ACTA CHEMICA SCANDINAVICA 10 (1956) 1—8

On the Structure of the Crystal Form A of Lauric Acid

ERIK von SYDOW

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The A-form of lauric acid, $C_{11}H_{23}COOH$, is triclinic with space group $P\bar{1}$. For structural reasons the centered cell $A\bar{1}$ has been used. It has the dimensions $a = 5.41$ Å, $b = 26.27$ Å, $c = 35.42$ Å, $\alpha = 69° 36'$, $\beta = 113° 9'$, and $\gamma = 121° 21'$. The centered cell contains 12 molecules. The hydrocarbon chains are arranged in a triclinic packing and from this point of view the structure can be regarded as a sixfold superstructure. There are no layers in the crystals with only carboxyl groups or methyl groups, respectively. They appear together in the same layers in groups of six.

Like all the other crystal forms of normal fatty acids the crystalline A-form of acids with an even number of carbon atoms was first detected in a "long spacing" investigation [1]. Trillat and v. Hirsch [2] determined the smallest axis-plane of stearic acid with electron-diffraction. Lomer [3] has recently determined the unit cell dimensions of the A-forms (γ-form) of lauric acid and myristic acid from powder data. He suggests that the cells are monoclinic, which however seems to be wrong. For the A-form of lauric acid he gives a volume which is about 6 % less than the volume of the one described here. Lomers observed density data are also inconsistent with these results.

PREPARATION OF CRYSTALS

The very pure lauric acid used was prepared by Professor E. Stenhagen and his collaborators. It melts at 44.5—44.8° C.

According to Stenhagen and the author [4,5] lauric acid may crystallize exclusively in the form A from light petroleum, pentane, acetone, ethyl alcohol, and carbon disulfide. The best single crystals for the X-ray investigation were obtained from carbon disulfide.

Crystals of normal fatty acids are usually in form of thin plates, but the A-form of lauric acid crystallizes in elongated parallelepipeds with irregular shortsides. The crystals are biaxial positive. No twinning could be observed under the polarizing microscope.

X-RAY DATA

Rotation and Weissenberg photographs were taken with Cu-K radiation using a calibrated camera. The following data were obtained:

Molecular formula: $C_{12}H_{24}O_2$.
Molecular weight: 200.31.
Density calculated: 1.027 ± 0.013 g cm^{-3}.
Density observed: 1.033 g cm^{-3}.
Unit cell: triclinic (primitive).
Six molecules per unit cell.
Number of electrons: 672.
Space group: C_i^1—$P\ \bar{1}$.

For structural reasons the following cell will be used in the text:

Unit cell: triclinic (A-centered).
$a = 5.41 \pm 0.01$, $b = 26.27 \pm 0.07$, $c = 35.42 \pm 0.13$ Å.
$\alpha = 69°\ 36' \pm 30'$, $\beta = 113°\ 9' \pm 26'$, $\gamma = 121°\ 21' \pm 34'$.
d(001) $= 32.02 \pm 0.06$ Å.
Twelve molecules per unit cell.
Number of electrons: 1 344.
Absent reflexions: (hkl) when $(k+l)$ odd.
Space group: C_i^1—$A\ \bar{1}$.

The absence of the piezo-electric effect (I am indebted to Mr. J. Baecklund for help with the measurements) is consistent with a center of symmetry.

No twinning was observed.

The intensities were estimated by eye from two different sets of multiple films exposed for different times. They were corrected with the normal polarization and Lorentz factors, but no absorption corrections were applied. The relative, observed structure factors obtained were later brought to an absolute scale by comparison with the calculated structure factors. The intensities of the low angle reflexions (002), (011) and (01$\bar{1}$) were estimated from a powder photograph.

Subcell

In the triclinic reciprocal lattice strong reflexions appear periodically along (hkl) when $k = 6n$. They give rise to a larger reciprocal cell, which also is triclinic. Its dimensions agree very well with those of the cell having triclinic packing of hydrocarbon chains, described by Müller and Lonsdale [6] and Vand and Bell [7]. The triclinic subcell coincides approximately with the A-centered cell of the A-form of lauric acid having two axes equal to a and a value close to $b/6$. Considering the chainpacking the main crystal structure can be regarded as a sixfold superstructure.

Patterson projections

If the carbon atoms lie strictly according to the triclinic subcell, they contribute only to structure factors $F(hkl)$ with $k = 6n$. The oxygen atoms in the carboxylic groups, however, contribute to all structure factors and are the only cause of $F(hkl)$ with $k \neq 6n$.

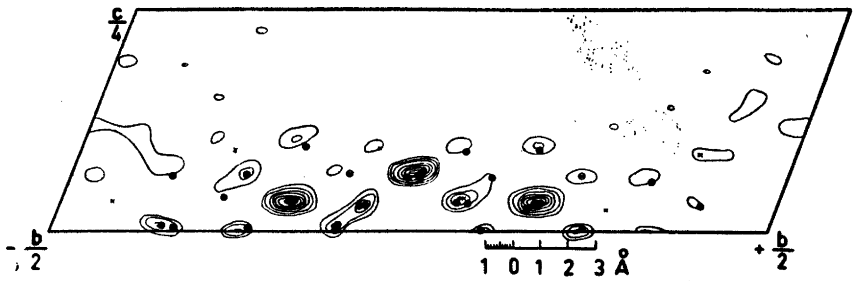

Fig. 1. Patterson projection with $F^2(0kl)$ *values for* $k \neq 6n$. *Origo: 15 contours.* × *single,* ⊗ *double oxygen-oxygen vectors calculated with the final oxygen coordinates.*

A Patterson synthesis with $F^2(hkl)$ for which $k = 6n$ should thus give interatomic distances in the hydrocarbon chains and a synthesis with $F^2(hkl)$ for which $k \neq 6n$ should give peaks which either represent at least approximate oxygen-oxygen vectors or have no significance at all. The latter is due to the fact that the contribution from the oxygen atoms to $F(hkl)$ with $k = 6n$ is not taken into consideration. This contribution may be comparatively large as there are two oxygen atoms bonded to each of the twelve hydrocarbon chains in the centered cell.

Two Patterson projections were carried out, one with $F^2(0kl)$ where $k = 6n$ and the other with $F^2(0kl)$ where $k \neq 6n$. Both were sharpened by multiplication by the function

$$M(S) = \left(\frac{1}{\hat{f}}\right)^2 \exp\left(-\frac{\pi^2}{p} S^2\right) \text{ with } p = 7.25$$

as suggested by Lipson and Cochran [9, p. 172].

The first gave carbon-carbon distances which fitted well with the subcell data given by Vand and Bell [7]. The second projection (Fig. 1) consisted of many peaks concentrated round (0, 0, 0) and (0, ½, ½) in agreement with the centering. It was treated by Buergers vector set method [10] and a set of relative positions was obtained. The carboxylic group and the hydrogen bonding between two acid molecules was supposed to be very similar to those in the other crystal forms of normal fatty acids, *e. g.* the C-form of lauric acid investigated by Vand, Morley and Lomer [8]. With this assumption it could be seen that some of the positions obtained by the vector set method were impossible and thus caused by the fact that the oxygen contribution to $F(0kl)$ with $k = 6n$ had not been accounted for. The remaining positions were supposed to be relative oxygen positions and agreed well with the assumptions above. From the knowledge of other crystal forms (*e. g.* Refs.[8, 13, 14]) they were placed relative to the carbon atoms.

Structure factors and electron-density projections

If all carbon atoms are assumed to be situated strictly according to the triclinic subcell, the structure factors can be calculated using the coordinates

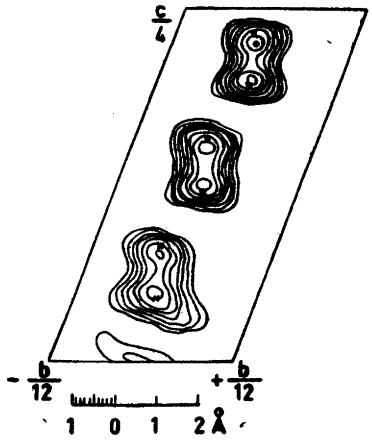

Fig. 2. Fourier projection along the shortest axis with 27 F(0kl) *where* k = 6n. *Arbitrary contour scale. The correct positions of the carbon atoms are marked with crosses.*

of only six carbon atoms (later with two hydrogen atoms each) and six oxygen atoms. This will cause small errors in the structure factors due to the non-existence of hydrogen atoms at the carbon atom in the carboxylic group, the existence of a hydrogen atom in the hydroxyl group and of a third hydrogen atom in the methyl group. This effect is, however, insignificant and has been ignored.

With the information obtained from the Patterson projections, structure factors were calculated without the hydrogens. Atomic scattering factors were taken from McWeeny [11] using for oxygen $f = \frac{1}{3}(f^{\perp} + 2f^{\parallel})$ and for carbon the values for "valence states".

A Fourier synthesis was carried out with relative, observed $F(0kl)$ values for $k = 6n$ using 27 signs from the first structure factor calculation. The projection obtained is given in Fig. 2 and shows clearly the six carbon atoms.

In order to obtain the oxygen positions another synthesis with relative, observed $F(0kl)$ values for $k \neq 6n$ was performed using 105 calculated signs (none of these was later found to be wrong). This projection can be seen in Fig. 3. For comparison the final coordinates of the atoms are marked with crosses in both figures.

Structure factors were now calculated again and a total electron-density projection along the shortest axis was prepared. The coordinates were refined using several $(F_o - F_c)$-syntheses and the hydrogen atoms were included in the

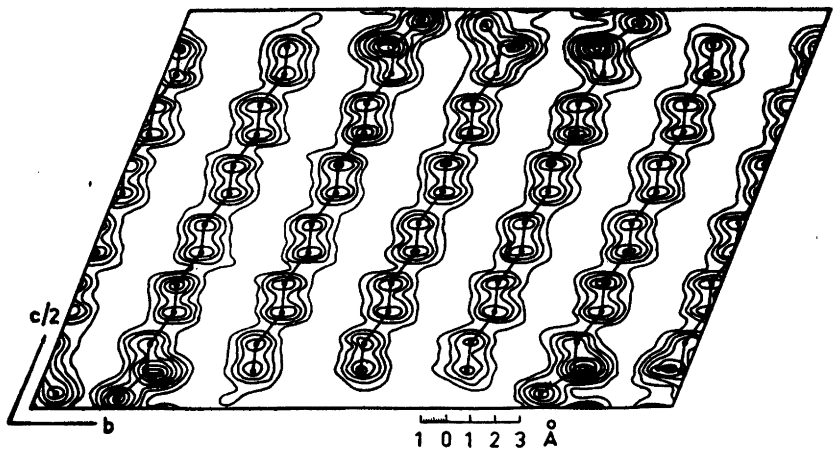

Fig. 4. The A-form of lauric acid. Electron-density projection along the shortest axis. Contour scale: 1 e Å^{-2}.

structure factor calculations as was mentioned above. Their positions relative to the carbon atoms were calculated from data given by Vainshtein and Pinsker [12]. A temperature factor, $\exp\left(-B\frac{\sin^2\Theta}{\lambda^2}\right)$ with $B = 4.2$, was applied.

The final coordinates are collected in Table 1, and observed and calculated structure factors in Table 2. The electron-density projection prepared with the values from Table 2 is shown in Fig. 4. The reliability index $R_1 = 0.15$

for all observed (0*kl*) reflexions and $R_1 = 0.16$ for observed (0*kl*) reflexions with $k \neq 6n$.

The 66 vectors between the oxygen atoms in six adjacent carboxylic groups calculated from the final coordinates are marked in the Patterson projection with $F^2(0kl)$ and $k \neq 6n$ in Fig. 1.

DISCUSSION OF THE RESULTS

The hydrocarbon chains of the A-form of lauric acid are arranged in the triclinic packing first found by Müller and Lonsdale [6] in a low-temperature form of a paraffin. In this packing all chain-planes are parallel. Form A′ of

acids with an odd number of carbon atoms [13,14] has the same hydrocarbon chain packing.

The dimers of the A-form of lauric acid are, however, entirely differently arranged, as compared with the A'-form. From the chain-packing point of view the structure of the A-form of lauric acid is a sixfold superstructure (Fig. 4). The carboxylic groups and the methyl groups are situated together in the same layers in the crystal in groups of six units (Fig. 4) giving rise to equal binding forces in every such layer (hydrogen bonds and van der Waals bonds). This is not the case with the other crystal forms of normal fatty acids where the carboxylic groups and the methyl groups, respectively, are situated in alternate layers. The binding forces are then much weaker in the methyl group layers (van der Waals bonds) than in the carboxylic group layers (hydrogen bonds). These different molecular arrangements affect the macrocrystalline shape as well as the cleavage properties. As was stated earlier normal fatty acids usually crystallize in thin plates, which can easily be split up into thinner plates, but the A-form of lauric acid grows in parallelepiped-shaped crystals, which do not split up in the same regular way as the crystals of the other polymorphic forms. The absence of twinning is also in accordance with the molecular arrangement.

The carboxylic groups fit so well into the chain-packing that none of the carbon atoms need be moved from its position in the subcell to allow hydrogen bonding between two carboxylic groups.

The increment of long spacing for this crystal form of acids with an even number of carbon atoms is 2.36 Å according to Stenhagen and the author [4]. Thus the angle of tilt will be between 69° and 65° if the distance between alternate carbon atoms is between 2.521 Å, given by Vand, Morley and Lomer [8], and 2.610 Å, given by Morley and Vand [15].

I am indebted to Professor Gunnar Hägg, Professor Einar Stenhagen and Dr. Ingvar Lindqvist for their interest in this work. I am also grateful to Mr. C. O. Jansson for help with the X-ray work and computations. The expenses involved have been defrayed by grants from the *Swedish Natural Science Research Council.*

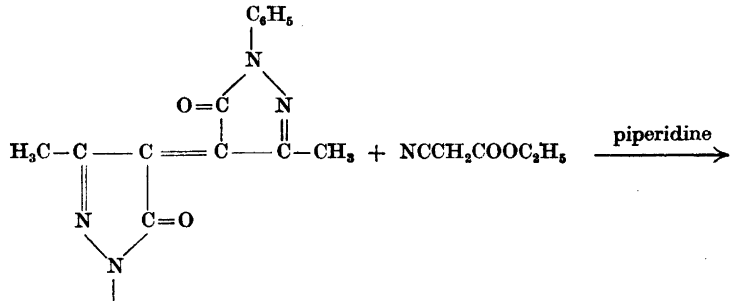
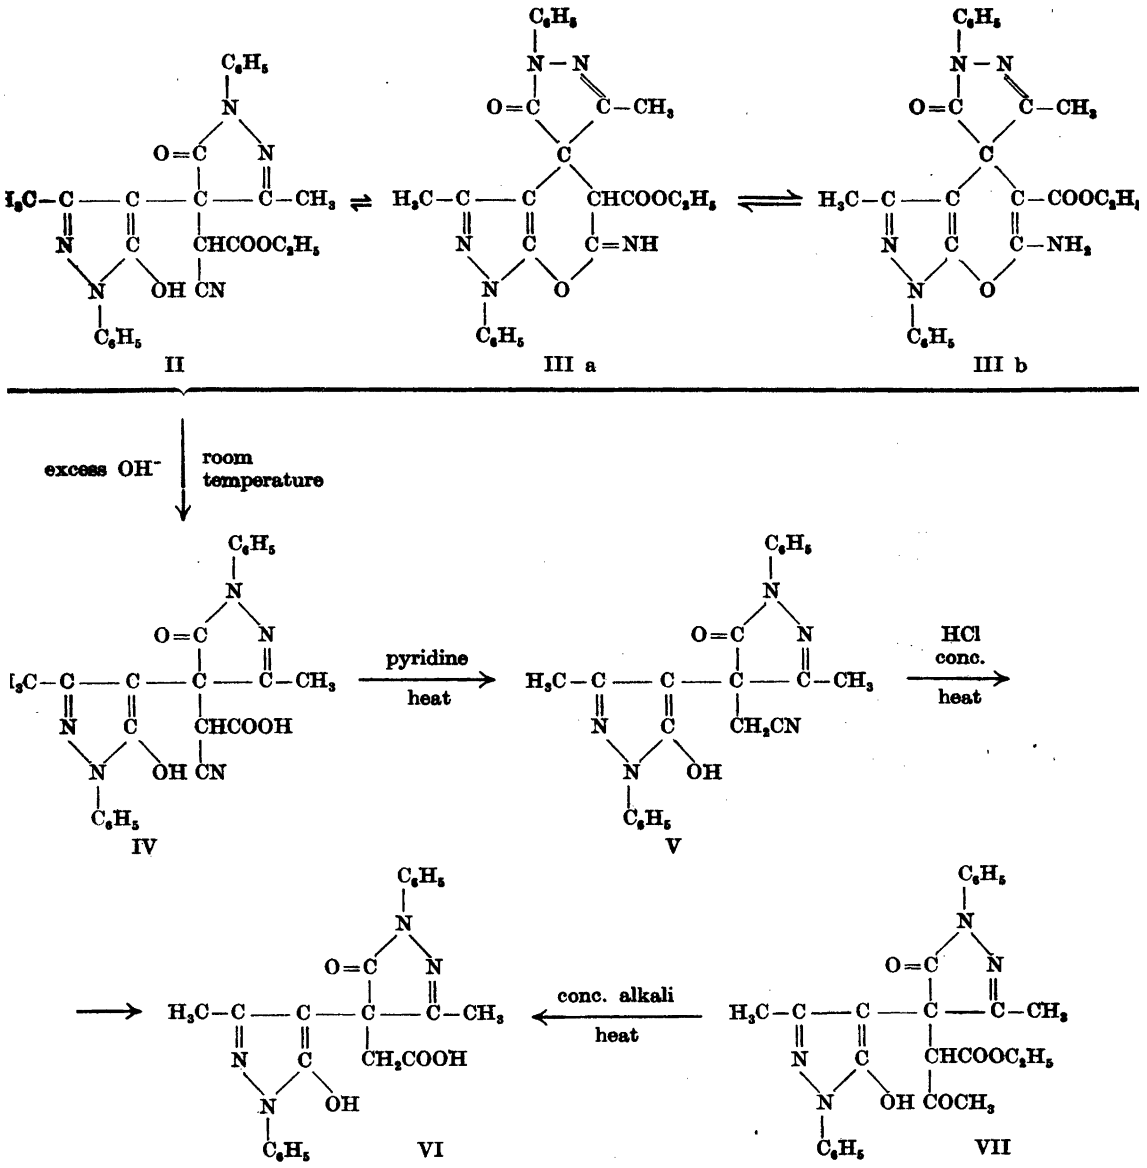
Studies on Pyrazolones

IX. Reactions between Pyrazole Blue and Ethyl Cyanoacetate



GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden



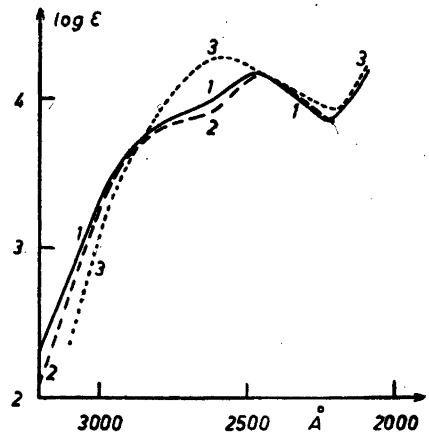
The addition compounds II and III have been prepared from pyrazole blue (I) and ethyl cyanoacetate. By degradation of the adducts some 4-substituted 1,1′-diphenyl-3,3′-dimethyl-[4,4′-bi-2-pyrazoline]-5,5′-diones have been synthesized, *viz.* bispyrazolonyl-cyanoacetic acid (IV), 4-cyanomethylbispyrazolone (V) and bispyrazolonylacetic acid (VI).

In the presence of a small amount of piperidine, a chloroform solution of pyrazole blue (I) was rapidly decolorized when boiled with an equimolar amount of cyanoacetic ester. The reaction product obtained was a neutral addition compound, $C_{25}H_{23}N_5O_4$. On treatment with excess of alkali at room temperature it yielded an acid, $C_{23}H_{19}N_5O_4$, for which structure IV is suggested on the basis of the following facts. It is a dibasic acid. On decarboxylation it gave a cyanomethylated bispyrazolone (V), which could be hydrolysed to the acid VI, identical with the product obtained by acid cleavage of the adduct, VII, from pyrazole blue and ethyl acetoacetate.

These degradation reactions show that both the bispyrazolonyl group and the cyanoacetic acid skeleton are present in $C_{25}H_{23}N_5O_4$. These facts together with the neutral reaction of the compound indicate that III (a, b or — presumably — an equilibrium of both) is the correct structure for this adduct.

I

The first step in the formation of III is considered to be a normal Michael addition of ethyl cyanoacetate to pyrazole blue giving the bispyrazolonylcyanoacetate, II. It is a well-known fact that both Michael condensations [1] and the reversible addition of alcohols to nitriles with formation of iminoethers are catalysed by basic compounds (Nef [2], Marshall and Acree [3]). In spite of the fact that the hydroxyl group of II has acidic properties, it is reasonable to



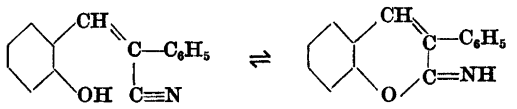


Fig. 1. UV absorption curves of the compounds II (1), III (3) and IV (2) in ethanol solution.

suppose that it adds to the cyano group of II in a way analogous to an alcoholic hydroxyl, *i. e.* that II is isomerized to III a (III a ⇌ III b). The ring closure ought to be facilitated since a six-membered ring is formed and since the structure III b is stabilized by resonance.

In order to check the proposed mechanism it was of interest to prepare and examine compound II. By performing the addition of ethyl cyanoacetate to pyrazole blue at room temperature, a mixture of the neutral compound, III, and the isomeric, acidic product, II, could be obtained. The components were separated by virtue of their different solubilities. The UV absorption curves of the two products were distinctly different. The curve of the acidic compound was very similar to the corresponding curve of IV (Fig. 1). Excess of dilute alkali at room temperature hydrolysed both products with formation of IV.

An ethanol solution of II was slowly isomerized to III even at room temperature. This isomerization was catalysed by a small amount of piperidine. In boiling chloroform containing a trace of piperidine (the same conditions as prevailed when III was prepared directly from pyrazole blue and ethyl cyanoacetate), the ring closure of II to form III was rapid. Dry hydrogen chloride (*cf.* Pinner [4]) in ethanol solution or heating of the solid compound also caused isomerization of II. All these facts are in favour of the proposed reaction sequence I→II→III. — The easy ring closure observed with II did not take place with the acids IV or V.

o-Hydroxy-*α*-phenylcinnamic nitrile [5] (VIII) has been found to isomerize in a similar manner to compound II but with greater ease. In ethanol solution it was completely transformed into the iminolactone, 2-imino-3-phenylcoumarine (IX) in a few hours. The solid nitrile slowly changed into the coumarine derivative even at room temperature.

VIII IX

The isomerization of II to form III is reversible, for brief treatment of III with an equivalent amount of alkali yielded compound II, in addition to compound IV. Long treatment with excess of alkali gave only IV.

Houben and Pfankuch [6] made the similar observation that the iminolactone ring of 2-imino-3-phenylcoumarine is split by alkali to form *o*-hydroxy-α-phenylcinnamic nitrile (*cf.* Schlesinger [7]).

The acidic properties of compound II are of interest. The introduction of the electron attracting bispyrazolonyl group into the ethyl cyanoacetate molecule increases the acidity of the active hydrogen atom in the α-position of the cyano group with the result that, though ethyl cyanoacetate is only slightly acidic towards alizarine yellow in ethanol-water solution, its bispyrazolonyl derivative could be titrated as a dibasic acid using the same indicator, though with a poor end point. In IV (and of course in III and V) the cyanoacetate hydrogen is not acidic towards alizarine yellow.

The IR spectra[9] of the two addition compounds of pyrazole blue and ethyl cyanoacetate have been studied. The acid II had a distinct, though not very strong nitrile band at 2 240 ± 15 cm^{-1}, whereas the neutral compound exhibited no C≡N absorption. This provides further support for III as the structure of the neutral adduct. However, great caution is necessary when drawing conclusions from the IR spectra of the nitriles. Thus a study of the absorption of IV, which compound certainly contains a cyano group, showed that the existence of a C≡N band in the spectrum of the free acid was doubtful, whereas the potassium salt of IV had a strong C≡N absorption band at 2 240 ± 15 cm^{-1}. Compound V (prepared from IV by decarboxylation) had a distinct but not very intense nitrile band at 2 240 ± 15 cm^{-1} (*cf.* Kitson and Griffith [8]).

EXPERIMENTAL

Preparation of compound III from pyrazole blue and ethyl cyanoacetate. Pyrazole blue (13.5 g), ethyl cyanoacetate (7 ml), chloroform (50 ml) and a few drops of piperidine were boiled until decolorization was complete (about 5 minutes). On standing a colourless product separated from the cooled solution. It was collected by filtration and washed with ethanol and ether. Impurities were removed by extraction with boiling ethanol. The product was dried *in vacuo* at 100°. Yield 17.4 g (97 %); m. p. about 245° with decomposition. The compound was only slightly soluble in most solvents. (Found: C 65.1; H 5.1; N 15.2. $C_{25}H_{23}N_5O_4$ requires C 65.6; H 5.1; N 15.3.) For UV absorption curve see Fig. 1.

Alkaline hydrolysis of compound III with the formation of IV. A suspension of III (7.6 g) in a solution of potassium hydroxide (8 g) in methanol (75 ml) and water (5 ml) was shaken for half an hour and then left overnight. The hydrolysate was precipitated with water and dilute sulphuric acid and the precipitate filtered, washed with water and air-dried. The crude product was dissolved in ethyl acetate at room temperature. From the solution the pure acid soon separated as colourless crystals. Yield 5.9 g of purified product, m. p. about 160° (decomp.) (Found: C 64.1; H 4.5; N 16.2; equiv. wt. 215. $C_{23}H_{19}N_5O_4$ requires C 64.3; H 4.5; N 16.3; equiv. wt. 215.) UV absorption see Fig. 1.

Decarboxylation of IV with formation of 1,1′-diphenyl-3,3′-dimethyl-4-cyanomethyl-[4,4′-bi-2-pyrazoline]-5,5′-dione (V). The bispyrazolonylcyanoacetic acid (IV) (5.8 g), ethyl alcohol (50 ml) and pyridine (0.75 ml) were boiled on a water bath for ten minutes. The decarboxylated product was precipitated with water and dilute hydrochloric acid. The precipitate was collected by filtration, washed with water and air-dried. After crystallization from ethyl acetate and ethanol, 2.9 g (56 %) of the colourless 1,1′-diphenyl-3,3′-dimethyl-4-cyanomethyl-[4,4′-bi-2-pyrazoline]-5,5′-dione (V) was obtained. It was

dried at 0.1 mm Hg, 100°. M. p. 160°. (Found: C 68.6; H 5.1; N 18.1; equiv. wt. 385 on titration using thymolphthalein indicator, 391 determined by means of the cyano group. $C_{22}H_{18}N_5O_2$ requires C 68.6; H 5.0; N 18.2; equiv. wt. 385.) The product was soluble in ethanol, chloroform and acetone, but only slightly soluble in ether and benzene.

Hydrolysis of 1,1'-diphenyl-3,3'-dimethyl-4-cyanomethyl-[4,4'-bi-2-pyrazoline]-5,5'-dione. The decarboxylated product (V) (0.2494 g) was boiled with a few ml of concentrated hydrochloric acid for one hour. The hydrolysate was precipitated with water, filtered, washed with water and air-dried. Impurities were removed by boiling the product once with ethyl acetate. The substance was then dissolved in ethyl alcohol and the solution evaporated to dryness, when an unstable modification was obtained, which was soluble in ethyl acetate. On scratching colourless crystals separated from the solution, m. p. 213° (decomp.) (Found: C 65.4; H 5.2; N 13.7; equiv. wt. 202. $C_{22}H_{20}N_4O_4$ requires C 65.3; H 5.0; N 13.9; equiv. wt. 202.)

To the mother liquor from the hydrolysis a large excess of sodium hydroxide was added, and the ammonia formed was distilled into 0.1050 N hydrochloric acid (10.00 ml). After distillation, 4.26 ml of 0.0966 N barium hydroxide solution was needed for neutralization. Hence the equiv. wt. of the cyano compound was 391 (calc. for the cyanomethylated bispyrazolone (V) 385).

Addition of ethyl acetoacetate to pyrazole blue with the formation of VII. Pyrazole blue (5.0 g), ethyl acetoacetate (2.4 g), ethyl alcohol (25 ml) and piperidine (0.5 ml) were mixed together. A rapid decolorization took place at room temperature. The colourless addition product separated immediately, but was dissolved by boiling the mixture briefly to ensure complete reaction. After cooling, the precipitation was completed by addition of water and dilute hydrochloric acid. The product was filtered off and washed with water and ethanol. Yield 6.7 g. Impurities were removed by extraction with ether and by crystallization from ethanol. The product was dried *in vacuo* (0.1 mm Hg) at 80°. It was difficult to obtain a solvent free product without decomposition taking place. M. p. 106°. (Found: C 64.8; H 6.0; N 11.6; equiv. wt. 475. $C_{26}H_{26}N_4O_5$ requires C 65.8; H 5.5; N 11.8; equiv. wt. 475.)

Acid cleavage of compound VII. The preceding product (VII) was heated on a boiling-water bath with ethanol and excess of concentrated potassium hydroxide solution for 5 minutes. On acidification the cleavage product separated. It was filtered off, washed with water and air-dried. Impurities were removed as previously described. M. p. 214° (decomp.) (Found: C 65.1; H 4.9; N 13.9; equiv. wt. 203. Calc. for $C_{22}H_{20}N_4O_4$: C 65.3; H 5.0; N 13.9; equiv. wt. 202.) The light absorption of this compound was identical with the absorption of the product obtained by hydrolysis of V.

Preparation of compound II from pyrazole blue and ethyl cyanoacetate. A mixture of pyrazole blue (1.35 g), ethyl cyanoacetate (0.7 ml), chloroform (5 ml) and a trace of piperidine was shaken at room temperature until decolorization took place. On addition of ethanol and scratching, crystals of III (0.25 g) separated.

The chloroform was rapidly removed from the filtrate *in vacuo* at room temperature, and the ethanol solution was immediately poured into N hydrochloric acid. The acid II, which precipitated, was collected by filtration, washed with water and dried *in vacuo*. The product could be purified by solution in cold benzene and precipitation with light petroleum. Benzene insoluble crystals (1.7 g) were obtained. The last trace of benzene was removed *in vacuo*. The product, which was hygroscopic, melted at 116—120°. When the heating was continued, the melt solidified, owing to ring closure with formation of III. At 240—245° it melted again with decomposition. (Found: C 65.2; H 5.0; N 15.3; equiv. wts 454 (potentiometric titration) and 230 (titration with sodium methoxide [10]). Calc. for $C_{25}H_{23}N_5O_4$: C 65.6; H 5.1; N 15.3; equiv. wts 457 and 229.) For UV absorption curve see Fig. 1.

The acid was isomerized to the neutral compound III, a) when heated in solid form or in solution, b) when kept in ethanol solution for several days (with piperidine as catalyst one day was sufficient), c) when its ethanol solution was treated with dry hydrogen chloride. The isomer III formed was in all cases identified by its melting point, neutral reaction, slight solubility in most solvents and UV absorption curve.

At room temperature alkali hydrolysed the ester but not the cyano group of II, compound IV being formed.

Partial hydrolysis of III. Product III (1.45 g) was shaken with 5 ml of 1.3 N methanolic potassium hydroxide solution for ten minutes. Undissolved material was removed by

filtration, and the filtrate was poured into N hydrochloric acid. The precipitate formed was washed with water and air-dried. The colourless product melted partly at 120°, solidified again and was decomposed at 160°. These facts as well as the equivalent weights of the product and the UV absorption (maximum at 250 mμ) indicate that a mixture of II and IV was formed.

o-Hydroxy-α-phenylcinnamic nitrile (VIII) and 2-imino-3-phenylcoumarine (IX). *o*-Hydroxy-α-phenylcinnamic nitrile (VIII) was prepared according to Borsche and Streitberger [5] and treated with alkali to transform any 2-imino-3-phenylcoumarine present into the hydroxynitrile. (Found: C 80.3; H 5.0; N 6.1. Calc. for $C_{15}H_{11}NO$: C 81.4; H 5.0; N 6.3.) 2-Imino-3-phenylcoumarine (IX) was prepared according to Houben and Pfankuch [6].

Treatment of an ethanolic solution of VIII with a small amount of piperidine for three hours and subsequent acidification with acetic acid yielded product IX. When a solution of VIII in ethanol was kept overnight without any catalyst, the same isomerization took place. The products were identified by their light absorption and different solubilities in concentrated hydrochloric acid (*cf.* Houben and Pfankuch [6]).

The analyses were performed by Mr. A. Grossman, Department of Organic Chemistry, University of Copenhagen, or by Miss M. Westerdahl, Department of Analytical Chemistry, University of Lund. I am indebted to Dr. Andreas Rosenberg, University of Uppsala, for carrying out the IR measurements.

The author wishes to thank *Statens naturvetenskapliga forskningsråd* for financial support and Prof. S. Bergström for permission to carry out this investigation at his Institute.

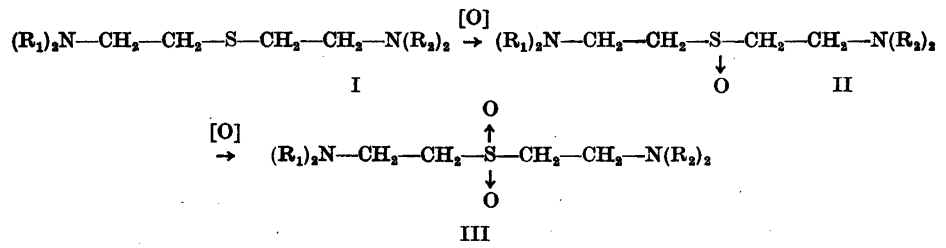
Bifunctional Amines and Ammonium Compounds

V*. Bis-trialkylammoniumethyl Disulfides, Sulfoxides, and Sulfones

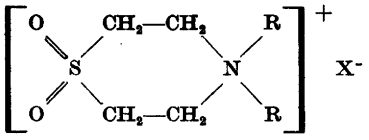
JØRGEN FAKSTORP



Aktieselskabet Pharmacia, Copenhagen V., Denmark

Oxidized derivatives of bis-alkylammonium sulfides were obtained by oxydation of the *tert.* thiols and sulfides with iodine and bromine water, followed by alkylation. The oxidation with acid or alkaline permanganate gave the expected *tert.* sulfones. However, the quaternization gave products which, most probably, were *1,1-dioxy-4,4-dialkylthiazanium salts.*

In continuation of work concerning the relation between structure and neuropharmacological activity within a series of simple "bolaform" [1] bis-onium salts containing a hetero atom in the alkylene chain, several substances containing an oxidized sulfur function have been prepared for pharmacological evaluation.



Bis-quaternary ammoniumalkyl sulfoxides and sulfones were available through the corresponding bis-chloro derivatives as described by Lawson and Reid [2] (*cf.*, however, Alexander and McCombie [3]) but in the work described here these types of substances were obtained starting from the corresponding bis-*tert.* aminoalkyl sulfides [4], by oxidation in acid solution with hydrogen peroxide, potassium permanganate or bromine water by conventional procedures[5].

Three sulfoxides were prepared and transformed to the six bis-quaternary salts containing only methyl and ethyl substituents at the nitrogen.

* Part IV. *Acta Chem. Scand.* 8 (1954) 350.

The alkylation of the sulfones to the quaternary ammonium salts met with unexpected difficulties. The products obtained could only in a single instance be purified to correct analysis. The main product of the reaction gave analytical values which were much better in accord with a ring closed product, 1,1-dioxy-4,4-dialkylthiazanium halide (IV).

IV

The appearance of this product is explained in terms of an intramolecular alkylation by a carbonium ion resulting from a cleavage of trialkylamine from normally formed monoquaternary sulfone,

$$(R_1)_2N—CH_2—CH_2—SO_2—CH_2—CH_2—N^+(R_2)_2R_3 \rightarrow$$

$$(R_1)_2N—CH_2—CH_2—SO_2—CH_2—CH_2\oplus + (R_2)_2NR_3 \rightarrow \text{IV}$$

The product obtained might also have been a trialkylammonium vinyl sulfone (V).

$$R_3(R_1)_2N^+—CH_2—CH_2—SO_2—CH=CH_2$$

None of the addition reactions expected are shown by the product obtained. It is also difficult to account for the appearance of the same salt from different starting products in terms of a vinyl sulfone. This appearance necessitates a retention of the N-alkyl substituents present in the original sulfone, while the vinyl sulfone salt should contain N-alkyl substituents of which at least one originated from the alkylating agent.

A dioxy-thiazanium salt (IV) should also result if a dioxy-thiazane was quaternized. The formation of dioxy-thiazane directly from the bis-*tertiary* sulfone is less easy to explain, although some earlier observations support it (see Lawson and Reid [2]). However, this route would also require thiazanium salts (IV) containing both ethyl and methyl at nitrogen. Such products have not been observed.

The four disulfide salts were obtained by the quaternization of bis-2-dimethylaminoethyl disulfide (*cf.* Andrews, Bergel and Morrison [9]) and bis-2-diethylaminoethyl disulfide which in turn resulted either from the corresponding sodium mercaptides by oxidation with iodine (*cf.* Gilman *et al.*[6]) or from iodine oxidation of the sodium aminoalkyl thiosulfates (Bunte salts) according to Bretschneider [7] (*cf.* Westlake and Dougherty [8], and also Peak and Watkins [5]).

Unfortunately no method is available for the preparation of "asymmetric" disulfides, a type of compound which would be of considerable pharmacological interest.

A report on the pharmacology of the compounds reported in this paper will appear elsewhere.

EXPERIMENTAL *

Bis-2-dimethylaminoethyl sulfoxide (II, $R_1 = R_2 = CH_3$)

The bis-hydrobromide was obtained according to Peak and Watkins [5] by oxidation of 17.6 g (0.1 mole) of bis-2-dimethylaminoethyl sulfide dissolved in 75 ml of water with 20 (approx. 0.2 mole) of bromine dissolved in 1 000 ml of water and 1 500 ml of 99 % ethanol. The evaporation residue was dissolved in 1 500 ml of 99 % ethanol containing 75 ml of water. Upon cooling the *bis-hydrobromide* separated. Yield 29 g (85 %), m. p. 215° C. (Found: Br 44.75. Calc. for $C_8H_{22}N_2SOBr_2$ (354.1): Br 45.13). It was not possible to isolate the free sulfoxide in a pure form neither from the bis-hydrobromide nor by oxidation of sulfide with hydrogen peroxide (v. s.) owing to decomposition of the free base during distillation.

The *bis-methoiodide* (As-7366) was obtained from 14.5 g (0.042 mole) of the bis-hydrobromide dissolved in 50 ml of anhydrous ethanol in which 1.94 g of sodium (0.084 mole) were previously dissolved. After removal of sodium bromide, 8 g of methyl iodide was added to the solution and this mixture kept overnight. There was obtained 12.5 g (64 %) of bis-methoiodide, m. p. 230–233° C (decomp.) (from methanol-water 5:1). (Found: I 53.19. Calc for $C_{10}H_{26}N_2SOI_2$ (476.2): I 53.30).

Bis-ethobromide (As-7367) obtained in like fashion from 14.5 g of the bis-hydrobromide and 11 g of ethyl bromide. Yield 11 %, m. p. 205–208° C (diss. methanol, reprecipitd. ether). (Found: Br 38.81. Calc. for $C_{12}H_{30}N_2SO\ Br_2$ (410.3): Br 38.96).

Bis-2-diethylaminoethyl sulfoxide (II, $R_1 = R_2 = C_2H_5$)

Bis-2-diethylaminoethyl sulfide, 11.6 g (0.05 mole) was mixed with 50 ml of water and then added to a cooled mixture of 8.4 g of 30 % hydrogen peroxide and 12 ml of concentrated hydrochloric acid in 70 ml of methanol. The volume was made up to 200 ml with water and the mixture allowed to stand at room temperature for two days. The contents were made strongly alkaline with sodium hydroxide solution, extracted with ether after supersaturation with sodium chloride, the ether extract dried over potassium carbonate, the ether removed through a 30 cm Vigreux column. The residue distils under evolution of a gas. There was obtained 9.5 g (78 %) of a deeply yellow oil, b. p. 148–149° C at 1 mm Hg. (Found: C 57.14; H 11.30; N 11.20. Calc. for $C_{12}H_{28}N_2SO$ (248.4): C 58.01; H 11.36; N 11.30).

Bis-methoiodide (As-7432) obtained at room temperature as previously described from base and an excess of methyl iodide in acetone containing ethanol. Yield 38 %, m. p. 235–238° C (decomp.) (from ethanol-water 5:1). (Found: N 5.31; I 46.48. Calc. for $C_{14}H_{34}N_2SOI_2$ (532.3): N 5.46; I 47.71).

Bis-ethobromide (As-7490). From 2.48 g (0.01 mole) of sulfoxide and 2.78 g of ethyl bromide in 25 ml of acetone containing 5 ml of ethanol. Yield 3.5 g (75 %), m. p. 211° C (acetone-methanol 2:1). (Found: Br 35.17. Calc. for $C_{16}H_{38}N_2SOBr_2$ (466.3): Br 34.29).

Bis-(2-dimethyl-2′-diethyl)-aminoethyl sulfoxide (II, $R_1 = CH_3$; $R_2 = C_2H_5$)

A bis-hydrobromide was prepared from 20.4 g of the corresponding sulfide. Yield 31 g (81 %), m. p. 210–212° C. (Found: Br 41.92. Calc. for $C_{10}H_{26}N_2SO\ Br_2$ (382.2): Br 41.81). The free base decomposed upon treatment of the hydrobromide with alkali and was not obtained pure.

Bis-methoiodide (As-7588). From the bis-hydrobromide in ethanol-sodium ethylate. Yield 59 %, m. p. 223–224° C (ethanol-water 5:1). (Found: I 50.55. Calc. for $C_{12}H_{30}N_2SOI_2$ (504.4): I 50.32).

* All melting points and boiling points are uncorrected. The nitrogen and halogen values are semi-micro determinations by Mrs. G. Speggers of this laboratory. Carbon and hydrogen values are micro determinations by Messrs. W. Egger and A. Grossmann, University of Copenhagen.

Bis-ethobromide (As-7589). The reaction was carried out in a sealed glass tube at 100° C for 3 hours. Yield 36 %, m. p. 163–170° C (methanol). (Found: Br 38.34. Calc. for $C_{14}H_{32}N_2SOBr_2$ (438.3): Br 36.46).

Bis-2-dimethylaminoethyl sulfone (III, $R_1 = R_2 = CH_3$)

The bis-hydrochloride prepared according to Peak and Watkins [5] by permanganate oxidation in acetic acid solution *. Yield 41 % m. p. 245–247° C (from ethanol-methanol-water 10:5:3). (Found: Cl 25.27. Calc. for $C_8H_{22}N_2SO_2Cl_2$ (281.3): Cl 25.21).

Bis-methoiodide (As-7696) directly from the bis-hydrochloride. Yield 30 %, m. p. 268–272° C (decomp.) (from dilute ethanol). (Found: I 49.37. Calc. for $C_{10}H_{26}N_2SO_2I_2$ (492.2): I 51.56). Another product is isolated by the fractional crystallization, m. p. 294° C, apparently a ring-closed product, *1,1-dioxy-4,4-dimethylthiazanium iodide* (IV, R = CH_3). (Found: I 44.13. Calc. for $C_6H_{14}NSO_2I$ (291.2): I 43.58).

1,1-dioxy-4,4-dimethylthiazanium bromide (IV, R = CH_3). Directly from the bis-hydrochloride. Yield approx. 10 %; m. p. 320° C (decomp.). (Found: C 29.35; H 5.77; Br 32.50. Calc. for $C_6H_{14}NSO_2Br$ (244.1): C 29.53; H 5.78; Br 32.73). It was not possible to secure any of the desired bis-ethobromide.

Bis-2-diethylaminoethyl sulfone (III, $R_1 = R_2 = C_2H_5$)

2-Diethylaminoethyl sulfide (23.8 g) dissolved in a stirred solution of 11.8 g of concentrated sulfuric acid in 150 ml of water was cooled to room temperature and a solution of 21.1 g of potassium permanganate was added at a rate sufficient to keep the mixture at a temperature of approximately 60° C. After one night the mixture is made strongly alkaline, the precipitate removed by suction on a layer of Theorit, the mixture extracted continuously with 400 ml of ether for 12 hours in a *Kutscher-Steudel* extractor, the ether extract dried over potassium carbonate and the bis-hydrochloride precipitated by addition of dry HCl gas. Yield 16.7 g (50 %), m. p. 204° C (Ref.[5] reports 202° C). (Found: Cl 21.10. Calc. for $C_{12}H_{30}N_2SO_2Cl_2$ (337.4): Cl 21.11). The free base decomposes when distilled or even by being kept in alkaline solution.

1,1-dioxy-4,4-diethylthiazanium iodide (IV, R = C_2H_5). Directly from an aliquot part of the ether extract by dilution with acetone and addition of a 50 % excess of methyl iodide. Yield 35 %, m. p. 225–227° C (dilute ethanol). (Found: I 39.83. Eq. w. (perchloric acid titration) 312. Calc. for $C_8H_{18}NSO_2J$ (319.2): I 39.76). None of the desired open chain methoiodide was ever isolated in numerous experiments.

1,1-dioxy-4,4-diethylthiazanium bromide (IV, R = C_2H_5). Prepared in similar fashion. Yield 11 %, m. p. 234° C (from dilute ethanol). (Found: Br 28.85. Calc. for $C_8H_{18}NSO_2Br$ (272.2): Br. 29.32).

Bis-(2-dimethyl-2'-diethyl)-aminoethyl sulfone (III, $R_1 = CH_3$, $R_2 = C_2H_5$).

A *bis-hydrochloride* prepared from 20.4 g of bis-(2-dimethyl-2'-diethyl)-aminoethyl sulfide was obtained by alkaline permanganate oxidation in a yield of 12 g (40 %), m. p. 250° C (from dilute ethanol). (Found: Cl 22.96. Calc. for $C_{10}H_{26}N_2SO_2Cl_2$ (309.4): Cl 22.96.)

Attempts to prepare the bis-methoiodide and the bis-ethobromide resulted in the above mentioned 1,1-dioxy-4,4-diethylthiazanium halides.

* There is an error in Peak's and Watkins' [5] experimental description. The amount of permanganate used should be three times higher.

Bis-2-dimethylaminoethyl disulfide

a) From 18.0 g (0.171 mole) of 2-dimethylaminoethane thiol according to the procedure of Gilman *et al.*[6]. Yield 11.3 g (32 %) of faintly yellow, pungent smelling liquid, b. p. 136—138° C at 18—20 mm Hg. (Found: C 45.88; H 9.47; N 13.00. Calc. for $C_8H_{20}N_2S_2$ (208.4): C 46.10; H 9.65; N 13.44).

b) From 36 g of the hydrochloride of 2-dimethylaminoethyl chloride was obtained 9.0 g (17 %) of sodium 2-dimethylaminoethyl thiosulfate, m. p. 152° C (from ethanol), following the procedure of Peak and Watkins[5]. (Found: N 6.73. Calc. for $C_4H_{10}O_3S_2NNa$ (207.3): N 6.77). The thiosulfate decomposes when exposed to moist air, presumably under formation of disulfide.

This product, 5.2 g (0.025 mole), dissolved in 90 ml of 1 % hydrochloric acid and treated with excess iodine according to Bretschneider [7] gave 2.7 g (42 %) of the disulfide, b. p. 134° C at 12 mm Hg. (Found: N 13.36. Calc. N 13.44). It was not possible to obtain the disulfide from the thiosulfate *in situ*.

Bis-methoiodide (As-11032). Yield 85.2 %, m. p. 238—240° C (washed with acetone). (Found: I 51.32. Calc. for $C_{10}H_{26}N_2S_2I_2$ (492.3): I 51.55).

Bis-ethobromide (As-11031). Yield 86.6 %, m. p. 237° C (from ethanol). (Found: Br 36.16. Calc. for $C_{10}H_{26}N_2S_2Br_2$ (426.4): Br 37.48).

Bis-2-diethylaminoethyl disulfide

Obtained in 37 % yield by the mercaptide-iodine procedure, b. p. 172° C at 12 mm Hg (Gilman *et al.* [6] report 155—160° C at 20 mm Hg). From the original alcoholic oxidation mixture a precipitate is secured which upon crystallization from dilute ethanol melts at 197° C and has been shown to be a *bis-hydroiodide*. (Found: N 5.34; I 47.36. Calc. for $C_{12}H_{30}S_2N_2I_2$ (530.3): N 5.38; I 48.78). This is obtained in amounts corresponding to 18 % free sulfide.

The total yield obtained *via* the thiosulfate route (*cf.* Bretschneider [7]) was 68 %. The disulfide could not be obtained directly from the thiosulfate reaction mixture.

Bis-methoiodide (As-8872). Yield 83 %, m. p. 208—210° C (from acetone-methanol 2:1). (Found: I 47.26. Calc. for $C_{14}H_{34}S_2N_2I_2$ (548.4): I 46.31).

Bis-ethobromide (As-8802). Yield 37 %, m. p. 215° C (from acetone-methanol 2:1). (Found: Br 33.76.) Calc. for $C_{12}H_{30}S_2N_2I_2$ (520.5): Br 33.16).

Enzymatic Formation of Nitrous Oxide from Nitrite

T. YAMADA* and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

A halotolerant *Micrococcus* strain evolved gas from nitrite (and nitrate) by reduction. Both dried cell preparations and a cell-free enzyme solution prepared from the organism was used in the experiments. The predominant product of the reduction was nitrous oxide. Nitrogen could not be established with certainty in the gas evolved. Practically no reduction of nitrite to hydroxylamine could be detected.

Several authors have observed the formation of nitrous oxide in experiments with denitrifying bacteria. Beijerinck and Minkman [1] and Kluyver and Verhoeven [2] succeeded to accumulate nitrous oxide in the gaseous products by using a higher concentration of nitrate and "vacuum experiments", respectively. The main product of the gas evolved by denitrifying bacteria under ordinary conditions was, however, nitrogen. Sacks and Barker [3] and Allen and van Niel [4] rejected the possibility that nitrous oxide might be a normal intermediate in denitrification. In their remarkable work Kluyver and Verhoeven are, on the other hand, of the opinion that molecular nitrogen is formed through reduction of nitrous oxide even if it is very probable that a part of the nitrogen can be formed also directly from the precursor of nitrous oxide.

The stepwise assimilatory reduction of nitrate to ammonia differs from denitrification on the stage between nitrite and hydroxylamine (*cf.* below). The original aim of the present investigation was to obtain further knowledge about the hitherto obscure reduction of nitrite to hydroxylamine, *i. e.* a reaction stage belonging to the assimilatory nitrate reduction. For this purpose we used both a dry cell preparation and a cell-free enzyme solution from the same halotolerant *Micrococcus* which Egami *et al.*[5] had used when establishing that specific nitrate reductase, nitrite reductase and hydroxylamine reductase act successively in assimilatory nitrate reduction which leads to ammonia. In our experiments even living cells of *Micrococcus* did not reduce nitrate and nitrite to ammonia but formed practically only gaseous products. This was also the case both with our dry cell preparations and cell-free enzyme

Side arm: 0.5 ml 0.02 M NO_3^- or NO_2^- solution added into the main chamber after 30 min. preincubation. Temp. 35° C. O—O NO_2^-, ●—● NO_3^-.

solutions. Our investigations came thus to be directed on the formation of nitrous oxide from nitrite.

Robinson *et al.*[6] using *Micrococcus halodenitrificans* and Najjar and Allen [7] using *Pseudomonas stutzeri* and *Bacillus subtilis* obtained cell-free enzyme systems which evolved gas from nitrite. In the former case the gas was suggested to be nitrogen and also in the latter case the predominant product was nitrogen (with smaller amounts of nitric oxide and nitrous oxide).

EXPERIMENTAL

Cultivation of Micrococcus *and preparation of dried cells.* The test organism was a strain of *Micrococcus*, isolated in the laboratory of Japan Marine Product Co., named tentatively halotolerant bacteria No. 203. The cultural medium was peptone broth containing 10 % of NaCl and 3 % of KNO_3. The cells harvested from 36—48 hours liquid cultures were washed several times with 10 % NaCl solution and lyophilized.

Preparation of enzyme solution. The dried cell suspension (2 g/80 ml) which had been dialysed overnight against diluted phosphate buffer, pH 6.8, was centrifuged at 0° C

Table 1. Gas evolution from nitrite by dried cells.

Total volume of reaction mixture	Volume of gas evolved if calculated as			
	N_2		N_2O	
ml	μl	10^{-5} M	μl	10^{-5} M
3.0	92	0.81	102	0.91
6.0	80	0.71	105	0.93
9.0	61	0.54	104	0.93

Main chamber: 1 ml bacterial suspension (20 mg/ml), 0.5 ml 1/2 M phosphate buffer (pH 6.8), 0.1 ml 0.01 M methylene blue solution, appropriate amount of water.

Side arm: 0.5 ml 0.02 M $NaNO_2$ solution added into the main chamber after 30 min. preincubation.

Table 2. The mass spectrometrical data of the gas evolved.

	Voltage observed on each peak			
	without NO_2^-		with NO_2^-	
Mass	Expt. 1	Expt. 2	Expt. 1	Expt. 2
28 (N_2)	1.13	2.33	1.43	1.42
30 (NO)	0.06	0.03	0.320	0.240 *
40 (Ar)	0.032	0.060	0.039	0.038
44 (N_2O)	0.127	0.076	1.17	0.950

for 30 min. at 15 000 × g. From the supernatant thus obtained the active protein was precipitated by potassium citrate between half and full saturation. The precipitate was resolved into 20 ml of distilled water and used as enzyme solution.

Measurement of gas evolution. The conventional Warburg apparatus was used. The gas phase was nitrogen unless otherwise mentioned. The *dried cells* maintained a rather strong activity of formic dehydrogenase, and formate was therefore used as hydrogen donor in the following experiments with dried cells. Methylene blue was added as intermediate hydrogen carrier to make the reaction rapid enough. The dehydrogenase activity of the *cell-free enzyme solution* was not strong enough and therefore leuco-methylene blue produced from methylene blue by hydrogen in the presence of palladium black carried on $BaSO_4$ was used as hydrogen donor in experiments with enzyme solution. Hydroxylamine was estimated according to the method of Csàky [8], ammonia to that of Conway [9].

RESULTS

In the present experiments with the halotolerant *Micrococcus* No. 203 the dried cells reduced nitrate to nitrite, and hydroxylamine to ammonia almost quantitatively, while on the other hand practically no, or possibly only a very weak, reduction of nitrite to hydroxylamine and ammonia could be detected. The principal end products of nitrite reduction were gaseous (Fig. 1).

The gas evolved was identified as follows. Because it was reasonable to suppose that the gaseous reduction product of nitrite would be nitrogen or/and nitrous oxide the solubility of the gas evolved was estimated. Table 1 shows the volumes of gas when the volume of the liquid phase in Warburg flasks was varied by addition of water. The values calculated as pure nitrogen or nitrous oxide suggest that the gas should be practically exclusively nitrous oxide.

By a mass spectrometric method Dr. Burris in the laboratory of the Department of Biochemistry, University of Wisconsin, kindly analysed the gas samples which were collected from Warburg flasks and sent to him. The gas phase was in these experiments hydrogen. The analytical data are presented in Table 2. The great differences between experiments with and without nitrite were observed at mass 30 and 44. The former peak corresponded de-

* Because a peak of about 1/5 the height of the N_2O peak is obtained as a NO peak arising from the cleavage of N_2O in the instrument the gas mixture contained practically no NO.

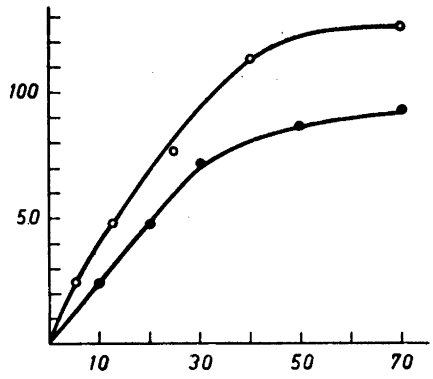

Fig. 2. Gas evolution in experiments with cell-free enzyme solution. Main chamber: 1 ml enzyme solution, 2 ml 1/2 M phosphate buffer (pH 6.8), 3 ml leuco-methylene blue solution. Side arm: 0.5 ml 0.02 M NO_2^- or NO_3^- solution added into the main chamber after 30 min. preincubation. Temp. 35° C. O—O NO_2^-, ●—● NO_3^-

finitely to nitric oxide. Although the latter could correspond both to carbon dioxide and nitrous oxide the possibility of carbon dioxide was excluded because the flasks contained KOH in the center wells. There was another peak at mass 28 corresponding to nitrogen but this probably was due to air contamination because a mass 40 peak for argon also was evident. There is, moreover, a considerable cleavage of nitrous oxide to nitric oxide in the mass spectrometer. A peak of about 1/5 the height of the parent nitrous oxide peak is obtained as a nitric oxide peak arising from the cleavage of nitrous oxide in the instrument. Thus a good share of the mass 30 peak could have arisen from nitrous oxide. Therefore, it may be concluded that the predominant product in the present experiments also on the basis of the mass spectrometric analysis was nitrous oxide.

The gas evolution from nitrite and nitrate even in experiments with cell-free enzyme preparation was strong, and no noticeable amounts of hydroxyl-

Table 3. Reduction of nitrite and hydroxylamine by cell-free enzyme solution and formation of hydroxylamine and ammonia.

Substrate	Substrate reduced	Reduction products (gaseous not estimated)	
	10^{-6} mole	NH_2OH 10^{-6} mole	NH_3 10^{-6} mole
$NaNO_2$	7.5	0.5 ? *	0.2
NH_2OH	6.9	—	4.9

Thunberg tubes were used. The contents were as follows: 1 ml enzyme solution, 2 ml 0.5 M phosphate buffer (pH 6.8), leuco-methylene blue solution 3 ml for NO_2^- and 2 ml for NH_2OH. Reaction time 1 h.

* After treatment with urea no hydroxylamine could be found. The presence of hydroxylamine is therefore not probable.

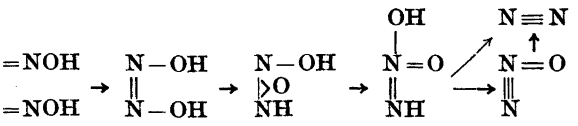
amine or ammonia were detected as shown in Fig. 2 and Table 3. In the experiment presented in Fig. 2 no nitrite could be found in the solution at the end of the experiment and also no hydroxylamine.

DISCUSSION

In our experiments the predominant product of nitrite reduction with halotolerant *Micrococcus* has been nitrous oxide, not only with dried cells but also in a system which consisted of cell-free enzyme solution, nitrite and leucomethylene blue. The results suggest that the reaction might proceed according to the following scheme:

$$2\ HNO_3 \rightarrow 2\ HNO_2 \rightarrow 2\ (=NOH) \rightarrow N_2O$$

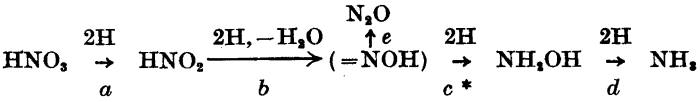
In the same halotolerant micro-organism, used in the present work, Egami *et al.* have established the specific nitrate, nitrite and hydroxylamine reductases. They have thus corroborated the conception that assimilatory nitrate reduction proceeds *via* the following reaction stages:



$$\underset{}{HNO_3} \xrightarrow[a]{} \underset{}{HNO_2} \xrightarrow[b]{} \underset{}{(?)} \xrightarrow[c]{} \underset{}{NH_2OH} \xrightarrow[d]{} \underset{}{NH_3}$$

In our experiments with dried cells as well as with cell-free enzyme solution the reactions *a* and *d* could be realized almost quantitatively. On the other hand nitrite was not reduced to hydroxylamine (and of course not to ammonia either) at least not in amounts which could be established with certainty. As the reduction product of nitrite practically only nitrous oxide was formed. Nitrogen could not be established in the gas mixture, not with certainty anyhow. Reaction stage *c* was accordingly inhibited under our reaction conditions and the reduction of nitrite was on account of this dissimilatory, nitrous acid being the only reaction product which could be established with certainty. It is difficult to understand why reaction *c* was lacking in our experiments although Egami *et al.* succeeded in reducing nitrite to hydroxylamine with the same bacteria. The only explanation is that the bacteria in our experiments for some unknown reason were lacking in the enzyme which catalyses reaction *c*.

The radical =NOH is the logical first reduction product of nitrite. It can be assumed that one molecule of water is split off under formation of one molecule of nitrous oxide when two radicals combine with each other: $2(=NOH) \rightarrow N_2O+H_2O$. When discussing possible precursors of nitrous oxide or molecular nitrogen, respectively, formed in denitrification Kluyver and Verhoeven have fixed their attention on imido-nitric acid, $HN=N=O$, for



$$\begin{array}{l} \\ | \\ OH \end{array}$$

which the wrong name "nitramide" has generally been used. They found that this compound rapidly and spontaneously decomposes into nitrous oxide and water at pH ranges where denitrification takes place. There is accordingly an experimental basis for the concept that this compound could be formed in denitrification and should thus be the long sought precursor of nitrous oxide. As Kluyver points out its formation is, however, obscure. He proposes tentatively the following mechanism

The concept about the formation of nitrous oxide from the radical = NOH *via* a simpler mechanism (*cf.* above) is tempting.

When taking into consideration the observations made by Egami *et al.* about the reduction of nitrite to hydroxylamine and our results concerning the formation of nitrous oxide as the only with certainty established reduction product of nitrite the following pathway can be proposed for assimilatory and dissimilatory nitrate reduction with the *Micrococcus* in question

Reaction stages *a*, *b*, *c*, and *d* are enzymatic, *e* at least partly spontaneous.

According to this idea the assimilatory nitrate reduction differs from denitrification because of lack of the enzyme which reduces the intermediate between nitrite and hydroxylamine. Thus bacteria causing denitrification could be formed *via* mutation from bacteria which reduce nitrate to ammonia and use it as their nitrogen source.

The authors are greatly indebted to Dr. R. H. Burris for his advice and his kindness in performing the mass spectrometric analyses.

*iso*Thiocyanates XV. *p*-Methoxybenzyl *iso*Thiocyanate, a New Natural Mustard Oil Occurring as Glucoside (Glucoaubrietin) in *Aubrietia* Species

ANDERS KJÆR, ROLF GMELIN and ROALD BOE JENSEN

Chemical Laboratory of the University of Copenhagen, Denmark

Fresh plants and seeds of various species of the crucifer genus *Aubrietia* have been demonstrated to contain a new glucoside, *glucoaubrietin*, enzymically hydrolysed to sulphuric acid, glucose and *p*-methoxybenzyl *iso*thiocyanate. This mustard oil, which has not been previously recognised in nature, has been identified by comparison of the crystalline derivatives, formed upon reaction with ammonia and benzylamine, with authentic specimens of *p*-methoxybenzylthiourea (I) and *N*-(*p*-methoxybenzyl)-*N'*-benzylthiourea (II).

In the course of studies of *iso*thiocyanates in plants it was incidentally noticed that fresh parts of the crucifer *Aubrietia hybrida* hort. possessed a sharp, anis-like taste which made a closer investigation desirable. Paper chromatography [1] revealed the presence of a single glucoside in fresh parts of various species of the genus *Aubrietia*, a hitherto unrecognised source of mustard oils. With *n*-butanol:acetic acid:water (4:1:3) as a solvent system, the *Aubrietia*-glucoside appeared as a spot possessing an R_F-value slightly above that of glucotropaeolin, the well-known glucoside containing benzyl *iso*thiocyanate. This location, in conjunction with the spectroscopical characteristics discussed below, precluded the identity of the *Aubrietia*-compound with any of the previously recognised glucosides. In accordance with common usage, the name *glucoaubrietin* has been adopted for the new glucoside.

Ultra-violet absorption spectra of various mustard oil glucosides in aqueous solutions have been determined here. Provided strongly absorbing groups are absent from the aglucone side chains the glucosides display a single maximum at 228 mμ (ε *ca.* 8 000) as seen from the examples in Fig. 1. A partly purified specimen of glucoaubrietin exhibited maximum absorption at about the same wave-length but had in addition a broad band of medium intensity at about 270 mμ (Fig. 2). This pattern was retained after enzymic hydrolysis (Fig. 2), indicating unusual absorption properties of the corresponding *iso*thiocyanate.

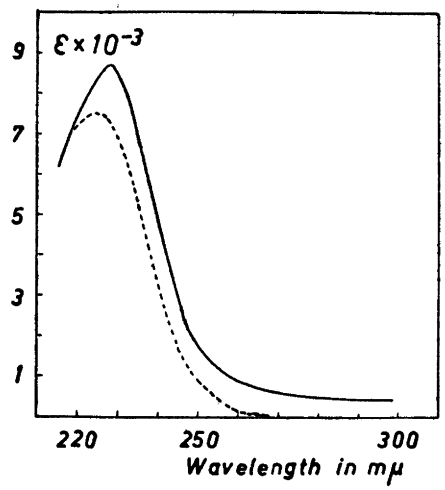

Fig. 1. Ultra-violet absorption spectra of aqueous solutions of : ———— *sinigrin;* — — — — *glucoiberin*[1].

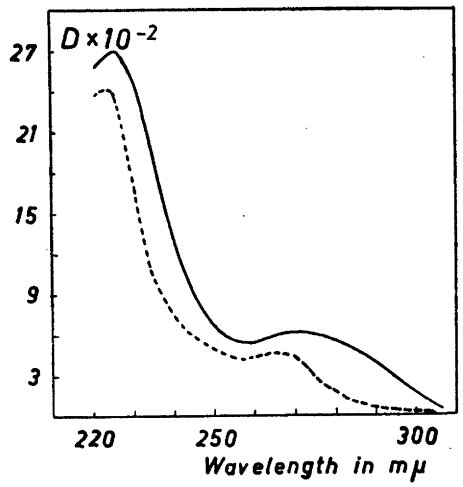

Fig. 2. Ultra-violet absorption spectra of: ———— *a partly purified extract of the glucoside of fresh parts of* Aubrietia columnae *Guss.;* — — — — *the corresponding crude* iso*thiocyanate. Solvent: water.*

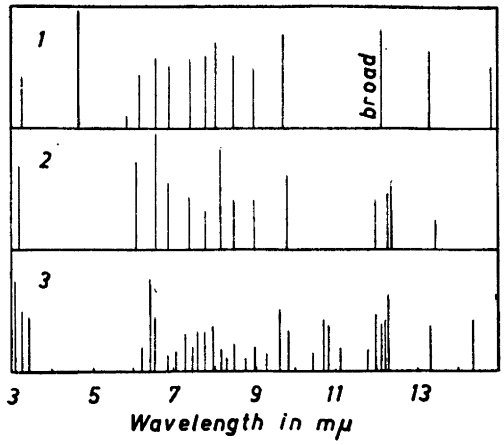
The absorption curve suggested that the latter was of aromatic character, most likely substituted by one or more auxochromic groups. The spectral similarity with compounds such as *p*-hydroxy- and *p*-methoxy-benzylpenicillin [2], tyrosine [3], the cresols [4] *etc.* was striking. No colour appeared on spraying the chromatograms with diazotised sulphanilic acid [1], a fact precluding the presence of free aromatic hydroxy- and amino-groups in the glucoside. During the enzymic action, the concomitant formation of sulphate and glucose was established, the latter by paper chromatography in two solvent systems. Hence, glucoaubrietin appears to be a glucoside of the usual type. No attempts were made to crystallise or further characterise the genuine glucoside.

Whole, fresh plants of *Aubrietia deltoidea* DC. served as the starting material for the provision of further quantities of the glucoside. A methanolic extract was partly purified by percolation through aluminium oxide and then submitted to enzymic hydrolysis. The liberated *iso*thiocyanate was isolated by ether extraction and without further purification transformed into well-crystallising thioureas by reaction with ammonia and benzylamine. Analyses of both derivatives proved the presence of one methoxy-group and established the composition C_9H_9ONS for the parent *iso*thiocyanate. The ultra-violet absorption spectrum of the simple thiourea in 96 % ethanol exhibited a maximum at 245 mμ (ε 14 000), displaced in water to 237 mμ (ε 15 900), and an auxiliary band at 275 mμ (ε 1 900), practically unchanged in aqueous solution. In the present case, the high-extinction band could be regarded as diagnostic of an aralkyl-substituted thiourea, because the only alternative, a substituted arylthiourea, should possess quite different absorption data. For example,



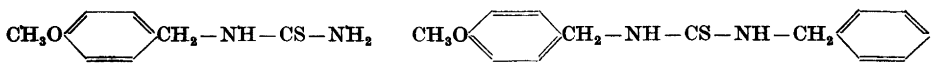


Fig. 3. Schematic presentation of the infra-red absorption spectra of: 1. p-*methoxybenzyl* isothiocyanate *(neat liquid, 0.1 mm layer); 2.* p-*methoxybenzylthiourea (I) (KBr pellet); 3.* N-(p-*methoxybenzyl*)-N'-*benzylthiourea (II) (KBr pellet).*

phenylthiourea in 96 % ethanol exhibits a maximum at 266 mμ (ε 15 400) with an inflection at 245 mμ (ε 10 000) and minimum at 227 mμ (ε 8 000), changed in water to a split peak at 248 and 240 mμ (ε 14 700 and 15 700). Hence, the mustard oil of glucoaubrietin must be one of the isomeric methoxybenzyl *iso*thiocyanates. In the literature [5,6] *p*-methoxybenzylthiourea is recorded with the m. p. 133—135°, sufficiently close to the m. p. 137° of the *Aubrietia*-thiourea to warrant a synthesis of an authentic specimen for comparison purposes.

p-Methoxybenzylamine was prepared in 34 % yield by reduction of anisaldoxime with zinc and acetic acid, according to Sunagawa *et al.*[7], or, more conveniently, from anisaldehyde by a Leuckart-reaction in 23 % yield as described by Lewis [8]. The amine was transformed into *p*-methoxybenzyl *iso*thiocyanate in 75 % yield by the Kaluza-Hodgkins synthesis, successfully employed recently by Ettlinger and Lundeen [9] for the preparation of the corresponding *m*-isomeride. The *iso*thiocyanate was formerly described by v. Braun and Deutsch [10] as a colourless liquid boiling over a rather wide range and suffering extensive decomposition on distillation at 16 mm. Here, the mustard oil appeared as a colourless, constant-boiling oil of agreeable odour and a burning taste, resembling that of fresh *Aubrietia* plants.

I II

By reaction with ammonia and benzylamine the synthetic mustard oil afforded the corresponding thioureas, (I) and (II). Analyses, melting points, mixed melting points and infra-red spectra served to establish the identity of the two *Aubrietia*-thioureas with the authentic specimens. The infra-red

spectra are schematically reproduced in Fig. 3. It has thus been proved that *p*-methoxybenzyl *iso*thiocyanate represents an addition to the rather extensive series of naturally occurring *iso*thiocyanates.

Besides its occurrence in fresh plants of *Aubrietia deltoidea* DC., *A. hybrida* hort. and *A. columnae* Guss., glucoaubrietin has been demonstrated to be present in seeds of *A. deltoidea* DC., *A. erubescens* Griseb. and *A. intermedia* Heldr. *et* Orph. In the seed samples, however, the glucoside is accompanied by the *p*-hydroxybenzyl *iso*thiocyanate glucoside and an unidentified glucoside, the latter two being present in minor amounts only (Fig. 4). Glucoaubrietin therefore appears to be a rather constant and characteristic constituent of the genus *Aubrietia*. Its possible occurrence in other genera is being investigated at present. The detection of *p*-methoxybenzyl *iso*thiocyanate in nature is not altogether surprising in view of the long recognised existence of *p*-hydroxybenzyl *iso*thiocyanate (*cf.* ref. 11) as the aglucone of the glucoside sinalbin which occurs in white mustard and a few other plants. Biological methylation of aromatic hydroxy-groups is a reaction too well-known in phytochemistry to need further comments.

At the conclusion of the present work, the authors were informed that Ettlinger and Lundeen [9] have recently established the occurrence of the isomeric *m*-methoxybenzyl *iso*thiocyanate in seed of the American plant *Limnanthes douglasii* R.Br., belonging to the family *Limnanthaceae*. The latter finding is remarkable because of the rare occurrence of *m*-disubstituted aromatic compounds in nature.

EXPERIMENTAL

All melting points are uncorrected and determined in capillary tubes in a glycerol bath.

Paper chromatography of Aubrietia *species.* Methanolic extracts of whole, fresh plants and seeds of various *Aubrietia* species were applied to Whatman paper No. 1 and chromatographed in *n*-butanol:acetic acid : water (4:1:3) by the descending technique. The chromatograms were developed as previously described [1] and the results are schematically presented in Fig. 4. Whereas extracts of the fresh plants gave only one glucoside-spot, the seed samples contained minor amounts of two additional glucosides. One of these (C in Fig. 4), appeared to be identical with the glucoside containing *p*-hydroxybenzyl *iso*thiocyanate. Like an authentic specimen of the latter, the *Aubrietia*-compound C developed a red colour on spraying the chromatogram with diazotised sulphanilic acid [1]. The nature of the other minor glucoside, (B), is unknown.

Properties of glucoaubrietin. A specimen of fresh parts of *Aubrietia columnae* Guss. (1 g) was extracted three times with boiling methanol. The solvent was removed *in vacuo* and the residue taken up in water (20 ml). Insoluble material was removed by filtration and the filtrate passed through a column of acid-washed aluminium oxide (2 g). After the column had been washed with water the glucoside was eluted with 1 % K_2SO_4-solution[1].

A small fraction of the eluate was used, after appropriate dilution, for the determination of the ultra-violet spectrum, while the remaining part was subjected to enzymic hydrolysis by adding a drop of a cell-free myrosinase preparation. After some hours, the reaction mixture was extracted with ether, the solvent removed and the residue dissolved in water. Again, the ultra-violet absorption spectrum of this solution was determined. The original aqueous phase was chromatographed in 1) *n*-butanol:acetic acid:water (4:1:3) and 2) pyridine:amyl alcohol:water (30:35:30), in both solvent systems accompanied by glucose as a reference substance. The R_F-values were 0.24 and 0.42, respectively, the same as of glucose in the two systems.

A separate plant extract, which was not further purified, served to establish the presence of sulphate after enzymic hydrolysis of the glucoside.

Crystalline derivatives of the Aubrietia *isothiocyanate.* It was established in preliminary experiments that the *iso*thiocyanate, corresponding to glucoaubrietin, was volatile with steam. The steam distillation, however, was accompanied by a considerable loss of material for reasons which are not quite clear. Therefore, it was preferred to extract the free mustard oil by ether after enzymic hydrolysis.

Fresh, whole plants of *Aubrietia deltoidea* DC. (1.2 kg) were repeatedly extracted with a total of 5 l of methanol. After removal of the latter, the residue was taken up in water (1 l) and filtered. The filtrate was divided into four parts and each was allowed to flow slowly through a column of acid-washed aluminium oxide (35 g). The percolates were pooled, a few ml of a myrosinase solution was added and the mixture set aside overnight. Next day, the *iso*thiocyanate was collected by ether extraction (3 × 100 ml) and the ether solution was divided into two parts.

Thiourea. To one of these was added a solution of ammonia in ethanol. After 12 hours, the solvents were removed and the partly oily residue was treated with charcoal in hot water and filtered. On cooling, the solution deposited colourless needles (49 mg). The product was recrystallised from water (3.5 ml) for analysis (43 mg), m. p. 137.5—138.5°. Paper chromatography of the thiourea in chloroform gave a spot with an R_{Ph}-value [12] of 1.03. The ultra-violet and infra-red spectra were determined. (Found: C 55.10; H 6.02; N 13.93; S 15.90; OCH_3 15.90. Calc. for $C_9H_{12}ON_2S$: C 55.05; H 6.17; N 14.27; S 16.33; OCH_3 15.83).

Benzylthiourea. To the other half of the ether solution was added an excess of benzylamine. Next day, the solvent was removed and the residue treated with water, containing a drop of hydrochloric acid. The partly crystalline product was recrystallised three times from 50 % ethanol to give colourless, nacreous platelets (66 mg), m. p. 105°. (Found: C 67.25; H 6.24; N 9.87; S 11.04; OCH_3 10.94. Calc. for $C_{16}H_{18}ON_2S$: C 67.10; H 6.34; N 9.78; S 11.20; OCH_3 10.83). The ultra-violet and infra-red spectra of the disubstituted thiourea were determined.

Synthesis of p-*methoxybenzyl* iso*thiocyanate.* *p*-Methoxybenzylamine was prepared by reduction of anisaldoxime with zinc and acetic acid, according to Sunagawa *et al.*[7], who

reported a yield of 75 %. Our yields were considerably smaller (30—40 %) and it was therefore preferred to prepare the amine by the Leuckart-reaction proposed by Lewis [8]. The stated yield (23 %) was obtained. The amine was distilled *in vacuo*, b. p. 115° at 12 mm.

The synthesis of the *iso*thiocyanate was performed exactly as described by Ettlinger and Lundeen [9] for the corresponding *m*-isomeride and proceeded in 75 % yield. The mustard oil appeared as a colourless liquid of a faint odour, but possessing a sharp and aromatic taste, b. p. 133° at 0.7 mm; n_D^{25} 1.5935. (Found: C 60.30; H 5.21; N 7.98; S 17.86. Calc. for C_9H_9ONS: C 60.31; H 5.06; N 7.82; S 17.89).

p-*Methoxybenzylthiourea* (I). The synthetic mustard oil was allowed to react with ammonia in dilute ethanol overnight. The resulting thiourea was obtained as clusters of colourless needles after recrystallisation from water, m. p. 138° alone or when mixed with the *Aubrietia*-thiourea above. (Found: C 55.20; H 6.15; N 14.24. Calc. for $C_9H_{12}ON_2S$: C 55.05; H 6.17; N 14.27.) The infra-red spectrum was found identical with that of the *Aubrietia*-thiourea.

N-*(p-Methoxybenzyl)*-N'-*benzylthiourea* (II). An ether solution of the mustard oil and benzylamine was left standing at room temperature overnight. Next day, the crystals were collected and recrystallised from 50 % ethanol. The benzylthiourea separated as colourless plates, m. p. 105°, alone or in admixture with the *Aubrietia*-derivative. (Found: C 67.00; H 6.33; N 9.82. Calc. for $C_{16}H_{18}ON_2S$: C 67.10; H 6.34; N 9.78). Again, the infra-red spectrum served to establish the identity of the compound with the benzylthiourea, derived from the *Aubrietia* mustard oil.

The authors wish to thank the *Botanical Garden of the University of Copenhagen* for placing at our disposal all the plant materials employed in the present investigation. Microanalyses were made in this laboratory by Mr. P. Hansen. The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*.

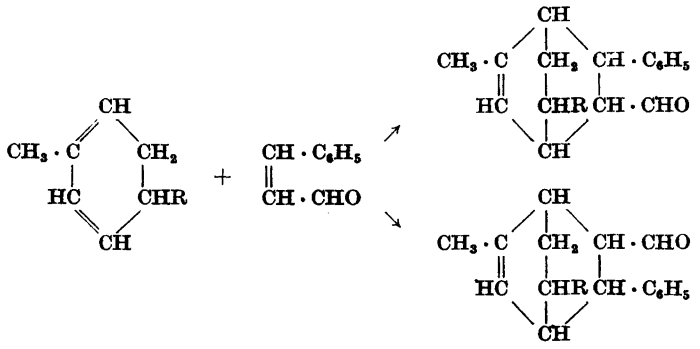
Diels-Alder Reaction of α-Phellandrene and Cinnamaldehyde

INGVALD AUGESTAD



Universitetets kjemiske institutt, Blindern-Oslo, Norway

An adduct of laevorotatory α-phellandrene and cinnamaldehyde has been prepared. The adduct, which is liquid and dextrorotatory seems to consist of one predominating form with at least one other isomeride present. On regenerating the adduct from its phenylhydrazone in methanolic solution the crystalline methyl acetal of the adduct was formed. The adduct of maleic anhydride and α-phellandrene is transformed into a lactonic acid by boiling with water.

Diels-Alder reactions of α-phellandrene have previously been carried out with symmetrical dienophiles such as maleic anhydride and naphthoquinone and with the unsymmetrical dienophiles acrolein and crotonaldehyde; for summary see Northon [1]. In the present paper the reaction with cinnamaldehyde is described. The α-phellandrene used was a commercial laevorotatory sample (Eastman) with a specific rotation of —124°. In order to check its reactivity it was treated with maleic anhydride when it readily gave a crystalline adduct as described by Diels and Alder [2]. It was found that this adduct by boiling with water was isomerized to the lactonic acid previously prepared by West [3].

The reaction of α-phellandrene with cinnamaldehyde was carried out by heating to 150°. On fractionating the reaction product in a vacuum a crude adduct was obtained which was purified by treatment with sodium hydrogen sulphite. After redistillation the adduct was obtained as an oil with the expected composition $C_{19}H_{24}O$ and with a specific rotation of +17.8°.

Theoretically the addition of an unsymmetrical dienophile to one of the optical components of α-phellandrene could give 8 isomeric adducts of two structurally different types as seen from the scheme (R = *iso*propyl)

In accordance with what has been found by Alder and Stein [4] the diene synthesis seems also in this case to lead mainly to one product with one other adduct present in small amount. If the adduct was treated with 2,4-dinitrophenylhydrazine two crystalline hydrazones could be isolated, the one being strongly dextrorotatory and the other strongly laevorotatory. With phenylhydrazine one crystalline hydrazone only was isolated and in good yield. It was dextrorotatory and is evidently a derivative of the predominating isomeride. An attempt to regenerate the aldehydic adduct from the phenylhydrazone by boiling with a methanolic solution of pyruvic acid led to a new crystalline compound $C_{21}H_{30}O_2$, m. p. 71°, $[\alpha]_D^{20} = +68°$ which was found to be the methyl acetal of the adduct. The acetal on catalytic hydrogenation took up one mole of hydrogen.

From the acetal the adduct itself could only partially be regenerated. Hydrolysis led to a mixture of crystalline acetal and oily adduct, the methoxyl content and rotation of which permitted the calculation of an approximate specific rotation of + 27° for the adduct. The oily part of the mixture gave the same dextrorotatory phenylhydrazone from which the acetal had been obtained and the dextrorotatory 2,4-dinitrophenylhydrazone, described above. It is therefore evident that the methyl acetal must be derived from a dextrorotatory component of the adduct.

The crystalline methyl acetal could be obtained directly from the original adduct, although only in poor yield, by heating methanolic solutions containing pyruvic acid, formic acid or 0.02 N hydrochloric acid.

Oxidation of the adduct under mild conditions with hydrogen peroxide gave two monocarboxylic acids. The one was a crystalline compound $C_{19}H_{24}O_2$, m. p. 157°, $[\alpha]_D^{20} = -67°$, and the other an oil with $[\alpha]_D^{20} = +34°$. The acids were boiled with water but no formation of lactones could be detected.

In order to establish the structure and the configuration of the adduct further experimental work will be necessary.

EXPERIMENTAL

α-Phellandrene and maleic anhydride

Optically pure α-phellandrene is rather difficult to obtain as shown by Hancox and Jones [5] who found the rotation to be $[\alpha]_D^{20} = -177°$. In the present case a commercial (−)-α-phellandrene (Eastman) of $[\alpha]_D^{20} = -124$ was used without further purification. The α-phellandrene and an excess of maleic anhydride on keeping for several days at −5° gave in 38 % yield the adduct described by Diels and Alder [2]. After recrystallization from petroleum ether it had m. p. 126°, $[\alpha]_D^{20} = -10°$ ($c = 3$ in chloroform). The adduct (3 g) was boiled with water (1 l) for one hour and the filtered solution then evaporated on the steam-bath to 200 ml in the course of 24 hours. The lactonic acid which had separated (1.6 g) was recrystallized from a mixture of ethyl acetate and ligroin, m. p. 170°, $[\alpha]_D^{20} = -37°$ ($c = 24$ in chloroform). (Found: C 66.65; H 8.08. Equiv. wt. 250. Calc. for $C_{14}H_{20}O_4$: C 66.70; H 8.05. Equiv. wt. for monobasic acid 252). Treatment of the acid m. p. 170° with an ethereal solution of diazomethane gave the corresponding lactonic ester, which after recrystallization from petrol ether had m. p. 105°. West [3] found 104°. $[\alpha]_D^{20} = -18.8°$ (chloroform). (Found: OCH_3 12.51. Calc. for $C_{15}H_{22}O_4$ 11.65).

α-Phellandrene and cinnamaldehyde

The same (−)-α-phellandrene as above (100 g) and cinnamaldehyde (50 g) purified by vacuum fractionation, were heated in sealed tubes for 24 hours at 150°. After removing most of the unreacted α-phellandrene by distillation at 12 mm Hg, the reaction product was fractionated in a high vacuum. The fraction distilling at 114—120°/0.01 mm amounted to about 20 %, based on the quantity of cinnamaldehyde employed in the reaction. The adduct (18 g) was shaken for 2 hours with 25 % sodium hydrogen sulphite (40 ml) and ethanol (20 ml) and the solution then extracted with ether in order to remove impurities. The adduct was regenerated from the bisulphite solution by heating on the steam-bath for 30 min. and was then taken up in ether. The adduct (14 g) distilled at 114—120/0.01 mm $[\alpha]_D^{20} = +17.8°$ ($c = 3$ in chloroform). (Found: C 84.86; H 9.01; Mol.wt. (camphor) 267; 270. Calc. for $C_{19}H_{24}O$: C 85.07; H 8.96. Mol.wt. 268).

By bromination in ether a liquid bromide was formed which contained 35.87 % Br; calc. for 1 double bond 37.33 %.

The adduct (12 g), in methanol (200 ml) to which 0.4 g platinum oxide had been added, absorbed 1 250 ml hydrogen (1.5 atm.). It was thus apparent that both the double bond and the aldehyde group had been reduced. Calc. for 2 moles of hydrogen; 1 460 ml. The hydrogenated product, after distillation at 152°/0.2 mm, had $[\alpha]_D^{20} = 49°$ ($c = 1$, in chloroform). (Found: C 84.12; H 10.34. Calc. for $C_{19}H_{28}O$: C 83.80; H 10.35).

2,4-Dinitrophenylhydrazones

The phosphoric acid method of Johnson [6] was used for the preparation of these hydrazones. A solution of 2,4-dinitrophenylhydrazine (5 g) in 85 % phosphoric acid (60 ml) was heated on the steam-bath, diluted with ethanol (40 ml) and filtered. To a solution of the adduct (1 g) in ethanol (20 ml) the calculated amount of the reagent was added. On standing for some hours at room temperature a mixture of red and yellow crystals separated. These were collected by filtration, washed with water and the mixture was crystallized first from glacial acetic acid and then from petrol ether containing 20 % benzene, when red crystals only were obtained, m. p. 191° $[\alpha]_D^{20} = +272°$ ($c = 1.2$, in chloroform). (Found: C 66.95; H 6.59; N 12.65. Calc. for $C_{25}H_{28}O_4N_4$: C 66.95; H 6.30; N 12.95).

In order to isolate the yellow form a fresh portion of the crystal mixture was prepared, dried at room temperature and refluxed with ether when mainly the yellow crystals dissolved. The filtered solution on cooling gave the yellow hydrazone which after recrystallization from glacial acetic acid had m. p. 176°, $[\alpha]_D^{20} = -210°$ ($c = 0.1$ in chloroform). (Found: C 67.24; H 6.40; N 12.38).

Phenylhydrazone

A solution of the adduct (12 g) and phenylhydrazine (3 g, calc. 4.04 g) in methanol (60 ml) was kept at 0° for 4 hours when colourless needles separated in a yield of 40 %. Recrystallized from methanol, m. p. 112°, $[\alpha]_D^{20} = +96°$ ($c = 1$ in ethanol). (Found: C 83.79; H 8.52; N 7.90. Calc. for $C_{25}H_{30}N_2$: C 83.79; H 8.38; N 7.85).

It should be mentioned that a phenylhydrazone with m. p. 124° and $[\alpha]_D^{20} = +151°$ ($c = 1$ in ethanol) was obtained in some cases when the adduct was prepared by heating to 120°. (Found: C 83.49; H 8.37; N 7.97). The two phenylhydrazones gave the same product when treated with a methanolic solution of pyruvic acid.

Oxidation of the adduct

To a vigorously stirred aqueous solution of sodium hydroxide (0.5 N, 100 ml) containing boric acid (0.1 g) and hydrogen peroxide (10 ml 40 %), a solution of the adduct (10 g) in benzene (20 ml) was added dropwise at room temperature. After 3 hours the

mixture was transferred to a separating funnel, and more benzene added. Next day the aqueous layer was acidified with hydrochloric acid and the oil which separated was washed with water. The oil was dissolved in a small quantity of ethanol and water added until turbidity was produced. On keeping in the refrigerator overnight crystals separated (3 g) which on recrystallization from 75 % methanol gave colourless needles with m. p. 157°, $[\alpha]_D^{20} = -67°$ ($c = 1.5$ in chloroform). (Found: C 79.95; H 8.50; Equiv. wt. 281. Calc. for $C_{19}H_{24}O_3$: C 80.24; H 8.51; Equiv. wt. 284.4).

On the addition of water to the mother liquor from the crystals m. p. 157°, an oil deposited which had $[\alpha]_D^{20°} = +22°$ ($c = 3.5$ chloroform). (Found: Equiv. wt. 279).

A chromatographic fractionation of this oily acid (1.4 g) was attempted on a column of cellulose, using as an eluant a mixture of ethyl acetate, benzene, *n*-propyl alcohol, water (5:1:2:1). Plotting the optical rotation against fraction number a sharp peak in the curve showed that the dextrorotatory acid was concentrated over a few fractions. From these fractions 1.2 g oily acid were recovered which had $[\alpha]_D^{20} = +34.2°$ ($c = 2.5$ in chloroform).

Phenylhydrazone of the adduct with pyruvic acid

A solution of the phenylhydrazone, m. p. 112° (6 g) and pyruvic acid (4 g) in methanol (60 ml) was refluxed for 3 hours. After cooling water (2 ml) was added and the solution kept in a refrigerator overnight when the methyl acetal of the adduct separated as needles (4.5 g). After recrystallization from 80 % methanol the m. p. was 71°, unchanged on recrystallization from a small volume of benzene. $[\alpha]_D^{20} = +68$ ($c = 2$ in chloroform). (Found: C 80.31; H 9.52; OCH_3 19.10. Calc. for $C_{21}H_{30}O_2$; C 80.21; H 9.61; OCH_3 19.72).

When water was added to the mother liquor the phenylhydrazone of pyruvic acid separated. After purification it had m. p. and mixed m. p. 182°.

Hydrogenation of the acetal, m. p. 71°

Platinum oxide (0.29 g) in glacial acetic acid (30 ml) was shaken in an atmosphere of hydrogen until absorption ceased. After adding the methyl acetal (0.564 g) 34.0 ml hydrogen (960 mm, 19°) were absorbed in the course of 100 min, calc. 34.1 ml. The filtered solution was poured into water, the precipitate taken up in ether and the ethereal solution washed with water and dried. After evaporating the ether the crystalline residue was recrystallized from methanol. M. p. 57–60°, $[\alpha]_D^{20} = +63°$ ($c = 3$ in chloroform). (Found: C 79.39; H 10.19; OCH_3 19.98. Calc. for $C_{21}H_{32}O_2$: C 79.68; H 10.19; OCH_3 19.60).

Hydrazones prepared from the acetal

A solution of the methyl acetal (1 g) and 2,4-dinitrophenylhydrazine (0.75 g) in ethanol (50 ml) was heated to boiling. On adding a few drops of conc. hydrochloric acid a reaction immediately took place and on cooling a red crystalline hydrazone precipitated (1.4 g). The hydrazone after recrystallization from petrol ether containing 20 % benzene, had m. p. 189° and $[\alpha]_D^{20} = +262°$ in chloroform. (Found: C 67.10; H 6.44; N 12.40. Calc. for $C_{25}H_{28}O_4N_4$: C 66.95; H 6.30; N 12.95).

The methyl acetal (4 g) was heated with N hydrochloric acid (100 ml) on a water-bath for 20 hours. On cooling a mixture of oil and crystals deposited. The oil was dissolved in 80 % methanol and the solution, after the addition of phenylhydrazine (1 g), was heated for a short time. When the solution was subsequently kept in a refrigerator colourless crystals separated which had $[\alpha]_D^{20} = +97°$ ($c = 0.6$ in ethanol) and m. p. 112° alone and mixed with the phenylhydrazone of the original adduct.

Preparation of acetal directly from adduct

A solution of the oily adduct (1 g) and pyruvic acid (5 g) in methanol (30 ml) was refluxed for 24 hours. After adding water until turbidity was produced the solution was kept in a refrigerator overnight when a small amount of crystalline material separated which, after recrystallization from petrol ether had m. p. 68–70° and $[\alpha]_D^{20} = +65°$ ($c = 1.1$ in chloroform).

Following the same procedure a small amount of the methyl acetal was also obtained when formic acid was used instead of pyruvic acid. Acetic acid had, however, no effect. On using 0.1 ml 5 N hydrochloric acid instead of pyruvic acid, 0.1 g (10 % yield) of the methyl acetal was obtained. It had m. p. 71° alone and mixed with acetal prepared from the phenylhydrazone.

Hydrolysis of the methyl acetal

A solution of the methyl acetal (1 g) in 75 % methanol (150 ml) to which 1.5 ml N hydrochloric acid had been added, was refluxed for 90 min. The methanol was distilled off, and the oil which separated was taken up in ether. The ethereal solution was washed with water and dried over potassium carbonate. After evaporating the ether the residue was dried in a vacuum over calcium chloride. The methoxyl content of the residue (6.1 %) showed that the acetal had not been completely hydrolysed. As the specific rotation of the residue was found to be +39.7° an approximate specific rotation of +27° could be calculated for the aldehyde corresponding to the acetal.

The author wants to express his gratitude to Professor E. Berner for having suggested this investigation and for his kind advice and valuable criticism during the work.

A grant from *Fridtjof Nansen Fond* is gratefully acknowledged.

Interaction of Pyridine-Nucleotide linked Enzymes

AGNAR P. NYGAARD* and WILLIAM J. RUTTER**

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The oxidations of lactate by lactic dehydrogenase (LDH), glutamate by glutamic dehydrogenase, and alcohol by liver and yeast alcohol dehydrogenase (ADH) have been found to be somewhat slower with diphosphopyridine nucleotide (DPN) bound to glyceraldehyde-3-phosphate dehydrogenase (TDH) than with free DPN. In contrast, the reduction of pyruvate by LDH and acetaldehyde by liver ADH was faster with reduced DPN (DPNH) bound to TDH than with free DPNH. The equilibrium constants of the systems were in all cases displaced towards the reduced substrate with bound DPN.

The overall kinetics of the liver ADH system using DPN(H) bound to TDH (TDH · DPN and TDH · DPNH) has been studied in some detail. The reaction mechanism appeared to be the same as with free DPN(H).

When liver ADH was added to TDH · DPNH which had been reduced by glyceraldehyde-3-phosphate, the absorption peak of DPNH shifted from 340 mμ to 330 mμ. If the bound DPN was reduced by liver ADH and alcohol, the absorption peak shifted down to 322 mμ, which is in the same region as the absorption peak of ADH·DPNH itself. No complex between liver ADH and TDH · DPNH could be observed in the ultracentrifuge.

Implications of these findings have been discussed.

Most oxidation-reduction reactions at the "substrate" level occur by virtue of pyridine nucleotide-linked (PN) enzymes. In the past it has often been explicitly or implicitly implied that the PN coenzymes themselves act as mobile oxidation-reduction (O/R) carriers between the various dehydrogenase systems. Several lines of evidence, however, allow alternative interpretations. Although these coenzymes are often readily dissociable from their respective apoenzymes, this is by no means always the case. Taylor *et al.*[1] have shown that crystalline triosephosphate dehydrogenase (TDH) contains firmly bound diphosphopyridine nucleotide (DPN) which cannot be removed by dilution or dialysis, but which rapidly exchanges with free DPN. Theorell and Bonnichsen[2] observed that the liver alcohol dehydrogenase, on the other hand, has a very

high affinity for reduced DPN (DPNH). As a matter of fact, the diversified manners by which pyridine nucleotides are bound may also be inferred from the different spectral manifestations of the coupling reactions of PN and PNH with their various apodehydrogenases [3].

These different types of binding of PN coenzymes could be the reflection of a complicated pattern of interaction between the PN enzymes themselves. In biological systems where the number of binding sites is of the same order of magnitude as the available PN molecules, interactions of apoproteins with bound PN could play a prominent role in physiological oxidation-reduction. It is therefore interesting that DPN-linked enzymes have been found to react with DPN of TDH (TDH · DPN). Cori, Velick and Cori observed [4] that when TDH · DPN was reduced by glyceraldehyde-3-phosphate (G-3-P), it could be reoxidized by addition of pyruvate and lactic dehydrogenase (LDH). The rate of the reaction made the intermediation of dissociated DPNH unlikely. Similar reactions of TDH · DPNH with DPNH cytochrome-c reductase have been reported by Mahler [5], and with various DPN degrading enzymes as well as other dehydrogenases by Astrachan [6]. Under the conditions studied, the rates of reactions were generally somewhat slower than with free DPN(H).

The implications of these data are manifest. The kinetic relations which have been the result of the study of isolated enzymes under the usual assay conditions involving high concentrations of free coenzyme and substrates may well not apply to situations in which apoprotein-holoenzyme interactions predominate. For example, Theorell and Chance [7], and Theorell, Nygaard and Bonnichsen [8] have been able to develop an apparently satisfactory kinetic treatment of the reactions of liver ADH without formal consideration of the formation of complex with the substrate. Under some experimental conditions, association-dissociation reactions of DPN(H) with the apoenzyme seemed to be rate-limiting steps. If, by virtue of interaction with other enzymes, the overall reaction occurred without association and dissociation of coenzyme, or if these reactions occurred at modified rates, then ADH might exhibit quite different reaction properties.

In this paper we wish to present some further information on the nature of the bound DPN(H) of TDH, especially its reactivity with various other dehydrogenases. Using the sensitive recording fluorimetric technique developed in this laboratory, it has been possible to study the kinetics of the interactions with liver ADH rather thoroughly. Some experiments on the mechanism of dehydrogenase interaction are also presented, and the implications of these data are discussed.

MATERIALS AND METHODS

Enzymes. TDH was prepared from rabbit muscle according to Cori *et al.*[9]. The preparation used was recrystallized 4 times, and contained 2.0 moles DPN/mole TDH as determined by reduction with G-3-P as well as with ADH and ethanol. The ratio of light absorption at 280 mμ *vs* 260 mμ was 1.12. This is in agreement with data previously reported by Velick and Hayes [10].

LDH was prepared from bovine heart muscle by the procedure of Straub [11]. It was recrystallized three times and contained both A and B components.

Crystalline preparations of liver ADH and glutamic dehydrogenase were generously supplied by Dr. Roger Bonnichsen. Crystalline yeast ADH was procured from C. F.

Boehringer & Soehne. Crude Zwischenferment was prepared from bottom yeast according to the method of Warburg and Christian [12]. DPN was prepared in this laboratory according to Åkeson and Neilands [13]. The sample used was 88 % pure, as judged by the ADH test. A sample of approximately 90 % pure TPN was obtained from Pabst laboratories. DPNH was prepared enzymatically according to Nygaard and Theorell [14].

Substrates. Glyceraldehyde-3-phosphate (G-3-P) was prepared essentially according to Meyerhof [15]. The other substrates were obtained commercially.

Kinetic measurements. The highly sensitive fluorimetric technique allowed kinetic measurements to be made without using inordinately large amounts of TDH. The experimental procedure is the same as used in the recent study of the ADH system [8]. The calibration of the total amounts of free DPN or bound DPN added in a given experiment was made with yeast ADH and ethanol.

The experiments involving bound DPNH (TDH · DPNH) were carried out in the following manner: The amount of G-3-P necessary to reduce a known amount of TDH · DPN nearly to completion was determined, and that amount was used to form TDH · DPNH for oxidation by the different pyridine-nucleotide systems. To get more than 90 % reduction of TDH · DPN it was not possible to avoid an excess of G-3-P. The initial velocities for oxidation of TDH · DPNH by the various dehydrogenase systems could accordingly never be maximum, because of the counter reaction.

RESULTS

The TDH reaction studied with the fluorescence technique

Before the proposed kinetic studies could be carried out, it was necessary to investigate with the fluorimetric technique certain aspects of the reaction in the presence of TDH. The basis of the technique as applied to the PN enzymes is that DPNH fluoresces while DPN does not. At the outset it was by no means certain that TDH · DPNH would exhibit the same fluorescence properties as free DPNH. It is known that FMN, for example, loses its fluorescence when it is coupled with the old yellow enzyme. Appropriate experiments demonstrated that TDH · DPNH does in fact fluoresce, and that the intensity of fluorescence of TDH · DPNH is the same as for free DPNH within experimental error (—5 %). A similar situation has been found for ADH · DPNH.

It was originally noted by Velick *et al.*[16] that DPNH undergoes a transformation with consequent loss of absorption in the 340 mμ region in the presence of TDH. This interesting fact has been further studied by Krebs *et al.*[17]. Such a "destruction" of DPNH bound to TDH was observed in the fluorescence apparatus. The product(s) of the reaction are therefore non-fluorescent. The reaction cannot represent a simple reoxidation to DPN since further addition of substrate did not elicit additional fluorescence, whereas addition of free DPN resulted in a rapid reaction reflected by an immediate increase in fluorescence. Since no free DPNH was added in these experiments, the reaction probably occurred at the binding site of DPNH on the TDH molecule. There was no observable destruction of DPNH by any of the other dehydrogenases tested.

It was consistently observed that 2 molecules DPN/molecule TDH could be reduced by ADH and ethanol at pH 10. Similar results could be obtained with G-3-P only in the presence of low arsenate concentrations (—10^{-4} M). At higher

concentrations, less than 2 molecules DPN/TDH were reduced (in 0.1 M arsenate the reduction of approximately one of the two DPN molecules on TDH was observed). This effect was not due to a rapid destruction of DPNH [16,17] by a reaction similar to that described above, since such destruction occurred very slowly, if at all, under the conditions of the experiments. High concentrations of arsenate did not inhibit the reduction of 2 DPN per TDH molecule by the ADH. The significance of these observations has not been investigated further, but a relationship to the inhibition of the reaction rate of TDH by arsenate as studied by Bücher [18] is suggested.

Because of the very large effects of pH as well as salts on the binding of FMN to the old yellow enzyme [19], several attempts to dissociate TDH · DPN by dialysis at different pH's in the presence of various salts were made. Whenever dissociation was observed, so also was loss of enzyme activity.

Interaction of LDH with TDH · DPN and TDH · DPNH

The interaction of the LDH system with TDH · DPN and TDH · DPNH first studied by Cori, Velick and Cori [4], has been reinvestigated in an attempt to get more quantitative estimate of the relative reaction rates of LDH with bound and free DPN(H). The 4 times recrystallized TDH preparation used in these experiments exhibited small but definite lactic dehydrogenase activity. Appropriate experiments indicated that "endogenous" LDH had properties different from the crystalline LDH. Figs. 1 and 2 show that the Michaelis constant (K_m) for pyruvate in the two systems is considerably different. Similar results were obtained using TDH · DPNH instead of free DPNH. In addition, the inhibition of activity of crystalline LDH in the presence of high pyruvate concentrations was not observed with "endogenous" LDH at pH 9.0, and was observed only at higher concentrations than with added LDH at pH 7.15. When crystalline LDH was added to the TDH preparation, an intermediate K_m for pyruvate was observed, the Lineweaver-Burk plot being almost the algebraic sum of the plots for the separate enzymes. "Endogenous" LDH activity was not immediately inhibited by 10^{-3} M *p*-chloromercuribenzoate. In this respect it resembles LDH, and contrasts with the known properties of TDH which is sensitive to SH reagents. It is possible that the LDH activity is due to an impurity of muscle LDH, which might have properties different from those of bovine heart muscle LDH.

At high pyruvate concentrations (— 1 mM), the endogenous LDH activity of TDH was great enough to make quantitative evaluation of the effects of added LDH difficult. However, at lower concentrations of the substrate the rate of the reaction due to "endogenous" LDH was much less and could be corrected for. The results with pyruvate concentrations around 20 μM (pH 8.8) showed that LDH oxidized TDH · DPN some 10 % faster than free DPNH. Since the rate of reaction with bound DPNH is submaximum (see materials and methods), this difference is all the more emphasized. An increased reaction rate of LDH with TDH · DPNH observed by Cori, Velick and Cori [4] was attributed to stabilization of LDH by TDH. It is believed that the present results cannot be attributed to such an effect since they are based

K_M *(pyruvate, TDH) = 150 μM*
K_M *(pyruvate, LDH) = 18 μM*

on the initial rate of the reaction, and the enzyme appeared to be stable at least for 30 seconds after the onset of the reaction.

In the reverse reaction, the oxidation of lactate, LDH definitely reacts with TDH · DPN at a slower rate than with free DPN, and the equilibrium constant is displaced towards lactate. These results are shown in Table 1. In this connection it was of interest to examine the influence of *p*-chloromercuribenzoate (PCMB) on the reaction of LDH and lactate with TDH · DPN, since it has been shown by Racker and Krimsky [20] that —SH— inhibitors affect the binding of DPN to TDP. As shown in Table 1, the reaction of LDH with TDH · DPN treated with PCMB proceeds at the same rate, and gives the same equilibrium constant as the reaction with free DPN. In contrast, incubation with iodoacetate (IAA) produced no effect, although TDH was completely inactivated by treatment with this inhibitor. Since Racker and Krimsky [20] have shown that IAA partially reverses the spectral shift obtained on combination of TDH with DPN, these observations suggest that the DPN nevertheless still remains attached to TDH.

Table 1. Oxidation of lactate by lactic dehydrogenase with free and TDH-bound DPN. The effect of iodoacetate and p-chloromercuribenzoate.

Coenzyme	Inhibitor *	Rate μM/sec	DPNH formed μM
Free	None	0.061	2.6
Free	Iodoacetate	0.065	2.5
Free	*p*-Chloromercuribenzoate	0.065	2.5
Bound	None	0.048	1.9
Bound	Iodoacetate **	0.043	1.8
Bound	*p*-Chloromercuribenzoate incubated 1 min.	0.064	2.5
	5 min.	0.061	2.5

Test conditions: Buffer 0.1 M glycine
DL-lactate: 8.3 mM
DPN, free or bound to TDH 8.2 μM
LDH: 6.8×10^{-9} M
Final pH = 9.0

* To TDH · DPN (25 μl, in phosphate $\mu = 0.1$, pH = 7.2) iodoacetate or *p*-chloromercuribenzoate to 5×10^{-2} M and 4.5×10^{-3} M, respectively, was added. Incubation at 0°. To the solutions with free DPN the same amounts of inhibitors were added.
** TDH was completely unable to oxidize G-3-P after incubation with iodoacetate.

Astrachan [6] has observed that DPN attached to reduced TDH reacts more slowly with a number of dehydrogenases than when attached to TDH in which some of the thiol groups had been oxidized. This is in contrast to our experiments with LDH as well as with those carried out with ADH from yeast and liver. Under our conditions it made no difference whether the solution of TDH was newly prepared, aged, or incubated with cysteine.

Table 2. Rate of oxidation of ethyl alcohol and glutamate by yeast ADH and glutamic dehydrogenase, respectively, using free DPN and DPN bound to TDH.

Enzyme	Concentration of Substrate mM	Concentration of DPN, free and bound μM	Rate of reduction of DPN:μM/sec.		DPNH formed μM	
			Free	Bound	Free	Bound
Yeast ADH	5	8.1	0.058	0.018	1.8	0.84

Glutamic dehydrogenase	66	8.1	0.035	0.008	5.5	3.2

Buffer: phosphate $\mu = 0.1$ + M/1 000 versene; pH = 7.11; temperature 23.5° C.

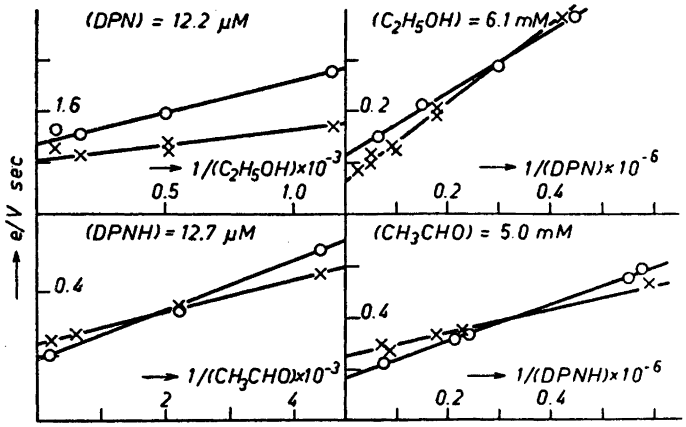

Fig. 3. Liver ADH, pH 8.8, 23° C. × Free DPN(H), O TDH bound DPN(H)

Interaction of yeast ADH and glutamic dehydrogenase with TDH·DPN

Some results obtained with these two enzymes are summarized in Table 2. The rate of reduction for TDH · DPN is much less than for free DPN and the equilibrium is shifted towards oxidized DPN. The reduction of acetaldehyde with bound DPNH was at least as fast as with free DPNH.

Interaction of liver ADH with TDH·DPN and TDH·DPNH

We have investigated the initial rates of the reactions of liver ADH with free and bound DPN(H), with varying concentrations of DPN(H), acetaldehyde, and alcohol. The results are shown in Fig. 3. It can be seen that the reaction with bound DPN(H) can be slower or faster than with free DPN(H), depending upon the concentrations of substrates and coenzyme. TDH · DPN did not oxidize acetaldehyde appreciably under the conditions used in these experiments.

The kinetics of the liver ADH system reacting with free DPN or DPNH have been satisfactorily interpreted according to the following equations [8]:

$$\text{ADH} + \text{DPNH} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{ADH} \cdot \text{DPNH} \qquad (1)$$

$$\text{ADH} \cdot \text{DPNH} + \text{ald} \underset{k_6}{\overset{k_4}{\rightleftharpoons}} \text{ADH} \cdot \text{DPN} + \text{alc.} \qquad (2)$$

$$\text{ADH} \cdot \text{DPN} \underset{k_3}{\overset{k_3}{\rightleftharpoons}} \text{ADH} + \text{DPN} \qquad (3)$$

Table 3. Reaction velocity constants — in the liver ADH system, using free DPN(H) and DPN(H) bound to TDH.

Velocity constants	Bound DPN	Free DPN
$10^{-6} \times k_1$	1.8	2.0
$10^{-6} \times k_5$	0.24	0.24
k_2	1.2	2.0
k_3	7.0	4.9
$10^{-6} \times [H^+]\ k_4$	0.019	0.022
$10^{-4} \times k_6$	0.38	0.58

Buffer: 0.1 M glycine + M/60 arsenate; final pH = 8.8; temperature 23.5° C.

In this scheme, no compound between substrate and enzyme is included. Such a complex is undoubtedly formed, but the kinetic data suggested that it must dissociate more rapidly (into product and ADH · DPN(H)) than does the protein · coenzyme complex, and that it therefore does not effect the kinetic constants indicated above. By means of the experimental data in Fig. 1 and the equilibrium constant we can test whether the above sequence of reactions is possible when the coenzyme is bound to TDH. The method of calculation of the constants k_1 ..... k_6 is the same as outlined previously [8], and the result is tabulated in Table 3. In Table 4 is shown the experimentally determined

Table 4. The equilibrium constant (K_{eq}) as related to reaction velocity constants for different reaction mechanisms [7,8,21].

equilibrium constants, and the equilibrium constants calculated from k_1..... k_6 on the assumption of different reaction schemes [12].

It is problematic whether in the present system the constants mean what they say, but it is interesting that the association constants k_1 and k_5 of DPNH and DPN, respectively, are not significantly different, while k_2 is *increased* from 4.9 to 7.6 sec^{-1}, and k_3 is *decreased* from 2.0 to 1.2 sec^{-1}. The decrease in k_6 may also be significant, since the ratio k_6/k_4 which determines the equilibrium constant was decreased.

Interaction of Zwischenferment with TDH · DPN

If one dehydrogenase could react with PN bound to another PN-linked enzyme without the PN actually changing proteins during the course of the reaction, then it appears possible that a TPN linked enzyme might utilize bound DPN. The possibility whether a TPN specific enzyme might react with the bound DPN of TDH was therefore experimentally tested. In the presence of glucose-6-phosphate Zwischenferment reduced TPN at a rapid rate. When DPN was substituted for TPN, no reaction was detected. When TDH · DPN was substituted for TPN, still no reaction was detected.

The interaction of liver ADH with TDH · DPNH studied spectrophotometrically

Since liver ADH · DPNH has a markedly different spectrum in the 340 mμ region [2] than TDH · DPN, it was possible to test whether a significant number of DPNH molecules reside on the ADH protein during the reactions

of ethanol and liver ADH with TDH · DPNH. The results are shown in Fig. 4. When TDH · DPN is reduced by G-3-P, it gives a spectrum with a maximum at 340 mμ. When TDH · DPN is reduced by G-3-P in the presence of ADH, however, the maximum is shifted downward to 330 mμ. If ethanol was used as substrate, then the maximum was shifted down to 322 mμ, in the same region as the ADH · DPNH compound itself. Under these latter conditions, therefore, most of the DPNH molecules must have been bound to ADH.

These results indicate ADH can compete successfully with TDH for DPNH and that the substrate may have an effect on the affinity of the coenzyme. The dissociation constant for liver ADH · DPNH has been found to be 4×10^{-7}, the dissociation constant for TDH · DPNH has not been accurately determined, but it is known that it must be larger than the dissociation constant for TDH · DPN whose upper limit according to Velick and Hayes [10] is 2×10^{-7}. Our results suggest that the two dissociation constants (ADH · DPNH and TDH · DPNH) must be of the same order of magnitude.

The interaction of liver ADH with TDH · DPNH studied ultracentrifugally

When small amounts of another dehydrogenase are allowed to react with substrate quantities of TDH · DPN or TDH · DPNH, and the reaction proceeds rapidly, the two proteins must either form a complex which dissociates very readily or it is possible that a more stabile complex is formed and a rapid exchange reaction occurs. The possibility that a more stabile complex is formed in the ADH—TDH · DPNH reaction was tested ultracentrifugally in cooperation with A. Ehrenberg. Approximately equal molar concentrations of ADH and TDH · DPNH, both in 0.1 M phosphate, pH 7.4, were centrifuged at 59 000 RPM in the Spinco Model E ultracentrifuge. The sedimentation patterns were compared with those obtained by running the enzymes separately. Because of the sizeable difference in sedimentation constants of the two proteins, it was estimated that complexes involving 10 % of the molecules would be readily detectable. In actuality the peaks in the combined sample were of the same height and symmetry as in the uncombined single runs, thus indicating no detectable formation of stabile complexes between the two proteins.

DISCUSSION

The results obtained in these studies virtually eliminate the obligatory intermediation of free DPN in the reaction of various dehydrogenases with TDH · DPN and TDH · DPNH. This is obviously so in reactions where the rate of oxidation of TDH · DPNH was faster than with free DPNH, but it is also evident for reactions with TDH · DPN where observed rates were much too fast to be compatible with Velick and Haye's [10] estimate of upper limit of the dissociation constant (2×10^{-7} M). In agreement with interpretations placed by previous investigators in their work, these data are most easily interpretable on the basis of direct interactions of the two dehydrogenases themselves. This is not to say that the PN coenzyme remains immobile during the

reaction. Although our experiments permit no unequivocal conclusions to be drawn on this point, they suggest that the PN switches proteins during the reaction. The spectral shift observed during the reaction of ADH and ethanol with TDH · DPN indicates the formation of ADH · DPNH. The facts that specificity for a particular PN coenzyme is maintained, and also the reaction mechanism of the liver ADH, are most easily interpretable on the basis of a direct exchange of PN from TDH to apodehydrogenase during interaction of the proteins. The ultracentrifugal experiments suggest the complex of the two proteins to be readily dissociated at least for the case of TDH · DPN · ADH.

The kinetics of the reaction of liver ADH with TDH · DPN and TDH · DPNH do not appear to be markedly altered from the kinetics of its reaction with free DPN. The fact that under certain conditions different rate of reaction can be obtained with bound DPN compared with free emphasizes the fact that the turnover rate of the enzyme under usual assay conditions may not correspond to its turnover rate in the living cell.

It must be emphasized that in these experiments, enzymes from widely different sources were employed. In a given physiological system, subtile differences in individual enzymes might well elicit more specific and quantitatively greater effects than those observed. The fact remains, however, that all of the dehydrogenases studied behaved in nearly the same manner, they reacted slower with TDH · DPN and faster with TDH · DPNH compared to the free coenzyme. This indicates some change in the O/R potential of the coupled systems, and together with the observations that the substrate may affect the affinity of dehydrogenase for PN, provides the basis for possible selective interactions under *in vivo* conditions.

But it is perhaps most intriguing to consider the possibility in which certain enzymes along a given metabolic pathway were unable to react with bound PN, either because of structural organization, or chemical disinclination, and were dependent upon free PN for activity. This would provide a reasonable means for selecting important pathways, synthetic, or energy yielding, according to imposed conditions simply by regulating coenzyme levels. This argument needs not be restricted to PN coenzymes but can be extended to all of the so called mobile coenzyme systems.

We are indebted to Professor Hugo Theorell for his interest in this work. Thanks are also due to Miss Ann Louise Swanson for skilful technical assistance.

The expenses connected with this work have been partly covered by grants from *Knut och Alice Wallenbergs Stiftelse, The Rockefeller Foundation, Statens naturvetenskapliga forskningsråd* and *Statens medicinska forskningsråd.*

The Rate of Swelling of Ion-Exchange Resin Particles in Different Salt Solutions

CARLOS PULIDO*

Institute of Physical Chemistry, University of Uppsala, Sweden

This note has been published mainly to point out the possibilities of the photographic method used and to show the length of time required for volume changes of ion exchange resin particles due to exchange of ions. Figures 5 to 10 are self-explanatory and it is seen that there is a marked difference in behaviour of the resin for different types of ions and valencies. It is also seen that the time required for these volume changes is such that they can be conveniently followed by the method used. As it seems of interest from many points of view to study the kinetic properties of ionic exchange resins in more detail in this way, a systematic investigation has now been undertaken and it has been found that the pretreatment of the resin is of the greatest importance in determining its behaviour.

Several papers have been presented during the last few years on the study of the swelling of ion-exchange resins, as well as on the diffusion of solutions in these resins. These, however, have dealt with columns or beds of resins.

Thus Boyd *et al.*[1] have used the same shallow bed arrangement used by Domaine *et al.*[2] The amount of exchanger they used was 100 mg or 10 mg depending on the concentration of the solutions. When the amount was 10 mg the shallow bed was a cylinder, roughly three particle diameters deep and about twenty particles in diameter. Hale and Reichenberg[3] have used a modification of Boyd's method[1] or, in the case of sulphonated cross-linked polystyrene, another method in which the hydrogen form of the resin was stirred with a solution in the presence of an indicator. Kressman and Kitchener[4] have employed for their experiments the limited bath method with a large number of particles — about 500.

Many other papers have been published on this subject but in all of them the resins were studied in quantities of at least about a hundred particles.

* Present address: Centros de Estudos da Energia Nuclear, Instituto Superior Técnico, Lisboa, Portugal.

Therefore it should be interesting to study the individual behaviour of the resin particles, and work is being carried on with this aim in view. The purpose of this paper is to present the first results.

RELATION BETWEEN SWELLING AND DIFFUSION

According to Boyd, Adamson and Myers [1], there are three principal stages to be considered in the mechanism of swelling, and each of them may be rate-controlling under appropriate conditions:

I. Diffusion of ions through a thin film of liquid surrounding the particles (or through liquid in macropores inside the particles).

II. Diffusion of ions through the resin material itself.

III. The chemical process of exchange.

However, diffusion in and through the solid material is rate-determining for the more concentrated solutions [1], about 0.1 N.

As the exchange reaction is accompanied by a change of volume, this change should be related to the diffusion inside the particles for concentrations in which this diffusion is rate-controlling. Actually, using 0.5 M solutions, values were found for the swelling of the particles which substantiated this relation.

MATHEMATICAL EQUATIONS

The diffusion of a liquid inside the spherical particles follows the same law as that of the heat transport in spheres [5].

The appropriate equation is

$$\frac{\partial u}{\partial t} = D^i \left(\frac{\partial^2 u}{\partial x^2}\right) \tag{1}$$

where

u $= C^s r$

r = radius of the spherical surface at a concentration C^s in the solid

D^i = internal diffusion coefficient

The solution of this equation was given by Barrer [6] and by Boyd [1]

$$C^s = kC^l + \frac{1}{r}\,(k\ C^l - C^s_0)\,\frac{2r_0}{\pi}\sum_{n=1}^{\infty}\frac{(-1)^n}{n}\sin\frac{n\pi r}{r_0}\cdot e^{-D^i n^2 t / r_0^2} \tag{2}$$

where

k = the distribution coefficient defined by $C^s_e = k\ C^l_e$

C^s_e = the equilibrium concentration in the solid

C^l_e = the equilibrium concentration in the liquid

C^s_0 = the initial concentration of adsorbate in the solid

r = the radius of the spherical adsorbent particle

r_0 = the initial radius of the spherical adsorbent particle.

The rate of permeation, P, *i. e.* the quantity transferred/unit time/unit area of unit thickness under a standard concentration difference is

$$P = -D^i \left(\frac{C^s}{r}\right)_{r=r_0} \tag{3}$$

and the total quantity of solution which crosses the unity of area in the time t is:

$$q = \int_0^t P \, dt \tag{4}$$

Supposing the initial concentration in the solid is zero, we obtain, from eqns. (2), (3) and (4)

$$q = \frac{2r_0}{\pi^2} \, k \, C^1 \left[\sum_{n=1}^{\infty} \frac{1}{n^2} \, e^{-D^i n^2 \pi^2 t / r_0^2} - \sum_{n=1}^{\infty} \frac{1}{n^2} \right] \tag{5}$$

The total quantity adsorbed, will be:

$$Q = 4 \, \pi \, r_0^2 \, q \tag{6}$$

and Q_∞ being the amount adsorbed at equilibrium ($t = \infty$), the expression for the fractional attainment of equilibrium, may be written [1]

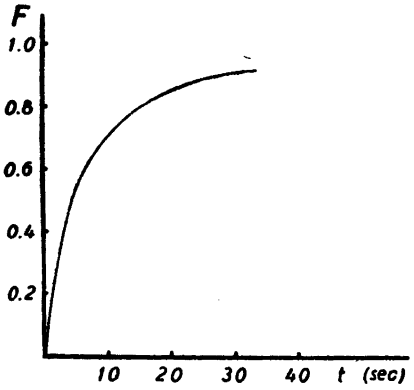
$$F = \frac{Q}{Q_\infty} = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \, e^{-D^i \pi^2 n^2 t / r_0^2} \tag{7}$$

since

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6}$$

Boyd [1] also gives the following solution for cases where the adsorbing particles are not spheres but slabs:

$$F = 1 - \frac{8}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^2} \, e^{-(2n-1)^2 \frac{\pi^2 D^i t}{4 \, x_0^2}}$$



where x_0 is the half-thickness of the slab. However, the equation for the spheres is more in agreement with experimental data.

Fig. 1 shows the curve corresponding to the equation (7) in which $\frac{D^i}{r_0^2}$ has the value 0.74×10^{-2}.

EXPERIMENTAL

a) *Preparation of materials.* A sulphonated cross-linked polystyrene ion-exchanger was employed. This synthetic resin showed great swelling owing to the low level of cross-linkage. The particles were air dried and granulometrically classified and a few spherical grains with diameters between 0.1 and 0.2 mm were taken from it. The following process was used for the choice of these grains:

A few grains were taken and placed on a slanted plate of glass or polished metal. Tapping gently on the plate, the spherical particles rolled down while the others remained on the plate.

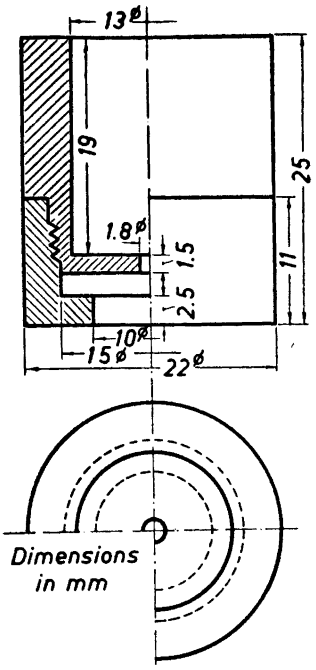


Fig. 1. Curve corresponding to eqn. (7). *Fig. 2. Cylindrical cell containing the resin.*

The spherical particles were gathered into a small container and were prepared as follows: washed, first with HCl, then with distilled water and finally with NaCl. This process was repeated and the particles were then placed in a small cylindrical cell (Fig. 2).

b) *Experimental procedure.* The rate of swelling was determined simply by photographing the particles at regular time intervals. The instrument employed to obtain the values of swelling is shown in Fig. 3.

A known number of spherical particles of resin was placed in the cell. The excess liquid was taken out by means of a curved pipette leaving only enough to cover the resin particles. By means of another pipette HCl was poured into the cell in such a way as to allow the particles to remain unmoved. They were kept there for 6 to 8 hours and then, using the same process the HCl was taken out and NaCl poured into the cell. After another period of 6 to 8 hours the same technique was repeated for three days running. After this preparation the resin was in good condition for measurements.

The concentration of the solutions was 0.5 M for NaCl, KCl, NH_4Cl, $BaCl_2$ and $LaCl_3$, 0.001 M for $BaCl_2$ and 0.5 M for HCl. The technique used was as follows: A photograph was taken of a known number of resin particles placed in the cell, in a given solution (Fig. 4). Afterwards the upper part of the liquid was taken out leaving only the minimum to keep the particles immersed. The solution containing the cation to exchange was then poured into the cell carefully by means of a curved pipette. The time was counted from the moment this solution came into contact with the resin, and two seconds later the first photograph was taken. More photographs were taken at intervals varying according to the reaction under study.

The system has no shutter as it was handled in a dark room and the exposure time was controlled by the lamp S. The diameters of the particles were thus measured in each

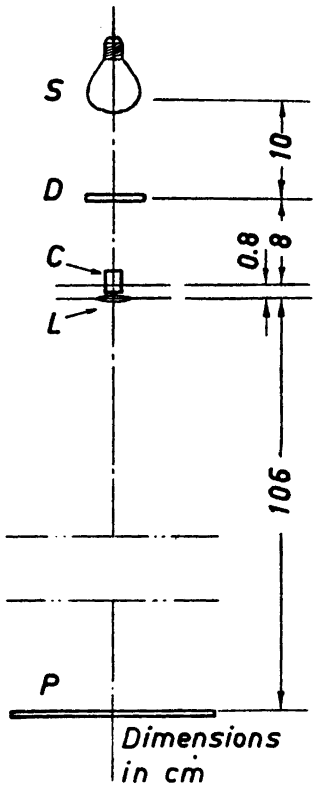

Fig. 3. Arrangement for determination of swelling. S lamp; D diaphragm; C cell containing the resin; L lens; P photographic plate. A 150 w, 220 V normal lamp was used. The lens was a microscope lens which could give a suitable enlargement (about 60 times). The photographic plates used were Gevaert Superchrome 32°. Exposure time about 3/4 sec.

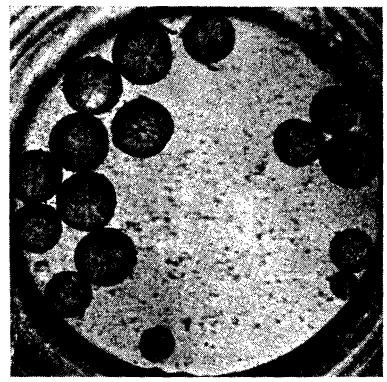

Fig. 4. Resin particles photographed as described in the text.

photograph, provided they had not moved. The average value of the diameters was then computed for each plate. The increasing or decreasing percentage of this average diameter, Δ ø (%), was then plotted against time.

EXPERIMENTAL CURVES

Figures 5 to 10 show the curves obtained, as explained above, with a synthetic resin of the sulphonated cross-linked polystyrene type and the cations mentioned. In each figure there are two curves, one obtained by measuring the diameters of particles which have first adsorbed hydrogen ions from HCl and then cations to be exchanged from the salt. The other curve was obtained

Cholyl-S-CoA as an Intermediate in the Conjugation of Cholic Acid with Taurine by Rat Liver Microsomes

JON BREMER*

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

The conjugation of cholic acid with taurine has been investigated.

The conjugation required the presence of coenzyme A (CoA) and adenosinetriphosphate (ATP) and was stimulated by magnesium, manganese, and fluoride and in some cases by cysteine and glutathione.

Cystine, pyrophosphate and adenosine-5-phosphate (AMP) inhibited the conjugation.

When hydroxylamine was added to the incubation medium, cholhydroxamic acid was identified as the reaction product.

A reaction mechanism, involving cholyl-S-CoA as an intermediate and AMP and pyrophosphate as reaction products, has been proposed.

In previous studies [1-3] we have shown that the enzyme system performing the conjugation of cholic acid with taurine or with glycine, was localized in the microsomic particles of the rat liver cell. When isolated microsomes were used, ATP and a heat stable factor in the particle free supernatant were found to be required in the conjugation. This factor was presumed to be CoA.

In the present paper further studies on the reaction mechanism are presented. A preliminary report on the results has been published [4].

MATERIALS AND METHODS

The biological conjugation of cholic acid with taurine was followed by means of ^{35}S-labelled taurine as earlier described [1]. The labelled taurine was synthesized according to Eldjarn [5], and the synthesis was kindly performed by L. Eldjarn and P. Fritzson in this institute.

A 75 % pure CoA, crystalline ATP (potassium salt), and ADP (sodium salt) were obtained from Nutritional Biochemicals Corporation, Cleveland, U. S. A.

A 2 % CoA preparation and tri-(hydroxymethyl)-amino-methane (TRIS) were obtained from Zigma Chemical Company, USA.

* Fellow of the Norwegian Cancer Society.

Preparation of rat liver microsomes

Livers from male rats of a mixed strain were used. The liver weights were usually 6—8 g. After preliminary slicing, the livers were homogenized in four parts 10 % sucrose for approximately 1½ minutes in a glass homogenizer with a plastic pestle doing 1 500 rev/min. Cell debris, nuclei and mitochondria were sedimented by centrifuging at 15 000 —18 000 × g for 15 minutes. The microsomic fraction was then sedimented at 25 000 × g for 110 minutes. The particle free supernatant was discarded, leaving behind the densely packed microsomic particles as a translucent cake of the typical red colour. All isolating operations were performed at 0° C. The sedimented microsomes were stored at —20° C until used.

Preparation of cholhydroxamic acid

The cholhydroxamic acid was synthesized from cholic acid ethyl ester prepared according to Bondi and Müller [6]. The cholic acid ethyl ester was converted to the hydroxamic acid by a modification of the method used by Kornberg and Pricer [7] in their preparation of fatty hydroxamic acids: 2.5 g of ethyl ester and 1 g of hydroxylamine hydrochloride were dissolved in 35 ml of absolute methanol in which 1.2 g metallic sodium had been dissolved beforehand. The mixture was refluxed for 30 minutes on a boiling water bath and neutralized with a mixture of one part concentrated hydrochloric acid in ten parts of absolute ethanol. Two volumes of ethyl ether were added and the precipitated salts filtered off. The filtrate was then evaporated to dryness under reduced pressure. The yellowish residue consisted of almost pure hydroxamic acid. The product was dissolved in 25 ml absolute ethanol, and 150 ml ethyl acetate was added. After storing overnight at 5° C, the precipitate which formed was filtered off and discarded. The clear filtrate was slowly evaporated to 1/5—1/10 of the original volume by passing a stream of air over the surface of the fluid. The hydroxamic acid then started to crystallize in rosettes. After storing overnight at —20° C, 2.15 g of the crystalline compound could be filtered off. When dried at 4 mm pressure and 80° C for 5 hours, the weight decreased by about 10 %. Recrystallization of the product with the same evaporation procedure gave no detectable change in purity as estimated from the colour reaction with ferric ions. The compound decomposed at 117° and was completely melted at 145° C. Elementary analysis showed (theoretical values in brackets): Carbon 68.22 % (68.39), hydrogen 9.54 % (9.39), nitrogen 3.31 % (3.64). When dissolved in concentrated sulphuric acid, the cholhydroxamic acid was shown to have light absorption spectrum and extinction coefficients between 220 and 600 mμ identical with those reported for cholic acid, taurocholic acid and glycocholic acid [8,9]. The compound gave the typical cherry-red colour of hydroxamic acids with ferric ions in acid solution [10]. The elaboration of two spectrophotometric methods for the estimation of biologically formed cholhydroxamic acid were based on these results.

Chromatographic and spectrophotometric estimation of cholhydroxamic acid

To estimate the cholhydroxamic acid formed in the incubation experiments, the acid was extracted from the incubation mixture with 1/3 volume *n*-butanol as described for the isolation of taurocholic acid [1].

Method 1. When the cholhydroxamic acid was estimated from its light absorption in concentrated sulphuric acid, the acid was separated from the unchanged cholic acid using a modification of Sjövall's [11] quantitative paper chromatography for conjugated bile acids. Paper pretreatment and stationary phase were identical with those described by Sjövall [11, 12]. Aliquots of 0.05 ml of butanol extract were put on the paper. Descending chromatography was used. As moving phase a mixture of one part *n*-butanol and two parts petroleum spirit (b. p. above 120° C) saturated with 4 % acetic acid was used. In this system the cholhydroxamic acid moved with an R_F value of 0.20—0.25 and the cholic acid with an R_F value of 0.40—0.45. There was some tailing on the paper, but a complete separation of the compounds was easily obtained. Further details of the method have been described by Sjövall [11].

Table 1. The extraction of cholhydroxamic acid with n-*butanol.*

Each vessel contained 1.5 ml 0.1 M potassium phosphate buffer (pH 7.2) and 0.5 ml *n*-butanol. After equilibration in a shaking machine for 25 minutes, 0.25 ml butanol phase was pipetted off and the content of hydroxamic acid determined according to method 2 (see text).

μmoles cholhydroxamic acid added per vessel		Density read at 525 mμ	
0.19	0.19	0.087	0.090
0.47	0.47	0.184	0.191
1.18	1.18	0.447	0.449
2.36	2.36	0.870	0.873
1.18 + microsomes from 500 mg liver		0.433	0.426

Method 2. As cholic acid gave no colour reaction with ferric ions, no chromatographic separation of the cholic acid and the cholhydroxamic acid was necessary. Aliquots of 0.25 ml of the butanol extract were diluted to 2 ml with the colour reagent, consisting of 0.33 % ferric chloride and 0.2 % perchloric acid in absolute ethanol. The density of the solution was measured in a 1 cm cuvette at 525 mμ. A solution containing 1 μmole hydroxamic acid per ml gave an extinction of 1.26 when measured in a Hilger quartz spectrophotometer, *i. e.* the $\varepsilon^{525}_{\mu mole} = 1\,260$.

The two analytical methods gave results in good agreement as seen from Table 4.

The extraction method had to be calibrated. For this purpose a series of vessels containing 1.5 ml of 0.1 M potassium phosphate buffer (pH 7.2) and 0.5 ml *n*-butanol were prepared. Known amounts of hydroxamic acid were dissolved in the added butanol beforehand. After 25 minutes' equilibration in a shaking machine, the colour developed by 0.25 ml butanol phase was measured in the usual way. As seen from Table 1, the extinction coefficient was proportional to the amount of hydroxamic acid added, and it was not significantly affected by addition of rat liver microsomes in amounts used in the incubation experiments.

EXPERIMENTAL

Before use, the microsomes stored in the frozen condition were thawed at 37° C and resuspended in 10 % sucrose by means of the homogenizer and pipetted as such. Microsomes from 300—500 mg of fresh liver were added to each vessel in the incubation experiments. The following concentrations were maintained in the incubation mixture if not otherwise stated: Potassium phosphate buffer (pH 7.4) 0.0022 M, potassium fluoride 0.2 M, magnesium sulphate 0.001 M, coenzyme A approximately 0.001 M, cysteine 0.0067 M. Cholic acid and ^{35}S-taurine were added as stated under the individual experiments. The incubation was performed at 37° C. Total volume was 1.5 ml per vessel. The results are given as micromoles taurocholate formed per vessel.

The pH-effect was evaluated in the following way: A solution containing all the factors needed for the reaction except the microsomes was prepared, using a phosphate buffer of pH 6.0. This solution was made more and more alkaline by adding normal potassium hydroxide under the control of a pH-meter. Aliquots of 1.4 ml were pipetted off when suitable pH-values were reached. The microsome suspension was later added before incubation without any further adjustment of pH. The diluting effect of the added potassium hydroxide solution did not exceed 2—3 %.

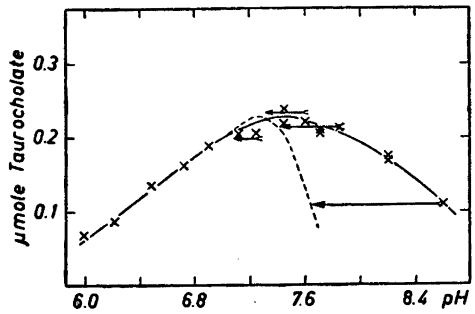

Fig. 1. The effect of pH. Microsomes from approx. 300 mg fresh liver per vessel. ^{35}S-taurine 0.8 µmoles/vessel, cholic acid 2 µmoles/vessel, ATP 4 µmoles/vessel, CoA (2 %) 3 mg/vessel. Potassium phosphate buffer 0.044 M, glutathione 0.0022 M, $MgSO_4$ 0.0025 M, NaF 0.15 M. Incubation time 90 minutes. The arrows indicate the fall of pH during incubation.

RESULTS

Effect of pH

The effect of pH on the conjugation of cholic acid with taurine is shown in Fig. 1. The pH optimum was found to be in the range 7.3—7.6 which is in good agreement with our earlier results when a system of microsomes and particle free supernatant was used [2]. As the buffering capacity of phosphate rapidly decreases at pH values above 7.5, the fall of pH during incubation was measured in some vessels. As indicated by the arrows in Fig. 1, there was a rather large fall in the pH values in the alkaline end of the curve. The decrease in conjugating capacity was therefore probably more abrupt with increasing pH than shown in the curve. A similar pH optimum has been found in the hippuric acid synthesis [13] and in the acetate activation [14]. In all later experiments, the incubation mixtures were adjusted to a pH of 7.40—7.45.

Effect of coenzyme A, glutathione, cysteine and cystine

Fig. 2 shows that there was an absolute requirement for CoA in the conjugation of cholic acid with taurine, and the results obtained with the two different CoA preparations used, showed that probably no other components of the CoA concentrates had any stimulating effect on the process.

Figs. 3 and 4 show that glutathione and cysteine had no significant stimulating effect when the 75 % pure CoA was used. The sulphydryl content of this preparation was titrated according to the method of MacDonnell *et al.*[15]. A sulphydryl content of 1.1 µmoles/mg was found, in good agreement with a content of 75 % CoA in the reduced form. The effect of cysteine and glutathione was therefore probably due to their reducing properties which kept the sulphydryl group of CoA in the reduced form. This sulphydryl group is known to be the functioning group of CoA [16], and other sulphydryl containing com-

pounds have been shown to protect it [17, 18]. Fig. 4 shows a peculiar inhibiting effect of cysteine in low concentrations. This inhibition was reversed by cysteine in higher concentrations. A correct explanation of this phenomenon cannot be given with any certainty, but from Table 2 it is seen that cystine had an inhibiting effect of the same magnitude. We have therefore presumed that cysteine in low concentrations catalyzes the oxidation of the CoA sulphydryl groups by some oxidizing contaminant in the 2% CoA preparation.

In higher concentrations both cysteine and glutathione had a weakly inhibiting effect, as is evident also from Table 4.

Effect of fluoride

Fluoride has been used in ATP-dependent reactions to depress ATP-ase and pyrophosphatase activity [19, 20]. Fig. 5 shows that fluoride had a profound stimulating effect in our experiments, and the optimal concentration was found to be astonishingly high (0.15—0.20 M). The ATP-ase activity of microsomes has been reported to be moderate [21]. We have therefore made some experiments to elucidate any possible additional effect of fluoride. Fig. 6 shows the time curves with and without fluoride. The initial reaction rate seemed to be nearly the same in both cases. To exclude the possibility that fluoride prevented an inactivation of the enzyme system, the experiment shown in Table 3 was undertaken. Inactivation could not explain the rapidly de-

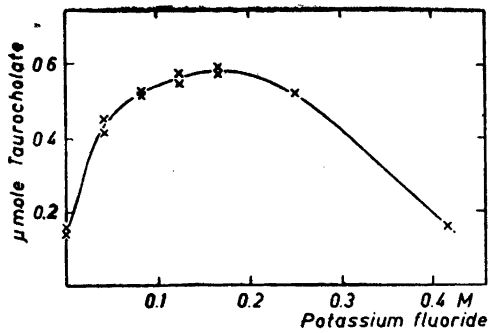

Fig. 5. Effect of fluoride. Microsomes from approx. 500 mg liver. ^{35}S-taurine 2 µmoles/vessel, cholic acid 2 µmoles/vessel, ATP 4 µmoles/vessel, CoA (2 %) approx. 0.1 µmole/vessel. creasing reaction rate when fluoride was omitted, as addition of another batch of ATP after 25 minutes resulted in an increased amount of taurocholic acid, whereas addition of another batch of microsomes had no effect. The effect of fluoride therefore seemed to be a saving of ATP, probably through the inhibition of ATP-ase present in the microsomes [21]. In an unpublished experiment an equivalent amount of potassium chloride was added instead of potassium fluoride. No effect on the conjugation was observed, neither stimulating nor inhibiting, showing that the stimulation was due to the fluoride ion, and not to an osmotic effect or to the potassium.

Effect of microsomes

When microsomes from less than approximately 500 mg of fresh liver were added to the vessels, the amount of taurocholate formed was proportional to

Cholhydroxamic acid formation

The requirement for CoA in the conjugation of cholic acid with taurine made it probable that an "activated cholic acid" in the form of cholyl-S-CoA represented an intermediate in the reaction. As hydroxylamine is known to react spontaneously with acyl-S-CoA at *ca.* pH 7 to form hydroxamic acids [7,19,22] the hydroxylamine represents a trapping agent for such activated carboxyl groups. Table 4 shows that cholhydroxamic acid was formed during the incubation when hydroxylamine was added to the incubation mixture instead of taurine. There was the same dependance on CoA, ATP and fluoride in this reaction as in the formation of taurocholic acid.

As expected cysteine was found to have no effect on the hydroxamic acid formation in this experiment, as the 75 % pure reduced CoA was used.

The same formation of cholhydroxamic acid has been reported in a short communication by Elliott [23].

Effect of preincubation without taurine

Further support for the existence of cholyl-S-CoA as an intermediate was obtained from the experiment cited in Table 5. An intermediate must have

Microsomes from approx. 500 mg liver. ^{35}S-taurine 0.8 μmoles/vessel (= 16 900 c/min/vessel), cholic acid 2 μmoles/vessel CoA (75 %) 0.3 μmoles/vessel, ATP 20 μmoles/vessel. Potassium phosphate buffer 0.022 M, KF 0.2 M. Total volume during preincubation 1.4 ml, after preincubation 1.5 ml.

Incubation conditions	Net c/min/0.1 ml butanol extract		μmoles taurocholate formed per vessel	
Complete system incubated for 9 min.	209	219	0.077	0.074
Preincubated for 10 min. without taurine, further for 9 min. with taurine	253	260	0.089	0.092

accumulated during the preincubation, as the reaction rate after addition of taurine was greater in the preincubated vessels. No isolation of the intermediate was attempted, as the amounts accumulated were evidently very small.

Effect of magnesium, manganese and calcium

Table 4 shows that magnesium had no effect when the isolated microsomes were used without any further treatment. This was probably due to magnesium (or manganese) following the microsomes. When the microsomes were dialyzed for 36 hours against 0.0025 M potassium phosphate buffer (pH 7.5), addition of magnesium had a stimulating effect both on the hydroxamic acid — and the taurocholic acid formation (Table 6). Any absolute requirement for

Table 6. Effect of Mg^{++}.

Microsomes from approx. 500 mg liver, dialyzed for 36 hours against 0.005 M potassium phosphate buffer (pH 7.4) at 5° C. ^{35}S-taurine 0.8 μmoles/vessel (= 17 000 c/min/vessel) or hydroxylamine 50 μmoles/vessel, cholic acid 2 μmoles/vessel, ATP 10 μmoles/vessel, CoA 0.15 μmoles/vessel. Potassium phosphate buffer 0.022 M, KF 0.2 M, glutathione 0.003 M. Incubation time 60 minutes.

Mn^{++} 0.4×10^{-3} M	0.17	0.18	0.38	—

Table 7. Effect of Mg^{++}, Mn^{++} and Ca^{++}.

0.8 ml solubilized microsomes dialyzed for 24 hours against 0.005 M potassium phosphate buffer (pH 7.5). ^{35}S-taurine 0.8 μmoles/vessel (= 20 000 c/min/vessel), cholic acid 2 μmoles/vessel, ATP 10 μmoles/vessel, CoA (75 %) 0.15 μmoles/vessel. Potassium phosphate buffer 0.015 M, KF 0.2 M. Incubation time 45 minutes.

Additions	Net c/min/0.1 ml butanol extract	μmoles taurocholate formed per vessel
None	152 153	0.046 0.046
Mg^{++} 0.2×10^{-3} M	245	0.074
Mg^{++} $1 + 10^{-3}$ M	228	0.068
Mn^{++} 0.2×10^{-3} M	265	0.080
Mn^{++} 1×10^{-3} M	223	0.067
Ca^{++} 1×10^{-3} M	115	0.034

magnesium could not be demonstrated, as further prolongation of the dialysis led to increasing inactivation of the enzyme system, and this inactivation could not be reversed by magnesium. It can be seen from Table 7 that manganese had a stimulating effect on the conjugation in contrast to our previously reported results with the microsomes-particle free supernatant system [2]. Solubilized microsomes (see later) dialyzed for approximately 24 hours against 0.0025 M potassium phosphate buffer were used in this experiment. Also in this case increasing inactivation of the enzyme system during dialysis was observed. Calcium had some inhibiting effect.

Effect of ATP, ADP, AMP, pyrophosphate and phosphate

As ATP was required in the reaction, it was found of interest to investigate the effects of the possible reaction products of ATP. Fig. 8 shows that ADP could substitute for ATP in the reaction, but ATP proved to be more than twice as effective in lower concentrations. AMP had, as expected, no effect. From the participation of ATP in the formation of cholyl-S-CoA it may be concluded that either ADP and phosphate or AMP and pyrophosphate must be reaction products. Fig. 9 shows that pyrophosphate had a stronger inhibiting effect on the taurocholate formation than had phosphate. The effect of pyrophosphate was also tested when fluoride was omitted from the incubation

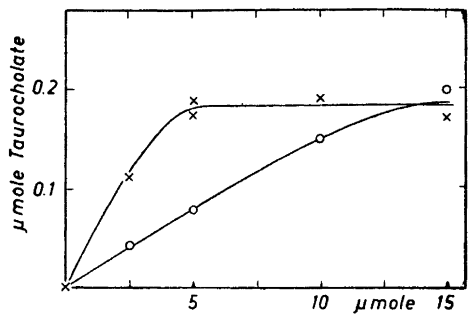

Fig. 8. Effect of ATP, ADP and AMP as energy donors. Microsomes from 300 mg liver. ^{35}S-taurine 0.8 µmoles/vessel, cholic acid 1 µmole/vessel, ATP 5 µmoles/vessel, CoA (75 %) 0.15 µmoles/vessel. TRIS-buffer 0.1 M, KF 0.2 M. Incubation time 60 minutes. +—+—+—+—+ *ATP,* O—O—O—O *ADP,* ▲—▲—▲— *AMP.*

mixture. In this case no inhibiting effect was observed at the pyrophosphate concentration used (0.04 M). As fluoride has been shown to inhibit pyrophosphatase [20, 24], this result indicated that the pyrophosphate ion itself was the inhibiting agent and not the phosphate resulting from its splitting by pyrophosphatase. From Table 8 it is seen that pyrophosphate and AMP together had an inhibiting effect stronger than could be explained by the inhibitions effected by the two compounds when added alone, indicating that the effect of one of them was dependent on the presence of the other. No such effect was observed with ADP and phosphate. These results strongly indicate AMP and pyrophosphate as reaction products. The action of ADP as energy donor (Fig. 8) must then be explained as a result of the myokinase reported to be present in liver [25, 26]. This assumption is contradicted by the fact that liver myokinase is claimed to be inhibited by fluoride [26, 27]. Further purification of the enzyme system is desirable for the clarification of this problem.

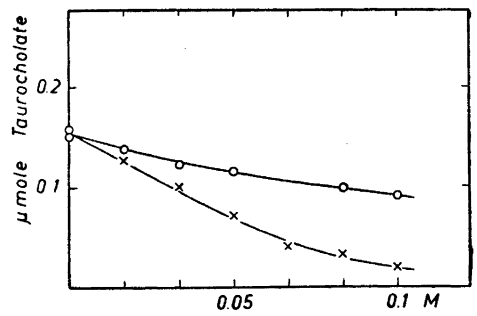

Fig. 9. Effect of orthophosphate and pyrophosphate. Microsomes from approx. 300 mg liver. ^{35}S-taurine 0.8 µmoles/vessel, cholic acid 1 µmole/vessel, ATP 5 µmoles/vessel, CoA (75 %) approx. 0.15 µmoles/vessel. TRIS-buffer 0.1 M, KF 0.2 M. Frozen and thawed once	184	0.36
Frozen and thawed twice	179	0.35
Frozen and thawed three times	227	0.44
Frozen and thawed six times	194	0.38

Stability and solubilization of the enzyme system

For a more careful investigation of the reaction mechanism, a further purification of the enzyme system was considered to be desirable. In preliminary experiments we have apparently succeeded in liberating the enzyme system from the microsomes. We used a method similar to that employed by Wainio *et al.*[28] for the liberation of cytochrome oxidase from cell particles. The microsome fraction was suspended in 0.1 M potassium phosphate buffer (pH 7.4) containing ½—1 % cholic acid. The suspension was frozen at —80° C and re-thawed at 37° C. After freezing and thawing once, the suspension got translucent. When centrifuged at 25 000 × g for 90 minutes, a small colourless sediment and a slightly turbid supernatant were formed, the latter containing at least 70—80 % of the enzyme activity. In Table 9 is shown an experiment where the total enzyme activity was recovered in the supernatant. It must be noted that both phosphate and cholic acid must be added to liberate the enzyme system from the particles. If cholate or phosphate were used alone, a practically inactive supernatant was obtained.

Whether the treatment resulted in a real solubilization or only in a decreased particle size could not be stated, as a faster centrifuge was not available. In preliminary experiments we did not obtain any further purification of the enzyme system, as both ammonium sulphate and acetone precipitation gave almost completely inactive precipitates. Whether this inactivation was due to denaturation or to loss of an unknown co-factor is not known. Thioctic acid has been reported to take part in the acetate activation [29], but this compound did not reactivate our ammonium sulphate — or acetone precipitates.

The enzyme system was very stable in the cold. Storing of the microsomes at —20° C for a fortnight did not lead to any appreciable loss in activity. The microsomes were also lyophilized, and the resulting dry powder showed full activity. Heating to 100° C gave immediately full inactivation.

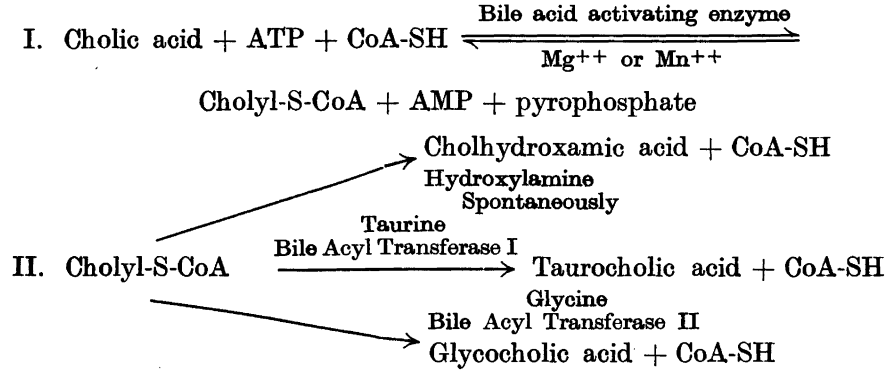
DISCUSSION AND CONCLUSION

Several biological mechanisms are known by which peptide bonds are formed [30]. CoA is required in the formation of the peptide bond in acetylsulfanilamide [19] and in hippuric acid [31]. Acetyl-S-CoA and benzoyl-S-CoA have been proved to be intermediates in these two reactions [19, 31], and in the acetylation of sulfanilamide two enzymes, one acetate activating and one acetyl transferring enzyme, are involved [19].

In all CoA-dependent reactions, the sulphydryl group of CoA forms thioester bonds with acyl groups [7, 31, 35], and these acyl-S-CoA compounds are known to react spontaneously with hydroxylamine to form hydroxamic acid [7, 18, 22]. The absolute requirement of CoA both in the conjugation of cholic acid with taurine and in the formation of cholhydroxamic acid from cholic acid and hydroxylamine therefore strongly indicates that cholyl-S-CoA is an intermediate in these reactions. The accumulation of an intermediate during the pre-incubation without taurine also supports this conclusion.

Admittedly, hydroxamic acids are also formed in other biological reactions, but in these cases CoA is not required [30, 36, 28].

In the acetate activation the following reaction mechanism has been found in the case of animals [32]



$$\text{Acetate} + \text{ATP} + \text{CoA-SH} \underset{\leftarrow}{\overset{\text{Enzyme} + \text{Mg}^{++}}{\rightleftharpoons}} \text{Acetyl-S-CoA} + \text{AMP} + \text{pyrophosphate}$$

A different reaction mechanism has been found in the activation of succinate [33]

$$\text{Succinate} + \text{ATP} + \text{CoA-SH} \underset{\leftarrow}{\overset{\text{Enzyme} + \text{Mg}^{++}}{\rightleftharpoons}} \text{Succinyl-S-CoA} + \text{ADP} + \text{Phosphate}$$

Both these reactions have been proved to be reversible [32, 33]. The acetate activation is inhibited by AMP and pyrophosphate [14], whereas the succinate activation is inhibited by ADP and orthophosphate [38]. Our results, which showed a much stronger inhibition of the taurocholate formation by AMP and pyrophosphate than by ADP and orthophosphate, therefore indicate a reaction mechanism in this process identical with that found in the acetate activation. This similarity to the acetate activation is also confirmed by the stimulating effect of magnesium ions on the taurocholate- and cholhydroxamic acid formation.

Recently we have carried out experiments indicating that the transfer of the cholyl group from CoA to taurine and glycine is irreversible [39], as the conjugated acids were not converted to cholhydroxamic acid in the presence of microsomes and CoA. We have further shown that rabbit liver microsomes conjugate free bile acids almost exclusively with glycine, whereas chicken liver microsomes conjugate exclusively with taurine. Rat liver microsomes conjugate both with taurine and glycine. These results probably indicate that two different enzymes transfer the cholyl group from CoA to taurine and glycine. The following reaction scheme therefore seems to be a reasonable conclusion on the experimental results:

A further purification of the enzyme system will probably be needed for a closer elucidation of the reaction mechanism. Thioctic acid has been reported to take part in the acetate activation [29], and results have been published which indicate that the acetate activation proceeds with enzyme-AMP and enzyme-S-CoA as intermediates.

Some Relationships among the Stabilities of Metal Complexes

HARRY IRVING and HAZEL ROSSOTTI

Inorganic Chemistry Laboratory, Oxford, England and Department of Inorganic Chemistry, the Royal Institute of Technology, Stockholm 70, Sweden

The stability constant, K_{ML}, of a first (1:1) metal-ligand complex, ML, can be related to the stability constant of the corresponding proton-ligand complex, HL, and to the partial molar free energies of the various species in solution. The relationship, (6), which is applicable both in water and in mixed aqueous-organic solvents, forms a basis for discussing the linear relationships which have been observed between the following terms:
(i) log K_{ML} and log K_{HL}, for complexes of one metal ion with a series of ligands, (8).
(ii) log K_{YL} and log K_{ZL}, for complexes of two metal ions, Y and Z, with a series of ligands, (12).
(iii) log K_{MP} and log K_{MQ}, for complexes of two ligands, P and Q, with a series of metal ions (13).
The relationships are illustrated using a wide variety of experimental data. Special reference is made to the disturbing effects of steric hindrance, and of differences in the co-ordinating power of the donor atoms in a chelating ligand. The variation of log K_{HL} and log K_{ML} with the organic content of a mixed solvent is also discussed.

The approach may be of use in analytical chemistry for predicting approximate values of stability constants, and for choosing suitable organic reagents for metal ions.

Many complexes, $ML_n^{(z-nJ)+}$ derived from a metal ion, M^{z+}, and an organic reagent H_JL, are of analytical importance. Any discussion of problems of theoretical analytical chemistry, such as the sensitivity or specificity of spot-tests, must take into account both the specific properties of the complex $ML_n^{(z-nJ)+}$ (*e. g.* its absorption spectrum, solubility in water and in organic solvents, etc.) and the position of equilibrium in the reaction

$$M^{z+} + n\ H_JL = ML_n^{(z-nJ)} + n\ H^+ \qquad (1)$$

by which it is produced [1,2].

In this connection it is desirable to know how the equilibrium constant of equation (1) is affected by changes in the metal M, *e. g.* by co-ordination of groups other than L, or by replacing M by a different metal. Can such changes be correlated with independently measurable parameters such as ionisation potential, ionic radius, electronic structure or electronegativity, and could they be predicted theoretically? It is also of interest to know how the equilibrium constant is affected when, for the same metal M, changes are made in the structure of the ligand L, and whether these effects can be correlated with concomitant changes in the acid dissociation constants of the reagent H_jL and in the stereochemistry of the complex system. Finally, it is important to consider the effects on equilibrium in each of these cases when an aqueous-organic mixed solvent replaces water as the reaction medium.

In the last ten years, many stability constants of complexes formed between metal ions and organic ligands have been measured, and numerous qualitative and semi-quantitative relationships between the stability of the complex and of the properties of the metal ion and of the ligand have been discussed (*e. g.* [3–12]). A number of authors have, for example, reported empirical relationships between dissociation constants of reagents, and the stability constants of complexes formed by the same metal ion with various ligands [3,15–19]. These relationships are by no means generally valid, but are usually only applicable to very limited series of closely related ligands. This paper indicates under what conditions relationships of this type are to be expected from considerations of the free energy changes which occur on complex formation, and suggests other types of relationships that may also exist. These conclusions have been tested on stability constants of metal oxinates and similar complexes (published elsewhere [19]) and on data in the literature; in favourable cases the relationships may be used to predict stability constants of complexes which have not yet been studied experimentally.

GENERAL CONSIDERATIONS

Limiting the discussion in the first instance to the first (1:1) metal-ligand and proton-ligand complexes, ML and HL respectively, the equilibrium constant for reaction (1) can be written in the form

$$K = [ML][H]/[M][HL] = {}^cK_{ML} / {}^cK_{HL} \qquad (2)$$

where the stoichiometric stability constants are defined by ${}^cK_{ML} = [ML]/[M][L]$ and ${}^cK_{HL} = [HL]/[L][H]$ and charges are omitted, here and elsewhere, for generality. If ${}^cK_{ML}$ and ${}^cK_{HL}$ are expressed in litres/mole, and if, for each species, S, the partial molar free energy is denoted $\bar{G}^\circ_S$, and the activity coefficient referred to the hypothetical one molar standard state is designated y_S, the following relationship is exact

$$\ln {}^cK_{ML} = \ln {}^cK_{HL} + \frac{1}{RT}(\bar{G}^\circ_M - \bar{G}^\circ_{ML} - \bar{G}^\circ_H + \bar{G}^\circ_{HL}) + \ln (y_M y_{HL} / y_{ML} y_H) \qquad (3)$$

Many organic reagents and their metal complexes are very sparingly soluble in water, and stability constants have often been measured in mixed aqueous-

organic solvents. Equation (3), which refers only to aqueous solution, must therefore be extended. Using heavy (***Clarendon***) type to denote factors which refer to a mixed aqueous-organic solvent, the exact equation corresponding to (3) is

$$\ln {}^{c}\boldsymbol{K}_{\mathbf{ML}} = \ln {}^{c}\boldsymbol{K}_{\mathbf{HL}} + \frac{1}{RT}(\bar{\boldsymbol{G}}^{\circ}_{\mathbf{M}} - \bar{\boldsymbol{G}}^{\circ}_{\mathbf{ML}} - \bar{\boldsymbol{G}}^{\circ}_{\mathbf{H}} + \bar{\boldsymbol{G}}^{\circ}_{\mathbf{HL}}) + \ln (\boldsymbol{\nu}_{\mathbf{M}}\boldsymbol{y}_{\mathbf{HL}}/\boldsymbol{y}_{\mathbf{ML}}\boldsymbol{y}_{\mathbf{H}}) \quad (3a)$$

$\bar{G}^{\circ}_{S}$ and $\bar{G}^{\circ}_{S}$ are related by the expression

$$\bar{G}^{\circ}_{S} - \bar{G}^{\circ}_{S} = \bar{G}^{\circ}_{S(transfer)} = RT \ln y_{S(o)} \quad (4)$$

where $\bar{G}^{\circ}_{S(transfer)}$ is the partial molar free energy of transfer of the solute species, S, at infinite dilution, from water to the binary mixed solvent, and $y_{S(o)}$ is the activity coefficient of the species S, at infinite dilution in the mixed solvent, referred to infinite dilution in water; thus log $y_{S(o)}$ represents the "primary medium effect" defined by Owen [20], *cf.*[21]. The relationship

$$\bar{G}^{\circ}_{S(transfer)} = n_{X} t_{S} \quad (5)$$

where n_X is the molar fraction of the organic component of the mixed solvent, and t_S is a constant for each combination of solute species and organic solvent, has been shown to hold for a number of solutes in water-methanol and water-ethanol mixtures [22–24]. If equation (5) is valid for each species in solution, the stoichiometric stability constants ${}^{c}\boldsymbol{K}_{\mathbf{ML}}$ and ${}^{c}\boldsymbol{K}_{\mathbf{HL}}$ measured in a mixed solvent will be related by the following equation

$$\ln {}^{c}\boldsymbol{K}_{\mathbf{ML}} = \ln {}^{c}\boldsymbol{K}_{\mathbf{HL}} + \frac{1}{RT}\left\{\bar{\boldsymbol{G}}^{\circ}_{\mathbf{M}} - \bar{\boldsymbol{G}}^{\circ}_{\mathbf{ML}} - \bar{\boldsymbol{G}}^{\circ}_{\mathbf{H}} + \bar{\boldsymbol{G}}^{\circ}_{\mathbf{HL}} + \boldsymbol{n}_{\mathbf{X}}(\boldsymbol{t}_{\mathbf{M}} - \boldsymbol{t}_{\mathbf{ML}} - \boldsymbol{t}_{\mathbf{H}} + \boldsymbol{t}_{\mathbf{HL}})\right\} + \ln (\boldsymbol{y}_{\mathbf{M}}\boldsymbol{y}_{\mathbf{HL}}/\boldsymbol{y}_{\mathbf{ML}}\boldsymbol{y}_{\mathbf{H}}) \quad (6)$$

Since the activity coefficients y_S are referred to infinite dilution in a particular mixed solvent, the term (log y_S—log y_S) represents Owen's "secondary medium effect" [20] *cf.*[21].

When the solvent is pure water, $n_X = 0$, ${}^{c}\boldsymbol{K}_{\mathbf{ML}} = {}^{c}K_{ML}$, ${}^{c}\boldsymbol{K}_{\mathbf{HL}} = {}^{c}K_{HL}$, $y_S = y_S$ and equation (6) reduces to (3). For thermodynamic stability constants ${}^{T}K_{ML}$ and ${}^{T}K_{HL}$ measured in water, the equation may be further simplified to

$$\ln {}^{T}K_{ML} = \ln {}^{T}K_{HL} + \frac{1}{RT}(\bar{G}^{\circ}_{M} - \bar{G}^{\circ}_{ML} - \bar{G}^{\circ}_{H} + \bar{G}^{\circ}_{HL}) \quad (7)$$

which was given previously by Duncan [25].

Since $\bar{G}^{\circ}_{H} = 0$, by definition, and values of $\bar{G}^{\circ}_{M}$ are tabulated [26], equation (7) may be used to calculate values of $(\bar{G}^{\circ}_{HL} - \bar{G}^{\circ}_{ML})$, which will be related to the properties of the metal ion and the ligand. For example, the value of $\bar{G}^{\circ}_{ML}$ would be decreased by an increase in the ionisation potential of the metal and, unless steric factors are involved, by a decrease in the radius of the metal ion. It would also depend on the co-ordination number and stereochemistry of the metal ion, and the possibility of favourable hybridisation changes accompanying complex formation. Both $\bar{G}^{\circ}_{HL}$ and $\bar{G}^{\circ}_{ML}$ would be influenced by the number and nature of the donor atoms in the ligand, by the effective charge on them,

by the size and stereochemistry of the ligand molecule and by changes in entropy and resonance energy accompanying the combination of the ligand with a metal ion or a proton.

As values of ${}^{T}K_{ML}$ and ${}^{T}K_{HL}$ have only been measured for a few systems, equation (7) must usually be replaced by the more general equation (6). This equation forms a useful basis for discussing the empirical relationships which have been observed among the stabilities of metal complexes. Four types of relationship are discussed below.

Type I. The relationship between the stabilities of metal-ligand, and proton-ligand complexes

Many authors [3, 15–19] have reported approximately linear relationships between $\log {}^{c}K_{ML}$ and $\log {}^{c}K_{HL}$ for complexes formed by a given metal ion with a series of closely related ligands. The conditions necessary for a relationship of this type may be deduced from equation (6). By rearrangement

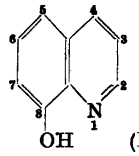
$$\ln {}^{c}K_{ML} = \ln {}^{c}K_{HL} + A + B \qquad (8)$$

where

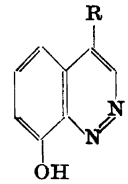
$$A = \frac{1}{RT}\left\{-\bar{G}^{\circ}_{ML} + \bar{G}^{\circ}_{HL} + n_X(-t_{ML} + t_{HL})\right\} - \ln y_{ML} + \ln y_{HL}$$

and

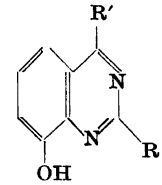
$$B = \frac{1}{RT}\left\{\bar{G}^{\circ}_{M} - \bar{G}^{\circ}_{H} + n_X(t_M - t_H)\right\} - \ln y_H + \ln y_M$$



The term B is independent of the nature of the ligand, and is constant for all complexes of a given metal ion, provided that the composition of the solvent, and the ionic strength, are kept constant. Thus, if a plot of $\ln {}^{c}K_{ML}$ against $\ln {}^{c}K_{HL}$ is found to be a straight line of unit slope, the term A must be constant, (or perhaps negligible compared with the term $\ln {}^{c}K_{HL}$). Similarly, if a straight line of non-unit slope is obtained, the term A must itself be a linear function of $\ln {}^{c}K_{HL}$. For dilute solutions in pure water ($n_X = 0$), and the value of A will be determined largely by the difference in magnitude of $\bar{G}^{\circ}_{ML}$ and $\bar{G}^{\circ}_{HL}$; it is unlikely to be negligible in comparison with $\ln {}^{c}K_{HL}$, but may possibly vary with change in HL in some comparatively simple manner (*cf.* p. 76).



As would be expected, these conditions only hold for series of reagents of very similar structure. For example, a replot of Calvin and Wilson's data for copper complexes of some derivatives of salicylaldehyde [15] (not reproduced) shows that the relationship



$$\log {}^{c}K_{ML} = a \log {}^{c}K_{HL} + b \quad (a \text{ and } b \text{ constants}) \qquad (9)$$

is approximately applicable only in cases where complex formation would lead to similar changes in resonance energy for each ligand in the series. For these complexes, $a = 1$ and the straight lines are of unit slope. The relationship (9, $a = 1$) is also approximately valid for the iron(III) complexes of some phenol derivatives [27]. As the substituents in the ligands were either *o*- or *p*- to the hydroxyl group, there was no steric hindrance to complex formation among these reagents. The effect of a substituent adjacent to a donor atom in

the ligand is shown in Fig. 1a, in which $\log {}^{c}K_{ML}$ is plotted against $\log {}^{c}K_{HL}$ for magnesium complexes of some derivatives of 8-hydroxyquinoline ("oxine" I) [19].

