initial KK_1 value, R', to the value R_1, is very short and the accuracy of the measurements in this region is small because of both the rapid resistance change and the lack of accuracy of the time determinations. The region from R_2 to R_3 is useless because the resistance change is too small to permit accurate determinations. Thus the middle region from R_1 to R_2 is the most suitable one for the measurements. This immediately suggests the possibility of altering MJ and NL_1 (see Fig. 3) so that the bridge is balanced when KK_1 is placed at the value R_1 and using such a heating current that the maximum galvanometer scale deflection is reached when the KK_1 resistance has increased to the value R_2. In this way the galvanometer's sensitivity can be used to the greatest advantage. For the experimental currents necessitated by the sensitivity of the galvanometer used here, the resistance R_1 was reached after about 4 sec.

A. In practice the value R_1 was found by trial and error (and MJ and NL_1 were altered so as to obtain balance). One outcome of this procedure was that the galvanometer circuit should not be closed during the experiment until 4 sec after the heating current has been switched on — this was to avoid galvanometer scale deflections in the negative direction which, because of the galvanometer hysteresis, would make inapplicable the previous calibration of galvanometer scale *versus* KK_1 resistance.

B. A similar procedure was adopted when the calibration resistance and its potential leads were placed in the circuit in order to determine the calibration curve — the KK_1 value for the calibration resistance was made equal to R_1 and the same values for MJ and NL_1 were used as were found in *A*. In this way, (1) the calibration curve started from the same KK_1 value as that from which the measurements were begun, (2) the other elements in the bridge, *e.g.* MJ, JK_1, NK, ML, LL_1, NL_1 were the same during the actual experiment with the cell and during the calibration, and thus (3) the calibration curve of galvanometer scale reading *versus* KK_1 resistance was applicable to the scale deflections obtained during the experiment.

An optical system was designed so that the galvanometer scale and a chronometer could be photographed simultaneously. Thus it was possible to calculate the resistance of the central platinum wire during the experiment as a function of time. The order in which the bridge adjustments were carried out in practice is summarized as follows:

1) The cell was connected into the bridge (*cf.* Fig. 3) and MJ and NL_1 were adjusted so that balance was obtained.

2) The calibration resistance was connected into the bridge and its KK_1 section was made equal to the KK_1 section of the cell resistances using the Leeds and Northrup potentiometer mentioned in section 2.

3) With the calibration resistance in the bridge, N_1K and JK_1 were adjusted so that balance was obtained.

4) With the cell in the bridge, the value of R_1 was found by trial and error (and MJ and NL_1 were altered to obtain balance, see *A.* above) after choosing a heating current such that the maximum galvanometer deflection was reached when the KK_1 cell resistance had increased to the value R_2.

5) The calibration resistance was connected into the bridge and its KK_1 section was made equal to the value R_1 found in (4). Using the values for MJ,

NL_1 and the heating current found in (4), the calibration curve was obtained by altering KK_1 stepwise from R_1 to R_2, photographing the scale after each alteration and plotting the scale values obtained against the KK_1 resistance.

6) The cell was then connected in and the heating current switched on. The galvanometer scale and the chronometer were photographed simultaneously about 20 times during the passage of current. Using the calibration curve, the resistance corresponding to each galvanometer scale reading could be obtained. Thus the resistance (and hence the temperature) of the central platinum wire could be calculated as a function of the time during the whole of the experiment.

In (1), (2), (3), (4) the potential placed across the bridge was chosen (using the resistance P_1, Fig. 3) sufficiently large to make the adjustment accurate enough but sufficiently small so that the resistances in the bridge were not appreciably altered.

Great care had to be taken with the design of the switches used to replace the cell resistances by the calibration resistance and its potential leads. All common types of switches were found to give much trouble due to their contact potentials and resistances. Because of the variability of these contact phenomena, it was difficult to maintain the balance of the bridge over long periods of time. All of the switches were therefore specially designed so that contact was made and broken between an amalgamated copper rod and mercury — the contact resistance and potential being negligible in that case.

Now the calibration curve was obtained when the galvanometer was stationary. Therefore a correction must be applied to each scale reading determined during the experiment since the galvanometer is then in motion and possesses a finite oscillation period. Moreover since the galvanometer speed varies during the experiment, the correction will also vary from point to point on the scale. However, instead of correcting each scale value, it is shown in the next section that a great simplification results if the correction is applied to the time values.

4. Galvanometer theory

The equation of motion for the galvanometer is

$$K_0 \frac{d^2\Phi}{dt^2} + \left(p_0 + \frac{q^2}{R_T}\right) \frac{d\Phi}{dt} + D\Phi = q\ I(t) \qquad (1)$$

where

Φ = angle of deflection of the mirror
= 1/2 (angle of deflection of the light beam)
K_0 = moment of inertia of the rotating system
$-p_0 \frac{d\Phi}{dt}$ = moment on the mirror due to air resistance
q = the dynamical galvanometer constant
R_T = total resistance of the galvanometer circuit
$-D\Phi$ = elastic torque
$I(t)$ = current through the galvanometer (a function of time).

The constants in this equation were calculated from experimental determinations of the following experimentally observable galvanometer properties:

statical galvanometer constant, oscillation period, logarithmic decrement and critical damping resistance.

Instead of the independent variable Φ, it is more convenient to use the deflection, x, on the galvanometer scale where $x = 10^2 \cdot 2\Phi$ (x is in cm). The equation of motion was found to be

$$2.44 \cdot 10^{-3} \frac{d^2x}{dt^2} + \left(1.77 \cdot 10^{-3} + \frac{10.3}{R_T}\right) \frac{dx}{dt} + x = 0.96 \cdot 10^7 \; I(t) = x_0(t) \quad (2)$$

where $x = x(t)$, a function of time, is obtained from the experimental film, and thus using equation (2) the value of $x_0(t)$ can be found. Hence every point of the experimentally found, $x(t)$ *versus* time, curve must be corrected using this equation. To avoid the time consuming numerical work, a zero time correction was tried instead. Equation (2) can be written as

$$x_0(t) = x + P \frac{dx}{dt} + Q \frac{d^2x}{dt^2} \quad (3)$$

Now the right hand side represents the first three terms in a Taylor expansion if $Q = 1/2\, P^2$. This condition can be satisfied since the value of P can be altered by changing R_T. If the terms in the Taylor expansion after the first three are neglected, equation (3) can be written

$$x_0(t) = x(t + P) \quad (4)$$

Thus instead of correcting all of the x values determined experimentally, it is only necessary to subtract the constant term P from all of the time values. Hence the galvanometer correction can be expressed by adding a positive term to the zero time. The resistance value, R_T, to make this simple correction possible is obtained from $Q = 1/2\, P^2$, which gives $R_T = 150$ ohm. Therefore, by arranging that the *total* resistance in the galvanometer circuit should have this value, the correction to be applied because of the finite oscillation time of the galvanometer can be expressed as a correction, P, in the zero time where $P = \sqrt{2\,Q} = 0.07$ sec. It can also be shown that the remainder term neglected above is negligible.

It is the sensitivity of the galvanometer which mainly determines the minimum heating current which can be used. Using the minimum current for the substances so far studied, it was found that the time required for the KK_1 resistance to increase from R' to R_2 (*i.e.* the experimental time length) was in all cases about 60 sec. It is of course possible to use higher currents by making a compensatory increase in the galvanometer series resistance MH, *cf.* Fig. 3 (and placing a certain resistance P_G in parallel with the galvanometer so that the condition, $Q = 1/2\, P^2$, is still valid). Moreover in practice slightly greater currents than the minimum were used for reasons of experimental convenience. By suitably increasing the galvanometer series resistance it is possible to obtain the same scale deflection as when the minimum current is used and in addition it results that the experimental time length will also be about 60 sec. However, if the current becomes too large, it may exceed the safe heating limit for some of the resistance elements in the bridge and also, in the case of liquids, it may be large enough to produce convection. In order that

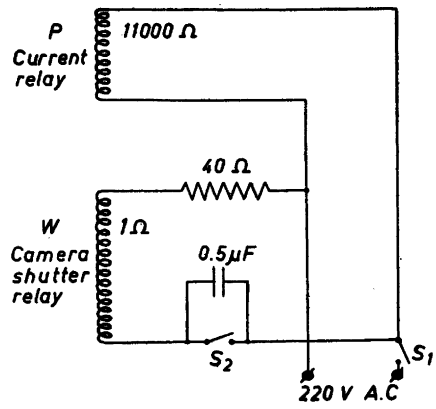

Fig. 5. Relay system for the simultaneous operation of the bridge current switch and the camera shutter.

the assumption of an infinite two dimensional medium should be valid, it is necessary to make the diameter of the cell greater than a certain minimum value. Using the experimental time length of 60 sec, a diameter of 3 cm was found to be suitable for the substances so far studied.

5. Zero time determination

The time determination was obtained by photographing a chronometer. To determine the absolute value t, the zero time when current first began passing through the cell must also be determined. To do this the relay P which switched on the current in the bridge circuit was connected in parallel with the relay W which operated the camera shutter. The circuit is shown in Fig. 5.

Passage of current through the electromagnetic relay P caused contact to be made between two mercury pools, one of which was in contact with the lead U and the other with the lead V (see Fig. 3). This type of relay was ideal for high precision electrical work because no contamination of the surfaces, by which contact was made and broken, took place. When current passed through the relay W, the camera shutter release was depressed and a photograph taken. The experiment was started thus: First switch S_2 was closed and then S_1 thrown. Both relays were therefore activated, *i.e.* the bridge current switched on and a photograph of the chronometer taken simultaneously. Switch S_2 was then opened and afterwards closed every time it was desired to photograph the galvanometer scale to obtain the scale reading. The zero time was the time shown by the chronometer in the first photograph.

However, the zero time must be corrected for the small time difference between the relays, *e.g.* the first photograph was actually taken 0.02 sec before the bridge current was switched on. This value remained constant to within $\pm$ 0.005 sec over a six months' period of daily operation. The time difference was determined using a Cossar double beam oscilloscope and placing a photomultiplier inside the camera. The pulse obtained from the photomultiplier, when the camera shutter opened, deflected one of the oscilloscope beams vertically whilst the passage of current through the switch S (Fig. 3),

when it was closed, was used to deflect the other beam vertically. A horizontal pulse was applied to both beams simultaneously during the interval when the two vertical pulses were registered. Thus by comparing the resulting wave trace with a sinusoidal time base curve, the time difference between the two operations could be determined.

6. Theory of the hot wire method

The two-dimensional solution of the heat conductivity equation, given by Eucken and Englert, assuming an infinite medium and an infinitely thin heating wire is

$$\lambda = \frac{Q}{4\pi} \cdot \frac{\Delta \ln t}{\Delta T} \tag{5}$$

(λ = thermal conductivity of the medium, t = time,
Q = heat liberated by the heating wire in cal/cm/sec,
T = temperature of the wire.)

Ideally, Q should remain constant during the experiment. However, in practice, the resistance of the heating wire alters due to its temperature change and thus Q actually varies with time. The necessary correction to eq. (5) was calculated as follows:

If Q is constant, then the temperature $T(t)$ at a certain point in the medium is

$$T(t) = Q\ f(t) \tag{6}$$

where $f(t)$ is a function of t.

However, if Q is dependent on t (and therefore written $Q(t)$), then the temperature $T_0(t)$, at the point under consideration, will be given by

$$T_0(t) = \frac{\delta}{\delta t} \int_0^t Q(\tau) f(t-\tau) d\tau \tag{7}$$

(this is known as Duhamel's integral [3]).