(I)

(II)

(III)

There are two types of deviation from the best straight line of unit slope. (i) Major deviations, where $\log {}^{c}K_{ML}$ is always smaller than predicted. These are invariably associated with reagents having substituents adjacent to the chelating nitrogen atom, and the stabilities of the metal complexes are clearly decreased by steric hindrance. (ii) Minor deviations, in which $\log {}^{c}K_{ML}$ may be either smaller or larger than predicted from the value of $\log {}^{c}K_{HL}$. Since each ligand has two donor atoms of differing character, *viz.* oxygen and nitrogen, the magnitude of $\log {}^{c}K_{HL}$ (which refers only to the dissociation of the O—H group) is not the only factor which influences $\log {}^{c}K_{ML}$. The observed minor deviations may well be due to differences in the co-ordinating power of the nitrogen atoms in the various ligands (*cf.* [2,19,28]).

Plots of $\log {}^{c}K_{ML}$ against $\log {}^{c}K_{HL}$ for several other series of complexes are straight lines of non-unit slope, indicating that the term A is an approximately linear function of $\log {}^{c}K_{HL}$. Data for the copper(II) complexes of some oxine derivatives [19] are plotted in Fig. 1b, together with the best straight line, which is of slope 2.2. Large deviations from the line are again observed for reagents with substituents adjacent to the chelating nitrogen atom. A similar linear plot [29], of slope 1.3, was obtained for complexes of the uranyl ion, UO_2^{2+}. The importance of steric factors is further emphasised by the fact that plots of $\log {}^{c}K_{ML}$ against $\log {}^{c}K_{HL}$, obtained by Van Uitert *et al.* [17,30] for complexes of 1,3-diketones with nickel(II) and cerium(III) in 74.5% v/v aqueous dioxan, gave three parallel lines, one for diketones with two terminal aromatic groups, a second for diketones with a single terminal methyl group, and the third for diketones with two terminal methyl groups. The complexes of copper(II) and barium behaved similarly; the slopes were always less than unity, and fell in the order Cu(II) > Ni(II) > Ba. The introduction of one or more terminal $-CF_3$ groups had a marked effect in depressing the stability of the copper complexes, somewhat less on the nickel complexes, and very little on the barium complexes. Plots of $\log {}^{c}K_{ML}$ against $\log {}^{c}K_{HL}$ for complexes of the silver(I) ion with ammonia and its derivatives also fall on three parallel lines [16], one for primary (and tertiary heterocyclic) amines and the others for secondary and tertiary aliphatic (or aromatic) amines. An explanation in terms of differences in the degree of hydration of free and co-ordinated amines has been suggested by Trotman-Dickenson [31]; attention has also been drawn to the possibility of steric hindrance [11].

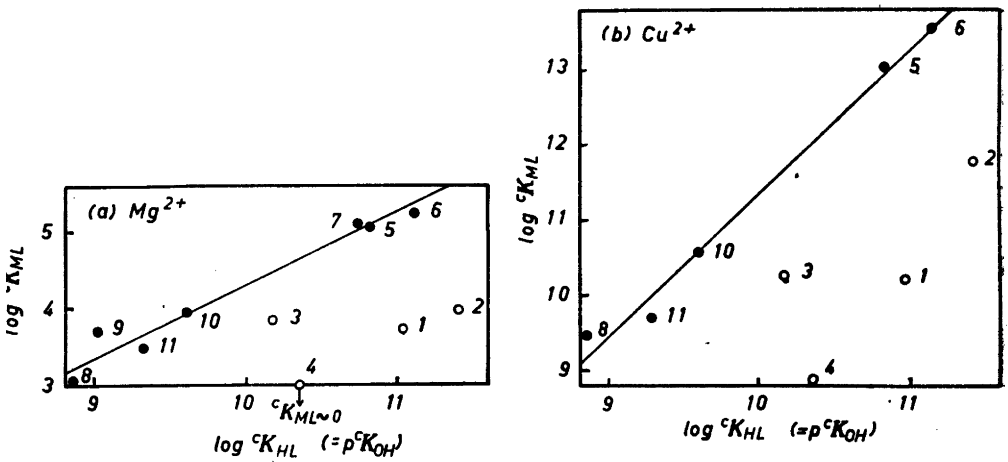


Fig. 1. Log$^cK_{ML}$ as a function of log$^cK_{HL}$ for complexes of oxine derivatives[19] *in 50 % v/v aqueous dioxan (0.3 M sodium perchlorate) at 20° C. Open points refer to reagents with a substituent adjacent to the chelating nitrogen atom: (1) 2-Methyl-oxine (2) 1,2,3,4-Tetrahydro-10-hydroxyacridine (3) 8-Hydroxy-2,4-dimethylquinazoline (4) 8-Hydroxy-4-methyl-2-phenylquinazoline. Full points refer to other reagents: (5) Oxine (6) 5-Methyl-oxine (7) 6-Methyl-oxine (8) 8-Hydroxycinnoline (9) 8-Hydroxy-4-methylcinnoline (10) 8-Hydroxyquinazoline (11) 5-Hydroxyquinoxaline.*

Data for the complexes of magnesium, calcium, strontium, barium and zinc with some aminopolycarboxylic acids indicate that linear plots are only obtained for series of complexes in which the number of rings, and the size of each ring is the same [18,32]; and different lines are obtained for complexes containing purely aliphatic chelate rings, and those in which a benzenoid system is fused to one of the chelate rings, *cf.*[3]. For complexes of substituted iminodiacetic acids $X—CH_2—N(CH_2COOH)_2$ ($X = CO_2^-$, SO_3^-, PO_3^{2-}) the slope of each plot is a linear function of the second ionisation potential, I, of the appropriate metal [18]. Thus, in this series of complexes $^cK_{ML}$ and $^cK_{HL}$ are related by the equation

$$\ln {}^cK_{ML} = \ln {}^cK_{HL}\,(c + dI) + e + B \qquad (10)$$

where c, d and e are constants.

It is not difficult to see why the simple relationship (9) is so seldom exactly followed. With monodentate ligands, differences between the size and deformability of the (solvated) proton and the (solvated) metal ion will lead to steric effects (*cf.* the F-strain discussed by Brown and co-workers [33]). Superimposed steric effects can arise when the spatial geometry of the free ligand is sufficiently modified by co-ordination to the metal (*cf.* Brown's B-strain [33]). With chelating ligands such as the glycinate ion ($L = NH_2CH_2COO^-$), the H—L bond is essentially one between hydrogen and nitrogen, giving the zwitterion $^+NH_3CH_2COO^-$, while in its metal complexes both metal-nitrogen and metal-oxygen bonds are involved. Similar arguments apply to ligands incorporating this basic skeleton within a hetrocyclic structure, *e. g.* 8-hydr-

oxyquinoline, 8-hydroxycinnoline (II, R = H), and 8-hydroxyquinazoline (III, R = R′ = H). Structural changes in L will change the strength of both metal-oxygen and metal-nitrogen bonds, but not necessarily to the same extent, or even in the same direction [2,19]. The greatest deviations from equation (9) will be expected with the metals which show the greatest tendency to form strong bonds, and which exhibit the greatest difference in the relative strength of their bonds to different donor atoms.

Type II. The relationship between the stabilities of complexes of two metal ions with a series of related ligands

The relationship between metal-ligand, and proton-ligand, complexes of a single metal has been discussed in the previous section, with reference to plots of log ${}^{c}K_{ML}$ against log ${}^{c}K_{HL}$. The stabilities of complexes formed by two different metal ions, Y and Z, with a series of ligands may be compared in an analogous way by plotting log ${}^{c}K_{YL}$ as a function of log ${}^{c}K_{ZL}$. Applying equation (6) to each metal ion in turn, and subtracting

$$\ln {}^{c}K_{YL} = \ln {}^{c}K_{ZL} + \frac{1}{RT}\{\bar{G}^{\circ}_{Y} - \bar{G}^{\circ}_{YL} - \bar{G}^{\circ}_{Z} + \bar{G}^{\circ}_{ZL} + n_{X}(t_{Y} - t_{Z} - t_{YL} + t_{ZL})\} + \ln(y_{ZL}y_{Y}/y_{YL}y_{Z}) \quad (11)$$

which can be written in the form

$$\ln {}^{c}K_{YL} = \ln {}^{c}K_{ZL} + C + D \quad (12)$$

where $$C = \frac{1}{RT}\{-\bar{G}^{\circ}_{YL} + \bar{G}^{\circ}_{ZL} + n_{X}(-t_{YL} + t_{ZL})\} - \ln y_{YL} + \ln y_{ZL}$$

and $$D = \frac{1}{RT}\{\bar{G}^{\circ}_{Y} - \bar{G}^{\circ}_{Z} + n_{X}(t_{Y} - t_{Z})\} - \ln y_{Z} + \ln y_{Y}$$

Thus equation (12) corresponds to (8), where the symbols Y, Z, C and D now replace M, H, A and B, respectively. Since D is independent of the nature of the ligand, L, the plot of $\ln {}^{c}K_{YL}$ against $\ln {}^{c}K_{ZL}$ will be a straight line of unit slope if C is a constant or is negligible compared with $\ln {}^{c}K_{ZL}$. A straight line of non-unit slope would result if C were a linear function of $\ln {}^{c}K_{ZL}$. The conditions necessary for a linear relationship between log ${}^{c}K_{YL}$ and log${}^{c}K_{ZL}$ are therefore exactly analogous to those necessary for a linear relationship between log ${}^{c}K_{ML}$ and log${}^{c}K_{HL}$ (see previous section).

As few stability constants for complexes of two closely related metals with the same group of ligands are available, this relationship cannot be tested thoroughly. However, values of log ${}^{c}K_{CuL}$ for fifty six ligands of very varied types are plotted against corresponding values of log ${}^{c}K_{NiL}$ in Fig. 2. The predicted behaviour is approximately followed for complexes ranging in stability from ${}^{c}K_{ML} = 10^{15}$ to $\sim 10^{0}$. Both monodentate and polydentate ligands have been included and while many of the measurements were made in aqueous

solution, a number of points refer to water-dioxan mixtures. No attempt has been made to distinguish between points for groups of closely related ligands (*e. g.* 1,3-diketones or 1,2-diamines), although they generally lie more closely

on linear plots. The line in Fig. 2 has a slope of unity. Divergencies will be due, at least in part, to differences in the preferred geometry of nickel and copper and to the fact that the co-ordination number of (planar) copper does not readily rise above four. That the best straight line through all the points should have a slope greater than unity implies that the difference in stability between the copper and nickel complexes increases with the increasing stability of the complexes.

Closer agreement with the predictions of equation (12) is found for complexes of a pair of metals of greater similarity, *e. g.* strontium and barium, and still better agreement would be expected for a pair of tripositive rare earth ions. At present there are insufficient data to subject equation (12) to really exhaustive tests.

Type III. The relationship between the stabilities of two ligands with a series of metal ions

The stabilities of complexes formed by two ligands, P and Q, with a series of metal ions may conveniently be compared by plotting log ${}^{c}K_{MP}$ as a function of log ${}^{c}K_{MQ}$. It has previously been found [19] that the experimental points for closely related pairs of ligands sometimes lie approximately on a straight line of unit slope and of intercept (log ${}^{c}K_{HP}$—log ${}^{c}K_{HQ}$). The theoretical relationship between ln ${}^{c}K_{MP}$ and ln ${}^{c}K_{MQ}$ may be derived from equation (6)

$$\ln {}^{c}K_{MP} - \ln {}^{c}K_{MQ} = \ln {}^{c}K_{HP} - \ln {}^{c}K_{HQ} + \frac{1}{RT}\{-\bar{G}^{\circ}_{MP} + \bar{G}^{\circ}_{MQ} + \bar{G}^{\circ}_{HP} - \bar{G}^{\circ}_{HQ} + n_X(-t_{MP} + t_{MQ} + t_{HP} - t_{HQ})\} + \ln (y_{HP}y_{MQ}/y_{MP}y_{HQ}) \quad (13)$$

$$= \ln {}^{c}K_{HP} - \ln {}^{c}K_{HQ} + E + F + H$$

where

$$E = \frac{1}{RT}\{(\bar{G}^{\circ}_{MQ} - \bar{G}^{\circ}_{MP}) - (\bar{G}^{\circ}_{HQ} - \bar{G}^{\circ}_{HP})\}$$

$$F = \frac{n_X}{RT}\{(t_{MQ} - t_{MP}) - (t_{HQ} - t_{HP})\}$$

and

$$H = \ln y_{MQ}/y_{MP} - \ln y_{HQ}/y_{HP}$$

Thus if the experimental data conform to the linear relationship

$$\log {}^{c}K_{MP} = \log {}^{c}K_{MQ} + (\log {}^{c}K_{HP} - \log {}^{c}K_{HQ}) \quad (14)$$

the term $(E + F + H)$ must be negligible compared with the other terms in equation (13). If $\bar{G}^{\circ}_{MQ} > \bar{G}^{\circ}_{MP}$ it is very probable that $\bar{G}^{\circ}_{HP} > \bar{G}^{\circ}_{HQ}$; hence the value of E, which depends on the difference between two terms which express the magnitude of these changes, will probably be insignificant in comparison with $\ln {}^{c}K_{MQ}$ and will tend rapidly to zero as P and Q approach each other in character. The same argument can be applied to the algebraic sum of the transfer coefficients, t_S, which determine the value of F, and to the activity coefficients included in the term H.

It is therefore not surprising that the relationship (14) is often valid for, though restricted to, very similar pairs of ligands. Values of log ${}^{c}K_{MP}$ for

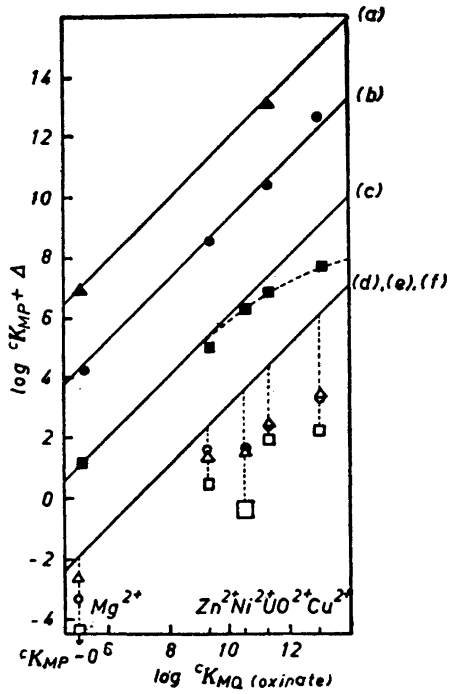

Fig. 3. Log$^cK_{MP}$ for complexes of oxine derivatives as a function of log$^cK_{MQ}$ for the corresponding oxinates. The constants were obtained [19] in 50 % v/v aqueous dioxan (0.3 M sodium perchlorate) at 20° C. The ordinates refer to complexes of: (a) 6-Methyl-oxine, Δ = 2.0 (b) 5-Methyl-oxine, Δ = −1.0 (c) 8-Hydroxycinnoline, (II, R = H), Δ = −2.0 (d) 2-Methyl-oxine (open circles), Δ = −7.0 (e) 8-Hydroxy-2,4-dimethylquinazoline (III, R = R′ = CH_3, open triangles), Δ = −6.3 (f) 8-Hydroxy-4-methyl-2-phenylquinazoline (III, R = phenyl, R′ = CH_3, open squares), Δ = −6.5. The abscissae refer to complexes of oxine. The full lines are of unit slope and of intercept, (log$^cK_{HP}$ − log$^cK_{HQ}$), predicted by equation (14).

complexes of a number of oxine derivatives [19] are plotted as a function of values of log $^cK_{MQ}$ for the corresponding oxinates in Fig. 3. When log $^cK_{MP}$ refers to complexes of 5-methyl-oxine (Fig. 3a) or 6-methyl-oxine (Fig. 3b), the experimental points fall closely on the theoretical lines of unit slope and of intercept (log $^cK_{HP}$— log $^cK_{HQ}$), as might be expected for reagents which differ only slightly from oxine in their structure and values of pK_{NH} (*cf.* [19]) and offer no steric hindrance to complex formation. Similar straight lines are also obtained for complexes of magnesium, zinc, nickel(II), copper(II) and uranyl with pairs of reagents chosen from among 5-fluoro-, 5-chloro-, 5-bromo- and 5-methyl-oxine [38].

The ordinates of Fig. 3d are values of log$^cK_{MP}$ for complexes of 2-methyl-oxine. The experimental points lie from 1 to 3 logarithmic units below the line drawn according to equation (14). This lowering of stability is undoubtedly due to steric hindrance to complex formation. As expected, deviations of the

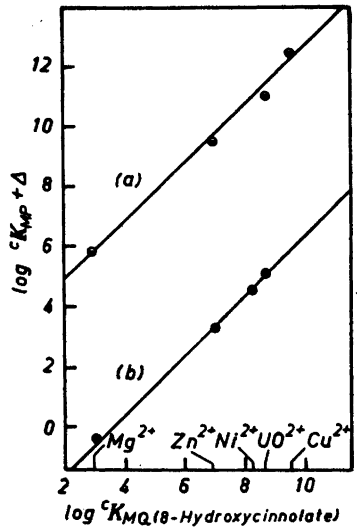

Fig. 4. Log$^cK_{MP}$ for complexes of oxine derivatives as a function of log$^cK_{MQ}$ for the corresponding complexes of 8-hydroxycinnoline. The constants [19] were obtained in 50 % v/v aqueous dioxan (0.3 M sodium perchlorate) at 20° C. The ordinates refer to complexes of (a) 8-Hydroxyquinazoline (III, R = R′ = H), Δ = 2.0 (b) 8-Hydroxy-4-methylcinnoline (II, R = CH_3), Δ = −4.0. The abscissae refer to complexes of 8-hydroxycinnoline (II, R = H). The full lines are of unit slope and of intercept (log$^cK_{HP}$ − log$^cK_{HQ}$), predicted by equation (14).

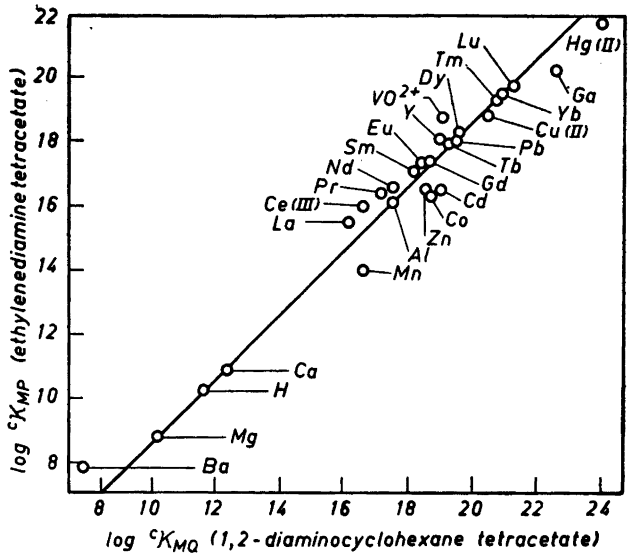
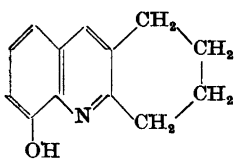
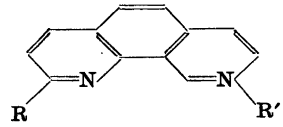
same order of magnitude are obtained for complexes of 8-hydroxy-2,4-dimethylquinazoline (III, R = R′ = CH_3; Fig. 3e) and 1,2,3,4-tetrahydro-10-hydroxyacridine (IV; graph [29] not reproduced here). When a phenyl group is adjacent to the chelating nitrogen atom (Fig. 3f), there are even greater deviations from the theoretical line, and no complex formation between 8-hydroxy-4-methyl-2-phenylquinazoline (III, R = phenyl, R′ = CH_3) and the magnesium ion could be detected.

Values of log $^cK_{ML}$ for complexes of 8-hydroxycinnoline (II, R = H) form the ordinates in Fig. 3c. The stability constant of the magnesium complex lies on the theoretical line, while that for the copper complex lies well below it. Points for other cations are in intermediate positions. The low value of pK_{NH} of 8-hydroxycinnoline as compared with the value for oxine [19] would be expected to reduce the stability of its copper complex, but to have little effect on the stability of the magnesium complex. Similar plots [29] (not reproduced here) are obtained if values of log $^cK_{MP}$ for complexes of 8-hydroxyquinazoline (III, R = R′ = H) and 8-hydroxy-4-methylcinnoline (II, R = CH_3) form the ordinates. Values of log $^cK_{MP}$ for complexes of both these reagents are plotted against values of log $^cK_{MQ}$ for the corresponding complexes of 8-hydroxycinnoline in Fig. 4. The experimental points lie much nearer the theoretical line than when the stabilities of the oxinates is made the basis of comparison, doubtless because the variation in pK_{NH} among these reagents is much smaller.







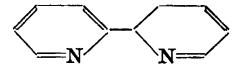


Fig. 5. Log$^cK_{MP}$ for complexes of ethylenediaminetetraacetic acid as a function of log$^cK_{MQ}$ for complexes 1,2-diaminocyclohexanetetraacetic acid. The constants [39,41] were obtained at 20° C (μ = 0.1 M). All the ions shown are in their usual valency state. The straight line is of unit slope and of intercept, (log$^cK_{HP}$ − log$^cK_{HQ}$), predicted by equation (14).

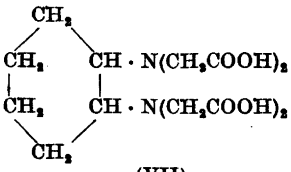
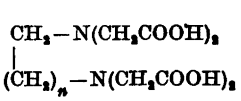
(IV)

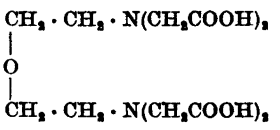


(V)



(VI)

Recent measurements [37] have shown that the 1:1 complexes of the divalent transition metals, manganese, iron, cobalt, nickel, copper and zinc with 1,10-phenanthroline (V, R = R′ = H; pK = 4.36) are consistently stronger than those of the stronger base 2-methyl-1,10-phenanthroline (V, R = H, R′ = CH_3; pK = 5.42). On the basis of equation (14) it is possible to calculate the stability constants which would have been expected from the change in basicity, and the instability arising from steric hindrance to complex formation is found to be from 2.5 to 3.5 kcal./mole. For the still less stable complexes of the even more basic reagent 2,9-dimethyl-1,10-phenanthroline (V; R = R′ = CH_3; pK = 5.85) the instability arising from steric factors is 4 to 5.5 kcal./mole. Although 1,10-phenanthroline ("phenan") and 2,2′-dipyridyl (VI; "dipy") are almost identical so far as their mode of chelating is concerned, complexes of the former are always the more stable. A plot of log $^cK_{M.dipy}$ against log $^cK_{M.phenan}$ (not reproduced) gives a good straight line for the transition metals, but the slope is 0.63



rather than unity; *i. e.* the difference between the stabilities of corresponding complexes of phenanthroline and dipyridyl decreases almost linearly with increasing stability from about 2.2 logarithmic units with manganese to 0.7 with copper. This example shows the limitations of equation (14) and the need for restricting its application to pairs of ligands of the greatest possible similarity.

(VII)

(VIII)

(IX)

Fig. 5 shows values of log ${}^{c}K_{MP}$ for 1:1 complexes of *o*-diaminocyclohexane-tetraacetic acid (VII; pK = 11.70) plotted against values of log ${}^{c}K_{MQ}$ for the corresponding complexes of ethylenediamine-tetraacetic acid [39] (VIII, n = 1; "ENTA"; pK = 10.26). The straight line shown is of unit slope and of theoretical intercept log ${}^{c}K_{HP}$—log${}^{c}K_{HQ}$. Although the complexes include those of monovalent, divalent and trivalent ions, and ions of both A and B subgroups of the periodic table, the general conformity to equation (14) is quite remarkable considering that the individual complexes differ in stability by as much as a factor of 10^{14}. The fact that values of log ${}^{c}K_{ML}$ for ENTA complexes of trivalent rare earth ions do not increase linearly with atomic number has been discussed by Wheelwright *et al.*[40] who first noted that a break in the curve occurs at gadolinium. From Fig. 5 it would appear that the complexes of VII with lanthanons of atomic number 57 to 62 are less stable than would be predicted from the values of log ${}^{c}K_{M.ENTA}$.

For complexes of diaminoethyl ether tetraacetic acid (IX) there is the possibility of co-ordination through the ethereal oxygen atom. Alternatively the 5-atom ring formed by the 1,2-diamine ENTA must be replaced by an 8-membered ring. Now increase of ring-size in the series $A_2N—(CH_2)_n—NA_2$ (A = —CH_2COOH) is reflected in a greatly decreasing stability of its alkaline earth complexes [5]. Thus log ${}^{c}K_{CaL}$ is 10.59, 7.12, 5.05 and 4.60 for n = 2, 3, 4 and 5, respectively. Were the oxygen atom entirely inactive in complex formation, the complexone IX would most closely resemble pentamethylene-tetraacetic acid (VIII, n = 4; pK = 10.58) for which the stability constant of the calcium complex is only $10^{4.6}$. While this complexone VIII is a very slightly weaker acid than ENTA, the complexone IX (pK = 9.49) is a considerably stronger acid, and would therefore be expected to form uniformly weaker complexes. In fact, when values of log ${}^{c}K_{MQ}$ for complexes of ENTA are plotted against values for the corresponding complexes of IX (for data *cf.*[41]) a straight line of unit slope and of theoretical intercept (not reproduced) passes through or close to points for magnesium, calcium, manganese(II), zinc and copper(II). The large ions barium and cadmium form complexes with IX which are 1.2 and 2.4 logarithmic units more stable than would be expected from the stability of the corresponding ENTA complexes. With these exceptions, all the complexes of IX are, as anticipated, weaker than those with ENTA. The anomalous be-

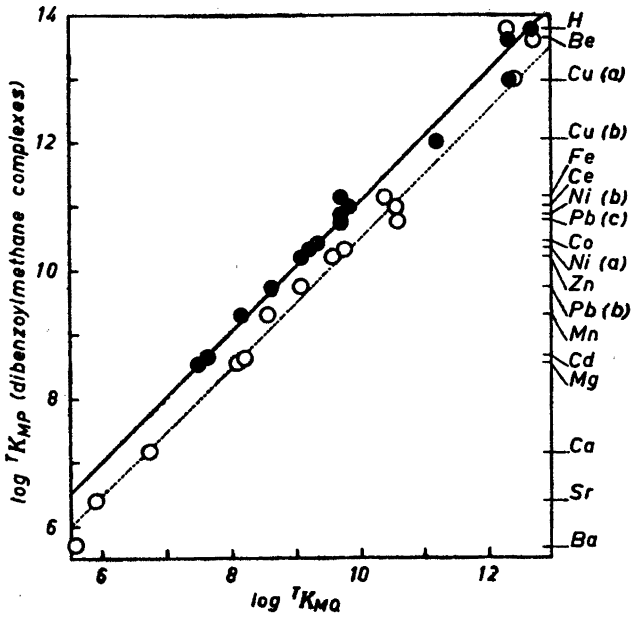


Fig. 6. Log $^{T}K_{MP}$ for complexes of dibenzoylmethane as a function of log $^{T}K_{MQ}$ for complexes of related 1,3-diketones. The thermodynamic constants were obtained [17] in 75 % v/v aqueous dioxan at 30° C. The ordinates refer to complexes of dibenzoylmethane. The abscissae refer to complexes of acetylacetone (full points and line) and of furoyl-thenoylmethane (open circles and dotted line). The full line is of unit slope and of intercept, (log $^{T}K_{HP}$ − log $^{T}K_{HQ}$), predicted by equation (14). The dotted line is the best straight line of unit slope through the open points. The letters (a), (b) and (c) denote chlorides, nitrates and perchlorates respectively; other metals were studied only in the presence of nitrate ions.

haviour of barium can be exploited analytically in a substitution titration of strontium and barium, or in the titration of these alkaline earths and magnesium using Eriochrome Black T as indicator [41].

Good straight lines are often obtained if values of log $^{c}K_{MP}$ are plotted against values of log $^{c}K_{MQ}$ for complexes of pairs of closely related α-diketones. In Fig. 6, complexes of dibenzoylmethane are compared with those of acetylacetone (full circles) and of furoyl-thenoylmethane (open circles). The majority of points for each pair of reagents lie on a straight line of unit slope. However, while the best (full) line for complexes of acetylacetone has the theoretical intercept predicted by equation (14), the best (dotted) line for complexes of furoyl-thenoylmethane has an intercept of 0.6 instead of log $^{c}K_{MP}$—log $^{c}K_{MQ}$ = 1.45. Thus all the complexes of the diketone with two heterocyclic end groups are about 0.8 logarithmic unit more stable than expected; similar, but smaller, deviations from predicted behaviour are observed for complexes of other pairs of 1,3-diketones. The effect of different terminal groups of diketones on the stability of their metal complexes has been discussed by Van Uitert *et al.*[17]; (*cf.* p. 76).

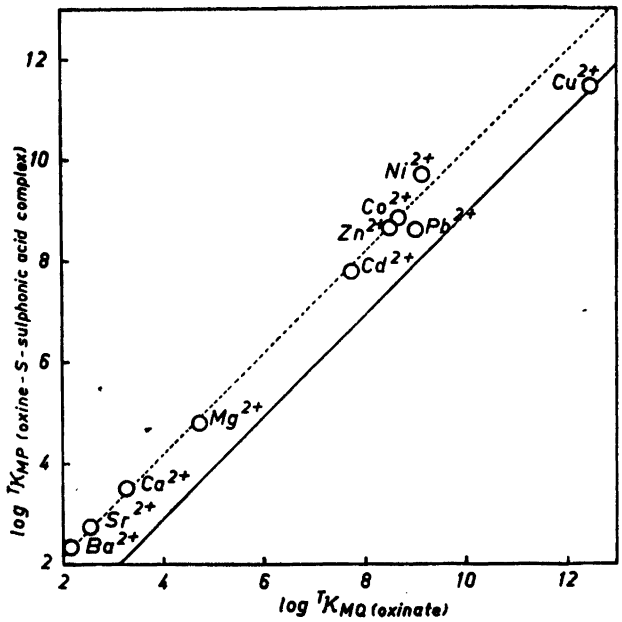

Fig. 7. Log $^{T}K_{MP}$ for complexes of oxine-5-sulphonic acid as a function of log $^{T}K_{MQ}$ for complexes of oxine. The thermodynamic constants were obtained [42-46] in water at 25° C. The full line is of unit slope and of intercept, (log $^{T}K_{HP}$ − log $^{T}K_{HQ}$), predicted by equation (14). The dotted line is the best straight line of unit slope through the experimental points.

The relationship (14) is not always valid, even if there is no possibility of steric hindrance and the ligands are very similar (*e. g.* oxine and oxine-5-sulphonic acid). It is well known that the corresponding complexes of these two ligands are of comparable stability, although the values of log $^{c}K_{HL}$ (= pK_{OH}) for the reagents differ considerably (oxine, pK_{OH} = 9.81; oxine-5-sulphonic acid, pK_{OH} = 8.75) [42,43]. Values of log $^{c}K_{MP}$ for complexes of oxine-5-sulphonic acid [44] are plotted against values of log $^{c}K_{MQ}$ for the corresponding oxinates [45,46] in Fig. 7, together with the theoretical (full) line. Although the complexes of oxine-5-sulphonic acid are much more stable than predicted by equation (14), the experimental points for complexes of many of the metal ions lie approximately on a straight line of unit slope (dotted line in Fig. 7). As the terms (ln $^{c}\mathbf{K}_{HP}$—ln $^{c}\mathbf{K}_{HQ}$) and E are constants for a given pair of reagents, this relationship, *viz.*

$$\log {}^{c}\mathbf{K}_{MP} = \log {}^{c}\mathbf{K}_{MQ} + \text{constant}$$

will only be obtained if the term

$$F = \frac{1}{RT}\{(\bar{G}^{\circ}_{MQ} - \bar{G}^{\circ}_{MP}) + n_{X}(t_{MQ} - t_{MP})\} + \ln y_{MQ}/y_{MP}$$

is negligible, or is a constant for complexes of the two ligands with a series of metal ions.

Type IV. The variation of stability with the composition of the solvent

As many organic reagents and their metal complexes are very sparingly soluble in water, stability constants are often determined in aqueous ethanol or aqueous dioxan and it is of interest to consider how these values would differ from those obtained in water. It has been found[2,21,47] that values of $\log {}^{c}K_{HL}$ for many proton-ligand complexes containing either O—H or N—H groups are approximately linear functions of the molar fraction, n_X, of the organic component of the solvent, at least for low values of n_X. Some plots of this type are shown in Fig. 8.

Now if equation (5) is valid for the species H, L and HL

$$\ln {}^{c}K_{HL'} - \ln {}^{c}K_{HL} = \frac{n_X}{RT}(t_H + t_{L'} - t_{HL'}) + \ln\left(\frac{y_H y_{L'}}{y_{HL'}} \Big/ \frac{y_H y_L}{y_{HL}}\right) \quad (15)$$

and the plot of $\log {}^{c}K_{HL'}$ against n_X will be a straight line of intercept $\log {}^{c}K_{HL}$, provided that the last term in equation (15) is (i) negligible compared with the other terms or (ii) proportional to n_X. The slope of the line is given by

$$\mathrm{d}(\log {}^{c}K_{HL'})/\mathrm{d}(n_X) = \frac{1}{2.303RT}(t_H + t_{L'} - t_L) \quad (16i)$$

or $$\mathrm{d}(\log {}^{c}K_{HL'})/\mathrm{d}(n_X) = \frac{1}{2.303RT}(t_H + t_{L'} - t_{HL'}) + d_H + d_{L'} - d_{HL'} \quad (16ii)$$

for cases (i) and (ii) respectively, where d_S is defined by

$$\ln y_S - \ln y_S = n_X \cdot d_S \quad (17)$$

Fig. 8 shows that the stabilities of complexes containing an O—H link increase with increasing organic content of the solvent, *i. e.* the term $\mathrm{d}(\log {}^{c}K_{HL'})/\mathrm{d}(n_X)$ is positive. However, an increase in the organic content of the solvent causes a decrease in the stabilities of proton-ligand complexes containing an N—H link, and for these compounds $\mathrm{d}(\log {}^{c}K_{HL'})/\mathrm{d}(n_X)$ is negative. An increase in the organic content of the mixed aqueous-organic solvent results in a decrease in the dielectric constant of the medium. This will increase the ionic interaction between a proton and a negatively charged oxygen atom to a greater extent than the ion-dipole interaction between the proton and the solvent. Thus, as n_X increases, the value of $\ln {}^{c}K_{HL'}$ should increase for proton-ligand complexes containing O—H bonds. Conversely, an increase in the organic content of the solvent would be expected to increase the ion-dipole forces between a proton and a nitrogen atom in the ligand to a lesser extent than the ion-dipole forces between a proton and the more electronegative donor oxygen atoms of the solvent (*cf.*[31,52]). A decrease in the value of $\ln {}^{c}K_{HL'}$ would therefore be expected for complexes containing N—H bonds.

The relationship between n_X and $\ln {}^{c}K_{ML'}$ for a metal-ligand complex corresponds exactly to equation (16), where M now replaces H. Thus

$$\ln {}^{c}K_{ML'} - \ln {}^{c}K_{ML} = \frac{n_X}{RT}(t_M + t_{L'} - t_{ML'}) - \ln\left(\frac{y_M y_{L'}}{y_{ML'}} \Big/ \frac{y_M y_L}{y_{ML}}\right) \quad (18)$$

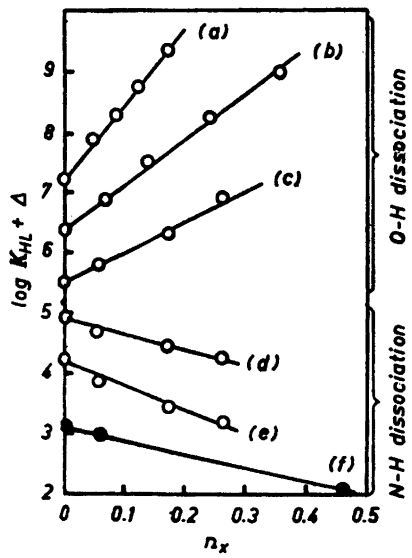

Fig. 8. Log$^cK_{HL}$ (= pK) as a function of the molar fraction, n_X, of the organic content of the solvent. Open and full circles refer to aqueous dioxan and aqueous methanol respectively. (a) to (c); compounds in which an O—H group dissociates: (a) Benzoic acid, Δ = 3.0. Thermodynamic constants [48] were obtained at 25° C. (b) m*-Chlorobenzoic acid, Δ = 2.5. Constants were obtained at 25° C and varying ionic strength [49, 50]. (c) Oxine-5-sulphonic acid, Δ = −3.0. Stoichiometric constants were obtained at 20° C in 0.3 M sodium perchlorate [29].*
(d) to (f); compounds in which an N—H group dissociates: (d) Oxine-5-sulphonic acid, Δ = 1.0. Stoichiometric constants obtained at 20° C in 0.3 M sodium perchlorate [29]. (e) Pyridine, Δ = −1.0. Stoichiometric constants obtained at 20° C in 0.3 M sodium perchlorate [29]. (f) Piperidine, Δ = −8.0. Stoichiometric constants [51] obtained at 25° C and ionic strength 0.1 M.

The conditions necessary for a linear relationship between log $^c\mathbf{K}_{ML}$ and n_X, and the possible values of d(log $^c\mathbf{K}_{ML}$)/d(n_X), are analogous to those given above for proton-ligand complexes. Van Uitert *et al.*[53] have shown that values of log$^c\mathbf{K}_{ML}$ for several acetylacetonates are linear functions of the molar fraction of dioxan in the solvent, and a replot of Maley and Mellor's data [54] (not reproduced here) shows that a similar relationship exists for the magnesium complex of salicylaldehyde. The stability of these complexes, which all contain O-metal links, is increased by an increase in the organic content of the solvent, *i. e.* d(log $^c\mathbf{K}_{ML}$)/d(n_X) is positive.

Combining equations (15) and (18),

$$\ln {}^c\mathbf{K}_{ML} - \ln {}^cK_{ML} = \ln {}^c\mathbf{K}_{HL} - \ln {}^cK_{HL} + \frac{n_X}{RT}(t_M - t_{ML} - t_H + t_{HL}) - \ln\left(\frac{y_{ML}y_H}{y_My_{HL}} \Big/ \frac{y_{ML}y_H}{y_My_{HL}}\right) \qquad (19)$$

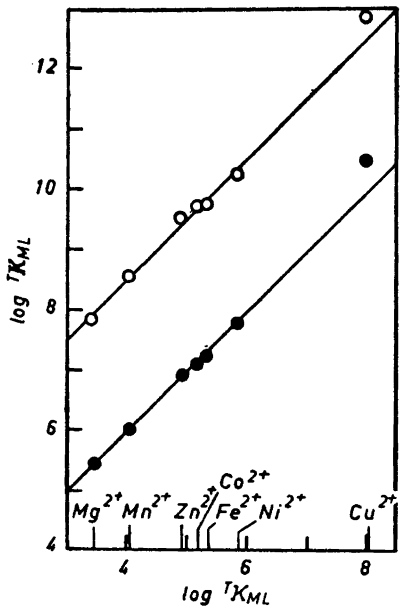

Fig. 9. Thermodynamic stability constants [53] *of metal acetylacetonates in aqueous dioxan at 30° C. The ordinates refer to values obtained in 75 % (open circles) and 50 % (full circles) v/v aqueous dioxan. The abscissae refer to values obtained in water. The lines are of unit slope and of intercept, (log* $^{T}K_{HL}$ *— log* $^{T}K_{HL}$*), predicted by equation (20).*

If the last two terms in equation (19) are negligible compared with the other terms, the equation reduces to

$$\log {}^{c}K_{ML} = \log {}^{c}K_{ML} + \log {}^{c}K_{HL} - \log {}^{c}K_{HL} \qquad (20)$$

and a plot of log $^{c}K_{ML}$ against log $^{c}K_{ML}$ for a series of complexes of different metal ions with the same ligand will be a straight line of unit slope and of intercept (log $^{c}K_{HL}$—log $^{c}K_{HL}$). This relationship is now found to be applicable to many of the data of Van Uitert *et al.*[53] for acetonylacetonates in 50 % and 75 % aqueous dioxan, which are shown in Fig. 9. Thus, for acetylacetone, a change in the composition of the solvent results in parallel changes in log $^{c}K_{ML}$ and log $^{c}K_{HL}$.

No simple relationship between stability and solvent composition would appear to exist for complexes containing N-metal bonds. An increase in the organic content of the solvent has little influence on the stabilities of certain complexes of ammonia [55–59], ethylenediamine [60–62], pyridine [29] and imidazole [63], although the complex $Ag(en)^{+}$ is more stable in pure ethanol and *iso*-propyl alcohol than in water [64].

No one author seems to have investigated the effect of solvent composition on the stabilities of complexes, such as the oxinates, which contain both O-metal and N-metal bonds. By analogy with simpler complexes, an increase in

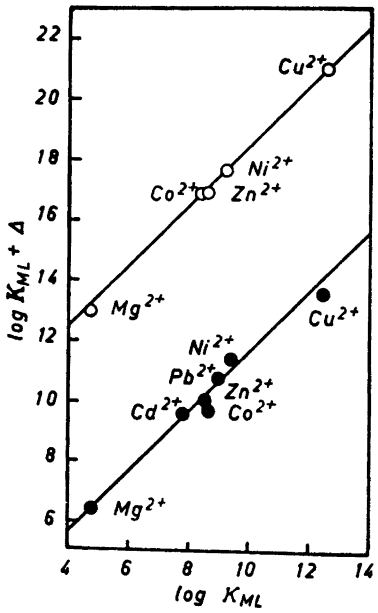

Fig. 10. Stability constants of metal oxinates in aqueous dioxan at 25° C. The ordinates refer to values obtained at varying ionic strengths in 70 % (open circles [54], Δ = 6.0) and 50 % (full circles [65], Δ = 0) v/v aqueous dioxan. The abscissae refer to thermodynamic values obtained in water. The straight lines are of unit slope and of intercept, $(\log^c K_{HL_2} - \log^c K_{HL})$, *predicted by equation (20).*

the organic content of the solvent might be expected to increase the stability of complexes in which the O-metal bond is of predominant importance, but to have less effect on the stability of complexes containing strong N-metal bonds. In Fig. 10, the stabilities of metal oxinates in 50 % and 75 % aqueous dioxan [54,65] are plotted against the corresponding values obtained in water [45,46]. Increased dioxan content leads to a marked increase in stability, in approximate agreement with equation (20). Thus for these complexes the last two terms in equation (19) are negligible compared with the other terms, and the variation of $\log {}^cK_{ML_2}$ with the composition of the solvent merely reflects the variation of $\log {}^cK_{HL}$. It would be of interest to know if this were also true for other complexes containing both O-metal and N-metal links.

APPLICATIONS

Equation (6) has been used above as a basis for discussing the various empirical linear relationships between the stabilities of related complexes. These plots are of interest from both practical and theoretical considerations.

If the stability constants of some closely related complexes have been measured, the stabilities of other complexes in the same series may be predicted by means of equations (9) and (14). For example, although the stability con-

stants of the zinc, nickel(II) and copper(II) 6-methyl-oxinates could not be measured in 50 % aqueous dioxan, on account of the low solubility of the uncharged complexes [19], approximate values, *viz.* 9.2, 10.4 and 12.9, can be estimated using equation (14) in conjunction with values of the stability constants of the corresponding oxinates, and of log ${}^{c}K_{HL}$ of the two reagents [19] (*cf.* Fig. 3b). The estimation of stability constants of very sparingly soluble complexes is especially important for analytical work involving the separation of metal ions by solvent extraction or selective precipitation [2].

It has been shown that plots of log ${}^{c}K_{ML}$ against log ${}^{c}K_{HL}$ are often linear for series of very closely related ligands. If divergent lines of different slope are obtained for different metal ions with the same series of ligands (*e. g.* complexes of magnesium, uranyl and copper(II) ions with derivatives of oxine [19]) a ligand with a high value of ${}^{c}K_{HL}$ will form metal complexes of more varied stability than those formed from a ligand of low ${}^{c}K_{HL}$, and will therefore be a more selective reagent for these metal ions. If only very closely related ligands are considered, deviations from linearity in plots of log ${}^{c}K_{ML}$ against log ${}^{c}K_{HL}$, and in plots of the type (14) indicate any tendencies to selective or specific behaviour. Ligands with bulky substituents adjacent to one of the donor atoms form much less stable metal-ligand complexes than would be expected from the stability of the corresponding proton-ligand complexes (*cf.* Fig. 3d, e, f). As this effect depends on the size of the central group, sterically hindered reagents are of use for the analytical separations of certain metal ions (*cf.* the reactions between 2-methyl-oxine and trivalent aluminium, gallium and indium ions, [66] and refs. therein). Even when no steric hindrance occurs, metal-ligand chelate complexes may deviate appreciably from predicted behaviour (*cf.* Fig. 3c). The formation of a metal chelate involves combination of the metal ion with two or more donor atoms, while the formation of the first proton-ligand complex involves only the atom which has the most basic (donor) character. The observed deviations probably reflect differences in the co-ordinating power of the other donor atoms throughout the series of ligands.

The value of ${}^{c}K_{HL}$ for proton-ligand complexes which are very sparingly soluble in water may be estimated by measuring ${}^{c}K_{HL}$ in a number of water-ethanol or water-dioxan mixtures; log ${}^{c}K_{HL}$ may then be obtained by linear extrapolation of the plot of log ${}^{c}K_{HL}$ against n_X, to the point $n_X = 0$ (*cf.* equation (15) case (i) or (ii)). The value of ${}^{c}K_{ML}$ can be estimated analogously be means of equation (18). If equation (19) is valid, an approximate value of K_{ML} in water may be predicted from the corresponding constant, ${}^{c}K_{ML}$, obtained in a mixed solvent, if the proton-ligand stability constants, ${}^{c}K_{HL}$ and ${}^{c}K_{HL}$, in both solvents are known. Although water has been used as a solvent for most analytical processes in homogeneous systems, a mixed solvent might be of value for absorptiometric work and for certain selective precipitation reactions. Titrations in solvents such as aqueous dioxan, acetic acid, or glycol-*iso*propyl alcohol mixtures are at present being developed extensively but empirically. Progress would be facilitated if more were known of the effect of change of solvent on the stability of proton-ligand and metal-ligand complexes of all types *cf.*[67]. Equations of the type (15), (18) and (19) might then be used to predict approximate values of stability constants in the appropriate solvent. As O-metal bonds appear to be more influenced by the composition of

the solvent than N-metal bonds, the effect of solvent composition on the stability of chelates containing the O-metal-N link might be an indication of the relative importance of these bonds.

Equation (6) and the foregoing discussion refer to the formation of the first metal-ligand complex, and suggest no correlation of the stabilities of complexes which contain more than one ligand group. Although some authors (*e. g.*[15]) have obtained approximate empirical relationships between log ${}^{c}K_{\mathrm{HL}}$ and log $K_{\mathrm{av}} = \frac{1}{2}$ log $[\mathrm{ML_2}]/[\mathrm{M}][\mathrm{L}]^2$ it would be expected that in many cases the formation of the complex ML modifies the properties of the metal ion and ligand group to such an extent that any quantitative comparison of equilibrium constants for reactions of the type

$$\mathrm{ML} + \mathrm{L} = \mathrm{ML_2}$$

would be unjustified.

As so few reliable measurements have been made of the enthalpy and entropy of complex formation, stability constants have been discussed purely in terms of overall changes in free energy. When more precise data become available, a further analysis of heat and entropy changes would be profitable using a similar approach.

Acknowledgements. We would like to thank Dr. James Duncan, University of Melbourne, for stimulating discussion in the early stages of this work, and Professor Lars Gunnar Sillén and Dr. F. J. C. Rossotti, for their helpful comments on the manuscript.

We are also grateful to *A. E. R. E.*, Harwell, and the *Swedish Atomic Energy Commisson*, for financial assistance.

On the Chemical State of ^{32}P and ^{33}P in a Sulphur Target

GÖSTA NILSSON

Division of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

The yields of ^{32}P, ^{33}P and ^{35}S by the irradiation of sulphur in the Norwegian D_2O-reactor at Kjeller have been determined for different sample positions in the reflector.

It was found that a large amount of ^{32}P and ^{33}P but hardly any ^{35}S followed the insoluble S_μ-fraction of the sulphur samples on dissolving in CS_2. Adsorption can be responsible for this phenomenon but an alternative explanation, assuming S_μ formation in "displacement spikes", is also given.

The initial S_μ content of the sublimated sulphur samples *decreased* on reactor irradiation.

No significant chemical difference was found between ^{32}P and ^{33}P after extraction from a solution of irradiated sulphur in CS_2 to a water phase.

The separation factor for a process where two atoms with recoil ranges r_1 and r_2 recoil from a spherical particle into a catcher phase surrounding the particle has been calculated and applied to the case of ^{32}P and ^{33}P recoiling from colloidal sulphur particles.

For a long time, ^{32}P has been one of the most frequently produced radioisotopes in nuclear reactors and the only isotope used as a radiotracer for phosphorus. Usually the isotope is made by irradiation of sulphur according to the endothermal reaction ^{32}S (n, p)^{32}P (I). Since the threshold energy for the reaction is 954 keV, fast neutrons must be used (Fig. 1).

In 1951, however, the new radioisotope ^{33}P was discovered in reactor-irradiated sulphur and the exothermal reaction ^{33}S (n, p)^{33}P (II) was found to be responsible for its formation [1–4]. Now, ^{33}P possesses properties which make it suitable for tracer applications and it is therefore of interest to produce as pure samples of ^{33}P as possible.

When preparing ^{33}P by irradiation of sulphur with neutrons, the only "impurities" introduced are ^{32}P and a large amount of ^{35}S formed by the exothermal reaction ^{34}S (n, γ) ^{35}S (III). This last "impurity", however, can always be removed chemically. Therefore the main problem is to get a high $^{33}P/^{32}P$ ratio in the irradiated samples.

Now Westermark [3] pointed out that ^{33}P, in contrast to ^{32}P, can be produced also by thermal neutrons, as seen from cross sections pictured in Fig. 1.

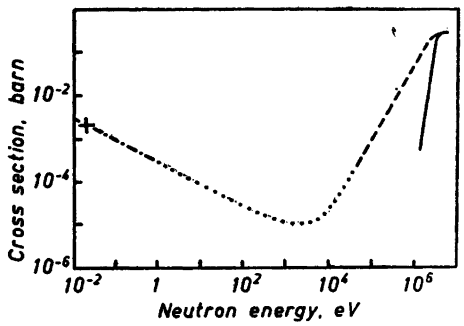

Fig. 1. Cross sections of the reactions ^{33}S (n, p) ^{32}P (I) and ^{33}S (n, p) ^{33}P (II).

———— *experimental cross section of reaction I according to Klema and Hanson* [5].
— — — — *cross section of reaction II calculated from the continuum theory* [6] *by B. Elbek* [7].
\+ *experimental cross section of reaction II according to Westermark* [3].
—·—·— *cross section of reaction II according to the "1/v law" for thermal neutrons.*

The cross sections indicate that an irradiation of a sulphur sample in the peripheral parts of a reactor where the thermal flux is high (compared with the fast flux) would give an optimum value for the $^{33}P/^{32}P$ ratio. One is thus forced to irradiate in a position where the activity of ^{33}P per gram sulphur becomes low. Furthermore, sulphur contains 95.1 % ^{32}S but only 0.75 % ^{33}S. This makes it difficult to establish a high $^{33}P/^{32}P$ ratio at all. Any method, chemical or physical which makes it possible to increase this ratio is therefore of value.

If, in order to get a high $^{33}P/^{32}P$ ratio, a sulphur sample is irradiated in a position where the ratio of thermal to fast flux is high, then the two isotopes are formed by neutrons with essentially different energies. This means that the most probable recoil energies of the isotopes are also different. As a result they might appear in different chemical states in the target, an effect which could be used to increase the $^{33}P/^{32}P$ ratio.

In order to study the $^{33}P/^{32}P$ ratio as a function of the distance from the centre of the reactor and the chemical state of the isotopes, several samples of sulphur were irradiated in the Norwegian D_2O-reactor at Kjeller.

EXPERIMENTAL

Measurement of sample activities

The content of ^{33}P, ^{32}P and ^{35}S in the samples was determined by absorption measurements in a standard geometry using aluminium foils as absorbers and an end-window G.M.-tube as detector (1.4 mg/cm² mica window). A thick aluminium backing established saturation backscattering in all cases and counting rates were corrected for dead time and background. Absorption curves were plotted according to Fig. 2, where I_0 is the extrapolated counting rate at 0 mg/cm². From this plot, the different activities were obtained using standard absorption curves for ^{32}P and ^{33}P. The ^{32}P curve was determined by absorption measurements on a nearly pure ^{32}P sample in the standard geometry. The corresponding ^{33}P curve was the result of measurements on samples containing ^{32}P, ^{33}P and very small amounts of ^{35}S.

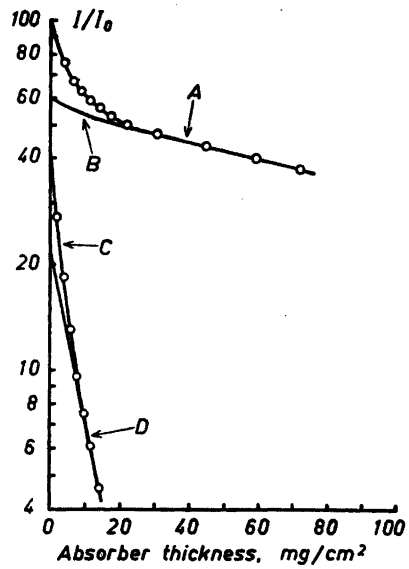

Fig. 2. Absorption curves in the standard geometry.
A = ^{32}P, ^{33}P *and* ^{35}S.
B = ^{32}P *standard curve.*
C = ^{33}P *and* ^{35}S.
D = ^{33}P *standard curve (half thickness 6 mg/cm²).*

The different activities obtained in this way were corrected for half life (*i. e.* the activities compared refer to a common time) and when necessary also for self-absorption in the samples. This method permitted a good comparison of the activities of the different sulphur samples. Since, however, no pure sample of ^{33}P was available, it was only possible to determine the absolute values of the ^{32}P activity with good accuracy.

Yields of the isotopes for different positions in the reactor

Since the ^{35}S activity was very high compared with the ^{33}P activity, it was not possible to determine the ^{33}P and ^{35}S contents by a direct measurement of the activities of the irradiated samples. From such measurements the ^{32}P activity and the sum of the ^{33}P and ^{35}S activities were obtained.

Samples for irradiation in the reactor were, however, prepared from sulphur containing a small amount of S_μ (*i. e.* amorphous sulphur) [6]. When dissolving such a sample in carbon disulphide and centrifuging the solution, it was found that a large amount of the radiophosphorus followed the insoluble S_μ-fraction. Since there was no or only a very small enrichment of ^{35}S in the S_μ-fraction (Table 1), this is a very simple way of separating a large amount of ^{32}P and ^{33}P from ^{35}S, *i. e.* samples were obtained in which the $^{33}P/^{32}P$ ratio could be determined. In addition, these samples had so low a weight per unit area (<1 mg/cm^2) that self-absorption for ^{33}P and ^{35}S could be neglected. If ^{32}P and ^{33}P, as seems reasonable, follow S_μ in proportion to their concentrations, then the $^{33}P/^{32}P$ ratio in the S_μ-fraction and the first measurement (mentioned above) give the amounts of ^{33}P and ^{35}S in the samples. The results are plotted in Fig. 3. They refer to irradiations in the reflector. Samples irradiated in the reactor tank are omitted, since the ^{33}P content was too low to be determined. The samples were irradiated for about 14 days at a reactor effect of 200–250 kW and the results refer to the end of the irradiation.

The carrier action of the S_μ-fraction on ^{32}P and ^{33}P

As previously mentioned, a large part of ^{32}P and ^{33}P was carried by the S_μ-fraction. The separation of S_μ was performed as follows:

Irradiated sulphur (0.5—0.6 g) was dissolved in 10 ml carbon disulphide. The insoluble S_μ was then collected on an aluminium foil by centrifuging in a special centrifuge tube. Before weighing and measuring the activity, the foil was placed for 5 min in pure carbon disulphide. The results are shown in Table 1.

Table 1. The carrier action of the Sμ-fraction of different samples on ^{32}P, ^{33}P and ^{35}S.

Sulphur sample	Distance from centre of reactor cm	% S_μ in sample	% Activity carried by S_μ		
			^{32}P	^{33}P	^{35}S

»	150	0.09	60	71	0.4
Cryst.	48	0.02	19	—	0.2
»	138	0.02	14	13	0.01

The treatment of the foils with CS_2, as described, resulted in a marked decrease in inactive sulphur and ^{35}S. The influence on ^{32}P and ^{33}P, however, was very small.

Some foils were placed for an additional 24 h in CS_2. Their weights, however, were unchanged and their total activities decreased by only 2—6 %; *i. e.* the results in Table 1 may be regarded as referring to S_μ.

A number of experiments was performed in order to find if ^{32}P and ^{33}P, in the form of phosphorus or a compound of phosphorus, were reversibly adsorbed on S_μ. This was done by studying the displacement of radiophosphorus from S_μ by phosphorus and different

phosphorus compounds added to the carbon disulphide solution. The time interval between adding the compound and centrifugation was about 30 min. The results are shown in Table 2.

Table 2. The displacement action of different substances on ^{32}P adsorbed on S_μ.

Substances added to the CS_2-solution	% of ^{32}P activity carried by S_μ

P_2S_3, P_2S_5, P_4S_7	67
P (yellow)	62
»	63
H_3PO_4	56
H_3PO_3	44

The solubilities of H_3PO_4 and H_3PO_3 in CS_2 are small, but certainly the concentrations become sufficient to partly displace the small amounts, if any, of radiophosphorus in the form of H_3PO_4 and H_3PO_3 adsorbed on S_μ.

Sublimated, unirradiated sulphur was added to an irradiated sample of low S_μ content in such an amount that the S_μ-fraction in the sample was doubled. This treatment, however, increased the amount of ^{32}P carried by only 2 %.

Separation of radiophosphorus as magnesium ammonium phosphate

An experiment of this type was performed to determine, if possible, the valency of the phosphorus isotopes in the sulphur target. It was thus necessary to prevent ^{32}P and ^{33}P from being oxidized in the separation process. For this reason, the process was carried out in a nitrogen atmosphere and all solutions added were saturated with nitrogen gas. The separation was performed as follows:

To a solution of irradiated sulphur in CS_2, an aqueous solution containing 0.2 mg/ml of each of H_3PO_4, H_3PO_3 and H_2SO_4 was added. The solution, contained in a tube, was shaken for 2 h in a mechanical shaker. Part of the water phase was separated through a filter and P(V) precipitated as magnesium ammonium phosphate. The addition of H_3PO_3 and H_2SO_4 was made to prevent adsorption of radiophosphorus as phosphite or ^{35}S as sulphate on the precipitate. It also prevented coprecipitation of radiophosphite.

The total amount of radiophosphorus extracted by the water phase was determined by oxidation of phosphite to phosphate by bromine water and precipitating P(V) as before.

Some experiments were carried out in exactly the same way but without protection against oxidation. The results are given in Table 3.

Table 3. The fraction of ^{32}P and ^{33}P extractable from a solution of sulphur in CS_2 to a water phase and the valency of the isotopes in that fraction.

DISCUSSION

In Fig. 3, A is a graph both of the yield of ^{32}P and also of the decrease of the fast neutron flux in the reflector. This is because reaction I requires fast neutrons. The fast flux, however, decreases more rapidly than the thermal flux and the reactions II and III have relatively large cross sections for thermal neutrons. The yields of ^{33}P (C) and ^{35}S (B), therefore, decrease more slowly and the $^{33}P/^{32}P$ ratio (D) increases with distance from the reactor core.

The most interesting result is that a large amount of radiophosphorus but almost no ^{35}S followed the S_μ-fraction (Table 1). Approximately equal amounts of ^{32}P and ^{33}P follow S_μ but the amounts seem to decrease with decreasing S_μ content of the irradiated sulphur.

At first sight this may be supposed to be due to adsorption of either radiophosphorus or a chemical compound of radiophosphorus on S_μ. However, addition to the CS_2 solution of phosphorus or some of the compounds most probably formed by radiophosphorus in this case had only a small effect (except for H_3PO_3) on the carried activity (Table 2). The increase in amount carried was also small after adding S_μ before dissolving the sample in CS_2. This seems to indicate that adsorption on S_μ of radiophosphorus in these chemical forms cannot alone be responsible for the carrying effect. Adsorption can, however, not be excluded. In any case it may be of value to discuss an alternative explanation:

A recoiling atom is assumed to melt or vaporize a small volume at the end of its track in a solid substance [9]. The local temperature in this "displacement spike" is very high and the quenching is very rapid [10]. This means that "displacement spikes" may also be produced in sulphur by recoiling ^{32}P, ^{33}P and ^{35}S atoms. It is further assumed that small aggregates of S_μ are formed by the rapid quenching of the "displacement spikes", in analogy with the formation of S_μ by the rapid quenching of sulphur vapour or liquid sulphur [8]. Radiophosphorus and ^{35}S trapped in these aggregates are difficult to extract by CS_2 and in the chemical operations the aggregates will follow the macro amounts of S_μ in the sample, *i. e.* the radioisotopes follow the S_μ-fraction.

Only radiophosphorus and hardly any ^{35}S follows the S_μ-fraction (Table 1). As seen from the following calculations, an explanation may be found in the different volumes of the "displacement spikes" produced.

The most probable recoil energies of ^{32}P and ^{33}P can be computed from the equation [11]

$$E_r = \frac{m_p}{M + m_p}\left[E_n\left(1 - \frac{m_n}{M + m_p}\right) + Q\right] \qquad (1)$$

where E_n is the neutron energy, m_n the mass of the neutron, m_p the mass of the proton and M the mass of the recoiling atom. The Q-values of the reactions are 925 (I) and 517 (II) keV [12]. The equation is valid if the compound nucleus has lost its recoil energy before emitting the proton [11]. This may be assumed to happen since the reactions take place in a solid substance [11].

When irradiating in the reflector, the ^{33}P atoms are most probably produced by neutrons having an energy of 0.025 eV, *i. e.* the most probable energy of the

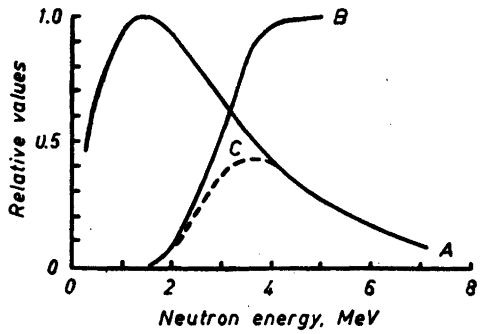

Fig. 4. Graphical determination of the most probable recoil energy of ^{32}P atoms produced in the reaction ^{32}S (n, p) ^{32}P (I) by neutrons of the fission spectrum (fast neutrons).

A = the flux of fission neutrons. The maximum of A is at a neutron energy of 1.4 MeV.
B = cross section of reaction I. The top of B corresponds to about 0.3 barns.
C = the product of flux and cross section. The maximum of C gives the most probable recoil energy of the ^{32}P atoms, i. e. *about 3.5 MeV.*

thermal flux at 20° C. This value gives a most probable recoil energy for the ^{33}P atoms of 15 keV.

It is more difficult to estimate the corresponding energy for ^{32}P. If the fast neutrons had the energy distribution of the fission spectrum [13], a graphical determination (Fig. 4) gives a value of about 3.5 MeV. The maximum of the fast flux in the reflector, however, is very likely at a lower energy. This means that ^{32}P is most probably produced by neutrons having energies between 3.5 and 0.954 MeV (the threshold value). Assuming 2.5 MeV for the neutron energy, the most probable recoil energy is 45 keV.

The recoil energy of the ^{35}S atoms can be calculated from the equation [14]

$$E_r = \frac{536\ E_\gamma^2}{M} \qquad (2)$$

where E_r is the recoil energy in electron volts, M the mass of the recoiling atom in atomic mass units and E_γ the energy of the emitted gamma ray in MeV. The number and the energy of the emitted gamma rays per neutron capture in reaction III, however, have not been determined. By extrapolation from a diagram by Kikuchi *et al.*[15], the maximum energy of the gamma rays is estimated to be 6 MeV, giving the ^{35}S atoms a maximum recoil energy of 0.55 keV. Since the mean number of gammas emitted per neutron capture in even Z-even N nuclei is about 1.7 [16], this value for the recoil energy is too high.

Maximum values of the melted volumes in the three cases can be crudely estimated by assuming that the recoil energy is entirely available for melting (this can be done since the recoil energy is of the same order of magnitude as the transition energy for melting as defined by Brinkman [9]) and that the energy necessary to melt sulphur at atmospheric pressure (about 0.02 eV/atom) [8] can be used. Under these assumptions the melted volumes produced by ^{32}P, ^{33}P and ^{35}S contain about 2×10^6, 8×10^5 and 3×10^4 atoms. Since each

sulphur atom occupies a volume [8] of 26 Å^3, these volumes, assumed to be spherical, would have diameters of about 460, 340 and 110 Å, respectively. Evidently a recoiling ^{32}P atom melts a volume more than ~70 times larger than that melted by a recoiling ^{35}S atom. The resolidification occurs with the surrounding S_α lattice acting as a crystallization nucleus. It is therefore most probable that a S_μ aggregate is formed in the centre of the melted volume — the probability of S_μ-formation increasing with the size of that volume. Assuming that the volumes melted by recoiling ^{35}S atoms are too small to produce S_μ-aggregates will explain why ^{35}S does not follow the S_μ-fraction to any great extent.

It may be pointed out that S_μ is also produced by recoil (knock-on) atoms formed in the slowing down of fast neutrons. An assumed formation of S_μ in these ways seems to conflict with the decrease in S_μ by reactor irradiation, the sublimated samples losing about 80 % of initial S_μ content whereas no change is found in the crystallized samples (Table 1).

In the first case the transformation of S_μ to S_α is evidently more effective than the assumed formation of S_μ in "displacement spikes". It is difficult to estimate the amount of S_μ formed but reasons for being small are:

1. Only a part of the energy of the primary knock-on atoms is effective in melting (*i. e.* their initial energy is larger than the transition energy for melting).

2. Only a small part of a melted volume is assumed to form S_μ.

It is known that S_μ spontaneously transforms to the stable modification [8] S_α. The transformation can be accelerated by heating, irradiation by X-rays and so on [8]. In our case irradiation must be responsible for the transformation since the temperature of the reflector was only 10° C. Maier-Leibnitz [17] and Erbacher [18] found a similar effect in the conversion of white phosphorus to the stable red form by the radiation from a Rn-Be source.

The transformation in the reactor of S_μ to soluble S_α means that a part of the radiophosphorus atoms trapped in S_μ are set free. It can be calculated (Appendix 1) that about 50 % are set free in this way assuming that the amount of S_μ formed can be neglected compared with the initial S_μ amount, *i. e.* that the rate of transformation is that shown by S_μ in the sublimated samples.

From the results given in Table 3 it is seen that the maximum amount of ^{32}P extracted from the CS_2-solution to the water phase was about 50 %. The amount of ^{33}P extracted was found in all cases to be smaller. Owing to the uncertainty in the determination of ^{33}P, it is hard to say whether this has any significance. The amount not extracted probably corresponds to ^{32}P and ^{33}P carried by S_μ.

The valency of extracted ^{32}P and ^{33}P is about the same, *i. e.* the difference in initial recoil energies seems to have no effect on the valency of the isotopes. This is to be expected since the chemical fate of a recoiling atom is determined when most of the recoil energy is lost, the initial energy being too high for any chemical compound to be formed [19].

The valency of the isotopes is not significantly altered by the precautions against oxidation. It is, however, probable that more rigorous precautions would have changed the results.

Thus, despite the difference in recoil energy, one can hardly expect to find ^{32}P and ^{33}P in different chemical states in the sulphur target. There they may exist as ions or atoms trapped within the lattice or in chemical combination with other atoms.

It is often assumed that the recoiling atoms are ionized and trapped as positive ions in the target. A good approximation to the upper limit of the kinetic energy at which a moving atom can be considered as un-ionized is $E = \frac{M}{m} I$ where M is the mass of the atom, m is the electronic mass and I is the ionization energy of the atom. The assumption made is that the atom loses all electrons whose orbital velocities are smaller than that of the recoiling atom. The ionization energy of the 3p electrons of phosphorus atoms is about 11 eV, *i. e.* the recoil energies of ^{32}P and ^{33}P must be at least 640 and 660 keV, respectively, in order to ionize the atoms. Comparing this with the maximum recoil energies ($E_n = 15$ MeV) of ^{32}P and ^{33}P (413 and 443 keV, respectively) shows that the ionic state can be excluded.

Owing to the high "temperature" of the atoms, it is more likely that they enter into chemical combination than that they become trapped as atoms in the target.

The phosphorus compounds most probably found in a sulphur target should be the sulphides. The concentration of radiophosphorus atoms, however, is so low (about 10^{13} atoms/cm^3) that the sulphides (all of them containing more than one P-atom) formed may be supposed not to have a stoichiometric composition. The atoms may also react with impurities in the target. In fact the chemical state of radiophosphorus in the target must to a large extent be a function of its purity and if the intention is to determine this state it must be very well protected in the separation process.

A better way of increasing the $^{33}P/^{32}P$ ratio than the chemical one seems to be a direct utilization of the differences in recoil range of the two isotopes in analogy with the separation of ^{198}Au from ^{197}Au by Magnusson [20] and ^{11}C from ^{12}C by Morinaga and Zaffarano [21]. In our case a similiar experiment is expected to be more difficult since both isotopes recoil.

An expression for the separation factor s has, however, been calculated (Appendix 2) for the case of two atoms with recoil ranges r_1 and r_2 ($r_2 > r_1$) recoiling from a spherical particle of radius R into a catcher phase surrounding the particle. The separation factor is defined as follows:

$$s = \frac{(N_1/N_2)_{\mathrm{I}}\ (\text{When } r_1 \neq 0 \text{ and } r_2 \neq 0)}{(N_1/N_2)_{\mathrm{II}}\ (\text{When } r_1 = r_2 \text{ or } R = \infty)} = \frac{(R + r_1/4)\ (R - r_1/2)^2}{(R + r_2/4)\ (R - r_2/2)^2} \qquad (3)$$

where N_1 and N_2 are the concentrations of the atoms in the particle. The separation factor varies between the R-axis ($r_1 = r_2$) and the solid curve ($r_1 = 0$, $r_2 \neq 0$) in Fig. 5. (The latter case corresponds to the separations made by Magnusson [20] and Morinaga and Zaffarano [21]). When $r_1/2 < R < r_2/2$, then all atoms with recoil range r_2 will leave the particle and the separation factor will be infinity. When $R < r_1/2$ both kinds of atoms will leave the particle. It is seen that s is more sensitive to variations in R than to variations in the value of r_2/r_1.

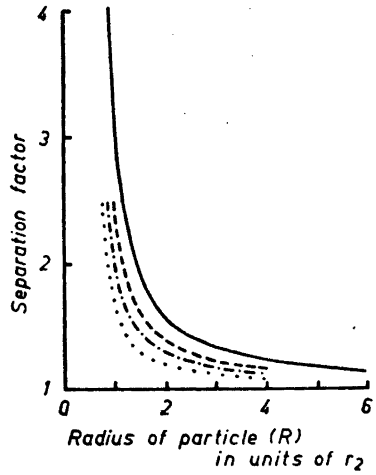

Fig. 5. The recoil separation factor for different values of r_2/r_1 *(the ratio between the recoil ranges) plotted as a function of particle radius. The particle radius is given in units of* r_2.

R — axis	r_2/r_1	$= 1.0$
. . . . .	»	$= 1.5$
—·—·—	»	$= 2.0$
— — —	»	$= 3.0$ *(our case)*
———	»	$= \infty$ $(r_1 = 0,\ r_2 \neq 0)$

The assumptions underlying (3) may be realized when ^{32}P and ^{33}P are produced for example by neutron irradiation of a sulphur sol. To determine s in this case the recoil ranges of ^{33}P and ^{32}P (r_1 and r_2) must be calculated. This can be done from the following equation [22] which is valid for $A_1 > A_2$ and thus probably only gives the right order of magnitude in this case:

$$r = 60 \frac{A_1 + A_2}{A_1} \sqrt{\frac{Z_1^{2/3} + Z_2^{2/3}}{Z_1 Z_2}} A_2 E_r 1/p \qquad (4),$$

where r is the recoil range in Å, E_r is the recoil energy in keV and p is the density of the absorber. (1 refers to recoil atom and 2 to absorber atom). Using the recoil energies calculated above (45 and 15 keV respectively), the most probable recoil ranges of ^{32}P and ^{33}P are 1 230 and 400 Å, respectively, *i. e.* $r_2/r_1 \sim 3$. The separation factor for this case is shown by the dashed curve in Fig. 5. Since sulphur sols with a particle radius of about 2 000 Å can be prepared [8], it would be possible to get a s-value of about 1.6. Trouble may, however, arise from the fact that the size of the particles in a sol increases with time and nothing is known about the behaviour of a sulphur sol in a strong radiation field. A disadvantage is that large volumes must be irradiated since the concentration of sulphur in such a sol is only a few percent. Also a large amount of ^{33}P recoils away from the sulphur particles, the loss being 48 % when $r_2 = 3r_1$ and $R = r_2/2$.

The author wishes to thank Dr. G. Aniansson for calling attention to the possibility of using the recoil phenomenon in a colloidal suspension, Miss Monica Sjöstedt for assistance with the experimental work and *The Swedish Atomic Committee* for financial support.

APPENDIX 1

Assume that R aggregates are formed and kFN are destroyed in the time interval from t to $t + \mathrm{d}t$, then

$$\mathrm{d}N = (R—kFN)\ \mathrm{d}t = (R—KN)\ \mathrm{d}t \qquad (1)$$

where N is the number of aggregates at the time t and F the neutron flux.

Integration gives:

$$N = N_0 \mathrm{e}^{-Kt} + R/K\ (1—\mathrm{e}^{-Kt}) \qquad (2)$$

where N_0 is the initial number of S_μ aggregates.

Assuming that the second term in (2) can be neglected compared with the first, then

$$\mathrm{e}^{-Kt_1} = 1/6 \qquad (3)$$

using the value for the decrease of S_μ in the sublimated samples in a time t_1 (Table 1).

The fraction of radiophosphorus set free in the same time is

$$f = \frac{Rt_1—R/K(1—\mathrm{e}^{-Kt_1})}{Rt_1} = 1—1/Kt\ (1—\mathrm{e}^{-Kt_1}) \qquad (4)$$

Combining with (3) gives $f = 0.54$.

APPENDIX 2

From a spherical particle will escape

$$n = \int C_1 \, w \, \mathrm{d}V \quad \text{recoil atoms/sec} \tag{1}$$

where C_1 is the rate of production of recoil atoms (atoms/cm^3 sec), $\mathrm{d}V$ the volume element and w the solid angle within which recoil atoms produced in $\mathrm{d}V$ escape from the particle.

Now $\mathrm{d}V = r^2 \sin\Theta \mathrm{d}\Theta \mathrm{d}\varphi \mathrm{d}r$ and it can be shown that

$$w = \frac{(r_1+r)^2 - R^2}{4r_1 r}, \quad (0<r_1<2R) \tag{2}$$

where r_1 is the recoil range, r the distance from the centre of the sphere to $\mathrm{d}V$ and R the radius of the particle. Then (1) transforms to

$$n = C_1 \int_0^{\pi} \int_0^{2\pi} \int_{R-r_1}^{R} \frac{(r_1+r)^2+R^2}{4r_1 r} \, r^2 \sin\Theta \mathrm{d}\Theta \mathrm{d}\varphi \mathrm{d}r = \pi C_1 r_1 (R^2 - r_1^2/12) \tag{3}$$

when $0<r_1<R$ and the same result is obtained when $R<r_1<2R$.

If two different atoms with recoil ranges r_1 and r_2 recoil from the particle then the ratio between their concentrations in the particle after a certain time would be

$$(N_1/N_2)_{\mathrm{I}} = C_1/C_2 \, \frac{4/3R^3 - r_1(R^2 - r_1^2/12)}{4/3R^3 - r_2(R^2 - r_2^2/12)}, \quad (0<r_1<r_2<2R) \tag{4}$$

If $r_1 = r_2$ or $R = \infty$, then $(N_1/N_2)_{\mathrm{II}} = C_1/C_2$, *i. e.* no separation would take place and a suitable definition of the separation factor would be

$$s = \frac{(N_1/N_2)_{\mathrm{I}}}{(N_1/N_2)_{\mathrm{II}}} = \frac{4/3R^3 - r_1(R^2 - r_1^2/12)}{4/3R^3 - r_2(R^2 - r_2^2/12)} = \frac{(R+r_1/4)(R-r_1/2)^2}{(R+r_2/4)(R-r_2/2)^2} \tag{5}$$

(It is assumed that the recoil atoms are stable but the same result is obtained for radioactive atoms).

Studies on the Extraction of Metal Complexes

XXII. The Complex Formation of Thorium with 1-Nitroso-2-naphthol and 2-Nitroso-1-naphthol

DAVID DYRSSEN, MARGARETA DYRSSEN and EBBE JOHANSSON

Research Institute of National Defence, Dept. 1. (FOA 1), Sundbyberg 4; Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The extraction of thorium with chloroform or hexone using 1-nitroso-2-naphthol and 2-nitroso-1-naphthol as complexing agents has been studied at 25° C. The perchlorate ion concentration in the aqueous phase was kept constant at 0.1 M.

The mean complexity constants are found to be $10^{8.50}$ for 1-nitroso-2-naphthol and $10^{8.30}$ for 2-nitroso-1-naphthol. These values are lower than for oxine, but higher than for acetylacetone.

It was shown by Fischer [1] in 1940 that the nitroso-naphtholates of transition metal cations like Fe^{2+}, Co^{2+}, Ni^{2+} and Cu^{2+} may be extracted into chloroform. It has also been reported by Harvey *et al.*[2] that plutonium(IV) gives a complex with 1-nitroso-2-naphthol, which is extractable with hexone (methyl *iso*butyl ketone) at pH 2, and we therefore expected that thorium could be extracted from aqueous solutions into chloroform or hexone using either of the two nitroso-naphthols as complexing agents. A study was carried out to confirm whether thorium was extracted in these systems and whether the data for the two-phase distribution of thorium as a function of the nitroso-naphtholate ion concentration would enable us to determine the complex formation between Th^{4+} and the nitroso-naphtholate ions. A summary of our data for thorium with other chelating agents was given in Part XXI [3] of this series.

EXPERIMENTAL

Only a few experimental details will be given here as the general experimental technique has been described in several previous papers of this series, *e. g.* Part VI [4]. In making our solutions we sometimes added 1 ml of 0.1 M sodium acetate per 15 ml to buffer our solutions. This small amount of acetate ion seemed to have no effect on the extraction of thorium. We are not entirely satisfied with our results on these systems as the mass balance ^{234}Th was not always very good (50—100 %; see Table 1, column 2). A possible

explanation is that even recrystallized analytical reagents might still contain some solid particles capable of adsorbing radioactivity. However, by centrifuging our solutions after shaking, we assumed that these particles did not interfere with the measurements of the distribution equilibria.

DATA AND EQUILIBRIUM CONSTANTS

The data are given in Table 1, and are plotted in Fig. 1. When the two-parameter method of Dyrssen and Sillén [5] was applied to the data it was found that a templet with a value of $b = 0.70$ fitted the experimental data very well for all of the nitroso-naphthol systems if it was moved parallel to the log q and $-\log[A^-]$ axes. In a plot of log q $-\log \lambda_4$ against $\log[A^-] + a$ (*cf.* Fig. 2 in Part V [5]) all data would consequently fall on the same curve.

Using this templet it was thus possible to determine the second parameter a for the complex-formation, as well as the distribution constants between chloroform and the aqueous phase, λ_4, of the uncharged, extractable thorium nitroso-naphtholate complexes. It is however assumed that complex formation in the aqueous phase is not greatly influenced by the presence of small amounts of the organic solvents.

The complexity constants are defined by

$$k_n = [MA_n]/[MA_{n-1}][A] \text{ or } \varkappa_n = [MA_n]/[M][A]^n$$

and the parameters a and b were so chosen that a defines the mean complexity constant

$$\sqrt{\varkappa_4} = 10^a$$

and $2b$ defines the mean spreading factor

$$k_n/k_{n+1} = 10^{2b}$$

Thus the approximate values of log k_n may be obtained from

$$\log k_n = a + b(5—2n)$$

The following sets of constants determine the distribution curves in Fig. 1:

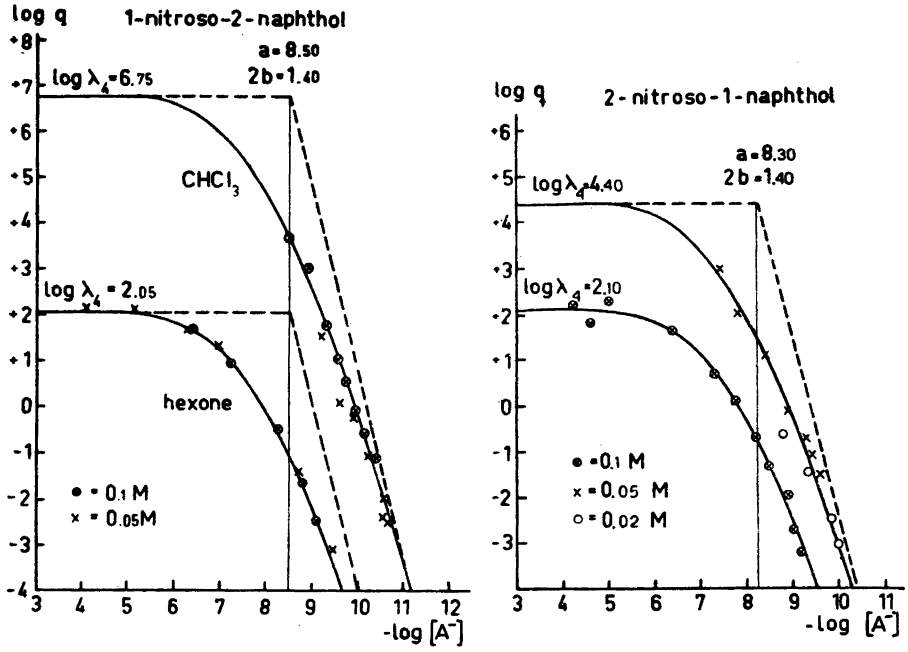

Fig. 1. The distribution ratio of Th-234Th as a function of the nitroso-naphtholate ion concentration in the aqueous phase. The fulldrawn curves are determined by the parameters λ_4, a *and* b, *and the broken lines by the equations log* $q = \log \lambda_4 + 4 \log[A^-]$ *and* $\log q = \log \lambda_4$, *(equations 7 and 8 in Part V[5]).*

For 1-nitroso-2-naphthol

$a = 8.50$; $2b = 1.40$
$\log \lambda_4 = 6.75$ for chloroform
$\log \lambda_4 = 2.05$ for hexone

For 2-nitroso-1-naphthol

$a = 8.30$; $2b = 1.40$
$\log \lambda_4 = 4.40$ for chloroform
$\log \lambda_4 = 2.10$ for hexone

STRENGTH OF COMPLEXES WITH 1-NITROSO-2-NAPHTHOL AND 2-NITROSO-1-NAPHTHOL

It was shown in Part XX[6] of this series that 2-nitroso-1-naphthol ($pk_a = 7.24$) is a stronger acid than 1-nitroso-2-naphthol ($pk_a = 7.63$) and consequently one would expect a lower value of the parameter a for the complex formation of Th with the former derivative. This seems to be the case, although the difference is not definitely outside the experimental error ($\pm$ 0.05 or 0.10).

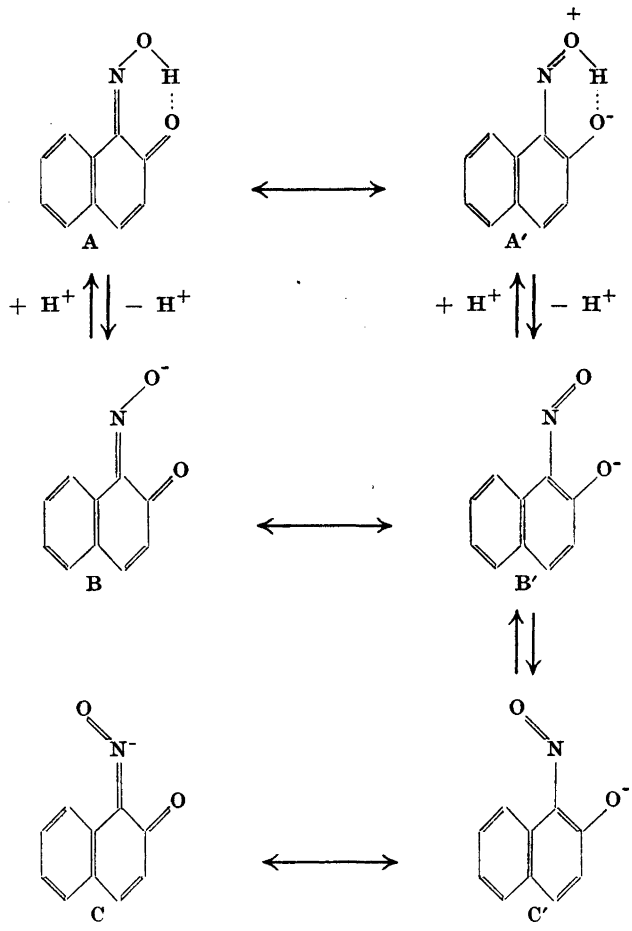
Jonassen and DeMonsabert [7] studied the zirconyl complexes of the two nitroso-naphthols in 50 % alcohol at pH 3.5 by a spectrophotometric method and concluded: "The d e c r e a s e in stability in the 1-nitroso-2-naphthol complex as compared to the 2-nitroso-1-naphthol is to be expected from a comparison of the reactions of α- and β-naphthols". The relation between the "instability constant", K, of these authors and the complexity constant k_1 defined above is

$$K = [ZrO^{2+}]\ [HA]/[ZrOA^{+}] = [H^{+}]/k_1k_a$$

From Jonassen and DeMonsabert's values of K and $[H^{+}]$ we obtain

$$k_1k_a = 10^{0.1 \pm 0.05} \text{ for 1-nitroso-2-naphthol}$$
$$k_1k_a = 10^{0.6 \pm 0.05} \text{ for 2-nitroso-1-naphthol}$$

The values of k_a are approximately $10^{-7.6-\delta}$ and $10^{-7.2-\delta}$ for the two nitroso-naphthols, respectively, where a value of $\delta \sim 0.5$ may be estimated from a value of $k_a = 10^{-8.7}$ for 1-nitroso-2-naphthol in 96 % alcohol [8]. We then arrive at $k_1 = 10^{8.2 \pm 0.05}$ for the complex formation of ZrO^{2+} with 1-nitroso-2-naphthol and $k_1 = 10^{8.3 \pm 0.05}$ for the 2,1 derivative, *i. e.* again in this case there is no significant difference between the two constants.



FORM OF THE CHELATE RING

In Part XX [6] we concluded that the two nitroso-naphthols should be regarded as quinone oximes having the structure A. It was also concluded that a structure A′ might contribute to a mesomeric state. Even if it seems to be well established that the proton forms a six-membered chelate ring with the nitroso-naphtholate ion, this does not necessarily have to be the case with metal cations, *i. e.* the nitroso-naphtholate ligand may have the form C$\leftrightarrow$C′ in these complexes. Feigl [9] has critically reviewed various opinions on this topic, and he accepted the form C on the basis of Pfeiffer's studies on nickel with dimethylglyoxime and similar compounds. Godycki *et al.*[10] have proved the existence of a five-membered ring in nickel dimethylglyoxime and have shown that it is stabilized by two short hydrogen bonds. However, such bonds cannot be formed in the case with the nitroso-naphthols. On the basis of the stability of the cobalt(III)complexes with 1-nitroso-2-naphthol and its 3,6-disulfonate in acid Feigl [9] also postulates a pH-dependent tautometric equilibrium. Studies by West [11] indicate, however, that this stability is due to a very slow exchange between cobalt and the proton.

No deductions about the size of the chelate ring can be made from the value of a as it lies between the value for oxine ($a = 9.70$), which forms a five-membered chelate ring (*cf.* Part XXI [3]), and the value for acetylacetone ($a = 6.70$), which forms a six-membered ring. X-ray measurements may settle this question.

CHOICE OF SYSTEM FOR EXTRACTION

The choice of a system for the extraction of thorium is somewhat arbitrary. If the price of the reagent is considered important one would choose 1-nitroso-

2-naphthol, and if one wants an organic solvent that is lighter than water one would choose hexone.

It is probably unimportant which of the nitroso-naphthols one chooses for the separation of metal cations. A few experiments were carried out with 1-nitroso-2-naphthol in order to see if Th^{4+} could be separated from UO_2^{2+} and trivalent ions such as La^{3+} and Sm^{3+}. These experiments revealed that the UO_2^{2+} ion was extractable, but that the trivalent ions were not. Fifty percent of the uranium was extracted at $-\log[H^+] = 3.07$ with an 0.1 M solution of 1-nitroso-2-naphthol in chloroform; the corresponding value for thorium was 1.66. Thus it is possible to separate Th^{4+} and UO_2^{2+} at pH 2, and it is also possible to separate these two ions from the trivalent ions at pH 4. Other metals that have been extracted with either of these nitroso-naphthols [1,2,13] are: Mn(II), Fe(II), Co, Ni, Cu(II), Pd(II), Ag, Cd, Hg(II) and Pu(IV).

In many cases it is important to extract in a low pH-range. This range is approximately defined by

$$\tfrac{1}{4}\log K = \log[H^+] - \log[HA]_{org} = \tfrac{1}{4}\log \lambda_4 + a - pk_a - \log k_d$$

The above equation was discussed in Part VIII [12]. The following values of $\tfrac{1}{4}\log K$ may be calculated for the four systems:

1-nitroso-2-naphthol and chloroform:	−0.41
1-nitroso-2-naphthol and hexone:	−1.17
2-nitroso-1-naphthol and chloroform:	+0.05
2-nitroso-1-naphthol and hexone:	−0.64

For a given value of $[HA]_{org}$ extraction occurs in the lowest pH range for the third system. It is also apparent that chloroform is the better solvent in this respect.

We wish to thank Professor G. Ljunggren and Professor L. G. Sillén for their interest in this work, which has partly been supported by *Atomkommittén*.

The Melting Temperatures of 66/6 Copolyamides

SVEN SÖNNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

A series of 66/6 copolyamides have been prepared by hydrolytic condensation polymerization. Methods of purification and identification of macroscopic melting points are described. Factors, influencing the numerical value of the melting temperature, are discussed. Measurements, carried out on isotropic samples, show appreciable discrepancies from reference values in some cases.

The existence of sharply measurable melting temperatures of polyamides, polyesters and polyurethans is a notable exception from the general behaviour of high polymers. In most cases the melting points of these substances can be observed in the same way and with the same degree of accuracy as on corresponding monomers. This should be compared with the general case, where fusion without decomposition is a rare phenomenon, and, in the best cases, occurs over a range of temperatures. In terms of molecular structure, the temperature of melting is depending on the equilibrium degree of crystallinity. From thermodynamical point of view it is thus convenient to consider the melting as a first order transition where crystallinity completely disappears, and the melting temperature as the highest one, where traces of crystallinity can be detected [1].

Even if this idea is a sound basis for theoretical considerations, experimental difficulties limit the application. The precision of the measurements should be largely depending on the sensitivity of the method employed to detect traces of crystallinity, a circumstance giving preference to combined dilatometric and optical methods. The dilatometric method implies observation of the phase transition in the presence of a diluent. But in the case of polyamides inert, high boiling diluents are uncommon, and, moreover, the 6 polymer releases its equilibrium amount of monomer (caprolactam) at elevated temperature, which interferes with the solvent action of the diluent. It does not seem likely that a dilatometric measurement would give a higher degree of accuracy than a direct observation of the melting process, provided that proper directions are observed to obtain a reproducible structure of the samples. The more important details will be shortly discussed here.

Polyamides and polyesters may show very divergent degrees of crystallinity, even in the isotropic state, but before all in oriented specimens, such as extruded, quenched filaments and cold drawn or annealed fibres. The macroscopic melting point is depending on the difference in crystallinity. This dependence of the prehistory of the polymer has been observed to be valid for many macromolecular substances, but it is especially clearly expressed in a recent investigation on polyester fibres [2], where a gradual increase in melting point of 3° C is observed by a penetrometer technique, when the degree of crystallinity is increased from 38 to 65 %. The simplest way to avoid the influence of the crystallinity is, of course, to prepare all samples in an identical equipment and allow the molten polymers to solidify at rest by rapid cooling. Equivalent result would be obtained by dispersing the polyamide in a good solvent, such as formic acid, and gradually adding a non-solvent (acetone or water) until incipient precipitation occurs. At this stage a large amount of the nonsolvent is added, sufficient to cause a complete separation of the polymer.

An even more important source of error, however, is the inherent sensitivity of polyamides to oxydation in air, even before melting. Chips of 66 nylon melt sharply at 264° C in the absence of air, but as low as 248—256° on a melting block Maquenne [3,4]. Unfortunately 66 nylon shows the highest melting point and the least thermal stability of all the actual polyamides [6]. Pure 6 nylon, poly-(ε-caproamide), melts at 214° C in equilibrium with its monomer, which partly prevents an oxidation on the phase boundary. But the application of an inert atmosphere is necessary even here on prolonged heating.

It seems difficult to find a satisfactory explanation for the large difference in melting temperatures between 6 and 66 nylon. If we start from the general formulation of melting point as a ratio between latent molar heat of fusion and entropy of fusion of the repeating unit, a fairly small difference would be expected, as seen from the following formula of the building sequences:

$$\underbrace{\text{—(CH}_2)_4\text{—CO—NH—(CH}_2)_6\text{—NH—CO—}}_{\text{Repeating unit of 66 nylon}} \qquad \underbrace{\text{—NH—(CH}_2)_5\text{—CO—}}_{\text{Repeating unit of 6 nylon}}$$

The two units show identical ratios between polar and non-polar groups. If any difference exists in the entropy change on fusion, the largest change would occur in the case of 66 nylon with asymmetric distribution of methylene groups.

The question has recently [5] been discussed from other points of view. In short, it seems clear that the "odd-even" effect, known from other homologous series of organic compounds, is of primary importance. At the ends of an odd methylene sequence, the bonds to the amide groups are inclined at an angle of 112°, when the ends of an even sequence are parallell. The analogy with energetic differences, arising from *cis* and *trans* isomerism, is apparent. Even if an exhaustive explanation is still remote, it is sufficient here to establish that steric differences between the structural units makes a mutual space unit cell impossible (isomorphous replacement). Condensation polymerization of caprolactam with increasing amounts of hexamethylenediammonium adipate would thus lead to a decrease in the melting point of the copolymer until a

minimum is reached. At still higher contents of 66 salt, a gradual increase in melting point is expected up to the limit (264° C) found only for the pure 66 polymer.

Copolymers are somewhat rubbery in character before melting, a factor making the temperature of phase transition more difficult to observe. Slow heating is essential. The melt viscosity also appears to be higher than for pure

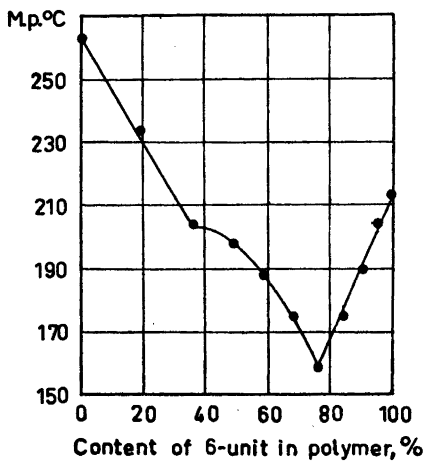

Fig. 1. The melting point of 6/66 copolyamides, according to the present investigation.

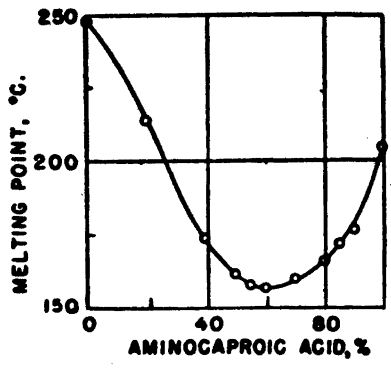

Fig. 2. The melting point of 6/66 copolyamides according to Reynolds [3] and Catlin et al.[4] Reproduced by permission from the Journal of Polymer Science.

polymers in the same range of molecular weight. This is most clearly expressed in the relation, found by Flory [7]:

$$\ln \eta = A + B\ M_w^{1/2} + E/RT$$

where η indicates the melt viscosity in arbitrary units, A and B constants, M_w the weight average molecular weight, E the activation energy of flow, R the gas constant and T the temperature in Kelvin units.

The discussion above has the purpose of searching out the main difficulties in carrying out melting point determinations on polyamides and copolymers. In the experimental part, the preparation and purification of a number of 66/6 copolyamides are described. On determination of their melting points, fairly large deviations are found from the figures in earlier references [3,4]. (Table 1, Figs. 1 and 2). The discussion above may be a guide to find an explanation for this discrepancy.

EXPERIMENTAL

Synthesis of 66/6 copolyamides, including pure 6 polymer.

Apparatus: Tubes of stainless steel, fitted with a cover and a needle valve as an in- or outlet for inert gases and water vapour. The steel tubes are shaped to contain a standard Pyrex test tube with an approximative volume of 50 ml.

Heating device: A cylindrical block of aluminium on an electrically heated plate. The metal cylinder contains six bores for the steel tubes at equidistant positions from the centre, where automatic control of temperature is applied.

Chemicals: *Caprolactam*, recrystallized from ethyl acetate and dried in a slow current of carbon dioxide at room temperature. Added to the reaction mixture as a saturated (80 % b. w.) aqueous solution.

Hexamethylenediammonium adipate. The commercial grade ("nylon salt") was dissolved in distilled water to give a 40 % aqueous solution. After filtering through a Pyrex C glass filter the solution was poured into a large excess of methanol. The transparent, large crystals appeared fairly slow, and only a main fraction was collected and dried in the same manner as the 6 monomer.

Schedule of reaction: Temperature range: 260—265° C. Time of hydrolytic polymerization step: 120 min. Gradual release of pressure and removal of water at atmospheric pressure: 120 min. Cooling to room temperature: 240 min.

Note: The water, removed from the reaction mixture, contains a noticeable amount of caprolactam. It was collected for determination of caprolactam, together with the water used in the subsequent purification of crude polymer.

Purification: The solid polymers are easily knocked free from the test tubes, especially if these earlier had been coated with a thin layer of a silicone oil. The rods were cut into pieces by sawing. The "sawdust" was collected and extracted in hot water for 24 hours together with the residue. After filtering the powder was dried, sieved and used for melting point determination. As a parallel test the large parts were dissolved in formic acid, precipitated with methanol, washed and dried. No difference in melting temperature was detectable even by the mixing of the two fractions. — The mother liquor was evaporated on a waterbath at reduced pressure. The residue was extracted with cold water. This fraction showed the melting point of caprolactam (70 °C) after recrystallization in ethyl acetate. The smaller, insoluble fraction was not studied further in this connection, but according to earlier work [8,9] its main components should be lower cyclic and linear oligomers. The amount of ε-aminocaproic acid formed during the reaction is known to be very low at high degrees of polymerization [8]. In fact, no change in solid content could be observed, when the water soluble fraction was passed over an anion exchanger of the strongly alkaline type. This seems to be in agreement with earlier work [9].

The precipitated polymers were also used for the determination of viscosity number (1 % solutions in 85.0 % formic acid at 20.0° C in an Ubbelohde viscometer).

Melting point determinations: A thin semimicro test tube was placed at the centre of a 50 ml Pyrex tube, containing a light silicone oil. The specimen in the inner tube was observed with a large pocket lens. Heating was carried out by an infrared furnace with a reflecting mirror as a bottom. The rate of heating was less than one degree min^{-1} above 150° C. A calibrated thermometer was selected with such a diameter as would just fill up the remaining volume of the inner test tube. Air was removed by flushing with dry carbon dioxide.

Preparation of Flavin Adenine Dinucleotide by Paper Electrophoresis

OTTO WALAAS and EVA WALAAS

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

Satisfactory separation of flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN) and riboflavin has been carried out by paper electrophoresis. By the same method FAD is separated from adenine nucleotides and pyridine nucleotides. Paper electrophoresis has been employed in the final fractionation of FAD from bakers' yeast. The FAD obtained is pure, judging from absorption measurement and enzymatic testing in the D-amino acid oxidase system. The fluorescence of FAD was 20 % of that of pure FMN.

The preparation of pure FAD * from bakers' yeast was originally carried out by Warburg and Christian [1]. Whitby [2,3] and Siliprandi and Bianchi [4] have recently given a summary of the modifications which have been employed later in order to produce a product with a higher yield. The main problem is to separate FAD from other nucleotides in the latter stages of the fractionation. A complete purification has not been achieved by paper chromatography [5], adsorption chromatography on alumina or powder cellulose [2]. A completely pure FAD was prepared by ion exchange chromatography followed by column electrophoresis [4]. As previously mentioned [6], we have prepared pure FAD by using paper electrophoresis in the final purification of FAD extracted from bakers' yeast.

EXPERIMENTAL

Paper electrophoresis. An apparatus similar to that described by Foster [7] has been used. In most experiments Whatman No. 1 filter paper was employed. Three strips of filter paper, 30 cm × 8 cm, were used simultaneously. The material to be separated was applied to the paper by means of an Agla micrometer syringe (Burroughs Wellcome Ltd.) and a volume of 10 μl was applied 5 cm from the end of the paper strip and dried in a stream of air. Repeated applications could be carried out. The strips were wetted with buffer and placed on the glass plate and connected with vessels each containing 400 ml

* Abbreviations: FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide; A-5-P, adenosine-5-phosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; DPN, diphosphopyridine nucleotide; TPN, triphosphopyridine nucleotide.

buffer. Each vessel was connected with another by means of a siphon filled with buffer. Carbon electrodes connected to a source of direct current were placed in the latter vessels. The voltage could be regulated by means of a transformer which permitted the use of 200—750 V. Usually 600 volt was employed which gave a potential gradient of 20 V per cm and a current of 5—10 mA, and the experiment was run for 4—5 hours. Cooling was achieved by the circulation of tap water through glass tubes attached to the bottom side of the lower glass plate. This prevented condensation on the upper glass plate covering the apparatus.

After each run the paper was dried in a stream of air. Riboflavin and its derivatives were detected under the fluorescent lamp. Other nucleotides were detected by photography in ultraviolet light [8]. Elution and quantitative estimation of the different products [9] were also carried out. Pieces of paper, 1 × 2 cm, were cut from the starting line and successively in the longitudinal direction of the paper, and each piece eluted with 4 ml of distilled water for 30 min. The spectra of the eluates in the ultra-violet, and near ultra-violet region, were determined using a Beckman spectrophotometer model DU. For the quantitative determination the absorptions at 260 mμ, 375 mμ and 450 mμ were used. By this method 90 % of the material was eluted from the paper. For analytical separation 20—50 μg FAD was applied to each spot. However, as much as 0.5 mg could be purified at the time in this apparatus.

For the preparative purification of larger amount of FAD an apparatus for continuous electrophoresis on paper was employed [10]. Isolation of dry FAD was achieved by freeze-drying the collected fractions.

In the experiments designed to test the possible separation of FAD from other nucleotides, the following materials from "Sigma" Chemical Company were used: A-5-P, ADP, ATP, DPN, TPN, FMN (synthetical product), riboflavin. FAD was prepared from bakers' yeast.

RESULTS

As shown in Fig. 1 complete separation of FAD, FMN and riboflavin was achieved at a pH near neutral both in phosphate buffer and ammonium acetate buffer. Furthermore it appears that the method permits the separation of FAD from DPN, TPN, A-5-P, ADP and ATP. The migration of the two latter compounds was so rapid that they moved off the paper in the time employed.

FAD was prepared from bakers' yeast as described by Warburg and Christian [1]. The main problem in obtaining pure FAD consists of the removal of other nucleotides which contaminate the preparation at a later stage in the fractionation.

Separation by paper electrophoresis was attempted after the stage in which the silver-salt of FAD was decomposed. As shown in Fig. 2 two products with absorption maximum at 260 mμ were found in addition to FAD. FMN was not present. The first peak corresponded to DPN, its presence was verified enzymatically by the alcohol dehydrogenase assay. The fastest moving substance corresponded to the position of TPN and A-5-P. Enzymatic assay with glucose-6-phosphate dehydrogenase gave, however, no evidence for the presence of TPN. FAD was somewhat contaminated by the other components as the ratio R between the light absorption at 260 mμ and 450 mμ was 5.6 calculated from the spectrum. At this stage in the fractionation, however, further purification of FAD was achieved by two-dimensional electrophoresis, initially at pH 3.4 and finally at pH 6.8. It was however more advantageous to continue the fractionation of crude FAD until the extraction with cresol. Electrophoresis at this stage showed the amount of contaminating ultraviolet absorbing

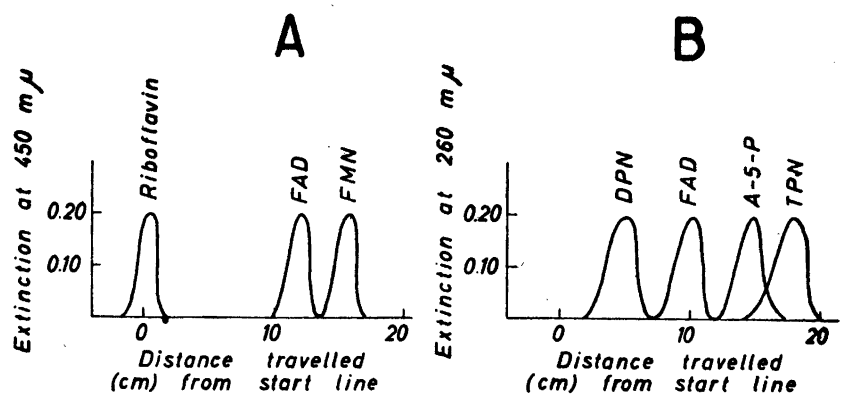

Fig. 1. A: Separation of riboflavin, FAD and FMN by paper electrophoresis. Ammonium acetate pH: 6.8. 5 hours, 600 V, 6 mA. B: Separation of FAD, DPN, TPN, A-5-P by paper electrophoresis. Ammonium acetate pH: 6.7. 4 ½ hours, 600 V, 10 mA.

material to be considerably reduced. Complete purification of FAD was achieved (Fig. 2) in ammonium acetate between pH 6—7, the best results obtained at pH 6.7.

DISCUSSION

As mentioned elsewhere [6] the activity of the D-amino acid oxidase is inhibited by nucleotides. Further, anions strongly dissociate the coenzyme-protein complex in the "old yellow enzyme" [12] and D-amino acid oxidase [6]. Thus in studies on flavin enzymes it is of importance to work with pure coenzymes. The electrophoretic separation of FAD obtained after cresol extraction, in ammonium acetate which is easily removed afterwards by evaporation, solves this problem. The great loss which accompanies the crystallization is avoided, and the method is of value as long as synthetic FAD [13] is not available for

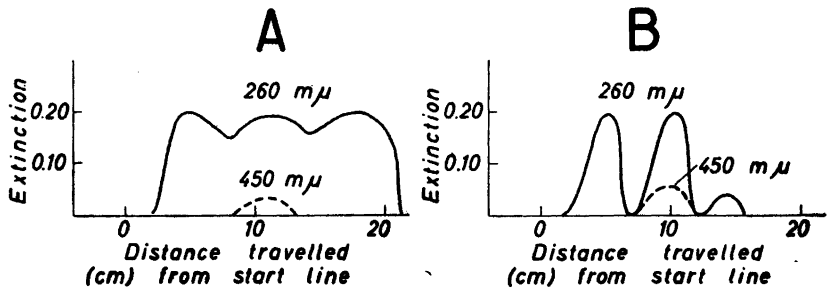

Fig. 2. Purification of FAD extracted from bakers' yeast by paper electrophoresis. A: After decomposition of the silver salt of FAD. Ammonium acetate pH:6.4, 6 hours, 600 V, 12 mA. B: After extraction of FAD with cresol. Ammonium acetate pH: 6.7. 4½ hours, 600 V, 15 mA.

ordinary work. Electrophoresis on paper for the purpose of analytical work also gives better separation of flavin derivatives than by paper chromatography [14].

The FAD prepared was not contaminated with ultraviolet absorbing material. Thus R = 260 mμ/450 mμ was for several samples at pH 7.0 between 3.30 and 3.40. R values previously quoted are 3.38 [1], 3.35 [2] and 3.275 [4]. Enzymatic testing of FAD in the D-amino-acid oxidase system with a highly purified apoenzyme [15] gave $K_M = 1.2 \times 10^{-7}$ M at pH 8.3 and 38° C. This is in accordance with Warburg and Christian [1] who under the same experimental conditions found $K_M = 1.4 \times 10^{-7}$ M.

By reduction of FAD with $Na_2S_2O_4$ the absorption at 450 mμ is reduced by 90 %. The fluorescence of FAD was 20 % of that of FMN purified by paper electrophoresis. 90 % quenching of the fluorescence of FAD occurred when $Na_2S_2O_4$ was added. Previous figures quoted for the fluorescence of FAD as compared to FMN are 20 % [11] and 9 % [7]. In the latter work FAD was not completely pure and the result can be explained by the well known quenching effect of nucleotides on the fluorescence of riboflavin and riboflavin derivatives [18,16].

Kinetics and Equilibria in Flavoprotein Systems

V. The Effects of pH, Anions and Partial Structural Analogues of the Coenzyme on the Activity of D-Amino Acid Oxidase

EVA WALAAS and OTTO WALAAS

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The effect of pH, anions and partial structural analogues of flavinadeninedinucleotide (FAD) on the activity of D-amino acid oxidase has been studied. The results suggest that the phosphoryl residues in FAD are linked to the apoenzyme. Furthermore it appears that the adenin residue as well as the ribosyl moiety of FAD takes part in the binding of the coenzyme to the surface of the protein. In contrast to some other flavin enzymes, the NH(3) group in *iso*alloxazine does not appear to be bound, because the D-amino acid oxidase is fluorescent.

The dissociation constant of the enzyme is lower at pH 9.2 ($K_M = 6 \times 10^{-8}$ M) than at pH 8.3 ($K_M = 1.2 \times 10^{-7}$ M). The experiments indicate a closer binding of coenzyme-protein at pH 9.2 than at 8.3. This may be a general phenomenon where flavin enzymes are concerned since the velocity of the association reaction between flavinmononucleotide (FMN) and the protein in the "old yellow enzyme" also increases in the pH region around 9 [1].

FMN and adenin nucleotides exhibit a pronounced inhibition of a competitive type. The inhibition is also shown by anions, the anions of strongly dissociated acids being the most effective inhibitors. The importance of these results on the physiological regulation of the enzyme activity is discussed.

Investigations carried out by Theorell and co-workers have shown that a number of anions affect the binding of coenzyme-apoenzyme, and thereby the velocity of the enzyme reactions. This has been demonstrated in the case of flavin enzymes such as the "old yellow enzyme" [1] and D-amino acid oxidase [2]. The same applies in the case of DPN- or TPN-linked enzymes such as alcohol dehydrogenase [3] and glucose-6-phosphate dehydrogenase [4]. The fact that enzymes are inhibited by partial structural analogues of the coenzyme has been shown in D-amino acid oxidase [5,2] and dehydrogenases [6,7].

A more thorough examination of the inhibitory effect of anions and substances structurally related to the coenzyme FAD on the D-amino acid oxidase has been carried out in the present work. The qualitative and quantitative nature of the inhibition has been characterised. The importance of these facts for the binding of coenzyme-apoenzyme is discussed.

METHODS

A highly purified apoenzyme of the D-amino acid oxidase from pig kidneys was prepared according to the method of Negelein and Brömel [8]. The lyophilized product has retained its activity unchanged for more than one year stored in a desiccator at + 1° C.

FAD was extracted from yeast as reported by Warburg and Christian [9] and purified until the cresol extraction stage. The further purification was carried out by paper electrophoresis [10] as shown in a previous paper. A pure preparation of FAD free from other nucleotides was obtained.

Activity measurements were carried out with D,L-alanin as substrate in the Warburg apparatus. The reaction mixture contained: 20 μg apoenzyme dissolved in 0.02 ml buffer, FAD in varying concentrations, most frequently 0.14 μM, 1 ml buffer, either M/10 pyrophosphate buffer pH 8.3 or M/10 glycine buffer pH 9.2. The reaction was started by introducing 0.2 ml 0.5 M D,L-alanin from the sidearm. Total volume was 3.6 ml. The enzyme activity was measured at 38° C. The O_2-consumption exhibited linear correlation with time for 30 min.

The inhibitors were dissolved in M/20 pyrophosphate buffer pH 8.3 and the pH of the solution adjusted to pH 8.30 when necessary. The final concentration of buffer in the incubation mixture was 0.028 M. A similar procedure was used with glycine buffer at pH 9.2 and other pH values. The inhibition was examined at two or more concentrations of inhibitor and with three or more concentrations of FAD in each experiment.

The following substances were used: FMN, synthetically prepared by "Sigma" Chemical Company. The product was purified by paper electrophoresis. The following preparations were also from "Sigma" Chemical Company: Adenylic acid (A-5-P), adenosine diphosphate (ADP), adenosine triphosphate (ATP), inosinic acid (I-5-P). The Ba-salts were converted to Na-salts by means of a cation-exchanger (Amberlite 120).

Other products used were: Ribose phosphate (R-5-P) (Schwarz), adenine (Hoffman-La Roche), adenosine (Hoffman-La Roche), hypoxanthine (Hoffman-La Roche), cytosine (Dougherty Chemicals), uracil (Eastman Kodak Company), imidazole (Eastman Kodak Company). Riboflavin from Hoffman-La Roche was recrystallised before use. Diphosphopyridine nucleotide (DPN) was prepared by Dr. R. K. Bonnichsen and had a degree of purity of 0.75. The fluorescence measurements were carried out on the apparatus constructed and described by Theorell and Nygaard [11].

Calculations [12,13]. Plotting of the reciprocal value of the reaction velocity (O_2-consumption), v, against the reciprocal value of the molar concentration of FAD resulted in a straight line. "Slope" and "intercept" on the $(1/v)$-axis were thereby determined. When the inhibition is competitive, the two curves which represent the reaction in the presence and absence, respectively, of inhibitor have a common intercept, but different slopes [14]. The inhibition constant K_I was calculated from the equation

$$\text{Slope} = (K_M / v_{Max}) \ (1 + [I] / K_I)$$

where: K_M = Michaelis constant

$1/v_{Max}$ = Intercept of the $(1/v)$-axis

$[I]$ = The molar concentration of inhibitor.

RESULTS

Absorption spectrum and fluorescence of D-amino acid oxidase

The fluorescence of FAD at neutral pH is 20 % of that given by FMN [10]. This quenching of the fluorescence of FAD is assumed to be due to a binding between the NH(3)-group in the *iso*alloxazine ring and the adenine part of the molecule (Bessey, Lowry and Love, 1945) [15]. These authors showed that on titration of FAD to lower pH value, an increase in the fluorescence took place. As seen in Fig. 1 the fluorescence of FAD decreases on titration in the alkaline

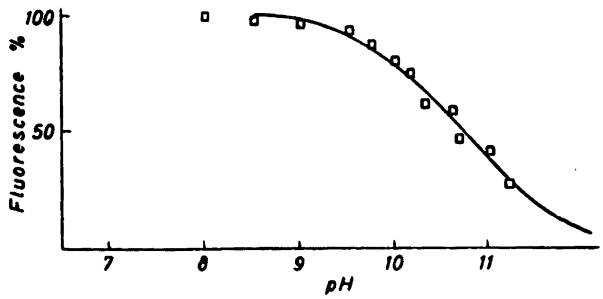

Fig. 1. The fluorescence of FAD at alkaline pH.

□ : *The fluorescence (Expressed in per cent of fluorescence at pH 7)*
———: *Theoretical titration curve* pK' = *10.5*

region. The points fit approximately a titration curve with pK' 10.5. Thus the quenching of the fluorescence at alkaline pH is probably due to the dissociation of the NH(3)-group. Similar results are shown for FMN[1], where the fluorescence decreases according to a titration curve with pK' 10.2.

When combining FAD with the apoenzyme, no quenching of fluorescence in the pH interval 7—9.5 occurred. Thus the D-amino acid oxidase is a fluorescent enzyme. Straub's diaphorase [16] behaves in a similar manner, while the apoenzyme in the "old yellow enzyme" produces quenching of the fluorescence in FMN, probably while the NH(3)-group in the *iso*alloxazine ring is bound [17]. This also applies to most other flavin enzymes [18]. Thus there is no evidence in the case of D-amino acid oxidase to prove that any binding of apoenzyme to free NH(3)-groups takes place.

Under aerobic conditions, no definite changes in the absorption spectrum either at 375 mμ or 450 mμ of FAD were found when combining with the apoenzyme. On the other hand, in accordance with previous investigations [8] a reduction in the absorption at 450 mμ of the reduced enzyme was found under anaerobic conditions.

Dissociation constant for FAD-apoenzyme

The dissociation constant for FAD-apoenzyme has previously been measured by activity determinations and is found [9] at 38° C to be 2.7×10^{-7} M at pH 8.3 in pyrophosphate buffer. It has been recalculated [19] to 1.4×10^{-7} M by taking into account the free amount of FAD which is present at equilibrium. In cases where the apoenzymes are of a greater degree of impurity, values quoted for K_M are [19,12] 4.7×10^{-7} M and 4.6×10^{-7} M, under the same conditions.

A reexamination of K_M at different pH's and in different buffers is carried out in this work. It appears from Fig. 2 that when the apoenzyme is approximately half saturated with FAD the pH-activity curve differs in pyrophosphate buffer and glycine buffer. The statement [20] that the enzyme in pyrophosphate buffer exhibits optimum activity between pH 8 and 9 has been

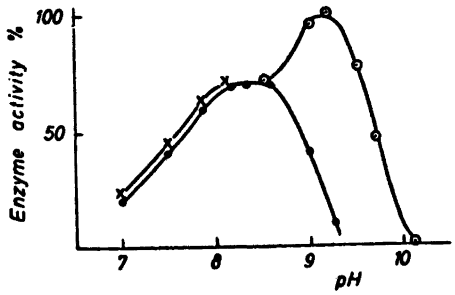

Fig. 2. The effect of pH on D-*amino acid oxidase activity.*
—●—●— : *In pyrophosphate buffer.*
—⊙—⊙— : *In glycine buffer.*
—×—×— : *In glycyl-glycine buffer.*
The concentration of FAD was 1.4×10^{-7} *M.*

confirmed. In glycine buffer however there occurs another optimum in the activity at pH 9.2. The explanation of this difference is that the pyrophosphate anion produces strong inhibition at pH > 9 similar to other anions.

As shown in Fig. 3 by plotting [14] the values for activity in glycine buffer, the curves at pH 8.3 and 9.2 have different slopes but the same intercept. This suggests that the binding between FAD and apoenzyme is stronger at pH 9.2, but probably without new points on the surface of the protein participating in the formation of the holoenzyme. Calculation of K_M gave 1.2×10^{-7} M at pH 8.3 while a lower value 6×10^{-8} M was found at pH 9.2.

It is very interesting to note that the association reaction for FMN and the apoenzyme in the "old yellow enzyme" exhibits a similar pH-dependence in the alkaline region as shown in the present work for the activity of the D-amino acid oxidase in glycine buffer. It is very likely that this is due to a beginning of the dissociation of the imino group in FAD ($pK' = 10.5$) and of the imino

group in FMN ($pK^1 = 10.2$)[1] at pH> 9, which results in an increased association velocity with the apoproteins in this pH region. The strong reduction in the activity of the D-amino acid oxidase that occurs at pH> 9.5 may be due to an abolishment of the association reaction when the number of positively charged groups on the protein is reduced considerably.

Inhibition of D-amino acid oxidase by anions

Table 1 shows the inhibition of enzyme activity by anions. As also indicated in Table 2, salts of strongly dissociated acids produced the strongest inhibition, while the inhibition by fluoride and acetate was weak. Thus the inhibition can most probably be ascribed to the anions. Furthermore the inhibition was of the same magnitude when potassium salts were used. Ammonium salts

on the other hand gave a stronger inhibition, indicating an effect of the ammonium ion on the protein.

In the experiments with NaI, catalase was added to decompose produced H_2O_2. Without catalase NaI gave complete inhibition in very low concentrations, probably because of the liberation of I_2 by H_2O_2. The competitive nature of the inhibition by anions indicates a competition with the dissociated phosphoryl groups in FAD. In Fig. 4 the inhibition with chloride is given as an example. It is reasonable to assume that negatively charged anions are bound to positively charged groups in the apoenzyme. The inhibition by anions was reversed when increasing the FAD concentration. The quoted experiments were all carried out in pyrophosphate buffer at pH 8.3. In experiments carried out at higher pH values the inhibition was stronger, as shown in Fig. 5.

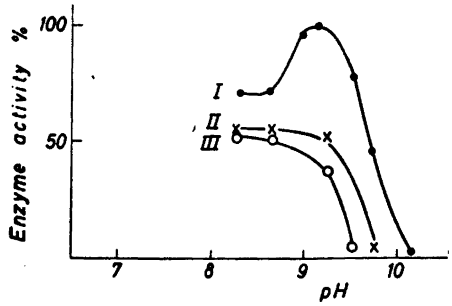

Fig. 5. Inhibition by chloride and phosphate.
Curve I: No inhibitor.
Curve II: 0.06 M NaCl.
Curve III: 0.075 M Na-phosphate.

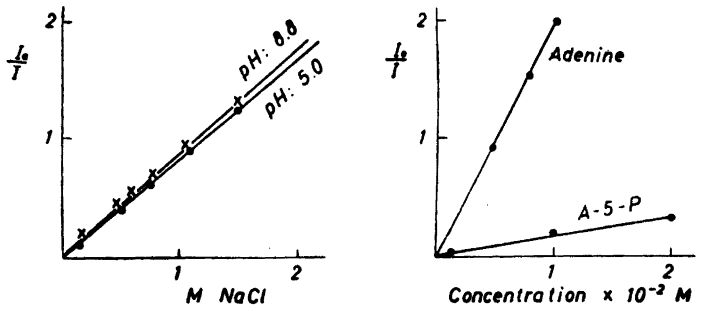

Fig. 6. Quenching effect of NaCl, adenine and A-5-P on the fluorescence of FAD. $\frac{I_0}{I}$: $\frac{\textit{Fluorescence without quencher}}{\textit{Fluorescence with addition of quencher}}$

After the addition of chloride or phosphate in concentrations which at a pH of 8.3 gives moderate inhibition, the inhibition is almost complete at pH 9.2 and the pH optimum of the enzyme activity at this pH almost disappears. Pyrophosphate is without effect at pH 8.3 to 8.6 but gives strong inhibition at higher pH. This explains why the enzyme activity is lost in pyrophosphate buffer at pH > 9. The inhibition by chloride and phosphate is competitive with FAD also at pH 9.2. This suggests that the mechanism of the inhibition is similar to that assumed for the inhibition at pH 8.3.

The activity of the enzyme drops rapidly at pH values above 9.5. This could be due to the fact that the number of positively charged groups in the protein is reduced. In the case of chloride and phosphate the strongly sloping part of the activity curve is shifted towards lower pH. The reason for this may be the well known fact that salts reduce the pK' values of proteins towards the isoionic point.

It is shown that NaCl at a relatively high concentration produces quenching of the fluorescence in FAD (Fig. 6). Provided that a non-fluorescent complex is formed: FAD + Cl^- → (FAD)Cl, the dissociation constant K can be calculated from the equation

$$K = \frac{I}{I_0 - I} \times C$$

C = concentration of NaCl.
I_0 = Fluorescence without NaCl
I = Fluorescence with NaCl

In acetate buffer at pH 5.0 K was 2.5 M and in glycin buffer at pH 8.8 2.2 M. NaCl, however, inhibits the enzyme activity in a concentration interval considerably lower than that producing the quenching effect on the fluorescence of FAD. The fact that the chloride inhibition of D-amino acid oxidase is strongly increased at a pH > 9, could not be explained by assuming that chloride inhibits the dissociation of the NH(3)-group in FAD. Any definite change in the pK of FAD by chloride in the alkaline region could not be detected.

Inhibition by partial structural analogues of FAD

Table 3 shows the inhibition by these compounds. Further the relative inhibition by this group of substances is shown in Table 4. The strongest inhibition was produced by FMN, A-5-P and other nucleotides. This group of substances with dissociated phosphoryl groups, all exhibited a competitive, reversible inhibition with FAD. One example is given in Fig. 7. Because of the competitive nature of inhibition, it is probable that the groups in the apoenzyme involved in the formation of the complex with the inhibitor, are the

same as in the FAD-apoenzyme complex. The experiments indicate that in addition to a binding of the dissociated phosphoryl group, the riboflavin and adenosine part are also linked to the protein.

The inhibition by riboflavin and adenosine was considerably less than in the case of FMN and A-5-P. Other purine and pyrimidine derivatives also produced a weaker inhibition. Furthermore the inhibition in this group was non-competitive with FAD, as shown by an example in Fig. 8. It has previously been shown [21] that the riboflavin analogues *iso*riboflavin, dichloroflavin

The concentration of FAD was 1.4 × 10^{-7} M.

and galactoflavin exhibit a competitive inhibition which is, however, not truly reversible. There is some evidence for believing that the ribose part of the molecule is of specific importance in the binding with the protein, since the inhibition with ribose-5-phosphate was considerably stronger than with phosphate. Adenine and adenosine, however, produced the same inhibition. The (6)-NH_2 group in the purine ring was without specific importance, since K_I for adenine and hypoxanthine was of the same magnitude. Likewise there was no difference in K_I for adenylic acid and inosinic acid.

It is known that adenine, adenosine and purines usually produce a quenching of the fluorescence in fluorescent molecules [22]. Quenching of FAD by purines has been demonstrated [23,5]. As shown in Fig. 6 adenine and to a lesser degree adenylic acid produce a quenching of the fluorescence in FAD. At the concentrations used a formation of a complex between adenine and FAD would make the latter inactive as a coenzyme. This might explain the inhibition found in enzyme-activity experiments. Such an explanation however, is not possible in the case of adenylic acid which inhibits at considerably lower concentrations. The inhibition by FMN, A-5-P and ATP were of the same degree at different pH (Fig. 9). This was also the case for the inhibition by riboflavin and adenine.

FMN, riboflavin and DPN could not operate as coenzymes for the D-amino acid oxidase when added in concentrations up to 5 × 10^{-4} M. Neither could FMN + adenylic acid when added in equimolecular concentrations function as a coenzyme.

DISCUSSION

The experiments have indicated that several linkages are involved in the formation of the slightly dissociated coenzyme-apoenzyme complex in the D-amino acid oxidase.

The competitive type of inhibition by anions with the coenzyme molecule, indicates that the phosphoryl residue in FAD is linked to the apoenzyme. The fact that anions of strongly dissociated acids produce the most pronounced

dissociation of the enzyme may be explained by assuming that the negatively charged phosphoryl groups in FAD are linked to positively charged groups in the apoenzyme. The strong inhibition produced by FMN and adenylic acid suggest attachment to the riboflavin part of the FAD molecule as well as to adenosine. There is some evidence to indicate the chemical groups which are of importance for the binding.

It is improbable that the free NH-(3) in *iso*alloxazine participates in a linkage, since the formation of the coenzyme-apoenzyme complex was not followed by a quenching of the fluorescence in FAD. The smaller dissociation constant of FAD at pH 9.2 than at 8.3, is probably due to the fact that the beginning of the dissociation of the NH-(3) group in *iso*alloxazine results in a closer binding to the apoenzyme. A direct binding of the NH-(3) group, however, does not appear to occur since the D-amino acid oxidase is also fluorescent at pH 9.2.

In this connection it should be emphasized, that the effect of pH in the alkaline region on the activity of the D-amino acid oxidase and on the association reaction of FMN and the protein in the old yellow enzyme is completely identical. In both cases the optimal peak of the reaction at pH 9.2 disappears when NaCl is added. Thus it is possible that the dissociation of the NH-(3) group in *iso*alloxazine is of general importance for the formation of the coenzyme-protein complex in flavin enzymes.

The (6)-NH_2 group in the adenin moiety was without specific importance since K_I for adenylic and inosinic acids were of the same magnitude. The importance of the ribosyl group was indicated by the fact that the inhibition by ribose-5-phosphate was considerably stronger than by phosphate. On the other hand K_I for adenine and adenosine were of the same magnitude. In the case of the latter two substances however, the inhibition can be explained by assuming the formation of non-fluorescent complexes with FAD.

In the reduced enzyme new tight bonds appear to occur since the reduced enzyme is almost undissociated [8]. By hydrogenation of *iso*alloxazine in FAD in the reduced enzyme, a reduction in the absorption at 450 mμ occurs. Preliminary investigations indicated that chloride did not dissociate the reduced enzyme. Thus, no detectable effect of NaCl on the formation of the complex coenzyme-apoenzyme occurred as examined by absorption measurements at 450 mμ. Continued investigations on the reduced enzyme are in progress.

It has recently been shown that a number of flavin enzymes are metal enzymes with, *e. g.*, Mo, Fe, or Cu as a component [24]. There is, however, no evidence to show that metal ions are of importance for the activity of the D-amino acid oxidase. Thus it has been shown that cyanide is without effect and in present experiments chelating agents such as versene (2×10^{-3} M) and 8-hydroxyquinoline (2×10^{-4} M) produced no inhibition.

The fact that anions produce dissociation of enzymes, which has been shown where flavin and pyridine nucleotides occur as coenzymes, may be a phenomenon of general importance. The practical result of the presence of anions in buffers has been clearly demonstrated by the fact that D-amino acid oxidase is completely inhibited at pH>9 when pyrophosphate buffer is employed. Furthermore it should be mentioned that tris(hydroxymethyl)aminomethane buffer produced complete inhibition at a concentration of 10^{-3} M.

It is very likely that inhibition of enzyme reactions by anions and by partial structural analogues of coenzymes is of physiological importance in the control of cellular metabolism. Thus it is well known that the optimal reaction velocity for enzyme reactions is greater in extracts and homogenates than in isolated tissue slices of the same organ [25]. It is therefore of interest to bear in mind that the chloride concentration in the extracellular fluid corresponds to a concentration which produces considerable inhibition in the D-amino acid oxidase system. The same applies in the case of the intracellular concentration of adenine nucleotides.

Short Communications

Constitution of Resin Phenols and their Biogenetic Relations

XX *. The Identity of Pseudocubebin and *d*-Sesamin

BERNT CARNMALM

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Recently fagarol was found to be identical with *dl*-sesamin [1]. In this paper pseudocubebin the last of the long known lignans of unsettled structure is proved to be *d*-sesamin (*cf.* Erdtman [2]).

In 1896 Peinemann [3] isolated a crystalline colourless substance (m. p. 122°) from the fruits of *Piper Lowong* Bl. From his analyses he calculated the formula $C_{20}H_{20}O_6$ which is the same as that for cubebin which had been isolated 60 years earlier from *Piper cubeba*. Peinemann showed that his substance was different from cubebin and he proposed the name pseudocubebin for the new compound.

Later Halberkann [4] found that pseudocubebin also occurred in the bark of *Ocotea usambarensis* Engl., Ibean Camphor tree, which occurs in East Africa, and on comparison of this substance with Peinemann's original preparation he showed that they were identical.

On oxidation with permanganate Peinemann obtained piperonylic acid. Attempted hydrolysis, transesterification and benzoylation invariably yielded unchanged starting material. Bromination afforded a dibromoderivative melting at 180° and nitration a substance giving the analytical figures for a dinitroderivative although no melting point was reported. From Peinemann's and Halberkann's results it appeared to be likely that pseudocubebin is a lignan most closely resembling sesamin.

Bark of *Ocotea usambarensis* was very kindly put at our disposal by Mr. B. G. Gilchrist, Lushoto Tanganyika.

The isolation of pseudocubebin was carried out mainly according to Halberkann. He reported a yield of about 0.5 % of pseudocubebin but our sample contained much less. The preparation melted at 122—123°, undepressed on admixture with authentic *d*-sesamin. The specific rotation was +64.5° (Halberkann gives +61°) and for *d*-sesamin the highest reported value is +69°. The series of colours developed when the compound was dissolved in sulphuric acid was identical with that for sesamin and also agreed with that given by Halberkann. Further the dibromoderivative of pseudocubebin was found to be identical with dibromo-*d*-sesamin as shown by melting point and mixed melting point determinations. Hence the "pseudocubebin" of *Ocotea usambarensis* is identical with *d*-sesamin.

Experimental. (All melting points uncorrected.) *Isolation of pseudocubebin.* The ground bark of *Ocotea usambarensis* (500 g) was exhaustively extracted with ether. The extract was distilled with steam and the non-volatile portion dissolved in ether and shaken with sodium hydroxide solution (2 N). The ether was evaporated and the oily residue dissolved in petroleum ether. After some time hard crystals (100 mg) deposited at the wall and bottom of the vessel. They were recrystallised from ethanol giving a colourless substance, m. p. 122—123°, $[\alpha]_D^{20}$ + 64.5° (*c* 1.75 in chloroform). The melting point was undepressed on admixture with an authentic sample of *d*-sesamin.

Dibromopseudocubebin. Pseudocubebin was brominated with bromine in chloroform. Crystallisation from ethanol gave very thin

X-Ray Crystallographic Data on some Nucleic Acid Components

S. FURBERG and A. HORDVIK

Institute of Chemistry, University of Bergen, Bergen, Norway
and

K. TAUGBØL

Joint Establishment for Nuclear Energy Research, Lillestrøm, Norway

X-Ray crystal structure analysis of decomposition products of nucleic acids may be expected to give valuable information on the structure of the macromolecule. The four nucleosides from RNA have earlier been studied by one of us [1]. In this paper the results of a preliminary investigation of some other nucleic acid components are reported.

Weissenberg and oscillation photographs were taken, using Cu$K\alpha$ and Fe$K\alpha$ radiation. Unit cell dimensions and space groups were derived and densities measured by the flotation method. The values given are believed to be accurate to within 1 %.

Crystals of thymine, D-ribose, 2-deoxy-D-ribose, deoxycytidine hydrochloride and thymidine were examined with the following result:

Thymine. Crystals grown from alcohol are needleshaped, elongated along b, with {100} prominent, whereas from water parallelepipeds are obtained, with all faces about equally developed. Both types of crystals are monoclinic with cell dimensions a = 12.87 Å, b = 6.83 Å, c = 6.72 Å and β = 105°. The density was found to be 1.46 g/cm³ and there are four (calculated 3.97) molecules in the unit cell. The only systematic absences occur in the $h0l$ reflections for l odd and in the $0k0$ reflections for k odd. The space group is therefore $P2_1/c$.

D-*Ribose.* Recrystallisation from a number of solvents yielded extremely small crystals, or syrups. From the melt, however, crystals big enough for X-ray work were grown at about 60° C. They had the shape of needles and were elongated along c. The diagrams showed them to be monoclinic twins with (100) as twin-plane. The twinning was difficult to detect, as the cell dimensions happen to be such that the reflections from the two twinned crystals very nearly coincide. The cell dimensions are: a = 6.57 Å, b = 21.59 Å, c = 4.80 Å and β = 113°. The density was found to be 1.59 g/cm³, corresponding to four molecules in the unit cell. The calculated density is also 1.59 g/cm³. The space group is $P2_1$.

Although a great number of simple sugars have been investigated by X-ray crystallographic methods by Cox *et al.*[2], and others, we have found no crystal data on ribose or 2-deoxy-ribose in the literature.

*2-Deoxy-*D-*ribose.* From the melt very thin flakes were obtained, with {100} prominent. The X-ray diagrams were rather poor; however, they showed that the crystals probably are orthorhombic, with a = 11.36 Å, b = 10.65 Å and c = 4.91 Å. The absences indicate the space group $P2_12_12_1$. Four molecules $C_5H_{10}O_4$ per unit cell gives a calculated density of 1.50 g/cm³.

Thymidine. This nucleoside crystallises in well-developed orthorhombic prisms elongated along c, with a = 16.27 Å, b = 13.86 Å and c = 4.86 Å. Four molecules per unit cell corresponds to a density of 1.47 g/cm³. Reflections $h00$ and $0k0$ are absent for odd values of h and k respectively. The $00l$ reflections were not all recorded, but as 001 and 003 appear to be absent, the space group is probably $P2_12_12_1$.

Deoxycytidine hydrochloride. Thin, monoclinic needles elongated along c, with a = 7.03 Å, b = 17.70 Å, c = 5.15 Å and β = 117°. Space group $P2_1$. Two mole-

needles, m. p. 180—181°, mixed m. p. with dibromo-*d*-sesamin 181—183°.

Space Groups and Molecular Symmetries of Two Thiocyanates

OLAV FOSS

Institutt for uorganisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The unit cells and space groups of two simple, covalent thiocyanates have been determined from single-crystal oscillation and Weissenberg photographs, using copper radiation, $\lambda(CuK\alpha) = 1.542$ Å.

Sulphur dithiocyanate [1], $S(SCN)_2$. Orthorhombic bipyramidal, $a = 10.12$ Å, $b = 12.83$ Å, $c = 4.34$ Å. Four molecules per unit cell; density, calc. 1.75, found 1.76 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. The unit cell dimensions, the absences, and the relative intensities of the reflections show that the crystals are isomorphous with those of selenium dithiocyanate[2], $Se(SCN)_2$, and selenium diselenocyanate [3], $Se(SeCN)_2$. The space group is thus D_{2h}^{16}-*Pnma*. From the known structures of the selenium analogues [2,3] it follows that the sulphur dithiocyanate molecule has an unbranched chain structure, with the middle sulphur atom located in a crystallographic mirror plane.

The compound was prepared from sulphur dichloride by reaction with an excess of silver thiocyanate suspended in carbon disulphide, and was recrystallized from the same solvent. Silver thiocyanate was found to react better than mercuric thiocyanate [4]. The crystals occur as plates {010}, bounded by {110} and {111}, and usually very thin. The bulk of crystals became yellow in the course of a day, due to the formation of an insoluble polymer [1,4], but individual crystals could be picked which were sufficiently stable.

Ethylene thiocyanate, $(CH_2SCN)_2$. Orthorhombic bipyramidal, $a = 7.39$ Å, $b = 7.81$ Å, $c = 11.48$ Å. Four molecules per unit cell; density, calc. 1.45, found 1.42 g/cm³. Systematic absences, $0kl$ when k is odd, $h0l$ when l is odd, $hk0$ when h is odd. The space group is thus D_{2h}^{15}-*Pbca*, which has eightfold general positions, and two fourfold sets of symmetry centres as special positions. With four molecules per unit cell, it follows that the ethylene thiocyanate molecules are centrosymmetric in the crystals. This agrees with the finding from infrared measurements [5] that the compound exists in *trans* configuration in the solid state.

Recrystallized from chloroform, the compound was obtained as plates {010}, or as perfect bipyramids {111} with, also here, {010} developed.

Further work on the crystal structures of the two thiocyanates is intended.

Space Groups and Molecular Symmetries of Two Thiocyanates

OLAV FOSS

Institutt for uorganisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The unit cells and space groups of two simple, covalent thiocyanates have been determined from single-crystal oscillation and Weissenberg photographs, using copper radiation, $\lambda(CuK\alpha) = 1.542$ Å.

Sulphur dithiocyanate [1], $S(SCN)_2$. Orthorhombic bipyramidal, $a = 10.12$ Å, $b = 12.83$ Å, $c = 4.34$ Å. Four molecules per unit cell; density, calc. 1.75, found 1.76 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. The unit cell dimensions, the absences, and the relative intensities of the reflections show that the crystals are isomorphous with those of selenium dithiocyanate[2], $Se(SCN)_2$, and selenium diselenocyanate [3], $Se(SeCN)_2$. The space group is thus D_{2h}^{16}-*Pnma*. From the known structures of the selenium analogues [2,3] it follows that the sulphur dithiocyanate molecule has an unbranched chain structure, with the middle sulphur atom located in a crystallographic mirror plane.

The compound was prepared from sulphur dichloride by reaction with an excess of silver thiocyanate suspended in carbon disulphide, and was recrystallized from the same solvent. Silver thiocyanate was found to react better than mercuric thiocyanate [4]. The crystals occur as plates {010}, bounded by {110} and {111}, and usually very thin. The bulk of crystals became yellow in the course of a day, due to the formation of an insoluble polymer [1,4], but individual crystals could be picked which were sufficiently stable.

Ethylene thiocyanate, $(CH_2SCN)_2$. Orthorhombic bipyramidal, $a = 7.39$ Å, $b = 7.81$ Å, $c = 11.48$ Å. Four molecules per unit cell; density, calc. 1.45, found 1.42 g/cm³. Systematic absences, $0kl$ when k is odd, $h0l$ when l is odd, $hk0$ when h is odd. The space group is thus D_{2h}^{15}-*Pbca*, which has eightfold general positions, and two fourfold sets of symmetry centres as special positions. With four molecules per unit cell, it follows that the ethylene thiocyanate molecules are centrosymmetric in the crystals. This agrees with the finding from infrared measurements [5] that the compound exists in *trans* configuration in the solid state.

Recrystallized from chloroform, the compound was obtained as plates {010}, or as perfect bipyramids {111} with, also here, {010} developed.

"*Trans*" Naphthodioxan Characterized by its Mercuric Chloride Compound

O. HASSEL and CHR. RØMMING

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

In 1950 Furberg and Hassel [1] determined the crystal structure of the lower melting compound (m. p. 111° C) found in the reaction between 2,3-dichloro-1,4-dioxan and ethylene glycol. They found

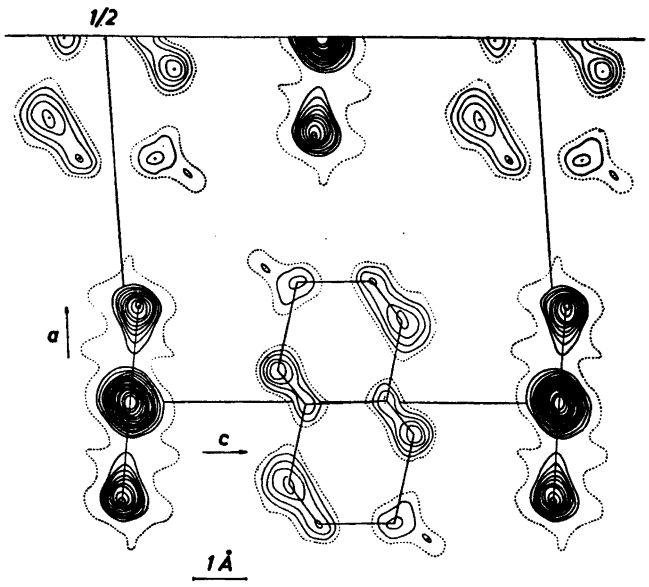

Fig. 1. Electron density map projected along the b-*axis. Intervals between the contour lines for Hg, Cl, C and O are in the ratio 25:10:4:4.*

that this substance is not a naphthodioxan as suggested by Böeseken *et al.*[2], but bi-1, 3-dioxa*cyclo*pentyl(2).

The structure of the higher melting product (m. p. 136° C) had still to be determined although it would of course be expected that this compound is indeed a naphthodioxan and preferably the "*trans*" form. The crystallographic data did not, however, invite to a direct crystal structure investigation [1]. Later on, it was found that addition compounds of the substance with mercury salts are readily formed [3] which might be suited for X-ray determination of the general shape of the organic molecule. We have chosen the mercuric chloride compound which has one short crystal axis (4.46 Å). Zero order layer line Weissenberg diagrams with rotation about the short axis were taken using the multiple film method. The intensities were estimated visually. The general trend of the intensities is a uniform decrease for increasing Bragg angles, which made us believe that the mercury atoms were in unique positions. Anticipating that the projection would contain the appropriate number of symmetry centres a Fourier projection could be worked out without making any assumptions regarding the positions of the chlorine, oxygen or carbon atoms. The resulting electron density map is reproduced in Fig. 1. Besides the projection of a linear symmetrical mercuric chloride molecule the map also contains a centrosymmetrical assembly of ten resolved peaks which corresponds satisfactorily to a picture which may be obtained from a naphthodioxan molecule in the "*trans*" form. The four peaks which in this case must correspond to oxygen atoms are in fact somewhat higher than the six remaining peaks representing carbon atoms.

Without trying to work out further projections which would no doubt exhibit serious overlapping of atoms, we feel entitled to draw the conclusion that the 136° substance is indeed "*trans*" naphthodioxan.

Structure of an Addition Compound Containing two Molecules of Iodine Monochloride and one Molecule of 1,4-Dioxan

O. HASSEL and J. HVOSLEF

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

It has been assumed that the interaction between an oxygen atom of an ether or a ketone with a halogen molecule results in a symmetrical bond type in which both halogen atoms take an equal part [1]. However, the first X-ray work on a solid addition product — the 1:1 compound between 1,4-dioxan and bromine [2] — revealed that in this case each ether oxygen is linked to *one* bromine atom only. Here the two atoms of a bromine molecule are situated

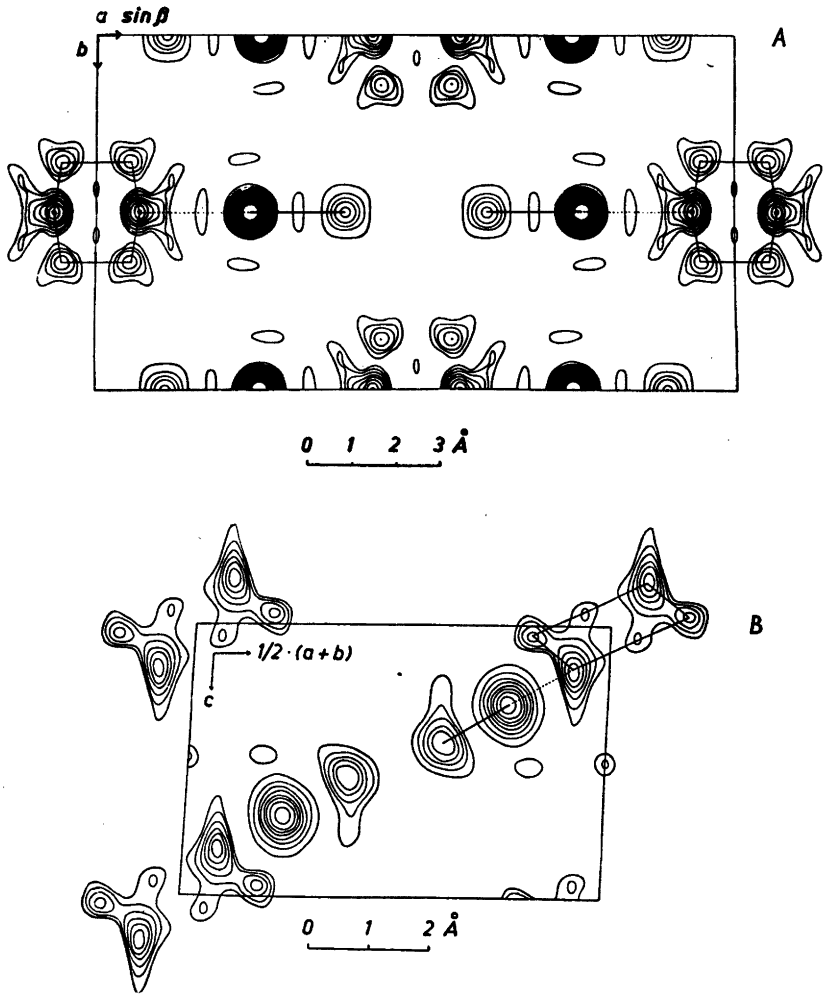

Fig. 1. Electron density maps projected. A) along [001]. Interval between contour lines for I and Cl:100 and between C and O:20. B) along [110]. Corresponding intervals are: I:100, Cl:30, C and O:10.

on the line joining the oxygen atoms of two neighbouring ether molecules. A similar structure is not to be expected if bromine is replaced by iodine monochloride, but we would expect the iodine atom to be directly linked to an ether oxygen and the angle O—I—Cl to be 180°. So far, we have not investigated this compound, but determined the structure of another compound which we obtained in the form of yellow needles (m. p. 103° C) directly from the vapours of the two compounds. Here the ratio of iodine monochloride and dioxan molecules is 2:1 as could easily be shown by dissolving the solid substance in an aqueous solution of potassium iodide and titrating the amount of iodine thereby set free.

The crystals of the new compound are *monoclinic* with $\beta = 95.2°$ and the space group is $C2/m$. The unit cell containing *four* molecules of iodine monochloride and two molecules of 1,4-dioxan have the constants $a = 14.62$, $b = 8.00$, $c = 4.56$. Approximate coordinates of the heavy iodine atoms could easily be found by conventional trial and error methods and Fourier maps computed using the signs of structure factors resulting from these coordinates. Only one refinement was necessary in order to arrive at the final maps reproduced in Fig. 1. The I and Cl coordinates thus obtained are: I: 0.242; 0; −0.290; Cl: 0.389; 0; −0.424. The coordinates of the light atoms derived from the maps are of course less accurate, but it is obvious that the centrosymmetrical dioxan molecules are of the "chair" form and the location of the oxygen atoms are good enough to show that each of them is linked to an iodine atom which has on its opposite side a chlorine atom, the O—I—Cl arrangement being linear or at least very nearly so. The O—I distance may safely be given as 2.6 Å, the I—Cl distance is 2.3 Å. The nearest Cl—Cl-approach, on the other side, is 3.38 Å showing that van der Waals forces only exist between chlorine atoms. The structure of the new compound thus provides a second example of a solid ether-halogen compound displaying a linear arrangement of the type O—Hal—Hal.

Structure of an Addition Compound Containing *two* Bromine Molecules and one Molecule of Hexamethylene Tetramine

GUNNAR EIA and O. HASSEL

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

As part of a research programme dealing with crystal structures of addition compounds between ethers, amines *etc.* and inorganic molecules, a bromine compound which, according to analyses, contains two molecules of bromine on every molecule of hexamethylene tetramine has been investigated. The result of the X-ray work shows that each bromine molecule is linked to one of the four tertiary nitrogen atoms, the arrangement of both groups being the same. The N-Br-Br group is *linear* and the line through the three atoms in question is symmetrically situated with respect to the three C—N bonds of the nitrogen atom. Four tetrahedral bonds are thus found by each nitrogen atom involved. The bond angles do not deviate much from the "regular" angle (109.5°). The fact that the N-Br-Br angle is 180° (or at least very nearly so) rules out the possibility that resonance effects in the NBr_2 group based on equivalence of the two bromine atoms are of any significance. The two N-Br-Br groups of a molecular complex are crystallographically independent and the fact that they are found (within the limits of error) to be identical in shape is of considerable interest. The Br-Br distance is found equal to 2.4 Å; for the N-Br distance the value 2.3 Å was obtained. These findings point to a strong interaction between the nitrogen atom and the nearest bromine atom and indicate a very marked weakening of the Br-Br bond. It would appear rather probable that in addition compounds of amines showing markedly stronger basic properties than hexamethylene tetramine, a dissociation of the bromine molecule may even occur. Investigations dealing with addition compounds of such amines are now in progress in our laboratory.

The yellow crystals of the compound between hexamethylene tetramine and two molecules of bromine are *monoclinic* and belong to the space group $P2_1/c$.

on the line joining the oxygen atoms of two neighbouring ether molecules. Structure of an Addition Compound Containing *two* Bromine Molecules and one Molecule of Hexamethylene Tetramine

GUNNAR EIA and O. HASSEL

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

As part of a research programme dealing with crystal structures of addition compounds between ethers, amines *etc.* and inorganic molecules, a bromine compound which, according to analyses, contains two molecules of bromine on every molecule of hexamethylene tetramine has been investigated. The result of the X-ray work shows that each bromine molecule is linked to one of the four tertiary nitrogen atoms, the arrangement of both groups being the same. The N-Br-Br group is *linear* and the line through the three atoms in question is symmetrically situated with respect to the three C—N bonds of the nitrogen atom. Four tetrahedral bonds are thus found by each nitrogen atom involved. The bond angles do not deviate much from the "regular" angle (109.5°). The fact that the N-Br-Br angle is 180° (or at least very nearly so) rules out the possibility that resonance effects in the NBr_2 group based on equivalence of the two bromine atoms are of any significance. The two N-Br-Br groups of a molecular complex are crystallographically independent and the fact that they are found (within the limits of error) to be identical in shape is of considerable interest. The Br-Br distance is found equal to 2.4 Å; for the N-Br distance the value 2.3 Å was obtained. These findings point to a strong interaction between the nitrogen atom and the nearest bromine atom and indicate a very marked weakening of the Br-Br bond. It would appear rather probable that in addition compounds of amines showing markedly stronger basic properties than hexamethylene tetramine, a dissociation of the bromine molecule may even occur. Investigations dealing with addition compounds of such amines are now in progress in our laboratory.

The yellow crystals of the compound between hexamethylene tetramine and two molecules of bromine are *monoclinic* and belong to the space group $P2_1/c$.

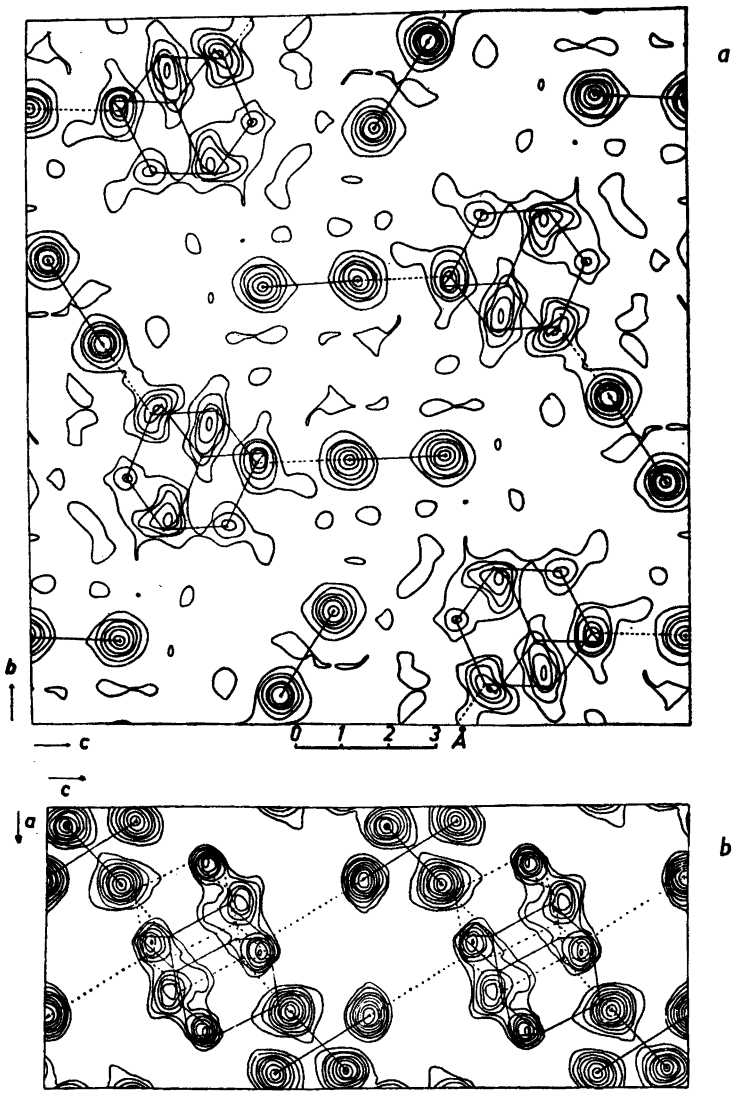

Fig. 1. Electron density maps projected a. along [100], b. along [010]. Interval between drawn contour lines four times larger for bromine than for carbon and nitrogen atoms.

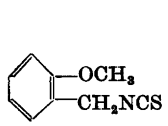
From the observed density (2.35) and the lattice parameters: $a = 6.05$; $b = 14.90$; $c = 13.88$ and $\beta = 91.4°$ follows that the unit cell must contain four molecules of hexamethylene tetramine and eight molecules of bromine. Patterson Charts combined with "trial and error" calculations resulted in approximate values of the bromine parameters which could be used as a basis for two dimensional Fourier syntheses. Reproductions of electron density maps, projected along [100] (Fig. 1 a) and

along [010] (Fig. 1 b) are given. The form of the organic part of the complex necessarily leads to overlapping in any projection. In the [010] projection overlapping of two amine molecules occurs. A difference synthesis — with subtraction of the bromine atoms — led to a chart in which the organic part was better resolved than in Fig. 1 a. All further details of the investigation — now practically finished — will be given in a forthcoming publication.

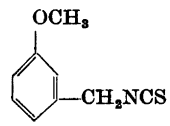
Received December 13, 1955.

*iso*Thiocyanates XVII. *o*-Methoxybenzyl *iso*Thiocyanate and some Derivatives



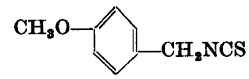
ANDERS KJÆR and ROALD BOE JENSEN

Chemical Laboratory of the University of Copenhagen, Denmark



Recently, Ettlinger and Lundeen [1] isolated *m*-methoxybenzyl *iso*thiocyanate (II) from seeds of the American plant *Limnanthes douglasii* R.Br. Coincidently, *p*-methoxybenzyl *iso*thiocyanate (III) was recognised in this laboratory as the aglucone of a glucoside, named glucoaubrietin, occurring in various species of the crucifer genus *Aubrietia* [2]. Both (II) and (III) were synthesised in the course of these investigations.

Ettlinger [4], and used also for the synthesis of (II) [1] and (III) [2]. Contrary to the latter two, which are liquids at ordinary temperature, the mustard oil (I) appeared as a low-melting solid. Its ultra-violet absorption spectrum in 2,2,4-trimethylpentane has a shoulder at about 255 mμ (ε *ca.* 1 550), maxima at 271 mμ (ε 2 400) and 277 mμ (ε 2 400) and minima at 236 mμ (ε 850) and 275 mμ (ε 2 200). These data are in accord with those reported for the *meta*-isomeride (II) [1], but differ considerably from the values determined for (III) in the same solvent, *viz.* shoulders at about 250 mμ (ε 2 300) and 285 mμ (ε 1 000), maxima at 228 mμ (ε 11 600) and 276 mμ (ε 1 730) and a broad minimum around 269 mμ (ε 1 550). In the wave-length region below 11 μ, the infra-red spectrum of (I) was comparable to that of (III), both displaying bands which deviated considerably from those reported for the *meta*-compound [1].



For the purpose of characterisation, (I) was converted into *N*-*o*-methoxybenzyl-thiourea and *N*-benzyl-*N'*-*o*-methoxybenzyl-thiourea on reaction at room temperature with ammonia and benzylamine, respectively. The mustard oil reacted much more sluggishly than generally experienced for *iso*thiocyanates, a fact suggesting a certain sterical influence of the neighbouring methoxy-grouping. In an attempt to enforce the reaction between (I) and benzylamine under more drastic conditions, amine exchange occurred, resulting in the formation of *N*,*N'*-dibenzylthiourea. This reaction presents no novelty in thiourea chemistry. Recently, Ettlinger and Hodg-

I

III

On this background it became of interest to prepare the heretofore unknown *o*-methoxybenzyl *iso*thiocyanate (I). The requisite *o*-methoxybenzylamine was obtained by Leuckart-reaction on *o*-methoxybenzaldehyde, according to Lewis [3], but in somewhat better yield (40 %). The amine was converted into (I) by the convenient modification of the Kaluza-synthesis which was recently introduced by Hodgkins and

kins [5] observed the formation of thiocarbanilide in the reaction of *N*-*t*-butyl-*N'*-phenylthiourea with aniline in boiling benzene, and referred to further examples in the literature. In the present case, it seems likely that sterical factors interfere with the usual thiamide-resonance, thus favouring the displacement of *o*-methoxybenzylamine. This view is supported by the infra-red spectra of the thioureas corresponding

along [010] (Fig. 1 b) are given. The form of the organic part of the complex necessarily leads to overlapping in any projection. In the [010] projection overlapping of two amine molecules occurs. A difference synthesis — with subtraction of the bromine atoms — led to a chart in which the organic part was better resolved than in Fig. 1 a. All further details of the investigation — now practically finished — will be given in a forthcoming publication.

Received December 13, 1955.

*iso*Thiocyanates XVII. *o*-Methoxybenzyl *iso*Thiocyanate and some Derivatives

On this background it became of interest to prepare the heretofore unknown *o*-methoxybenzyl *iso*thiocyanate (I). The requisite *o*-methoxybenzylamine was obtained by Leuckart-reaction on *o*-methoxybenzaldehyde, according to Lewis [3], but in somewhat better yield (40 %). The amine was converted into (I) by the convenient modification of the Kaluza-synthesis which was recently introduced by Hodgkins and

kins [5] observed the formation of thiocarbanilide in the reaction of *N*-*t*-butyl-*N'*-phenylthiourea with aniline in boiling benzene, and referred to further examples in the literature. In the present case, it seems likely that sterical factors interfere with the usual thiamide-resonance, thus favouring the displacement of *o*-methoxybenzylamine. This view is supported by the infra-red spectra of the thioureas corresponding

to (I), (II) and (III). Whereas the latter two exhibit normal "thioureid" absorption bands at 6.58 μ and 6.57 μ [6], a displacement of the band to 6.38 μ is noticed in the spectrum of *o*-methoxybenzylthiourea.

The three methoxybenzylthioureas were subjected to descending paper chromatography in water-saturated chloroform and the R_{Ph}-values [7] 1.14, 0.99 and 1.02 determined for the *o*-, *m*- and *p*-derivative, respectively. The high value of the *ortho*-compound indicates a rather pronounced chelation of this isomeride in solution. So far, the mustard oil (I) has not been encountered in nature.

Experimental *. o-*Methoxybenzylamine.* *o*-Methoxybenzaldehyde [8] (50 g) was treated with ammonium formate (200 g), and the mixture subsequently hydrolysed with conc. HCl (400 ml) as previously described [3], except that the reaction time was increased to 6 hours. The amine distilled at 114° at 14 mm, yield 20 g (40 %); the previously reported yield was 30 %.

o-*Methoxybenzyl* iso*thiocyanate* (I). The above amine (7.6 g) was converted to (I) by the method formerly used for preparing the corresponding *m*-derivative [1]. The *iso*thiocyanate distilled at 133° and 4 mm, and solidified to a colourless crystalline mass, m. p. 28°, yield 6.8 g (68 %). (Found: C 60.50; H 5.03; N 7.70; S 17.97. Calc. for C_9H_9ONS: C 60.31; H 5.06; N 7.82; S 17.89). The infra-red spectrum, determined in a KBr disc, showed bands at 3.33, 4.65 (very strong, N=C=S), 6.18, 6.57, 6.86, 6.90, 7.40, 7.70, 8.05 (v. s., aryl ether), 8.49, 8.87, 9.45, 9.70, 11.98 and 13.23 μ (v. s.).

N-o-*Methoxybenzylthiourea.* A solution of (I) (500 mg) in ethanol (5 ml), saturated with dry ammonia, was set aside at room temperature for 4 days. The separated thiourea crystallised from water, containing a little ethanol, as colourless needles (361 mg), m. p. 122°. (Found: C 54.90; H 6.35; N 14.12. Calc. for $C_9H_{12}ON_2S$: C 55.05; H 6.17; N 14.27). The infra-red spectrum (KBr pellet) had prominent bands at: 2.93, 3.08, 6.04, 6.38, 6.64 (weak), 6.89, 7.34, 7.51 (w.), 7.68, 7.98, 8.54, 8.87, 9.50, 9.64, 9.86, 10.71, 11.91, 12.74, 13.14 (strong), 13.36 and 14.20 μ.

N-*Benzyl*-N'-o-*methoxybenzyl-thiourea.* An ether solution of (I) (500 mg) and benzylamine (2 ml) was kept at room temperature for 4 weeks. The solvent was removed and the oily residue treated with dilute HCl. After being kept at 0° for some hours the syrup crystallised. After two recrystallisations from 70 % ethanol, an analytical specimen was obtained as colourless needles (494 mg), m. p. 82.5°. (Found: C 66.90; H 6.38; N 9.86. Calc. for $C_{16}H_{18}ON_2S$: C 67.10; H 6.34; N 9.78).

In an attempt to enforce this reaction, (I) (500 mg) was heated to reflux for one hour in benzylamine (10 ml). Excess amine was removed *in vacuo* and the residue triturated with dilute HCl. The now crystalline product was recrystallised twice from ethanol, yielding colourless prisms (329 mg), m. p. 149—150°. (Found: C 70.30; H 6.21; N 10.64. Calc. for $C_{15}H_{16}N_2S$: C 70.29; H 6.29; N 10.93). The composition, in conjunction with reported values for the m. p., *e. g.* 147—148° [9], indicated the identity of the reaction product as *N-N'*-dibenzylthiourea.

Microanalyses were performed in this laboratory by Mr. P. Hansen. The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*.

Separation of Saturated Straight Chain Fatty Acids III. Quantitative Paper Chromatography

OLAVI PERILÄ

Finland Institute of Technology, Laboratory for Wood Chemistry, Helsinki, Finland

The lower fatty acids, separated by paper chromatography as their salts, may be determined quantitatively by the area method [1]. The basis of another method of quantitative estimation of the ammonium salts of organic acids is that if an acid is added to a neutralized solution of an acid indicator the anion of which is distinctly coloured, then the depth of the colour due to the anion is inversely proportional to the amount of acid added between 20 and 80 % neutralization [2]. The value of both these methods is somewhat reduced because of the sensitivity of the indicators towards atmospheric (or dissolved) carbon dioxide. As hydroxamic derivatives, the acids may be estimated in more stable conditions. Stadtman [3] describes a method of this kind for the acyl phosphates of C_2. . .C_6, in which the chromatographed hydroxamic derivatives of the acids are extracted from the paper and estimated colorimetrically. Block [4] used a corresponding procedure for the same acids, chromatographing them according to the method of Thompson [5] and estimating them colorimetrically directly on the paper. Wagner [6] describes a quantitative chromatographic method for the long chain acids (C_{12}. . .C_{22}) in which he used the chromatographic procedure of Kaufmann [7] and estimated the amounts of the acids colorimetrically directly on the paper, first converting the acids by the method of Kaufmann into their copper salts and then the copper into the ferrocyanide complex, the amount of which was easily estimated colorimetrically. In the present study corresponding investigations were carried out. The amount of copper was determined colorimetrically by the dithizone method from the ash of the spot cut from the chromatogram. It was found that the amount of combined copper was not quite equivalent to the amount of fatty acid on the paper, but that very small amounts of acids combined with copper in a molar ratio. In the following, procedures now found suitable for the separation and estimation of fatty acids from formic to cerotic acid are described.

The acids from formic to valeric acid may be separated from each other and estimated by converting them into their hydroxamic derivatives and chromatographing with the solvent *n*-butanol:benzene:water (1:1:1, upper layer) by the circular method, which is the most suitable in this case. The acids are located by spraying the paper with $FeCl_3$ solution. The spots are extracted in cuvette solutions containing $FeCl_3$ and the amounts of acids are estimated colorimetrically.

The acids from caproic to pelargonic acid are analysed in the same manner as in the former group, but chromatography is carried out with the solvent benzene: formic acid:water (1:1:1, upper layer).

The acids from capric to cerotic acid may be separated by the method previously described by the author [8]. Quantitative estimation of the acids is achieved by converting them into silver salts on the paper, removing the excess of silver and determining the amount of silver in each spot colorimetrically by the dithizone method.

Experimental: Separation and estimation of the acids from formic to valeric acid. A slight excess of diazomethane dissolved in ether was added at room temperature to the methanol solution of the fatty acids and the excess of diazomethane was evaporated. The methyl esters obtained were converted into hydroxamic derivatives by the method of Thompson [5], adding to the solution of esters obtained alkaline hydroxylamine solution. The reaction was allowed to proceed for half an hour at room temperature, after which the solution was acidified with acetic acid. The sodium acetate precipitate was filtered off and the solution was concentrated in vacuum. Chromatography is most conveniently carried out by the circular method (*cf.* Perilä [8]) using as solvent the upper layer of the mixture *n*-butanol:benzene:water (1:1:1) [9]. Because the solubility of water in the solvent is poor, it is advisable to keep a sheet of filter paper wetted with the water layer of the above-mentioned mixture on the bottom of the chromatographic chamber. Any Whatman double-washed paper is suitable for these analyses. After development, the paper was dried at room temperature and sprayed with $FeCl_3$ solution (*e. g.* 50 grams of $FeCl_3 \cdot 6H_2O$ dissolved in one litre of N HCl in ethanol [3]). For qualitative detection 0.05 micromoles of each acid are sufficient, but for quantitative estimation an acid concentration of 0.1—1 μM/ml is needed. This concentration

then determines the amount of acids to be taken for the chromatography. The spots obtained were cut out, and the ferric complexes of the hydroxamic derivatives of the fatty acids were extracted with a $FeCl_3$ solution (5 g $FeCl_3 \cdot 6H_2O$ + 25 ml conc. HCl + 575 ml water [3]). This solution was then analysed colorimetrically at a wavelength of 5 200 Å. According to Goddu [10] the accuracy of the measurement is ± 2 %. The accuracy is somewhat reduced, however, because of the chromatographic procedure. In the conditions described the following R_F-values were obtained: formic 0.24, acetic 0.34, propionic 0.51, butyric 0.69, valeric 0.83, and caproic acid 0.90.

Separation and estimation of the acids from caproic to pelargonic acid. The analyses were carried out in the same conditions as those of the preceding group, except that the chromatographic solvent was the upper layer of the mixture benzene:formic acid:water (1:1:1) [5]. The following R_F-values were obtained: valeric 0.18, caproic 0.33, oenanthylic 0.49, caprylic 0.62, pelargonic 0.72, and capric acid 0.76.

Separation and estimation of the acids from capric to cerotic acid. The chromatography was carried out by the method previously described by the author [8], using a paper saturated with hydrocarbon and as solvent a mixture of acetic acid and water (9:1) saturated with hydrocarbon. The hydrocarbon was evaporated and the paper treated for half an hour with an 1.5 % aqueous solution of $AgNO_3$. The excess of silver was removed by washing with deionized water, after which the paper was rapidly dried and sprayed with 0.05 % ethanolic *p*-diethylaminobenzylidenrhodanine. After drying, the silver spots were conveniently visible in ultraviolet light. The spots were cut out and the paper was burned in the usual manner with sulfuric acid-perchloric acid-nitric acid. The amount of silver was determined colorimetrically by the dithizone method at a wavelength of 6 250 Å[11]. For qualitative detection with the silver reagent mentioned 0.05 μM of each acid is sufficient, but for quantitative estimation it is advisable to use 0.2—2 μM of each acid. According to several determinations the accuracy of the method is about ± 5 %.

Purification of Clearing Factor from Postheparin Plasma

ESKO A. NIKKILÄ and RAINER PESOLA

Department of Medical Chemistry, University of Helsinki, Finland

Since the original discovery by Hahn [1] of the lipemia clearing effect of heparin upon injection and the subsequent demonstration of an *in vitro*-active clearing principle in plasma withdrawn after heparin administration [2] much successful work has been done to elucidate the mechanism of this peculiar phenomenon. Evidence has accumulated to show that the clearing factor acts as a lipoprotein lipase [3]. In spite of these advances only a few attempts have so far been made for the purification of the active principle from postheparin plasma. Anfinsen *et al.*[4] showed that the clearing factor falls in Fraction III-1,2,3 in the ethanol fractionation scheme of Cohn and they could thus achieve an about fourteen-fold purification of the activity. Later, Anfinsen and Quigley [5] reported a purification up to 100- to 200-fold by a relatively laborious procedure based on a complex formation between the clearing factor and low density lipoproteins (enzyme-substrate complex). Earlier studies in this laboratory revealed that the clearing activity was precipitated quantitatively from plasma at a low ionic strength at pH 5.6 along with 1/20 to 1/25 of the plasma proteins [6]. This finding was confirmed by Hood *et al.*[7] and the method has since been used by a

Purification of Clearing Factor from Postheparin Plasma

ESKO A. NIKKILÄ and RAINER PESOLA

Department of Medical Chemistry, University of Helsinki, Finland

Since the original discovery by Hahn [1] of the lipemia clearing effect of heparin upon injection and the subsequent demonstration of an *in vitro*-active clearing principle in plasma withdrawn after heparin administration [2] much successful work has been done to elucidate the mechanism of this peculiar phenomenon. Evidence has accumulated to show that the clearing factor acts as a lipoprotein lipase [3]. In spite of these advances only a few attempts have so far been made for the purification of the active principle from postheparin plasma. Anfinsen *et al.*[4] showed that the clearing factor falls in Fraction III-1,2,3 in the ethanol fractionation scheme of Cohn and they could thus achieve an about fourteen-fold purification of the activity. Later, Anfinsen and Quigley [5] reported a purification up to 100- to 200-fold by a relatively laborious procedure based on a complex formation between the clearing factor and low density lipoproteins (enzyme-substrate complex). Earlier studies in this laboratory revealed that the clearing activity was precipitated quantitatively from plasma at a low ionic strength at pH 5.6 along with 1/20 to 1/25 of the plasma proteins [6]. This finding was confirmed by Hood *et al.*[7] and the method has since been used by a

number of workers for obtaining a crude preparation of clearing factor.

Because of the irreversible inactivation of clearing factor in concentrated salt solutions its purification by the conventional salting out procedures is not possible. In the search for more effective methods of purification our attention was drawn to the recent findings of Nilsson and Wenckert [8], who demonstrated that heparin is adsorbed to known prothrombin adsorbents and elutable with citrate and that a natural heparin-like anticoagulant occurs in plasma bound to prothrombin. It was thought that also the clearing factor, which most probably contains heparin, might behave like prothrombin against adsorbents, either due to the formation of a complex with the latter or due to its heparin content as such. Thus, the known prothrombin purification methods could possibly be advantageously applied for the purification of lipemia clearing activity as well. This proved in fact to be the case.

The clearing activity of postheparin plasma is completely adsorbed on calcium phosphate gel and can be eluated with 0.1 M citrate. By this means a *40-fold* purification is achieved. Elution of the adsorbate with physiological NaCl removes about half of the proteins adsorbed but none of the clearing activity. Thus, washing of the precipitate with saline before the citrate elution increases the grade of purification up to about *85-fold*. The supernatant liquid of the $Ca_3(PO_4)_2$ adsorbate has the same acceptor-protein activity as untreated plasma and can therefore be used in the assay of clearing activity. In the course of these experiments it was found that citrate is a powerful activator of the clearing reaction, also in oxalated plasma.

Further purification of the clearing factor could be attained by diluting the eluate, after removal of citrate by dialysis, with distilled water and adjusting the pH to 5.5. The precipitate formed contained about 60 % of the original clearing activity purified about *400-fold* over the initial plasma on the protein-tyrosine basis.

Being undialysable the clearing factor differs from the natural heparin-like anticoagulant, which was reported by Nilsson and Wenckert [3] to dissociate from its union with prothrombin during dialysis. The possible identity of clearing factor and the thermolabile anticoagulant described by Fiala [9] remains to be established.

Oxalated plasma was found to have a lower clearing activity than the mere postheparin plasma, thus suggesting that the active principle is adsorbed on calcium oxalate as well (like heparin and prothrombin).

The details of the purification procedure and a description of the properties of the active preparation thus obtained will be published shortly.

Syntheses of Choline Esters of Monobasic Carbonic Acids

L.-E. TAMMELIN

Research Institute of National Defence, Dept. I, Sundbyberg 4, Sweden

A convenient method which gives good yields of choline esters is shown by the following scheme:

$$(CH_3)_2NCH_2CH_2OH + OC_2O_2R_2 = (CH_3)_2NCH_2CH_2OCOR + RCOOH$$

$$(CH_3)_2NCH_2CH_2OCOR + CH_3I = (CH_3)_3N^+CH_2CH_2OCOR + I^-$$

The first step has been used by Campbell *et al.*[1] in theoretical studies of the amino alcohols. Using this method of synthesis acetylcholine, propionylcholine and butyrylcholine have been prepared in yields of more than 90 % of the theoretical, calculated on the dimethylaminoethanol.

The only step that requires special comment is the first. When the reaction between the alcohol and the anhydride is finished the reaction mixture is distilled

number of workers for obtaining a crude preparation of clearing factor.

Because of the irreversible inactivation of clearing factor in concentrated salt solutions its purification by the conventional salting out procedures is not possible. In the search for more effective methods of purification our attention was drawn to the recent findings of Nilsson and Wenckert [8], who demonstrated that heparin is adsorbed to known prothrombin adsorbents and elutable with citrate and that a natural heparin-like anticoagulant occurs in plasma bound to prothrombin. It was thought that also the clearing factor, which most probably contains heparin, might behave like prothrombin against adsorbents, either due to the formation of a complex with the latter or due to its heparin content as such. Thus, the known prothrombin purification methods could possibly be advantageously applied for the purification of lipemia clearing activity as well. This proved in fact to be the case.

The clearing activity of postheparin plasma is completely adsorbed on calcium phosphate gel and can be eluated with 0.1 M citrate. By this means a *40-fold* purification is achieved. Elution of the adsorbate with physiological NaCl removes about half of the proteins adsorbed but none of the clearing activity. The only step that requires special comment is the first. When the reaction between the alcohol and the anhydride is finished the reaction mixture is distilled

under reduced pressure. It has been shown that all fractions up to a certain boiling point contain the dimethylaminoethyl ester. Thus all fractions are collected from the beginning of the distillation until temperature exceeds the boiling points given in Table 1.

Experimental: Dimethylaminoethylesters. One mole of acid anhydride was refluxed with 1 mole of dimethylaminoethanol on waterbath overnight. The reaction mixture was distilled at reduced pressure and all fractions collected up to and including the fraction at the temperature given in Table 1.

Choline esters. The combined fractions from the esterifications were dissolved in eight parts of dry ether. Methyl iodide was added in about 100 % excess and the reaction mixture was allowed to stand for three days in a stoppered round-bottomed flask at 25° C. The iodides were obtained as colourless crystalline precipitates which were filtered off and dried in a desiccator. Recrystallisation of the products was found to be unnecessary. Data for the syntheses are given in Table 2 and the analyses are given in Table 3.

My sincere thanks are due to Professor G. Ljunggren, Director of this institute for his kind interest in this work.

Purification of Bovine and Human Fibrinogen

Birger Blombäck and Margareta Blombäck

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

A prerequisite for the study of different coagulation systems is a supply of purified and stable substrates. When studying the inhibition of thrombin by heparin + cofactor we found fibrinogen prepared by salt precipitation or by freezing out [1] to be too impure and unstable. During the course of our work we succeeded in getting a stable and pure fibrinogen by treating fraction I of Cohn's [2] method 6 with glycine.

The effect of glycine on the solubility of proteins has been thoroughly studied by a number of authors [3-6]. As has been pointed out by Cohn *et al.* a polar substance such as glycine strongly reduces the protein-protein interaction. This principle was adopted by Cohn *et al.*[7] in their method 10 of 1950 for the isolation of γ-globulin and β_1-lipoprotein from a human plasma precipitate.

We have found that the salting-in effect on fibrinogen increases sharply in rising the glycine concentration to 0.5 M (at an ionic strength of 0.3) and that at higher glycine concentrations there is a salting-out effect. Thus if Cohn's fraction I is extracted during one hour at —3° C with a solution of 1 M glycine in a citrate buffer of pH 6 and ionic strength 0.3 containing 6.5 % ethanol the fibrinogen and the cold insoluble globulins are almost insoluble. On the other hand the other proteins contaminating fibrinogen in fraction I, including prothrombin, are dissolved and thus removed.

The insoluble fraction is then dissolved at +25° C in a citrate buffer, pH 6.35 and ionic strength 0.3, containing 0.12 M glycine. When this solution is cooled to 0° C and ethanol added to a concentration of 2 % the cold insoluble globulins, described by Edsall [8,9] are precipitated. They are removed and the fibrinogen is precipitated by increasing the ethanol concentration to 6.5 % at —3° C. The final product has a clottable / non clottable ratio of 96—97 %. It is now free of prothrombin, plasmin, heparin-cofactor and the antihemofilic globulin. It is also practically free of plasminogen and of the proactivator of plasminogen. Electrophoresis in the Tiselius apparatus at pH 6.6 showed only one single boundary. The yield was 70 % calculated on the fibrinogen in fraction I, thus considerably higher than in the procedure of Kekwick *et al.*[10]. The technique works equally well on human as on bovine plasma.

Chromatography and Partition of Cells and Cell Fragments

Per-Åke Albertsson

Institute of Biochemistry, Uppsala, Sweden

The adsorption behavior of cells and cell fragments has been studied in order to apply the chromatographic method for their separation. Cells of *Chlorella pyrenoidosa* have been adsorbed on calcium phosphate columns and eluted with phosphate buffers, thus giving fractions with different cell sizes. From disintegrated *Chlorella* cell walls and starch grains have been separated into almost pure fractions by the same procedure. The partition of particles between two liquid phases has also been studied.

The work is in progress and will be published later.

Protein Chromatography on an Anion Exchange Resin

Hans G. Boman

Institute of Biochemistry, Uppsala, Sweden

Serum albumin and different enzymes have been used in order to study the behavior of proteins on columns of Dowex 2. Separations have been carried out both with stepwise elution and displacement technique. A detailed paper is under preparation.

Crystalline Beef Cytochrome c

Stephen A. Kuby, Sven Paléus, Karl-Gustav Paul and Hugo Theorell

Medicinska Nobelinstitutet, Biokemiska avdelningen, and Wallenbergstiftelsens laboratorium för fysiologisk kemi, Stockholm, Sweden

Crystalline precipitates of beef heart cytochrome c have been obtained from slightly ammoniacal ethanol solutions at —20° C. Iron analysis and enzymatic activity agreed favourably with the best preparations obtained by Paléus and Neilands [1].

Phenyl *iso*Thiocyanate as a Reagent in Protein Chemistry

Pehr Edman

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Reversible Loss of Enzymatic Activity due to N→O Acyl Migration

Lars Josefsson and Pehr Edman

Department of Physiological Chemistry, University of Lund, Lund, Sweden

It has been found that an N-peptidyl → O-peptidyl rearrangement can be brought about in lysozyme by keeping the enzyme for a few hours in formic acid solution at room temperature. During this treatment the enzyme is gradually inactivated. However, the activity can be completely restored by keeping the inactivated enzyme in aqueous solution at a neutral reaction. Using a pH-stat, it was found that at pH 7.5 the reactivation is accompanied by a consumption of alkali. Both the reactivation and the alkali consumption follows a first order reaction with a specific rate constant at 20° C of 1.15×10^{-2}.

A Comparative Study of Some Methods Used for the Quantitative Determination of Proteins

Bengt von Hofsten

Institute of Biochemistry, University of Uppsala, Sweden

Work on fractionation and metabolism of proteins at this Institute requires methods for protein determination. In many cases it is sufficient with rather approximate values on a large number of samples, whereas more precise methods are required when chromatographic recoveries and protein synthesis are studied.

The following methods have been compared as to relative simplicity, speed, sensitivity and specificity:

Direct turbidimetric method with trichloroacetic acid,

Biuret reaction,
Direct ninhydrin reaction,
Hydrolysis and ninhydrin reaction,
Bromsulfalein method,
Folin reaction according to Lowry *et al.*,
Ultra violet absorption at 280—290 mμ,
Total nitrogen determination (modified Kjeldahl or hypobromite titration).

Certain practical modifications have been introduced in some of these methods. Comparative data are given on protein material of different origin, and the relative merits of the methods are discussed.

Zone Electrophoresis of Low Molecular Weight Compounds in Cellulose Columns

Jerker Porath

Institute of Biochemistry, University of Uppsala, Sweden

The behavior of charged low molecular weight substances in cellulose columns under different conditions has been studied for some time at this Institute. From the experience accumulated, it has been possible to work out suitable methods for effective electrophoretic fractionation of synthetic and natural mixtures of amino acids, peptides and other compounds in quantities ranging from micrograms to 25 grams and more. A description of apparatus, working conditions and results will be given.

Exchange Reactions between D_2O and Proteins or Protein Models

K. Linderstrøm-Lang

Chemical Department, Carlsberg Laboratory, Copenhagen, Denmark

It has been shown by Harrington, Hvidt, Linderstrøm-Lang and Schellman that peptides like clupein, the A-chain of insulin, and oxidized ribonuclease are devoid of secondary and tertiary structures and exist in aqueous solutions in an unfolded state. On the other hand important investigations by Elliot, Doty, Katchalski and Berger have definitely demonstrated the presence of secondary structures in certain synthetic polyamino acids. Thus poly-DL-alanine, copolymers between aspartic acid and lysine and polyglutamic acids seem to form stable α-helices in aqueous solution. This is supported by studies of deuterium exchange carried out by Berger. The reason for the phenomena observed and the possible forces and bonds at play in the stabilization of these helices will be discussed with special reference to sidechain interactions of the following type

a. Electrostatic interaction
b. Hydrophobic forces
c. Hydrogen bonds, 1. neutral, 2. ionic.

Determination of Amino Acids as Phenyl Thiohydantoins

John Sjöquist

Department of Physiological Chemistry, University of Lund, Lund, Sweden

A method for the quantitative determination of amino acids as 3-phenyl-2-thiohydantoin derivatives using partition chromatography was briefly described in a preliminary report [1]. This work has been continued and it is now possible to separate most of the natural amino acid derivatives. The partition system consists of aqueous propionic acid as stationary phase with Celite as an inert support and heptane with increasing concentrations of ethylene chloride as moving phase. Quantitative recoveries from 10—20 μg of each phenyl thiohydantoin are obtained. Through automatic registration of the ultraviolet absorption in the effluent, the composition of the amino acid mixture is obtained directly.

Protein Chromatography on Columns of Calcium Phosphate

Arne Tiselius

Institute of Biochemistry, Uppsala, Sweden

A review of recent work at the Institute of Biochemistry regarding the chromatographic separation of a number of proteins and protein mixtures. A detailed paper will be published shortly.

Open Peptide Chains in α-Chymotrypsin

B. Meedom

Chemical Department, Carlsberg Laboratory, Copenhagen, Denmark

After oxidation of either α-chymotrypsin or di-*iso*propyl - phosphat - α - chymotrypsin with performic acid it is in both cases possible to separate the reaction products in three fractions: The reaction mixture is dissolved in alkali, and pH brought down to 6, whereby a precipitate (fraction B) is formed. The supernatant is placed on a small Dowex 50 column (H^+ form). By elution with water fraction A is collected and by subsequent elution with NH_4OH fraction C is obtained. Fraction A is a peptide of 13 amino acids having N-terminal cysteic acid and C-terminal leu. Preliminary experiments seem to indicate that fraction C mainly consists of a peptide of 22 amino acids having N-terminal ala, but no C-terminal residue susceptible to attack by carboxypeptidase. Fraction B seems to be a long peptide chain containing N-terminal leu or ileu, and C-terminal tyr. In the case of DIP-chymotrypsin this fraction contains all the phosphorus. It seems to be possible to correlate the results with the structural model for α-chymotrypsin which has been proposed by Neurath and by Desnuelle.

Dielectric Increment and Dispersion of Tropomyosin — a Highly Polar Protein

L.-G. Allgén

Chemistry Department, Karolinska Institutet, Stockholm, Sweden

A specimen of pure tropomyosin from rabbit skeletal muscle [1] (kindly supplied by Drs Bailey and Tsao, Cambridge) has been studied dielectrically in pure aqueous solution. With concentrations between 0.01 and 0.1 g/100 ml (pH about 6.7) dielectric increments between 1.6 and 7.0 dielectric constant units were obtained. From these values reduced dielectric increments per g per liter, $\Delta\varepsilon/g$, between 4.5 and 7.7 were calculated. There was a slight tendency for the $\Delta\varepsilon/g$ values to increase at low concentrations. As the solutions of tropomyosin showed marked time effects (mainly a decrease of the increment with age of solution) this tendency is not considered significant, however. $\Delta\varepsilon/g$ is thus essentially independent of concentration as has also been found with other simple proteins studied. Such proteins give $\Delta\varepsilon/g$ values between 0 and 2. The $\Delta\varepsilon/g$ obtained for tropomyosin is thus about 3 times higher than with the most polar protein studied so far (β-lactoglobulin).

Dielectric dispersions were obtained for tropomyosin which were markedly influenced by concentration, the critical frequency being displaced towards lower frequencies with decreasing concentration. This is contrary to the case with other simple proteins for which the critical frequency is independent of concentration or displaced towards higher frequencies with decreasing concentration (β-lactoglobulin). The dispersion curve corresponds approximately to a single relaxation time in each case. No further dispersion was obtained down to very low frequencies. The relaxation times calculated varied between 0.75×10^{-7} sec. at 0.10 % concentration and 1.5×10^{-7} sec. at 0.027 %.

The type of dielectric dispersion and the order of the dielectric increments obtained for tropomyosin (and for a nucleotropomyosin previously reported to the Society in 1953) approach those of a number of polyelectrolytes studied dielectrically, but differ markedly from those of other simple proteins. This is probably due to the unusually high content of free ionizable groups [1] (from arginine, lysine and especially glutamic acid residues) and the linear shape [2] (double chain, asymmetry *ca.* 30) of tropomyosin. Tropomyosin shows polyelectrolyte properties also in other respects. The marked viscosity and streaming birefringence of aqueous tropomyosin solutions is sharply reduced by small amounts of simple electrolytes [2]. This has been ascribed to a desaggregation [2], but a contraction of the molecules due to electrostatic screening may also contribute. There is thus a suggestive parallelism between this contractile muscle protein and synthetic mechano-chemical systems obtained by crosslinking acid polyelectrolytes to 3-dimensional networks [3].

Application of the pH-Stat for the Measurement of Proteolysis

M. Ottesen

Chemical Department, Carlsberg Laboratory, Copenhagen, Denmark

The methods ordinarily used to follow the opening of peptide bonds in proteins often fail in cases of limited proteolysis due to lack of sensitivity. Provided that the enzymatic reaction takes place at pH-values which are so high that most of the liberated amino groups exist in the unionized form, it is, however, possible to follow the opening of the peptide bonds by continuous titration at a constant pH by means of a Jacobsen-Léonis pH-stat. Different constructions of this device will be discussed. Using the pH-stat it is possible at pH 8 to follow the opening of a single peptide bond in the conversion of ovalbumin to plakalbumin. It has been attempted to correlate the opening of this bond with the change in solubility and crystal form. It was further observed that the salt-free ovalbumin solutions need a small continuous addition of alkali in order to keep pH constant, and the rate of this alkali addition seems to depend on the pH at which the ovalbumin was stored previously to the experiment.

Studies on a Myosin Fragment Obtained by Ammonium Sulphate Treatment of Myosin

Olle Snellman

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

Some preliminary data about the fragmentation of myosin with neutral ammonium sulphate have been given in another communication [1].

By treatment of the myosin with ammonium sulphate at 20° C two different fragments are obtained in nearly equal amounts by weight. Further studies have now been performed on the water-soluble fragment (H_{20}). This fraction precipitates in the preparation process between 40—50 % saturation of ammonium sulphate but cannot, after having been redissolved, be precipitated again with ammonium sulphate. It does not show any ability to associate with actin. The fragment is unstable and with time it is transformed to a large extent into dialysable pieces. During the deterioration process many different ultraviolet spectra can be obtained by different treatments. The fraction seems at first to break into three different parts as indicated by paper-chromatographic analysis. The final product obtained is dialyzable and has a high positive charge. Amino acids can no longer be obtained from it by acid hydrolysis.

Different means have been tried to stop the deterioration of the H_{20} fragment when it just has been obtained by the ammonium sulphate treatment. It has hereby been found that a treatment of the newly formed fragment with calcium hydroxide can stop the deterioration and a product is obtained which has the ability to associate with actin with an ensuing viscosity increase. This actin complex responses to ATP with a viscosity decrease independent of the salt concentration, and the viscosity increases again after a certain time to the normal level. A treatment with potassium oxalate of the calcium hydroxide-treated H_{20} fragment does not alter this effect. If the calcium hydroxide is added in a later step when the deterioration has begun, no effect of it will be found. As yet no other means have been found to restore the activity. The protein treated with calcium hydroxide shows an UV absorption spectrum with a maximum at 260—270 mμ.

From different experiments it is quite obvious that the myosin molecule must possess a unique structure. Probably some compound containing calcium is of importance in the reactions of the myosin, and when the calcium ions are removed this compound is very labile.

Studies on Human Acute Phase Protein (C-reactive Protein)

Inger Brattsten and Per Hedlund

The Institute of Biochemistry, University of Uppsala, Sweden; The Hospital for Contagious Diseases, and State Bacteriological Laboratory, Stockholm, Sweden

The fractionation of a sample containing sera from two persons in the acute phase of streptococcal pharyngitis and maxillary sinusitis, respectively, has been reported by Hed-

lund and Brattsten [1]. The fractionation was carried out by continuous zone electrophoresis [2] in a starch supporting medium at pH = 8.5 and the ionic strength = 0.03. The presence of acute phase protein in the fractions was determined by the capsular swelling reaction (Löfström [3]). Pneumococci suspensions of type 23 B were used. Reactive substance was found in the γ-globulin fractions exclusively, the capsular swelling titration curve showing a rather striking conformity with the γ-globulin distribution curve.

In order to check these results the same fractions were afterwards analysed against a pneumococci suspension of type 27, which was even more sensitive than type 23 B, and by precipitation with C-reactive protein antiserum (obtained from Schieffelin & Co., New York). Both tests confirmed the findings reported.

In the fractions obtained in the electrophoretic separation the reactive substance was present in mixture with other proteins of the γ-globulin type. This material has been studied as to its solubility in the presence of ammonium sulfate. As judged from the capsular swelling analyses, the reactive substance remains in solution at half saturation of this salt, but some precipitation occurs as the salt content is further increased. However, complete precipitation could not be achieved this way; even at saturation of ammonium sulfate the supernate showed a relatively strong activity reaction.

The initial fractionation experiment also showed that adequate isolation of acute phase protein could be obtained at a considerably lower total resolution than that used. Hence the procedure could be simplified by increasing the rate of fractionation. In subsequent work a quantity corresponding to 1.5 ml of undiluted serum has been fractionated per hour. In all, 65 ml of serum has been worked up. This includes material from three different cases of pneumonia in the acute stage. In order to establish a possible influence of the ionic strength on the mobility of the active material two fractionations have also been carried out at the ionic strength 0.06, other conditions remaining unchanged. After enrichment of the proteins, the fractions have been analysed by the capsular swelling reaction using type 23 B and 27 pneumococci suspensions and the C-reactive protein antiserum test. In all instances complete qualitative agreement with the primary result was obtained, thus showing that acute phase protein, developed in the diseases stated, resembles the γ-globulins in electrophoresis under the reported conditions.

The capsular swelling reaction was found to be more sensitive than the antiserum reaction.

Six months of storage in the frozen state (at —10° C, in Ringer's solution) did not affect the titer of the active substance.

On the Localization and Composition of Phosphoprotein in *Esherichia coli B*

Gunnar Ågren

Institute of Medical Chemistry, University of Uppsala, Sweden

In an earlier communication the preparation of a new phosphorylated amino acid in *Lactobacillus casei* has been reported [1,2]. Several peptides containing this compound were also found. In attempts to prepare more high molecular phosphoproteins the following experiments were carried out with *E. coli B*.

The bacteria was cultivated on Friedleins synthetic medium containing Na-lactate as the carbon source and NH_4Cl as nitrogen source [3]. To this medium was added 1 mC radioactive phosphate per liter. Procedures for cultivation and separation of bacteria have been described by Palmstierna and Holme [4,5]. In this experiment the initial bacterial density was 1.25×10^9 cells/ml. At the end after 120 minutes of incubation the density was 1.95×10^9 cells/ml. 24 g of freeze-dried bacteria was obtained.

Suspensions containing 0.5 g dry weight bacteria/20 ml in 0.04 M Tris-buffer were shaken in the Raytheon disintegrator for 30 minutes during continous cooling. The cell walls possibly contaminated with some cytoplasmatic debris [6] were removed from the lysed solution by centrifugation at 40 000 r.p.m. One part of

At the end after 120 minutes of incubation the density was 1.95×10^9 cells/ml. 24 g of freeze-dried bacteria was obtained.

Suspensions containing 0.5 g dry weight bacteria/20 ml in 0.04 M Tris-buffer were shaken in the Raytheon disintegrator for 30 minutes during continous cooling. The cell walls possibly contaminated with some cytoplasmatic debris [6] were removed from the lysed solution by centrifugation at 40 000 r.p.m. One part of

Table 1. R_G-values of the two ninhydrin-reacting substances from fraction 3 and 5 of the cell wall after complete hydrolysis. Run in different organic solvents on Munktell OB filter paper. The corresponding values for the hydrolyzed amino acid from L. casei are included.

$$R_G \text{ value} = \frac{R_F \text{ value of unknown substance}}{R_F \text{ value of glycine}}$$

	E. coli		*L. casei*
	Fraction 3	Fraction 5	
Phenol	0.41	0.95	1.26
Pyridine-water	1.77	0.95	1.96
n-Butanol-HAc-water	0.80	1.10	1.81
*Iso*butyric acid-NH_3-water	0.90	1.85	1.00
Pyridine-*iso*amylalcohol-water	1.10	1.50	2.11

centrifugate was fractionated at low temperature with ethanol and Zn-acetate mainly according to Cohn [7] and the other part with acetone [8] and Zn-acetate. From the five fractions of the ethanol and acetone precipitations and the cell wall the Schneider protein was prepared as previously described [1,9]. The partial acid hydrolysates were chromatographed on Dowex 50 columns.

The peaks containing ninhydrin-positive material were analyzed for activity. About 80 % of the total activity was present in the 5 peaks of the cell wall hydrolysate while the remaining 20 % were rather evenly distributed on the 17 peaks of the ethanol and acetone hydrolysates (Table 2). 20 % by weight of the dried bacteria was recovered as cell walls.

After complete hydrolysis all fractions were run on one dimensional chromatogram. The material from the two main peaks of the cell wall hydrolysate (3 and 5) gave one major spot with only traces of other ninhydrin-positive compounds. Table 1 shows the positions of these spots in several solvent systems. It seems probable that these two substances differ from the phosphorylated amino acid in *L. casei*. Furthermore on paper electrophoresis the two new substances behaved as more basic amino acids. With the copper complex method [10] the most basic material reacted like a non α-amino acid. The two new phosphorylated compounds were also present in the ethanol and acetone fractions of the bacterial cytoplasmic material.

Table 2.

Fractions numbered as leaving the Dowex 50 Column	Specific activity in cpm/μg P					
	Cell walls	50 % ethanol	Zn-acetate in 80 % ethanol	40 % acetone	60 % acetone	Zn-acetate in 60 % acetone
1	1 022	1 013	1 030	518	736	—
2	933	835	855	386	640	—
3	1 126	778	451	755	565	—
4	545	496	—	735	405	—
5	658	—	—	455	—	—
6	—	—	—	756	—	—

Table 2 shows the specific activity values of the phosphorylated amino acids and phosphopeptides. The values for the two main fractions of the cell wall are of the same order as the data obtained from the purified phosphorylated amino acid of the *L. casei* at the end of the lag phase.

Fluorescence of Steroids

S. Arrhenius

Kemiska Avdelningen, Kgl. Veterinärhögskolan, Stockholm, Sweden

It has previously been shown that the Zimmermann reaction cannot be ascribed to the 17-ketosteroids. Thus, the only reaction available at present for the characterization of steroids is their irreversible transformation into lumisteroids [1], *e. g.*, the more stable stereoisomers with the 18-methylgroup in *cis*-position to the hydrogen atom at carbon 14. This reaction, naturally occurring to all steroids, is induced by concentrated sulphuric or phosphoric acid (sometimes alkalies), and by UV light of wave lengths shorter than 3 130 Å.

This fluorescence is generally not observed with other steroids than estrogens and D-substances. It depends on the complicated nature of fluorescence, being a combination of at least five phenomena

1. The absorbtion of light energy by the electrons of one atomic group.

2. The re-emission of light by this or another atomic group.

3. The transformation of energy from the absorbing to the re-emitting group by molecular collisions or intramolecularly.

4. Quenching of energy by other atomic groups transforming the quenched energy into heat or light of unsuitable frequences or dissociation.

5. The re-absorbtion of the re-emitted light by the solutions.

Thus, the formula of Perrin [2] for the total intensity of fluorescence:

$$f = k_1 c \exp(k_2 c) = k_1 c \exp(c/c_{max})$$

will only apply when absorbing and re-emitting groups are combined in the same molecule, and quenching or re-absorbtion may be neglected.

If the principal part of the light energy is absorbed by a molecule which is totally free from the re-emitting atomic group, the intensity of fluorescence is directly proportional to the concentration of this group *e. g.* an amount of fluorescence suitable for quantitative analysis in all regions of concentration. However, the intensity of the absorbed energy must be sufficient for re-emission as well as for quenching to take place. The fluorescence must be measured in a wave length region where the steroid solutions have no absorbtion. An absolute requirement is that the fluorescence is not induced by light of so high frequencies that it will cause dissociation or polymerisation of steroids, *e. g.* UV light.

Both the absorbtion and the fluorescence of a steroid solution will always be spread over a broad wave length region. The maximum of the fluorescence intensity will be recorded by the photo cell when the filter between the light source and the container for the fluorescent medium has transmitted all visible light absorbable by this medium. The filter in front of the photo cell should ideally transmit light of all wave lengths absorbed by the former filter. The only way to approach this ideal filter system is to use certain solutions. Those of nickel sulphate and potassium bichromate have been used in a special type of fluorimeter.

On the Synthesis and Breakdown of a Glycogen-like Polysaccharide * in *Escherichia coli B*

T. Holme and H. Palmstierna

Bacteriological Department and Chemical Department I, Karolinska Institutet, Stockholm, Sweden

The following experiment was intended to elucidate the synthesis and breakdown of a glycogen-like polyglucose in bacterial cells.

Experimental. *E. coli* cells were cultivated in Friedleins medium with a restricted nitrogen source in the same way as previously described [1]. During the starvation phase, the cell concentration was 6×10^8 cells per ml, corresponding to 142 mg of cells per liter of culture (corrected dry weight). During this phase no net synthesis of protein occurred but glycogen was synthesized at an initially high rate. At the beginning of this phase, β-labeled ^{14}C-lactate was added. The cells were spun down 45 minutes after the addition of the labeled lactate. Then the cells were suspended in the Friedlein medium devoid of the carbon source. The nitrogen source contained ^{15}N to an excess of 15.6 %. After 90 min. in this medium the cells were harvested. The aeration, the harvesting procedures, and the chemical methods were the same as those previously described [2]. For measuring the radioactivity, the samples were spread on aluminium planchets and counted at infinite thinness in a windowless gas flow counter, flushed with a helium-*iso*butane mixture. Since the layer of material did not exceed 0.05 mg per cm^2, no correction was made for self-absorption.

Results. The specific activity of the glycogen carbon in the cells 45 min. after the addition of the labeled lactate was sixteen times higher than the specific activity of the protein carbon (Table 1, sample II). When these cells had been cultivated for 90 min. in the nitrogen-containing, carbonless medium (sample III), the specific activity of the glycogen carbon had decreased to about one sixth of the value in sample II. The glycogen per liter of culture decreased only to about two thirds of the value in sample II. During the same time there was a net synthesis of protein amounting to 12 % of the amount in sample II. The ^{15}N excess in the protein was 1.3 in sample III. The specific activity of the protein carbon in sample III was eight times the value in sample II.

The results may be interpreted in the same way as the results of Stetten and Stetten [3], working with rats injected once with labeled glucose. When the rats were killed a short time after the injection and their glycogen partially degraded by enzymes, it was found that the specific activity of the limit dextrins was less than the specific activity of the glucose split off. The interpretation may be that those glucose residues, which were the last ones to be formed, were preferentially attached to the ends of the glucose chains in the glycogen. The present results suggest that this "peripheral tier" of glucose residues was the first one to be utilized. Other explanations, taking an inhomogeneity of the glycogen into consideration, are also possible. Part of its carbon was possibly utilized in protein synthesis.

Table 1.

	I	II	III
C.p.m. per milliatom of glycogen carbon	0	110×10^3	17×10^3
C.p.m. per milliatom of protein carbon	0	7×10^3	57×10^3
^{15}N-excess of the protein	0	0	1.32
Protein-nitrogen, per cent of dry weight	6.7	6.4	7.3
Glycogen-glucose, per cent of dry weight	19.7	21.6	15.5

The roman numerals at the top of the table refer to the times at which the samples for analysis were taken. Sample I was taken at the moment of addition of the labeled lactate (205 min. after the inoculation of the nitrogen-deficient culture). Sample II was taken 45 min. after the addition of the labeled lactate, e. g. at the time the cells were spun down and resuspended in the nitrogen-containing, carbon-free medium. Sample III was taken 90 min. after the inoculation into this medium.

* For the sake of brevity called glycogen.

Kinetics of Hyaluronidase

Svend Olav Andersen and John Graae

Universitetets fysisk kemiske institut, Copenhagen, Denmark

The enzymatic splitting of hyaluronic acid is studied by means of viscometry. The reaction is followed to more than 90 % reduction in the specific viscosity.

The substrate was potassium hyaluronate prepared from umbilical cords according to Jensen [1]. The enzyme was a commercial hyaluronidase "Invasin Lundbeck". The investigations were carried out in a modified Ostwald viscosimeter. All experiments were carried out at 20° C and pH = 7.0 in a McIlvaine phosphate-citrate-sodium chloride buffer solution.

Taking η/η_0 as a reaction parameter and calling $\eta/\eta_0 = y$ we find empirically that the results in the investigated interval fit the chronometric integral

$$E \cdot t = A(1/y—1) + B(1/y^2—1),$$

where t is time, A and B are constants and E is the enzyme concentration which varied by a factor of 4 in different runs.

The concentration of potassium hyaluronate was in all experiments 0.4 %. The above mentioned expression is different from other expressions found in the literature to describe the degradation of hyaluronic acid. Most of these involve a first order decay of the specific viscosity [2] or a Michaelis expression [3].

The interpretation of these results is not obvious. If we accept the Staudinger equation $\eta_{spc} = KMc$, (where K is a constant, M the average number of units in the high molecular substance and c the concentration in weight %) and if we furthermore assume that the enzyme splits a constant number of bonds per time unit, we can derive the expression

$$E \cdot t = K(1/y—1)$$

which accounts for the dominating term in our expression.

More details on these experiments are published at the time of the meeting [4].

Biliary Excretion of Cholesterol and Bile Acids in Bile Fistula Rats

Sten Eriksson

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The main metabolic end products of cholesterol in the rat have been shown to be taurocholic and taurochenodeoxycholic acids [1]. Several authors [2,3] have studied the daily excretion of cholic acid and cholesterol in bile fistula rats but due to the lack of a suitable analytical method no detailed analysis of the excretion pattern has so far been undertaken. In the present study bile has been collected from rats with a bile fistula. The amount of bile and its content of taurocholic and taurochenodeoxycholic acid has been determined at various intervals during the 14 days following the operation. The bile acid content was determined by the methods developed by Sjövall [4].

In Table 1 some typical values obtained are shown. The output of bile acids during the first 6 hours after the operation is considerably higher than the output during the subsequent 6 hours periods. A minimum generally occurs between 12 and 18 hours after the operation. The amount of bile acids excreted during the first 6 hours largely represents the amount of bile salts circulating in the intact animal [5]. Following the minimum excretion between 12 and 18 hours there is a rapid increase in the

Table 1. Excretion of Na-taurocholate (TC) and Na-taurochenodeoxycholate (TCD) in bile fistula rats.

Hours after operation	Rat No. 1		Rat No. 2	
	TC mg	TCD mg	TC mg	TCD mg
0— 6	10.4	3.44	13.4	4.9
6— 12	3.86	0.94	3.4	1.5
12— 18	1.97	0.78	1.7	1.0
18— 24	5.25	1.85	2.7	0.95
24— 48	49.1	10.1	33.6	4.0
48— 72	52.2	15.9	39.2	12.0
72— 96	37.6	13.8	31.2	28.0
96—120	35.3	16.5	36.4	12.0
120—144	47.3	19.1	35.8	12.0
144—168	45.2	14.9	26.0	10.8
168—192	39.4	19.2	—	—

amount excreted and a constant level is reached after the second day with a total excretion of bile salts ranging between 50 and 80 mg/day. These amounts have to be compared with the daily synthesis of bile acids in an intact animal. From the turnover time of labelled bile acids [6] and the determinations of the amount of bile acids in the enterohepatic circulation by isotope dilution [5] a daily synthesis of 2—3 mg of bile acids in a 200 g rat has been calculated. In a bile fistula rat there is thus a 20—30 fold increase of the normal bile acid production. This synthesis of bile acids in bile fistula rats is thus the result of a broken enterohepatic circulation. Further studies are in progress to elucidate factors regulating this process and its relation to the metabolism of cholesterol.

Urea Solution as a Solvent for the Viscosimetric Determination of Lichenase Activity

Eskil Hultin

Institutet för organisk kemi och biokemi, Stockholm, Sweden

Viscosimetric methods are generally more sensitive than other methods for the determination of the activity of enzymes which are capable of breaking down polymer-homologous substances. It follows as a matter of course that a viscosimetric determination of enzymic activity can only be carried out with such substrates as are completely soluble and give solutions with a high viscosity.

Lichenin is a polysaccharide which is easily soluble only in warm alkaline water solution, and much of it is precipitated if the temperature and the pH are lowered to such values as are suitable for the investigation of the activity of lichenase. A new method for obtaining solutions of lichenin is suggested here.

It has turned out that lichenin is soluble in water solutions of urea.

The viscosimetric determination of lichenase can be carried out as follows. Lichenin is dissolved in a warm urea solution, containing 0.3 to 0.5 g urea for each gram of water. A lichenin concentration of a few per cent may have a viscosity of about 3 or 4 times that of the urea solution, which is convenient.

One ml of an enzyme solution and 1 ml of a buffer solution are transferred to an Erlenmeyer flask. Two ml of the lichenin solution are added, and the contents are thoroughly mixed. Two ml of the reaction mixtures are transferred to a dry Ostwald viscosimeter, and a timer is started. The flow time is measured several times.

The inverse value of the specific viscosity is computed for each flow time by dividing the flow time for the solvent by the flow time of the reaction mixture diminished by the flow time of the solvent.

The inverse values of the specific viscosity are plotted in a diagram *versus* the times, for which they are valid, and a straight line is fitted to the points. The inclination of the line, multiplied by the square of the concentration of lichenin in the reaction mixture, is a measure of the enzyme activity.

By this viscosimetrical method it was shown that sperm of *Paracentrotus lividus* contain lichenase in small quantities.

The method suggested here — dissolving lichenin in a urea solution — has the advantage, that the true solution of even a high molecular fraction of the naturally occurring substrate, and not its hydroxy ethyl or carboxy methyl ether — as is the case with cellulose and chitin — can be used for the assay of enzymes capable of splitting β-1,4 glucoside linkages.

Sialic Acid and Neuraminic Acid

Gunnar Blix

Institute of Medical Chemistry, University of Uppsala, Sweden

The structure of sialic acid and of neuraminic acid is discussed principally on the basis of group analyses and periodate oxidations and with particular regard to the ideas recently put forward by Gottschalk [1]. The structures proposed by this author are in the main in good agreement with our findings.

This synthesis of bile acids in bile fistula rats is thus the result of a broken enterohepatic circulation. Further studies are in progress to elucidate factors regulating this process and its relation to the metabolism of cholesterol.

Urea Solution as a Solvent for the Viscosimetric Determination of Lichenase Activity

Eskil Hultin

Institutet för organisk kemi och biokemi, Stockholm, Sweden

Viscosimetric methods are generally more sensitive than other methods for the determination of the activity of enzymes which are capable of breaking down polymer-homologous substances. It follows as a matter of course that a viscosimetric determination of enzymic activity can only be carried out with such substrates as are completely soluble and give solutions with a high viscosity.

Lichenin is a polysaccharide which is easily soluble only in warm alkaline water solution, and much of it is precipitated if the temperature and the pH are lowered to such values as are suitable for the investigation of the activity of lichenase. A new method for obtaining solutions of lichenin is suggested here.

It has turned out that lichenin is soluble in water solutions of urea.

The viscosimetric determination of lichenase can be carried out as follows. Lichenin is dissolved in a warm urea solution, containing 0.3 to 0.5 g urea for each gram of water. A lichenin concentration of a few per cent may have a viscosity of about 3 or 4 times that of the urea solution, which is convenient.

One ml of an enzyme solution and 1 ml of a buffer solution are transferred to an Erlenmeyer flask. Two ml of the lichenin solution are added, and the contents are thoroughly mixed. Two ml of the reaction mixtures are transferred to a dry Ostwald viscosimeter, and a timer is started. The flow time is measured several times.

The inverse value of the specific viscosity is computed for each flow time by dividing the flow time for the solvent by the flow time of the reaction mixture diminished by the flow time of the solvent.

The inverse values of the specific viscosity are plotted in a diagram *versus* the times, for which they are valid, and a straight line is fitted to the points. The inclination of the line, multiplied by the square of the concentration of lichenin in the reaction mixture, is a measure of the enzyme activity.

By this viscosimetrical method it was shown that sperm of *Paracentrotus lividus* contain lichenase in small quantities.

The method suggested here — dissolving lichenin in a urea solution — has the advantage, that the true solution of even a high molecular fraction of the naturally occurring substrate, and not its hydroxy ethyl or carboxy methyl ether — as is the case with cellulose and chitin — can be used for the assay of enzymes capable of splitting β-1,4 glucoside linkages.

Sialic Acid and Neuraminic Acid

Gunnar Blix

Institute of Medical Chemistry, University of Uppsala, Sweden

The structure of sialic acid and of neuraminic acid is discussed principally on the basis of group analyses and periodate oxidations and with particular regard to the ideas recently put forward by Gottschalk [1]. The structures proposed by this author are in the main in good agreement with our findings.

Information about the Structure of Phthiocerol from Mass Spectral and X-Ray Crystallographic Data

Ragnar Ryhage

Laboratory for mass spectroscopy, Biochemical Institute, Karolinska Institutet, Stockholm

Einar Stenhagen

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala
and

Erik von Sydow

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Phthiocerol, the optically active wax alcohol found in the waxes of several types of tubercle bacilli [1,2] has the empirical composition $C_{34}H_{67}(OH)_2OCH_3$. The carbon skeleton of phthiocerol corresponds to 4-methyltritriacontane [3-5]. Recent attempts to determine the structure of phthiocerol by degradative methods have led Demarteau-Ginsburg and Lederer [6], and Hall and Polgar [7] to formulate phthiocerol as 4-methyl-5-methoxy-8,10-dihydroxytritriacontane and 4-methyl-4-methoxy-9,10-dihydroxytritriacontane,respectively.

The above formulations appeared to be at variance with the results of monolayer experiments [8] which suggested that one of the polar groups must be situated near one end of the chain. We have therefore tried to obtain further evidence on the structure of phthiocerol from a study of its mass spectrum and X-ray diffraction pattern [9,10].

A striking feature of mass spectrum is an extremely strong peak at mass number 73. The corresponding fragment must contain one oxygen atom, which in this case means that it must contain the intact methoxyl group. For this to be possible, the methoxyl group must occupy position 2 or 3 in the intact phthiocerol molecule. The strongest peak in the mass spectrum of methyl-*n*-heneicosyl ether is due to the fragment $CH_3—O—CH_2—$; by analogy position 3 appears more probable than position 2 for the methoxyl group in phthiocerol. There is evidence that elimination of methoxyl or hydroxyl groups in the fragmentation process in the mass spectrometer introduces a double bond in α,β-position to the carbon atom initially carrying the oxygen atom. A similar reaction mechanism would explain that Demarteau-Ginsburg and Lederer [6] were able to isolate methyl-*n*-propyl ketone after ozonization of the ene-diol obtained after removal of the methoxyl group.

The mass spectrum of phthiocerol shows further points of interest and may allow a direct determination of the position of the two hydroxyl groups when mass spectral data have been obtained for simple long chain glycols.

The X-ray diffraction pattern of phthiocerol [4] shows a series of orders of a long spacing of 46 Å with a characteristic intensity distribution. Using reasonable assumptions regarding the arrangements of the molecules in the lattice we have calculated the intensities of the 00*l* reflexions for different molecular models with the methoxyl group in position 2, 3, 4 and 5, respectively. Good agreement with experiment was found only when the methoxyl group occupied position 2 or 3.

Details of this work will be published later.

Infrared Absorption of Monoketo-Stearic Acid Methylesters

Ingrid Fischmeister

Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

The infrared spectra of the monohydroxy- and monoketo-stearic acids and their methyl esters, known from the work of Bergström *et al.*[1], are being investigated in view of the possibility of identification. Out of this group, only the monoketo-stearic acid methylesters are not too complicated with respect to polymorphism; they were therefore investigated first.

The spectra of these positionally isomeric esters — dispersed in the solid state in potassium bromide — show characteristic differences between 7.4 and 15 μ, which allows complete identification. In the region between 7.4 and 8.4 μ there is a sort of band progression, similar to that known from the homologous series of fatty acids. Parallel investigations on methyl esters of keto-fatty acids of varying chain length show that these absorption bands are determined mainly by the chain length between the ester and keto group.

Quasi-racemic Compounds in Homologous Series of Branched Long Chain Acids

Bo Hallgren

Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

We have previously [1] demonstrated the existence of a quasi-racemic compound between optically active forms of isomeric methyl-substituted long chain acids. In the present work quasi-racemic compounds have been found between optically active forms of homologous 3-methyl-substituted long chain acids. When (+)-3D-methyltricosanoic acid [2] of m. p. 62.1—62.3° is mixed in equimolecular proportions with (—)-3L-methyltetracosanoic acid [3] of m. p. 65.4—65.6° it is found that the mixture melts at 68.6°, that is higher than either component. The melting point curve for this binary system shows that mixtures containing from about 10 to about 90 % of one of the enanthiomorphs can exist in two different forms. The stable, higher-melting form corresponds to the racemic compound. The melting point curve of the unstable, low-melting form shows a simple eutectic point only. The melting point diagram of the binary system of (+)-3D-methyltricosanoic acid and (+)-3D-methyltetracosanoic acid also shows the existence of an eutectic point only.

We have recently found that the enanthiomorphs of 3-methyltetracosanoic acid form quasi-racemic compounds with the enanthiomorphs of 3-methyldocosanoic acid [4] and 3-methyloctadecanoic acid [5] having the opposite configuration.

Adenine Deoxyriboside Polyphosphates

Hans Klenow, Eleanor Lichtler and Bjørn Andersen

Institute of Cytophysiology, University of Copenhagen, Denmark

In the past few years the enzyme catalyzed phosphorylation of a number of nucleoside mono- and diphosphates by nucleoside triphosphates has been recognized. Evidence has also been obtained that deoxyadenylic acid (deoxy-AMP), deoxycytidylic acid and thymidylic acid act as phosphate acceptors in different enzyme systems [1-3].

We have incubated adenosine triphosphate (ATP) with the deoxyribose analogues of adenylic acid (AMP) or guanylic acid in the presence of red bone marrow extract, muscle extract or myokinase. By two dimensional paper chromatography two additional deoxyribose compounds were found to have been formed. The products formed from reactions between ATP and deoxy-AMP have been isolated in preparative scale. This was accom-

plished by chromatography on columns of an anion exchanger. The fractions obtained containing the ultraviolet absorbing peaks were then rechromatographed on cellulose powder columns using an alcoholic borate solution as eluant. The analysis and the chromatographic behaviour of the six adenine compounds isolated suggest that they are AMP, adenosine diphosphate (ADP) and ATP, and their three deoxyribose analogues (deoxy-AMP, deoxy-ADP and deoxy-ATP, respectively).

The deoxy-ADP and deoxy-ATP were tested with some enzyme systems known to react with ADP or ATP. Deoxy-ADP was assayed spectrophotometrically with pyruvate kinase, using phosphopyruvate, reduced diphosphopyridine nucleotide and lactic dehydrogenase. It was found that deoxy-ADP reacted with a rate which was about 10 % of that of the same concentration of ADP. When both compounds were present in equimolar amounts, the reaction rate was reduced to about 80 % of that with ADP alone. When diphosphopyridine nucleotide (DPN) pyrophosphorylase from yeast [4] was tested with deoxy-ATP and nicotinamide mononucleotide (NMN) in the presence of excess inorganic pyrophosphatase, it was found that two compounds were formed. One of them was ortho phosphate, and the other was a compound which in the presence of alcohol and alcohol dehydrogenase or glutamic acid and glutamic acid dehydrogenase gave rise to light absorption at 340 mμ. It is therefore assumed that it is a dinucleotide of NMN and deoxy-AMP.

Incorporation of ^{32}P into Nucleic Acids of Normal and Synchronized Protozoan Cultures

Otto Scherbaum

Institute of Cytophysiology, University of Copenhagen, Denmark

Cultures of *Tetrahymena pyriformis GL*, grown under controlled conditions [1] were incubated with ^{32}P in different growth phases.

Three parallel cultures were grown up to a density of 5×10^4 cells per ml. They were subjected to intermittent heat treatment to produce synchronized divisions [1]. Each of these cultures was incubated for 20 minutes with ^{32}P at one of the three different growth steps: 1) During normal logarithmic multiplication; 2) after the last of the standard heat treatments, and 3) just prior to the first synchronous division. An acetone powder was prepared as described earlier [2], yielding dry weights of about 150—350 mg for each sample. Nucleic acids were separated and RNA was degraded according to the method of Schmidt-Thannhauser-Schneider. Special consideration was given to the removal of inorganic P. The amounts of DNA and of RNA-ribotides were determined by optical density λ_{260} in the Beckmann Spectrophotometer and the radioactivity per density unit (DU = Vol. (ml) × extinction at 260 mμ) measured. This specific activity indicated the rate of incorporation of ^{32}P during the incubation period. The ribotides of RNA were chromatographed on paper in ammoniumsulphate-propanol solvent, the spots eluted and optical density similarly determined.

The dry weight follows closely the threefold volume increase during treatment, while the estimated content of both nucleic acids, expressed as DU per mg dryweight is almost constant. The specific activity of both nucleic acids is remarkably reduced during the treatment to about 7 % of the control logarithmic phase, but prior to the first synchronous division it rises to about 30—40 % of the values obtained in normal growth. While the overall picture of the specific activity of RNA shows a remarkable decrease after the heat-treatment, also the composition of the RNA, expressed as the ratios of the specific activities of AMP/GMP/UMP+CMP shows changes in the different steps. In Table 1 this is illustrated.

Table 1. Specific activity (SA) of the four ribotides of RNA in different growth phases. The numbers 1, 2 and 3 refer to the earlier mentioned steps of growth.

	1		2		3	
	SA	%	SA	%	SA	%

The Catabolism of Uracil in Rat Liver Slices

Per Fritzson* and Karl F. Nakken

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

Fink *et al.*[1] have clearly established the conversion of dihydrouracil to β-alanine *in vitro*. β-Ureidopropionic acid could be detected [2]. Attempts to demonstrate the formation of dihydrouracil and β-alanine from uracil were unsuccessful.

We have now studied the catabolism of uracil in rat liver slices by means of labeled compounds [3,4].

One μmole of uracil-4-^{14}C, dihydrouracil-4-^{14}C and β-alanine-1-^{14}C, respectively, were incubated with rat liver slices. The incubation mixture was analysed by means of paper chromatography in different systems. The distribution of the activity on the paper strips was determined.

The data recorded in Table 1 together with data from β-alanine catabolism [5] indicate the following pathway of uracil catabolism in the rat: uracil → dihydrouracil → β-ureidopropionic acid → β-alanine → acetic acid + CO_2.

The difficulty in detecting dihydrouracil and β-ureidopropionic acid as intermediates in the uracil catabolism, is probably due to the rapid conversion of dihydrouracil to β-alanine.

period to be investigated 1 one liter culture was centrifuged in 750 ml tubes with funnel-shaped bottoms at 200 g for 5 minutes, the cells collected, resuspended in 50 ml of proteose-peptone medium and transferred back to the original shaking-aeration-temperature conditions. The isotope was added to this concentrated culture, and at the conclusion of the 20 minute incubation-period acetone powder was made of the ciliates. 1/10 of the powder dried *in vacuo* was submitted to a classical Schmidt-Tannhauser-Schneider procedure. The remaining 9/10 were extracted with 80 % saturated ammonium sulphate and the extract submitted to differential dialysis against Norite [1]. The nucleotides were isolated from the Norite eluate by subsequent chromatography in three different solvent systems.

The results (Table 1) are taken from one experiment, point 1 representing normal growth, point 2 the last 20 minutes of heat-treatment, point 3 the 20 minutes just prior to the first burst of division. The same amount of isotope was added to the cultures.

More detailed results will be presented on other points in support of the following working hypothesis, that the increase in cell size and nucleic acid content [3] in this induced abnormal growth is due to a failure of the cell to produce the normal precursors for nucleic acid synthesis, and that this is not due to a decrease in the permeability of the cell.

Aspartate Carbamyl Transferase from *E. Coli*

Peter Reichard

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Extracts from lyophilized cells of *E. Coli* contain an enzyme which catalyzes the formation of ureidosuccinate (carbamyl aspartate) from aspartate and an "active" carbamyl compound [1]. The recent discovery of carbamyl phosphate as the carbamyl donor in enzymic citrulline synthesis [2] has made possible a further investigation of the mechanism of carbamyl aspartate synthesis. With a 90 fold purified enzyme it was possible to demonstrate the stoichiometric reaction: carbamyl phosphate + aspartate ⇌ carbamyl aspartate + phosphate. The equilibrium of the reaction was shifted far towards synthesis of carbamyl aspartate. In the original bacterial extract ornithine and aspartate served about equally well as acceptors for the carbamyl group. With the purified enzyme, however, only aspartate out of *ca.* 30 different amino acids gave rise to a carbamyl compound.

In the absence of aspartate, there was no enzymic exchange of isotope between ^{32}P-phosphate and carbamyl phosphate. Neither could any enzymic isotope exchange be observed between ^{14}C-aspartate and carbamyl aspartate. These experiments tend to exclude the intermediate formation of a carbamylated enzyme. When the reaction was carried out in H_2O^{18} no isotope was found in the reisolated carbamyl phosphate or in the carbamyl group of the carbamyl aspartate formed. A probable mechanism for the carbamyl transfer reaction will be discussed.

The Catabolism of Uracil in Rat Liver Slices

Per Fritzson* and Karl F. Nakken

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

Fink *et al.*[1] have clearly established the conversion of dihydrouracil to β-alanine *in vitro*. β-Ureidopropionic acid could be detected [2]. Attempts to demonstrate the formation of dihydrouracil and β-alanine from uracil were unsuccessful.

We have now studied the catabolism of uracil in rat liver slices by means of labeled compounds [3,4].

One μmole of uracil-4-^{14}C, dihydrouracil-4-^{14}C and β-alanine-1-^{14}C, respectively, were incubated with rat liver slices. The incubation mixture was analysed by means of paper chromatography in different systems. The distribution of the activity on the paper strips was determined.

The data recorded in Table 1 together with data from β-alanine catabolism [5] indicate the following pathway of uracil catabolism in the rat: uracil → dihydrouracil → β-ureidopropionic acid → β-alanine → acetic acid + CO_2.

The difficulty in detecting dihydrouracil and β-ureidopropionic acid as intermediates in the uracil catabolism, is probably due to the rapid conversion of dihydrouracil to β-alanine.

Incorporation of ^{32}P into the Purine Ribonucleotides of *Tetrahymena pyriformis* in Heat-treated Cultures

Paul Plesner

Institute of Cytophysiology, University of Copenhagen, Denmark

The incorporation of ^{32}P into synchronized cultures of *Tetrahymena pyriformis* has been investigated by a modification of the technique previously described [1]. In each experiment 3 one liter cultures were simultaneously submitted to intermittent heat-treatment as described by Scherbaum and Zeuthen [2]. 20 minute periods of incubation with isotope were used. 30—20 minutes before the beginning of the

ACTA CHEMICA SCANDINAVICA 10 (1956) 163—173

Studies on the Extraction of Metal Complexes

XVI. Distribution Studies on the Complex Formation of U(VI) with Salicylic Acid and Methoxybenzoic Acid

BRITA HÖK-BERNSTRÖM

Research Institute of National Defence, Dept. 1, (FOA 1), Sundbyberg 4; Institute of Inorganic and Physical Chemistry, University of Stockholm, Sweden

The complex formation of UO_2^{2+} and salicylic acid, H_2A, has been studied by means of distribution data. The solvent system was hexone — 0.1 M $NaClO_4$ and the temperature 25° C. The UO_2^{2+} concentration was varied between 10^{-3} M and 5×10^{-5} M, while the salicylic acid concentration was varied between 1 M and 10^{-2} M. The results indicate that the predominant species in the hexone phase are (for the representation of the complexes, *cf.* Ref.[9]) $UO_2(H_2A)_2(H^+)_{-2}$ and $UO_2(H_2A)_3(H^+)_{-2}$. Complexes formed in appreciable amounts in the aqueous phase in the pH-range 3—5 seem to be $UO_2(H_2A)(H^+)_{-1}$ and $UO_2(H_2A)(H^+)_{-2}$. The equilibrium constants for the formation of these complexes are given in Table 1. Comparative experiments were run with methoxybenzoic acid (HB). The extractable complex is UO_2B_2. In the aqueous phase $UO_2(B)(OH)$ seem to form. The equilibrium constants for the methoxy-complexes are given in Table 2.

Although salicylic acid, H_2A, is known to form complexes with U(VI) and use of this tendency has been made in analytical chemistry [1], no quantitative information can be found regarding how the complexes are built up or about their stability.

Salicylic acid is a dibasic acid. The first dissociation constant $k_a' = 10^{-2.82}$ and the distribution constant $k_d = 10^{2.51}$ of the acid between hexone and water have been determined previously [2]. The second dissociation constant k_a'' due to the phenolic hydrogen, is approximately [3,15] 10^{-13}. In acidic and neutral solutions only undissociated acid, H_2A, and the ion HA^- will be present. However, there are reports in the literature that salicylic acid very often forms chelate compounds with metals [4,5]. The following reaction is therefore conceivable

$$UO_2^{2+} + HA^- \rightleftharpoons UO_2A + H^+ \qquad (1)$$

The ligand may thus be either HA^- or $A^=$. The ability to form a chelate compound by removal of the phenolic hydrogen is lost with methoxybenzoic acid

as the ligand. Since the ligands are very similar, a comparison of these two reagents was made in order to see whether the data indicated that a displacement of the phenolic hydrogen during complex formation took place.

In the present paper extraction data for the system U(VI)-salicylic acid -H_2O-hexone are presented. The data are analysed in order to find which complexes are formed in appreciable amounts and possible equilibrium constants for the formation of these complexes are calculated. Data are also presented for the system U(VI)-methoxybenzoic acid-H_2O-hexone so that comparison of the two ligands can be made.

EXPERIMENTAL

Chemicals. A standard solution of $UO_2(ClO_4)_2$ in 0.1 M $HClO_4$ was prepared by dissolving UO_3 of a very pure quality in a known excess of acid. The concentration of the solution was determined by evaporation of an aliquot and ignition to U_3O_8. Salicylic acid of analytical grade was used without further purification. The hexone used was of technical grade. After filtration it was washed with $HClO_4$ and NaOH in order to remove any basic and acidic impurities and thereafter several times with water.

Procedure. All experiments were carried out at 25° C and the ionic strength was adjusted to 0.1 M with $NaClO_4$. In the experiments a solution of salicylic acid in hexone was shaken for at least 18 hours with an equal volume of an aqueous UO_2^{2+} solution. After equilibration, the two phases were centrifuged and separated. The hydrogen ion concentration of the aqueous phase was measured with a Radiometer valve potentiometer, type 3i. The uranium analyses were made by a fluorimetric method [6] (the fluorimeter used was constructed at *AB Atomenergi*). Only the phase containing the smaller fraction uranium was analysed. The uranium content of the other phase was obtained by difference from the total uranium content. Tests for material balance were only made in a few cases since no precipitate was ever noticed in the solutions. Aliquots of the sample liquid were taken out for analyses and evaporated on a platinum disc. Hexone solutions with high salicylic acid concentration were extremely difficult to evaporate without loss. Furthermore, there was a risk that too large a residue would catch fire in the fusion procedure. 90 % NaF and 10 % Na_2CO_3 was used as mixed flux. Blank determinations were run at the same time and subtracted. A calibration curve was obtained from known $UO_2(ClO_4)_2$-solutions.

The colorimetric determination of uranium by the oxine-extraction method [7] gave no reliable results because of too high blank readings of the salicylic acid.

The experiments were started with constant initial concentration of salicylic acid in the organic phase $[H_2A]_{tot}$. In all experiments $[H_2A]_{tot} \gg [U]_{tot}$ so that the addition of $[U]_{tot}$ does not change the ligand concentration in the solution. The calculation of the concentrations $[HA^-]$ and $[H_2A]_{aq}$ at different pH was made according to eqns. (2) and (3) for equal phase volumes

$$[HA^-] = \frac{k_a\,[H_2A]_{tot}}{[H^+]\,(k_d + 1 + k_a/[H^+])} \tag{2}$$

$$[H_2A]_{aq} = \frac{[H_2A]_{tot}}{(k_d + 1 + k_a/[H^+])} \tag{3}$$

Since k_d is large, the denominator in eqn. (3) is unaffected of the ratio $k_a/[H^+]$ for $[H^+] \geq k_a$; thus $[H_2A]_{aq}$ remains constant in the aqueous phase up to pH $\sim$ 3 after which it starts to decrease with increasing pH.

RESULTS

The U(VI)-salicylic acid system

For mononuclear complex reactions q, the distribution ratio of the metal, must be independent of the metal concentration. For this purpose the initial uranium concentration was varied between 10^{-3} M and 5×10^{-5} M. In Fig. 1 the logarithm of the distribution ratio q is plotted against $-\log[H^+]$ for different initial salicylic acid concentrations. The curves show no systematic spread for uranium concentrations $\leq 2.5 \times 10^{-4}$ M. It may therefore be concluded that the presence of polynuclear complexes can be neglected in solutions of U(VI) and salicylic acid when $[U]_{tot} \leq 2.5 \times 10^{-4}$ M.

For $[U]_{tot} = 10^{-3}$ M the points fall on the curves of the lower uranium concentrations up to a pH about 3 (Fig. 1). However, for $[H_2A]_{tot} = 0.1$ M, the

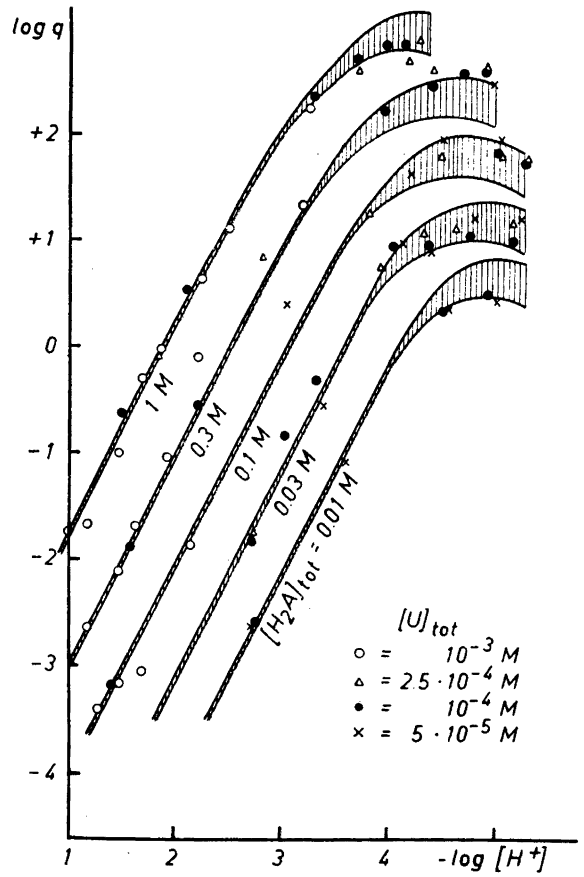

Fig. 1. Variation of the distribution ratio q *of U(VI) with* $-\log [H^+]$ *for different initial salicylic acid concentrations,* $[H_2A]_{tot}$. *The full lines enclosing the shaded area represent the estimated limits of error, when curves are calculated according to eqn. (15).*

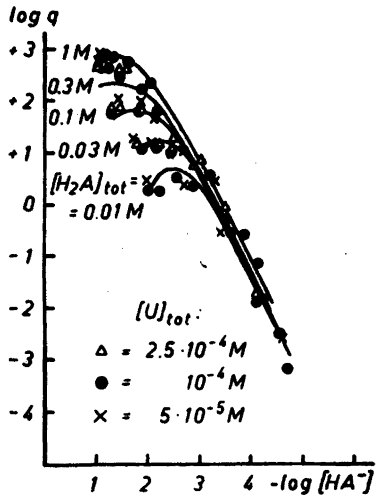

Fig. 2. Variation of the distribution ratio q *of U(VI) with* $-\log [HA^-]$ *for different initial salicylic acid concentrations,* $[H_2A]_{tot}$.

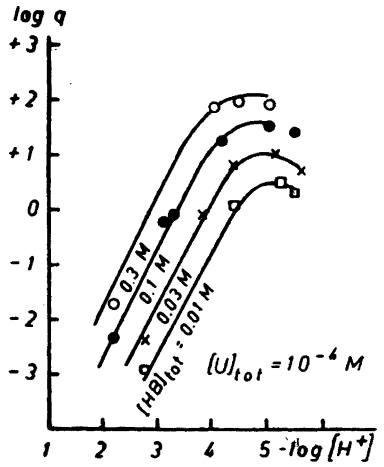

Fig. 3. Variation of the distribution ratio q *of U(VI) with* $-\log [H^+]$ *for different initial methoxybenzoic acid concentrations,* $[HB]_{tot}$.

lowest reagent concentration tested with $[U]_{tot} = 10^{-3}$ M, a marked decrease of the values of q was noticed for pH > 3.5 indicating polynuclear complexes. These data have not been recorded in Fig. 1 for the sake of clarity ($\Delta \log q > 0.3$).

The U(VI)-methoxybenzoic acid system

The investigation was carried out for $[U]_{tot} = 10^{-4}$ M since this concentration could be expected from the experiments with salicylic acid to involve chiefly mononuclear reactions. Because of the lower solubility of methoxybenzoic acid in hexone the highest reagent concentration that was tested was 0.3 M (saturated solutions in hexone ~0.7 M). In order to calculate the anion concentration the ratio k_a/k_d was determined by a two phase titration. Two different titrations gave an average value of $k_a/k_d = 10^{-5.43 \pm 0.01}$. For the same ionic strength (0.1 M) a value of $k_a = 10^{-3.89 \pm 0.01}$ is derived from values reported in the literature [8], whence $k_d = 10^{1.54 \pm 0.02}$. If HB refers to undissociated methoxybenzoic acid, $[B^-]$ is calculated according eqn. (2). The data are represented in Figs. 3—4.

Calculation of the formation constants

In all experiments the uranium concentration was kept smaller than the ligand concentration by a factor of 10^2 or more. The change in ligand concentration due to formation of uranium complexes can therefore be disregarded. Furthermore, only uncharged complexes are believed to dissolve in the organic phase.

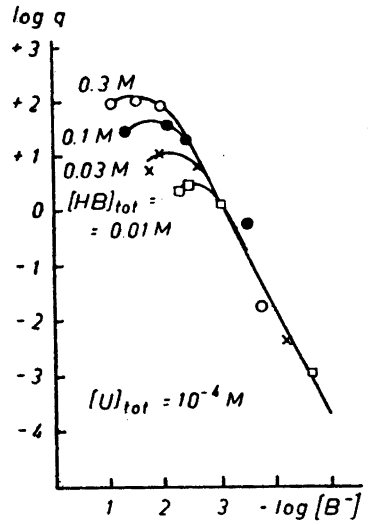

Fig. 4. Variation of the distribution ratio q *with* $-\log [B^-]$ *for different initial methoxybenzoic acid concentrations,* $[HB]_{tot}$.

In Fig. 2 the graphical representation of log q *versus* $-\log [HA^-]$ is given. If q were a function of $[HA^-]$ only all the curves would coincide for varying $[H_2A]_{tot}$ and the data could be explained by the standard approach that the simplest uncharged complex, in this case $UO_2(HA)_2$, dissolves in the organic phase. However, q is observed to increase with increasing $[H_2A]_{tot}$, which indicates that the complex in the organic phase must have H_2A-molecules associated with it.

Let the general formula $UO_2(H_2A)_x(H^+)_{-y}$ describe the complexes present [9]. The complexity product of these complexes is denoted by K_{xy} and the distribution coefficient of the uncharged complexes by Λ_{x2}. The general equation of the distribution ratio q then takes the following form (*cf.* Ref. [9])

$$q = \frac{\Sigma \Lambda_{x2} K_{x2} [H_2A]^x [H^+]^{-2}}{1 + [H^+]^{-1} \Sigma K_{x1} [H_2A]^x + [H^+]^{-2} \Sigma K_{x2} [H_2A]^x + [H^+]^{-3} \Sigma K_{x3} [H_2A]^x + \ldots} \quad (4)$$

As a reasonable assumption the pure hydroxo complex $UO_2(OH)_2$ was not considered to dissolve in the organic phase, which means that $x > 1$ in the numerator in eqn. (4). Furthermore, from the slope of plots of log $q\,[H^+]^2$ against log $[H_2A]_{aq}$ for various pH's it was confirmed that x must be > 2. In Fig. 5 log $q\,[H^+]^2\,[H_2A]^{-2}$ is plotted against log $[H_2A]_{aq}$ for varying pH; values of q were taken from the smooth curves drawn through the experimental points in Fig. 1 at pH 1.0, 1.6, 2.0, etc. With decreasing pH the curves coincide to one curve indicating that $q\,[H^+]^2\,[H_2A]^{-2}$ is independent of the hydrogen ion concentration and approaches the following expression (*cf.* eqn. (4))

$$q\,[H^+]^2\,[H_2A]^{-2} = \Lambda_{22} K_{22} + \Lambda_{32} K_{32} [H_2A] + \Lambda_{42} K_{42} [H_2A]^2 + \ldots \quad (5)$$

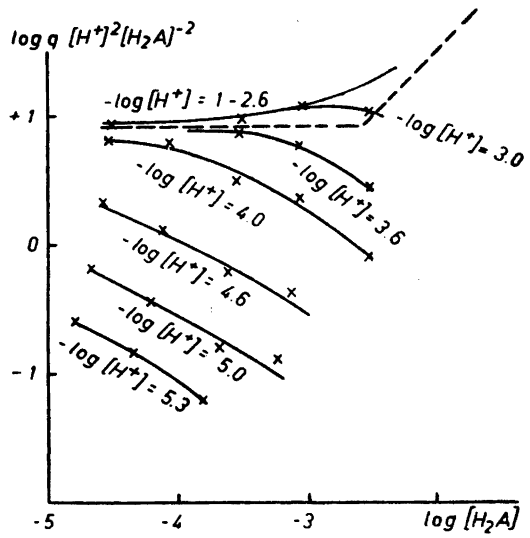

Fig. 5. The calculation of the coefficients $\Lambda_{x2}K_{x2}$ according to eqn. (5).

The unknown constants Λ_{x2} K_{x2} in eqn. (5) can be determined by a graphical procedure recommended by Sillén [10]. The curve for pH 1.0—2.6 in Fig. 5 was first compared with a plot log y (log x) where $y = 1 + x$ to test whether $\Lambda_{42}K_{42} = 0$. Since a good agreement was obtained when the two curves were fitted with each other it was concluded that $\Lambda_{42}K_{42} = 0$ in eqn. (5) and that the polynomial was of the first order. The unknown coefficients $\Lambda_{22}K_{22}$ and $\Lambda_{32}K_{32}$ are obtained from the points of intersection of the asymtotes (dotted lines in Fig. 5)

$$\log \Lambda_{22}K_{22} = 0.92 \pm 0.02 \tag{6}$$

$$\log \frac{\Lambda_{32}K_{32}}{\Lambda_{22}K_{22}} = 2.56 \pm 0.05 \tag{7}$$

$$\therefore \log \Lambda_{32}K_{32} = 3.48 \pm 0.07 \tag{8}$$

For pH $\geq$ 3 the curves in Fig. 5 are no longer independent of the hydrogen ion concentration. The data show that the UO_2^{2+} ions here form complexes in the aqueous phase. In order to find which complexes the following function was set up

$$\varphi = q^{-1}\,[H_2A]^2\,[H^+]^{-2}\,(10^{0.92} + 10^{3.48}\,[H_2A]) \tag{9}$$

Suppose that a stepwise formation of the complexes $UO_2(HA)^+$ and $UO_2(HA)_2$ takes place in the aqueous phase, then φ would be a function of $[H_2A][H^+]^{-1}$ only. Fig. 6 shows that this is not so; φ has been calculated for experimental points obtained with $[U]_{tot} = 10^{-4}$ M. The function ψ defined by eqn. (10) was calculated next

$$\psi = (\varphi - 1)\,[H_2A]^{-1}\,[H^+] \tag{10}$$

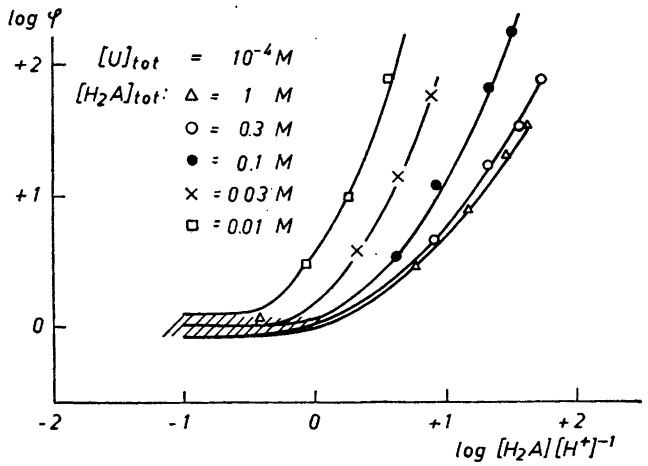

Fig. 6. Variation of log φ with log $[H_2A][H^+]^{-1}$. φ is calculated according to eqn. (9) for experimental points obtained with $[U]_{tot} = 10^{-4}$ M.

In Fig. 7 log ψ has been plotted against $-\log [H^+]$. Now, according to eqn. (4) the function ψ is when developed for $x \geqslant 1$.

$$\psi = K_{11} + K_{12}\,[H^+]^{-1} + \ldots [H_2A]\,(K_{21} + K_{22}\,[H^+]^{-1} + \ldots) + \\ + [H_2A]^2\,(K_{31} + K_{32}\,[H^+]^{-1} + K_{33}\,[H^+]^{-2} + \ldots) + \ldots . \qquad (11)$$

From Fig. 7 it is seen that log ψ increases with $-\log[H^+]$. On the other hand, for a value of $-\log [H^+]$ that is fixed, log ψ appears to decrease if anything with increased $[H_2A]_{tot}$ or $[H_2A]$. This decrease of ψ cannot be real since K_{xy} must be positive because of the law of mass action. It was therefore concluded that the experimental data spread around the curve: $\psi = K_{11} + K_{12}\,[H^+]^{-1}$. From the point of intersection of the asymptotes (dotted lines in Fig. 7) the coefficients K_{11} and K_{12} were estimated

$$\psi = 10^{-0.62 \pm 0.05} + 10^{-4.5 \pm 0.2}\,[H^+]^{-1} \qquad (12)$$

The complexes that seem to form in the aqueous phase are therefore according to eqns. (10) and (11)

$$[U]_{tot\ aq} = [UO_2^{2+}] + [UO_2(H_2A)(H^+)_{-1}] + [UO_2(H_2A)(H^+)_{-2}] \qquad (13)$$

The complexes present in the organic phase are (*cf.* eqns. (6) and (8) with (5))

$$[U]_{tot\ org} = [UO_2(H_2A)_2(H^+)_{-2}] + [UO_2(H_2A)_3(H^+)_{-2}] \qquad (14)$$

The equilibrium constants are summarized in Table 1. With these sets of constants the equation of the distribution ratio follows eqn. (15)

$$q = \frac{[H_2A]^2\,[H^+]^{-2}\,(10^{0.92 \pm 0.02} + 10^{3.48 \pm 0.07}\,[H_2A])}{1 + 10^{-0.62 \pm 0.05}\,[H_2A][H^+]^{-1} + 10^{-4.5 \pm 0.2}\,[H_2A][H^+]^{-2}} \qquad (15)$$

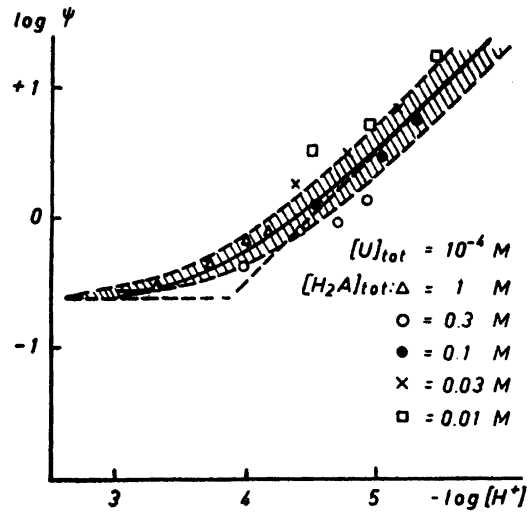

Fig. 7. The calculations of K_{11} *and* K_{12} (cf. *eqn. (11)). Abscissa:* $-\log [H^+]$. *Ordinate* $= \log \psi$, *which is calculated according to eqn. (10) for experimental points obtained with* $[U]_{tot} = 10^{-4}$ *M. The broken lines enclosing the shaded area represent the estimated limits of error for a curve following eqn. (12).*

In Fig. 1 the shaded area represents eqn. (15) with the above uncertainty estimated for the constants. In Fig. 8 the percentage of the different U(VI) complexes in the aqueous phase is plotted as functions of the salicylate concentration, and the hydrogen ion concentration.

Although methoxybenzoic acid was studied in less detail and therefore less reliance can be put on the constants derived, the same treatment of the data was made. In the case of methoxybenzoic acid the only complex extracted

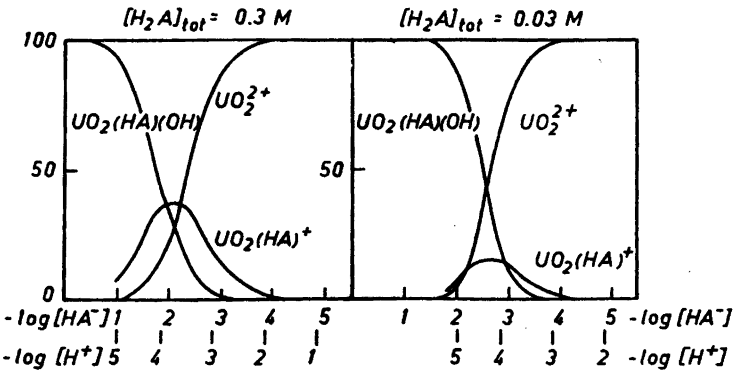

Fig. 8. The fraction of different U(VI) complexes in the aqueous phase. Abscissa: $-\log [HA^-]$ *or* $-\log [H^+]$. *Ordinate: the percentage of a certain complex (the vertical distance of the curve above the zero line represents the percentage).*

into the organic phase seems to be $UO_2(HB)_2(H^+)_{-2}$ or $UO_2(B)_2$. The experimental data can be approximated assuming only the complex $UO_2(HB)(H^+)_{-2}$ or $UO_2(B)(OH)$ in the aqueous phase. With this assumption the equation for q takes the following form

$$q = \frac{10^{-1.56 \pm 0.05}\ [HB]^2[H^+]^{-2}}{1 + 10^{-5.85 \pm 0.10}\ [HB][H^+]^{-2}} \qquad (16)$$

The full curves in Fig. 3 are calculated according to eqn. (16). Estimated values of the equilibrium constants are given in Table 2.

Table 1. Equilibrium constants derived for U(VI) from distribution data with salicylic acid, H_2A, in the system hexone — 0.1 M $NaClO_4$.

$$\Lambda_{22}K_{22} = 10^{0.93 \pm 0.02} \quad \frac{[UO_2(H_2A)_2(H^+)_{-2}]_{org}}{[UO_2(H_2A)_2(H^+)_{-2}]_{org}[H_2A]_{org}} = 10^{0.65 \pm 0.12}$$

$$\Lambda_{32}K_{32} = 10^{3.48 \pm 0.07}$$

$$K_{11} = \frac{[UO_2(H_2A)(H^+)_{-1}]}{[UO_2^{2+}][H_2A][H^+]^{-1}} = 10^{-0.62 \pm 0.05} \frac{[UO_2(HA)^+]}{[UO_2^{2+}][HA^-]} = 10^{2.2}$$

$$K_{12} = \frac{[UO_2(H_2A)(H^+)_{-2}]}{[UO_2^{2+}][H_2A][H^+]^{-2}} = 10^{-4.5 \pm 0.2} \frac{[UO_2(HA)(OH)]}{[UO_2^{2+}][HA^-][OH^-]} = 10^{12.1}$$

Table 2. Equilibrium constants derived for U(VI) from distribution data with methoxybenzoic acid, HB, in the system hexone — 0.1 M $NaClO_4$.

$$\Lambda_{22}K_{22} = 10^{-1.56 \pm 0.05}$$

$$K_{12} = \frac{[UO_2(HB)(H^+)_{-2}]}{[UO_2^{2+}][HB][H^+]^{-2}} = 10^{-5.85 \pm 0.10} \frac{[UO_2(B)(OH)]}{[UO_2^{2+}][B^-][OH^-]} = 10^{11.9}$$

DISCUSSION

Formula of the complexes. In the previous section the salicylate complexes have been described by the general formula $UO_2(H_2A)_x(H^+)_{-y}$ and x and y were determined for the predominant species in the two phases (eqns. (13) and (14)). As was mentioned in the beginning of the present paper the structure of the salicylate complexes can be imagined as nonchelates (the ligand = HA^-) or as chelate compounds (the ligand = $A^=$). Since the complexes ($x = 2$, $y = 2$) and ($x = 3$, $y = 2$) are found in the organic phase, the following isomeric formulae are possible

$UO_2(HA)_2$ and $UO_2(HA)_2 \cdot H_2A$ if the ligand = HA^-

$UO_2A \cdot H_2A$ and $UO_2A \cdot 2\ H_2A$ » » » = $A^=$

In the aqueous phase complexes corresponding to ($x = 1$, $y = 1$) and ($x = 1$, $y = 2$) are shown to form. The former complex ($x = 1$, $y = 1$) is not compatible with $A^=$ as the ligand. The complexes possible in the aqueous phase are therefore $UO_2(HA)^+$ and $UO_2(HA)(OH)$ or UO_2A. To distinguish between the above formulae is not possible. However, the close resemblance of the distribution curve found with methoxybenzoic acid suggests that the salicylate complexes are built up by HA^- ligands. Only two methoxybenzoic acid mole-

cules is found in the extracted uranyl complex. The fact that an additional acid molecule is not found with methoxybenzoic acid may be ascribed to the more limited space around the central group due to the $-CH_3$ (*cf.* the results obtained with Th [11]).

Comparison with earlier work. Weinland and Hager [12] have reported compounds with two and three molecules of salicylic acid attached to the uranium. These compounds were formed in presence of alkali and organic bases and the authors proposed a structure where the uranyl group entered in the anion, as in $C_5H_5N \cdot H[UO_2(HA)_3]$ with three salicylic acid molecules. Migration experiments with uranyl salicylate [13] gave to result that the main part of the uranium migrated towards the cathode even at high concentrations of HA^-. It seems therefore more plausible to assign the following structure to the above complex: $C_5H_5N \cdot [UO_2(HA)_2 \cdot H_2A]$.

Foley and Anderson [14] have studied the complex formation between uranyl and sulfosalicylic acid (H_3R) spectrophotometrically. Some of the measurements were made in acetate buffers, which might invalidate the investigation. The ratio of uranyl to sulfosalicylate was found to be 1:1 in a pH range up to 6.1. The same ratio 1:1 of uranyl to salicylic acid is found by us in the aqueous phase in the present study. Further, the uranyl sulfosalicylate complex shows maximum absorption at a pH $\sim$ 4.7. Since the second dissociation constant [14,15] of sulfosalicylic acid is about $10^{-2.7}$ the main part of the acid will be in the form $HR^=$ at pH = 4.7. The decrease of absorption above pH 4.7 is explained as due to hydrolysis effects. No extraction into benzene or carbon tetrachloride was found. An apparent equilibrium constant $K = \frac{[UO_2^{2+}][R]}{[UO_2R]}$, where [R] stands for sulfosalicylic acid in all forms, was calculated to be 1.9×10^{-4} (25° C).

In Table 1 the equilibrium constant for the formation of $UO_2(HA)^+$ is given, *i. e.* $10^{2.2}$. This value may be compared with the equilibrium constant for the first uranyl acetate complex, which has been determined by Ahrland [16] to $10^{2.6}$.

The hydrolysis of UO_2^{2+}. The data of the present investigation have been treated as if only mononuclear complex formation took place. Now the hydrolysis of the ion UO_2^{2+} has been investigated and discussed as a polymeric process [17]. To find out whether the experiments in the present study were carried out in a concentration range of polynuclear hydrolysis, a value of the function X is needed

$$X = \log [U]_{\text{tot aq}} - 2 \log [H^+] \qquad (16)$$

By comparison with Ahrland's diagram (*cf.* Ref.[17], Fig. 1 or Fig. 5) one sees that for $X < 5$ no appreciable amounts of hydrolysis complexes are formed. Let us calculate a value of X for the lowest H_2A concentration used, *i. e.* $[H_2A]_{tot} = 10^{-2}$ M. A value of $[U]_{\text{tot aq}}$ is estimated from the distribution curves in Fig. 1, since $[U]_{\text{tot aq}} = [U]_{tot}/(q + 1)$. Thus at pH = 5 one obtains a value of $X = 5.4$, which suggests that these distribution experiments might be affected by the hydrolysis of the ion UO_2^{2+}. For H_2A concentrations $> 10^{-2}$ M and $[U]_{tot} = 10^{-4}$ M there is no danger of hydrolysis effects. For $[U]_{tot} =$

10^{-3} M and $[H_2A]_{tot} = 10^{-1}$ M the distribution curve was found to deviate from those obtained with lower $[U]_{tot}$, when pH increased above 3.5. The lower values of q that was obtained, indicate that water soluble polymeric complexes are formed. In this case the value of X is around 5.6.

Polymeric hydroxo complexes have been reported in the reactions of uranyl and organic acids (H_2R) such as citric acid, maleic acid and tartaric acid [18]. The uranium concentration and the concentration of the organic reagent were both 0.05 M. Dimers of the complexes UR held together by oxygen bridges were believed to be formed when the pH was raised to 3.5.

I am indebted to Professor G. Ljunggren, FOA 1, for his continued interest and to Professor L. G. Sillén for his valuable advice and criticism. My thanks are also due to Professor A. Ölander, Dr. J. Rydberg and Dr. D. Dyrssen. The English in this paper has been revised by Dr. F. Rossotti.

Studies on the Extraction of Metal Complexes

XXIII. On the Complex Formation of Thorium with Salicylic Acid, Methoxybenzoic Acid, and Cinnamic Acid

BRITA HÖK-BERNSTRÖM

Research Institute of National Defence, Dept. 1, (FOA 1), Sundbyberg 4; Institute of Inorganic and Physical Chemistry, University of Stockholm, Sweden

The extraction of thorium with salicylic acid H_2A, methoxybenzoic acid HA, and cinnamic acid HA has been studied at 25° C in the solvent systems: methyl *iso*butyl ketone-aqueous solution and chloroform-aqueous solution at a constant ionic strength of 0.1 M.

The complex formation in the aqueous phase between thorium and the acids is described by two parameters a and b [5] which are given in Table 7. The thorium complex extracted into the hexone solution of salicylic acid has been found to have an associated salicylic acid molecule. By comparison with methoxybenzoic acid it seems plausible to write the formula as $Th(HA)_4 \cdot H_2A$.

In our studies of the metal extraction with some phenylcarboxylic acids (Part XXIV [1]) a considerable number of data are reported for thorium.

In the present paper the data for thorium with salicylic acid, methoxybenzoic acid and cinnamic acid are given. Calculations of the data are made in order to draw some conclusions about the complexes formed and if possible to estimate the relevant equilibrium constants.

The distribution of thorium between the organic and aqueous phase was measured radiometrically, using $^{234}Th(UX_1)$ as a tracer for thorium. The distribution was measured after a shaking time of 18 hours at 25° C. The organic solvent was methyl *iso*butyl ketone (hexone) or chloroform and the aqueous phase was made 0.1 M by addition of $NaClO_4$. The hydrogen ion concentration of the aqueous phase was determined with a glass electrode after equilibration. The anion concentration was then calculated by means of the constants given in Part XV [2]. In the experiments the thorium concentration was kept $\sim 10^{-5}$ M by addition of inactive thorium perclorate. Only mononuclear complex formation was assumed to take place at this low metal concentration.

Salicylic acid

In a previous work the distribution of UO_2^{2+} in the system salicylic acid-hexone- 0.1 M $NaClO_4$ was studied (Part XVI [3]). If salicylic acid

is denoted H_2A, it was shown that the complexes formed in appreciable amount in the organic phase are $UO_2(H_2A)_2(H^+)_{-2}$ and $UO_2(H_2A)_3(H^+)_{-2}$, which we presumed to correspond to the formulae $UO_2(HA)_2$ and $UO_2(HA)_2 \cdot H_2A$. In the present study we started to assume that the ligand combining with thorium was HA^-.

The experimental data for the hexone system are given in Table 1. I'_{org} and I'_{aq} represent the radiometric counts obtained from equal aliquots of the organic and aqueous phases. The distribution ratio q involves a correction factor taken from Part X [4] for the density of the sample solution. In Fig. 1 the data are represented by plotting log q against $-\log[HA^-]$. For a given concentration of HA^- the values of q are found to increase when the H_2A concentration is raised. Thus q is a function not only of $[HA^-]$ but also of $[H_2A]_{aq}$.

When log $(q/[H_2A]_{aq})$ is now plotted against $-\log[HA^-]$ for thorium, as in Fig. 2, the curves for varying initial reagent concentrations are found to coincide. The experimental data can therefore be explained by the very simple assumption that the predominant complex in the organic phase is $Th(HA)_4 \cdot H_2A$.

The slope of the curve in Fig. 2 is seen to decrease from 4 to 0; thus at one end Th^{4+}, and at the other $Th(HA)_4$ predominates in the aqueous phase. The curve deviates from the calculated curve (*cf.* Fig. 2, dotted line), where the only thorium species are assumed to be Th^{4+} and $Th(HA)_4$. This clearly shows that intermediate complexes $Th(HA)_n^{4-n+}$ are also formed. For the equilibria in the aqueous phase we shall use an approximation, which has been successfully applied to many of the systems studied in this series [5]. Approximate values of the complexity constants k_n of the successive complexes are obtained from the formulae (1)—(4)

$$k_1\ k_2\ k_3\ k_4 = 10^{4a} = \varkappa_4, \tag{1}$$

$$k_1/k_2 = k_2/k_3 = k_3/k_4 = 10^{2b} \tag{2}$$

$$k_n = \frac{[Th(HA)_n]}{[Th(HA)_{n-1}]\ [HA]} \quad (n = 1,\ 2,\ 3,\ 4) \tag{3}$$

$$\varkappa_n = \frac{[Th(HA)_n]}{[Th]\ [HA]^n} \quad (n = 1,\ 2,\ 3,\ 4) \tag{4}$$

In the organic phase only the species $Th(HA)_4 \cdot H_2A$ need be considered. Presumably the distribution coefficient of $Th(HA)_4$ between the two phases is very low and that of $Th(HA)_4 \cdot H_2A$ very large. Thus $Th(HA)_4$ is not detected in the organic phase, and $Th(HA)_4 \cdot H_2A$ is not detected in the aqueous phase.

In the present case we need only consider the reaction

$$Th(HA)_4(aq) + H_2A(aq) \rightleftharpoons Th(HA)_4 \cdot H_2A\ (org) \tag{5}$$

with the equilibrium constant

$$K = \frac{[Th(HA)_4 \cdot H_2A]_{org}}{[Th(HA)_4]_{aq}\ [H_2A]_{aq}} \tag{6}$$

The equation for q then follows eqn. (7)

$$q = \frac{[Th]_{tot\ org}}{[Th]_{tot\ aq}} = \frac{[Th(HA)_4 \cdot H_2A]_{org}}{[Th]_{tot\ aq}} = \frac{K\varkappa_4\ [HA^-]^4[H_2A]_{aq}}{\sum_0^4 \varkappa_n[HA^-]^n} \tag{7}$$

where $\varkappa_n$ is defined by eqn. (4) ($\varkappa_0 = 1$).

By introducing the parameters a and b in eqn. (7) the curve in Fig. 2 may be described by

$$\log(q/[H_2A]_{aq}) = \log\ K + 4a + 4\ \log\ [HA^-] -$$

$$-\log\ (1 + [HA^-] \times 10^{a+3b} + [HA^-]^2 \times 10^{2a+4b} + [HA^-]^3 \times 10^{3a+3b} +$$

$$+ [HA^-]^4 \times 10^{4a}) \tag{8}$$

Using a similar method as in Part V [5] one can now compare the experimental curve in Fig. 2 with curves calculated for different values of b, *i. e.* log Z (log $y)_b$, where

$$\log Z = 4 \log y - \log (1 + y \times 10^{3b} + y^2 \times 10^{4b} + y^3 \times 10^{3b} + y^4) \quad (9)$$

The two asymptotes to this family of curves are

$$y \to 0 \quad \log Z = 4 \log y \quad (10)$$
$$y \to \infty \quad \log Z = 0 \quad (11)$$

The curve in Fig. 2 is now moved parallel with the log Z- and log y-axes until a position is found, where the experimental curve coincides with one of the curves in the family; then from eqn. (8) and (9)

$$\log Z = \log (q/[H_2A]_{aq}) - \log K \quad (12)$$
$$\log y = a + \log [HA^-] \quad (13)$$

The experimental data in Fig. 2 were found to fall between the calculated curves for $b = 0.40$ and $b = 0.50$ (shown in Fig. 2 by broken lines). One finds from eqn. (12) and Fig. 2 for log $Z = 0$

$$\log K = \log (q/[H_2A]_{aq}) = 5.7 \quad (14)$$

For log $y = 0$, one gets from eqn. (13) and Fig. 2

$$a = -\log [HA^-] = 2.9 \quad (15)$$

The full lines in Fig. 1 are calculated according to eqn. (8) with the values of the constants found above ($a = 2.9$, $b = 0.45$ and log $K = 5.7$).

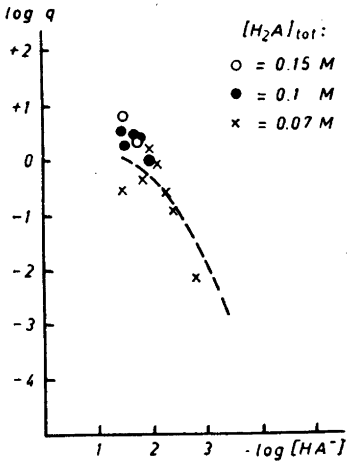

Fig. 3. Plot of log q *against* $-\log [HA^-]$ *for the distribution of* $^{234}Th-UX_1$ *between* $CHCl_3$ *and* H_2O *with salicylic acid as the organic reagent* (H_2A).

The results obtained with chloroform as organic solvent are given in Table 2 and recorded in Fig. 3 by a plot of log q against $-\log [HA^-]$. Because of the low solubility of salicylic acid in chloroform, the highest reagent concentration which could be used in the distribution experiments was $[H_2A]_{tot} = 0.15$ M. If the complex formation in the aqueous phase is assumed to be independent of the organic solvent, the distribution curve in Figs. 2 and 3 ought to have the same shape [6] (broken line in Fig. 3). However, the irregular results obtained with chloroform were not sufficient to confirm the results previously obtained with hexone.

Methoxybenzoic acid

For comparison the distribution of thorium was studied with *o*-methoxybenzoic acid, the methyl ether of salicylic acid, in the same solvent systems. The anion concentration was calculated on the basis of the following constants (log k_d — log k_a was obtained from two-phase titrations)

solvent system	log k_d − log k_a	−log k_a	log k_d
hexone-0.1 M $NaClO_4$	5.43 ± 0.01	3.89 ± 0.01 [7]	1.54 ± 0.02
chloroform-0.1 M $NaClO_4$	5.49 ± 0.01		1.60 ± 0.02

The distribution data are given in Tables 3—4 and plots of log q against $-\log[A^-]$ are recorded in Figs. 4—5. Since a variation of $[HA]_{tot}$ does not affect the distribution curve in the present system, it is concluded that the organic solvent dissolves the uncharged complex ThA_4, while the aqueous phase contains the complexes ThA^{3+}, ThA_2^{2+}, ThA_3^+ and ThA_4. Let us assume as before that the complex formation in the aqueous phase is described by the parameters a and b (eqns. (1) and (2)) and let λ_4 denote the distribution coefficient of ThA_4 between the two phases. To find the constants λ_4, a and b the experimental curves are compared with the family of curves log $Z(\log y)_b$. The parameter b is thus easily determined from the best fitting curve, whereas, in this case, log $\lambda_4 = \log q$ for log $Z = 0$ and $a = -\log [A^-]$ for log $y = 0$. If the

accuracy admits it and the experimental data approach the two asymptotes (eqns. (10) and (11)), one may determine the unknown λ_4, a and b from the curve $\log Z$ $(\log y)_{b=-\infty}$ (recorded in Figs. 4—7 by a broken line). b is then determined by measuring the vertical distance at $\log y = 0$ between this curve and the experimental one.

The following results were obtained for methoxybenzoic acid

$$a = 2.8 \qquad b = 0.3$$
$$\log \lambda_4 = 1.2 \text{ for the hexone system}$$
$$\log \lambda_4 \sim 1.6 \text{ for the chloroform system}$$

In the chloroform system especially some points fall outside the distribution curves at the lower HA concentrations (Fig. 5). These points correspond to a loss of radioactivity (*cf.* Table 4). After equilibration of the solutions particles are occasionally seen at the boundary between the phases. In such cases the irregularities may be explained by losses of thorium due to adsorption.

Cinnamic acid

The experimental results obtained for thorium with cinnamic acid are given in Tables 5—6 for the two solvent systems studied. The data are plotted in

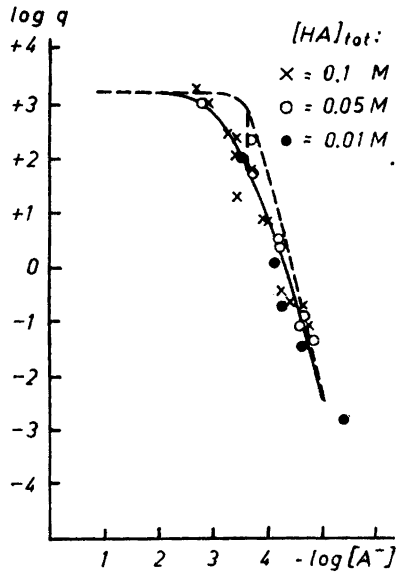

Fig. 7. Plot of log q against −log [A⁻] for the distribution of $^{234}Th-UX_1$ between $CHCl_3$ and H_2O with cinnamic acid as the organic reagent (HA).

Figs. 6—7. The constants, a, b and λ_4, were determined in the same way as before. For cinnamic acid one then obtains

$$a = 3.6 \qquad b = 0.2$$
$$\log\lambda_4 \sim 3.7 \text{ for the hexone system}$$
$$\log\lambda_4 \sim 3.2 \text{ for the chloroform system}$$

A certain spreading of the data is to be seen in Fig. 6. As will be discussed below the effects are probably due to the hydrolysis of thorium.

DISCUSSION

A summary of the constants obtained is given in Table 7, together with the dissociation constants and distribution coefficients of the acids. In the methoxy-compound thorium is only bound to the carboxyl group, while for salicylic acid one also has the possibility that the phenolic hydrogen participates in the reaction. However, the slope in Fig. 2 approaches 4, which suggests, that the salicylic acid ligand is HA^-. It is seen in Table 7 that the parameter a calculated for salicylic acid with the ligand HA^- is about the same as for methoxybenzoic acid.

The salicylate complexes of Cu^{2+}, Be^{2+} and Fe^{3+} have been reported [8-10] as chelate compounds, with the dissociation of the phenolic hydrogen. In the

* K is defined by eqn. (6).

last work [10] the first complex between Fe^{3+} and salicylic acid H_2A is written as FeA and the complexity constant $\varkappa_1$ is defined

$$\varkappa_1 = \frac{[H^+]\ [FeA]}{[HA]\ [Fe]}$$

The actual complex could equally well be of the isomeric form Fe(OH)(HA) with the following equilibrium constant

$$K = \frac{[Fe(OH)(HA)]}{[Fe][HA][OH]}$$

The weak complex formation between Fe^{3+} and methyl salicylate [11], however, gives evidence for displacement of the phenolic hydrogen in this case. X-ray measurements of salicylates of K, Rb, NH_4 [12] and of Zn [13] have been made. The composition of the latter compound seemed to be $Zn(HA)_2 \cdot 3H_2O$. It might be pointed out in this connection that the parameter a for thorium (*cf.* Table 7) when complexed with the acids studied in this work is much smaller than for typical inner complex formers, such as oxine ($a = 9.8$ [14]), cupferron ($a = 6.8$ [14]) and acetylacetone ($a = 6.7$ [4]; *cf.* also [5]).

The present results give evidence for the association of a salicylic acid molecule to the uncharged complex both for thorium and UO_2^{2+}, *i. e.* the complexes found are written as $Th(HA)_4 \cdot H_2A$ and $UO_2(HA)_2 \cdot H_2A$. When a methyl group replaces the phenolic hydrogen the data indicated no such association of an extra acid molecule, which may be explained by the more limited space available around the central group in this case.

Chloroform is found to be a poor solvent for the salicylate complex. The solubility of the complex is markedly improved when the phenolic group is replaced by a methoxy group (*cf.* Figs. 3 and 5 and Table 7). The distribution of the metal complexes and of the actual acids are roughly parallel (*cf.* Table 7).

Because of the strength of the acids a high anion concentration is attainable at relatively low pH values. Thereby it was thought possible to avoid hydrolysis effects. In a recent publication by Hietanen[15] the hydrolysis of thorium has been discussed. The concentration of total thorium ranged from 2×10^{-2} M down to 10^{-3} M and the data were explained by the formation of successive polynuclear complexes. Under the experimental conditions of the present study the total thorium concentration in the aqueous phase was always $<10^{-5}$ M. Although the hydrolysis process may be chiefly mononuclear at these low metal concentrations one may nevertheless estimate a maximum value of the hydrolysis from Hietanen's data. If the function $X = \log [Th]_{aq\ tot} - 3 \log [H^+]$ is <7 (*cf.* Fig. 3, Ref.[15]) one can state that the experiments will be very little affected by hydrolysis. Since $[Th]_{aq\ tot}$ is obtained from $[Th]_{tot}/(q+1)$ and the hydrogen ion concentration has been measured in each case, it is easy to calculate X. It was found that difficulties due to hydrolysis could be expected for salicylic acid and cinnamic acid at the lowest concentrations studied in the hexone system. A spread of the data was also noticed here with occasional losses of thorium. With methoxybenzoic acid extraction was carried out on the border, where the thorium hydrolysis might start to become appreciable.

The author wishes to thank the head of FOA 1, Professor G. Ljunggren, and Professor A. Ölander for the interest in this work. She also wants to express her gratitude to Professor L. G. Sillén and Dr. D. Dyrssen for valuable and helpful discussions. Dr. F. Rossotti has been kind enough to revise the manuscript.

This work is part of a program supported by *Atomkommittén*.

Some Graphical Methods for Determining Equilibrium Constants II. On "Curve-fitting" Methods for Two-variable Data

LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

A survey is given of graphical methods for determining a number of unknown constants (parameters) p_1, p_2 . . . from a set of data $y(x)$ when the function $y(x, p_1, p_2 \ldots)$ is known. If x, y, and p_i may be so chosen that one or two parameters can be connected with the variables to form "normalized variables" $X = x + p_1$, $Y = y + p_2$, the parameters may be found by fitting normalized curves. Such "curve-fitting" is preferable to numerical or "elimination" methods (see Table 1). For instance, with three parameters, $y(x)$ may be fitted to a family of curves $Y(X, p_3)$; p_1 and p_2 are obtained from the shifts of the coordinate axes, and p_3 from the shape of the curve. — A linear plot is a special case of curve-fitting; linear plots, however, have limitations which often make curved plots preferable.

Some examples are given from the determination of one or two complexity constants, and the determination of coefficients in simple polynomials.

If there are more than 2—3 parameters, "sweeping" and successive approximation may be used; the first procedure should not be used without the second. The use of smoothed curves, instead of the experimental points, requires great caution.

The determination of the equilibrium constants in a complicated system is a special case of the problem of finding a set of unknown constants from a series of experimental data. By choosing as many experimental points as one has unknown parameters, one may obtain a set of equations and solve them straight-forwardly [e.g. 1, 2] or by successive approximations [3, p. 36]. Graphical methods have the advantage over such numerical ones that the information from a much greater number of data may be considered simultaneously.

The usual tendency among chemists who apply graphical methods seems to be that of transforming the experimental data into a diagram of two variables that should give a *straight line*. From the slope and intercept of the best straight line, one may then determine two unknown constants. If there are

more than two unknowns, they may be obtained by a series of successive linear extrapolations, which is a special case of "sweeping" below.

In previous papers by Dyrssen [4] and Sillén [4-6] a somewhat different method has been applied to some special cases, namely fitting a diagram of the experimental data to a family of calculated curves. The shape and position of the curve with the best fit then gives the required information. — In the work on equilibria with polynuclear complexes to be published, various "curve-fitting" methods have proved useful. It has then seemed timely to classify what such methods may achieve.

The present paper will first give a rather general survey of graphical ways of determining one, two, or three unknown parameters from a given collection of experimental data $y(x)$. The application of methods of curve-fitting will then be shown for a number of special cases. A linear plot is only a special case of curve-fitting; it will be argued that the straight line is sometimes, but not always, the best curve.

The way of treatment given below may be common usage in some other branches of pure or applied science. However, it does not seem to be well known to all chemists.

SYMBOLS

a	concentration of free A (6)
b	concentration of free B (6)
f	experimentally determined function in (21) and following
K	equilibrium constant (6)
K_1, K_2	stepwise formation constants of complexes (text above eq. 12)
k_0, k_1, k_2	unknown coefficients in (21) and following
p_1, p_2, p_3	unknown constants (parameters) to be determined
v	auxiliary variable (7, 12a, 23, 27a, 28a)
X, Y	normalized values for x and y (2, 3)
x, y	variables determined experimentally
x_0, y_0	values for x and y coinciding with $X = 0$, $Y = 0$ at best fit (2b, 3a)
Z	average number of A bound per B (7, 12)
β_1, β_2	complexity products (12)
Subscript)$_x$	indicates that x is constant

THE PROBLEM

Table 1 gives a schematic survey of possible ways of treating a collection of experimental data (x, y) in order to determine one or more unknown constants (parameters) $p_1, p_2 \ldots$. If the experimental "points" are sets of two variables (x, y), they may be plotted in a planar diagram $y(x)$. — The case of three experimental variables (x, y, w), which cannot be reduced to a two-dimensional form, will be treated in a following paper.

We shall assume that x and y can be calculated directly from the experimental data, although they may not be the quantities actually measured. Nor need $p_1, p_2 \ldots$ be the equilibrium constants etc. ultimately sought for, although

Table 1. Methods for finding unknown constants p_i *from experimental data* y(x).

Number of parameters	normalized variables	Compare (x, y) graph with calculated graph	Eliminate y to give graph	Two-dimensional projection
1 (p_1)	1(x)	X, y		Curve $y(X)$ and plot $y(x)$
	0		x,p_1	Plot $p_1(x)$
2(p_1,p_2)	2(x,y)	X,Y		Curve $Y(X)$ and plot $y(x)$
	1(x)	X,y,p_2		a) Family of curves $y(X)_{p_2}$ and $y(x)$ plot b) $p_2(X)_y$ and proj. strip $(x)_y$
	0		x,p_1,p_2	a) Horizontal line in family $p_2(x)_{p_1}$ b) Intersection of curves $p_2(p_1)_x$
3(p_1,p_2,p_3)	2 (x,y)	X,Y,p_3		Family of curves $Y(X)_{p_3}$
	1(x)	X,y,p_2,p_3		—
	0		x,p_1,p_2,p_3	—

one must be able to calculate the latter, once the p_i are known. — In fact, it may often require a fair amount of trial to devise the most suitable functions x and y of the primary data, and the most suitable parameters p_i.

For each special problem we know the mathematical relationship between y, x, and the p_i, *e. g.* in the form

$$\begin{aligned} y &= y(x,\ p_1) \\ y &= y(x,\ p_1,\ p_2) \\ \text{or } y &= y(x,\ p_1,\ p_2,\ p_3) \end{aligned} \qquad (1)$$

We shall define our *primary* problem as finding the best possible values for the p_i, assuming that the function (1) is correct, and not as testing the validity of (1).

Table 1 shows two main ways of treating the problem graphically: eliminating one variable (say y), or comparing a plot of $y(x)$ with a calculated "normalized graph".

We shall not discuss graphical methods like that of Scatchard [7] in which the intercepts and slopes of two limiting tangents of a curve give approximate values for four parameters which are, however, then refined numerically. This method does not seem easily adaptable for graphical refinement of the constants.

Eliminating y

One parameter. When the values (x, y) for the experimental points are inserted into $y(x, p_1)$, each point gives a value for p_1. If p_1 is now plotted

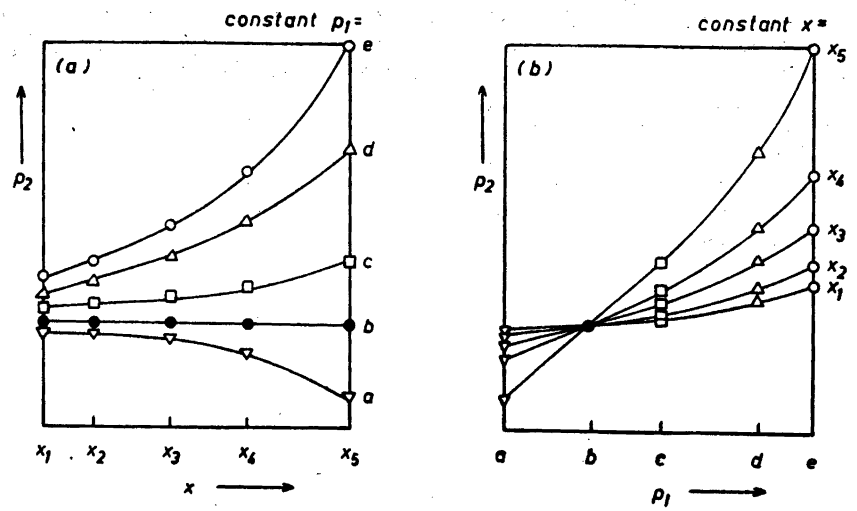

Fig. 1. Finding two parameters from y(x) *data by elimination: a)* $p_2(x)_{p_1}$ *curves: horizontal line for correct value of* p_1*; b)* $p_2(p_1)_x$ *curves: intersection at required point* p_2,p_1.

against x, one would expect to find the points scattered randomly around a horizontal line, since p_1 is really a constant. Usually no plot is made but the average value for p_1 is calculated numerically. The diagram $p_1(x)$ is drawn only if one wants to test for a trend in p_1 (which would show that the equation $y(x, p_1)$ in (1) is not quite correct), or to illustrate the spread in p_1.

Two parameters. The insertion of a pair of experimental values (x, y) into $y(x, p_1, p_2)$ gives a functional relationship between p_1 and p_2, which may be thought of as a planar curve $p_2(p_1)_x$ in (x, p_1, p_2) space. (The subscript "$_x$" indicates that x is kept constant.) A number of these curves would give a three-dimensional surface $p_2(p_1, x)$. Since p_1 and p_2 are constants by definition, the correct set (p_1, p_2) must be possible for all values of x, and thus corresponds to a straight line which is parallel to the x axis and lies entirely on the surface $p_2(p_1, x)$.

This set may be found in two ways:

a) One may plot $p_2(x)_{p_1}$, testing various constant values for p_1, until one finds the value for p_1 that makes $p_2(x)$ a horizontal line (Fig. 1a).

b) One may also plot $p_2(p_1)_x$, each experimental point giving rise to one curve, and find the required set (p_1, p_2) at the common point of intersection of these curves (Fig. 1b). An example of the second method is given in (20) below (Schwarzenbach [8]). It is in general more expedient if one wants accurate values for p_1 and p_2; however, the first method may have advantages if one wants to test for systematic errors in certain parts of the range of x.

Three parameters. Each experimental point $y(x)$, when combined with $y(x, p_1, p_2, p_3)$ in (1), gives rise to a surface $p_1(p_2, p_3)$ in (p_1, p_2, p_3) space; this surface may be thought of as a section at constant x of a four-dimensional super-surface $p_1(p_2, p_3, x)$.

The set (p_1, p_2, p_3) sought for is the common point of intersection of all these surfaces $p_1(p_2, p_3)_x$. If one of the parameters, say p_3, may be estimated rather accurately, so that only two or three values of p_3 need be considered, one might construct a plot $p_1(p_2)_{x,p_3}$ for each of these values of p_3. By studying the range where these curves intersect in each section, one may locate the point of intersection of the surfaces $p_1(p_2, p_3)_x$.

However, in general it seems impractical to vary more than two parameters simultaneously using the elimination procedure. One would then rather resort to successive approximation (see below).

Normalized graphs

The calculations are much simplified if one may normalize one variable or both.

One parameter. Suppose, for instance, that by suitable choice of variables and parameter we may arrange that the function $y(x, p_1)$ contains as the only variable the sum of x and p_1

$$X = x + p_1 \tag{2}$$

The function, which we may thus write

$$y = y(X) \tag{2a}$$

(X = "normalized x"), may then be plotted as a graph (*cf.* Fig. 2a), and moved along the x axis of the experimental diagram $y(x)$ (*cf* Fig. 2b) until the best fit is obtained (cf. Fig. 2c). In this position one reads the x value, x_0, corresponding to $X = 0$, and finds

$$X = 0;\ x = x_0 = -p_1 \tag{2b}$$

as required by (2).

In this laboratory, such curve-fitting is generally made by superimposing the experimental and calculated diagrams, drawn on an ample scale, on a table of opalescent glass, 50 cm × 60 cm, illuminated from below.

Two parameters. If it is possible to normalize both variables

$$X = x + p_1;\ Y = y + p_2 \tag{3}$$

the function $y = y(x, p_1, p_2)$ is reduced to the form $Y = Y(X)$. The curve $Y(X)$ is calculated, and moved on top of the experimental data — this time allowing parallel movement along both coordinate axes — until the best fit is obtained. The coordinates of the point (x_0, y_0) coinciding with the origin of the normalized graph ($X = 0$, $Y = 0$) are read

$$(X = 0,\ Y = 0);\ x = x_0 = -p_1;\ y = y_0 = -p_2 \tag{3a}$$

This procedure provides a great simplification compared with the "elimination" procedure above.

Even if one does not find a suitable way of normalizing two variables, the gain of normalizing one is also considerable. In this case we have a normalized function

$$y = y(X,\ p_2) \tag{4}$$

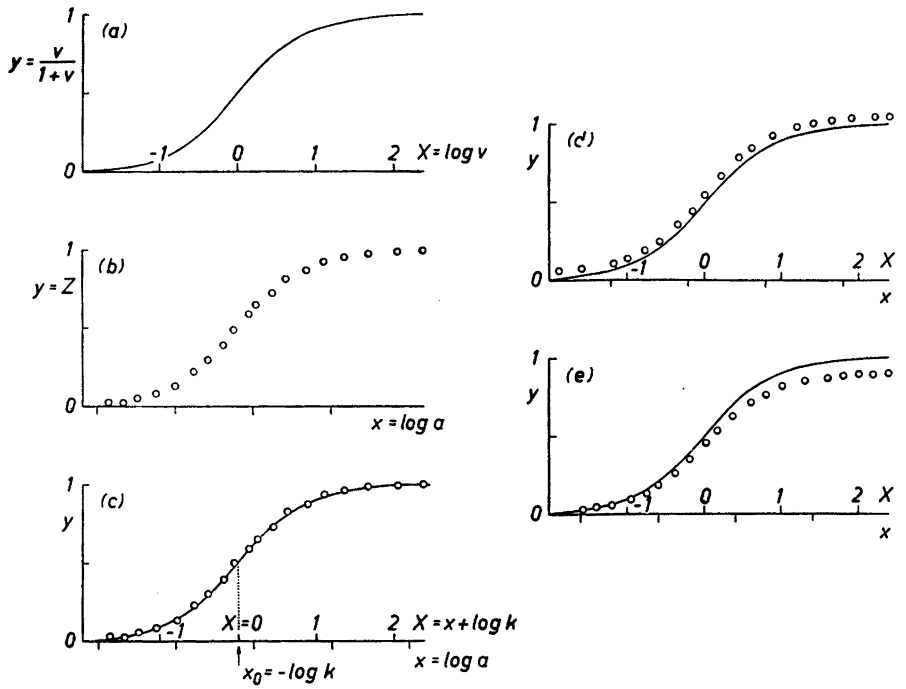

Fig. 2. Single complex: a) calculated curve y(X), *eq (8a) and (8b); b) imaginary experimental data* y(x), *eq (8); c) best fit of a and b; d, e) effect of systematic analytical errors: d) constant error in assumed amount of A, e) constant error in assumed ratio of A to B.*

to which the data $y(x)$ may be fitted. We may imagine $y(X, p_2)$ as a three-dimensional surface, to which the plane curve $y(x)$ may be fitted by shifts along the X and p_2 axes. One might consider working with a three-dimensional model, but two-dimensional plots are more easily handled and represented in print. Two approaches have been attempted:

a) In some earlier papers (Sillén [6], Hietanen and Sillén [9], Rossotti and Rossotti [10], using the "two-parameter" approximation [4]) a family of curves $y(X)_{p_2}$ was compared with the experimental diagram $y(x)$. Then p_2 was obtained from the parameter of the curve that gave the best fit, and $-p_1$ from x_0 at the best position. For improving an approximate value of p_2 one may either draw curves for intermediate values of p_2, or use some characteristic measure of the curve, such as the horizontal distance $x(y_2)$—$x(y_1)$ between two fixed values of y, or the slope dy/dx at a certain value of y.

b) A subsequent paper by Rossotti, Rossotti, and Sillén [11] will show the advantages of constructing curves $p_2(X)_y$ for a series of round values of y, and comparing them with a projection strip $(x)_y$ of the experimental data.

Three parameters, finally, may in principle be determined by fitting $y(x)$ to a three-dimensional surface $Y(X, p_3)$, provided that both x and y can be normalized. Conveniently, $y(x)$ is compared with a family of normalized

curves $Y(X)_{p_s}$: p_1 and p_2 are found from the shifts along the coordinate axes (thus from x_0 and y_0), and p_3 from the shape of the curve. Examples are given in a paper by Dyrssen and Sillén [4], and more will be given below.

If only one variable can be normalized, we have to fit $y(x)$ to a four-dimensional super-surface $y(X, p_2, p_3)$. This problem may be transformed to two-dimensional diagrams, *e. g.* by some method of successive approximation.

Linear plots are a special case of a family of normalized curves. If the two functions y and x are devised so as to give a linear plot, say

$$y = p_2 x + p_1 p_2 = p_2 X \tag{5}$$

the construction of the best line through the data $y(x)$ may be considered as the fitting of $y(x)$ to a family of curves $y(X)_{p_s}$, which are in this special case a bundle of straight lines $y = p_2 X$. In practice they are generally not constructed since a templet (*i. e.* a ruler) for these curves is always available.

Fitting a straight line of a given slope to the $y(x)$ is a special case of fitting a single normalized curve $y(X)$.

In the following sections it will be shown by means of a few simple examples that the use of a suitably chosen set of non-linear normalized curves may have advantages compared with a linear plot. Finally some methods will be discussed — successive approximation, "sweeping" — which are resorted to when the number of parameters is so great that a single two-dimensional diagram will not suffice.

APPLICATIONS TO SIMPLE CASES OF COMPLEX FORMATION

Z (log a) data for single complex

If two reagents, A and B, form the single complex AB, the only constant to be determined is the equilibrium constant K

$$\mathrm{A} + \mathrm{B} \rightleftharpoons \mathrm{AB};\ [\mathrm{AB}] = [\mathrm{A}]\ [\mathrm{B}]\ K = abK \tag{6}$$

(If, for instance, $\mathrm{A} = \mathrm{H}^+$, $\mathrm{B} = \mathrm{Ac}^-$, and $\mathrm{AB} = \mathrm{HAc}$, then $K = K_{\mathrm{acid}}^{-1}$ for HAc.) Let us assume that the concentration a of free A is measured for a series of solutions. For each solution the analytical data, together with a, give us Z, the number of A bound per B. The relationship is

$$Z = \frac{[\mathrm{AB}]}{[\mathrm{B}] + [\mathrm{AB}]} = \frac{aK}{1 + aK} = \frac{v}{1 + v} \tag{7}$$

Data $Z(a)$ are often used for determining complexity constants and acidity constants. As seen from (7), Z is a function of the single variable $v = aK$. Choosing our experimental variables, and the single parameter as

$$x = \log\ a;\ y = Z;\ p_1 = \log\ K \tag{8}$$

we may use a normalized variable (2)

$$X = \log\ v = \log\ a + \log\ K \tag{8a}$$

The normalized curve $y(X)$, which may easily be constructed, is obtained from (7, 8, 8a):

$$y(X) = \frac{v}{1+v} = \frac{10^X}{1+10^X} \tag{8b}$$

This calculated curve $y(X)$, Fig. 2a, is moved parallel with a plot of the experimental data $y(x)$, Fig. 2b, until the best fit is obtained, Fig. 2c. Then one may read, from the value of x coinciding with $X = 0$

$$x_0 = -p_1 = -\log K \tag{8c}$$

Calculated curves of the shape (8b) have been used in several laboratories; *e. g.* Simms [12] mentions the use of a paper mould of this shape for finding acidity constants.

Comparison with alternative methods. One may find K from the same data $Z(\log a)$ by normalized graphs, using the same x and X (8, 8a), but choosing y so as to obtain a linear plot [13]

$$\left.\begin{aligned} x &= \log a;\ X = \log a + \log K \\ y &= \log \frac{Z}{1-Z} = \log aK = X \end{aligned}\right\} \tag{9}$$

Plotting $y = \log Z/(1-Z)$ versus $x = \log a$, one would thus get a straight line of slope 1, which may be fitted to a normalized curve $y = X$. At $X = 0$ one reads $x_0 = -p_1 = -\log K$ as in (8c).

One might also use the elimination method, calculating

$$K = Za^{-1}(1-Z)^{-1} \tag{10}$$

from each experimental point, and taking the average.

In comparison with these methods, the choice of variables in (8) has some real advantages. The variables $\log a$ and Z are so close to the data primarily measured that one may mark out in the diagram how much an experimental point $y(x)$ would be changed by a certain experimental error — say by 0.3 mV in the emf in measuring a, or by 0.5 % in the analysis of A or B. So one may judge whether the deviations from the normalized curve are reasonable in view of the expected experimental accuracy.

Further, systematic analytical errors are easily recognized and corrected for since they give rise to a parallel shift along the y axis (Fig. 2d), or to a small change of scale along the y axis (Fig. 2e). With (9) or (10) such errors would give a trend in K but it would not be as easy to see the cause immediately. Treatment with the least square method, as usual, would do no good in the presence of systematic errors.

If it is found necessary to correct for small analytical errors of both kinds, one may connect these errors in Z with two parameters, one p_2 involving a shift along the y axis, and another p_3 a shift in the y scale. With

$$x = \log a;\ y = Z;\ p_1 = \log K \tag{8}$$

$$X = x + p_1 = \log v;\ Y = y + p_2 = p_3 v(1+v)^{-1} \tag{11}$$

we have a system with two normalized variables and three parameters, which may be solved by means of a set of $Y(X)_{p_2}$ curves. The two other methods are not so easily adapted to correcting for analytical errors.

Z(log a) data for two complexes

If the reactants A and B form two complexes, AB and A_2B, with the overall formation constants ("complexity products") $\beta_1 = K_1$ and $\beta_2 = K_1K_2$ (K_1 and K_2 stepwise formation constants), we have

$$\left.\begin{aligned} [AB] &= \beta_1 ab;\ [A_2B] = \beta_2 a^2 b \\ Z &= \frac{[AB] + 2[A_2B]}{[B] + [AB] + [A_2B]} = \frac{\beta_1 a + 2\ \beta_2 a^2}{1 + \beta_1 a + \beta_2 a^2} \end{aligned}\right\} \quad (12)$$

Setting as before (*cf.* 8, 8a)

$$x = \log\ a;\ y = Z;\ X = x + p_1 = \log\ v \quad (12a)$$

we may normalize log a, leaving one parameter in the expression for y. Two possible ways are, expressing for convenience the relationship $y(X, p_2)$ by means of the auxiliary variable v in (12a)

$$p_1 = \log \beta_1\ ;\ p_2 = \beta_2\beta_1^{-2}\ ;\ y = \frac{v + 2\ p_2v^2}{1 + v + p_2v^2} \quad (13)$$

$$p_1 = \tfrac{1}{2}\ \log \beta_2 = \tfrac{1}{2}\ \log\ K_1K_2\ ;\ p_2 = \beta_1\beta_2^{-\frac{1}{2}} = (K_1K_2^{-1})^{\frac{1}{2}}\ ;\ y = \frac{p_2v + 2\ v^2}{1 + p_2v + v^2} \quad (14)$$

Fig. 3 shows a family of curves $y(X)_{p_2}$, calculated using the second approach (14). They may be regarded as sections of the three-dimensional surface $y(X, p_2)$. — The properties of functions like (12) have been discussed by Auerbach and Smolczyk[14]. A family of curves like Fig. 3 was given by J. Bjerrum[3, p. 26]. Neither seems to have used them for curve-fitting. J. Bjerrum's average constant is 10^{p_1}, and his spreading factor is $\frac{1}{2}\ p_2$, in (14).

To find the required parameters, the experimental data $y(x)$ should be moved along the p_2 and X axes until the best fit is found. By comparison with the family of curves $y(X)_{p_2}$, Fig. 3, one may first test for, and if necessary correct for, systematic analytical errors, like in Figs. 2d and e. Then p_2 can be estimated from the two curves giving the nearest fit; a better value may be found by inserting curves for intermediate values of p_2, or by using some suitable measure (say, the difference between $X(y = 1.5)$ and $X(y = 0.5)$, *cf.* Irving and Rossotti[1]). The other parameter is found from the values of x_0 corresponding to $X = 0$.

For determining the parameters accurately, the method described by Rossotti, Rossotti and Sillén[11] is advantageous: a projection strip $(x)_y$ of the experimental data is moved parallel with the X and p_2 axes to give the best fit with the family of curves $p_2(X)_y$.

Alternative methods

Linear plot. We may transform (12) to the form

$$Z + \beta_1 a(Z - 1) + \beta_2 a^2(Z - 2) = 0 \quad (15)$$

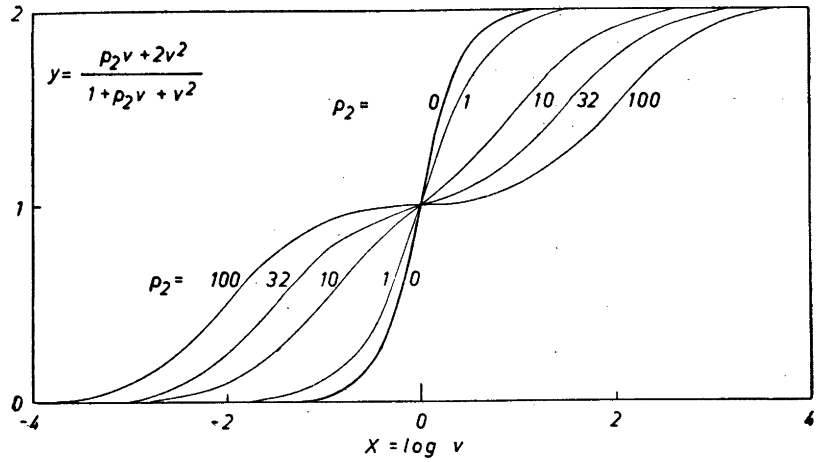

Fig. 3. Two complexes: calculated curves $y(X)_{p_2}$ *(eq (12a) and (14) for various values of* p_2.

Dividing by suitable factors and rearranging, this equation may be reduced to the linear form, with X normalized

$$y = p_2 x + p_1 p_2 = p_2 X \tag{5}$$

by any of six transformations, three of which are given here (in the other three, x and y are only interchanged)

$$a^2(2-Z)Z^{-1} = \beta_1\beta_2^{-1}a(Z-1)Z^{-1} + \beta_2^{-1} \tag{16}$$

$$Za^{-1}(Z-1)^{-1} = \beta_2 a(2-Z)\ (Z-1)^{-1} - \beta_1 \tag{17}$$

$$Za^{-2}(2-Z)^{-1} = -\beta_1 a^{-1}(Z-1)\ (2-Z)^{-1} + \beta_2 \tag{18}$$

For instance, with (16) we have

$$y = a^2(2-Z)Z^{-1}\ ;\ x = a(Z-1)Z^{-1}\ ;\ p_1 = \beta_1^{-1}\ ;\ p_2 = \beta_1\beta_2^{-1} \tag{16a}$$

Equation (16) is essentially identical with that given by Speakman [15] and (17) with that of Irving and Rossotti [1], also used by Rossotti and Rossotti [10].

The method given by Schwarzenbach, Willi, and Bach [8] may be classified as an *elimination* method, using the parameters

$$p_1 = \beta_1^{-1}\ ;\ p_2 = \beta_2\beta_1^{-1} \tag{19}$$

and dividing (17) by β_1 to obtain

$$p_1 \frac{Z}{a(Z-1)} = p_2 \frac{a(2-Z)}{Z-1} - 1 \tag{20}$$

Each experimental point (Z, a) gives a straight line (20) in a plot (p_1, p_2), which is conveniently constructed from the intercepts $-a(Z-1)Z^{-1}$ and $(Z-1)a^{-1}\ (2-Z)^{-1}$. All these lines should intersect at the point (p_1, p_2)

which gives the correct set (β_1, β_2) by means of (19). (For a dibasic acid H_2X, as discussed in Ref.[8], with $A = H^+$ and $B = X^{2-}$, the acid dissociation constants are related to the formation products by $K_{a1} = \beta_1\beta_2^{-1}$ and $K_{a2} = \beta_1^{-1}$).

Linear versus curved plots. The search for the best straight line (5) is a special case of curve-fitting. The advantage of a linear plot is the simplicity of construction. However, considering the time that will usually be spent in getting accurate data, the little extra work of constructing a set of normalized curves is negligible.

There are several limitations to the linear plots, which may often make it worthwhile to try a curved plot.

1) The connection between the functions used and the experimental data will often be so remote in a linear plot that it may be hard to decide whether a certain deviation is compatible with the experimental accuracy. With curved plots one has a greater freedom to choose variables more *directly connected with* the *experimental data*. Compare, for instance, the variables $y = Z$ and $x = \log a$ in the curved plots (Figs. 2 and 3) with the complicated functions of Z and a used in the linear plots (eqns. 16, 17, 18).

2) *Systematic errors* may make a linear plot deviate from linearity; however, such deviations are not always readily explained and corrected for. A curved plot may be devised so that systematic errors to be expected (say, analytical errors) are easily recognized and corrected for. The systematic error may be treated as one or two extra parameters to be determined, as in (11).

3) In studies of chemical equilibria, the concentrations of the reacting species are often varied by several powers of ten — and should be so varied, wherever possible. Then the scale of a linear plot may become awkward: the experimental points being scarce at one end and compressed at the other. A small experimental error may cause much greater deviations in some parts than in others. In estimating the best line, it is difficult to weigh deviations in different parts of the diagram against each other, especially if the variables plotted, y and x, are also rather remote from the measured quantities.

With curved plots this difficulty is overcome by using a *logarithmic concentration scale*, which is also very convenient for normalization. Especially with emf measurements, the accuracy at different parts of a logarithmic scale is approximately the same, and this facilitates the estimation of the best curve.

4) A single linear plot can give only two parameters, whereas a curved plot will allow the simultaneous determination of *three parameters*.

5) Sometimes one may want to use the data for choosing between different hypotheses, each of which gives a different expression (1) for y. If one insists upon linear plots, the various hypotheses will in general give very different variables, and so it is hard to make a good comparison between them. Using curved plots, one has a greater freedom of choice. It is often possible to use a plot of the same variables to *test for several different hypotheses*, *e.g.* in ref [6,9], where mechanisms with a single polynuclear complex, with series of "core + links" polynuclear complexes, and with the formation of a precipitate, could be tested on the same plot $y(x)$; in this case, $y = Z/t$, $x = t \log a + \log B$. Thus it is easier to judge which deviations are really to be considered as essential.

The scale should of course be so chosen that full advantage is made of the experimental accuracy. Thus, for a rather accurate set of data it may prove desirable to use a plot on a much larger scale than would seem necessary for another set of data, otherwise using a plot with the same normalized functions.

DETERMINING THE COEFFICIENTS IN POLYNOMIALS

Suppose that we have measured, over a certain range of the variable a, a number of experimental points (a, f), where f is related to a by

$$f(a) = k_0 + k_1 a + k_2 a^2 \tag{21}$$

k_0, k_1 and k_2 being unknown constants to be determined.

For instance, in studies of systems with complexes A_nB, a may be the concentration of free A, and $-59.16 \log f$ may be the change in the emf of a B electrode; or $a^2 f^{-1}$ may be the distribution ratio of B_{total} between an organic solvent and an aqueous solution of A.

Problems of this kind may be solved by using normalized curves. Setting as experimental variables

$$x = \log\ a;\ y = \log\ f \tag{22}$$

we may use the following normalization

$$\left.\begin{aligned} X &= x + p_1 = \log\ v \\ Y &= y + p_2 = \log(1 + p_3 v + v^2) \end{aligned}\right\} \tag{23}$$

Solving p_1, p_2, and p_3 from (21), (22), and (23) we find

$$\left.\begin{aligned} -x_0 &= p_1 = \tfrac{1}{2} \log\ k_2 - \tfrac{1}{2} \log\ k_0 \\ -y_0 &= p_2 = -\log\ k_0 \\ \log\ p_3 &= \log\ k_1 - \tfrac{1}{2} \log\ k_0 - \tfrac{1}{2} \log\ k_2 \end{aligned}\right\} \tag{23a}$$

Fig. 4a gives a family of curves $Y(X)_{p_3}$ calculated from (23). The curves have two common asymptotes, $Y = 0$ and $Y = 2X$. If a given set of experimental data $y(x)$, eqn. (22), is moved so as to give the best fit (Fig. 4b), the shape of the curve gives p_3, and the coordinates (x_0, y_0) coinciding with $(X = 0, Y = 0)$ give $-p_1$ and $-p_2$.

To refine the value of p_3 one may interpolate in some way between the calculated curves, possibly inserting new curves with intermediate values of p_3. If the accuracy admits it, one may use the vertical distance $y - y_0$ from the experimental curve to (x_0, y_0); at this point $X = 0$, and (23) gives

$$\text{for } X = 0;\ v = 1;\ Y = y - y_0 = \log(2 + p_3) \tag{23b}$$

The required constants are calculated using (23a)

$$\left.\begin{aligned} \log\ k_0 &= -p_2 \\ \log\ k_1 &= p_1 - p_2 + \log\ p_3 \\ \log\ k_2 &= 2p_1 - p_2 \end{aligned}\right\} \tag{23c}$$

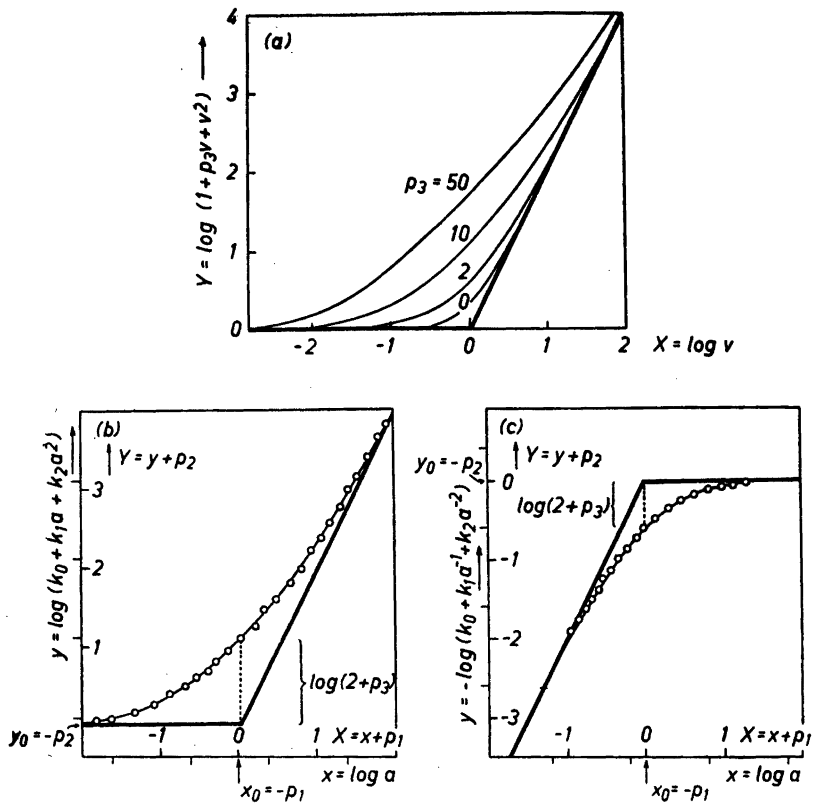

Fig. 4a. Family of curves (23), $X = log\ v$, $Y = log\ (1 + p_3v + v^2)$ *for finding coefficients of polynomials* $k_0 + k_1a + k_2a^2$.

b. Fit of experimental data.

c. Fitting inverted curve, $X = -log\ v$, $Y = -log(1 + p_3v + v^2)$, *eq (26), to data* $x = log\ a$, $y = log\ f = -log(k_0 + k_1a^{-1} + k_2a^{-2})$.

It should be noted that the same set of curves may be used also to find the coefficients of functions of the types

$$f(a) = k_0 + k_1a^{-1} + k_2a^{-2} \quad (24)$$

$$f(a) = (k_0 + k_1a + k_2a^2)^{-1} \quad (25)$$

$$f(a) = (k_0 + k_1a^{-1} + k_2a^{-2})^{-1} \quad (26)$$

One needs only reverse the signs of the X axis for (24), of the Y axis for (25), or of both for (26). For (26) we have for instance (Fig. 4c) $X = -\log v$, $Y = -\log(1 + p_3v + v^2)$.

In practice, the reversal is simply made by rotating the paper, on which the curves have been drawn, by 180° around a vertical or horizontal axis.

Separate curves should be drawn for the values $k_0 = 0$ and $k_2 = 0$ which appear only as limiting cases in the treatment by means of (23). With $k_2 = 0$ we have

$$f(a) = k_0 + k_1 a \tag{27}$$

We may use the same coordinates

$$x = \log\ a;\ y = \log\ f \tag{22}$$

and normalize, using the auxiliary variable v

$$X = x + p_1 = \log\ v;\ Y = y + p_2 = \log(1 + v) \tag{27a}$$

Solving p_1 and p_2 from (22), (27), and (27a) we find

$$p_1 = \log\ k_1 - \log\ k_0;\ p_2 = -\log\ k_0 \tag{27b}$$

With $k_0 = 0$ we have correspondingly

$$f(a) = k_1 a + k_2 a^2 \tag{28}$$

Using the same set of experimental variables (22), and normalizing

$$X = x + p_1 = \log\ v;\ Y = y + p_2 = \log\ (v + v^2) \tag{28a}$$

we would find

$$p_1 = \log\ k_2 - \log\ k_1;\ p_2 = \log\ k_2 - 2\ \log\ k_1 \tag{28b}$$

The curves (27a) and (28a) are shown in Fig. 5; they can of course, like those in Fig. 4a, be applied to functions with inverted values of f or a, just by reversing one coordinate axis or both.

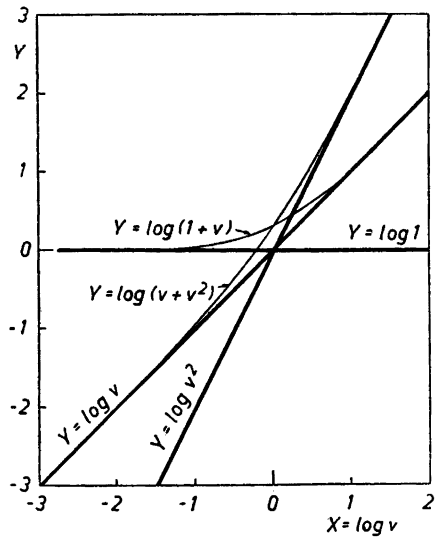

Fig. 5. Normalized curves (27a) and (28a) for finding coefficients in $f = k_0 + k_1 a$ *and* $f = k_1 a + k_2 a^2$.

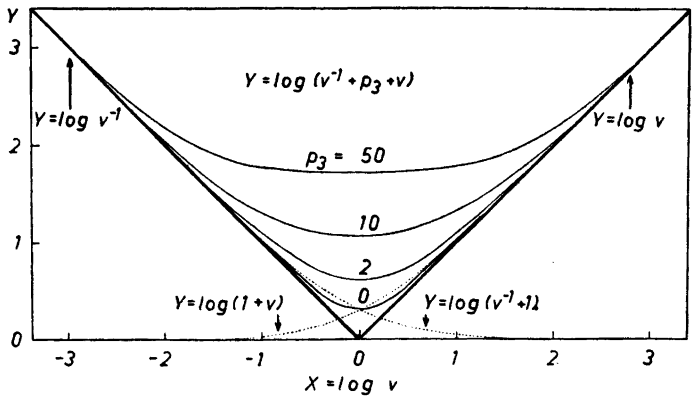

Fig. 6. Normalized curves (29) for finding coefficients of polynomial $k_0 + k_1a + k_2a^2 = f$, *by comparison with log* fa^{-1} *(log a) diagrams. Curves are also drawn for cases with one or two coefficients = 0.*

Using the double-logarithmic plot (22), all three unknowns in $f = k_0 + k_1a + k_2a^2$ may be found by comparing with the curves in Figs. 4a and 5. — It may seem surprising that a curve-fitting method is advocated for problems which have usually been solved by linear plots, and would seem admirably suited to such. However, with experimental data extending over a number of powers of 10, a logarithmic plot may give a better estimate of the real accuracy (see above, p. 196).

The same approach may be used for any polynomial with only three parameters, say $f(a) = k_1a + k_3a^3 + k_4a^4$ etc. It may prove useful in some cases to use as y, not log f but for instance log fa^{-1} or log fa^2. Thus the polynomial (24) may also be treated by considering $y = \log fa^2 = \log (k_2 + k_1a + k_0a^2)$, which may be treated with the curves (23).

Even the polynomial (21) $f = k_0 + k_1a + k_2a^2$ may sometimes preferably be treated using (Fig. 6)

$$\left.\begin{aligned} x &= \log a;\ X = \log v \\ y &= \log fa^{-1};\ Y = \log(v^{-1} + p_3 + v) \end{aligned}\right\} \qquad (29)$$

Equations (23 a, b, c) still hold. Thus p_3 is found from the intersection of the Y axis for $X = 0$: $Y = \log(2 + p_3)$.

SMOOTHED CURVES

It seems a good rule to select such graphical methods as allow one to retain a good feeling for the possible effect of experimental errors. Thus one would like to plot each experimental point as a separate point, with such coordinates that the influence of an experimental error can be readily estimated. In studies of complexity equilibria, this principle has been especially strongly advocated by Leden[e.g. 16].

Thus, it does not seem advisable to draw from the onset a smoothed curve through a set of data, and then to keep strictly to that curve. This approach is

especially dangerous if the data have only intermediate accuracy, and the points are rather scarce in some part of the diagram. On scrutinizing such "smoothed curves" one may find that the position of certain points will unduly influence the way of drawing the curve. If it so happens that from a certain "smoothed curve" one has calculated values for the unknown constants that give a fair agreement with the original smoothed curve, one is too often inclined to think that one has found the right set of parameters, without trying to imagine how wide a domain in parameter space (p_1, p_2 . . .) would also have given an acceptable agreement. Only if a smoothed curve gives constants that fail to reproduce it, it is emphasised that the curve must be incorrectly drawn, *i. e.* that it does not belong to the right family of curves.

Sometimes it may be unavoidable to use a smoothed curve, especially when a differentiation or integration is necessary. To avoid the dangers of smoothing the wrong way, one should use the following precautions:

1) Besides the best "smoothed curve" one should also draw two or more curves that deviate from it but would still give an acceptable agreement with the data. A comparison with constants calculated from these curves will give an indication of the real accuracy.

2) The results obtained with a smoothed curve should be compared with those obtained by other, independent methods.

METHODS FOR SEVERAL PARAMETERS

Successive approximation

The experimental range may often be divided into several parts so that one or two parameters, which give the main effect in one part of the range, give only a small correction in the other. Suppose for instance that we have an experimental quantity $y(x, p_1, p_2, p_3, p_4)$, and that p_1 and p_2 predominate in one range of x whilst p_3 and p_4 give a small correction, whereas in another range it is the other way round. Then p_1 and p_2 may be determined from the first range by one of the methods for a two-parameter problem, using approximate values for p_3 and p_4 or even neglecting them; then p_3 and p_4 are determined by some two-parameter method in the other range, assuming the first approximate values for p_1 and p_2. Using these values for p_3 and p_4 in the first range, better approximations for p_1 and p_2 are found etc.

In this way four or more parameters may be obtained by successive approximation using two-parameter methods. This procedure is not necessarily unsatisfactory, since one need never lose the contact with the experimental data.

"Sweeping" methods

Especially for the determination of consecutive constants of complex formation, another type of method has been used, which may be described as "sweeping" for the parameters. The term will indicate that, just like with a sweeping search-light, the interest is centered on one or two constants at a time, and that the centre of interest is moved along the series of parameters.

The function $y(x, p_1, p_2, p_3, p_4 \ldots)$ is first reduced to a two-parameter problem by neglecting other parameters than p_1 and p_2. In the range where

p_1 and p_2 are predominant, a plot (usually linear) is made from which approximate values for p_1 and p_2 are found. The value for p_1 is accepted and inserted into the function y. Now the function $y(x, p_2, p_3 \ldots)_{p_1}$ is considered, keeping p_1 constant, neglecting p_4 and following parameters, and having p_2 and p_3 as unknown parameters to be determined. This plot gives a value for p_2, which is then used in a new plot with p_3 and p_4 as unknown parameters. The procedure may be speeded up if one accepts both values for p_1 and p_2 obtained from the first plot, and thus gets two parameters from each plot. It is often advantageous to use different experimental functions y and x in different parts of the range.

With such a method there is a danger that errors in the values for the first parameters p_1, p_2 etc will accumulate, making the plots for p_4 and p_5 somewhat unreliable; at any rate, the feeling of contact with the experimental data is definitely lost, and it is very hard to estimate the real accuracy.

The parameters obtained may be checked and improved:

1) by sweeping the series of parameters from both ends; an example is given in part I [10]. The deviations will give an indication of the accuracy.

2) by successive approximation. After a first approximate set of parameters has been obtained, the terms corresponding to the higher parameters are inserted into the first plot for finding p_1 and p_2, which gives better values for these parameters. The process may be repeated, either always from one end, or sweeping from alternate ends of the parameter series, depending on the problem and type of data. As a rule, this simple precaution appears to have been neglected previously.

If curved plots are also considered, one would have a greater freedom of choice.

I wish to thank my friends George Biedermann, David Dyrssen, Brita Hök-Bernström, Gösta Lagerström, Francis Rossotti, Hazel Rossotti, and Jan Rydberg for pleasant cooperation and for many valuable discussions.

Some Graphical Methods of Determining Equilibrium Constants III. A Projection Strip Method for Two-Parameter Systems

F. J. C. ROSSOTTI, HAZEL ROSSOTTI and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Experimental data may often be represented by a single curve $y(x)$. It is sometimes possible to describe this function, either rigorously or approximately, in terms of only two parameters, p_1 and p_2, such that the value of p_2 determines the shape of the curve $y(x)$, while the value of p_1 fixes its position on the x axis. Values of p_1 and p_2 may always be obtained by comparing the shape and position of the experimental $y(x)$ curve with theoretical $y(X)_{p_2}$ curves calculated for different values of p_2. It is, however, more convenient to determine them by fitting the data in the form of a projection strip $(x)_y$ to the set of theoretical curves $p_2(X)_y$, where the normalised function $X = x + p_1$. This device is used to calculate equilibrium constants for a number of systems containing polynuclear hydrolysis products, and its application to systems of mononuclear complexes is indicated. The set of curves $p_2(X)_y$ is also useful for the rapid calculation of theoretical $y(x)$ curves for systems in which the values of p_1 and p_2 are known.

In studies of equilibria in a solution containing complexes formed from a central group, M, and a ligand, L, the measurements may often be explained, within the limits of experimental error, in terms of two parameters. For the special case where only the first two mononuclear complexes, ML and ML_2, are formed, two parameters, K_1 and K_2, suffice for a rigorous mathematical description of the system. (Here the stability constant of the species ML_n is given by $K_n = [ML_n]/[ML_{n-1}][L]$ and charges are omitted.) A number of methods for calculating K_1 and K_2 from the experimental data have been described, and are discussed critically elsewhere [1]. When $N > 2$ mononuclear complexes are formed, an exact treatment requires N parameters, $K_1, K_2 \ldots K_N$, which may be determined experimentally if the data are sufficiently precise [2]. However, it may not be possible to obtain more than two independent stability constants from less accurate data, *e. g.* some partition measurements, and it is often convenient to give an approximate description of systems of this type

in terms of only two parameters [3]. A rigid mathematical treatment of a system containing polynuclear complexes, M_qL_p ($1 \leq p \leq P$, $1 \leq q \leq Q$) requires PQ parameters, which could only be determined if a very large number of precise data were available [4]. In practice, it is seldom possible to obtain more than three or four independent constants for these systems, and in many cases the experimental data may again be satisfactorily explained in terms of only two parameters [5-7].

A general discussion of the determination of two or more parameters by curve-fitting, successive extrapolations, or other methods is given elsewhere [2,8]. This paper is restricted to the calculation of equilibrium constants for systems in which the experimental data are of the form $y(x)$, and which may be described in terms of only two parameters, p_1 and p_2, where p_1 fixes the position of the $y(x)$ curve on the x axis, and p_2 determines the shape of the curve. It is always possible to determine the values of p_1 and p_2 by direct curve-fitting [8], using the family of normalised curves $y(X)_{p_2}$, where

$$X = x + p_1 \tag{1}$$

An approximate value of p_2 may be obtained from the parameter of the calculated curve which gives the best fit, and the value of p_1 obtained from the experimental value of x corresponding to $X = 0$. The family of theoretical curves $y(X)_{p_2}$ is useful as a first approach for testing whether the experimental data are compatible with a certain hypothesis, and for recognising and correcting for systematic errors [8].

If the experimental $y(x)$ data are found to fit in with the family of theoretical $y(X)_{p_2}$ curves, the values of p_1 and p_2 may conveniently be refined by comparing a projection strip of the experimental $y(x)$ curve with the family of curves $p_2(X)_y$. The method is used as follows.

The experimental data (yx) are plotted using the same abscissa scale as in the family of curves $p_2(X)_y$. For each value of y tabulated, the corresponding value of x, together with the experimental uncertainty in this value, is marked off on the x axis (*cf.* Fig. 1a). This projection strip $(x)_y$ of the data $y(x)$ is then superimposed on the family of curves $p_2(X)_y$, parallel to the X axis, and in such a position that the best possible fit is obtained for all the values of y shown (*cf.* Fig. 1b).

The value of p_2 is then obtained as the ordinate, corresponding to the best position of the strip. The maximum limits of error in this value may be estimated from the vertical distance through which the projection strip may be moved, whilst allowing the calculated values of $(X)_y$ to remain within the experimental uncertainty. The value of p_1 is obtained as $(-x_0)$ where x_0 is read at the point of intersection of the p_2 axis ($X = 0$) with the projection strip (*cf.* eqn. 1). The maximum error in p_1 is then given by the permissible horizontal displacement of the strip. If data are only available in a very narrow range of y, a number of additional theoretical $p_1(X)_y$ curves may be calculated in this range. The value of p_2 can be found as described above, and the value of p_1 obtained by producing the projection strip to the point of intersection with the line ($X = 0$).

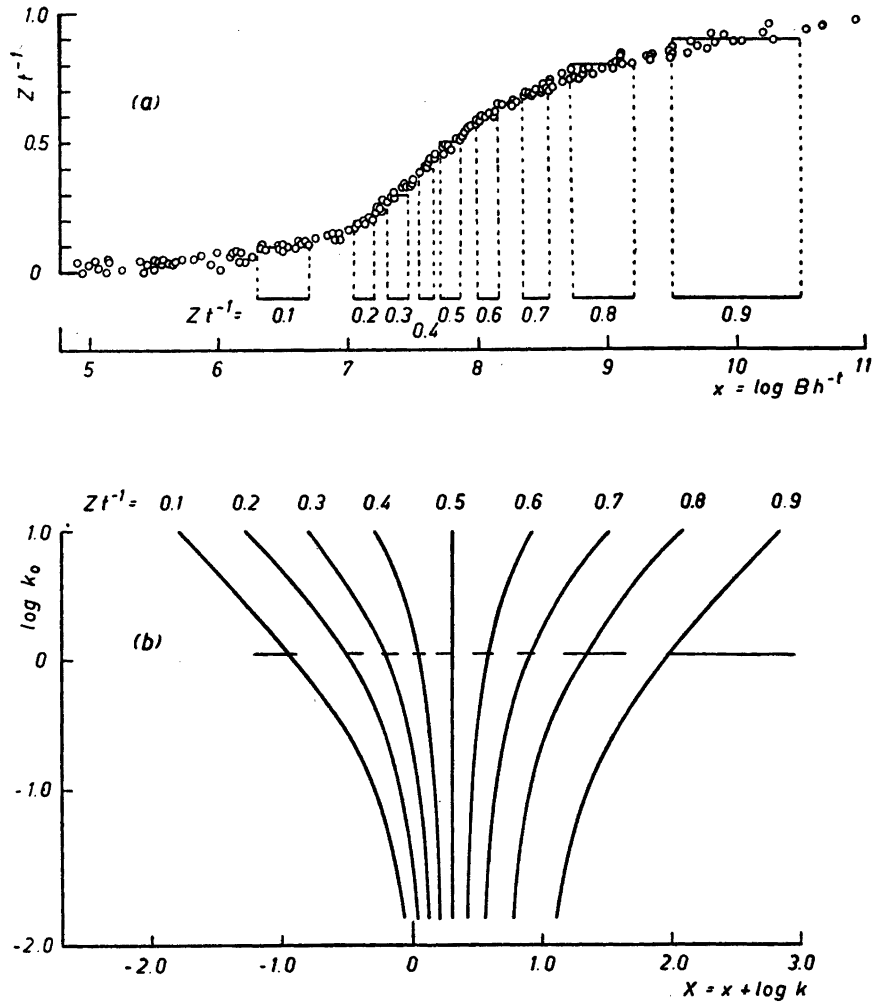

Fig. 1. The determination of the hydrolysis constants of the Th^{4+} ion in a 1.0 M perchlorate medium at 25° C. (a) Experimental curve $y = Zt^{-1}$ *as a function of* $x = \log Bh^{-t}$ *(Hietanen [12]) and projection strip. Points for different total concentrations of metal are not differentiated. (b) Projection strip of the* y(x) *curve superimposed on the family of theoretical curves log* $k_0(X)_y$, *in the position corresponding to log* $k_0 = +0.06$ *and log* $k = -7.53$.

When both p_1 and p_2 are known, the set of curves $p_2(X)_y$ may be used to calculate the theoretical curve $y(x)$. Values of X are obtained as the abscissae corresponding to the value of p_2 previously calculated, for a number of values of y. As p_1 is known, these values of X may then be substituted into equation (1) to give values of x.

The present method for calculating the parameters is no less accurate than those described elsewhere [2,8], and may be used much more rapidly, once

a preliminary check with the $y(X)_{p_2}$ curves has been made. Moreover, it may give a clearer estimate of the limits of error in the values of p_1 and p_2 obtained. Its application to the determination of equilibrium constants in systems of polynuclear hydroxyl complexes is described below. The adaptation of the treatment to other two-parameter systems is also indicated.

LIST OF SYMBOLS

B	total concentration of metal ions
b	concentration of free metal ions
H	total analytical excess concentration of hydrogen ions, assuming no hydrolysis
h	concentration of free hydrogen ions
K_n	stability constant of complex ML_n, defined by $K_n = [ML_n]/[ML_{n-1}][L]$
k	equilibrium constant, defined by $k = k_{n+1}\, k_n^{-1}$ (Hypothesis IIIa)
k_n	equilibrium constant, defined by $[Me((OH)_tMe)_n]/b^{n+1}h^{-t}$
k_0	equilibrium constant, defined by $k_0 = k_n k^{-n}$ (Hypothesis IIIa)
N	maximum value of n (mononuclear systems)
n	number of L groups in complex ML_n, or number of $Me(OH)_t$ "links" in "core + links" complex, $Me((OH)_tMe)_n$
$\bar{n}$	average value of n
P	maximum value of p
p	number of L groups in complex M_qL_p
p_1	parameter determining position of $y(x)$ curve on x axis
p_2	parameter determining shape of $y(x)$ curve
Q	maximum value of q
q	number of M groups in complex M_qL_p
t	number of hydroxyl groups per metal ion in "link", $Me(OH)_t$
$X =$	$x + \log k$
$x =$	abscissa of experimental curve
$x_{\frac{1}{2}} =$	value of x corresponding to $y = \frac{1}{2}$
$y =$	ordinate of experimental curve
Z	average number of hydroxyl groups per metal ion $= (H\text{-}h)B^{-1}$
α_S	fraction of total metal in the form $ML_S = [ML_S]/\sum_{n=0}^{n=N} [ML_n]$
$\eta =$	$\log Bb^{-1}$
$\beta_n =$	$\prod_1^n K_n$

THE CALCULATION OF EQUILIBRIUM CONSTANTS OF POLYNUCLEAR "CORE + LINKS" COMPLEXES

Previous work in this laboratory has indicated that the main products of hydrolysis of many metal ions, Me, are polynuclear "core + links" hydroxyl-complexes, of general formula $Me((OH)_tMe)_n$, where n is variable and t constant (Ref.[9] and refs. therein). A treatment of equilibria involving complexes of this type, together with methods for obtaining the value of t has been given elsewhere [7,10]. The equilibrium constant $k_n = [Me((OH)_tMe)_n]/[Me]^{n+1}[H]^{-t}$ for the formation of the complex $Me((OH)_tMe)_n$ may then be determined if certain

simplifying assumptions are made [7]. Potentiometric measurements for a number of systems, *e. g.*[11-14] may be explained by assuming that complexes with all positive integral values of n are formed, and that the ratio of successive equilibrium constants k_n/k_{n+1}, is constant ([7] hypothesis IIIa). The system may then be approximately described in terms of two parameters, k and k_0, such that

$$p_1 = \log\ k = \log\ k_{n+1} - \log\ k_n \tag{2}$$

and

$$p_2 = \log\ k_0 = \log\ k_n - n\ \log\ k \tag{3}$$

These parameters may readily be determined by the method described above.

Treatment of the data B, H, h

If the total concentrations of metal, B, and hydrogen, H, and the concentration of free hydrogen ions, h, are known, it is convenient to plot $Z = (H\text{-}h)B^{-1}$ as a function of $\log h$. If only "core + links" complexes are formed in appreciable amounts, the curves $Z(\log h)_B$ will be parallel, and the value of t may be determined from the spacing between them [10]. When $y = Z/t$ is plotted against $x = \log Bh^{-t}$, the experimental points fall on a single curve, which may often be approximately represented in terms of two parameters (*cf.* (2) and (3)). The shape of the curve is determined by the value of $\log k_0$ (parameter p_2) and its position on the x axis by the value of $\log k$ (parameter p_1).

If the experimental curve $y(x)$ is found to fit in with a set of theoretical curves, calculated for a few widely separated values of k_0 assuming hypothesis IIIa (*cf.*[7], Fig. 2a), the value of k_0 may be calculated by one of the methods described previously [7]:

a) The shape of the experimental curve may be compared with $y(X)$ curves calculated for different values of k_0,

where

$$X = x + \log\ k \tag{4}$$

This method makes use of the whole range of experimental data, and as it has the further advantage of revealing systematic errors in y, it is a good first approach. For subsequent refining of the parameters it is somewhat time-consuming, as fresh curves will usually have to be calculated for values of k_0 not already available.

b) The value of k_0 may be calculated from corresponding values of y and x, using the equation

$$k_0 = y\ [1-10^X\ (1-y)]^2\ [10^X\ (1-2y)^2]^{-1} \tag{5}$$

where

$$X = \log\ 2 + x-x_{\frac{1}{2}} \tag{6}$$

and where $x_{\frac{1}{2}}$ is the value of x for $y = \frac{1}{2}$. If full use is to be made of the data, k_0 should be calculated for many values of y, and this method would also be rather laborious.

c) The slope of the curve $y(x)$ at the point $y = \frac{1}{2}$ is given by

$$(\mathrm{d}y/\mathrm{d}x)_{y=\frac{1}{2}} = \tfrac{1}{2}\ \ln\ 10 \cdot (1 + 2\sqrt{k_0})^{-1} \tag{7}$$

Even if the data are of the highest precision and extend to values of $y > \frac{1}{2}$, it may be difficult to measure this slope with any great accuracy. Moreover, this method only uses data in one small region of the curve, and does not indicate whether the value of k_0 so obtained gives a good description of the curve as a whole.

The value of log k has previously been calculated from the relationship [7] obtained by combining eqns. (4) and (6)

$$\log k = \log 2 - x_{\frac{1}{2}} \tag{8}$$

but as the value of $x_{\frac{1}{2}}$ is obtained directly from the midpoint of the $y(x)$ curve, this method does not make full use of all the experimental data.

Values of k_0 may be obtained rapidly by the present method, which makes use of the set of theoretical curves log $k_0(X)_y$. Corresponding values of log k_0 and X have been calculated for different values of y, using equation (5), and are shown in Table 1 and Fig. 1b.

−0.301	−0.684	−0.344	−0.109	0.097	0.301	0.523	0.787	1.140	1.731
0.301	−1.166	−0.708	−0.353	−0.026	0.301	0.646	1.029	1.502	2.208
0.699	−1.529	−1.022	−0.594	−0.162	0.301	0.718	1.274	1.819	2.565
1.000	−1.812	−1.289	−0.823	−0.306	0.301	0.925	1.501	2.088	2.863

As an illustration of the method described above, values of k_0 and k have been calculated for the products of hydrolysis of the ions Th^{4+}, UO_2^{2+} and In^{3+}, and are compared with the values obtained by the original authors, *cf.* pp. 210-211.

When the values of both k_0 and k are known, the theoretical curve $y = Zt^{-1}$ as a function of $x = \log Bh^{-i}$ may be calculated rapidly with the aid of Fig. 1b. For a given value of log k_0, values of X may be obtained from the curves for the values of y tabulated. As log k is also known, these values may be substituted into eqn. (4) to give values of x.

Treatment of the data B, H, b and h

If the free concentrations of both metal ions, b, and hydrogen ions, h, can be measured, the data may be plotted in the form $\eta = \log Bb^{-1}$, as a function of log h. If "core + links" complexes predominate, the curves η (log $h)_B$ are parallel, and the value of t may be obtained from the spacing between them [10]. When $y = \eta$ is plotted as a function of $x = \log Bh^{-i}$, the experimental points will therefore lie on a single curve which may approximately be described in terms of the parameters log k_0 and log k (eqns. (2) and (3)).

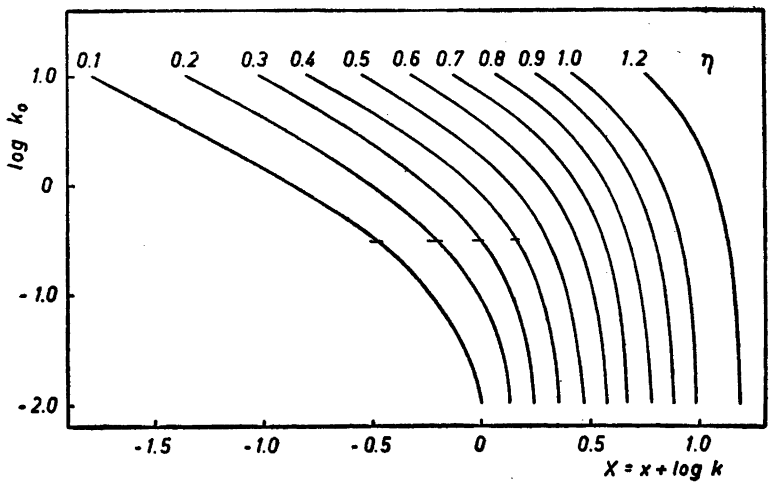

Fig. 2. The determination of the hydrolysis constants of the In^{3+} ion in a 3.0 M perchlorate medium at 25° C. Projection strip of plot of $y = \eta$ *against* $x = \log Bh^{-t}$ *(Biedermann [14]) superimposed on the family of theoretical curves* $\log k_0 (X)_\eta$ *in the position corresponding to* $\log k_0 = -0.50$ *and* $\log k = -4.70$.

The present method for determining these parameters may again be more convenient than that [7] of calculating theoretical curves $\eta(X)$ for hypothesis IIIa to compare with the experimental data $\eta(x)$. Corresponding values of log k_0 and X have been calculated for different values of η, using the equation [7]

$$X = \log \left(1 - \sqrt{\frac{k_0}{10^\eta - 1 + k_0}}\right) + \eta \qquad (9)$$

and are given in Table 2.

The experimental curve $\eta(\log Bh^{-t})$ is plotted using the same abscissa scale as for the curves $\log k_0(X)_\eta$, and a projection strip on the x axis is prepared as before. The values of $\log k_0$ and $\log k$, together with the limits of error, are then obtained by a method exactly analogous to that described above (*cf.* Fig. 2). The method has been applied to the hydrolysis of the In^{3+} ion and the results are given on p. 211.

Fig. 2 may also be used to construct theoretical $\eta(x)$ curves for systems in which k_0 and k are known. From the intersection of the curves with the horizontal line at the required value of $\log k_0$, a number of corresponding values (X, y) are obtained. The corresponding values of x are given by $X = x + \log k$ (eqn. 4).