The battery potential is denoted by E. This voltage is put across the central platinum wire (with resistance R_J at $t=0$, this is the resistance over the *whole* length L_1M_1, *cf.* Fig. 1) and, in series with it, a constant resistance R_K (equal to the resistance P_1 plus the resistance LL_1, *cf.* Fig. 3). Then, if $T_0(t)$ is the temperature at the boundary surface between the wire and the medium, the variable amount of heat liberated during the experiment $Q(t)$ is given by

$$Q(t) = \frac{0.2389}{l} \cdot R'(1 + \alpha\ T_0(t)) \cdot \left[\frac{E}{R_K + R_J(1 + \alpha\ T_0(t))}\right]^2 \tag{8}$$

where R' ohm is the resistance of the KK_1 section of the wire at $t = 0$, l cm is the length of this section and α the temperature coefficient of this resistance. Equation (8) can be written

$$Q(t) = \frac{0.2389\ R'}{l} \left(\frac{E}{R_K + R_J}\right)^2 \cdot (1 + \alpha\ T_0(t))\ (1 + \frac{\alpha R_J}{R_K + R_J}\ T_0(t))^{-2}$$

which, remembering that $\alpha T_0(t) < 0.01$, becomes

$$Q(t) = \frac{0.2389\ R'}{l}\left(\frac{E}{R_K + R_J}\right)^2 (1 + \frac{R_K - R_J}{R_K + R_J} \cdot \alpha \cdot T_0(t)) \qquad (9)$$

We now assume that the value $Q = \frac{0.2389\ R'}{l}\left(\frac{E}{R_K + R_J}\right)^2$, *i. e.* the heat liberated at the start of the experiment, is the one which is to be used in equation (5) for the calculation of λ. Now the wire temperatures $T(t)$, which would be obtained with this ideal constant heat generation Q, can be calculated by applying a correction to the actual wire temperatures $T_0(t)$ obtained during the experiment, as is seen in the following:

Putting $\eta = \frac{R_K - R_J}{R_K + R_J}$, equation (9) becomes

$$Q(t) = Q(1 + \alpha\eta\ T_0(t))$$

Placing this value for $Q(t)$ in equation (7), we get the following value for the temperature of the wire

$$T_0(t) = \frac{\delta}{\delta t}\int_0^t [Q + \alpha\eta\ Q\ T_0(\tau)] f(t-\tau)\ \mathrm{d}\tau$$

which, using eq (6), gives

$$T_0(t) = T(t) + \alpha\eta\ \frac{\delta}{\delta t}\int_0^t T_0(\tau)\ T(t-\tau)\ \mathrm{d}\tau \qquad (10)$$

The second term on the right hand side is only a small correction and hence in it $T_0(\tau)$ can be replaced by $T(\tau)$. For small values of $r^2/4at$ it can be shown that

$$\frac{\delta^2}{\delta t^2}\int_0^t T(\tau)\ T(t-\tau)\ \mathrm{d}\tau = \frac{\delta}{\delta t}[T(t)]^2 \qquad (11)$$

which gives

$$\frac{\delta}{\delta t}\int_0^t T(\tau)\ T(t-\tau)\ \mathrm{d}\tau = [T(t)]^2 - \text{constant} \qquad (12)$$

Equation (10) then becomes

$$T(t) = T_0(t) - \alpha\ \eta\ [T(t)]^2 + \text{constant} \qquad (13)$$

Now, equation (13) shows that the correction is nonlinear and thus ought to be made separately for each experimental point used for the determination of the thermal conductivity. However, in the temperature range used in the present experiments, the correction term is small and does not change greatly. Thus the correction can be made more simply as follows:

From equation (13), using the delta symbol for the changes in the variables and dropping the notation for the independent variable t, we have

$$\Delta T = \Delta T_0 - \alpha\eta\Delta T^2 \simeq \Delta T_0 - \alpha\eta\Delta T_0^2$$

Now if T_1 is the temperature of the central platinum wire when resistance measurements are begun and if T_2 is the temperature at the end of the resistance

measurements (*i.e.* T_1 and T_2 correspond respectively to R_1 and R_2 which are the end points of the experimental resistance range in Fig. 4) then

$$\frac{\Delta T}{\Delta T_0} = 1-\alpha\eta \frac{\Delta T_0^2}{\Delta T_0} = 1-\alpha\eta \left(\frac{T_2^2-T_1^2}{T_2-T_1}\right) = 1-\alpha\eta\ (T_2 + T_1)$$

Thus $\frac{\Delta T}{\Delta T_0} = 1-2\ \alpha\eta T_c$ (14) where T_c is the mean temperature. For the experimental evaluation of this correction factor it is more convenient if T_c is expressed in terms of resistances which can be measured during the experiment. Now $\alpha T_c = \frac{1}{R'}\ [R'(1 + \alpha T_c)-R']$.

If the resistance of the central platinum wire is R_c when its temperature is T_c then $R_c = R'(1 + \alpha T_c)$.

Therefore $\alpha T_c = \frac{1}{R'}\ [R_c-R']$

and $$\frac{\Delta T}{\Delta T_0} = \frac{R'-2\eta(R_c-R')}{R'} \qquad (15)$$

This correction equation is used as follows: In the experiment $\frac{\Delta \ln t}{\Delta T_0}$ is actually measured but, according to equation (5), $\frac{\Delta \ln t}{\Delta T}$ is required. Equation (5) can be written:

$$\lambda = \frac{Q}{4\pi} \cdot \frac{\Delta \ln t}{\Delta T_0} \cdot \frac{\Delta T_0}{\Delta T}$$

and using equation (15)

$$\lambda = \frac{Q}{4\pi} \cdot \frac{\Delta \ln t}{\Delta T_0} \cdot \frac{R'}{R'-2\eta(R_c-R')} \qquad (16)$$

If I amp is the current through the central platinum wire at $t = 0$ and R ohm the resistance of the KK_1 section of this wire during the experiment, then

$$\lambda = \frac{R'I^2}{4\pi l} \cdot 0.2389 \cdot \alpha\ R' \cdot \frac{\Delta \ln t}{\Delta x} \cdot \frac{\Delta x}{\Delta R} \cdot \frac{R'}{[R'-2\eta(R_c-R')]} \qquad (17)$$

Using equation (17), it is seen that the thermal conductivity, λ, can be calculated from determinations of the slope of the calibration curve, $\frac{\Delta x}{\Delta R}$, and the slope of the experimentally-determined galvanometer scale reading *versus* ln time curve, $\frac{\Delta \ln t}{\Delta x}$. All of the other quantities in this equation are constants and can be obtained from direct potentiometric measurements on the particular cell used.

7. Correction for the differing heat capacities of the heating wire and of the medium

In the theoretical case, heat is generated in a mathematical line and then flows out into the medium. However, in the method used here, heat is generated in a thin cylinder of radius 0.005 cm. In order to apply the theory of the

theoretical case, it is therefore necessary to assume that, if the heat generated is the same, the heat flow in the medium for radial distances $r \geqslant 0.005$ cm is the same in both cases (assumption A).

Now, in the theoretical case, the medium situated in the region $r < 0.005$ cm will take up a certain amount of heat depending on its heat capacity. However, this amount of heat will be different to that taken up by the platinum wire in the actual case because of the wire's different heat capacity. The correction to be applied will now be estimated.

If we assume a constant amount of heat Q cal/cm/sec generated in the platinum wire, then the amount $c_1\gamma_1\pi r_2^2\ T_0'(t)$ is taken up by the wire and the rest $Q_1(t)$ streams out from the wire into the medium, where

$$Q_1(t) = Q - c_1\ \gamma_1\pi\ r_2^2\ T_0'(t) \tag{18}$$

(c_1 = specific heat of platinum, γ_1 = density of platinum, r_2 = radius of the wire (0.005 cm), $T_0(t)$ = temperature of the wire and $T_0'(t) = \frac{\delta}{\delta t}\ [T_0(t)]$).

The platinum wire is now replaced by a hypothetical wire of the same specific heat (c) and density (γ) as the medium. If we again assume a constant heat supply, Q, then the part streaming out from the wire is, to a first approximation,

$$Q_2(t) = Q - c\gamma\pi r_2^2 T_0'(t) \tag{19}$$

Using this value for $Q_2(t)$ and the notation of Duhamel's integral (equation (7)), we find that the temperature of this hypothetical wire, and hence the temperature $T(t)$ at $r = 0.005$ cm in the medium in the theoretical case (this follows from assumption A above), is given by an expression

$$T(t) = \frac{\delta}{\delta t}\int_0^t [Q\ -\ c\gamma\pi r_2^2 T_0'(\tau)]\ f(t-\tau)\ \mathrm{d}\tau \tag{20}$$

Substituting the value for Q from equation (18), we get

$$T(t) = \frac{\delta}{\delta t}\int_0^t Q_1(\tau)\ f(t-\tau)\mathrm{d}\tau + \frac{\delta}{\delta t}\int_0^t (c_1\gamma_1 - c\gamma)\pi r_2^2\ T_0'(\tau)\ f(t-\tau)\ \mathrm{d}\tau \tag{21}$$

Now the first term on the R.H.S. is the temperature $T_0(t)$ of the platinum wire and hence, putting $\beta = (c_1\gamma_1 - c\gamma)\ \frac{\pi r_2^2}{Q}$ and neglecting second order terms, we can write

$$T(t) = T_0(t) + \beta\ \frac{\delta^2}{\delta t^2}\int_0^t T_0(\tau)\ T_0(t-\tau)\ \mathrm{d}\tau \tag{22}$$

Using equation (11), we find

$$T(t) = T_0(t) + \beta\ \frac{\delta}{\delta t}\ [T_0(t)]^2$$

$$i.e.\ T(t) = T_0(t) + 2\beta\ T_0(t)\ T_0'(t) \tag{23}$$

This can be written as a Taylor expansion

$$T(t) = T_0(t + 2\beta\ T_0(t)) \tag{24}$$

since the remainder term which has been neglected is negligible. Thus the correction for the differing heat capacities of the wire and the medium can be expressed by adding a correction term τ_3 to the zero time where

$$\tau_3 = 2\beta\ T_0(t) \tag{25}$$

The numerical evaluation of τ_3 can be performed sufficiently accurately as follows:

For ideal two-dimensional heat flow with a constant amount, Q, of heat liberated at a mathematical line in an infinite medium, the temperature at a point r cm from the line is given by

$$T(t) = \frac{Q}{4\pi\lambda} \int_0^t (e^{-r^2/4a\tau}/\tau)d\tau \tag{26}$$

where $a = \frac{\lambda}{c\gamma}$.

For small values of $r^2/4at$, *i. e.* for relatively large time values, equation (26) becomes

$$T(t) = \frac{Q}{4\pi\lambda} (\ln t + \ln \frac{4a}{r^2} - \gamma') \tag{27}$$

where γ' is Euler's constant (0.5772).

Now $T_0(t)$, the temperature of the wire, is given sufficiently accurately by equation (27) on putting $r = r_2$. During the experiments log t increased from 0.5 to 1.5 and could be taken equal to 1.0 for the calculation of τ_3 since the resultant error was small. Thus

$$T_0(t) = \frac{Q}{4\pi\lambda} (\ln \frac{4a}{r_2^2} + 1.7) \tag{28}$$

Putting this value for $T_0(t)$ in equation (25), substituting the value for β and noting that $c_1\gamma_1 = 0.64$ for platinum, we get

$$\tau_3 = \frac{r_2^2}{2\lambda} (0.64 - c\gamma) (\ln \frac{4a}{r_2^2} + 1.7) \tag{29}$$

For all solutions studied, τ_3 was found to be small due to the thinness of the heating wire, *e. g.* $\tau_3 = +0.03$ (naphthalene), -0.02 (water), -0.01 (glycerol) sec. This correction was combined with the two other zero time corrections given above, *i. e.*

(1) the time difference between the current and camera shutter relays (p. 649).
(2) the zero time correction due to the inertia of the galvanometer (p. 648).

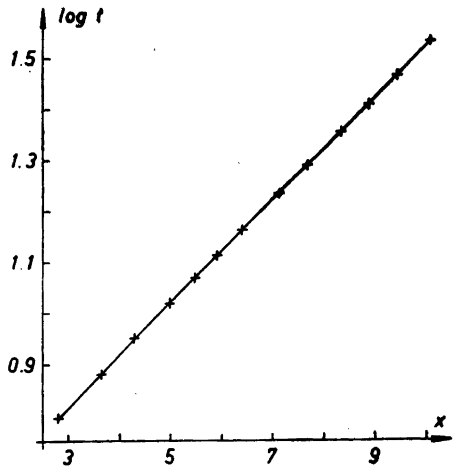

Fig. 6. x (the galvanometer scale reading) as a function of log t for a diphenylmethane/ naphthalene mixture. Temp.: 20.0° C, I = 0.28 amp.