The experimental data B, H, b and h could also be plotted in the form $\eta(x—\eta)$, and curves of this type could be treated analogously by means of a set of curves $\log k_0(x - \eta)_\eta$.

Application of the method to the hydrolysis of some metal ions

It has previously been found [12–14] that the experimental Zt^{-1} (log Bh^{-t}) curves for the ions Th^{4+}, UO_2^{2+} and In^{3+}, and the log Bb^{-1} (log Bh^{-t}) curve for In^{3+} fitted in with the appropriate families of theoretical curves [7], calculated assuming hypothesis IIIa. Values of log k_0 and log k have now been calculated from the theoretical curves by the method described above. The limits of error quoted represent the maximum uncertainly both of individual measurements and of the validity of hypothesis IIIa. The preparation of a projection strip for a system, and the determination of the constants may be carried out in about ten minutes, once the diagrams $y(x)$ and $\eta(x)$ are available.

The Th^{4+} *ion.* The experimental curve [12], $y = Zt^{-1}$ as a function of $x = \log Bh^{-t}$, and the projection strip obtained from it, are shown in Fig. 1a. In Fig. 1b, the strip is superimposed on the family of curves log $k_0(X)_y$. The best fit is obtained with the following values of the constants, which are in satisfactory agreement with those given by Hietanen [12].

Present method	$\log k_0 = +0.06 \pm 0.04$	$\log k = -7.53 \pm 0.05$
Hietanen [12]	$\log k_0 = -0.15 \pm 0.15$	$\log k = -7.50$

The UO_2^{2+} *ion.* The projection strip of the experimental curve, $y = Zt^{-1}$ as a function of $x = \log Bh^{-t}$, for the hydrolysis of the uranyl ion [13] is shown in Fig. 3a. Using Fig. 1b and eqn. (4), the following values were obtained, in good agreement with those previously calculated [13]

Present method	$\log k_0 = 0.3 \pm 0.3$	$\log k = -6.40 \pm 0.18$
Ahrland, Hietanen and Sillén [13]	$\log k_0 = 0.3$	$\log k = -6.35 \pm 0.10$

The In^{3+} *ion.* The projection strip of $y = Zt^{-1}$ as a function of $x = \log Bh^{-t}$ for the hydrolysis of the In^{3+} ion [14] is shown in Fig. 3b, and the constants obtained using the family of curves log $k_0(X)_y$ are given below. As the concentration of free indium ions, b, could be measured, the constants

may also be calculated from the experimental curve $y = \eta$ as a function of $x = \log Bh^{-t}$. The projection strip of this curve is superimposed on the set of curves log $k_0(X)_\eta$ in Fig. 2

	log k_0	log k
Present method Zt^{-1} (x)	-0.5 ± 0.1	-4.72 ± 0.04
Present method η (x)	-0.5 ± 0.1	-4.70 ± 0.05
Biedermann [14]	-0.52	-4.70 ± 0.05

The constants obtained by the present method are in excellent agreement with those calculated by Biedermann [14].

DISCUSSION

Comparison of the sets of curves log $k_0(X)_{Zt^{-1}}$ and log $k_0(X)_\eta$ shown in Figs. 1b and 2b emphasizes that the value of k_0 has a much greater influence on the shape of the former set. Thus, small uncertainties in the experimental curve η (x) lead to much greater uncertainties in k_0 than do small uncertainties in the curve $Zt^{-1}(x)$. If h and b could be determined with equal precision, constants calculated from the curves Zt^{-1} (x) would probably be more reliable than those obtained from $\eta(x)$ curves, although curves of both types are valuable for determining the nature of the species in solution. However, it is sometimes

possible to measure b with much greater accuracy than h, and in such cases the curves Zt^{-1} (x) and $\eta(x)$ may be of comparable value for the determination of the constants.

The shape of the curves $\eta(x-\eta)$ is also influenced by the value of $\log k_0$ to a greater extent than the shape of the curves $\eta(x)$, but the $\eta(x-\eta)$ curves have the disadvantage that any experimental uncertainty in η appears in both the value of the ordinate and the abscissa. The curves are therefore less suitable for determining equilibrium constants than are Zt^{-1} (x) and η (x) curves, especially if the data are not of the highest precision. The present method could also be readily adapted for use with hypotheses other than IIIa provided that not more than two parameters are required to describe a system.

ADAPTATION OF THE METHOD TO OTHER TWO-PARAMETER SYSTEMS

Several other types of experimental curves $y(x)$ may also be described, either rigorously or approximately, in terms of only two parameters, p_1 and p_2, such that p_2 determines the shape of the curve, and p_1 fixes its position on the x axis. If the curve $y(x)$ is found to fit in with the family of theoretical curves $y(X)_{p_2}$, small systematic errors may be corrected for, and approximate values of p_1 and p_2 obtained [8]. These values may be refined by superimposing a projection strip of the experimental $y(x)$ curve on the family of theoretical curves $p_2(X)_y$, as described above.

Systems of mononuclear complexes

If $N>2$ mononuclear complexes are formed, the experimental data may be plotted in the form $y(x)$, where

$$y = \bar{n} = \frac{\sum_{n=1}^{n=N} n[\mathrm{ML}_n]}{\sum_{n=0}^{n=N} [\mathrm{ML}_n]} = \frac{\sum_{n=1}^{n=N} n\beta_n[\mathrm{L}]^n}{\sum_{n=0}^{n=N} \beta_n[\mathrm{L}]^n} \tag{10}$$

or

$$y = \log \alpha_S = \log \frac{[\mathrm{ML}_S]}{\sum_{n=0}^{n=N} [\mathrm{ML}_n]} = \log \frac{\beta_S[\mathrm{L}]^S}{\sum_{n=0}^{n=N} \beta_n[\mathrm{L}]^n} \tag{11}$$

and

$$x = \log [\mathrm{L}] \tag{12}$$

Here $0 \leqslant S \leqslant N$ and $\beta_n = \prod_1^n K_n$. If the species ML_S is distributed between two phases, the term α_S may be obtained from partition data, provided that the value of the partition coefficient $[\mathrm{ML}_S]_{org}/[\mathrm{ML}_S]_{aq}$ can be determined; and if $S = 0$, α_S may be measured potentiometrically by means of an electrode which is reversible to free metal ions.

The present method can only be used if the number of parameters can be reduced to two by some assumption about the relationship between successive stability constants K_n. For example, if the ratio $K_n K_{n+1}^{-1}$ is fixed ($= k$), or a function of n ($= k\ \psi\ (n)$), the parameters p_1 and p_2 may be chosen as

$$p_1 = \frac{1}{N} \sum_{n=1}^{n=N} \log K_N = \frac{1}{N} \log \beta_N \tag{13}$$

and

$$p_2 = \tfrac{1}{2}\log \left\{K_n K_{n+1}^{-1}/\psi(n)\right\} = \log \left\{\beta_n^2 \beta_{n+1}^{-1} \beta_{n-1}^{-1} \,/\, \psi(n)\right\} \tag{14}$$

Then from eqns. (1), (12), and (13)

$$X = \log\ [\mathrm{L}] + \frac{1}{N} \log\ \beta_N \tag{15}$$

Although it would be possible to devise equations for the "statistical" case [15], where

$$\psi\ (n) = \frac{(N-n+1)\ (n+1)}{(N-n)\ n} \tag{16}$$

the present discussion will be limited to Dyrssen and Sillén's simpler approximation [3] that $\psi\ (n) = 1$.
In this case

$$\log\ \beta_n = n\ p_1 + n(N-n)p_2 \tag{17}$$

and from eqns. (13) and (15)

$$\log\ [\mathrm{L}] = X - p_1 \tag{18}$$

Whence

$$\log\ \beta_n\ [\mathrm{L}]^n = n\ \left\{X + p_2\ (N-n)\right\} \tag{19}$$

and y may be expressed in terms of p_2, S and N, and of the normalised variable X.

Thus

$$y = \bar{n} = \frac{\sum_{n=1}^{n=N} n 10^{n\{X+p_2(N-n)\}}}{\sum_{n=0}^{n=N} 10^{n\{X+p_2(N-n)\}}} \tag{20}$$

and

$$\log\ \alpha_S = S\left\{X + p_2(N-S)\right\} - \log \sum_{n=0}^{n=N} 10^{n\{X+p_2(N-n)\}} \tag{21}$$

Approximate values of p_1 and p_2 may be found by direct comparison of the experimental data $y(x)$ with the set of curves $\bar{n}\ (X)_{p_2}$ or $\log\ \alpha_S(X)_{p_2}$, calculated from eqns. (20) and (21) using the appropriate value of N and S. The values of p_1 and p_2 may very conveniently be refined using the projection strip method, and the set of curves $p_2(X)_{\bar{n}}$ or $p_2(X)_{\log\ \alpha_S}$.

If only two mononuclear complexes, ML and ML_2 are formed, the system may be rigorously defined in terms of the two parameters

$$p_1 = \tfrac{1}{2}\ \log\ K_1 K_2 = \tfrac{1}{2}\ \log\ \beta_2 \tag{13a}$$

and

$$p_2 = \tfrac{1}{2}\ \log\ K_1 K_2^{-1} = \log\ \beta_1 \beta_2^{-\frac{1}{2}} \tag{14a}$$

In eqns. (13a) and (14a) $(\frac{1}{2} \cdot 10^{p_2})$ is the spreading factor, and 10^{p_1} is the average constant, defined by J. Bjerrum [15].

When $N = 2$, equation (20) reduces to

$$\bar{n} = \frac{10^{X+p_2} + 2.\ 10^{2X}}{1 + 10^{X+p_2} + 10^{2X}} \tag{20a}$$

If p_2 is defined alternatively as $\sqrt{K_1 K_2^{-1}}$, eqn. (20a) reduces to eqn. (14) in Part II [8].

Accurate values of p_1 and p_2 may be determined using the projection strip method, as described above. A somewhat similar device, which makes use of the symmetrical properties of the $\bar{n}$ (x) curves for systems of this type, has been described previously [1].

Studies on the Interaction of Paraffin Chain Alcohols and Association Colloids

IV. The Effect of Decanol-1 on the Viscosities of Some Association Colloid Solutions

KAAPO PASSINEN and PER EKWALL

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

The effect of decanol on the viscosities of solutions of sodium oleate, sodium lauryl sulphate and sodium myristyl sulphate has been studied. When the oleate concentration is low, below about 0.2 *M*, the viscosity increases slowly with the amount of decanol added and the viscosity curve reveals no noticeable irregularities at the turbidity point where a new phase composed of decanol, oleate and water begins to separate. At higher oleate concentrations three ranges can be distinguished in which the effect of decanol on the viscosity differs depending on the amount of decanol added. As long as all the decanol is solubilized in the micelles, the viscosity increases. When the new phase appears, the viscosity decreases at first as decanol is added, then passes through a minimum and begins to increase again when more decanol is added. Some observations on the effect of *p*-xylene on the viscosity of a sodium oleate solution have also been made. The factors which determine the observed variation of the viscosity are discussed. In homogeneous systems at low oleate concentrations the increase in the viscosity caused by decanol (or xylene) can be fairly well explained on the assumption of an increase in the micelle volume; at higher oleate concentrations (above *ca.* 0.2 *M*) large changes in the form and the structure of the micelles must be assumed. The decrease in the viscosity in the heterogeneous systems depends on the decrease in the concentration of the mixed micelles in the aqueous solution caused by the separation of the new phase. When the amount of this new phase becomes so large that it influences strongly the flow of the solution, the viscosity begins to increase rapidly.

The viscosities of solutions of association colloids with and without added inorganic salts have been thoroughly investigated, but the effect of solubilized substances on the viscosities of association colloid solutions has not been systematically studied.

The effect of lower paraffin chain alcohols was investigated by Bose and coworkers [1-5] (methanol to hexanol, different soaps, sodium chloride) and by Rossi and Ragno [6] (ethanol, sodium oleate). The measurements were carried out on clear homogeneous solutions; the alcohol contents used were very high, between 10 and 50 % of the volumes of the soap solutions. The alcohols caused an increase in the viscosity; in some cases Bose observed that the viscosity decreased when greater amounts of alcohol were added. The effect of higher alcohols seems to have been studied only by Klevens [7] (octanol, potassium myristate, potassium chloride), de Jong and van Alphen [8] (methanol to octanol, sodium oleate, potassium chloride) and Ekwall, Passinen and Danielsson [9] (decanol, sodium oleate). The qualitative observations of Klevens show that in myristate solutions containing potassium chloride the viscosity increases with the amount of octanol, passes through a maximum and then begins to decrease; the maximum appears at an octanol content less than that required to effect turbidity. Also Ekwall and coworkers observed a viscosity maximum but this maximum occurs at the point where the system becomes heterogeneous; their solutions contained no added inorganic electrolyte.

The effect of polar-nonpolar compounds other than alkanols has also been studied. Thus, Angelescu and coworkers [10-12] studied the effect of different cresols on the viscosities of some soap solutions. They found that the viscosity increases slowly with the amount of cresol added when the soap concentration is low. At higher soap concentrations, the viscosity increases rapidly to a maximum, then decreases to a minimum and subsequently begins to increase slowly as the amount of cresol is increased further. All the systems studied were homogeneous. The effect of cresols on the viscosities of solutions of soap mixtures was also studied [13]; the viscosity curves were similar in form to those for solutions of the single soaps. Angelescu and coworkers studied also the joint effect of fatty acid and cresol [14] and of electrolytes and cresol [15] and the effect of some other substances [16, 17] (phenol, hydroquinone, resorcinol, nitrophenol, aminophenol, naphthol). In most cases curves similar to those obtained with cresol were obtained, but in some cases no maximum was observed. Philippoff [18] studied the effect of *m*-cresol on the viscosity of a 0.45 *M* sodium oleate solution and found that the viscosity increases with the amount of cresol added, then passes a maximum and begins to decrease. He also established that the addition of cresol effects a pronounced structural viscosity. Ekwall and Henriksson [19] found that the addition of terpineol first effects a pronounced increase in the viscosity of a 0.3 *M* sodium oleate solution, and as more terpineol is added, the system becomes heterogeneous and the viscosity of the system decreases rapidly, goes through a minimum, passes a second less pronounced maximum and finally remains approximately constant. McBain and McHan [20] showed that a 0.10 *M* potassium laurate solution saturated with dimethyl phthalate has a slightly greater viscosity than the pure laurate solution.

Some observations on the effect of solubilized nonpolar compounds have also been made. Hahne [21] and Kiessig and Philippoff [22] studied the effect of benzene on a sodium oleate solution (0.3 *M*) and found that the viscosity first increases rapidly to a maximum when benzene is added, decreases then to a minimum and finally increases slowly. The maximum in the viscosity curve appears at a benzene content much below the solubility value. When the system becomes saturated with benzene, addition of more benzene does not effect any further change of viscosity. No structural viscosity was established in the pure oleate solution, in the solution of maximum viscosity, or in the system saturated with benzene [22]. Stainsby and Alexander [23] found that the addition of chlorobenzene produces marked changes in the viscosities of hexadecyl pyridinium chloride solutions.

It thus seems to be typical of the effect of solubilization on the viscosity that the viscosity attains a maximum when a certain amount of solubilizate has been added. In most cases this maximum occurred in homogeneous systems [7, 10-18, 21, 22] but in two cases it appeared at the point where the system became heterogeneous [9, 19]. The results are complicated by the fact that the systems studied have in most cases contained varying amounts of inorganic electrolytes in addition to association colloid, the solubilized substance and water.

The purpose of the present work was to study the effect of a relatively long paraffin chain alcohol, decanol-1, on the viscosity of association colloid solutions without any other additives and to correlate these data with our previous studies of the solubility of decanol and the effect of decanol on the electrical conductance of these same solutions (Part I [24], Part II [25] and Part III [26] of this series). Some experiments have also been made with the purpose of comparing the effect of solubilization of a hydrocarbon on the viscosity with that of decanol.

MATERIALS AND METHODS

The compounds used were those employed in our previous studies [24-26]. The solutions were prepared in the manner described in Part I[24]. They were shaken at 40° C for periods from three to six days.

The viscosities were measured with an Ostwald viscosimeter. The temperature was held constant at 40° C ± 0.05° C. The viscosity of each solution was measured three times, and the average values were recorded. The viscosities are relative viscosities, η_{rel} (water = 1). The relative viscosity values are accurate to ± 0.5 to 1 %. When the value of $\eta_{rel} = (d_s/d_w)/(t_s/t_w)$, where d_s and d_w are the densities of the solution and water, and t_s and t_w the times of flow of the solution and water, respectively, was calculated, the density ratio d_s/d_w was taken to be unity.

The concentration of the association colloid is given in moles per 1 000 g of solution (denoted by M).

EXPERIMENTAL RESULTS

Sodium oleate solutions containing decanol. The effect of decanol on the viscosities of sodium oleate solutions has been studied at oleate concentrations between 0.05 and 0.3 M (Fig. 1). When the oleate concentration is low, below approximately 0.15 M, the viscosity increases slowly as the amount of decanol is increased. In these dilutions no marked change is observed in the course of the viscosity curve at the point where the addition of decanol effects the separation of a new phase. When the oleate concentration is 0.189 M, the rise of the viscosity curve is slightly arrested in this region. When the oleate concentration is above 0.2 M, the viscosity rises rapidly as long as the decanol added is solubilized in the micelles. When the amount of decanol is so great that the system becomes heterogeneous, the viscosity begins to decrease with increasing amount of decanol added, then passes a minimum and finally increases again rapidly. When more decanol is added the system becomes gel-like.

Thus, at oleate concentrations above 0.2 M, three different regions can be distinguished in which the effect of decanol on the viscosity of the oleate solutions differs. There is first a region where an addition of decanol increases the viscosity, then a region where the viscosity decreases and finally a region where the viscosity increases again as more decanol is added. The boundary between the first and second region coincides with the point where the system becomes heterogeneous owing to the separation of a new phase composed of decanol, oleate and water (turbidity point) and above which the electrical conductance of the solution undergoes an abrupt decrease [25]. The minimum in the viscosity curve appears at a decanol content of approximately 0.3—0.4 mole of decanol per mole of oleate and in the vicinity of the turbidity maximum in the same system [25]; the experimental data are, however, too meagre to permit a

decision whether viscosity minimum and turbidity maximum always coincide. In every case the viscosity minimum appears at a much lower decanol content than that at which the electrical conductance becomes constant (see Part II[25]); *e. g.* in a 0.232 *M* oleate solution the viscosity minimum occurs when 14 ml of decanol have been added per litre of solution, whereas the conductance becomes constant when approximately 30 ml of decanol have been added per litre.

The curves in Fig. 2 show how the effect of decanol on the viscosity varies with the concentration of oleate. Curve *a* gives the viscosities of the pure oleate solutions and is of the type generally found for the concentration dependence of the viscosity in solutions of association colloids. It increases slowly and linearly to a concentration of about 0.2 *M* and then begins to increase more rapidly. Curve *b* gives the viscosities of the oleate solutions containing decanol at the turbidity point, and curve *c* the viscosities of solutions containing 0.10 mole of decanol per mole of oleate. The difference between the

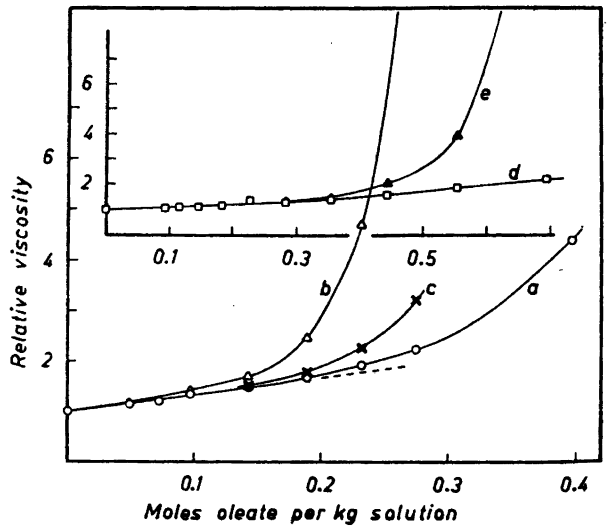

Fig. 2. *a) Relative viscosities of pure sodium oleate solutions. 40° C.*

e) Relative viscosities of sodium lauryl sulphate solutions containing 0.116 mole of decanol per mole of lauryl sulphate. 40° C.

viscosity values of curves *b* and *a*, the increase in viscosity at the turbidity point, is very small up to an oleate concentration of about 0.15 *M*, but above this limit the difference increases rapidly with the oleate concentration. In respect of the oleate concentration there are thus two regions, the first up to a concentration of about 0.15 *M* and the second above this limit where the effect of decanol on the viscosity differs greatly.

Sodium oleate solutions containing p-*xylene.* The viscosities of a series of 0.200 *M* oleate solutions containing various amounts of *p*-xylene were also measured (Fig. 3, curve *a*). The viscosity rises slowly and nearly linearly with increasing additions of xylene up to a point close to the solubility limit of xylene where it becomes approximately constant. The increase of viscosity caused by xylene is much smaller than that caused by the same volume of decanol (Fig. 3, curve *b*).

The specific volumes of sodium oleate solutions containing decanol. In order to determine whether the density ratio d_s/d_w can be taken as unity in the calculation of the relative viscosities, the densities of oleate solutions containing decanol were measured. Fig. 4, curve *a*, shows that the specific volume of a 0.300 *M* solution increases linearly with the amount of decanol added until the new phase is formed; at the latter point the curve changes its slope and continues again as a straight line. The density ratio is seen to be very near unity even for the highest decanol contents. Curve *b* shows the variation of the

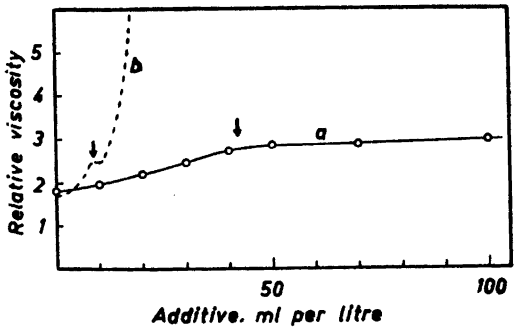

Fig. 3. a) Relative viscosities of 0.200 M *sodium oleate solutions containing p-xylene. 40° C.*

The arrows indicate the points where the systems become heterogeneous.

partial molar volume of decanol with the amount of decanol added. The dotted horizontal line in the figure gives the molar volume of pure decanol, 193.7 ml per mole. In the mixed micelles of oleate and decanol the partial molar volume of decanol is 190.9 ml per mole and in the turbid solutions 196.9 ml per mole. The decanol is thus slightly more densely packed in the mixed micelles than in the pure state, and its partial volume in the two-phase system is greater than that of pure decanol.

Sodium myristyl and sodium lauryl sulphate solutions containing decanol. The effect of decanol on the viscosity of sodium myristyl sulphate solutions has

been studied only at one colloid concentration, 0.300 *M* (Fig. 5, curve *a*). The viscosity increases slowly at first, then more rapidly with the amount of decanol added. In spite of the relatively high concentration of myristyl sulphate, no maximum and minimum values analogous to those observed in equally concentrated decanol-oleate systems were observed. Weak signs of a break point can, however, be noted at the point where the new phase composed of decanol, myristyl sulphate and water begins to separate. The viscosity curve for a decanol-oleate system with approximately the same colloid concentration has been drawn in Fig. 5 (curve *b*) for the sake of comparison; the viscosity of the oleate solution increases appreciably more rapidly than that of a myristyl sulphate solution on adding decanol.

The curves *d* and *e* in Fig. 2 show the variation of the viscosities of pure sodium lauryl sulphate solutions and of solutions containing 0.116 mole of decanol per mole of lauryl sulphate. These systems are homogeneous. The curves are similar in form to the corresponding curves for the decanol-oleate system (Fig. 2, curves *a* and *c*).

DISCUSSION

As we have seen above, the viscosities of pure and decanol-containing oleate solutions increase linearly with the oleate concentration up to the approximately 0.2 *M* concentration. Decanol effects a definitely greater increase in viscosity above the latter limit than below it. We have previously observed [24] that in the higher concentration range the solubility of decanol begins to increase faster than at lower concentrations. The effect of this increase of solubility on the viscosity is, however, very small. We have also found

that the effect of decanol on the conductance is altered at this same concentration (Part III[26], Table 1). Furthermore, the solubility of hydrocarbons undergoes a change [27,28], the conductance of pure oleate solutions passes through a minimum [29,30] and the so-called I band appears in the X-ray diffraction pattern [31] at the same colloid concentration. There is thus strong evidence that the properties of oleate solutions, both in the absence and presence of foreign substances, undergo pronounced variation at about this concentration (0.1—0.2 *M*). There seems to be sufficient reason to speak about a concentration limit in this concentration range; for the lack of a better name, this limit is called the 2nd critical concentration [28,32,33].

We shall first consider the homogeneous systems in which the added substance is solubilized, *i. e.* completely incorporated in the micelles. The increase in viscosity that is observed when decanol (or *p*-xylene) is added to the system may be caused by four factors, 1. the micelle volume increases, 2. changes occur in the electroviscous effect, 3. the micelles become deformed and 4. the degree of aggregation and number of micelles are altered. Actually, of course, these different factors co-operate and depend on each other. Our purpose is, however, to study how great is the effect of each of the factors on the viscosity and to investigate whether any one of them can alone explain the observed increase in viscosity.

The volumes of the micelles increase because the solubilized compound enters the micelles. We have attempted to estimate how much this increase in volume can alter the viscosity. The proportion of the total volume of the solution taken up by the micelles, the volume fraction, can be calculated for a certain concentration from the partial molal volume of the oleate using the data of Ekwall and Smeds [28]. If it is assumed that the incorporated compound effects no other change in the structure of the solution than an increase in the micellar volume, the variation of the specific viscosity with the amount of compound added may be represented by the equation $\eta_{sp} = K \Phi$, where Φ is the combined volume fraction of the micelles and the added compound. The value of the constant K is calculated from the known values of the specific viscosity and volume fraction in pure oleate solutions. The viscosity values calculated for solutions containing solubilized *p*-xylene (0.200 *M* sodium oleate, Fig. 3) are found to be only slightly lower than the experimental values. For 0.3 *M* oleate solutions containing benzene, however, the calculated values are much smaller than the values reported by Kiessig and Philippoff [22] for the range where the viscosity passes through a maximum with increasing benzene content. Also the calculated viscosity values for solutions containing decanol are close to the observed values at low oleate concentrations, but are much too small at higher oleate concentrations. In the concentrated oleate solutions other factors than the increase in the volume of the micelles must thus be responsible for the observed great viscosity changes. This is the case also if the hydration of the alcohol molecules is taken into consideration.

The incorporation of decanol brings about a change in the structure and properties of the micelle surface; among other things the charge density on the micelle surface is altered. This may be expected to effect changes in the electroviscous effect but these changes can be assumed to be insignificant in these systems in view of their high electric conductance.

The interaction between the hydroxyl groups of the solubilized alcohol and the ionized carboxyl groups is known to lead to a denser packing in the palisade layers of the micelles [34,35]. That the solubilized decanol actually is more densely packed than in the bulk is shown by our density measurements (see above). This must obviously influence the form of the micelle. By the light-scattering method it has been found that micelles become more anisodiametric when higher paraffin chain alcohols are solubilized in them [36]. Already a very slight change in the ratio of the axes of the micelle causes a marked increase in viscosity. From Simha's formula for rod-like particles [37] we have computed the degree of deformation that alone can lead to the observed increase in viscosity. From the known viscosities and volume fractions we have computed values of the axis ratio for pure soap solutions and for soap solutions containing solubilized substance. In this way comparatively high axis ratios are obtained for pure oleate solutions (about 10 in the 0.2 *M* concentration range) due to the fact that the viscosity of these solutions is not only caused by the deformation of the micelles and that Simha's formula is strictly valid only at low colloid concentrations. At oleate concentrations below *ca.* 0.2 *M*, a 10—20 % increase in the axis ratio at the turbidity point is sufficient to explain the increase in viscosity caused by decanol (or *p*-xylene). To explain the strong influence of added decanol on the viscosity of concentrated oleate solutions (above *ca.* 0.2 *M*), it is, however, necessary to assume much higher values for the axis ratio (*e. g.* in the 0.275 *M* oleate solution, the axis ratio should increase from about 11 in the pure solution to about 42 in the decanol-containing solution at the turbidity point). This implies that the mixed micelles formed by decanol and oleate at high oleate concentrations are long rod-shaped particles. It seems doubtful, however, whether the relatively small amounts of decanol in question are actually able to effect such great changes in the form of the micelle. We are therefore of the opinion that in the oleate solutions exceeding 0.2 *M* the deformation of the micelles cannot alone explain the observed increase in viscosity.

It has been previously assumed that an aggregation of micelles to larger and more or less anisodiametric lamellar micelles, called large micelles, occurs at higher association colloid concentrations [38,18]. These aggregates have been assumed to be responsible for the appearance of the so-called I band in the X-ray diffraction pattern and for the pronounced structural viscosity [39] of these solutions. Since apparatus for the measurement of structural viscosity was not available, we cannot present any evidence for the occurrence of micelle aggregation in oleate solutions containing decanol. It may be noted, however, that the decrease in the charge density, and the resulting increase in the hydrophobic properties of the surfaces of the micelles, decreases the stability of the micelles in the solution and hence facilitates an aggregation of the decanol-containing micelles. Even if micelle aggregates were not present in a pure 0.275 *M* oleate solution, it is possible that such aggregates might be formed when decanol is solubilized. If lamellar micelles or aggregates of cylindrical micelles are formed, water layers must be located between the hydrophilic layers and this must lead to a marked increase in micellar volume.

As a summary of the discussion of the factors which may cause the observed increases in the viscosity in the homogeneous solutions, the following can

be said. At low oleate concentrations an increase in the volumes of the micelles due to the incorporated decanol (or xylene) can explain nearly the whole observed increase. At higher oleate concentrations (above *ca.* 0.2 *M*) the deformation and aggregation of the micelles are apparently the most important factors.

We shall now proceed to discuss the factors which determine the courses of the viscosity curves in the region above the turbidity point.

When xylene in excess of the amount solubilized is added to an oleate solution, the excess is emulsified in the solution. Conductance measurements (Part III [26]) have shown that the emulsified xylene binds practically no oleate and hence the oleate concentration of the solution is not altered. In accordance with this the viscosity remains practically constant.

As already mentioned, the viscosities of oleate solutions above 0.2 *M* decrease when the new phase containing decanol, oleate and water separates on adding decanol. The new phase is composed of microscopic anisotropic particles of marked stability. Its formation reduces the decanol and oleate contents of the aqueous phase and the number of mixed micelles in this phase therefore decreases. We have estimated the magnitude of the decrease in viscosity which results from the decrease in the concentration in the aqueous phase. We have here assumed that the only changes effected by decanol are that the concentration of the mixed micelles in the aqueous phase decreases and particles of a new phase appear. When only a slight excess of decanol has been added above the turbidity point, the number of these particles is so small that they do not alter the viscosity. With the aid of conductance data (Part II[25]), the concentration of mixed micelles in the aqueous phase can be determined above the turbidity point for different amounts of added decanol.

The calculation will be illustrated by an example. The relative viscosity of a 0.275 *M* oleate solution at the turbidity point is 12.7. A concentration of 0.275 mole of mixed micelles per litre thus gives a specific viscosity equal to 11.7 and hence $\eta_{sp}/c = 11.7 / 0.275 = 42.5$. In the solution containing 0.275 mole of oleate and 15 ml of decanol per litre, the mixed micelle concentration is according to the conductance data 0.221 *M*. If the specific viscosity varied linearly with the mixed micelle concentration, the specific viscosity of the solution should be $42.5 \times 0.221 = 9.40$ and the relative viscosity 10.4. The agreement with the experimental value 9.8 is satisfactory.

The calculated viscosities for concentrated oleate solutions containing varying amounts of decanol are plotted in Fig. 1 (curves *g* and *h*). The agreement with the experimental values is good as long as the excess of decanol (above the turbidity point) is small. For greater excesses, the viscosities are much higher than the calculated values owing to the effect of the particles of the separated phase present in the solution.

At low oleate concentrations below *ca.* 0.15 *M*, no marked variation is observed in the viscosity when the solutions become heterogeneous. The calculated curve *j* in Fig. 1 for the 0.0493 *M* oleate solution shows that the decrease in viscosity is more than compensated for by the increase in viscosity caused by the particles of the new phase, and hence the viscosity curve exhibits no break point when the solution becomes turbid. This is because the specific viscosity due to the micelles that are removed from the solution

is so slight that although their concentration in the water phase diminishes greatly on adding decanol, the viscosity does not undergo any appreciable change. Therefore the particles of the separated phase exert their effect on the viscosity immediately and the viscosity increases gradually and uniformly. The same applies in the case of the 0.300 *M* sodium myristyl sulphate solution, the viscosity curve for which does not either exhibit any pronounced irregularity when the turbidity appears.

The viscosities of concentrated oleate solutions, after passing a minimum, finally begin to increase rapidly with increasing decanol content. The abrupt increase in viscosity begins when the amount of the new phase becomes so large that it begins to influence greatly the flow of the solution.

It is thus possible to connect the changes in viscosity with other phenomena that occur when decanol and *p*-xylene are solubilized by association colloid solutions, *i. e.* to the formation of mixed micelles and the appearance of a new phase. It has also been possible to point out those factors that influence the viscosity. The viscosity phenomena confirm our earlier conclusions that the properties of oleate solutions undergo appreciable changes in the 0.10—0.20 *M* concentration region. Decanol promotes the structural changes which occur in this range also in pure oleate solutions.

As pointed out in the introduction, the solubilization of polar-nonpolar compounds generally results in a more or less marked increase in viscosity. The above conclusions apply to all these cases and are in accordance with the views of other investigators. The factors that cause the viscosity to pass through a maximum in homogeneous systems, as reported by various workers, will not be discussed here. In the systems we have studied no such maxima have been reached, the increase in viscosity being terminated by the appearance of a new phase which leads to a decrease in viscosity due to the decrease in the concentration of micellar substance.

When this publication was already written, we noted an abstract of a study of Markina, Posspelova and Rebinder [40] very similar to ours. As far as it is possible to judge from the abstract, their experimental results and conclusions are in accordance with those presented here.

Studies on the Interaction of Paraffin-Chain Alcohols and Association Colloids

V. The Soap Concentration where Interaction with Decanol-1 Begins and its Dependence on the Chain Length of the Soap

PER EKWALL, OLOF SÖDERBERG and INGVAR DANIELSSON

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Turbidity measurements show that interaction of decanol-1 and fatty acid soaps begins at a clearly defined soap concentration. This concentration is the same as that where the soap begins to interact with its parent fatty acid (the limiting concentration, L. A. C.). The value of the L. A. C. decreases with increasing chain-length of the soap; there is a nearly linear correlation between the logarithm of the L. A. C. and the number of carbon atoms in the hydrocarbon chain of the soap. The value of the L. A. C. increases somewhat with temperature. The L. A. C. lies considerably lower than the C. M. C. of the pure soap and below the concentration where micelle formation begins to increase rapidly in soap solutions that contain added alcohol.

We have previously established [1-5] two separate turbidity maxima in dilute association colloid solutions containing small amounts of decanol-1. The curves showing the variation of the turbidity with the association colloid concentration are similar in form to the schematic curve drawn in Fig. 1.

In the turbidity range I observed at low colloid concentrations, the turbidity is due to emulsified decanol. The turbidity in range II at higher colloid concentrations is caused by a birefringent liquid composed of decanol, association colloid and water which is dispersed in very small droplets. The upper limit of the turbidity range I is sharply defined. It lies considerably below the critical concentration for micelle formation in pure association colloid solutions and it defines the conditions at which interaction between decanol and association colloid begins.

In this and in three following papers of the present series, a considerable body of experimental data relating to the first stages of the above-mentioned interaction will be presented and some of the factors on which this interaction

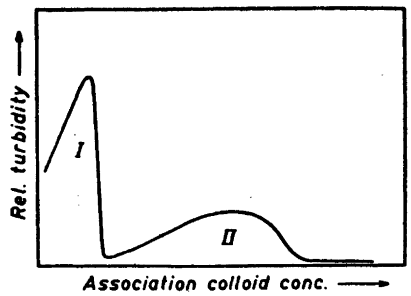

Fig. 1. The turbidity of association colloid solutions containing added decanol. Schematic curve.

depends will be discussed. In the first place, we wish to illustrate how the concentration where interaction between decanol and fatty acid soaps begins depends on the chain length of the soap and on the temperature.

EXPERIMENTAL

The soaps investigated were potassium caprylate, caprate, laurate, myristate, palmitate and stearate, and sodium caprylate, caprate, laurate, and myristate. The soaps were prepared in the usual manner from purest fatty acids and potassium or sodium ethylate.

Dilution series were prepared from each soap in which the molar ratio of decanol-1 (Eastman Kodak Co, Rochester, redistilled) to colloid was constant. Aliquots of the solutions were sealed in glass ampoules and mixed by shaking in a thermostat. The specific conductance of the water employed as solvent was less than 10^{-6} rec. ohm. To suppress the hydrolysis of the soaps, a known quantity of alkali was added to each of the solutions. Care was taken to prevent carbon dioxide from the air from entering the solutions.

In a number of cases it was found more advantageous to add a constant weight of decanol to each of the solutions instead of keeping the molar ratio constant. The decanol was added from an Agla micrometer syringe.

The turbidites were measured directly in the ampoules without opening them. Since the measurements were to be conducted at several temperatures, the shaking of the ampoules was begun and the turbidity first measured at the lowest temperature and then the ampoules were transferred to the next higher temperature and shaken two hours before the turbidity was again measured.

The turbidities were measured with a Zeiss nephelometer fitted to a Pulfrich photometer.

The following series were investigated:

Potassium caprylate + 2, 5, 7.5 and 10 moles of decanol per 100 moles of soap at 20, 30, 40, 50 and 60° C.

Potassium caprate + 1, 2, 3 and 8 moles of decanol per 100 moles of soap at 20, 30, 40, 50 and 60° C.

Potassium laurate + 1, 2, 5, 10 and 15 moles of decanol per 100 moles of soap at 20, 30, 40, 50 and 60° C.

Potassium myristate + 13, 20, 25, 30 and 35 moles of decanol per 100 moles of soap at 20, 30, 40, 50 and 60° C.

Potassium palmitate + 10, 20, 30, 40, 50 and 60 moles of decanol per 100 moles of soap at 50, 55, 60 and 65° C.

Potassium stearate + 0.33 ml of decanol per litre at 47, 59, 72.5, 84 and 97° C.

Sodium caprate + 2, 3, 4 and 6 moles of decanol per 100 moles of soap at 20, 30, 40, 50 and 60° C.

Sodium laurate + 3.2, 5.25, 7.35, 10.5, 15.7 and 21 moles of decanol per 100 moles of soap at 40° C.

THE RESULTS OF THE MEASUREMENTS

The experimental data have been used to draw curves which plot the relative turbidity as a function of the soap concentration. Figs. 2—6 show typical turbidity curves for several potassium soaps; each curve represents a series of measurements at constant temperature on solutions with different soap concentrations but with a constant mole ratio of added decanol to soap.

It is evident in all the curves that a marked turbidity occurs in relatively high dilutions (turbidity range I) and that this turbidity disappears completely or practically completely when the soap concentration attains a certain level. This concentration level is quite independent of the amount of added decanol as long as this remains within moderate limits. It is obvious that the ability of the soap to bind decanol undergoes a pronounced change at this concentration. Microscopic examination and other studies (*e. g.* conductance measurements) show that below this soap concentration decanol is present in the free form in an emulsified state, while above this concentration decanol interacts with the soap [2, 3, 9, 10]. The decanol-soap complex that is formed in the latter case appears to have a limited solubility in water, and when somewhat larger amounts of decanol are added, a new extremely finely dispersed precipitate is formed which produces a turbidity (turbidity range II) differing from that due to free emulsified decanol observed at low colloid concentrations. The amount of decanol necessary to effect this turbidity varies with the soap. In caprylate solution the turbidity is almost undetectable when 7.5 moles of decanol are added per hundred moles of soap, whereas in the case of caprate and laurate solutions a similar addition produces a quite marked turbidity. This second turbidity range extends to higher soap concentrations when the amount of decanol added is increased until finally, when the amount of the latter is high enough, the turbidity no longer disappears with increasing soap concentration.

As mentioned above the turbidity phenomena were studied at several temperatures. All curves in each of the Figs. 7—11 refer to a constant decanol content (expressed in moles per hundred of soap); they were, however, measured at different temperatures. In range I the intensity of the turbidity increases somewhat with increasing temperature in many cases, but in range II the intensity decreases. The upper limit of the first turbidity range shifts to higher soap concentrations, while the upper limit of the second turbidity range shifts to lower soap concentrations with increasing temperature.

We have observed quite similar turbidity phenomena also in solutions of sodium soaps containing added decanol [1, 2].

DISCUSSION

The reaction that causes the free decanol to disappear from the solution occurs in a narrow concentration range. This range lies between the maximum of the first turbidity range and the somewhat higher concentration where this turbidity disappears. We have used data from all series to determine the limits of this concentration range for the different soaps at different temperatures (Table 1). When doing this, we have taken into consideration that the range

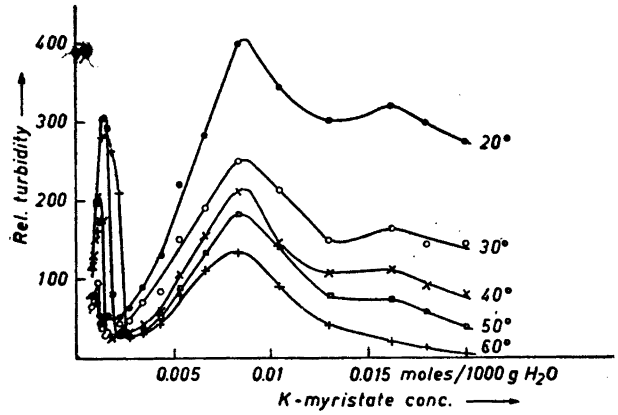

Fig. 10. The turbidities of potassium myristate solutions containing 30 moles of decanol-1 per hundred moles of soap at different temperatures.

certainly becomes more clearly defined when the amount of added decanol increases, but that at high decanol contents a tendency of the range to shift to higher concentrations is observed in some cases. It was in most cases easier to determine the upper limits of the turbidity range than the turbidity maximum. Because of this we shall in the following in general use the concentration at the upper limit to define the conditions where the interaction between soap and decanol begins, although we are fully aware that the interaction actually begins at a somewhat lower concentration.

The interaction begins at about the same soap concentrations in the solutions of the sodium and potassium salts of a fatty acid.

The variation of the upper limit of turbidity range I with increasing temperature is shown in Fig. 12. In most cases the dependence on temperature is practically linear.

From the data in Table 1 it is seen that the soap concentration at which the interaction begins decreases as the length of the hydrocarbon chain of the soap increases. In Fig. 13 the logarithm of the soap concentration at which inter-

action with decanol begins is plotted against the number of carbon atoms in the hydrocarbon chain of the soap molecule. These curves are not quite linear; the curvatures are, however, so slight that the interaction concentration can be approximately calculated from the following logarithmic equations, where n indicates the number of carbon atoms in the paraffin chain of the fatty acid.

20° C.: $\log C = -0.364\ n + 1.66$
30° C.: $\log C = -0.345\ n + 1.53$
40° C.: $\log C = -0.334\ n + 1.48$
50° C.: $\log C = -0.326\ n + 1.45$
64° C.: $\log C = -0.310\ n + 1.40$

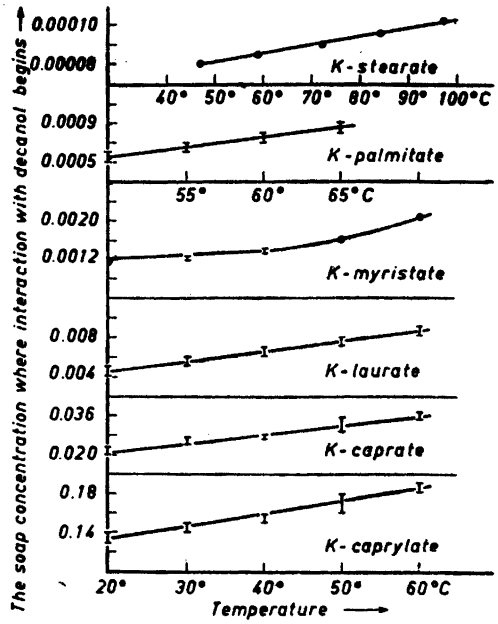

Fig. 12. The temperature dependence of the upper limit of the turbidity range I.

We have noted earlier[1-5] that the concentration at which interaction between decanol and soap begins lies very close to the lowest concentration at which hydrolysis in the soap solution leads to the formation of acid soap or at which the soap forms acid soap when fatty acid is added to the solution. In

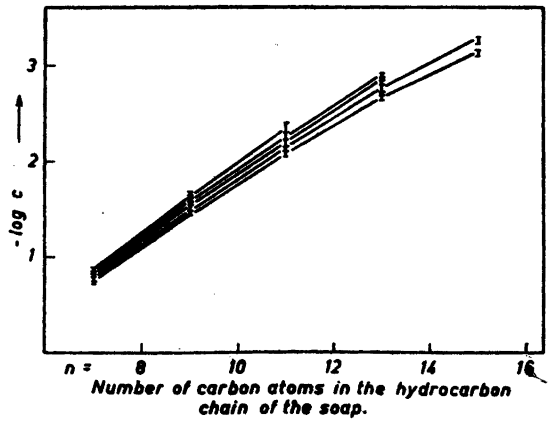

Fig. 13. The dependence of the upper limit of the turbidity range I on the chain length of the soap.

Table 2 the concentrations at which acid soap is formed are compared with the concentrations at which soap and decanol begin to interact. From these data it is seen that in the case of caprate, laurate and myristate solutions the concentration ranges where interaction begins with fatty acid and with decanol are almost identical. Also for palmitate solutions the two concentration ranges are nearly the same. In the case of the interaction between stearate and stearic acid, only earlier observations on strongly hydrolysed stearate solutions are available and for this and other reasons the upper limit of the first turbidity range is probably too high.

It is thus established that interaction between soap and decanol begins at approximately the same soap concentration as the interaction between a soap and its fatty acid. The concentration in question is that which has been previously termed the limiting concentration or the limiting association concentration (L. A. C.) [6,7,1,2].

Also the location of the critical concentration in decanol-containing soap solutions becomes evident in some cases in the turbidity curves although not always very clearly. The C. M. C. is as usually defined as the concentration where the aggregation to micelles begins to increase rapidly. When the amounts of decanol added are small, the C. M. C. appears at the upper limit of the turbidity range II or at the maximum of the turbidity curve in this range, *i. e.* at that soap concentration where the precipitate of the second turbidity range has just disappeared or begins to disappear because of the formation of soluble decanol-containing mixed micelles. At higher decanol contents however, the turbidity maxima, tend to shift to higher concentrations and above a certain decanol content characteristic for each soap the turbidity does not disappear at all. Because of this and the fact that soap is precipitated from the solution it is difficult to determine exactly where micelle formation begins from the turbidity curve.

The values in the last column of Table 3 are from experiments with small amounts of added decanol, and are the lowest values of the C. M. C. in decanol-

Table 3. The critical concentrations in pure and decanol-containing soap solutions.

	Pure soap solutions		Soap solutions containing decanol	
Soap	°C	C. M. C.	°C	C. M. C.
Caprylate	25	0.40	60	0.24 −0.28
Caprate	20	0.097	60	0.055−0.085
Laurate	20	0.028	60	0.020−0.025
Myristate	30	0.007	60	0.005−0.007
Palmitate	50−60	0.0032	60	0.003

containing soap solutions that we have observed in the turbidity measurements. (They agree rather well with the results of solubility measurements which will be presented in later parts of this series.) These C. M. C. values are somewhat lower than the C. M. C.'s in pure soap solutions, but appreciably higher than the limiting concentrations.

The limiting concentration may be confused with the critical concentration and the appearance of the former may be considered an indication of a displacement of the C. M. C. to very low concentrations due to presence of the added alcohol. This is not correct, however. The phenomena at the critical concentrations and those at the limiting concentrations have been known for more than 25 years and numerous experimental measurements (measurements of surface tension, hydrolysis, and conductance, microscopical observations, determination of the solubility of fatty acids and later also of alcohols, conductometric and potentiometric titrations, *etc.*) have shown that they appear simultaneously in numerous colloid systems, but at different colloid concentrations.

Studies on the Interaction of Paraffin-Chain Alcohols and Association Colloids

VI. The Sodium Caprate Concentration where Interaction with Long-Chain Alcohols Begins and its Dependence on the Chain Length of the Alcohol

PER EKWALL and CLAES FREDRIK AMINOFF

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Turbidity measurements show that interaction of sodium caprate with hexanol-1, octanol-1, decanol-1, and dodecanol-1 begins at approximately the same concentration of the soap, at the L. A. C., and hence irrespective of the chain-length of the alcohol. Also with tetradecanol-1, hexadecanol-1 and octadecanol-1, at temperatures above their melting points, interaction begins at only slightly higher soap concentrations. The temperature dependence of the interaction concentration is the same for all alcohols. The first step in the interaction is the formation of soluble alcohol-soap aggregates. The part different intermolecular interactions play in determining the L. A. C. is discussed and it is shown that the most decisive factor in determining the position of the L. A. C. is the chain length of the soap.

In the preceding paper of this series [1], it was shown on the basis of extensive experimental data that the soap concentration where interaction between decanol-1 and different fatty acid soaps begins shifts to lower values with increasing chain length of the soap molecule. The interaction concentration was observed to increase slightly with temperature. It was further established that the lowest concentration limit for interaction between soap and decanol is approximately the same as the concentration where the soap begins to react with its parent fatty acid (the limiting concentration, L. A. C.). We have used the same nephelometric technique to determine how the concentration where the soap begins to interact with different long-chain alcohols varies with the chain length of the alcohol and how this concentration depends on the temperature.

EXPERIMENTAL

The soap employed in the experiments was sodium caprate. The interaction with the following alcohols was studied: hexanol-1 (B. D. H. London), octanol-1, decanol-1, dodecanol-1, tetradecanol-1, hexadecanol-1, and octadecanol-1 (Eastman Kodak Company, Rochester). The samples were distilled or recrystallized.

The solutions of soap and alcohols were prepared and their turbidities measured as described in the previous paper [1].

The measurements were conducted at temperatures between 20° and 60° C, but in each case only above the melting point of the alcohol in question. In most cases the amounts of alcohol added were also varied.

The following series were investigated;

Sodium caprate + 0.65 ml of hexanol per litre at 20°, 30°, 40°, 50° and 60° C and with 0.61 ml of hexanol per litre at 20° C.

Sodium caprate + 24.6 and 36 moles of octanol per 100 moles of soap at 20°, 30°, 40°, 50° and 60° C.

Sodium caprate + 2, 3, 4 and 6 moles of decanol per 100 moles of soap at 20°, 30°, 40°, 50° and 60° C.

Sodium caprate + 1.5, 2.5 and 6.1 moles dodecanol per 100 moles of soap at 20°, 30°, 40°, 50° and 60° C.

Sodium caprate + 1.2, 1.9 and 2.8 moles tetradecanol per 100 moles of soap at 40°, 50° and 60° C.

Sodium caprate + 0.65 and 0.95 moles hexadecanol per 100 moles of soap at 60° C.

Sodium caprate + 0.4 moles octadecanol per 100 moles of soap at 60° C.

THE RESULTS OF THE MEASUREMENTS

The measurements gave turbidity curves that are similar in form to those previously found for decanol in which two turbidity ranges are separated by a

Octadecanol-1	60	– 0.039	0.057 – 0.059

region of almost clear solutions. The turbidity in the first range (I) is due to emulsified alcohol, in the second range (II) to a birefringent liquid substance composed of alcohol, soap and water. The last-mentioned substance results from the interaction between alcohol and soap that begins in the concentration range between the point of maximum turbidity of the first turbidity range and the upper limit of this range. The purpose of the study was to determine the sodium caprate concentrations at which interaction begins, and hence the complete nephelometric curves were not recorded in all cases. Only one curve recorded at 50° C for each of the alcohols, hexanol, octanol, decanol, dodecanol, and tetradecanol (with different additions of these alcohols) is reproduced in Fig. 1. The results of all the experiments are collected in Table 1.

The caprate concentration at which the turbidity due to emulsified alcohol disappears completely is clearly defined. As previously, we shall use this concentration to define the conditions where interaction begins (last column in Table 1) although the interaction actually begins at a somewhat lower con-

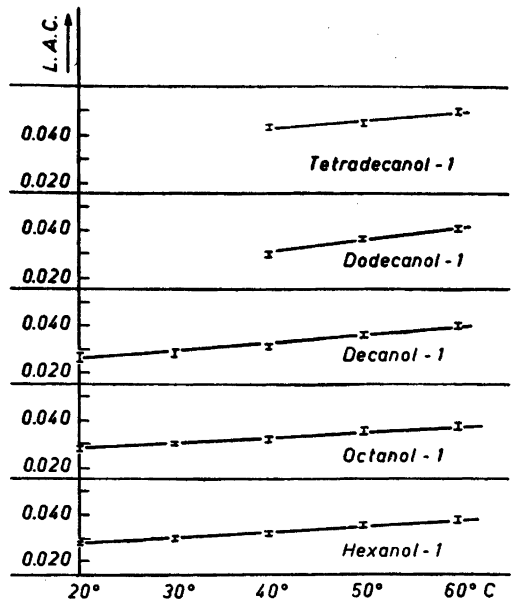

Fig. 2. The temperature dependence of the limiting concentration, L. A. C., of sodium caprate.

centration, *i. e.* at the turbidity maximum. Fig. 2 shows how the concentration mentioned varies with temperature; the curves are seen to be practically linear for all of the alcohols studied.

From the data in Table 1 it is seen that the interaction between the caprate and the four lower alcohols begins at almost the same caprate concentration. This is illustrated by the curves in Fig. 3. With tetradecanol, hexadecanol and octadecanol, the upper limits of the first turbidity range occur at somewhat higher caprate concentrations than with the lower alcohols. In the case of the two highest alcohols, measurements were conducted at only 60° C; only two different additions of hexadecanol and only one of octadecanol were employed (the temperature 60° lies close to the melting point of octadecanol).

DISCUSSION

It is seen that the lower limit for interaction between the soap and the various alcohols, at least for those with 6 to 12 carbon atoms, occurs at approximately the same soap concentration irrespective of the chain length of the alcohol (in the case of the higher alcohols, this soap concentration deviates only slightly from that found for the lower alcohols). As mentioned above, this limit coincides with the lowest concentration at which interaction occurs between the soap and its parent fatty acid. For the fatty acid and all the alcohols the interaction concentration is observed to shift with increasing temperature in a similar manner. We may therefore conclude that this limit is

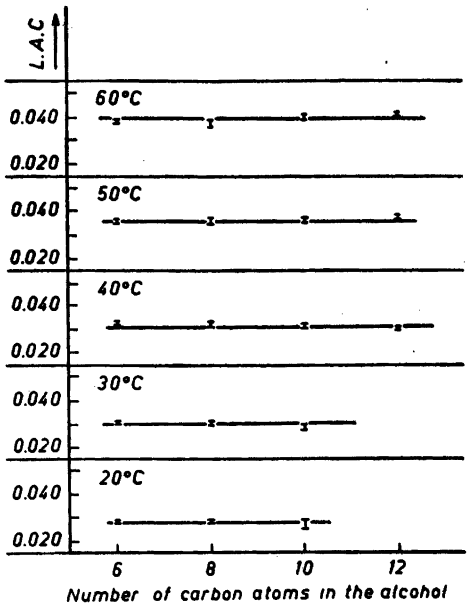

Fig. 3. The dependence of the limiting concentration, L. A. C., of sodium caprate on the chain-length of the alcohol.

fairly well defined and that it thus seems appropriate to refer to it by a special term, the limiting association concentration (L. A. C.) of the soap.

At the maximum of the first turbidity range, the soap solutions contain more alcohol than dissolves in water and in dilute soap solutions. Although the alcohol content increases with the soap concentration, the turbidity disappears completely, *i. e.* the alcohol dissolves in cases where the mole ratio of alcohol to soap is not too high. This shows that the solubility of alcohol increases when the limiting concentration is exceeded. This conclusion has been verified by measurements of the solubility of decanol [2,3]. The increase of the solubility must be due to the formation of complexes between the alcohol molecules and soap ions. The first phenomenon occurring at the limiting concentration is thus the formation of soluble alcohol-soap aggregates and not the formation of a new precipitate. That this is the case also in the interaction between fatty acid and soap has been shown previously [4,5]. The alcohol-soap aggregates (and fatty acid-soap aggregates) formed at the limiting concentration must, however, be rather hydrophobic, for the increase in the solubility is fairly small and the new liquid phase composed of soap, water and alcohol (or of soap, water and fatty acid; in some cases crystalline acid soap is formed) begins to separate when more alcohol (or fatty acid) is added.

When the mole ratio of alcohol to soap exceeds a certain value, the turbidity does not disappear completely but decreases considerably. The new precipitate that is formed effects a much weaker turbidity than emulsified alcohol [3]. In

these cases both factors, the increase in the solubility of the alcohol and the decrease of the opacity of the reaction product together effect the rapid fall in the turbidity curve at the L. A. C.

The association or complex formation above the limiting concentration complies with the law of mass action. The first steps of the interaction may be described by general equations such as (1) and (2);

$$xR'Ac^- + yR''OH = (R''OH)y\ (R'Ac^-)x \quad (1)$$

$$\frac{[(R''OH)y\ (R'Ac^-)x]}{[R'Ac^-]^x \cdot [R''OH]^y} = K \quad (2)$$

In a later paper of this series, when more experimental observations have been published, we will return to a quantitative treatment of the interaction between alcohols and soap. Now we only wish to make some comments.

The same forces that effect the association in pure soap solutions must take an active part also in the formation of the soluble aggregates between soap and polar-nonpolar compounds such as alcohols and fatty acids. In addition, there occurs ion-dipole interaction and probably also formation of hydrogen bonds between the carboxylate groups of the soap ions and the hydroxyl groups of the alcohols or the carboxyl groups of the fatty acids.

An interesting question is the part these different intermolecular interactions play in determining the concentration level where the L. A. C. occurs. Surely the interaction between the ionized carboxyl groups and the alcohol groups determines in some degree the phenomena that are characteristic of the interaction between soaps and alcohols. An interesting fact is, however, that for a certain soap the L. A. C. occurs at almost the same concentration level also when the polar-nonpolar compound is not an alcohol but a fatty acid. This shows that in any case the ion-dipole interaction and the formation of hydrogen bonds do not alone determine the position of the L. A. C. The van der Waals forces between the hydrocarbon chains seem to play a decisive role.

Another interesting fact is that while the L. A. C. is displaced to lower soap concentrations when the chain length of the soap ions increases, the position remains nearly unchanged with increasing chain length of the alcohol (from 6 to 12 carbon atoms). It may be that the lower solubility of the alcohols in water with increasing chain length contributes to this behaviour. The fact remains, however, that according to all our observations made hitherto the most decisive factor in determining the position of L. A. C. is the chain length of the soap ion. This could be interpreted as an indication that the intermolecular forces between the soap ions themselves are decisive for the phenomena that occur at the concentration we have termed the limiting association concentration and that the association tendency between the soap ions is a predominating factor. In the same direction points also the fact that there exists a formally similar relation between the number of carbon atoms in the soap ions and the position of L. A. C. as in the case of the C. M. C. [8,9]; this relation applies up to at least 60° C.

If this last interpretation were correct, it would mean that the phenomena occurring at the L. A. C. are not primarily caused by the alcohol or fatty acid, but must be ascribed to the fact that the association tendency of the soap

anions attains a threshold value at this concentration. The role of the alcohol and fatty acid would then be to promote the association, for instance by decreasing the repulsion between the ionic groups and thus to function like an indicator, which makes the tendency to associate observable.

Whether the phenomena at the limiting concentration only give evidence of the association between soap ions and the molecules of the polar-nonpolar substance or indicate that the tendency to associate has attained a certain level also in the pure soap solution, they must be characterized as deviations from the typical behaviour of normal 1-1 electrolytes, and as far as we know, the first deviations from this behaviour that occur with increasing soap concentration. It seems, however, that the location of the limiting concentration cannot be defined by giving an absolute value for the concentration and it must suffice to report a concentration range within which the first signs of association become evident. Depending on the experimental method employed, the first signs may be observed at somewhat different points in this range. Of importance is, however, that it is possible to detect association phenomena in soap solutions far below the C. M. C's of the pure soaps and also far below the concentrations where the micelle formation occurs in soap solutions containing alcohol or fatty acid.

Our present experimental material relates primarily to fatty acid soap solutions. We have, however, previously found [6,7] that similar phenomena occur also in solutions of alkali metal alkyl sulphates and of alkyltrimethyl ammonium and cetylpyridinium salts; also in these solutions the limiting concentrations (sodium myristyl sulphate 0.0003 M, hexadecyl trimethyl ammonium bromide 0.0004 M) are far below the critical concentrations of the colloids. We believe that a limiting concentration can be determined for all association colloids of the paraffin-chain type.

On the Reaction between Urea and Formaldehyde in Neutral and Alkaline Solutions

VI. Experimental Studies of the Activation Energy and the Heat of Reaction

NILS LANDQVIST

Rydboholms A.B., Rydboholm, Sweden

The activation energies of the formation and hydrolysis of mono- and dimethylol urea were determined. The activation energies of the reactions between urea — formaldehyde and monomethylol urea — formaldehyde were found to be 15.4 kcal/mole, and the activation energies of the corresponding hydrolysis reactions 20.4 kcal/mole. The heat of reaction of the formation reactions was found to be the same in both cases: 4.9 kcal/mole.

The activation energy of the reaction between urea and formaldehyde at equal concentrations was determined by *e.g.*: (1) Smythe [1]; the amount of unreacted formaldehyde of the 4 M unbuffered reaction solutions was determined by means of the hydroxylamine titration method. The activation energy obtained was 14.7 kcal/mole; (2) Smythe [2]; the reactions in dilute, unbuffered solutions (0.1 M) were studied by means of polarography. Activation energy obtained: 15.3 kcal/mole; (3) Crowe and Lynch [3]; polarographic determinations in 0.05 M LiOH at low concentrations of the reactants. Activation energy: 15.9 kcal/mole.

The activation energy of the reaction between monomethylol urea and formaldehyde was determined by Květoň and Králová [4]. ~2 M reaction solutions and the amount of unreacted formaldehyde determined by means of the hydroxylamine method. Activation energy: 12.2 kcal/mole.

The activation energy of dimethylol urea hydrolysis was also studied by Květoň and Králová [4]. Hydroxylamine method used, activation energy: 16.9 kcal/mole.

As regards the moderate accuracy of the hydroxylamine titration method, reference is given to Landqvist [5].

The purpose of the following paper is to describe experimental studies of the activation energies of mono- and dimethylol urea formation and hydrolysis. The heat of reaction of the forward reactions is given.

Table 1. The activation energy of mono- and dimethylol formation and hydrolysis reactions.

* In all cases such an amount of a chloride of the buffer cation was added that a cationic strength corresponding to 0.200 M solutions was maintained.

THE ACTIVATION ENERGIES

The activation energy investigations were carried out as previous studies at 20° C; Landqvist [5]. The temperature interval was 20—40° C. The pH values of the reaction solutions refer to 20° C.

Since the pK of the buffers are dependent on the temperature, and the OH^- catalysis of the reactions is comparatively small, it seems to be most important to keep the concentration of the buffer acid and base as constant as possible (Landqvist [5-8]).

The compositions of the reaction solutions and the reaction rate constants obtained can be found in Table 1. The activation energy, E, from experimental data are included in the table. Examples of the Arrhenius equation relationship are given in Fig. 1.

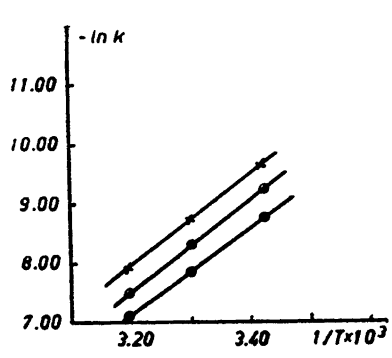

Fig. 1. The relationship between the logarithm of the reaction rate constant and the inverse of the temperature. 4.0 M $CO(NH_2)_2$ + 0.40 M HCHO; $C_{KH_2PO_4}$ = 0.025 (×), 0.050 (○) and 0.100 (●). pH 6.70.

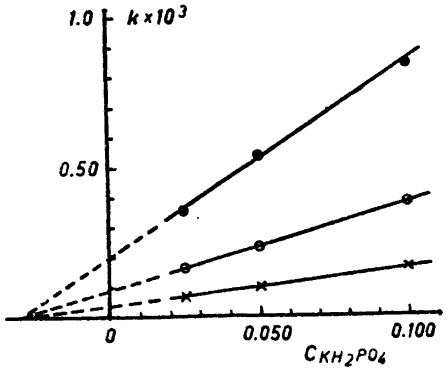

Fig. 2. The relationship between the reaction rate constant and the concentration of the KH_2PO_4 buffer at pH 6.70. The temperatures were: 20° C (×), 30° C (○) and 40° C (●).

At all temperatures and reactions acid — base catalysis as previously reported (Landqvist[5-8]) occurred. An example of the reaction rate constant-buffer concentration (constant cationic strength) relationship is given in Fig. 2. If the curves corresponding to the different temperatures are extrapolated to a reaction rate constant equal to zero, the same (negative) abscissa value was found. These observations support the assumption that the changes in pH due to the change in temperature can be neglected, as regards their influence on the catalysis. The change in the buffer activity is unknown. The activation energies of KH_2PO_4 and borax buffered solutions support an assumption that the influence from this is moderate. In the case of Na_2CO_3 buffers slightly different figures are obtained. The differences between the formation and hydrolysis activation energies are all of the same order, why the carbonate behaviour is probably due to changes in the catalytic properties.

From Table 1 we find reasons to accept the activation energy value 15.4 kcal/mole of the formation reactions; the corresponding hydrolysis figure is 20.4 kcal/mole.

HEAT OF REACTION

The heats of reaction of mono- and dimethylol urea formation were determined calorimetrically. In order to reduce the influence from side reactions; *i. e.* formation of dimethylol urea from urea and formaldehyde and mono- and dimethylol urea hydrolysis, and in order to obtain as complete reactions as possible, the study was made on solutions containing an excess of urea or formaldehyde respectively. In the latter case no formation of tri- and tetramethylol urea is likely to occur, as could be concluded from the consumption of formaldehyde. The catalytic properties were selected to give proper reaction rates. The experiments were carried out as follows.

Monomethylol urea formation. An amount of 500 ml of a 4.0 M urea solution, 0.025 M with respect to Na_2CO_3, pH 11.50, was poured into a Dewar vessel. Through holes in the cork stopper of the vessel a stirrer and a Beckman thermometer were immersed in the urea solution. Through another hole in the stopper a "test tube" was immersed. The tube was made of a polyethylene sheet, and contained 50 ml of a 4 M formaldehyde solution, pH 11.50. When a constant temperature was obtained, 20° C, the tube was torn and the two reactants quickly mixed. Heat transfer through the vessel was corrected for by extrapolation of the time — temperature curve. Corrections for the heats of dilution of the reactants were obtained by replacing the formaldehyde respective urea by distilled water with the same buffers dissolved. The specific heat of the reaction solution was determined by immersing a polyethylene "test tube" containing a known amount of ice. The heat absorption by the calorimeter was determined by the same technique and with distilled water in the vessel.

Dimethylol urea formation. The same technique was used in this case as well. The solution was 500 ml 1.0 M formaldehyde, 0.050 M Na_2CO_3, pH 11.50. The tube contained 4.5 g dry monomethylol urea. Solid monomethylol urea was used in order to prevent influence from hydrolysis reactions. The substance was brought into solution rapidly, and disturbances from this step of the experiment were negligible.

The chemicals used were of A. R. quality, except for the formaldehyde, which was a Merck product containing only traces of methyl alcohol and formic acid ($<4.10^{-4}$ M in solutions containing 380 g/l). The monomethylol urea was prepared in accordance with Walter and Gewing [9]; cryoscopic molecular weight: 90 ± 2.

The heat of reaction was found to be the same for both mono- and dimethylol urea formation, namely 4.9 kcal/mole.

It may be of some interest to compare the activation energy differences ΔE, and the heat of reaction, Q. For processes in solutions we have: $\Delta E \cong Q$. The average difference between the formation and hydrolysis activation energies are 5.0 kcal/mole (Table 1). This figure, as compared with the heat of reaction 4.9 kcal/mole, shows that a good agreement is present.

The author wishes to thank the board of *Rydboholms A. B.* for permission to publish this paper, and is also indebted to Mr G. Johansson and Miss U. Larsson for their valuable assistance in the experimental work.

The Configuration of *endo*-Dehydro-norborneol and α-Norborneol

PEKKA HIRSJÄRVI

Institute of Chemistry, University of Helsinki, Finland

The 5-hydroxy-*cyclo*pentane-1,3-*cis*-dicarboxylic acid (5-hydroxy-norcamphoric acid), m.p. 169—170°, prepared by permanganate oxydation and hydrolysis of the so called "*endo*"-dehydro-norbornyl acetate, is a *cis*-hydroxy acid according to the intramolecular hydrogen bonding verified by the author on the infrared absorption spectra of its dimethylester in carbon tetrachloride. From this configuration it follows that "*endo*"-dehydro-norborneol and α-norborneol, its hydrogenation product, have both an *endo*-configuration, as has been generally supposed, but never established. The "*endo*"-dehydro-norbornyl acetate prepared through diene syntheses of vinyl acetate and *cyclo*pentadiene, used as starting material in this work, was catalytically hydrogenated. The hydrolysis product of the hydrogenation product was composed of 75.3 % α-norborneol and 24.7 % β-norborneol on the basis of the infrared spectral analysis. The effect of an addition of boric acid on the electrical conductivity of the solutions of the 5-hydroxy-norcamphoric acid (m.p. 169—170°) in water was investigated. The results are discussed.

In a previous paper [1] a method to investigate the *cis- trans*-configurations of β-hydroxy-*cyclo*pentane-carboxylic acid esters was presented. With this method based on the verification of the intramolecular hydrogen bond formation by means of the infrared absorption spectra, I have now investigated the dimethylester of the 5-hydroxy-norcamphoric acid, prepared by permanganate oxydation of the so called "*endo*"-dehydro-norbornyl acetate*.

The "*endo*"-dehydro-norbornyl acetate is prepared from vinyl acetate and *cyclo*pentadiene through diene syntheses [3]. Owing to the general spectrospecific course (*cf.* Ref. [4]) of the diene syntheses proved by them on other classes of adducts only [5], Alder and Rickert [3] supposed that this compound analogically has *endo*-configuration. The hydrogenation of "*endo*"-dehydro-norborneol yields α-norborneol [6]. Applying their *exo*-addition theory to the catalytic hydrogenation of norcamphor, Alder and Stein [7] drew the conclusion that

* A reaction carried out previously by others in this laboratory [2].

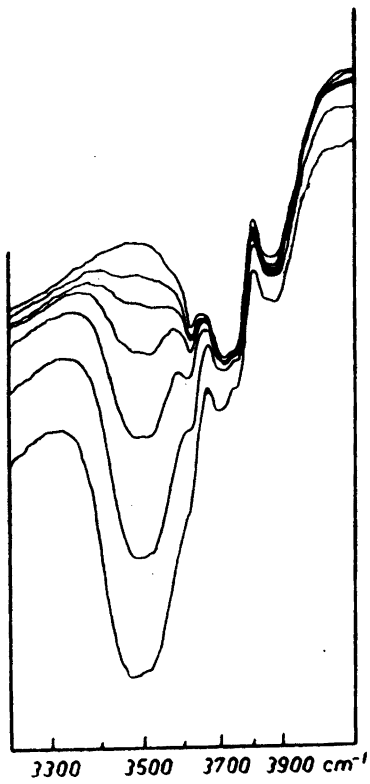

Fig. 1. Infrared absorption spectra of 0.0224—0.0007 M solutions of the 5-hydroxy-norcamphoric acid dimethylester (prepared from the endo*-dehydro-norbornyl acetate) in CCl_4 and that of the solvent in the region of 3 200—3 900 cm^{-1}.*

α-norborneol must have *endo*-configuration, whereas the "*endo*"-dehydro-norborneol and its acetate must have *endo*-configuration. Direct evidence for the configurations of norborneols and dehydro-norborneols has not been presented; Alder and Stein [7], however, have communicated that they are (1936) studying the configuration of α-norborneol in order to prove it. Their method seems possible in theory, but so far no results have been published.

In the Bertram-Walbaum-reaction of a mixture of norbornylene and nortricyclene β-norbornyl acetate is obtained [8]. On the basis of this fact the conclusion may be drawn that the latter has *exo*-configuration (*cf.* Ref. [9]).

According to H. Toivonen [10] the oxydation of α-norborneol with concentrated nitric acid yields norcamphor, whereas β-norborneol in the same circumstances yields nitric acid ester. Further, according to H. Toivonen [11] the *endo*-form of the terpene alcohols for which the *endo-exo*-configurations are chemically explained, *viz.* for borneol, *iso*borneol [12], α-fenchol and β-fenchol [13], is oxidised with nitric acid to the corresponding ketone, while the *exo*-form is esterified. In this reaction thus α-norborneol behaves like the aforementioned *endo*-alcohols and β-norborneol like their *exo*-forms.

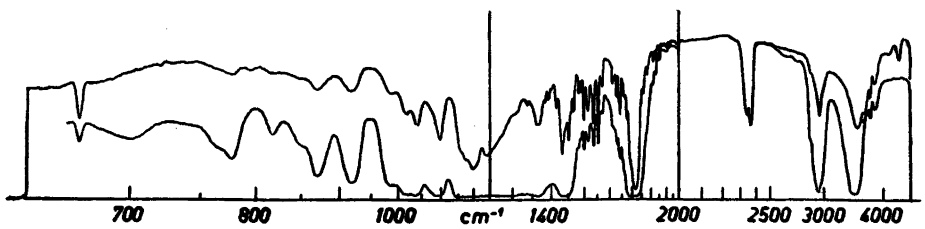
To check the steric purity of the starting material in this work a part of the dehydro-norbornyl acetate used was hydrogenated and hydrolysed. Ac-

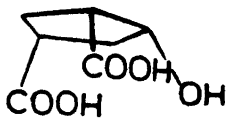
Table 1. Transmission of the solution of 5-hydroxy-norcamphoric acid dimethylester in CCl_4 on hydrogen bonded O-H-absorption band (3 468 cm^{-1}) (Fig. 1).

Concentration mole · l^{-1}	$\log_{10}\frac{P}{P_0}$	k $l \cdot mole^{-1}$
0.0224	0.150—1	38.0
0.0112	0.574—1	38.0
0.0056	0.789—1	37.7
0.00280	0.8965—1	37.0
0.00140	0.9474—1	37.6
0.00070	0.9731—1	38.5

cording to the infrared spectral analysis[14] the product was composed of 75.3 % α-norborneol and 24.7 % β-norborneol (*cf.* Ref. [4]). 33.9 % of theory of the crystalline, in ether very slightly soluble 5-hydroxy-norcamphoric acid isomer (m.p. 169—170°) was isolated from the permanganate oxydation product of the dehydro-norbornyl acetate. On the basis of the amount of the yield this isomer can arise only from the dehydro-norbornyl acetate of the α-norborneol series.

The infrared absorption spectra of 5-hydroxy-norcamphoric acid dimethylester (0.0224—0.0007 M solutions in carbon tetrachloride) in the region 3 900—3 200 cm^{-1} investigated in this work are given in Fig. 1. The absorption band of the (hydrogen-)bonded hydroxyl group is here broader (double (?) 3 468, 3 515 cm^{-1}) than in the case of the 5-*cis*-hydroxy-*iso*fenchoic acid dimethylester and 5-*cis*-hydroxy-camphoric acid dimethylester [1]. Even in such a small concentration as 0.00070 M one cannot with certainty verify the absorption band of the free hydroxyl group (in the region of 3 600—3 640 cm^{-1}). The values of $\frac{P}{P_0}$ were obtained from the center of the 3 468 cm^{-1} absorption band in the spectra given and the values of the coefficient k in the Beer's law formula $\log_{10}\frac{P}{P_0} = -k \cdot c, (k = a \cdot b)$ were calculated and are given in Table 1. (The same $b = 1.003$ cm quarz cell was used as in the previous work [1]). The value of k is constant in the limits of experimental error. The hydrogen bond absorption band must thus in this case belong to the intramolecular one [1].





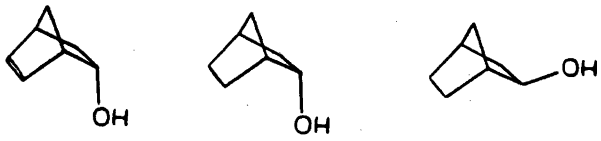


Fig. 2. Infrared absorption spectrum of cis-*5-hydroxy-norcamphoric acid dimethylester (with atmospheric background, upper a capillary film and lower a 0.05 mm thick sample).*

This intramolecular hydrogen bonding on the 5-hydroxy-norcamphoric acid dimethylester is possible only when the (1-)carboxyl group and the (5-) hydroxyl group are in *cis*-position with regard to the five ring; since, further, this is a *cis*-dicarboxylic acid (anhydride formation [2] and preparation by the permanganate oxydation from dehydro-norborneol), the hydroxyl and both carboxyl groups must be on the same side of the five ring plane. This 5-hydroxy-norcamphoric acid isomer is thus 5-*cis*-hydroxy-*cyclo*pentane-1,3-*cis*-dicarboxylic acid (*cf.* Fig. 3).

From this configuration it follows that α-norborneol and "*endo*"-dehydro-norborneol have both *endo*-configuration and that β-norborneol must have *exo*-configuration:

endo-Dehydro-norborneol α-Norborneol β-Norborneol

The absorption band of the bonded O-H-stretching frequency is here broader, as mentioned above, and the value of k is smaller (38.0) than it was in the case of the β-hydroxy-*cyclo*pentane carboxylic acid esters studied in the mentioned previous work [1] (69.0). The 5-*cis*-hydroxy-*cyclo*pentane carboxylic acid dimethylester can form at least four different intramolecular hydrogen bonds (the hydrogen atom of the hydroxyl group is directed either below the molecule or outwards and the bonding occurs either with the carbonyl- or the ether-oxygen atom); *cf.* Fig. 3. The free rotation of the (5-)hydroxyl group and of the (1-)carboxyl group is hindered only by one another. (If the carboxyl group rotated unhindered, the shortest distance between the centers of the oxygen atom of hydroxyl group and of the nearest oxygen atom of (1-)carboxyl group would be *ca.* 2.0 Å. The oxygen-oxygen distance varies in unstrained hydrogen bonds from 2.5 to 2.9 Å). The occurrence of different intramolecular hydrogen bonding possibilities seems to cause a broadening in the absorption band related to the bonded O-H-stretching vibration.

The effect of boric acid on the electrical conductivity of the solution in water of the 5-hydroxy-norcamphoric acid isomer, studied in this work, was also investigated. The method is described elsewhere [1]. The results are given in Table 2. There is no change in the specific conductance when ¼ M boric acid is used as solvent instead of water. Of all β-hydroxy-*cyclo*pentanecarboxylic acids previous studied [1,15,16] boric acid causes an increase in specific conductance of *cis*-hydroxy acid isomers and a slight decrease in that of *trans*-hydroxy acid isomers. In these latter compounds the boric acid complex formation is not possible for steric reasons. On the basis of these facts the results reported in Table 2 can mean boric acid complex formation, though to so very slight an extent that no certain conclusions can be drawn.

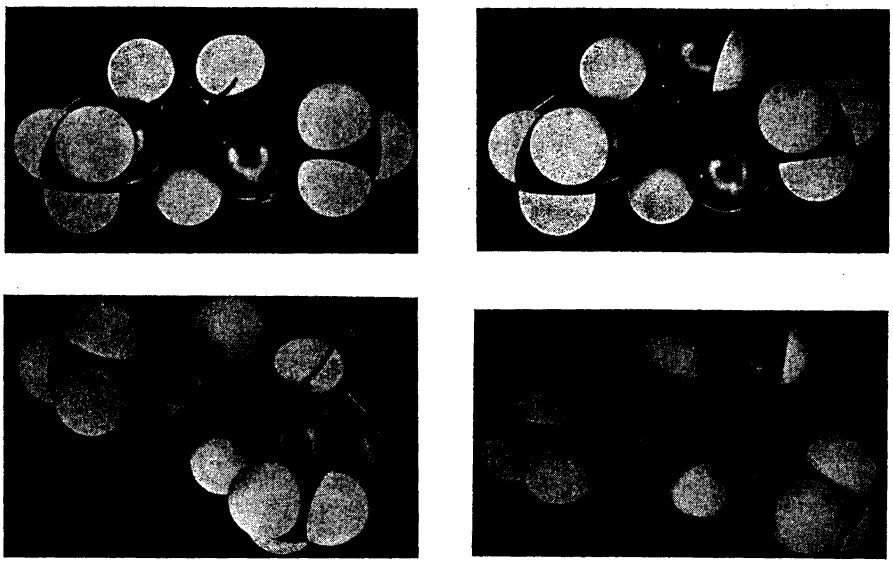

Fig. 3. Stuart-Briegleb models of four different possible intramolecular hydrogen bond types on 5-cis-*hydroxy*-cyclo*pentane-1.3*-cis-*dicarbonic acid dimethylester*

The hydrogen ion activities of the conductivity measurement solutions were compared in pairs. In all concentrations studied, the solution of 5-hydroxy-norcamphoric acid in ¼ M boric acid was more acidic than that of the same concentration in pure water and the difference in pH was greater than that calculated when no boric acid complex formation was taken into consideration. There can thus be weak boric acid complex formation.

Table 2. The electrical conductivity of the solutions of 5-hydroxy-norcamphoric acid (m.p. 169—170°) in water and in ¼ M boric acid—water solution at 25°. The cell constant: 0.283 cm^{-1}. Water $\varkappa^{25}$ 1.42 · 10^{-6}ohm^{-1} · cm^{-1}; ¼ M boric acid—water solution $\varkappa^{25}$ 9.25 · 10^{-6}ohm^{-1} · cm^{-1}.

Concentration mole · l^{-1}	Solvent			
	Water		¼ M boric acid	
	Resistance of the solution ohms	Specific conductance of the solution 10^4 $\varkappa$ ohm^{-1} · cm^{-1}	Resistance of the solution ohms	Specific conductance of the solution 10^4 $\varkappa$ ohm^{-1} · cm^{-1}
1/8	295	9.60	—	—
1/16	407	6.95	405	6.98
1/32	587	4.82	585	4.84
1/64	835	3.39	835	3.39
1/128	1 190	2.38	1 190	2.38
1/256	1 720	1.65	1 720	1.65

As mentioned before, in all previously studied cases the boric acid has caused, in general, a considerable increase in the electrical conductivity of *β-cis*-hydroxy-*cyclo*pentane carboxylic acids and a slight decrease in the conductivity of *β-trans*-hydroxy-*cyclo*pentane carboxylic acids. In this case the possible weak boric acid complex formation can be explained as follows: The intramolecular hydrogen bonding is here very strong and sterically favored, and it competes with success with boric acid complex formation for the not hydrogen bonded hydroxy acid molecules. The magnitude of the equilibrium constants of both reactions and their relation determine the concentration of boric acid complex molecules and the extent of the increase in specific conductance.

EXPERIMENTAL

"endo"-*Dehydro-norbornyl acetate* was prepared from vinyl acetate and di*cyclo*pentadiene by a method similar to that of Alder and Rickert [3]. The product was distilled four times under reduced pressure with an efficient column, and fraction b.p. 67.5° (11.5 mm) was employed. n_D^{20} 1.4693, d_4^{20} 1.0502. A part of this sample of dehydro-norbornyl acetate (4.50 g) was hydrogenated in the presence of a Raney-nickel catalyst at 65° and 100 atm. initial pressure. The product was hydrolysed with sodium hydroxide in water-ethanol. The reaction mixture was extracted with ether-light petroleum mixture (50 + 50) and dried over potassium carbonate. After removal of the ether and light petroleum, 3.68 g of white crystalline powder, m.p. 142.5—145°, was obtained. According to the infrared spectral analysis [14] this is a mixture of 75.3 % α-norborneol and 24.7 % β-norborneol.

5-Hydroxy-norcamphoric acid. To a mixture of 26.6 g of "*endo*"-dehydro-norbornyl acetate, 100.0 g of $MgSO_4 \cdot 7\ H_2O$ and 500 ml of water 73.2 g of potassium permanganate was gradually added during two hours. When the color of the permanganate had disappeared, 450 ml of 2 N sodium hydroxide was added. After 12 hours staying the mixture was filtered, and the filtrate extracted with ether for removal of the neutral materials. The water layer was acidified with sulphuric acid and extracted with ether in a continuous extraction apparatus for 50 hours. A part of the ether extract precipitated during the extraction as a white crystalline powder and was filtered off; 9.87 g, m.p. 165—168°. The ether solution was dried over sodium sulphate, and the ether was removed. Of the oily residue the acetic acid was evaporated in a vacuum and additional 0.45 g of crystals m.p. 165.5—170° was isolated by means of rubbing with ether. The yield of oily product was 10.68 g. In all, 10.32 g (33.9 % of theory) of crystals was obtained. After recrystallisation of water the m.p. was 169—170°. (Found: C 48.15; H 5.84. Calc. for $C_7H_{10}O_5$: C 48.27; H 5.79. The acid was titrated with 0.1 N NaOH: equiv.wt. 87.0. Calc. for twobasic acid $C_7H_{10}O_5$: equiv.wt. 87.1). This 5-hydroxy-norcamphoric acid is very soluble in water and very slightly soluble in ether.

5-Hydroxy-norcamphoric acid dimethylester was prepared in ether of the silver salt and methyl iodide. The product, a colorless, viscous liquid, very soluble in water, was distilled in a high vacuum, n_D^{20} 1.4694. (Found: C 53.60; H 6.88. Calc. for $C_9H_{14}O_5$: C 53.46; H 6.98. Total hydrolysis: equiv.wt. 101.0. Calc. 101.1.) Infrared spectrum in Fig. 2.

ACTA CHEMICA SCANDINAVICA 10 (1956) 256—260

On the Isomerism of Hydroxyurea

VII. The Reaction of Hydroxylamine with Cyanic Acid in Anhydrous Ether

HELMER KOFOD

Royal Danish School of Pharmacy, Dept. of Organic Chem., Copenhagen, Denmark

By the reaction of hydroxylammonium ion and cyanate ion a mixture of two isomeric hydroxyureas is formed, differing *inter alia* by melting point. In previous work the *lower melting* product was found to predominate, when the reaction was performed in aqueous solution at 0° C.

Experiments reported in the present paper indicate that the corresponding reaction between the uncharged molecules in anhydrous ether solution leads to predominantly the *higher melting* product. A possible correlation of the isomerism with the postulated tautomerism of cyanic acid is briefly discussed.

In part II of the present series [1] it was concluded that the ionic process $HONH_3^+ + {}^-OCN \rightarrow CH_4O_2N_2$ (hydroxyurea) in aqueous solution at 0° C leads to roughly equal amounts of the two known isomerides, which for the sake of brevity will be denoted OU_{72} and OU_{140}, respectively. The index is the characteristic decomposition temperature. The proposed ratio was inferred from the preparative yields, making some allowance for the greater lability of OU_{72}.

More accurate polarographic measurements [2] have indicated that under the said conditions rather more of OU_{72} is formed than of its isomer, the ratio OU_{72}/OU_{140} being probably between 1 and 2.

Although the formation of two isomeric products in a chemical process need not by necessity originate in structural ambiguity of the reactants but may be merely a matter of statistic probabilities, it is, however, striking that both cyanic acid and hydroxylamine display certain dualistic properties.

The structure of cyanic acid has been intensely studied by many investigators and has been a subject of much controversy. The most reliable interpretation is probably that given by Birckenbach and Kolb[3] *cf.* [6] from classical

chemical arguments and by Goubeau [4] from Raman-spectroscopic data. According to these authors cyanic acid exists in the tautomeric equilibrium

$$\underset{a}{H—\underline{N}=C=\underline{\bar{O}}} \rightleftharpoons \underset{b}{|N\equiv C—\underline{\bar{O}}—H},$$

a, which is believed to be the more stable form, predominates in the free cyanic acid and in solutions in "non-polar" solvents, whereas *b* appears to represent the structure of cyanic acid dissolved in "polar" solvents, all provided that equilibrium is attained. The crystalline salts of cyanic acid presumably contain the mesomeric anion

$$\left(\underset{a}{\underline{\bar{N}}=C=\underline{\bar{O}}} \leftrightarrow \underset{b}{|N\equiv C—\underline{\bar{O}}|} \right)^-$$

the actual electron-distribution being close to *a* in the salts of complex-forming metals with a bond type approximating the covalent one and close to *b* in the essentially ionic salts, such as the alkali cyanates. Most salts have been isolated in one form only, corresponding to either structure *a* or *b*, but in a few instances, *e. g.* mercury, individually existing isomeric salts could be isolated by the authors quoted [3].

Let it be assumed that the isomerism of hydroxyurea is somehow the result of the tautomerism of cyanic acid. It is evident, then, that OU_{72}, which is formed in major amounts by the ionic process in aqueous solution, must be associated with cyanic acid of structure *b*, since this electron-distribution is predominant in aqueous solution. As a consequence the reaction of free hydroxylamine-base and cyanic acid in, *e. g.*, ether (structure *a*) should produce exclusively or predominantly the higher melting hydroxyurea OU_{140}.

As a matter of fact this has been experimentally confirmed and some support has therefore been carried to the hypothesis.

The experimentation presented certain difficulties, owing to both reactants being exceedingly unstable. Free hydroxylamine base decomposes rapidly into ammonia, nitrogen and water, and cyanic acid is apt to polymerize and to decompose. After a number of introductory experiments the following procedure was found to work satisfactorily.

The reaction was performed at 0° C in anhydrous ether solution. Under these conditions hydroxylamine is sufficiently soluble and relatively stable, and cyanic acid is very soluble and does not polymerize too rapidly. The reactants were freshly prepared immediately prior to use.

Cyanic acid was obtained [10] by depolymerization of cyanuric acid $(HNCO)_3$; the latter was prepared according to Walther [5] by heating urea with anhydrous zinc chloride at 220° C. The product was recrystallized from water and dried to constant weight at 105° C.

The cyanic acid generator is shown in Fig. 1. A few grammes of cyanuric acid was placed in the quartz combustion tube and a slow stream of dry nitrogen was passed through it, while the part containing the cyanuric acid was heated with a flame until sublimation occurred. The trimer partly sublimes and partly undergoes depolymerization, and the heating and nitrogen flow were regulated in such a way that the sublimate was redeposited within the

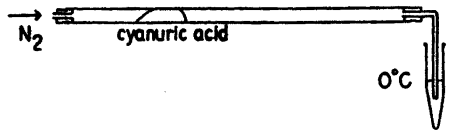

Fig. 1. Cyanic acid generator.

quartz tube and only the gaseous monomer was allowed to leave the outlet. It was absorbed in some milliliters of anhydrous ether in the centrifuge tube, which was immersed in an ice-water bath to retard polymerization of the cyanic acid. By proper operation the contents of the centrifuge tube was a clear solution with the characteristic acetic acid-like smell of cyanic acid.

Hydroxylamine was most conveniently obtained by the method of Hurd [7] with some technical modifications. A solution of sodium butoxide was prepared by refluxing 7.8 g (1/3 mole) of sodium with 100 ml of redistilled butanol-1. The equivalent amount (23 g) of hydroxylammonium chloride (analytical grade, finely ground and thoroughly dried), 3 mg of phenolphthalein and 30 ml of butanol were placed in a 250 ml pyrex-flask fitted with a magnetic stirring device and a delivery funnel containing the butoxide solution. The funnel was heated to about 40° C by exposing it to infra-red radiation in order to prevent crystallization. The butoxide solution was added dropwise with continuous stirring at such a rate that the pink colour never predominated. The "neutralization" required 1.2 hour. Sodium chloride was filtered off and washed with butanol and anhydrous ether and the combined colourless liquids were cooled to —10° C. Hydroxylamine was obtained in good yield as large colourless flakes. It was washed with anhydrous ether and dried *in vacuo* at —10° C to remove solvents; the melting point, taken immediately, was

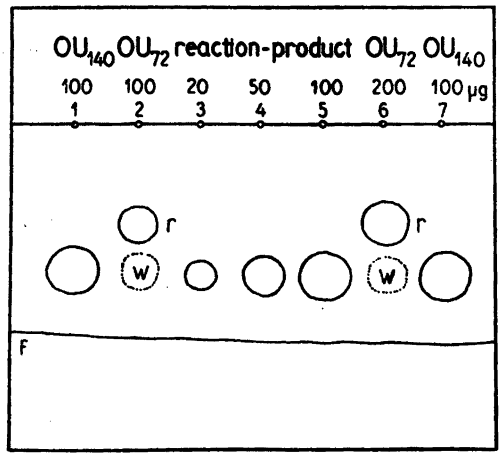

Fig. 2. Descending paper-chromatogram of the reaction product and authentic samples of hydroxyurea isomerides. b. 3.0 mg reaction product in 5 ml of buffer as under a.
c. 0.25 mg authentic lower melting hydroxyurea (OU_{72}) in 5 ml of buffer.

32° C; Ref.[7] 33° C. The substance was used forthwith for the actual experiment as described below. The remaining crop was stored at 0° C; nevertheless it was completely decomposed the following day.

Anhydrous ether (4 ml) was saturated with hydroxylamine at 0°. A freshly prepared solution of cyanic acid in anhydrous ether (0° C) was added dropwise. A colourless, crystalline precipitate was formed, and the addition of cyanic acid was continued until no further precipitation occurred. The contents of the reaction vessel were centrifuged, and the supernatant ether poured off. The solid was washed with 2 × 1 ml cold anhydrous ether, in which both hydroxyureas are insoluble, and dried *in vacuo*. The product gave the characteristic blue-violet colour produced by OU_{140} on addition of ferric chloride. Paper-chromatographic analysis according to the previously reported technique[8] proved that the product was identical with OU_{140} isolated from the ionic process. In Fig. 2 is reproduced a descending paper-chromatogram of the product (Nos. 3—5) run together with authentic samples of the two known isomerides. The irrigation solvent was a mixture of 70 ml of ethanol and 30 ml of 4 N hydrochloric acid. In this solvent both hydroxyureas are sufficiently stable and the isomerization is very slow[8]. The weak OU_{140}-spot to be seen in the runs 2 and 6 is due to the fact that the sample of OU_{72} was 1 month old, and hence partly isomerized. The spot in run No. 5 is comparable in size to the authentic spot in runs Nos. 1 and 7. As the amount applied to the paper is the same, it may be concluded that the reaction product consists almost entirely of OU_{140}. There was not on the original paper-sheet any trace of the characteristic red OU_{72}-spot to be seen in the runs 3—5.

The still more sensitive polarographic method[9], however, revealed the presence of approximately 10 % OU_{72}. In Fig. 3a is reproduced a blank current-voltage curve of the supporting buffer, pH 7.2 (*vide* Ref.[9]), curve *b* is a polarogram of 3.0 mg reaction product dissolved in 5 ml of the same buffer. It

represents the usual OU_{72}-wave at —1.5 V *vs.* SCE. Curve *c* is a polarogram recorded under identical conditions of a solution of 0.25 mg of authentic OU_{72} in 5 ml of buffer. From the relative heights (linear relationship has been found between concentration and wave height, Ref.[9] Fig. 4) of *b* and *c* it may be estimated, that the 3.0 mg of reaction-product weighed out contain approximately 0.3 mg or 10 % of the lower melting isomer. The identity of the wave *b* was further established by adding authentic OU_{72} to the cell-solution; this caused an increase in wave-height but neither displacement nor distortion of the wave.

The thermal decomposition interval of the product (Kofler hot-stage microscope) was in accordance with the above results. The content of OU_{72} was evidently too small to produce any visible change at 72° C, but decomposition and melting occurred abnormally low and over a large interval, 120—135° C. The decomposition temperature normally found for the pure OU_{140} is 135—140° C, depending upon the rate of heating.

The formation of hydroxyurea isomerides described in the present paper is directly comparable with previous experiments on the ionic process [1,2], in that both reactions were carried out at 0° C and cyanic acid was added to hydroxylamine and not *vice versa*. The observed ratio OU_{72}/OU_{140} was over 1 with the ionic process and approximately 0.1 with the reaction described in this paper. This result strongly suggests that the isomerism of hydroxyurea has some relation to the postulated tautomerism of cyanic acid, a point of view, which is quite interesting, because it means that the isomerism of hydroxyurea is at least formally analogous to that of urea and isourea, which, as far as the parent compounds are concerned, do not seem capable of individual existence. A detailed discussion of formation mechanisms and structure will be presented in a final publication.

The Structure Parameters of Dimethyldiacetylene

A. ALMENNINGEN, O. BASTIANSEN* and T. MUNTHE-KAAS

Universitetets Kjemiske Institutt, Blindern — Oslo, Norway

Electron diffraction studies have been carried out on the structure of dimethyldiacetylene. The following structure parameters have been obtained, C-H = 1.09 Å, C≡C = 1.208 Å, C_2-C_4 = 1.377 Å, C_1-C_2 = 1.450 Å and HCC = 111.6°

Accurate determinations of bond distances in conjugated systems seem to be of considerable interest. A new electron diffraction apparatus now in operation in Oslo has made it possible to determine internuclear distances with a rather high accuracy. A series of compounds containing conjugated systems is now being studied with the new technique. The investigations include dimethyldiacetylene, vinylacetylene, butadiene and *cyclo*octatetraene. In the present note the results for dimethyldiacetylene will be described.

As the new electron diffraction apparatus and the calculation technique have been described elsewhere [1,2] only a few comments concerning the procedure will be given. The intensity values obtained in this case range from about $s = 1$ up to $s = 60$ Å^{-1}. From the intensity data radial distribution curves have been calculated. Various damping factors have been used. The radial distribution curve presented in Fig. 1. is calculated by applying a damping factor of $e^{-0.0015\,s^2}$. The inner complex of peaks ranging from about 1 Å until 1.6 Å contains the bond distances. The peaks beyond this point contain internuclear distances between atoms which are not directly linked together. In the curve of Fig. 1 the inner complex of peaks is not very well resolved. A better resolution is obtained by applying a smaller damping factor or simply by omitting the damping factor altogether. Detailed studies of this inner complex in the various radial distribution curves, including the use of normal curves, lead to the four first entries in the first column of Table 1. A study of the outer part of the radial distribution curve gives the other internuclear distances listed in the table.

* Present address: Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway.

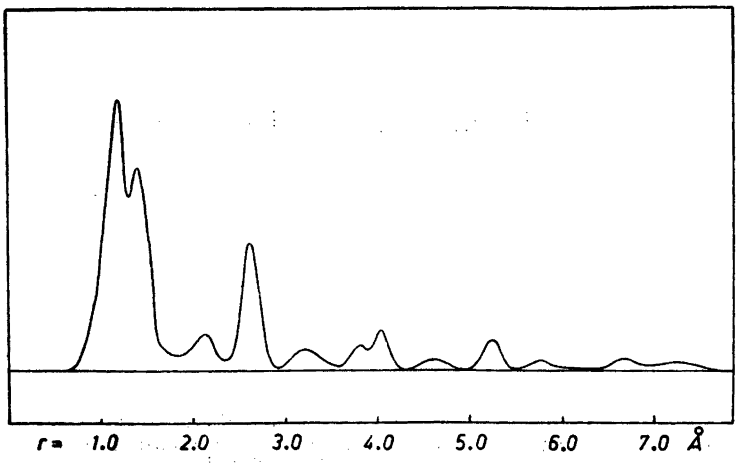

Fig. 1. Radial distribution curve of dimethyldiacetylene.

The geometry of the carbon skeleton is determined by three parameters if a linear arrangement is assumed. These three parameters were obtained from the nine experimental C—C distances by a least-square procedure. The two parameters necessary for the location of the hydrogen atoms were calculated in a similar way. The best structural parameters thus obtained from our experiment are the following: C—H = 1.09 Å, $C_2 \equiv C_3$ = 1.208 Å, C_3—C_4 = 1.377 Å, C_1—C_2 = 1.450 Å and ∠ HCC = 111.6°. These values are in good agreement with those obtained by Jeffrey and Rollett for dimethyltriacetylene [3]. On the basis of the five parameters obtained all the internuclear C—C and C—H distances were calculated. These values are listed in the second column of the table. The correspondence between the values read off from the radial distribution curves and those calculated from the best parameters is in general remarkably good. For the carbon skeleton the average deviation between the two sets of distances is between 0.2 and 0.3 %. This indicates a rather high accuracy in the distance determination, though it does not give any indication concerning the absolute values. Estimations of the various sources of errors, and comparison between results obtained by our electron diffraction procedure and microwave studies seem to indicate that our scale error is about of the same order of magnitude as the deviation observed within a single radial distribution curve [4].

The positions of the hydrogen atoms are not determined with the same degree of accuracy as the carbon atoms. The C—H bond distance does not lead to a resolved peak in the radial distribution curve, and the longer C—H distances are not well suited for accurate determinations of the C—H bond and the HCC angle.

By studying the half widths of the peaks of the radial distribution curves experimental values for the root mean squares of the deviations from the equilibrium distances have been calculated. These values for the C—H bond and

Table 1. Experimental and calculated distances and average displacements from equilibrium, all in Ångstrom units.

$C_1 - C_6$	6.661	6.693	0.080	0.065
$H - C_2$	2.110	2.110		
$H - C_3$	3.220	3.222		
$H - C_4$	4.571	4.550		
$H - C_5$		5.734		
$H - C_6$	7.201	7.166		

all the C—C distances are listed in the third column of the table. In the last column of the table are listed the corresponding theoretical values calculated applying the stretching vibrations known from spectroscopical data [5] assuming a temperature of 310°K. As one sees, the correspondence between these sets of values obtained in two entirely different ways is fairly good.

A comparison between the experimental and calculated distances in Table 1 seems to indicate a systematic deviation between the two sets of values for the largest C—C distances. For the four largest C—C distances the experimental values are smaller than the calculated ones, while the opposite is the case for the shorter distances. This fact might be explained by taking into consideration the bending vibrations of the molecule. These vibrations should lead to a decrease in the long distances. If this argument is correct, the longest C—C distances should perhaps have been omitted in the least-square procedure. A correction for this effect, however, would lead only to very small changes in the structure parameters.

Acknowledgement. The authors wish to extend their thanks to Professor E. R. H. Jones for having placed a sample of dimethyldiacetylene at their disposal.

Added in proof: Since this article was submitted for publication an article concerning the structure of dimethylacetylene has been published [6]. In this article a report from Ohio State University has been quoted dealing with the structure of dimethyldiacetylene [7]. Unfortunately the latter was unknown by the present authors. Both compounds were studied by X-ray methods, and the agreement with the present work is very good.

The Infrared Spectra of some Modifications of Arsenic Trioxide and Antimony Trioxide

O. BORGEN and J. KROGH-MOE

Institutt for teoretisk kjemi, Norges Tekniske Høgskole, Trondheim, Norway

The infrared spectra of cubic and monoclinic arsenic trioxide and cubic and orthorhombic antimony trioxide have been compared with the spectra of the vitreous modifications. The latter show best agreement with the spectra of the cubic modifications.

The structures of the crystalline modifications of the trioxides of arsenic and antimony are quite well known. The cubic forms are built up of As_4O_6 and Sb_4O_6 molecules [1], whereas the monoclinic arsenic trioxide [2] and the orthorhombic antimony trioxide [3] have chain or layer structures. The existence of other crystalline modifications has been suggested [2].

The structures of the vitreous form are, however, a matter of controversy. Shulman and Shumb [4] inferred from the devitrification of arsenic trioxide glass that it is rather closely related to the cubic form. A comparison of the densities (cubic [5] 3.87, monoclinic [6] 4.14, glass [7] 3.70) seems to strengthen this inference.

As Zachariasen's theory of glass structures [8] seems to be incompatible with the existence of As_4O_6 molecules, Bötticher, Plieth, Reuber-Kürbs and Stranski [9] were led by this and other evidence [10] to carry out an X-ray investigation of the vitreous phase. Their conclusion, the similarity of the vitreous and the monoclinic modifications, seems in the light of later investigations [11] on the errors involved in this kind of determinations rather uncertain.

In order to compare the structures of the above trioxides, their infrared spectra have been obtained in the sodium chloride region.

EXPERIMENTAL

The spectra were obtained on a Perkin-Elmer 21 recording spectrometer in the interval of 2 to 15 microns. The samples were prepared by the potassium bromide technique with 2 or 10 milligrams of oxide in 2 grams discs of about one inch diameter. A pressure of 20 tons was applied for 15 minutes.

The trioxide modifications were prepared from Merck *pro analysi* reagents after recrystallisation. The identities were ascertained by means of the X-ray diffraction patterns.

The samples were as follows

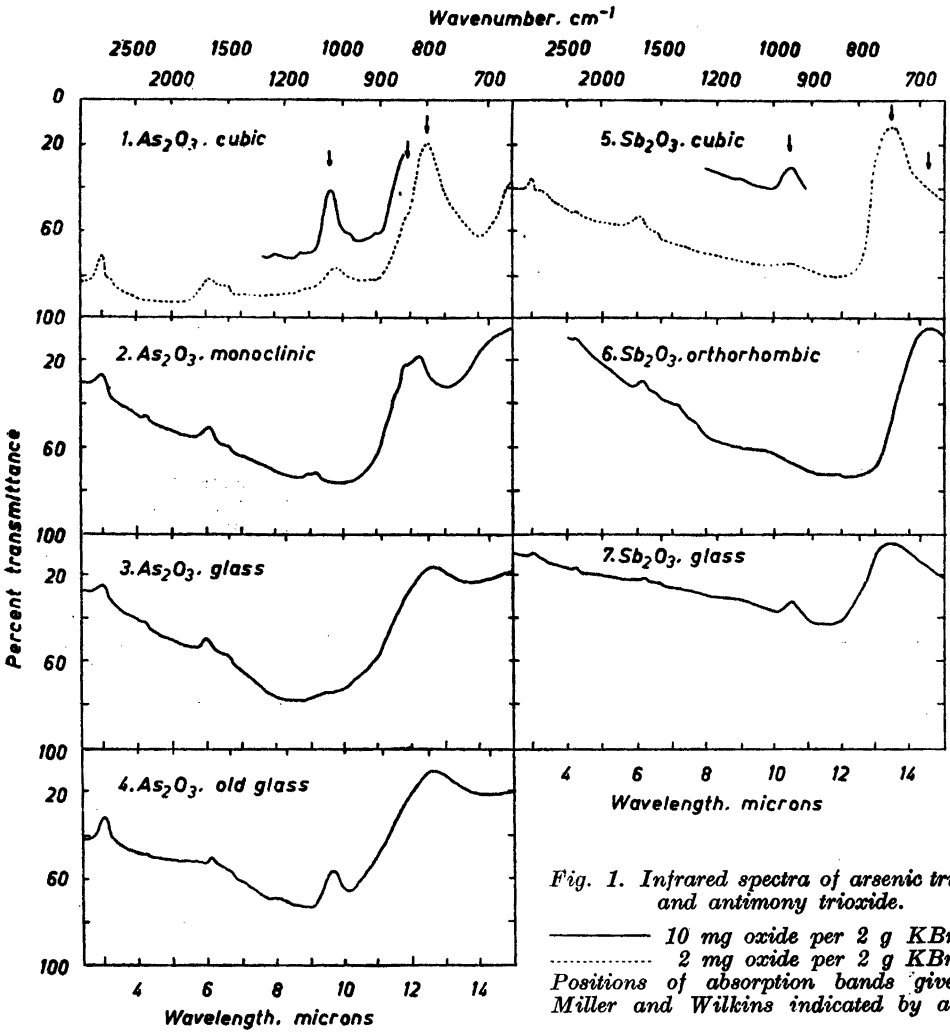

Fig. 1. Infrared spectra of arsenic trioxide and antimony trioxide.
——— *10 mg oxide per 2 g KBr.*
····· *2 mg oxide per 2 g KBr.*
Positions of absorption bands given by Miller and Wilkins indicated by arrows.

Arsenic trioxide: 1) cubic, 2) monoclinic [4], 3) glass, freshly prepared by quenching melted oxide, 4) glass, stored over P_2O_5 for a month after grinding with potassium bromide.

Antimony trioxide: 5) cubic, 6) orthorhombic [12], 7) glass, two days old, prepared by pouring melted oxide into water.

The resulting spectra are shown in Fig. 1.

RESULTS AND DISCUSSION

A number of recurrent absorption bands between 2 and 6.5 microns are caused by water and other impurities. Infrared spectra of arsenic and antimony trioxides of unknown purity have been obtained by Miller and Wilkins [13].

They agree well with our spectra of the cubic forms. These are quite similar in appearance with the bands displaced towards lower wavenumbers in the case of antimony trioxide, as would be expected.

In the spectrum of monoclinic arsenic trioxide the principal band is found at higher wavenumbers than for the cubic form. The corresponding band of orthorhombic antimony trioxide, however, is displaced towards lower wavenumbers. This seems to indicate a structural difference between the modifications of lower symmetry.

For both the vitreous modifications, the principal band is found at the same position as for the cubic modifications. The bands are of less peak intensity and quite broad. Old arsenic trioxide glass and antimony trioxide glass have a secondary band at the same position as found for the cubic modifications. It therefore seems that these samples are partially transformed to the cubic forms. By comparison of all spectra, the vitreous modifications seem to be closer related to the cubic forms than to those of lower symmetry.

The authors are grateful to professor N. A. Sørensen for placing equipment at their disposal.

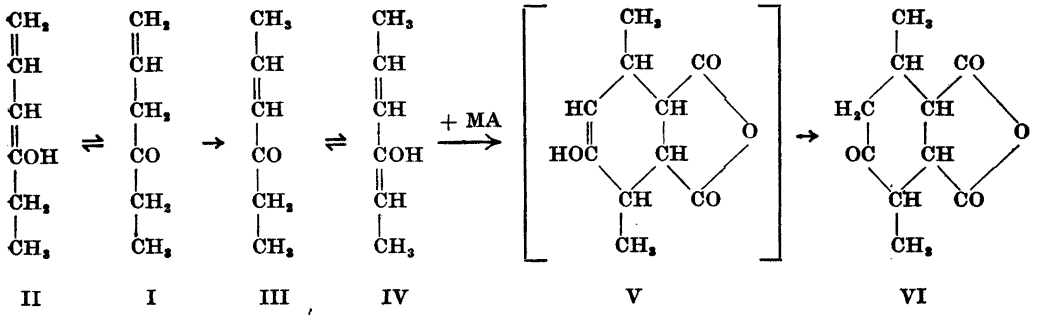
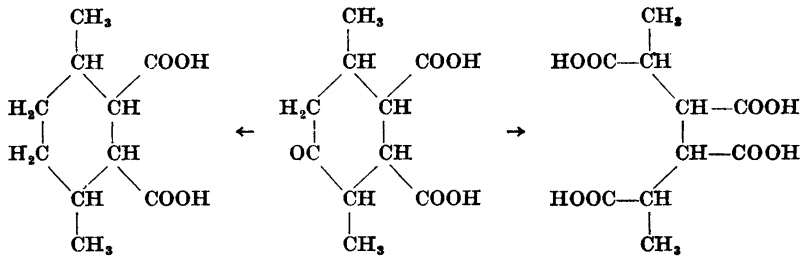
Ethyl Propenyl Ketone as a ψ-Diene in the Diels-Alder Reaction



ENDRE BERNER

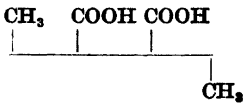
Universitetets kjemiske institutt, Blindern — Oslo, Norway

A crystalline adduct was formed by heating ethyl allyl ketone with maleic anhydride. The ψ-diene was, however, found to be ethyl propenyl ketone into which the ethyl allyl ketone isomerizes during the heating. The adduct by Clemmensen reduction gave a 3,6-dimethylhexahydrophthalic acid which could be resolved optically.



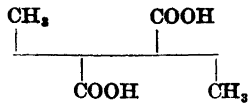
Some years ago the author [1] pointed out that a β-diketone might exist in a dienol form containing conjugated double bonds and accordingly ought to react with maleic anhydride and other dienophilic compounds. It was indeed found that acetylacetone reacted with maleic anhydride but the reaction proceeded in a way quite different from the expected one, an adduct being actually formed from two molecules of maleic anhydride and one of the diketone. Subsequently it was found that also citraconic anhydride reacted with acetylacetone, but neither in this case did the reaction proceed as expected, the reaction product being a furan derivative [2].

From the literature [3] some few examples are known showing that unsaturated aldehydes or ketones can react as ψ-dienes in Diels-Alder reactions. In the present case it was found of interest to investigate the behaviour of ethyl allyl ketone (I) as its enol (II) would contain a conjugated system. The ketone I actually reacted with maleic anhydride when heated for some days to 90°, but the crystalline adduct, although it had the calculated composition, did not behave as expected if the enol II had been the diene component. The adduct was thus completely saturated and had retained the carbonyl function of the ketone. The reason for this is that the ethyl allyl ketone on heating with the maleic anhydride did isomerize to ethyl propenyl ketone (III) the enol of which (IV) reacted with the maleic anhydride (MA) to give the adduct VI. The enolic form V is obviously an unstable intermediate. For the preparation of the adduct it was then of course found practical to isomerize the ethyl allyl ketone in a separate operation and then carry out the Diels-Alder reaction with the pure ethyl propenyl ketone.



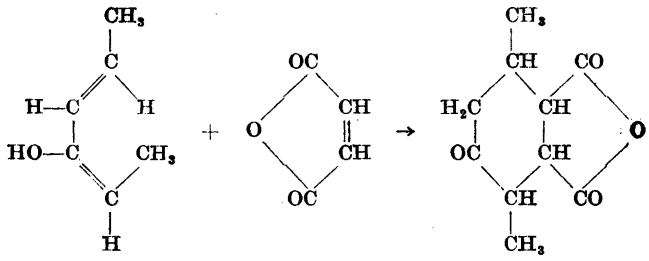
II I III IV V VI

The free dicarboxylic acid (VII) corresponding to the adduct could be resolved into optically active components. By reduction the same acid gave a hydroxy-acid which was easily transformed into a lactone. The acid VII further on Clemmensen reduction gave a 3,6-dimethylhexahydrophthalic acid (VIII) and on oxidation with nitric acid the open-chained hexane-2,3,4,5-tetracarboxylic acid (IX).



VIII VII IX

As the hexahydrophthalic acid VIII could be resolved optically and the carboxyl groups, due to their origin from maleic anhydride, must be *cis* to each other the methyl groups can only be in *trans* position to each other. The acid VIII ought therefore to be identical with the $3^c,6^t$-dimethyl*cyclo*hexane-$1^c,2^c$-dicarboxylic acid prepared by Alder and Vogt [4] by hydrogenating the adduct of *cis-trans*-1,4-dimethylbutadiene and maleic anhydride. These authors, designating the acid according to their scheme as the Bα-form (X), gave the m. p. as 134°, while we have found 121° for the inactive acid. The discrepancy may most probably be due to dimorphism. It could also be due to a partial spontaneous resolution taking place during the crystallization (we have found m. p. 138° for the active acid), but we have on crystallizing the acid repeatedly from the same solvent as used by Alder and Vogt never observed any deviation of the m. p. from 121°. That the acids m. p. 121° and 134° are identical is, however, evident from the fact that both on isomerization by heating with concentrated hydrochloric acid procured the all-*trans* form XI (Bβ) for which we found the m. p. 185°, while Alder and Vogt gave m. p. 183°.



X (Bα)

XI (Bβ)

From the configuration of the acid VIII and the general rules set up by Alder and Schumacher [5], 1) that the diene component reacts according to the "*cis*-principle", 2) that an acyclic diene reacts in its quasi-cyclic form, and 3) that the orientation-complex has maximum congestion of the double bonds, it can be concluded that the enol IV taking part in our reaction must have the configuration *cis-trans* (*cis* referring to the position of the methyl group at the double bond formed by the enolization). The formation of the adduct, which may be designated as the anhydride of 2,5-dimethyl-3,4-dicarboxy*cyclo*hexanone, can therefore be written

IV VI

However, from the experimental data available it is not possible to decide whether the methyl group in position 2 or that in 5 (CO = 1) is the one being in *trans* position to the three other substituents.

EXPERIMENTAL

(Melting points not corrected)

Ethyl allyl ketone and maleic anhydride. Ethyl allyl ketone (25 g), prepared according to Blaise [6], and maleic anhydride (25 g) were mixed and heated for 4 days to 90°, the colour in the end becoming brownish red. After cooling to room temperature the mixture was inoculated with crystals obtained by a preliminary experiment. Next day the adduct was filtered off by suction and washed thoroughly with ethanol when it became practically colourless. It weighed 15.2 g. The mother liquor from this first fraction after heating for three more days gave 4.8 g crystalline adduct. Yield in all 40 %. Recrystallized from ethyl acetate. M. p. 146°. (Found: C 61.38, 61.25; H 6.19, 6.16. Calc. for $C_{10}H_{12}O_4$ (196.2): C 61.21; H 6.17.)

Isomerization of ethyl allyl ketone. Ethyl allyl ketone was mixed with twice its volume of 20 % sulphuric acid and refluxed for one hour. The ketone was taken up in ether and the solution dried with sodium sulphate. After removing the ether the residue was fractionated twice. The fraction boiling at 137—138° consisted of the ethyl propenyl ketone which gave a semicarbazone with m. p. 160° (Blaise [6] found 157°).

Ethyl propenyl ketone and maleic anhydride. The ketone (13.5 g) and maleic anhydride (13.5 g) were heated for 3 days to 90° when a first fraction of adduct (6.0 g) was obtained.

Further heating for 3 days of the mother liquor gave a second fraction of 5.2 g adduct, both fractions washed with ethanol. Yield in all 41.5 %. After recrystallization from ethyl acetate, m. p. as above 146°.

Investigation of the adduct. The adduct could be sublimated unchanged in a high vacuum, after which it had m. p. 145°, recrystallized from ethyl acetate m. p. 146°. A solution of the adduct in chloroform did not add bromine, nor did an aqueous solution react with bromine-water.

The free acid (VII) was obtained by dissolving the adduct in N sodium hydroxide and adding an excess of 2 N sulphuric acid. On standing hard crystals separated which after recrystallization from water had m. p. 206—207°. The same acid was obtained by dissolving the adduct in boiling water and evaporating the solution or by dissolving it in conc. sulphuric acid and pouring the solution on ice. (Found: C 55.93, 55.89; H 6.63, 6.54; M by titration 216.4. Calc. for $C_{10}H_{14}O_5$ (214.4): C 56.07, H 6.59.)

The original adduct was recovered from the acid VII by dehydration. For this purpose the acid (0.5 g) was pulverized and refluxed for 2 hours with acetyl chloride (5 ml). The solution on evaporation in a vacuum desiccator above potassium hydroxide gave a crystalline residue which after recrystallization from ethyl acetate had m. p. and mixed m. p. 145°.

The methyl ester of the acid VII was prepared by means of diazomethane. After evaporating the ethereal solution the ester crystallized spontaneously. It had m. p. 52—53° but was not recrystallized owing to its great solubility in most solvents. For preparation of the hydrazone a solution of 2,4-dinitrophenylhydrazine in hydrochloric acid was added to the ester dissolved in ethanol. The hydrazone separated immediately as an oil which crystallized on scratching. Recrystallized from ethanol, m. p. 177°. (Found: C 51.30; H 5.25; N 13.26. Calc. for $C_{18}H_{22}O_8N_4$: C 51.18; H 5.25; N 13.26.)

Optical resolution of the acid VII. Preliminary experiments gave crystalline salt of the acid with strychnine when used in the molecular ratio 1:1. The acid (2.7 g) and strychnine (4.2 g) were dissolved in water (50 ml) at room temperature and the solution inoculated. The strychnine salt (2.1 g) which had separated during the night was decomposed by adding 10 ml N hydrochloric acid. After removing the strychnine hydrochloride by filtration the active acid was extracted with ether and was obtained as a crystalline mass (0.35 g) which melted at 195—199° and had $[\alpha]_D^{20} = -21.5°$ (water, *c* 3).

Oxidation of the acid VII with nitric acid. To a solution of the adduct (2 g) in water (60 ml) was added conc. nitric acid of sp. gravity 1.4 (11 ml) and the solution heated on the steam-bath. In a few minutes the solution became light blue, the colour soon changing into greenish and then yellow and an evolution of nitric oxide set in. After heating for 20 min. the solution was evaporated slowly at room temperature. The crystalline residue was washed with a small amount of water and crystallized twice from water. A final recrystallization from 2 N hydrochloric acid gave beautifully developed hexagonal prisms, M. p. 202°. (Found: C 45.81; H 5.31. Calc. for $C_{10}H_{14}O_8$ (262.2): C 45.80; H 5.38.)

Esterification: A solution of the acid m. p. 202° (0.2 g) in 20 ml methanol containing 4 % hydrogen chloride was refluxed for 7 hours. A part of the methanol (15 ml) was distilled off and replaced by new methanol containing hydrogen chloride. The refluxing was continued for 4 hours after which most of the methanol was evaporated. The residue was neutralized with sodium carbonate and the ester taken up in ether. From the ethereal solution the ester was obtained as an oil (0.17 g) which after some time crystallized. Recrystallized from dilute methanol. M. p. 50°. (Found: C 52.59; H 7.05; OCH_3 38.90. Calc. for $C_{14}H_{22}O_8$ (318.3): C 52.82; H 6.97; OCH_3 39.00.)

Reduction of the acid VII with sodium amalgam. The adduct (2 g) dissolved in 0.5 N sodium hydroxide (40 ml) was treated with 4 % sodium amalgam at 50—60° until a sample did not give precipitate with dinitrophenylhydrazine. The solution was neutralized and concentrated somewhat on the water-bath. After adding 10 ml 5 N sulphuric acid and standing over night the hydroxy-acid had separated (1.7 g). Recrystallized from water. M. p. 196—197°. (Found: C 55.55; H 7.47. Calc. for $C_{10}H_{16}O_5$ (216.2): C 55.54; H 7.46.)

On refluxing the above 2,5-dimethyl-3,4-dicarboxy*cyclo*hexanol with five times its weight of acetic anhydride for 2 hours it was converted into a lactone. The lactone after being isolated by evaporating the solution in a vacuum was recrystallized twice from ben-

zene. M. p. 135°. Dissolved in dilute ethanol it could be titrated as a monobasic acid. (Found: C 60.52; H 7.14; M 200.0. Calc. for $C_{10}H_{14}O_4$ (198.2): C 60.59; H 7.12.)

Clemmensen reduction of the acid VII. Pieces of zinc sheet (10 g) were treated for half an hour at room temperature with a 5 % solution of mercuric chloride. After washing the zinc with water 15 % hydrochloric acid (20 ml) and adduct (4 g) were added and reduction effected by refluxing for 3 hours. The dimethylhexahydrophthalic acid separated as an oil which crystallized on standing. It was isolated by extraction with ether. Yield 3.0 g. The acid after crystallization from water had m. p. 120°. On recrystallization from acetonitrile the m. p. rose to 121° and this m. p. remained unchanged on recrystallizing the acid repeatedly from the same solvent. (Found: C 59.95, 59.84; H 8.10, 8.07; M by titration 203.7. Calc. for $C_{10}H_{16}O_4$ (200.2): C 59.98; H 8.06.)

Resolution of the acid m. p. 121°. Strychnine and cinchonine did not give crystalline salts. Brucine, however, when used in the ratio 2 moles alkaloid to 1 mole acid was effective. The acid (1 g) and brucine (3.4 g) were dissolved in ethanol (10 ml) by heating gently. On standing at room temperature for 5 days 1.2 g brucine salt had separated. It was dissolved in 2 N hydrochloric acid and the active acid (0.23 g) isolated by extraction with ether. This crude acid which in ethanol had $[\alpha]_D^{20} = -13.0°$ was recrystallized from a small amount of water. The first fraction consisted of practically inactive acid, m. p. 120–121° and $[\alpha]_D^{20} = -1.6°$. Evaporation of the mother liquor gave a laevorotatory acid with m. p. 138° and $[\alpha]_D^{20} = -29.3°$ (ethanol, *c* 2.5). The filtrate from the 1.2 g brucine salt gave a crude dextrorotatory acid with $[\alpha]_D^{20} = +4.2°$.

Isomerization of the acid m. p. 121°. The acid (0.4 g) was heated to 180° in a sealed tube with conc. hydrochloric acid (5 ml) for 5 hours. After diluting with water extraction with ether gave a partly crystallized residue which on a porous tile left 0.2 g crystalline acid. Recrystallized several times from acetonitrile, m. p. 185°.

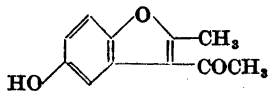
Some New Benzodifurans and Naphthofurans from Quinones and β-Diketones

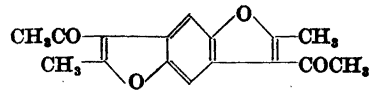
ERLING BERNATEK

Universitetets Kjemiske Institutt, Blindern — Oslo, Norway



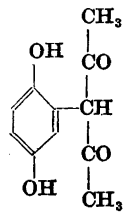
In connection with work on stable ozonides two new benzodifurans and several new naphthofurans have been synthesized from quinones and β-diketones. The reactivity of some substituted naphthoquinones has been tested.

As pointed out by Criegee [1] well-defined ozonides are only rarely encountered in literature. The same author therefore devoted himself to the preparation of stable ozonides as well as to the complete elucidation of their degradative reactions and their rearrangements. He was able to show [2] that in the ozonization of 9,10-octalin no stable ozonide was formed as supposed by Hückel [3], the reaction product turning out to be a dimeric peroxide of *cyclo*decanedione-1,6. Likewise the "ozonide" from 2-phenyl-3-ethyl-indenone described by Frank and collaborators [4] could be shown to consist of a mixed anhydride of *o*-propionylbenzoic acid and benzoic acid.



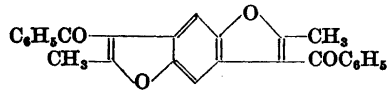
Are thus the stable and well-defined ozonides even more rare than previously supposed, a notable exception is displayed in the ozonides of unsaturated five-membered rings. The reason for this is probably of a steric nature [5]. Such stable ozonides can be prepared from certain steroid derivatives [6,7], indole derivatives [8,9], disubstituted maleic imides [10], *cyclo*pentene [11], cyclic sulphones [12] and 2,3-disubstituted indenones [13]. Recently a new class of compounds has been found to yield stable, monomeric ozonides, *viz.* the benzo [1.2-b, 4.5-b'] difurans [14]. As a preliminary to further work in this field the author has undertaken the synthesis of some new suitably substituted benzodifurans and naphthofurans.

The synthesis of benzofuran and benzodifuran derivatives from quinone and ethyl acetoacetate was established by v. Pechmann [15] and Ikuta [16]. Later Graebe and Levy [17] extended the synthesis to include toluquinone but expressed on the same occasion doubt as to the correctness of some of Ikuta's structural formulae. These, however, seem to have been confirmed by more recent work [18]. Further extensions of the synthesis have been made through the investigation of the reaction between acetylacetone and quinone [18,19].

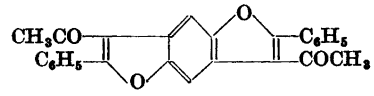


The structure of two new furan derivatives from these works are given in the formulae I and II.

I



II

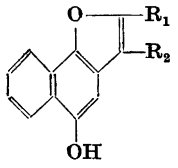


III

These compounds are supposed to be formed by ring closure of intermediate quinols of the type represented by formula III (or its tautomeric form). The determination of the structures I and II was considerably facilitated by the fact that acetylacetone is a symmetrical diketone. Thus the two possible directions of enolization in III are identical and only one product can result from a ring closure. (III will of course give I.)

We now have investigated the reaction between benzoylacetone and quinone in methanolic zinc chloride solution. Only one reaction product could be isolated. Its composition $C_{26}H_{18}O_4$ corresponded to a benzodifuran derivative and in analogy to our earlier results the structure of this product could be either IV or V.

IV



V

The carbonyls in $C_{26}H_{18}O_4$ were relatively unreactive. With ordinary carbonyl reagents, *e. g.* 2,4-dinitrophenylhydrazine, it yielded only a monohydrazone. The iodoform test was negative. In order to decide between IV and V the presumed benzodifuran was treated with methyl magnesium iodide whereby both carbonyls were converted into tertiary alcohol groups, the resulting compound having the composition $C_{28}H_{26}O_4$. The same compound could be prepared by treating II with phenyl magnesium bromide. Consequently the possibility of structure V is ruled out.

Benzoylacetic ester reacted only very sluggishly with quinone under the conditions tried and gave in extremely low yield a substance $C_{28}H_{22}O_4$ which probably is a benzodifuran (V, $COOC_2H_5$ instead of $COCH_3$). This compound was not investigated further.

1,4-Naphthoquinone reacted smoothly with acetylacetone to give a compound $C_{15}H_{12}O_3$ corresponding to one mole of each of the reactants minus one

mole of water. The reaction medium was as usual methanolic zinc chloride solution and only one reaction product could be isolated. With 2,4-dinitrophenylhydrazine it gave a monohydrazone and with acetyl chloride a monoacetate was obtained. The substance was contrary to expectation not soluble in warm 2 N sodium hydroxide. It is supposed to have the naphthofuran structure VI.

VI $R_1 = CH_3$, $R_2 = COCH_3$
VII $R_1 = CH_3$, $R_2 = COOC_2H_5$
VIII $R_1 = C_6H_5$, $R_2 = COOC_2H_5$
IX $R_1 = CH_3$, $R_2 = COC_6H_5$
X $R_1 = CH_3$, $R_2 = C(OH)(CH_3)C_6H_5$

After this part of the investigation was completed it was found in the literature that Ebine [20] also had prepared the substance VI. His findings are in good agreement with ours. In the same paper Ebine reports the synthesis of II and gives the melting point 232—233° which is rather low as compared to our value [19] of 248°. Likewise the found percentage of carbon is by 1.7 smaller than calculated. It is suspected that Ebine has not had the pure compound II in hands but a mixture of II and I. The latter has the melting point 238° and its carbon content is by 1.6 lower than for II[18]. The reason for this contamination is that I and II are always formed together in the condensation of acetylacetone with quinone. Unless I is extracted with alkali (which Ebine has not done) the mixture is very difficult to separate by mere recrystallization. Ebine's dioxime seems to have the correct composition a fact which probably can be explained by different solubilities of the monoxime of the benzofuran and the dioxime of the benzodifuran; the latter most likely being less soluble than the former and therefore separates first from solvents.

In analogy with VI we have prepared VII with ethyl acetoacetate, VIII with benzoylacetic ester, and IX with benzoylacetone. All these compounds could be acetylated to give the monoacetates but were insoluble in 2 N sodium hydroxide. In the case of the benzoyl product there were two structural possibilities, *viz.* one methyl-benzoyl derivative (IX) and one phenyl-acetyl derivative. This question was settled in the same way as for IV by reacting VI with phenyl magnesium bromide and IX with methyl magnesium iodide and obtaining the same tertiary alcohol X in both cases. The identity of the alcohols could not be established by mixed melting point as they readily lost water and melted over a long range. Their infrared spectra were therefore recorded and were found to be absolutely identical.

2-Methyl-1,4-naphthoquinone did not react at all with acetylacetone under the usual reaction conditions while 2-hydroxy-1,4-naphthoquinone gave the corresponding methyl ether and 2-chloro-1,4-naphthoquinone gave bi-1,4-naphthoquinone, $C_{20}H_{10}O_4$.

Naphthazarin and its diacetate were tried as representatives of naphthoquinones with substituents in the benzene ring. In order to avoid alcoholysis the diacetate was treated with acetylacetone in ethereal zinc chloride. Neither the hydroxyquinone nor the diacetate could be induced to react. This is in

agreement with the recent findings of Bruce and Thomson [21] who examined the reactivity of naphthazarin and the diacetate towards several reagents. They conclude that naphthazarin is a relatively unreactive quinone towards nucleophilic and electrophilic reagents (in our reactions we have to deal with the nucleophilic acetylacetonate ion) but reacts normally with substances which add by a radical mechanism (*e. g.* toluene-*p*-thiol) while the diacetate is somewhat, but not markedly, more reactive.

EXPERIMENTAL

(In part with A. Wulff and S. Steinsvik)

p-Benzoquinone and benzoylacetone

p-Benzoquinone (2.0 g) and benzoylacetone (3.0 g) were added to a solution of zinc chloride (10 g) in anhydrous methanol (12.5 ml). The mixture was heated for 7 hours on a water-bath and left overnight at room temperature. Next day a crystalline substance (0.55 g) had separated. Recrystallized twice from glacial acetic acid. M. p. 221°. (Found: C 79.27; H 4.65. Calc. for $C_{26}H_{18}O_4$: C 79.20; H 4.62).

Dinitrophenylhydrazone. Dinitrophenylhydrazine (0.3 g) was dissolved in hydrochloric acid (20 ml, 2 N) to which was added ethanol (10 ml) and IV (0.2 g). The mixture was heated for 7 hours on a water-bath with occasional additions of small amounts of ethanol. Next day the separated crystalline substance was isolated and dissolved in a mixture of chloroform and ligroin (1:1). The solution was passed through a column of silica gel where the dissolved substance was adsorbed in different zones, the predominating one being bright red. This zone was separated from the rest of the column and extracted with chloroform. After evaporation of the chloroform the residue was orange-red and weighed 65 mg. M. p. 249—250°. (Found: N 9.71. Calc. for $C_{32}H_{22}N_4O_7$: N 9.75). The substance seems to be a monohydrazone of the benzodifuran.

Methyl magnesium iodide and IV. To a solution of methyl magnesium iodide (from 0.5 g magnesium) in dry ether (20 ml) was added IV (0.5 g). After the vigorous reaction had subsided the reaction mixture was refluxed for 15 minutes and decomposed with water and dilute hydrochloric acid. The ethereal layer was dried and evaporated, the residue weighing 0.44 g. Recrystallized twice from dilute ethanol. M. p. 194—195°. (Found: C 79.89; H 6.14. Calc. for $C_{28}H_{26}O_4$: C 78.86; H 6.15).

Phenyl magnesium bromide and II

To a solution of phenyl magnesium bromide (from 0.5 g magnesium) in dry ether (20 ml) II (0.5 g) was added. After the moderate reaction had subsided the reaction mixture was refluxed for 25 minutes and decomposed with water and dilute hydrochloric acid. The ethereal layer was dried and evaporated. The residue, which was a yellow plastic mass with a conspicuous smell of biphenyl, was extracted twice with boiling ligroin and recrystallized thrice from dilute ethanol (charcoal). M. p. 197°. Mixed melting point with the substance from the foregoing experiment 197°. (Found: C 80.09; H 6.31. Calc. for $C_{28}H_{26}O_4$: C 78.86; H 6.15).

p-Benzoquinone and benzoylacetic ester

To a solution of zinc chloride (10 g) in anhydrous methanol (15 ml) benzoylacetic ester (3.5 g) was added and thereafter in small portions *p*-benzoquinone (2 g). The mixture was heated on a water-bath for 5.5 hours and placed in a refrigerator. After several days a small amount of a crystalline material had separated. After recrystallization from glacial acetic acid (charcoal) it was yellowish and had m. p. 163°. Due to the very small yield six of the above portions were reacted and worked up. The collected products were

recrystallized five times from glacial acetic acid (charcoal) and then had the constant m. p. of 185—186°. Very small, white needles (45 mg). (Found C 73.66; H 4.82. Calc. for $C_{28}H_{22}O_6$: C 74.00; H 4.88).

1,4-Naphthoquinone and acetylacetone

1,4-Naphthoquinone (1.5 g) and acetylacetone (2 ml) were dissolved in a solution of zinc chloride (5 g) in dry methanol (6 ml). The mixture was refluxed for 5 minutes when it solidified into a crystal mass. Isolated by suction and washed with methanol (0.90 g). Recrystallized twice from glacial acetic acid (charcoal) it had m. p. 262°. (Found: C 74.71; H 5.04. Calc. for $C_{15}H_{12}O_5$: C 74.98; H 5.03).

Dinitrophenylhydrazone. VI (0.2 g) was dissolved in boiling ethanol (25 ml) to which was added a solution of 2,4-dinitrophenylhydrazine (0.2 g) in hydrochloric acid (25 ml, 2 N). Immediately a bright red voluminous precipitate was formed. After 2.5 hours on a water-bath the separated substance was isolated (0.31 g) and recrystallized from glacial acetic acid. M. p. 271—272°. (Found: C 59.82; H 3.94; N 13.22. Calc. for $C_{31}H_{16}N_4O_6$: C 60.01; H 3.84; N 13.33).

Acetate. VI (0.5 g) and acetyl chloride (50 ml) were refluxed for 1.5 hours and the cooled solution poured into icewater (1 l) when a white substance separated. Recrystallized from dilute alcohol and from benzene. White needles. M. p. 152.5—153.5°. (Found: C 72.21; H 4.92. Calc. for $C_{17}H_{14}O_4$: C 72.33; H 5.00).

1,4-Naphthoquinone and ethyl acetoacetate

1,4-Naphthoquinone (5 g) and ethyl acetoacetate (6 ml) were added to a solution of zinc chloride (15 g) in dry methanol (25 ml). The mixture was heated on a steam-bath for 1 hour and cooled to room temperature. The separated crystals (3.5 g) were washed with methanol and recrystallized thrice from glacial acetic acid. White needles. M. p. 208—209° (Kofler bench) (Found: C 70.94; H 5.08. Calc. for $C_{16}H_{14}O_4$: C 71.06; H 5.22).

Acetate. VII (0.6 g) and acetyl chloride (50 ml) were refluxed for 3 hours and poured into ice-water (1 l). The separated, white substance was recrystallized twice from glacial acetic acid. White needles. M. p. 147—148°. (Found: C 68.89; H 5.22. Calc. for $C_{18}H_{16}O_5$: C 69.23; H 5.16).

1,4-Naphthoquinone and benzoylacetic ester

1,4-Naphthoquinone (4 g) and benzoylacetic ester (5 ml) were added to a solution of zinc chloride (25 g) in dry methanol (30 ml) and refluxed for 15 minutes when the reaction mixture solidified to a crystal mass. The crystals (4 g) were washed with methanol and recrystallized thrice from glacial acetic acid (charcoal). M. p. 194—195°. (Found: C 75.88; H 4.94. Calc. for $C_{21}H_{16}O_4$: C 75.90; H 4.85).

Acetate. VIII (0.5 g) and acetyl chloride (20 ml) were refluxed for 2 hours and poured into ice-water (1 l). The separated white substance was recrystallized twice from 80 % ethanol. White needles. M. p. 119.5—120° (Found: C 73.60; H 4.65. Calc. for $C_{23}H_{18}O_6$: C 73.79; H 4.84).

1,4-Naphthoquinone and benzoylacetone

1,4-Naphthoquinone (5 g) and benzoylacetone (7 g) were added to a solution of zinc chloride (25 g) in dry methanol (30 ml) and refluxed for 2.5 hours. After cooling the separated crystals (3.5 g) were washed with warm ethanol and recrystallized thrice from glacial acetic acid. Yellow needles. M. p. 240°, decomp. (Kofler-bench). (Found: C 79.36; H 4.68. Calc. for $C_{20}H_{14}O_3$: C 79.47; H 4.67).

Acetate. IX (0.48 g) and acetyl chloride (50 ml) were refluxed for two hours and poured into ice-water (1 l). The precipitated, white substance was recrystallized thrice from 70 % ethanol. White rhombic crystals. M. p. 144.5—146°. (Found: C 76.38; H 4.70. Calc. for $C_{22}H_{16}O_4$: C 76.70; H 4.68).

VI and phenyl magnesium bromide

The Grignard reagent was prepared from magnesium (1.6 g) and bromobenzene (10 g) in anhydrous ether (25 ml). To a suspension of VI (1 g) in anhydrous toluene (15 ml) were added dropwise 5 ml of the above reagent. The naphthofuran dissolved gradually as the reaction proceeded and to the clear solution an additional amount of dry toluene (35 ml) was added. The solution was heated to 50° for 15 minutes and decomposed with ice and sulphuric acid (20 %). Excess sulphuric acid was neutralized with sodium hydrogen carbonate when a white substance separated on the interface between the aqueous and the toluene layers. This substance was recrystallized twice from dilute alcohol and twice from dilute acetone. No definite melting point. (Found: C 78.70; H 5.79. Calc. for $C_{21}H_{18}O_3$: C 79.20; H 5.71).

IX and methyl magnesium iodide

The Grignard reagent was prepared from magnesium (1 g) and methyl iodide (6 g) in anhydrous ether (10 ml). To a suspension of IX (0.5 g) in dry toluene (15 ml) 6 ml of the reagent were added dropwise. The ensuing reaction led also in this case to a clear solution. From here the procedure was exactly as in the above experiment. The product had no definite melting point. (Found: C 78.83; H 5.81. Calc. for $C_{21}H_{18}O_3$: C 79.20; H 5.71).

The Crystal Structure of Tellurium Dibenzenethiosulphonate

PAUL ØYUM and OLAV FOSS

Institutt for teoretisk kjemi and Institutt for uorganisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The crystal structure of tellurium dibenzenethiosulphonate, $Te(S_2O_2C_6H_5)_2$, has been determined from X-ray data, by two-dimensional Patterson and Fourier methods. The crystals are orthorhombic bipyramidal; space group D_{2h}^{14}—*Pbcn*, with $a = 14.46$ Å, $b = 11.18$ Å, $c = 10.48$ Å, and four molecules per unit cell. A twofold axis of molecular symmetry is present.

The molecule contains an unbranched and non-planar S-S-Te-S-S chain, the three middle atoms of which are divalent, whereas to each of the terminal sulphur atoms are attached two oxygen atoms and a phenyl group. The values, 2.08 Å and 2.41 Å, respectively, were found for the S-S and S-Te bond lengths, and 104° and 97°, respectively, for the S-S-Te and S-Te-S bond angles. The molecule occurs in a *trans* form, with a dihedral angle of 79° between the S-S-Te and S-Te-S planes.

The unit cells and space groups of two pentathionic compounds, *viz.*, sulphur dibenzene- and di-*p*-toluenethiosulphonate, were reported by Dawson, Mathieson and Robertson [1] in 1948. The substances, which are also called *bis*-sulphonyl trisulphides, are derived from pentathionic acid by substitution of aryl groups for the hydroxyl groups. The crystals of the two compounds are isomorphous; space group D_4^4—$P4_12_12$ (or the enantiomorph) with four molecules per unit cell, and $a = 7.74$ Å, $c = 26.29$ Å for the benzenethiosulphonate, and $a = 7.70$ Å, $c = 29.50$ Å for the *p*-toluenethiosulphonate. Concerning sulphur dibenzenethiosulphonate the authors said [1 p. 327], "Patterson and Harker projections have been made, but the large number of parameters (31) renders the interpretation difficult. Further work is in progress". No further account has, as far as we know, appeared in literature.

Meanwhile, the selenium and tellurium analogues of the above compounds, *viz.*, selenium and tellurium dibenzene- and di-*p*-toluenethiosulphonate, and triselenium dibenzene- and di-*p*-toluenesulphinate, have been prepared by one of us [2,3], and the unit cells and space groups determined [3]. Of the six new compounds, four are isomorphous with sulphur dibenzene- and di-*p*-toluenethiosulphonate; the two benzene compounds, tellurium dibenzenethiosulphonate and triselenium dibenzenesulphinate, being the only ones which do not crystallize in the tetragonal space group referred to above.

The detailed structure of tellurium dibenzenethiosulphonate has now been worked out, and is reported below. The structure of the molecule, which arises from sulphur dibenzenethiosulphonate by substitution of tellurium for the middle, divalent sulphur atom of the latter, is closely analogous to that of tellurium dimethanethiosulphonate [4], and of the telluropentathionate ion in ammonium telluropentathionate [5]. The three telluropentathionic compounds

$$Te(S_2O_2CH_3)_2; \qquad (NH_4)_2Te(S_2O_3)_2; \qquad Te(S_2O_2C_6H_5)_2$$

have thereby been shown to contain unbranched and non-planar S—S—Te—S—S chains.

EXPERIMENTAL

The yellow crystals of tellurium dibenzenethiosulphonate, $Te(S_2O_2C_6H_5)_2$, are orthorhombic bipyramidal, and show the forms {111} and {100}. The latter is frequently the more predominant, thus giving the crystals the appearance of plates. The axial lengths are [3], $a = 14.46 \pm 0.04$ Å, $b = 11.18 \pm 0.02$ Å, $c = 10.48 \pm 0.02$ Å. There are four molecules per unit cell; density, calc. 1.86, found 1.88 g/cm^3. Systematic absences, $hk0$ when $h + k$ is odd, $h0l$ when l is odd, $0kl$ when k is odd. The space group is therefore uniquely determined as D_{2h}^{14}—*Pbcn*.

The intensities of the $h0l$ and $hk0$ reflections were read visually from Weissenberg photographs about the b and c axes. Unfiltered CuK radiation (α wave-length, 1.54 Å) was used, and crystals having cross-sections of 0.04 × 0.08 mm and 0.07 × 0.08 mm, respectively, in the case of the b and c axis photographs. There are 101 $h0l$ and 114 $hk0$ reflections accessible with Cu$K\alpha$ radiation; of these, 76 and 94, respectively, were recorded on the films with measurable intensities, with values ranging from about thousand to one. The intensities were corrected for the Lorentz and polarization factors, and were converted to relative structure amplitudes, which were eventually put to an approximately absolute scale by comparison with the calculated structure factors. No corrections for absorption were made.

The crystals used for the X-ray photographs had been prepared two years earlier [3], and were still unchanged. On exposure to X-rays, a slight liberation of tellurium took place, which, however, did not appear to affect the intensities of the reflections to any observable degree.

The Patterson and Fourier summations were made at 6° intervals by means of Beevers-Lipson strips.

ANALYSIS OF THE STRUCTURE

The space group, D_{2h}^{14}-*Pbcn*, has eightfold general positions, and the four molecules in the unit cell must accordingly lie in special positions, of which there are three fourfold sets, two having a centre and one a twofold axis of symmetry. Since the molecule cannot reasonably have a centre of symmetry, it must possess a twofold axis, which passes through the tellurium atoms in the positions:

$$0,\ y,\ \tfrac{1}{4};\quad 0,\ \bar{y},\ \tfrac{3}{4};\quad \tfrac{1}{2},\ \tfrac{1}{2}+y,\ \tfrac{1}{4};\quad \tfrac{1}{2},\ \tfrac{1}{2}-y,\ \tfrac{3}{4}.$$

Although the x and z coordinates of tellurium are thus fixed, at $x = 0$, $z = \frac{1}{4}$, a direct solution of the projection along the b axis is not possible, since the tellurium atom does not contribute to $h0l$ reflections having odd h indices.

As the first steps, Patterson and Fourier maps, based on $h0l$ data with even values of h only, and Fourier signs corresponding to the tellurium contributions alone, were prepared. Both maps have mirror planes normal to the

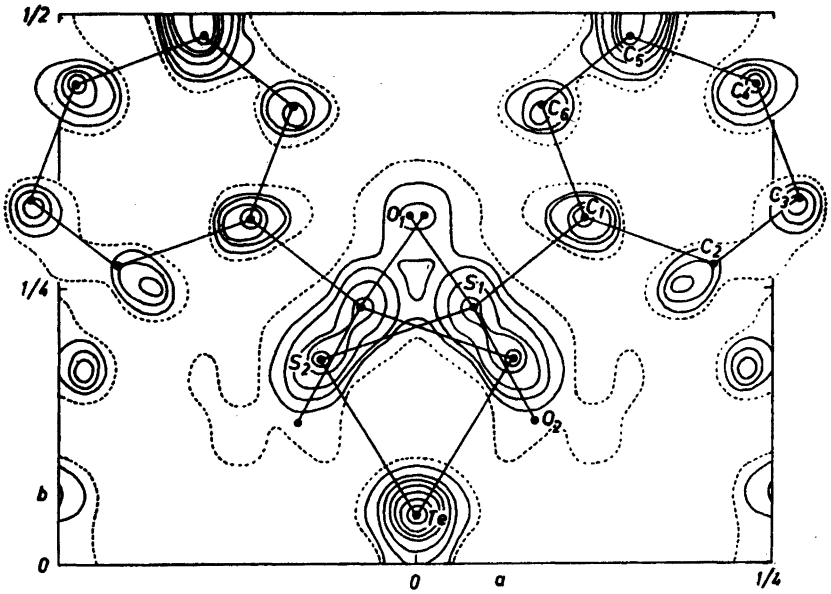

Fig. 1. Electron density projection of $Te(S_2O_2C_6H_5)_2$ *along the c axis, showing two asymmetric units. Contour lines are at intervals of 1 e·Å^{-2} for carbon atoms, 5 e·Å^{-2} for sulphur and oxygen atoms and 15 e·Å^{-2} for the tellurium atom, starting with 6, 10 and 15 e·Å^{-2}, respectively. The 5-electron line is dashed.*

a axis at $x = \frac{1}{4}$, due to the omission of the odd *h* data. The signs used in the Fourier summation were later found to be correct, but for a single reflection, 202. Peaks due to the two sulphur atoms of the asymmetric unit appeared in both maps, and allowed approximate coordinates to be determined for these atoms. The *z* coordinate of S_1 turned out to be equal to or close to $\frac{1}{2}$. With this *z* value, S_1 does not contribute, or contributes very little, to *h*0*l* reflections with *h* odd. Signs of most of the latter reflections were then calculated on the basis of the S_2 contributions alone, and these data when included in the Fourier summation served to remove the false symmetry elements and show S_1 a little displaced from $z = \frac{1}{2}$. The oxygen and carbon positions were uncertain, however, and further work on this projection was not made until the *c* axis projection had been worked out.

In the Patterson projection along the *c* axis, the Te-Te vector at $u = 0$, $v = 2y$ was found to lie close to $v = 0$, and the centre was located through graphical removal of the origin peak, its curvature along $u = 0$ being taken to be the same as along $v = 0$. The *y* coordinate of tellurium, 0.043, found in this way is the same as the final value. In the first Fourier synthesis of the *hk*0 data, signs were calculated from the tellurium contributions alone, and 79 out of the 94 observed terms were included; of these, only one sign was later found to be wrong. Although considerable overlapping of sulphur and oxygen atoms occurs, the resulting map allowed trial coordinates for these atoms to

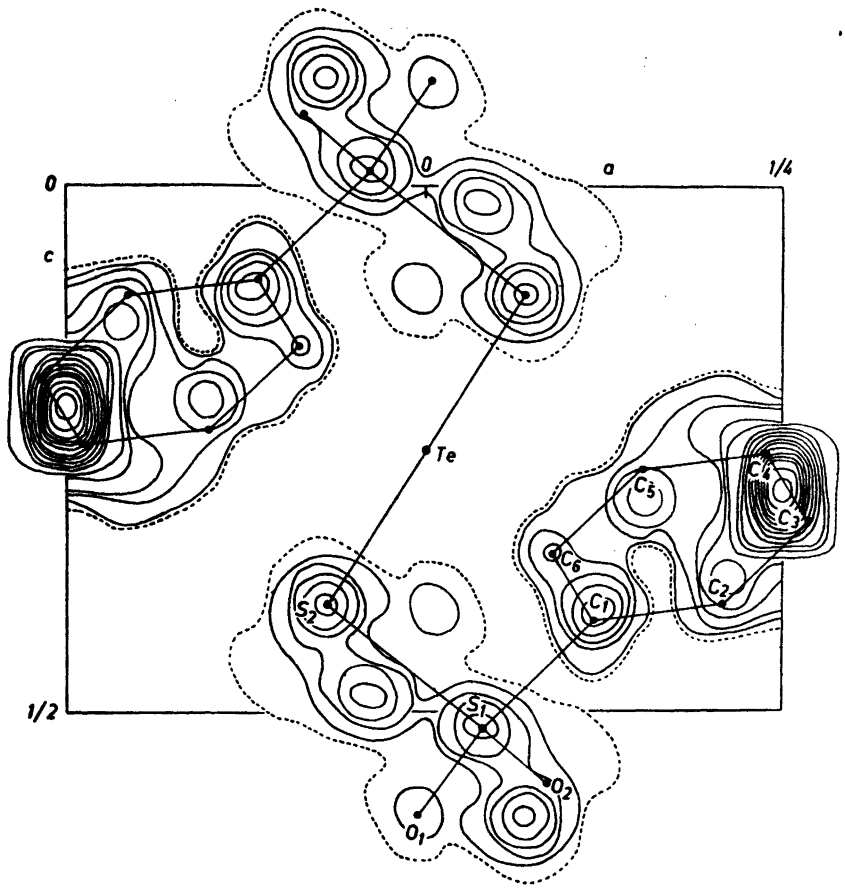

Fig. 2. Electron density projection of $Te(S_2O_2C_6H_5)_2$ *along the* b *axis, with the tellurium atom removed. Two asymmetric units are shown. Contour lines as in Fig. 1.*

be determined and used to calculate signs of the remaining *hk*0 reflections. In the next Fourier map, the benzene ring was recognizable, and the projection was then refined through successive approximations in the usual way.

With the x coordinates of the oxygen and carbon atoms thus known, work on the *h*0*l* data was resumed, and refinement of the b axis projection successfully carried out. In this projection, where the tellurium coordinates are known exactly, the heavy atom diffraction effects were studied through removal of the tellurium peak, by subtracting the calculated, temperature-corrected tellurium contributions from the scaled, observed *h*0*l* structure factors. This procedure needs to be carried out for reflections with even h indices only. The resulting difference map showed better resolved C_6 and O_1 peaks, and lead to an adjustment of the O_1 coordinates which changed the S_1—O_1 distance from 1.39 Å to 1.44 Å and gave a more reasonable value for the $S_2S_1O_1$ angle.

The *hk*0 Fourier map, and the *h*0*l* Fourier map with the tellurium peak removed as described above, are reproduced in Figs. 1 and 2, respectively. The atomic positions are marked with dots, and lines are drawn to show the outline of the molecule.

In both projections, the coordinates of the carbon atoms were adjusted so as to give the best fit with the observed structure factors on the basis of positions defining the corners of a regular hexagon with edges of 1.39 Å, and a linear arrangement of the S_1, C_1 and C_4 atoms.

The position of the tellurium peak in the *c* axis projection corresponds to a tellurium *y* coordinate of 0.046. This coordinate gives a Te-S_2 distance of 2.39 Å and a S_2TeS_2' angle of 99°. It was found, however, that the value, $y = 0.043$, derived from the Patterson map gave a better agreement between observed and calculated *hk*0 structure factors. The displacement of the tellurium peak may be due to diffraction effects, produced by the equivalent atom on the other side of the glide plane *c* at $y = 0$.

Table 1. Atomic coordinates for tellurium dibenzenethiosulphonate, in fractions of cell edges. Origin at a centre of symmetry.

	x	*y*	*z*		*x*	*y*	*z*
Te	0	0.043	0.250	C_1	0.117	0.312	0.413
S_2	−0.068	0.186	0.395	C_2	0.207	0.271	0.396
S_1	0.041	0.233	0.514	C_3	0.268	0.316	0.316
O_1	−0.006	0.316	0.598	C_4	0.238	0.435	0.253
O_2	0.083	0.139	0.566	C_5	0.148	0.476	0.270
				C_6	0.087	0.414	0.349

The final atomic coordinates are listed in Table 1. In Table 4, observed and calculated values of structure factors are compared for all *h*0*l* and *hk*0 reflections within the range of Cu*Kα* radiation. The calculated values are based on the coordinates of Table 1, and the atomic scattering curves of the *International Tables*, with a temperature factor of $B = 2.38$ Å^2 for both zones. The hydrogen atoms of the phenyl group have been ignored. The reliability factor, $R = \Sigma||F_{obs}| - |F_{calc}||/\Sigma|F_{obs}|$, with non-observed reflections included in the difference only when $|F_{calc}|$ in greater than the lowest observable value of $|F_{obs}|$, is 0.157 and 0.172, respectively, for the *h*0*l* and *hk*0 reflections. The largest discrepancy occurs for F_{200}, the observed and calculated values of which are 237 and 352, respectively. This reflection is the strongest one, and is probably subject to extinction. If F_{200} is not included, the *R* values drop to 0.142 and 0.160, respectively, for the two zones.

THE TELLURIUM DIBENZENETHIOSULPHONATE MOLECULE

The present structure is the third to be reported for a telluropentathionic compound, the two earlier ones being those of the methane analogue, tellurium dimethanethiosulphonate [4], and of ammonium telluropentathionate [5]. The compounds are built up of S—S—Te—S—S chains, with the three middle atoms in the divalent state, whereas to each of the terminal sulphur atoms are attached three oxygen atoms, or in the case of the thiosulphonates, two oxygen

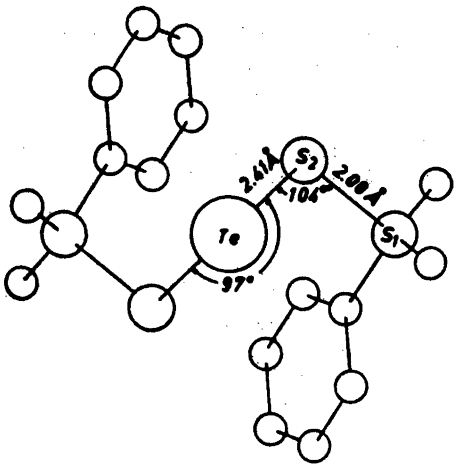

Fig. 3. The tellurium dibenzenethiosulphonate molecule as seen along the twofold axis, showing some bond lengths and angles.

atoms and a methyl or a phenyl group. The chains are non-planar, the terminal sulphur atoms being rotated out of the plane of the three middle atoms, to opposite sides of the plane. This is the *trans* configuration [6] of pentathionic compounds; the *cis* configuration [6], where the terminal atoms are located on the same side of the plane of the three middle atoms, has been found in the crystals of barium pentathionate [7] and selenopentathionate [8] dihydrate.

The shape of the tellurium dibenzenethiosulphonate molecule will appear from the electron density maps of Figs. 1 and 2, which also show the numbering of atoms, and from the line drawing of one isolated molecule in Fig. 3. The principal bond lengths and angles, calculated on the basis of the coordinates of Table 1, are given in Table 2, together with non-bonded Te—S and S—S distances within the molecule. The molecule possesses an exact twofold axis of symmetry, and a prime is used, when relevant, to denote the equivalent of an atom produced by the operation of the twofold axis. In Table 2, data for

tellurium dimethanethiosulphonate [4] and ammonium telluropentathionate [5] are included for comparison; the latter compounds possess no exact molecular symmetry element in the crystals studied, and the two figures listed for these where one only occurs for the benzenethiosulphonate, refer to the two, here not quite identical halves.

The three structure determinations are probably about equally accurate, with probable errors of about 0.03—0.04 Å for Te—S and S—S distances, and 2—3° for bond angles involving these atoms. It appears that the only differences in dimensions which can be considered significant, are the larger dihedral angles in ammonium telluropentathionate, and the correspondingly larger $S_1—S_2'$ and $S_1—S_1'$ non-bonded distances. These distances, and the dihedral angles, are dependent on rotations about the Te—S bonds, and may vary without change of Te—S and S—S bond lengths and angles.

The benzenesulphonyl groups, data for which are given in Table 3, have dimensions very like those found for the same group in sulphur dibenzenesulphinate [9] and selenium dibenzenesulphinate [10].

Table 3. Dimensions of the benzenesulphonyl groups.

Bond lengths and bond angles.

$S_1—O_1 = 1.44$ Å	$\angle S_2S_1O_1 = 100°$	$\angle O_1S_1O_2 = 120°$
$S_1—O_2 = 1.43$ Å	$\angle S_2S_1O_2 = 110°$	$\angle O_1S_1C_1 = 106°$
$S_1—C_1 = 1.77$ Å	$\angle S_2S_1C_1 = 104°$	$\angle O_2S_1C_1 = 111°$

Non-bonded distances (in Å units).

$O_1—O_2 = 2.49$	$S_2—O_1 = 2.73$
$O_1—C_1 = 2.57$	$S_2—O_2 = 2.90$
$O_2—C_1 = 2.65$	$S_2—C_1 = 3.03$

As mentioned above, the benzene ring has been assumed to be a regular hexagon with C—C bond lengths of 1.39 Å, and with a linear arrangement of the S_1, C_1 and C_4 atoms. Within the benzenesulphonyl group, the shortest oxygen-carbon approaches are $O_2—C_2 = 2.99$ Å and $O_1—C_6 = 3.13$ Å. The

plane of the benzene ring and S_1 makes angles of 5°, 121° and 251°, respectively, with the $O_2S_1C_1$, $S_2S_1C_1$ and $O_1S_1C_1$ planes.

There are no particularly short intermolecular approaches in the crystals; *e. g.*, the shortest Te—S distance of this kind is 4.00 Å and occurs between Te and S_1 atoms.

THE TETRAGONAL ANALOGUES

In the tetragonal crystals of sulphur [1] and selenium [3] dibenzenethiosulphonate, and sulphur [1], selenium and tellurium di-*p*-toluenethiosulphonate and triselenium di-*p*-toluenesulphinate [3], of space group D_4^4—$P4_12_12$ (or the enantiomorph) with four molecules per unit cell, a twofold axis of molecular symmetry is required, as in orthorhombic tellurium dibenzenethiosulphonate. As shown in a note [11] following the preliminary report on the present structure [12], the similarities extend further, there being a close correspondence between the *b* and *c* axis projections of the orthorhombic structure and the *b* axis projection of the tetragonal structure in the centered setting, $C4_122_1$. In fact, the structure of tetragonal tellurium di-*p*-toluenethiosulphonate was solved by means of direct reference to the *b* and *c* axis projections of the orthorhombic benzene analogue. The dimensions found for the S-S-Te-S-S chain of the *p*-toluenethiosulphonate [11] agree well with those reported here for the benzenethiosulphonate.

The Crystal Structure of Triclinic Barium Pentathionate Dihydrate

OLAV FOSS and OLAV TJOMSLAND

Institutt for uorganisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The unit cell of triclinic barium pentathionate dihydrate has the dimensions, $a = 5.00$ Å, $b = 10.36$ Å, $c = 11.53$ Å, $\alpha = 109°$, $\beta = 97°$, $\gamma = 90°$. The space group is $C_i^1-P\bar{1}$ with $Z = 2$. Fourier projections along the a and b axes show that the pentathionate ion has an unbranched, *cis* configuration, with $S_1-S_2 = 2.13$ Å, $S_2-S_3 = 2.04$ Å, $S_3-S_4 = 2.04$ Å, $S_4-S_5 = 2.11$ Å (all $\pm$ 0.04 Å), $\angle S_1S_2S_3 = 106°$, $\angle S_2S_3S_4 = 107°$, $\angle S_3S_4S_5 = 105°$ (all $\pm$ 3°), and the dihedral angles, $S_1S_2S_3/S_2S_3S_4 = 108°$ and $S_2S_3S_4/S_3S_4S_5 = 107°$. These values agree within the experimental errors with those found earlier for the orthorhombic dimorph.

The crystals of triclinic and orthorhombic barium pentathionate dihydrate are composed of layers which have the same internal structure in both dimorphs, but are differently arranged relative to each other.

A study of the crystal chemistry of barium salts of pentathionic, selenopentathionic and telluropentathionic acids has recently led to the structure determination of the isomorphous salts, barium pentathionate [1] and selenopentathionate [2] dihydrates. The orthorhombic crystals have four-molecule unit cells based on the space group, $D_{2h}^{16}-Pnma$, with $a = 5.00$ Å, $b = 10.30$ Å, $c = 21.78$ Å for the pentathionate. No orthorhombic dihydrate of barium telluropentathionate has been found, although two dihydrates, one monoclinic and one triclinic, have been characterized and will be described later.

As mentioned earlier [3], a triclinic dimorph of barium pentathionate dihydrate exists. The unit cell dimensions, from oscillation and Weissenberg photographs taken with copper radiation, $\lambda(\mathrm{Cu}K\alpha) = 1.54$ Å, are [3]

$a = 5.00$ Å,	$b = 10.36$ Å,	$c = 11.53$ Å
$\alpha = 109°$	$\beta = 97°$	$\gamma = 90°$

There are two molecules per unit cell, and the space group is the centrosymmetric one, $C_i^1-P\bar{1}$.

It is seen that within the experimental accuracy ($\pm$ 0.5 %) the lengths of the a and b axes of the triclinic and orthorhombic dimorphs are the same, as are also the γ angles. The spacing of the triclinic c plane, $d_{001} = 10.78$ Å,

is close to half the orthorhombic c axis, 10.89 Å. Both dimorphs exhibit perfect cleavage along the c plane, and appear as prisms, elongated along the a axis and with {001} predominant.

In the orthorhombic space group, $00l$ reflections are systematically absent for odd values of l and as many are thus present as in the triclinic crystals. The intensities of the $00l$ reflections of the two dimorphs, with the orthorhombic l indices halved, are very similar. The one-dimensional projections on to a line perpendicular to the c planes of the two unit cells should thus be the same, and the common features noted above indicate further structural similarities.

A preliminary report on the structure of the triclinic crystals has been published [4], giving atomic coordinates and principal bond lengths and angles *.

Barium salts of pentathionic acid were apparently the first salts of the acid to be isolated, over a century ago. Lenoir [5] prepared a barium pentathionate in 1847, one year after the discovery of the acid by Wackenroder [6]. Lenoir crystallized the salt from aqueous solutions containing ethanol, and although he noted that the salt contained ethanol, he described it as a dihydrate. Fordos and Gélis [7], in 1848, stated that the salt always retains some ethanol when precipitated from water by means of ethanol, and said that the best method for the isolation of an ethanol-free salt, a dihydrate, was to crystallize from water by addition of ether containing some ethanol. Lewes [8], in 1881, isolated barium pentathionate without the use of ethanol, but gave the composition as that of a trihydrate, the same water content as he erroneously gave for barium tetrathionate. Debus [9], of the same laboratory as Lewes, in 1888 referred to Lewes' barium pentathionate as but 'nearly pure'. In 1933, Deines and Christoph [10] in a footnote reported on the isolation of barium polythionates, presumably also the pentathionate, from aqueous solutions by addition of ethanol or acetone, but did not give the compositions.

The present authors have isolated trihydrates of barium selenopentathionate and telluropentathionate, but of barium pentathionate, only dihydrates.

Of the earlier authors cited above, it appears that only Fordos and Gélis may have obtained a pure dihydrate. It will be shown later that several organic solvents, among them ethanol and acetone, give solvates when used for the crystallization of barium pentathionate. Lenoir, and Deines and Christoph, probably obtained solvates, and not pure hydrates.

EXPERIMENTAL

The barium pentathionate dihydrates were prepared as follows. A crude salt was obtained by mixing, at a temperature not above 40° C, saturated solutions of potassium pentathionate and a slight excess of barium perchlorate, filtering off the precipitated potassium perchlorate, and addition of ethanol and cooling. The crude preparation, which contained ethanol, was stable for months.

The triclinic dihydrate resulted when an aqueous solution of the crude product, saturated at 40—50° C, was allowed to cool to room or ice temperature. The orthorhombic dihydrate was obtained by addition of methanol to an aqueous solution saturated at 20—30° C. About 0.2 N hydrochloric acid, instead of pure water, was used to dissolve the pentathionates.

No study of the relative stabilities of the dimorphs at various conditions has been made. When pure, they both remain unchanged for months, and appear to be about equally stable.

The salts were analyzed iodometrically by means of the sulphite method [11]. In order to remove the barium as sulphate, so as to prevent the precipitation of barium sulphite which would interfere in the titration with iodine, some sodium sulphate was added to

* In that report [3] and the earlier one [4], values for the α and β angles, respectively, were given which are larger than the present ones, believed to be more correct, by one degree. The change of β from 98° to 97° has led to bond lengths and angles which in a few cases differ slightly from those given in the preliminary report.

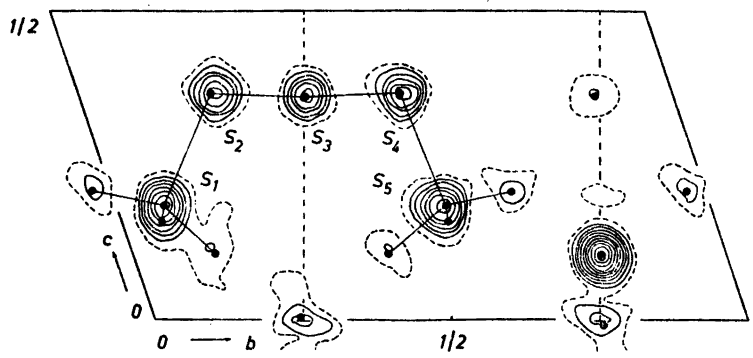

Fig. 1. Electron density projection of triclinic $BaS(S_2O_3)_2 \cdot 2H_2O$ along the a axis. The atomic positions are marked with dots, and lines are drawn to show the outline of the pentathionate ion. The 5-electron line is dashed. Contour intervals: 10 e·Å^{-2} for the barium ion, and 4 e·Å^{-2} for sulphur and oxygen atoms and water molecules.

the barium pentathionate solution before the addition of sodium sulphite reagent. One mole of pentathionate reacts with sulphite to produce two moles of thiosulphate, which is titrated with iodine after masking of excess of sulphite by means of formaldehyde.

Since analytical data have not been included in earlier communications on the salts [1,3], analyses of both modifications are reported here.

Orthorhombic dihydrate. 0.2839 × $\frac{1}{5}$ g substance: 26.20 ml of 0.01010 N iodine.

Triclinic dihydrate. 0.2719 × $\frac{1}{5}$ g substance: 24.88 ml of 0.01019 N iodine.

$BaS(S_2O_3)_2 \cdot 2H_2O$ (429.7) Mol. weights found, 429.2 and 429.0, respectively.

Absence of tetrathionate was checked through control analyses by means of the cyanide method.

The intensities of the 0*kl* and *h*0*l* reflections of triclinic barium pentathionate dihydrate were estimated visually from zero layer Weissenberg photographs taken with copper radiation. Small crystals were used in order to minimize absorption, for which no correction was made. The ready cleavage along the *c* plane made it difficult to cut the crystals for photographs about the *b* axis, and as in the case of the orthorhombic structure [1], the observed intensities of the *h*0*l* reflections are therefore probably less reliable than those of the 0*kl* reflections. The intensities were corrected for the Lorentz and polarization factors, and converted into relative structure factors. They were later put to an approximately absolute scale through comparison with the calculated values.

Patterson and Fourier projections along the *a* and *b* axes were made. The summations were performed by means of Beevers-Lipson strips, the Patterson and first Fourier summations at 12° intervals along the axes, and the final Fourier refinements by summations at 6° intervals along the two longest axes. No great accuracy in bond lengths and angles was aimed at, the chief objective being to establish the relation of the structure to that of the orthorhombic dihydrate.

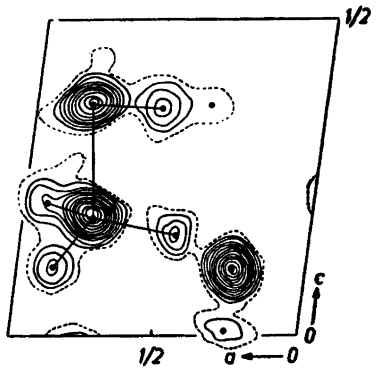

Fig. 2. Electron density projection of triclinic $BaS(S_2O_3)_2 \cdot 2H_2O$ along the b *axis. The 8-electron line is dashed. Contour intervals: 8 e·Å^{-2} for the barium ion, otherwise as in Fig. 1.*

DETERMINATION OF THE STRUCTURE

The 0*kl* Patterson map was prepared first, early in 1953, and on the basis of the barium y and z coordinates derived from the map, signs were calculated and used in a Fourier synthesis of 185 of the 265 observed 0*kl* reflections. The resulting map revealed the positions of the sulphur atoms, in accordance with the barium-sulphur vectors of the Patterson map, and also some of the oxygen atoms. At that phase of the work, attention was shifted from the triclinic to the orthorhombic dihydrate, the latter having a more favourable space group, and work on the former was resumed two years later, with Fourier refinement of the 0*kl* projection through successive approximations in the usual way.

The projection along the b axis was also solved by means of the heavy atom technique, using for the first sign calculation the already known z coordinate of barium and the x coordinate derived from the $h0l$ Patterson map. As was expected from the a axis projection and the orthorhombic structure, sets of two sulphur atoms and three oxygen atoms were found to overlap, having within the experimental accuracy the same x and z coordinates.

The electron density maps are shown in Figs. 1 and 2. The final atomic positions are marked with dots, and lines are drawn to show the sulphur-sulphur and sulphur-oxygen bonds. The coordinates of the positions, in fractions of cell edges and referring to the triclinic axes, are listed in Table 1.

Orthogonal coordinates, in Å, are given in Table 2 under the heading $P\bar{1}$. They refer to the same origin as in Table 1 and to the a, b and c' axes, where, since $\gamma = 90°$, c' is chosen normal to a and b. The coordinates listed in Table 2 under the heading *Pnma*, are those found in the orthorhombic dihydrate, cal-

In Table 4, observed and calculated values of structure factors are compared for all 0*kl* and *h*0*l* reflections within the range of Cu$K\alpha$ radiation. The calculated values are based on the coordinates of Table 1, and the atomic scattering curves of the *International Tables*, with the xenon curve for the barium ion, and a temperature factor of $B = 2.2$ Å^2 for both zones. The reliability factor, $R = \Sigma \| F_{obs} | - | F_{calc} \| / \Sigma | F_{obs} |$, with non-observed reflections included only when $| F_{calc} |$ is greater than the smallest observable value of $| F_{obs} |$, is 0.18 for the 0*kl* and 0.19 for the *h*0*l* reflections.

DISCUSSION

The average differences between the atomic coordinates of the triclinic and orthorhombic structures, as listed in Table 2, are 0.01 Å for the barium ion, 0.03 Å for the five sulphur atoms, 0.07 Å for the six sulphonate oxygen atoms, and 0.16 Å for the two water oxygen atoms. These differences are considered to be within the probable errors of the two structure determinations.

It follows that the configuration of the pentathionate ion in the triclinic crystals is the same as in the orthorhombic ones, and within the probable errors this applies also to the dimensions. The sulphur chain is unbranched and occurs in a *cis* form. The sulphur-sulphur bond lengths given in Table 3, and angles involving these atoms, are considered to be correct to within 0.04 Å and 3°, respectively.

Table 3. Sulphur-sulphur bond lengths and angles.

$S_1-S_2 = 2.13$ Å	$\angle S_1S_2S_3 = 106°$	$S_4-S_5 = 2.11$ Å
$S_2-S_3 = 2.04$	$\angle S_2S_3S_4 = 107°$	$S_3-S_4 = 2.04$
	$\angle S_3S_4S_5 = 105°$	

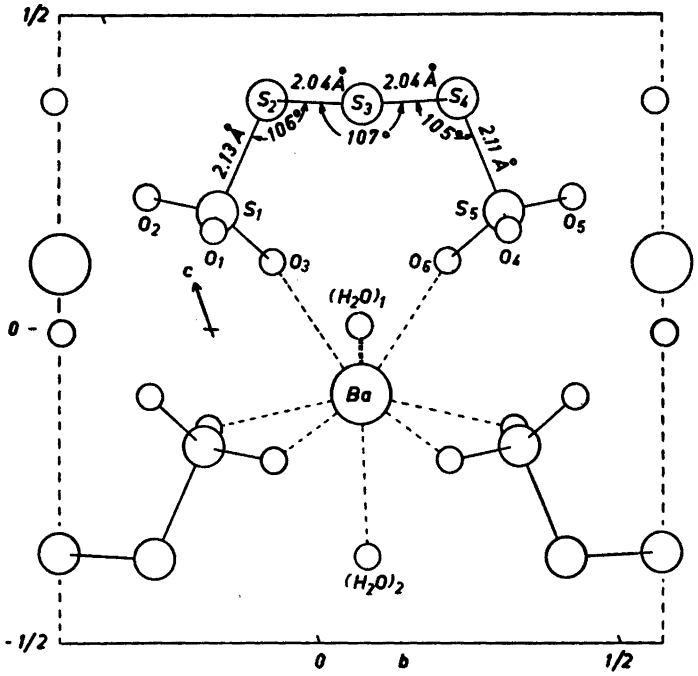

Fig. 3. Arrangement of the ions as seen along the a axis. Origin at the midpoint of the left half of the figure.

The dihedral angles, $S_1S_2S_3/S_2S_3S_4$ and $S_2S_3S_4/S_3S_4S_5$, are 108° and 107°, respectively. The corresponding data for the orthorhombic structure are [1], $S_1-S_2 = S_4-S_5 = 2.14$ Å, $S_2-S_3 = S_3-S_4 = 2.04$ Å, $\angle S_1S_2S_3 = \angle S_3S_4S_5 = 103°$, $\angle S_2S_3S_4 = 106°$, and the dihedral angles, 110°.

The six sulphur-oxygen bonds of the sulphonate groups have an average length of 1.46 ± 0.01 Å. The electron density peaks of the oxygen atoms are rather low and diffuse, and the oxygen atoms were moved within the peaks to give reasonable and uniform S—O distances.

Each barium ion is surrounded by nine oxygen atoms, of which six are sulphonate oxygen atoms and three are water oxygen atoms. The average distance to barium for these nine atoms is 2.78 Å in both dimorphs. The water molecule, $(H_2O)_1$, is coordinated to two barium ions, at distances of 2.89 Å and 2.66 Å, and forms hydrogen bonds to the oxygen atoms O_1 and O_4, at distances of 3.04 Å and 3.15 Å and an angle of 108°.

In the orthorhombic space group, the barium ion and the middle sulphur atom of the pentathionate chain, as well as the two water oxygen atoms, lie in a mirror plane of symmetry. Although the triclinic space group possesses no crystallographic mirror plane of symmetry, an apparent mirror plane is present. From the Fourier maps, and the orthogonal coordinates of Table 2, is seen that the asymmetric unit possesses mirror plane symmetry within the

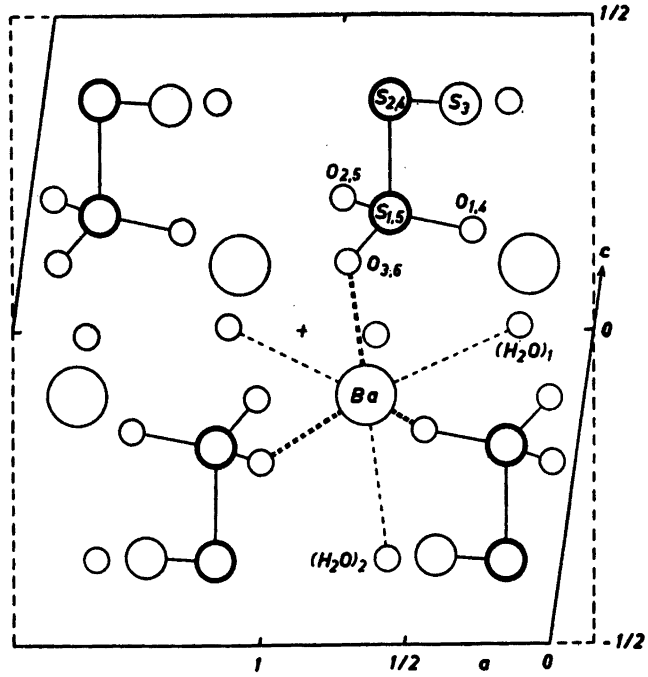

Fig. 4. Arrangement of the ions as seen along the b *axis.*

experimental error. The mirror plane, depicted through broken lines in Fig. 1, is normal to the b axis at $z = 0$, $y = \frac{1}{4}$ and $\frac{3}{4}$, as in the orthorhombic space group, and passes through the same atoms.

The similarity of atomic arrangement in the triclinic and orthorhombic dimorphs extends to within the boundaries of layers parallel to the c planes. The centres of symmetry which have been chosen as the origins of the coordinate systems are located in the middle of a layer, the thickness of which is equal to the triclinic c spacing, $d_{001} = 10.78$ Å, and half the orthorhombic c axis, $c/2 = 10.89$ Å. The line diagrams of Figs. 3 and 4, with boundaries at $z = \frac{1}{2}$ and $-\frac{1}{2}$, cover the thickness of one layer. The similarity of structure within a layer is apparent from a comparison of these diagrams with the corresponding ones for the orthorhombic structure [1].

The triclinic and orthorhombic dimorphs differ in the way in which the layers are arranged relative to each other. In the space group, D_{2h}^{16}-*Pnma*, layers are related to each other through glide planes a in their interface, at $z = \frac{1}{4}$ and $-\frac{1}{4}$, whereas in the space group C_i^1—$P\bar{1}$, the layers are related through symmetry centres in the interface. Since the layer thickness equals the triclinic c spacing, and the α and β angles are different from 90°, the symmetry centres operate to produce a simple repetition of layers, with successive relative displacements in the directions of the a and b axes. A transition from the orthorhombic to the triclinic structure, or *vice versa*, requires a rotation of

180° of every second layer about an axis normal to the *c* plane, as well as displacements of layers along the *a* and *b* axes.

In both structures, weak van der Waals contacts only, between sulphur atoms, occur across the layer interfaces, and account for the ready cleavage of the crystals along the *c* plane. The different arrangements of layers lead to different sulphur-sulphur approaches, but the distances of the closest ones are practically the same, *viz.*, 3.61 Å and 3.78 Å in the orthorhombic and 3.51 Å, 3.57 Å, 3.73 Å and 3.74 Å in the triclinic structure.

The work has been aided by grants from *Norges Almenvitenskapelige Forskningsråd* and from *Norges Tekniske Høgskoles Fond.*

On the Hydrolysis of Trialkylphenoxysilanes

EVERT ÅKERMAN

Department of Organic Chemistry, University of Lund, Lund, Sweden

The acid and base catalysed hydrolysis of $R_3SiOC_6H_5$ in aqueous ethanol has been studied for R = methyl, ethyl, *n*-propyl, *n*-butyl and *n*-amyl. The specific rate of reaction follows the equation

$$k = k_a\ [H^+] + k_{sp} + k_b\ [\text{base}]$$

k_a being the catalytic constant for hydrogen ions, k_b that for a mixture of hydroxyl and ethoxide ions, k_{sp} the specific rate of the spontaneous hydrolysis, and [base] the sum of hydroxyl and ethoxide ion concentrations. The first two members are negligible in alkaline solution and the last two members in acid solution. The rate of reaction diminishes with increasing length of the alkyl groups.

Kinetic investigations of the hydrolysis of silanes of the type R_3SiX where R is an alkyl or aryl group and X is a hydrolysable functional group are scarce. Swain, Esteve and Jones [1] found the rate of hydrolysis of triphenylsilylfluoride in 50 % water, 50 % acetone to be proportional to the concentration of silane and that it is not influenced by hydrogen ions but accelerated by hydroxyl ions. From the influence of solvent, neutral salts and substituents they deduced that the hydrolysis possibly proceeded through a pentacovalent silicon intermediate. Krieble and Burkhard [2] found that the acid hydrolysis of dimethyldi-D-2-butoxysilane gave 2-butanol with the same optical activity as the original 2-butanol. This fact indicates that the silicon-oxygen bond is broken and not the carbon-oxygen bond.

As a part of the work in this laboratory five trialkylphenoxysilanes $R_3SiOC_6H_5$ with R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, and *n*-C_5H_{11} have been investigated. The rate of hydrolysis of such compounds can be easily determined spectrophotometrically. In aqueous ethanol with water in great excess over the silane this is hydrolysed according to the formula

$$R_3SiOC_6H_5 + H_2O \rightarrow R_3SiOH + C_6H_5OH$$

in some cases followed by formation of hexaalkyldisiloxanes and in alkaline solutions by the reaction

$$C_6H_5OH + OH^- \rightleftharpoons C_6H_5O^- + H_2O$$

The phenol was identified from its ultraviolet spectrum. Trialkylsilanes and phenol — and the phenolate ion in alkaline solutions — absorb in the ultraviolet region, but the absorption maximum of the silanes is displaced by *ca.* 5 mμ from that of phenol, and the extinction coefficient at the maximum is only half that of phenol. Fig. 1 shows the absorption spectra of phenol, phenolate and trimethylphenoxysilane. The spectra of the other four alkylphenoxysilanes are very similar to that of trimethylphenoxysilane. Trialkylsilanol and hexaalkyldisiloxane do not absorb in this spectral region. The hydrolysis was carried out in water-ethanol mixture, (51.4 weight-% ethanol), since the silanes are insoluble in water, but with water in great excess, thus making the water concentration constant during the run. From the optical density D of the sample the expression log $(D_\infty - D_t)$ was calculated, where D_t is the optical density at the time t and D_∞ is the optical density at infinite time. This expression, when plotted against time, gives a straight line (Fig. 2 shows some typical plots). The reaction is consequently of the first order in silane, following the rate equation

$$k = \frac{1}{t} \log \frac{D_\infty - D_0}{D_\infty - D_t} \qquad (1)$$

D_0 being the optical density at $t = 0$.

The hydrolysis was carried out in diluted HCl or NaOH or buffers of various composition. In the last-mentioned case the concentration of hydrogen and hydroxyl ions was measured electrometrically. In a water-ethanol solution of sodium hydroxide the anions are present partly as ethoxide ions and the

catalytic effect of hydroxyl *and* ethoxide ions is measured. The equilibrium constant for the reaction

$$OH^- + C_2H_5OH \quad \rightleftharpoons \quad H_2O + C_2H_5O^- \qquad (2)$$

has been determined by Caldin and Long [3]. Their values show that in 53 weight-% ethanol at 25° C about 17 % of added hydroxide is converted to ethoxide. If k_{OH} and k_{OEt} are the catalytic constants for hydroxide and ethoxide ions, the rate constant k of the reaction is supposed to be

$$k = k_{OH}\,[OH^-] + k_{OEt}\,[C_2H_5O^-]$$

For stoichiometric reasons the following equation is valid for solutions where the concentration of phenolate ion is negligible.

$$[Na^+] = [OH^-] + [C_2H_5O^-]$$

From equation (2) follows, as ionic strength, solvent and concentrations of water and ethanol are constant,

$$[C_2H_5O^-] = K\,[OH^-]$$

From these three equations follows

$$k = [Na^+]\frac{k_{OH} + Kk_{OEt}}{1 + K} = [Na^+]\,k'$$

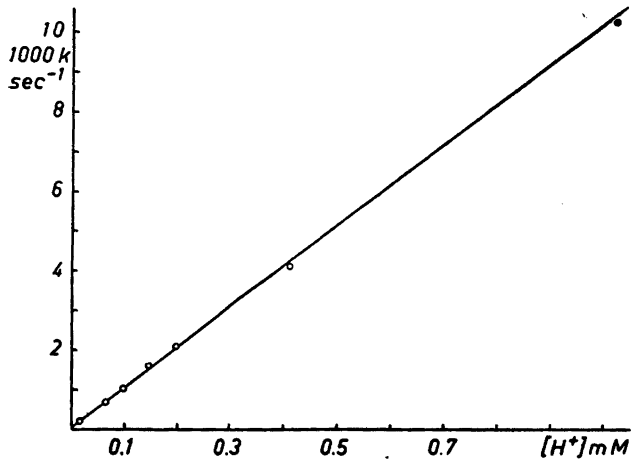

Fig. 3. Acid hydrolysis of trimethylphenoxysilane. Rate constant vs *hydrogen ion concentration.*
○ *: in glycine-HCl buffer.*
● *: in dil. HCl.*

Thus the rate constant of the reaction is proportional to the amount of added sodium hydroxide, *i.e.*, [base].

The values k_a and k_b were calculated (Tables 1, 2) and are found to be constant for each compound. The hydrolysis of trimethylphenoxysilane is very rapid. Fig. 3 shows its acid hydrolysis and the slope of the line is $k_a = 10.4\ M^{-1}\ sec^{-1}$. The alkaline hydrolysis of trimethylphenoxysilane is still more rapid and more complicated. The results obtained from reactions in glycine-NaOH buffers show that the ratio $\frac{k}{[OH^-]}$ is highly dependent on the buffer concentration, but still the reaction seems to be of the first order in hydroxyl ions with $k_b \approx 330\ M^{-1}\ sec^{-1}$. Three runs at the neutral point in a Na_2HPO_4-NaH_2PO_4 buffer seem to indicate a very slow spontaneous hydrolysis of trimethylphenoxysilane with a rate constant $k_{sp} \approx 10^{-5}\ sec^{-1}$, but the rate of reaction here is also dependent on the buffer concentration. Thus the rate of hydrolysis of trimethylphenoxysilane follows the equation

$$k = k_a [H^+] + k_{sp} + k_b [\text{base}]$$

which probably is valid also for the other four compounds, but the spontaneous hydrolysis is too slow to be noticed. The values of k_a and k_b are collected in Table 3.

The investigation will be continued with examination of compounds with other alkyl or aryl groups and with substituents in the phenoxy group.

EXPERIMENTAL

The phenoxysilanes were prepared from phenol and trialkylethoxysilane (in the case of the *n*-propyl compound) or trialkylchlorosilane in the same way as similar compounds were prepared by Larsson [4] and Jörg and Stetter [5]. One example is given.

Tri-n-butylphenoxysilane. 29.3 g (0.125 mole) of tri-*n*-butyl-chlorosilane and 11.8 g (0.125 mole) of phenol were refluxed in a dry atmosphere until no more hydrochloric acid was evolved (60 hours). The product was distilled at reduced pressure in a 33 cm glass helix packed column and gave 23 g (88 % yield) of pure tri-*n*-butylphenoxysilane.

Boiling points, refractive indices (determined with an Abbe refractometer), densities (determined with an Ostwald-Sprengler pycnometer of 1.5 ml), molecular refractivities (calculated from the Lorenz-Lorentz formula) and analyses are given in Table 4. For the calculated molecular refractivities the group refractivities given by Smith [6] have been used. Smith does not give the group refractivity *r*-$SiOC_6H_5$, but from his value of the group refractivity *r*-SiC_6H_5 and the bond refractivities Si-C aromatic, Si-O, and C-O ether given by Vogel [7] and Warrick [8], the group refractivity *r*-$SiOC_6H_5$ was calculated to 28.31 ml. The equivalent weight was determined by hydrolysing the silane in a mixture of glacial acetic acid an 1 N hydrochloric acid for some hours and determining the phenol according to Sprung [9]. Silicon analyses were performed according to Smith [6]. The reactions were carried out in 51.4 weight-% ethanol obtained from 20.00 ml of water made up with redistilled 96 % ethanol to 50.00 ml. Sodium chloride was added to give an ionic strength μ = 0.05 M, calculated from the formula

$$\mu = \frac{1}{2} \sum_i c_i z_i^2$$

where c = ion concentrations and z = valency. The concentration of silane was about 10^{-4} M, in some cases of alkaline solutions of low buffer capacity $0.5\ 10^{-4}$ M. (It is not necessary to know the exact concentration, *cf.* eqn. (1)). The optical density was measured in a 1 cm quartz cell with a tight cover in a Beckman DU spectrophotometer provided with a 4 300 photomultiplier attachment. By means of an arrangement designed by the author the walls of the cell compartment were tempered with circulating water from a thermostat. The temperature of the solution was 25.0 ± 0.2° C. The slit width was 0.6 mm and the wave length generally 280 mμ, in some cases of alkaline solutions 290 mμ (see Fig. 1). The first reading D_0 could be made one minute after mixing and the last

one was made after a time equal to ten times the half life. For the reactions with a half life longer than one hour, King's[11] method was used. As a »blank» was used a solution of exactly the same composition as the sample, but where the reaction had started two to three half-lives earlier. The rate equation (1) is in this case transformed to

$$k = \frac{1}{t} \log \frac{D_0'}{Dt'}$$

D' being the optical density read on the photometer. Plotting $D't$ *versus* time gives a straight line, the slope of which is $-k$. The reactions were followed to at least 70 % hydrolysis. All constants were calculated from graphs.

Hydrogen and hydroxyl ion concentrations greater than 0.001 M were obtained by diluting standardized hydrochloric acid and carbonate-free sodium hydroxide solutions. In buffer solutions the concentrations were determined electrometrically using a glass electrode with a saturated calomel electrode as reference electrode and with exclusion of the carbon dioxide of the air. Nernst's equation gives the relation between electromotive force E and activity, but as the ionic strength was constant this relation is supposed to be valid also for concentrations

$$E_{0H} = E - \frac{RT}{F} \ln [H^+] \tag{3}$$

The equation

$$k_w = [H^+] \cdot [OH^-] \tag{4}$$

is supposed to be valid in this ethanol-water mixture. Eqns. (3) and (4) give the equation

$$E_{0OH} = E + \frac{RT}{F} \ln [OH^-] \tag{5}$$

These assumptions are verified in Tables 5 and 6. The electromotive forces were measured in diluted hydrochloric acid and sodium hydroxide and sodium chloride was added to give an ionic strength of 0.05 M. Each value of the electromotive force E is a mean of at least two readings. In the most alkaline solutions the E.M.F measured with the glass electrode does not exactly follow eqn. (5), but these high concentrations were never used for the kinetics. Besides the constancy of E_{0OH} is not very good, although sufficient, especially in poorly buffered solutions.

The author is indebted to Professor Erik Larsson for suggesting the subject of this investigation and his kind interest during its course.

Two Volumetric Methods for the Determination of Glyoxal

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

Two different methods have been developed for the quantitative determination of glyoxal. The first method is an alkalimetric titration and is based on the Cannizzaro reaction of glyoxal. In the second method the glyoxal-bisulphite addition reaction has been applied. The development of both methods was based on an investigation of the rates and equilibria of the corresponding reactions under conditions similar to those prevailing during the analysis. Both methods have been found to give identical results, the errors being no greater than the random titration error.

Several methods have been described previously for the quantitative determination of glyoxal. In the semiquantitative gravimetric method used by Glasstone and Hickling [1], glyoxal is precipitated as glyoxal 2,4-dinitrophenylhydrazone. Ariyama [2] has developed a colorimetric method, and Gabrielsson and Samuelsson [3] have presented a method based on the use of ion exchangers. The only volumetric method thus far developed is that described by Friedemann [4]. The method is based on the oxidation of glyoxal to oxalic acid by hydrogen peroxide in alkaline solution and the titration of the excess alkali with standard acid. This method, however, cannot be used in the presence of other oxidizable compounds. In the following, two new volumetric methods for the quantitative determination of low glyoxal concentrations are suggested which have been employed in kinetic investigations [5].

ALKALIMETRIC METHOD

In the presence of alkali, glyoxal is readily converted to glycolic acid by the Cannizzaro reaction:

$$CHO—CHO + OH^- \rightarrow CH_2OH—COO^-$$

When the alkali is present in excess, the reaction goes to completion [5] and glyoxal can be determined by back titration of the excess alkali with a standard acid solution.

For the evaluation of the time required by the reaction to go to completion under the conditions prevailing during the analysis, the results obtained in kinetic investigations [5] may be applied. It was observed that the Cannizzaro

reaction of glyoxal is of the third order, the reaction rate being proportional to the first power of the glyoxal concentration and to the square of hydroxyl ion concentration. The specific rate at 20° C, which corresponds approximately to the conditions of analysis at room temperature, is 87 l^2 $mole^{-2}$ sec^{-1}. The reaction time can be evaluated from the formula for a third order reaction:

$$t = \frac{1}{k(b-a)}\left[\frac{1}{(b-a)}\ln\frac{a(b-x)}{b(a-x)} - \left(\frac{1}{b-x} - \frac{1}{b}\right)\right] \qquad (1)$$

in which k is the specific rate, b and a the initial concentrations of alkali and glyoxal, respectively, and x the concentration of glyoxal reacted during time t. When, for instance, 20 ml of 0.05 N alkali, the excess of alkali corresponding to at least 50 % of the amount of glyoxal present, is added to give a total volume of the reaction solution not exceeding 30 ml, a reaction time of 8 minutes is found to be sufficient for the reaction to proceed nearly to completion at 20° C. After this time less than 0.1 % of the glyoxal initially present remains in the reaction solution.

The above facts lead to the following procedure for the determination of glyoxal:

To a neutral solution containing not more than 0.66 millimoles of glyoxal in a volume not exceeding 10 ml, 20 ml of 0.05 N sodium hydroxide solution are added. After 8 minutes an amount of standard hydrochloric acid equivalent to the amount of sodium hydroxide added initially is run in and the excess acid is titrated with the 0.05 N sodium hydroxide solution using phenol red as indicator. The amount of alkali consumed in the titration corresponds directly to the amount of glyoxal present. All of the operations must be performed in the absence of carbon dioxide.

In case the conditions are not the same as described above it is to be noted that a standing period four times as long is necessary if the volume of the reaction solution is twice that given above. Similarly, the use of concentrations twice as high shortens the reaction time to one fourth of that given.

BISULPHITE METHOD

This method is based on a procedure presented earlier [6,7] by the author for the determination of several other aldehydes. In this procedure the bisulphite addition reaction is carried out at pH 7.3 in a phosphate buffer in order to effect a very rapid addition reaction, after which the excess bisulphite is titrated with standard iodine in a solution acidified to below pH 4.5 in order to prevent the decomposition of the bisulphite compound during the titration. Before the method could be applied for the determination of glyoxal, it was necessary to investigate the kinetics and equilibria of the glyoxal-bisulphite reaction under the conditions of analysis, taking into account that in this case the reaction involves two successive carbonyl additions.

The experiments indicated that in the case of glyoxal the addition to the first carbonyl group takes place almost quantitatively as compared with the addition to the second carbonyl group. If Gl denotes glyoxal, B sulphite present in the solution in any form *cf.* [6], GlB the monobisulphite compound and GlB_2 the dibisulphite compound of glyoxal we have the following equilibria:

$$\frac{[GlB][B]}{[GlB_2]} = K_1 \qquad \frac{[Gl][B]}{[GlB]} = K_2 \qquad (2)$$

in which K_1 and K_2 are, respectively, the first and the second dissociation constants of the glyoxal-dibisulphite compound. When the dissociation of the glyoxal-dibisulphite compound was investigated, it was observed that $K_1 \gg K_2$ and therefore the second dissociation causes no error in analysis. Table 1 contains examples of the experiments. The dissociation constant K_1 has been calculated from the first of the foregoing equations by taking into account that in the present case [GlB] = [B].

Table 1. The dissociation of glyoxal-dibisulphite compound in phosphate buffer at pH 7.3 at 20° C. Analyses of equilibrium solutions.

$[GlB_2]1^{-1}$ mole^1	$[B]1^{-1}$ mole^1	$10^4 \times K_1 1^{-1}$ mole^1

0.01216	0.001817	2.71
0.00795	0.001511	2.87
0.00385	0.001009	2.64
		Average K_1 = 0.000272 1^{-1} mole^1.

The value of the equilibrium constant K_1 is approximately the same as that of benzaldehyde [7] under similar conditions. From the analytical viewpoint, the equilibrium is not favourable enough for the formation of the dibisulphite compound and therefore a small correction due to the unreacted monobisulphite compound should be applied when accurate results are required.

The correction may be evaluated as follows. Let x denote the concentration of glyoxal that has reacted with bisulphite and y the concentration of glyoxal-dibisulphite compound present at equilibrium, and b the initial total concentration of sulphite. The first of eqns. (2) can then be written in the form $(x - y)(b - x - y)/y = K_1$, from which it follows that the relative error is approximately $(x - y)/2y = K_1/2\ (b - x - y) = K_1/2\ c$, in which c is the concentration of excess sulphite in the reaction solution. Using the value given above for K_1, 0.000272 1^{-1}mole^1, the correction, which is to be added to the amount of glyoxal found, is thus $0.0136/c$ per cent. Table 2 contains some sample

Table 2. analyses. The constancy of the values given in the last column of the table shows that conforming analytical results are obtained in experiments with various intial concentrations when the correction is taken into account.

Similarly as in the case of other aldehydes [6,7] the necessary reaction times for the glyoxal-bisulphite addition reaction were evaluated on the basis of results obtained in rate measurements. It was found that the glyoxal-bisulphite reaction is of the second order, the rate at constant pH being proportional to the product of the concentrations of glyoxal and total sulphite. The bisulphite addition to the second carbonyl group was found to take place immeasurably rapidly as compared with the addition to the first carbonyl group which is the rate-determining reaction. In a phosphate buffer at pH 7.3, the second order specific rate of the glyoxal-bisulphite reaction was 6.0 $l^1 mole^{-1}$ sec^{-1} at 20° C, and 4.9 l^1 $mole^{-1}$ sec^{-1} at 18° C. The rate of the glyoxal-bisulphite reaction differs thus only slightly from that of the formaldehyde-bisulphite reaction under similar conditions [6], the specific rate of the latter reaction being 5.2 l^1 $mole^{-1}$ sec^{-1} at pH 7.3 at 18° C. Thus the standing periods evaluated for the formation of the formaldehyde-bisulphite compound are nearly the same in the case of glyoxal.

On the basis of the foregoing discussion, the following procedure is suggested for the determination of glyoxal by the bisulphite method:

To a solution containing not more than 0.75 millimoles of glyoxal 10 ml of phosphate buffer (0.5 mole/l Na_2HPO_4, 0.125 mole/l KH_2PO_4) and 20 ml of approximately 0.1 M sodium bisulphite solution are added. If the total volume of the reaction solution does not exceed 40 ml, a reaction time of three minutes is sufficient, after which 5 ml of 1 N hydrochloric acid are added and the excess of bisulphite is titrated with an approximately 0.1 N standard iodine solution. The titration should be carried out rapidly in order to avoid the decomposition of the bisulphite compound near the end point. The glyoxal content is calculated from the difference between the iodine consumptions corresponding to the amount of bisulphite initially added and to that present after the addition reaction. To the result obtained a correction is added which is $0.0136/c$ % the value directly obtained, in which c is the molar concentration of excess bisulphite in the solution.

When the volumes of the reaction solution or the concentrations of the standard solutions deviate from those proposed above, the reaction time must be changed correspondingly.

EXPERIMENTAL

Glyoxal and glyoxal disodium bisulphite were prepared according to Ronzio and Waugh [8]. For further purification the latter compound was crystallized twice from 40 % ethanol and dried in air. All water used in the experiments was carbon dioxide-free distilled water. The water used in the experiments in which the kinetics and equilibria of glyoxal-bisulphite reaction were investigated, was also freed from dissolved oxygen by passing a stream of nitrogen through it during a period of 24 hours. The water was stored in a nitrogen atmosphere. The kinetic and equilibrium measurements required in the development of the analytical methods were performed as described elsewhere [5,6,7].

Table 3 contains some examples of experiments in which both methods described above were compared with each other. The values given in the table are averages of 3—5 determinations. The values calculated for the concentration of the glyoxal stock solution show that both methods give conforming results, the deviations being no greater than the ordinary titration errors. In cases in which relatively low glyoxal concentrations are analysed, the bisulphite method is more accurate and should be preferred, because the iodine equivalent of glyoxal is one fourth of its sodium hydroxide equivalent.

Table 3. A comparison between the bisulphite and alkalimetric methods for the determination of glyoxal. v = ml of glyoxal stock solution taken for analysis. V = approximate volume of the reaction solution in ml. ml I = ml of 0.0703 N iodine solution consumed in the titration of excess bisulphite. ml I_g = ml of 0.0703 N iodine equivalent to the amount of glyoxal reacted. ml NaOH = ml of 0.0522 N sodium hydroxide equivalent to the amount of glyoxal. The Kinetics of the Cannizzaro Reaction of Glyoxal

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

The kinetics of the Cannizzaro reaction of glyoxal have been investigated in water solution at different temperatures. The reaction is very rapid and is of the third order, the rate being proportional to the first power of the glyoxal concentration and to the square of hydroxyl ion concentration. The reaction is characterized by a very strong positive salt effect. The observed kinetics and salt effect have been discussed and a reaction mechanism has been suggested in which the slow and rate-determining reaction is a reaction between hydroxyl ion and a univalent negative ion which is formed from glyoxal and hydroxyl ion in a primary rapid reaction.

The kinetics of the Cannizzaro reaction of monoaldehydes have been extensively investigated as compared with those of α-dicarbonyl compounds, glyoxal and some of its derivatives, which are known to undergo the Cannizzaro reaction in the presence of alkali. The only observations thus far made, which are to be found in the literature, are those of Ariyama [1] and Alexander [2]. When developing a colorimetric method for the determination of glyoxal Ariyama found that the rate of the Cannizzaro reaction of glyoxal increases more rapidly than the hydroxyl ion concentration of the solution. Alexander found that the conversion of phenyl glyoxal into mandelic acid under the influence of alkali is a first order reaction with respect to both reactants.

It seemed of interest to investigate the kinetics of the Cannizzaro reaction of glyoxal

$$CHOCHO + OH^- \rightarrow CH_2OHCOO^- \qquad (A)$$

more extensively in order to elucidate the reaction mechanism, particularly because, owing to the two carbonyl groups in glyoxal, the reaction involves formally only two reacting molecules, whereas three reacting molecules participate in the Cannizzaro reaction of monoaldehydes. This was expected to give rise to differences in the reaction mechanism.

The order of the reaction

The progress of reaction (A) could be followed by determining both the hydroxyl ion concentration and glyoxal concentration remaining in the reaction solution at different times by methods described in the experimental

part. Both methods gave nearly identical results, but owing to the rapidity of the reaction, relatively low concentrations had to be used in which case the determination of glyoxal concentration was found to give more accurate results *cf.* [3]). Therefore, the latter results were used in the calculation of specific rates.

The results obtained indicate that the rate of reaction (A) is proportional to the first power of glyoxal concentration and to the square of hydroxyl ion concentration. The specific rates were calculated from the integrated form (2) of the differential equation (1)

$$\frac{dx}{dt} = k\ (a - x)\ (b - x)^2 \tag{1}$$

$$k = \frac{1}{t(a-b)}\left[\frac{1}{b-x} - \frac{1}{b} - \frac{1}{a-b}\ln\frac{b(a-x)}{a(b-x)}\right] \tag{2}$$

by applying the initial condition $x = 0$, when $t = 0$. In these equations a and b are the initial concentrations of glyoxal and hydroxyl ion, respectively, and x the concentration of glyoxal reacted at time t, and k is the specific rate. In the experiments, in which equimolar concentrations were employed, *i.e.* $a = b$, eqns. (1) and (2) were replaced by eqns. (1a) and (2a)

$$\frac{dx}{dt} = k\ (a - x)^3 \tag{1a}$$

$$k = \frac{1}{2t}\left[\frac{1}{(a-x)^2} - \frac{1}{a^2}\right] \tag{2a}$$

Table 1 contains results obtained in experiments in which the order of the reaction was determined by using various initial concentrations of the reactants. The values obtained for the specific rate k are nearly the same; the small deviations may be due to experimental errors. The slight increase in the values with increasing hydroxyl ion concentration is probably due to the heat of the reaction which effects a small increase in the temperature of the reaction solution, but this source of error is eliminated when relatively low alkali concentrations are used in which case the reaction is slower and the temperature can be kept constant during the reaction. Tables 2 and 3 give details of two typical runs.

Average k = 161 l^2 mole^{-2} sec^{-1}

The effect of temperature

The specific rates measured at different temperatures are given in Table 4. In all of these experiments the initial hydroxyl ion concentration was relatively low, about 0.005 N, in order that the reactions would proceed at a measurable rate and to avoid the influence of the heat of reaction. The table contains also the values of the activation energy E and the logarithm of the frequency

Table 4. The effect of temperature on the Cannizzaro reaction of glyoxal in water solution.

°C	0	15	25	35
k l^2 mole^{-2} sec^{-1}	9.28	45.1	161	398

E = 18 200 cal/mole, log A = 15.52

factor A calculated according to the Arrhenius equation from the values of log k at different temperatures by the method of least squares.

The value of the activation energy, 18 200 cal per mole, is considerably lower than the activation energy of the Cannizzaro reaction of formaldehyde in water solution, 22 300 cal per mole, determined by Pajunen [4]. Similarly, the value of log A, 15.52, is considerably higher than the corresponding value for formaldehyde, 11.90, both of which factors effect an enhanced reactivity of glyoxal as compared with formaldehyde.

Salt effect

Table 5 contains results obtained in experiments in which the effect of increase in electrolyte concentration on the reaction rate was investigated in solutions containing added sodium chloride. Table 6 gives details for one of the individual runs. As it is seen from Table 5, the Cannizzaro reaction of glyoxal is characterized by a very pronounced positive salt effect, the specific rate increasing rapidly with increasing electrolyte concentration. The magnitude of the salt effect is of a much higher order of magnitude than that generally observed in reactions between ions and neutral molecules taking place in water solution [5].

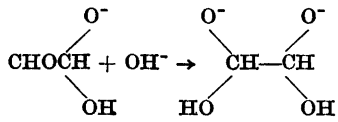
k	341	340	358	363	347	352	344

Average k = 349 $l^2 mole^{-2} sec^{-1}$

DISCUSSION



On the basis of the results presented above, a more detailed picture of the Cannizzaro reaction of glyoxal may be attempted. Although the reaction is of the third order, it is highly improbable that an actual termolecular reaction mechanism is involved. Using a method of calculation described by Tommila [6], a value of the order of 2×10^{10} $l^2 mole^{-2} sec^{-1}$ is obtained for the frequency of a ternary collision between two hydroxyl ions and a glyoxal molecule at 25° C. If every collision between activated molecules were to lead to a reaction the frequency factor A should be of this order of magnitude in the case of a termolecular reaction, but actually a lower value for the frequency factor would be expected, because it is improbable that every collision between activated molecules will effect a reaction. The measured value of the frequency factor A is 3.3×10^{15} $l^2 mole^{-2} sec^{-1}$, which is of a much higher order of magnitude than that evaluated for a ternary collision.

It is thus very probable that the reaction takes place in several successive steps, of which the first (B) involves a rapid equilibrium reaction between glyoxal and hydroxyl ion

(fast) (B)

The negatively charged addition product then reacts with another hydroxyl ion in a second step (C), which is slow and rate-determining

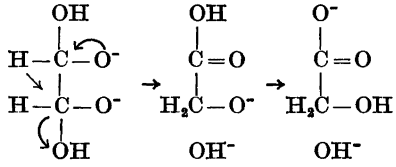
(slow) (C)

In the subsequent steps, discussed below, the reactive divalent anion formed in reaction (C) reacts rapidly to yield the final product, the anion of glycolic acid, but these rapid steps do not affect the kinetics of the reaction and cannot be kinetically distinguished.

The reactions (B) and (C) are in good accord with the observed reaction order. For the rate v of the reaction we have

$$v = k' [OH^-] [CHOCH(OH)O^-] \tag{3}$$

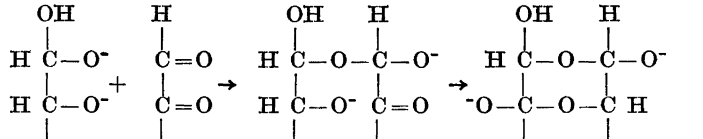
in which k' is the specific rate of the rate-determining step (C). For the equilibrium (B) we obtain



$$\frac{[CHOCH(OH)O^-]}{[CHOCHO][OH^-]} = K \tag{4}$$

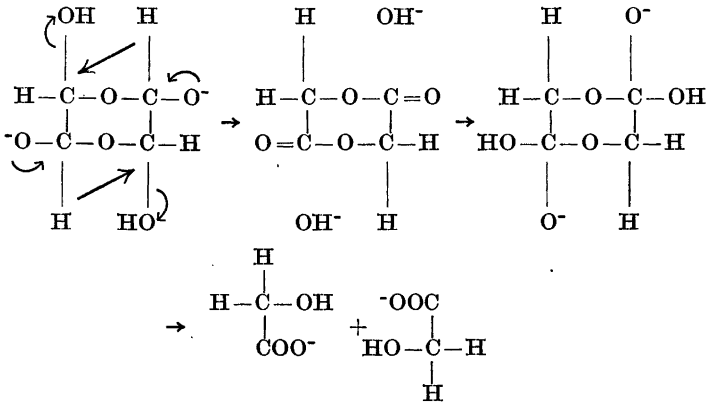
in which K denotes the equilibrium constant. From eqns. (3) and (4) we obtain for the reaction rate the expression

$$v = k'K[CHOCHO][OH^-]^2 \tag{5}$$



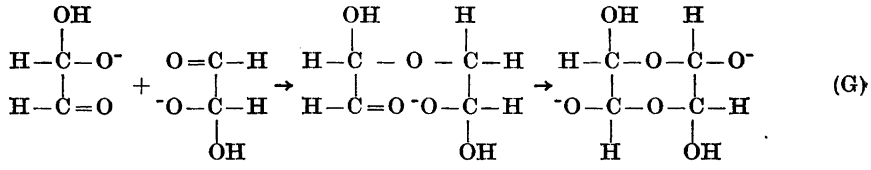
which is the same as that found experimentally if the experimental third order specific rate k is substituted for $k'K$.

The rapid subsequent reaction steps which follow reactions (B) and (C) are probably complicated as in the case of the Cannizzaro reaction of monoaldehydes [6-9]. The subsequent reaction of the anion formed in (C) may take place by an intramolecular hydrogen shift



(D)

or, the anion may react first with another glyoxal molecule according to (E), after which the symmetrical product formed is converted to the final product by a mechanism (F) essentially similar to that suggested by Ingold, Wilson and Tommila [6-9] for monoaldehydes



(E)

(F)

The mechanism (D) is in the present case the most probable. In the formation of the symmetrical product in (E) the attainment of the transition state involves a large increase in order, *i.e.* the activation entropy is negative and the frequency factor relatively low as compared with reaction (D). Similarly, the activation energy of the reaction path (D) has probably a much lower value than that of (E), since the latter involves typical carbonyl addition reactions that take place at a measurable speed, whereas in (D) as well as in (F), intramolecular hydrogen shifts take place in which much lower values of the activation energy are to be expected. The rapidity of the subsequent steps following the rate-determining reaction (C) are thus not as readily understood on the basis of mechanism (E) as in the case of the intramolecular mechanism (D). Also Alexander [2] assumed an intramolecular hydrogen shift to take place in the conversion of phenyl glyoxal to mandelic acid under the influence of alkali. The latter reaction was found to be of the second order, the rate being proportional to the first powers of hydroxyl ion and phenyl glyoxal concentrations. In this case the hydrogen shift was assumed to take place directly in the univalent anion corresponding to that formed in reaction (B), in accordance with the observed reaction order. The difference between the reaction mechanisms of glyoxal and phenyl glyoxal can be ascribed to the $-M$ effect of the phenyl group [10] which greatly facilitates the hydrogen shift to the adjacent carbon atom, as a result of which the reaction corresponding to (B) becomes the slowest and hence rate-determining.

If the Cannizzaro reaction of glyoxal were to take place formally similarly as in the case of monoaldehydes [6-9], the rate-determining reaction following (B) would take place between two anions formed in (B) and would lead to a symmetrical product

(G)

The subsequent reactions could be presented by eqn. (F). This type of mechanism is in principle similar to that suggested by Karrer [11] for the Cannizzaro reaction of glyoxal and would lead to fourth order kinetics. If it is taken into account that in the Cannizzaro reaction the step corresponding to (B) generally takes place very rapidly, one must assume that in the case of glyoxal the reaction takes place by an easier and more rapid way than (G). Owing to the presence of two carbonyl groups in glyoxal, there is the possibility that another relatively rapid reaction (C), which in principle is similar to (B), occurs. This would explain the low value of the activation energy for the glyoxal reaction, 18 200 cal per mole, as compared with the formaldehyde reaction, the activation energy of which is 22 300 cal per mole [4]. The fact that reaction (C) is slower than (B) conforms with the mesomeric effect of substituents [10]. The $-M$ influence of the second carbonyl group, which facilitates the addition of hydroxyl ion to the first carbonyl, no longer remains after reaction (B) has occurred.

From the value of log A (Table 4), 15.52, the activation entropy can be calculated according to the theory of absolute reaction rates [12]. From the formula

$$\Delta S^* = R \ln \frac{A h}{e k T} \tag{6}$$

one obtains for the activation entropy, ΔS^*, of the Cannizzaro reaction of glyoxal the value 37.9 cal × deg^{-1}mole^{-1} at 25° C. A is here expressed in cm^{6}mole^{-2}sec^{-1}. Similarly as in the case of formaldehyde [4], the reaction is characterized by a very high positive activation entropy. The corresponding value for formaldehyde is 21.2 cal × deg^{-1}mole^{-1}. A large positive activation entropy corresponds to a large decrease in order in the attainment of the transition state. Pajunen [4] explained the large positive activation entropy of formaldehyde as being due to the hydratation of the carbonyl group, which is not possible in the critical complex; this leads to a decrease in order. This may also be one of the main reason for the large activation entropy of the glyoxal reaction, and its high value as compared with that of the formaldehyde reaction may be ascribed to the presence of two hydrated carbonyl groups in the case of glyoxal.

The fact that in the glyoxal reaction the rate determining stage (C) takes place between two ions is in good accord with the strong positive salt effect observed. In the case of monoaldehydes, as with formaldehyde [4], the influence of electrolytes on the reaction rate is very slight since the rate-determining stage takes place between an ion and a neutral molecule. In Fig. 1 values of log k for the Cannizzaro reaction of glyoxal in sodium chloride solutions are plotted against the ionic strength and against the square root of the ionic strength.

Although the observed salt effect is of nearly the same order of magnitude as is to be expected for reactions between ions, the application of Debye-

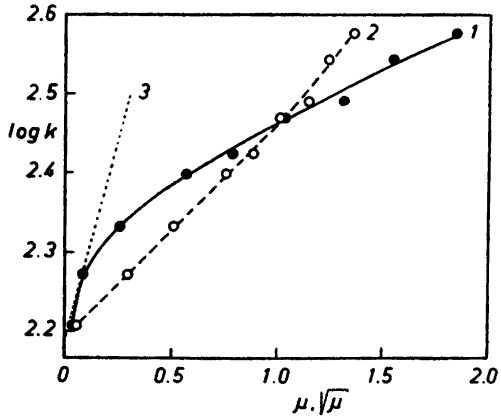


Figure 1. The Cannizzaro reaction of glyoxal in sodium chloride solutions at 25° C. 1. Plot of log k versus *the ionic strength. 2. Plot of log* k versus *the square root of the ionic strength. 3. Debye-Hückel limiting law.*

Hückel theory does not give satisfactory results when the activity coefficient of the critical complex of reaction (C) is taken to be equal to that of a divalent ion. If a_{Gl}, a_{GlOH^-}, a_{OH^-} and a_x denote the activity coefficients of glyoxal, the ion formed in reaction (B), hydroxyl ion, and the critical complex of reaction (C), respectively, we obtain for the specific rate of reaction (C) from the Brönsted rate equation the expression:

$$k' = k_0' \frac{a_{GlOH^-} a_{OH^-}}{a_x} \tag{7}$$

and for the equilibrium constant of the reaction (B):

$$K = K_0 \frac{a_{Gl} a_{OH^-}}{a_{GlOH^-}} \tag{8}$$

in which K_0 is the thermodynamic equilibrium constant. When $k_0' K_0$ is denoted by k_0, and it is taken into account that the measured specific rate k is equal to $k'K$, it follows from eqns. (7) and (8)

$$\log k = \log k_0 + \log a_{Gl} + 2 \log a_{OH^-} - \log a_x \tag{9}$$

If the changes in a_{Gl} effected by changes in the ionic strength are neglected, and the activity coefficients of hydroxyl ion and the critical complex are calculated from the Debye-Hückel theory by considering the critical complex a divalent negative ion, the expression (10) is obtained for the influence of ionic strength on the specific rate at 25° C

$$\log k = \log k_0 + \frac{1.02 \sqrt{\mu}}{1 + a \sqrt{\mu}} - B \mu \tag{10}$$

a and B are constants. Eqn. (10) predicts that in the plot of log k versus the square root of the ionic strength the initial slope should be 1.02. From Fig. 1 it is seen that experimentally determined initial slope is considerably smaller, about 0.25, and the curve shows a slight drift upwards with increasing ionic strength. In many other reactions involving ions of greater charge than one, large deviations from the Debye-Hückel theory have been observed [13]. The Debye-Hückel derivation involves the assumption of a spherical symmetry of the potential field around the ion, which assumption is not justified in the present calculation of the activity coefficient of the doubly charged critical complex of the reaction (C), since in the transition state the two univalent negative charges are situated relatively far apart. Assuming that, as a limiting case, the logarithm of the activity coefficient of the critical complex is the same as that of two univalent ions, the plot of log k versus the ionic strength would be approximately linear owing to the cancellation of the terms containing the square root of the ionic strength. In view of the plot of log k versus the ionic strength shown in Fig. 1, it is also possible that an intermediate case is involved, in which the value of the activity coefficient of the critical complex is somewhere between the values calculated from the Debye-Hückel theory for a divalent ion and for two univalent ions.

EXPERIMENTAL

The solution of glyoxal in water was prepared and purified according to Ronzio and Waugh [14]. For the kinetic experiments, about 0.25 M stock solutions of glyoxal and sodium hydroxide were prepared. All water used in the experiments was distilled water freed from carbon dioxide by boiling.

The kinetic measurements were carried out in electrically heated water thermostats, the temperature of which was kept constant within $\pm$ 0.02° C by a mercury contact regulator. A well stirred ice-water mixture was used as a thermostat at 0° C. All-glass reaction vessels were employed. When the reaction solution, which contained usually about 0.01 mole of glyoxal per liter, had attained the temperature of the thermostat, a volume of sodium hydroxide stock solution was added with vigorous shaking. Except in the experiments in which the order of the reaction was determined, the initial concentration of sodium hydroxide used was relatively low, about 0.005 M, because the rapidity of the reactions at higher sodium hydroxide concentrations did not permit the determination of the specific rates as accurately as when lower concentrations were employed. After the components were mixed, the progress of the reaction was followed by taking 8—11 samples of the reaction mixture with a 20 ml semiautomatic pipette during the course of the reaction. Zero time was the time of taking of the first sample. The samples were run into conical flasks which contained an excess of approximately 0.025 N standard hydrochloric acid solution, and the excess acid was titrated with approximately 0.025 N standard sodium hydroxide solution using phenol red as indicator. This titration gave the hydroxyl ion concentration of the reaction solution at the time of taking of the sample. After this titration, the glyoxal present in the sample was determined by the bisulphite method described in the preceding paper [3] using an approximately 0.05 N standard iodine solution and an approximately 0.05 M bisulphite solution. Both methods, the determination of the hydroxyl ion concentration and the glyoxal concentration gave nearly identical results when applied to the calculation of the specific rates, but owing to the relatively low concentrations used in the experiments, the determination of glyoxal was found to be more accurate *cf.* [3]. For this reason, the results of the latter determination were generally employed in the calculation of the specific rates.

The author wishes to thank Prof. A. Meretoja and Prof. R. Leimu for their interest in this work and for many helpful discussions. The author is also indebted to the authorities of the *University of Turku* for a grant awarded to young scientists by the *Finnish Government.*

The Mechanism of the Silver(I) Catalyzed Reaction between Cerium(III) and Ammonium Persulphate

STURE FRONÆUS and CARL OTTO ÖSTMAN

Department of Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The kinetics of the decomposition of ammonium persulphate and of the redox reaction with cerium(III), both of them catalyzed by silver(I), are investigated in an acid perchlorate-sulphate ionic medium. From the kinetic laws determined it is found that the two reactions have the same rate determining step. Furthermore, exactly two cerium(III) ions are oxidized for every persulphate ion decomposing in the silver catalyzed reaction, in contrast to what is the case with the corresponding uncatalyzed reaction.

On the basis of different facts a reaction mechanism is proposed, involving the formation of silver(II) and the radical ion SO_4^- in the rate determining step.

It is found that silver(II) reacts more rapidly with ammonium ions than with water, while the reverse is valid for the reactivity of SO_4^-.

In a previous paper the decomposition of ammonium persulphate in aqueous solution and its redox reaction with cerium(III) in the absence of silver ions was investigated by the present authors [1]. There it was found that at the acid concentrations used only a very small part of the decomposing persulphate was operating in the redox reaction. On the other hand, it is well known that in the presence of silver ions the persulphate ion is a much more effective oxidizing agent. Some workers [2–4] have studied the silver ion catalyzed self-decomposition of ammonium persulphate, while in other investigations [5–12] also various reducing agents have been added. In the latter case it has often been postulated *a priori* that practically only the agents supplied were persulphate consuming, and it is remarkable that no one seems to have determined separately the kinetic laws of the self-decomposition and of the redox reactions under identical experimental conditions. From the different results reported it is only clear that in many cases the kinetic laws are of the same form and that the rate constants are of about the same order of magnitude. Thus it is easily understood that the discussions of reaction mechanisms have been very scanty or quite lacking.

It is the aim of the present investigation to study separately the silver ion catalyzed self-decomposition of ammonium persulphate and the redox reaction with cerium(III) in the same ionic medium and at the same temperature. Furthermore, the results arrived at in the previous investigation [1] with silver-free solutions will be taken into consideration in order to obtain a reliable basis for the discussion of the reaction mechanism.

EXPERIMENTAL

Chemicals. Silver perchlorate was prepared by precipitating silver oxide, washing carefully and dissolving in perchloric acid of analytical grade. The concentration of the stock solution was determined by titration according to Volhard.

Other chemicals and stock solutions used were prepared as before [1].

The redox reaction. Equal volumes of two solutions, one containing cerous perchlorate, ammonium persulphate, and perchloric acid and the other containing silver perchlorate, sodium sulphate, and sodium perchlorate, were tempered separately at 25.0 °C and then mixed as quickly as possible. At this temperature the redox reaction is very slow in the absence of silver ions, and thus a well defined starting-time for the reactions to be studied was obtained. Part of the reaction mixture was transferred to a light absorption cell, and at certain intervals the light extinction was determined at the wave length 400 mμ with a Beckman DU Spectrophotometer, modified to keep the cell temperature constant.

Since the decomposition of persulphate is slow at 25 °C even in the presence of silver ions (see below) it was necessary to have sodium sulphate present in advance, otherwise the cerium(IV) formed precipitated. Then, with a practically constant ionic medium it was possible to count on a constant value of the molar extinction of cerium(IV) in a measurement series. The molar extinction was calculated from the final extinction, corresponding to a complete oxidation of cerium(III), and thus the ceric concentrations at the different times were obtained.

The persulphate decomposition. The solutions were prepared and tempered as in the redox measurements above. Then equal volumes were mixed, samples were withdrawn and purified nitrogen was bubbled through them for ten minutes while still in the thermostat. Dilute sulphuric acid, an excess of ferrous sulphate and hot water were added rapidly, the time at the addition of the water being taken as the stop of the self-decomposition of persulphate in the sample. The analysis was completed as in the previous investigation [1].

In those cases where the solutions contained cerium, a correction for the ceric concentration had to be applied. This was easily performed, if the first sample in a run was withdrawn when all of the cerium was oxidized to cerium(IV) according to the measurements above.

THE DETERMINATION OF THE RATE LAWS

Symbols used in the equations below:

a = the initial cerium(III) concentration,
$b(t)$ = the persulphate concentration at the time t,
c = the silver(I) concentration,
x = the cerium(IV) concentration,
y = the concentration of the radical ion SO_4^-,
z = the silver(II) concentration.

Kinetics of the persulphate decomposition. In Fig. 1 $\ln b(t)$ has been plotted against t for different values of the parameters a, $b(0)$, and c and for the ionic medium 500 mM $HClO_4$ + 150 mM Na_2SO_4 + 50 mM $NaClO_4$. The straight

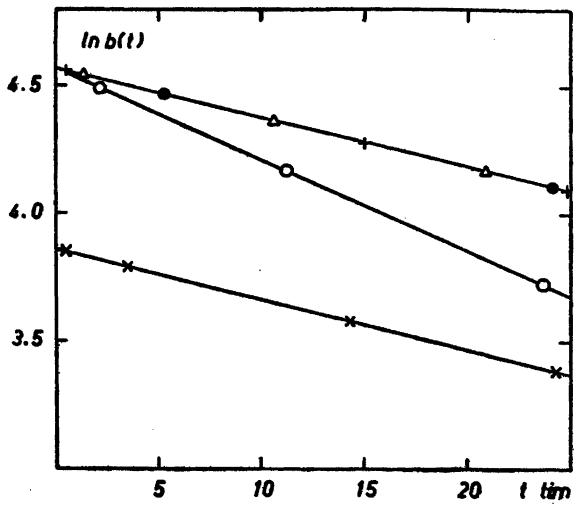

Fig. 1. ln b (t) *as a function of* t *at different values of* a, b(0) *(48.0 and 96.0 mM), and* c. a = *0,* c = *1.20 mM (+ and ×); a = 1.74 mM,* c = *1.20 mM (△); a = 8.69 mM,* c = *1.20 mM (●); a = 0,* c = *2.40 mM (○).*

lines obtained indicate a first order reaction with respect to persulphate. The slope $-k_0'$ of the lines proves to be independent of a and $b(0)$ but almost proportional to c.

Since there is a competition between the silver ion catalyzed decomposition and the one existing in silver-free solutions we can expect the expression for k_0' to be of the form:

$$k_0' = k_0 + k_1' \cdot c \qquad (1)$$

At the acid concentration used k_0 should be approximately equal to the rate constant of the hydrogen ion catalyzed decomposition [1]. For $c = 1.20$ mM $k_0' = (3.20 \pm 0.05) \times 10^{-4}$ min^{-1} while for $c = 2.40$ mM we get $k_0' = (5.90 \pm 0.05) \times 10^{-4}$ min^{-1}. From these values we can calculate $k_0 = (5 \pm 2) \times 10^{-5}$ min^{-1} and $k_1' = 0.225 \pm 0.010$ M^{-1} min^{-1}. Thus k_0 is only a correction term in the present case. If its value is combined with $k_0 = 3.8 \times 10^{-3}$ min^{-1}, determined in the previous work [1] for the same ionic medium but at 61 °C, the activation energy 24 ± 2 kcal is obtained. Kolthoff and Miller [13] give the value 26 kcal for the same reaction.

Kinetics of the redox reaction with cerium (III). In Fig. 2 the ceric concentration x has been plotted against t for different values of the parameters a, $b(0)$, and c and for the same ionic medium as above. It is evident that when the $(a-x)$-values are not very low x is independent of a. Furthermore, since the variation in $b(t)$ is very slight for the short times used in the runs the curves in Fig. 2 consist of approximately straight lines. Thus it is easily found

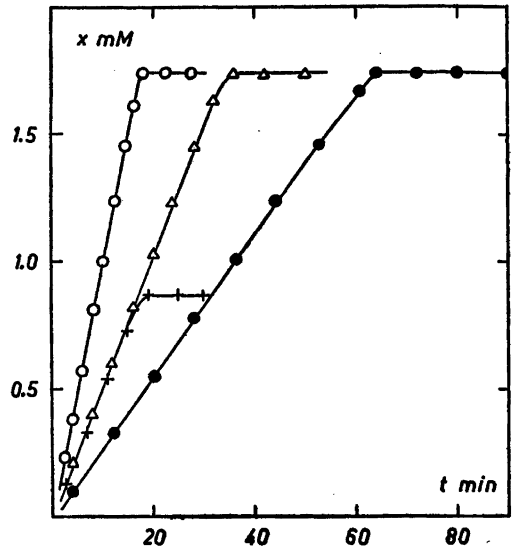

Fig. 2. x *as a function of* t *at different values of* a, b(0), *and* c. a = *0.870 mM*, b(0) = *96.0 mM*, c = *1.20 mM* (+); a = *1.74 mM*, b(0) = *96.0 mM*, c = *1.20 mM* (△); a = *1.74 mM*, b(0) = *47.6 mM*, c = *1.20 mM* (●); a = *1.74 mM*, b(0) = *96.0 Mm*, c = *2.40 mM* (○).

from the slope of the first part of the curves that the reaction rate is proportional to the silver and persulphate concentrations.

$$\frac{dx}{dt} = k\ b(t)\ c \qquad (2)$$

For the rate constant k the different runs give the average value 0.46 ± 0.01 $M^{-1}min^{-1}$. This means that within the limits of experimental random errors the relation $k = 2\ k_1'$ has been found to be valid.

Since $dx/dt = 0$ for $x = a$, it is clear that eqn. (2) cannot be applicable for very small values of $a-x$, and it is very plausible that the first power of $a-x$ enters into the complete differential equation, as was the case with the corresponding equation for the uncatalyzed redox reaction [1].

THE REACTION MECHANISM AND THE COMPLETE RATE LAW

Among the different partial reactions operating in the oxidation of cerium (III) we have the uncatalyzed persulphate decomposition, studied in the previous work [1]. However, preliminary measurements showed that this reaction is quite negligible at 25 °C. Thus the silver(I) catalyzed decomposition is the predominant starting reaction.

For this one Yost [5] was the first to propose the mechanism

$$Ag^+ + S_2O_8^{2-} \rightarrow Ag^{3+} + 2\ SO_4^{2-} \qquad (3)$$

as the rate determining step. However, the experimental evidence for the formation of silver(III) is not very strong, and presumably the real reason for the formulation was the fact that the formation of the radical ion SO_4^- was not known at that time. Since the existence of silver(II) is certain we propose the following formulation of the first step

$$Ag(I) + S_2O_8^{2-} \xrightarrow{k_1'} Ag(II) + SO_4^- + SO_4^{2-} \quad (4)$$

in analogy with the formulation for the uncatalyzed reaction [1]. The formation of SO_4^- according to (4) is supported by the fact that on addition of silver(I) to persulphate this becomes more effective in initiating polymerizations (*cf.* Bacon [14] and Morgan [14]).

In the previous work [1] the rate law obtained proved that in the absence of silver the amount of SO_4^- not consumed in the oxidation of cerium(III) disappeared in a reaction with the rate $k_2[SO_4^-]$, where k_2 is a *constant*. Thus it was concluded that SO_4^- reacted with water giving free oxygen (*cf.* Kolthoff and Miller [13]) and not with the ammonium ions, the concentration of which was not the same in the different runs.

In the presence of silver(I), on the other hand, measurements showed that also in cerium-free solutions practically no oxygen was evolved, even if the persulphate decomposition was considerable. Thus we must conclude that silver(I) reacts more readily than water with SO_4^- according to

$$Ag(I) + SO_4^- \xrightarrow{k_2'} Ag(II) + SO_4^{2-} \quad (5)$$

Furthermore, we have the two simultaneous reactions

$$Ce(III) + SO_4^- \xrightarrow{k_3} Ce(IV) + SO_4^{2-} \quad (6)$$

$$Ce(III) + Ag(II) \xrightarrow{k_3'} Ce(IV) + Ag(I) \quad (7)$$

where (6) is the reaction studied in the previous investigation [1].

Finally, since no oxygen is evolved the amount of silver(II) not consumed in reaction (7) evidently must attack the ammonium ions. According to Marshall [2] ammonium persulphate decomposes in the presence of silver salts with the formation of nitrate ions. Thus we have the stoichiometric formula

$$8\ Ag(II) + NH_4^+ + 3\ H_2O \rightarrow 8\ Ag(I) + 10\ H^+ + NO_3^- \quad (8)$$

Of course the reaction (8) involves several steps, and we can presume, that the reaction is first order with respect to silver(II). Then the reaction rate is equal to $\varphi \cdot z$, where φ may be a function of different concentrations.

If the mechanism (4)—(8) is correct the following system of differential equations should be applicable.

$$\frac{dx}{dt} = (a - x)\ (k_3 y + k_3' z) \tag{9}$$

$$\frac{dy}{dt} = k_1'\ b(t)\ c - \left\{k_2' c + k_3\ (a - x)\right\}\ y \tag{10}$$

$$\frac{dz}{dt} = c\ \left\{k_1'\ b(t) + k_2'\ y\right\} - \left\{\varphi + k_3'\ (a - x)\right\}\ z \tag{11}$$

Referring to the deductions of the previous paper [1] and remembering that $b(t) = b(0)e^{-k_0' t}$ we can establish that if the condition $k_2' \gg k_1'$ (that is $k_2' c \gg k_1' c \approx k_0'$) is fulfilled the steady-state approximation is valid for SO_4^- at all cerous concentrations. Thus we can put $dy/dt = 0$ in eqn. (10) and get an expression for y. When this expression is introduced into eqn. (11) it is found that an equation of a similar type as eqn. (10) is obtained, and the necessary and sufficient condition for the applicability of the steady-state approximation also to silver(II) at all cerous concentrations is that $\varphi \gg k_1' c$.

Applying the steady-state approximations we can easily eliminate the variables y and z, and for dx/dt we get the following complete expression:

$$\frac{dx}{dt} = \frac{k_1'\ (a - x)\ b(t) c}{\varphi + k_3'\ (a - x)} \left\{2\ k_3' + \frac{k_3\ \varphi}{k_2' c + k_3 (a - x)}\right\} \tag{12}$$

If φ is a quantity negligible in comparison with $k_3'\ (a - x)$ this equation becomes identical with the simple eqn. (2) with $k = 2\ k_1'$, which is experimentally verified for not very low cerous concentrations. Thus the mechanism proposed with the reaction (4) as the rate determining step and with the different rate constants fulfilling the conditions stated seems plausible.

According to this mechanism silver(II) reacts more rapidly with ammonium ions than with water, while, as mentioned in the foregoing, the reverse is valid for the reactivity of the radical ion SO_4^-. This state of things could be due to a tendency of silver(II) to form ammine complexes. Then in our acid solutions the equilibrium

$$Ag^{2+} + NH_4^+ \rightleftharpoons AgNH_3^{2+} + H^+ \tag{13}$$

would exist, followed by a rapid decomposition of the ammine complex in a first order reaction involving an electron transfer from the ligand to the central ion. In this case the function φ can be expected to be of the form $\varphi =$ constant$\cdot [NH_4^+]$, since $[H^+]$ is constant.

The measurements of the persulphate decomposition show clearly that c did not vary with time, even if the decrease in $b(t)$ was considerable. This means that z was either very small in comparison with c or a constant fraction of the total silver concentrations. Now, applying the steady-state approximations to the cerium-free solutions and using the expression for φ we get $z/c =$ constant $\cdot\ b(t) / [NH_4^+]$. But from the reactions (4), (5) and (8) it is evident that $b(t) / [NH_4^+]$ decreases with time, and thus z must be $\ll c$ throughout the runs.

After the completion of the present investigation a paper by Bawn and Margerison [16] about the rate of persulphate decomposition has appeared. For the silver catalyzed reaction they have also proposed (4) as the rate determining step. For the uncatalyzed reaction, however, they have accepted the previous mechanism of Bartlett and Cotman [17], which has turned out to be inconsistent with experimental facts [1].

This investigation has been supported by a grant from the *Swedish Natural Science Research Council* which is gratefully acknowledged.

Short Communications

Small Angle Scattering of X-Rays in Aqueous Solutions of Bile Acid Salts

PER EKWALL and KRISTER FONTELL

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Freezing point determinations, studies on the solubilization of water-insoluble lipophilic dyes, hydrocarbons etc. and electrical conductance measurements have provided conclusive evidence that an association to micelles takes place in aqueous bile acid salt solutions [1-7]. Up to now, however, it has generally been considered that in contrast to the solutions of association colloids of the paraffin chain salt type these solutions do not give long spacing X-ray interferences. The lack of interferences has been taken as evidence that the order in the micelles of the bile salts is of much lesser degree than in the micelles of compounds of the paraffin chain type [8,9].

McBain and Hoffman [8] X-rayed 20 % aqueous solutions of sodium desoxycholate for 12—15 hours with a film-to-sample distance of 200 mm. They reported that there was no suggestion of "a long spacing line, and therefore nothing corresponding to a McBain micelle, a Hess micelle, or an interparticle spacing. Evidently in these solutions the colloid consists of particles too irregular in shape and size and distance from each other to give either a lattice spacing from within the micelles or an interparticle spacing between them".

We have, however, been able to obtain X-ray patterns with aqueous solutions of bile acid salts.

Experimental. The X-ray unit, a Philips Norelco X-ray unit with Cu target, operated at 45 kV, 15 mA; Ni-filtered radiation was employed. Three cameras were used: 1) A small angle vacuum camera with collimator slits, principally of the same design as described by Harkins [10]. Collimator width 0.2 mm, distance between collimators 110 mm, sample-to-film distance 229 mm. 2) A small angle vacuum camera with pinhole collimators of the design described by Kiessig [11]. Sample-to-film distance 212 mm. 3) Pinhole powder camera, diameter 114.6 mm.

Desoxycholic acid (Hoffman La Roche, Basle) was purified by the ether-choleic acid method, dissolved in absolute ethanol and recrystallized twice; m.p. 174—175° C. The acid was dissolved in absolute ethanol, and neutralized with ethanolic sodium ethylate. The crystallized sodium salt was filtered and dried in vacuum over P_2O_5 at 78 °C. All solutions were made by weighing, redistilled water ($\varkappa < 10^{-6}$ mho) being used. The solutions were X-rayed at 25 °C in glass-capillaries, diameter 0.7 mm, wall thickness 0.01 mm. Times of exposure: 1) camera with collimator slits 20 h, 2) camera with pinhole collimators 60 h, 3) powder camera 3 h. The exposed films were measured with a Zeiss nonrecording photometer. Three parallel runs were made on every film, readings being taken at every 0.1 mm of the film.

Results. The diffraction pattern for sodium desoxycholate solutions obtained with the small angle vacuum cameras resembles those for solutions of association colloids of paraffin chain type. We have, however, observed only one intensity maximum in the former patterns; this maximum is not so distinct as the so-called I-band of the last mentioned colloids.

Fig. 1 shows the shape of the photometric curves of the halo obtained with different desoxycholate concentrations. For solutions below the 0.05 M concentration the curves are identical with those for pure water, but already in the 0.06 M solution there occurs a very small difference. With increasing concentration the peak becomes more and more pronounced.

In spite of the long exposure time the patterns in all cases are rather weak. It is difficult to determine the exact position of the intensity maximum. If, however, an attempt is made to determine the maxi-

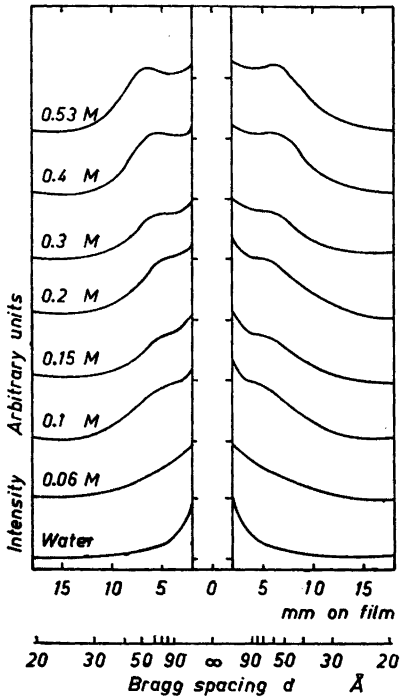

Fig. 1. Photometer traces of the small angle scattering from aqueous solutions of sodium desoxycholate.

mum, and if it is supposed that Bragg's law is valid in this case (compare Guinier's and Fournet's criticism of earlier methods of treating the experimental results [12]), the spacings given in Fig. 2 are obtained. It is seen that the spacing value undergoes a variation with increasing concentration. With the powder camera a short spacing of 6.0—6.2 Å was obtained in addition to the water halo of about 2.7—3.3 Å. This short spacing is not altered by changes in the concentration. We have obtained a pattern of similar character in solutions of sodium cholate.

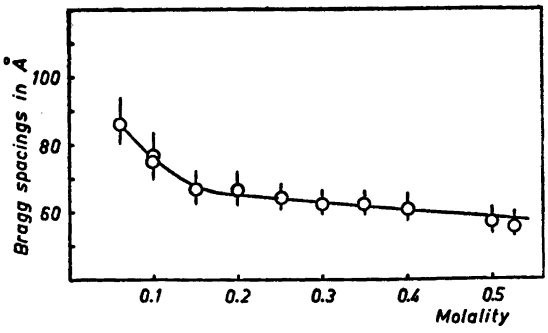

Fig. 2. Graph of the variation of the "band spacing" with sodium desoxycholate concentration.

Previously [5-7] it has been shown that micelle formation begins in sodium desoxycholate solutions at the 0.005 M concentration and becomes fully developed from 0.01 M upwards; a third concentration limit where many of the properties of the desoxycholate solutions are altered lies at 0.045 M. The small angle X-ray patterns thus have been observed in desoxycholate solutions down to the third concentration limit. The spacings in Fig. 2 vary with the colloid concentration in a similar way as the I-band spacing in solutions of association colloids of the paraffin chain type.

The micelles in bile salt solutions are thus regular enough in shape and size to give a small angle X-ray pattern similar in type to those given by micelles in solutions of paraffin chain association colloids. This does not exclude the possibility that the micelles of these two compound groups possess different structures.

On the Solvent Dependence of the Spectra of Complex Ions

JANNIK BJERRUM, A. W. ADAMSON* and OLE BOSTRUP**

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

In recent studies of the absorption spectra of dissolved complexes of transition group elements the so-called crystal field bands are treated as due to electronic transitions between levels caused by the perturbation of the electric fields of the ligands in the first co-ordination sphere. In order to examine the correctness of the assumption of the non-influence of the second sphere we have measured the spectra of some robust complexes of iron(II), chromium(III) and cobalt(III) in other solvents than water. Acetone, nitromethane, chloroform, ethanol, and especially methanol were used as solvents, and in the cases where the complexes were sufficiently soluble the spectra of the solutions were measured at a Cary recording spectrophotometer.

Of the complexes examined dicyano-bis (*o*-phenanthroline)iron(II) was prepared according to Barbieri [1] and recrystallized from chloroform until the spectrum was unchanged by further recrystallization. (Found: Fe 10.81; N 16.32; C 60.90. Calc. for $[Fe(o\text{-phen})_2(CN)_2],3H_2O$: Fe 10.70; N 16.22; C 60.25). Tris(*o*-phenanthroline)-iron(II) bromide was prepared according to Blau [2] and recrystallized once. The Reinecke's salt $K[Cr(NH_3)_2(SCN)_4]$ was prepared after Nordenskjöld [3]. An analyzed preparation of $(NH_4)_3[Cr(SCN)_6]$, $4H_2O$ was kindly made to us and measured in water, methanol and acetone by C. E. Schäffer. Pure samples of Nos. 4—10 in Table 1 were kindly put at our disposal by Professor Fred Basolo, who prepared [4] the compounds during his stay at this laboratory.

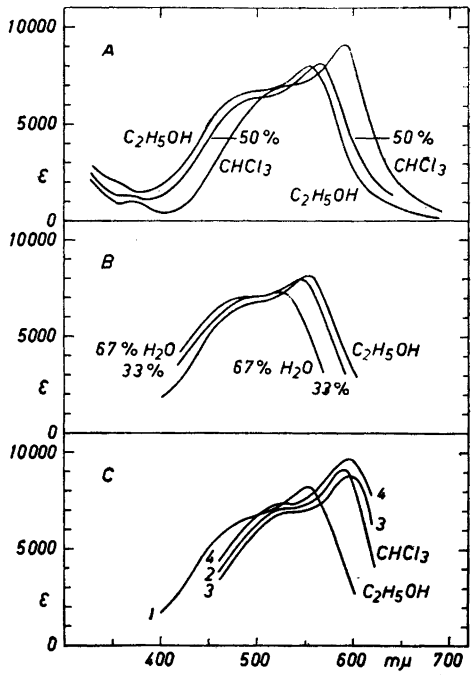

Fig. 1. Extinction curves for $[Fe(o\text{-phen})_2(CN)_2]$ in different solvents.

A. In $CHCl_3$, 50 % $CHCl_3$+50 % C_2H_5OH and C_2H_5OH

B. In C_2H_5OH, 67 % C_2H_5OH+33 % H_2O, 33 % C_2H_5OH+67 % H_2O

C. In C_2H_5OH (curve 1), $CHCl_3$ (curve 2), 50 % $CHCl_3$ + 50 % petrolether (curve 3), 50 % $CHCl_3$ + 50 % CCl_4 (curve 4).

The data for 10 complex salts are summarized in Table 1. For each absorption band are given the value of λ_{max} (wavelengths of maximum in mμ) and ε_{max} (molar extinction coefficient) in water, and for the organic solvents the changes in λ_{max} and ε_{max} as % of values in water. The examples given in the table show that λ_{max} usually is practically independent of the solvent. A significant change of λ_{max} is only found in one case, *viz.* $[Co(en)_2(SCN)_2](SCN)$. This compound has a crystal field band (ε_{max} =

340) as well as an electron transfer band (ε_{max} = 2 900), and it is noteworthy that it is only the last mentioned band which is displaced considerably (6—8 %) by going from water to organic solvent. The influence of the solvent on the intensities of the bands is more varied, and ε_{max} shows some changes in most cases. The data seem to show that compared with water ε_{max} is generally higher for cations and lower for anions in methanol. For one and the same solvent Beer's law was found to be sufficiently obeyed in all cases in which measurements were performed at different concentrations.

$[Fe(o\text{-phen})_3(CN)_2]$ represents a case even more anomalous than *cis*$[Co(en)_2(SCN)_2](SCN)$. The dicyano complex is so insoluble in water, carbon-tetrachloride and ether that measurements cannot be performed in the pure solvents, but it is sufficiently soluble in methanol, ethanol and chloroform. In Fig. 1 extinction curves for this non-electrolyte in different solvents are shown. It is seen that three electron transfer bands are found in visible and near ultraviolet, *e. g.* in chloroform at the wavelengths 591 mμ, 525 mμ (shoulder) and 367 mμ, respectively. The whole appearance of the curves, and the absence

of any isobestic points rule out the possibility of a chemical equilibrium between two forms which shift with solvent composition. *cis*[Coen$_2$(SCN)$_2$](SCN) behaves similarly in water-methanol mixtures. Evidence for a true solvent effect is also found in the fact that light absorption in the various solvents does not show any time effect.

That a crystal field band of a saturated complex ion only to a slight degree is dependent on the solvent can be predicted from the theoretical expression for λ_{max}

$$1/\lambda_{max} = \text{const. } \mu/r^6$$

(see *e. g.* Ballhausen [5]) where μ is the point dipole moment and r the distance of the ligand from the central atom. Denoting the quantities in the first and second spheres by μ', μ'', and r', r'', respectively, the relative contribution of the second sphere to the wavelength is given by

$$\frac{\Delta\lambda_{max}}{\lambda_{max}} = \frac{\mu''}{\mu'} \cdot \left(\frac{r'}{r''}\right)^6$$

Now introducing $\mu' \gtrsim \mu''$ and $r'' = 2r'$, we get

$$\frac{\Delta\lambda_{max}}{\lambda_{max}} \lesssim \frac{1}{64}$$

According to this estimation the displacement of a crystal field band of a saturated complex should always be smaller than 2 % in agreement with what is found experimentally. The greater variability of the electron transfer band found in some cases is quite natural considering that the orbitals of the solvent molecules are closer to the orbitals of the ligands than to the electron systems of the central atom.

On the Proton Conductivity in Water

JAN KROGH-MOE

Department of Physics, University of Missouri, Columbia, Missouri, U.S.A.

It is commonly agreed that the large mobilities of the H_3O^+ and OH^- ions in water must be explained by a proton transfer over hydrogen bridges. By assuming this proton transfer mechanism, Gierer and Wirtz [1,2] derived the following equation to explain the mobility as a function of temperature:

$$u = \frac{C}{T} f(T) \exp\left(-\frac{q}{RT}\right) \qquad (1)$$

Here u is the mobility of the H_3O^+ or OH^- ion in excess of the value expected for ions of that size. C is a factor which incorporates some constants of the system, T is the absolute temperature and q is the activation energy of the rate determining process. $f(T)$ is a function of temperature (and also pressure), which describes the influence of the liquid structure upon the mobility.

If this equation is to be useful, the structural influence $f(T)$ should be known. Gierer and Wirtz used Eucken's structure model of water [3] for their treatment. Eucken assumed that the water structure consisted of a few definite types of molecular species. There is very little evidence to support this assumption, however. An alternative derivation of $f(T)$ from the model of water proposed by Grjotheim and Krogh-Moe [4] shall therefore be suggested.

If the proton transfer across a hydrogen bridge is the rate determining process, one might expect $f(T)$ to be proportional to the total number of hydrogen bonds present in water. Contrary to this assumption the extra mobility increases with temperature in a certain temperature interval, though the number of hydrogen bonds decreases monotonously. By assuming that $f(T)$ is proportional to the number of water molecules with only one hydrogen bond established, consistent results may be derived. This is reasonable if the breaking of the hydrogen bond is the rate determining process. When a proton transfer over a hydrogen bridge has occurred, a reorientation of the water molecule is necessary if the molecule is to participate in further proton transfers. A water molecule

of any isobestic points rule out the possibility of a chemical equilibrium between two forms which shift with solvent composition. *cis*[Coen$_2$(SCN)$_2$](SCN) behaves similarly in water-methanol mixtures. Evidence for a true solvent effect is also found in the fact that light absorption in the various solvents does not show any time effect.

That a crystal field band of a saturated complex ion only to a slight degree is dependent on the solvent can be predicted from the theoretical expression for λ_{max}

$$1/\lambda_{max} = \text{const. } \mu/r^6$$

(see *e. g.* Ballhausen [5]) where μ is the point dipole moment and r the distance of the ligand from the central atom. Denoting the quantities in the first and second spheres by μ', μ'', and r', r'', respectively, the relative contribution of the second sphere to the wavelength is given by

$$\frac{\Delta\lambda_{max}}{\lambda_{max}} = \frac{\mu''}{\mu'} \cdot \left(\frac{r'}{r''}\right)^6$$

Now introducing $\mu' \gtrsim \mu''$ and $r'' = 2r'$, we get

$$\frac{\Delta\lambda_{max}}{\lambda_{max}} \lesssim \frac{1}{64}$$

According to this estimation the displacement of a crystal field band of a saturated complex should always be smaller than 2 % in agreement with what is found experimentally. The greater variability of the electron transfer band found in some cases is quite natural considering that the orbitals of the solvent molecules are closer to the orbitals of the ligands than to the electron systems of the central atom.

On the Proton Conductivity in Water

JAN KROGH-MOE

Department of Physics, University of Missouri, Columbia, Missouri, U.S.A.

It is commonly agreed that the large mobilities of the H_3O^+ and OH^- ions in water must be explained by a proton transfer over hydrogen bridges. By assuming this proton transfer mechanism, Gierer and Wirtz [1,2] derived the following equation to explain the mobility as a function of temperature:

$$u = \frac{C}{T} f(T) \exp\left(-\frac{q}{RT}\right) \qquad (1)$$

Here u is the mobility of the H_3O^+ or OH^- ion in excess of the value expected for ions of that size. C is a factor which incorporates some constants of the system, T is the absolute temperature and q is the activation energy of the rate determining process. $f(T)$ is a function of temperature (and also pressure), which describes the influence of the liquid structure upon the mobility.

If this equation is to be useful, the structural influence $f(T)$ should be known. Gierer and Wirtz used Eucken's structure model of water [3] for their treatment. Eucken assumed that the water structure consisted of a few definite types of molecular species. There is very little evidence to support this assumption, however. An alternative derivation of $f(T)$ from the model of water proposed by Grjotheim and Krogh-Moe [4] shall therefore be suggested.

If the proton transfer across a hydrogen bridge is the rate determining process, one might expect $f(T)$ to be proportional to the total number of hydrogen bonds present in water. Contrary to this assumption the extra mobility increases with temperature in a certain temperature interval, though the number of hydrogen bonds decreases monotonously. By assuming that $f(T)$ is proportional to the number of water molecules with only one hydrogen bond established, consistent results may be derived. This is reasonable if the breaking of the hydrogen bond is the rate determining process. When a proton transfer over a hydrogen bridge has occurred, a reorientation of the water molecule is necessary if the molecule is to participate in further proton transfers. A water molecule

with only one hydrogen bond reorientates readily when the bond breaks.

The description of excess mobility presented here implies a number of assumptions, of which the following are the most important:

1) The model of water applied [3] is assumed adequate for the purpose, though it is only a rough idealization of the real conditions. Hence x, the ratio of the number of established hydrogen bonds to the number of possible bonds, is known.

2) It is assumed that the H_3O^+ ions and the OH^- ions in dilute solutions have the same structural environment as the water molecules.

3) A random distribution of the hydrogen bonds between the molecules will be assumed. The ratio w of one-bonded molecules to the total number of molecules is then given by the following equation:

$$w = 4x(1-x)^3 \qquad (2)$$

Any coupling between the breaking of the bonds is disregarded in deducing this equation.

4) The assumption that the factor $f(T)$ in equation (1) is proportional to the number of molecules with one hydrogen bond is only valid within a limited temperature interval. For instance differences in mean chain lengths for transfers taking place over chains of hydrogen bridges are not taken into account. Coupling between the breaking of bonds is again disregarded.

5) Eqn. (1) is not quite exact, but assumed to be adequate.

In view of these assumptions and approximations the results obtained should be regarded as of only a semiquantitative nature. However, by plotting $\log u + \log T - \log x(1-x)^3$ against $1/T$, using the values of u given for the H_3O^+ ion by Gierer and Wirtz [1] or by Bjerrum [5] and the values of x given by Grjotheim and Krogh-Moe [4], a straight line is obtained for temperatures up to 200° C. The slope of the line corresponds to an activation energy of 1.7 kcal/mole. This value compares favourably with the values 1.3—2.6 kcal/mole obtained by Grjotheim and Krogh-Moe for the breaking of a bond in water. It should be noted that this value for the hydrogen bond includes only the part of the total interaction responsible for the tetrahedral configuration of the water molecules.

The activation energy for the OH^- ion conductivity is shown to be 0.6 kcal/mole higher than that for the H_3O^+ ion [1]. This means that an OH^- ion cannot have quite the same surroundings on average as the H_3O^+ ion. The energy of the hydrogen bond appears to be slightly different in these two cases. Rather than a single energy, however, we have in these systems an energy distribution. A single hydrogen bond energy seems to be a fairly good approximation, however.

The previous considerations enable us to understand why the extra mobility increases with pressure in a certain temperature range. In this temperature range the breaking of a hydrogen bond results in a decrease in volume [4]. Therefore increased pressure means a smaller number of bonds in the liquid. This leads to a larger number of water molecules with only one bond, as may be seen by introducing into eqn. (2) the appropriate values of x. Consequently an increase in extra mobility with pressure is expected. If the factor $f(T)$ of structural influence in eqn. (1) were proportional to the number of established hydrogen bonds, the pressure dependence of extra mobility could not be explained.

The Vitamin Content of Pollen after Storing

NIELS NIELSEN

Research Department, AB Kabi, Stockholm, Sweden

In a previous paper [1] the results of an investigation concerning the content of some B-vitamins in pollen from different plants were given. The samples examined were obtained from *Zea mays*, *Alnus glutinosa*, *A. incana* and *Pinus montana*. The following vitamins were determined: riboflavin, nicotinic acid, pantothenic acid, pyridoxine, biotin and inositol. The determinations were carried out during October

with only one hydrogen bond reorientates readily when the bond breaks.

The description of excess mobility presented here implies a number of assumptions, of which the following are the most important:

1) The model of water applied [3] is assumed adequate for the purpose, though it is only a rough idealization of the real conditions. Hence x, the ratio of the number of established hydrogen bonds to the number of possible bonds, is known.

2) It is assumed that the H_3O^+ ions and the OH^- ions in dilute solutions have the same structural environment as the water molecules.

3) A random distribution of the hydrogen bonds between the molecules will be assumed. The ratio w of one-bonded molecules to the total number of molecules is then given by the following equation:

$$w = 4x(1-x)^3 \qquad (2)$$

Any coupling between the breaking of the bonds is disregarded in deducing this equation.

4) The assumption that the factor $f(T)$ in equation (1) is proportional to the number of molecules with one hydrogen bond is only valid within a limited temperature interval. For instance differences in mean chain lengths for transfers taking place over chains of hydrogen bridges are not taken into account. Coupling between the breaking of bonds is again disregarded.

5) Eqn. (1) is not quite exact, but assumed to be adequate.

In view of these assumptions and approximations the results obtained should be regarded as of only a semiquantitative nature. However, by plotting $\log u + \log T - \log x(1-x)^3$ against $1/T$, using the values of u given for the H_3O^+ ion by Gierer and Wirtz [1] or by Bjerrum [5] and the values of x given by Grjotheim and Krogh-Moe [4], a straight line is obtained for temperatures up to 200° C. The slope of the line corresponds to an activation energy of 1.7 kcal/mole. This value compares favourably with the values 1.3—2.6 kcal/mole obtained by Grjotheim and Krogh-Moe for the breaking of a bond in water. It should be noted that this value for the hydrogen bond includes only the part of the total interaction responsible for the tetrahedral configuration of the water molecules.

The activation energy for the OH^- ion conductivity is shown to be 0.6 kcal/mole higher than that for the H_3O^+ ion [1]. This means that an OH^- ion cannot have quite the same surroundings on average as the H_3O^+ ion. The energy of the hydrogen bond appears to be slightly different in these two cases. Rather than a single energy, however, we have in these systems an energy distribution. A single hydrogen bond energy seems to be a fairly good approximation, however.

The previous considerations enable us to understand why the extra mobility increases with pressure in a certain temperature range. In this temperature range the breaking of a hydrogen bond results in a decrease in volume [4]. Therefore increased pressure means a smaller number of bonds in the liquid. This leads to a larger number of water molecules with only one bond, as may be seen by introducing into eqn. (2) the appropriate values of x. Consequently an increase in extra mobility with pressure is expected. If the factor $f(T)$ of structural influence in eqn. (1) were proportional to the number of established hydrogen bonds, the pressure dependence of extra mobility could not be explained.

The Vitamin Content of Pollen after Storing

NIELS NIELSEN

Research Department, AB Kabi, Stockholm, Sweden

In a previous paper [1] the results of an investigation concerning the content of some B-vitamins in pollen from different plants were given. The samples examined were obtained from *Zea mays*, *Alnus glutinosa*, *A. incana* and *Pinus montana*. The following vitamins were determined: riboflavin, nicotinic acid, pantothenic acid, pyridoxine, biotin and inositol. The determinations were carried out during October

Table 1.

		Zea mays		*Alnus glutinosa*		*Alnus incana*		*Pinus montana*	
		µg/g	%	µg/g	%	µg/g	%	µg/g	%
Riboflavin	1954	6.2		11.2		12.1		5.6	
	1955	6.6	106	11.4	102	8.9	74	3.5	63
Nicotinic acid	1954	71.8		82.7		82.3		79.8	
	1955	65.7	92	73.1	88	79.0	96	64.9	81
Pantothenic acid	1954	12.7		4.2		5.0		7.8	
	1955	9.9	78	0.6	14	1.9	38	5.6	72
Pyridoxine	1954	5.5		5.7		6.8		3.1	
	1955	5.7	104	5.4	95	6.0	88	3.0	97
Biotin	1954	0.55		0.65		0.69		0.62	
	1955	0.50	91	0.67	103	0.65	94	0.70	113
Inositol mg/g	1954	30		3.0		3.5		9.0	
	1955	30	100	2.8	93	3.5	100	8.0	89

and November 1954, shortly after the pollen samples had been collected. The samples were stored in a cool and dry place immediately after collection.

Now, after one year, the pollen samples have been re-examined to determine, whether the vitamin content had changed. Throughout the year the samples were stored in containers in a cool, dry place. The vitamins determined were the same as in the previous investigation. For the methods employed the reader is referred to the paper mentioned [1].

It is evident from the results presented in Table 1 that the stability of the vitamins in the different pollen samples varies greatly. The pantothenic acid content shows a substantial decrease in all the samples, especially in the pollen taken from the two *Alnus* species. For instance in the sample from *A. glutinosa* only 14 % of the pantothenic acid found in 1954 remains. The biotin and inositol content is practically unaltered in all the samples, the variation being within the limits of the accuracy of the analytical methods. The contents of riboflavin, pyridoxine and nicotinic acid remain the same in some samples and show a decrease in others. With the exception of pantothenic acid, the vitamin content of the pollen from *Zea mays* shows hardly any change. On the other hand, in the pollen from *Alnus incana* a marked decrease is seen not only in the pantothenic acid content but also in the amounts of riboflavin and pyridoxine.

The marked decrease found in the pantothenic acid content may prove to be due to a binding of this vitamin and not to its destruction. For the determination of the pantothenic acid no enzymatic liberation was used.

The previous examination [1] of the pollen samples showed that the two samples from *Zea mays* that were collected in 1953 and 1954 contained different amounts of nicotinic acid. It was assumed that this difference might have been due to the storage of the sample collected in 1953, but the results reported here make this explanation unlikely. Therefore the difference found in 1954 must be due to a variation between different samples.

This repeated investigation shows that the stability of vitamins in pollen (in so far as the six vitamins investigated are concerned) depends on the kind of pollen used. The greatest stability is found in pollen from *Zea mays* in which the contents of five of the vitamins remain practically unchanged. The least stable vitamins are found in pollen from *Alnus incana*.

Pantothenic acid seems to be the most unstable vitamin.

Effect of some Metal Ions on the Stability of Natural Vitamin A

KARL BACK

Division of Food Chemistry, Royal Institute of Technology, Stockholm, Sweden

Metal ions have been shown to accelerate the oxidation of fat even when present in very small concentrations. As vitamin A is destroyed when the fat in which it is contained turns rancid through oxidation, some experiments have been carried out to investigate the concentrations of some metal ions required to cause a measurable acceleration of the vitamin A destruction.

Fish liver oil concentrates *, containing about 100 000 IU of vitamin A per g, were used in the experiments. The metal ions of the oil samples were removed by percolating a solution of equal parts of oil and propanol-2 (with some benzene added to ensure complete miscibility) through a cation exchanger in the hydrogen form. Solutions of metal chlorides in absolute ethyl alcohol were then added to the samples so that a final concentration of 2 % ethyl alcohol and 1, 10, or 100 parts per million (ppm) of metal ion was obtained. The metals used in these experiments were Al, Cu, Fe, Ni, Sn and Zn. The samples were distributed in a number of vials which were stored for different lengths of time at a temperature of 34.5° C according to the Schaal oven test modified by Simons *et al.*[1]. At intervals two vials of each sample of oil were removed from the oven and individual determinations of the vitamin A content were immediately made.

Vitamin A was determined by measuring the absorption at 312 mμ, 325 mμ (or the absorption maximum in the interval 325 mμ—328 mμ), and 334 mμ of a solution of the oil in hexane, purified by percolation through a column of defatted bone meal according to Dowler and Laughland [2]. The absorption was corrected using the Morton-Stubbs equation and the content of vitamin A was calculated using a conversion factor of 1 900.

* The oil samples were kindly supplied by Kjellbergs Successors AB, Stockholm.

Table 1. The figures in the table represent the ratios of the time for 50 % destruction of vitamin A in oils containing various concentrations of metal ions, to the time for the same destruction of vitamin A in oil containing no metal ions.

Metal ion	Concentration of metal ion, ppm		
	1	10	100
Al	0.9	0.7	0.5
Cu	0.8	0.5	0.5
Fe	1.0	0.7	0.2
Ni	0.9	0.7	0.4
Sn	0.9	0.9	0.7
Zn	0.9	0.9	0.8

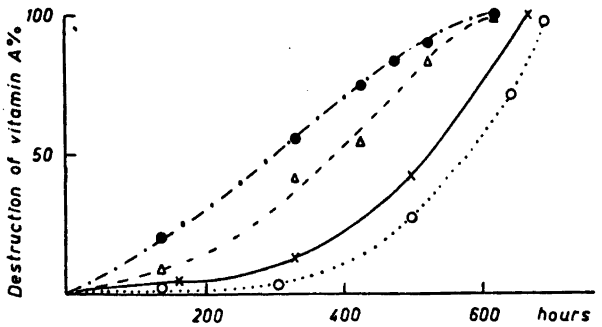

Fig. 1. Destruction of vitamin A in oil from which metal ions had been removed and to which various amounts of Al had been added (as $AlCl_3$). The samples were kept in the dark and exposed to air at 34.5 °C for different lengths of time.

○·····○ *Oil, (metal ions removed)*
×——× " " " " + *1 ppm Al*
△- - - - - -△ " " " " + *10 ppm Al*
●——·——● " " " " +*100 ppm Al*

A typical diagram showing the percentage destruction of vitamin A relative to time is shown in Fig. 1.

The results of the experiments are summarized in Table 1.

It should be emphasized that the figures given in Table 1 are only approximate as they depend on several factors, *e. g.* variations in the composition of different batches of oil, and the storage conditions before testing.

*iso*Thiocyanates XVIII. Glucocapparin, a New Crystalline *iso*Thiocyanate Glucoside

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark

A previous paper of this series [1] described the detection of methyl *iso*thiocyanate as a new natural mustard oil, present in various species of the family *Capparidaceae* as a glucoside, provisionally named *glucocapparin*. We now wish to report on the isolation and characterization of glucocapparin in crystalline condition.

The new glucoside was readily obtained as colourless needles from an extract of seeds of *Cleome spinosa* Jacq., purified as described in the experimental part. The analytical data indicated the composition $C_8H_{14}O_9NS_2K$ for glucocapparin which is the formula expected for a glucoside containing methyl *iso*thiocyanate in the traditional combination with sulphuric acid, potassium and glucose. When glucocapparin was subjected to enzymic hydrolysis, methyl *iso*thiocyanate was liberated and could be identified as *N*-methylthiourea after distillation and treatment with ammonia. The concomitant formation of sulphate and glucose was demonstrated, the latter by paper chromatography in two solvent systems. The ultra-violet absorption spectrum of glucocapparin displayed a maximum at 225 mμ (ε 9 850) in aqueous solution, very similar to the spectra determined in this laboratory for other mustard oil glucosides (Refs. [2,3] and unpublished data). Again, the infra-red absorption spectrum was closely comparable to the spectra of sinigrin [4] and glucoiberin [5], redetermined in this laboratory, a fact suggesting that glucocapparin has a chemical structure closely related to that of other mustard oil glucosides.

For the purpose of further characterization glucocapparin was transformed into a crystalline tetraacetate. That this process was not accompanied by structural changes appeared from the fact that deacetylation with ammonia afforded unchanged glucocapparin as established by the infra-red spectrum and paper chromatography. Recently, acetylation has been successfully employed by Schultz and Wagner [6] for characterizing several mustard oil glucosides as crystalline derivatives.

Glucocapparin adds another representative to the still rather limited group of crystalline *iso*thiocyanate glucosides, heretofore comprising sinigrin, sinalbin, glucocheirolin [7] and glucoiberin [5]. The new glucoside is remarkable in being the first of this type crystallizing without water of crystallization. So far, its known occurrence is limited to species of the family *Capparidaceae*.

Experimental. Isolation. Finely ground seeds (160 g) of *Cleome spinosa* * were extracted with ligroin, containing some *iso*propanol, in order to remove fatty material. The residue (107 g) was subjected to exhaustive extraction, first with 70 % methanol (800 ml) and then with pure methanol (300 ml). The extracts were pooled, a precipitate removed by filtration and the solution concentrated to about 150 ml *in vacuo*. After removal of a new precipitate, the solution was rapidly sucked through a column of neutral aluminium oxide (40 g) in order to remove further impurities. The column was washed with water (100 ml) and the joined filtrate and washing liquid was allowed to flow slowly through another column containing 80 g of anionotropic alumina (Woelm) which quantitatively retained the glucoside [4]. The column was washed with water and then eluted with a 1 % solution of potassium sulphate. The end-point was conveniently estimated by the appearance of a brownish colour in the eluate, emerging simultaneously with the first sulphate ions. The eluate was taken to dryness *in vacuo* and the glucoside separated from traces of inorganic material by repeated

*iso*Thiocyanates XVIII. Glucocapparin, a New Crystalline *iso*Thiocyanate Glucoside

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark

A previous paper of this series [1] described the detection of methyl *iso*thiocyanate as a new natural mustard oil, present in various species of the family *Capparidaceae* as a glucoside, provisionally named *glucocapparin*. We now wish to report on the isolation and characterization of glucocapparin in crystalline condition.

The new glucoside was readily obtained as colourless needles from an extract of seeds of *Cleome spinosa* Jacq., purified as described in the experimental part. The analytical data indicated the composition $C_8H_{14}O_9NS_2K$ for glucocapparin which is the formula expected for a glucoside containing methyl *iso*thiocyanate in the traditional combination with sulphuric acid, potassium and glucose. When glucocapparin was subjected to enzymic hydrolysis, methyl *iso*thiocyanate was liberated and could be identified as *N*-methylthiourea after distillation and treatment with ammonia. The concomitant formation of sulphate and glucose was demonstrated, the latter by paper chromatography in two solvent systems. The ultra-violet absorption spectrum of glucocapparin displayed a maximum at 225 mμ (ε 9 850) in aqueous solution, very similar to the spectra determined in this laboratory for other mustard oil glucosides (Refs. [2,3] and unpublished data). Again, the infra-red absorption spectrum was closely comparable to the spectra of sinigrin [4] and glucoiberin [5], redetermined in this laboratory, a fact suggesting that glucocapparin has a chemical structure closely related to that of other mustard oil glucosides.

For the purpose of further characterization glucocapparin was transformed into a crystalline tetraacetate. That this process was not accompanied by structural changes appeared from the fact that deacetylation with ammonia afforded unchanged glucocapparin as established by the infra-red spectrum and paper chromatography. Recently, acetylation has been successfully employed by Schultz and Wagner [6] for characterizing several mustard oil glucosides as crystalline derivatives.

Glucocapparin adds another representative to the still rather limited group of crystalline *iso*thiocyanate glucosides, heretofore comprising sinigrin, sinalbin, glucocheirolin [7] and glucoiberin [5]. The new glucoside is remarkable in being the first of this type crystallizing without water of crystallization. So far, its known occurrence is limited to species of the family *Capparidaceae*.

Experimental. Isolation. Finely ground seeds (160 g) of *Cleome spinosa* * were extracted with ligroin, containing some *iso*propanol, in order to remove fatty material. The residue (107 g) was subjected to exhaustive extraction, first with 70 % methanol (800 ml) and then with pure methanol (300 ml). The extracts were pooled, a precipitate removed by filtration and the solution concentrated to about 150 ml *in vacuo*. After removal of a new precipitate, the solution was rapidly sucked through a column of neutral aluminium oxide (40 g) in order to remove further impurities. The column was washed with water (100 ml) and the joined filtrate and washing liquid was allowed to flow slowly through another column containing 80 g of anionotropic alumina (Woelm) which quantitatively retained the glucoside [4]. The column was washed with water and then eluted with a 1 % solution of potassium sulphate. The end-point was conveniently estimated by the appearance of a brownish colour in the eluate, emerging simultaneously with the first sulphate ions. The eluate was taken to dryness *in vacuo* and the glucoside separated from traces of inorganic material by repeated

* Commercially obtained from E. Benary, Hann.-Münden, Germany.

extractions with hot methanol. The organic solvent was removed, leaving a colourless lac which was dissolved in hot 80 % ethanol. Upon cooling and scratching crystals separated (330 mg); pure glucocapparin (271 mg) was obtained as glistening, colourless needles after recrystallization from 80 % ethanol. The above procedure could most likely be modified to give an improved yield of glucocapparin, but no systematic studies were performed with this aim.

Properties of glucocapparin. Glucocapparin decomposes gradually above 198°. Its rotation was determined in aqueous solution, $[\alpha]_D^{25}$ —28.6° ± 1.5° (c = 2.2). (Found: C 25.90; H 3.96; N 3.71; S 17.47. Calc. for $C_8H_{14}O_9NS_2K$: C 25.86; H 3.80; N 3.77; S 17.27). The infra-red spectrum, determined in a KBr pellet, displayed prominent bands at 2.80 (v.s., OH-stretching), 6.28 (m.), 6.93 (m.), 7.17 (w.), 7.31 (w.), 7.51 (m.), 7.72 (s.), 7.82 (s.), 8.14 (v.s., broad), 8.87 (w.) *, 9.00 (w.) *, 9.16 (s.), 9.34 (v.s.), 9.46 (v.s.), 9.74 (s.) **, 10.87 (m.), 11.27 (s.) and 12.43 μ (v.s.).

Glucocapparin (50 mg) was dissolved in a phosphate buffer of pH 6.6 (2 ml) and a drop of a myrosinase solution was added. Next day, the *iso*thiocyanate was removed by distillation and transformed into its thiourea-derivative with ammonia. The thiourea was identified as *N*-methylthiourea on paperchromatographic comparison with an authentic specimen in two solvent systems, *viz.* water-saturated chloroform and *n*-butanol-ethanol-water (4:1:4). Furthermore, the ultra-violet absorption spectrum coincided with that of authentic *N*-methylthiourea. The latter exhibited a maximum at 235 mμ (ε 11 900) and a minimum at 218 mμ (ε 6 300) in water.

An enzymically hydrolyzed solution of glucocapparin (5 mg) was taken to dryness and the residue extracted with methanol. The insoluble part was dissolved in water and the presence of sulphate ions demonstrated as $BaSO_4$. The methanolic extract was chromatographed on paper in two solvent systems, *viz.* *n*-butanol-ethanol-water (4:1:4) and pyridine-amyl alcohol-water (35:30:30), and the presence of glucose established by comparison with authentic specimens.

Glucocapparin-tetraacetate. A solution of glucocapparin in dry pyridine and excess acetic anhydride was kept at 50° for 3 hours. A large volume of ether was added to the pink solution, resulting in precipitation of the crystalline acetyl-derivative, which was recrystallized twice from methanol and separated as tiny, colourless needles, m. p. 209—210° (uncorr., decomp.); $[\alpha]_D^{25}$: —31.0° ± 1.5° (c = 1.82, water). (Found ***: C 35.63; H 4.21; N 2.42; S 11.68. Calc. for $C_{16}H_{22}O_{13}NS_2K$: C 35.62; H 4.21; N 2.60; S 11.88). In aqueous solution the ultra-violet absorption spectrum of the tetraacetate was similar to that of glucocapparin, possessing λ_{max}: 221 mμ (ε_{max} 9 340)[4]. The infra-red spectrum (in KBr) had conspicuous bands at: 5.72 (v.s., ester CO-band), 6.93 (m.), 7.24 (s.), 7.70 (s.), 8.09 (v.s., broad), 9.12 (m.), 9.37 (v.s.), 9.50 (s., plateau), 10.92 (m.), 11.23 (s.) and 12.90 μ (s., broad).

Glucocapparin-tetraacetate (60 mg) was dissolved in anhydrous methanol, saturated with ammonia at 0°, and kept at room temperature. Next day, the solvent was removed and the residue recrystallized from aqueous ethanol to give glucocapparin (33 mg, 80 %), identified by its infra-red spectrum and paperchromatographic comparison. R_F-values of 0.06 and 0.44 were determined in descending paper chromatograms at 24° on Whatman paper No. 1 for glucocapparin and its tetraacetate, respectively, with *n*-butanol-ethanol-water (4:1:4) as a solvent system.

Microanalyses were performed in this laboratory by Mr. P. Hansen. The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*.

7. Schneider, W. and Schütz, L. A. *Ber.* **46** (1913) 2634.

* Probably C—O-stretching- (or OH-deformation-)modes of secondary OH-groupings; the bands disappear on acetylation.

** Probably C—O-stretching-(or OH-deformation-) mode of the primary OH-grouping; the band disappears on acetylation.

*** As also experienced elsewhere [6], attempted O-acetyl determinations on this and other glucoside acetates consistently gave too high values.

Received February 18, 1956.

Estimation of Microquantities of Thiocholine Esters

EDITH HEILBRONN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

In order to determine the spontaneous hydrolysis and the initial enzymatic hydrolysis of several thiocholine esters an exact method for their quantitative analysis was sought for. The method developed by Hestrin [1] for the estimation of choline esters and other carboxylic acid derivatives was tried and was found to be applicable to the thiocholine esters as well.

This method makes use of the fact that choline esters react quantitatively with hydroxylamine in alkaline solution according to the following scheme

$$RCOOR' + H_2NOH \rightarrow RCONHOH + R'OH$$

The resulting hydroxamic acid can be determined by the coloured complex with ferric chloride in acid solution.

The thiocholine esters used in this investigation, except acetylthiocholine iodide, were synthesized by Hansen [2]. The following esters were used:

acetylthiocholine iodide
acetyl-α-methylthiocholine bromide
acetyl-β-methylthiocholine bromide
propionylthiocholine bromide
butyrylthiocholine bromide
valerylthiocholine bromide
benzoylthiocholine bromide

Experimental. The same reagents as in Hestrin's method [1] for carboxylic acid derivatives were used.

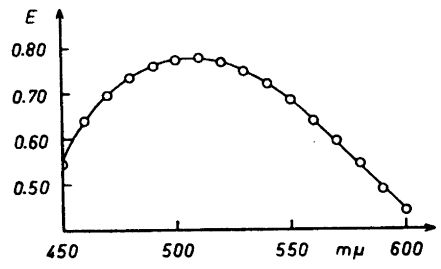

Fig. 1. Absorption curve of the ironhydroxamic acid complex.

Standard solutions: 0.5—10.0 mmole thiocholine ester in Clark and Lubs' [3] phosphate buffer solution at pH 8.00 or in barbital buffer solution [4] at pH 8.07 were used.

The buffer solutions were allowed to reach the thermostat temperature in a volumetric flask. The thiocholine esters were weighed excluding moisture as much as possible and rapidly dissolved in the buffer solution. 1.00 ml of the samples was immediately withdrawn and analysed according to the method developed by Hestrin [1]. The colour was measured in a 10 mm cell with a Beckman B spectrophotometer.

Table 1. Extinction of different concentrations of acetylthiocholine iodide in phosphate buffer solution after varying reaction time with hydroxylamine.

Acetylthiocholine iodide mmole/l	*E* time in min. 1	2	3
10	1.800	1.815	1.807
8	1.441	1.439	1.433
6	1.080	1.072	1.075
4	0.720	0.720	0.741
2	0.365	0.366	0.369
1	0.184	0.186	0.190
0.5	0.093	0.095	0.097

Results. The absorption maximum for the coloured complex was found to be at 510 mμ as shown in Fig. 1.

The reaction with hydroxylamine was carried out for 1, 2 and 3 minutes at room temperature. The extinction appears to be independent of time after 1 minute as can be seen from Table 1. The variation of optical density with ester concentration is shown in Fig. 2 for acetylthiocholine iodide and benzoylthiocholine bromide. It appears from these curves that Lambert Beer's law is obeyed. The lower limit of measurement is about 0.05×10^{-3} mmole of final solution. The upper limit exceeds 2×10^{-3} mmole of final solution. At concentrations of 6×10^{-3} mmole of final solution and above, a precipitate, which is very difficult to centrifuge off, was observed. The precipitate may be sulfur.

The molar extinction coefficient, ε, of the two thiocholine esters was calculated

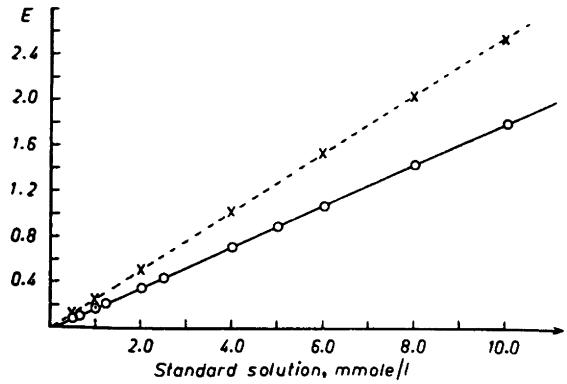

Fig. 2. Density of colour as a function of thiocholine ester concentration.

×--× *benzoylthiocholine bromide*
O—O *acetylthiocholine iodide*

Table 2. Chromogenic activity per thiocholine ester equivalent. Acetylthiocholine iodide = 100.

Compound	Chromogenic activity
Acetyl-α-methyl thiocholine bromide	100
Propionylthiocholine bromide	100
Butyrylthiocholine bromide	104
Valerylthiocholine bromide	104
Benzoylthiocholine bromide	143

from the calibration curves by the equation:

$$E = c \cdot d \cdot \varepsilon$$

where c = mole/l standard solution and d = thickness of the layer in cm. The extinction coefficient was found to be 1.80×10^2 l mole^{-1} cm^{-1} for acetylthiocholine iodide and 2.55×10^2 l mole^{-1} cm^{-1} for benzoylthiocholine bromide. The chromogenic activity of the analysed thiocholine esters is seen from Table 2.

The colour of acetylthiocholine iodide was also determined in barbital buffer solution. The extinction obtained in this case was about 3 % lower than in phosphate buffer solution. Small amounts of protein, enough for determination of enzymatic hydrolysis, did not disturb the reactions.

My sincere thanks are due to Professor G. Ljunggren, Director of the Research Institute of National Defence, Dept. 1, and to Professor A. Tiselius, Director of the Institute of Biochemistry, University of Uppsala, for their kind interest in this work.

Reduction of some Haemo Proteins by Ultraviolet Light

JAN SCHUBERTH

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

During some experiments with oxygen-free solutions of ferrimyoglobin exposed to CO it was noticed that the spectrum of ferrimyoglobin was not stable but slowly changed to that of MgbCO. Apparently ferrimyoglobin was reduced to ferromyoglobin, which subsequently reacted with CO. An examination of the actual conditions revealed that occasional irradiation

with ultraviolet light had caused the reduction. Some preliminary experiments have been performed on ferrimyoglobin, ferrihaemoglobin, ferricytochrome c, and catalase.

Methods. A low pressure water-conditioned mercury lamp was used as the UV source. The solutions were irradiated in a 1 cm Beckman quartz cell connected to the different gas tanks *via* a stopcock system. The specimen was introduced into the cuvette, the system evacuated and flushed with argon 4—5 times. In some experiments argon was replaced by CO in the last filling. The cuvette was kept at a distance of 7 cm from the arc. Na-phosphate buffer (pH 7.1, 0.05 M) was used as solvent.

The concentrations of the haem proteins were for myoglobin 70, haemoglobin 50, cytochrome c 50, and for catalase 20 μM (2 μM for experiments in the Soret band region). During the irradiations readings were taken at regular intervals at suitable wavelengths in a Beckman DU spectrophotometer.

Photoreduction of ferrimyoglobin. After ten minutes 50 % and after 25 min. 90 % of the ferri-Mgb had been reduced and converted to MgbCO, as calculated from the light absorptions at 580 mμ. The addition of dithionite raised the optical density at 580 mμ to the value calculated for complete conversion to MgbCO. If no CO was present a haemochromogene type spectrum was obtained with maxima corresponding to those of $MgbO_2$. The very low concentration of oxygen decreased during irradiation as determined polarographically. This was probably due to the fact that the minute amounts of oxygen present at the beginning of the experiments were gradually taken up by Mgb. There did not seem to be any liberation of oxygen during irradiation. The addition of catalase did not influence the reaction velocity.

Photoreduction of ferrihaemoglobin. Half reduction and conversion to HbCO was obtained after 10 min. and 80 % HbCO after 20 min. Addition of dithionite gave a 7 % too low value, probably due to destruction. Irradiated Hb showed, within the errors of the method, the same affinity for CO as Hb, reduced with dithionite.

Photoreduction of ferricytochrome c. No CO was present in these experiments. Ferricytochrome was half reduced after 12 minutes and 75 % reduced after 20 min. (followed at 549.5 mμ). In this reaction cytochrome c seemed to be highly sensitive even to traces of oxygen. It was in no case possible to obtain the expected light absorption at 549.5 mμ by reduction with dithionite of an irradiated solution. Between 10—15 % of the total cytochrome seemed to have been destroyed. The maxima of the absorption bands of photoreduced cytochrome c were found at 549.5 mμ and 520.5 mμ, exactly in the same positions as those of cytochrome c reduced with dithionite.

Photoreduction of catalase. During the irradiation of liver catalase a change in the absorption spectrum could be noticed and after 45 min. weak absorption bands at 550 mμ and 580 mμ could be observed. In the absence of CO no spectral change was seen. In the presence of dithionite (which does not reduce catalase but acts as an oxygen remover) and without CO a broad absorption band at about 560 mμ appeared. Upon the addition of CO to this solution the same spectrum appeared as obtained without dithionite but with CO initially present. During irradiation in the presence of dithionite the Soret band maximum at 405 mμ shifted to 422 mμ and became somewhat reduced in height. In this case CO partly reversed the shift, from 422 to 418 mμ. The changes of the catalase caused by the irradiation seemed to be fully reversible. Contact with air restored the initial density value at 575 mμ. The activities of a specimen [1] before and after its irradiation with UV light were the same.

A detailed report of these experiments will be published shortly. The investigations are being continued.

The Reaction Between Thiocyanogen and Azide Ions

N. HOFMAN-BANG

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Iodine, as triiodide ions, does not react with azide ions to give nitrogen and iodide ions. However, sulphidic sulphur does catalyze this reaction [1]. Browne *et al.* [2,3] showed that bromine and chlorine give fine analogous bromine- and chlorine-azide reactions, but controlling experiments showed that bromine and chlorine together with sodium azide alone, give slow evolutions of nitrogen. Recently Griffith and Irving [4] have investigated the bromine-azide reaction catalyzed by thiosulphate and by tetrathionate, and the direct reaction between bromine and azide ions.

Taking into consideration that the redox potentials of chlorine, bromine, iodine and thiocyanogen are, respectively, −1.36, −1.07, −0.54 and −0.77 volts, it seems quite possible that thiocyanogen, which often behaves like a halogen, will oxidize azide ions to nitrogen.

Thiocyanogen, $(SCN)_2$, was prepared as a carbon tetrachloride solution according to Söderbäck [5]. This solution, when brought into contact with aqueous sodium azide solution, gave a brisk evolution of gas, while, at the same time, some decomposition of thiocyanogen took place. The gas evolved in the following experiment was analyzed according to Christiansen and Wulff [6]. 25 ml 1 M aqueous solution of sodium azide was allowed to react with 25 ml about 1 M solution of thiocyanogen in carbon tetrachloride. The gas evolved was collected over water and paraffin oil, the latter solvent to extract vapours of carbon tetrachloride in the gas. Analysis of the gas gave the results:

99.6 % N_2 and 0.5 % O_2
99.7 % N_2 and 0.4 % O_2

The reaction is presumably:

$$(SCN)_2 + 2\ N^-_3 \rightarrow 2\ SCN^- + 3\ N_2$$

As thiocyanogen as well as thiocyanate ions catalyze the iodine-azide reaction, it is not unlikely that the above reaction is catalyzed by thiocyanogen as well as by thiocyanate ions. Until now attempts to obtain a homogeneous reaction between thiocyanogen and azide ions in non-aqueous solution have not succeeded.

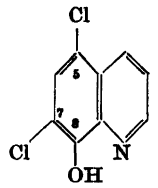
Studies on the Extraction of Metal Complexes

XXXI. Investigations with some 5,7-Dihalogen Derivatives of 8-Quinolinol



DAVID DYRSSEN, MARGARETA DYRSSEN and EBBE JOHANSSON

Research Institute of National Defence, Dept. 1 (FOA 1), Sundbyberg 4; Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Some equilibrium constants describing the chloroform extraction of La(III), Th(IV) and U(VI) complexes with the 5,7-dichloro, 5,7-dibromo, 5,7-diiodo and 5-chloro-7-iodo derivatives of 8-quinolinol (oxine) have been investigated at 25 °C. The ionic strength in the aqueous phase was kept constant at 0.1 M. The overall equilibrium constant K (eqn. 8) for the extraction of metal complexes is increased by halogen substitution of the reagent (Table 6). This effect, which is very pronounced for thorium, is discussed in terms of the separate dissociation and distribution equilibria (eqns. 2—6). The dihalogen substituted oxines are stronger acids than oxine, but the mean complexity constant, $\sqrt[N]{\varkappa_N} = 10^a$, for the complex formation of thorium ($N = 4$) with dichloro-oxine is about the same ($10^{9.90}$) as with oxine ($10^{9.80}$). The distribution constants of both the reagent, k_d, and of the metal complex, λ_4, are increased by halogen substitution. The molar solubilities of the dihalogen reagents in chloroform are considerably smaller (<0.06 M) than the solubility of oxine (2.63 M), whereas thorium dichloro-oxinate is much more soluble in chloroform (0.0135 M) than is thorium oxinate (0.00088 M). A favorable property of the 5,7-dihalogen derivatives is the fact that they are not extracted as oxinium ions from chloroform by moderately acidic solutions (Fig. 1). Our studies suggest that 5,7-dichloro-oxine may often be preferable to ordinary oxine as a reagent for solvent extraction.

An important aspect of our studies on the extraction of inner complexes of the lanthanides and actinides is to investigate the influence of the structure of the chelating agent. This may be done both by investigating various types of reagents and by studying derivatives of one particular compound. In this paper, the results obtained with some 5,7-dihalogen derivatives of oxine are reported. Moeller and Jackson [1] have previously pointed out that 5,7-dichloro-oxine is preferable to oxine for the extraction of neodymium and er-

bium. Recently Rulfs, De, Lakritz and Elving [2] state that oxine is a better reagent than its dichloro and dibromo derivatives for the extraction of uranium(VI).

5,7-dichloro-oxine

The effect of structural changes in a reagent on the various factors that govern metal extraction has been discussed by Martell and Calvin [3]. We shall extend their discussion somewhat, using our own symbols and apply it to the dihalogenated derivatives of oxine.

One may regard the extraction of a metal ion M^{N+} with an organic reagent HA as a stepwise complex formation of M^{N+} with the ligand ion A^- giving among other complexes an uncharged extractable complex MA_N. If the complexes in the aqueous phase are neglected, the distribution ratio is given by

$$q = [MA_N]_{org}/[M^{N+}] \tag{1}$$

The ligand concentration $[A^-]$ is determined by the reagent concentration and the pH as well as by the two dissociation constants

$$k_1 = [H^+]\,[HA]\,/\,[H_2A^+] \text{ and } k_2 = [H^+]\,[A^-]\,/\,[HA] \qquad (2,\ 3)$$

and the distribution constant

$$k_d = [HA]_{org}\,/\,[HA] \tag{4}$$

The formation of MA_N is determined by the complexity product

$$\varkappa_N = \frac{[MA_N]}{[M^{N+}]\,[A^-]^N} \tag{5}$$

and the distribution of MA_N by the distribution constant

$$\lambda_N = [MA_N]_{org}\,/\,[MA_N] \tag{6}$$

For a given system the main experimental variables governing q are generally the reagent concentration $[HA]_{org}$ and the hydrogen ion concentration $[H^+]$ (pH). Thus using eqns. (3)—(6) we may transform (1) to

$$q = \frac{[HA]^N_{org}}{[H^+]^N} \cdot \varkappa_N \cdot \lambda_N \cdot \left(\frac{k_2}{k_d}\right)^N \tag{7}$$

The overall equilibrium constant K we then define by

$$K = \varkappa_N \cdot \lambda_N \cdot \left(\frac{k_2}{k_d}\right)^N \tag{8}$$

Although halogen substitution would be expected to increase both the dissociation constant k_2 of the reagent, and the distribution constant λ_N of the uncharged metal complex, these changes will probably be offset by an increase in the distribution constant k_d of the reagent (*cf. e. g.* Collander [4]) and possibly also by a decrease in the complexity constant $\varkappa_N$. The total effect on the extraction constant K may therefore be rather small.

Eqn. (7) is based on the approximation that the organic phase contains only the uncharged complex MA_N, and the aqueous phase only the uncomplexed metal ion M^{N+}. As has been pointed out by Dyrssen and Sillén [5], eqn. (7) corresponds to the asymptote

$$\log q = \log \lambda_N + \log \varkappa_N + N \log [A^-] \quad (9)$$

to the distribution curve log q *versus* log $[A^-]$ (see Fig. 2 and 3).

Using eqns. (7) and (8), we may in many cases obtain an approximate value of the pH (— log $[H^+]$) for 50 % extraction ($q = 1$):

$$\log [H^+] = \frac{1}{N} \log K + \log [HA]_{org} \quad (10)$$

Since the tendency for the lanthanide and actinide ions to form inner complexes is rather small compared with their tendency to hydrolyze, it is important to extract in a low pH range; *i. e.* a high value of $\frac{1}{N}$ log K and of the reagent concentration $[HA]_{org}$ is desirable.

EXPERIMENTAL

Many details in the experimental technique are described in previous parts in this series. As usual, the measurements were carried out at 25 °C, and — log $[H^+]$ denotes the hydrogen ion concentration. The ionic strength was kept constant at 0.1 M by the addition of Na^+ or ClO_4^- ions.

Reagents. The chloroform was saturated with water and alcohol-free, and the methyl *iso*butyl carbinol (hexol) was shaken with a 10 % sodium bicarbonate solution. 8-Quinolinols of analytical quality were purchased from Merck-Darmstadt (oxine) and Schuchardt, and were used without further purification. Pure 5,7-dichloro-oxine was however prepared according to Berg [6]. Other reagents were of analytical grade.

Measurements on the oxines. The solubilities in chloroform were obtained by weighing after careful evaporation of the chloroform at 40—50° C. The solubility of 5,7-dichloro-oxine was checked by diluting 1 ml of a saturated solution to 250 ml and determining the concentration by spectrophotometric analysis at 330 mμ. This method gave a solubility of 0.0584 M, which agreed well with the value obtained by weighing (see p. 346).

The values of (pk_2 + log k_d) were obtained by shaking 15 ml of a 0.01—0.05 M chloroform solution of the dihalogen substituted oxine with 15 ml of a 0.1 M sodium borate-perchlorate buffer (— log $[H^+]$ = 9.50—9.60, 0.05 M in boric acid + sodium borate). The oxine concentration in the aqueous phase ($\cong [A^-]$) was determined spectrophotometrically at 350—370 mμ. The values of (pk_1—log k_d) were determined in a similar manner by shaking with 0.1 M perchloric acid. The determination of the oxine concentration in the aqueous phase ($\cong [H_2A^+]$) was carried out at 370 mμ.

The distribution constants k_d were determined by shaking 50 ml of a 0.01—0.05 M chloroform solution of the dihalogen substituted oxine with 900 ml of 0.1 M $NaClO_4$ + 100 ml of 0.1 M phthalate buffer (pH = 5) previously saturated with chloroform. The

aqueous phase was centrifuged, 250—750 ml were drawn off and shaken with 10 ml of fresh chloroform. The oxine concentration in this chloroform layer was determined spectrophotometrically at 325—340 mμ.

If 25 cm cuvettes are available, an alternative method is quite useful for the determination of k_d. Ten ml of a 0.01—0.05 M solution of the dihalogen substituted oxines in the organic solvent is shaken with 99 ml of 0.1 M $NaClO_4$ + 1 ml of 0.1 M phthalate buffer (pH = 5). The aqueous phase is centrifuged and acidified to pH = 1 with 1 ml conc. $HClO_4$. The oxine concentration of this solution is determined spectrophotometrically at 370 mμ. This method was used with hexol.

Extraction of the metals. The use of small amounts of buffering substances such as 1 ml of 0.1 M anilinium perchlorate, sodium acetate, hydrazinium perchlorate, or ammonium perchlorate per 15 ml, does not appear to have any

influence on the extraction. The pH and the volume of the solution were adjusted with 0.1 M $HClO_4$, NaOH and $NaClO_4$.

The distribution ratios of La and Th were measured radiometrically using ^{140}La and ^{234}Th (UX_1) as tracers. The distribution of U(VI), however, was determined spectrophotometrically at 390 mμ with a Beckman DU spectrophotometer with 1 cm cells, using a 0.05 M solution of 5,7-dichloro-oxine of chloroform in the blank cell. With this technique, the following values for the molecular extinction coefficient were obtained:

$\varepsilon \cdot 10^{-4}$ M^{-1}	0.816	0.821	0.855	0.818	0.738	0.646
λ mμ	370	380	390	400	410	420

The absorbancy of the blank became too high below 370 mμ. Moeller and Ramaniah [8] have pointed out that the determinations, which are made on steep parts of the absorption curves, will be very sensitive to small errors in

wave-length setting. This objection is, however, not serious since the wave-length is not altered in shifting from the blank to the sample. The free ligand concentration was calculated from the relationship

$$\log[A^-] = \log[HA]_{org} - \log\,[H^+] - pk_2 - \log\,k_d \qquad (11)$$

SOME PROPERTIES OF THE OXINES

It is clear from the introductory discussion that a high value of $[HA]_{org}$ favors the extraction of the metal. A limit is of course set by the solubility of the reagent in wet chloroform. The following solubilities were obtained at 25° C:

Oxine	(M.W. 145.15):	2.63 ± 0.08 M
5,7-Dichloro-oxine	(M.W. 214.05):	0.0587 ± 0.0003 M
5,7-Dibromo-oxine	(M.W. 302.97):	0.0302 ± 0.0003 M
5,7-Diiodo-oxine	(M.W. 396.97):	0.0109 ± 0.0003 M
5-Chloro-7-iodo-oxine	(M.W. 305.51):	0.0585 ± 0.0003 M

The solubility of 5,7-dichloro-oxine in hexol is only 0.0119 M.

In this respect the dichloro and chloro-iodo compounds are the best extracting agents of these dihalogen substituted oxines. They are, however, about 45 times less soluble in chloroform than is oxine itself.

Table 5. Stoichiometric acid dissociation constants and chloroform/water distribution constants of oxine and some of its 5,7-dihalogen derivatives at 25 °C. Ionic strength in the aqueous phase = 0.1 M.

Constants	5,7-Substituent				
	H, H	Cl, Cl	Br, Br	I, I	Cl, I
$pk_2 + \log k_d$	12.24	*11.27* [c]	*11.47*	*12.15*	*11.79*
$\log k_d$	*2.58* [a]	*3.86±0.06* [d]	*4.15±0.1* [d]	*4.15±0.1*	*3.88±0.1*

pk_1	*5.00* [b]	2.9 [e]	2.6	2.7	2.7

Values determined experimentally are given in italics; where not stated they have an error of ±0.01−0.02 units.

a) This distribution ratio is shown to be somewhat dependent on $[HA]_{org}$: 2.61 at 0.1 M, 2.64 at 0.2 M and 2.70 at 0.5 M.
b) Reported in Part IV [9].
c) A value of 11.28 was obtained by a two-phase titration (*cf.* Part IV [9]).
d) For hexol we obtained 3.14 (dichloro-oxine) and 3.36 ± 0.09 (dibromo-oxine).
e) From thermodynamic dissociation constants given by Näsänen [10] (2.887 and 7.617 at 25 °C) one may calculate $pk_1 = 2.89$ and $pk_2 = 7.47$.

The ligand concentration is also determined by the two-phase dissociation constant k_2/k_d. In the discussion above it is emphasized that an increase in k_2/k_d is desirable, provided the decrease in $\varkappa_N \cdot \lambda_N$ is not too large. Table 5 shows that 5,7-dichloro-oxine has the most favorable value ($10^{-11.27}$); the value for oxine being about 10 times less.

A valuable property of the dihalogen compounds is their very low values of $(pk_1 - \log k_d)$ in comparison with unsubstituted oxine (see Table 5). This means that while oxine is extracted out of the chloroform phase into moderately acidic solutions (pH < 3) as an oxinium salt, its dihalogen derivatives will show this behavior only in very acidic solutions (pH < −0.5; see Fig. 1).

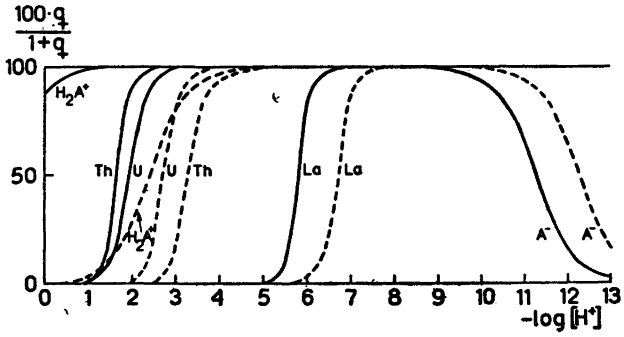

Fig. 1. Comparison of oxine (dashed curves) and 5,7-dichloro-oxine (full curves) as extracting agents. The distribution of La(III), Th(IV) and U(VI) is calculated for the case where a 0.05 M solution of the reagent in chloroform is shaken with an equal volume of an aqueous solution. The H_2A^+ and A^- curves show the extraction of the oxines into the aqueous phase as oxinium and oxinate ions.

The values of the dissociation constants k_1 and k_2 in Table 5 emphasizes the well-known fact (*cf. e. g.* Watson [11]) that the influence of halogen substituents on aromatic nuclei cannot be expressed completely in terms of their inductive effects. The order of pk_1, Br $\sim$ I $<$ Cl, and of pk_2, Br $\sim$ Cl $<$ I, was also found by Feldman and Powell [12] for the 7-halogen derivatives of 8-quinolinol-5-sulfonic acid. It may be assumed from data reported by Minegishi and Nagakura [13] and by Judson and Kilpatrick [14] on monochloro phenols that the lowering of pk_2 of oxine by halogen substitution is primarily due to the 7-substituent.

Since the values of k_d are so very large for the dihalogen compounds, it was very difficult to obtain accurate results for these distribution constants. This uncertainty is reflected in the values of pk_1 and pk_2 calculated from the two-phase dissociation constants $k_1 \cdot k_d$ and k_2/k_d. Table 5, however, shows that there is a more than tenfold increase of k_d on substitution.

EXTRACTION OF La(III), Th(IV) AND U(VI)

The results given in the preceding section show that the 5,7-dihalogen substituted oxines are much stronger acids than unsubstituted oxine. We also found larger distribution constants k_d with the dihalogen substituted compounds. In the introductory discussion it was indicated that one might expect analogous changes for the metal chelate, *i. e.* a decrease in $\varkappa_N$ and an increase in λ_N, thus leaving the overall equilibrium constant K unchanged.

The results of an investigation of UO_2^{2+}, La^{3+} and Th^{4+} with 5,7-dichloro-oxine are given in Tables 1, 2 and 3 and summarized in Table 6 and Fig. 1. These results show that for the same initial concentration of reagent in the chloroform phase (*e. g.* 0.05 M), 5,7-dichloro-oxine extracts in a lower pH range than oxine (Fig. 1); *i. e.*, $\frac{1}{N} \log K$ has increased on halogen substitution (Table 6). The effect ($\Delta \frac{1}{N} \log K$) is in fact so large for Th^{4+} *that it reverses its position in relation to* UO_2^{2+} (Fig. 1).

Eqn. (8) can be written as

$$\frac{1}{N} \log K = \frac{1}{N} \log \varkappa_N \cdot \lambda_N - (pk_2 + \log k_d) \qquad (12)$$

Table 6. Comparison of some chloroform extraction constants for oxine and 5,7-dichloro-oxine.

Metal	N	$\frac{1}{N} \log \varkappa_N \cdot \lambda_N$		$\Delta \frac{1}{N} \log \varkappa_N \cdot \lambda_N$	$\frac{1}{N} \log K$		$\Delta \frac{1}{N} \log K$

* Calculated from data on 0.05 M oxine in Part VIII [15].
** Calculated from data in Part XVII [16].

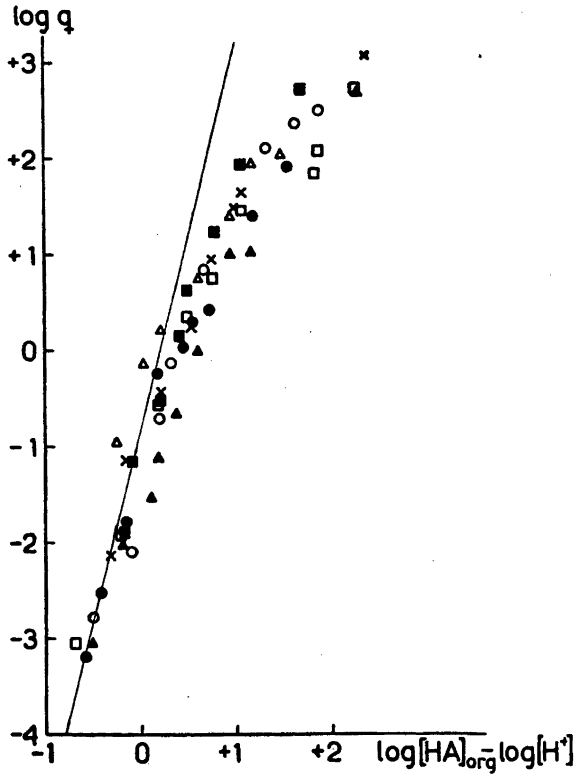

Fig. 2. Comparison of some 5,7-dihalogen substituted oxines as extracting agents for thorium. The distribution ratio of Th—^{234}Th between chloroform and 0.1 M perchlorate solutions is given as a function of $\log[HA]_{org} - \log[H^+]$ *(*$= \log[A^-] + pk_2 + \log k_d$*). Dihalogen derivative and its total concentration in the organic phase (*$[HA]_{org}$*): dichloro: ■ 0.05 M, ● 0.02 M, ▲ 0.01 M; dibromo: □ 0.02 M; diiodo: ○ 0.01 M; chloro-iodo: △ 0.05 M, × 0.02 M.*

and thus values of $\frac{1}{N} \log \varkappa_N \cdot \lambda_N$ may be calculated using the values of ($pk_2 + \log k_d$) given previously in Table 5. The values of $\frac{1}{N} \log \varkappa_N \cdot \lambda_N$ are given in Table 6. As λ_N probably is larger for the 5,7-dichloro-oxinates, it seems as if the complexity products $\varkappa_N$ of UO_2^{2+} and La^{3+} are smaller with dichloro-oxine than with oxine. In order to evaluate $\varkappa_4$ and λ_4 for Th^{4+} a separate investigation was carried out using hexol (methyl *iso*-butyl carbinol) as a solvent. The results are reported below.

Fig. 2 shows the results obtained with Th^{4+} and the various 5,7-dihalogen substituted oxines. The distribution ratio q of Th^{4+} between chloroform and the aqueous phase does not obey eqn. (7) with $\frac{1}{4} \log K = -0.22$, but as was pointed out in the introduction this line should be regarded as an asymptote,

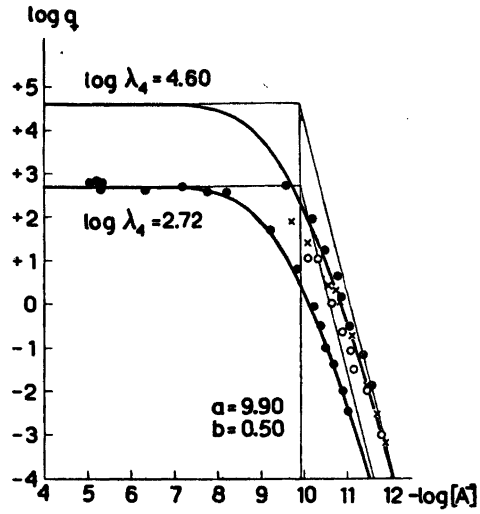

Fig. 3. The distribution ratio of Th as a function of the 5,7-dichloro-oxinate ion concentration in the aqueous phase. Hexol: ● 0.01 M dichloro-oxine; chloroform: ⊗ 0.05 M, × 0.02 M and ○ 0.01 M dichloro-oxine.

and the deviation is undoubtedly due to the presence of Th complexes in the aqueous phase. Values outside log $q = \pm 3.2$ are not included since they are rather unreliable. Furthermore it seems as if there is no significant difference between the dihalogen substituted compounds in this plot. This means that the values of $\frac{1}{4}$ log K are about the same and consequently that according to eqn. (12) the values of $\frac{1}{4}\log \varkappa_4 \cdot \lambda_4$ are shifted by an amount equal to the changes of their ($pk_2 + \log k_d$) values. One might then be tempted to think that equal shifts in the constants for the proton complexes, k_2 and k_d, and in the constants for the thorium complexes, $\sqrt[4]{\varkappa_4} = 10^a$ and $\sqrt[4]{\lambda_4}$, compensate each other.

COMPLEX FORMATION OF THORIUM WITH 5,7-DICHLORO-OXINE

In order to evaluate $\frac{1}{4}$ log $\varkappa_4$ and $\frac{1}{4}$ log λ_4 separately for thorium, 5,7-dichloro-oxine was studied using hexol (methyl *iso*butyl carbinol) as a solvent. Hexol was chosen instead of chloroform so that log λ_4 would be lower and in a measurable range of log q. However, the solubility of 5,7-dichloro-oxine is much lower in hexol (0.0119 M) than in chloroform (0.0587 M). The solubility of hexol in water is only 1.6 % and should not affect $\varkappa_4$ very much.

The results with hexol are given in Table 4 and plotted in Fig. 3 together with the chloroform data. The thick curves in Fig. 3 are calculated with the

parameters (*cf.* Part V[5]) $a = 9.90$, $b = 0.50$, $\log \lambda_4 = 2.72$ (hexol) and $\log \lambda_4 = 4.6$ (chloroform) and have consequently the same shape. The thin lines represent the asymptotes to the distribution curves,

$$\log q = \log \lambda_4 \quad \text{and} \tag{13}$$
$$\log q = \log \varkappa_4 + \log \lambda_4 + 4 \log[A^-] \tag{9a}$$

A reinvestigation of the thorium-oxine-chloroform system (*cf.* Part VI [7]) gave $a = 9.80$, $b = 0.35$ and $\log \lambda_4 = 2.63$. Within a reasonable limit of error in a ($\pm$ 0.05 or 0.10) we may say that there is no significant difference between the mean complexity constants ($= 10^a$) for the thorium complexes of oxine and of 5,7-dichloro-oxine. This result was not expected, and cannot alone form a basis for a theoretical discussion. Future investigations may show if it is merely an exception. We may note that the dichloro-oxinate of thorium is much more soluble in chloroform (0.0135 M) than is the oxinate (0.00088 M).

GENERAL CONCLUSIONS

The extraction properties of the dihalogen substituted oxines investigated here are very much alike. The pH range for the extraction of La(III), Th(IV) and U(VI) with chloroform is lower for dichloro-oxine than for oxine itself. The effect is very large for Th^{4+} (1.56 pH units), but not so large for La^{3+} (0.74) and UO_2^{2+} (0.58). A very favorable property of the 5,7-dihalogen substituted oxines is that they form oxinium ions (H_2A^+) only in very acidic solutions (Fig. 1). Furthermore, the solubility of the thorium complex in chloroform is increased many fold on dichloro substitution.

To summarize, we believe that the 5,7-dihalogen substituted oxines have certain advantages over oxine as solvent extraction agents, and would repay more general use in the future. The 5,7-dichloro compound is preferred because it has the largest solubility in chloroform, and because it is very simple to prepare the pure reagent from oxine [6] with a good yield.

We wish to thank Professor G. Ljunggren and Professor L. G. Sillén for their interest in this work, which has partly been supported by *Atomkommittén*.

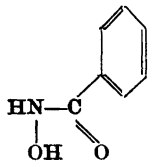
Studies on the Extraction of Metal Complexes

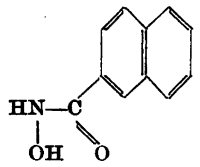
XXXII. N-Phenylbenzohydroxamic Acid

DAVID DYRSSEN



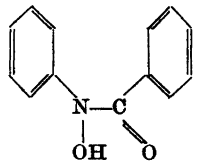
Research Institute of National Defence, Dept 1 (FOA 1), Sundbyberg, Sweden

N-Phenylbenzohydroxamic acid (PBHA) has been investigated at 25 °C as a solvent extraction agent for La(III), Th(IV) and U(VI). Chloroform was used as the organic solvent and the ionic strength in the aqueous phase was kept constant at 0.1 M by addition of $HClO_4$ and $NaClO_4$. The values of $\frac{1}{N}\log K$ (eqn. 3) for La, Th and U are -4.80, -0.17 and -1.57, respectively. Fig. 1 shows that Th and U may easily be separated from La by batch extraction, while a good separation of Th and U would require a simple extraction column.



The stoichiometric dissociation constant k_a of PBHA is $10^{-8.15\pm0.01}$ and its distribution constant k_d between chloroform and water is $10^{2.33\pm0.01}$. The mean complexity constant 10^{α} for the formation of Th *tetra*-N-phenylbenzohydroxamate is $10^{9.45}$ and the distribution constant λ_4 of this complex between chloroform and water is $10^{3.45\pm0.03}$.

Benzohydroxamic acid (BHA) and α-naphtohydroxamic acid (NHA) have been used [1] for the extraction of trivalent lanthanide and actinide ions. Shome [2] has pointed out that a stable compound, N-phenylbenzohydroxamic acid (PBHA) was obtained, if the nitroso group in cupferron (N-nitrosophenylhydroxylamine) was substituted with benzoyl, and Lutwick and Ryan [3] have prepared several of these hydroxamic acids (or aromatic hydroxylamines). In Part VIII [4] of this series it was shown that cupferron was a very good reagent for the extraction of the tetravalent ions Hf^{4+} and Th^{4+}.



These were the main facts that led to the investigation of N-phenylbenzohydroxamic acid (or N-benzoylphenylhydroxylamine) as a solvent extraction agent for lanthanide and actinide ions. The complex formation and partition of Th phenylbenzohydroxamate was studied in some detail. The dissociation and distribution constants of PBHA were determined so that the free ligand concentration $[A^-]$ could be calculated.

BHA

NHA

PBHA

EXPERIMENTAL

N-Phenylbenzohydroxamic acid (N-benzoylphenylhydroxylamine) was kindly prepared Mr. Bertil Takman and Mr. Sven Lindström, University of Stockholm. They used Shome's modification [2] of Bamberger's [5] method. The product was, however, finally recrystallised from benzene. M. p. 121 °C. (Found: C 73.2; H 5.0; N 6.6. Calc. for $C_{13}H_{11}NO_2$: C 73.2; H 5.2; N 6.6). Chemicals used were of analytical grade, and the chloroform was saturated with water and alcohol-free.

Values of k_a and k_a/k_d were determined by means of the titration technique described in Part IV [6]. However, saturated KCl was used in the reference electrode instead of 0.1 M $NaClO_4$/4 M NaCl. The light absorption curve of PBHA in 0.005 M $HClO_4$ + 0.095 M $NaClO_4$ has a peak at 253 mμ with an extinction coefficient of $0.765 \cdot 10^4$ M^{-1}. Alkaline solutions of PBHA are however yellow. The distribution constants k_d between chloroform and 0.005 M $HClO_4$ + 0.095 M $NaClO_4$ ($-\log[H^+] = 2.30$) were determined for 0.1—0.02 M solutions of PBHA in chloroform by measuring the hydroxamic acid concentration in the aqueous phase at 250—280 mμ with a Beckman Model DU spectrophotometer (1 cm cells).

The radioisotopes ^{140}La and ^{234}Th (UX_1) were employed for the determination of the distribution of La(III) and Th(IV). The distribution of U(VI) was, however, determined in the following way: a 5 ml portion of the 10 ml aqueous phase was removed, and the pH of the solution was adjusted to about 3.3 with 0.1 M sodium acetate. The solution was then shaken with 5 ml of 0.05 M 5,7-dichloro-oxine in chloroform and the absorbancy of the chloroform layer was measured at 390 mμ (*cf.* Part XXXI [7]).

The ionic strength of the aqueous phase was kept constant at 0.1 M by addition of 0.1 M solutions of $HClO_4$, $NaClO_4$ and NaOH. In the distribution measurements of La, Th and U the aqueous phase was sometimes buffered with 1 ml of 0.1 M anilinium perchlorate, sodium acetate or hydrazinium perchlorate per 15 ml. The hydrogen ion concentration, $[H^+]$, was measured with a Radiometer pHM3i potentiometer equipped with glass and calomel electrodes, which were standardized against a 0.01 M $HClO_4$ + 0.09 M $NaClO_4$ buffer ($-\log[H^+] = 2.00$).

All experiments were carried out in thermostated rooms at 25.0 ± 0.3 °C.

THE DISSOCIATION AND DISTRIBUTION CONSTANTS OF PBHA

The dissociation constant k_a and distribution constant k_d of PBHA are given in Table 4 together with the solubilities in chloroform and in 0.005 M $HClO_4$ + 0.095 M $NaClO_4$. The thermodynamic dissociation constant K_a may be calculated as $10^{-8.30}$ using activity coefficients given by Conway [10]. This value seemed much too low in comparison with the value $10^{-6.7}$ for benzohydroxamic acid, reported by Oliveri-Mandalá [11]. Recently Wise [12] has shown, however, that the values calculated from electrical conductance measurements of Oliveri-Mandalá were about a hundred times larger than his potentiometric data. Wise reports $10^{-8.88}$ for the mixed (Brönsted) dissociation constant of benzohydroxamic acid at 20 °C and ionic strength 0.005 M. No values of the dissociation and distribution constants of PBHA have been reported. The value of k_d seemed to increase slightly with the concentration of PBHA in chloroform (0.02—0.1 M). This effect was, however, almost entirely concealed by the experimental error (±0.01) in the determination of log k_d. A two-phase titration (*cf.* Part IV [6]) of 50 ml of 0.01 M PBHA in chloroform gave pk_a + log k_d = 10.46, in good agreement with the separate determinations of pk_a and log k_d. The value of the solubility of PBHA in water, given in Table 4 is in good agreement with the value, 0.40 g/l (0.0019 M), reported by Lutwick and Ryan [3].

THE EXTRACTION OF La(III), Th(IV) AND U(VI)

The results for the extraction of La^{3+}, Th^{4+} and UO_2^{2+} are given in Fig. 1 and in Tables 1—3. The ligand concentration [A$^-$] is calculated from the equation

$$-\log [A^-] = \log [H^+] - \log [HA]_{org} + pk_a + \log k_d \qquad (1a)$$

Introducing the values of pk_a and $\log k_d$ from Table 4:

$$-\log [A^-] = \log [H^+] - \log [HA]_{org} + 10.48 \qquad (1b)$$

As the distribution constant k_d for PBHA is so large, the initial reagent concentration in chloroform is $\approx [HA]_{org}$, provided that the pH in the aqueous phase is not too high (<9). Fig. 1 shows that the La, U and Th may be extrac-

Solubility in 0.005 M $HClO_4$ + 0.095 M $NaClO_4$	0.00195 M

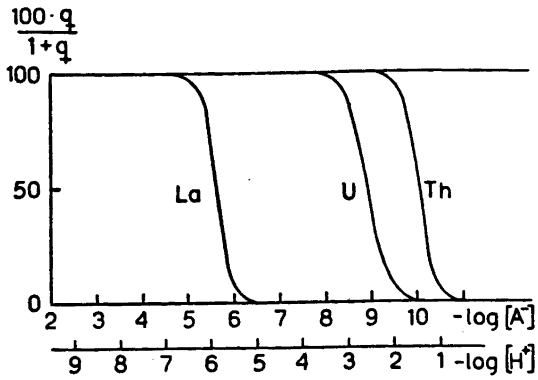

Fig. 1. The distribution of La(III), U(VI) and Th(IV) between chloroform and 0.1 M perchlorate solutions as a function of the N-phenylbenzohydroxamate ion concentration in the aqueous phase. The corresponding values of —log [H⁺] are calculated for 0.1 M PBHA in chloroform.

ted very well with chloroform, using PBHA as a complexing agent. As usual lanthanum is extracted in a much higher pH-range (higher range of log [A⁻]) than uranium and thorium, and may well be separated from the latter elements by a single extraction at pH = 4.5 with a 0.1 M solution of PBHA in chloroform. A good separation of U and Th would however require some degree of fractionation. Compared with cupferron (*cf.* Part VIII[4]) PBHA is a much more stable compound, and the extraction of La(III) and U(VI) is very much better.

If the distribution data on lanthanum (Table 1) and uranium (Table 2) are plotted against log [A⁻], they will fit rather well to straight lines with slopes

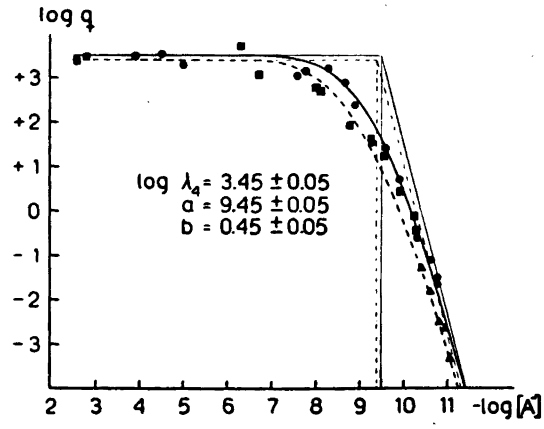

Fig. 2. The distribution ratio of Th(IV) as a function of the N-phenylbenzohydroxamate ion concentration in the aqueous phase. The curves are drawn with two sets of parameters (see text). Total concentration of PBHA in chloroform: ■ 0.1 M, ● 0.05 M, ▲ 0.025 M.

equal to 3 and 2. The general equation for these lines is (eqn. 9 in Part XXXI [7] or eqn. 7 in Part V[13])

$$\log q = \log \varkappa_N \lambda_N + N \log[A^-] \quad (2)$$

Thus for La^{3+} ($N = 3$) one obtains

$$\log \varkappa_3 \lambda_3 = 17.04$$

and for UO_2^{2+} ($N = 2$)

$$\log \varkappa_2 \lambda_2 = 17.82$$

The data for thorium, which are plotted in Fig. 2, cannot be represented by eqn. (2) and this undoubtedly is due to the presence of thorium complexes in the aqueous phase. Using the value of $\log \lambda_4 = 3.45 \pm 0.03$ calculated in Table 3, the two-parameter method described in Part V[13] gave the following values:

$$a = \frac{1}{4} \log \varkappa_4 = 9.45$$

$$b = 0.45$$

The two parameters a and b determine the mean complexity constant 10^a ($= \sqrt[N]{\varkappa_N}$) and the mean spreading factor 10^{2b} ($= k_n/k_{n+1}$).

In order to estimate the limits of error of the parameters two curves are drawn in Fig. 2; the full curve has $a = 9.50$, $b = 0.40$ and $\log \lambda_4 = 3.50$, and the dashed curve has $a = 9.40$, $b = 0.50$ and $\log \lambda_4 = 3.40$. As all of the points do not fall inside these two curves, the errors in each of these constants may be somewhat larger than ± 0.05.

The value of a for PBHA is definitely higher than for tropolone [9] ($a = 8.14$), but somewhat lower than for oxine [1] ($a = 9.80$). All these reagents form five-membered chelate rings. A summary of our work will be published shortly [14], where these values will be discussed together with data for other reagents.

In Part XXXI [7] the overall equilibrium constant K was defined, and it was stated that the pH for 50 % extraction was approximately determined by the terms $\log [HA]_{org}$ and

$$\frac{1}{N} \log K = \frac{1}{N} \log \varkappa_N \lambda_N - (pk_a + \log k_d) \quad (3)$$

The following values of $\frac{1}{N} \log K$ may be calculated using eqn. (3)

La(III):	—4.80
U(VI):	—1.57
Th(IV):	—0.17

If these values are compared with those for other reagents [14], it is found that the values for La(III) and Th(IV) are rather favorable; aromatic N-substituted hydroxamic acids (keto hydroxylamines) may prove to be a very useful group of compounds for the extraction of tri- and tetravalent lanthanide and actinide ions.

The author wishes to thank the head of FOA 1, Professor Gustaf Ljunggren for his interest in these studies, and Mr. Bengt Carlsson and Mr. Ebbe Johansson for their technical assistance.

Part of this work was carried out at the Department of Inorganic Chemistry, Royal Institute of Technology, with financial support from *Atomkommittén*. Sincere thanks are due to Professor Lars Gunnar Sillén for his advice, and to Mrs. Margareta Dyrssen for her technical assistance.

Mass Distributions of Unfractionated and Fractionated Polymethyl Methacrylates Determined by Ultracentrifugation and Fractional Precipitation

A. FREDRIK V. ERIKSSON

Institute of Physical Chemistry, University of Uppsala, Uppsala, Sweden

A new modification of the analysis of sedimentation curves from a velocity ultracentrifugation has been applied on synthetic high molecular weight samples of very different heterogeneity. The high influence of the hydrostatic pressure on organic solvents has been taken into account. The mass distributions obtained in this way have been found to be in good accordance with the results from other methods.

The purpose of this investigation has been to determine the distribution of mass over the different sedimentation constants occurring in a synthetic high polymer by sedimentation analysis of ultracentrifuge data and to test the validity of the method. This has been done in two ways, by comparing the distributions obtained from sedimentation experiments on two different unfractionated polymers with those obtained by precipitation fractionation and by comparing the results of analyses on mixed fractions with those on the separate fractions.

PREVIOUS THEORIES

A knowledge of the distribution of mass over the different molecular species occurring in a sample of a synthetic high molecular weight polymer is in many cases of importance. For instance a determination of the molecular weight frequency function can give a very good picture of the progress of the polymerization reaction itself, and in studying the polymerization kinetics it provides a means to determine the termination mechanism of the growing molecules. The stop mechanism by which the active radicals will turn to dead molecules can involve either a combination of two radicals to one single polymer molecule or a disproportionation between two radicals. In the latter case a hydrogen atom moves from one growing polymer chain to another, giving

rise to two separate macromolecules. These two kinds of deactivation reactions will give different molecular weight distributions. It is also of interest to know the heterogeneity of an unfractionated or fractionated polymer in connection with such physico-chemical determinations as the measurement of intrinsic viscosity, osmotic pressure, light scattering, and diffusion or sedimentation constant of the polymer in solution. Even in the bulk properties of a polymeric material the polydispersity must be considered. For instance it may influence the mechanical properties and the general behaviour of a synthetic plastic.

For this reason, many attempts have been made to determine how the mass is distributed over the different molecular weights or over the different intrinsic viscosities or sedimentation constants occurring in the polymer. The most commonly used methods are fractionation, turbidimetric titration, determination of different average molecular weights with the aid of an equilibrium ultracentrifuge, dB/dx-measurement or analysis of the sedimentation peak in a velocity ultracentrifuge. In the first method the sample is divided into fractions, usually by fractional precipitation or fractional solution. This procedure gives good results but is very time-consuming because of the necessity of having equilibrium between solution and precipitate for every fraction. For this reason it can take two weeks to a month to complete one single fractionation. It is also easy to lose material during the many manipulations necessary. The turbidimetric method has been used on polymethyl methacrylate with success [1], but as a rule it seems to give results inferior to those obtained by fractional precipitation. This is probably due to the difficulty of getting stable and reproducible values of the turbidity itself. The procedure is valuable when one wants a rapid but rough estimate of the polydispersity of a sample. In the third method, an arbitrarily assumed parametric function is fitted to different observed average ultracentrifuge molecular weights obtained by means of an equilibrium centrifuge. This has been employed in many cases, however, the large deviation from ideality of the polymethyl methacrylate solutions will probably make it impractical for this substance. The dB/dx measurement, first developed by Gralén [2], has been widely used on macromolecular substances with a coiled chain configuration in solution such as occurs with polymethyl methacrylate. In this method, the width (B) of the experimental sedimentation curve is defined as the ratio of area to maximum height of the sedimentation curve:

$$B = \frac{\int_{-\infty}^{+\infty} \frac{dc}{dx}\, dx}{\left(\frac{dc}{dx}\right)_{max.}} \qquad (1)$$

where x is the distance from center of rotation and c is the polymer concentration at a point x and at a given time (t) after full speed of the rotor. This width is plotted as a function of the position x of the peak of the sedimentation curve. It is found to vary in a linear fashion with the distance from center of rotation. The slope dB/dx of this curve is graphically determined for a series of different

concentrations and extrapolated to infinite dilution. This (dB/dx), at zero concentration, is then taken as a measure of the heterogeneity of the polymer. This method has been used among others by Gralén and Rånby [3] on cellulose derivatives. In all these cases it was possible to neglect the influence of diffusion on the spreading of the sedimentation curve. For polymethyl methacrylate the contribution of diffusion to the width of the curve is appreciable because of the high diffusion constant compared with the low sedimentation constant in fractions of moderate molecular weight. An attempt to correct the experimentally measured width for the influence of diffusion in this case has been made by the author [4]. The (dB/dx) method is rapid but it can never reveal details in the distribution and it fails entirely in the case where the frequency function has more than one maximum as can happen for unfractionated polymers prepared by bulk polymerization at high degrees of conversion [5-8].

It is, however, possible to obtain more detailed information about the distribution of mass over the different sedimentation constants contained in a polymer with the aid of a velocity ultracentrifuge. The method of sedimentation analysis was first applied to a high polymer by Signer and Gross [9]. If the polymer solution contains only one species having a constant sedimentation coefficient throughout the entire cell, it is easy to show that the concentration of polymer (c) will be independent of the position in the cell from the boundary between solution and pure solvent down to the bottom. But as a consequence of the sector shape of the centrifuge cell and the increasing strength of the centrifugal field with increasing distance from the center of rotation, the concentration (c) will change with time according to the following square law [10]

$$c = c_0 \ (x_0/x)^2 \tag{2}$$

where c is the actual concentration at the time (t) when the boundary has reached the position (x) in the cell; c_0 is the initial concentration and x_0 the distance from the center of rotation to the position of the meniscus. If the solution consists of more than one component having different but constant sedimentation coefficients, each species will give a separate boundary and a constant concentration in the entire cell from its boundary to the bottom. The square dilution law will still be valid if one uses the x-value of the boundary belonging to the corresponding component.

In the case of a polymer solution with a more or less continuous spectrum of sedimentation constants one can divide the experimental sedimentation curve into a number of strips. The increase of concentration $(dc/dx)dx$ in such an interval $x_1 - dx/2$ to $x_1 + dx/2$, corrected for the dilution effect by multiplication with $(x/x_0)^2$, will then represent the fraction of material having sedimentation constants in the interval $s_1 - ds/2$ to $s_1 + ds/2$, where s_1 is the sedimentation constants for the components having its boundary at the point x_1 at the time of exposure (t).

$$x = x_0 \ e^{\omega^2 ts} \tag{3}$$

We thus have the expressions

$$dx/ds = x \ \omega^2 \ t \tag{4}$$

and

$$g(s) = \frac{dc}{ds} = \left(\frac{dc}{dx}\right) \left(\frac{x}{x_0}\right)^2 x\ \omega^2\ t \qquad (5)$$

with the aid of which we can transform the experimental sedimentation curve to a mass frequency function $g(s)$. This procedure is, however, only valid for the case where the sedimentation coefficients are independent of concentration, that is they are real constants, and where the broadening of the boundary peak is entirely due to the distribution of mass over different sedimentation constants and not at all caused by diffusion of the macromolecules. These conditions were fulfilled in the case of the polystyrene fraction investigated by Signer and Gross. If the contribution from diffusion is great enough, the distributions calculated by the method of Signer and Gross from exposures taken at different times after the start of the experiment will not coincide. The frequency curves determined from earlier exposures are broader than those from later ones.

For the case where diffusion cannot be neglected, Baldwin and Williams [11,12] have developed an extension of the theory by which it is possible to sort out the contribution from sedimentation from that of diffusion. These authors have pointed out that if the concentration is so low that diffusion and sedimentation occur independently of each other the second moment of the experimental sedimentation curve will be equal to the second moment that would have arisen if there had taken place a pure sedimentation process without any diffusion plus the second moment of the curve had there been a pure diffusion without any sedimentation. That is:

$$\sigma^2_{\text{total}} = \sigma^2_{\text{sed.}} + \sigma^2_{\text{diff.}} \qquad (6)$$

where σ^2_{total} = the square of the standard deviation for the experimental curve
$\sigma^2_{\text{sed.}}$ = the square of the standard deviation for an imaginary curve from a pure sedimentation process
$\sigma^2_{\text{diff.}}$ = the square of the standard deviation for the curve from a pure diffusion process.

According to Lamm [13]

$$\sigma^2_{\text{diff.}} = \frac{2Dt}{1 - \omega^2\ st} \qquad (7)$$

where D = the diffusion constant for a homogeneous sample,
s = the sedimentation constant,
ω^2 = the angular velocity of the rotor,
t = time after the start of the combined sedimentation and diffusion process.

Baldwin and Williams calculated the square of the standard deviation of a pure sedimentation curve and found that

$$\sigma^2_{\text{sed.}} = p^2\ \omega^4\ x^2_{\text{m}}\ t^2 \qquad (8)$$

where p^2 = the square of the standard deviation of the distribution of sedimentation constants,

x_m the distance from the center of rotation to the first moment of the gradient curve.

From eqns. (6), (7), and (8) it follows that the fraction of the total standard deviation of the experimental sedimentation curve which is due to the contribution from diffusion will be less important with increasing time (t) and zero when t goes to infinity. In eqn. (7) we have to use average values for the diffusion and sedimentation constants for the inhomogeneous polymer. Baldwin and Williams calculate an apparent distribution $g(s)$ * from each sedimentation curve obtained from the different exposures taken during the same run by means of the equation

$$g(s)^* = \frac{(dc/dx)}{A_{t=0}} \left(\frac{x}{x_0}\right)^2 x\ \omega^2\ t \qquad (9)$$

where $A_{t=0}$ is the area of the sedimentation curve extrapolated to zero time. In order to get the real distribution $g(s)$ undisturbed by the influence of diffusion they then determine $g(s)$ * for a series of fixed s-values and plot these $g(s)$ * values against $1/t$. These values extrapolated to $1/t = 0$ then give the real distribution of sedimentation coefficients. Gosting [14] has examined the question of extrapolation in detail and has found that if t is fairly large $g(s)$ * is a closely linear function of $1/xt$.

Up to this point we have only discussed the problem for the case where the sedimentation is independent of the polymer concentration or the hydrostatic pressure in the cell. The first of these two questions has been treated independently by both Baldwin [15] and Williams [16,17]. If the sedimentation is concentration-dependent, the concentration of each species will no longer be constant throughout the cell as was the case when the sedimentation coefficient was independent of the concentration. Instead, the concentration of the different species will now change with the position in the cell in such a way that a slower component will appear to have a higher and a faster one a lower concentration if calculated in the usual manner. That is, one obtains a so-called Johnston-Ogston effect [18]. Secondly, one does not obtain the distribution of sedimentation constants but rather a distribution of sedimentation coefficients for different concentrations. The concentration is highest for the fastest component and decreases with decreasing sedimentation rate of the species down to zero concentration for the slowest one. Both these effects can be eliminated if we extrapolate the observed distribution function to zero concentration. According to the method of Williams, which is purely graphical, the distributions of sedimentation coefficients derived from a series of concentrations are extrapolated to infinite dilution. This is done by determining the $g(s)$ values for given s values and by plotting these $g(s)$ values as a function of concentration c. The procedure given by Baldwin is, however, analytic. By this method it is possible to calculate the final distribution of sedimentation constants from one single sedimentation run. But this theory requires a knowledge of how the different sedimentation coefficients depend on concentration. This dependence is, however, not identical with the usually determined s—c function as evaluated from the midpoints of the sedimentation peaks. In the

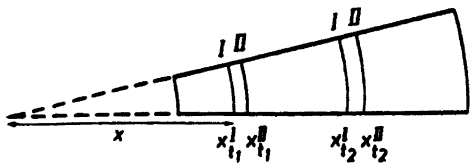

Fig. 1. The centrifuge cell.