EXPERIMENTAL

In equation (17), a and l were determined for each cell before it was used for experiments while I, R′ and R_c were determined during the experiment using the Leeds and Northrup potentiometer mentioned in section 2. $\frac{\Delta x}{\Delta R}$ was determined from the calibration curve giving the scale reading (x cm) as a function of the KK_1 resistance (R ohm). This curve was almost exactly linear — its mean slope was used for the value of $\frac{\Delta x}{\Delta R}$ and the slight curvature was corrected for by adding small corrections to the x values obtained during the experiment and used for the determination of $\frac{\Delta \ln t}{\Delta x}$.

Initially experiments were carried out on a homogeneous mixture of diphenylmethane and naphthalene containing 2.6 % of the former. Fig. 6 is a plot of x *versus* log t obtained during a typical experiment on this mixture.

The slope of the line was denoted by k. Because it is difficult to see how accurately the line fits the points with such a graph, a simultaneous plot (Fig. 7) of k log $t-x$ *versus* x was always made (with a scale for k log $t-x$ which was 10 times larger than that for x).

By inspection of this latter graph (which should be a horizontal line if the graph of x *versus* log t is linear) it could be seen whether the deviations from linearity fell within the experimental error.

Values obtained from independent measurements for the thermal conductivity, $\lambda \cdot 10^6$, of the mixture of diphenylmethane and naphthalene were: 835, 836, 839, 836, 834, 837, 835, 838, 840, using heating currents from 0.22 amp to 0.28 amp.

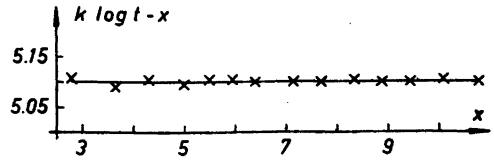

Fig. 7. k log t—x versus x for the same experiment as in Fig. 6. k = 9.92, λ = 0.000835.

The errors in the quantities used in equation (17) were:

$$I^2, \pm 0.1\ \%; \frac{\Delta x}{\Delta R}, \pm 0.3\ \%; \frac{\Delta\ ln\ t}{\Delta x}, \pm 0.1\ \%; l, \pm 0.05\ \%$$

The errors in the resistances used in this equation were negligible and thus the total experimental error was about $\pm$ 0.5 %. Various other errors such as the heat lost from the central heating wire through the potential wires and by radiation, the error resulting from the cross-sectional unevenness of the central wire and others were investigated and found to be negligible. As seen from the above results and also from results on experiments with water and aqueous solutions, at temperatures not too far from the maximum density point, and highly viscous liquids such as glycerine (a following paper), it was possible in practice to reproduce thermal conductivities to within $\pm$ 0.3 %.

Precision Measurements of the Thermal Conductivities of certain Liquids using the Hot Wire Method

D. G. GILLAM and OLE LAMM

Division of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

Experiments have been performed on water, glycerol and aqueous solutions of glycerol, ethyl alcohol and sucrose. In these experiments, no convection was observed during a determination when it was carried out at the temperature of maximum density. But it was found that the further the experimental temperature was from this temperature of maximum density, the earlier the convection started. However, using the experimental readings obtained before convection began, it was possible to calculate the thermal conductivity without any loss of accuracy. Accurate experiments have in this way been performed up to 20° C. The electrically heated wire was always placed vertically so as to minimize convection — it was found that the greater the angle between the wire and the vertical, the sooner the convection began. The method gave an automatic indication of the presence of convection, thus making possible the determination of suitable conditions for precision measurements. The high accuracy, of which this method is capable, is obtainable for highly viscous liquids but is otherwise limited to fluids of low thermal dilatation.

Using the method described in the previous article [1], the thermal conductivities of various liquids and solutions were determined and, in addition, the influence of convection on measurements of this type was investigated. The convection effect can be considered in the following manner. During the first instants of the experiment when convection has not had time to be effective, a straight x *versus* log t curve will be obtained whose slope is determined by the value of the thermal conductivity (and hence the k log t—x *versus* x curve will be a straight horizontal line) where x is the galvanometer scale reading, t the time and k the slope of the x *versus* log t graph (*cf.* Figs. 6 and 7 in Ref.[1]). When convection begins, heat will be lost quicker from the central heating wire because cooler liquid will be moving up to the wire by convection. Thus the thermal conductivity will appear to be greater and the k log t—x graph will curve upwards.

However, if the cell is placed vertical, convection should initially take place in concentric cylindrical surfaces and the convection effect should therefore be

less than in any other case. For example, a typical experiment on a 4.9 % solution of sucrose in water gave the following graph, Fig. 1. The measurement was performed at 4.0° C, near the density maximum of the solution where the thermal dilatation is small.

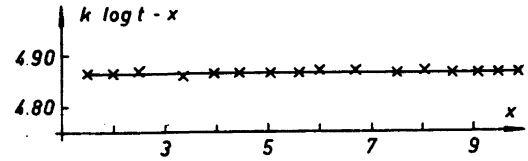

Fig. 1. k log t—x versus x (the galvanometer scale reading) for a 4.9 % aqueous sucrose solution. k = 8.71. Temp: 4.0° C, Cell: placed vertical, I = 0.28 amp (the heating current).

The straightness of the graph indicates the absence of convection. The value calculated for the thermal conductivity was $\lambda = 0.001328$. However, when the cell was placed at an angle of 45° to the vertical, the graph in Fig. 2 was obtained:

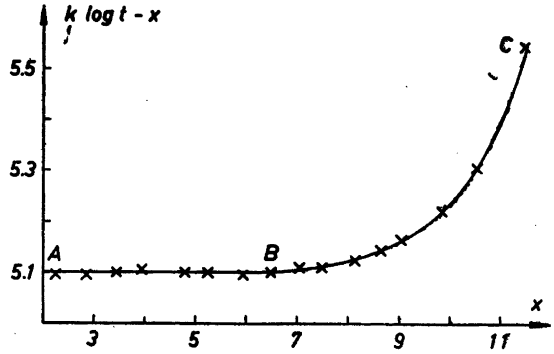

Fig. 2. k log t—x versus x for same solution as in Fig. 1. k = 10.17. Temp: 4.0° C, Cell: 45° to the vertical, I = 0.28 amp, AB: convection—free period, BC: effect of convection.

Convection began at the point *B* after 14 sec. (The total time from *A* to *C* was, for all determinations, about 60 sec.) In an experiment in which the convection effect is greater, the point *B* will occur earlier during the experiment and the deviation of the *BC* section from the horizontal will be larger. However, it should be possible to calculate the thermal conductivity from the initial section, *AB*. A value, $\lambda = 0.001330$, was obtained from the *AB* section in close agreement with the value calculated from Fig. 1. This shows that, if convection did occur in an experiment and a curved k log t—x graph was obtained, it was still possible to calculate an accurate value for the thermal conductivity using the initial, straight portion of the graph. Apart from several

further experiments carried out to check this important conclusion, the cell was always placed vertically so as to minimize convection from this source.

However, there are various other factors which must be taken into account. Firstly, convection will be influenced by the effect of the solute on the viscosity of the solvent. Secondly, convection will be at a minimum at the temperature of maximum density (t.m.d.) and that is why convection was not apparent during the experiments, carried out at 4° C, on the less concentrated aqueous solutions. However, an increase in the concentration results in a decrease of the t.m.d. and should hence give rise to a larger convection effect if the experiment is performed at the t.m.d. of pure water. This explains the occurrence of convection in the experiments on the more concentrated solutions carried out at 4° C.

With glycerol/water mixtures for example, it was found that the convection effect (as judged by the k log t—x graph) increased with increasing glycerol concentration until such a concentration was reached at which the properties of the glycerol became more dominant and that then, because of the high viscosity of solutions containing a high percentage of glycerol, the convection effect decreased as the concentration increased to 100 %. In all cases studied, however, it was possible to calculate the thermal conductivity from the initial, straight portion of the k log t—x graph.

With distilled water at 4° C, no convection was detected both when the cell was vertical and when it was placed at an angle of 45° to the vertical. This shows that the convection arising from a 45° inclined heating wire, under these conditions, is negligible at the t.m.d. However, with water at 20° C and the cell placed vertically, convection began as soon as 20 sec (point E) after the heating current was switched on (Fig. 3).

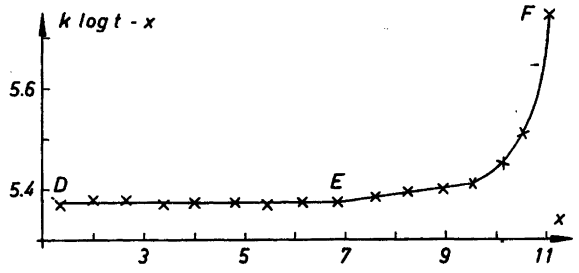

Fig. 3. k log t—x versus x for water. k = 9.47. Temp.: 20.0° C, Cell: placed vertical, I = 0.27 amp. DE: convection-free period, EF: effect of convection.

The thermal conductivity calculated from the DE section was 0.001442.

RESULTS

The measurements are summarized in Table 1. Each value is a mean of up to 8 independent determinations.

Table 1.

Medium	Concentration (weight %)	Current (amp)	Thermal conductivity λ	Convection appeared after	Temp. (° C)
Solution of glycerol in water	4.94	0.28	0.00131_7	20 sec	4.0
	16.00	0.27	0.00123_0	19 sec	4.0
	31.06	0.27	0.00111_0	22 sec	4.0
	63.50	0.28	0.00087_0	—	4.0
	95.24	0.28	0.00069_2	—	4.0
Solution of ethyl alcohol in water	4.0	0.28	0.00129_0	—	4.0
	14.15	0.28	0.00114_9	50 sec	4.0
	28.9	0.28	0.00096_8	20 sec	4.0
Solution of sucrose in water	4.9	0.28	0.00133_0	—	4.0
	15.5	0.28	0.00126_2	—	4.0
	24.75	0.28	0.00119_8	—	4.0
Water		0.27 and 0.32	0.00135_4	—	4.0
»		0.27	0.00144_2	20 sec	20.0

Bravais' and Kossel-Stranski's Theories of Homopolar Crystals and their Application to Elements

GÖSTA WRANGLÉN

Division of Applied Electrochemistry, Royal Institute of Technology, Stockholm, Sweden

The two theories are shown to be in fair agreement for simple lattices. The results obtained by the author with the Kossel-Stranski theory differ from those reported by Stranski and co-workers. Both theories conform well with experimental data, as is shown for the crystal habit and structure of a number of common elements, including Cu, Ag, Au, Pb, Pt, Fe, W, V, C, Si, Be, Ti, Mg, Zn, Cd, Se, Te, Sn. In the case of Se and Te serious deviations from the Kossel-Stranski theory have been reported earlier due to inadequate theoretical predictions. The agreement between theory and experiment is best if the outer disturbances are small, as in sublimation, while deviations are found on metal crystals, electrodeposited from complex or molten salts. Electrodeposition as such is not a very disturbing factor.

It is of great interest to relate the habit, *i. e.* the external face development of a crystal to its internal structure. Two main such attempts have been made.

About 1850 Bravais suggested that the order of decreasing importance of the outer surfaces would be the same as the order of decreasing close-packing of the corresponding lattice planes [1]. Hence, this idea has also been referred to as the "reticular density" theory [2]. It has been elaborated in later years, mainly by mineralogists [3–5].

The other theory was developed in 1928 by Kossel [6] and has later been elaborated by Stranski and co-workers [7–9]. This theory considers the number of closest neighbors of a lone particle, settling on a face to begin a new layer. It may therefore be termed the "nearest neighbors' " theory. It was reviewed by several authors [2,10–12].

BRAVAIS' OR RETICULAR DENSITY THEORY

The more closely packed with molecules a set of planes is, the wider is their spacing. It is easily shown that $D = \frac{n}{V} \cdot d$, where D = reticular density (number of molecules per unit area), d = interplanar spacing, V = volume of unit cell, n = number of molecules per unit cell.

The reticular density theory can be formulated in the following way: In close-packed planes the molecules form a dense aggregate and neutralise each other's bonds so that few free valencies are directed towards the outer space. Furthermore, a molecule trying to start a new such close-packed plane will be located relatively far from the molecules of the crystal and will form an excrescence on the surface of the latter. Hence, the new molecule will be but loosely bonded and the tendency for the formation of a seed will be low. On the other hand, a less densely packed plane will consist of molecules less tightly knitted together, which will therefore have more residual valencies pointing out from the crystal. Furthermore, a molecule trying to start a new plane will be close to the molecules of the outermost planes of the crystal and will not project very much above the surface of the crystal. Hence, it will have a greater tendency to stay and form a seed. It should be stressed that the reticular density theory does not take account merely of the outermost plane since a small spacing will mean that the lone molecule is close to the entire crystal.