Baldwin method one must determine the value of s for a particular species and this value is not identical with that which would be obtained if one could isolate a narrow range of species around the one in question and determine its sedimentation coefficient. Every narrow range of components is influenced by the presence of a much broader distribution of sedimentation coefficients and this is as a rule not symmetrically arranged around the range in question. It is possible to determine the desired function experimentally but because of the large amount of work involved the method has not been used in the present investigation. Both Baldwin and Williams have applied their theories to aqueous solutions of dextran and gelatin [15–17]. Both have obtained good results.

PRESENT IMPROVEMENTS

When organic solvents are used, as is necessary for polymethyl methacrylate, the great influence of the high hydrostatic pressure in the cell on the density and viscosity of the solvent must be taken into account. This pressure varies from about 1 atm. at the meniscus to 200—400 atm. at the bottom of the cell depending on the density of the solvent used and on the speed of the rotor. The sedimentation coefficient has to be reduced to the value of 1 atm. by means of the formula [19]

$$s_1 = s_p \frac{\eta_p(1-V_1\delta_1)}{\eta_1(1-V_p\delta_p)} = s_p \cdot \mathrm{f}(x) \qquad (10)$$

where s and V are the sedimentation coefficient and partial specific volume of the solute, η and δ the viscosity and density of the solvent, and the subscripts 1 and p refer, respectively, to the values at one and p atmospheres. As a rule there is no available data on how the partial specific volume varies with the pressure but it is generally assumed that this variation is small enough that in calculating the correction factor f(x) one may put V_p equal to V_1.

In order to obtain a relation between the concentration of a component (i) and the position coordinate x we may consider two cylindrical surfaces I and II through the centrifugal cell (see Fig. 1). At any given time these two surfaces will move with the same velocities as the (i) components having the same position coordinates. At the time $t = t_1$ the surfaces I and II will be at the points $x^{I}_{t_1}$ and $x^{II}_{t_1}$ and at the time $t = t_2$ at $x^{I}_{t_2}$ and $x^{II}_{t_2}$, respectively. By integration of the equation defining the sedimentation coefficient:

$$\omega^2 \, \mathrm{d}t = \frac{\mathrm{d}x}{x} \frac{\mathrm{f}(x)}{s} \qquad (11)$$

the following expressions are obtained

$$\omega^2 \ (t_2 - t_1) = \int_{x^{I}_{t_1}}^{x^{I}_{t_2}} \frac{f(x)}{x} \frac{dx}{s(c^{I})} = \int_{x^{II}_{t_1}}^{x^{II}_{t_2}} \frac{f(x)}{x} \frac{dx}{s(c^{II})} \tag{12}$$

This equation can be rearranged to

$$\int_{x^{I}_{t_1}}^{x^{II}_{t_1}} \frac{f(x)}{x} \frac{dx}{s(c^{I})} + \int_{x^{II}_{t_1}}^{x^{I}_{t_2}} \frac{f(x)}{x} \frac{dx}{s(c^{I})} = \int_{x^{II}_{t_1}}^{x^{I}_{t_2}} \frac{f(x)}{x} \frac{dx}{s(c^{II})} + \\ + \int_{x^{I}_{t_1}}^{x^{II}_{t_2}} \frac{f(x)}{x} \frac{dx}{s(c^{II})} \tag{13}$$

In these equations, $f(x)$ is the correction factor introduced in order to take into account the influence of the hydrostatic pressure. The surface II will always move in a more concentrated solution than the surface I so it may be valid to assume that

$$c^{I}(x) \leq c^{II}(x) \tag{14}$$

where $c^{II}(x)$ is the total polymer concentration at the point x at the time when the surface II passes this point and $c^{I}(x)$ has a corresponding meaning for the surface I. As a first approximation it can further be assumed that the sedimentation coefficient s of the component (i) decreases with increasing total concentration. We thus obtain the following inequality with the aid of (14)

$$\frac{1}{s \ (c \ (x))} \leq \frac{1}{s \ (c^{II}(x))} \tag{15}$$

This expression and equation (13) give the following inequality

$$\int_{x^{I}_{t_1}}^{x^{II}_{t_1}} \frac{f(x)}{x} \frac{dx}{s(c^{I})} \geq \int_{x^{I}_{t_2}}^{x^{II}_{t_2}} \frac{f(x)}{x} \frac{dx}{s(c^{II})} \tag{16}$$

And if the interval x^{I} to x^{II} is sufficiently small

$$\left\{\frac{f(x)}{x} \frac{dx}{s(x)}\right\}_{x_{t_1}} \geq \left\{\frac{f(x)}{x} \frac{dx}{s(x)}\right\}_{x_{t_2}} \tag{17}$$

Denoting the concentration of component (i) between the two surfaces by c, the volume element between these two surfaces by v and remembering the sector shape of the cell it is possible to write

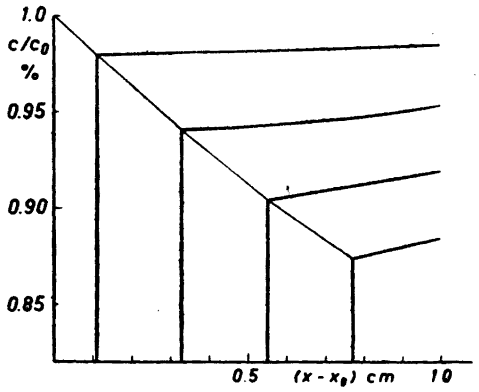

Fig. 2. The relative concentration as a function of $(x-x_0)$ *calculated from equation (19) for different positions of the meniscus.*

$$\frac{c_{t_1}}{c_{t_2}} = \frac{v_{t_2}}{v_{t_1}} = \frac{x_{t_2}(\mathrm{d}x)_{t_2}}{x_{t_1}(\mathrm{d}x)_{t_1}} \leq \frac{(x_{t_2})^2\, \mathrm{f}(x_{t_1})}{(x_{t_1})^2\, \mathrm{f}(x_{t_2})} \frac{s(x_{t_2})}{s(x_{t_1})} \qquad (18)^*$$

As a special case valid without any approximation at all

$$\frac{c_{t_1}}{c_{t_2}} = \frac{(x_{t_2})^2\, \mathrm{f}(x_{t_1})}{(x_{t_1})^2\, \mathrm{f}(x_{t_2})} \qquad (19)$$

if there is no concentration dependence of the sedimentation coefficient. With the aid of this equation the concentration in the cell has been calculated for different positions and at different times for the case of polymethyl methacrylate in ethyl acetate. As can be seen from Fig. 2 the concentration increases with increasing values of x even for sedimentation independent of concentration but dependent on the pressure in the cell **. This increase in concentra-

* This formula is valid for a polydisperse or a monodisperse solute in a solvent, where the influence of the hydrostatic pressure can not be neglected. Working with aqueous solutions Trautman [20] and Schumaker have previously treated the case of no hydrostatic pressure effect. They found that in a region where $(\mathrm{d}c/\mathrm{d}x) = 0$, the dilution will follow the square law

$$c/c_0 = (x/x_0)^2$$

This problem will also be discussed by Moring-Claesson [23] and Kinell [24,25]. Investigating the Ogston effect in a system of a few discrete components Moring-Claesson obtains the same formula as Trautman but in a different way; Kinell will consider in more detail the assumptions made by Trautman *et al.*

** It can be shown that the expression

$$(\partial c/\partial x)_t \equiv 0 \qquad (1)$$

is only possible if the correction function $\mathrm{f}(x)$ fulfils the conditions that

$$\frac{\mathrm{d}\left(x^2\, \frac{1}{\mathrm{f}}\right)}{x\, \mathrm{d}x} = \text{constant} \qquad (2)$$

Cont. on p. 368.

tion is more serious than the corresponding Johnston-Ogston effect caused by the concentration dependence of sedimentation because it can not be eliminated by extrapolation to infinite dilution in the usual way. It will, however, be so small that it will not be further considered here. For the dilution at the boundary one obtains

$$c_0 = c \left(\frac{x}{x_0}\right)^2 \cdot \frac{1}{f(x)} \tag{20}$$

since the pressure correction factor is equal to 1 at the meniscus. Not only will the dilution law change, but it follows from the integrated form of equation (11) that the derivative $\frac{dx}{ds}$ must now be written

$$\frac{dx}{ds} = \frac{1}{f(x)} x \omega^2 t \tag{21}$$

Instead of eqns. (5) and (3) the following expressions are valid for a concentration independent but pressure sensitive sedimentation

$$g(s) = \left(\frac{dc}{dx}\right) \left(\frac{x}{x_0}\right)^2 \frac{1}{f(x)^2} x \omega^2 t \tag{22}$$

$$s = \frac{1}{\omega^2 t} \int_{x_0}^{x} \frac{dx}{x} f(x) \tag{23}$$

When it is impossible to keep the temperature of the centrifuge solution and the angular velocity of the rotor perfectly constant the s-values must be corrected to the same temperature and the same speed of the rotor. The temperature is therefore read at short intervals of time and the sedimentation coefficient calculated for this interval reduced to a temperature of 20° C by means of the formula

$$s_{20} = s_t \frac{\eta_t}{\eta_{20}} \frac{(1 - V_{20}\varrho_{20})}{(1 - V_t \varrho_t)} \tag{24}$$

Cont. from p. 367.

This follows from the equation of continuity

$$\left(\frac{\partial c}{\partial t}\right)_x = - \frac{\omega^2 \partial (x^2 \frac{1}{f} c s)}{x \partial x_t} = - \omega^2 c s \frac{d\left(x^2 \frac{1}{f}\right)}{x\, dx} - \frac{\omega^2 x}{f} \frac{\partial (c s)}{\partial x_t} \tag{3}$$

which in the case of condition (1) reduces to

$$\left(\frac{\partial c}{\partial t}\right)_x = - \omega^2 c s \frac{d\left(\frac{1}{f} x^2\right)}{x\, dx} \tag{4}$$

Equations (1) and (4) can only be simultaneously valid if

$$\frac{d\left(x^2 \frac{1}{f}\right)}{x\, dx} = \text{constant}$$

where all symbols have their usual significance. The subscripts 20 and t refer to the temperature 20 and t °C. Small errors in the determination of temperature or of rotor speed will cause a shift in the whole $g(s)$ curve. This in turn may produce serious errors in the extrapolation of $g(s)$ to infinite time and infinite dilution. For this reason formula (22) has not been used in this investigation. Another procedure to calculate the distribution has therefore been developed. The experimental sedimentation curve dc/dx against x is read at constant x intervals and the dc/dx values corrected for dilution effects with the aid of eqn. (20). This corrected frequency curve is then integrated and starting from the origin the x_p values were determined for successive 10 % increments of the integral distribution curve. The index p refers to an increase of p % in the integral mass distribution. By means of equation (23) the ratio s_p/s_{50} is then calculated from the different x_p. In order to eliminate the contribution from diffusion the ratios s_p/s_{50} from different exposures are plotted against $1/(s_{50} \cdot t)$ and extrapolated to infinite time. The extrapolated values of the ratio s_p/s_{50} have to be converted to s_p-values. This can be done with the aid of eqn. (23) using the experimentally determined values of the integral $\int_{x_0}^{x_{50}} \frac{f(x)}{x} dx$ which are found to be a linear function of time.

This curve crosses the t axis at a small negative value indicating that the sedimentation starts a little before the rotor has reached the operating speed. The s_{50}-values calculated in this way are found to lie close to the $s_{max.}$-value determined in the usual manner from the maximum point of the sedimentation diagram. So in the case of homogeneous fractions it may be preferable to use values of s_{50} calculated from the known relation

$$\frac{1}{s} = \frac{1}{s_{max.}} (1 + kc) \qquad (25)$$

where $s_{max.}$. is the sedimentation constant of the maximum point extrapolated to infinite dilution and k is a constant expressing the concentration dependence of the sedimentation coefficient. Both $1/s_{max.}$ and k have of course been determined by means of the method of least squares from a long series of experimentally found $1/s$, c pairs. In order to obtain the real distribution, $1/s_p$ has to be plotted against c and extrapolated to infinite dilution. This procedure is facilitated by the fact that $1/s_p$ is a closely linear function of c.

EXPERIMENTAL AND RESULTS

Materials. The method of determining the distribution of mass over the different sedimentation constants in a synthetic high polymer has been tested on polymethyl methacrylate in ethyl acetate as solvent. In order to obtain polymers of highly different heterogeneity covering a broad interval of molecular sizes, samples of unfractionated and fractionated polymers as well as mixed fractions have been investigated. The polymethyl methacrylates have been prepared by bulk polymerization with benzoyl peroxide as initiator. Both the concentration of initiator and the degree of conversion have been varied. The reaction conditions will be given in detail later [22]. The polymers were fractionated by precipitation and the sedimentation constants were determined for every

fraction in ethyl acetate. Details of fractionation and sedimentation technique are given in Ref.[12]. The ethyl acetate used was "Baker Analyzed Reagent" and was not further purified.

Influence of the correction factor. The choice of correction factor has only a small influence on the distribution s_p/s_{50} calculated from a sedimentation diagram. This can be seen from Table 1, where the ratio

$$\frac{s_p/s_{50} \text{ corrected with the factor } (x/x_0)^2}{s_p/s_{50} \text{ not corrected for dilution}}$$

has been given for different percents (p) and at five times during the same run. The sample used was an unfractionated polymer /B(714)/ and therefore had an unusually broad massdistribution. The concentration was 0.157 g per 100 ml solution. The dilution-correction will only affect the value of s_{50}. The value of s_{50} calculated by the method of least squares after applying the correction factors, $(x/x_0)^2$ and $(x/x_0)^2 \cdot 1/f(x)$ and no correction, was 13.95 and 13.84 and 13.72, respectively.

Table 1. The ratio $\frac{s_p/s_{50} \text{ corrected with the factor } (x/x_0)^2}{s_p/s_{50} \text{ not corrected for dilution}}$ *for different percents (p) and at five times during the same run in the ultracentrifuge.*

Extrapolation of s_p/s_{50} to infinite time. With the method used here to get the mass distribution it is not possible to give an unequivocal theoretical justification for the procedure of extrapolating the ratio s_p/s_{50} to infinite time. In two special cases, however, $(s_p - s_{50})^2/s_{50}^2$ will be a linear function of $1/t$, namely if the substance is monodisperse or if the mass is distributed over the different s values in accordance with a Gaussian frequency curve and the diffusion constant is the same for all molecules. In both these cases it can be shown that the experimental sedimentation curves will be Gaussian if diffusion and sedimentation occur independently of each other in the cell. It was experimentally found that for polymethylmethacrylate s_p/s_{50} plotted against $1/(s_{50}t)$ gives a straight line. In order to investigate if different extrapolation methods could give different results, all s_p/s_{50} values for each concentration used (fraction B(712) XIV) were treated in two different ways, in one case s_p/s_{50} and in the other $(s_p/s_{50})^2$ was plotted against $1/(s_{50}t)$. This material has a high diffusion constant but a low sedimentation constant and hence the dependence of s_p/s_{50} on time after the start of the experiment is unusually large. The final distribution extrapolated to zero concentration did not show any systematical trend with the two methods. The mean difference between two corresponding s-values was less than 0.5 % and can be

considered to lie within the experimental accuracy of the procedure. As the difference can be expected to be still less for a more polydisperse substance or fraction with a lower diffusion constant, the method of extrapolating s_p/s_{50} as a linear function of $1/(s_{50}t)$ was chosen in order to save time. The two methods of extrapolation are illustrated in Figs. 3 and 4 for the two concentrations 0.792 and 0.199 g polymethyl metacrylate per 100 ml ethyl acetate solution. The fact that the dependence of s_p/s_{50} on time is much smaller for a more polydisperse sample is shown in Fig. 5 for the two concentrations 0.358 and 0.157 g/ml. The sample used was an unfractionated polymer B(714).

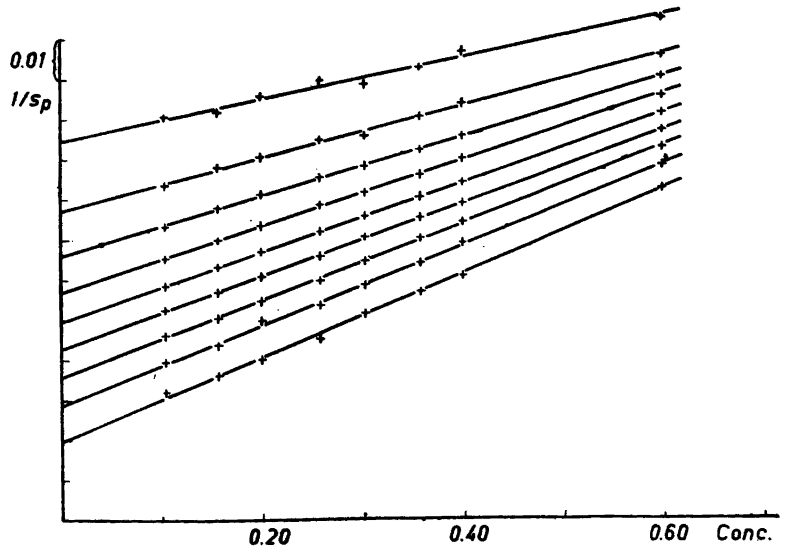

Fig. 6. $1/s_p$ as a function of concentration. In order to spread out the data the lines have been displaced from each other by 0.025 units. Sample B (714).

Comparison of the distributions of mass obtained by means of the velocity ultracentrifuge with those obtained by means of precipitation fractionation. The contribution of diffusion to the total width of the sedimentation peak is relatively small for a polymer with a reasonably heterogeneous composition of different molecular sizes. This is of course quite natural as the spreading from diffusion is determined only by the average diffusion constant and not at all by the width of the distribution of this constant. However, the spreading due to sedimentation is proportional to the mean sedimentation constant multiplied by the standard deviation of the function expressing the mass frequency over this constant. This is the reason why s_p/s_{50} is almost independent of t for all percents (p) except for the last fraction with the highest molecular weight. The function s_p/s_{50} plotted against $1/(s_{50}t)$ was shown in Fig. 5. If the average molecular size is not extremely high it is further possible to use more concentrated solutions in order to minimize the errors from the inaccuracy in the drawing of the base line of the gradient curve, dc/dx against x. The uncertainty in the determination of this line is greatest for polydisperse material and for low concentrations, where the sedimentation peak is very broad and flat. The mass distribution of two unfractionated polymers with an average sedimentation constant of 16.80 and 11.38 have been determined by analysis of the sedimentation diagrams. The first polymer is designed by B(714) and the second by B(712). The $s_{50}(c)$ values used were obtained from an eqn. similar to eqn. 25, the constants being derived by the method of least squares using the experimental s_{50} values for 8 and 5 concs., resp. in the 2 above cases. The coefficients $1/s_p$ were in every case found to lie on a straight line as shown in Fig. 6 for the polymer B(714). The final mass distribution over the sedimentation constant is shown in Fig. 7. In these figures the integral distributions obtained from precipitation fractionation are also given. These have been constructed under the assumption that half the mass of a fraction has a sedimentation constant lower than the average value determined for the fraction. The result is that the curves obtained from the two methods lie close to one another. A part of the small parallel displacement of the curves can possibly be explained by the fact that the sedimentation measurements on the different fractions were performed some years before the determinations on the unfractionated polymer. During this time the thermo-elements giving the rotor temperature have been exchanged and therefore the zero point of the temperature scale re-determined. The method of determining the integral distribution of mass by means of analysis of the sedimentation peaks is considered to be as accurate as the laborious and time-consuming technique of precipitation fractionation. Another advantage with the method of sedimentation analysis is that it can be applied directly on the initial reaction product diluted with the monomer. In this way it will be unnecessary to separate the polymer from the unreacted monomer.

Comparison of the distribution of mass obtained for mixtures of two fractions by means of the velocity ultracentrifuge with those obtained on the separate fractions by means of the same method. In order to get further proof of the usefulness of sedimentation analysis on high polymers, the investigation has been extended to higher molecular sizes and to more homogeneous material composed of one single fraction or mixtures of two fractions in equal parts. The more

essential properties of the fractions used in this study are summarized in Table 2. The values of s_{max} are the sedimentation constant as determined from the maximum point of the sedimentation curve. The experimentally determined relation $1/s = 1/s_{max}\ (1 + k_s c)$ has been used to calculate s_{50}. This has been done because it was found that the s_{50} values for this rather homogeneous sample are very nearly equal to s_{max} and because there was a greater number of data available on which to apply the method of least squares for the determi-

Table 2. Summary of the properties of the polymethyl methacrylate fractions that have been used for the sedimentation analyses.

Fraction		s_{max}	Weight of the fraction in percent of the total weight of the polymer product	Weight of material in the initial polymer product having a higher sedimentation constant than that of the fraction used
B(712)	XIV	6.29	7.68	89.25
B(709)	X	16.38	9.22	69.69
B(709)	XIII	10.50	6.75	90.09
B(709)	X+XIII	13.09 (s_{50})	—	—
B(713)	IV	30.36	4.40	3.40
B(713)	VI	27.05	5.45	10.00
B(713)	IV+VI	28.43	—	—

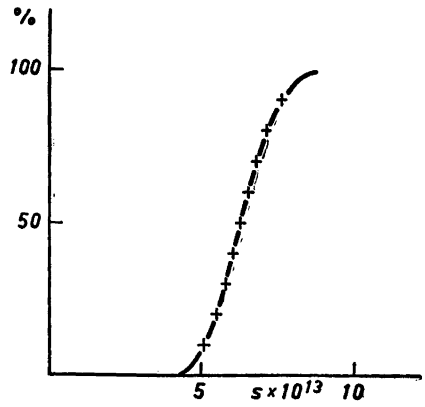

Fig. 8. Integral distribution of B(712) XIV.

nation of the constants $1/s_{max}$ and k_s. The different s_{max} are given in the second column of Table 2. In the next column the amount of each fraction is given in weight percent of the total polymer product, and the last column shows the total amount of material in the initial polymer product having higher sedimentation constant than that of the fractions used. As can be seen from the table, in polymer B(709) the mass of the two fractions between X and XIII was about 11 % of the total polymer. This was enough to give the mixture of the two fractions X and XIII a double peaked sedimentation curve. It was therefore impossible to determine any s_{max}. In this case the observed values of the sedimentation coefficient s_{50} for the five concentrations employed for the sedimentation analysis were used instead to calculate the sedimentation coef-

ficient at infinite dilution and the constant k_s that expresses the concentration dependence of this coefficient. Five or six concentrations have been used in the sedimentation analysis of each fraction or mixture of fractions. The lowest concentration in each series was about 0.1 g per 100 ml. The upper concentration limit was 1.0, 0.6 and 0.4 g per 100 ml for polymers designated by B(712) B(709) and B(713), respectively. In these concentration intervals it has been possible to extrapolate $1/s_p$ linearly with concentration. The calculated integral distributions of mass are shown in Figs. 8, 9 and 10. The dotted line in Fig. 9 is the mass distribution of the mixture of equal parts of the two fractions B(709) X and B(709) XIII, that has been calculated from the experimentally determined mass distributions of the two fractions separately. As can be seen from the figure this line is in reasonably good accordance with the mass distribution that has been obtained from sedimentation analysis applied directly on the mixture. A part of the small discrepancy may have been caused by errors in the determinations of the different $1/s_{50}$ values at infinite dilution. The result of the sedimentation analysis on the mixture of equal parts of the two fractions B(713) IV and B(713) VI is also very good (Fig. 10). Unfortunately the two fractions lie close together. It is therefore a little difficult to judge the extent to which the good agreement is due only to the reliability of the method. It may be that part of the agreement is due to the fact that the method gives approximately the same errors in all these three cases. It can, however, be concluded from these experiments that the analysis of the sedimentation curves will give integral mass distributions that are at least in broad outline correct even for relatively homogeneous materials.

This investigation has been financially supported by grants from *Statens Tekniska Forskningsråd* och *Stiftelsen Svensk Gummiforskning* (AB. Sieverts Kabelverk, AB. Liljeholmens Kabelfabrik, Goodyear Gummifabriks AB., Svensk Gummifabriks AB., Viskafors Gummifabriks AB.).

The author wishes to acknowledge his indebtness to Professor The Svedberg and Professor Stig Claesson for their kind interest and for the many facilities which have been put at the author's disposal.

The author also wishes to thank Doctor P.-O. Kinell, Doctor K. O. Pedersen and Assistent E. Hellman for their interest in this study.

Sedimentation, Diffusion and Viscosimetric Measurements on Polymethyl Methacrylate Fractions Obtained at Different Degrees of Conversion

A. FREDRIK V. ERIKSSON

Institute of Physical Chemistry, University of Uppsala, Uppsala, Sweden

It has been found from the nature of the relations between the sedimentation constant s, the intrisic viscosity $[\eta]$ and the molecular weight M that polymethyl methacrylate molecules formed at higher degrees of conversion do not have the same configuration as those molecules obtained during the stationary stage of the polymerisation. The relations between s, $[\eta]$ and M obtained for polymer molecules prepared at low degrees of conversion have been compared with Flory's theory for chain molecules. Slight systematic deviations of the experimental values from the theoretically expected relations have been observed.

The work reported in this paper is a part of an investigation of the molecular weight distribution in polymethyl methacrylate. The purpose of the present part has been to determine empirical relations between the sedimentation constant, the intrisic viscosity and the molecular weight of polymethyl methacrylate molecules.

MATERIAL

The monomer methyl methacrylate has been polymerisated in nitrogen atmosphere with various amounts of benzoylperoxide as initiator. The polymerisation temperature was 60° C for samples B(704) and B(720) and 80° C for samples B(714) and B(712). The degrees of conversion are 18, 72, 14, and 47 % for B(704), B(720), B(714), and B(712), respectively. A detailed account of the polymerisation technique and the method of fractionation will be given elsewhere [1]. Ethyl acetate has been used as solvent for all measurements. The quality of the ethyl acetate was "Baker Analyzed Reagent" and it was used without further purification.

VISCOSITY MEASUREMENTS

The intrinsic viscosity $[\eta]$ has been determined by means of an Ostwald viscometer at 20° C in ethyl acetate. The value of $[\eta]$ was obtained by extrapolating η_{sp}/c to infinite dilution, the reduced viscosity η_{sp}/c being determined for four concentrations (c). The

extrapolation was facilitated by the fact that η_{sp}/c is a linear function of concentration in the concentration range used. All measurements were made at concentrations lower than 0.4 g/100 ml.

SEDIMENTATION MEASUREMENTS

Technique. The sedimentation measurements have been performed in an oilturbine ultracentrifuge of the Svedberg type. A detailed account of the ultracentrifuge process has been given in the monograph by Svedberg and Pedersen [2] so only certain technical data will be mentioned here. The distance between the meniscus and the axis of rotation was 5.9 cm. The speed of the rotor was 800 revs/sec. for all measurements except for those on fractions of the sample B(704). In this latter case the rotor speed was only 600 revs/sec. For the observation of the sedimentation velocity Lamm's [3] scale method was used. The temperature of the rotor was regulated by cooling the turbine oil, and the temperature recorded by means of a thermocouple immediately adjacent to the rotor. The observed sedimentation coefficients have been corrected to 20.0° C and to 1 atm. pressure in the usual manner [4].

In order to test the reliability of the pressure correction formula

$$s_{1\text{ atm.}} = s_p \frac{\eta_p(1-V_1\varrho_1)}{\eta_1(1-V_p\varrho_p)}$$

in the case of the present system of polymer and solvent the sedimentation rate of a polymethyl methacrylate fraction was determined for three different rotor speeds and three different dilutions. The corrected value of the sedimentation coefficient was found to be independent of the rotor speed [5].

Dependence of the sedimentation coefficient on concentration. Because of the large extension of the flexible polymethyl methacrylate molecules the decrease of the sedimentation velocity with increasing concentration is considerable. At a concentration of about 0.8 g per 100 ml all fractions except the ones with molecular weights lower than about two hundred thousand sediment with the same velocity (Fig. 1). This means that they have entirely lost their individuality as molecules and sediment as a clouster. The usual formula

$$\frac{1}{s} = \frac{1}{s_0}(1 + k_s c) \qquad (1)$$

has been used for the extrapolation of the sedimentation coefficient to infinite dilution. It was, however, found that the inverse value of the sedimentation coefficient is a linear function of concentrations only if the dilution is great. This can be seen from Table 1 where the values of s and k_s are given for twelve fractions. For samples with sedimentation constants higher than about 20 the sedimentation coefficient will increase with the dilution more rapidly than is predicted by eqn. (1). For the two fractions with the highest molecular weights the values of s and k_s are considerably greater if calculated from the concentration interval 0.03—0.20 than from the concentration interval 0.15—0.8. All values have of course been obtained by means of the method of least squares. In order to avoid any systematical error from the method of extrapolating $1/s$ to infinite dilution, concentrations higher than 0.20 g per 100 ml have not been used. Six concentrations were used in carrying out the extrapolation.

Reproducibility of the determination of the sedimentation constant. In order to investigate the reliability of the determined values of the sedimentation

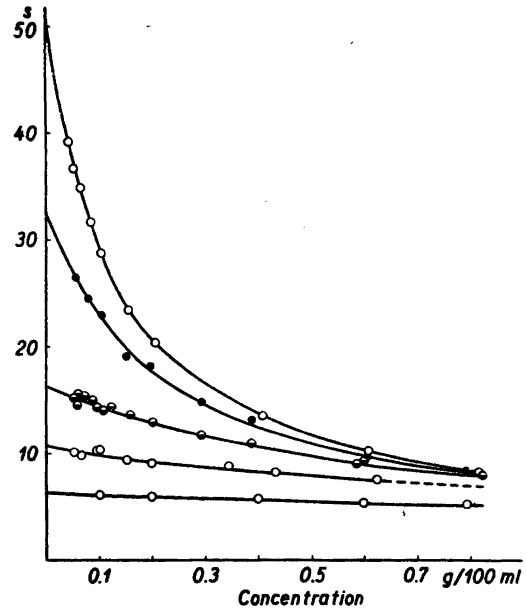

Fig. 1. The dependence of the sedimentation coefficient on concentration for samples B(720) I, B(713) IV, B(709) X, B(709) XIII and B(712) XIV respectively.

Table 1, showing how the value of the sedimentation constant s at infinite dilution and the value of the constant k_s, as obtained from a linear extrapolation of 1/s, depend on the concentration range, from which the extrapolation is performed.

constant, double determinations have been performed for six fractions, the two centrifugal runs for the same sample being made on different parts of the fraction and at a time interval of at least one year. The results are given in Table 2. From this it can be seen that the mean error is less than 2 %. This is, however, not a value of the reproducibility of the sedimentation coefficient itself which is considerably greater. The main part of the deviation is due to inhomogeneity of the sample and variations of the solvent used.

DIFFUSION MEASUREMENTS

Technique. The diffusion coefficient was determined in ethyl acetate at 20° C. The diffusion cell used was of the old Claesson [6] type. (During the course of this investigation a new diffusion cell with increased reproducibility has been constructed by Claesson *et al.*[7]) The diffusion was followed by means of Lamm's scale method [3].

Dependence of the diffusion coefficient on concentration. Because of the strong dependence of the sedimentation velocity on concentration it was considered essential to use as low concentrations as possible for the diffusion measurements. In the initial experiments the highest concentration was 0.4 g/100 ml [5]. Later, however, the concentration range was extended to 0.6 in order to increase the reliability of the determination and to be able to study the concentration dependence of the diffusion coefficient itself. Within the experimental accuracy this coefficient was found to be a linear function of the concentration as can be seen from Fig. 2, where D_m and D_A are plotted against the original concentration of the solution. When the diffusion coefficient is dependent on concentration the experimental curves will no longer be symmetrical around the position of the original boundary between solution and solvent. If, as in this case, the diffusion coefficient increases with increasing concentration the maximum of the diffusion curve must be displaced to the pure solvent side of the boundary [8,9] — the negative side — according to the theory of Boltzmann [8]. The experimentally obtained diffusion curves were also found to be

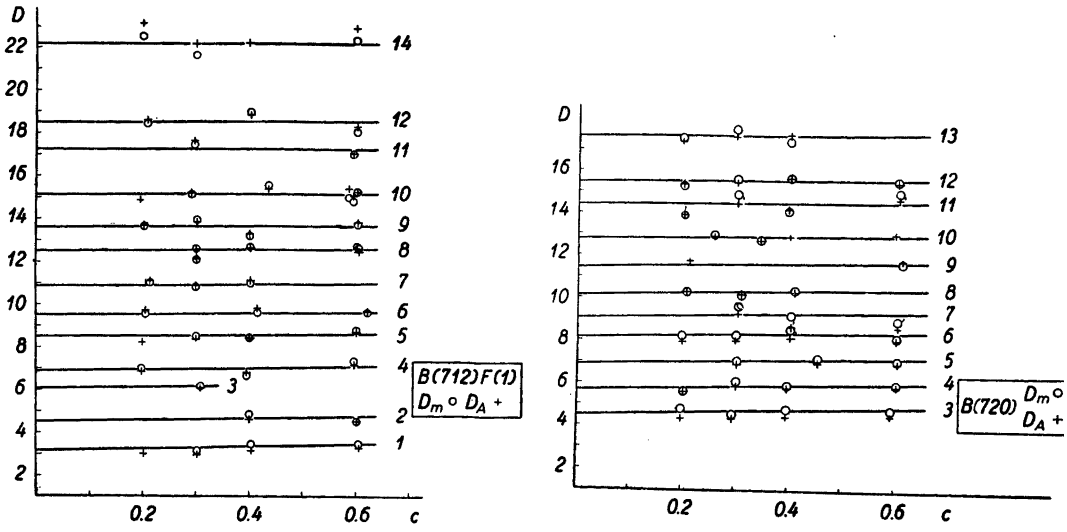

Fig. 2. The dependence of the diffusion coefficient on concentration. Circles represent D_m *and crosses* D_A *values. The figures on the ordinate mark the zero points of the fractions indicated by corresponding numbers on the right. The distance between each scale line is* 10^{-13} *units of* D.

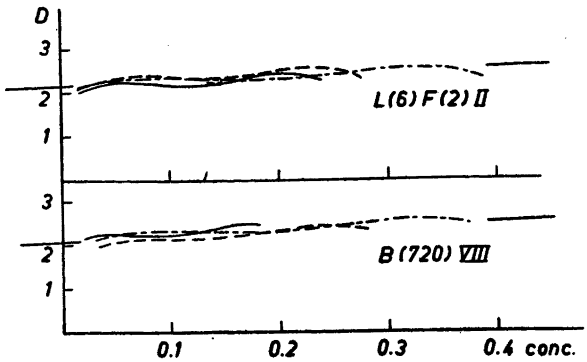

Fig. 4. The dependence of the diffusion coefficient on concentration obtained by Boltzmann analyses. The straight lines at the end of the figures indicate the concentration dependence calculated from the skewness of the diffusion curves according to the method of Gillis et al.

skew and with a negative displacement of the maximum. This is illustrated in Fig. 3 where the normalized diffusion curves [3] from five exposures taken during the same diffusion experiment from 14.6 to 35.6 hours after the start of the diffusion process are given. The experimental points from the five normalized curves fall on the same curve.

Method of extrapolation of the diffusion coefficients. Unfortunately the spread of the D_m and D_A values is rather large at the low concentration — D_m and D_A being, respectively, the diffusion coefficients determined with the method of moments and areas. Two different methods have been used to determine the constant k_D in the equation:

$$D(c) = D_0 \ (1 + k_D c) \tag{2}$$

Method 1. According to the theory of Boltzmann [8-10] it is possible to determine the value of D for every value of the concentration (c) from zero to the initial concentration (c_0) of the solution, $D(c)$ being given by the expression:

$$D(c) = -D_m \cdot \frac{1}{dc/dz} \int_{-\infty}^{z} z \cdot \frac{dc}{dz} \cdot dz \tag{3}$$

where D_m is the obtained value of the diffusion coefficient determined in the usual way by the moment method, dc/dz and z the coordinates of the normalized diffusion curve. In the derivation of eqn. (3) it has been assumed that the diffusing material is monodisperse. As has been shown by Beckmann and Rosenberg [10] the experimentally obtained relation between $D(c)$ and c will show a minimum near the concentration $c = c_0/2$ if eqn. (3) is applied to the diffusion curve of a polydisperse sample.

In Fig. 4 the results of Boltzmann's analyses are shown for two different fractions L(6)F(2) II and B(720) VIII and at three different concentrations. All six curves have minima in the vicinity of $c = c_0/2$. Owing to uncertainty

in the determination of D_m the three curves are also at little displaced parallel to one another. However, they all show the same tendency. An average value of D_0 at infinite dilution and of k_D for the different molecules in the fraction has been defined by the equations

$$D_0 \cdot k_D \frac{c_0}{2} = \frac{\int_{c_0/2}^{c_0} D(c)\mathrm{d}c}{c_0/2} - \frac{\int_{0}^{c_0/2} D(c)\mathrm{d}c}{c_0/2} \tag{4}$$

$$D_m = D_0 \left(1 + k_D \frac{c_0}{2}\right) \tag{5}$$

The last equation [9, 11] can be obtained if one integrates $D(c)$ over the whole concentration interval remembering eqns. (2) and (3).

$$\frac{\int_0^{c_0} D(c)\mathrm{d}c}{c_0} = \frac{\int_0^{c_0} D_0(1+k_D c)\mathrm{d}c}{c_0} = D_0 \left(1 + \tfrac{1}{2} k_D c_0\right) \tag{6}$$

or

$$\frac{\int_0^{c_0} D(c)\mathrm{d}c}{c_0} = \frac{\int_{-\infty}^{+\infty} D_m \mathrm{d}z \int_{-\infty}^{z} z \frac{\mathrm{d}c}{\mathrm{d}z}\mathrm{d}z}{c_0} =$$

$$\frac{D_m}{c_0}\int_{-\infty}^{+\infty} z^2 \frac{\mathrm{d}c}{\mathrm{d}z}\mathrm{d}z - \frac{D_m}{c_0}\left[z \int_{\infty}^{z} z \frac{\mathrm{d}c}{\mathrm{d}z}\mathrm{d}z \right]_{-\infty}^{+\infty} = D_m \tag{7}$$

It may be worth-while to point out that eqn. (7) does not imply that D_m, the diffusion coefficient calculated by the moment method, is a weight average. The whole derivation is strictly valid only for a monodisperse sample. Eqn. (7) expresses only a relation between D_m and the concentration dependence of $D(c)$.

Method 2. The second method used to determine k_D and D_0 is given by Gillis and Kedam [11]. Assuming

$$D(c) = D_0 \left(1 + k_D c\right) \tag{8}$$

they have solved the Fick equation

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(D(c) \frac{\partial c}{\partial x} \right) \tag{9}$$

in an approximate manner and calculated the relation between the product $k_D \times c_0$ and the ratio ϱ of the slope of the diffusion curve at the two points where $\mathrm{d}c/\mathrm{d}z = \frac{1}{2}(\mathrm{d}c/\mathrm{d}z)_{max}$, $(\mathrm{d}c/\mathrm{d}z)_{max}$ denoting the maximum value of the diffusion curve. After having determined k_D from the ratio ϱ one obtains D_0

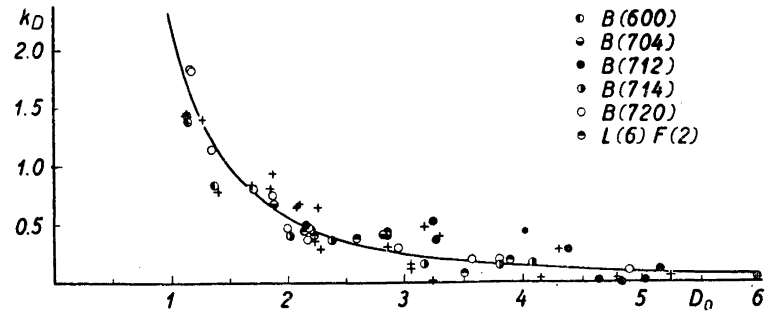

Fig. 5. The dependence of k_D *on the diffusion constant* D_0. *The circles are calculated from the skewness of the diffusion curves, the crosses from analyses according to Boltzmann.*

from eqn. (5). The derivations are rather complicated and cannot be reproduced here; for further details reference must be made to the original work [11]. The derivations are of course only strictly valid for a monodisperse sample. Gillis and Kedam have also calculated the dependence of $(dc/dz)_{max}$ on the ratio ϱ. The results of these calculations are expressed in the form of a table. This table has been used to correct the diffusion coefficients D_A determined in the present investigation. The value of the ratio ϱ has been evaluated from the normalized diffusion curve obtained from about five or six different exposures during the diffusion process.

The results of the two methods to determine k_D and D_0 are given in Fig. 5, where the obtained values of k_D are plotted against the corresponding D_0. The crosses are obtained by method one, the circles by method two. The line corresponds to the equation $k_D = 2.24 \cdot 1/D_0^2$. The constant 2.24 has been determined by applying the method of least squares to the values of k_D and D_0 obtained by method two. After having established this relation between k_D and D_0, the D_0 of each fraction has been calculated by the equation:

$$\frac{\Sigma D_m}{n} = D_0 + \tfrac{1}{2} k_D D_0 \frac{\Sigma c}{n} \tag{10}$$

$$k_D = 2.24 \frac{1}{D_0^2} \tag{11}$$

where $\frac{\Sigma D_m}{n}$ and $\frac{\Sigma c}{n}$ are, respectively, the average value of the diffusion coefficient D_m at finite concentrations and the average concentrations used. The lines drawn in Fig. 2 have been obtained with the aid of eqns. (10) and (11).

MOLECULAR WEIGHT DETERMINATIONS

The molecular weights M_{sD_m} and M_{sD_A} of the different fractions have been calculated with the aid of Svedberg's formula [2]

$$M = \frac{RT\,s}{D(1-V\varrho)} \tag{12}$$

Table 3, summarizing the main properties of the different polymethyl methacrylate fractions. In each series the linear and nonlinear regions in the log s —log [η] plot are separated from each other by a line.

where T = the absolute temperature
R = the universal gas-constant
V = the partial specific volume of the polymer
ϱ = the density of the solvent
The value [5] 0.787 has been used for V.

The molecular weights calculated from the values of $(D_m)_0$ and $(D_A)_0$ at zero concentration can be found in Table 3.

DISCUSSION

(Relations between intrinsic viscosity, sedimentation constants and molecular weights.) According to the current theories [12] describing the hydrodynamic behaviour of flexible polymer molecules, the dependence of the intrinsic viscosity $[\eta]$ and of the frictional coefficient, f_0, of the chain molecule at infinite dilution on the molecular weight M can be expressed by the equations

$$[\eta] = \Phi \left(\frac{r_0^2}{M}\right)^{3/2} M^{1/2} \alpha_\eta^3 \tag{13}$$

and

$$f_0 = \eta_0 P \left(\frac{r_0^2}{M}\right)^{1/2} M^{1/2} \alpha_f \tag{14}$$

where α_η and α_f represent the ratio of r the effective radius of the molecule in the given solvent to r_0 the root mean square distance between the ends of the polymer chain in a solvent where the second and higher osmotic virial coefficients are zero. Φ and P are universal constants for all flexible polymers irrespective of molecular weight, temperature or solvent used. The sedimentation constant at infinite dilution is further connected with the frictional coefficient f_0 by the expression

$$s_0 = \frac{(1 - V\varrho)M}{Nf_0} \tag{15}$$

where N is Avogadro's number.

Inserting the value of f_0 given by eqn. (14) in eqn. (15) gives

$$s_0 = \frac{(1-V\varrho)}{\eta_0 N\, P} \frac{1}{\left(\frac{r_0^2}{M}\right)^{\frac{1}{2}}} \frac{M^{\frac{1}{2}}}{\alpha_f} \tag{16}$$

By combining (13) and (16) one obtains

$$\frac{s_0[\eta]^{\frac{1}{3}}}{M^{2/3}} \cdot \frac{\eta_0 \cdot N}{(1-V\varrho)} = \Phi^{1/3} P^{-1} \frac{\alpha_\eta}{\alpha_f} \tag{17}$$

In the above equations it is generally assumed that $\alpha_\eta = \alpha_f = \alpha$. A statistical treatment of the long-range intramolecular interaction gives the expression

$$\alpha^5 - \alpha^3 = C_T\, M^{\frac{1}{2}} \tag{18}$$

where C_T is a constant for a given polymer-solvent system. For a not too large molecular weight interval it is therefore possible to assume that

$$[\eta] = K_\eta M^{a_1} \tag{19}$$

and

$$s = K_s M^{a_2} \tag{20}$$

where a_1 and a_2 take into account the extension of the molecule over that which would be obtained by random flight. A log s — log $[\eta]$ plot of the values for the different fractions does not give a straight line as predicted by eqns. (19) and (20), see Fig. 6. The points for the highest molecular weight fractions tend to lie below the straight line. This is most clearly seen for the series B(720) and B(712) for which the polymerization reaction had passed the first stationary stage. The direction of the deviation in the log s — log $[\eta]$ curve indicates that the polymers with the highest molecular weight, which have been formed during the second "explosive" stage of the polymerization, have a more extended configuration. Two explanations are possible, either the molecules are

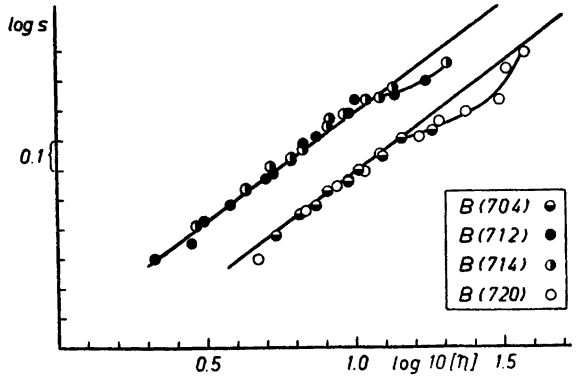

Fig. 6. Log s *plotted against log 10* $[\eta]$. *The upper curve has been displaced 0.2 units upward. The straight lines are drawn with the aid of the equation log* s = *0.74 log* $[\eta]$ + *1.29.*

connected by branching or so tightly entangled with one another that they never behave freely in the dissolved stage. The problem will be treated in detail elsewhere [1] so it will not be discussed further here. The points on the curved part of the line have been excluded in the determination of the constants in the equations describing the relations between sedimentation constant, intrinsic viscosity and molecular weight given in Table 4. In these calculations both M_{sD_m} and M_{sD_A}, the molecular weights obtained from D_m and D_A respectively, have been used. As can be seen from the last row in the table these two kinds of molecular weights give exactly the same relation with s and $[\eta]$ in spite of the fact that for a polydisperse sample D_A must be lower than D_m[3, 9]. The reason for the high values of D_A may be an undercorrection of the concentration effect. In extrapolating the experimentally obtained values of the diffusion coefficients, in accordance with the calculations by Gillis and Kedam, a lower concentration dependence has been assumed for D_A than for D_m. This causes $(D_A)_0$ at infinite dilution to be nearly equal to $(D_m)_0$ although the measured value of the former is lower at finite concentrations (See Fig. 2).

A calculation of $\Phi^{1/3}P^{-1}\frac{\alpha_\eta}{\alpha_f} \times 10^{-6}$ from expression (17) gives lower values for the last fractions in each series. From an analysis of all 34 values in the region where log s is a linear function of log $[\eta]$, one obtains the following mean values 2.37, 2.44 and 2.52 for the molecular weight intervals $< 2.5 \times 10^5$, 2.5×10^5 to 5×10^5 and $> 5 \times 10^5$, respectively. The number of fractions in each region is 9, 13 and 12, respectively. The values of $\Phi^{1/3}P^{-1}$ calculated for polymethyl methacrylate in acetone from data obtained by Meyerhoff show the same trend to increase for the lowest molecular weights [13]. The average value of $\Phi^{1/3}P^{-1}$ calculated from different polymers in different solvents, is $(2.5 \pm 0.1) \times 10^6$. The reason for the low value obtained for the last fractions can be either that these have a different degree of heterogeneity from the others

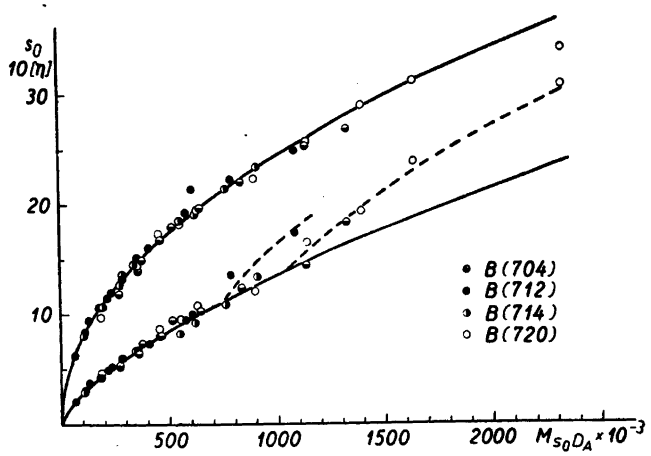

Fig. 7. s_0 *and 10* [η] *as functions of* M_{sD_A}. *The solid lines are the curves obtained from the constants in Table 4. The dotted lines are drawn through points that give a curved log s — log* [η] *line. Upper curve s, lower curve* [η].

or that the shapes of the polymer chains are such that they can not be approximated with an equivalent effective sphere, giving $\alpha_\eta/\alpha_t \neq 1$. (See Ref. 1).

The dependence of the sedimentation constant, the intrinsic viscosity, and the constant $\Phi^{1/3}P^{-1}$ on molecular weight is graphically represented in Figs. 7 and 8. The solid lines in Fig. 7 are the curves obtained from the constants in Table 4. The dotted lines are drawn through points that give a curved log s —log [η] line. This figure shows that the anomalies in intrinsic viscosity occurs at a lower molecular weight for polymers prepared at 80° C — B(712) and B(714) — than those at 60° C — B(704) and B(720). The deviation of the observed sedimentation constants from the solid line at high molecular weights is not so pronounced as in the case of intrinsic viscosity. This must also be expected from eqns. (13) and (16), s being inversely proportional to α and [η] directly proportional to the third power of α.

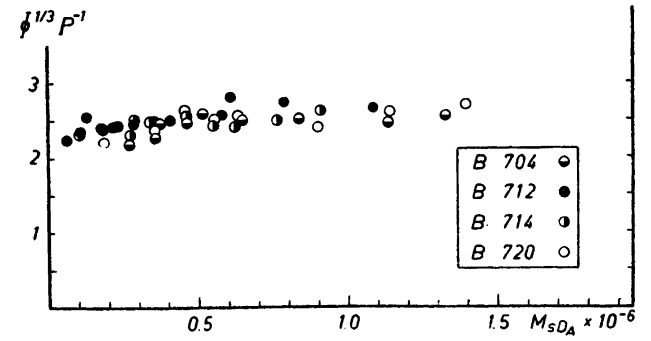

Fig. 8. $\Phi^{1/3}P^{-1}$ *as a function of* M_{sD_A}.

(The concentration dependence of the sedimentation coefficient.) The effect of the concentration on the sedimentation velocity of chain molecules has been investigated by Wales and Holde [14]. In their treatment the coiled polymer is considered as a sphere obeying Stokes' law

$$6\pi\eta_0 \; a = \eta_0 \, P \; r \tag{21}$$

where r is the effective radius of the equivalent sphere and

$$r = r_0 \; \alpha_f \tag{22}$$

The concentration dependence of the sedimentation coefficient of spherical particles is given by Burgers' relation

$$\frac{1}{s} = \frac{1}{s_0}\left(1 + \frac{55}{8} \, n \; v\right) \tag{23}$$

where n is the number of molecules in unit volume and v the volume of a molecule. Eqns. (13)—(15) and (21)—(23) together with the empirically found relation for the concentration dependence of the sedimentation coefficient

$$\frac{1}{s} = \frac{1}{s_0}\left(1 + k_s c\right) \tag{24}$$

give

$$\frac{k_s}{[\eta]} = \frac{\frac{55\,N}{8}\left(\Phi^{1/3} P^{-1}\right)^{-3}}{16\,200\pi^2} \tag{25}$$

and

$$M = \pi N \left(\frac{16\,200}{\frac{55}{8}}\right)^{1/2} k_s^{1/2} \left(\frac{s_0 \eta_0}{(1 - V\varrho)}\right)^{3/2} \tag{26}$$

If the value of $\Phi^{1/3} P^{-1}$ is considered to be 2.5×10^6 one obtains

$$k_s / [\eta] = 1.66 \tag{27}$$

As is seen from Table 3 there is a spread in the individual values of $k_s/[\eta]$ for the different polymethyl methacrylate fractions. However, the average value of $k_s/[\eta]$ in the three molecular weight intervals $< 2.5 \times 10^5$, 2.5×10^5—5×10^5 and $> 5 \times 10^5$ are 1.48, 1.57 and 1.71, respectively, the number of values in each interval being 9, 13 and 12. As can be seen from these figures $k_s/[\eta]$ gives approximately the value predicted by Wales and Holde, but increases slowly with increasing molecular weight. Thus both $k_s/[\eta]$ and $\Phi^{1/3} P^{-1}$ increase with molecular weight contrary to the predictions of eqn. (25).

The molecular weights, M_{calc}, of the different fractions calculated by eqn. (26) are given in Table 3. These are in fairly good agreement with those obtained by direct determination of the molecular weight M_{sD_A}. An analysis of the values in the three molecular weight intervals previously used shows that M_{calc}/M_{sD_A} is about 88, 94 and 103 % and increases with increasing M_{sD_A}. The nature of the average obtained by eqn. (26) is very complicated. It has been

found by the present author that for a symmetrical distribution of s the value of k_s is not very much influenced by the width of the distribution (unpublished work). This means that under the given assumption the average obtained by eqn. (25) would be equal to that calculated by inserting a weight average of s and a weight average of $1/D$ in eqn. (12). As the harmonic mean is less than the arithmetic mean this results in a molecular weight greater than M_{sD} calculated from a weight average of both s and D.

This investigation has been financially supported by grants from *Statens Tekniska Forskningsråd* and *Stiftelsen Svensk Gummiforskning* (Ab. Sieverts Kabelverk, AB. Liljeholmens Kabelfabrik, Goodyear Gummifabriks AB., Svenska Gummifabriks AB., Viskafors Gummifabriks AB.).

The author wishes to acknowledge his indebtness to Professor The Svedberg and Professor Stig Claesson for their very kind interest and for the many facilities which have been put at his disposal.

The author also wishes to thank Dr. P.-O. Kinell and Assistent Evald Hellman for their interest in this study and for many valuable discussions.

The Structure of Alpinone

JARL GRIPENBERG, ERKKI HONKANEN and KAJ SILANDER

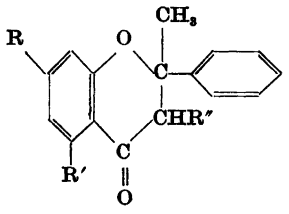
Department of Chemistry, Institute of Technology, Helsinki, Finland

The seeds of *Alpinia japonica* Miq. contain alpinone and its 3-acetate. The former has been shown to be identical with pinobanksin-7-methylether (V). 3-Hydroxy-5,7-dimethoxy-2-methylflavanone has been synthesised.

In 1936 Kimura and Hoshi [1] advanced the formula (I) for alpinone, a constituent of the seeds of *Alpinia japonica* Miq. The evidence they cited in support of this structure was, however, not very convincing. In particular the very easy loss of the methyl group in position 2, when alpinone was treated with alkali, appears to be extremely improbable. A reinvestigation of the structure of alpinone became even more necessary, when it could be shown that one of the key compounds in Kimura and Hoshi's arguments, namely the so called "apoalpinonemonomethylether" was wrongly formulated [2].

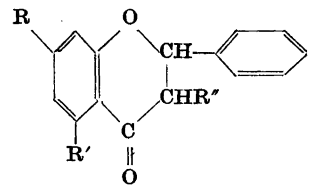
Two different approaches towards the solution of this problem were used. The first was to synthesise a compound with the structure (I) and compare it with alpinone, and the second was a reinvestigation of authentic alpinone. The second approach eventually led to a solution of the problem and the synthetic route was therefore left uncompleted, but the results obtained in the synthesis up to this time are reported in this paper.

When the seeds of *Alpinia japonica* were extracted with light petroleum two crystalline substances were obtained. They could be separated from one another by virtue of their different solubilities in toluene. The less soluble compound had m. p. 179—180°, $[\alpha]_D^{20}$ + 91° (pyridine), —12° (chloroform) and gave a benzoate of m. p. 208—210°. Kimura and Hoshi [1] report for alpinone m. p. 178°;$[\alpha]_D^{29}$ + 79.11 (pyridine), and for its dibenzoate m. p. 208—209°. It is thus evident that this compound is identical with the alpinone of Kimura and Hoshi [1]. Its analysis agrees, however, far better with $C_{16}H_{14}O_5$ than with $C_{17}H_{16}O_5$, as proposed by the Japanese authors. They converted alpinone with alkali into the so called apoalpinone, which upon methylation gave a dimethylether. This was identical with the methylether of a compound which Kimura and Hoshi synthesised and believed to be 3-hydroxy-5,7-dimethoxyflavanone (II) [1]. It has, however, recently been shown that this compound is 2-benzyl-2-hydroxy-4,6-dimethoxycoumaran-3-one (III) [2], from which it follows that "apoalpinone" must be (IV). The formation of (IV) from alpinone under alkaline conditions together with the analytical results mentio-



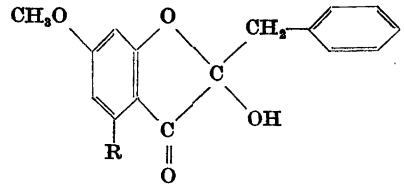
ned above, strongly suggest that alpinone is 3,5-dihydroxy-7-methoxyflavanone (V). It should thus be either identical with pinobanksin-7-methylether [3] or a stereoisomer of this compound. The following comparison clearly establishes that the two compounds are identical, as has been previously reported in a preliminary note [4].

	m. p.	$[\alpha]_D^{20}$ in pyridine	$[\alpha]_D^{20}$ in chloroform	m. p. of dibenzoate
Alpinone	179—180°	+ 91°	— 12°	208—210°
Pinobanksin-7-methylether	181—182° [3]	+ 92°	— 19° [3]	208—210°

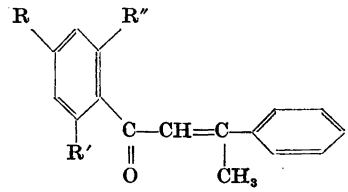


No depression of m.p.s was observed on mixing either the compounds themselves or their dibenzoates.

The same conclusion regarding the structure of alpinone has also been reached by Kotake, Sakan and Kubota [5].



As mentioned above, the extraction of the seeds of *Alpinia japonica* gave in addition to alpinone a second compound, more soluble in toluene. This has m. p. 135°; $[\alpha]_D^{20}$ + 17° (pyridine) and corresponds to the formula $C_{17}H_{13}O_5(OCH_3)$. It gave the same colour reactions with ferric chloride and with magnesium and zinc and hydrochloric acid as alpinone and its U.V.-spectrum is almost indistinguishable from that of alpinone (λ_{max} 292 mμ; log ε 4.28). On hydrolysis with strong acids it gave alpinone and acetic acid. It must thus be a monoacetate of alpinone and its positive colour reaction with ferric chloride places the acetyl group on the hydroxyl in position 3, enabling it to be formulated as (VI). When alpinone was acetylated with acetic anhydride and pyridine the same acetate was obtained. This is, as far as the present authors are aware, the first instance, that a 3-hydroxyflavanone has been found in Nature as its acetate. This compound occurs in an amount about equal to that of alpinone and it is difficult to see why Kimura and Hoshi were unable to isolate it.



I R = OCH_3; R′ = R″ = OH
IX R = R′ = OH; R″ = H
X R = R′ = OCH_3; R″ = H
XI R = R′ = OCH_3; R″ = OH

II R = R′ = OCH_3; R″ = OH
V R = OCH_3; R′ = R″ = OH
VI R = OCH_3; R′ = OH; R″ = $OCOCH_3$

III R = OCH_3
IV R = OH

VII R = R′ = R″ = OCH_3
VIII R = R′ = OCH_3; R″ = OH

Of the methods available for the synthesis of 3-hydroxyflavanones, the two methods due to Oyamada [6,7] appeared to be most promising for the synthesis of (I). In the first of these [6] bromine is added to the double bond of the acetate of the corresponding chalcone. The dibromide is then treated with silver acetate and the diacetoxydihydrochalcone is submitted to acid hydrolysis giving the 3-hydroxyflavanone. The starting material was in this case 2',4',6'-trimethoxy-β-methylchalcone (VII) obtainable from phloroglucinoltrimethylether and β-methylcinnamoyl chloride under Friedel-Crafts conditions. This was partially demethylated to (VIII) using aluminium bromide in benzene. Addition of bromine to the acetate of (VIII) was, however, unsuccessful. Only intractable tars were obtained.

The second method involves oxidation of the corresponding flavanone with lead tetra-acetate, followed by hydrolysis of the thus formed 3-hydroxyflavanone acetate. The flavanone (IX) has been prepared, although in low yield, by Lindstedt and Misiorny [7] and by Kotake [8]. Because the hydroxyl groups have to be protected during the lead tetra-acetate oxidation it was found more convenient to synthesise its dimethylether (X) from the corresponding chalcone (VIII). The lead tetra-acetate oxidation of (X) gave a very low yield of (IX). For reasons given above, no attempt was made to improve the yield in this step or to carry out the reaction on a larger scale in order to obtain sufficient material for carrying the synthesis to completion.

EXPERIMENTAL

Isolation of alpinone and its 3-acetate. The finely ground seeds of *Alpinia japonica* were extracted in a Soxhlet apparatus with light petroleum for 6 hours. The solvent was distilled off and the residue was steam distilled in order to remove volatile components. The dried residue was boiled with toluene, leaving a green amorphous mass undissolved. Fractional crystallisation of the toluene soluble part gave, as a less soluble component alpinone, m. p. 179—180°, $[\alpha]_D^{20}$ + 91° (*c* 3.46 in pyridine); −12° (*c* 2.64 in chloroform). (Found: C 66.50; H 4.82. $C_{16}H_{14}O_5$ requires C 67.12; H 4.93). The dibenzoate was prepared with benzoyl chloride and pyridine on a water bath; m. p. 208—210°.

The more soluble component was alpinone-3-acetate, m. p. 135°, $[\alpha]_D^{20}$ + 17° (*c* 4.7 in pyridine). (Found: C 66.12; H 4.97; OCH_3 9.60. $C_{17}H_{13}O_5(OCH_3)$ requires C 65.85; H 4.91; OCH_3 9.46).

Alpinone and its 3-acetate have widely different R_F-values (0.42 and 0.76, respectively, in ligroin:water:methanol (100:50:1)).

Hydrolysis of alpinone-3-acetate. Alpinone-3-acetate (330 mg) was boiled in a nitrogen atmosphere for one hour with a solution of hydriodic acid (9 ml) in abs. ethanol (1.5 ml). Water was then added and the precipitate recrystallised from methanol, m. p. 181—182°, undepressed when mixed with alpinone. (Found: C 67.21; H 4.94; OCH_3 10.94. $C_{15}H_{11}O_4(OCH_3)$ requires C 67.12; H 4.93; OCH_3 10.84). The same result was also obtained by using conc. hydrochloric acid or 42 % sulphuric acid. In the last case the volatile acid formed in the reaction was distilled off and its half distillation value (determined according to Virtanen and Pulkki [10]) was found to be 37, which is the value given for acetic acid [10].

Synthesis of alpinone-3-acetate. Pinobanksin-7-methylether [3] (30 mg) was dissolved in acetic anhydride and one drop of pyridine was added. After standing overnight at room temperature water was added. The oil which precipitated crystallised after some time and was recrystallised from methanol. M. p. 135—136°, undepressed when mixed with natural alpinone-3-acetate. (Found: C 65.33; H 5.11. $C_{18}H_{16}O_6$ requires C 65.85; H 4.91).

2',4',6'-Trimethoxy-β-methylchalcone (VII). Phloroglucinoltrimethylether[11] (18.1 g) and β-methylcinnamoylchloride[12] (19.5 g) were dissolved in nitrobenzene (100 ml). The mixture was cooled with ice and stirred, and powdered aluminium chloride (14.0 g) was added in small portions during two hours. Stirring was continued for three hours at room temperature. The precipitate was filtered off, washed with dry ether, and then added in small portions to ice-cold hydrochloric acid. The remaining solid was filtered off, dried, and recrystallised from methanol giving light yellow leaflets, m. p. 127—128°. Yield 16.5 g (50 %). (Found C 72.5; H 6.5. $C_{19}H_{20}O_4$ requires C 73.1; H 6.5).

2'-Hydroxy-4',6'-dimethoxy-β-methylchalcone (VIII). 2',4',6'-Trimethoxy-β-methylcalcone (15.6 g) was dissolved in dry benzene (100 ml) and to this was added during half an hour a solution of aluminium bromide (14.5 g) in benzene (100 ml). The mixture was then refluxed on a water bath for two hours. The solvent was removed in vacuum and the residue was treated with ice-cold hydrochloric acid. The solid was filtered off and recrystallised from methanol. Yellow prisms, m. p. 75—77°. Yield 12.2 g (81 %). (Found: 72.1; H 6.1. $C_{18}H_{18}O_4$ requires C 72.5; H 6.1). Other demethylating agents gave much inferior yields.

The acetate was obtained by boiling the chalcone with acetic anhydride, either in pyridine solution or in the presence of anhydrous sodium acetate. Almost colourless leaflets, m. p. 87—88°. (Found: C 70.04; H 6.47 $C_{20}H_{20}O_5$ requires C 70.57; H 5.92 %).

5,7-Dimethoxy-2-methylflavanone (X). 2'-Hydroxy-4',6'-dimethoxy-β-methylchalcone (6.0 g) was dissolved in hot ethanol (100 ml) and to this was added 2 N sodium hydroxide (50 ml). The mixture was then poured into 400 ml of cold water and allowed to stand for 24 hours. The precipitate was filtered off and recrystallised from ethanol. Colourless crystals, m. p. 135—136°. Yield 5.1 g (85 %). (Found: C 72.2; H 6.1. $C_{18}H_{18}O_4$ requires C 72.5; H 6.1).

3-Hydroxy-5,7-dimethoxy-2-methylflavanone (XI). 5,7-Dimethoxy-2-methylflavanone (3.0 g) was dissolved in glacial acetic acid (50 ml) and lead tetra-acetate (4.7 g) was added. The mixture was kept at 85—90° for 3 hours and then poured into 200 ml of cold water. The precipitate was dissolved in ethanol (100 ml) and conc. hydrochloric acid was added. The mixture was then warmed for half an hour on a water bath in a stream of carbon dioxide, and poured into water (200 ml). This was allowed to stand for 24 hours, whereafter the precipitate was filtered off and recrystallised from methanol. Colourless needles, m. p. 166—167°. Yield 0.06 g. (Found: C 69.1; H 5.8. $C_{18}H_{18}O_5$ requires C 68.8; H 5.8).

The analyses were carried out by Dr. J. Hukki of this Institute, Dr. A. Bernhardt, Mülheim, and Dr. A. Schoeller, Kronach. The authors wish to thank Prof. H. Erdtman, Stockholm, for a generous sample of pinobanksin and Prof. S. Hattori and Dr. Y. Kimura, Tokyo, for providing us with the seeds of *Alpinia japonica*.

Essential Groups in DPN-linked Lactic Dehydrogenase

AGNAR P. NYGAARD*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden, and Johan Throne Holst's Institutt for Ernæringsforsking, Blindern, Oslo, Norway

Sulfhydryl groups in lactic dehydrogenase from ox heart (LDH) have been determined both amperometrically with mercuric chloride and spectrophotometrically with *p*-chloromercuribenzoate (PCMB). The enzyme appeared to contain 7—9 SH groups, but only 3 of these reacted with PCMB in the native enzyme. LDH was slowly inhibited by PCMB [4], but rapidly by mercury and silver ions; slowly by periodate, but rapidly by iodine, which oxidized SH groups. Incubation of LDH with acetic anhydride blocked amino groups, increased the reactivity of SH groups to PCMB and caused a strong inhibition. This inhibition was not reversed under conditions which hydrolyzed phenyl acetate and thiol acetate. Also a temporary inhibition by acetic anhydride was observed, which existed while acetic anhydride was present in the solution.

The great majority of DPN-linked ** enzymes contain essential sulfhydryl groups which are susceptible to most SH reagents [1]. In contrast, DPN-linked lactic dehydrogenase from ox heart (LDH) is not readily inhibited by a number of SH reagents [2,3], and was for that reason believed not to require SH groups for activity. Recently, however, *p*-chloromercuribenzoate (PCMB) has been found to react slowly with the enzyme, thus causing inhibition [4]. In this work the reactivity and essentiality of SH groups in LDH have been further investigated.

Many enzymes are known to depend on SH groups for their activity. Less is known about other kinds of functional groups. Ideal reagents are lacking in many cases. Further work may reveal other groups as frequently involved in the regulation of enzyme activity as are SH groups. In this study, the essentiality of amino groups in LDH has been investigated. As carriers of positive charge, these groups could be expected to play a role in the electrostatic interaction of enzyme and coenzyme or substrate. Extensive studies have revealed

* Fellow, Norwegian Research Council.

** The following abbreviations are used: DPN: diphosphopyridine nucleotide, DPNH: reduced diphosphopyridine nucleotide, LDH: DPN-linked lactic dehydrogenase from ox heart, PCMB: *p*-chloromercuribenzoate and SH: sulfhydryl (thiol) group.

this kind of interaction between flavin mononucleotide and the apoprotein of the old yellow enzyme [5].

Also included in this work is the detection of what appears to be a very labile acetyl compound of LDH.

A short account on the work with SH groups in LDH has already been published [6].

MATERIALS AND METHODS

Crystalline LDH, containing fractions A and C [3,4] was prepared according to Straub [7]. The enzyme concentration was determined from optical density measurements at 280 mμ. In the calculation, a molar extinction coefficient of 20.1×10^4 and a molecular weight of 135 000 were used [3,4].

Crystalline liver alcohol dehydrogenase was a gift from Dr. R. Bonnichsen.

DPN, 90 % pure, was procured from Sigma Chemical Company, St. Louis, Mo.

DPNH was prepared by enzymatic reduction of DPN [8].

Sodiumpyruvate was made from commercial pyruvic acid [9].

DL-*Lactic acid* was Baker's analyzed reagent.

Oxidoreduction of DPN(H) was measured with a fluorimeter of the type described elsewhere [10,11].

Iodination of the enzyme was carried out at 0° C. The iodinating agent was 0.1 M iodine dissolved in 96 % alcohol.

Acetylation of the enzyme and of cysteine and tyrosine was accomplished by the addition of 1 μl quantities of acetic anhydride to approximately 1 ml of the protein (amino acid) solution buffered with 2.5 M sodium acetate and kept at 0° C [12]. To the control the same amount of acetic anhydride was added to the acetate solution half an hour before the enzyme (amino acid) was added.

Thiol groups were determined both spectrophotometrically with PCMB according to Boyer [13] and amperometrically according to Kolthoff *et al.*[14] In the spectrophotometric determinations the change in optical density at 250 mμ was recorded and a molecular extinction coefficient of 7.6×10^3 was used to calculate the extent of the reaction. Spectrophotometric determinations were carried out both with the native and denatured enzyme. Denaturation was accomplished by incubation of the enzyme in 10 % lauryl sulfate. Foaming prevented amperometric titration of a protein denatured with lauryl sulfate. The amperometric titration had to be carried out within 10 minutes, otherwise the potentials drifted and measurements were impossible. Cysteine treated with acetic anhydride gave no reaction with PCMB or with mercury ions in the amperometric titration. This shows that the thiol groups were blocked and that the acetyl-thiol linkage was stable under the conditions of analysis. Cysteine treated with acetic anhydride will be designated S-acetyl cysteine. Undoubtedly, the amino group was also acetylated in this compound.

Tyrosine was estimated by the Millon-Lugg procedure [15], and the diiodotyrosine formed was calculated from the difference in tyrosine content determined by this procedure before and after iodination [12].

Amino groups were determined by Van Slyke amino nitrogen analysis [16], which was carried out on dialyzed samples containing approximately 15 mg of protein. A 15 minute reaction time was found sufficient to give maximum values.

Phenol groups were estimated by means of Folin's phenol reagent [17], the protein first being denatured with lauryl sulfate [18]. When tyrosine had been treated with acetic anhydride the color reaction was negative, indicating that phenolic hydroxyl was acetylated and that the linkage was stable under the conditions of analysis. Tyrosine treated with acetic anhydride is designated O-acetyl tyrosine. This compound was undoubtedly also acetylated in the amino group.

Hydrolysis of phenol acetate and thiol acetate can be accomplished by incubation at pH 11 for about 5 minutes [12]. The acetyl-amino linkage is stable under these conditions. Therefore, if no reactivation of an acetylated enzyme takes

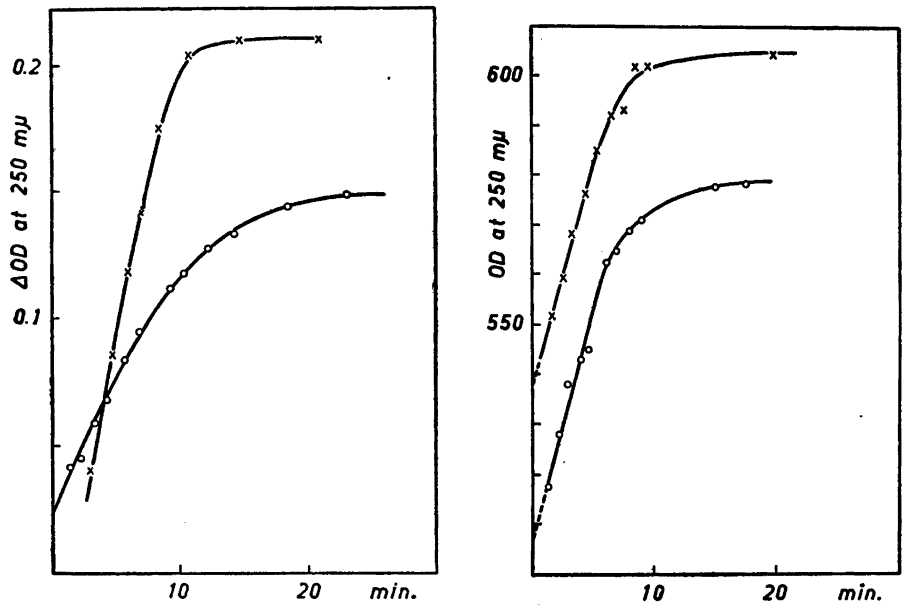

Fig. 1. Reaction of LDH with p-chloromercuribenzoate, before and after treatment of the enzyme with acetic anhydride.

Test conditions: To 2.6 ml 0.2 M phosphate buffer were added 94 mμmoles of PCMB and 14.5 mμmoles of LDH. Final volume 3.0 ml. For unmodified enzyme Δ OD = 0.108 Therefore $\frac{0.108 \times 3 \times 10^6}{7.6 \times 10^3 \times 14.5} = 2.9$ SH groups per mole enzyme.

LDH was acetylated as follows: To 20.1 mμmoles LDH in 0.4 ml 2.5 M sodium acetate pH 7 were added 5 × 1 μl of acetic anhydride at 0° C with one minute's intervals. 290 μl of the solution was allowed to react with PCMB. The enzyme activity decreased 45 % by the acetylation. × × × acetylated LDH O O O LDH, unmodified.

In order to measure total thiol groups, the enzyme dissolved in a few μl solution was allowed to react with 100 μl of 10 % lauryl sulfate before the addition of buffer and PCMB. The denatured enzyme reacted instantaneously with PCMB, as also did cysteine.

Fig. 2. Reaction of liver alcohol dehydrogenase (ADH) with p-chloromercuribenzoate before and after treatment with acetic anhydride.

Test conditions: To 2.66 ml 0.2 M phosphate buffer were added 159 mμmoles PCMB and 8.7 mμmoles ADH. Final pH 6.3. Total volume 3.0 ml Δ OD = 0.070. Therefore $\frac{0.07 \times 3 \times 10^6}{7.6 \times 10^3 \times 8.7} = 3.1$ SH groups per mole ADH.

ADH was acetylated as follows: To 32.6 mμmoles enzyme in 0.4 ml of 2.5 M sodium acetate pH 7 was added 5 × 1 μl acetic anhydride at 0° C with one minute intervals. 106 μl of the solution was allowed to react with PCMB. The enzyme activity decreased 62 % by the acetylation. None of the activity was recovered by incubation in 1 M glycine pH 9.5. × × × acetylated ADH O O O ADH, unmodified

place with incubation at pH 11, essential phenol or thiol groups have probably not been acetylated [19]. However, incubation at pH 11 may cause denaturation of some proteins. We have found that high alkalinity can be avoided by the use of high concentrations of glycine. Thus, O-acetyl tyrosine and S-acetyl cysteine

were found to be hydrolyzed within a few minutes by incubation in 1 M glycine at pH 9.5 but not affected by 0.1 M glycine at pH 9.5. The evidence was that Folin's phenol color (for tyrosine) and the reaction with PCMB (for cysteine) reappeared. LDH, liver alcohol dehydrogenase and the apoenzyme of the old yellow enzyme were perfectly stable in 1 M glycine pH 9.5. The acetyl-amino linkage in acetylated LDH was not hydrolyzed under these conditions, as there was no increase in Van Slyke amino group analysis.

RESULTS

Neilands [3] observed that 10^{-3} M PCMB had no instantaneous effect on LDH activity. However, incubation with the reagent caused inhibition, which was reversed by cysteine [4]. These observations have been confirmed in this study. The reaction between PCMB and LDH, reflecting the inhibition of the enzyme, is shown in Fig. 1. Under the conditions used, 2.8 SH groups reacted with PCMB, whereas Neilands [4] recorded 2 SH groups combining. Also included in Fig. 1 is the more extensive and more rapid reaction between PCMB and an acetylated form of the enzyme. Evidence for specific acetylation of amino groups will be presented later. In contrast to LDH, an acetylated form of liver alcohol dehydrogenase and the unmodified enzyme reacted similarly

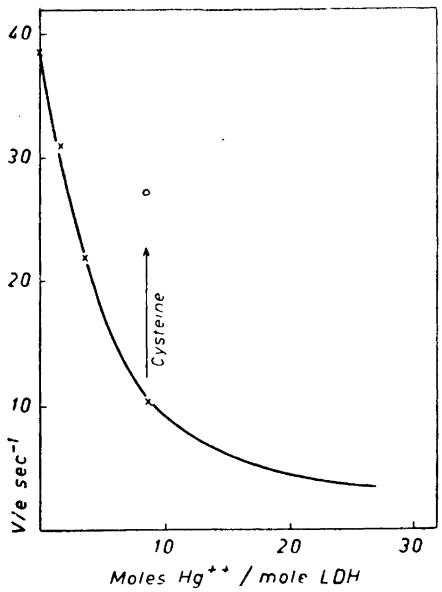

Fig. 3. Inactivation of LDH by $HgCl_2$.

10^{-2} or 10^{-3} M $HgCl_2$ was added to 1.14 mμmoles LDH in 25 μl of 0.02 M phosphate pH 7.2 and the mixture was allowed to react for 2 minutes at 0° C. The solution was then diluted to 500 μl with water and 5 μl were used for testing of activity in 3.0 ml of 0.1 M glycine pH 9.0. Conc. DL-lactate: 8.3 μM. Conc. DPN: 420 μM. To one sample (see figure) 10 μl of 0.5 M neutralized cysteine were added after dilution to 500 μl. The inhibition did not increase with a longer incubation time than 2 minutes.

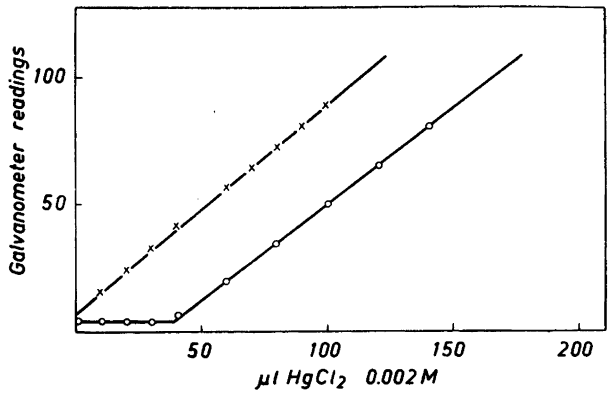

Fig. 4. Amperometric titration of LDH with $HgCl_2$.

The buffer used was 0.01 M in NaH_2PO_4, 0.08 M in Na_2HPO_4 and 0.5 N in KCl [14]. The titration was carried out within 10 min. 11 mμmoles LDH were found to bind 39 μl of 0.002 M $HgCl_2$. That is, 7.1 SH groups per mole LDH reacted with mercuric chloride. × × × blank O O O 11 mμmoles LDH.

with PCMB. This is shown in Fig. 2. For LDH denatured with lauryl sulfate, the reaction with PCMB was too rapid to be followed in a Beckman spectrophotometer; a total of 9.3 SH groups appeared to react.

In contrast to the slow inhibition of LDH by PCMB, mercuric and silver salts have been found to cause a very rapid inactivation of the enzyme. Thus, when 0.018 mμmole of LDH was added to 3.0 ml glycine buffer at pH 9.0, which was 8.3 mM in DL-lactate, 300 μM in DPN and 0.33 μM in Ag_2SO_4, no reduction of DPN was observed. The enzyme must have been inactivated within a few seconds. Inactivation of LDH as a function of added mercuric chloride is illustrated in Fig. 3. The incubation time was 2 minutes. Under the conditions used, 10 moles of mercury per mole of enzyme caused 75 % inhibition. A similar result was observed with Ag_2SO_4. Only 95 % inhibition was obtained with heavy metal ions some five-fold in excess of the total number of thiol groups. Cysteine counteracted the inhibition by $HgCl_2$ and Ag_2SO_4 to varying degrees, apparently depending upon the conditions of the incubation. In one case, a sample which had been completely inhibited by Ag_2SO_4 was reactivated completely. Fig. 4 shows the results of an amperometric titration [14] of LDH with $HgCl_2$ whereby 7 thiol groups were titrated. This is 2 SH groups less than obtained with the spectrophotometric titration with PCMB.

Incubation with iodine resulted in a rapid decrease of the LDH activity. The inhibition illustrated in Fig. 5 was registered within a few minutes after the addition of the reagent, which rapidly lost its color. The following observations suggest strongly that the inhibition was due to oxidation of essential SH groups, mainly to the disulfide stage, and not to substitution of tyrosine [12]: 1) No diiodotyrosine was formed, even in the most iodinated sample (See Fig. 5). 2) The reaction of LDH with PCMB disappeared with iodination of the protein. 3) The amount of iodine necessary for complete inactivation corres-

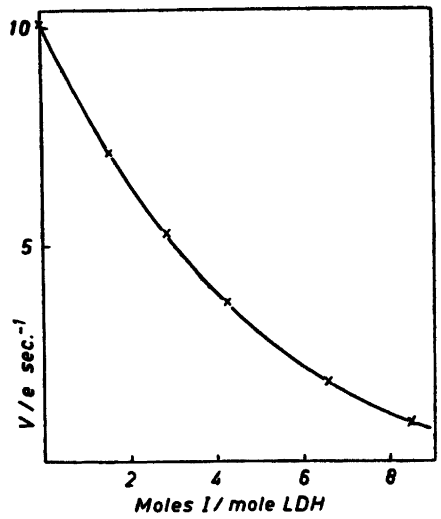

Fig. 5. Inactivation of LDH with iodine.

To 28.2 mμmoles LDH in 0.7 ml of 0.1 M phosphate pH 7.3, 0° C, were added 1 μl quantities of 0.1 M I in alcohol with 5 minute's intervals. To the controls corresponding amounts of alcohol were added. 2 μl of the enzyme solution were used for testing in 3.0 ml of 0.1 M glycine buffer pH 9.0 at 23° C. Conc. DL-lactate: 2.6 mM and conc. DPN 108 μ*M*.

25.8 moles of tyrosine per mole LDH were found with the Millon-Lugg analysis [15] in the most iodinated sample as well as in the control. However, when LDH was iodinated in 0.1 M glycine pH 9.2, 13 % of the iodine was used for substitution of tyrosine to form diiodotyrosine in the most iodinated sample.

ponded roughly to the total number of thiol groups (Fig. 5). 4) Cysteine reactivated the iodinated enzyme. This has also been observed by Neilands [4].

In contrast to the rapid inactivation with iodine, the strong oxidizing reagent, periodate, affected the enzyme only slowly, thus showing that the essential SH groups were unreactive to this reagent. When 5.9 mμmoles LDH were incubated at pH 5.5 with 50 mμmoles periodate in 110 μl 0.6 M acetate, only 25 % of the activity was lost after 1.5 hours incubation. The inactivation took place continuously. Liver alcohol dehydrogenase was inactivated within a few minutes under the same conditions.

The observations reported in the literature [2,3] that LDH is not inhibited by O-iodosobenzoate or iodoacetate have been confirmed.

Acetylation of LDH with acetic anhydride inactivated LDH strongly. Table 1 shows the activity of acetylated LDH as a function of free amino groups. Acetic anhydride has been claimed to be specific for amino groups in all proteins tested [12]. However, the reagent does not necessarily react in the same manner with all proteins. The blocking of SH and phenolic hydroxyl groups appeared as a possibility because ketene, which is a stronger acetylating reagent than is acetic anhydride [12], has been found to acetylate these groups in some proteins. Moreover, acetic anhydride forms O-acetyl tyrosine and S-

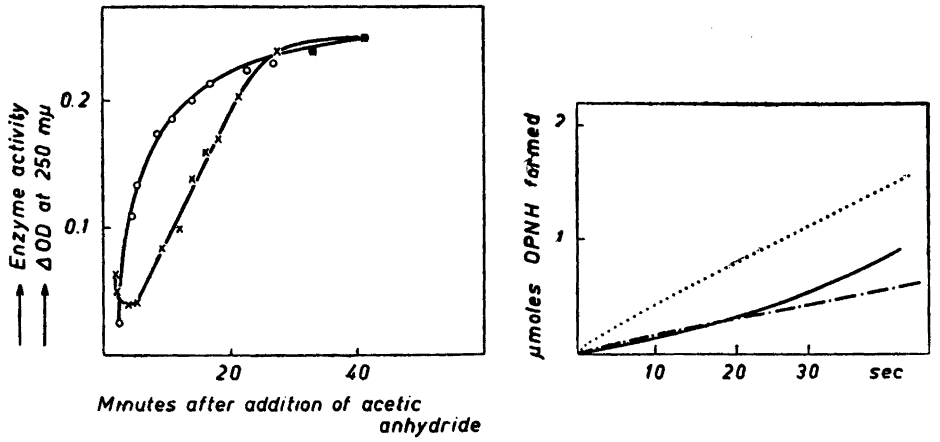

Fig. 6. Reactivation of acetylated LDH and change of optical density of the solution.
a. To 11.1 mμmoles LDH in 0.19 ml buffer (2.5 M in acetate, 0.1 M in Na_2HPO_4) were added 5 × 1 μl acetic anhydride with some seconds intervals. Temp. 0° C. Immediately after the last addition of acetic anhydride, 3.11 ml phosphate buffer (μ = 0.1, pH 7.13) were mixed with the enzyme solution. Final pH: 6.45, temp. 23° C. The change of optical density of this solution at 250 mμ was followed in a Beckman spectrophotometer. Activity measurements of aliquots of the same solution were carried out simultaneously in 0.1 glycine pH 9.75. Conc. DPN: 400 μM and conc. DL-lactate 1.77 mM.

acetyl cysteine. Now, if essential SH or phenolic hydroxyl groups in LDH were acetylated, incubation in 1 M glycine at pH 9.5 should reactivate the enzyme to the same degree as these groups were involved (see Methods). But no reactivation of acetylated LDH took place provided the samples were tested at least half an hour after the addition of acetic anhydride *. Furthermore, the Folin's phenol color was not significantly decreased in the acetylated sample, and amperometric titration gave the same result before and after acetylation, around 7 SH groups being titrated in both cases. Therefore, neither phenyl acetate nor thiol acetate appeared to be formed with acetylation of LDH, thus indicating that acetic anhydride was also specific for amino groups in LDH.

Preliminary experiments with formaldehyde and phenylisocyante showed that LDH is sensitive to these amino group reagents. Thus, incubation of a 0.8 % solution of LDH with 0.25 M formaldehyde at pH 7.4 (0° C) decreased the activity by 38 % in one minute and 47 % in 10 minutes. Incubation of 65 μl 0.8 % LDH with 1 μl phenylisocyanate at pH 7.4 (0° C) decreased the activity by 89 % in 3 minutes.

As mentioned above, no reactivation of acetylated LDH took place by incubation with 1 M glycine pH 9.5 provided the samples were tested at least

* For further elaboration on this point, see below.

half an hour after the addition of acetic anhydride. If, however, the activity was tested immediately after the addition of acetic anhydride, reactivation took place within one minute in 1 M glycine at pH 9.5, and within one hour if the enzyme remained in the acetate solution. The same level of enzymatic activity was reached in both cases, some inhibition remaining due to acetylation of amino groups. Fig. 6a shows the reactivation of the enzyme in 2.5 M sodium acetate pH 6. Under these conditions, O-acetyl tyrosine and S-acetyl cysteine were stable. The initial decrease in activity shown in Fig. 6a is probably due to continued acetylation when relatively large amounts of acetic anhydride were still present in the solution. Fig. 6b illustrates reactivation of the same acetylated enzyme during oxidation of DL-lactate in 0.1 M glycine at pH 9.7. A similar reactivation of acetylated LDH was observed during reduction of pyruvate. In an attempt to discover spectral changes of the protein as the activity was restored, we observed that acetic anhydride itself caused a strong spectral absorption in the 250 mμ region, which disappeared upon hydrolysis. In Fig. 6a is included the spectral change that occurred simultaneously with the reactivation. A similar spectral change took place with acetic anhydride in the absence of protein. From the figure it is apparent that reactivation occurs until all acetic anhydride has disappeared from the solution, thus suggesting that this compound prevents the hydrolysis of a labile acetyl compound of LDH.* Also liver alcohol dehydrogenase ** and the apoenzyme of the old yellow enzyme [20] have been incubated with acetic anhydride. Although both proteins were strongly affected by the reagent, apparently by specific acetylation of amino groups, neither of them behaved like LDH with respect to temporary inhibition of acetic anhydride. The activity of liver alcohol dehydrogenase as well as the recombination rate of the apoprotein and FMN were not increased when acetic anhydride disappeared from the solution.

DISCUSSION

The requirements of an ideal inhibitor are that it should react rapidly and specifically with a protein group, and that it should be possible to regenerate the enzyme after treatment with the inhibitor [19]. Silver and mercury ions appear to be ideal inhibitors for SH groups in LDH. PCMB, on the other hand, reacts too slowly, and some of the effects of this reagent may be due to structural alteration. Therefore, the observation that only half or less of the SH groups reacted with PCMB to cause almost complete inactivation [4] does not necessarily imply that the essential SH groups are more reactive to PCMB than are the other SH groups. In the case of mercury and iodine inactivation, the data presented in Figs. 3 and 5 indicate the essential groups to have the same reactivity as the other SH groups toward these reagents.

* Experiments with crystalline LDH from sceletal muscle (C. F. Boehringer & Soehne, Mannheim) and with 80 % pure rat liver LDH (a gift from Dr. Carl S. Vestling, Un. of Illinois) have shown that these enzymes behave in the same manner as ox heart LDH regarding temporary inhibition by acetic anhydride.

** No reactivation of acetylated liver alcohol dehydrogenase took place in 1 M glycine at pH 9.5. See Fig. 2.

Table 1. The decrease of LDH activity with acetylation of amino groups.

pH	Number of free amino groups			
	97 *	76	67	58
	E/V sec	% of the activity of unmodified		
7.1	8.6	57	38	30
9.0	19.7	61	31	29
9.5	25.7	66	36	36

To 95 mμmoles LDH in 0.8 ml of 2.5 M acetate pH 7 were added 1, 3 × 1 or 4 × 1 μl of acetic anhydride at 0° C. The activity was tested one hour after the addition of acetic anhydride, in phosphate buffer (μ = 0.1) pH 7.15, in 0.1 M glycine pH 9.0 and in 0.1 M glycine pH 9.5. Conc. DL*-lactate: 1.7 mM. Conc. DPN: 415 μM.*

The findings that 10 moles of mercury or silver ions per mole of enzyme caused only 75 % inhibition, whereas the number of thiol groups appear to be 7—9, could be the result of high dilution of the enzyme in the activity measurements. Thus, in the titration experiments with mercury the enzyme concentration was about 10^{-6} M, whereas the final dilution in the activity measurements was approximately 10^{-9} M. If a rapid equilibrium were established between SH and the mercury ions, the above discrepancy could perhaps be accounted for in terms of dissociation of the mercaptide. The difference between 7 SH groups per mole enzyme titrated with mercuric chloride and 9.3 SH groups determined spectrophotometrically with PCMB remains unexplained.

The rapid reaction of silver and mercury ions and of iodine with SH groups in LDH, the slow reaction of PCMB and periodate, and the inertness to such SH reagents as O-iodosobenzoate, iodoacetate and N-ethylmaleimide may reflect different permeabilities of molecules of different sizes to the masked SH groups.

The fact that specific acetylation of amino groups inactivated LDH suggest that amino groups are essential for activity. This conclusion is supported by the observation that LDH is inactivated by formaldehyde and phenylisocyanate under conditions where these reagents are fairly specific for protein amino groups. If it is assumed that the extent of inhibition represents the fraction of essential groups which have been acetylated, then the essential amino groups are more reactive to acetic anhydride than are the other amino groups [20]. Table 1 shows that the activity decreases more rapidly than would have been the case if the blocking took place at random. However, the finding that PCMB reacted faster with acetylated enzyme than with the control shows that acetylation beside blocking amino groups also may alter the protein structure so as to increase the reactivity of thiol groups. Unfortunately, the reversibility of this alteration could not be determined. The

* Unmodified.

acetyl-amino linkage can hardly be hydrolyzed without denaturation of the enzyme. The alteration is not likely to be surface denaturation in view of the stability of other proteins to acetic anhydride [12], including liver alcohol dehydrogenase (see Fig. 2).

The activity measurements of acetylated LDH at different hydrogen ion concentrations recorded in Table 1 indicate that the decrease in activity is not due to a general discharge of the protein molecule. At pH 9.5 the number of positive charges of the enzyme should be much less than at pH 7.1, but the relative decrease in activity was roughly the same whether the activity was determined at pH 9.5, 9.0 or 7.1.

The observation that acetic anhydride effected a temporary inactivation of LDH may be explained if it is assumed that essential groups gave readily hydrolyzable acetates. The fact that the activity was regained much faster in 1 M glycine at pH 9.5 than in neutral acetate solution supports this conclusion. N-acetylimidazole has been shown to be a very labile compound [21], and it appears possible that an essential imidazol group in LDH has been acetylated. However, there are other possible explanations. Although S-acetyl cysteine and O-acetyl tyrosine are more stable than the acetyl compound of LDH, these groups may nevertheless be involved. Thus, the sluggishly reactive SH groups could form an acetyl compound more labile than S-acetyl cysteine. Unfortunately, because of the lability of the acetyl LDH compound, measurements for the blocking of these groups were impossible.

The suggestion has been made that thiol groups are involved in the binding of coenzyme or substrate in some DPN-linked enzymes [1]. In view of the low reactivity of SH groups in LDH to PCMB, periodate, iodosobenzoate, iodoacetate and N-ethylmaleimide these groups may not be sufficiently reactive to bind such relatively large molecules as lactate, pyruvate, DPN or DPNH. However, participation of amino groups in the binding could facilitate binding to the SH group(s), in the same way as the reactivity of SH groups increases when amino groups are acetylated. Such an interaction would require a compulsory sequence of reactions between protein, coenzyme and substrate.

Thanks are due to professor Hugo Theorell for his interest in this work, to Dr. Ryo S. Sato for a sample of LDH which started out this work, and to Miss Ann Louise Swanson for valuable technical assistance. A personal grant from *A/S Freias Chocolade Fabriks arbeidsfond for ernæringsforsking* is gratefully acknowledged.

Reaction Velocities of DPN-linked Lactic Dehydrogenase

AGNAR P. NYGAARD*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden, and Johan Throne Holst's Institutt for Ernæringsforsking, Oslo, Norway

Lineweaver-Burk plots of the reaction velocities of crystalline lactic dehydrogenase from ox heart gave straight lines with low concentrations of the reactants. Relationships between Michaelis constants, maximum velocities and the equilibrium constant have been used for selecting a possible mechanism.

The relationships between Michaelis constants, maximum velocities and the equilibrium constant developed for certain mechanisms of enzyme reactions [1–3] have been useful in the determination of the probable mechanism of liver alcohol dehydrogenase [4] and a possible mechanism of yeast alcohol dehydrogenase [5]. In the present study, an attempt has been made to establish a possible reaction mechanism for lactic dehydrogenase from ox heart (LDH) **. The reaction is as follows:

$$\text{pyruvate} + \text{DPNH} + \text{H}^+ \rightleftharpoons \text{lactate} + \text{DPN}^+$$

This enzyme is of particular interest in this connection because the dissociation constant of LDH—DPNH, like that of liver ADH—DPNH, has been determined spectrophotometrically in a single reaction step [6].

MATERIALS AND METHODS

The materials and methods used in this study were the same as those applied in a recent investigation of the essential groups in LDH [7]. L-Lactic acid was procured from Pfahnstil.

RESULTS AND DISCUSSION

Several investigators have determined Michaelis constants and maximum reaction velocities in the DPN-linked LDH system [8–13]. However, the experiments have been carried out under different conditions and with LDH from

* Fellow, Norwegian Research Council.

** The following abbreviations are used: LDH: DPN-linked lactic dehydrogenase from ox heart, DPN: diphosphopyridine nucleotide, DPNH: reduced diphosphopyridine nucleotide, ADH: alcohol dehydrogenase.

		V_r sec.$^{-1}$	400	440

* V_f is maximum velocity of lactate oxidation.
V_r is maximum velocity of pyruvate reduction.

pyruvate and DPN at pH 7.15 and with high pyruvate concentration at pH 9.0, the velocities passed through a maximum and then decreased. In all the experiments illustrated in Figs. 1 and 2 the concentration of the second reactant (which was kept constant) was selected so as to be just below the inhibiting concentration of this reactant. At pH 7.15 the inhibiting pyruvate concentration was only three times its Michaelis constant. However, the affinity constants of DPNH and pyruvate at pH 7.3 have been found to be practically independent of the concentration of the second reactant [10].

Table 1 summarizes the maximum velocities (V_f and V_r**) and Michaelis constants calculated from Figs. 1 and 2. In the determination of V_f and V_r the straight lines were extrapolated to infinite concentration and the calculation was made on the basis of infinite concentration of both reactants. All the experimental points in the figures are the average of at least three determinations, which did not vary more than ± 5 % except at the lowest concentrations of DPNH. The velocity determinations with low concentrations of the reactants are less accurate. For that reason, the least square method has not been used in drawing the lines. The kinetic constants in Table 1 are determined within ± 5 % accuracy with the exception of the Michaelis constant of DPNH. This constant is estimated to be within ± 10 %. In Table 2 the data from Table 1 are inserted into formulae representing different reaction mechanisms. Included in the table are the numbers obtained when the errors involved are added up in one direction.

** V_f: maximum velocity of pyruvate reduction.
V_r: maximum velocity of lactate oxidation.

	I The intramolecular transformation of ternary complex is rate-limiting. General mech. of Alberty[3]	II Special case of I. Affinity of coenzyme for LDH not influenced by substrate, or *vice versa* [3]	III A group in the enzyme is ox/red by substrate or coenzyme with the formation of enzyme-substrate or enzyme-coenzyme intermediates [3]	IV Dissociation of enzyme-coenzyme or enzyme-substrate is rate-limiting [2,3]. Probable mechanism of liver ADH [4]
pH	$K_{eq} = \frac{V_f}{V_r} \cdot A$ ** $\times 10^{12}$	$K_{eq} = \frac{V_f}{V_r} \cdot B$ *** $\times 10^{12}$	$K_{eq} = \left(\frac{V_f}{V_r}\right)^2 \cdot B$ $\times 10^{12}$	$K_{eq} = \left(\frac{V_f}{V_r}\right)^3 \cdot B$ $\times 10^{12}$
7.15	—	6.2 4.1—9.0	1.3 0.76—2.1	0.27 0.14—0.47
9.0		15.6 11—23	5.9 4.0—10.2	2.2 1.4—4.5

$K_{eq} = 4.6 \times 10^{-12}$ over the whole pH range [14].

** $A = \frac{K_m \cdot pyr_{DPNH} \cdot (H^+)}{K_m \cdot lactate_{DPN}}$ For the definition of these constants, see Alberty [3]. A has not been determined, but becomes identical with B when the affinity constants are independent of the concentration of the second reactant.

*** $B = \frac{K_{mDPN} \cdot K_m \text{ pyr} \cdot (H^+)}{K_{mDPN} \cdot K_m \text{ lactate}}$

The mechanism described in column 2, Table 2, agrees rather well with the experimental data. Furthermore, the Michaelis constant of L-lactate at pH 7.15 is nearly independent of the concentration of DPN (see Table 1), and the data of Schwert and Hakala [10] indicate that the affinity constants of DPNH and pyruvate are nearly independent of the concentration of the second reactant at pH 7.3. LDH may therefore follow mechanism 2 at pH 7.15, or nearly so. Mechanisms 3 and 4 are excluded. At pH 9.0, mechanism 2 is excluded and 4 is highly unlikely. Mechanism 3 is improbable for other reasons [7,15]. Experiments by Gibson *et al.*[12] indicate that around this pH the binding of DPN affects the binding of substrate strongly. Mechanism 1 has not been investigated at this pH because of the difficulties in obtaining accurate measurements at very low concentrations of DPNH.

If mechanism 1 or 2 is followed, the rate-limiting reaction in the reduction of pyruvate is the transformation of the ternary complex:

$$\text{LDH—DPNH-pyruvate} + H^+ \rightarrow \text{LDH—DPN-lactate}$$

If the hydrogen ion were taken from the solution, V_r should be proportional to H^+, but V_r was observed to be independent of pH. The enzyme molecule could instead deliver the proton.

If mechanism 2 is followed at pH 7.15, the Michaelis constants represent the dissociation constants of the reactants at this pH. The Michaelis constant of DPNH is 2.5×10^{-6} (23°), as compared to 7×10^{-6} obtained of Chance and Neilands [6] by direct measurements. In view of the uncertainty of the direct measurements [6], the disagreement is not too serious. The 34-fold increase in K_M for pyruvate from pH 7.15 to 9.0 could reflect the discharge of the protein binding site of this substrate, which could be an imidazol group. K_M for lactate is the same at pH 7.15 and 9.0, and may therefore be bound to another site.

The dissociation of Enzyme-DPNH is likely to be the rate-limiting step in the oxidation of alcohol by liver alcohol dehydrogenase [2,4]. LDH oxidizes lactate about 50 times faster than ADH oxidizes alcohol, and the dissociation constant of LDH—DPNH is more than 10 times higher than that of ADH—DPNH. From these observations Chance and Neilands [6] suggested that the dissociation of Enzyme-DPNH was also rate-limiting in the oxidation of substrate in the LDH system, and that a high dissociation constant for Enzyme-DPNH may in general reflect a high rate of oxidation. However, it is evident from Table 2 that mechanism 4, which is probably followed by liver ADH, is not possible for LDH, at least not at pH 7.15. This is supported by the dissociation constant calculated for LDH—DPNH on the assumption that mechanism 4 is followed. It comes out to be $K = \frac{V_f}{V_r} K_{M\ DPNH} = 0.52 \times 10^{-6}$, which is 13—14 times smaller than the measured dissociation constant, and about equal to the dissociation constant of liver ADH found from overall reaction velocities [4].

The fact that DL-lactate has a higher Michaelis constant than has the L-isomer alone suggest that the D-form can also combine on the substrate site without being oxidized, as shown previously [11]. However, the observations that DL gives a higher maximum rate than L alone and that no inhibition is observed with high concentrations of DL show that the D-form also in some other way effects the kinetic constants.

Constituents of Pollen

I. Low-molecular Carbohydrates in Pollen from *Pinus montana* Mill.

MARTIN NILSSON

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Sucrose, glucose, fructose, myo-inositol, sequoitol and pinitol have been isolated from pollen of *Pinus montana* Mill. Of these substances pinitol and sequoitol have not been previously found in pollen.

The literature on pollen chemistry has been recently reviewed by Lundén [1]. Not very much systematic work has been carried out on the low-molecular weight carbohydrates in pollen and only a few substances have been isolated in the crystalline state: sucrose [2], lactose [3] and myo-inositol [4]. However, paper chromatographic investigations indicate the presence of glucose [5], fructose [5], raffinose [6] and stachyose [6] also.

For *Pinus silvestris* various authors (for detailed references and discussion see Ref.[7]) have determined the contents of "reducing" and "non-reducing sugars" as 0—2 % and 8—12 % in uncontaminated pollen. The non-reducing sugars were shown to consist mainly of sucrose. Recently Nielsen, Grömmer and Lundén [8] investigated various pollen using microbiological methods and found after acid hydrolysis 0.9 % myo-inositol in pollen from *Pinus montana*.

The pollen samples used in this investigation were collected in 1954 by *A. B. Cemille*, Vegeholm, Sweden, and contained at least 99 % of pollen from *Pinus montana* Mill.[8] (subgenus Diploxylon). The water-soluble part of the methanol-extract from the pollen was, after a preliminary treatment, fractionated by chromatography on a carbon-celite column [9]. Sucrose (9 %), myo-inositol (0.1 %) and sequoitol (0.05 %) were thus obtained directly in the crystalline state. Pinitol, fructose and glucose could not be separated on the carbon column. From the mixture of these substances pinitol (1.2 %) was separated by crystallisation. The remaining sugars were isolated as *iso*propylidene derivatives as described by Bell [10]. Thus crystalline derivatives of fructose (0.7 %) and glucose (0.3 %) were obtained.

Parts of these sugars might originate from sucrose and other saccharides present by hydrolysis during the storage of the pollen and perhaps also during the extraction and purification process. However, it was found that the first

extracts showed strong spots corresponding to glucose and fructose on paper chromatograms.

Pinitol and sequoitol have not been previously reported to occur in pollen. Pinitol appears to occur in the needles of all conifers [11] and has also been found in the heartwood of pines belonging to the subgenus *Haploxylon* [12]. Sequoitol has only been encountered once in pines; in the heartwood of *Pinus Lambertiana* [13] (Haploxylon).

EXPERIMENTAL

All melting points are uncorrected. Evaporations were carried out *in vacuo* at 40–50°. Paper chromatograms were run in *n*-butanol, ethanol, water (5:1:4) and/or ethyl acetate, acetic acid, water (3:1:1) and developed with the silver nitrate-sodium ethoxide reagent.

Air-dried pollen from *Pinus montana* Mill. (250 g) was extracted with ether in a Soxhlet apparatus for two weeks and then with methanol for three weeks. As the solvent flow through the pollen layer was very slow the extraction temperature was about 25°. The methanol extract on evaporation yielded a semi-solid mass (72 g), which was extracted with water (1.5 l, in portions). The solution was filtered (celite), the filtrate extracted with ether (2 × 300 ml) and purified by the lead acetate method [14]. It was shown by paper chromatography that practically no cyclitols were precipitated or adsorbed under the conditions chosen (pH 5). The aqueous solution was deionized (IR 120 and IR 4 B) and evaporated to dryness. The resulting syrup (42 g) was dissolved in water (400 ml) and fractionated on a carbon-celite column (50 × 6 cm. Ethanol 0–20 %, 15 l, afterwards washed with ethanol, 50 %, 10 l). The eluate was divided into fractions which were investigated by paper chromatography and checked for optical rotation. The first run gave 12.9 g of easily eluted components, 28.0 g of sucrose fraction and 1.3 g of higher sugars. The sucrose fraction on treatment with methanol yielded crystalline sucrose (19.6 g). The easily eluted components were refractionated on the same column (Ethanol 0–10 %, 16 l) giving crystalline myo-inositol (0.23 g), sequoitol (0.12 g) and sucrose (2.2 g). From fractions containing a mixture of pinitol, fructose and glucose (8.1 g), pinitol (3.0 g) was obtained by crystallisations from ethanol. The material in the mother liquors was treated with acetone and sulphuric acid converting the sugars to di*iso*propylidene derivatives, the remaining pinitol being unaffected. Mild hydrolysis of the chloroform-soluble substances and partition of the products obtained gave crystalline 2,3–4,5-di(O-*iso*propylidene)-fructopyranoside (1.2 g) and 1,2-O-*iso*propylidene-glucofuranoside (0.48 g), corresponding to fructose (0.8 g) and glucose (0.4 g).

A reference experiment showed 80 % and 50 % recovery of the fructose and glucose derivatives, respectively, from a mixture of equal parts of pinitol, glucose and fructose. Paper chromatographic investigation of the water-soluble material after the acetone treatment showed the presence of pinitol and glucose only.

The fraction of higher sugars and the sucrose mother liquors were investigated by paper chromatography and were found to contain in addition to sucrose several components with lower R_F-values. Some of the spots could be developed with the anisidine-phosphoric acid reagent and some also with resorcinol-hydrochloric acid. These facts point to the presence of tri- and tetrasaccharides. The isolation of these substances was not, however, attempted.

The *sucrose* m. p. 178–184° was homogeneous on the paper chromatograms. $[\alpha]_D$ +68° (*c* 1.8, water). Octa-acetate (acetic anhydride, pyridine), m. p. and mixed m. p. 89–90°, $[\alpha]_D$ +59° (*c* 6,4, chloroform).

The crude *pinitol* m. p. 180–90° was sublimed and recrystallised from water-ethanol, m. p. and mixed m. p. 188–189°, $[\alpha]_D$ +63° (*c* 6,2, water); pentaacetate (acetic anhydride, perchloric acid), m. p. and mixed m. p. 99–100° $[\alpha]_D$ −6,9 (*c* 6,4, chloroform).

The *myo-inositol* m. p. 219–224° was recrystallised from water-ethanol, m. p. and mixed m. p. 225–228°; hexaacetate (acetic anhydride, perchloric acid) m. p. and mixed m. p. 216–218°.

The *sequoitol* m. p. 233—238° was recrystallised from water-ethanol, m. p. and mixed m. p. 238—239°; pentaacetate (acetic anhydride, perchloric acid), m. p. and mixed m. p. 196—197°.

2,3—4,5-di(O-isopropylidene)-fructopyranoside, m. p. 83—98°, was recrystallised from ether-petrol, m. p. and mixed m. p. 95—96°, $[\alpha]_D$ −21° (*c* 1.4, chloroform).

1,2-O-isopropylideneglucofuranoside, m. p. 100—120°, was recrystallised from ethyl acetate, m. p. and mixed m. p. 159—160°, $[\alpha]_D$ −4.2 (*c* 7.3, ethanol).

Barium Salts of Telluropentathionic Acid

OLAV FOSS and OLAV TJOMSLAND

Institutt for uorganisk kjemi, Norges tekniske høgskole, Trondheim, Norway

A study has been made of the crystal chemistry of barium telluropentathionate hydrates. On crystallization from water, a monoclinic trihydrate (I) occurs. Two dihydrates were obtained, one triclinic (II) by crystallization from aqueous methanol, and one monoclinic (III) by crystallization from aqueous acetone. The unit cell dimensions and space groups are:

I, $a = 11.16$ Å, $b = 5.24$ Å, $c = 21.30$ Å, $\beta = 107°$; space group, $C_{2h}^5 - P2_1/c$ with $Z = 4$.

II, $a = 4.99$ Å, $b = 10.57$ Å, $c = 12.38$ Å, $\alpha = 106°$, $\beta = 101\frac{1}{2}°$, $\gamma = 90°$; space group, $C_i^1 - P\bar{1}$ with $Z = 2$.

III, $a = 4.99$ Å, $b = 10.59$ Å, $c = 23.61$ Å, $\beta = 98°$; space group, $C_{2h}^3 - A2/m$ with $Z = 4$.

Isomorphism of II with triclinic barium pentathionate dihydrate, and the requirement in III of a mirror plane of molecular symmetry, show that the telluropentathionate ion occurs in a *cis* form in these salts.

The first salts of telluropentathionic acid, those of sodium and potassium, were isolated in 1949 [1]. Later, the ammonium, rubidium and cesium salts were prepared, and unit cells and space groups determined for these and the potassium salt [2]. Detailed crystal structure analyses of ammonium telluropentathionate [3], as well as of orthorhombic [4] and triclinic [5] barium pentathionate dihydrate and orthorhombic barium selenopentathionate dihydrate [6], were subsequently carried out.

Pentathionate chains may occur in two rotational-isomeric forms, which have been termed *cis* and *trans* [7]. The telluropentathionate ion in the ammonium salt occurs in the *trans* form, whereas the *cis* form was found for the pentathionate and selenopentathionate ions in the barium salts. It was of interest to see whether in barium salts also the telluropentathionate ion would have the *cis* form. This has now been found to be the case, in two crystalline modifications of barium telluropentathionate dihydrate. Together with the earlier structure determination of the ammonium salt, the work on barium salts serves to establish the occurrence of different rotational-isomeric forms of the telluropentathionate ion in different salts.

SYNTHESIS OF SALTS

Three distinct barium telluropentathionate hydrates were obtained, on recrystallization under various conditions of crude samples prepared from the sodium salt [1] by metathesis with a slight excess of barium perchlorate. The sodium and barium perchlorates being readily soluble in water, barium telluropentathionate crystallized readily on mixing concentrated solutions of the reactants, and cooling. This procedure was used also for the preparation of crude barium selenopentathionate [6].

When crystallized from water, without the use of an organic solvent to depress the solubility, barium telluropentathionate separates as a trihydrate. Under such conditions also barium selenopentathionate gives a trihydrate, whereas barium pentathionate comes out as a triclinic dihydrate.

From aqueous methanol, barium pentathionate and selenopentathionate separate as orthorhombic dihydrates. Attempts to prepare an orthorhombic barium telluropentathionate dihydrate in this way have failed so far; instead, a triclinic dihydrate, isomorphous with the triclinic pentathionate, was obtained. On crystallization from aqueous acetone, barium pentathionate and selenopentathionate give solvates, whereas barium telluropentathionate crystallized as a monoclinic dihydrate.

The order of decreasing stability of the crystals of the three barium telluropentathionate hydrates, with respect to liberation of tellurium on keeping, appears to be: Trihydrate, monoclinic dihydrate, and triclinic dihydrate. The two former salts are stable for months, and also crystallize readily, with well developed forms free from twinning, whereas the triclinic dihydrate shows a pronounced tendency of irregular growth and twinning. Although crystals of the dihydrates, when moistened, gradually dissolve and recrystallize as the trihydrate, no transition of one crystalline hydrate to another has been observed on keeping at room temperature and ordinary humidity conditions.

The trihydrate has a yellowish green colour, whereas the dihydrates are yellow. The crystals of the monoclinic dihydrate, in daylight and more rapidly on exposure to X-rays, develop an orange colour but give unchanged X-ray photographs.

EXPERIMENTAL

Sodium telluropentathionate dihydrate was prepared from tellurium dioxide and sodium thiosulphate as described earlier [1]. To 25 g of the crude sodium salt, dissolved in 40 ml of 0.2 N hydrochloric acid by gentle heating, and filtered and cooled in ice, was added a solution of 25 g of barium perchlorate trihydrate in 15 ml of water. Crystals of barium telluropentathionate rapidly began to separate out. After a few minutes, the product was filtered off, and washed with methanol and ether. Yield, about 18 g. The recrystallizations were performed as follows.

Trihydrate (I). The crude barium salt was dissolved in four to five times the amount of 0.2 N hydrochloric acid at 40—50° C, and the solution was filtered and allowed to cool, first at room temperature and then in ice.

Triclinic dihydrate (II). To a solution prepared as above, but about half as concentrated, of the crude salt or the trihydrate was added about twice the amount of methanol. The crystallization took place at or slightly above room temperature. If the solution is cooled in ice, the preparation will have a composition intermediate between di- and trihydrate.

Monoclinic dihydrate (III). 1 g of the trihydrate was dissolved in 8 ml of 0.2 N perchloric acid, and the solution was filtered and warmed to 40–50° C. Then 8 ml of acetone was added from a pipet, with stirring, and the solution was allowed to cool to room temperature.

The crops of crystals were filtered with suction on sintered glass filters, and I, II and III were washed with ethanol, methanol and acetone, respectively, and then with ether. They were dried for a short time in a vacuum over sulphuric acid; small crops were dried on a plate in air. On prolonged keeping over sulphuric acid, the water of crystallization is given off.

The salts were analyzed by direct titration with iodine, as described earlier [1]. Absence of tetrathionate was checked through subsequent analysis of the titrated solutions by means of the sulphite method [1].

0.3322 g of I: 24.60 ml of 0.09954 N iodine.
$BaTe(S_2O_3)_2 \cdot 3H_2O$ (543.3). Mol. weight found, 542.6.
0.2744 g of II: 21.01 ml of 0.09954 N iodine.
$BaTe(S_2O_3)_2 \cdot 2H_2O$ (525.3). Mol. weight found, 524.9.
0.1530 g of III: 11.70 ml of 0.09954 N iodine.
$BaTe(S_2O_3)_2 \cdot 2H_2O$ (525.3). Mol. weight found, 525.5.

As mentioned above, barium selenopentathionate on crystallization from water occurs as a trihydrate, like barium telluropentathionate. This trihydrate has not been described, and is therefore included here. Crude barium selenopentathionate [6] was dissolved in about three times the amount of 0.2 N hydrochloric acid at 40–50° C, and the solution was filtered and cooled in ice. It was advantageous, for better crystallization, to add a little barium perchlorate before cooling. The salt was oxidized with potassium bromate and subsequently analyzed iodometrically by means of the Norris and Fay method, as described earlier [6].

0.1989 g substance: 16.10 ml of 0.09954 N sodium thiosulphate.
$BaSe(S_2O_3)_2 \cdot 3H_2O$ (494.6). Mol. weight found, 496.4.

The salt is more stable than the orthorhombic dihydrate [6]; thus, a sample kept in a dark bottle was found unchanged after five years. The pale greenish crystals occur as prisms, of much the same habit as the trihydrate I above, but often flattened almost to leaves and with a tendency of irregular growth. It appears probable that the salt may be isomorphous with I, but no X-ray measurements have been made.

CRYSTALLOGRAPHIC DATA

The crystals of the barium telluropentathionate hydrates were characterized by means of X-ray oscillation and Weissenberg photographs. Copper radiation was used, $\lambda(CuK_\alpha) = 1.542$ Å. The axial lengths recorded below are believed to be accurate to within 0.5 %. The densities of the crystals were determined by flotation in suitable solvents.

Barium telluropentathionate trihydrate, $BaTe(S_2O_3)_2 \cdot 3H_2O$ (I). Monoclinic, $a = 11.16$ Å, $b = 5.24$ Å, $c = 21.30$ Å, $\beta = 107°$. Four molecules per unit cell; density, calc. 3.03, found 3.0 g/cm^3. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus C_{2h}^5—$P2_1/c$. The crystals occur as flat prisms, extended along the b axis and with {100} predominant.

Barium telluropentathionate dihydrate, $BaTe(S_2O_3)_2 \cdot 2H_2O$ (II). Triclinic, $a = 4.99$ Å, $b = 10.57$ Å, $c = 12.38$ Å, $\alpha = 106°$, $\beta = 101\frac{1}{2}°$, $\gamma = 90°$. Two molecules per unit cell; density, calc. 2.84, found 2.84 g/cm^3. No systematic absences. The crystals occur as prisms, extended along the a axis and usually flattened along the b axis. There is perfect cleavage along the c plane.

The unit cell dimensions are not far from those of triclinic barium pentathionate dihydrate [5]. The γ angle of 90°, and the characteristic cleavage, are retained, and the b axis and c spacing are a little larger, as may be expected

when tellurium is substituted for sulphur. A comparison of the intensities of the $0kl$ and $h0l$ reflections of the two triclinic dihydrates adds further support to the assumption that the salts are isomorphous. The space group of II has therefore been taken as C_i^1—$P\bar{1}$.

Barium telluropentathionate dihydrate, $BaTe(S_2O_3)_2 \cdot 2H_2O$ (III). Monoclinic, $a = 4.99$ Å, $b = 10.59$ Å, $c = 23.61$ Å, $\beta = 98°$. Four molecules per unit cell; density, calc. 2.82, found 2.80 g/cm^3. Systematic absences, hkl when $k + l$ is odd. The crystals occur as prisms, extended along the a axis and ordinarily flattened along the b axis. The habit is monoclinic prismatic, and the forms {001}, {011} and {110} occur, with the former the more predominant one. There is a pronounced cleavage along the c plane.

On the basis of the systematic absences, three space groups are possible, *viz.*, C_{2h}^3—$A2/m$ and two of lower symmetries. In the crystals of orthorhombic barium pentathionate [4] and selenopentathionate [6] dihydrates, of space group D_{2h}^{16}—$Pnma$ with four molecules per unit cell, $0kl$ reflections are present only when $k + l$ is even, as in III, and the a axis projections of these and of III have also very like dimensions. A comparison of the intensities of the $0kl$ reflections, allowing for the different scattering powers of sulphur, selenium and tellurium, shows that the $0kl$ zone of III has the same intensity distribution as the $0kl$ zones of the orthorhombic dihydrates. The space group and $0kl$ zones of the latter being centrosymmetric, the same applies, beyond reasonable doubt, to the $0kl$ zone of III. The space group is therefore the centrosymmetric one, C_{2h}^3—$A2/m$.

In III, the telluropentathionate ion lies in a crystallographic mirror plane of symmetry, and has thus a *cis* configuration, as contrasted with the *trans* configuration found earlier in the crystals of ammonium telluropentathionate [3]. The crystals of II being isomorphous with those of triclinic barium pentathionate dihydrate, the *cis* configuration occurs also in II. The triclinic space group possesses no crystallographic mirror plane, but the pentathionate ion has mirror plane symmetry also in those crystals [5].

The orthorhombic structure of barium pentathionate and selenopentathionate dihydrate, of space group D_{2h}^{16}—$Pnma$, is built up of layers related to each other through glide planes a in their interface [4,6]. From the correspondence of unit cell dimensions, the cleavage, and the similar intensities of the $0kl$ zones of reflections, it is to be expected that the monoclinic structure of barium telluropentathionate dihydrate, of space group C_{2h}^3—$A2/m$, is built up of layers which have the same internal structure as in the orthorhombic analogues, but are related to each other through twofold rotation axes instead of glide planes. A complete structure determination of III will be made.

The unit cell dimensions of triclinic and monoclinic barium telluropentathionate dihydrate show close correspondence, with $a = 4.99$ Å, $b = 10.57$ Å and 10.59 Å, and $d_{001} = 11.64$ Å and 2×11.69 Å, respectively. The intensities of the $00l$ reflections, with the l indices of III halved, are very similar. The structural difference should be the same as between triclinic and orthorhombic barium pentathionate dihydrate [4,5], and thus consist in a different arrangement of like layers relative to each other.

The work has been aided by grants from *Norges Almenvitenskapelige Forskningsråd* and from *Det Videnskapelige Forskningsfond av 1919.*

Solvates of Barium Pentathionates with Ethanol

OLAV FOSS and OLAV TJOMSLAND

Institutt for uorganisk kjemi, Norges tekniske høgskole, Trondheim, Norway

Barium pentathionate and selenopentathionate crystallize from aqueous ethanol as solvates containing one mole of water and one mole of ethanol per mole of salt. The crystals are isomorphous, and have eight-molecule unit cells based on the space group, D_{2h}^{15}—*Pcab*, with $a = 9.18$ Å, $b = 13.27$ Å, $c = 21.25$ Å for the pentathionate and $a = 9.19$ Å, $b = 13.30$ Å, $c = 21.37$ Å for the selenopentathionate. The solvates are relatively stable.

Barium telluropentathionate gives a solvate which probably contains one mole of ethanol but no water.

In 1847, one year after the discovery of pentathionic acid by Wackenroder [1], Lenoir [2] reported the isolation of barium pentathionate by crystallization from aqueous ethanol. Although the salt by analysis was found to contain 2.93 % of ethanol, the ethanol was regarded as an impurity, and the salt described as a dihydrate. Fordos and Gélis [3], in 1848, stated that barium pentathionate always retain some ethanol when precipitated from water by means of ethanol, but no particular significance was attached to the ethanol content.

It is the purpose of this article to show that barium pentathionate and selenopentathionate, when crystallized from aqueous ethanol, are obtained as solvates containing one mole of water and one mole of ethanol per mole of salt. The formulae are:

$$BaS(S_2O_3)_2 \cdot H_2O \cdot C_2H_5OH; \qquad BaSe(S_2O_3)_2 \cdot H_2O \cdot C_2H_5OH$$

The crystals of the two solvates are isomorphous. Lenoir [2] described his crystals as quadratic prisms, and they are later [4] referred to as tetragonal. In fact, the solvates usually occur as prisms having frequently a quadratic cross-section, but they are orthorhombic bipyramidal, not tetragonal. The correct percentage of ethanol in the pentathionate is 10.1 and thus considerably higher than found by Lenoir.

The ethanol appears to be relatively firmly held in the crystal lattice. When kept in closed bottles, the majority of the individual crystals remain unchanged for months, as revealed by microscopic and X-ray examination, although on opening the bottles, an odour of ethanol is perceptible. With re-

gard to the ordinary decomposition reactions of the pentathionates, *i. e.*, the liberation of sulphur or selenium, the solvates are at least as stable as the corresponding hydrates.

These are apparently the first recorded instances of solvates of barium salts with ethanol. According to Sidgwick [5], "the halides (and sometimes the hydroxide and nitrate as well) of barium will combine with glycerol, sugar alcohols, sugars, carboxylic acids, and aminoacids; strontium halides will also combine with alcohol and acetone". As will be shown later, barium pentathionates form well-defined solvates also with acetone and other simple organic solvents.

EXPERIMENTAL

To solutions of crude barium pentathionate [6] and barium selenopentathionate [7] in about 0.01 N hydrochloric acid, saturated at 40—50° C, and filtered if necessary and still warm, were added about equal volumes of ethanol. On cooling, first at room temperature and afterwards in ice, the solvates slowly crystallized. The crops of crystals were filtered with suction on sintered glass filters, washed with ethanol and then with ether, and dried for less than an hour in a vacuum over sulphuric acid. The same procedure was used for recrystallizations.

The crystals of the pentathionate are colourless and those of the selenopentathionate pale greenish.

The pentathionate was analyzed iodometrically by means of the sulphite method [8], after removal of the barium by addition of sodium sulphate [6]. Two equivalents of iodine correspond to one mole of pentathionate. Through control analyses by means of the cyanide method, the salt was found to be free from tetrathionate.

0.3007 × $\frac{1}{5}$ g substance: 26.04 ml of 0.01010 N iodine.

$BaS(S_2O_3)_2 \cdot H_2O \cdot C_2H_5OH$ (457.8): Mol. weight found, 457.3.

The selenopentathionate was oxidized with potassium bromate and subsequently analyzed iodometrically by means of the Norris and Fay method, as described earlier [9].

0.2011 g substance: 16.10 ml of 0.09954 N sodium thiosulphate.

$BaSe(S_2O_3)_2 \cdot H_2O \cdot C_2H_5OH$ (504.7): Mol. weight found, 501.8.

In order to check the presence of ethanol in the crystals, aqueous solutions were oxidized with chromic acid — sulphuric acid. Acetaldehyde was thereafter distilled off and characterized by means of 2,4-dinitrophenylhydrazine.

Experiments made with barium telluropentathionate have shown that also this salt gives a solvate with ethanol. The yellow crystals, obtained from the trihydrate [10] as described for the above solvates, were small and not suited for single-crystal X-ray work. According to analyses, performed by direct titration with iodine [11], the composition corresponds to one mole of ethanol per mole of barium telluropentathionate, but no water. The presence of ethanol in the crystals was checked as described above.

0.2012 g substance: 15.04 ml of 0.1001 N iodine.

$BaTe(S_2O_3)_2 \cdot C_2H_5OH$ (535.3): Mol. weight found, 534.6.

In lack of X-ray data, there remains some doubt concerning the absence of water in this solvate, since some ethanol or water may have escaped from the crystal lattice before the analysis. Similar analytical results have been obtained with some of the solvates of barium pentathionates with acetone and tetrahydrofuran, and there, isomorphism of the whole series of solvates indicates that the questionable mole of water is present, regardless of the analytical results.

CRYSTALLOGRAPHIC DATA

The solvates of barium pentathionate and selenopentathionate with ethanol are orthorhombic, and ordinarily occur as prisms, elongated in the direction of the *a* axis and bounded by {010} and {001}. The cross-section is frequently quadratic or nearly so. There is perfect cleavage along the *c* plane.

Oscillation and Weissenberg photographs were made on single-crystal specimens, using copper radiation, $\lambda(\mathrm{Cu}K_a) = 1.542$ Å. Densities were measured by a flotation method. The following unit cell dimensions, believed to be accurate to within 0.5 %, were derived.

	a	*b*	*c*
$BaS(S_2O_3)_2 \cdot H_2O \cdot C_2H_5OH$	9.18 Å	13.27 Å	21.25 Å
$BaSe(S_2O_3)_2 \cdot H_2O \cdot C_2H_5OH$	9.19	13.30	21.37

There are eight molecules per unit cell; densities, calc. 2.35 and 2.57 g/cm^3, respectively; found, 2.34 and 2.59 g/cm^3. Systematic absences, $0kl$ when l is odd, $h0l$ when h is odd, $hk0$ when k is odd. The space group is thus unambiguously determined as D_{2h}^{15}—*Pcab*. The unit cell dimensions, the space group extinctions, and the relative intensities of the reflections show that the two salts are isomorphous.

The number of general positions of the space group being eight, the asymmetric unit corresponds to one formula unit. No detailed structure analysis of any of the salts is contemplated at present.

The work has been aided by grants from *Norges Almenvitenskapelige Forskningsråd* and from *Det Videnskapelige Forskningsfond av 1919*.

Solvates of Barium Pentathionates with Acetone and Tetrahydrofuran

OLAV FOSS and OLAV TJOMSLAND

Institutt for uorganisk kjemi, Norges tekniske høgskole, Trondheim, Norway

Barium pentathionate and selenopentathionate crystallize from aqueous acetone as solvates containing one mole of water and one mole of acetone per mole of salt. Analogous solvates, containing tetrahydrofuran instead of acetone, occur when barium pentathionate, selenopentathionate and telluropentathionate crystallize from aqueous tetrahydrofuran.

The solvates with acetone and tetrahydrofuran are isomorphous; the space group is C_{2h}^2—$P2_1/m$ with $Z = 2$. The barium ion, the middle atom of the pentathionate chain, the water molecule and the organic molecule lie in a crystallographic mirror plane. Unit cell dimensions are given for the five solvates, and their structure discussed in relation to the structures of barium pentathionate, selenopentathionate and telluropentathionate dihydrates.

In preparations of the solvates, some of the individual crystals give off the acetone or tetrahydrofuran relatively rapidly, while others are more stable.

In earlier papers on the crystal chemistry of barium salts of pentathionic, selenopentathionic and telluropentathionic acids, five dihydrates have been described, which crystallize in three different space groups. The salts are, triclinic barium pentathionate [1] and telluropentathionate [2] dihydrates, space group C_i^1—$P\bar{1}$ with $Z = 2$; orthorhombic barium pentathionate [3] and selenopentathionate [4] dihydrates, space group D_{2h}^{16}—$Pnma$ with $Z = 4$; and monoclinic barium telluropentathionate dihydrate [2], space group C_{2h}^3—$A2/m$ with $Z = 4$. The present paper, on solvates in which one of the water molecules of the dihydrates is replaced by an acetone or tetrahydrofuran molecule, introduces a fourth, closely related structure type, of space group C_{2h}^2—$P2_1/m$ with $Z = 2$.

The solvates of barium pentathionates with acetone and tetrahydrofuran occur very readily, on addition of the solvents to aqueous solutions of the salts. The solvates are relatively stable, although the dissociation pressures of the organic molecules above the solvate crystals appear to be higher than in the case of the corresponding solvates with ethanol [5]. Within a preparation, some individual crystals give off the solvate molecules and become opaque rapidly, while others are quite stable and remain transparent and unchanged for weeks.

The crystals retain the solvate molecules better if immediately after filtering and washing, with the solvate solvent and then with ether, the crop of crystals is spred out on a large surface for drying in air. Crystals, once stable and thus picked and cut for X-ray measurements, mounted on a glass fibre in air in the ordinary way, have not been observed to disintegrate during the exposures to X-rays.

No solvates of barium salts with acetone or tetrahydrofuran appear to have been reported earlier. Deines and Christoph [6] may have had the solvate of barium pentathionate with acetone in their hands, inasmuch as they in 1933 in a footnote reported on the isolation of barium polythionates, presumably also the pentathionate, from aqueous solutions by addition of ethanol or acetone.

EXPERIMENTAL

Solutions of barium pentathionate [1], selenopentathionate [4] and telluropentathionate [5] hydrates, saturated at room temperature, were filtered if necessary and warmed to about 40° C, and from one to two times the volume of acetone or tetrahydrofuran was added with stirring. The solvates crystallized as the solutions were allowed to cool, to room temperature or in ice. Pure water or about 0.2 N perchloric acid was used to dissolve the hydrates, since hydrochloric acid which ordinarily is used to stabilize solutions of the pentathionates, caused contamination of the solvates with barium chloride.

Under the above conditions, the solvates with acetone appear to be less soluble and crystallize more rapidly than those with tetrahydrofuran. As with the hydrates, the solubilities decrease in the order, pentathionate, selenopentathionate and telluropentathionate.

The pentathionates were analyzed iodometrically by means of the sulphite method [7], some sodium sulphate being added to the sample before the addition of the sodium sulphite reagent in order to remove the barium as sulphate. Two equivalents of iodine correspond to one mole of pentathionate. Absence of tetrathionate was checked through control analyses by means of the cyanide method.

0.3048 × $\frac{1}{5}$ g, 0.3442 × $\frac{1}{5}$ g, 0.2820 × $\frac{1}{5}$ g substance: 26.38 ml, 27.10 ml, 24.58 ml of 0.01010 N, 0.01099 N, 0.01010 N iodine, respectively.

$BaS(S_2O_3)_2 \cdot H_2O \cdot (CH_3)_2CO$ (469.8). Mol. weights found, 457.3, 462.3, 454.3.

0.1834 × $\frac{1}{5}$ g, 0.2525 × $\frac{1}{5}$ g, 0.2497 × $\frac{1}{5}$ g substance: 13.99 ml, 18.97 ml, 19.08 ml, respectively, of 0.01099 N iodine.

$BaS(S_2O_3)_2 \cdot H_2O \cdot (CH_2)_4O$ (483.8). Mol. weights found, 477.0, 484.4, 476.3.

The selenopentathionates were titrated with potassium bromate and subsequently analyzed iodometrically by means of the Norris and Fay method, as described earlier [8]. The bromate titration values served as a check on the absence of tetrathionate [8].

0.2808 g, 0.2474 g, 0.2765 g substance: 22.43 ml, 19.15 ml, 21.91 ml, respectively, of 0.09954 N sodium thiosulphate.

$BaSe(S_2O_3)_2 \cdot H_2O \cdot (CH_3)_2CO$ (516.7). Mol. weights found, 503.0, 519.2, 507.1.

0.1983 g, 0.2066 g substance: 15.02 ml, 15.64 ml, respectively, of 0.09954 N sodium thiosulphate.

$BaSe(S_2O_3)_2 \cdot H_2O \cdot (CH_2)_4O$ (530.7). Mol. weights found, 530.6, 530.8.

The telluropentathionate was analyzed by direct titration with iodine, as described earlier [9]. Absence of tetrathionate was checked through subsequent analyses of the titrated solutions by means of the sulphite method [9].

0.3360 g, 0.1500 g, 0.2496 g substance: 24.26 ml, 10.98 ml, 17.70 ml, respectively, of 0.1001 N iodine.

$BaTe(S_2O_3)_2 \cdot H_2O \cdot (CH_2)_4O$ (579.4). Mol. weights found, 553.5, 546.0, 563.4.

Different analyses reported for a substance were on different preparations.

The presence of organic molecules in the solvates was apparent from the strong characteristic odours of acetone or tetrahydrofuran which appeared when the solvates were dissolved in a little water. The acetone was, furthermore, characterized by means of 2,4-dinitrophenylhydrazine.

The solvate of barium selenopentathionate with tetrahydrofuran is the only one which gave consistent analytical results in agreement with the theoretical composition of the solvate. In the case of the other solvates, the results indicate that some water or, more likely, some acetone or tetrahydrofuran may have escaped from the crystal lattices before analysis. There is also a possibility that the solvates are non-stoichiometric, in the sense that, regarding them as derived from dihydrates, a water molecule of the latter is not completely, but only partly replaced by the organic molecule. That is, in the crystal lattice of the solvates some of the acetone or tetrahydrofuran positions are occupied by water.

CRYSTALLOGRAPHIC DATA

The solvates of barium pentathionates with acetone and tetrahydrofuran occur as plates {001}, bounded by {110}. The plates are usually rhomb-shaped and very thin, but do on slow crystallization grow thicker. There is perfect cleavage along (001), and some tendency of cleavage along another plane parallel to the *b* axis, probably (100). Twinning on (001) frequently occurs. The acetone solvates have also been obtained as prisms elongated in the direction of the *a* axis and with, also here, {001} predominant.

The unit cell dimensions were determined from oscillation and Weissenberg photographs about the *a* and *b* axes, using copper radiation. The axial lengths given in Table 1 are based on $\lambda(\mathrm{Cu}K_\alpha) = 1.542$ Å and are believed to be correct to within 0.5 %.

Table 1. Unit cell dimensions of isomorphous acetone and tetrahydrofuran solvates.

	a	*b*	*c*	*β*
$BaS(S_2O_3)_2 \cdot H_2O \cdot (CH_3)_2CO$	5.04 Å	10.47 Å	13.61 Å	104°
$BaSe(S_2O_3)_2 \cdot H_2O \cdot (CH_3)_2CO$	5.02	10.56	13.78	105°
$BaS(S_2O_3)_2 \cdot H_2O \cdot (CH_2)_4O$	5.03	10.56	13.81	104°
$BaSe(S_2O_3)_2 \cdot H_2O \cdot (CH_2)_4O$	5.03	10.69	13.97	105°
$BaTe(S_2O_3)_2 \cdot H_2O \cdot (CH_2)_4O$	5.00	10.82	14.21	106°

The densities of the first and third of the solvates were measured by flotation in bromoform-carbon tetrachloride mixtures and found to be 2.25 and 2.27 g/cm^3, respectively, as compared with the calculated values of 2.24 and 2.26 g/cm^3 for two molecules per unit cell. The only systematic absences are, for all five solvates, $0k0$ when k is odd. A comparison of the intensities of the $0kl$ and $h0l$ zones of reflections, and the close correspondence of unit cell dimensions, leave no doubt that the solvates are isomorphous. The diffraction symmetry being monoclinic, there are two space groups compatible with the systematic absences, of which the centrosymmetric one, C_{2h}^2—$P2_1/m$, has been found to be the correct one through Patterson and Fourier projections along the *a* and *b* axes of the solvate of barium pentathionate with acetone.

With two formula units per unit cell, either centres of symmetry or mirror planes are required as molecular symmetry elements. Since pentathionate ions, water molecules and acetone or tetrahydrofuran molecules cannot reasonably be centrosymmetric, they must lie in mirror planes, as does also the barium ion according to the projections mentioned above.

The work so far done on the crystal structure of the solvate of barium pentathionate with acetone shows, as was expected from the unit cell dimensions and space group and the known structures of barium pentathionate, selenopentathionate and telluropentathionate dihydrates, that the solvate crystals are built up of layers which have the same internal structure as in the dihydrates, but for the substitution of a water molecule by an organic molecule. In the dihydrate structures [1–4], one of the water molecules, $(H_2O)_I$, is firmly bound, being coordinated to two barium ions and forming hydrogen bonds to two oxygen atoms, whereas the other water molecule, $(H_2O)_{II}$, is coordinated to one barium ion only, forms no hydrogen bonds and has a relative spacious environment. It is this water molecule, $(H_2O)_{II}$, of the dihydrates which in the solvates is replaced by acetone or tetrahydrofuran, the internal structure of the layers otherwise being the same.

The dihydrates crystallize in three different space groups [1–4], *viz.*, C_i^1—$P\bar{1}$ with $Z = 2$, D_{2h}^{16}—$Pnma$ with $Z = 4$, and C_{2h}^3—$A2/m$ with $Z = 4$. The space group, C_{2h}^2—$P2_1/m$ with $Z = 2$, of the acetone and tetrahydrofuran solvates represents a fourth structure type. The unit cell dimensions of the dihydrates and the solvates are very like, with $a = 5.0$ Å and $b = 10.3$—10.8 Å, and c spacings as discussed below. The isostructural layers are parallel to the c planes, and the crystals show a corresponding perfect cleavage along this plane. The internal layer symmetry, $2_1/m$, is crystallographically required by all space groups except the triclinic one, but is realized even there [1]. The structure types differ only in the way in which the layers are arranged relative to each other. In the crystals of space group C_i^1—$P\bar{1}$, there is a repetition of layers with relative displacements in the directions of the a and b axes; in C_{2h}^2—$P2_1/m$, there is a repetition with displacements in the direction of the a axis only; in D_{2h}^{16}—$Pnma$, successive layers are related through glide planes a in their interface, and in C_{2h}^3—$A2/m$, through twofold rotation axes parallel to the b axis in the interface.

In the solvates, the oxygen atom of the organic molecule coordinates to the barium ion, like the oxygen atom of the replaced water molecule, and is located between the barium ion and the nearest layer interface, with the rest of the molecule directed towards the interface. It is interesting to compare the space requirements of the water and organic molecules with the observed variations of layer thicknesses. The layer thickness is equal to the c spacing when there are two formula units per unit cell, and half the c spacing when there are four. The distances from the centre of the oxygen atom, along the molecular axis to the van der Waals sphere of the methyl or methylene groups, are calculated as 4.0 Å for acetone and 4.3 Å for tetrahydrofuran, using dimensional data from electron diffraction studies [10,11] and taking the van der Waals radius of methyl and methylene groups [12] as 2.0 Å. For water, the corresponding distance is 1.8 Å. The observed c spacings of the solvates with tetrahydrofuran are, in fact, a little larger than of those with acetone, *viz.*, 0.19 Å for the pentathionates and 0.18 Å for the selenopentathionates. Also, the c spacings of the solvates are larger, by 2.0—2.4 Å, than the c spacings, or half these values, of the corresponding dihydrates [1–4]. Although the molecules probably do not point directly towards the layer interface, but are more or less inclined to it in the direction of the a axis, it appears that there is a

dependence of layer thickness on the space requirements of the replaceable molecules.

The work has been aided by grants from *Norges Almenvitenskapelige Forskningsråd* and from *Det Videnskapelige Forskningsfond av 1919.*

The Infrared Spectrum of 1,2-Butylene Oxide

An Azeotropic System (1,2-Butylene Oxide/Chloroform) with a Maximum Boiling Point

BERTIL NYCANDER and CARL OLOF GABRIELSON

Research Laboratory, Mo och Domsjö AB, Örnsköldsvik, Sweden

Pure 1,2-butylene oxide has been obtained by fractional distillation of a mixture rich in isomeric butylene oxides. The infrared spectrum of the pure substance is recorded. 1,2-butylene oxide forms with chloroform an azeotrope with a maximum boiling point of 69.0° C at atmospheric pressure. The azeotrope contains 39.4 % by weight of the oxide.

In connection with an investigation of impurities in raw technical ethylene chloride obtained as a by-product during the manufacture of ethylene oxide by the ethylene chlorohydrin process, it was found that 1,2-butylene oxide forms with chloroform an azeotropic system with a maximum boiling point. This azeotrope does not seem to have been described in literature before.

EXPERIMENTAL

Distillation apparatus. A Podbielniak Hyper-Cal apparatus, Cat. No. HC-701-A, Series "D", has been used for all distillations. Butylene oxide or mixtures of this and other substances have been fractionated in a 25 mm I. D. × 72″ long Heli-Grid packed column. The chloroform was distilled in the same kind of column which in this case was only 36″ long. The distillation temperature was measured with an iron-constantan thermocouple which was calibrated against a standardized thermometer.

Analysis. Butylene oxides were analysed by a method given by Swern *et al.*[1] using the reaction of epoxides with hydrochloric acid in absolute ethyl ether.

1,2-Butylene oxide. In order to obtain this substance in a pure form, a fraction was used which had been enriched in butylene oxides during a technical distillation of raw ethylene chloride which contained butylene oxides as impurities. The mixture was fractionated in the above mentioned apparatus with a reflux ratio of 100:1. When the distillation temperature reached the boiling point of ethylene chloride, the distillation was stopped. The distillate was redistilled with a reflux ratio of 200:1. Three main fractions were obtained in the second distillation.

The first one had a boiling point of 54° C at atmospheric pressure, which is close to the value 53.5° C that Winstein and Lucas [2] found for *trans*-2,3-butylene oxide. The identi-

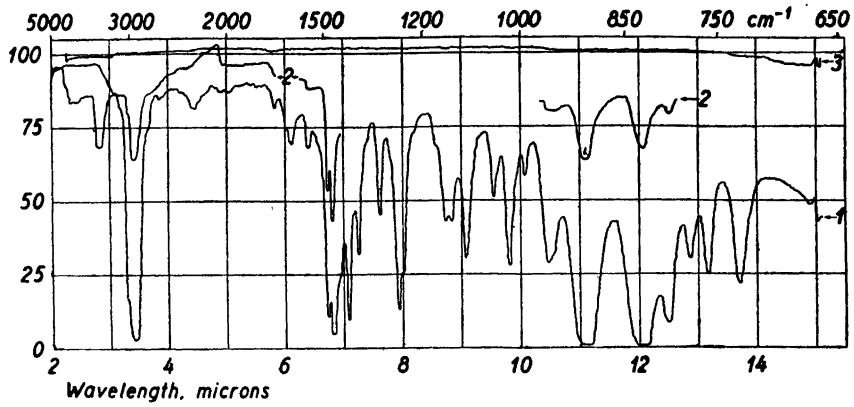

Fig. 1. Infrared spectrum of 1,2-butylene oxide. Phase: Liquid. Thickness: 1 = 0.05 mm; 2 = cap. Prism: NaCl. Resolution: 895. Response: 1. Gain: 6. Speed 2. Suppression: 1; 3 = Example of compensation with the same adjustments. Ordinate: Transmittance (% Transmission).

fication was confirmed by recording the infrared spectrum of the fraction and comparing this with the spectrum of *trans*-2,3-butylene oxide published by Patterson [3].

The second fraction boiled at 58–60° C, indicating that it consists of *cis*-2,3-butylene oxide since, according to Winstein and Lucas [2], the boiling point of this compound is 59.7 ° C. The identification was also in this case confirmed when the infrared spectrum was found to be identical with the one published by Patterson [3].

The third main fraction boiled at 65° C and ought to consist of 1,2-butylene oxide. Analysis of this fraction gave 99.8 (99.6, 99.8, 100.1) % butylene oxide. Its infrared spectrum (Fig. 1) shows that it does not contain any *cis*- or *trans*-2,3-butylene-oxide.

In order to confirm that it really was 1,2-butylene oxide, this substance was synthetized from ethyl bromide and monochloro acetaldehyde by a method used by Andersson [4]:

$$C_2H_5MgBr + OHC \cdot CH_2Cl \rightarrow C_2H_5CH(OH)CH_2CL \xrightarrow{OH^-} C_2H_5CH \cdot CH_2$$
$$\qquad\qquad\qquad

The azeotrope contained 39.4 (39.4, 39.4) % by weight of 1,2-butylene oxide.

The boiling point was determined by boiling the azeotrope slowly under reflux in a Claisen flask and the temperature was read on a standardized thermometer graduated to 0.1° C. At 769 mm Hg the boiling point was 69.0° C.

In the same way the boiling points of the pure 1,2-butylene oxide and chloroform was found to be 63.2 and 61.2° C, respectively, at 763 mm Hg. The boiling point of chloroform at atmospheric pressure is given [5] as 61.2° C and that of 1,2-butylene oxide [6] as 63.7° C at 767 mm Hg.

The infrared spectrum of the pure 1,2-butylene oxide was recorded on a Perkin-Elmer Model 21 Double Beam Infrared Spectrometer at Uppsala University *. The positions of the strongest absorption maxima are 3.39, 6.72, 6.80, 7.07, 7.93, 11.08, 12.06 μ. The wave lengths of the absorption maxima were determined by calibration against the spectrum of polystyrene [7].

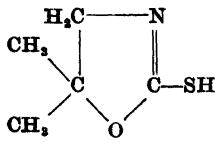
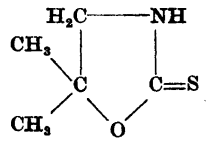
*iso*Thiocyanates XVI. Glucoconringiin, the Natural Precursor of 5,5-Dimethyl-2-oxazolidinethione



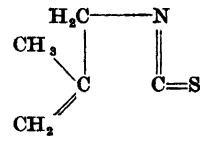
ANDERS KJÆR, ROLF GMELIN and ROALD BOE JENSEN

Chemical Laboratory of the University of Copenhagen, Denmark



Seed of the crucifer *Conringia orientalis* (L.) Andrz. has been shown to contain a new glucoside, *glucoconringiin*, characterised as a crystalline tetraacetate (IV) and affording glucose, sulphuric acid and 2-hydroxy-2-methyl-propyl *iso*thiocyanate (V) on enzymic hydrolysis. The mustard oil cyclises spontaneously to 5,5-dimethyl-2-oxazolidinethione (II), a fact accounting for the previously reported isolation of (II) from the same seed.

A modified synthesis of the heterocyclic compound is described. A paperchromatographic method has disclosed the presence of glucoconringiin also in three species of the genus *Cochlearia*, further substantiated by the isolation from *Cochlearia officinalis* L. of crystalline 5,5-dimethyl-2-oxazolidinethione after enzymic hydrolysis. Evidence is available of the existence of additional 2-oxazolidinethione-producing glucosides in plants.



In 1938 Hopkins [1] reported the isolation of 5,5-dimethyl-oxazoline-2-thiol (I) from seed of the common Canadian weed *Conringia orientalis* L. (Dumort) *.

I

II

III

The structure of (I) followed from its identity with a synthetic sample, prepared by Bruson and Eastes [2]. On the basis of infra-red studies, Ettlinger [3] later provided evidence in favour of the thione structure (II). It appeared from Hopkins' studies that the heterocyclic compound was formed by enzymic cleavage of a parent glycoside, the aglycone of which was considered to be

* The species should be more correctly designated as *Conringia orientalis* (L.) Andrz. (= *Erysimum orientale* Mill.).

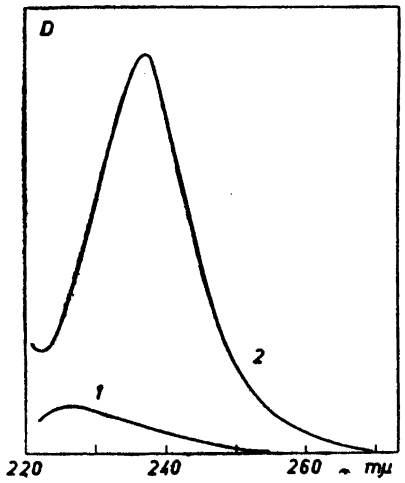


Fig. 1. Ultra-violet absorption spectra of: 1. an aqueous solution of glucoconringiin; 2. an aqueous solution of the ether-soluble product, (II), formed by enzymic cleavage of glucoconringiin.

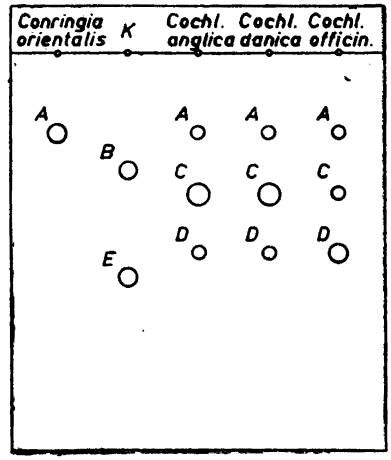

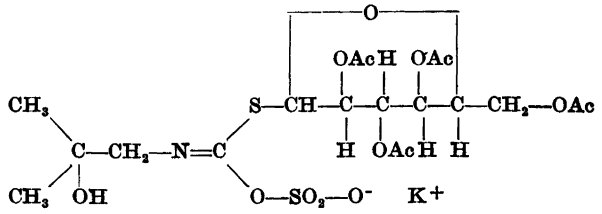

Fig. 2. Descending paper chromatogram, run in n-butanol: acetic acid : water. Sprayed with ammoniacal silver nitrate solution. K: control solution; A: glucoconringiin; B: sinigrin; C: glucoputranjivin; D: glucocochlearin; E: glucotropaeolin.

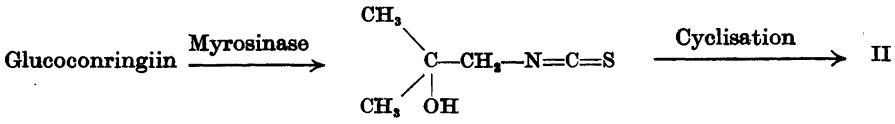
2-methylallyl *iso*thiocyanate (III). Addition of water to the *iso*thiocyanate-grouping of the latter, followed by spontaneous cyclisation of the intermediate thiocarbamic acid to (I) was regarded as a likely mode of formation. When synthetic 2-methylallyl *iso*thiocyanate became available in this laboratory [4], it was established that no such tendency to water addition and ring-closure existed.

As pointed out in a previous paper of this series [5], seed of *Conringia orientalis* yielded no volatile *iso*thiocyanates on enzymic hydrolysis. Paper chromatography [6] of a seed extract has now, however, disclosed the presence of a single glucoside, giving a spot in the lower R_F-region (Fig. 2). The glucoside solution exhibited an absorption spectrum of the usual type (Fig. 1), as known for, *e. g.*, sinigrin [7], a fact precluding the presence of chromophors, such as the heterocyclic ring system (II), in the *Conringia*-glucoside, for which the name *glucoconringiin* is proposed.

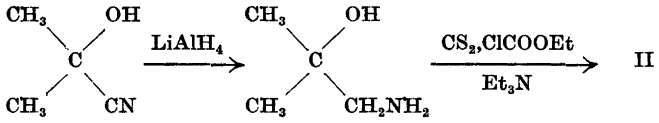


Upon enzymic hydrolysis of glucoconringiin an ether-soluble substance arose, with spectroscopical characteristics (Fig. 1) similar to those reported for (II) by Hopkins [1] and Astwood *et al.*[8] The concomitant formation of glucose and sulphate was established. During the summer of 1955, *Conringia orientalis* (L.) Andrz. was cultivated on a larger scale in the Botanical Garden of the University of Copenhagen. The seed material thus obtained was employed for the isolation of further quantities of glucoconringiin, which did not show signs of crystallisation, but could be transformed into a crystalline acetyl-derivative with the composition $C_{19}H_{28}O_{14}NS_2K$. Analytical data indicated the presence of four O-acetyl groupings; on the assumption that these are

located in the glucose moiety, as rendered highly probable by model preparation of the analogous tetraacetyl-sinigrin, and provided sulphuric acid is bound as generally believed in this type of glucosides, the structure (IV) appears to account for the properties of acetylglucoconringiin.

IV

As expected, the hydroxy-grouping of the side-chain escaped acetylation due to its tertiary character. The derivative (IV) was not attacked by myrosinase. Its infra-red spectrum was determined in the solid state and found very similar to that of acetylsinigrin. Probably due to association, no band attributable to the tertiary hydroxy-function was observed in the spectrum of (IV). That acetylation was not accompanied by secondary changes appeared from the fact that (IV) could be smoothly deacetylated to glucoconringiin, the identity of which followed from its rapid enzymic hydrolysis, resulting in the formation of (II). There can be little doubt, therefore, that (II) is to be considered as a secondary product, arising from the initially formed 2-hydroxy-2-methyl-propyl *iso*thiocyanate (V) by spontaneous cyclisation.



V

The cyclisation proceeds at a measurable rate. It was spectroscopically established that a partly purified glucoconringiin preparation, subjected to enzymic hydrolysis for four hours at room temperature, afforded the cyclic product in a yield of only about 40 %; about 24 hours were required for the cyclisation to go to completion. From analogous cases it appeared very unlikely that the enzymic hydrolysis is the rate-determining step in the present reaction.

For further studies a synthetic sample of (II) became desirable. As in previously described syntheses [2,9,10] of this compound, 1-amino-2-methyl-2-propanol (VI) was selected as a starting material. Several methods have been described [11,12] for the preparation of this aminoalcohol, which has recently been isolated from the phospholipid fraction of *Neurospora crassa* [13] and established as the amine moiety of sanshoamide, an amide isolated from *Zanthoxylum piperitum* [14]. Whereas Meisenheimer and Chou [15] were unsuc-

cessful in attempts to reduce acetone cyanohydrin catalytically, a mixture of amines, with unstated yield of the desired primary derivative, was formed by high-pressure reduction with Raney-nickel as a catalyst, according to a patent claim [16]. We found that acetone cyanohydrin could be reduced to (VI) with lithium aluminium hydride. Analogous reductions of the cyanohydrins of benzaldehyde [17] and *cyclo*hexanone [18] have been reported previously.

Several methods of converting 1,2-aminoalcohols into 2-oxazolidinethiones have been proposed, all proceeding *via* dithiocarbamates by means of reagents, traditionally employed for converting the latter into *iso*thiocyanates [10,19,20]. The Kaluza method of *iso*thiocyanate synthesis, modified according to Hodgkins and Ettlinger [21], belongs to this type of reaction and has proved to be useful for the preparation of 2-oxazolidinethiones also *. We subjected (VI) to this reaction in a non-aqueous system with triethylamine as a base and obtained (II) in 78 % yield. Several attempts to isolate the intermediate *iso*thiocyanate (V) proved unsuccessful, probably due to the cyclisation being facilitated under basic conditions. The identity of the final product was established by comparison with an authentic specimen of (II), kindly furnished by Dr. Ettlinger.

VI

In the course of our systematic studies on the distribution of *iso*thiocyanates in plants, it was found that oxazolidinethiones could be separated by paper chromatography in the solvent system heptane: *n*-butanol: 90 % formic acid, introduced by Sjöquist [22] for the separation of phenylthiohydantoins. By this technique, oxazolidinethiones were recognised in other plants also. For example, glucoside chromatography disclosed the presence in *Cochlearia anglica* (L.) Asch. & Grb., *C. danica* L. and *C. officinalis* L. of three glucosides (Fig. 2), two of which were recognised as the previously known species glucoputranjivin and glucococchlearin, affording *iso*propyl [23] and *sec*-butyl [5] *iso*thiocyanate, respectively, on enzymic hydrolysis. The third glucoside spot could be attributed to glucoconringiin because of its enzymic cleavage to a compound, indistinguishable from (II) by paper chromatography in the heptane system. Final proof of its identity was provided when a crystalline specimen was obtained from a seed sample of *C. officinalis* L. The natural product was found to be identical with an authentic specimen of (II).

It should be noticed that the structurally analogous *l*-5-vinyl-2-oxazolidinethione has been recognised as a constituent of several species of the important genus *Brassica* [8]. We have spectroscopical evidence that this compound is formed in a similar way from an analogous genuine glucoside of more wide-

* Applied by Dr. Ettlinger in a synthesis of 4-vinyl-2-oxazolidinethione (private communication).

spread occurrence than previously reported and derivable from one of the stereoisomeric 2-hydroxy-3-butenyl *iso*thiocyanates.* Additional natural representatives of the class of oxazolidinethione-progenitors have been discovered and are at present being further studied. An account of the results will form the subject of forthcoming communications.

EXPERIMENTAL

Melting points are uncorrected and determined in capillary tubes in a glycerol bath, if not otherwise stated. Infra-red spectra were determined in potassium bromide discs on a Beckman IR-2 instrument.

Detection and nature of glucoconringiin. Seed of *Conringia orientalis* (L.) Andrz. (1 g) was extracted with hot methanol and the solvent was removed by evaporation. The residue was taken up in water, the solution filtered and a drop of the filtrate used for descending paper chromatography in *n*-butanol:acetic acid:water (4:1:3), essentially as described by Schultz and Gmelin[6]; a single glucoside-spot of glucoconringiin appeared (Fig. 2).

The glucoside solution was purified by exchange on a small column of acidic aluminium oxide, eluted with a 1 % solution of K_2SO_4 and a sample withdrawn for ultra-violet absorption measurement (Fig. 1). A few drops of a myrosinase preparation were added to the eluate which was set aside for 24 hours. The now turbid solution was extracted three times with ether; the solvent was removed, the residue dissolved in water (200 ml) and the ultra-violet absorption spectrum determined (Fig. 1). A high-extinction band was observed at 239 mμ, displaced in alkali to 232 mμ, and a minimum at about 222 mμ, both values agreeing well with those previously published [8].

Samples of the aqueous phase were chromatographed for sugars in *n*-butanol:acetic acid:water and in pyridine:amyl alcohol:water. In both solvent systems, the presence of glucose was established upon comparison with control spots. A separate sample of glucoconringiin, which had not been purified by ion exchange, served to establish the presence of sulphate after the enzymic fission.

Preparation and properties of acetylglucoconringiin **. *Conringia* seed (100 g) was extracted with two portions (each 500 ml) of hot 70 % methanol and the solution taken to dryness *in vacuo*. The residue was dissolved in water (300 ml) and impurities precipitated by adding excess lead acetate solution. After filtration and removal of excess lead salt as PbS, the solution was again taken to dryness *in vacuo*, leaving glucoconringiin as an almost colourless, glassy mass.

After thorough drying the product was dissolved in a mixture of dry pyridine (25 ml) and acetic anhydride (25 ml) and set aside for 24 hours. Volatile reagents were then removed *in vacuo* and the brown residue dissolved in a large volume of hot ethanol. The solution was treated with charcoal, filtered and chilled. A slight amount of amorphous material was removed and the filtrate concentrated, whereupon the crystalline acetyl-derivative (663 mg) separated. Two recrystallisations from 96 % ethanol, containing a little methanol, afforded an analytical specimen (397 mg) as tiny, colourless needles, m. p. 152° (decomp.) on rapid heating. The acetyl-derivative is easily soluble in water, moderately soluble in methanol and slightly soluble in ethanol. $[\alpha]_D^{24}$ −5.3° (H_2O, c = 5.3). (Found: C 37.95; H 4.85; N 2.25; S 10.80; CH_3CO 30.9. Calc. for $C_{19}H_{23}O_{14}NS_2K$: C 38.18; H 4.73; N 2.34; S 10.73; 4 CH_3CO 28.8). The infra-red spectrum had characteristic bands

* *Note added in proof:* After this paper was submitted for publication, Greer [26] announced the isolation of this glucoside, "progoitrin", as a crystalline sodium salt. The composition and provenance of the glucoside "glukorapiferin", recently characterized by Schultz and Wagner [27] as a crystalline pentaacetate, strongly indicate the identity of "progoitrin" and "glukorapiferin".

** According to a personal communication to one of us (R.G.) from Prof. O.-E. Schultz, Tübingen, acetylation has been used in his laboratory for the purpose of characterising *iso*thiocyanate glucosides, *cf.* Ref.[27]

at: 5.67 (very strong, C = O stretching vibration), 5.99 (weak), 7.24 (strong), 7.97, 8.10 (split peak, v. s.), 8.46 (w.), 8.80 (w.), 9.06 (w.), 9.40 (v. s.), 10.10 (w.), 10.92 (medium), 11.12 (m.), 11.45 (w.), 11.95 (w.) and 12.60 μ (s.).

A solution of acetylglucoconringiin in ethanolic ammonia was kept at room temperature for five days. The solvent was then removed and a sample of the residue subjected to paper chromatography in *n*-butanol:acetic acid:water. A single spot was observed, indistinguishable from that of glucoconringiin. The remaining part of the reaction product was hydrolysed enzymically, and the ether-soluble reaction product was identified as 5,5-dimethyl-2-oxazolidinethione by its absorption spectrum and by paperchromatographic comparison with an authentic sample.

Acetylsinigrin. In a model experiment, sinigrin was subjected to acetylation by a similar procedure. Previously, Gadamer [24] reported failure in obtaining a crystalline derivative by treatment of sinigrin with acetic anhydride.

Sinigrin (200 mg) was dissolved in hot pyridine (4 ml), and acetic anhydride (2 ml) added after cooling. After 4 hours, the separation of acetylsinigrin started and was completed by careful addition of ether. The crude product was recrystallised twice from aqueous ethanol and once from methanol to give pure tetraacetylsinigrin as thin, colourless needles (77 mg), m. p. 192–93° (dec.), determined in an electrically heated block. The solubility properties were the same as those of acetylglucoconringiin. $[\alpha]_D^{24}$ −18.6° (H_2O, c = 3.6). (Found: C 38.15; H 4.36; N 2.30. Calc. for $C_{18}H_{24}O_{13}NS_2K$: C 38.24; H 4.28; N 2.48). The infrared spectrum had conspicuous bands at 5.67 (v. s., C = O stretching vibration), 6.00 (w.), 7.24 (s.), 7.76 (s.), 7.97 (v. s. —C—O-vibration), 8.62 (w.), 9.39 (v. s.), 10.43 (w.), 10.64 (w.), 10.84 (w.), 11.20 (medium) and 12.60 μ (s.).

1-Amino-2-methyl-2-propanol (VI). To a well-stirred solution of $LiAlH_4$ (9.1 g) in dry ether (200 ml) was slowly added a solution of acetone cyanohydrin (8.9 g) in dry ether (100 ml). The reaction was performed in a nitrogen atmosphere, and completed upon heating to reflux temperature for 30 minutes. Then water (10 ml) and 15 % NaOH (25 ml) were cautiously added, the precipitate filtered off and thoroughly washed with ether, and the ether solution dried over KOH. The ether was removed and the colourless, viscous amine (4.6 g, 50 %) distilled, b. p. 150°, in agreement with several literature values. No attempts were made to raise the yield by systematic variations of the conditions. It was found, however, that reduction in the presence of $AlCl_3$, a recently introduced modification in the reduction of ordinary nitriles [25], gave a much lower yield (25 %), due to cleavage of the cyanhydrin. In this case, a rather large proportion of pinacol was also isolated as a secondary product.

5,5-Dimethyl-2-oxazolidinethione (II). The above amine was converted into (II) by a recently published method of *iso*thiocyanate synthesis [21]. To a stirred solution of (VI) (4.6 g) in dioxan (7.5 ml) and triethylamine (7.5 ml), kept at −10°, carbon disulphide (3.1 ml) was slowly added and the solution allowed to come to room temperature. After cooling again, ethyl chlorocarbonate (5.6 ml) was added very slowly, and the mixture again brought to room temperature. Triethylammonium chloride was removed by filtration and washed with a little dioxan. A solution of triethylamine (7.5 ml) in chloroform (15 ml) was then added and the solution heated shortly to 50°. After removal of all volatile constituents at 50° and 12 mm, crystalline (II) remained (5.31 g, 78 %). A pure sample was obtained as colourless platelets by recrystallisation, first from ether and then from benzene, m. p. 107°, alone or in admixture with an authentic specimen, kindly furnished by Dr. Ettlinger.

Isolation of (II) from seed of Cochlearia officinalis *L.* When a seed sample of *C. officin.* L. was assayed by the method described for the determination of 5-vinyl-2-oxazolidinethione in plant tissues [8], a content of about 45 mg per 100 g of seed was found.

500 g of seed were employed for isolation of the heterocyclic compound. With minor modifications, the procedure was the same as that used for the isolation of the vinyl-derivative [8]. The mainly crystalline, crude product (100 mg) was purified by recrystallisation, first from ether and then from benzene. Thus, colourless flat prisms were obtained (22 mg), m. p. 105°. A mixture of this compound and the synthetic specimen of (II) melted at 106°. (Found: C 46.05; H 7.25; N 10.18. Calc. for C_5H_9ONS: C 45.78; H 6.91; N 10.68). As further proof of identity, the infra-red spectra of the two products were determined and found to coincide. The spectral pattern was essentially the same as that previously reported for (II) [3].

Microanalyses were performed in this laboratory by Mr. P. Hansen. We wish to thank the *Botanical Garden of the University of Copenhagen* for the cultivation of *Conringia orientalis* (L.) Andrz. on a larger scale, and for various seed samples.

The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*.

Double Bond Migration and Dehydrogenation of Squalene on Hydrogenation Catalysts *

JOHANNES DALE and TORSTEIN ÅRTUN

Forsvarets Forskningsinstitutt, Kjeller, Norway

From infrared spectroscopic evidence it has been concluded that considerable double bond migration takes place during the catalytic hydrogenation of squalene. Dehydrogenation has been observed after treating the olefin with catalysts, in particular with Raney nickel. Ultraviolet spectra indicate the presence of chromophores consisting of 2, 4, and 6 conjugated double bonds, but none with 3, 5, or 7, which suggests a reversed 1,4-addition as a possible mechanism.

Catalytic dehydrogenation has also been achieved with esters of oleic acid.

In the course of a study of the catalytic hydrogenation of the triterpenoid hydrocarbon squalene,

it was observed that the partially hydrogenated product showed infrared absorption bands that were not present either in the starting material, natural squalene, or the completely saturated product, squalane. Thus, in the C=C double bond stretching region a new band had developed at 6.07 μ in addition to the original band at 6.01 μ. Stronger bands had developed at 10.35 μ and at 11.27 μ (only weak in natural squalene); also a weak band appeared at 14.4 μ. These latter bands are generally attributed to the out-of-plane deformation vibrations of ethylenic C—H bonds [2] and are characteristic for the various types of alkyl substitution at a double bond, as indicated in Fig. 1. The obvious conclusion was therefore that the double bonds had in part migrated from the trisubstituted position (absorption at 12.0 μ) and along the chain to give *trans*- or *cis*-disubstituted double bonds, or to the methyl groups to give asymmetrically disubstituted double bonds.

* This work has been preliminarily mentioned in a survey article on squalene [1].

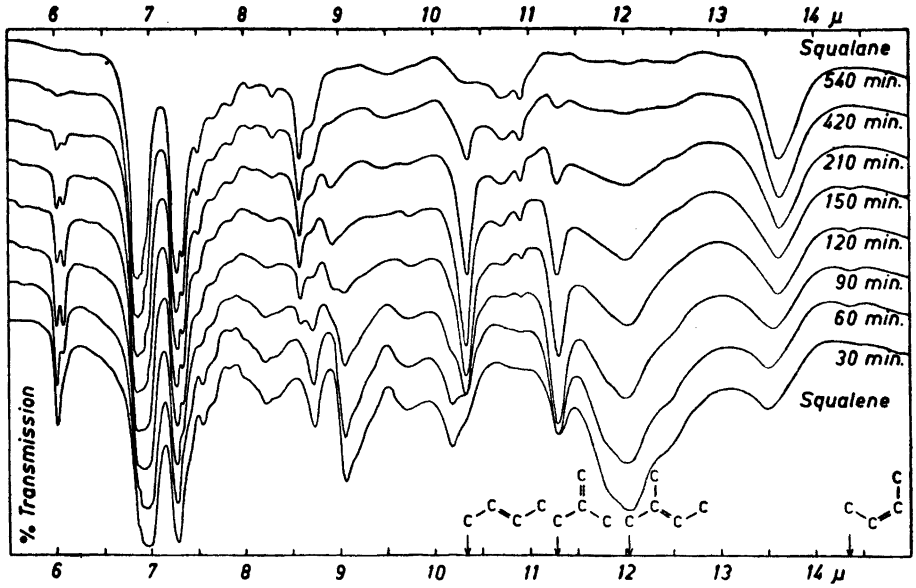

Fig. 1. Infrared spectra taken at intervals during an ordinary hydrogenation of squalene with Raney nickel. Cell thickness: 0.055 mm.

Further systematic studies revealed that this *double bond migration* is quite general and always takes place during the hydrogenation of squalene, irrespective of reaction velocity, temperature, pressure, and of activity and type of catalyst used (nickel, platinum, palladium). Fig. 1 shows the gradual change in the infrared spectrum that occurs during a typical hydrogenation experiment using Raney nickel as a catalyst. The variation in the amount of

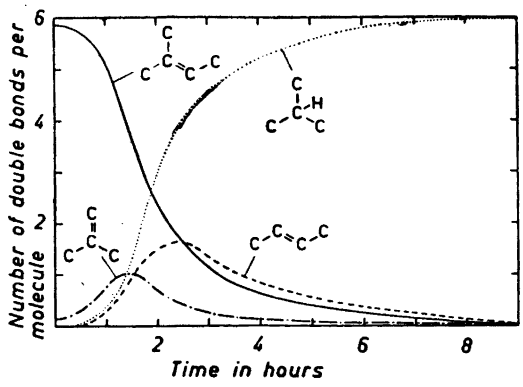

Fig. 2. Approximate amounts of the various types of double bonds during hydrogenation of squalene as estimated from the spectra in Fig. 1. The increase of tertiary hydrogen (absorption at 8.57 μ) has been included for comparison.

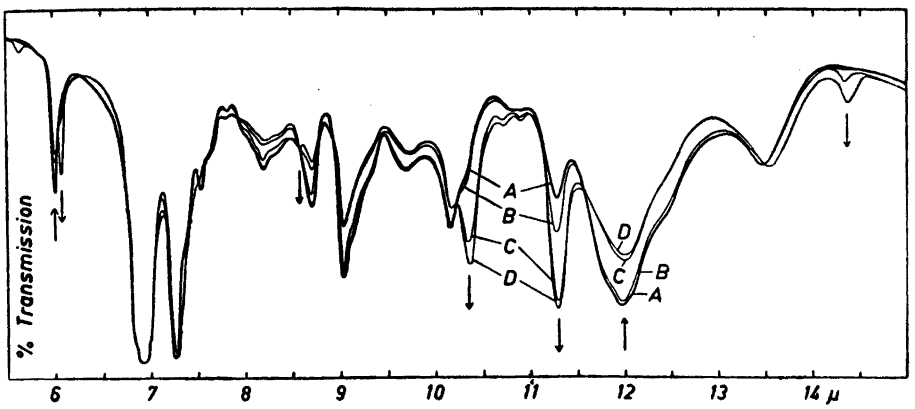

Fig. 3. Changes in the infrared spectrum of squalene during treatment with a Raney nickel catalyst (no hydrogen).
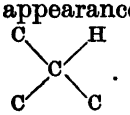
Curve A: heavy line: starting material.
Curve B: after 15 hours.
Curve C: 72 hours.
Curve D: 158 hours. Cell thickness: 0.055 mm.

the various types of double bonds during hydrogenation has been estimated from these spectra using approximate extinction values known from other systems [3], and the results are given graphically in Fig. 2. As can be seen from these curves the *trans*-disubstituted bonds tend to lag behind and are the last ones to become saturated.



It is here interesting to note that Heilbron, Hilditch and Kamm concluded, from the course of the hydrogenation of squalene, that it was strongly selective [4]. From our results, however, it is more likely that the change in reaction velocity is merely a secondary effect, and not due to real differences in hydrogenation velocity of the original double bonds. That these authors have actually had to do with double bond migration is shown by the oxidation products which were obtained from partially hydrogenated squalene (5/6 saturation) [5]. Together with reasonable cleavage products, there were also isolated C_{19}- and C_{24}-ketones and C_6- and C_{11}-acids which cannot be expected from ozonization of the original double bonds. Furthermore, the corresponding products were not obtained by oxidation of squalene itself [6].

Dehydrogenation has also been observed on hydrogenation catalysts. In one case, evolution of hydrogen started immediately after mixing squalene with a Raney nickel catalyst that had been prepared in a somewhat abnormal manner (see Experimental Part). When the gas evolution slowed down, heat, vacuum, and stirring were applied, and the reaction was made to proceed for many days. The colourless oil became yellow, then orange, and eventually red, and a greenish fluorescence developed. The corresponding changes in the infrared spectrum are shown in Fig. 3, and are strikingly similar to the changes observed during hydrogenation.

The red oil was chromatographically separated into fractions that, when examined for ultraviolet absorption, showed the maxima characteristic for two, four, and six conjugated double bonds, the yields decreasing rapidly in the given order. There was no indication of the formation of chromophores consisting of three, five, or seven conjugated bonds.

Considering the structure of squalene, it may be seen that the exclusive formation of chromophores with an even number of double bonds must result if the assumption is made that the dehydrogenation proceeds as a sort of reversed 1,4-addition; that is, the hydrocarbon may be adsorbed on the catalyst *via* the double bond, and then desorbed, while one hydrogen atom on each side of the double bond is retained by the catalyst. This idea receives some support from the observation that chemisorption of ethylene on nickel films is accompanied by dehydrogenation to give an acetylene complex [7]. In squalene acetylene formation is not possible and may be replaced by diene formation.

By comparing the number of double bonds (~10 %) that are in conjugation, as estimated from ultraviolet absorption, and the decrease in trisubstituted double bonds estimated from infrared absorption (~30 %), it is evident that the main effect is still double bond migration. This is confirmed by the appearance of an absorption band at 8.57 μ which is due [3] to the grouping

. Also, no significant increase in iodine number, determined by hydrogenation [8], could be detected, so apparently most of the hydrogen released is used for the saturation of other double bonds.

At first it was found surprising that there was no detectable displacement or doubling of the new infrared absorption bands due to conjugation, like that reported for the simpler conjugated olefins [2,9]. However, recently reported spectra of polyenes with a similar isoprenoid skeleton, show that the bands have in many cases reverted to the isolated position [10-12]. Also, a slight displacement might be obscured by the strong absorption of isolated double bonds.

When *ethyl oleate* was tried, and later *triolein*, to make possible the use of higher temperatures and lower pressure, the main effect was a rapid elaidinization. Whether it was accompanied by migration, could not be decided from the infrared spectra, but migration is known to occur during hydrogenation [13]. An increase in ultraviolet absorption at 232 mμ, due to the diene chromophore, indicated that some dehydrogenation had taken place, in accordance with the results of Forbes and Neville [14]. In the infrared spectrum the stretching frequency underwent a normal displacement from 6.05 μ to 6.22 μ.

It is an open question, which deserves consideration, whether double bond migration on contact with catalysts might actually proceed *via* dehydrogenation and subsequent partial hydrogenation (1,2-addition) of the diene formed. One indication of such a mechanism is the fact that the double bonds of squalene migrate from trisubstituted to disubstituted positions. The general tendency is for double bonds to migrate towards higher substitution. Furthermore, alkali treatment is quite ineffective in conjugating the double bonds of squalene [15].

Unfortunately, it was not possible to reproduce a catalyst with such a high activity as the Raney nickel catalyst we first tried. A systematic search revealed that there is some dehydrogenating effect with all types of hydrogenation catalysts. However, even the least active catalyst in this respect caused extensive double bond migration when used for hydrogenation. This is in accord with earlier findings that the presence of adsorbed hydrogen promotes isomerization [16] and disproportionation [17].

EXPERIMENTAL

Materials. The squalene used for the experiments was prepared from a concentrate obtained by technical distillation of basking-shark liver oil. Ethyl oleate and triolein were prepared by esterification of oleic acid that had been carefully purified through its urea adduct.

For most of the hydrogenations and dehydrogenations a W-6 Raney nickel catalyst [18] was used. In cases where washing with water had to be interrupted, the catalyst could not later be washed free from alkali in the continuous apparatus without too much loss, and a discontinuous process was used. In one particular case several days were needed, and this was the one catalyst that proved to be especially efficient for dehydrogenation.

Hydrogenation experiments. These were usually performed with about 2.5 litres of purified squalene and 50 g Raney nickel in an autoclave fitted with stirrer and cooling coil. With a hydrogen pressure of 90 atm and initial temperature of 155° C, complete saturation was obtained within 3 minutes, whereby the temperature rose to 210° even with full cooling. At 10 atm and 170° C, saturation was obtained in about 3 hours.

Sometimes the hydrogen uptake ceased before complete saturation. This we believe is a poisoning effect due to CO, and can be avoided by repeatedly expelling the gas with fresh hydrogen. When working at atmospheric pressure by bubbling hydrogen through the oil-catalyst mixture, the hydrogenation was always complete.

Dehydrogenation experiments. These were performed on 100 g squalene and 20 g Raney nickel under a vacuum of 1 mm Hg and with vigorous shaking. The temperature was gradually increased to keep the gas evolution constant, and stayed at 140—150° C most of the time. After 160 hours there was little further change in the infrared spectrum (Fig. 3), and the oil was chromatographed from petrol ether on zinc carbonate. Most of the oil passed through the column; it showed a strong U. V. maximum at 238 mμ (diene). The lower part of the column contained a broad colourless, blue-fluorescent zone with U. V. maxima at 334, *317*, and 302 mμ (tetraene). Above this was a narrow yellow, blue-fluorescent zone with U. V. maxima at 397, *379*, and 352 mμ (hexaene), and on the top were several coloured zones without distinct spectral maxima. The eluted polyene fractions were very easily autoxidized.

Ultraviolet spectra were measured in hexane with a Beckman spectrophotometer, Model DU. Infrared spectra were recorded in a Perkin-Elmer instrument, Model 21.

Pinoresinol and its Dimethyl Ether from *Araucaria angustifolia* *

ELISABETH DRYSELIUS and BENGT LINDBERG

Träkemiska avdelningen, Svenska Träforskningsinstitutet and Institutionen för Träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

Pinoresinol and its dimethyl ether have been isolated from the coniferous wood *Araucaria angustifolia*, order *Araucariales*.

The resin obtained by ethanol extraction of "ligno-tubers" (outgrowths from the roots, the sap wood of which had decayed) from *Araucaria angustifolia*, was investigated some years ago at this Institute. In connection with this work a colourless, crystalline substance, m. p. 106—107°, was isolated by chromatography on aluminium oxide but was not further investigated.

We have now reinvestigated the extract and found that the same substance is easily obtained from the neutral fraction. It melted at 107—109° and had a specific rotation of +65° in chloroform. These values agree with those of the lignan derivative pinoresinol dimethylether [1], m. p. 107—108°, $[\alpha]_D$ +65°, and the melting point was undepressed on admixture with that substance. From the phenolic fraction pinoresinol was isolated in a low yield and characterised as its diacetate. Pinoresinol dimethylether has not been found in Nature before but its optical antipode, eudesmine, has been isolated from several *Eucalyptus* species [2]. The phenol, pinoresinol, has been isolated from several pine and spruce species (*Pinus* and *Picea*, order *Pinales*) and the pinoresinol type of lignans is widespread in Nature. (*Cf.* Ref.[3]). It is of interest that these lignans have now been found in another order of *Coniferae*, *Araucariales*.

EXPERIMENTAL

The resin (55 g) was triturated with ether (3 × 100 ml). The ether was distilled off, the residue (9.2 g) dissolved in ethanol (15 ml) and a solution of potassium hydroxide (10 g) in water (4 ml) was added. Yellow crystals slowly deposited and after 24 hours the salt (0.7 g) was collected and recrystallised from ethanol. The potassium salt was acetylated by heating with acetic anhydride (5 ml) for 2 hours on the steam bath, the solution

* Also XXI. contribution on the Constitution of resin phenols and their biogenetic relations. Part XX, this journal 10 (1956) 134.

was poured into ice water and the precipitate collected and crystallised twice from ethanol. Yield, 80 mg. M. p. 162—163°, undepressed on admixture with authentic pinoresinol diacetate.

The alkaline mother liquors were concentrated under reduced pressure, water was added and the solution extracted with ether. The ether solution was washed with water, dried over anhydrous sodium sulphate and concentrated. The residue (0.8 g) partly crystallised on standing and was purified by crystallisations from methanol. Yield, 240 mg. M. p. 107—109° (corr.). $[\alpha]_D^{20}$ + 65° (*c* 2.0 in chloroform). A mixture of the substance and authentic pinoresinol dimethyl ether showed no depression of m. p.

We are indebted to Professor T. Streyffert, Stockholm, for the identification of the wood sample.

The Change in Reduced Diphosphopyridine Nucleotide (DPNH) Fluorescence upon Combination with Liver Alcohol Dehydrogenase (ADH)

P. D. BOYER and HUGO THEORELL

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

Measurement of the intensity of fluorescence at different wave lengths has shown that the fluorescence of DPNH is shifted from a maximum at about 450 millimicrons to about 415 millimicrons and increased in intensity upon combination of the DPNH with liver alcohol dehydrogenase.

Previous communications from this laboratory have described a fluorescence recorder and its application to the study of the combination of riboflavin phosphate with the old yellow enzyme and the velocity of the formation or disappearance of DPNH [1-3]. The measurements had shown that DPNH gave the same intense fluorescence whether it was free in solution or combined with liver alcohol dehydrogenase (ADH). In view of the shift in absorption spectra shown by DPNH when it is bound to ADH [4] together with the known spectral shifts of many dyes upon binding to proteins, it seemed possible that DPNH might show some change in the intensity of fluorescent light emitted at different wavelengths upon binding to ADH. Simple modifications of the apparatus previously used allowed test of this possibility. The results obtained are given in this paper. They show that the binding of DPNH by ADH results in a definite lowering of the wavelength for the fluorescence maximum and an increase in the intensity of the fluorescence.

EXPERIMENTAL

The apparatus previously described [1] was modified by removing the exit filter and placing before the phototube a suitable, covered compartment for insertion of various interference filters in the exit beam.

The ADH was prepared essentially as described by Bonnichsen [5], with final crystallization from dilute phosphate buffer at pH 7. The colorless preparation used was recrystallized twice, and was approximately 70 % pure based on activity tests assuming that

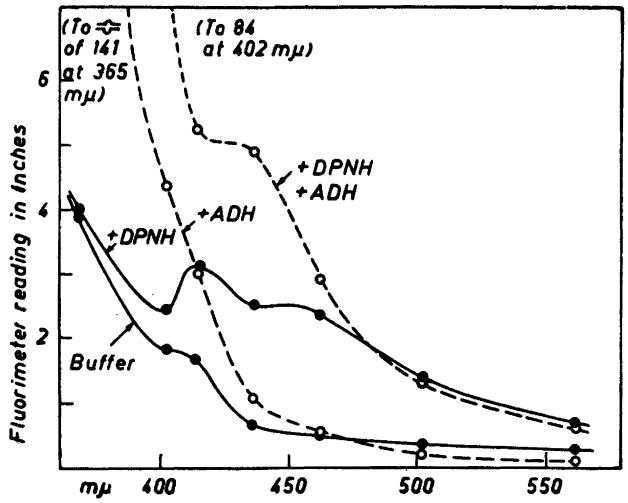

Fig. 1. Observed fluorimeter readings at different wavelengths. [DPNH] at 4 × 10⁻⁶ M [ADH] at approximately 4 × 10⁻⁶ M, in 0.09 M phosphate buffer, pH 7.0, 0.01 M semicarbazide and 0.03 M ethanol. Inlet slit at 7 mm, exist slit at 6 mm, and potentiometer sensitivity at 0.1 volt per 10 inches. (Expt. F-13).

all the material absorbing at 280 mμ was ADH [4]. The DPNH was a preparation of Sigma Chemical Company with a ratio of absorption at 260 mμ to that at 340 mμ of 2.59. It was over 98 % reduced as measured by treatment with ADH and ethanol in the presence of semicarbazide, and the absorption at 340 mμ was nearly completely abolished by treatment with ADH and acetaldehyde.

In the experiments reported herein the DPNH was dissolved in 2.65 ml of 0.1 M phosphate buffer, pH 7.0, 0.3 ml of 0.1 M semicarbazide pH 8, and 0.05 ml of 1:10 ethanol. A small catalytic amount of ADH was added and the solutions allowed to stand for one hour to reduce the final traces of DPN. This insured that any observed shifts in fluorescence in later experiments were not the result of reduction of DPN.

Comparisons of fluorescence were made with the same buffer mixture as that used for dissolving the DPNH, with addition of appropriate small volumes of ADH crystal suspension or solution in approximately 0.01 M phosphate buffer, pH 7.0.

RESULTS AND DISCUSSION

In Fig. 1 are shown the observed fluorimeter readings at different wavelengths for the buffer mixture, buffer + DPNH, and buffer + ADH, and buffer + DPNH and ADH. The amount of ADH was in excess of that of the DPNH as ADH contains two active combining sites per mole [4].

In Fig. 2 are shown the fluorescence increments for free and ADH-bound DPNH.

The data show clearly that the combination of the DPNH with ADH results in a rather pronounced increase in fluorescence intensity together with a decrease in the wave-length for the maximum observed fluorescence. This shift in observed fluorescence likely results from changes in the properties of the

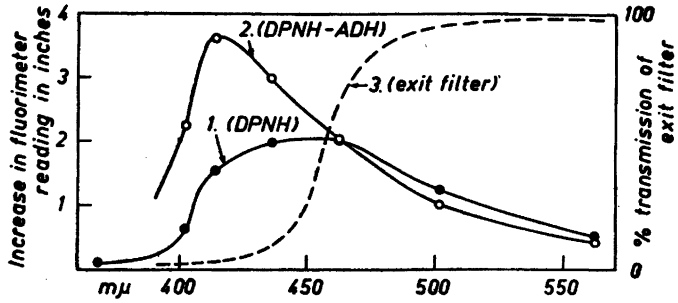

Fig. 2. Increase in fluorimeter reading at different wavelengths for DPNH (1) and DPNH—ADH (2), corrected for the fluorescence of ADH. The points represent the averages of these experimental series under conditions as for Fig. 1. Also shown is the per cent transmission of the exit filter used in the apparatus as previously described (3).

DPNH molecule upon binding, but the possible formation of a new fluorescent grouping by the combination of DPNH with ADH also merits consideration.

Previously it was reported that combination of ADH with DPNH did not result in any change in the measured fluorescence [6]. This observation was entirely valid under the experimental conditions used in those experiments. The exit filter of the original apparatus was chosen primarily for measurement of flavin fluorescence. As noted in Fig. 2, the light transmission by this exit filter was fortuitously of such characteristics as to completely mask the change in the DPNH fluorescence.

The observed fluorescence increase as given in Fig. 1 may be corrected for the known sensitivity of the photomultiplier tube used (RCA IP21) to give a closer approximation of the actual relative intensity of the emitted fluorescence. Such corrections only increased the observed maximum of the DPNH fluorescence by about 5 mμ and did not change that of the ADH-bound DPNH.

Titrations of the approximate combining capacity of ADH for DPNH based on the fluorimetric shift gave values in the range expected from the activity and the absorption at 280 mμ of the ADH. However, further instrumental modifications are necessary for accurate measurement of combining proportions based on fluorescence changes.

Possible instrumental modifications which would facilitate more accurate measurements of the fluorescence shift and use of the shift for stoichiometric and kinetic measurements should be mentioned. A particularly troublesome difficulty was the high fluorescence given by ADH in the lower wavelength region (see Fig. 1). In part this difficulty may be decreased by use of exciting light such that none of the light can pass through the exit filter and thus reach the photocell by reflection. The inlet filter of the present instrument allows some light in the 400—430 mμ region to pass and this results in variations in fluorescence due to the presence of dust particles in the solutions used or small amounts of turbidity in the ADH preparations. Also by the judicious selection of filters or use of suitable monochromators it may be possible to

decrease the fluorescence of the ADH by eliminating the lower wavelengths of light which brings about the fluorescence of ADH.

A definite limitation in the use of filters and monochromators is the decreased sensitivity of the measurements. For example, the data reported in Figs. 1 and 2 were obtained employing the maximum sensitivity of the instrument.

The results with the liver alcohol dehydrogenase suggest further experiments, preferably with improved experimental conditions, to find if the combination of DPNH with other dehydrogenases will result in fluorescence shifts or if the shift is limited to liver alcohol dehydrogenase. Also, other fluorescent coenzymes and substrates may show shifts in fluorescence upon combination with their respective apoenzymes. Measurement of such fluorescent shifts may become a valuable experimental tool.

Mr. B. Hellström and Mr. L. Salomonsson gave valuable assistance in modification of the apparatus. One of us (P.D.B.) is indebted to a grant from the *Guggenheim Foundation* which made this work possible.

Polarographic Investigation of Oximes as an Indication of the Polarographic Behaviour of Hydroxamic Acids

TH. ØSTERUD and MILDA PRYTZ

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

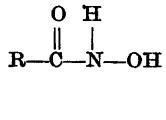
The polarographic behaviour of several oximes has been investigated.

The oximes were readily reduced at the dropping mercury electrode giving well defined, reproducible waves.

The pH of the buffer used as supporting electrolyte influences the position of the half wave by shifting the half wave potential towards more negative values with increasing pH.

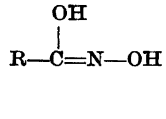
The form of the curves, and studies using the log plot method and the Ilkovic equation for determining the number of electrons consumed by the reaction, show that the reduction waves are irreversible.

The height of the polarographic waves decreases as the pH increases, indicating that neutral and alkaline buffers have insufficient protons for the reduction process.



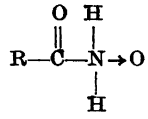
For some oximes double waves have been obtained within certain pH limits. Of the simple aliphatic monoximes only ethanal oxime gave a series of unmistakable double waves but in the case of 2,3-butanedione dioxime a number of polarograms exhibited pronounced double waves.

In the application of the polarographic method to organic problems greater difficulties are encountered than in the inorganic field. Consequently, the practical study of the polarographic reduction of organic compounds is still somewhat incomplete and many problems remain unsolved — among these is the determination of aliphatic esters. Although a direct polarographic reduction of simple saturated aliphatic esters seems out of the question, several attempts have been made. Thus Stackelberg and Stracke [1] investigated different types of organic compounds and found that ethyl acetate caused no rise of the polarographic curve as distinct from ethyl benzoate which gave a reduction wave with the half wave potential $E_{\frac{1}{2}} = -2.14$. Brdicka [2] concluded that ethyl acetoacetate is not reducible at the dropping mercury electrode. The present authors have endeavoured to obtain polarographic reduction with various saturated aliphatic esters by increasing the applied voltage as far as



possible, but have concluded that such esters are not reducible within the potential range of the dropping mercury electrode.

Since direct polarographic reduction of the esters was impracticable an attempt was made to find readily prepared derivatives which would give well-defined reduction waves. The polarographic determination of these compounds might then be used to estimate the corresponding esters.



Primarily we were interested in the hydroxamic acids. The colour reaction between hydroxamic acids and ferric chloride was introduced by Feigl [3] as a spot test, but gives equally good results in macro analysis [4,5]. The hydroxamic acids with the molecular formula R—CO—NHOH are generally assumed to be tautomeric substances to which may be assigned the hydroxyamide structure (I) and the hydroxy-oxime structure (II). They may also be interpreted [6,4] as amide oxides (III).

(I)

(II)

(III)

Both the hydroxy-amide group —CO—NHOH and the oxime group >C=N—OH have been chemically reduced by a variety of methods giving the corresponding amide, resp. amine for instance:

$$R-CO-NHOH + 2H \rightarrow R-CO-NH_2 + H_2O$$
$$R-CH=N-OH + 4H \rightarrow R-CH_2-NH_2 + H_2O$$

The hydroxamic acids, containing these groups, may, accordingly, be expected to undergo similar reductions. Moreover, if a simple oxime can be polarographically reduced yielding a distinct reduction wave it is possible that the hydroxamic acids themselves may also be polarographically reduced.

In order to test the above assumptions we first studied the polarographic behaviour of some simple aliphatic oximes, *viz.* ethanal oxime, $CH_3CH=N-OH$, and propanal oxime, $CH_3CH_2CH=N-OH$. The diketone oxime, 2,3-butanedione dioxime, $H_3C-C(=N-OH)-C(=N-OH)-H_3C$, was also tested. All these compounds gave very well defined polarographic waves. As supporting electrolyte McIlvaine buffers were used within the pH limits 2.2 → 6.0. The reduction of two aromatic oximes, *viz.* the salicylaldehyde oxime, $HO-C_6H_4-CH=N-OH$, and the ketoxime benzoin-1-oxime, $C_6H_5-CHOH-C(=N-OH)-C_6H_5$, was also examined, and both of them were shown to give distinct waves.

The above mentioned measurements were carried out with a mercury pool anode, but some polarograms were also recorded using a saturated calomel electrode as external anode. Since the primary interest is in the aliphatic oximes these were re-examined in the case of ethanal oxime and propanal oxime and the investigation was supplemented by a study of 2-methylpropanal oxime.

EXPERIMENTAL PROCEDURE

A recording polarograph (Radiometer, Copenhagen) was used in these experiments and for some of the records use was made of its counter current compensation arrangement. The usual precautions against oxygen interference were taken, the solutions in the electrolysis vessel being kept under an inert gas, the flow of which was stopped during the recording of the polarogram.

The molar concentrations of the oxime solutions were of the order 10^{-3} to 10^{-4}. The McIlvaine buffer solutions were prepared in the usual way and the oximes were not added until a polarogram showed that the buffer solution was oxygen-free — a suitable amount of the oxime solution in 50 % ethanol was then transferred to the polarographic cell. The pH of the solution was always determined at the start and controlled at the completion of the experiment.

EXPERIMENTAL RESULTS

The records made applying counter current compensation gave very distinct polarographic waves. The aliphatic monoximes, however, showed a tendency towards the formation of maxima at pH values lower than 3; but when the pH values approached 4 the curves became completely regular. Conversely, the formation of maxima in solutions of aromatic oximes only appears at values of pH where the solutions can no longer be characterized as acid.

In addition to the chief wave some of the oximes show a small second wave with $E_{\frac{1}{2}}$ at more negative voltages. This was the case for ethanal oxime within the pH limits 5.4 → 6 but for propanal oxime, and for the two aromatic oximes, salicylaldehyde oxime and benzoin-1-oxime, only one wave was obtained. On the other hand 2,3-butanedione dioxime gives well pronounced second waves within the pH limits 3.7 → 5.4. Polarographic records of these experiments are given in Figs. 1—4.

The polarographic records for which the counter current compensation was omitted did not give such pronounced reduction waves as those already tabulated but they nevertheless confirmed the previous results. Since a saturated calomel electrode was used as external reference anode the half-wave

potentials were less negative in these latter curves than in the earlier ones and the tendency to form maxima was present at higher values of pH. The aliphatic oximes, ethanal oxime, propanal oxime and 2-methyl-propanal oxime, were examined in this way. A curve is given for each of these oximes (Fig. 5).

DISCUSSION

The polarographic records show that the electrolytic reduction of both aliphatic and aromatic oximes readily takes place in buffered solutions using the customary applied e.m.f. s and that very well defined waves are produced. Carruthers [7] obtained the same result when using salicylaldehyde oxime for the indirect determination of Cu, and good oxime curves were obtained by Kolthoff and Langers [8] during amperometric titrations of Ni^{++} with dimethylglyoxime (2,3-butanedione dioxime) and by Langers [9], in the amperometric titration of copper with α-benzoin oxime.

With increasing values of pH our half wave potentials showed a slight but regular shift towards more negative values indicating that the ease of reduction decreases slightly as the supporting electrolyte becomes less acid. Some of the oximes give a second wave as the acidity of the medium grows less.

Thus, as might be expected, the diketone dioxime shows double waves within certain pH limits. At pH = 3.7 the half wave potential values (against mercury anode) are —1.22 V. and —1.57 V. respectively, while at pH = 5.4 the heights of both waves have decreased, the second wave being hardly discernible and disappearing entirely at still higher pH values.

Double waves in connection with the polarographic reduction of organic substances occur frequently, and these are sometimes attributed to tautomerism or isomerism. Since oximes can show tautomerism as well as *cis-trans* isomerism these properties may be instrumental in producing anomalous waves. However, of the simple aliphatic aldehyde oximes, only ethanal oxime gave pronounced double waves and these did not appear until a pH of at least 5.4 was reached. Propanal oxime gave a very indistinct second wave at pH = 5.6.

It is a well known fact that both the buffer system and the pH of the buffer influence the ease of reduction of organic substances. Thus many organic compounds which are weak bases may add protons from acid buffers and give more easily reducible compounds; this seems to be the case for the oximes inasmuch as the half wave potentials increase with increasing pH. It is to be expected that the ease of reduction of the oximes, which have both weakly acid and weakly basic properties, may depend on the pH of the solution, and it is possible that the substituted hydroxylamines exhibit auto-ionization corresponding to the well known autoionization of hydroxylamine itself:

$$NH_2OH + NH_2OH \rightleftharpoons NH_3OH^+ + NHOH^-$$

In acid solution the hydroxylammonium form will predominate and it is not inconceivable that this form is the one most easily reduced since the wave height decreases with increasing pH of the supporting electrolyte, *i. e.* with a decreasing concentration of the hydroxylammonium form.

The fact that protons are used in the reduction of organic compounds also contributes to a more facile reduction in solutions of high hydrogen ion concentration.

For the reduction of organic substances one may write the general equation:

$$R + n\ H^+ + n\ e^- \rightleftharpoons RH_n$$

There are several methods for the determination of n. When the electrode reaction is reversible the log plot method has proved suitable. In our case, however, the form of the curves indicated that the electrolytic reduction of the oximes was an irreversible electrode reaction; calculations of $\frac{V}{\log [i/(i_d - i)]}$ gave exceptionally high values while the slope of the log plot was much greater than that calculated for any probable value of n. Similarly, attempts to estimate n from the Ilkovic equation did not give reliable values with this method although Hartnell and Bricker [10] appear to have been successful in their calculations for methyl-4,5-diketo-2-pentenoate-5-oxime.

The authors are indebted to Bjørn Hansen and K. Maartmann-Moe for the recording of the polarograms.

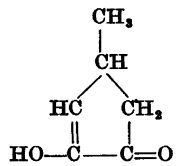
Über isomere Dithiosemicarbazone von Methyl*cyclo*pentenolonen

G. R. GUMMERUS und TERJE ENKVIST

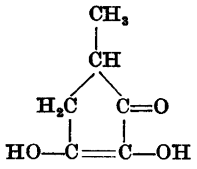


Chemisches Institut der Universität Helsinki, Helsinki, Finland

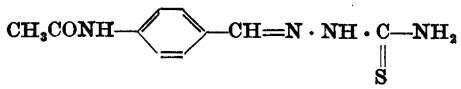
Es wurden je zwei isomere Dithiosemicarbazone der beiden Methyl*cyclo*pentenolone I bzw. II dargestellt. Die Art der Isomerie dieser Dithiosemicarbazone sowie ein Fall der Überführung einer Form in eine andere über die Bleiverbindung (Fig. 2) werden diskutiert. Eines der Isomeren hat starke tuberkulostatische Wirkung, ist aber nicht weniger toxisch als das Conteben.

Die vorliegende Arbeit bezieht sich auf die Darstellung isomerer Thiosemicarbazone von zwei strukturisomeren Methyl*cyclo*pentenolonen, nämlich 1-Methyl-*cyclo*penten-(3)-ol-(3)-on-(2) (Formel I)[1-3] und 1-Methyl-*cyclo*penten-(2)-ol-(3)-on-(4) (Formel II), sowie die Prüfung der tuberkulostatischen Eigenschaften dieser Thiosemicarbazone.

I



II



Die genannten Methyl*cyclo*pentenolone reduzieren wie Aldehyde ammoniakalische Silberlösung und bilden mit Carbonylreagenzien wie Hydroxylamin, Semicarbazid und 2,4-Dinitrophenylhydrazin keine Monoderivate, sondern ausschliesslich Derivate der entsprechenden Diketone. Die Verbindungen I und II sind also in gewisser Hinsicht eigenartige Ketone, die in ihrer Struktur sogar Ähnlichkeit mit solchen physiologisch stark wirksamen Verbindungen wie die Methylreduktinsäure (III) aufweisen, die ein Hauptbestandteil des nordafrikanischen Pfeilgiftes ist[4].

Es wurden die Thiosemicarbazone der Methylcyclopentenolone I und II dargestellt, zunächst in der Hoffnung, hierdurch vielleicht zu tuberkulosta-

tisch wirkenden Verbindungen zu kommen, die weniger toxisch wären als das bekannte Conteben (IV).

III

IV

Diese Hoffnung wurde nicht erfüllt. Die erhaltenen Thiosemicarbazone, die in der Arzneifabrik Medica in Helsinki untersucht wurden, hatten zwar tuberkulostatische Wirkung, und der Effekt eines von ihnen gegen einige Stämme von *Mycobacterium tuberculosis* war sogar etwa ebenso stark wie der des Contebens oder des Isoniazids (Tab. 3), seine Toxizität war jedoch nicht geringer als die des Contebens *. Die Verbindungen erbieten ein stereochemisch interessantes Problem, da sie in mehreren isomeren Formen auftreten. Bisher sind von den Thiosemicarbazonen der Methyl*cyclo*pentenolone I und II je zwei isomere Formen isoliert worden, die sich von einander in Bezug auf Schmelzpunkt, Lage des Absorptionsmaximums in ultraviolettem Licht und vor allem in der Löslichkeit unterscheiden, wie Tabelle 1 näher zeigt.

Tabelle 1.

	I a	I b	II a	II b

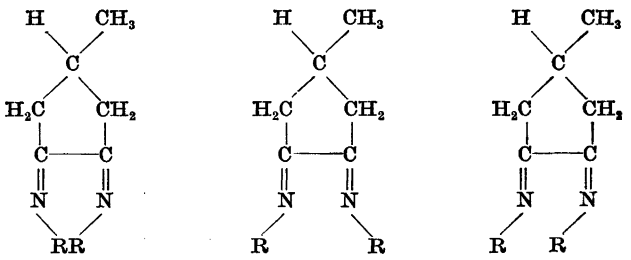
Ia und Ib: Die Thiosemicarbazone der Verbindung I.
IIa und IIb: Die Thiosemicarbazone der Verbindung II.



Die Verhältnisse sind sowohl experimentell als auch theoretisch recht kompliziert und die Untersuchung ist noch nicht abgeschlossen. Der im Folgenden gemachte Versuch, den verschiedenen Isomeren eine gewisse Konfiguration zuzuerteilen ist daher teilweise noch als Arbeitshypothese zu betrachten.

Nach Spinks [6] bilden einige Thiosemicarbazone von substituierten Benzaldehyden in Lösungen Strukturisomere, wenn die Lösungen mit ultraviolettem Licht bestrahlt werden:

* Toxizitätsbestimmungen von Dr. G. Östling.

Die von uns hergestellten Isomeren konnten durch Bestrahlung mit ultraviolettem Licht nicht ineinander übergeführt werden (Fig. 3). Man hat darum an andere Arten der Isomerie zu denken. Die vorliegenden Dithiosemicarbazone sind Derivate von Diketonen und daher besteht hier Analogie mit den Verhältnissen bei den bekannten geometrischen Isomeren des Benzildioxims. Danach wären z. B. von der Verbindung II die folgenden Isomeren in Betracht zu ziehen: eine Synform (V), eine Antiform (VI) und eine Amphiform (VII).

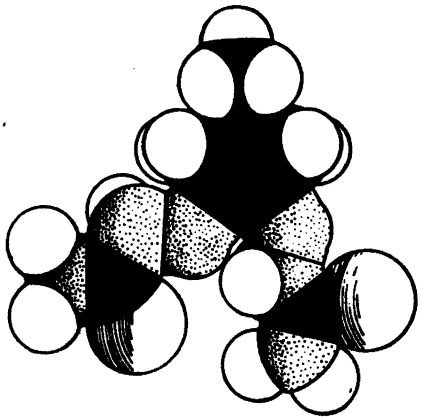
V VI VII

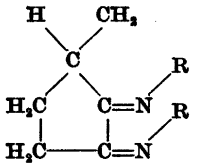
Ein Studium an Stuartschen Molekülmodellen (Fig. 1) zeigt jedoch, dass die Synform hier nicht möglich ist, weil die Atome in einer solchen Form nicht Raum genug finden. Es sind nur die Anti- und die Amphiform denkbar.

Bei Zusatz einer methylalkoholischen Bleiacetat-Lösung zu Lösungen der isomeren Dithiosemicarbazone des Methyl*cyclo*pentenolons II in organischen Lösungsmitteln wird eine rote, kristallinische Bleiverbindung gefällt, die unter Zersetzung bei 245—246° schmilzt. Sie ist in Wasser löslich und zeigt im Ultraviolett ein Absorptionsmaximum bei denselben Wellenlängen (340 mμ) wie die höherschmelzende Form des Dithiosemicarbazons. Beide isomere Formen scheinen dieselbe Bleiverbindung zu liefern und zwar so, dass die höherschmelzende Form momentan die Bleiverbindung bildet, während die niedrigschmelzende Form erst nach einiger Zeit ausfällt. Bei der Zersetzung des Bleiniederschlags mit Schwefelwasserstoff wird die höherschmelzende Form erhalten. Dieses Verhalten könnte vorläufig mit folgendem Schema erklärt werden (Fig. 2):

Die Bleiverbindung wäre also ein Komplexsalz der Antiform, und die Amphiform liesse sich über dieses in die Antiform umlagern.

Von dem Thiosemicarbazon des Methyl*cyclo*pentenolons I sollten zwei Amphiformen möglich sein (VIII und IX). Sie sind noch nicht isoliert worden,





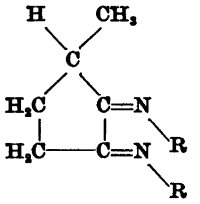


Fig. 1. Modell der Amphiform VII.

aber das Verhalten der bei der Reaktion entstehenden, niedrig schmelzenden Substanz deutet die Möglichkeit an, dass diese noch in zwei Formen aufgespaltet werden könnte.

VIII

IX

Es ist vielleicht von gewissem, allgemeinem Interesse, dass die Isomerenpräparate der Thiosemicarbazone Unterschiede in der tuberkulostatischen Wirkung zu haben scheinen (Tabelle 3). Ein physiologischer Unterschied geometrisch isomerer Formen von Thiosemicarbazonen ist unseren Wissens bisher noch nicht bekannt, gibt aber Anlass zu fortgesetzten Studien.

VERSUCHSTEIL

Thiosemicarbazone der Verbindung I

0,448 g 1-Methyl-*cyclo*penten-(3)-ol-(3)-on-(2) (aus Blasenteer nach Hellström isoliert [5]) wurden in 20 ml 50 %igem Äthylalkohol gelöst und mit einer Lösung von 0,730 g Thiosemicarbazid in 40 ml Wasser versetzt. Nach einstündigem Sieden auf dem Wasserbad war die anfangs farblose Lösung schwach gelblich und nach 7 Stunden stark gelb. Es wurde in allem 20 Stunden lang erhitzt. Nach Abkühlen der Lösung wurden die gebildeten, gelben Kristalle abfiltriert. Schmp. ca. 220° (Zers). Die Kristalle lösten sich in Dioxan und Eisessig völlig, in heissem Wasser und Alkohol teilweise, waren aber unlöslich in Benzol, Aceton und Chloroform. Beim Behandeln der Kristalle mit viel kochendem Wasser löste sich ein Teil. Die ungelöst verbliebenen, gelben Kristalle wurden sogleich aus der Lösung abfiltriert und mit viel heissem Wasser gewaschen. Schmp. 225—

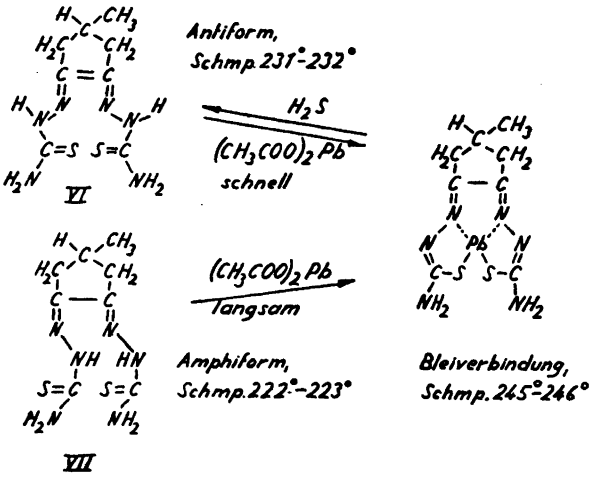

Fig. 2.

227° (Zers.) (Substanz Ia). Versuche, die Substanz umzukristallisieren, waren vergeblich. Über Löslichkeit siehe Tab. 1. — Aus dem warmen Filtrat begannen bald bräunliche Kristalle auszufallen (Substanz Ib), die abfiltriert wurden. Das Filtrat war jetzt farblos. Schmp. 237—238° (Zers.), nach Umkristallisation aus Äthylalkohol 242—244° (Zers.). Über Löslichkeit siehe Tab. 1. — Der Mischschmelzpunkt der Substanzen Ia und Ib betrug ca. 220° (Zers.), zeigte also Depression. Analysen, siehe Tab. 2.

Short Communications

Note on the Preparation of Phenyl Thiohydantoins from Glutamine, S-Carboxymethyl Cysteine and Cysteic Acid

PEHR EDMAN and KONRAD LAUBER

Department of Physiological Chemistry, University of Lund, Lund, Sweden

In an earlier paper [1] the preparation of the phenyl thiohydantoins (PTH) from most of the natural amino acids has been described. Some of these amino acids did not yield the expected thiohydantoins owing to decomposition during the preparation, which involved prolonged refluxing of the phenyl thiocarbamyl (PTC) amino acids in N hydrochloric acid. Under these conditions PTC-cystine and PTC-cysteine gave off hydrogen sulfide and formed undefined products. The PTC derivatives of the β-hydroxyamino acid lost water and became α-β-unsaturated which at least for serine led to polymerization. However, since then Ingram [2] has described a satisfactory synthesis of PTH-serine and PTH-threonine using milder conditions for the cyclization. It has now been found that two derivatives of cysteine, cysteic acid and S-carboxymethyl cysteine, form normal thiohydantoins of sufficient stability for identification purposes in the amino acid sequence determination [3]. By appropriate treatment of the peptide under investigation it should be possible to form these derivatives [4,5]. The preparation of PTH-glutamine is also described *.

To avoid side reactions ring closure of the PTC-amino acids was brought about under mildest possible conditions in respect to concentration of acid and temperature. It was then helpful to follow the ring closure by measuring the ultraviolet absorption (in ethanol) of a sample, since the PTC-amino acids have two maxima at approx. 248 mμ and 268 mμ whereas the PTH-amino acids show only one maximum at approx. 268 mμ. At pH 1—2 and room temperature the ring closure was generally completed in less than 48 hours.

Experimental. Elementary analyses except micro-Kjeldahl were made at the Analytical Laboratory, Department of Chemistry, University of Lund and at the Chemical Laboratory, University of Copenhagen.

Melting points were determined on a heating block (Fisher-John) and are uncorrected.

Paper chromatography was carried out as described by Sjöquist [6]. All R_F-values are referred to PTH-glycine, R_F for PTH-X / R_F for PTH-glycine = q.

3-Phenyl-2-thio-5-hydantoinpropionamide. A suspension of L-glutamine (1.46 g) in pyridine-water (3:2, 30 ml) was brought to pH 8.6 by the addition of N sodium hydroxide. Under stirring phenyl *iso*thiocyanate (5 ml) was added and pH was kept at 8.6 by the continuous addition of N sodium hydroxide. After two hours the reaction mixture was extracted three times with 1 vol. of benzene, which was then discarded. The aqueous solution was brought to pH 1 by the addition of 4 N hydrochloric acid and left overnight at room temperature. The crystals (1.9 g) were filtered off and crystallized and recrystallized from boiling glacial acetic acid. M. p. 201—211° (decomp.).

Paper chromatography: Solvent A, q=0.23; solvent B, q = 0.08; solvent C, q = 0.82.

Analyses. N (Kjeldahl) 15.87; S (Zimmermann [7]) 12.2. $C_{12}H_{13}O_2N_3S$ requires: N 15.95; S 12.2.

5-(Carboxymethylmercaptomethyl)-3-phenyl-2-thiohydantoin. L-β-(Carboxymethylmercapto)-alanine (S-carboxymethyl cysteine) was prepared essentially as described by Dickens [5]. This preparation (1.79 g) was dissolved in

* Recently Ramachandran *et al.*[9] have reported the preparation of this compound.

pyridine-water (3:2, 30 ml) and pH was adjusted to 8.4 by the addition of N sodium hydroxide. Phenyl *iso*thiocyanate (4 ml) was added with stirring and pH was kept at 8.4 by the addition of N sodium hydroxide. After seven hours the reaction mixture was extracted three times with equal volumes of benzene, which were then discarded. The aqueous phase was brought to pH 2.7 and exhaustively extracted with ethyl acetate (90 ml). The extracts were combined and the ethyl acetate was evaporated *in vacuo* (temperature not above 30° C). To the oily residue water (20 ml) was added and pH was adjusted to 8 by the addition of N sodium hydroxide. A small precipitate was removed and the filtrate then extracted with ethyl acetate (30 ml), which was discarded. The solution was acidified to pH 2 by the addition of 4 N hydrochloric acid which resulted in an oily precipitate. After 24 hours the oil had crystallized (1.8 g). Recrystallization twice from ethanol-petroleum ether. M. p. 164°.

Paper chromatography: Solvent A, decomposition with the appearance of several spots; solvent B, $q = 0.23$; solvent C, $q = 0.98$.

Analyses. N (Dumas) 9.30; S (Cuck and Grim [8]) 21.3. $C_{12}H_{12}O_3N_2S_2$ requires: N 9.45; S 21.6.

5 - (Potassiummethylsulfonate) - 3 - phenyl - 2-thiohydantoin. A solution of L-cysteic acid (1.7 g) in pyridine-water (3:2, 30 ml) was brought to pH 8.6 by the addition of N potassium hydroxide. Under stirring phenyl *iso*thiocyanate (4 ml) was added and pH was then kept at 8.6 by the continuous addition of N potassium hydroxide. After three hours the reaction mixture was extracted three times with equal volumes of benzene, which were then discarded. The aqueous phase was brought to pH 1 by the addition of 4 N hydrochloric acid and the solution was left overnight at room temperature. The solution was then brought to pH 4.2 with N potassium hydroxide and concentrated *in vacuo* to dryness. The residue was dried in a desiccator over phosphorus pentoxide and the dry product extracted with aqueous acetone which left the potassium chloride undissolved. The acetone solution was concentrated *in vacuo* to a viscous solution. On addition of acetone crystallization set in and was completed in the ice box (2.2 g). The product was taken up in a small volume of water and pH adjusted to 5 with potassium hydroxide. On the addition of abs. ethanol the preparation crystallized in fine needles. Recrystallization twice from water-ethanol. The product was highly hygroscopic and was dried *in vacuo* over phosphorus pentoxide at 110°. M. p. 193—7° (decomp.).

Paper chromatography: Solvent A, $q = 0$; solvent B, $q = 0$; solvent C, $q = 0.11$.

Analyses: N (Dumas) 8.62; S (Cuck and Grim [8]) 19.4. $C_{10}H_9O_4N_2S_2K$ requires: N 8.64; S 19.8.

This investigation has been supported by grants to one of us (P.E.) from Eli Lilly and Company and from *Statens medicinska forskningsråd*, which is gratefully acknowledged.

Note on the Reaction between Linear Polyamides and Ethylene Carbonate

SVEN SÖNNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

In connection with an investigation on the interaction between polyamides and cyclic esters the observation was made, contrary to earlier statements elsewhere [1] that ethylene carbonate may act, under particular conditions, as a hydroxyethylating agent upon homopolymers of ε-aminocaproic acid or hexamethylenediammonium adipate. The reaction is observable just in the temperature range, where the polymers are dissolved by the cyclic ester (approximately 180—185° C). At still higher temperatures (200—220° C) *water soluble* derivatives are obtained by heating the polymer in a tenfold excess of ethylene carbonate for 4 hours. An inert gas, such as dry carbon dioxide, should be present to prevent side reactions (oxidation, depolymerization).

In a system, containing an unstabilized polymer, no simple kinetic scheme can be

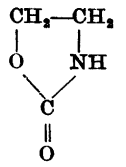
Note on the Reaction between Linear Polyamides and Ethylene Carbonate

SVEN SÖNNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

In connection with an investigation on the interaction between polyamides and cyclic esters the observation was made, contrary to earlier statements elsewhere [1] that ethylene carbonate may act, under particular conditions, as a hydroxyethylating agent upon homopolymers of ε-aminocaproic acid or hexamethylenediammonium adipate. The reaction is observable just in the temperature range, where the polymers are dissolved by the cyclic ester (approximately 180—185° C). At still higher temperatures (200—220° C) *water soluble* derivatives are obtained by heating the polymer in a tenfold excess of ethylene carbonate for 4 hours. An inert gas, such as dry carbon dioxide, should be present to prevent side reactions (oxidation, depolymerization).

In a system, containing an unstabilized polymer, no simple kinetic scheme can be



suggested *a priori*. At least the following five steps must be considered:

1. Decomposition of ethylene carbonate into ethylene oxide and carbon dioxide.
2. Etherification of the polyamide at unstabilized end groups.
3. Formation of graft polymers by etherification at the amide links.
4. Ester interchange between polymer and solvent. (The incorporation of small amounts of carbonate ester unit is already reported from an analysis of infrared spectra [1]).
5. The formation of pure polyethylene oxide (linear polyether) by thermal or ionic polymerization in the anhydrous system.

Preliminary studies have been carried out on the water soluble compounds obtained from nylon 6 and nylon 66 polymer. Solubility is not limited to pure water, in fact it seems clear that when once water solubility is reached, a similar solubility in organic solvents such as methanol, acetone, and several aliphatic esters is also obtained, which is in contrast to the insolubility of the parent polymers. Fractional precipitation with a nonsolvent has thus not been feasible up to now. The only successful method for the separation of polymer has been the addition of strong sodium hydroxide solution until the polymer appears as a *coacervate*, which can be collected as an upper layer. Since homopolymers of ethylene oxide of the moderate molecular weight possible in a synthesis carried out at the actual high temperature do not show this behaviour, it is believed that the coacervate (in the most complex case) represents a mixture of graft polymer and block copolymer (steps 2 and 3 in the scheme above). The remaining part of the sodium hydroxide is easily removed from the polymer phase by separating the two layers in a small funnel, adding water and deionising with a hydrogen saturated ion exchanger.

Water soluble ethylene oxide "adducts" from fatty alcohols, fatty amines and alkyl phenols are known to give well defined precipitates with ferrocyanic acid [2]. The actual derivatives from nylon 6 and nylon 66 show the same behaviour. If the purified aqueous solution of the coacervate, mentioned above, is acidified with hydrochloric acid, a slight yellow precipitate is immediately obtained on adding potassium ferrocyanide. Nylons of low molecular weight give a highly dispersed precipitate, passing most filter papers. At higher molecular weight (*e. g.* plastic grades of polymer) the precipitate gradually coalesces to a yellow mass of pronounced rubbery character. A modified Zeisel analysis (according to Morgan [3]) indicates large, but varying amounts of accessible hydroxyethyl groups in the polymers, and it remains to be seen if a more detailed picture of the distribution of the etherifying agent can be obtained.

In this connection it should be mentioned that oxazolidone (I) dissolves polyamides above 80° C. On heating to 170° C it slowly decomposes into carbon dioxide and ethylene imine [4], thus representing a potential source for the analogous grafting of the polyamide with ethylene imine monomer. In this case, however, solubility in water is never reached, but water soluble polyethylene imine can be isolated by condensing the escaping gases on a "cold finger". The carbon dioxide apparently serves as a gaseous phase activator, similar to its action in aqueous systems [5].

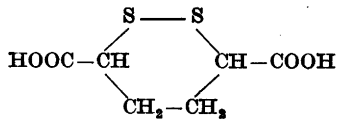
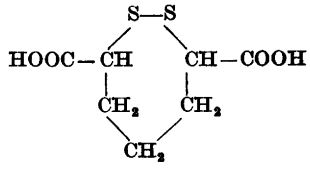
Polarographic Studies on Cyclic Disulphides

BENGT NYGÅRD and
LENNART SCHOTTE



Chemical Institute, University of Uppsala
Uppsala, Sweden

In the course of recent work by one of the authors (L.S.) on cyclic disulphides related mainly to glutaric [1,2] and pimelic [3,4] acid it seemed to be of interest to examine the polarographic behaviour of analogous compounds, especially as very little attention has hitherto been devoted to this subject in polarography. It has recently been shown that the disulphide linkage in 6,8-thioctic acid (α-lipoic acid) is reducible at the dropping mercury electrode [5]. However, no conclusions were drawn about the ring system.



The α,α′-disubstituted dicarboxylic acids, *racem*-1,2-dithiolane-3,5-dicarboxylic acid (I), 1,2-dithiane-3,6-dicarboxylic acid (II) and 1,2-dithiepane-3,7-dicarboxylic acid (III) have been investigated together with the related dimercaptans. For (II) and (III) both the diastereomers were examined. The substances have all been studied in standard buffer solutions and at a concentration of 1.00×10^{-3} M.

(I)

(II)

(III)

Racem-(I) gives in acid solution a very good wave, reversible in character, with a half-wave potential of −0.330 V *vs.* the sat. calomel electrode (S.C.E.) at pH = 2.2. In neutral medium, on the other hand, the wave is quite deformed and at higher pH no waves are found.

Racem- and *meso*-(II) give polarographic waves only in acid solution. The waves are rather drawn out indicating irreversible electroreduction. The half-wave potential value is −0.75 V.

Analogous behaviour, as compared with (II) exists for *racem*- and *meso*-(III). The corresponding value for the half-wave potentials is −0.92 V.

The wave height and the relation log $[i/(i_d - i)]$ *vs.* the applied potential E for *racem*-(I) suggest a two electron reduction. Analogous to the polarographic behaviour of a number of aliphatic disulphides (cystine, glutathione) the wave obtained seems to be due to the reduction of Hg-complexes, which are formed on the drop at the rupture of the S−S linkage. The pronounced irreversible appearance of (II) and (III) in acid solution indicates that the primary reaction — the cleavage of the S−S group — in these cases does not proceed so readily as with *racem*-(I). A greater ring stability for the six- and seven-membered cyclic disulphides as compared with the 1,2-dithiolane derivative is apparent. This is in agreement with data from spectrochemical studies [6-8] and from the characteristics of the unsubstituted heterocycles [9].

An interesting analogy supporting our interpretation can be found *i. a.* in the behaviour of dithio- and diseleno-diglycolic acid. Leussing and Kolthoff [10] have shown that dithio-diglycolic acid gives only irreversible polarographic waves. On the other hand, one of us (B.N.) [11] has found that the corresponding diselenide is characterized by reversible effects over the whole pH range. Thus the radical cleavage necessary for the formation of electroreducible Hg-complexes on the mercury drop is more easily realized for the selenium compound. Fredga [12] has already established a striking difference between the aliphatic S−S and Se−Se groups in reactivity against Hg.

The α,α′-dimercapto dicarboxylic acids related to (I), (II) and (III) have been found to give polarographic effects, the qualitative nature of which resemble each other. Thus a double wave is obtained in acid and neutral media; the smaller one remains in basic solution. Its half-wave potentials vary with pH.

It is obvious from the foregoing that the polarographic effects of the 1,2-dithiolane derivatives may be of special interest. For a closer investigation of this disulphide system a number of 4-substituted com-

pounds [7] (originally prepared by Backer and co-workers) were also examined. They all gave good polarographic waves over the whole pH range indicating a two electron reduction. Especially in acid solution the agreement between their half-wave potentials and that of *racem*-(I) is excellent. — In this connection the polarographic method has been used to further emphasize the improbability of coordinated sulphur-sulphur bonds [8].

This general polarographic character of the five-membered cyclic disulphide has also been found to include that of 6,8-thioctic acid.

Experimental. The investigation was performed at 25° C with a Leybold Polarograph model 54. In order to minimize the influence of the cathodic mercury on the solution a special type of polarographic cell according to Schwabe and Berg was used.

In connection with a current polarographic investigation of a number of aliphatic diseleno dicarboxylic acids a closer examination of the above subject will be undertaken.

The authors are indebted to Professor Mark von Stackelberg for valuable discussions and for making it possible for one of us (B.N.) to carry out this preliminary study at the Institute of Physical Chemistry, University of Bonn, Germany. — Thanks are also due to Professor Arne Fredga for kind interest in our work and for placing certain materials at our disposal. The sample of 6,8-thioctic acid was kindly supplied by Docent Stig Sunner.

Carotene Isomers in some Red Algae

BJØRN LARSEN and ARNE HAUG

Norwegian Institute of Seaweed Research, Trondheim, Norway

According to previous investigations, β-carotene is the only carotene isomer present in most red algae (Table 1). An investigation of the unsaponifiable matter of *Rhodymenia palmata*, carried out at the Institute of Organic Chemistry at the Norwegian Technical University in Trondheim, seemed to indicate the presence of both α- and β-carotene in this alga. As this was contrary to previous observations of Heilbron *et al.* [1] (Table 1), it was decided to carry out a further investigation of the carotene isomers in red algae.

Samples of the more common red algae were collected in the Trondheimsfjord during the months of May to August 1955. The samples were blanched with steam at 100° C as soon as possible after harvesting and dried at approximately 35° C overnight. This proved to be the best procedure, since quantitative extraction of the carotene from fresh material was difficult to accomplish and no carotene breakdown was observed during the steam-treatment and drying [2]. After having been ground to pass a 60 mesh sieve, 1 g of the sample was moistened with 5 ml of water, and extracted overnight with 25 ml of acetone. The extraction was repeated until the extract was colourless. The carotene was extracted from the acetone solution, after addition of more water, with light petroleum, and the light petroleum extract concentrated to a small volume on a water bath. The carotenes were separated from chlorophylls and other carotenoids by chromatography on magnesium oxide — Hyflo Super-Cel (1:3). The carotene zones were washed through the column with light petroleum containing 0.5 % acetone, the eluate made up to 50 ml and the carotene concentration determined by reading the optical density at 436 mμ in a Beckman spectrophotometer.

In the case of *Rhodymenia palmata*, two zones were observed on the column, apart from the stationary chlorophyll and carotenoid zones: A fast moving yellow zone, and a slower moving brick-red zone. Complete separation of the two pigments was

pounds [7] (originally prepared by Backer and co-workers) were also examined. They all gave good polarographic waves over the whole pH range indicating a two electron reduction. Especially in acid solution the agreement between their half-wave potentials and that of *racem*-(I) is excellent. — In this connection the polarographic method has been used to further emphasize the improbability of coordinated sulphur-sulphur bonds [8].

This general polarographic character of the five-membered cyclic disulphide has also been found to include that of 6,8-thioctic acid.

Experimental. The investigation was performed at 25° C with a Leybold Polarograph model 54. In order to minimize the influence of the cathodic mercury on the solution a special type of polarographic cell according to Schwabe and Berg was used.

In connection with a current polarographic investigation of a number of aliphatic diseleno dicarboxylic acids a closer examination of the above subject will be undertaken.

The authors are indebted to Professor Mark von Stackelberg for valuable discussions and for making it possible for one of us (B.N.) to carry out this preliminary study at the Institute of Physical Chemistry, University of Bonn, Germany. — Thanks are also due to Professor Arne Fredga for kind interest in our work and for placing certain materials at our disposal. The sample of 6,8-thioctic acid was kindly supplied by Docent Stig Sunner.

Grants from the *Swedish Natural Science Research Council* are gratefully acknowledged.

obtained by chromatography on calcium hydroxide from light petroleum, and developing with the solvent mentioned above. The two zones were cut out of the column and the pigments extracted with acetone. After filtering off the adsorbent, the acetone was removed by evaporation *in vacuo* and the pigments redissolved in carbon disulphide (spectroscopic grade). The absorption spectra were read in a Beckman spectrophotometer. The pigment from the yellow zone showed an absorption pattern in carbon disulphide identical with that of α-carotene, with the peaks at 509 and 477 mμ (Fig. 1). Further identification was carried out by means of carotene isolated from carrots. This well known mixture of α- and β-carotene showed exactly the same picture as that from *Rhodymenia* when chromatographed on the same adsorbent. Both isomers were isolated from carrots and a "misch"-chromatogram with the corresponding zones from *Rhodymenia* was run on calcium hydroxide. Both mixtures behaved as homogeneous substances. In order to rule out the possibility of the first zone being a *cis-trans* isomer of the second, the pigments from the yellow zone of *Rhodymenia* and carrots were isomerised by boiling under reflux in light petroleum. Chromatography of the isomerised pigments showed exactly the same zones in

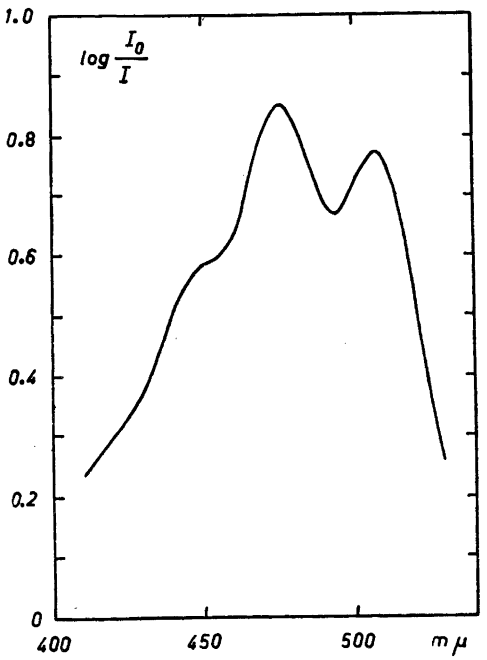

Fig. 1. Absorption spectrum of the pigment from the yellow zone.

both cases, and no brick-red zone could be observed above the yellow one.

Since Carter *et al.*[3] and Kylin [5] state that *Ceramium rubrum* contains both α- and β-carotene, we also carried out a comparison between this alga and *Rhodymenia*. Chromatography of the light petroleum extract on magnesium oxide and calcium hydroxide showed exactly the same picture for both species, and the isolated pigments were indistinguishable with respect to their absorption spectra in carbon disulphide. According to these experiments, therefore, we find it safe to conclude that *Rhodymenia palmata* contains both α- and β-carotene.

Several other species of *Rhodophyceae* were investigated along the same lines. The results are given in Table 1. The results from earlier investigations are shown in the same table. As the table shows, 11 of the 16 investigated species were found to contain α-carotene.

The table also shows the total amounts of carotene (α + β) given as mg per 1 000 g dry matter. The amounts were found to depend strongly on the season and the treatment of the samples. The figures given here should, however, give a fairly correct picture of the variation between the species during the summer months.

The relative amounts of α- and β-carotene were determined in 6 species. The results are given in Table 2 as the amount of α-carotene divided by the amount of β-carotene. The amounts are calculated from the optical densities in carbon disulphide and the molar extinction of α- and β-carotene in the same solvent. As the table shows, the amount of α-carotene in the investigated species was of the same order of magnitude as that of β. *Delesseria sanguinea* was found to be particularly rich in α-carotene. Contrary to the total amounts of carotene, the relative amounts seemed to be approximately constant, independent of the season (samples from the winter months were not investigated) and the treatment of the samples.

Phycodrys sinuosa differed markedly from the other investigated species, as in this alga we were not able to show the presence of β-carotene. Samples from different localities and collected at different seasons gave the same result. We are thus forced to conclude that *Phycodrys sinuosa* either has a specific mechanism for a rapid destruction of β-carotene, or that the amount of β-carotene, if this is present at all, was very small compared with α-carotene. Whatever the explanation may be, this species seems to deserve a further investigation.

Carotene Breakdown in *Rhodymenia palmata* (L.) Grev.

ARNE HAUG and BJØRN LARSEN

Norwegian Institute of Seaweed Research, Trondheim, Norway

During an investigation of the carotene breakdown in some Norwegian seaweeds and seaweed meals an extraordinary rapid loss of carotene was observed in the red alga *Rhodymenia palmata*. This alga, therefore, seemed to be a convenient object for further studies of the breakdown mechanism. The carotene present in *Rhodymenia palmata* was found to consist of about equal amounts of the α- and β-isomers [1].

both cases, and no brick-red zone could be observed above the yellow one.

Since Carter *et al.*[3] and Kylin [5] state that *Ceramium rubrum* contains both α- and β-carotene, we also carried out a comparison between this alga and *Rhodymenia*. Chromatography of the light petroleum extract on magnesium oxide and calcium hydroxide showed exactly the same picture for both species, and the isolated pigments were indistinguishable with respect to their absorption spectra in carbon disulphide. According to these experiments, therefore, we find it safe to conclude that *Rhodymenia palmata* contains both α- and β-carotene.

Several other species of *Rhodophyceae* were investigated along the same lines. The results are given in Table 1. The results from earlier investigations are shown in the same table. As the table shows, 11 of the 16 investigated species were found to contain α-carotene.

The table also shows the total amounts of carotene (α + β) given as mg per 1 000 g dry matter. The amounts were found to depend strongly on the season and the treatment of the samples. The figures given here should, however, give a fairly correct picture of the variation between the species during the summer months.

The relative amounts of α- and β-carotene were determined in 6 species. The results are given in Table 2 as the amount of α-carotene divided by the amount of β-carotene. The amounts are calculated from the optical densities in carbon disulphide and the molar extinction of α- and β-carotene in the same solvent. As the table shows, the amount of α-carotene in the investigated species was of the same order of magnitude as that of β. *Delesseria sanguinea* was found to be particularly rich in α-carotene. Contrary to the total amounts of carotene, the relative amounts seemed to be approximately constant, independent of the season (samples from the winter months were not investigated) and the treatment of the samples.

Phycodrys sinuosa differed markedly from the other investigated species, as in this alga we were not able to show the presence of β-carotene. Samples from different localities and collected at different seasons gave the same result. We are thus forced to conclude that *Phycodrys sinuosa* either has a specific mechanism for a rapid destruction of β-carotene, or that the amount of β-carotene, if this is present at all, was very small compared with α-carotene. Whatever the explanation may be, this species seems to deserve a further investigation.

Carotene Breakdown in *Rhodymenia palmata* (L.) Grev.

ARNE HAUG and BJØRN LARSEN

Norwegian Institute of Seaweed Research, Trondheim, Norway

During an investigation of the carotene breakdown in some Norwegian seaweeds and seaweed meals an extraordinary rapid loss of carotene was observed in the red alga *Rhodymenia palmata*. This alga, therefore, seemed to be a convenient object for further studies of the breakdown mechanism. The carotene present in *Rhodymenia palmata* was found to consist of about equal amounts of the α- and β-isomers [1].

Table 1.

Drying conditions		Carotene content as per cent of the content of the fresh samples		
		23/2	23/3	25/4
	Fresh	100(197)	100(217)	100(259)
Indoors	1 week, dark	74		
	2 days, diffuse light		79	
	1 week, » »	65		73
	2 days, u.v.-light		79	
Open air	2 days, protected against rain		64	
	3 » » » »			57
	3 » subjected to rain			15
	1 week, » » »	0		
	2 hours at 80° C			86
	Steam blanched 5 min., dried, milled			109

The analytical procedure used for the quantitative determination of carotene has been described in a previous paper [1]. Estimation of the carotene content in fresh samples needed special attention. The quantitative extraction of carotene from fresh *Rhodymenia palmata* was found to be difficult to accomplish. The highest values for fresh algae were obtained when the material was ground in a mortar with quartz sand and solid carbon dioxide, followed by immediate extraction with acetone. However, as will be shown below, still higher values for the initial carotene content in the samples, and which we think are more reliable, were obtained when the samples were steam blanched and dried overnight.

In order to determine the influence of light, heat and rain on the breakdown rate, three series of simple drying experiments were carried out. The results are shown in Table 1. The figures in brackets refer to the carotene content in fresh samples given as mg carotene per 1 000 g dry matter. The amount of carotene in the samples increased from February to April due to seasonal variation.

It will be seen that the breakdown rate was approximately the same for samples dried in darkness, in diffuse light or in ultraviolet light, while samples dried in open air, subjected to direct sunlight, showed a more rapid breakdown. The results seem to indicate that the reaction is slightly photosensitive, and that the active part of the spectrum is in the visible region. This observation is in good agreement with observations by Griffith and Thompson [2] for the carotene breakdown in alfalfa during drying.

When the samples were dried at 80° C only a slight breakdown was observed, while steam blanching led to no carotene loss. The steam blanched samples could be dried overnight without any breakdown taking place. That the figure for the steam blanched sample is higher than for the fresh material is supposed to be due to incomplete extraction of the latter and to small losses of dry matter during the steam blanching.

The samples dried in open air and subjected to rain during the drying period lost their carotene content very rapidly compared with samples protected against rain.

The results from the drying experiments indicated that the carotene breakdown in *Rhodymenia palmata* might be of enzymatic nature. To further establish this, some experiments with fresh material were carried out.

If the fresh alga was stored before carotene determination a considerable carotene loss was observed. A sample blanched within 1 hour after harvesting was found to contain 280 mg carotene per 1 000 g dry matter. When the sample was stored for 20 hours before blanching only 135 mg per 1 000 g dry matter (48 %) was found.

If the sample was ground as described above, and allowed to thaw before acetone was added, the breakdown was extremely rapid as shown in Table 2. Attempts were made to inhibit this breakdown by means of enzyme inhibitors. The inhibitors were ground together with the samples in the mortar in concentrations of approximately

Table 2.

	Vacuum desiccator, 20 mm Hg		29

0.5 % and the samples set aside for 20 hours before acetone was added. It will be seen from Table 2 that sodium fluoride had no effect and that mercury chloride was only slightly effective. A slight inhibition was also observed when the sample was stored in a vacuum desiccator at a pressure of approximately 20 mm Hg. On the other hand, both potassium cyanide and sodium sulphide were fairly effective. The inhibition obtained with sodium sulphide may be due to the anaerobic conditions set up by this substance. In the case of potassium cyanide, however, the effect must be due to the inhibition of an enzymatic reaction. It seems, therefore, to be safe to conclude, that an enzymatic reaction must be involved in the carotene breakdown in *Rhodymenia palmata*.

A similar inhibition of the carotene breakdown by means of potassium cyanide was observed in alfalfa by Mitchell and Hauge in 1946 [3]. The enzyme system responsible for the carotene breakdown in alfalfa has later been found to be lipoxidase. The carotene is oxidised by some of the intermediate reaction products formed in the enzymatic oxidation of unsaturated fatty acids. Whether a similar reaction is responsible for the destruction of carotene in *Rhodymenia palmata* has not been established.

Demonstration of Reichstein's Substance S in Dog Adrenal Vein Blood by Countercurrent Distribution

HANS CARSTENSEN

Institute of Physiology, University of Upsala, Upsala, Sweden

The two major corticosteroids of dog adrenal vein blood, from a quantitative point of view, are cortisol and corticosterone, as demonstrated by several physical and chemical methods [1-4]. Among other possible components, the presence of minor amounts of Reichstein's substance S (Δ^4-pregnene-17*a*,21-diol-3,20-dione) seems to have considerable interest [5] (*cf.* Eberlein *et al.*[6]).

Further evidence of its occurrence in dog adrenal vein blood is provided here by its demonstration after countercurrent distribution. A sample of 330 ml blood was collected from the left adrenal of a mongrel male dog weighing 18 kg during 60 minutes and extracted with ethyl acetate as previously outlined [4]. The common corticosteroid fraction was recovered from the polar phase after double distribution between *n*-hexane and 50 % ethanol in water and subjected to successive countercurrent distributions (Table 1).

Table 2.

	0.92		Substance S (K = 0.88)	77		28	45	
F	0.24		Corticosterone (K = 0.25)	68				

* Figures in brackets indicate cortisone equivalents. If no figure is stated, a positive reaction is denoted + and a negative reaction —.
UV: Specific extinction at 240 mμ in ethanol.
BT: Reduction of blue tetrazolium [12].
PS: Porter-Silber reaction [7].
SA: Sulfuric acid chromogen at 280 mμ [8].
An: Anthrone reaction with specific extinction at 600 mμ [9].
** Ketonic fraction after Girard separation.

The identity with substance S is suggested by the following criteria:

1) identical partition coefficient within the limits of the method,

2) specific extinction at 240 mμ in ethanol (α,β-unsaturated ketone),

3) positive Porter-Silber reaction, carried out according to Wilson and Fairbanks [7] (dihydroxy acetone side chain at C_{17}),

4) pink sulfuric acid chromogen with the typical second peak in the region at about 550 mμ, as well as the peak at 280-290 mμ indicative of a Δ^4-3-keto configuration [8].

The final amount recovered was 28 μg. This is probably much less than the original amount owing to repeated losses during the many different steps preceding the last determination. The higher values obtained by estimating the specific ultraviolet extinction at 240 mμ (77 μg) and the sulfuric acid chromogen at 280 mμ (45 μg) may be explained by the simultaneous occurrence of some Δ^4-pregnene-21-ol-3,11,20-trione (K = 0.75). — The other component of System E (K = 0.1) may contain a very small amount of cortexone (Δ^4-pregnene-21-ol-3,20-dione), having a specific extinction at 600 mμ with the anthrone reagent [9]. At the same time a very sharp and high peak appeared at 418 mμ, indicating the presence of a constituent which was not further characterized.

Besides cortisol, corticosterone and a small amount of cortisone, several other

components are demonstrated which have not yet been identified. The use of countercurrent distribution for separating corticosteroids has previously been described [10] but a more detailed discussion will appear elsewhere [11].

On the Hydrolysis of the Bi^{3+} Ion — a Preliminary Note

FREDRIK GRANÉR, ÅKE OLIN and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

In 1947, Granér and Sillén [2] studied the hydrolysis of bismuth(III) in 3 M $NaClO_4$ medium, measuring $[H^+]$ with quinhydrone and glass electrodes, and $[Bi^{3+}]$ with bismuth amalgam electrodes. A mechanism was proposed which seemed to agree well with their data, which covered the range $[Bi]_{tot}$ = 10 to 50 mM.

One of us (Å.O.) has now undertaken a study with similar methods, but with total Bi concentrations ranging from 0.1 to 50 mM, thus a factor of 1 : 500 instead of 1 : 5. The present data can be explained by assuming the presence of only two complexes, the mononuclear $BiOH^{2+}$ and the hexanuclear $Bi_6(OH)_{12}^{6+}$ (as usual, plus or minus an unknown amount of water) with the preliminary equilibrium constants:

$$Bi^{3+} + H_2O \rightleftharpoons BiOH^{2+} + H^+ \qquad K_{1,1} = 0.026 \text{ M}$$

$$6\ Bi^{3+} + 12\ H_2O \rightleftharpoons Bi_6(OH)_{12}^{6+} + 12\ H^+ \qquad K_{12,6} = 2.14 \text{ M}^7$$

This result agrees with the findings of Kraus, Holmberg and Johnson [2] in so far as their "equilibrium ultracentrifugations suggest predominance of a low molecular weight polymer (N = *ca.* 5 or 6)". In a more narrow concentration range Souchay and Peschanski [3] concluded that there is only one complex present; they ascribed to it the formula, $Bi_4O_4^{4+}$.

The old data of Granér and Sillén were slightly distorted by the fact, then unknown, that quinone is a base and attracts protons at the highest acidities (Biedermann and Sillén [4]). After a correction for this effect, the present data are in general found to agree well with those of Granér and Sillén. This little deviation, however, sufficed (together with the narrowness of the $[Bi]_{total}$ range) to indicate an incorrect mechanism.

Attempts are now being made, in collaboration with Professor Cyrill Brosset, to study the structure of the complex by means of X-ray diffraction on aqueous solutions.

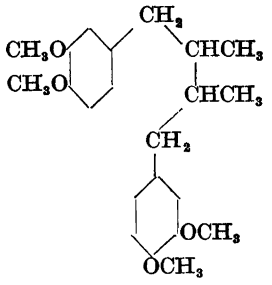
Constitution of Resin Phenols and their Biogenetic Relations

XXII *. On the Absolute Configuration of Lignans

BERNT CARNMALM

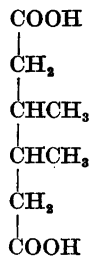
Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The sterical relationships between the known members of the lignan series are largely established (for references see Erdtman [1] and Hearon and MacGregor [2]). If therefore the absolute configuration of one of the lignans could be determined this would simultaneously establish the confiration of all the interrelated lignans.



The work of Bijvoet *et al.*[3] has shown that the absolute configuration of glyceraldehyde is the same as that arbitrarily adopted by Fischer. In order to correlate the lignans with glyceraldehyde the conversion of dextrorotatory bis(hydroxymethyl)-succinic acid dilactone, obtained from pinoresinol, into compounds of known configuration has been investigated. These experiments have hitherto been unsuccessful, however, a promising route for the solution of the problem has now been found.

(−)-Dihydroguaiaretic acid dimethylether(I) afforded a weakly dextrorotatory dimethyladipic acid (II) on ozonolysis followed by oxidation with hydrogen peroxide. This acid was very readily converted into a dimethyl*cyclo*pentanone which shows a very high negative rotation. The formation of the *cyclo*pentanone demonstrates that the ozonolysis in fact has given the expected acid (II).



Work is in progress to correlate this acid with dimethylsuccinic acid (III) both by synthetic and degradative methods. By removing the carboxyl group of the half-ester of the dimethylsuccinic acid it is hoped to obtain α-methylbutyric acid (IV) which has already been correlated with glyceraldehyde (*cf.* Crombie and Harper [4]). The details of these correlation experiments and a discussion of the results will be published shortly.

Optical Resolution of α-Phenylglutaric Acid

ARNE FREDGA and LARS WESTMAN

Chemical Institute, University of Uppsala, Uppsala, Sweden

In connection with current work on steric relationships, the authors have resolved α-phenylglutaric acid into its

optical antipodes. Quinine in ethanol and brucine in methanol were found to give the best results.

The racemic acid, prepared through the anhydride [1], had the m.p. 100–102°. The value 82–83° reported by previous authors [2] obviously refers to an unstable modification. The optically active acid melted at 129–131°.

Experimental. The anhydride was prepared by conventional methods [1]. After distillation *in vacuo* and recrystallisation from ethyl acetate + hexane, it melted at 94–95°. It was hydrolysed with boiling water (30 minutes); after extraction with ether and evaporation of the solvent, the acid was obtained as a gradually crystallising syrup. After recrystallisation from formic acid, it melted at 98–101°; further recrystallisation from ether + petrol ether raised the m.p. to 100–102°.

33.5 g racemic acid and 104 g quinine were dissolved together in 800 ml 96-% ethanol. The salt obtained after standing over-night was recrystallised seven times from the same solvent. The activity of the acid was practically constant from the fourth recrystallisation. The salt obtained (32.8 g) was decomposed with dilute sulphuric acid and the phenylglutaric acid isolated by extraction with ether. M. p. 129–131°. (Found: equiv.wt 104.7. $C_{11}H_{12}O_4$ requires 104.1. $[\alpha]_D^{25} = +85.8°$, $[M]_D^{25} = +178.5°$ in ethanol solution.)

The mother liquor from the first crystallisation of the quinine salt was evaporated and the acid liberated. 13.7 g with $[\alpha]_D^{25} = -46.8°$ was obtained. It was dissolved with 62 g brucine in 150 ml methanol. The salt obtained after 24 hours was recrystallised seven times from the same solvent; after five recrystallisations, the activity of the acid was constant and had practically the same maximum value as the antipode. The yield of salt was 27.9 g.

Synthesis of Racemic Methyl Phthienoate

CECILE ASSELINEAU, JEAN ASSELINEAU* and STINA STÄLLBERG-STENHAGEN

Institute of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden, and

EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

In the lipids of a human strain of the tubercle bacillus Anderson and Chargaff in 1929 [1,2] found a dextrorotatory, branched chain fatty acid which they called phthioic acid. When injected into animals, this acid was found [3] to produce epitheloid cell tissue reaction characteristic of tuberculosis. The elucidation of the chemical structure of the compound proved difficult and has been achieved only recently, mainly as a result of work by Polgar *et al.*[4–6] at Oxford and by Cason *et al.*[7–9] at Berkeley. After the α,β-unsaturation of the acid had been recognized [4,7] the new names mycolipenic acid-I[b] and C_{27}-phthienoic acid [8] were suggested. According to Cason and Sumrell [8] several homologues of C_{27}-phthienoic acid are present in the lipids of tubercle bacilli.

On the basis of the above-mentioned degradation studies at Oxford and Berkeley, and synthetic work performed at Uppsala, Ställberg-Stenhagen [10] suggested that C_{27}-phthienoic acid ** is *trans*-2,4L, 6L-trimethyl-$\Delta^{2:3}$-tetracosenoic acid. This conclusion has been strengthened by Fray and Polgar's recent synthesis [11] of (+)-2L,4L-dimethyldocosanoic acid, a degradation product of the natural compound. The synthesis of the *cis*- and *trans*-DL-erythro isomers of methyl 2,4,6-trimethyl-$\Delta^{2:3}$-tetracosenoate has now been performed through the following sequence of reactions:

* Rockefeller Foundation fellow.

** We prefer this name because of its similarity with the name originally proposed by R. J. Anderson.

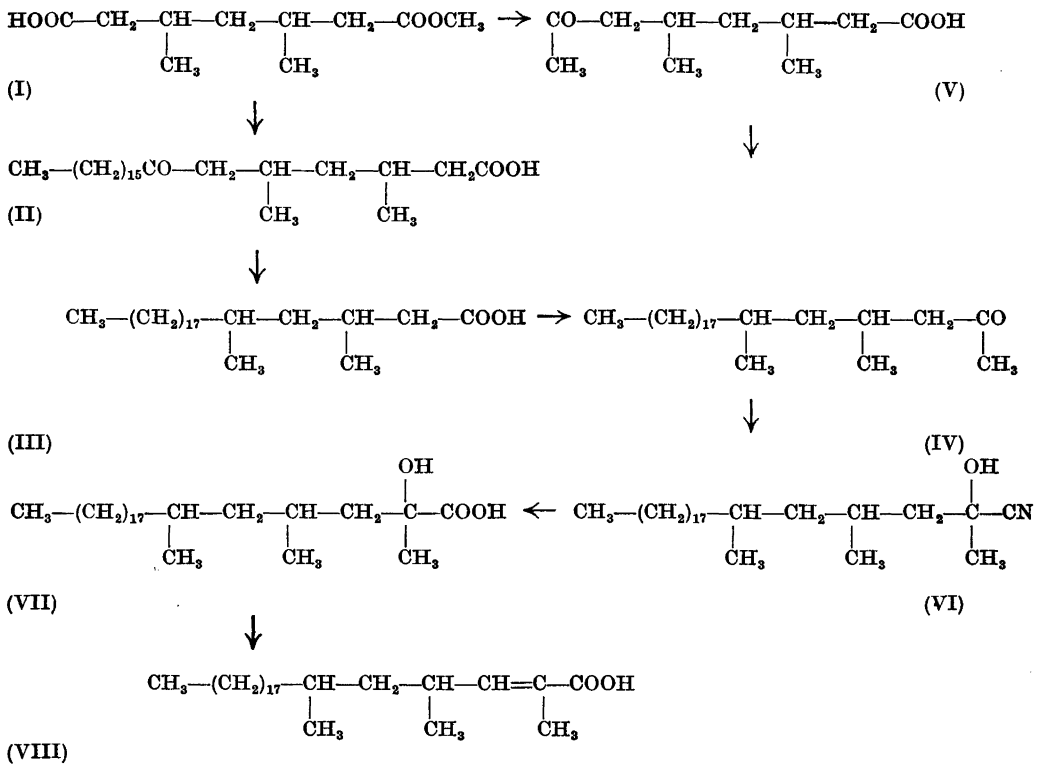
Synthesis of Racemic Methyl Phthienoate

CECILE ASSELINEAU, JEAN ASSELINEAU* and STINA STÄLLBERG-STENHAGEN

Institute of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden, and

EINAR STENHAGEN



Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

In the lipids of a human strain of the tubercle bacillus Anderson and Chargaff in 1929 [1,2] found a dextrorotatory, branched chain fatty acid which they called phthioic acid. When injected into animals, this acid was found [3] to produce epitheloid cell tissue reaction characteristic of tuberculosis. The elucidation of the chemical structure of the compound proved difficult and has been achieved only recently, mainly as a result of work by Polgar *et al.*[4–6] at Oxford and by Cason *et al.*[7–9] at Berkeley. After the α,β-unsaturation of the acid had been recognized [4,7] the new names mycolipenic acid-I[b] and C_{27}-phthienoic acid [8] were suggested. According to Cason and Sumrell [8] several homologues of C_{27}-phthienoic acid are present in the lipids of tubercle bacilli.

On the basis of the above-mentioned degradation studies at Oxford and Berkeley, and synthetic work performed at Uppsala, Ställberg-Stenhagen [10] suggested that C_{27}-phthienoic acid ** is *trans*-2,4L, 6L-trimethyl-$\Delta^{2:3}$-tetracosenoic acid. This conclusion has been strengthened by Fray and Polgar's recent synthesis [11] of (+)-2L,4L-dimethyldocosanoic acid, a degradation product of the natural compound. The synthesis of the *cis*- and *trans*-DL-erythro isomers of methyl 2,4,6-trimethyl-$\Delta^{2:3}$-tetracosenoate has now been performed through the following sequence of reactions:

* Rockefeller Foundation fellow.

** We prefer this name because of its similarity with the name originally proposed by R. J. Anderson.

Experimental. The starting material, *meso*-3,5-dimethylpimelic acid, has been prepared from 3,5-dimethyl*cyclo*hexanone: free acid m. p. 98.6—99.8°; monomethyl ester (I) n_D^{25} 1.4438, d_4^{25} 1.037; dimethyl ester n_D^{22} 1.4334, d_4^{22} 1.002. By means of Bowman's synthesis 3,5-dimethyl-7-oxotricosanoic acid (II), m. p. 51.3—52.2° and 29.0—29.3° (dimorphism) was prepared (semicarbazone m. p. 104—109° (decomp.)). Reduction of this acid, either by Huang-Minlon's modification [12] of the Wolff-Kishner procedure or by treatment of the ethylene mercaptal with Raney nickel [13] gave 3,5-dimethyltricosanoic acid (DL-erythro form) (III), m. p. 46.4—48.4° and 27.0—27.3° (dimorphism). Methyl ester: m. p. 18.3—18.8°, $n_D^{21.5}$ 1.4500, $d_4^{21.5}$ 0.858; ethyl ester: m. p. 14.8—15.3°, n_D^{22} 1.4495, d_4^{22} 0.854. Through reaction of the acid chloride of the last mentioned acid with methyl cadmium [14] 4,6-dimethyltetracosanone-2 (IV) was obtained, m. p. 20.9—21.4°, n_D^{20} 1.4530, d_D^{20} 0.846 (semicarbazone m. p. 82—83°). The same ketone was also obtained from 3,5-dimethyl-7-oxooctanoic acid (V) (n_D^{22} 1.4494, d_4^{22} 0.9988) and stearic acid through the Kolbe reaction. Treatment of the ketone with hydrocyanic acid gave the cyanhydrin (VI) which without further purification was hydrolyzed to 2,4,6-trimethyl-2-hydroxytetracosanoic acid (VII), m. p. 51.2—52.5° (mixture of diastereoisomers) (methyl ester: m. p. 22.5—23.1°, n_D^{25} 1.4527; I. R. spectrum: bands at 2.85 and 5.77 μ). Pyrolysis of the free hydroxy-acid gave a mixture from which, after methylation and chromatography on alumina, *cis*- and *trans*-isomers of methyl DL-erythro-2,4,6-trimethyl-$\Delta^{2,3}$-tetracosenoate (VIII) were isolated: *cis*-isomer m. p. 35.2—36.6° and 16.3—16.6° (dimorphism), n_D^{25} 1.4587, U. V. spectrum: λ_{max} 217 mμ, ε = 10.240; *trans*-isomer m. p. 14.3—14.7°, n_D^{25} 1.4600, U. V. spectrum: λ_{max} 215 mμ, ε = 12.930 (hexane).

The assignment of geometrical configuration of 2-methyl-2-alkenoic acids has been discussed by Ställberg-Stenhagen [10]

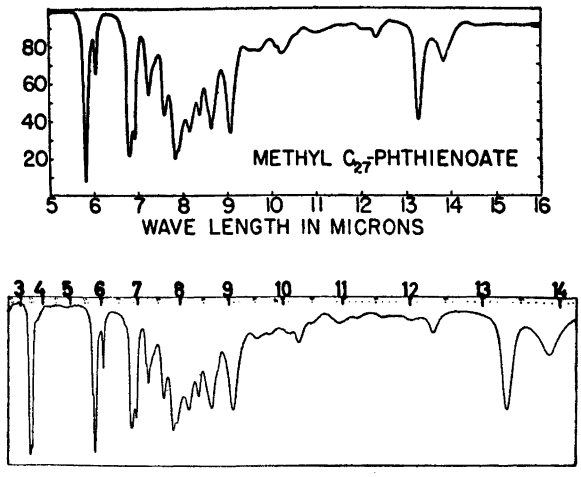


Fig. 1. Infrared absorption spectra.

Upper curve: Methyl C_{27}-phthienoate according to Cason et al.[9]
Lower curve: Synthetic methyl trans-DL-*erythro-2,4,6-trimethyl-$\Delta^{2:3}$-tetracosenoate (liquid, cell 0.02 mm thick).*

and Cason and Kalm [15]. The results of these authors are supported by the X-ray crystallographic work of Robertson and Porte [16] on angelic and tiglic acid.

The infrared absorption spectra of the *cis-* and *trans-*isomers in liquid state are considerably different especially in the region 10 to 15 μ. The spectrum of the *trans-*isomer proved identical with that of a specimen of methyl C_{27}-phthienoate recently isolated by one of us (J.A.) from the strain test of the tubercle bacillus. As shown in Fig. 1 the spectrum also appears identical with that for methyl C_{27}-phthienoate published by Cason *et al.*[9]. The *trans-*configuration of the ester derived from bacterial sources [10,15] is thus confirmed.

Methyl hydrogen 3,5-dimethylpimelate(I) has been resolved into the antipodes, $[\alpha]_D^{25} \pm 1.5°$, and we are now engaged in the synthesis of the optically active *cis-* and *trans-*isomers.

The Ethylenic Bond in Dihydroabietic Acid

HENRIK H. BRUUN*

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Sweden

The position of the double bond in the isomeric dihydroabietic acids has not been established. The suggested sites are Δ 7, 8(14), 9(14) and 13 (Fig. 1) **. For two dihydroabietic acids prepared by partial hydrogenation of abietic acid, the α- and β-dihydroabietic acids of Lombard [5,6], Simonsen and Barton [7] have proposed the position 9(14) and 13, respectively. This proposal is supported by the recent molecular rotation studies of Klyne [8].

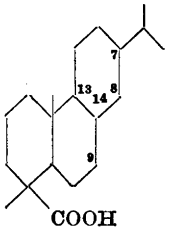

Fig. 1.

Trisubstituted ethylenic bonds ($R_1R_2C=CHR_3$) can generally be distinguished from the tetrasubstituted bonds ($R_1R_2C=CR_3R_4$) by infrared absorption measurements by means of the C—H out-of-plane deformation vibrations in the spectra of the former. Complex molecules studied by this method are triterpenes (Ruzicka, Jeger *et al.*[9,10] and a number of sterols (Hirschmann [11]). For sterols the absorption band occurs at a wavelength of 12.5 μ. In the present study, the infrared absorption in this range has been recorded for dihydroabietic acid and for several other abietic and pimaric acids of known structure. The aim has been to determine whether the infrared spectrum of dihydroabietic acid shows the band in question or not. A negative result would suggest that the double bond is tetrasubstituted, *i. e.* the position is at 13; however, this would not be fully conclusive in view of the frequently weak and varying intensity of the band. A positive result would imply without reservation that the double bond is of the trisubstituted type, *i. e.* it would be situated somewhere else in the molecule.

Experimental. The infrared absorption spectra were recorded with a double beam spectrophotometer (built by Dr. M. Skogh) of the type described by Hornig, Hyde and Adcock [12]. The samples were prepared by the potassium bromide technique, the tablets were 0.8 mm thick and 13 mm in diameter, and contained 3—3.2 mg of the acid per 300 mg of potassium bromide.

The samples of the dihydro-, tetrahydro- and dehydroabietic acids and *iso*dextropimaric acid were obtained from the Research Laboratory of Hercules Powder Company, Wilmington, Delaware. According to Dr. C. G. Harris of that laboratory, the dihydroabietic acid had been prepared by partial hydrogenation of abietic acid and was a mixture of isomeric acids, but otherwise pure. M. p. 133.8—136.8, $[\alpha]_D^{20}$ + 19° ± 2°. Tetrahydroabietic acid, m.p. 149.4—152.4, $[\alpha]_D^{20}$ + 11° ± 2°; dehydroabietic acid, m. p. 173.3—174.6, $[\alpha]_D^{20}$ + 66° ± 1°; *iso*dextropimaric acid, m. p. 162.9—164.9, $[\alpha]_D^{20}$ 0°.

The dextropimaric acid was obtained from Dr. O. Jeger at the Eidg. Techn. Hochschule, Zürich.

The abietic acid was obtained in the form of its butylamine salt from Dr. E. Back of the Swedish Forest Products Research Laboratory, Stockholm. Before use, the acid was liberated from its salt with an aqueous boric acid solution. M. p. 170.2—172.7, $[\alpha]_D^{20}$ —104° ± 1°.

The melting points were determined by the capillary method (diameter of the capillary tubes 1 mm). The values were corrected. The optical rotations in absolute alcohol (0.01 g per ml) were measured with a Lippich polarimeter.

For monolayer data relating to the same samples of rosin acids, see Ref. [13].

Results. The infrared absorption spectra of the rosin acids for the range 12—13 μ are shown in Fig. 2. There is a band at 12.5 μ in the spectrum of dihydroabietic acid (*a*). The two pimaric acids have a trisubstituted etylenic bond at 8(14) and the corresponding band is evident in the spectra. For *iso*dextropimaric acid (*b*), the band is of a relatively high intensity,

* Address: Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland.

** For reviews, see *e. g.* Refs. [1-4].

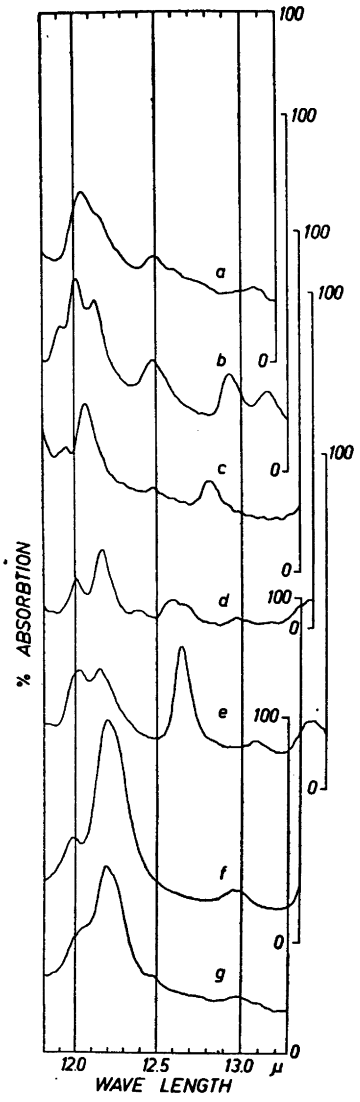

Fig. 2.

while that for dextropimaric acid (*c*) is of much lower intensity. The band is not evident in the spectrum of the fully saturated tetrahydroabietic acid (*d*), in the spectrum of the abietic acid (*e*) with conjugated double bonds or in the spectrum of the hydroaromatic dehydroabietic acid (*f*). In a mixture containing equal parts of the last mentioned and dihydroabietic acid (*g*) the band at 12.5 μ is still observed.

Discussion. The evidence presented above strongly suggests that the dihydrobietic acid studied contains a trisubstituted ethylenic bond. If we assume provisionally that the sample is a mixture of Lombard's α- and β-acids (*cf.* Refs. [7,8]), the appearance of the band in the spectrum of the mixture in spite of the strong background absorption implies that the α-acid content in the sample is relatively high. This conclusion is supported by the optical rotation value of the sample; a comparison with the values for Lombard's α- and β-acids ($-26°$ and $+128°$, respectively) points to a concentration of about 70 %.

I wish to express my sincere gratitude to Professor Einar Stenhagen for placing the facilities of the department at my disposal. I am indebted to Dr. Ingrid Fischmeister for assistance with the spectrophotometric measurements. This work has been made possible by a grant from the *Committee for the Advancement of Natural Sciences* appointed by the Finnish Government.

Organic Hydroxylamine Compounds Formed from Nitrite in *Torulopsis utilis*. II. Acetylhydroxamic Acid

ARTTURI I. VIRTANEN and NILS-ERIK SARIS

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In an earlier paper [1] we reported results which showed that "bound hydroxylamine", which is formed in small amounts in the cells of *Torulopsis utilis* suspended in a nitrite-containing nutrient solution, contains oximes of α-keto acids. In all experiments the amount of the oxime of pyruvic acid was highest, next came the oxime of α-ketoglutaric acid, the smallest amounts being those of the oximes of oxypyruvic, oxalacetic, and glyoxalic acids. The amounts and mutual relations of different oximes varied appreciably in different experiments, as can be expected since the amount of the corresponding keto acids varies in the cells and is dependent on many different factors.

When continuing our investigations special attention was given to hydroxamic acids which could possibly be formed in addition to oximes. In the experiment described in our first paper about 70 % of "bound hydroxylamine" was reduced by sodium amalgam to amino acids. The rest of the "bound hydroxylamine" could thus consist of hydroxamic acids. In most experiments practically all the "bound hydroxylamine" passed through the Dowex 50 column. On the basis of this *Torulopsis* cells do not contain noticeable amounts of the hydroxamic acids of amino acids. The hydroxamic acids of such carboxylic acids which do not contain basic groups were instead to be expected in the solution emerging from the Dowex column. In our very first experiments we found this to be the case, as in fact a reddish spot was obtained with ferric chloride on the paper chromatogram of the solution. The chemical nature of the compound remained obscure, however, and was not therefore dealt with in our earlier paper.

A closer investigation has now been made on the nature of the hydroxamic acid formed when *Torulopsis* reduces

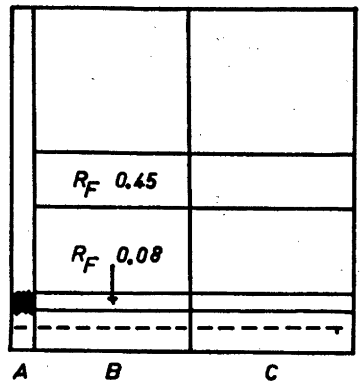

Fig. 1. Paper chromatogram of »bound hydroxylamine» in Torulopsis *cells. Solvent: amylacetate/formic acid/water (4:1:1). Dotted line = starting line.*

A. Paper strip sprayed with ferric chloride solution. Reddish spot with R_F *0.08.*

B. After hydrolysis hydroxylamine could be found mostly in the zones with R_F *0.08 and 0.45.*

C. The corresponding zones were analyzed. The zone with R_F *0.45 gave on reduction with sodium amalgam alanine and accordingly contained the oxime of pyruvic acid. The zone with* R_F *0.08 contained acetylhydroxamic acid (*cf. *Fig. 2).*

nitrite. The extract obtained from the cell mass was passed through a cellulose powder column with butanol-acetic acid as solvent (Dowex treatment was omitted). "Bound hydroxylamine" passed through comparatively quickly. The combined fractions containing "bound hydroxylamine" were evaporated to a small volume. The solution obtained was spread along a starting line at the bottom of a Whatman No. 4 paper, and using amylacetate/formic acid/water (4:1:1) as solvent the chromatogram was developed. A narrow strip cut off from the margin of the paper was sprayed with a solution of ferric chloride upon which the reddish spot appeared, R_F 0.08 (Fig. 1 A). The sheet was then cut in two lengthwise and one of the halves again was cut crosswise into 16 strips which were extracted with water (Fig. 1 B). The solutions obtained were hydrolyzed with sulphuric acid and hydroxylamine was determined by the method of Csàky. The values showed that "bound

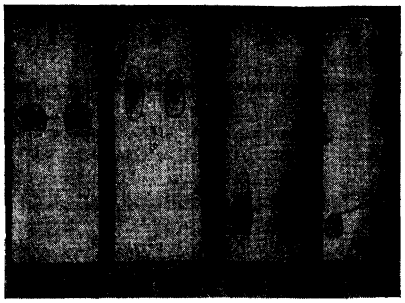

Fig. 2. Comparison between synthetic acetylhydroxamic acid and the hydroxamic acid found in Torulopsis *cells. A. Synthetic acetylhydroxamic acid. X. Hydroxamic acid found in* Torulopsis *cells. Solvents: 1 butanol/acetic acid/water (63:27:10), 2) amylacetate/formic acid (80 %)/water (4:1:1), 3) ethylacetate/butanol/water (8:2:1), 4) ethylacetate/propanol/acetic acid/water (5:2:2:1).*

hydroxylamine" had mostly divided into two zones: R_F 0.08 and R_F 0.45. From the other half of the paper (Fig. 1 C) the zones corresponding to hydroxylamine maxima were cut off and eluted with water. From the zone corresponding to R_F 0.45 alanine was obtained by reduction with sodium amalgam (identified by paper chromatography). This zone accordingly contained the oxime of pyruvic acid. The hydroxylamine compound obtained from the strip with R_F 0.08, which corresponded to the red spot, was used for several paper chromatograms with different solvents: butanol/acetic acid/water (63:27:10), amylacetate/formic acid (80 %)/water (4:1:1), ethylacetate/butanol/water (8:2:1), and ethylacetate / propanol / acetic acid / water (5:2:2:1) (Fig. 2). Corresponding paper chromatograms were made for comparison with synthetic acetylhydroxamic acid.

The synthetic acid was prepared from ethylacetate and hydroxylamine-HCl in an alkaline methanol solution at 30° C. The solution was neutralized with HCl upon which KCl precipitated. The precipitate was filtered off and the solution evaporated to dryness *in vacuo*. The residue was dissolved in ethanol, ether was added, and the precipitate was filtered off. The clear solution was evaporated to dryness and the residue crystallized from acetone. M.p. 88—89 °C. According to the determination of hydroxylamine in the preparation it is pure acetylhydroxamic acid. It gives an intensely red colour with ferric chloride.

The hydroxamic acid found in *Torulopsis* cells is according to chromatographic analyses, presented in Fig. 2, acetylhydroxamic acid.

Acetylhydroxamic acid is not reduced by sodium amalgam (1.5 %), whereas oximes are reduced quantitatively to the corresponding amino acids. On the basis of this the following experiment was performed: from the alcoholextract of the cell mass of *Torulopsis* alcohol was evaporated, and the oximes in the solution were reduced with sodium amalgam. The amount of hydroxylamine which disappeared on reduction indicated the amount of oximes. The difference between the total "bound hydroxylamine"-N and the reduced oxime-N indicates the amount of acetylhydroxamic acid. In two different experiments 30 and 50 %, respectively, of the total "bound hydroxylamine" was acetylhydroxamic acid, whereas 50—70 % of "bound hydroxylamine" thus corresponded to the oximes of keto acids, mainly to that of pyruvic acid.

In the earlier paper we reported that appreciable amounts of "bound hydroxylamine" were formed in nitrite solution only at low oxygen concentration. We have now found that *Torulopsis* cells with low N-content form "bound hydroxylamine" both from nitrate and nitrite in aerated suspensions. At best about 10—20 μg NH_2OH-N/g fresh yeast was accumulated in the cells during the first ten to twenty minutes.

Our results indicate that "bound hydroxylamine" is accumulated in *Torulopsis utilis* cells suspended in a nitrate or nitrite containing nutrient solution. In this nitrogen fraction the oximes of α-keto acids as well as acetylhydroxamic acid are found. The oximes are obviously formed through a chemical reaction between hydroxylamine and α-keto acids [2]. Acetylhydroxamic acid is probably formed either from hydroxylamine and acetyl-CoA [3] or from hydroxylamine and acetylphosphate [4].

Since the amount of oximes rapidly decreases in *Torulopsis* cells there must be some mechanism through which "bound hydroxylamine" is either reduced or hydrolyzed in the cells. Virtanen has earlier advanced the hypothesis that the oximes of α-keto acids should be reduced to the corresponding amino acids. For the present we have not been able to demonstrate this reduction. The observations made by

Yamafuji [5] on this point cannot be regarded as conclusive evidence. The question is thus still open. The other possibility that the oximes formed are hydrolyzed, and that the free hydroxylamine is then reduced to ammonia also lacks experimental evidence.

At the moment it seems very likely that the physiological function of the formation of "bound hydroxylamine" is the "trapping" of hydroxylamine in case it is not reduced to ammonia quickly enough. On the other hand, it is still unsettled if the formation of oximes at the same time constitutes a special pathway for amino acid synthesis. The significance of acetylhydroxamic acid is also obscure.

Activation Energies in the Alkaline Hydrolysis of Saturated Aliphatic Esters

EERO A. HALONEN

Institute of Chemistry, University of Helsinki, Finland

The volatility and low solubility of saturated aliphatic esters in water may lead to appreciable errors in the determination of the rates of hydrolysis.

In the present study, the air volume above the solution was kept small by using two ampoules, one of about 6 ml capacity and the other of about 10.5 ml, which were connected by a short length of rubber tubing. 5 ml of an 0.02 M aqueous solution of the ester was measured into the larger ampoule and 5 ml of 0.02 M aqueous sodium hydroxide into the other. After the rubber tubing was closed with a screw fastener, the ampoules were placed alongside each other in the thermostat; in this way evaporation of the ester into the alkali solution was avoided. After both ampoules had attained the thermostat temperature, the tubing was opened, the alkali was transferred into the ester solution with vigorous shaking, and the tubing was closed again. The ampoules were taken from the thermostat after suitable intervals, the tubing was removed, and the reaction mixture poured rapidly into an ice-cold hydrochloric acid solution. The excess of hydrogen chloride was titrated with baryta solution using phenolphtalein as indicator. The rate constants were calculated from the second-order rate equation. The values of the ate constants obtained are given in Table 1 (the values for ethyl formate from a publication of Tommila and Maltamo [1] have been included for comparison).

The rate constants for all the esters studied are in good agreement with the values reported by Salmi and Leimu [2], and those for ethyl acetate with the values published by Tommila and coworkers [3,4]. From the calculated activation energy and frequency factor values given in the table it is seen that for the last three esters the decrease in the rate is mainly due to a decrease in the frequency factor, and that the activation energy increases from ethyl formate to ethyl acetate and then decreases slowly in the series ethyl acetate, ethyl propionate and ethyl *iso*butyrate. On the other hand, the activation energies for ethyl propionate and ethyl *n*-butyrate do not differ from each other. The rate falls greatly from ethyl formate to ethyl acetate and the difference between the rates of ethyl propionate and ethyl butyrate is abnormally large (*cf.* Ref.[4]). The rate decreases only slightly from ethyl acetate to ethyl propionate in the temperature range studied (as calculated from the Arrhenius plot, ethyl propionate hydrolyses more rapidly than ethyl acetate at temperatures below $-3°$ C).

The differences in the rates of hydrolysis can be explained by assuming that the activation energy differences are mainly determined by hyperconjugation and that the differences in the inductive and steric effects appear mainly in the frequency factors. In a previous study [5], it was concluded that the conjugation between the

Activation Energies in the Alkaline Hydrolysis of Saturated Aliphatic Esters

EERO A. HALONEN

Institute of Chemistry, University of Helsinki, Finland

The volatility and low solubility of saturated aliphatic esters in water may lead to appreciable errors in the determination of the rates of hydrolysis.

In the present study, the air volume above the solution was kept small by using two ampoules, one of about 6 ml capacity and the other of about 10.5 ml, which were connected by a short length of rubber tubing. 5 ml of an 0.02 M aqueous solution of the ester was measured into the larger ampoule and 5 ml of 0.02 M aqueous sodium hydroxide into the other. After the rubber tubing was closed with a screw fastener, the ampoules were placed alongside each other in the thermostat; in this way evaporation of the ester into the alkali solution was avoided. After both ampoules had attained the thermostat temperature, the tubing was opened, the alkali was transferred into the ester solution with vigorous shaking, and the tubing was closed again. The ampoules were taken from the thermostat after suitable intervals, the tubing was removed, and the reaction mixture poured rapidly into an ice-cold hydrochloric acid solution. The excess of hydrogen chloride was titrated with baryta solution using phenolphtalein as indicator. The rate constants were calculated from the second-order rate equation. The values of the ate constants obtained are given in Table 1 (the values for ethyl formate from a publication of Tommila and Maltamo [1] have been included for comparison).

The rate constants for all the esters studied are in good agreement with the values reported by Salmi and Leimu [2], and those for ethyl acetate with the values published by Tommila and coworkers [3,4]. From the calculated activation energy and frequency factor values given in the table it is seen that for the last three esters the decrease in the rate is mainly due to a decrease in the frequency factor, and that the activation energy increases from ethyl formate to ethyl acetate and then decreases slowly in the series ethyl acetate, ethyl propionate and ethyl *iso*butyrate. On the other hand, the activation energies for ethyl propionate and ethyl *n*-butyrate do not differ from each other. The rate falls greatly from ethyl formate to ethyl acetate and the difference between the rates of ethyl propionate and ethyl butyrate is abnormally large (*cf.* Ref.[4]). The rate decreases only slightly from ethyl acetate to ethyl propionate in the temperature range studied (as calculated from the Arrhenius plot, ethyl propionate hydrolyses more rapidly than ethyl acetate at temperatures below $-3°$ C).

The differences in the rates of hydrolysis can be explained by assuming that the activation energy differences are mainly determined by hyperconjugation and that the differences in the inductive and steric effects appear mainly in the frequency factors. In a previous study [5], it was concluded that the conjugation between the

* Computed from the Arrhenius equation.

carboxyl carbonyl group and the α,β-unsaturated bond is an important factor determining the activation energy in alkaline ester hydrolysis. As compared with ethyl formate, ethyl acetate contains a methyl group which enters into conjugation with the carboxyl carbonyl group and also possesses weak inductive and steric effects. The ethyl group in the acid part of ethyl propionate possesses stronger inductive and steric effects, but a weaker hyperconjugative effect, than the methyl group in ethyl acetate. The decreased hyperconjugation lowers the activation energy and hence increases the hydrolysis rate, which is in accordance with the fact that the ethyl propionate hydrolyses more rapidly than ethyl acetate at low temperatures. This increase in the hydrolysis rate is opposed by the strengthened inductive and steric effects. In ethyl *iso*butyrate the inductive and steric effects are even larger, but there is no hyperconjugation. If the hyperconjugation alone determined the differences in the activation energies, the activation energy should be the same for both ethyl *iso*butyrate and ethyl formate. Since the observed difference is 490 cal, it must be concluded that also the inductive and steric effects increase the activation energy in some degree.

The hyperconjugation is the same in both ethyl propionate and ethyl *n*-butyrate, and so also are the activation energies. The change in the inductive effect is slight, and hence the observed abnormal fall in the rate is due to a marked steric effect in ethyl *n*-butyrate. The steric effect may evidently be considered to involve geometrical hindrance, since there is no difference in the activation energies. Quantitatively this steric effect is comparable with the difference in the rates of hydrolysis of the methyl and ethyl esters of acids in general. The mean ratios of the rates of both pairs are both approximately 1.8 (see Table 1 and the data of Leimu and Salmi [2]). The decisive influence of the steric effect is also apparent from the observation that the ratio of the rates of hydrolysis of the methyl and ethyl esters increases rapidly as the degree of branching increases in the acid component of the ester [2].

Confirmation of the Structure of Thujic Acid by Nuclear Magnetic Resonance

JARL GRIPENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

In a previous paper [1] it was pointed out that there are two likely structures for thujic acid, namely (I) and (II).

Degradation and synthesis [1,2] were definitely in favour of (I), which has therefore been regarded as the correct structure of thujic acid.

Confirmation of this structure by some independent means, preferably by a method not involving chemical reactions appeared, however, to be very desirable. Corey *et al.*[3] have recently solved a similar problem in the eucarvone series by the use of nuclear magnetic reasonance [4].

Dr. J. N. Shoolery of Varian Associates has been kind enough to measure the N M R spectrum of thujic acid methylester, which is reproduced in Fig. 1.

The shift in resonance is expressed as mgauss relative to benzene as zero standard, with an applied magnetic field of 7 050 gauss. There are three different bands of absorption. The very complex one at A is due to the ethylenic hydrogens. The sharp peak at B is due to the ester methyl group, while the *gem*-dimethyl hydrogens absorb at C. There is no absorption at about 35 mgauss, where the tertiary bridge hydrogens of (II) should absorb [3]. Furthermore the area under A is close to that under C, but much greater than that under B, which is also in agreement with structure (I) with five ethylenic hydrogens.

There is thus no doubt that (I) correctly represents thujic acid.

The author wishes to express his thanks to Dr. J. N. Shoolery, Varian Associates, Palo Alto, California, for taking the N M R spectra and for his comments on them.

A Method for the Determination of the Content of Glycogen-like Polysaccharides in Small Amounts of Bacteria

H. PALMSTIERNA and R. ELIASSON

Chemistry Department I, Karolinska Institutet, Stockholm, Sweden

In order to obtain a survey of the amount of glycogen-like polysaccharides * present in bacterial cells at different times of growth and under different cultivation conditions, it was found desirable to use a less time-consuming and less elaborate method than that previously employed [1,2]. The method described in the following involves no precipitation of the polysaccharides and it is therefore possible to use small amounts of cells. The test organism was *Escherichia coli* B.

Method: Between 5 and 20 mg of lyophilized cells were hydrolysed in 0.2 ml 3 N KOH for two hours in small Pyrex glass test tubes (Length 100 mm, inner diameter 6 mm). The upper end of the test tube was drawn to a capillary in order to avoid losses of fluid. After the alkaline hydrolysis, the pH was adjusted to about 1 with 4 N sulfuric acid and hydrolysed for thirty minutes. Both hydrolyses were performed on a boiling water-bath. The glucose was isolated from the hydrolysate by means of ion-exchangers. The hydrolysate was first passed through Dowex 50 in the H^+-form, and thereafter through Dowex 2 in the acetate-form; both were thoroughly washed. It is necessary to use the ion-exchangers in the order mentioned, since the reverse order seriously affects the yield of glucose. The ion-exchangers were placed in a column between thin layers of Pyrex glass wool. The inner diameter of the column was 6 mm and the length of each of the ion-exchange layers was 90 mm. The mesh size of the ion-exchangers was between 20 and 40. The level of the fluid in the column was kept constant at the top of the ion-exchangers. The hydrolysate was slowly washed through the column. The total volume of the effluent amounted to 15 ml. When required, the volume was reduced by blowing thoroughly filtered air over the fluid, which was heated to between 50 and 60° C. It is necessary to keep the temperature at this high level, since the yield of glucose might otherwise be reduced by bacterial contaminations. The glucose was determined by a modification of Dische's carbazol method [3].

Results. The effluent from the column contained no ninhydrin positive substances, and was free from ultraviolet absorption between 240 and 320 mμ. Ascending paper chromatograms (butanol saturated with water) were performed. Slight traces of ribose were found in most instances. For the same reasons as mentioned previously, the presence of galactose could not be excluded [2].

Forty determination were performed. The results are shown in Table 1.

Table 1.

Sample	Glycogen-glucose in per cent of the dry weight. Precipitation method.	Glycogen-glucose in per cent of the dry weight. Method described in this paper.
A	1.2	1.7 ± .5
B	2.9	3.2 ± .7
C	3.5	3.5 ± .6
D	7.4	7.9 ± .9
E	8.0	8.9 ± 1.2
F	9.3	9.4 ± .7
G	10.1	10.8 ± 1.2
H	15.0	16.2 ± 1.0

As previously shown by the isotope dilution method [2], the values obtained by the precipitation method are about 5 per cent too low.

Discussion. If other bacteria than *E. coli* B are under examination, it is necessary to ascertain that the glucose obtained is substantially free from other carbohydrates. The method is not as accurate as that previously used by the authors, but since the variations in the glycogen content of *E. coli* B are very large, the method described gives useful information. It is easily performed on small amounts of bacteria and is not as time-consuming as methods involving precipitation of the alkalistable polysaccharides.

* For the sake of brevity called glycogen in the following.

Isolation of ^{32}P-Labeled Phosphoserine from a Yeast Hexokinase Preparation, Incubated with Labeled ATP or Glucose-6-Phosphate

GUNNAR ÅGREN and LORENTZ ENGSTRÖM

Institute of Medical Chemistry, University of Uppsala, Sweden

In earlier communications from this laboratory we reported the incorporation of radioactive inorganic phosphate into phosphoserine isolated from the Schneider protein residues of several rat organs [1]. The maximum incorporation for all organs investigated occurred at approximately three hours after injection of radioactive phosphate [2]. This seemed to infer that some intracellular phosphoproteins may function as transphosphorylating enzymes.

The incorporation of radioactive inorganic phosphate into a new phosphorylated amino acid [3], prepared from the protein of *Lactobacillus casei*, was also compared with the phosphorus uptake of nucleotide and nucleic acid fractions in an attempt to trace the source and the destination of the amino acid phosphorus [4]. However, all these measurements can only give an average value for presumably different kinds of phosphoproteins of different loci within the cell.

As an alternative it seemed of interest to study pure phosphoproteins, as hexokinase or phosphoglucomutase, which are known to be involved in the transfer of phosphorus. The possibility that this transfer might include the formation of an enzyme-phosphate intermediate has been suggested by many authors [5]. Recently this hypothesis received support from the demonstration by Najjar and Pullman [6], that phosphoglucomutase exists in two states, a phosphoenzyme and a dephosphoenzyme. The former transfers phosphate to glucose-1-phosphate or glucose-6-phosphate. Glucose-1,6-diphosphate is formed in the process.

In the present study we have shown the formation of an enzyme -phosphate intermediate in the hexokinase reaction by isolating phosphoserine from the acid hydrolysate of the enzyme, incubated with ^{32}P-labeled ATP [7] in the presence of glucose. In another experiment we also obtained phosphoserine from the enzyme incubated with glucose-6-phosphate isolated from the reaction mixture of the enzyme and AT^{32}P.

The enzyme was purified according to the first six steps of the methods of Berger *et al.*[8] and contained one per cent of glucose *. About 20 mg of this protein was incubated for a few seconds with 1—2 mg ATP, containing about 1—2 mC of phosphorus activity and in the presence of 0.01 M $MgCl_2$. The enzyme was precipitated with 10 % trichloroacetic acid. The protein was hydrolysed and fractionated on a Dowex 50-column according to Ågren *et al.*[1]. The peak eluted after the inorganic phosphate in the expected position of phosphoserine weighed less than 0.1 mg. A part of this material was run through a Dowex 1 formate column according to Busch *et al.*[9] with the addition of non-labeled phosphoserine. The ninhydrin colour from the non-labeled phosphoserine and the activity from the isolated fraction were eluted in the same column volume. Other parts of the activity together with non-labeled phosphoserine were analyzed with one-dimensional paper chromatography using *iso*butyric acid-ammonia and benzene-propionic acid systems. After development of the ninhydrin colour, the paper strips were scanned in the apparatus previously described [2]. The ninhydrin colour from the non-labeled phosphoserine and the activity from the isolated fraction completely agreed.

The trichloroacetic acid centrifugate from the reaction mixture of enzyme and AT^{32}P was run through a Dowex 1 formate column according to Siekevitz and Potter[10], and the column volume containing the radioactive glucose-6-phosphate was incubated with more enzyme solution, con-

* The enzyme was kindly furnished by professor O. Lindberg, Wenner-Gren Institute, Stockholm.

* The enzyme was kindly furnished by professor O. Lindberg, Wenner-Gren Institute, Stockholm.

taining glucose. $MgCl_2$ was added as before. From the hydrolysed enzyme phosphoserine was identified in the same manner as previously described.

Our present method to show that the phosphorus atom is linked to the protein molecule consists in the isolation of a phosphorylated amino acid as phosphoserine from the hydrolysed protein. It therefore seems that the transfer of phosphorus in the hexokinase system is at least a two-step reaction. The phosphorus atom is first transferred from the donator molecule to the enzyme and secondly donated from the enzyme to the acceptor. We therefore consider that our results suggest that an enzyme-phosphate is an intermediate in the hexokinase reaction. Hexokinase and phosphoglucomutase are examples of phosphoproteins functioning as transphosphorylases. It is highly possible that other phosphoprotein-enzymes may be engaged in the transfer of phosphorus in a similar way. This assumption is in line with the previously published high values for the incorporation of radioactive phosphate in the proteins from different cells [3].

An Absolute Determination of the Rate of the Exchange Reaction between Cadmium Amalgam and Cadmium Cyanide Solutions

STURE FRONÆUS

Department of Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The kinetics and mechanism of the heterogeneous exchange reaction at equilibrium electrode potential between cadmium amalgams and cadmium cyanide solutions containing sodium cyanide in excess was investigated by a radioactive tracer method in a previous work [1]. Preliminary measurements showed that the rate of exchange in this system was not controlled by the diffusion of cadmium in the solution phase, as was the case in perchlorate solutions [2] or in solutions containing cadmium complexes of moderate strength [3].

In order to attain sufficiently high accuracy in the isotopic exchange determinations, the main measurements were performed according to a procedure where the amalgam and the solution were shaken under reproducible conditions. For an activation-controlled exchange process a relationship of the following form should be obtained

$$r = k\, c^{1-\alpha}\, q^{\alpha}\, [CN^-]^{-j(1-\alpha)} \qquad (1)$$

where r denotes the rate of exchange, c the total concentration of cadmium in the solution, q the total concentration in the amalgam and k a constant. The exponent α is also a constant, fulfilling the condition $0<\alpha<1$, and j is the number of cyanide ligands in the complex that predominates in the exchange process. Actually an expression of the form (1) for r was obtained in the investigation with the values $\alpha = 0.34 \pm 0.02$ and $j = 2.2 \pm 0.1$. Thus the measurements indicated that under the existing concentration conditions the exchange reaction is activation-controlled and that the predominating reversible transfer reaction is the following one:

$$Cd(CN)_2 + 2e^-(\text{electrode}) \rightleftharpoons Cd(\text{amalgam}) + 2CN^- \qquad (2)$$

taining glucose. $MgCl_2$ was added as before. From the hydrolysed enzyme phosphoserine was identified in the same manner as previously described.

Our present method to show that the phosphorus atom is linked to the protein molecule consists in the isolation of a phosphorylated amino acid as phosphoserine from the hydrolysed protein. It therefore seems that the transfer of phosphorus in the hexokinase system is at least a two-step reaction. The phosphorus atom is first transferred from the donator molecule to the enzyme and secondly donated from the enzyme to the acceptor. We therefore consider that our results suggest that an enzyme-phosphate is an intermediate in the hexokinase reaction. Hexokinase and phosphoglucomutase are examples of phosphoproteins functioning as transphosphorylases. It is highly possible that other phosphoprotein-enzymes may be engaged in the transfer of phosphorus in a similar way. This assumption is in line with the previously published high values for the incorporation of radioactive phosphate in the proteins from different cells [3].

An Absolute Determination of the Rate of the Exchange Reaction between Cadmium Amalgam and Cadmium Cyanide Solutions

STURE FRONÆUS

Department of Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The kinetics and mechanism of the heterogeneous exchange reaction at equilibrium electrode potential between cadmium amalgams and cadmium cyanide solutions containing sodium cyanide in excess was investigated by a radioactive tracer method in a previous work [1]. Preliminary measurements showed that the rate of exchange in this system was not controlled by the diffusion of cadmium in the solution phase, as was the case in perchlorate solutions [2] or in solutions containing cadmium complexes of moderate strength [3].

In order to attain sufficiently high accuracy in the isotopic exchange determinations, the main measurements were performed according to a procedure where the amalgam and the solution were shaken under reproducible conditions. For an activation-controlled exchange process a relationship of the following form should be obtained

$$r = k\, c^{1-\alpha}\, q^{\alpha}\, [CN^-]^{-j(1-\alpha)} \qquad (1)$$

where r denotes the rate of exchange, c the total concentration of cadmium in the solution, q the total concentration in the amalgam and k a constant. The exponent α is also a constant, fulfilling the condition $0<\alpha<1$, and j is the number of cyanide ligands in the complex that predominates in the exchange process. Actually an expression of the form (1) for r was obtained in the investigation with the values $\alpha = 0.34 \pm 0.02$ and $j = 2.2 \pm 0.1$. Thus the measurements indicated that under the existing concentration conditions the exchange reaction is activation-controlled and that the predominating reversible transfer reaction is the following one:

$$Cd(CN)_2 + 2e^-(\text{electrode}) \rightleftharpoons Cd(\text{amalgam}) + 2CN^- \qquad (2)$$

Since in the present case there is no transfer of electrons through the rigid part of the electrode double layer but a transfer of cadmium ions free from all ligands, the same process can also be denoted

$$Cd(CN)_2 \rightleftharpoons Cd^{2+}(amalgam) + 2CN^- \quad (3)$$

By electrode impedance measurements, giving the exchange current density i_0 of the transfer step, Gerischer [4] also has arrived at the result that $j \approx 2$ at low values of the cyanide ion excess, though the exponent 0.25 ± 0.02 of q diverges somewhat from our α-value.

In the investigation with the radioactive tracer it was possible to keep the average area of the interface constant, as was indicated by the measurements [1], but, since it was not possible by the method used to determine this area, the value of the constant k in eqn. (1) could not be obtained. However, a comparison between the resultant rate of the exchange r and the exchange current density i_0, measured by Gerischer, is of great interest, and for this reason the present complementary investigation was performed.

The experimental procedure was the same as in the preliminary measurements of the previous investigation [1], *viz.* to let a stream of small amalgam droplets pass at a great velocity through the radioactive cadmium cyanide solution, containing sodium cyanide in excess. For a description of the apparatus used and other experimental details about the exchange measurements the reader is referred to an earlier work [2]. In another paper [3] it was shown how this apparatus was calibrated, so that the surface area of the droplets and the time of contact between the phases was known, and accordingly absolute values of the rate r were obtained.

Since the kinetic law (1) has already been verified, a determination of r for a single set of values of c, q, and $[CN^-]$ is sufficient to obtain the value of the constant k. In the experiments of the present investigation the concentrations $c = 7.0 \times 10^{-3}$ M, $q = 1.2$ M (1 % by weight) and $[CN^-] = 2.7 \times 10^{-2}$ M were used, and the ionic strength was 1 M with sodium perchlorate as an additional electrolyte. The rate of exchange measured was $r = 3.2 \times 10^{-8}$ mole cm^{-2} sec^{-1}. Thus we have

$$r = 1.5 \times 10^{-7}\, c^{0.66}\, q^{0.34}\, [CN^-]^{-0.46} \quad (4)$$

if r is expressed in mole cm^{-2} sec^{-1} and the concentrations in M. From the figures in the paper by Gerischer [4], it is found that for $c = 2 \times 10^{-3}$ M, $q = 2 \times 10^{-2}$ M, and $[CN^-] = 2 \times 10^{-2}$ M and at the ionic strength 5 M with sodium chloride as an additional electrolyte the exchange current density is $i_0 = 0.5 \times 10^{-3}$ A · cm^{-2}. If i_0 is divided by $2F$, we get the rate 0.3×10^{-8} mole · cm^{-2} · sec^{-1} of the transfer reaction (3).

Now, if the expression (4) determined refers to the same partial reaction, we can use eqn. (4) for the calculation of the rate of this step for the last-mentioned values of c, q, and $[CN^-]$, even if the tracer method would possibly have given another kinetic law for the over-all exchange reaction for such a low value of the amalgam concentration q. Then we find $r = 0.4 \times 10^{-8}$ mole · cm^{-2} · sec^{-1}. Of course, this good agreement with the value obtained from i_0 is somewhat changed for varying values of c and q, since the exponents in eqn. (4) are not exactly the same as those found by Gerischer, but in any case the two methods give the same order of magnitude of r. Thus it is conclusively proved that for the ranges of concentrations used in the previous investigation [1] the over-all exchange reaction is controlled by the charge transfer between the phases.

In a paper about the kinetics of electrode processes, Vetter [5] has discussed among other things the transfer reaction (3) above. He assumes that the two cyanide ions form a complex $(CN)_2^{2-}$ without any bond energy (in German "Begegnungskomplex" according to a notation of Weller [6]), which coordinates to the cadmium ion, leaving the amalgam. However, the assumption does not seem very plausible, especially if a corresponding conception is meant to be applicable to the transfer reaction for high values of the cyanide ion excess, where the third complex $Cd(CN)_3^-$ predominates in this step (*cf.* Gerischer [4]).

According to the opinion of the present author it may be assumed that when the "naked" cadmium ion leaves the amalgam, two cyanide ions are coordinated consecutively without an intermediate coordination of water. First after this the more loosely bound water ligands are coordinated, forming an activated, hydrated complex with the central ion in the rigid part of the electrode double layer. For the reverse process, where all ligands are split off, we may assume the same stages, occurring in the reverse order.

Thus, since no other hydrated complex of the system is formed intermediately in the charge transfer reaction, it is justifiable to say that this step proceeds by way of the hydrated complex $Cd(CN)_2$, though in all probability the ligands cannot be coordinated or split off simultaneously.

Chemically Induced Mutation and Sterility in Barley

L. EHRENBERG, Å. GUSTAFSSON, and U. LUNDQVIST

Institute for Organic Chemistry and Biochemistry, University, Stockholm; Forest Research Institute, Stockholm, and Institute of Genetics, University, Lund, Sweden

This paper gives some preliminary results from investigations concerning the induction, by chemical means, of mutations in higher plants. The experiments are complementary to treatments of the material with ionizing radiations [1], which seem rather unspecific since they always cause mutation as well as sterility, the latter effect especially at higher ion densities. A variation within wide limits of the linear energy transfer and irradiation conditions gives only small changes as regards relative frequencies of mutation types, possibly except the erectoides case [2]. It was, therefore, our hope that an application of (a) chemically reactive compounds affecting biological materials differently, and (b) biochemically active compounds interfering with processes important to the synthesis of the gene material would, apart from an elucidation of the radiation induced mutation process, increase our possibilities to direct the mutation process.

In treatments of wet tissue with "radiomimetic" chemical agents [3], also when these are specifically nucleotoxic, it is extremely difficult to establish quantitative relationships based on a dosimetry. As compared to radiations, where active ions and radicals are formed anywhere in the tissue, diffusing molecules form gradients of change from outside towards inside of the tissue, cell, or cell nucleus. To some degree such difficulties might be overcome when dry resting seeds, which are in fact very insensitive to toxic agents, are treated with gaseous reactive chemicals. The imbibition of water and, in consequence, at least part of the final steps of the reactions will then follow afterwards. In the present study barley seeds containing 10–11 % H_2O were treated with a gas phase containing ethylene oxide, iodine, or chlorine. — Non-volatile compounds have to be applied in solution. Either resting seeds, or presoaked seeds, the germination process of which had been initiated by soaking in water for 24 hours, were immersed for different times in solutions of the agents studied.

All treatments were done at 20° C. Afterwards the seeds were sown in the field, and the mature plants obtained were analysed for survival, mutation, and sterility according to standard methods (*cf.* Ehrenberg and Nybom [1]). Below, "sterility" is defined as the frequency of spikes with more than 10 % empty spikelets.

Tested compounds; results. The following subdivision as to the expected mode of action can be made (*cf.* Table 1):

(a) *Alkylating agents*, which after radicalization or ionization react with nucleophilic groups, such as amino and ionized acid groups. Effects of *mustards* have been described earlier [1,4]. — *Ethylene oxide*, earlier found mutagenic in other organisms [5,6], was in part given, for 6 days, in the gas phase with 20 % air; in this treatment seeds survive if they contain less than 10 % H_2O; partly presoaked seeds were treated for 2 hours with solutions (0.5 % kills the seeds). — *Formaldehyde*, which, attacking amino and other groups, induces methylene groups and bridges, gives according to Favret [7] mutations in barley. Under Favret's conditions, as well as in presence [6] of H_2O_2 it was found inactive, however, although some sterility appeared.

(b) *Oxidizing agents. Chlorine* (24 h, 80 % being lethal) and *iodine* (saturated vapours, 48 hour's treatment lethal, 24 h used; washing in 10 % KI has to follow treatment) might oxidize (or substitute) almost everything.

Thus, since no other hydrated complex of the system is formed intermediately in the charge transfer reaction, it is justifiable to say that this step proceeds by way of the hydrated complex $Cd(CN)_2$, though in all probability the ligands cannot be coordinated or split off simultaneously.

Chemically Induced Mutation and Sterility in Barley

L. EHRENBERG, Å. GUSTAFSSON, and U. LUNDQVIST

Institute for Organic Chemistry and Biochemistry, University, Stockholm; Forest Research Institute, Stockholm, and Institute of Genetics, University, Lund, Sweden

This paper gives some preliminary results from investigations concerning the induction, by chemical means, of mutations in higher plants. The experiments are complementary to treatments of the material with ionizing radiations [1], which seem rather unspecific since they always cause mutation as well as sterility, the latter effect especially at higher ion densities. A variation within wide limits of the linear energy transfer and irradiation conditions gives only small changes as regards relative frequencies of mutation types, possibly except the erectoides case [2]. It was, therefore, our hope that an application of (a) chemically reactive compounds affecting biological materials differently, and (b) biochemically active compounds interfering with processes important to the synthesis of the gene material would, apart from an elucidation of the radiation induced mutation process, increase our possibilities to direct the mutation process.

In treatments of wet tissue with "radiomimetic" chemical agents [3], also when these are specifically nucleotoxic, it is extremely difficult to establish quantitative relationships based on a dosimetry. As compared to radiations, where active ions and radicals are formed anywhere in the tissue, diffusing molecules form gradients of change from outside towards inside of the tissue, cell, or cell nucleus. To some degree such difficulties might be overcome when dry resting seeds, which are in fact very insensitive to toxic agents, are treated with gaseous reactive chemicals. The imbibition of water and, in consequence, at least part of the final steps of the reactions will then follow afterwards. In the present study barley seeds containing 10–11 % H_2O were treated with a gas phase containing ethylene oxide, iodine, or chlorine. — Non-volatile compounds have to be applied in solution. Either resting seeds, or presoaked seeds, the germination process of which had been initiated by soaking in water for 24 hours, were immersed for different times in solutions of the agents studied.

All treatments were done at 20° C. Afterwards the seeds were sown in the field, and the mature plants obtained were analysed for survival, mutation, and sterility according to standard methods (*cf.* Ehrenberg and Nybom [1]). Below, "sterility" is defined as the frequency of spikes with more than 10 % empty spikelets.

Tested compounds; results. The following subdivision as to the expected mode of action can be made (*cf.* Table 1):

(a) *Alkylating agents*, which after radicalization or ionization react with nucleophilic groups, such as amino and ionized acid groups. Effects of *mustards* have been described earlier [1,4]. — *Ethylene oxide*, earlier found mutagenic in other organisms [5,6], was in part given, for 6 days, in the gas phase with 20 % air; in this treatment seeds survive if they contain less than 10 % H_2O; partly presoaked seeds were treated for 2 hours with solutions (0.5 % kills the seeds). — *Formaldehyde*, which, attacking amino and other groups, induces methylene groups and bridges, gives according to Favret [7] mutations in barley. Under Favret's conditions, as well as in presence [6] of H_2O_2 it was found inactive, however, although some sterility appeared.

(b) *Oxidizing agents. Chlorine* (24 h, 80 % being lethal) and *iodine* (saturated vapours, 48 hour's treatment lethal, 24 h used; washing in 10 % KI has to follow treatment) might oxidize (or substitute) almost everything.

Table 1.

Group	Compound	Concn. %	Sterility %	Mutations %	Mutations No. of spikes analysed	Relative frequencies of chlorophyll mutation types, % *albina*	*viridis*	*xantha*	others	Total no. of cases

X-rays for comparison (1 000 r on resting seeds)		—	15	0.6	∞	51	34	6	10	∞

Sacharoff [8] found the latter compound mutagenic in *Drosophila*. — Due to the role ascribed to peroxides in radiation action, *peroxide*-containing *p-dioxan* was used (resting and presoaked seeds stand 24 h soaking in 5 % solution; 2—8 h used in experiments).

(c) *Purine derivatives* might be supposed to interfere specifically with nucleic acid metabolism. The *8-ethoxycaffeine* was found by Kihlman to break chromosomes in plant roots, the action being coupled to oxidative phosphorylation [9]. *Nebularine*, the tuberculostatic principle from *Clitocybe nebularis*, was used since it was found by Löfgren and Lüning [10] to be purine-9-D-riboside, *i. e.*, a nucleoside not occurring in nucleic acids of higher plants. — Resting or presoaked seeds were treated for 24 h with these compounds, the ethoxycaffeine at different oxygen tensions [9].

(d) In a comprehensive experiment we tested the mutagenicity of *acridines* claimed by D'Amato [11]. When applied as described by this author as well as under other conditions, *acridine orange* and *acriflavine* gave in 20 000 spike progenies only 4 mutation cases, *i. e.*, not different from the spontaneous rate.

When discussing the results (Table 1) it should be remembered that the third generation has not yet been studied. Since we are dealing with agents not tested before in barley, the induction of *Dauer*-modifications or plasmon mutations is not excluded offhand.

The experiments prove with full evidence that sterility (dependent on chromosomal rearrangements) and mutation are not induced by the same mechanism: Ethoxycaffeine gives rise to sterilities corresponding to those obtained by a treatment with up to 6 000 r, without any significant increase of the mutation frequency (at this sterility X-rays give about 4 %

chlorophyll mutations). With the reservations just expressed, the nebularine, on the other hand, gives a fairly high mutation rate without any simultaneous induction of sterility. In addition, this compound gives a distribution of mutation types (*virides* being dominating) quite different from that obtained in other treatments. It seems probable, therefore, that the application of agents disturbing the metabolism (incl. synthesis) of nucleic acids causes effects much more specific than those obtained with radiations.

The alkylating and oxidizing agents are, as expected, more unspecific, causing sterility as well as mutation. Ethylene oxide gives about the same distribution of mutation types as is obtained in X-ray experiments, whereas deviations from this distribution is indicated in other cases.

It should be added that optimum conditions for mutation induction by means of the compounds studied is not yet worked out. Therefore some series are omitted from the table. The fact that nebularine is most active at low concentrations (0.1 % which gives lower mutation frequencies, is omitted) indicates that the action of the compound is only manifested when metabolism is fairly undisturbed. Ethylene oxide, on the other hand, acts proportionally to concentration.

We are indebted to Dr. Nils Löfgren for supplying us with nebularine.

On the Use of the Senses of Taste and Smell in Determining the End Point of an Acid-Base Titration

E. RANCKE-MADSEN and J. A. KROGH

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

While the sense of taste is hardly applicable to the fixation of the end point of a titration, the examination reported in the following shows that the sense of smell is quite applicable. Five different smell indicators are mentioned: Sodium butyrate, sodium sulphide, quinoline, pyridine, and ammonium chloride, the first four of which are applicable in the strong acid/strong base titration with an uncertainty on the single determination of 0.2 % or less.

The recognition of the end point of a titration is based either on a visual impression or on a measurement of a physical quantity which is altered at or in the neighbourhood of the equivalence point. In the former case use is made of the sense of sight, but the question forces itself on one as to whether other senses could be used. In ancient chemistry the senses of taste and smell were used as much as possible; in the 18th century it was customary to use the taste of a substance — among other criteria — as a qualitative test, and also the smell of the substance was observed whenever possible.

Also when neutralizing with preparative purposes the sense of taste was used. By way of example may be quoted de Lassone [1], who wished to prepare ammonium acetate: "Lorsque par le mélange successif de l'esprit acéteux et de l'alkali volatile, on est parvenu à une saturation exacte et complète, ce que la saveur et les autres indices font reconnoître."

However, the estimation of the sense of taste as a chemical help decreased, and the use of it became extinct. Thus already Bergmann (quoted from Tabor's German translation of Bergmann's Latin text) [2] wrote as follows in "Meditationen über das System der Fossilien":

"*Geschmack.* Dieser hängt von der Empfindlichkeit der Zunge ab, und ist, wie die Erfahrung lehret, sehr verschieden, denn was bey dem einen die Nerven=Wärzgen mercklich reizet, reizet sie bey einem andern nicht. Man kann also auf diese Eigenschaft nur sehr wenig bauen."

In 1898, however, Richards [3] made the question of the possible applicability of the sense of taste in titrations the subject of a debate. He found

that the taste of a 0.001 N strong acid can be recognized, and that it should therefore be possible to fix the end point of a strong acid/strong base titration with an accuracy of 1—2 %. He reported a few experiments with still better results (greatest deviation 0.9 %).

We have tested the strong acid/strong base titration (25 ml 0.1 M hydrochloric acid with 0.1 M sodium hydroxide and *vice versa*) and found that it is not possible with any certainty to taste the difference between solutions with pH between just under 3 and just under 11 (*i. e.* that OH^- can be tasted in a little lower concentration than H_3O^+). We did find that the end point in such a titration cannot be fixed by means of the sense of taste with deviation of less than 2 or 3 %. Even though individual differences are attached to the sense of taste, it can be established that the taste cannot with any reasonable accuracy be used in this way as indication in the strong acid/strong base titration.

As, for various reasons, any method based upon the taste must be inadequate, we have not wished to continue working in this direction. We may add only that the sole possibility of obtaining results of any reasonable accuracy by means of the sense of taste will probably be to add a taste indicator, *i. e.* a weak acid-base system, in which the weak acid has a different taste from that of the corresponding weak base.

As to the use of the sense of smell in titrations an article on this subject was written in 1913 by Sacher [4]. He titrated *iso*valeric acid with an excess of sodium hydroxide and titrated back with hydrochloric acid, since the appearance of the smell of *iso*valeric acid is more easily recognizable than the disappearance. He further titrated ammonia with hydrochloric acid until the disappearance of the smell of ammonia. He also tried to titrate acetic acid and phenol. In all cases he obtained results that group themselves around the theoretical results, but with rather great deviations (up to 6 %).

We are of the opinion, however, that if the sense of smell has to be used in connection with a titration, it must be done by adding to the titration system a smell indicator, which in an acid-base titration should be a weak acid-base system in which the weak acid has a different smell from that of the corresponding weak base.

As indicators of this type the following substances have been examined: 1) Sodium butyrate, 2) sodium sulphide, 3) quinoline, 4) pyridine, and 5) ammonium chloride. Of all five indicators a weak acid-base system can be made, one component of which is odourless, and the other has a characteristic smell. In all experiments mentioned in the following, titrations were carried out until the appearance of a smell.

0.1 M sodium hydroxide, free from carbon dioxide, was used in the experiments, and the solution was standardized against hydrazine sulphate. Further 0.1 M hydrochloric acid was used (the same hydrochloric acid in the experiments in connection with the first two indicators and a different hydrochloric acid in connection with the last three indicators). *Ca.* 25 ml titrand was used and to this was added 21—22 ml titrator. It was not till then that the indicator was added, and titration was made by dropwise addition of titrator.

1) *Indicator 0.01 M sodium butyrate* ($pK_s = 4.8$ for butyric acid). Titrand NaOH; titrator HCl. The molarity of the hydrochloric acid was found to be

Table 1. Determination of the molarity of a hydrochloric acid by means of titration of standard sodium hydroxide and with a 0.01 M sodium butyrate as smell indicator.

Expt. series	Number of expts.	Quantity of indicator ml	Molarity of HCl (found)	Greatest deviation from mean value	Uncertainty in % on single determination	Uncertainty in % on mean value
I	10	0.10	0.1002	0.0005	0.3	0.10
II	10	0.10	0.1001	0.0005	0.4	0.13
III	10	0.05	0.1002	0.0005	(0.3)	(0.11)
IV	10	0.10	0.10020	0.0003	0.2	0.07

0.10046, if methyl red was used as indicator. (Mean value of 10 determinations; greatest deviation from mean value 0.00010; uncertainty on a single determination 0.07 %; uncertainty on the mean value 0.02 %.)

The results are given in Table 1. In series I a smelling liquid was used for comparison, whereas the other series of experiments were performed without such a liquid. In series III, three of the experiments were unsuccessful owing to the small quantity of indicator; the calculations of uncertainty were carried out for the remaining 7 experiments. Series IV was carried through exactly as No. II, and it is seen that training in the recognition of the smell of butyric acid may increase the accuracy.

Besides, the butyric acid was found to be easily liberated by local excess of a strong acid, which fact may lead to a wrong estimation of the end point; the hydrochloric acid should therefore be added carefully and the addition be accompanied by vigorous shaking.

Conclusion: After some training in the use of the method, 0.10 ml 0.01 M sodium butyrate can be used as a smell indicator in the titration of strong acid/strong base; uncertainty on a single determination *ca.* 0.2 %.

2) *Indicator 0.01 M sodium sulphide* ($pK_s = 7.2$ for hydrogen sulphide). Titrand NaOH; titrator HCl. The molarity of the hydrochloric acid was found to be 0.10068 when bromothymol blue (6.0—7.6 in pH) was used as the indicator. (Mean value of 10 determinations; greatest deviation from mean value 0.00011; uncertainty on a single determination 0.06 %; uncertainty on the mean value 0.02 %.)

The results are given in Table 2. In series I and III, but not in series II and IV, a smelling liquid was used for comparison. It is seen that this comparison liquid is unnecessary. Liberation of hydrogen sulphide in connection

Table 2. Determination of the molarity of a hydrochloric acid by means of titration of standard sodium hydroxide and with a 0.01 M sodium sulphide as smell indicator.

Expt. series	Number of expts.	Quantity of indicator ml	Molarity of HCl (found)	Greatest deviation from mean value	Uncertainty in % on single determination	Uncertainty in % on mean value
I	6	0.10	0.10068	0.00023	0.15	0.06
II	6	0.10	0.10074	0.00025	0.15	0.06
III	6	0.05	0.10079	0.00018	0.15	0.06
IV	6	0.05	0.10077	0.00019	0.14	0.06

Table 3. Determination of the molarity of a hydrochloric acid by means of titration with standard sodium hydroxide and with a 0.01 M quinoline as smell indicator.

Expt. series	Number of expts.	Quantity of indicator ml	Molarity of HCl (found)	Greatest deviation from mean value	Uncertainty in % on single determination	Uncertainty in % on mean value
I	6	0.10	0.1002	0.0004	0.29	0.12
II	6	0.10	0.1002	0.0002	0.19	0.08
III	6	0.20	0.10023	0.00030	0.20	0.08
IV	6	0.20	0.10029	0.00018	0.14	0.06

with local excess of acid during the titration did not take place to any disturbing degree — in contradistinction to what was the case with butyric acid.

Conclusion: Without special training sodium sulphide can be used as a smell indicator in the titration of a strong acid/strong base; uncertainty on a single determination *ca.* 0.15 %.

3) *Indicator 0.01 M quinoline* dissolved in 20 % ethanol ($pK_s = 4.9$ for quinolinium ion). Titrand HCl; titrator NaOH. The results are given in Table 3. A smelling liquid was used for comparison in series I and III, but not in

Table 4. Determination of the molarity of a hydrochloric acid by means of titration with standard sodium hydroxide and with a 0.01 M pyridine as smell indicator.

Expt. series	Number of expts.	Quantity of indicator ml	Molarity of HCl (found)	Greatest deviation from mean value	Uncertainty in % on single determination	Uncertainty in % on mean value
I	6	0.10	0.10019	0.00019	0.14	0.06
II	6	0.10	0.10039	0.00028	0.14	0.06
III	6	0.20	0.10021	0.00025	0.13	0.05
IV	6	0.20	0.10029	0.00023	0.15	0.06

series II and IV; it is seen that this liquid is unnecessary. Liberation of quinoline in local excess of base during the titration did not take place to any disturbing degree. About one half of the experiments with addition of only 0.05 ml 0.01 M quinoline were unsuccessful.

In the titrated solutions pH (electrometrically found) was 6.1 on an average; the deviations from the mean value of pH corresponded well to the deviations of the results from the mean value of these.

Conclusions: Quinoline is quite applicable as a smell indicator in the titration of strong acid/strong base; uncertainty on a single determination *ca.* 0.2 %.

4) *Indicator 0.01 M pyridine* dissolved in water ($pK_s = 5.2$ for pyridinium ion). Titrand HCl; titrator NaOH. The results are given in Table 4. In series I and III a comparison smelling liquid was used; it is seen that this liquid is superfluous. The sense of smell appears to be somewhat dulled by pyridine if the experiments are carried out one immediately after the other. In the experiments reported here the titrations were performed with intervals of about 7 minutes. Eight out of ten experiments with addition of only 0.05 ml 0.01 M pyridine were unsuccessful. In the titrated solutions pH was 6.9 on an average.

Table 5. Determination of the molarity of a hydrochloric acid by means of titration with standard sodium hydroxide and with a 0.01 M ammonium chloride as smell indicator.

Expt. series	Number of expts.	Quantity of indicator ml	Molarity of HCl (found)	Greatest deviation from mean value	Uncertainty in % on single determination	Uncertainty in % on mean value
I	6	0.20	0.1007	0.0001	0.10	0.04
II	6	0.20	0.1012	0.0006	0.49	0.20

Conclusion: Pyridine is quite applicable as a smell indicator in the titration of strong acid/strong base; uncertainty on a single determination *ca.* 0.15 %.

5) *Indicator 0.01 M ammonium chloride* ($pK_s = 9.3$ for ammonium ion). Titrand HCl; titrator NaOH. The results of the experiments are shown in Table 5. In series I a comparison smelling liquid was used, which was not the case in series II. The comparison liquid is useful here, but the sense of smell should be accustomed beforehand to the smell of ammonia. A smaller quantity than 0.20 ml 0.01 M NH_4Cl could not be used; with 0.10 ml most of the experiments were unsuccessful. In the titrated solutions pH was 10.0 on an average.

Conclusion: Ammonium chloride can be used as a smell indicator, even though its applicability does not come up to that of the indicators mentioned above.

Consequently, it is possible to carry out acid-base titrations using smell indicators. In the titration of weak acids or bases an indicator system with a suitable pK_s should be used. The titrations can be carried out in coloured solutions and require here no special apparatus (as *e. g.* ultraviolet radiation when using fluorescence indicators, conductance cells, *etc.*).

Complexes of the 4d- and 5d-Groups

I. Crystal Field Spectra of Rhodium(III) and Iridium(III)

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

In octahedral complexes with six d-electrons and singlet (*i. e.* diamagnetic) ground state, the crystal field theory predicts transitions to two singlet and two triplet levels. Several authors have studied the case of cobalt(III), and in this paper the four bands are found in rhodium(III) and iridium(III) complexes, *e. g.* with six bromide or chloride ligands. The slow aquation of these complexes in HCl and $HClO_4$ is studied, and rhodium(III) aquo ions prepared in $HClO_4$. The solutions of $Rh(OH)_3$ in acids show a high ultraviolet absorption, which disappears slowly, presumably owing to acidolysis of polymer hydroxo complexes. The hexammine and nitro-, iodo-, bromo-, chloro-, hydroxo-, and aquo-pentammine rhodium complexes of S. M. Jørgensen and the oxalato and ethylenediamine complexes exhibit the shifts predicted from the spectrochemical series, as also $Ir(NH_3)_5Cl^{++}$ and $Ir\ en_3^{+++}$. The relative intensities of singlet and triplet transitions are explained by the deviations from the Russell-Saunders coupling, which are important in the heavy atoms. Later papers of the series will discuss why the concept of molecular orbitals is compatible with the approximate validity of the electrostatic model using $(E_1 - E_2)$ as empirical parameter.

Nearly all the applications of the crystal field theory [1–17] to the absorption spectra of the complexes with partly filled d-shells have concerned the first transition group with 3d-electrons. The $4d^3$-system molybdenum(III) in $MoCl_6^{---}$ was investigated by Schmidt [18] who found that the energy differences in the 4d-case are *inter alia* larger than in the 3d-case. Similar conclusions were drawn by Orgel [13] from qualitative observations of the colours of the platinum group complexes, compared to cobalt(III). In the present paper the complexes of rhodium(III) and iridium(III) will be compared to the diamagnetic cobalt(III) complexes, which are all regularly octahedral. The ground state [6, 9–11] is ${}^1\Gamma_1$ from the closed shell configuration γ_5^6, and the next electron distribution $\gamma_5^5\gamma_3$ has the four levels ${}^3\Gamma_4$, ${}^3\Gamma_5$, ${}^1\Gamma_4$ and ${}^1\Gamma_5$. All authors agree that the two relatively strong bands with $\varepsilon \sim 100$ are due to the transitions to ${}^1\Gamma_4$ and ${}^1\Gamma_5$. It is not yet certain which of the bands corresponds to ${}^1\Gamma_4$, but the theory of Tanabe and Sugano [10] with pure 3d-configura-

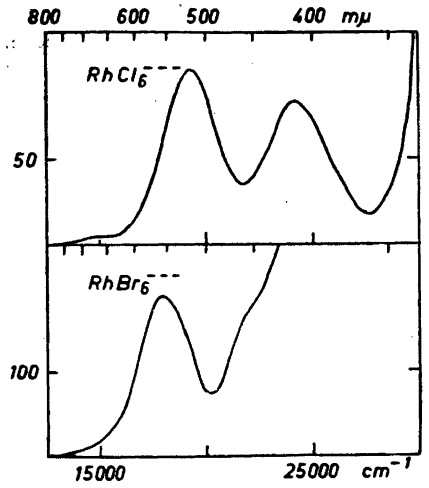

Fig. 1. Absorption spectra of hexachloro- and hexabromo-rhodium (III) ions.

From 0.01 M to 0.3 M Na_3RhCl_6 in 4 M HCl and H_2O, immediately measured. 0.01 M $RhBr_6^{---}$ in 4M HBr.

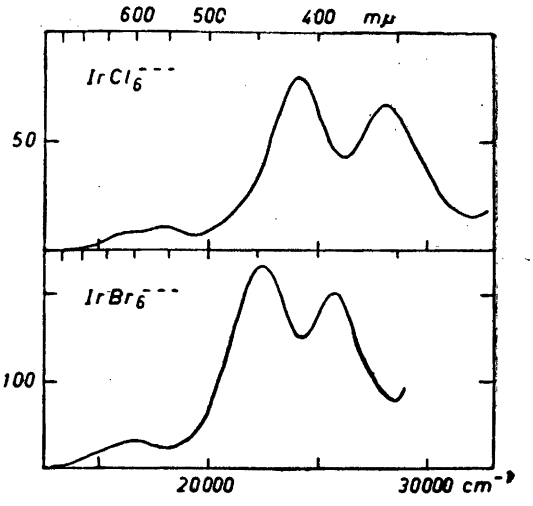

Fig. 2. Absorption spectra of hexachloro- and hexabromo-iridium (III) ions.

From 0.01 M to 0.1 M K_3IrCl_6 in 4 M HCl and H_2O, immediately measured. 0.005 M to 0.015 M $IrBr_6^{---}$ in 4 M HBr.

tions imply that it is the band with lowest wavenumber. The present author [8] and Kondo [10] have found a weak band with $\varepsilon \sim 0.4$ of $Co(NH_3)_6^{+3}$ and $Co\,en_3^{+3}$ in the far red. This must be due to either $^3T_4$ (which has the lowest energy [10]) or $^3T_5$. This band is found here with relatively higher intensity in rhodium(III) and iridium(III) complexes.

HEXACHLORO- AND HEXABROMO-COMPLEXES

Fig. 1 gives the absorption spectra of $RhCl_6^{---}$ and $RhBr_6^{---}$, and Fig. 2 those of $IrCl_6^{---}$ and $IrBr_6^{---}$, while Tables 1 and 2 give the wavenumbers, wavelengths, and molar extinction coefficients of the maxima [19] and the half-widths and oscillator strengths of the bands [16, 19].

Samuel and Uddin [20] have measured $RhCl_6^{---}$ in H_2O (partly aquated, with maxima at 503 and 393 mμ), in a saturated solution of NaCl (at 520 and 409 mμ, nearly as here) and in saturated KBr (at 540 and 420 mμ) probably transformed into bromo complexes. Babaeva [21] has found maxima at 499 and 390 mμ of $RhCl_6^{---}$ and at 480, 418 and 359 mμ of $IrCl_6^{---}$. The first complex must be aquated, while the second is slightly oxidized. As discussed in the next paper of this series, $IrCl_6^{--}$ has 40 times higher bands than $IrCl_6^{---}$. Inamura and Kondo [22] have measured $IrCl_6^{---}$ and several other iridium(III) complexes.

It is seen from Figs. 1 and 2 that the second band is lower than the first in all four complexes. According to C. E. Schäffer of this laboratory, similar be-

haviour is found for nearly all chromium(III) and cobalt(III) complexes except the aquo ions and a few others. The small, spin-forbidden bands are discussed below in a special section. In the tables, the two transitions to the triplet levels are denoted a and b, while the stronger transitions to singlet levels are denoted c and d with increasing wavenumber.

THE AQUATION OF HEXACHLORO-COMPLEXES

It has been known for many years that rhodium(III) occurs in brownish-red and orange complexes containing less chloride than the raspberry-red $RhCl_6^{---}$. Thus, Meyer and Kawczyk [22] recognized the non-ionized red $RhCl_3(H_2O)_3$ and the yellow ion $Rh(H_2O)_6^{+++}$ in solutions of $Rh(OH)_3$ in HCl, and these authors stressed the analogy with the chromium complexes $Cr(H_2O)_6^{+++}$, $CrCl(H_2O)_5^{++}$, and $CrCl_2(H_2O)_4^{+}$ investigated by N. Bjerrum [24]. Delépine [25, 26] studied the reversible transformations of $RhCl_6^{---}$ to $RhCl_5(H_2O)^{--}$ and $IrCl_6^{---}$ to $IrCl_5(H_2O)^{--}$.

The chloro complexes of the platinum metals are often assumed to have high formation constants [27]. Even if they are robust, *i. e.* their reaction velocities are very low, they seem to have rather small formation constants, at least for the last chloride ligands. The latter effect is partly due to statistical reasons and to the electrostatic part of the residual effect [28].

Table 3 gives the wavelengths of the maxima, as well as points with half the maximum value of ε, and minima of the absorption spectra of $RhCl_6^{---}$ in 1 M HCl and 1 M $HClO_4$ as function of time at room temperature 18 ± 2° C. It is seen that the two absorption bands move towards shorter wavelengths, corresponding to the exchange of chloride with water. In 1 M HCl, a steady state seems to be reached within some weeks, while the reaction continues in 1 M $HClO_4$ where the total chloride concentration is due only to the original

0.018 M Na_3RhCl_6. In 6 M HCl, there seems to be no change in a month, and a stock solution in 4 M HCl, which has been stored for nine months, is not more aquated than the solution in 1 M HCl after 3 minutes. The reciprocal process of $Rh(OH)_3$ dissolved in 1 M HCl is extremely slow at room temperature, and even by boiling with 4 M HCl the colour is only changed from yellow to orange after 10 minutes.

It is seen from Table 3 that by the aquation the second maximum increased strongly, while the first is somewhat decreased. It is interesting to note that the halfwidths of the bands are not greatly increased. Generally, a mixture of several complexes tends to have higher halfwidths, *i. e.* the bands are blurred out. In this particular case, the reaction rates for expelling chloride ions, k_{-6}, k_{-5}, ... seem to be highly decreasing with decreasing number of chloride ligands at constant pH. Thus, the system may contain mainly two complexes at the same time, as it gives not so levelled a spectrum as a mixture of many components. Definite maxima of $RhCl_n(H_2O)_{6-n}^{3-n}$, have not yet been assigned but if the maxima are a linear function of n, *e. g.* their wavenumber

$$\nu = \frac{n}{6}\nu(RhCl_6^{---}) + \frac{6-n}{6}\nu(Rh(H_2O)_6^{+++}) \qquad (1)$$

then the steady state obtained in 1 M HCl corresponds to $n \doteq 4.4$ from the first band and 4.5 from the second, while the state in 1 M $HClO_4$ after four weeks corresponds to $n = 3.5$ and 3.7.

Sundram and Sandell [29] have shown that the four first consecutive formation constants of palladium(II) with Cl^- are higher than 500, while the fifth and sixth constants are about 1. Palladium(II) is strongly tetragonal [12] analogously to Cu(II) and has probably anomalously high constants for the four first ligands, while the next two should be much more loosely bound. In the regular octahedral Rh(III), the constants were expected to be more nearly equal, but owing to the higher external charge, higher affinity for halide ions would be predicted than for Pd(II). However, the sixth formation constant in the rhodium(III)-chloride system cannot be larger than 0.5. The enhanced stability of $RhCl_6^{---}$ in stronger HCl can be ascribed to the activity conditions in this medium [30]. Mr. C. E. Schäffer has kindly pointed out to me that the crystal field stabilization [12] is negative for anion complexes with less crystal field strength than the aquo ions. Thus, each of the six consecutive

formation constants of $RhCl_6^{---}$ should be decreased by a factor 10^5 of this cause. However, this large effect is probably somewhat counter-acted by intermixing of other molecular orbitals than the 4d-electrons, *viz.* the 5s- and 5p-orbitals.

Table 4 shows that $IrCl_6^{---}$ is also slightly aquated in 1 M HCl or 1 M $HClO_4$ during some weeks. In stronger HCl, the ion is either stable or much more slowly reacting. In 10 M HCl, a 0.013 M K_3IrCl_6 was changed in five days from the pale olive-green colour to brownish red. This was due to oxidation to $IrCl_6^{--}$, the spectrum of which demonstrated the presence of 0.0001 M. As discussed in the experimental section, ascorbic acid reduces momentaneously iridium(IV). The intensity of the second band of $IrCl_6^{---}$ increases also during the aquation, but here the formation of hydroxo complexes cannot be excluded as easily as in the case of rhodium(III). Delépine [25] described the curious change of visible colour of $IrCl_6^{---}$ with increasing concentration: from lemon yellow over olive-green and reddish brown to black. The spectra were measured of several concentrated solutions in H_2O, which are only slowly aquating. $IrCl_5(H_2O)^{--}$ is more brownish yellow [25]. A similar effect of the sensitivity of the eye is observed with $RhBr_6^{---}$, which changes from greyish green to cherry red by increasing concentration or by use of tungsten light in the place of daylight. Two or more absorption bands of different intensity or with nearly complementary colours produce this type of dichroism.

THE HYDROXO AND AQUO COMPLEXES OF RHODIUM(III)

Analogously to the behaviour [31] of chromium(III), the exchange reactions of rhodium(III) complexes are highly catalyzed by hydroxyl ions.* Thus, $RhCl_6^{---}$ and the other chloro complexes form purple intermediates and after some minutes a yellow precipitate of $Rh(OH)_3$. This precipitate is weakly amphoteric and dissolves in NaOH with pale yellow colour. The weaker base $BaCO_3$ precipitates $Rh(OH)_3$ quantitatively by boiling.

Moderately strong acids dissolve the hydroxide to yellow solutions, which can be assumed to contain the hexaaquo ion. Fig. 3 shows a titration curve of a 0.01 M Rh(III) in 1 M $NaClO_4$ with NaOH and $HClO_4$. This preliminary experiment shows that pH is a reversible function of added and consumed amounts of hydrogen ions per Rh. The hydroxide is seen to be soluble in one equivalent of hydrogen ions, as also found by Grube and Kesting [32]. The pK for this process is 5.0, and the acid product formed must be $Rh(OH)_2(H_2O)_4^+$ or some polymer with lower content of water. It cannot be seen from the curve whether the di-hydroxo complex takes up further hydrogen ions **, but in any case pK is less than 2.5.

Thus, it is useful to study the absorption spectra of rhodium hydroxide, dissolved in 0.01 M—10 M $HClO_4$. A solution of 0.015 M Rh in 0.06 M $HClO_4$

* However, preliminary experiments seem to show that the aquation of $RhCl_6^{---}$ has the same velocity in 0.1 M as in 1 M HCl.

** The hexaaquo ion does not seem to be a very strong acid, since the aqueous solution of $CsRh(SO_4)_2$, 12 H_2O is only weakly acidic, according to Krauss and Umbach[62]. The electric conductance of the hexaaquo ion is of the same magnitude [23] as that of $Cr(H_2O)_6^{+++}$.

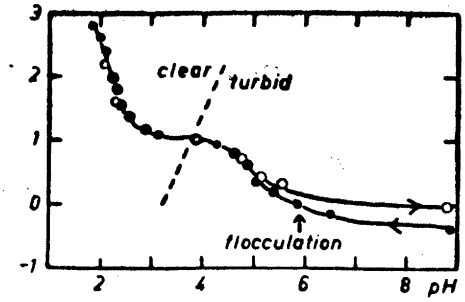

Fig. 3. Titration curve of rhodium (III) hydroxide in 1 M $NaClO_4$ at 20° C. 0.01 M Rh.

pH as function of added hydrogen ions (or consumed hydroxyl ions) per rhodium atom. Empty circles titration from acid range with NaOH and filled circles titration from alkaline range with $HClO_4$. Turbidity appears at pH over 3.8 and disappears below this value, marked on the figure.

was measured and $HClO_4$ added in small quantities until a concentration of 0.4 M was reached. Fig. 4 gives the nearly identical absorption spectra of these two solutions. This might have been an argument for the two first pK-values of $Rh(H_2O)_6^{+++}$ being less than 0.3. But when the spectrum was measured two days later (the original operations lasted two hours), the high absorption in the near ultraviolet was somewhat decreased, and much more so after 12 days. As seen in Fig. 4, a similar preparation from $BaCO_3$ + $Rh(OH)_3$ exhibited similar properties. Since the reactions between monomeric hydroxo complexes and hydrogen ions presumably are very fast, the high absorption below 400 mμ is probably due to a hydroxo complex with at least two rhodium atoms. This can be compared with the dimeric $Fe(OH)_2Fe^{+4}$ found by Mulay and Selwood [33], which also has a strong electron transfer spectrum at lower wavenumbers than $FeOH(H_2O)_5^{++}$. Many rhodium(III) complexes have electron transfer spectra below 300 mμ, *e. g.* $RhCl_6^{---}$ has a shoulder at 242 mμ with $\varepsilon \sim 14\,000$ (it is decreased to 7 000 at 270 mμ). In strongly alkaline solution, the polymer hydroxo complexes seem to disappear — two bands of ordinary intensity are observed at 415 and 326 mμ.

The high absorption in the ultraviolet of hydroxo complexes can hardly be due to higher oxidation states of rhodium, since ascorbic acid has no influence, except reducing a trace of iridium(IV) with absorption at 480 mμ. If rhodium (III) is oxidized in alkaline solution, blue solutions of Rh(VI) and green of Rh(IV) can be obtained, as studied by Grube and Autenrieth [34]. The present author has measured the green solution in 1 M $HClO_4$ and found a broad absorption band around 770 mμ. *Cf.* the measurements by Ayres [64].

If the solution in 0.4 M $HClO_4$ mentioned above is added to stronger $HClO_4$, only small changes are observed, but the strong absorption limit decreases faster in 5 M $HClO_4$. If the solutions are boiled, the second crystal field band appears as a shoulder ~320 mμ. The best way found to eliminate the polymers is to boil Na_3RhCl_6, 12 H_2O with 5 M $HClO_4$ for half an hour. The hydrochloric acid is evaporated, and the yellow solution exhibits two distinct

Curve 6. 0.015 M Rh in 1 M $HClO_4$, from Na_3RhCl_6 boiled with $HClO_4$.

crystal field bands at 393 and ~305 mμ (Fig. 4) when diluted to 1 M $HClO_4$. It is highly probable that these maxima correspond to $Rh(H_2O)_6^{+++}$. The half-width of the first band is not very large, and the position in the spectrochemical series is that predicted (Table 1) as compared to $Rhox_3^{---}$ with the maximum at 398 mμ; and the sulphato complexes (prepared from metal and $HNO_3 + H_2SO_4$ boiled nearly down) with maximum at 401 mμ and a shoulder ~320 mμ.