According to the above, the smaller the reticular density and interplanar spacing of a surface is, the faster will it grow normally to itself. It is obvious, however, that the most rapidly growing surfaces will soon disappear from the crystal and in the final crystal only the surfaces of slowest perpendicular growth will persist. But these are the close-packed surfaces.

Burton and Cabrera [13] and also Hartman and Perdok [14] have divided the faces of a crystal into three different classes, *viz.* close-packed or flat faces, F-faces, containing 2 or more intersecting sets of parallel, close-packed atom chains; stepped or S-faces, containing one set of parallel, close-packed atom chains; and kinked or K-faces, containing no such chains. The directions of close-packed atom chains, called periodic bond chain vectors by Hartman and Perdok [14], correspond to the preferred directions of growth and to important zone directions of the crystal.

It is interesting to note that the order of decreasing importance of the crystal faces according to the reticular density theory will be the same as the sequence in which the first order reflections appear on an X-ray powder recording, proceeding from small to large angles [3]. If the space lattice is known the order of decreasing spacings d can easily be calculated from formulas given in textbooks of X-ray crystallography. The calculation may be checked with the ASTM X-ray data cards.

KOSSEL-STRANSKI'S OR NEAREST NEIGHBORS' THEORY

According to the Kossel-Stranski theory the number of nearest, second-nearest and third-nearest neighbors (and so on) of a lattice particle, put together in an expression $n_1/n_2/n_3...$, are considered to be a measure of the bonding energy of the particle in question. Growth of the crystal will normally proceed by the addition of a molecule to an uncompleted lattice row. This process is called the *wiederholbarer Schritt* (the repeatable step) and the lattice site that the molecule then occupies is known as the *Halbkristall-Lage* (half-crystal position, growth position). The number of neighbors of a par-

ticle in the *Halbkristall-Lage* is exactly *half* of that of a particle in the interior of the crystal.

As far as the *wiederholbarer Schritt* is concerned, there is no difference between the various lattice planes of a crystal [4,6]. However, as one plane is completed a new one has to be started. A simplifying provision of the Kossel-Stranski theory is that all neighbors at a certain distance are equal. In reality, their bond energies are more or less utilized owing to their position. If this is disregarded it is easily demonstrated that a new layer of molecules will start from its middle and not from its edge, since the seed molecule will have more neighbors in the former case.

If a lone particle, settling on a face to begin an entirely new layer, has a great number of closest neighbors, it is obvious that this face will grow fast normally to itself, since new layers are easily nucleated.

If the corresponding neighbor numbers are recorded for the various lattice planes of a three-dimensional model, it is easy to arrange the faces in order of increasing normal growth velocity, *i. e.* in order of decreasing importance on the final crystal. The counting of the neighbors should be performed in a space lattice model of considerable size (20—30 unit cells).

In reality, the kinetics of crystal growth are more complicated than is provided in the Kossel-Stranski theory. Growth layers of visible thickness can be observed microscopically. They are easily studied in the electrodeposition of metals. They are about one micron thick and usually spread from a point in the interior of the crystal surface, though at high current densities from the edges. These thick growth layers are always to be found in the most close-packed surfaces. They are sometimes due to screw dislocations, a phenomenon that has played a great role in the literature on crystal growth lately [15].

CUBIC STRUCTURES

For cubic lattices the interplanar spacings d are calculated from the formula

$$d = a / \sqrt{h^2 + k^2 + l^2}$$

where a is the edge length of the unit cube and h, k, l the Miller indices of the surface. All sets of values h, k, l that are a multiple of 2, 3 or 4 of a former set should be excluded since they will correspond to higher order reflexions but not to physical lattice planes. For interlacing lattices certain other restrictions apply in addition. These are given in the table headings.

The reticular densities (number of atoms in the area a^2) are obtained from the relation $D = \frac{n}{V} \cdot d$ and are recorded in the second column in the tables. In the third column the number of nearest neighbors of a molecule starting a new plane is given. The last column, finally, gives the sequence according to column 3. In determining this order the following should be observed. Due to the rapid falling off of homopolar forces with distance, the expression $n_1/n_2/n_3$ may be considered as a kind of (decimal) fraction where one molecule in the first place corresponds to several in the second and so on. If, for instance, the

bonding energy is proportional to r^{-6}, as is often assumed [16], and if $r_2 = r_1\sqrt{2}$, one molecule in the first place will correspond to 8 in the second. If r_2 is only 10 % longer than r_1, the proportion will still be 1:1.8. Hence, we may safely adopt the following principle: The relative value of the expression $n_1/n_2/n_3$ is generally determined by n_1. If two expressions have the same n_1, their relative positions will be determined by n_2. If both the n_1:s and n_2:s are equal, n_3 will decide and so on.

The discrepancies between the two theories will be obvious from the last column of the tables. An X in the last column denotes the faces enumerated by Stranski and co-workers [7,8]. They are usually, but not always, given by them in the same order as here. It should also be noted that there are several misprints in the tables in the paper by Stranski and Kaischew [7] that are cited uncorrected by later writers [10,12,17,18]. One curious feature in the paper mentioned is that the authors [7] arbitrarily leave out some important low-indexed surfaces, particularly those that give the same expression in column 3 of the tables. This omission does not seem justified since these surfaces, *e. g.* 331, 211, 310 and 511 in the face-centered cubic lattice, are often observed on crystals (Table 3).

According to Stranski, any molecule on the surface of the crystal must at least be as strongly bonded as in the *Halbkristall-Lage*. His method to derive the equilibrium form is therefore to start from an arbitrarily simple form and substitute surfaces for corners and edges until the above provision is fulfilled. It appears that this method is arbitrary and is apt to exclude certain faces. Furthermore, the imagined removal of molecules from the corners and edges of the simple form has only to be carried so far that surfaces of the extension of a few tens of Ångström units are created. This does not necessarily imply that these surfaces will be detected by microscopic means on the final crystal. For instance, Stranski in a number of papers takes considerable pains to explain [16] why on body-centered cubic crystals the surface 211 appears but not the surface 111. It is now obvious from Table 4 that the former is theoretically

much more important than the latter and it will obviously be sufficient if 111 is present in submicroscopic extension.

In the first three lattices dealt with here, the spacing d assumes only one value for any sequence of parallel planes. This is not the case with the diamond cubic lattice (Fig. 1). An inspection of the space model will show that the 111 planes are spaced in a narrow-wide-narrow-wide sequence (Fig. 2). The identity spacing d obtained by X-ray analysis is $d = p + q$. This means that in determining the reticular density two narrow-spaced planes are considered to be one plane of double density. In applying the Kossel-Stranski theory, the molecule starting a new layer should be located at the distance q from the outer surface of the crystal (*e. g.* if the crystal surface is plane 2, the lone molecule will be in plane 3). The same condition is found with some other planes in

Table 4. Body-centered cubic lattice.

Restriction: $h + k + l = 2\ n$. $r_1 = a\sqrt{3}/2 = 0.866\ a$; $r_2 = a$; $r_3 = a\sqrt{2}$

the lattices dealt with below. Such "double" planes are marked "D" in the first column in the tables.

In Tables 3 and 6, the two theories are tested on elements with cubic structures. Most of the experimental data have been taken from P. Groth, Chemische Krystallographie [19], which contains an abundance of material that does not seem to have been utilized in this connection earlier. The third column in the tables gives the observed crystal faces in order of decreasing importance. Above and below the index figures, the ordinal numbers of the various faces according to Bravais' and Kossel-Stranski's theories are given with small figures. These numbers show the correlation between the two theories and experimental results.

HEXAGONAL STRUCTURES

In hexagonal lattices, the spacings d are obtained from the formula

$$\frac{1}{d^2} = \frac{4}{3a^2}(h^2 + k^2 + hk) + \frac{l^2}{c^2}$$

The hexagonal lattice is indexed with only three indices here. The fourth index i often given is related to h and k by the equation $h + k + i = 0$. In the hexagonal and following lattices, interplanar spacings are used instead of reticular densities. They are expressed in relative measure or in Ångström units.

In the hexagonal close-packed lattice, c equals $a\sqrt{8/3} = 1.633\ a$. Mg ($c = 1.627\ a$), Be and Ti ($c = 1.590\ a$) are close to the ideal value. In Cd ($c = 1.890\ a$) and Zn ($c = 1.855\ a$) the c-axis is relatively longer and the sequence of planes will be somewhat different. Earlier workers [11,28] treated Zn and Cd as ideally close-packed. It will be obvious from the tables, however, that the correlation with observation will be better if account is taken of the stretching of the c-axis.

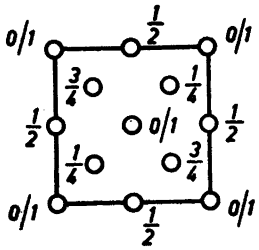

Fig. 1. Diamond cubic lattice, unit cell, basal projection. The figures denote the position of atoms above the basal plane.

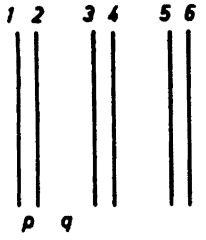

Fig. 2. Arrangement of the 111-planes of the diamond cubic lattice. $q = 3p$. $d = p + q$.

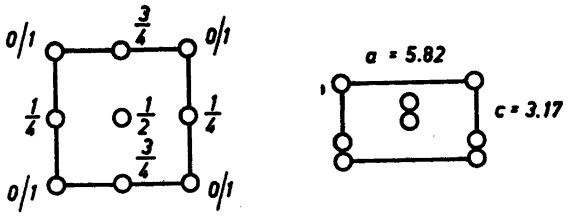

Fig. 4. Unit cell of white tin. a) Unit cell seen from top. b) Unit cell seen from side.

The elements selenium and tellurium have a more complex hexagonal structure. A basal projection of their unit cell is shown in Fig. 3. The lattice is built up of chains of atoms which are arranged in a spiral around an immaterial axis. The chains are perpendicular to the plane of the figure. Some data of importance are collected in Table 10.

These elements are of particular interest since deviations from the Kossel-Stranski theory have been reported with them. Stranski and co-workers [8] predicted the surfaces 101, 001, 102 and 100. Straumanis [11,29,30] in experiments on sublimated crystals of Se and Te did not find 001 and 102. The absence of the basis, 001, was particularly conspicuous. However, it seems clear that 001 should indeed *not*, according to the Kossel-Stranski theory, belong to the most important surfaces of the crystals. Since the closest neighbor is

Table 7. Hexagonal close-packed lattice (Be, Ti, Mg).

Restriction: $l = 2n$, if $h-k = 0$ or $3p$.

$r_1 = a$; $r_2 = a\sqrt{2}$; $r_3 = a\sqrt{8/3} = 1.633\ a$.

112	0.441 *a*	3/2/3	7

Same result with six kinds of neighbors.

in the same chain the continuation of a chain is obviously more favored than the starting of a new chain. Since 001 consists of ends of chains it should grow fast and hence not appear in the final crystal. Actually, Straumanis [29] found the *c*-axis to be the preferred direction of growth and that needles along this axis often resulted. In the case of Se and Te, the *c*-axis is obviously the most important periodic bond chain vector in the sense of Hartman and Perdok [14]. On the other hand, the surfaces parallel to the chains, *i. e.* the prism faces, requiring nucleation of new chains for their normal growth, should grow slowly and thus be important surfaces in the final crystal. In fact, four out of five faces observed by Straumanis [29] on selenium were prism faces. Although the Kossel-Stranski theory cannot distinguish between the higher prism faces, Table 11 shows that it is in good agreement with the observed faces on selenium. The Bravais theory is somewhat less successful since it does not take full account of the favored length growth of the chains and thus gives the pyramid faces, 102, 111 *etc.* a too important position.

Table 9. Hexagonal close-packed elements.

Element	Mode of crystallization	Order of observed crystal faces compared to theories
Be	Reduction of $BeCl_2$ with Na [19]	2 1 5 3 4 001, 100, 110, 101, 102 1 3 4 2 5

332	1.03	2/1/1/4	

Same result with five kinds of neighbors.

Observed sequence: Solidification [16]	$\overset{1}{100},$	$\underset{2}{\overset{2}{101}},$	$\underset{1}{\overset{3}{110}},$	$\underset{3}{\overset{6}{112}}$			
Electrodeposition from simple salts [19,22]	$\underset{2}{101},$	$\underset{1}{100},$	$\underset{3}{112},$	$\underset{-}{332},$	$\underset{5}{110},$	$\underset{4}{301}$	

In applying the Kossel-Stranski theory to the latter faces, one finds that they are spaced in a narrow-narrow-wide sequence. The lone atom considered should be across a wide spacing from the surface of the crystal since this will correspond to the bottle-neck in the growth process. Furthermore, different results may be obtained owing to the position of the surface in relation to the axis cross. The smallest value has been chosen, since this will correspond to the appearance of the surface on the final crystal. Often only every second of the pyramid faces are present on the crystals.

It has been assumed that the growth of Se and Te occurs by addition of atom by atom to the crystal. With some pyramid faces one would then find that as an atom is added to a chain it would have no nearest neighbor in the chain but just a hole below itself. Since this cannot be the case, one is led, on purely geometric grounds, to assume that the particles added are actually diatomic molecules. This is in accordance with the fact that selenium vapor consists of diatomic molecules.

Tellurium will obtain the same theoretical equilibrium form as selenium according to the Kossel-Stranski theory. Owing to other lattice dimensions the faces will appear in a somewhat different order according to Bravais as shown in Table 12. It is obvious that the agreement between theory and fact is good also for tellurium.

TETRAGONAL TIN STRUCTURE

White tin crystallizes in a tetragonal interlacing body-centered lattice, the unit cell of which is shown in Fig. 4 in basal and side projections. The spacings d are obtained from the formula

$$\frac{1}{d^2} = \frac{h^2 + k^2}{a^2} + \frac{l^2}{c^2}$$

The tin lattice may be considered as a diamond cubic lattice, compressed in the c direction. It is obvious from Fig. 4 b that the plane 101 is of the same nature as the octahedral plane 111 in the diamond cubic lattice, having alternating narrow and wide spacings.

The experimental data derived from Groth [19] (originally published by Miller in 1843) had to be recalculated by turning the axis cross 45° around the c-axis. While the two theories do not agree too well in the case of tin, experimental data correlate well with the nearest neighbors' theory.

ORTHORHOMBIC STRUCTURES

Sulfur and iodine crystallize in the orthorhombic system. Sulfur has a complicated face-centered unit cell with 128 atoms belonging to it. The space group restrictions are: All *hkl* even or all odd; $h + k = 4n$ in *hk*0 *etc.* Donnay and Harker [3] maintain that sulfur crystallizes in accordance with the Bravais theory. According to Hartman and Perdok [14] better results are obtained for sulfur with the reticular density theory, if the flat, stepped and kinked surfaces are considered separately. All the authors mentioned take account only of the appearance of the surfaces, not of their relative importance. The latter is given by Groth [19]. Correlation of his data with decreasing d-values, considering the above restrictions, shows the following:

Orthorhombic sulfur, natural crystals [34]:

1	3	4	2	14	7	6	5	11	9	10	8
111,	113,	011,	001,	010,	110,	115,	101,	112,	133,	013,	131

Orthorhombic sulfur, sublimated:

$$\overset{2}{001},\ \overset{10}{013},\ \overset{4}{011},\ \overset{14}{010},\ \overset{7}{110},\ \overset{1}{111},\ \overset{3}{113},\ \overset{6}{115},\ \overset{15}{117}$$

Orthorhombic sulfur, solidified from melt:

$$\overset{1}{111},\ \overset{4}{011},\ \overset{3}{113}$$

Orthorhombic sulfur, crystallized from solutions:

$$\overset{1}{111},\ \overset{14}{010},\ \overset{3}{113},\ \overset{2}{001},\ \overset{4}{011},\ \overset{7}{110},\ \overset{22}{100}$$

Iodine has a less complicated structure with 4 I_2-groups in the unit cell and with the following space-group restrictions: $h + k = 2n$ in hkl; $h = 2n$, $k = 2n$ in $hk0$; $h = 2n$, $l = 2n$ in $h0l$; $k = 2n$ in $0kl$. Iodine crystals, obtained in various ways, show the following surfaces in order of decreasing importance[19] and with the correlations with decreasing d-values noted: $\overset{2}{111}$, $\overset{1}{001}$, $\overset{3}{010}$, 313, 316, 110, 119. The last four faces will obtain ordinal numbers ranging between 10 and 20.

On the whole, these elements do not conform very well with the Bravais theory.

DISCUSSION OF RESULTS

It will be obvious from the tables that the two theories are in fair agreement for simple structures. They almost coincide for the face-centered cubic lattice and the stretched hexagonal close-packing (Zn, Cd). Kossel-Stranski's theory seems to correlate somewhat better with experimental results. However, it should be noted that this is fictitious to some extent, because this theory is less selective so that two or more planes will often obtain the same ordinal number. It is noteworthy that the agreement is best with metallic structures, although these, consisting of positive metal ions and a negative electron gas, are not strictly homopolar. With more complicated structures, such as those of sulfur and iodine, deviations from the Bravais theory are found, while the Kossel-Stranski treatment will be too intricate. In general, the Bravais theory is much easier to apply.

It is further obvious from the tables that the degree of correlation between theory and experiment is dependent on the conditions of the crystallization process. This is natural because both theories take account of only the lattice geometry and not the environment (diffusion, adsorption *etc*). Since both theories are energetic they imply conditions close to equilibrium, *i. e.* a small supersaturation, supercooling or polarization and hence generally a slow crystallization process. As the influence of the environment becomes more pronounced the crystals conform less well with the theories. It is natural that the best agreement is found with sublimated crystals: Sublimation is a slow process, occurring at high temperature, favoring equilibrium, and no foreign molecules are present to disturb the crystallization. On the other hand, in deposition from solutions, as by reduction agents (natural crystals seem to belong to this group) and sometimes by electrolysis, great disturbances and

deviations from the theories occur. It seems that the outer disturbances increase, *i. e.* the conformity with the theories decreases, somewhat in the following order: sublimation, solidification of melt, electrolysis of solutions of simple salts, chemical reduction, electrolysis of molten salts, electrolysis of complex salt solutions.

Electrodeposition as such, *i. e.* the superposition of an electric field on the lattice forces does not seem to influence the crystallization considerably, as is sometimes assumed [11,31]. If the electrocrystallization of metals is observed under the microscope it is often striking how little the direction of stream-lines means in comparison with the direction of preferred growth in the lattice. A crystal needle may grow not only at right angles to the general direction of the stream-lines but actually just opposite it, *i. e.* towards the *cathode*. The fact that electrocrystallization as such conforms so well with the theories of homopolar crystal growth supports the view that the particles that are built into the lattice on the cathode are neutral atoms, not ions [12].

The nature of the crystallizing particles seems to be of minor influence as long as the lattice is the same. For instance, Table 3 shows that, in general, Cu, Ag and Au develop the same surfaces, particularly on natural crystals [32].

Determination of Small Amounts of Total Cholesterol by the Tschugaeff Reaction with a Note on the Determination of Lathosterol

HENRIK K. HANEL and HENRIK DAM

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

A simple sensitive method for the determination of cholesterol based on Tschugaeff's color reaction is described.

No color is obtained with dihydrocholesterol or epicholestanol. Coprosterol gave a faint reaction (absorbance about 1/10 of that of cholesterol).

Amounts of cholesterol as low as 0.004 mg per ml reaction mixture can be determined with an accuracy of about 3 %.

Δ-7-cholestenol (lathosterol) gives a yellow color reaction under the same conditions as cholesterol with absorbance maximum of 395 mμ and almost no absorbance at 528 mμ where cholesterol yields maximum absorbance.

The Tschugaeff reaction (with acetyl chloride and zinc chloride) [1] is the obvious means to use for the determination of small amounts of cholesterol in biological material, since it is much more sensitive than the Liebermann-Burchard reaction used by most investigators. The present method is a modification (and simplification) of the one originally described by Görtz [2,3] for use with blood.

EXPERIMENTAL

Reagents.

Aqueous KOH solution 33 %.
Petroleum ether, b. p. below 50° C.
Ethanol, absolute
Sodium sulfate, anhydrous, analytical grade.
Glacial acetic acid » » *
Acetyl chloride » » *
Chloroform » » *
Zinc chloride, anhydrous » » (sticks).

* These reagents must be miscible with each other without turbidity.

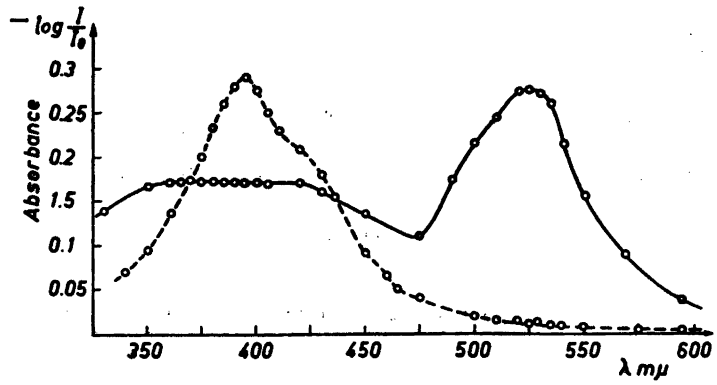

Fig. 1. Absorption curves. O———O *cholesterol, 0.0108 mg per ml reaction mixture.* O- - - -O *lathosterol, 0.0031 mg per ml reaction mixture.*

Zinc chloride solution in glacial acetic acid was prepared as follows.

40 g anhydrous $ZnCl_2$ (sticks, analytical grade) were quickly crushed and weighed in a dry 250 ml bottle and mixed with 153 ml glacial acetic acid. The bottle was shaken, stoppered and kept at 80° C for 2 ½ hours with occasional shaking. After cooling to room temperature the solution was filtered by suction through a glass filter.

The $ZnCl_2$-reagent was kept in a dark bottle with a tight glass stopper and could be used until it took up sufficient moisture to become turbid when shaken with chloroform. We were able to use the reagent at least 3 months.

Procedure. A. Extraction. The sample, *e. g.* 200—300 microliter bladder bile (or 2—3 ml fistula bile) or 0.5 g liver was placed in a 25 ml Erlenmeyer flask, then 33 % KOH and alcohol were added to make the mixture 17 % with respect to KOH, and 50 % with respect to C_2H_5OH. The mixture was heated on a steam bath either with the flask sealed with a glass ball, or, when the amount of cholesterol was particularly small, in a nitrogen atmosphere. In case of bile the time of heating was about ½ hour, tissue was heated 2 to 3 hours according to the fat content and time required for homogenization.

After cooling to room temperature each sample was extracted three times with 5 ml portions of petroleum ether (b. p. below 50° C). The extracts were combined and washed with water until neutrality to lithmus. The combined extract was now dried over anhydrous Na_2SO_4, and filtered by suction, the sodium sulfate being washed with petroleum ether. The anhydrous solution was evaporated *in vacuo* at 40—50° C, and the residue transferred with chloroform into a 10 ml test tube. The main part of the chloroform was then evaporated on the steam bath to give a final volume of about 2 ml.

B. Color reaction. To each of the above tubes, containing about 2 ml chloroform solution, was added 1 ml of the $ZnCl_2$-reagent and 1 ml of acetyl chloride. The addition of acetyl chloride was most conveniently done with a burette. The contents of the tubes were then mixed with a glass rod, and the tubes were placed in a water bath at precisely 65° C for exactly 15 minutes. Thereafter the tubes were cooled in ice water and the reaction mixture was transferred to a 5 ml volumetric flask; the tubes were washed several times with small amounts of chloroform to bring the volume in the flask up to the 5 ml mark. The eosin-red solution was then placed in a 10 mm cuvette and the light absorbance (density, $d = -\log \frac{I}{I_0}$) was measured within 30 minutes at 528 mμ in a Beckman spectrophotometer. The same reaction was carried out with 2 ml of a standard solution of cholesterol in chloroform (*e. g.* 0.02 mg/ml) and with 2 ml chloroform as a blank.

Because of the sensitivity of the reaction to variations in the permissible low concentration of water, it is advisable to use a standard with cholesterol for each series of determinations.

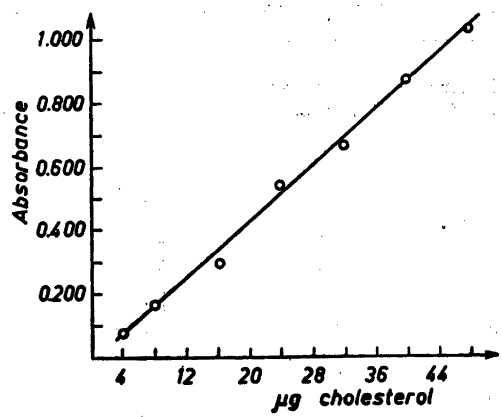

Fig. 2. Absorbance of cholesterol at 528 mµ after reaction with $ZnCl_2$-AcCl.

DISCUSSION OF THE METHOD

Development of the color at 65° C in 15 minutes was found more satisfactory than at 70° C in 12 minutes (as by Görtz [3]) or at 50° C in 20 minutes.

The maximal light absorbance was at 528 mµ. Fig. 1 shows the light absorbance curve found for 0.0108 mg cholesterol per ml reaction mixture and the corresponding curve for 0.0031 mg lathosterol. The developed color follows Beer's law in the concentration range from 0.004 to 0.048 mg cholesterol per ml reaction mixture as shown in Fig. 2.

We found that the proportion of the reagents mentioned gave the greatest color stability. The stability of the color is shown in Fig. 3 *.

Table 1 shows the results obtained by the present method and by the method of Sperry and Webb [4] as applied to hamster liver. The extraction of samples was carried out as described. The same extracts were used for both

		average	4.502	

methods, but with our procedure we used aliquots only one-tenths as large as those used for the Sperry-Webb determinations.

At the same occasion it was shown that the specific light absorbance at our method was 8 times that of the Liebermann-Burchard reaction used in the Sperry-Webb method.

ACCURACY OF THE METHOD

From a standard solution of cholesterol in chloroform different known aliquots were taken and the described procedure was carried out. The results are shown in Table 2.

The mean square error of the single measurement is $\sqrt{\frac{\Delta^2}{n-1}} = \pm 0.155$.

The mean square error of the average of the measurements is $\sqrt{\frac{\Delta^2}{n(n-1)}} = \pm 0.044$.

SPECIFICITY OF THE REACTION

In Table 3 are given the absorbances obtained with cholesterol, some cholesterol esters and some other sterols.

Dihydrocholesterol and epi-cholestanol gave no color.

Mixtures of cholesterol and dihydrocholesterol in varying proportions gave absorbances proportional to the amount of cholesterol.

Two samples of coprosterol prepared from different materials gave a faint reaction with absorption maximum at the same wave length as cholesterol but with absorbance of about 1/10 of that of cholesterol.

Mixtures of cholesterol and coprosterol in varying proportions gave absorbances lying on a straight line between the absorbances of the two substances.

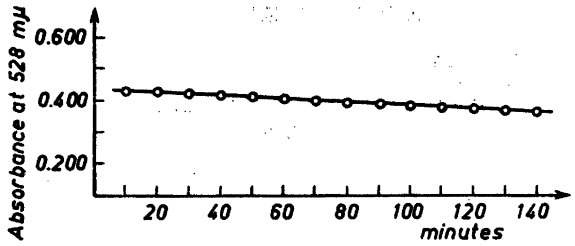

Fig. 3. The effect of time on the color stability of the reaction at 20° C. (Determined by means of a recording spectrophotometer).

The following bile acids: cholic, desoxycholic, chenodesoxycholic, glycocholic and taurocholic acid gave a yellowish-brown color reaction; the maximal absorbance of these acids was in the interval 375—450 mμ.

Δ-7-cholestenol, "lathosterol", gave a yellow color with a maximal light absorbance at 395 mμ (Fig. 1) and almost no absorbance at 528 mμ. The absorbance at 395 mμ follows Beer's law at least in the concentration interval 0.003—0.028 mg lathosterol/ml of the final mixture. Mixtures of cholesterol and lathosterol gave absorbances lying on a straight line. The present method may be utilized for simultaneous determination of cholesterol and lathosterol.

ACTA CHEMICA SCANDINAVICA 9 (1955) 683—688

A Method for the Estimation of the Taurine Content and its Conjugation with Cholic Acid in Rat Liver. Bile Acids and Steroids 22

JON BREMER*

Norsk Hydro's Institute for Cancer Research, Oslo, Norway, and Department of Physiological Chemistry, University of Lund, Lund, Sweden

A method for the determination of the taurine content of rat liver and for the taurine conjugation with cholic acid in rat liver homogenates is described. The taurine content of fresh rat liver was found to be 0.1—0.6 mg/g in male rats, and 0.7—1.1 mg/g in female rats.

Under the conditions described 2.2 μmole taurocholic acid was formed per g fresh liver. Due to the relatively high taurine content of the rat liver, addition of taurine to the reaction mixture had only an insignificant effect on the yield of taurocholic acid.

Homogenates centrifuged free from cell debris and nuclei were twice as effective as the total homogenates.

The taurine conjugation and the α-hydroxylation of desoxycholic acid have been effected by rat liver slices [1] and homogenates [2].

The present paper is primarily concerned with a simplified procedure to measure the taurine concentration and taurine conjugation in rat liver homogenates with the aid of ^{35}S-labelled taurine **.

The measurements of taurocholic acid formed was based on a selective extraction of taurocholic acid with *n*-butanol while the free taurine remained almost quantitatively in the water phase. Some of the factors influencing the synthesis of taurocholic acid from taurine have also been investigated and are reported here.

EXPERIMENTAL

The ^{35}S-labelled taurine had an activity of approximately 400 000 c/min./mg as measured in infinite thin layer with a TG 2 Tracerlab tube.

---

* Fellow of the Norwegian Cancer Society, Oslo, Norway.

** The author wishes to express his appreciation to L. Eldjarn and P. Fritzson, *Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway*, for the synthesis of ^{35}S-labelled taurine [3].

Albino rats, weighing 200—250 g, were used. The animals were killed by a blow on the neck. The livers were immediately removed and dropped into ice-cold isotonic KCl solution and weighed by differences.

The homogenate was prepared in a glass homogenizer with a loose-fitting pestle according to the method of Bergström and Gloor [3]. The homogenizing medium consisted of sucrose, potassium phosphate buffer of pH 7.4, magnesium chloride and nicotinamide [4]. One part of liver and three parts of homogenizing medium were homogenized for 45 seconds. The resulting homogenate was either used as such, or centrifuged free from cell debris and nuclei at 400 × g for 5 minutes.

In the incubation experiments 2 ml of the homogenate were added to each vessel with the appropriate additions. The total volume per vessel was 2.5—2.8 ml. The following concentrations were maintained in the incubation experiments: Potassium phosphate buffer (pH 7.4) 0.034—0.037 *M*, nicotinamide 0.016—0.018 *M*, $MgCl_2$ 0.004 *M*, sucrose 0.068—0.076 *M*, KCl 0—0.022 *M*.

The vessels were shaken in a Warburg apparatus at 37—38° C with a frequency of 100 strokes per minute. The gas phase was air and the incubation time was two hours.

The reaction was stopped by immersing the vessels for half a minute in boiling water. Much of the proteins was precipitated by this treatment. After cooling to room temperature, 1/3 volume of *n*-butanol was added and the vessels were shaken for 15 minutes in a shaking machine to establish equilibrium between the phases. The contents of the vessels were then centrifuged in narrow tubes at 400 × g for two minutes in order to obtain a clear separation of the two phases with the precipitated proteins at the interphase.

A suitable aliquot of the upper butanol layer (0.05—0.1 ml) was finally pipetted off for paper chromatography or plating. In the latter case empirical corrections of the counting data for self-absorbtion were made.

Analytical methods. The analytical technique was essentially based on the advantageous distribution of the taurocholic acid between the water and butanol phases. As the butanol and the water are partially miscible, it was found convenient to determine empirically the correlation between the original concentration in the water phase before extraction, and the concentration in the butanol phase after extraction with 1/3 volume *n*-butanol.

The analytical technique was tested by means of the quantitative paper chromatographic method as described by Eriksson and Sjövall [5,6].* In this system the taurine migrates with a speed approximately 1/3 of that of taurocholic acid. These compounds could therefore easily be separated.

The butanol phase could be applied directly on the paper, since the dry matter was only 5—6 mg/ml butanol. A sample of 0.05—0.1 ml was placed on the paper in small portions under a stream of warm air. After chromatography the spots were eluted with absolute alcohol and the eluate evaporated to a small volume for plating, or to dryness for spectrophotometric measurement in concentrated sulphuric acid at 389 mμ, using a Beckman quartz spectrophotometer.

Table 1 shows the results of some of these control experiments. It appears that the addition of radioactive taurine corresponding to 30 000 c/min. to 2.8 ml gave rise to only 15—20 c/min./0.05 ml butanol phase. It is also evident that no detectable amount of any extractable radioactive compound other than taurocholic acid had been formed. The slightly higher activity of the chromatographed sample was due to the smaller self-absorbtion, as most of the impurities in the butanol disappeared during the chromatographic procedure.

Further there is a close proportionality between the taurocholic acid formed and the amount of labelled taurine conjugated, the former determined spectrophotometrically, the latter by plating and counting of the butanol phase.

The effect of the pH on the distribution of the taurocholic acid between the water- and the butanol phases was studied. For this purpose ^{35}S-labelled taurocholic acid was prepared biologically as described above. Aliquots were dissolved in phosphate buffers of varying pH and shaken with 1/3 volume of butanol. Table 2 shows the resulting distri-

* The author is indebted to S. Erihsson and J. Sjövall, Department of Physiological Chemistry, University of Lund, for the use of their unpublished method for the quantitative determination of bile acids by paper chromatography.

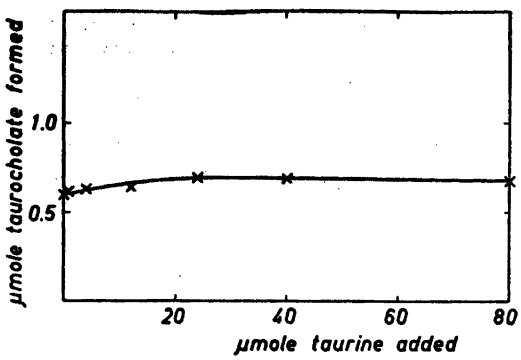

Fig. 1. Total volume 2.5 ml. 2 ml 25 % homogenate centrifuged at 400 g for 5 min. Substrate additions 2.5 µmole cholic acid, 0—80 µmole taurine. 0.05 ml butanol phase chromatographed, eluted and measured spectrophotometrically in concentrated H_2SO_4.

bution. By acidifying the solution, a greater concentration of taurocholic acid was achieved in the butanol phase. Nevertheless, we preferred to extract without acidifying the solution, as the addition of acid greatly affected the rate of migration of the bile acids on the paper chromatograms.

Table 3 shows the control of the distribution coefficient in the concentration interval used in the experiments to be described. Homogenate and a constant amount of ^{35}S-labelled taurocholic acid (0.2—0.3 µmole per vessel) were added to the vessels. Further there were added increasing amounts of inactive taurocholic acid. It appears that a constant concentration relationship between the butanol and water phases was obtained. Consequently there was no trapping of taurocholic acid in the precipitated proteins, and the partition coefficient also remained constant within the concentration range studied.

THE ESTIMATION OF FREE TAURINE IN RAT LIVER

As we could follow the formation of taurocholic acid in the rat liver homogenate both spectrophotometrically and by means of the ^{35}S-labelled taurine, we had the opportunity to calculate the taurine content of rat liver. Thus in the experiment shown in Table 1, only 0.32 µmole of the added 0.8 µmole labelled taurine had been conjugated, although the total amount taurocholic acid formed was 1.1 µmole, as determined spectrophotometrically (Table 1, B and C). To each vessel there were added 2 ml of a 25 % homogenate, *i. e.* 500 mg fresh liver. The amount of preformed taurine in the liver could consequently be calculated as follows:

$$\frac{(1.1-0.32) \times 0.8}{0.32} = 1.95 \text{ µmole/500 mg liver} = 0.49 \text{ mg taurine/g fresh liver.}$$

Similar calculations were performed in nine experiments with male rats. The taurine content was found to range between 0.1—0.6 mg/g liver (average 0.35 mg/g).

Three experiments with female rats gave a taurine content of 0.7—1.1 mg/g liver (average 0.9 mg/g). There were great variations in the values, but a sex difference seemed to be present.

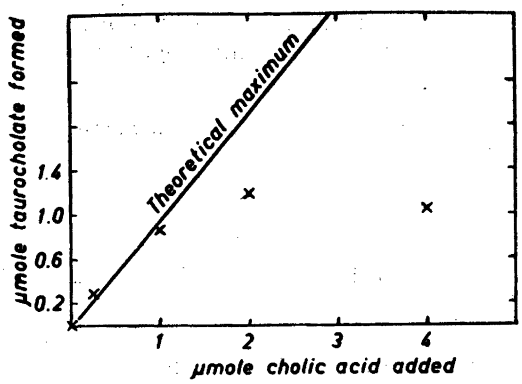

Fig. 2. Total volume 2.5 ml, 2 ml 25 % homogenate centrifuged at 400 g for 5 min. Substrate additions 1.6 µmole taurine, 0—4 µmole cholic acid. 0.05 ml butanol phase chromatographed, eluted and measured spectrophotometrically in 1 ml concentrated sulphuric acid.

This result seems to be in contrast with the findings of Sloan-Stanley [7] and of Blaschko *et al.*[8] who found the cysteic acid decarboxylase activity to be much higher in the male rat liver than in the female rat liver. This discrepancy may be another indication that taurine is formed through other metabolic channels than by the decarboxylation of cysteic acid [9-11].

The taurine content in male rat liver was reported by Wu [12] to be 0.104 ± 0.09 mg/g liver on a standard diet. After nine dayes fasting the content had increased to 0.6 ± 0.14 mg/g.

The relative high taurine content of the rat liver may also explain the insignificant effect of added taurine on the yield of taurocholic acid in the experiment shown in Fig. 1. This experiment was performed with inactive taurine and spectrophotometric determination of the taurocholic acid formed. Addition of 20 µmole taurine or more had only a weakly stimulating effect. This indicates that the preformed 2—3 µmole taurine present in the homogenate was enough to give optimal conditions for the reaction.

Fig. 2 illustrates the effect of increasing amounts of cholic acid on the synthesis of taurocholic acid. The amount formed levelled off at about 1 µmole cholic acid added. No taurine-conjugated or free cholic acid seemed to be present in the liver.

COMMENTS ON THE TAURINE CONJUGATION

The taurine conjugation and 7-hydroxylation of desoxycholic acid in liver slices and liver homogenates have been reported by Bergström *et al.*[1,2]

In preliminary experiments we were able to show that also cholic acid was conjugated in liver slices when incubated in Ringer buffer solution. In Table 1 is shown that rat liver homogenates effected conjugation of cholic acid with taurine, and that this conjugation was doubled when the homogenates were

centrifuged free from cell debris and nuclei at 400 × g for five minutes (Table 1, C and D). This result warrants further investigations on the localization of the process within the cell.

Studies on the Conjugation of Cholic Acid with Taurine in Cell Subfractions. Bile Acids and Steroids 23

JON BREMER* and URS GLOOR

Department of Physiological Chemistry, University of Lund, Lund, Sweden, and Norsk Hydro's Institute for Cancer Research, Oslo, Norway

The conjugation of cholic acid with taurine has been studied in subfractions of rat liver homogenate.

The full conjugating activity of the total homogenate was retained in the crude supernatant (III) after centrifugation at 12 000 × g for 10 minutes. The microsomic fraction (IV) and the particle-free supernatant (V) were each inactive, but recombination restored the full activity when ATP was added. Partial reactivation was achieved when fresh microsomes were incubated with boiled supernatant and ATP, or with an acetone powder of the particle-free supernatant (V), DPN and ATP.

The conjugation in crude supernatant (III) was stimulated by nicotinamide, DPN, ATP, Mg^{++}, the complex forming agent versene and possibly by TPN.

At low taurine and cholic acid concentrations, the conjugation was almost quantitative.

When ATP was omitted cyanide strongly inhibited the conjugation. When ATP was added, cyanide had no effect.

Recently we have published a simple method to follow the formation of taurocholic acid from cholic acid and ^{35}S-labelled taurine together with preliminary results on the conjugation in liver homogenates [1]. The present paper deals with some further studies on this process in cell subfractions.

EXPERIMENTAL

The experimental procedure previously reported [1] has been slightly modified for these studies.

Due to the higher taurine content in the female rat liver [1], we have used male albino rats weighing 200—250 g throughout the study. The homogenization of the liver was performed as previously described [1,2]. Four parts of homogenizing medium were used to one part of liver (crude homogenate = I). The homogenizing medium consisted of 5 parts of 0.11 *M* potassium phosphate buffer of pH 7.7 and 7 parts of 10 % sucrose.

* Fellow of the Norwegian Cancer Society, Oslo, Norway.

In the fractionation experiments, nuclei and cell debris were taken down by centrifugation at 400 × g for 5 minutes (homogenate = II), mitochondria at 12 000 × g for 10 minutes (crude supernatant = III), and the microsomic fraction at 100 000 × g for 30 minutes (IV), leaving in solution the particle-free supernatant (V). The mitochondria were washed once by resuspension in homogenizing medium and recentrifugation. When recombination of the different fractions was undertaken, the microsomic and the mitochondrial fractions were resuspended in homogenizing medium to 1/10 of the original homogenate volume and pipetted as such.

In all the experiments 1 ml of homogenate was used per vessel. Additions to the following final concentrations were made: nicotinamide 0.017 *M*, MgCl 0.00065 *M*, versene (ethylenediamine tetraacetate) 0.00075 *M*. The mixture was finally brought to a volume of 1.75 ml with a 1.15 % solution of potassium chloride. Incubation, protein precipitation and butanol extraction were performed as previously described [1].

In order to evaluate the relative amount of taurocholic acid formed, ^{35}S-labelled taurine * was added to the incubation mixture, and the radioactivity of taurocholic acid formed was determined. The absolute amount of taurocholic acid formed was evaluated from the amount of preformed taurine present in the homogenate batch used [1]. The results are given in micromoles taurocholic acid formed per vessel, *i. e.* per 200 mg of liver. Duplicates were always run.

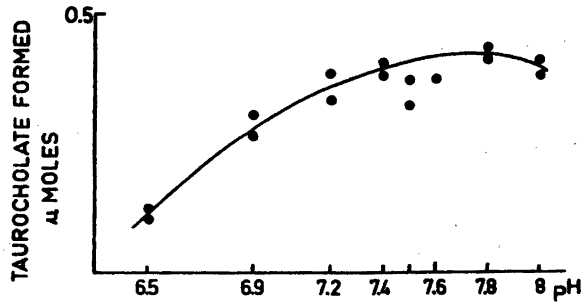

Fig. 2. Effect of pH. Crude supernatant + the following additions: 0.4 μmole ^{35}S-taurine, 1.0 μmole cholic acid, 1.2 μmole ATP.

RESULTS

The results from experiments with cell subfractions obtained by differential centrifugation are shown in Fig. 1.

The conjugating enzyme system was found to be localized in the crude supernatant fraction (III) of the liver cell, as the homogenate freed from nuclei and mitochondria by centrifugation at 12 000 × g for 10 minutes showed full activity (Fig. 1 C).

Neither the microsomic fraction alone (F) nor the particle-free supernatant (D) showed any activity. Full activity was obtained after recombination of these fractions in the presence of ATP (H).

We have performed several experiments with isolated microsomes without obtaining any conjugation of the added cholic acid and taurine. Addition of ATP, magnesium and coenzyme A was without any influence. Unfortunately the only preparation of coenzyme A available was a very crude extract. The possible role of coenzyme A will be subject to further studies.

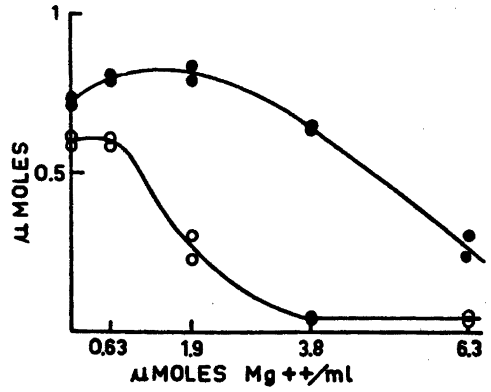

Fig. 3. Effect of Mg^{++}. Crude supernatant + the following additions: 0.4 μmole ^{35}S-taurine, 1.0 μmole cholic acid. Further with 1.2 μmole ATP (●), and without ATP (○). Magnesium concentrations 0—0.0065 M.

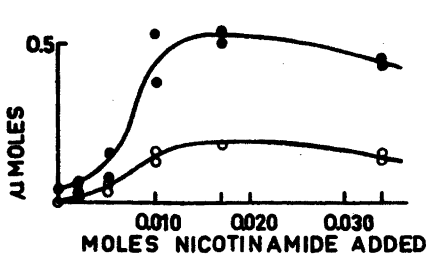

Fig. 4. Effect of nicotinamide. Crude supernatant + the following additions: 0.4 µmole ^{35}S-taurine, 1.0 µmole cholic acid, 1.2 µmole ATP were indicated (●). No ATP (○), nicotinamide concentrations 0—0.034 M.

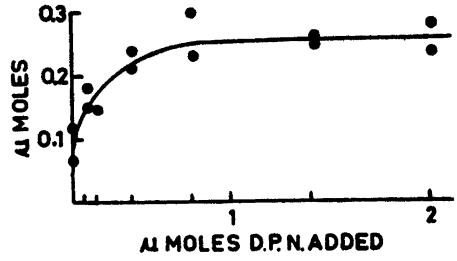

Fig. 5. Effect of DPN. Crude supernatant + the following additions: 0.4 µmole ^{35}S-taurine, 1.0 µmole cholic acid. 0—2.25 µmole DPN per vessel.

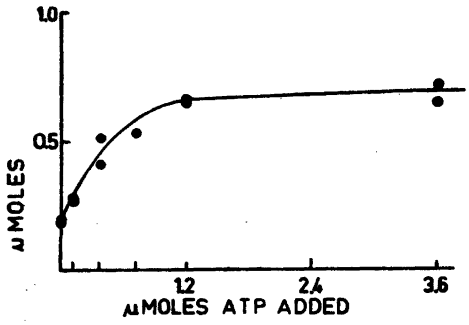

Fig. 6. Effect of ATP. Crude supernatant + the following additions: 0.4 µmole ^{35}S-taurine, 1.0 µmole cholic acid. Nicotinamide conc. 0.017 M, *0—3.6 µmole ATP per vessel.*

Effect of pH. No distinct pH-optimum was found (Fig. 2). Homogenates were almost equally effective when homogenizing media of pH 7 to pH 8 were used. At lower and higher pH values the activity decreased. Therefore a potassium phosphate buffer of pH 7.7 was used throughout. In these experiments the pH changed from 7.7 to 7.3—7.2 during the incubation period.

Effect of Mg-ions. Magnesium had a weak but distinct stimulating effect on the conjugation in the presence of ATP. Without addition of ATP the effect was purely inhibiting (Fig. 3). We also tried the effect of manganese chloride, since Ernster [3] and Lindberg have recently shown manganese to have a stimulating effect on the regeneration of energy rich phosphate bonds. In our experiment the addition of 1 µmole $MnCl_2$ gave a 90 % inhibition.

Effect of nicotinamide, DPN, ATP, and TPN. Figs. 4, 5, 6 and Table 1 show the effects of nicotinamide, DPN and ATP on the conjugation when the three other factors were excluded. As ATP had no, or only a very small effect when nicotinamide was omitted, the effect of ATP was investigated in the presence of this compound.

All these experiments are made with a crude supernatant(III). Consequently no mitochondria were present. Since nicotinamide and DPN show such a marked effect, however, there must still be enzymes present in the microsomes

or the particle free supernatant capable of producing the necessary energy for the conjugation.

We have also tried the effect of TPN and found it to have a stimulating effect of approximately the same order as DPN. Our TPN preparation was very impure, containing only 6 % of the compound. Presumably DPN was one of the main contaminants.

Table 1 shows the effect of the different combinations of nicotinamide, DPN and ATP. The data indicate that ATP requires the presence of nicotinamide or DPN in order to show any significant effect. In the presence of nicotinamide and ATP, the addition of DPN gave no further stimulation. We did not find any significant effect when cytochrom c or fumarate were added alone or in combinations with the other factors tried.

Table 1. Effect of stimulating and inhibiting factors. Crude supernatant — 2 µmole taurine, 2 µmole cholic acid.

1.2 µmole ATP	1.5 µmole DPN	Nicotinamide 0.017 *M*	Cyanide (8.5×10^{-4} *M*)	Dinitrophenol (2.8×10^{-4} *M*)	1 µmole Taurocholate	µmole Taurocholate formed	
—	—	—	—	—	—	0.06	0.06
+	—	—	—	—	—	0.05	0.06
—	+	—	—	—	—	0.39	0.39
—	—	+	—	—	—	0.40	0.40
—	—	+	+	—	—	0.12	—
—	—	+	—	+	—	0.38	0.27
+	+	—	—	—	—	0.45	0.49
—	+	+	—	—	—	0.72	0.70
+	—	+	—	—	—	0.85	0.85
+	+	+	—	—	—	0.84	0.84
+	—	+	+	—	—	—	0.77
+	—	+	—	+	—	0.74	0.77
+	—	+	—	—	+	0.37	0.31

When compared with the results of Cohen and McGilvery [4] in their work on the *p*-aminohippuric acid synthesis in rat liver homogenates, several dissimilarities appear. These authors found a purely inhibiting effect with nicotinamide. DPN and ATP added together inhibited their system if fumarate was omitted, but both DPN and ATP stimulated when added alone.

Our results seem to be in good accordance with the findings of Mann and Quastel [5] who showed that nicotinamide protects DPN against a DPN-splitting enzyme in liver and brain, and with the findings of Rowen and Kornberg who showed that the following reactions take place in the liver

1. Nicotinamide + ribose-1-phosphate → nicotinamideriboside
2. Nicotinamideriboside + ATP → nicotinamidemononucleotide [6]
3. Nicotinamidemononucleotide + ATP → DPN + pyrophosphate [7]

The form of the curve illustrating the nicotinamide effect (Fig. 4) also indicates that in this case a more complex mecanism was involved than when DPN was added (Fig. 5).

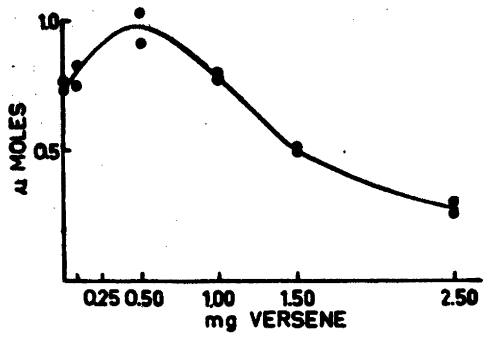

Fig. 7. Effect of versene. Crude supernatant + the following additions: 0.4 μmole ^{35}S-taurine, 1.0 μmole cholic acid, 1.2 μmole ATP, versene 0—2.5 mg per vessel.

Table 1 also shows that cyanide had a strongly inhibiting effect when ATP was omitted, whereas 2,4-dinitrophenol was almost without any effect in the concentration used (2.8×10^{-4} *M*). The addition of sodium taurocholate (1 μmole) gave a 50 % inhibition. The icterus-promoting compound icterogenin [8] was tried, but was found to have no effect.

Effect of versene. Fig. 7 shows that the addition of the complexforming agent versene had a positive effect on the formation of taurocholic acid, presumably by binding heavy metal impurities in the medium. Addition of more than 0.5 mg (7.5×10^{-4} *M*), gave an inhibiting effect. A similar effect of versene on the 7 α-hydroxylation of taurodesoxycholic acid has earlier been observed [9].

Effect of taurine and cholic acid. In experiments previously reported [1], taurine was found to be without effect on the conjugation efficiency when added to the homogenate system used. This was found to be due to the relatively high taurine content of the rat liver. However, when added to the

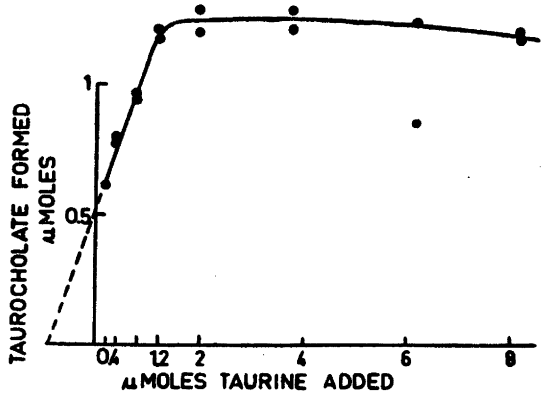

Fig. 8. Effect of taurine. Crude supernatant + the following additions: 2.5 μmole cholic acid, 0.2—0.4 μmole ^{35}S-taurine, 0—8 μmole unlabelled taurine. The conjugation was calculated from the amount of taurine added, the counting data and the calculated taurine content of the liver.

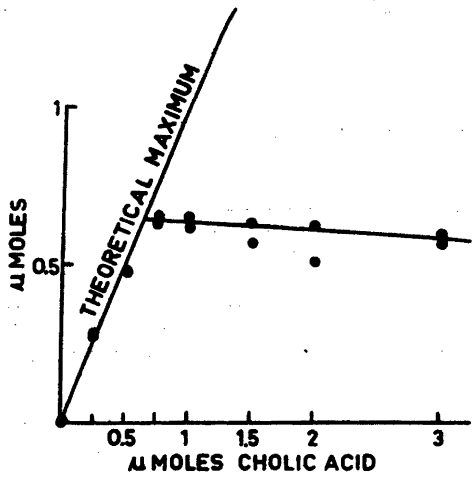

Fig. 9. Effect of cholic acid. Crude supernatant + the following additions: 0.4 μmole ^{35}S-taurine, 1.2 μmole ATP, 0—3 μmole cholic acid.

fortified system described in the present report, the formation of taurocholic acid was more than doubled (Fig. 8). The rise is almost linear up to the optimal taurine concentration (> 1.2 μmole added). Beyond this point, further addition had no effect.

Extrapolation of the curve gave a taurine content of approximately 0.8 μmole per 200 mg liver, *i. e.* 0.5 mg/g fresh liver. This is in good agreement with our earlier results on the normal taurine concentration in male rat liver [9].

In Fig. 9 is shown the effect of cholic acid on the formation of taurocholic acid in the presence of 0.4 μmole ^{35}S-labelled taurine. The conjugation of the cholic acid was quantitative until 90 % of the taurine was conjugated. Further addition had no effect. (Probably a still greater fraction of the taurine was conjugated, since the labelled taurine synthesized according to Eldjarn's procedure [10] has been shown to contain 3—4 % sulphate [11]). The form of the curve shows that the conjugation occurs almost quantitatively when equimolar amounts of taurine and cholic acid are added in small concentrations.

Stability of the enzyme system. The homogenate showed a rapid decrease of the activity when stored at 0° C. After 24 hours it was completely inactive. When stored for the same length of time in the frozen condition at —20° C, it had about 70 % of the activity left. A homogenate frozen and thawed again twice in rapid succession had still an activity of 85 %.

The isolated microsomes were completely unaffected by freezing, and they also showed full activity after 60 minutes' treatment with distilled water. No enzyme went into solution neither by this treatment, nor when the microsomes were frozen twice in distilled water.

Precipitation of the crude supernatant (III) or the isolated microsomes (IV) with acetone produced completely inactive powders, even when recombined

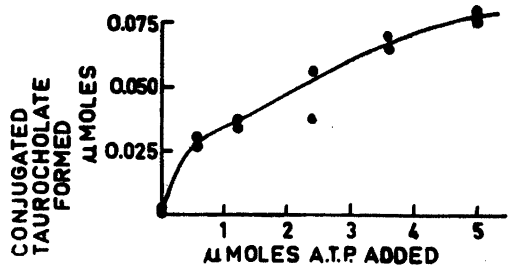

Fig. 10. Effect of ATP in the presence of boiled supernatant. Total volume 1.75 ml. 0.1 ml microsome suspension + 0.9 ml boiled supernatant from a 20 % homogenate kept in boiling water for five minutes and centrifuged free from precipitated proteins.

with fresh particle-free supernatant (V). The results were the same whether the homogenate or the microsomes were precipitated at 0° C or in the frozen condition.

On the other hand, when fresh microsomes from 1 ml homogenate were combined with acetone powder from 1—2 ml particle-free supernatant in the presence of ATP and DPN approximately 65 % of activity was restored. The possible influence of nicotinamide was not investigated in this preparation.

In Fig. 10 is shown that the boiled supernatant also was able partly to restore the activity of the microsomes when ATP was added. Thus in the presence of 5 μmole ATP approximately 20 % of the original activity was achieved. The possibility that fresh supernatant contaminated the isolated microsomes was excluded by an experiment where ATP was added also to isolated microsomes suspended in homogenizing medium. Only traces of activity could be detected. The ATP therefore had a greater effect when boiled supernatant was used than when fresh particle-free supernatant (V) was used. In the latter case ATP required addition of nicotinamide to give any effect (*cf.* Table 1). In the microsome+boiled supernatant system nicotinamide and DPN showed no effect.

DISCUSSION

Peptide bond synthesis has been studied by several workers in different systems.

Cohen and McGilvery [12] have published a series of works on the *p*-aminohippuric acid synthesis from *p*-aminobenzoic acid and glycine in rat liver slices and rat liver homogenate. They found the conjugation to be performed on the expence of phosphate bond energy by an enzyme system confined to the insoluble particles of the liver and kidney cell. Anaerobically the conjugation was strongly depressed if ATP was omitted from the reaction mixture. The conjugation was also depressed aerobically by substances known to inhibit oxidative processes, such as cyanide, azide and malonate.

Kielly and Schneider [13] have shown that the enzyme responsible for the conjugation of *p*-aminobenzoic acid is located in the mitochondria of the mouse liver cell, and Chantrenne [14] has succeeded in making an acetone extract from

mitochondria which catalyzes hippuric acid synthesis from benzoic acid and glycine when ATP, Mg^{++} and coenzyme A are added.

Schachter and Taggar [15] prepared benzoyl-coenzyme A and showed that this compound is active as a precursor to hippuric acid without any addition of ATP, Mg^{++} or coenzyme A. Their results strongly indicate that benzoyl-CoA is the "activated benzoic acid".

The biological synthesis of glutathion has been studied by Bloch [16,17]. Speck [18] has investigated the formation of glutamine from glutamate and ammonia. The participation of ATP and magnesium were also reported by these workers.

Coenzyme A has only been found to be necessary in the hippuric acid synthesis.

The results described in the present report show that the conjugation of taurine with cholic acid is very similar to the conjugation of glycine with benzoic acid or *p*-aminobenzoic acid, though the localization of the enzyme systems within the cell is different. The processes are all stimulated by factors concerned with oxygenation processes which procure energy for phosphate bond formation, and they are inhibited by substances interfering with these processes (cyanide).

Where probably most of the ATP-synthesizing enzymes have been omitted by combining fresh microsomes with boiled supernatant, no conjugation is achieved if ATP is omitted. In this case DPN and nicotinamide had no effect, whereas the effect of ATP was greater than when it was added alone to intact crude supernatant. At least one unknown factor from the supernatant must be necessary, as the isolated microsomes were inactive with all additions tried. This factor seems to withstand immersion in boiling water for five minutes and to follow the proteins when precipitated with acetone. In several isolation methods for coenzyme A, both boiling and precipitation with acetone are parts of the procedure [19]. Although we did not find any stimulating effect on the conjugation by the addition of a 6 % coenzyme A preparation, this compound may well be the unknown supernatant factor. Further work on this question is in progress.

Preparation of 3β-Hydroxychol-5-enic Acid from Hyodesoxycholic Acid and Corresponding 24-^{14}C-labelled Acids. Bile Acids and Steroids 24

SUNE BERGSTRÖM and KARIN PÄÄBO

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The preparation of 3β-hydroxychol-5-enic acid-24-^{14}C *via* the dimethanesulphonylderivative of hyodesoxycholic acid-24-^{14}C is described. The preparation of the latter compound is also described.