It has not been possible by similar methods to find the crystal field bands of $Ir(H_2O)_6^{+++}$, which most likely is a strong acid. If K_3IrCl_6 is boiled with $HClO_4$, black-red K_2IrCl_6 precipitates at first, owing to oxidation. It redissolves with bluish purple colour, which does not change by dilution of the cooled solution to 1 M $HClO_4$. This can be reduced by ascorbic acid, except for small precipitate of blue IrO_2, to a straw-yellow solution. This solution has only steeply increasing absorption in ultraviolet, as $Irox_3^{---}$ discussed below. Marino [35] prepared alums of iridium(III) and found yellow crystals and solutions. These are oxidizable by air to a purple colour, but can be reduced with H_2S. This reagent precipitates the solution in 1 M $HClO_4$ mentioned above.

TRIS(OXALATO) COMPLEXES

The orange $Rhox_3^{---}$ and the yellow $Irox_3^{---}$ have been much studied, owing to their optical activity and extreme robustness. Lifschitz and Rosenbohm [36] found that $Rhox_3^{---}$ has a low band at 25 000 and a higher band at 35 000 cm^{-1}.

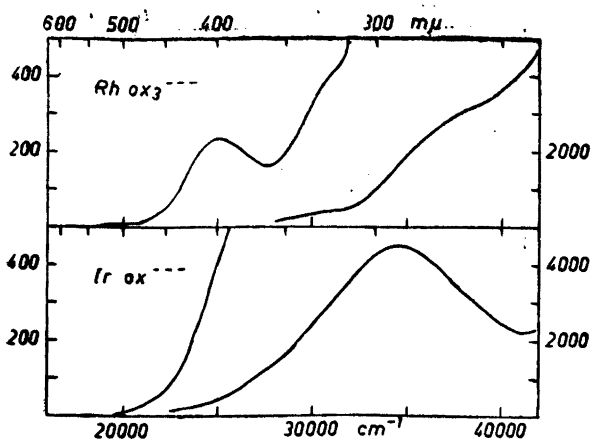

Fig. 5. Absorption spectra of tris-oxalato complexes of rhodium (III) and iridium (III).

0.1 M $Rhox_3^{---}$ in 0.6 M K_3ox, warmed at 100° C for 4 hours, and subsequently diluted. 0.01 M $Irox_3^{---}$ from similar method, and 0.0005 M to 0.02 M K_3Irox_3 from Professor Marcel Delépine.

Fig. 5 shows that the first band is the first crystal field band, while the other is a strong electron transfer band, as expected of an oxalato complex. The second crystal field band can be seen as a shoulder on the red side of this band. Delépine [37] has described the extremely slow reactions of $IrCl_6^{---}$ with one, two, and three oxalate ions. The third consecutive reaction takes ten hours at 130° C. Fig. 5 gives the spectrum of a solution which contains mainly $Irox_3^{---}$. It has also high absorption in the ultraviolet, but a shoulder can be observed at 360 mμ. This is a very reasonable place for the first crystal field band estimated from the value for $Rhox_3^{---}$ and the hypsochromy of iridium(III) complexes compared to rhodium(III).

HEXAMMINE AND PENTAMMINE COMPLEXES

S. M. Jørgensen [38] found an analogy to the chromium(III) and cobalt(III) ammine complexes in the rhodium(III) complexes, and prepared the hexammine and iodo-, bromo-, chloro-, and nitro-pentammine complexes used for this study. Palmær [39] studied the similar iridium(III) complexes, of which only $IrCl(NH_3)_5^{++}$ is examined here. The aquopentammine rhodium(III) salt, which with base gives the hydroxopentammine ion, was made from one of S. M. Jørgensen's preparations as a perchlorate by Brønsted and Volqvartz [40]. These authors found $pK = 6.3$.

Fig. 6 gives the spectra of the rhodium(III) complexes. The hexammine is remarkable by its very deep minimum at 220 mμ, which shows the absence of both an electron transfer spectrum and of impurities. The two high bands resemble very much the spectrum of $Co(NH_3)_6^{+++}$, displaced towards higher wavenumbers, and the first band is highest as in $RhCl_6^{---}$.

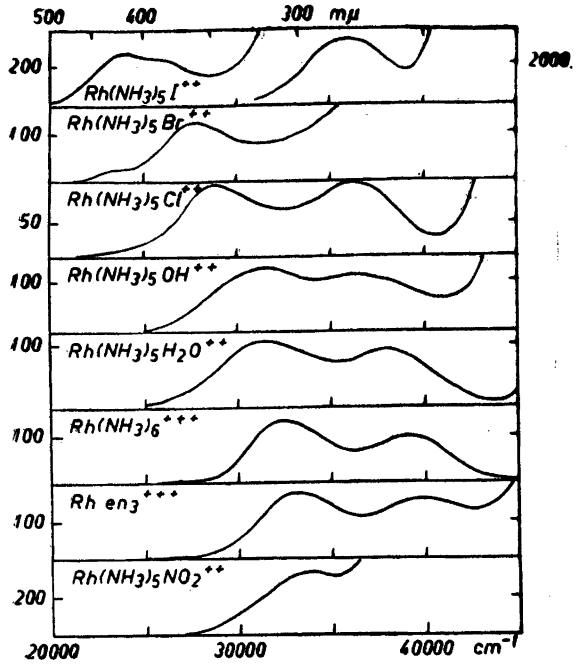

Fig. 6. Absorption spectra of hexammine and pentammine complexes of rhodium (III).

0.001 M to 0.01 M $[Rh(NH_3)_5I]Cl_2$ in H_2O.
0.01 M $[Rh(NH_3)_5Br]Br_2$ in H_2O.
0.01 M $[Rh(NH_3)_5Cl]Cl_2$ in H_2O.
0.01 M $[Rh(NH_3)_5H_2O](ClO_4)_3$ in 0.1 M Na_2CO_3 (forming $Rh(NH_3)_5OH^{++}$) and in 0.05 M $HClO_4$.
0.01 M $[Rh(NH_3)_6]Cl_3$ in H_2O.
0.008 M $Rh\ en_3^{+++}$ in 0.1 M en.
0.003 M $[Rh(NH_3)_5NO_2]Cl_2$ and 0.06 M $[Rh(NH_3)_5NO_2](NO_3)_2$ in H_2O.

$Rh(NH_3)_5H_2O^{+++}$ shows the same displacement towards lower wavenumbers as all "roseo" salts, compared to "luteo" salts, and $Rh(NH_3)_5OH^{++}$ has a smaller distance between the two bands, as usually found. The halidopentammine complexes were expected to have tetragonal splittings, since the two ligands are so distant in the spectrochemical series [14]. It cannot be excluded that the first band of $RhCl(NH_3)_5^{++}$ is slightly split by tetragonal field effects, producing the flat minimum between the two bands as in $Rh(NH_3)_5OH^{++}$. The second band is masked by the electron transfer spectrum in $RhBr(NH_3)_5^{++}$ and $RhI(NH_3)_5^{++}$. In the former ion, a weak shoulder is observed on the red side of the first band, while the shoulder is larger on the blue side in the latter case. The band in the bromo complex is presumably one of the triplet transitions which are intermixed with the strong singlet transitions [16]. If the double band in the iodo complex is not due to a similar intermixing, it is a

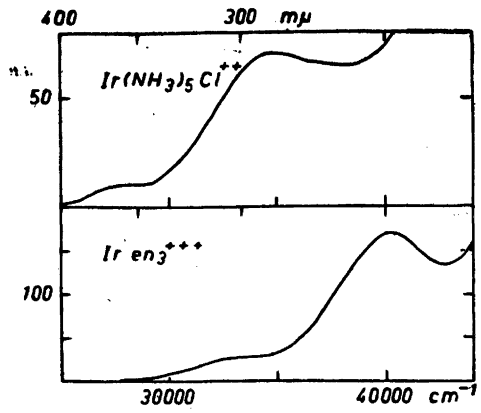

Fig. 7. Absorption spectra of chloropentammine- and tris(ethylenediamine)iridium (III) ions.

0.015 M $[Ir(NH_3)_5Cl]Cl_2$ and 0.004 M $[Iren_3]Br_3$, $2H_2O$ in H_2O, from J.-P. Mathieu's preparations.

genuine tetragonal splitting. But the theory for this splitting [4, 7, 14, 17] is not easy to correlate with the observations.

The ammine complexes of rhodium(III) are exceedingly robust, as shown by Christiansen and Asmussen [41], who in nearly all cases found the salts prepared fifty years before by S. M. Jørgensen undecomposed. The halide ions in the pentammine complexes exchange very slowly with water and even with hydroxyl ions, as found to a higher degree for iridium(III) pentammines by Palmær [39] and Lamb and Fairhall [42].

It has been assumed by Grünberg [43] that $Rh(NH_3)_6^{+++}$ is a weak acid with $pK \sim 11.2$, forming the amidopentammine complex $Rh(NH_2)(NH_3)_5^{++}$. The present author has measured $Rh(NH_3)_6^{+++}$ in 5 M and 1 M NaOH and $Rh\ en_3^{++}$ and $Rh(NH_3)_5OH^{++}$ in 1 M NaOH and found no observable deviation from the ordinary spectrum; especially are the band maxima displaced less than 1 mμ. Since the amido complexes presumably would be displaced much more towards the red, the pK for their formation seems to be > 15, *i. e.* they are not formed to a high degree in any aqueous solution. There is evidence [44] from reaction kinetics that the base hydrolysis of cobalt(III) complexes proceeds by an acid-base equilibrium followed by dissociation of the amido complex.

In the third paper of this series, which will concern the complexes prepared by M. Delépine, it will be shown that the base [45] assumed to be $Ir(NH_2)(NH_3)_3py_2^{++}$ has the same pK, *viz.* 5.1, as $Ir(OH)(NH_3)_3py_2^{++}$ and thus probably does not have the presumed composition. Thus, Rh(III) and Ir(III) do not seem to exhibit amine acidity in aqueous solution contrary to Pt(IV) discussed in the second paper of this series.

In Figure 7, $Ir(NH_3)_5Cl^{++}$ exhibits a rather narrow and weak band at 360 mμ, which can be ascribed to the first transition to a triplet level, while the second band at 286 mμ is due to the first excited singlet level with some

evidence for tetragonal splitting. These two positions are displaced toward shorter wavelengths compared to $Rh(NH_3)_5Cl^{++}$ as can be extrapolated from the behaviour of $IrCl_6^{--}$ and $RhCl_6^{--}$.

The first crystal field band can also be distinguished in $Rh(NH_3)_5NO_2^{++}$, while the second is hidden by or intermixed with electron transfer absorption. The intensity of the first band is not exceedingly large, as also observed in nitropentamminecobalt(III) ions. $Rh(NO_2)_6^{---}$ has a band at 270 mμ with $\varepsilon \sim 17\,000$, which cannot reasonably be described as a crystal field band.

TRIS(ETHYLENEDIAMINE) COMPLEXES

The colourless Rh en_3^{+++} was studied by Werner[46] and Jaeger[47]. Lifschitz and Rosenbohm[36] give the two absorption bands at $\sim$ 33 000 and $\sim$ 39 500 cm^{-1}, as also Mathieu[48]. The two crystal field bands are seen from Fig. 6 to be slightly hypsochromic, compared to $Rh(NH_3)_6^{+++}$.

The very robust Ir en_3^{+++} has according to Lifschitz and Bosenbohm[36], shoulders at 32 500 and $\sim$ 38 000 cm^{-1}, while Mathieu[48] found a broad shoulder at 31 000 cm^{-1}. Both bands are observed here in Mathieu's preparation, but with smaller intensity (Fig. 7 and Table 2). Thus, the first shoulder must be a triplet band. This band is $\sim$15 % singlet-like as in the other iridium(III) complexes and the distance between the first triplet and first singlet level of the configuration $\gamma_5^5\gamma_3$ seems to remain rather constant at increasing crystal field strength.

COMPARISON OF COBALT(III), RHODIUM(III) and IRIDIUM(III).

In Table 5 are given the evolution of the spectrochemical series and the distances between the two singlet levels of the electron configuration $\gamma_5^5\gamma_3$, represented by the two band maxima. The energy difference (E_1—E_2) between

Table 5. Comparison of crystal field strength in nickel (II), chromium (III), cobalt (III), rhodium (III) and iridium (III) complexes.

ν/ν_{aq} is the wavenumber of the first band of the complex, divided with the wavenumber of the first band of the aquo ion. $\Delta\nu$ is the difference in wavenumber between the two first bands, which are not spin-forbidden. The measurements of Cr(III) and Co(III) are made by Mr. C. E. Schäffer, and those of Ni(II) taken from Ref. 16.

a γ_3- and a γ_5-electron corresponds directly to the first band in octahedral d^3- and d^8-systems, therefore chromium(III) and nickel(II) complexes [16] are also considered in Table 5. Since the distance between the two bands of the same first-order electron configuration has considerable interest for the theory of intermixing of molecular orbitals, *i. e.* beginning covalency, the wavenumber difference has been given not only for all three diamagnetic d^6-systems, but also for $\gamma_5^2\gamma_3$ of chromium(III). Mr. C. E. Schäffer has kindly informed me about all his measurements of chromium(III) and cobalt(III) complexes.

In the case of d^6-systems, $(E_1—E_2)$ is undoubtedly [10] somewhat larger than the wavenumber of the first singlet band. This is due to different energies of electrostatic interaction between the electrons in the groundstate $^1\Gamma_1$ and the excited state, which according to Tanabe and Sugano [10] is $^1\Gamma_4$ and not $^1\Gamma_5$. But since the exact meaning of $(E_1—E_2)$ in the diamagnetic d^6-complexes is rather dispersed, owing to the interaction with other electron configurations, the wavenumber of the first band will be used as reference here.

The hexaaquo ion is chosen as standard for each element with 8 500 cm^{-1} in nickel(II), 17 400 cm^{-1} in chromium(III), 16 600 cm^{-1} in cobalt(III), and 25 500 cm^{-1} in rhodium(III). Since $Ir(H_2O)_6^{+++}$ is not known, it has been assigned the hypothetical value 31 500 cm^{-1}, which makes the ratios between the wavenumbers of hexachloro and hexaaquo ions equal in rhodium(III) and iridium(III). As already proposed by Tsuchida [49], $CrCl_6^{---}$ is represented by the anhydrous $CrCl_3$, in which the environment of each chromium ion is a regular octahedron of six chloride ions [50].

While Table 5 illustrates the relative crystal field strengths of different ligands for the same ion, it is also possible to investigate the relative tendency of high crystal field strengths, *i. e.* hypsochromy, for the three related central ions, Co^{+3}, Rh^{+3}, and Ir^{+3}. Since the deviations of the ratios in Table 5 are rather small and scattered without a pronounced tendency, the assumed values of the hexaaquo ions can be applied as constants: If a given ligand gives the crystal field strength 1.00 in a cobalt(III) complex, the same ligand will within a few per cent uncertainty give 1.54 in rhodium(III) and 1.90 in iridium(III). Since Ir^{+3} does not have a much larger ionic radius than Rh^{+3}, owing to the lanthanide contraction, there seems to be a specific difference between the 3d-, 4d-, and 5d-electrons, which probably evolves from the different interaction with the molecular orbitals. The purely electrostatic model with hydrogenic d-wave functions [3,7] can hardly explain these facts and the strong increase of $(E_1—E_2)$ with the external charge [9].

THE INTERMIXING OF SINGLET AND TRIPLET LEVELS

In the pure Russell-Saunders coupling [51], the levels of the free ions can be classified in the multiplet terms with a given combination of S (the total spin quantum number) and L (the total angular momentum quantum number). These are quantized vector sums of the quantum numbers of the individual electrons, denoted by small letters: s (always $= \frac{1}{2}$) and l ($= 0$ for s-, 1 for p-, 2 for d-, 3 for f-electrons . . . .). In the heavy atoms, the levels deviate from the Russell-Saunders coupling, as shown *e. g.* by Rasmussen [52] or by the author from the absorption spectra of lanthanide and actinide ions [53]. The vector sum

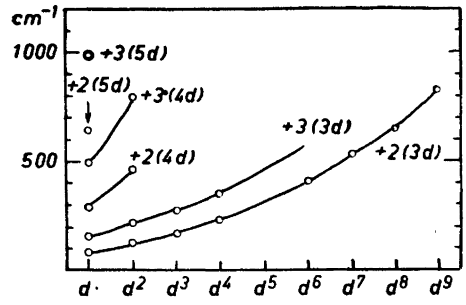

Fig. 8. Lande's multiplet splitting factor ζ_{nd} as function of the number of electrons in the partly filled nd-shell.

Divalent and trivalent ions of the 3d-, 4d- and 5d-groups [54]. The steep increase of the curve for *e. g.* trivalent $4d^n$-ions can be interpolated from the value $\zeta_{4d} = 2\,325$ cm^{-1} in Cd^{+++}, which has nine 4d-electrons.

J of L and S of each level is preserved when the q levels of a given electron configuration with the same J intermix, and the energy levels produced can be described by the eigen-values of a matrix of degree q. The elements of this matrix consist of the energies of the centres of the multiplet terms; and of constants multiplied by the Lande's multiplet splitting constant ζ_{nl} where n and l are the quantum numbers characteristic for each electron. The deviations from the Russell-Saunders coupling can be quantitatively described by increasing values of ζ_{nl}. For isoelectronic species, ζ_{nl} increases roughly proportionally to the square of Z_0^2 (the external charge is $= Z_0 - 1$), and varies much with the value of the principal quantum number n, *i. e.* in the second and third transition group compared to the first [54]. Fig. 8 gives the values of ζ_{nl}, known from atomic spectroscopy, as function of the number of nd-electrons.

The crystal field theory, when applied to d^n-systems, assumes that the crystal field strength is much larger than ζ_{nl}. Then, the total spin S is "a good quantum number", and the levels can be described by the combination Γ_n and S in the theory of Bethe [55]. The energies of the levels develop as a function of the crystal field strength as the q eigen-values of a matrix of q'th degree, if q levels present the same combinations [11] of Γ_n and S. This matrix can have either as diagonal elements the weak-field energies [1, 13, 15] with defined L from the free ion, or the strong-field energies [6, 10, 14] with defined electron configurations $\gamma_5^a\gamma_3^b$. The final results are of course equal, but the former type of matrix has exclusively crystal field strengths in the non-diagonal elements, while the latter type has exclusively electrostatic interaction energies (from multiplet distances in the free ions) in the non-diagonal elements. In both types of matrices, the diagonal elements are linear combinations of electrostatic interactions and crystal field strengths.

But as seen from Fig. 8, the assumption of much larger $(E_1 - E_2)$ than ζ_{nl} is weakened in the ends of each transition group, and especially in the later groups with 4d- and 5d-electrons. Unfortunately, atomic spectroscopy has no information about Co^{+3} and most $4d^n$- and $5d^n$-systems, while most other

$3d^n$-systems are well known [56]. In Ni^{++}, the absorption spectra [16] demonstrate an interaction of the level $^1\Gamma_3$ with $^3\Gamma_5$ and $^3\Gamma_4(F)$ with the non-diagonal elements 500 and 800 cm^{-1}, while $\zeta_{3d} = 600$ cm^{-1}. Generally, the intermixing in the squares of the wave functions is approximately $\left(\frac{k\zeta_{nl}}{E_a - E_b}\right)^2$, where k in the non-diagonal element $k\zeta_{nl}$ is a small number near 1, and $(E_a - E_b)$ is the energy distance between the two interacting levels. The selection rule that transitions are only allowed between levels with the same S, is weakened exactly to the extent, the two levels (originally with different S) have the same S, owing to intermixing effects. This is the explanation [5] of the observation of spin-forbidden bands [1, 8, 10, 53]. In cobalt(III) complexes, where the weak triplet bands [8] demonstrate an intermixing ~ 0.005, the value of $k\zeta_{nl}$ is thus 500 cm^{-1}, if the nearest singlet is the only cause of intermixing. From Fig. 8 ζ_{3d} can be extrapolated to 600 cm^{-1}. The groundstate $^1\Gamma_1$ is presumably intermixed with triplet states ~ 0.001, which perhaps causes the temperature-independent paramagnetism of some cobalt(III) complexes [57]. Sloth and Garner [58] have found relatively strong paramagnetism of $IrCl_6^{--}$ and $IrCl_5(H_2O)^{--}$, agreeing well with the large ζ_{5d}.

In the hexachloro complexes of rhodium(III) and iridium(III), the intermixing of singlet character in the triplet levels is about 0.03 and 0.12, corresponding to $k\zeta_{4d} = 900$ cm^{-1} and $k\zeta_{5d} = 2\,000$ cm^{-1}, respectively. The evolution

$$\zeta_{5d} \cong 2\ \zeta_{4d} \cong 5\ \zeta_{3d} \tag{2}$$

is predicted from Fig. 8, analogous to the relation $\zeta_{5f} = 2\ \zeta_{4f}$ found in the actinides and lanthanides [53].

$IrCl_6^{--}$ has evidently two weak triplet bands with the distance 1 700 cm^{-1} (Table 2), and $RhCl_6^{--}$ seems also to have two triplet bands, since the shoulder towards the red is so broad (Fig. 1). The two bands are probably due to transitions to $^3\Gamma_4$ and $^3\Gamma_5$ with increasing energy [10]. It cannot be excluded that the splitting in the weak band of $IrCl_6^{--}$ is due to different levels of the Γ_J type discussed below, since their distance is not larger than ζ_{5d}; but it is a quite paradoxical fact that such a splitting has never as yet been observed in a band with a defined Γ_n except in the tetrahedral $CoCl_4^{--}$ [59].

Tanabe and Sugano [10] pointed out that the quantum numbers of the levels must be written Γ_J, where the ordinary Bethe-level (S, Γ_n) split into the class of Γ_J given by the internal vector product [14]

$$C(\Gamma_J) = C(\Gamma_n) \times C(S) \tag{3}$$

For integral numbers of S, $C(S)$ is equal to the usual [14] $C(L)$ with $S = L$, *e. g.* Γ_1 for $S = 0$; Γ_4 for $S = 1$; $\Gamma_3 + \Gamma_5$ for $S = 2$; *etc.* For half-numbered values of S, the double-groups Γ_6, Γ_7, and Γ_8 must be used [55].

Thus [16], the triplet levels $^3\Gamma_4$ and $^3\Gamma_5$ should each divide into four levels with distances which are of the order of magnitude ζ_{nl}, as calculated for γ_5^a by Kotani [60] and Griffiths, Owen and Ward [61]. Absorption bands due to transitions [8,10], where one electron changes from γ_5 to γ_3 have a halfwidth between 1 000 and 2 000 cm^{-1}. Thus, it should be possible in many cases to distinguish the Γ_J components. Especially Mr. Schäffer has continued the investigations

of Gaussian shape of absorption bands [19] and found no sign of extra bands, except those due to intermixing of other values of S. The two sharp lines of Cr^{+++} in the ruby are due to $^2\Gamma_3$ and the broader band groups with higher wavenumber due to $^2\Gamma_4$ in the red and $^2\Gamma_5$ in the blue. The two latter groups are perhaps each divided into two Γ_J-bands, but it cannot easily be decided.

In the next paper of this series, the influence of other molecular orbitals than the γ_5 and γ_3 (from d-electrons) will be discussed for the octahedral complexes of the second and third transition groups.

EXPERIMENTAL

The measurements of absorption spectra were performed on a Cary spectrophotometer, ~25° C. The titration curve of $Rh(OH)_3$ was measured with a glass electrode pH-meter Radiometer M 22.

Na_3RhCl_6, $12H_2O$. Rhodium metal from S. M. Jørgensen's collection (partly from Johnson and Matthew, London) was mixed with 10 moles sodium chloride per Rh and treated with chlorine for six hours at 600 – 700° C in a pyrex tube, electrically heated. The cooled mass was perfectly soluble in 4 M HCl, except for a few per cent of anhydrous $RhCl_3$ formed. By addition of ethanol to such a solution, most rhodium crystallizes after some days as Na_3RhCl_6, $12H_2O$. But this method is disadvantageous, since metal tends to precipitate from the filtrate when boiled. Rather, fractionated crystallization of the melted mass in dilute HCl can be recommended. $Rh(OH)_3$ can be regenerated from the solutions with NaOH or $BaCO_3$.

The iridium content was found to 0.4 % and 0.2 % in two samples, from the absorption spectra in HCl + Cl_2. There were found 17 % Rh from precipitation of the metal by $TiCl_3$ and 37 % Cl from Mohr's titration of the filtrate from $BaCO_3$ (calc. 17.1 % Rh and 35.1 % Cl).

$RhBr_6^{---}$ was prepared in solution by prolonged boiling of Na_3RhCl_6, $12H_2O$ with 6 M HBr till the spectrum of different solutions did not change. Even though Poulenc [63] has prepared solid salts of $Rh_2Br_9^{-3}$, $RhBr_5^{-2}$ and $Rh_2Br_{11}^{-5}$, it is here assumed that these complexes with bromide bridges are not abundant in strong HBr.

$Rh(H_2O)_6^{+++}$ was made by boiling 0.5 g Na_3RhCl_6, $12H_2O$ with 50 ml 5 M $HClO_4$ in a 100 ml beaker, covered with a watch-glass. The dark-red colour turns first orange, then a red-brown precipitate is formed, which redissolves to a dark brown solution. By dilution of the residual 4 ml to 50 ml with water, a clear yellow solution is obtained.

$Rh\,ox_3^{---}$ was made by heating 4 hours to 100° C of a solution, originally 0.1 M $RhCl_6^{---}$ and 0.6 M K_2ox.

$Rh(NH_3)_6Cl_3$, *$[Rh(NH_3)_5NO_3](NO_3)_2$*, *$[Rh(NH_3)_5I]Cl_2$*, *$[Rh(NH_3)_5Br]Br_2$ and $[Rh(NH_3)_5Cl]Cl_2$* were taken from the collection of S. M. Jørgensen. The last salt was prepared for the determination of the atomic weight of Rh.

$[Rh(NH_3)_5H_2O](ClO_4)_3$ of Brønsted and Volqvartz [40] was kindly furnished by Professor J. A. Christiansen. It was measured in 0.05 M $HClO_4$ and in H_2O, giving the aquo form, and in 0.1 M Na_2CO_3 and 1 M NaOH, giving the hydroxo ion. Further, it was compared with the solution of sodium aquopentammine rhodium(III) pyrophosphate (S. M. Jørgensen) in 1 M HCl and in 5 M NH_3.

$Rh\,en_3^{+++}$ was prepared by Werner [46] by reacting Na_3RhCl_6, $12H_2O$ with 50 % ethylenediamine. If the solution is more dilute, a yellow precipitate ($Rh(OH)_3$?) is formed by warming, and the quantitative reaction is slow. For the experiments, 0.5 g Na_3RhCl_6, $12H_2O$ was dissolved in 2 ml H_2O and added a solution of 0.5 ml ethylenediamine hydrate (Merck's No. 946) in 10 ml 0.2 M HCl. The solution was evaporated cautiously to 1 ml under stirring.

In the next paper of this series the preparation of iridium compounds from the metal will be described. Here, it can be mentioned that $IrCl_6^{--}$ was reduced by H_2S or ascorbic acid for some repeated measurements. In most cases were used:

K_3IrCl_6, $3H_2O$, supplied from Dansk Hollandsk Ædelmetal (H. Drijfhout and Zoon).

IrBr$_6^{---}$, prepared by boiling this salt with 6 M HBr.

Ir ox$_3^{---}$, made by warming 30 hours at 110° C of a solution 0.05 M K_3IrCl_6, $3H_2O$ and 0.8 M K_2ox, in a stoppered bottle. Professor Marcel Delépine, Collège de France, has kindly presented me with a series of iridium(III) and rhodium(III) complexes, which will be the subject of the third paper of this series. K_3Irox_3, $4.5H_2O$ of this collection has a spectrum similar to that given in Fig. 5.

[Ir (NH$_3$)$_5$Cl]Cl$_2$ and [Ir en$_3$]Br$_3$, 2H$_2$O (the l-form), kindly furnished by Professor Jean-Paul Mathieu. The spectrum of Ir en$_3^{+++}$ was also measured in 0.3 M NaOH and showed no change.

Acknowledgments. I am very much indebted to Professor J. Bjerrum for his interest in the work. Further, I thank Mr. C. E. Schäffer for interesting discussions and valuable information about his measurements of chromium(III) and cobalt(III) complexes, and Miss Bodil Friis for assistance with the preparation of Na_3RhCl_6, $12H_2O$. Finally, I thank Professor Jean-Paul Mathieu of Université de Paris for the valuable samples of iridium(III) amine complexes.

Complexes of the 4d- and 5d-Groups

II. Crystal Field and Electron Transfer Spectra of Ruthenium(II) and (III), Iridium(IV) and Platinum(IV)

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The octahedral complexes of the platinum metals often exhibit relatively strong absorption bands. The electron transfer bands with the lowest wavenumbers are assumed to be due to π-electrons from the ligands, which are transferred to holes in the 4d- and 5d-shells. In the halido complexes of ruthenium(III) and platinum(IV), the crystal field bands of d^5- and d^6-systems, respectively, can be observed. The acidity of $Pt(NH_3)_6^{+4}$ and $Pt(NH_3)_5Cl^{+3}$ is measured; the formations of the monoamido complexes have $pK = 7.75$ and 8.7, respectively. The theory of molecular orbitals is compared to the explanation by the crystal field theory of the energy difference between γ_3- and γ_5-electrons. Probably, it will be necessary to consider the interaction between different configurations of molecular orbitals.

In the first paper [1] of this series, the regularly octahedral complexes of the d^6-systems rhodium(III) and iridium(III) were studied. Their absorption spectra can be explained as the crystal field bands, also found of the complexes of cobalt(III). However, this proves by no means that the electrostatic model of the crystal field, acting on the d-electrons [2] is a very good approximation for the actual states of the transition group complexes. Van Vleck [3] has pointed out that the theory of molecular orbitals of Mulliken [4] gives several of the results of the crystal field theory, thus the 10-fold degenerate d-shell in an octahedral complex is split to four γ_3-electrons with higher energy and six γ_5-electrons with lower energy. This analogy has been extended further by Hartmann [5], Orgel [6,7], Owen [8], Tanabe and Sugano [9]. Experimental evidence for the intermixing of molecular orbitals with the γ_5-electrons was found by paramagnetic reasonance measurements of $IrCl_6^{--}$ and $IrBr_6^{--}$ by Owen and Stevens [10] and Griffiths and Owen [11]. The present paper is a contribution to the discussion of molecular orbitals, applied to the electron transfer spectra.

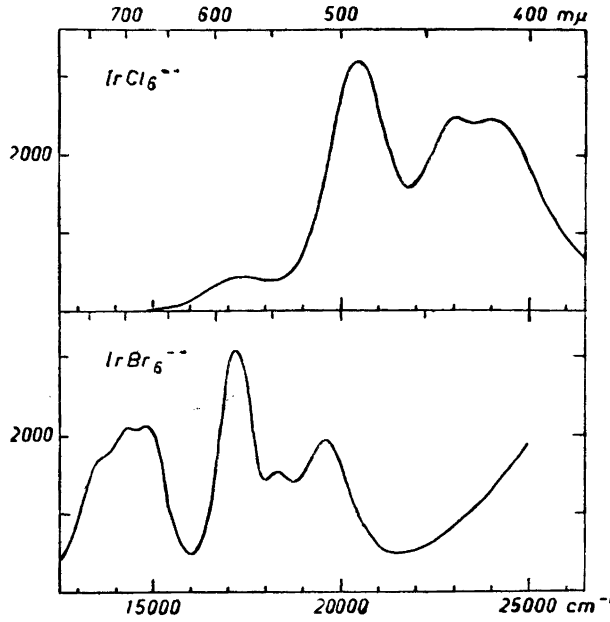

Fig. 1. Absorption spectra of hexachloro- and hexabromo-iridium(IV) ions.

0.0005 M Na_2IrCl_6, measured in different solutions in water and dilute hydrochloric acid, which was not changed by addition of free chlorine, and from $K_3IrCl_6 + Cl_2$. 0.0005 M $IrBr_6^{--}$ from Na_2IrCl_6 in 0.1 M HBr.

HEXACHLORO- AND HEXABROMO-COMPLEXES OF IRIDIUM(IV).

The absorption spectra of the red-brown $IrCl_6^{--}$ and violet-blue $IrBr_6^{--}$ are given in Fig. 1 and Table 1. The band maxima of $IrCl_6^{--}$ have been found by Babaeva [12] at 490, 424 and 286 mμ. The doublet structure of the second band was found by Inamura and Kondo [13]. The complex $IrBr_6^{--}$ is only stable under special conditions of temperature and concentrations. Thus, the dark-blue crystals of tetramethylammonium hexabromo iridate(IV) dissolves under complete decomposition in 6 M hydrobromic acid, which contains some free bromine. Only quite dilute solutions of HBr do not favorize the trivalent anion $IrBr_6^{---}$ so much, and $IrBr_6^{-}$ has been measured here. Therefore, the values of ε in Table 1 may be uncertain minimum values, but the relative heigth of the peaks is reproducible in many different solutions, since the decomposition product $IrBr_6^{---}$ is much less coloured [1].

There are six discernible absorption bands in the visible range of $IrBr_6^{--}$, but only four of $IrCl_6^{--}$. This can be ascribed to the larger energy differences between the two lowest levels $^2P_{3/2}$ and $^2P_{1/2}$ in the free halogen atom (404 cm^{-1} in F, 881 cm^{-1} in Cl, 3 685 cm^{-1} in Br and 7 603 cm^{-1} in I[14]) *i. e.* increasing ζ_{np} with increasing principal quantum number n[1]. This was early found by Scheibe [15] from the double absorption band in the far ultraviolet of Br^- and I^-, compared to Cl^-.

Table 1. Absorption bands of iridium(IV) complexes.

Wavelength λ_n, wavenumber ν_n and molar extinction coefficient ε_n of each maximum, halfwidths $\delta(-)$ towards smaller and $\delta(+)$ towards higher wavenumbers, and the oscillator strength P of each band [27].

	λ_n mμ	ν_n cm^{-1}	ε_n	$\delta(-)$ cm^{-1}	$\delta(+)$ cm^{-1}	$P \cdot 10^{-5}$
$IrCl_6^{--}$	575	17 400	460	1 200	—	500
	489	20 450	3 200	900	—	2 600
	431	23 200	2 540	—	—	4 000
	414	24 200	2 480	—	1 400	
$IrBr_6^{--}$	737	13 600	1 550	600	—	2 000
	698	14 300	2 050	—	—	
	675	14 800	2 100	—	—	
	583	17 200	3 070	500	500	1 400
	544	18 400	1 500	—	—	1 500
	511	19 600	1 800	—	800	

The absorption spectrum of $IrCl_6^{--}$ (Fig. 1) resembles much the spectrum of $IrCl_6^{---}$ (Ref. 1, Fig. 2) multiplied in height by 40 and displaced 4 000 cm^{-1} towards the red. This might perhaps suggest that iridium has the oxidation state +3 in $IrCl_6^{--}$, involving as ligands the resonance structure of five chloride ions and one chlorine atom. Hovewer, this is impossible, since Owen and Stevens [10] found the magnetic hole (the missing electron in the γ_5^5-shell) is on an average, to 80 % near the iridium nucleus and to 3 % near each of the six chloride nuclei, *i. e.* about 20 % intermixing of the molecular orbitals with symmetry γ_5. The question may be raised whether the oxidation state of Ir is an integral number, *e. g.* +3 or +4. In the author's opinion it is not deciding that the number of electrons within a volume defined as "the central atom" is some decimal fraction. Rather, the oxidation state of the central ion can be defined from the number of electrons in the highest γ_3- and γ_5-orbitals, which would have been pure d-electrons, if no intermixing occurred. *E. g.*, iridium is trivalent with γ_5^6 and quadrivalent with γ_5^5 as groundstate. This has nearly an exact meaning, since the interaction between different electron configurations is small in strong crystal fields, and since by chance the groundstates in weak crystal fields often contain an integral number of γ_3- and γ_5-electrons (*cf.* Santen and Wieringen [16]). It is known from applications of molecular orbital theory that the electron configurations can be highly intermixed by increasing nuclear distances and correspondingly weaker bonding, as pointed out by Slater [53] and Mc Weeny [54].

Thus, the absorption spectra of $IrCl_6^{--}$ and $IrBr_6^{--}$ must be interpreted as transitions of one electron from the ligands to the central ion, which achieve the oxidation state +3, as defined above. The orbitals between which the electron moves, will be discussed below in a special section. The bathochromic effects of chloro-, bromo- and iodo-complexes (*cf.* platinum(IV) below) is qualitatively well understood. Thus, by a constant electron affinity of Ir^{+4}, less energy is necessary to remove an electron from the most reducing ligand [17], *i. e.* the heaviest halide ion. But the effect is larger than expected (one electron

volt corresponds to 8 067 cm^{-1}). However, the electron affinities of free halogen atoms are not easily compared with the conditions in aqueous solution, and are further influenced by the stabilization by resonance of the excited state of the iridium(IV) complexes.

HEXACHLORO-, HEXABROMO-, AND HEXAIODO COMPLEXES OF PLATINUM(IV)

The colourless PtF_6^{--}, yellow $PtCl_6^{--}$, red-orange $PtBr_6^{--}$, and dark purple-red PtI_6^{--} was already measured by Schlesinger and Tapley [18], and Wheeler, Perros and Naeser [19] have later re-examined the two weak bands ($\varepsilon \sim 50$) of PtF_6^{--} at 318 and 275 mμ. Babaeva [12] has found bands of $PtCl_6^{--}$ at 440, 348 and 254 mμ. Fig. 2 and Table 1 give the measurements by the present author of $PtCl_6^{--}$, $PtBr_6^{--}$ and PtI_6^{--}.

Platinum(IV) is a d^6-system with strong tendency of forming diamagnetic complexes with regularly octahedral configuration. Thus, the crystal field bands analogous to these of cobalt(III), rhodium(III) and iridium(III) [1] may be predicted. They are present as the relatively weak shoulders in the spectra of $PtCl_6^{--}$ and $PtBr_6^{--}$. The weakest bands at 453 and 525 mμ, respectively, are identified as the transition from $^1\Gamma_1$ (γ_5^6) to one of the triplet levels $^3\Gamma_4$ or $^3\Gamma_5$ ($\gamma_5^5\gamma_3$); and the stronger bands at 353 and 435 mμ, respectively, with the lowest singlet level, *viz.*[9] $^1\Gamma_4$ ($\gamma_5^5\ \gamma_3$). The ratio between the wave-number of this band and the corresponding band in the iridium(III) complexes [1] will then have the values:

	$PtCl_6^{--}/IrCl_6^{---}$	$PtBr_6^{--}/IrBr_6^{---}$
Triplet level	1.24	1.14
Singlet level	1.17	1.03

This is reasonable evolution for two isoelectronic species with increasing oxidation state. The energy difference (E_1—E_2) between γ_3- and γ_5-electrons is thus at least double as large in platinum(IV) complexes as in cobalt(III) complexes *inter alia* as discussed earlier [1]. This explains the high tendency of magnetic anomaly in the platinum metal complexes ($S = 0$ for even and $S = \frac{1}{2}$ for odd number of electrons) since the distances in the free ion of terms with different S in the heavy elements is either less or equal to the distances in the first transition group, and they seem decreased in the complexes, relative to gaseous ions [7,8,9].

The two bands in PtF_6^{--} are presumably the transitions to the two singlet levels of $\gamma_5^5\ \gamma_3$. The three electron transfer bands in PtI_6^{--} are superposed the predicted places of the crystal field bands, which may show some intermixing effects.

AMMINE PLATINUM(IV) COMPLEXES

Like other d^6-systems, platinum(IV) forms very robust hexammine complexes. They have been difficult to prepare before Tronev and Shumilina [20] recently demonstrated that $Pt(NH_2)(NH_3)_5Cl_3$ is formed by the action at room temperature of liquid NH_3 on $(NH_4)_2PtCl_6$. This base reacts with hydrogen ions and forms the normal "luteo" ion:

$$Pt(NH_2)(NH_3)_5^{+++} + H^+ \rightleftharpoons Pt(NH_3)_6^{++++} \qquad (1)$$

The titration curve, Fig. 3, shows that pK for this process is 7.75. Grünberg and Faerman [55] determined pK = 8.9 by the more uncertain method of dis-

D. 0.002 M $[Pt(NH_3)_5Cl](NO_3)_3$ in 1 M NH_3

solving the pure $Pt(NH_3)_6Cl_4$ in water and inserting the measured pH in Ostwald's square-root formula for the dissociation of a weak acid. Already Grünberg and Faerman [55] demonstrated the change of absorption spectrum of $Pt(NH_3)_6^{+4}$ by addition of one equivalent of OH^-, the absorption limit is displaced towards longer wavelengths. Fig. 4 gives the spectra of $Pt(NH_3)_6^{+4}$ $Pt(NH_3)_5NH_2^{+3}$, $Pt(NH_3)_5Cl^{+3}$ and $Pt(NH_3)_4(NH_2)Cl^{+2}$. The spectrum of $Pt(NH_3)_5NH_2^{+3}$ is not further displaced in 1 M NaOH, and the titration curve Fig. 3 demonstrates that the next proton does not dissociate with pK lower than 12. Thus there might be involved an electrostatic effect, which separates the two consecutive values of pK by more than 5 units. However, $Pt(NH_3)_5Cl^{+3}$ is not a much weaker acid than $Pt(NH_3)_6^{+4}$. The titration curve in the lowest part of Fig. 3 gives pK = 8.7. The reversible titration demonstrates that the chloride ligand is not exchanged by OH^- during the measurements. Grünberg and Faerman [55] found pK = 9.0. Before this investigation was made, Professor F. Basolo informed me kindly that Pt en_3^{+4} is also a weak acid, forming amido complexes with the absorption band displaced towards lower wavenumbers.*

Sidgwick's concept of complexes as having "inert gas configurations" is in some way exemplified by the whitest of all ammonia complexes with partly filled d-shells $Pt(NH_3)_6^{+4}$. The characteristic property of an inert gas with

* Grünberg has later determined the consecutive values of pK for Pt en_3^{+4}, *viz.* 5.5, 9.7, and 10.7; of $Pt(NH_3)_6^{+4}$, *viz.* 7.9 and 10.1; and of Pt $(NH_3)_5Cl^{+3}$, *viz.* 8.1 and 10.3.

a closed shell-groundstate is that the excited states have much higher energy than the ground-state. The singlet levels of $\gamma_5^5\gamma_3$ are hidden by the electron transfer band below 240 mμ, but the triplet level can perhaps be observed as the shoulder at 300 mμ.

RUTHENIUM(III) COMPLEXES

A most unsual discussion was once made of the oxidation states of ruthenium. Howe [22] prepared a rose-red isomer of the dark-brown K_2RuCl_5, H_2O, and maintained [23] that these two salts and the yellow-brown anhydrous K_2RuCl_5 do all contain trivalent ruthenium. Charonnat [24] demonstrated that the dark-brown salt really was $K_2RuCl_5(OH)$ with quadrivalent Ru, and finally Howe [25] agreed.

By a profound investigation, Charonnat [26] demonstrated the many analogies between ruthenium(III) and rhodium(III). Thus, two red complexes $RuCl_6^{---}$ and $RuCl_5(H_2O)^{--}$ are known, of which the first is only stable in very strong HCl, and the brownish green Ru ox_3^{---} forms salts, which are isomeric with those of Rh ox_3^{---} and many other tris(oxalato) complexes of trivalent metals. The octahedral configuration of ruthenium(III) is thus evident, even though Charonnat [26] proposes octa-coordination in several complexes. Since the d^5-systems with $S = \frac{1}{2}$ are liable to rhombic distortion [27] while d^6-systems with $S = 0$ are regularly octahedral, a distortion is predicted as found [28] in the corresponding $Fe(CN)_6^{---}$. Thus, the anhydrous K_2RuCl_5 and the orange pentanitrites as $K_2Ru(NO_2)_5$ may be penta-coordinated, but they are rather under suspicion for being dimeric with two anion bridges.

Wehner and Hindman [29] have later investigated the solutions of ruthenium (III) and (IV) in $HClO_4$, where hydroxo- and aquo-complexes are expected. Since the spectrum of the trivalent form is equal in 9 M and 1 M $HClO_4$ (one peak at 300 mμ with $\varepsilon \sim 2\,000$), it is assumed to be due to the hexaaquo ion. This might very well have been a stronger acid; the tendency for deviation from regularly octahedral complexes gives higher affinity for the two first hydroxyl ions (*cf.* copper(II) and manganese(III) compared to the regular neighbors nickel(II), zinc(II), chromium(III) and iron(III)) [27].

Fig. 5 and Table 3 give the spectra of ruthenium(III) in strong HCl and HBr, which can be assumed to contain $RuCl_6^{---}$ and $RuBr_6^{---}$. Mr. K. G. Poulsen has kindly pointed out to me that metallic silver is a good reducing agent in these media for providing the oxidation state +3; and even a green solution, containing a trace of + 2 can be produced. However, upon standing in the air, a strawberry-red solution is obtained in HCl. This is slowly oxidized over a period of weeks to a yellow-brown solution with increasing amounts of +4. When the solution does not contain much ruthenium, less than 0.001 M, it is almost colourless in +3, while oxidation to +4 produces a strong colour. At this concentration, ruthenium(IV) has the same characteristic brownish orange colour as dilute $IrCl_6^{--}$ and nearly the same absorption spectrum, which is rather curious for this d^4-system. The solution of ruthenium (III) in 4 M HBr is dark purple-brown.

It is seen from Fig. 5 and Table 3 that the chloro complex has much higher absorption in the near ultraviolet (as also has the aquo ion [29]) and the bromo

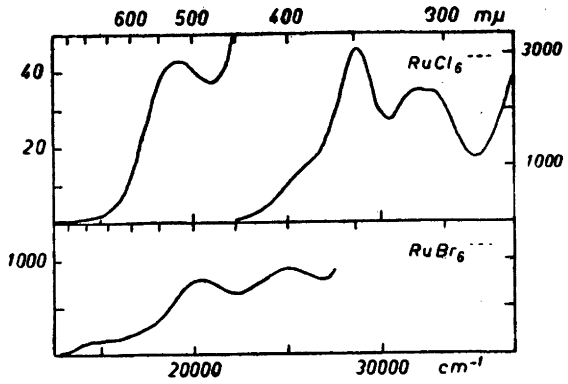

Fig. 5. Absorption spectra of chloro and bromo complexes of ruthenium(III).
0.0005 M to 0.05 M ruthenium(III) in 10 M HCl, reduced with Ag powder.
0.002 M to 0.05 M ruthenium(III) in 6 M HBr, reduced with Ag powder.

complex in the visible than found for rhodium(III)[1]. These bands are undoubtedly due to electron transfer and will be discussed below. But there are also signs of crystal field bands: the relatively weak band at 521 mμ and the shoulder at 388 mμ in the chloro complex and perhaps also the shoulder at 653 mμ in the bromo complex. The intensity of these bands classify them as spin-allowed transitions from the groundstate $^2\Gamma_5(\gamma_5^5)$ to one of the doublet levels[30] of $\gamma_5^4\,\gamma_3$. If they were spin-forbidden, the asymmetry of the ruthenium(III) complex must be so large that the hemiedric crystal field[31] have made the spin-allowed crystal field bands nearly as allowed as electron transfer band. The present author has sought for spin-forbidden bands out to 1 100 mμ, but found at most a background with $\varepsilon \sim 1$.

According to Tanabe and Sugano's calculation on pure d^n-configurations[9] the order of energy of $\gamma_5^4\,\gamma_3$-levels in strong crystal fields will be

$$^4\Gamma_4,\ ^4\Gamma_5,\ ^2\Gamma_2,\ ^2\Gamma_4,\ ^2\Gamma_5,\ ^2\Gamma_3 \cdots\cdots \qquad (2)$$

Table 3. Absorption bands of ruthenium(III) and (II) complexes. Notation as in Table 1.

	λ_n mμ	ν_n cm^{-1}	ε_n	$\delta(-)$ cm^{-1}	$\delta(+)$ cm^{-1}	$P \cdot 10^{-5}$
$RuCl_6^{---}$?	521	19 200	43	2 000	—	70
	388	25 800	800	—	—	~1 000
	349	28 700	3 000	1 400	1 300	3 700
	313	32 000	2 300	—	—	~5 000
	307	32 600	2 300	—	—	
$RuBr_6^{---}$?	655	15 300	130	1 500	—	180
	485	20 600	770	1 600	—	1 100
	400	25 000	900	—	—	—
Ru(II) in 2 M HCl	660	15 200	1 250	—	—	~5 000
	570	17 600	1 130	—	—	

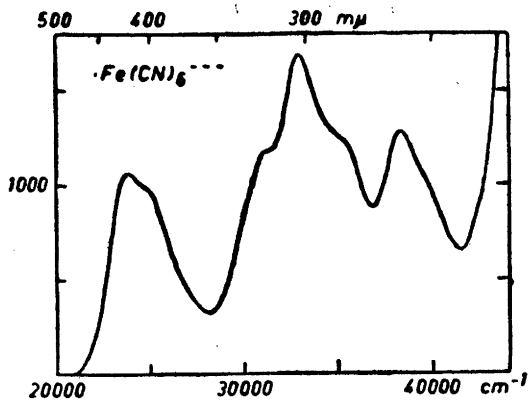

Fig. 6. Absorption spectrum of iron(III)hexacyanide ions.
0.001 M $K_3Fe(CN)_6$ in H_2O.

within a relatively narrow range of energy, about 50 B, where the Racah parameter B presumably is about 1 000 cm^{-1} in the gaseous ion, but is decreased in complexes [7,8,9]. Since the four bands in d^6-systems should be placed [9]:

$$\begin{aligned} {}^3\Gamma_4 &: (E_1 - E_2) - 3\ C \\ {}^3\Gamma_5 &: (E_1 - E_2) + 8\ B - 3\ C \\ {}^1\Gamma_4 &: (E_1 - E_2) - C \\ {}^1\Gamma_5 &: (E_1 - E_2) + 16\ B - C \end{aligned} \qquad (3)$$

with $C \cong 4.5$ B, the first singlet band in $RhCl_6^{---}$ corresponds to $(E_1 - E_2) =$ 21 000 cm^{-1} and the distance between the two singlet bands *, which is somewhat less than 16 B due to the influence of non-diagonal elements, implies B = 400 cm^{-1} for $RhCl_6^{---}$. If similar values are applied to $RuCl_6^{---}$, Tanabe and Sugano's theory predicts the first quartet band at 11 800 cm^{-1} and the first doublet band at 18 000 cm^{-1}.

For comparison with the electron transfer bands of ruthenium(III), Fig. 6 gives the spectrum of $Fe(CN)_6^{---}$. The six strong bands agree with the measurements of Kiss, Abraham and Hegedüs [32], and the present author has also found the very weak, broad band at 550 mμ with $\varepsilon \sim 0.3$. This seems to be a spin-forbidden crystal field band, even if it is tempting to ascribe it to impurities of the Turnbull's blue type. Gleu *et al.*[33–35] have prepared robust ruthenium(III) ammine complexes with nearly the same colours as the corresponding rhodium(III) ammines:

* It will be shown later that the values of B in d^n-complexes are only compatible with an average radius of the d-shell larger than the ionic radius. Thus, the partly occupied orbitals must be localized also on the ligands, eventhough a decreased central field relative to the gaseous ion (produced by the presence of some electrons donated from the ligands) co-operates in decreasing B.

$Ru(NH_3)_6^{+++}$	colourless
$Ru(NH_3)_5H_2O^{+++}$	colourless
$Ru(NH_3)_5Cl^{++}$	yellow
$Ru(NH_3)_5Br^{++}$	dark yellow
cis-$Ru(NH_3)_4Cl_2^+$	orange
trans-$Ru(NH_3)_4Cl_2^+$	red-orange
cis-$Ru(NH_3)_4Br_2^+$	red
trans-$Ru(NH_3)_4Br_2^+$	purple
$Ru(NH_3)_4\ ox^+$	yellow
$Ru(NH_3)_3\ Cl_3$	red

These colours demonstrate a bathochromic influence which is larger for bromide than for chloride, and which is slightly larger for *trans*- than for *cis*-complexes. The latter fact is of interest for the theory of tetragonal complexes. Since the spectrochemical series of crystal fields $Br^- < Cl^- < ox^{--} < H_2O < NH_3$ varies nearly as the decreasing tendency to give electrons off, it cannot be said with certainty if the colours are due to crystal field or electron transfer bands.

When sufficient ammonium chloride is added to prevent the precipitation of $Ru(OH)_3$, solutions of $Ru\ Cl_6^{---}$ in HCl reacts with concentrated ammonia water under formation of a clear, pink solution. It is difficult to separate the colourless hexammines and pentammines, probably formed in this reaction, from the traces of highly coloured ruthenium red. The constitution of the latter compound is not yet elucidated; it is diamagnetic [35] and probably a polynuclear complex with hydroxo bridges. Its formation in the solution mentioned above is reversible.

RUTHENIUM(II) COMPLEXES

Already Claus [36] observed a dark blue solution of ruthenium with strong reducing agents. This solution contains ruthenium(II) as shown by titrations with sodium amalgam (authors who assumed K_2RuCl_5OH to be $K_2RuCl_5(H_2O)$ found of course +1). The present author can add but a few new arguments to the vivid debate about the green colour formed, when yellow ruthenium solutions (with traces of +4?) are reduced with zinc amalgam or other metals, and which turn lavender blue with excess of reducing agent [37–43]. Grube and Nann [44] found that the actual oxidation state +1 in few minutes disproportionates to the metal and +2; and that +2 in 2 M HCl in two days is 5 % disproportionated to metal and +3. Grube and Fromm [45] later investigated $RuCl_3$ and its hydrates and found the emerald-green $RuCl_2^+$, which may resemble the green isomer of $RuCl_4(H_2O)_2^-$ (the other isomer is red) which Gall and Lehmann [41] assume to be a mixture of +2 and +3.

The reaction between yellow +4 and blue +2 requires some minutes, so that a green intermediate colour can be observed. Besides this the blue solution has only been measured in solutions 1 M to 4 M in HCl. In stronger hydrochloric acid, the spectrum of the solution is displaced towards red with resulting green colour: The maximum at 660 mμ to 710 mμ and the shoulder at 568 mμ to 578 mμ. The influence of the halide ion was studied by reduction of a chloride-free ruthenium(III) solution in 4 M HBr (see experimental section). Similar blue and green solutions with broad bands in the red are obtained.

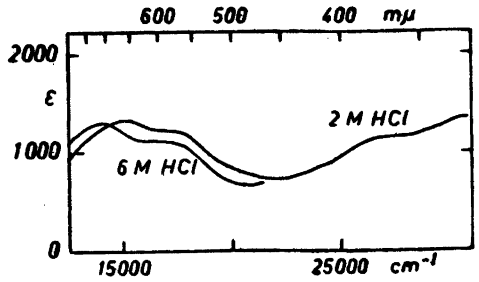

Fig. 7. Absorption spectra of ruthenium (II) complexes.

0.001 M ruthenium in 2 M and 6 M HCl, reduced with zinc amalgam.

The absolute extinction coefficients cannot be determined exactly, due to the impurities of +3 and the metal. But the value of $\varepsilon \sim 1\,100$ is too high for an ordinary crystal field band. Thus, it is probably an electron transfer band. It cannot be excluded *a priori* that ruthenium(II) is a stronger oxidizing agent, *i. e.* has larger electron affinity, than ruthenium(III). The disproportionation [44] supports this possibility, analogous to the behaviour of copper(I).

Ruthenium(II) is a d^6-system and may thus be expected to form diamagnetic complexes ($S = 0$). But only the colourless $Ru(CN)_6^{-4}$ and several sulphito-ammine complexes [46] are known to be six-coordinated, while the blue complexes are often assumed to be $RuCl_4^-$. If they have a planar configuration, they have probably the groundstate $\gamma_5^5\,\gamma_3$ with $S = 1$. Even if Tanabe and Sugano [9] have proven that no groundstate of an octahedral complex has $S = 1$ in d^6 and $S = \frac{3}{4}$ in d^5-systems, tetragonal complexes may stabilize the intermediate values of S.

ELECTRON TRANSFER FROM MOLECULAR ORBITALS

In Mulliken's theory of molecular orbitals [4], the symmetry of the distribution of atomic nuclei in the molecule determines the possible quantum numbers of the orbitals, analogous to the symmetry of the crystal field from the ligands, acting on the central ion [2]. In this paper the notation of Bethe [2] will be used also for molecular orbitals of octahedral complexes. The translation table is:

Mulliken:	a_1	a_2	e	t_1	t_2	(4)
Bethe:	γ_1	γ_2	γ_3	γ_4	γ_5	

While small letters denote the states of electrons, the corresponding states of whole systems, here molecules, are denoted by capital letters $A_1 = \Gamma_1$. In a complex with a centre of symmetry, the states can further be divided into two classes with different parity: odd and even. This is denoted by the small letters u (ungerade) and g (gerade) after the numbers: γ_{1g}, Γ_{3u}. The parity of a system is equal to the sum of parities of the electrons, defined by the addition rules:

$$\begin{aligned} g + g &= g \\ u + g = g + u &= u \\ u + u &= g \end{aligned} \qquad (5)$$

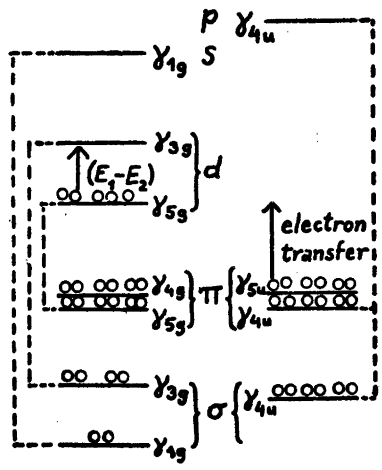

Fig. 8. Molecular orbitals of an octahedral complex MX_6 with partly filled d-shell in M. Even orbitals (g) at left-hand and odd (u) at right-hand side. Arrows denote possible interactions between orbitals with the same Γ_n and parity.

In a single atom or ion, an electron has the quantum number 1, and the parity is g for even values of 1, *i. e.* for s-, d-, g-electrons *etc.* and u for odd values of 1, *i. e.* for p-, f-, h-electrons etc. Thus, all the values of γ_n and Γ_n encountered in the theory for pure d^n-configurations are even, and the "g" is often neglected in the quantum numbers.

The electrons of the six ligands of an octahedral complex can be classified as σ-electrons, π-electrons, etc. according to their angular momentum around the straight line connecting central ion-ligand's centre being 0 or 1, etc. The chemical bonds between the ligands and the central ion can be described by the intermixing of orbitals having the same γ_n and parity, from the ligands and the central ion. Thus, the chemical bonds can be classified as σ-bonds, π-bonds *etc.* according to the electrons, participating from the ligands.

Van Vleck [3] pointed out the σ-bonds in an octahedral complex with an unfilled nd-shell is due to the three pairs of intermixing orbitals:

$$\begin{aligned} &\gamma_{3g} \text{ with } \gamma_{3g}(\mathrm{nd}) \\ &\gamma_{4u} \text{ with } \gamma_{4u}(\mathrm{n}+1\mathrm{p}) \\ &\gamma_{1g} \text{ with } \gamma_{1g}(\mathrm{n}+1\mathrm{s}) \end{aligned} \qquad (6)$$

The three types of orbitals can accumulate 4, 6, and 2 electrons, respectively, 12 bonding and 12 anti-bonding electrons (six electron-pairs in the localized valence picture). According to Hartmann [5], the energy of the bonding orbitals decrease in the order, given in eqn. 6. It is evident that the d^2sp^3-hybridization discovered by Pauling [47,48] is equivalent to complete intermixing of the three pairs of orbitals. The molecular orbital theory has the advantage that the electrostatic crystal field model and Pauling's hybridization can be described as two limiting cases [5] with, respectively, pure d^n-configurations and complete intermixing (which is 50 % in the squares of the wavefunctions). Owen [8] pointed out that the intermixing coefficients can be different for the three orbital types γ_{3g}, γ_{4u} and γ_{1g}. Thus, the evolution from the "ionic" to "co-

valent" structure [48] must be described by three independent parameters. In all cases of intermixing, the parameter may happen to exceed 50 % in the squares, corresponding in this case to higher energy of the original σ-electrons than of the electron of the central ion.

The 24 π-electrons from six monatomic ligands of the type Cl^- are distributed in the four orbitals (*cf.* Orgel [7]) of which two are intermixed [8]:

$$\begin{aligned} \gamma_{4u} &\text{ — with } \gamma_{4u} \text{ (n +1 p)} \\ \gamma_{4g} &\text{ —} \\ \gamma_{5u} &\text{ —} \\ \gamma_{5g} &\text{ — with } \gamma_{5g}\text{(nd)} \end{aligned} \qquad (7)$$

There are no orbitals in the central ions of the type γ_{4g} and γ_{5u}, and the ligand orbitals are thus non-bonding (*cf.* Fig. 8).

The effect of intermixing of orbitals [3,8] is to increase (E_1—E_2) by σ-bonding (which increases the energy of γ_{3g}(d)) and to decrease (E_1—E_2) by π-bonding (which increases the energy of the relatively low γ_{3g}(d)). This type of intermixing is connected with the non-orthogonality of the orbitals in the central ion and the ligands, which thus have "overlap" integrals contrary to the orbitals used in monatomic problems. Another type of intermixing can be found between two levels of the system with the same Γ_n, due to two configurations with a different distribution of electrons in the molecular orbitals. The latter type of intermixing gives generally smaller effects [49,50], but it must be realized that the molecular orbital theory does not give a detailed picture, when more levels are possible from a given configuration: the four levels $^3\Gamma_4$, $^3\Gamma_5$, $^1\Gamma_4$ and $^1\Gamma_5$ of the d^6-systems $\gamma_5^5\,\gamma_3$ have different energies even in a strong crystal field, while the distribution of electrons in the molecular orbitals is identical in the four levels. The concept of molecular orbitals is more distinct in the compounds outside the transition groups, where most configurations of interest do only contain one level.

The crystal field bands, which are characteristic for the complexes with partly filled d-shells are thus in the molecular orbital language due to transitions between the possible levels Γ_n of the electrons in γ_{5g} and γ_{3g}, while the other molecular orbitals are invariably filled or empty during the transition. The low intensities demonstrate [31] that the parity "g" is at least a 99 % good quantum number; and the orbital quantum numbers γ_{5g} and γ_{3g} are only affected by relatively small intermixings with other configurations, while Γ_n is only intermixed by (L, S) coupling effects. But the orbitals γ_{5g} and γ_{3g} cannot be seen from the absorption spectra to be pure d-electrons; they may contain considerable amounts of π- and σ-antibonding character, respectively. Owen [8] concludes from the decreased values of ζ_{3d} in the first transition group complexes, found by paramagnetic measurements, that the σ-intermixing of γ_{3g} varies between 17 % in $Ni(H_2O)_6^{++}$ to 37 % in $Cr(H_2O)_6^{+++}$. By the more direct method of measuring the contribution of nuclear fine-structure of Ir, Cl and Br to the paramagnetic reasonance curves of $IrCl_6^-$ and $IrBr_6^-$, Owen and Stevens [10] found 20 % π-intermixing of γ_{5g} in these much more distinctly "covalent" complexes, while the σ-intermixing is assumed to be rather complete, *i. e.* 50 % in the platinum group complexes.

In d^5-systems, the excited states of the electron transfer bands correspond presumably to the closed shell γ_5^6, which can be only in one state, $^1\Gamma_{1g}$. Since $\gamma_{5g}^5\gamma_{3g}$ in iridium(III) is situated [1] about 25 000 cm^{-1} above γ_{5g}^6, the next type of excited state $\gamma_{5g}^5\gamma_{3g}$ will be far in the ultraviolet. Besides (L, S) coupling effects, each band should thus correspond to one type of hole in the molecular orbitals, which have lower energy than the partly filled γ_{5g}-shell (if this is not be case, the electron transfer would be spontaneous). It can be presumed that these orbitals of highest energy are of the π-electron type, while the stronger bonding σ-orbitals have lower energy. This is supported by the observed intensities in iridium(IV) and ruthenium(III) complexes (see Tables 1 and 3). The intensity of a transition is increasing with the coincident presence in space of the groundstate ψ_1 and the excited state ψ_2, *i. e.* proportional to [51]:

$$\left(\int \psi_1 \; r \; \psi_2 \; dr\right)^2 \tag{8}$$

The π-electrons which are mainly removed from the central ion, has a relatively low value of this integral, corresponding to the oscillator strength $P \sim 0.02$. When the σ-electrons are excited to anti-bonding states, much higher values of P are expected at higher wavenumbers. Since γ_{4u} is weakly bonding, while γ_{5u} is not bonding at all, the configuration $\gamma_{5g}^6\gamma_{4u}^{-1}$ (π) has probably slightly higher energy than $\gamma_{5g}^6\gamma_{5u}^{-1}$ (π), when a hole in a molecular orbital is denoted $\gamma_u^{-1}(\pi)$ or (σ).

The two high bands with $\varepsilon \sim 2\,000$ in $RuCl_6^{---}$, $RuBr_6^{---}$ and $IrCl_6^{--}$ should thus correspond to $^2\Gamma_{5u}$ at lower and $^2\Gamma_{4u}$ at higher wavenumber. By effects of intermediate coupling, the two bands should each divide into two bands:

$$\begin{aligned} {}^2\Gamma_5 \times \Gamma_6 &= \Gamma_7 + \Gamma_8 \\ {}^2\Gamma_4 \times \Gamma_6 &= \Gamma_6 + \Gamma_8 \end{aligned} \tag{9}$$

Due to deviations from the cubic symmetry, the band Γ_8 can further divide into two, but Kramer's degeneracy permits only three levels to be formed from the six states in $^2\Gamma_4$ or $^2\Gamma_5$. This accounts for $IrBr_6^{---}$ exhibiting six bands with a splitting, comparable to $\zeta_{4p} = 2\,458$ cm^{-1} in atomic Br, while the smaller $\zeta_{3p} = 588$ cm^{-1} in Cl is only indicated by the splitting in $IrCl_6^{--}$ at 23 200 and 24 200 cm^{-1}.

Since the even $\gamma_{4g}(\pi)$ and $\gamma_{5g}(\pi)$ presumably have similar energy as the odd π-orbitals, the observation of weak electron transfer bands from these states is not very probable. But the weak shoulder of $IrCl_6^{--}$ at 17 400 cm^{-1} is not yet identified; it resembles very much a spin-forbidden band as discussed above, but quartet levels are only possible in configurations with at least two partly filled shells with each an electron or a hole. It may be a crystal field band $^2\Gamma_{ng}$ of the type discussed above for ruthenium(III) complexes, highly intermixed by hemiedric fields with the odd levels of electron transfer. However, this necesitates interactions between two levels, which are mainly different by two electrons.

In the platinum(IV) and other d^6-systems, the excited configuration of an electron transfer band must be $\gamma_{5g}^6\gamma_{3g}$. The relatively high energy of this configuration explains very well the lower oxidizing character of platinum(IV),

compared to iridium(IV) and of rhodium(III), compared to ruthenium(III). The electron transfer bands seem to be about 10 times higher in the d^6-systems than in the d^5-systems, suggesting the transfer of $\gamma_{4u}(\sigma)$.

In the first transition group, the d^6-systems of cobalt(III) exhibit similar very strong electron transfer bands, as shown by Linhard and Weigel [52]. Smaller bands with $\varepsilon \sim 1\,000$ occur only in the case of ligands with internal transitions, *e. g.* SCN^- or NO_2^-. An analogy to ruthenium(III) and iridium(IV) with one hole in a closed shell, which moves by the transition, can be found in the d^9-system copper(II). Besides the strong absorption in the far ultraviolet, a band of $CuCl_4^{--}$ can be distinguished at 26 000 cm^{-1} with $\varepsilon \sim 1\,500$. In the dark-red solutions of copper(II) in HBr, presumably containing $CuBr_4^{--}$, a double band is found by the author at 588 mμ ($\varepsilon = 1\,000$) and 512 mμ ($\varepsilon = 2\,100$). These bands are probably due to transfer of a γ_{t5u} electron. This level is the only tetragonal one, which can split due to intermediate coupling, maintaining Kramer's degeneracy. Belford [56] has recently applied the molecular orbital theory to copper(II) complexes, especially with two acetylacetonates in the plane and different solvents perpendicular to the plane. Ito and Kuroda [57] have published four papers on the molecular intermixing of d-orbitals in general. Only the japanese text of the three first has been available to the present author, but Ito and Kuroda seem to place the bonding σ-orbitals γ_3 and γ_{4u} very close below γ_5 (3d), thus exaggerating their influence. Rather, the crystal field splitting must constitute roughly 50 % of $(E_1 - E_2)$, as pointed out by Belford [56] who calculated the influence of the crystal field on a Hartree's self-consistent field copper ion, rather than the unprobable hydrogen-like 3d-electron [5] with $Z = 7.85$.

Fig. 6 gives the spectrum of $Fe(CN)_6^{---}$, one of the few $3d^5$-systems with $S = \frac{1}{2}$. The six bands found may be compared to those of $IrBr_6^{--}$. However, in this case the diatomic ligands have empty molecular orbitals to which γ_{5g}-electrons from the central ion can be excited. The triple bond between carbon and nitrogen in CN^- is equivalent to one σ- and two π-orbitals of anti-bonding type, which are empty in the ground-state. The excited states in this ion must have high energy, since ε first exceeds 1 at 265 mμ and $\varepsilon = 10$ at 215 mμ.

EXPERIMENTAL

The spectra were measured on a Cary spectrophotometer, furnished with a tungsten lamp in the range 800 – 325 mμ and with a hydrogen lamp 400 – 220 mμ; 1 cm absorption cells were used. While the Beckman spectrophotometer has its optimum accuracy at optical densities in the range 0.3 to 0.6, the similar range seems to be 0.8 to 1.5 on the Cary.

Preparation of the solutions of ruthenium complexes. Ruthenium metal powder from "Dansk Hollandsk Ædelmetal" (H. Drijfhout and Zoon) was melted with the ten-fold weight of Merck's potassium hydroxide in a nickel dish. Air-oxidation produces K_2RuO_4, but KNO_3 or $KClO_3$ mixed with the metal finishes the reaction in ten minutes. For preparation of the ruthenium(III) bromide solution, $KBrO_3$ was used as oxidizing agent. In all cases the cooled, tomato-red mass was dissolved in water (small gas-bubbles were evolved) and a few ml 96 % ethanol was added. After some seconds, the ruthenium is quantitatively reduced and precipitated as a black tetrahydroxide from a greenish, intermediate colour. It was washed several times with water and soon (to evade ageing) dissolved by boiling for 30 minutes with 6 M HCl or HBr. The clear, dark-brown solution

in HCl can be reduced with excess of precipitated silver powder to a strawberry-red solution of $RuCl_6^{--}$ and $RuCl_5(H_2O)^{--}$, while further reduction with stronger reducing agents (Zn, Al) gives green and finally blue-violet ruthenium(II), as described above. $Ru(OH)_4$ boiled with HBr liberates Br_2 and a dark purple-brown solution is formed.

Preparation of the solutions of iridium(IV) complexes. Iridium metal powder from "Dansk Hollandsk Ædelmetal" was more difficult to oxidize. 3.3 g was mixed with 10 g NaCl and heated to 600–700° C in a vitreosil tube in a stream of chlorine. The cooled mass yielded only 1.3 g Ir soluble in water as $IrCl_6^{--}$. The coarse crystalline residue was melted six hours with NaOH + $NaNO_3$ in a nickel crucible; only 0.4 g was dissolved. Then, it was melted with 5 g BaO_2 + 5 g $Ba(NO_3)_2$, dissolving 0.5 g. The main portion of the rest was dissolved by melting with pure barium dioxide in the same crucible at 700° C for two hours. In all cases, the alkaline solutions precipitated, on boiling and dilution, most iridium as blue tetrahydroxide, which could be washed and dissolved in 10 M HCl. This gives a dark-blue colour, which after four days at room temperature or by boiling turns red-brown. The alkaline filtrate is pale lavender-blue and is unchanged by addition of acids. The absorption spectrum exhibits maxima at 575 mμ (very broad, often with a shoulder at 740 mμ) and a shoulder at 356 mμ. If boiled with $BaCO_3$, the acid solution precipitates $Ir(OH)_4$.

Na_2IrCl_6, $6H_2O$. A sample of fine quality from the laboratory's collection was used. K_2IrCl_6 of unknown origin was found to contain much Pt; "Crude IrO_2" of S. M. Jørgensen had a high content of Os, *etc.*

The purple chloride-free solutions of iridium(IV) have been made [1] from Na_2IrCl_6 boiled with $HClO_4$. Ayres and Quick [58] have investigated the solutions in mixtures of $HClO_4$, H_3PO_4, and HNO_3 and demonstrated the oxidation state to be +4. The maximum at 564 mμ has ε = 2 650 and is displaced, when pH increases over 3 to 584 mμ at pH = 5. The analytical method does not seem to be more advantageous than the determination of $IrCl_6^{--}$ in strong HCl + Cl_2 and seems to have the same drawbacks: Ru and Os interfere strongly, while Rh, Pd and Pt in both cases have ε only a few per cent of Ir. Although $Ir(OH)_4$ forms blue and purple, colloidal solutions [59,60], it cannot be regarded as certain, if the purple solutions in strong acids (which already were discovered by Vauquelin [61]), are not simply monomer or dimer hydroxo-aquo complexes.

$[N(C_2H_5)_4]_2PtCl_6$, K_2PtBr_6 and $[N(C_2H_5)_4]_2PtBr_6$ were taken from S. M. Jørgensen's collection. PtI_6^{--} was prepared several times from different solutions of $PtCl_6^{--}$ and KI and always showed identical spectra.

$[Pt(NH_3)_6]Cl_4$ was prepared according to Tronev and Shumilina [20]. $(NH_4)_2PtCl_6$ of the laboratory's collection was treated with liquid ammonia in a test tube, surrounded by a steel micro-autoclave. The pale yellow powder was extracted with water and made 5 M in HCl, which precipitated the white chloride. Since nearly all salts of $Pt(NH_3)_6^{++++}$ are feebly soluble, the ionic strength was maintained at only 0.1 during the titration with the glass-electrode pH-meter Radiometer M22.

$[Pt(NH_3)_5Cl](NO_3)_3$ was kindly furnished by Professor J. A. Christiansen. For study of the influence of nitrate ions the spectra were compared with $[Pt(NH_3)_4(NH_2)Cl]Cl_2$ dissolved in HCl, which exhibited also the weak band at 286 mμ.

$K_3Fe(CN)_6$ was recrystallized from "Anala R" by Miss Lene Rasmussen.

Acknowledgments. I am very much indebted to Professor J. Bjerrum for his interest in the work. Further, I thank Miss Bodil Friis for assistance with preparation of ruthenium complexes.

The Solubility of Silver Iodide in Aqueous Solutions of Silver Perchlorate

IDO LEDEN and CURT PARCK

Department of Inorganic Chemistry, Chalmers Institute of Technology, Göteborg, Sweden

The reaction between solid silver iodide and silver ions (*vide* formula (2) below) was studied at 25° C and at an ionic strength of 4 M by saturating 4 M solutions of silver perchlorate and sodium perchlorate and mixtures of these two solutions with silver iodide. The concentration of silver perchlorate in the mixtures ranged from 10^{-5} M to 3 M. The solubility of silver iodide in aqueous solutions of silver salts has been determined by previous authors only at rather high silver ion concentrations (for literature, *vide* Sillén [1]).

Solubilities above 5×10^{-4} M (molar silver ion concentration, $[Ag^+]$, >0.5) were determined by diluting the saturated solutions with hot water to a silver ion concentration of 0.025 M, where the solubility ($\sim 2 \times 10^{-6}$ M at 25° C) of silver iodide is negligible compared with the solubility at those high silver ion concentrations. The silver iodide, precipitated by the dilution, was filtered off from the solution after cooling and then weighed. The method was controlled by dissolving known (~0.1 g) amounts of silver iodide in a 4 M solution of silver perchlorate, which was then diluted as mentioned above. Three such experiments were made and the difference between the weights of silver iodide dissolved and recovered was in all three cases less than 0.05 %. It was determined by analyses that no solid phases other than AgI were formed by contact with any of the silver perchlorate solutions.

In the range $10^{-5} < [Ag^+] < 10^{-1}$ the solubilities were determined by using silver iodide labelled with ^{131}I (from Harwell). Radioactive silver iodide was prepared by mixing an aqueous solution of carrier-free iodide ^{131} with a solution of inactive sodium iodide to a known concentration of iodide, say 10^{-2} M, and precipitating the silver iodide with silver perchlorate. Before the precipitation a small part of the active solution of sodium iodide was diluted 10^3 or 10^5 times (with inactive iodide), so that its activity could be conveniently determined in a 10-ml G. M. tube for liquids (Type M6 from 20th Century Electronics Ltd., combined with a Predetermined Count Scaler PW 4035 from Philips). The precipitate of labelled silver iodide was washed carefully first with water and then with the solution, in which its solubility was finally de-

termined by shaking in a thermostat. About 10 mg precipitate were used to prepare 100 ml of solution. Samples were taken from the solution after 8, 24, and 48 hrs and filtered under pressure at 25° C through a collodion filter in a Thiessen apparatus. During this time no other change of the activity of the saturated solution could be detected than that depending on the decay of ^{131}I (half-life 8.0 days), although the silver iodide darkened obviously in a few hours and was quite black after 2 days. The specific activity of the solid silver iodide had to be at least 100 millicuries per gram, when the lowest solubilities were measured. Further experimental details are given elsewhere [2].

The results are listed in Table 1. The accuracy (*vide* Table 1) of the radio assay method is rather low, mainly because of the low specific activity of the solutions, which corresponded to 10 to 30 cpm for the lowest solubilities, measured with a 30 cpm background count.

The solubility, l can be described by the equation

$$l = \sum_{n=-1}^{N} K_n [Ag^+]^n \qquad (1)$$

if the activity constants maintain constant values in all the solutions, and if the silver iodide is dissolved according to the reactions

$$m\ AgI(s) + n\ Ag^+ \rightleftharpoons Ag_{m+n}I_m^{n+} \qquad (2)$$

i. e., to produce species with the charges n (*cf.* Ref. [3]). By graphical methods or by trial and error the following constants are easily calculated ($N = 3$): $K_0 = 6 \times 10^{-9}$, $K_1 = 10^{-6}$, $K_2 = 7 \times 10^{-4}$, $K_3 = 3.7 \times 10^{-3}$. For K_{-1} the value 4.5×10^{-17} has been used, which is the value of the solubility product of silver iodide in a 4 M solution of sodium perchlorate, as determined in this laboratory by e.m.f. measurements. The experimental values of the solubility

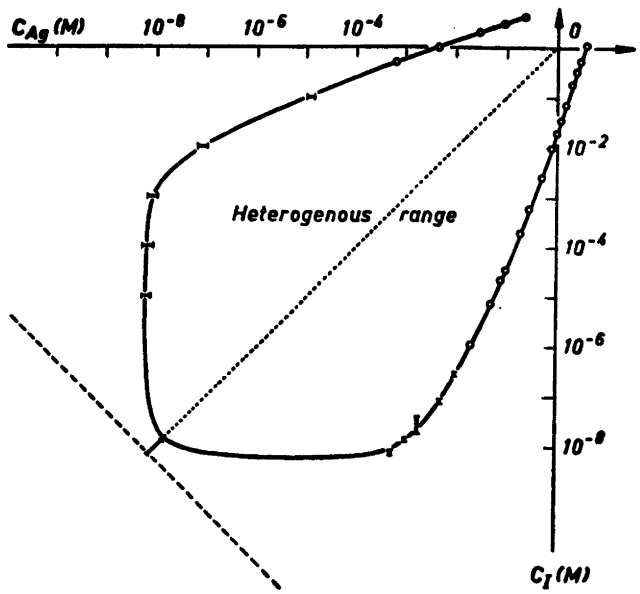

Fig. 1. The solubility of silver iodide in aqueous silver perchlorate and sodium iodide at 25° C. Ionic strength 4 M ($NaClO_4$).

are compared with those computed from eqn. (1) in Table 1. The concentration of free silver ions may be considered to be equal to the concentration of silver perchlorate in the solvent except for the pure sodium perchlorate, where the value $\sqrt{K_{-1}}$ has been used, and for the last four determinations in Table 1. In these latter cases the solubility can be neglected no longer, when compared with the contents of silver perchlorate. For the calculation of $[Ag^+]$ of these four solutions the constants K_n have been used, and it has been assumed that every complex contains only one iodide atom, *i. e.*, that the dominating species are Ag_4I^{3+} and Ag_3I^{2+}. As is seen from Table 1 the solubility is described well by eqn. (1) in all solutions except three, *viz.*, those of pure sodium perchlorate and 3 and 4 M silver perchlorate. In sodium perchlorate the reproducibility is also less than elsewhere, being dependent perhaps on the difficulty in washing away the silver perchlorate from the precipitate so carefully that its remaining concentration becomes small compared with 10^{-8} M. In the two last solutions with high silver ion concentrations the lack of success in describing the results with eqn. (1) can depend on any or all of the following reasons: (a) changes of activity factors, as most of the sodium perchlorate is here substituted by silver perchlorate; (b) formation of complexes with charges higher than 3, *i. e.*, $N > 3$ in eqn. (1), which would then contain more than five terms; (c) formation of complexes with several iodide atoms, *e. g.* $Ag_6I_3^{3+}$ instead of Ag_4I^{3+}, which would cause a smaller decrease of the free silver ions of the silver perchlorate than that calculated at the bottom of Table 1 and hence higher values of l_{calc}.

Fig. 1 is a graphical representation of the data of Table 1 and contains also the solubility of silver iodide in solutions of sodium iodide as determined in this laboratory. The curve above the line $c_{Ag} = c_I$, (dotted in Fig. 1) is calculated from the constants K_n and thus represents eqn. (1). The part of the curve under the same line describes the solubility in sodium iodide solutions. c_{Ag} and c_I are the t o t a l contents of silver and iodide of a system. Every point outside the curve signifies an unsaturated solution, the composition of which is given by the co-ordinates of the point. A point inside the curve signifies a heterogeneous system, containing both solid silver iodide and a saturated solution, the composition of which can be obtained easily from the diagram in the following way. Let Δ be the difference between the known total contents of silver and iodide of the heterogeneous system. Then the intersection of the solubility curve in Fig. 1 and the curve $c_{Ag}-c_I = \Delta$ gives the composition of the saturated solution. It is to be noted that $c_{Ag}-c_I = \Delta \neq 0$ is not a straight line, if drawn in a l o g a r i t h m i c diagram like Fig. 1. The dashed line to the left of Fig. 1 would describe the solubility of silver iodide, if no complexes were formed between silver and iodide ions.

From the constants K_n the distribution of iodide on the different complexes in a saturated solution can be calculated. If α_n is that fraction of the dissolved iodide, which is contained in a species with the charge n, the following expression is valid (*cf.* Ref.[4])

$$\alpha_n = \frac{K_n\,[Ag^+]^n}{l} \qquad (n = 0,\ 1,\ 2,\ \text{or}\ 3) \tag{3}$$

The distribution of iodide as calculated from eqn. (3) is given in Fig. 2, from which the values of α_n at a given silver ion concentration are obtained by drawing a vertical line through the corresponding abscissa. The curves divide this line in parts, each of which is equal to that α_n, whose number n has been written in the area between two curves. A remarkable feature of the distribution diagram is the almost complete predominance of uncharged molecules in a broad range of silver ion concentrations.

From solubility measurements alone it is not possible to conclude, whether the species formed contain one or several iodide atoms (*vide* Ref. [3]). As the solubility of silver iodide is very small in most of the solutions studied, it seems rather probable, however, that the species with the charges 0, 1, 2, and 3 simply are AgI, Ag_2I^+, Ag_3I^{2+}, and Ag_4I^{3+}. If this be the case, the distribution shown by Fig. 2 is also valid for u n s a t u r a t e d solutions containing silver iodide dissolved in aqueous silver perchlorate.

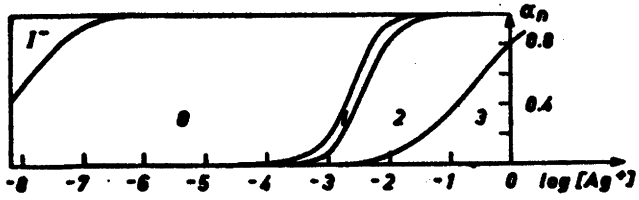

Fig. 2. The distribution of dissolved iodide on species with charges 0, 1, 2, and 3 in aqueous solutions of silver perchlorate saturated with silver iodide. Ionic strength 4 M ($NaClO_4$).

Obviously silver iodide is a very weak electrolyte. The degree of ionic dissociation of silver iodide in a pure aqueous solution is only about 50 % in spite of the low concentration. (See Fig. 2, which starts to the left with a solution of silver iodide in pure aqueous sodium perchlorate.) The dissociation constant for $AgI \rightleftharpoons Ag^+ + I^-$ (referring to d i s s o l v e d silver iodide) is $K_{-1}/K_0 = 7.5 \times 10^{-9}$, if the silver-iodide molecules are monomeric. The corresponding dissociation constants for silver chloride and silver bromide are about 8×10^{-4} and 4×10^{-5}, respectively (*vide* Refs.[2,4]).

Our thanks are due to Professor C. Brosset, who kindly permitted the use of the equipment of his laboratory for the G. M. measurements reported in this paper. We also wish to thank Professor J. Pepper, Saskatoon, Canada, for his work at our manuscript to make it more readable. The work was financially supported by *Statens Naturvetenskapliga Forskningsråd.*

A Potentiometric Study of the Complex Formation between Silver and Iodide Ions

IDO LEDEN

Department of Inorganic Chemistry, Chalmers Institute of Technology, Göteborg, Sweden

The e.m.f. of the cell (1) below was measured at 25° C in the range $0.003 < c_{Ag} < 0.08$ and with enough sodium iodide (<4 M) to prevent solid silver iodide from being precipitated. In this range the solutions contained significant amounts of four silver iodide species, *viz.* AgI_3^{2-}, AgI_4^{3-}, $Ag_2I_6^{4-}$, and $Ag_3I_8^{5-}$. The corresponding equilibrium constants were computed (Table 2) and the solubility product of silver iodide at the given ionic strength 4 M ($NaClO_4$) was determined.

The following cell, e. m. f. E mV, was measured at 25° C. All concentrations throughout the paper are given in gram formula weight per litre (M)

$$+\ \mathrm{Ag,AgI}\left|\begin{array}{l}c_{Ag}\ \mathrm{M\ AgClO_4}\\(4-c_{Ag})\ \mathrm{M\ NaClO_4}\end{array}\right|\mathrm{NaNO_3\ (sat.)}\left|\begin{array}{l}\mathrm{4\ M\ NaI}\end{array}\right|\begin{array}{l}c_{Ag}\ \mathrm{M\ AgClO_4}\\c_I\ \mathrm{M\ NaI}\\(4-c_{Ag}-c_I)\ \mathrm{M\ NaClO_4}\end{array}\Bigg|\ \mathrm{Ag}\quad(1)$$

The solutions of the right hand half-cell were obtained by mixing an original solution in the electrode vessel, containing c_{Ag} M $AgClO_4$ and $(4-c_{Ag})$ M NaI, with a solution from a burette containing c_{Ag} M $AgClO_4$ and $(4-c_{Ag})$ M $NaClO_4$. Portions of this latter solution were added until silver iodide was precipitated in the vessel. In some cases E was determined by measuring the two halves of the cell above against a reference electrode, $Hg,Hg_2Cl_2\,|\,4\ M\ NaCl\,|\,NaNO_3$ (sat.). The silver electrodes consisted of silver plated platinum wires, from which the silver-silver iodide electrodes were produced by anodic oxidation in a solution of sodium iodide acidified with hydrogen perchlorate (*cf.* Brown[1]). The sodium iodide was of *pro analysi* quality. Other chemicals used are described elsewhere (Ref. [2,3]), and here also the experimental details may be found.

The results of the measurements are given in Table 1. If the concentration of uncomplexed silver ions in the right hand solution of cell (1) is $[Ag^+]$, Nernst's formula gives

$$E = 59.16\ \log \frac{c_{Ag}}{[Ag^+]} \qquad (2)$$

					0.926	0.86	862.2	$L = 4.6 \times 10^{-17}$	

From the solutions below the lines silver iodide has been precipitated. Hence the solubility product, L, can be computed from the values of E, measured in these solutions.

●, ○, □, +: These signs are used in Figs. 1 and 2 to distinguish the four titration series.

As the variation of $c_{Ag}/[Ag^+]$ is about 1000:1 within a titration series, it is more practical to use the function (*cf.* Ref.[3])

$$F_4 = \frac{c_{Ag}}{[Ag^+]\ [I^-]^4} \tag{3}$$

for the graphical representation as the range of variation of F_4 is only 3:1 at most. F_4, drawn as a function of $1/[I^-]$, gives some of the equilibrium constants more directly than does a logarithmic representation.

To calculate F_4 and on the whole to analyse the data of Table 1, it is necessary to compute the concentration of the f r e e iodide ions of the solution. This has been done (*cf.* columns c_I and $[I^-]$ of Table 1) by reducing c_I with the small term of correction $\bar{n} \cdot c_{Ag}$, where $\bar{n}$, defined by the well-known eqn. (4), is the mean number of iodide ions bound per silver ion in the solution.

$$[I^-] = c_I - \bar{n} \cdot c_{Ag} \tag{4}$$

A sufficiently accurate value of $\bar{n}$ can be deduced from Bodländer's formula, approximated to (*cf.* Ref.[4])

$$\frac{\Delta E}{\Delta \log c_I} = 59.16\ \bar{n} \qquad (5)$$

where ΔE and Δc_I are the differences between two consecutive values of E and c_I in a titration series of Table 1. Though this approximation is certainly far from accurate, especially as the solutions contain polynuclear complexes, it gives values of $[I^-]$ from eqn. (4), which agree in all cases to within 1 % with the final values computed below. Hedström [5] has recently given an exact and general method to calculate the concentration of free ligands of a complex system, but in the present case a sufficient number of titration series has not been measured in order to make it possible to carry out the graphical integration necessary in Hedström's method.

The complex formation can be described by the equilibria

$$m\ Ag^+ + n\ I^- \rightleftharpoons Ag_mI_n^{m-n} \qquad (6)$$

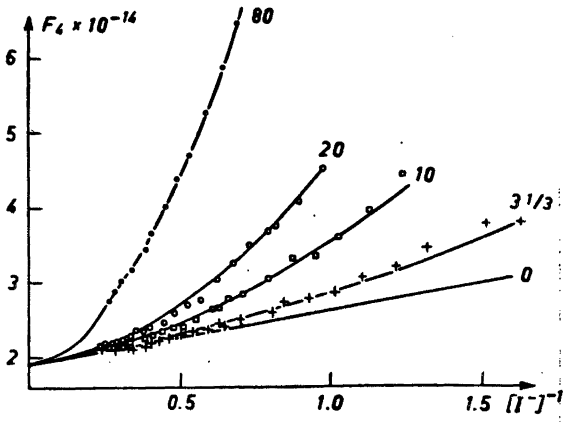

Fig. 1. F_4 *as a function of* $1/[I^-]$. *The numbers at the curves denote* $10^3 \times c_{Ag}$. *The ordinates of the points are obtained from the experiments by means of eqn. (3). The curves are calculated from the values of* $\beta_{m,m+n}$ *in Table 2 with the aid of eqns. (11) and (12).*

with the over-all complexity constants $\beta_{m,n}$. The law of mass action then gives ($\beta_{1,0} = 1$)

$$c_{Ag} = \sum_{m=1}^{M} \sum_{n=0}^{N} m\,[Ag_m I_n^{m-n}] = \sum_{m=1}^{M} \sum_{n=0}^{N} m\beta_{m,n}[Ag^+]^m[I^-]^n \qquad (7)$$

and hence F_4 can be written as

$$F_4 = \sum_{n=0}^{N} \beta_{1,n}[I^-]^{n-4} + \sum_{m=2}^{M} \sum_{n=1}^{N} m\beta_{m,n}[Ag^+]^{m-1}[I^-]^{n-4} \qquad (8)$$

where the first sum of the right hand member originates from the mononuclear and the double sum from the polynuclear species. Obviously

$$\lim_{c_{Ag} \to 0} F_4 = F_4^\circ = \sum_{n=0}^{N} \beta_{1,n}[I^-]^{n-4} \qquad (9)$$

F_4 is drawn as a function of $1/[I^-]$ in Fig. 1, from which it is seen that the curves for the two series with lowest silver contents coincide for low values of $1/[I^-]$. This gives immediately F_4°, which can be described by a straight line, *i. e.*

$$F_4^\circ = \beta_{1,4} + \beta_{1,3} / [I^-] \qquad (10)$$

for sufficiently high values of $[I^-]$. $\beta_{1,3} = (7 \pm 2) \times 10^{13}$ is obtained as the slope and $\beta_{1,4} = (19 \pm 1) \times 10^{13}$ as the extrapolated ordinate of this line. In Fig. 1 F_4° is drawn as a straight line in all that range, where potentiometric measurements have been made. This could be done, as some measurements of the solubility of silver iodide in aqueous sodium iodide, carried out in this

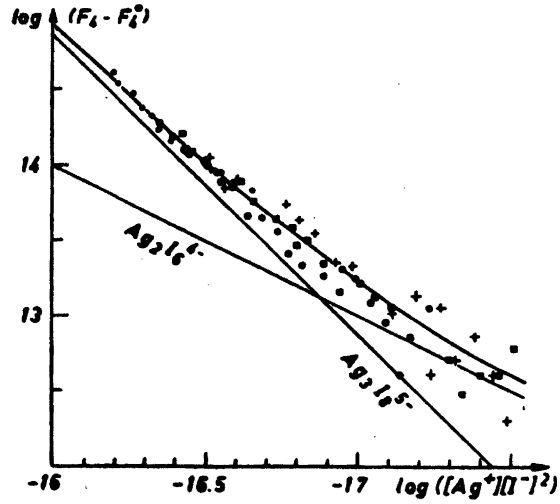

Fig. 2. (F_4—F_4°) *is a function of* $[Ag^+][I^-]^2$ *solely for all the four series measured. The straight lines show how* (F_4—F_4°) *can be separated into two terms, corresponding to the two complexes marked.*

laboratory, show definitely that the succeeding terms of F_4°, *viz.* $\beta_{1,2}/[I^-]^2$ and so on, are quite negligible, when $[I^-] > 0.5$.

The polynuclear species and their strength can be obtained by studying the difference (F_4—F_4°), F_4° now being known from eqn. (10). This has been done in Fig. 2, where log (F_4—F_4°) has been drawn as a function of log ($[Ag^+][I^-]^2$) (*cf. e.g.* Hietanen and Sillén [6]). In this diagram the points from all the four series measured fall on one single curve. This means that the only terms to be considered in the double sum of eqn. (8) are those of the form $\beta_{m,\,2m+2}$ $([Ag^+][I^-]^2)^m$, corresponding to one or several of the species $Ag_mI_{2m+2}^{(m+2)-}$. At the higher values of (F_4—F_4°) the curve of Fig. 2 is described rather well by a straight line with slope —2, which means that the species $Ag_3I_8^{5-}$ dominates. At lower values the accuracy is small, as (F_4—F_4°) is small compared with F_4. At all events it seems obvious that the points here lie over the line mentioned, and hence a term of first degree in $[Ag^+]$ $[I^-]^2$ has been introduced, representing the silver tied up in $Ag_2I_6^{4-}$. Hence the only polynuclear complexes to be considered are $Ag_2I_6^{4-}$ and $Ag_3I_8^{5-}$. The distribution of the silver between those is shown by the two straight lines in Fig. 2. Their positions are settled by the over-all complexity constants $\beta_{2,6} = (5 \pm 3) \times 10^{29}$ and $\beta_{3,8} = (25 \pm 5) \times 10^{45}$, which have been obtained from the straight line resulting, when (F_4—F_4°) · $[Ag^+]^{-1}$ $[I^-]^{-2}$ is drawn in a diagram as a function of $[Ag^+]$ $[I^-]^2$. From such a diagram the accuracy of the constants can also be judged.

From the discussions above it follows, that only four complexes, *viz.* AgI_3^{2-}, AgI_4^{3-}, $Ag_2I_6^{4-}$, and $Ag_3I_8^{5-}$, are to be considered in the range, where e.m.f. measurements have been carried out. Hence eqn. (7) is simplified in this range to

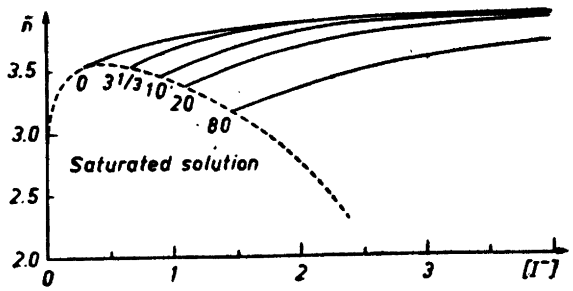

Fig. 3. The mean number, $\bar{n}$, of iodide ions bound per silver ion in unsaturated solutions with total silver contents marked as $10^3 \times c_{Ag}$ at the corresponding curves. The dashed curve is calculated from the solubility of AgI in aqueous solutions of NaI.

$$c_{Ag} = \beta_{1,3}[Ag^+][I^-]^3 + \beta_{1,4}[Ag^+][I^-]^4 + 2\beta_{2,6}[Ag^+]^2[I^-]^6 + 3\beta_{3,8}[Ag^+]^3[I^-]^8 \quad (11)$$

and correspondingly

$$c_I - [I] = 3\beta_{1,3}[Ag^+][I^-]^3 + 4\beta_{1,4}[Ag^+][I^-]^4 + \\ + 6\beta_{2,6}[Ag^+]^2[I^-]^6 + 8\beta_{3,8}[Ag^+]^3[I^-]^8 \quad (12)$$

where the pertinent constants $\beta_{m,n}$ are now known from the graphical computations, described above. Hence $\bar{n}$, representing the value of the right hand member of eqn. (12) divided by the right hand member of eqn. (11), may be calculated for each titration series, by solving for $[Ag^+]$ and $[I^-]$ from eqns. (11) and (12) for some values of c_I. The same values of $[Ag^+]$ and $[I^-]$ have also been used to calculate the F_4-curve of Fig. 1. The corresponding $\bar{n}$-curves are to be seen in Fig. 3, which has been used to calculate the values of $[I^-]$ in Table 1 from eqn. (4). On the whole this computation gives the same result as the first approximation from Bodländer's formula, eqn. (5), and the same values of $[I^-]$ were also obtained by several other approaches, tried by the author to describe the complex formation. The reason for this is of course that c_I is in all cases so much larger than c_{Ag} that even a very rough approximation of $\bar{n}$ gives a rather correct value of $[I^-]$ from eqn. (4).

The two polynuclear complexes found above are formed quite reasonably by the two consecutive condensation reactions

$$2AgI_4^{3-} \rightleftharpoons Ag_2I_6^{4-} + 2I^- \text{ and } Ag_2I_6^{4-} + AgI_4^{3-} \rightleftharpoons Ag_3I_8^{5-} + 2I^- \quad (13)$$

with the equilibrium constants $b_{2,6} = \beta_{2,6} \cdot (\beta_{1,4})^{-2} = 15 \pm 10$ and $b_{3,8} = \beta_{3,8} \cdot (\beta_{2,6} \cdot \beta_{1,4})^{-1} = 250 \pm 150$, respectively. It seems rather probable that analogous condensation reactions continue to produce larger species of the form $Ag_mI_{2m+2}^{(m+2)-}$ with increasing total silver concentrations. It could certainly be possible to draw the curve of Fig. 2 less rectilinear in its upper part and so make room for more highly condensed species at the expense of $Ag_3I_8^{5-}$. Such an increased curvature would be rather arbitrary, however. It is known (Sillén [7]) that the method used in the present paper is "a rather un-

favourable case, as $[Ag^+]$ is measured, but the difference $(c_I - [I^-])$ cannot be calculated with enough accuracy to be of much help". Hence there is not much reason to speculate about the higher condensation products. Perhaps it could be said that it is rather probable that the equilibrium constant, $b_{4,10}$, of the next member of the series, $Ag_4I_{10}^{6-}$, is less than $b_{3,8}$, as $b_{4,10} > b_3$ would give a quite pronounced curvature to the upper part of the curve of Fig. 2. The description above of the silver-iodide system is in better agreement with the experimental data than an infinite series of complexes would be, in which all the equilibrium constants $b_{m,2m+2}$ have the same value for $m > 2$. There is also the possibility that a reaction, *e. g.* a ring closure:

$$Ag_mI_{2m+2}^{(m+2)-} \rightleftharpoons Ag_mI_{2m}^{m-} + 2I^- \qquad (14)$$

cuts off the series at some step in the postulated continuing condensation.

The results obtained from the e.m.f. measurements agree quantitatively with those from the solubility determinations already mentioned. These latter measurements moreover gave some information about the silver iodide species with negative charges less than —2. They also proved the existence of complexes with negative charges higher than —5 in solutions with silver contents larger than those studied in the present paper.

Table 2. The over-all complexity constants $\beta_{m,m+n}$ for the reaction (6) and $k_{m,n}$ for the reaction (16). $L = 4.5 \times 10^{-17}$.

Complex	$\beta_{m,m+n}$	$k_{m,n}$
AgI_3^{2-}	$\beta_{1,3} = (7 \pm 2) \times 10^{13}$	$k_{1,2} = (3 \pm 1) \times 10^{-3}$
AgI_4^{3-}	$\beta_{1,4} = (19 \pm 2) \times 10^{13}$	$k_{1,3} = (9 \pm 1) \times 10^{-3}$
$Ag_2I_6^{4-}$	$\beta_{2,6} = (5 \pm 3) \times 10^{29}$	$k_{2,4} = (10 \pm 6) \times 10^{-4}$
$Ag_2I_8^{5-}$	$\beta_{2,8} = (25 \pm 5) \times 10^{45}$	$k_{2,5} = (23 \pm 5) \times 10^{-4}$

The solubility product, L, of silver iodide in 4 M sodium perchlorate could be computed from the values of E in those solutions at the end of the titration series (*vide* Table 1), where solid silver iodide was formed. It was also determined by measuring the e.m.f. of the following cell

$$+ \text{Ag,AgI} \left| \begin{matrix} 0.016 \text{ M } AgClO_4 \\ 3.98 \text{ M } NaClO_4 \end{matrix} \right| 4 \text{ M } NaClO_4 \left| \begin{matrix} c_I \text{ M NaI} \\ (4 - c_I) \text{ M } NaClO_4 \end{matrix} \right| \text{Ag,AgI} - \qquad (15)$$

The e.m.f. was 723.8 mV for $c_I = 0.005$ and 801.7 for $c_I = 0.1$, which gives $L = 4.6_6 \times 10^{-17}$, respectively $4.5_0 \times 10^{-17}$. The average of all the determinations is $L = (45 \pm 1) \times 10^{-18}$. This value has been used in Table 2 to calculate the equilibrium constants, $k_{m,n}$, valid for the reactions between solid silver iodide and iodide ions

$$m \text{ AgI(s)} + n \text{ } I^- \rightleftharpoons Ag_mI_{m+n}^{n-} \qquad (16)$$

Hence

$$k_{m,n} = L_m \times \beta_{m,m+n} \qquad (17)$$

The author is grateful to Professor J. Pepper for his revision of the English of the manuscript and to L. E. Marthén for experimental assistance. *Statens Naturvetenskapliga Forskningsråd* supported the work financially.

Aspartate Carbamyl Transferase from *Escherichia coli*

PETER REICHARD and GUNNAR HANSHOFF

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Carbamyl phosphate was found to be an intermediate in the biosynthesis of carbamyl aspartic acid (= ureidosuccinic acid). Strong evidence was obtained that enzymically prepared and purified compound X was identical with synthetic carbamyl phosphate.

An enzyme was purified *ca.* 100 fold from extracts of lyophilized *E. coli* which catalyzed the following stoichiometric reaction:
Carbamyl phosphate + L-aspartate → L-carbamyl aspartate + P_i

The name aspartate carbamyl transferase is proposed for this enzyme. The equilibrium of the reaction was shifted very far towards synthesis of CA-aspartate.

Out of 31 tested amino acids only L-aspartic acid served as acceptor for the carbamyl group. The enzyme is distinct from the citrulline forming enzyme and the enzyme forming β-ureidopropionic acid.

The enzyme was inhibited by *p*-chloromercuribenzoate and the inhibition could be completely reversed by glutathione. Aspartate + carbamyl phosphate protected the enzyme from the inhibition, while each substrate alone had no effect.

Inorganic ^{32}P showed no enzymic exchange with the phosphate moiety of carbamyl phosphate in the absence of aspartate, and the enzyme catalyzed no exchange of isotope between L-aspartate-^{14}C and carbamyl aspartate.

When the reaction was carried out in $H_2{}^{18}O$ no isotope was found in the carbamyl group of carbamyl aspartate or carbamyl phosphate.

A probable mechanism for the reaction is discussed.

Extracts from various organs of the rat and from lyophilized *E. coli* contain an enzyme which has the ability to catalyze the formation of carbamyl asparacid (= ureido succinic acid *) from aspartic acid and an activated carbamyl compound, called compound X[1,2]. This reaction shows a close analogy to the previously demonstrated formation [3] of citrulline from ornithine + compound X. With a partially purified enzyme from *E. coli* we could demonstrate the stoichiometric formation of one molecule of CA-aspartate ** per one molecule

*. In earlier communications the name ureidosuccinic acid was used instead of the synonym carbamyl aspartic acid. The enzymic mechanism involved in the formation of this substance makes us now prefer the latter name.

**. The following abbrevations are used in this paper: ATP, adenosine triphosphate; CA, carbamyl; CAP, carbamyl phosphate; CMBA, *p*-chloromercuribenzoate; P_i, inorganic phosphate; tris, trishydroxymethylaminomethane; PCA, perchloric acid.

of aspartate and one molecule of compound X. Since it was believed [3] that compound X contained acetylglutamate and phosphate as well as the carbamyl group, the reaction was tentatively formulated as follows:

$$\text{Compound X} + \text{L-aspartate} \rightleftharpoons \text{CA-aspartate} + \text{acetyl glutamate} + P_i \quad (1)$$

Jones *et al.*[4] have recently synthesized carbamyl phosphate and have presented very strong evidence that this compound is the carbamyl donor in enzymic citrulline synthesis and therefore identical with compound X. Their work prompted us to reinvestigate the formation of CA-aspartate with the bacterial enzyme. It was found that the earlier enzymically prepared and purified compound X was identical with synthetic CAP. The easy availability of the latter compound made feasible a further purification and a closer study of the CA-aspartate forming enzyme and the mechanism of its action. The enzyme was found to catalyze the transfer of a carbamyl group from phosphate to L-aspartate in a stoichiometric manner:

$$\text{Carbamyl phosphate} + \text{L-aspartate} \rightarrow \text{L-carbamyl aspartate} + P_i \quad (2)$$

The name aspartate carbamyl transferase is proposed for this enzyme.

EXPERIMENTAL

L-Acetyl glutamic acid was synthesized according to Karrer *et al.*[5], the labeled *L-aspartic acids* according to Wu and Rittenberg [6], and *carbamyl phosphate* according to Jones *et al.*[4] *DL-CA-aspartate* was synthesized according to Nyc and Mitchell [7]. Since the L-isomer does not crystallize readily it was purified by chromatography as described below, lyophilized and utilized directly for the demonstration of the back reaction. *Compound X* was prepared enzymically as described earlier [8,1].

Enzyme assay. Method 1: L-Aspartate-^{15}N was used as substrate and the CA-aspartate formed was determined after addition of carrier DL-CA-aspartate as described earlier [9]. The reaction was terminated by acidification with PCA instead of heat denaturation used in previous studies. In this way it was possible to avoid significant non-enzymic formation of CA-aspartate at substrate concentrations below 0.1 M. When conditions were the same as described for method 2, identical results were obtained with both methods. In most cases, however, only 0.03 M aspartate-^{15}N was used in order to preserve isotope. Under those conditions the obtained value for CA-aspartate formation could be multiplied by a factor of 1.5 in order to obtain a comparison with standard conditions.

Method 2: This method depended on the direct determination of the inorganic phosphate formed during the enzyme reaction. It was the method of choice with the purified enzyme whenever, in a set of experiments, it was possible to work with a relatively low and constant concentration of CAP, and no substances were present which interfered with phosphate analysis.

The enzyme was added to a solution containing 100 μmoles of L-aspartate, 20—30 μmoles of CAP and 150—500 μmoles of tris buffer, pH 7.5, the final volume being 1.0 ml *. Incubation was carried out for 15 minutes at 37°. The reaction was stopped by immersion of the sample in an ice bath and P_i determined directly on aliquots by the Lowry-Lopez [10] method. A blank containing the same constituents with the exception of aspartate (or enzyme) was carried through the same procedure in order to make possible a correction for the non-enzymic decomposition of CAP. The P_i value of the blank was subtracted from that of the complete sample. Under those conditions proportionality

*. The lithium salt of CAP and the potassium salt of L-aspartic acid were used in all experiments. Li-CAP was dissolved immediately before use in each experiment. No difference was found in the reaction rate when sodium aspartate was used instead of the potassium salt.

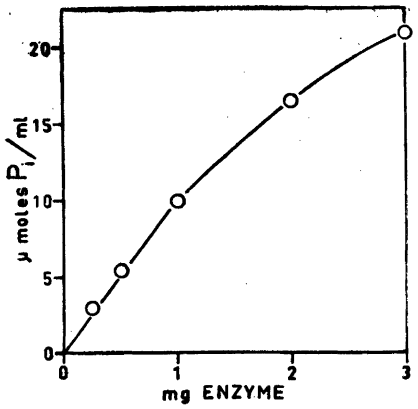

Fig. 1. Formation of P_i from CAP with different amounts of enzyme (ammonium sulfate fraction).

The solutions contained per ml: 100 μmoles of L-aspartate, 25 μmoles of CAP and 150 μmoles of tris buffer, pH 7.5. Incubation for 15 minutes at 37°.

between amount of enzyme added and P_i formed was observed up to *ca.* 10 μmoles (Fig. 1).

One unit of enzyme activity was defined as the amount of enzyme which formed one μmole of P_i or CA-aspartate under the above conditions. The specific activity of the enzyme was defined as units per mg protein. Up to and including the ammonium sulfate fractionation step protein concentration was determined by nitrogen analysis of the PCA precipitate, assuming a nitrogen content of 16 %. Subsequently protein was determined by light absorption measurements at 280 and 310 mμ. It was found that 1 mg of protein of the lyophilized ammonium sulfate fraction dissolved in 1 ml of water showed a value for $E_{280}-E_{310}$ of 0.60. This value was used for calculation of protein concentrations during and after the chromatographic purification step.

The activity of the *citrulline forming* enzyme was measured under identical conditions as described above for CA-aspartate, except that ornithine was substituted for aspartate. The citrulline formed was determined colorimetrically according to Koritz and Cohen [11].

Purification of the enzyme. Lyophilized *E. coli* were handled as forty grams samples. The first steps including extraction, protamine precipitation and ammonium sulfate fractionation were carried out as described earlier [1] with one exception. Incomplete precipitation with protamine was encountered in a few cases. Therefore this precipitation was performed in an ice bath and the solution allowed to stand for 30 minutes in the cold room prior to centrifugation in the Spinco centrifuge (30 000 g for 10 minutes). In this way less than 15 % of the enzyme activity remained in the supernatant in all cases. After the ammonium sulfate step a 7—12 fold purification of the enzyme had been achieved. The enzyme could be lyophilized and stored at —15° without appreciable loss of activity for at least 6 months.

Further purification of the enzyme was carried out by chromatography [13] on DEAE columns *. The column (diameter 2 cm) was prepared from 12 g of DEAE-cellulose (0.9—1.0 % nitrogen, prepared from Whatman's standard grade paper powder). It was washed first with *ca.* 500 ml M KCl, followed by 200 ml of 0.01 M imidazole : HCl buffer, pH 6.5, containing KCl at 0.02 M concentration. The last wash and all the following operations were carried out at 2—4°.

The dialyzed enzyme, after the ammonium sulfate step (from 40 g of bacteria, dissolved in 15—20 ml of 0.01 M phosphate buffer, pH 6.5), was then adsorbed on the column, which was connected with a 1 000 ml mixing flask containing 0.01 M imidazole buffer (pH 6.5) : 0.02 M KCl. This flask received 0.75 M KCl from a reservoir flask. The protein was eluted by gradient chromatography (*cf.* Ref [13]). Half hour fractions with a volume of *ca.* 10 ml were collected.

*. We wish to thank Drs. E. A. Peterson and H. A. Sober who most generously made available to us a manuscript of their work prior to publication.

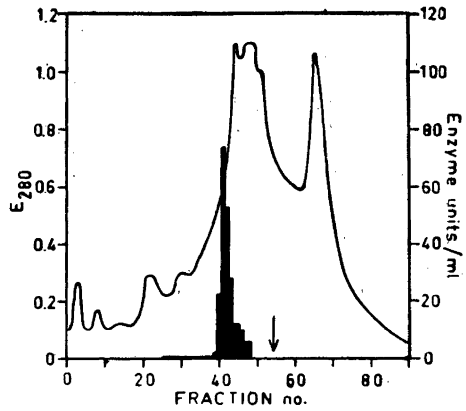

Fig. 2. Chromatography of transferase (560 mg, 5 300 units) on DEAE cellulose.

KCl concentration changed to 2 M at arrow. Stepped curve = enzyme activity, continuous curve = E_{280}.

Protein concentration was determined in each fraction by direct measurement of the light absorption at 280 mμ in a Beckman spectrophotometer, model DU. Furthermore, aliquots from each fraction (usually 0.1 ml) were analyzed for transferase activity according to method 2. A typical diagram obtained in this way is shown in Fig. 2.

The total recovery of enzyme activity after chromatography was *ca.* 75 %. More than 60 % of the recovered activity was located in two or three middle fractions. By chosing only these fractions for further work the chromatographic step resulted in a 8—13 fold purification of the enzyme with a recovery of 45—50 % of the total activity.

To the combined chromatographic fractions were added 1 ml of M K_2HPO_4 and 100 μmoles of neutralized reduced glutathione. The enzyme was then precipitated by addition of solid ammonium sulfate to 65 % saturation. The solution was first attached to a water pump for 15 minutes in order to remove most of the dissolved air and then centrifuged. The resulting precipitate was suspended in 2 ml of 0.1 M tris buffer, pH 7.5, and centrifuged. The supernatant contained 80—100 % of the transferase activity of the combined chromatographic fractions. It was frozen and stored at −15°. Lyophilization could not be carried out at this point without heavy losses. During storage different preparations showed a varying decline of enzyme activity. Addition of glutathione (final concentration 0.05 M) seemed to preserve enzyme activity for a longer time (at least 2—3 weeks).

The results obtained by the chromatographic step were very reproducible. The enzyme could always be localized in an approximate way from the E_{280} curve, since it coincided with a more or less pronounced "shoulder" of this curve before the first large peak.

A summary of a typical purification procedure is given in Table 1.

Table 1. Purification of transferase.

	mg protein	total units	specific activity	recovery %
Extract from lyophilized bacteria (40 g)	12 300	13 900	1.13	100
Extract from protamine precipitate	2 350	12 200	5.2	88
Ammonium sulfate fraction (30—45 % sat.)	675	7 800	11.6	57
After chromatography and ammonium sulfate precip.	28	3 550	127	25

Chromatographic separations. CA-aspartate and aspartate were separated by gradient elution from a Dowex-2 formate column. This separation was carried out both during the demonstration of the back reaction of the enzyme and during the chemical synthesis of L-CA-aspartate. In the latter case the solution (pH 9—10) was applied to a 3 cm^2 × 10 cm column connected with a 500 ml mixing flask containing water. Gradient elution with M formic acid separated aspartate (emerging after *ca.* 6 column volumes) from CA-aspartate (after *ca.* 13 column volumes). A small peak, which appeared at 9 column volumes and coincided with the position of 5-acetic acid hydantoin was completely separated from the other substances. The peaks were localized by their radioactivity and by spot tests with ninhydrin (aspartate) and *p*-dimethylaminobenzaldehyde (CA-aspartate [14]). For the separation of CA-aspartate from aspartate during the demonstration of the back reaction four columns, 0.63 cm^2 × 10 cm, connected with one 500 ml mixer flask were chromatographed simultaneously as described above.

Separation of CAP and P_i by gradient elution was carried out during the isotope exchange experiments. Four columns of Dowex-2 formate, 0.62 cm^2 × 10 cm, were connected with one 1 000 ml mixing flask containing water. During chromatography the mixing flask received M ammonium formate, pH 5.0. P_i appeared after *ca.* 16 column volumes completely separated from CAP, which appeared after *ca.* 24 column volumes. The peaks were localized by determination of radioactivity and by phosphate analysis. The chromatography was carried out at +4°.

Isotope determinations. ^{15}N and ^{13}C were measured as N_2 and CO_2, respectively, in the mass spectrometer. ^{14}C and ^{32}P were determined on infinite thin samples in a Tracerlab SC-18 windowless flow counter.

^{18}O*-analyses* were performed directly on CAP and CA-aspartate. For this purpose *CAP* was isolated from the incubation mixture in the following way. After cooling in an ice bath the solution was acidified with M PCA and evacuated with an oil pump to remove CO_2 as completely as possible. The solution was neutralized with M NaOH (CO_2-free) with phenolphtalein as internal indicator. Then 0.25 ml of 2 M barium acetate were added and the resulting precipitate removed by centrifugation at 0°. Two volumes of alcohol were added to the supernatant and after standing for 5 minutes the resulting barium salt of CAP was collected by centrifugation, washed twice with 2 ml of 50 % alcohol and dried in a desiccator.

The Ba-CAP was finely ground and poured into a glass tube of 3 mm internal diameter which was sealed at one end. It was directly attached to the inlet system of the mass spectrometer by a ground glass joint. After evacuation of the system the bottom of the tube was immersed in a metal bath of 350°. At this temperature Ba-CAP decomposed thermally, while $BaCO_3$ was relatively stable. This was important since CO_2, during incubation, equilibrated with the isotope of $H_2{}^{18}O$ and since Ba-CAP might contain some $BaCO_3$. To ascertain the maximum amount of possible contamination a mixture of 2.5 mg of $Ba^{13}CO_3$ (32 % excess) and 10 mg of non-labeled Ba-CAP were analyzed under the described conditions. The CO_2 contained 0.14 % excess ^{13}C, indicating that less than 0.5 % was derived from the $BaCO_3$.

CA-aspartate for ^{18}O *analyses* was isolated directly from the incubation mixture by chromatography as described earlier. After addition of carrier (DL-form) it was crystallized from water.

CA-aspartate could be thermally decomposed at 200° *in vacuo* in the same way as described for CAP. Since the purpose was to analyze the ^{18}O content of the carbamyl group, it was necessary to determine the contribution of this group to the CO_2 evolved during the thermal decomposition. Thus ^{13}CA-aspartate was synthesized [15,7] from $K^{13}CN$ (atom per cent excess = 5.0) and the gas mixture resulting from the decomposition of ^{13}CA-aspartate was analyzed in a mass spectrometer [16] (Table 2). It can be seen that by far the most intensive peak had a mass number of 44 (CO_2). In a separate experiment the excess ^{13}C was accurately determined from the mass ratio 44/45 and found to be 4.91. This result demonstrated that within experimental error all the carbon of the CO_2 obtained by thermal decomposition of ^{13}CA-aspartate was derived from the carbamyl carbon. Therefore half of the oxygen from this peak corresponded to the carbamyl oxygen.

In the same experiment measurements of the ratio 28/29 (CO and/or N_2) were performed. On the assumption that the ratio was completely due to CO a ^{13}C-value of 4.65 atom per cent excess was obtained (as compared to the theoretical value of 5.0). The presence of either nitrogen or CO arising from another source than the carbamyl group

would have lowered the ^{13}C-value. The observed value therefore demonstrated that 90—95 % of the peaks with a mass number of 28 and 29 consisted of CO derived from the carbamyl group of CA-aspartate. In the case of CO all oxygen arose from the carbamyl oxygen.

Table 2. Thermal decomposition of ^{13}CA-aspartate.

Mass number	Intensity of peak
16	4.1
17	2.2
18	7.7
22	0.9
28	5.6
29	0.4
44	100.0
45	7.0
46	0.47

The analysis of the gas mixture was carried out in a recording mass spectrometer [16]. The carbamyl group of CA-aspartate contained 5.0 per cent excess ^{13}C. Decomposition was carried out at 200° in a high vacuum. The intensity of the peak with a mass of 44 is arbitrarily chosen as 100.

In the actual experiments both the 44/46 and 28/30 ratios were used for the calculations of ^{18}O.

Attempts to characterize the non volatile products of this interesting thermal decomposition have not been successful.

RESULTS

CAP as substrate for CA-aspartate formation

Our earlier experiments [1] had been carried out with enzymically prepared compound X and for further work it was of the greatest interest to establish the possible identity of this substance with synthetic CAP [4], especially in view of differences of opinion in the literature concerning this point [17,18].

For this purpose compound-X-^{14}C was prepared enzymically from labeled $NaHCO_3$ and purified as earlier. It was then co-chromatographed on paper with synthetic nonlabeled CAP in two different solvents and subjected to paper electrophoresis (Table 3). In each experiment one radioactive spot was obtained which coincided with one spot obtained by a phosphate spray [19].

When a small amount of compound-X-^{14}C was co-chromatographed with CAP on Dowex-2 as described in the experimental part for CAP, radioactivity emerged from the column simultaneously with CAP (by phosphate analysis), and a constant ^{14}C/phosphate ratio was obtained in the different fractions (Table 4).

The identity of the two substances was also established in enzyme experiments. Using aspartate-^{14}C and ^{13}CAP as substrates the amount of CA-aspartate formed from each precursor could be calculated by the isotope dilution method. Identical amounts were formed from each precursor. In different experiments increasing amounts of compound-X-carbamyl-^{15}N were added simultaneously with constant amounts of ^{13}CAP and aspartate-^{14}C. When the amount of CA-aspartate formed in the different experiments was calculated independently from the three different isotopes the results demonstrated in Fig. 3 were obtained. The total amount of CA-aspartate formed (calc. from

Table 3. Paper chromatography and paper electrophoresis of CAP and compound-X-carbamyl-^{14}C.

Solvent system	cm from start		Front cm
	radioactive spot	phosphate spot	
n-Propanol:water:conc.NH_3:versene [20] 6 : 10 : 3 : 0.01	3.5 – 8.5	3.7 – 8.3	28
Methanol: 2 N NH_3 : versene [22] 7 : 3 : 0.01	22.5 – 27.5	23 – 27	30
Paper electrophoresis (saturated tetraborate in 0.01 M versene) [21]	13.0 – 16.0	13.4 – 15.6	

In each experiment 0.5 – 2 μmoles of CAP were chromatographed together with 0.05 μmoles of labeled compound X (60 000 ct/μmole). At the end of the experiment the position of the radioactive spots was first determined, and then the paper sprayed with a phosphate reagent [19].

Electrophoresis (12 volts/cm) was carried out for 4 hours. All operations were performed at temperatures between 0 and +4°.

^{14}C) was constant in all experiments and equalled the sum of the amounts formed from CAP (calc. from ^{13}C) and from compound X (calc. from ^{15}N). Furthermore, with increasing amounts of compound X, increasing amounts of CA-aspartate were formed from ^{15}N and decreasing amounts from ^{13}C. The two curves were the mirror images of each other. These results are explained, if compound X and CAP are freely interchangeable with each other in the enzyme reaction.

The same type of behaviour was observed when the concentrations of compound X and aspartate were kept constant, while increasing amounts of CAP were added (Fig. 4).

The intermediate position of CAP in the synthesis of CA-aspartate from NH_3, CO_2, aspartate and ATP could be demonstrated in extracts from rat liver mitochondria. In different experiments CA-aspartate was synthesized from constant amounts of $^{15}NH_4Cl$, $NaHCO_3$, aspartate-^{14}C, ATP and acetyl-

Phosphate analysis [10] was carried out after heating for 5 minutes in a boiling water bath. For the determination of radioactivity samples of 0.05 ml + 0.05 ml of 0.1 M NaOH were dried and counted.

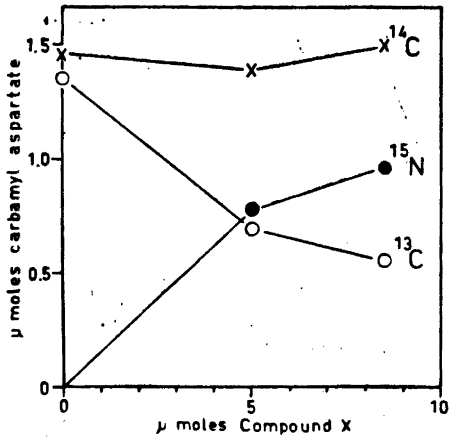

Fig. 3. Influence of compound-X-^{15}N on the synthesis of CA-aspartate from ^{13}CAP.

Substrate (per ml): 30 μmoles of L-aspartate-^{14}C (12.000 ct/μmole), 5 μmoles of CAP (31 atom per cent excess ^{13}C), 150 μmoles of tris buffer, pH 7.5, and 3 units of transferase (spec. activity 10). Compound-X-^{15}N (atom per cent excess $^{15}N = 32$) as indicated on abscissa. Incubation for 15 minutes at 37°.

In each experiment 160 μmoles of carrier DL-CA-aspartate were added, and the content of the different isotopes in the reisolated CA-aspartate was determined.

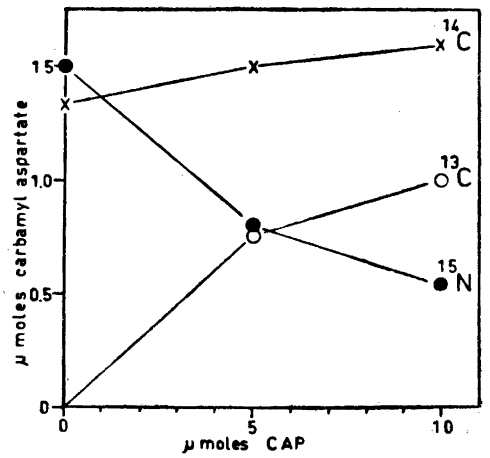

Fig. 4. Influence of ^{13}CAP on CA-aspartate synthesis from compound-X-^{15}N..

Substrate (per ml): 30 μmoles of L-aspartate-^{14}C, 5 μmoles of Compound-X-^{15}N, 150 μmoles of tris buffer, pH 7.5, and 3 units of transferase. ^{13}CAP as indicated on abscissa.. The experiments were conducted as in Fig. 3.

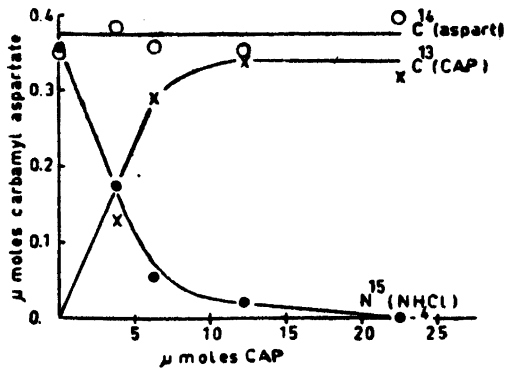

Fig. 5. Influence of ^{13}CAP on CA-aspartate synthesis from $^{15}NH_4Cl$, $NaHCO_3$, ATP and L-aspartate-^{14}C in an extract from rat liver mitochondria.

Substrate (per 3 ml): 20 μmoles of L-aspartate-1,4-^{14}C (12 000 ct/μmole), 20 μmoles of $^{15}NH_4Cl$ (32 atom per cent excess), 100 μmoles of $NaHCO_3$, 10 μmoles of ATP, 60 μmoles of 3-phosphoglycerate, 20 μmoles of acetylglutamate, 100 μmoles of $MgSO_4$, 200 μmoles of phosphate buffer, pH 7.5, and 5 mg of a muscle protein fraction (Ratner, S. and Pappas, A. *J. Biol. Chem* **179** (1949) 1183). ^{13}CAP (31 atom per cent excess) as indicated on the abscissa.

The mitochondrial enzyme (1.51 mg nitrogen per experiment) was prepared as described earlier [1].

Incubation for 60 minutes at 37°. Carrier added as in Fig. 3.

glutamate, while increasing amounts of ^{13}CAP were added. When the formation of CA-aspartate from the different isotopic substances was studied (Fig. 5), the results demonstrated that CAP had a large dilution effect on the ^{15}N-incorporation. At the highest CAP concentration studied practically no CA-aspartate was formed from ammonia, while identical amounts were formed from CAP and aspartate.

The experiments are in full agrement with the idea that CAP is the active carbamyl compound in the bacterial enzyme reaction and that it is also an intermediate in CA-aspartate formation in rat liver.

Properties of the transferase reaction

The *stoichiometry* of reaction (2) could be demonstrated with the ammonium sulfate fractionated enzyme (Table 5). The slightly larger formation of P_i than CA-aspartate is fully explained by some non-enzymic decomposition of CAP under the experimental conditions.

Isolation of L-CA-aspartate. Only L-aspartate could act as substrate (see below) and the CA-aspartate formed during the reaction was also the L-isomer. This was demonstrated by the isolation of its barium salt from a large scale experiment. Two mmoles of L-aspartate and 3 mmoles of CAP were incubated with 520 units of enzyme (specific acitivity = 11) at 37° for 60 minutes. After chromatography on Dowex-2 the fractions containing CA-aspartate were combined and the formic acid was removed by evaporation *in vacuo*. The

Table 5. Stoichiometry of transferase reaction.

Expt. No.		CAP	P_i	L-aspartate	CA-aspartate
			μmoles		
1	Initial	31.2	3.0	30.0	0
	Final	11.9	23.1	13.6	16.8
	Δ	19.3	20.1	16.4	16.8
2	Initial	31.2	2.1	30.0	0
	Final	26.9	6.8		
	Δ	4.3	4.7		

Incubation was carried out at 37° for 15 minutes in 1 ml volume.

Experiment 1: 1.5 mg of ammonium sulfate fractionated enzyme, experiment 2: no enzyme.

CAP + P_i was determined by heating an aliquot of the sample in 0.01 N HCl at 100° for 1 minute [4] before phosphate analysis [18].

L-Aspartate (32 atom per cent excess ^{15}N in substrate) was determined by the isotope dilution method. One mmole of carrier L-aspartate was added to an aliquot of the solution. After acidification the aspartic acid was crystallized to a constant isotope content.

CA-aspartate was determined by method 1 and according to Koritz and Cohen [11].

residue was dissolved in a minimum amount of water and the barium salt (160 mg) prepared as described earlier [23]. It showed $[\alpha]_D^{25} = +25.7°$ (as compared to the earlier obtained value of +24.1° for synthetic L-CA-aspartate).

A *time curve* of the reaction is given in Fig. 6.

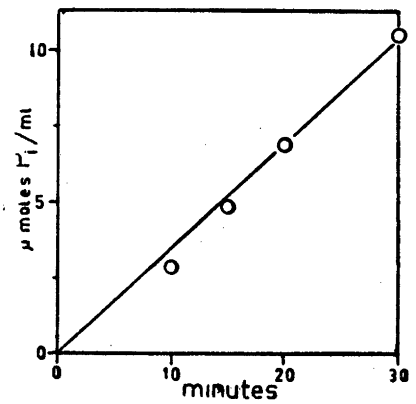

Fig. 6. Time curve of transferase action.

In each experiment volume = 1.0 ml. 5 units of transferase (spec. activity = 11) were incubated with 100 μmoles of L-aspartate, 30 μmoles of CAP and 150 μmoles of tris buffer, pH 7.5. Enzyme assay according to method 2.

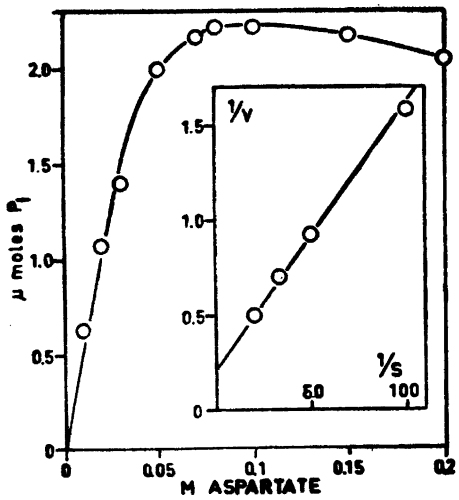

Fig. 7. Influence of aspartate concentration.

Transferase (2 units, spec. activity = 90) was incubated for 15 min. at 37° with 8 μmoles of CAP, 150 μmoles of tris buffer, pH 7.5, and L-aspartate as indicated on the abscissa. Final volume = 1.0 ml. Enzyme assay by method 2.

Dependance on substrate concentration. The influence of *aspartate concentration* on the reaction rate is shown in Fig. 7. As indicated earlier [1] large amounts of substrate were necessary for enzyme saturation. Furthermore, at concentrations above 0.1 M a clear inhibition by aspartate did take place. When a Lineweaver-Burk plot was made from the values obtained below 0.05 M aspartate concentration a value of $K_M = 0.065$ was obtained. In a different experiment at higher CAP concentration (0.1 M) and using method 1 for the determination of reaction rate the value for K_M was 0.060.

The influence of *CAP concentration* is demonstrated by Fig. 8. No inhibition was observed up to 0.3 M concentration. $K_M = 0.45 \times 10^{-3}$.

The *pH-curve* of the reaction is shown in Fig. 9. This curve differs significantly from the one given earlier [1], which had been obtained under somewhat different conditions. The reason for the discrepancy is not understood. In the present investigation a pH optimum of 7.5 was obtained in five different experiments with both methods of enzyme assay, using tris or imidazole buffer.

Specificity of the reaction. Ureidopropionic, ureidoglutaric and ureidosuccinic acids, citrulline and urea could not serve as carbamyl donors in place of carbamyl phosphate.

With a 90 fold purified enzyme L-aspartate alone could serve as acceptor for the carbamyl group of CAP. 31 amino acids and related compounds were tested for their ability to bring about the enzymic dephosphorylation of CAP. Furthermore, the appearance of a new carbamyl compound was sought by the method of Koritz and Cohen[11]. Those non reacting compounds were: L-α-alanine, β-alanine, DL-α-aminoadipic acid, α, β, and γ-aminobutyric acids,

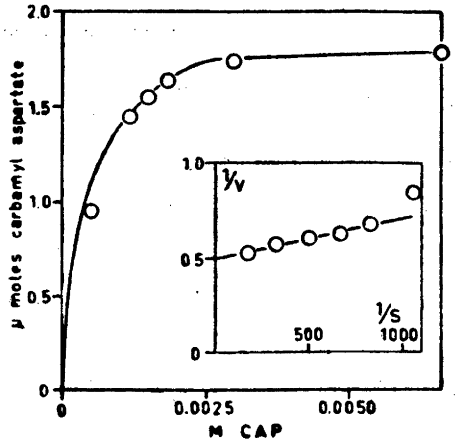

Fig. 8. Influence of CAP concentration.

Incubation (volume = 3.0 ml): 2 units of transferase (spec. activity = 90) were incubated for 15 min. at 37° with 300 µmoles of L-aspartate-^{15}N (32 atom per cent excess ^{15}N), 400 µmoles of tris buffer, pH 7.5, and CAP as indicated on abscissa. Enzyme assay by method 1.

L-arginine, L-asparagine, D-aspartic acid, L-citrulline, L-cysteic acid, L-cysteine, L-glutamic acid, L-glutamine, glycine, L-histidine, DL-homoserine, L-hydroxylysine, L-*iso*leucine, L-leucine, L-lysine, L-methionine, L-ornithine, L-phenylalanine, L-proline, L-serine, taurine, L-threonine, L-tryptophane and L-valine*.

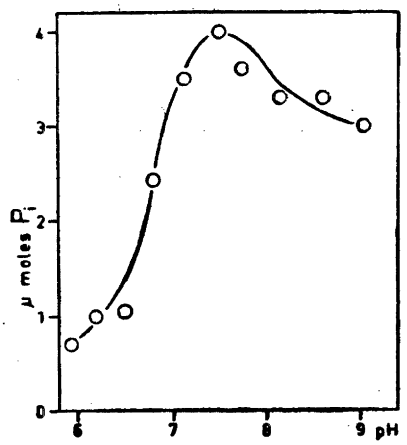

Fig. 9. pH curve.

Transferase (4 units, spec. act. 90) was incubated for 15 min. at 37° with 100 µmoles of L-aspartate, 20 µmoles of CAP and 300 µmoles of tris (pH range 7—9) or imidazole (pH range 6—7.5) buffers. Volume = 1.0 ml. Enzyme assay by method 2.

*. The amino acids were commercial products. We wish to thank Drs. G. Ågren and Z. Bánhidi for gifts of some of these amino acids.

Table 6. Aspartate and ornithine carbamyl transferase activity during enzyme fractionation

» » 30—45 »	87	10
» » >45 »	0	4.2
After DEAE chromatography	52	0

The CA-aspartate forming enzyme was determined by method 1.
The substrate for the citrulline forming enzyme contained 60 μmoles of DL-ornithine. instead of 30 μmoles of L-aspartate, but apart from this conditions were the same.
Protamine precipitation in this preparation was performed at room temperature.

The ammonium sulfate fractionated enzyme showed activity in catalyzing the reaction between CAP and L-ornithine to form citrulline. It was thought of interest to make a comparison between CA-aspartate formation and citrulline formation at various stages of purification of the enzyme. The result, summarized in Table 6, clearly demonstrated the existence of two different carbamyl transferases, one forming CA-aspartate and the other forming citrulline.

Inhibition of transferase activity. Several amino acids showing structural relationship to L-aspartate were investigated as possible inhibitors of the reaction. In these experiments 30 μmoles of L-aspartate and 20 μmoles of CAP were used as substrate together with 5—10 units of transferase. Usually 150 μmoles of the substance under investigation were added and the formation of P_i measured by method 2. No inhibition was observed with, α-, β- or γ-aminobutyric acids, L-asparagine, D-aspartate, L-cysteic acid, L-glutamate and DL-homoserine.

Table 7. Inhibition of transferase reaction.

Inhibitor	concentration (M)	% inhibition
NaCN	0.01	
Versene	0.05	
Arsenate	0.1	
Phosphate	0.1	
Hydroxylamine	0.1	
Phenylhydrazine	0.01	0
Semicarbazide	0.01

Iodosobenzoate	0.004	
Iodoacetate	0.01	5—10
CMBA	0.003	90—95
CMBA	0.001	45

The inhibitor was added to the buffered enzyme solution (5—10 units, spec. activity 90) at room temperature (volume 0.8 ml). After 10 minutes the solution was cooled in an ice bath for 5 minutes. Then 100 μmoles of L-aspartate + 25 μmoles of CAP were added, final volume 1.0 ml. Incubation for 15 minutes at 37°.

Table 8. Protection from CMBA-inhibition by substrates.

Added at time 0 min.	Added at time 15 min.	μmoles P_i formed	% inhibition
Enz.	CAP + asp.	7.9	
Enz. + CMBA	CAP + asp	4.0	49
Enz. + CAP	asp.	8.1	
Enz. + CAP + CMBA	asp.	4.0	51
Enz. + asp.	CAP	7.6	
Enz. + asp. + CMBA	CAP	4.1	46
Enz. + CAP + asp.	—	8.8	
Enz. + CAP + asp. + CMBA	—	7.3	17

The experimental conditions were as described in Table 7 with additions as indicated. Final CMBA concentration = 0.001 M.

Table 7 demonstrates the results obtained with different types of inhibitors. In all cases, except with versene, phosphate and arsenate, method 2 was used for enzyme assay. Significant inhibition was only observed with CMBA and only at relatively high concentration of the inhibitor.

When, in an experiment at 0.001 M CMBA concentration, 5 μmoles of reduced glutathione were added 5 minutes before the start of the incubation at 37° (*cf.* conditions of Table 7), no inhibition was observed. This experiment demonstrates that inhibition with CMBA could be completely reversed by glutathione.

No protection of the enzyme wat observed by CAP or L-aspartate alone However, a mixture of both substrates partially protected the enzyme from the action of the inhibitor (Table 8).

Reversibility of transferase reaction. The equilibrium of the reaction was shifted very far towards synthesis of CA-aspartate. Unsuccessful attempts

Table 9. Formation of aspartate from CA-aspartate.

Experimental conditions	total counts in aspartate fractions	μmoles aspartate formed
Complete	730	0.76×10^{-2}
No enzyme	515	0.54×10^{-2}
No phosphate	525	0.55×10^{-2}
No enzyme or phosphate	540	0.56×10^{-2}

The complete experiment was carried out with 30 μmoles of CA-aspartate-^{14}C (0.96×10^5 ct/μmole), 50 μmoles of phosphate buffer, pH 7.5, 100 μmoles of tris buffer, pH 7.5, and 80 units of transferase (spec. activity 130). Final volume: 1.0 ml. Incubation for 30 minutes at 37°. The reaction was terminated by addition of 0.4 ml of M PCA. Three ml of water were added together with 30 μmoles of non-labeled aspartate. The pH was adjusted to 9—10 (phenolphtalein). Chromatographic separation of aspartate and CA-aspartate was then carried out as described in the experimental part. Aspartate was localized in the effluent by spot tests with ninhydrin. The total radioactivity in the pooled aspartate fractions was determined, and the amount of aspartate formed calculated from this value.

were made to measure the enzymic formation of aspartate from CA-aspartate and P_i (back reaction) by coupling the reaction with glutamo-oxaloacetic-transaminase [24] and malic dehydrogenase [25] after addition of α-ketoglutarate and DPNH.

The reversibility of the reaction could be demonstrated and measured by the use of carboxyl labeled CA-aspartate-^{14}C as substrate. It could be demonstrated that maximum amounts of aspartate-^{14}C were formed only in the presence of both enzyme and P_i (Table 9). The "background" formation of aspartate resulted from the presence of small amounts of this amino acid in the synthetic CA-aspartate and to a lesser extent from non enzymic breakdown during experiments of long duration. A further complication for any quantitative determinations of the equilibrium position was the chemical lability of CAP, the other product formed during the back reaction. Attempts to determine the equilibrium constant for the transferase action from the back reaction using CA-aspartate-^{14}C did not show conclusive results. It was evident, however, that the equilibrium position was shifted very far towards synthesis of CA-aspartate.

The mechanism of the reaction

Isotope exchange experiments. It was thought possible that the carbamyl group of CAP was first transferred to the enzyme, followed by a carbamyl transfer from the enzyme to aspartate:

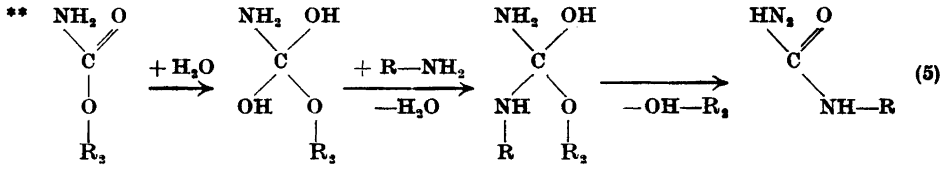
$$\text{CAP} + \text{Enzyme} \rightleftharpoons \text{CA-Enzyme} + P_i \quad (3)$$

$$\text{CA-Enzyme} + \text{L-aspartate} \rightleftharpoons \text{L-CA-aspartate} + \text{Enzyme} \quad (4)$$

This mechanism was tested by isotope exchange experiments. According to reaction (3) an enzymic exchange of $^{32}P_i$ with phosphate in CAP should take place in the absence of aspartate. Table 10 demonstrates that such an *enzymic* exchange does not take place. Some ^{32}P was found in CAP in the absence of the enzyme, and addition of enzyme did not increase the specific acticity of the

Table 10. Isotope exchange experiments with $^{32}P_i$.

	Reisolated P_i		Reisolated CAP	
	μmoles	ct/μmole	μmoles	ct/μmole
Complete	59	0.62×10^6	10	2.6×10^3
No aspartate	48	0.77×10^6	18	1.3×10^3
No enzyme	47	0.71×10^6	23	1.5×10^3
No enzyme and asp.	50	0.70×10^6	16	1.7×10^3



The complete experiment contained 35 μmoles of CAP, 40 μmoles of $^{32}P_i$ (0.83×10^6 ct/μmole), 15 units of transferase (spec. act. 90), and 250 μmoles of tris buffer, pH 7.5. Incubation for 15 min. at 37°. The solution was then cooled in ice, adsorbed directly on a Dowex-2-formate column and chromatographed (see experimental part). Fractions containing P_i and CAP respectively were pooled, and the radioactivity and phosphorus content were determined on aliquots.

reisolated CAP. However, after addition of L-aspartate a small but significant increase was observed. Table 10 demonstrates results typical of 5 different experiments at pH 7.5 and 6.5. The enzymic isotope exchange in the presence of aspartate again demonstrated the reversibility of the reaction while the absence of enzymic isotope exchange without aspartate made reaction (3) seem unlikely.

Further evidence against reaction (3) was obtained from experiments with arsenate. If reaction (3) took place in the presence of arsenate one might expect that the CA-enzyme formed would give rise to CA-arsenate, which in turn would decompose to carbamate + arsenate. The net effect would be an accelerated breakdown of CAP in the presence of enzyme and arsenate. Such an effect was not observed when 40 μmoles of CAP, 50 units of transferase and 100 μmoles of arsenate were incubated for 15 minutes at 37° *.

Reaction (4) was made improbable by an exchange experiment with L-aspartate-2,3-^{14}C (50 μmoles, 19 000 ct/μmole), CA-aspartate (48 μmoles) and enzyme (50 units). After incubation for 1 hour at 37° no radioactivity was found in the reisolated CA-aspartate.

Experiments with $H_2{}^{18}O$. Another possible mechanism involved the hydration of CAP as a first step, followed by condensation of the hydrate with aspartate by removal of water and subsequent dephosphorylation of the formed intermediate to give rise to CA-aspartate:

(5)

The participation of water in such a mechanism could be investigated by carrying out the transferase reaction in $H_2{}^{18}O$. In such an experiment no ^{18}O was incorporated into the carbamyl group of CA-aspartate, nor was there any significant enzymic exchange of the oxygen of water with that of CAP (Table 11).

DISCUSSION

CA-aspartic acid is known to be an intermediate in the biosynthesis of orotic acid both in microbial[26,27] and mammalian[21,28] systems. The demonstration that L-aspartate and the carbamyl group of CAP are the two groups from which the pyrimidine ring originates links together pyrimidine synthesis with both the tricarboxylic acid cycle and the urea cycle. The occurrence of the enzyme in various mammalian organs and in microbial extracts together with the fact that the equilibrium of the reaction is shifted far towards synthesis of

*. The decomposition of CAP in these experiments was measured by the formation of ammonia. The reaction was stopped by acidification with PCA. After neutralization the mixture was adsorbed on a small Dowex-2-formate column (0.62 cm² × 5 cm). The column was washed with 15 ml of water and aliquots of the eluant were analyzed for ammonia.

**. $R_2 = H_2PO_3$; $R—NH_2$ = L-aspartic acid.

Table 11. Transferase reaction in $H_2{}^{18}O$.

	Atom per cent excess ^{18}O in		
	CAP	Carbamyl group of CA-aspartate	
		from CO	from CO_2
Complete	0.003	0.000	0.001
No aspartate	0.001		
No enzyme	0.005		

Complete experiment: 100 μmoles of CAP, 100 μmoles of L-aspartate-^{14}C (10^3 ct/μmole), 125 μmoles of tris buffer, pH 7.5, 30 units of transferase (spec. act. 130). Incubation for 15 min. at 37° in 1 ml of $H_2{}^{18}O$ (1.4 atom per cent excess).

Two complete experiments were conducted, one for the isolation of CAP, the other for the isolation of CA-aspartate.

Ba-CAP was isolated and analyzed for ^{18}O as described in the experimental part.

CA-aspartate was separated by chromatography and localized by its radioactivity (26 μmoles of L-CA-aspartate). After addition of 80 μmoles of carrier DL-CA-aspartate, the substance was crystallized from water, decomposed and analyzed for ^{18}O.

CA-aspartate makes it very likely that this reaction represents a general first step in pyrimidine biosynthesis.

The purified enzyme showed the very specific capacity to catalyze a transfer of a carbamyl group attached to phosphate in "high energy" linkage to the amino group of L-aspartate. The extreme position of the equilibrium towards CA-aspartate synthesis together with the low affinity of the enzyme for aspartate and the instability of CAP made it impossible to measure the equilibrium constant of the transferase reaction. The existence of a back reaction could be demonstrated with the aid of $^{32}P_i$ (Table 10) and CA-aspartate-carboxyl-^{14}C (Table 9). Although a quantitative determination of the equilibrium position could not be carried out, it is clear from the data of Tables 9 and 10 that the back reaction proceeds at a very slow rate, and that the transferase reaction greatly favours synthesis of CA-aspartate.

Only one enzyme seemed to be involved in the reaction and no evidence could be obtained for the participation of a prosthetic group or an activator. The enzyme was named aspartate carbamyl transferase since this name seems to describe its function properly, although previously described transferases do not generally show such extreme equilibrium positions. The enzyme is distinct from the citrulline forming enzyme[3] and the enzyme forming β-ureidopropionic acid[29]. The latter two enzymes have as yet not been described in detail, but it seems highly probable that they also belong to the class of carbamyl transferases.

The isotope exchange experiments gave no evidence for the formation of a carbamylated enzyme. The experimental conditions allowed the demonstration of the reversibility of the sum of reactions (3) and (4), *i.e.* enzymic exchange of ^{32}P between P_i and CAP in the presence of aspartate. This makes

it improbable that the failure to find evidence from isotope exchange experiments for reaction (3) *or* reaction (4) depended on a limited reversibility of these two reactions, but rather argues against the actual existence of reactions (3) and (4).

The experiments with $H_2{}^{18}O$ speak against the participation of water and the formation of a phosphorylated intermediate as depicted in reaction (5). Such a type of mechanism can, however, not be completely ruled out if the whole reaction sequence were to be considered as taking place with enzyme bound intermediates and if the same molecule of water were first added and then removed.

It would appear, however, that the most probable explanation for all of the experimental results is that the transferase reaction involves a single displacement mechanism of the same type as earlier suggested for phosphate transferases[30]. According to this view both CAP and L-aspartate are first attached to the enzyme. By a nucleophilic attack of the nitrogen atom of aspartic acid on the carbon atom of CAP the carbon-oxygen bond is broken simultaneously with the formation of the new carbon-nitrogen bond.

Inhibition of the enzyme by CMBA could be demonstrated. Glutathione completely reversed the inhibition, which was probably due to the interaction of CMBA with active SH-groups. The absence of inhibition by less powerful SH-reagents does not necessarily speak against the concept that inhibition by CMBA was due to combination with SH groups (*cf.* Refs. [31,32]). Of interest for the understanding of the transferase mechanism was the finding that CAP + aspartate showed the ability to protect the enzyme against inhibition, while CAP or aspartate alone showed little effect. This finding is explained if both substrates compete with CMBA for SH groups of the enzyme. The results therefore tentatively indicate that both aspartate and CAP, during the action of the enzyme, are attached to SH groups.

Glycogen-like Polyglucose * in *Escherichia coli B* during the First Hours of Growth

H. PALMSTIERNA

Chemical Department I, Karolinska Institutet, Stockholm, Sweden

A method is described by which it is possible to estimate the mean dry weight of bacterial cells.

A polysaccharide occurring in *Escherichia coli B* is shown to be of a glycogen-like nature. This glycogen accumulated before the cells began to divide, and the glycogen content of the culture diminished when the nitrogen-containing cell constituents per litre of culture increased at the highest rate the culture conditions allowed.

It is shown that during the period of growth observed, the incorporation of ^{14}C from β-labeled lactate into the glycogen was smaller than could have been expected if all the glycogen had been synthesized from lactate in the medium only.

It is shown that the glycogen incorporated some carbon from carbon dioxide.

If is shown that glycogen could be synthesized from intracellular carbon sources as well as from carbon sources supplied with the medium.

The glycogen increased in the cells during the lag phase and decreased during the log phase in both glucose medium and broth, in the same way as in lactate medium. An increase of the same magnitude was noted in all culture volumes and at all cell concentrations used.

Escherichia coli B contains an alkalistable polyglucose as previously reported [1]. An alkalistable polysaccharide has also been observed in enteric bacteria by Levine *et al.*, detected by means of infra-red spectrophotometry [2]. Isolations of glycogen-like polysaccharides from *Mycobacterium tuberculosis* [3], *Neisseria perflava* [4] and *Bacillus megaterium* [5] have also been reported.

In the present paper the glycogen content of the cells was studied at different phases of growth. A very rapid increase in the glycogen content of the cells was noted to occur before the first cell divisions, followed by a decrease when the cells began to divide.

* For the sake of brevity called glycogen in the present paper.

BACTERIOLOGICAL METHODS

Media. The salt medium with sodium lactate as the sole source of carbon was that originally described by Friedlein [9]. The salt medium with glucose as the sole source of carbon was the one used by Hook and co-workers [10].

The broth was prepared in the usual way and buffered to pH 7.0 with 0.1 M phosphate buffer and sodium chloride was added up to a concentration of 0.5 g per litre. The medium was stored for 24 hours at 0 °C. The precipitate was filtered off and the medium sterilized in steam under pressure (1.5 kg/cm^2). This procedure was repeated twice. In this way it was possible to get a clear broth in which hardly any precipitate was formed during growth and during the cooling down of the culture.

The nitrogen-free medium was that used by Friedlein, from which the ammonium chloride was omitted. In the lactate- and nitrogen-free medium both ammonium chloride and lactate were left out. A completely nitrogen- and carbon-free medium was prepared by using this last-mentioned medium and filtering the air through an "Ascarite" filter, two flasks containing 50 % KOH and one flask containing saturated barium hydroxide. The air was dispersed by means of sintered glass discs.

Cultivation technique. The cultivation techniques are modifications of the techniques used by Cavanna *et al*[6]. Lyophilized cells, grown from one and the same culture of *E. coli B* were used in all the experiments. The cells were spread onto two agar slants and incubated for 24 hours at 37° C. Then the cells were suspended in 5 ml of culture medium. The suspension was inoculated into a 6 litre Erlenmeyer flask containing 4 or 5 litres of medium. The medium in this praeculture was of the same composition as that of the medium in the final culture. The praeculture was grown for 18 hours at 37° C and the cells were spun down at 0 °C in an International refrigerated centrifuge at 2 000 × g for 90 min. The cups were thoroughly rinsed, but not sterilized, before centrifugation. The loss of cells into the supernatant was too small to be estimated in a Beckman spectrophotometer, equipped with turbidimetric facilities. The cells were washed in fresh medium and suspended again in 200 ml of medium. The cell concentration was determined by counting the cells in the Bürker chamber under the phase contrast microscope. The final culture was inoculated with an appropriate amount of the suspension. The cultures were kept at 36.5—36.7 °C by means of a water-bath (volume 1 m^3) and shaken vigourously. The aeration current was filtered through tightly packed, sterilized cotton-wool and dispersed by sintered glass filters. The rate of aeration was 1 litre per minute and litre of medium as estimated by means of rotameters. The media were aerated for at least five minutes prior to inoculation. The air entering the praeculture was moistened by passing it through sterile, distilled water at 37 °C. From a culture of 5 litres, the loss of fluid from the praeculture did not exceed 0.2 litres in 18 hours.

Harvesting procedure. Aliquots of the culture were withdrawn by suction and the samples immediately cooled down to 4 °C by means of a sling of stainless steel tubing through which alcohol of −40 °C circulated. The time taken from the commencement of the suction to the finish of the cooling did not exceed 4.5 minutes, with the samples ranging from 1 to 12 litres. The samples called 0 were taken from the suspension used for inoculation. The samples were stored at 0 °C and centrifuged within 12 hours. It was found, however, that they could be stored for three days at 0 °C without any detectable change in the glycogen content occurring.

Determination of the mean dry weight of the cells. The volume of the cell suspension was determined, and the number of cells per ml estimated in a Bürker chamber under the phase contrast microscope. The cells were spun down at 0 °C and 2 000 × g for two hours in the afore mentioned centrifuge. In order to prevent the cells from whirling up again when the centrifuge slowed down, the bottoms of the centrifuge tubes were covered with a double layer of fine mesh stainless steel netting. The tubes were divided up into four chambers by means of baffles. The losses of cells were checked by estimating the amount of cells in the supernatant with the turbidimeter mentioned. (The supernatant was compared with a sample of the original suspension, diluted 25—50 times with fresh medium, to which formaldehyde was added to give a final concentration of approximately 0.3 %). The losses were lower than 2.4 % when the original suspension contained 10^8 to 5×10^8 cells per ml. When the cell concentration was higher than 5×10^8 cells per ml, the losses were too small to be estimated by the method used. All the data presented have been corrected for the losses of cells during centrifugation.

The cells were washed twice with fresh medium. The centrifugations were performed in an International refrigerated centrifuge typ PR-1 with a multispeed attachment (0 °C, 4 minutes, 24 000 × g at the bottom). The losses amounted to 3 000 cells per ml of washing fluid. This estimate was arrived at by counting the number of colonies produced on endo agar plates. The volume of the washing fluid was less than 60 ml. No corrections were introduced for these small losses.

The cells were washed in medium, since they lost appreciable amounts of ultra-violet absorbing substances into the washing fluid when they were treated with water or 0.9 % sodium chloride. This was especially the case with cells harvested during the last part of the lag phase and the first part of the log phase of growth. No losses of ultraviolet absorbing matter were observed when the cells were washed in fresh medium.

The washed samples were weighed in wet state and lyophilized. All analyses were performed on this freeze-dried material, with the exception of the nitrogen determinations. These determinations were performed on 15 to 25 mg of the material dried to constant dry weight over P_2O_5 at 90 °C *in vacuo*.

The difference between the wet weight and the constant dry weight was taken as medium water. All values presented were corrected for the amount of medium constituents, that is contained in the corresponding amount of medium.

The sum of the corrections amounted to between 8 and 15 % of the freeze dry weight.

The mean dry weight of the cells was calculated by dividing the corrected dry weight of the cell material per unit volume of culture by the number of cells per unit volume of culture.

All cultures were tested for purity by means of blood and endo agar cultures. In no case were any contaminations observed.

CHEMICAL METHODS

Isolation of the glycogen-like polysaccharide. Between 80 and 150 mg of the lyophilized material was treated with 0.1 ml of 30 % KOH per 10 mg of lyophilized material for three hours on a boiling water-bath. Immediately after the hydrolysis, three volumes of water and 8 volumes of 99 % ethanol were added. The precipitate was washed twice with 60 % ethanol and dried with ethanol and ether. When it was expected that the cells would contain small amounts of the polysaccharide only, they were treated with boiling ether prior to the alkaline hydrolysis, in order to remove most of the lipids which go down with the polysaccharide at the first precipitation with alcohol.

The polysaccharide obtained in this way is called here crude glycogen.

When deemed necessary, the crude glycogen was purified in the following way: 100 mg of the crude glycogen was dissolved in 1 ml of water, cooled down to 0 °C and precipitated again by adding glacial acetic acid to a final concentration of 80 %. This procedure was repeated twice. The precipitate was again dissolved and precipitated by adding alcohol to a final concentration of 60 %. The precipitate was dried with ethanol and ether. The glycogen purified by the acetic acid treatment is called here purified glycogen. Analyses of this glycogen are presented in the following.

The preparation and quantitative determination of glucose from the glycogen-like polysaccharide. The crude glycogen was submitted to hydrolysis in either 0.6 N HCl, or N H_2SO_4, for three hours on a boiling water-bath. No difference between the yields of glucose in the two kinds of hydrolysis could be observed. The glucose thus obtained was purified by passing the hydrolysate through a column of "Dowex 50" in the H^+-form and "Dowex 2" in the acetate-form. The columns had a length of 20 cm and an inner diameter of 0.7 cm. The ion exchange resins (40—100 mesh) were thoroughly washed with distilled water prior to use.

The purified glucose solutions were brought to dryness by heating to about 50° C in a strong air current.

Glucose (2, 4, and 10 mg in 10 ml of water) was passed through the columns, and 103 %, 99 % and 97 %, respectively, of the glucose were recovered.

All estimations of glucose were performed according to a modification of Disches' method [7].

Table 1. Isotopic dilution of glycogen in E. coli B.

Recovery of the glycogen (Chemical method) percentage	95.2	97.1	96.4	97.3
Recovery according to the dilution of the isotope, percentage	92.9	96.0	97.5	96.9

^{14}C-glycogen was added to samples of lyophilized cells (ranging between 50 and 100 mg) with a known content of glycogen. The glycogen was isolated and determined as glucose according to a modification of Dische's colorimetric method. The dilution of the isotope ranged between 10 and 60 per cent. Aqueous solutions of the hydrolyzed glycogen was spread directly on aluminium planchets and counted with a windowless gas flow counter, flushed with a helium-*iso*butane mixture. Since the layer of the material on the planchets did not exceed 0.03 mg/cm^2, no correction was made for self-absorption.

Protein isolation and nitrogen determination. Protein was isolated from the cells according to Schneider [8]. The nitrogen determinations were performed according to the micro-Kjeldahl method.

The isolation of glycogen and the determination of glucose checked by isotope dilution. In order to obtain ^{14}C-glycogen of bacterial origin, a culture was performed with sodium lactate, labeled in the β-carbon with ^{14}C, as the sole source of carbon. The isotopic lactate was synthesized by L. Reio and purified by ion exchange chomatography by S. Aqvist [15]. The culture volume was 5 litres, the initial cell concentration 5.5×10^8 cells per ml and the cultivation time 90 min. The concentration of the lactate was one-third of the concentration in the experiments mentioned in the following. The yield of glycogen was 13.1 % of the cells in the lyophilized state. The specific activity of the purified glycogen was 58.7 c.p.m. per microgram of glucose carbon. This ^{14}C-glycogen was used for determinations by the isotope dilution method. (Table 1.)

RESULTS

Analysis of the glycogen. Apart from glucose, no other sugar could be observed on the routine paper chromatograms (butanol saturated with water). The separation of glucose and galactose in this solvent is not satisfactory.

In order to exclude the presence of any sugar other than glucose in the polysaccharide, the purified glycogen was hydrolysed in N sulfuric acid for ten hours and chromatographed according to a modification of the method of Gardell [11], introduced by himself. (Butanol, propanol and water were used in the proportions 3:2:1 instead of in the proportions 4:1:1, and the column was heated to 40° C.) With this kind of hydrolysis, the polysaccharide sugar was destroyed to an extent of between 7.1 and 10.2 %. When hydrolysed and chromatographed in this way, 92.2, 91.7, and 91.3 % of the polysaccharide were recovered as glucose. If a correctior is allowed for the amount of sugar destroyed during hydrolysis, this would mean that between 99 and 105 % of the polysaccharide was revocered after chromatography. No traces of mannose, galactose or any other sugar were found. It is possible, however, that there were other sugars besides glucose present in the polysaccharide, and that these sugars were selectively destroyed during hydrolysis, since the linkages in the polysaccharide might influence the effect of the acid on the sugar itself.

	960	— **	—	—	0.5	6.2 *	—

* In experiment A no precautions were taken to prevent loss of water from the culture. In experiment B loss of water was prevented by moistening the air entering the culture.

** It was not possible to get a reliable estimate of the cell concentration due to scanty contrast in the cells.

When glucose was added to the hydrolysate, a single symmetrical peak was observed on the chromatogram. When galactose was added, two distinctly separated peaks were obtained.

The polysaccharide was partly degradable with β-amylase and gave the same reddish-brown colour with iodine as that obtained with rabbit and rat liver glycogen.

Due to the difficulty of obtaining a clear solution of the bacterial glycogen, even when purified glycogen was used, the specific optical rotation could not be determined exactly (*cf.* Ref.[2].) It lies somewhere between $+185°$ and $+200°$ (rat liver glycogen $+198°$ to $+200°$).

The polysaccharide had a slight reducing power prior to hydrolysis. After hydrolysis for ten hours in N sulfuric acid it gave a yield of 91 % of the theoretically expected value.

The phosphorus content of three different batches of purified glycogen was 0.8, 0.8, and 0.7 %, the nitrogen content 0.1, 0.15, and 0.3 %, respectively. These values are calculated on the ash-free polysaccharide. The ash content

was 2.4, 1.9, and 2.0 %, respectively. The carbon content of the ash-free polysaccharide was 43.7 ± 0.7 % (four determinations).

The glycogen content of the cells at different intervals after inoculation. The results from the cultures in sodium lactate medium are shown in Figs. 1 and 2, and in the Tables 2, 3 and 4.

The glycogen-glucose content of the cells increased very rapidly during the lag phase of growth. The increase was most pronounced during the first ten minutes after inoculation. The increase in glycogen accounted for most of the increase in dry weight of the cells during the first part of the lag phase.

In the time between ten minutes after inoculation and the time of the first cell divisions (70—90 min. after inoculation) the increase in glycogen-glucose per unit weight of cells was less pronounced. The glycogen-glucose per dryweight and litre of culture, still showed a rapid increase during the same period. This difference is due to the increasing synthesis of other cell constituents during the last part of the lag phase (*cf.* the protein per litre values, Table 2). During the log phase * the glycogen-glucose per cell decreased up to 240 minutes after inoculation, after which it remained constant at a value of the same magnitude as the zero time value. This was also the case with the glycogen-glucose per unit weight value. The glycogen-glycose per dryweight and litre of culture (in the following called total glycogen) also decreased up to 240 minutes after inoculation. The decrease coincided with the time at which the culture attained its highest cell division rate (Fig. 2). The total glycogen-glucose increased again when the cell division rate began to slow down (about 240 min. after the inoculation). This increase in total glycogen-glucose was due to an increase in the cell concentration, without any significant increase in the glycogen-glucose per cell.

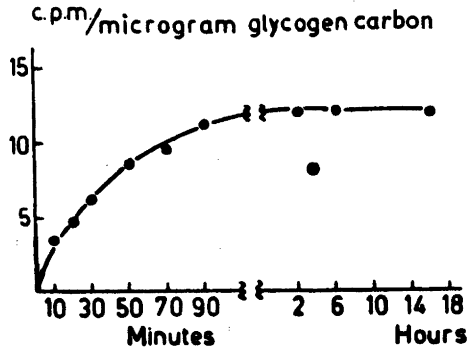

Fig. 1. In experiment A (Table 2) the cells were cultivated in Friedlein's medium in which the lactate was labeled in the β-carbon with ^{14}C. The specific activity was 32.2 c.p.m. per microgram of lactate carbon, as estimated by diluting a sample of the original, highly active sodium lactate. The radioactivity measurements were performed in the same way as described under Table 1. The ^{14}C-lactate used was to a slight extent contaminated with ^{14}C-alanine.

* The log phase is here defined as follows: beginning when the first cell divisions are found and lasting until the cells have stopped dividing, as checked by counting the cells in the Bürker chamber under the phase contrast microscope.

Table 3. Glycogen-glucose of E. coli B *cells incubated into Friedlein's medium from which nitrogen source has been left out.*

Exp.	Carbon source	Time after inoculation, in minutes	Number of cells × 10^{-8} per ml	Glycogen-glucose in per cent of the dry weight
H	Lactate and CO_2	0	1.3	1.7
		90	1.4	7.1
J	CO_2	0	1.0	1.3
		60	1.0	3.8
		90	1.0	3.5
K	None	0	1.6	2.1
		90	1.7	1.4
L	Lactate No CO_2	0	1.2	1.2
		90	1.2	9.3

In these experiments, Friedlein's lactate medium was used, but the usual source of nitrogen, ammonium chloride, was omitted. The carbon dioxide is that present in the air entering the culture. In experiments K and L the carbon dioxide was absorbed before the air entered the culture.

Incorporation of labeled lactate into bacterial glycogen. When sodium lactate, labeled in the β-carbon with ^{14}C, was used as the sole source of carbon, the specific activity of the glycogen carbon increased rapidly during the whole lag phase. Thereafter the specific activity remained constant at a value of about one-third of the specific activity of the substrate carbon (Fig. 1).

The glycogen content of the cells when cultivated in other media. When the cells were incubated in the Friedlein medium from which the nitrogen source had been omitted, they were still able to synthesize glycogen for at least 90 min. The glycogen-glucose content increased from 1.7 % to 7.1 % of the dry weight. The increase in glycogen-glucose was considerably lower when both the nitrogen source and the lactate were omitted, but there was still an increase (from 1.3 % at zero time to 3.5 % at 90 min.). If the air entering the culture was freed from carbon dioxide, and both the nitrogen and the lactate were excluded from the medium, no glycogen was formed by the cells. When lactate was present, and the carbon dioxide supply to the culture was prevented, the glycogen-glucose increased from 1.2 to 9.3 % of the dry weight (Table 3).

When the cells were cultivated in a glucose medium, the glycogen-glucose increased during the lag phase and decreased during the log phase in the same way as when the cells were grown in Friedlein's medium (Table 4, expt. G). The major difference consisted in a higher glycogen-glucose content of the cells at the moment of inoculation compared with cells grown in a lactate medium. The glycogen-glucose content of cells grown in broth also behaved in the same way (Table 4, expt. F). The increase in glycogen-glucose was however not so pronounced during the lag phase as in the lactate medium. This may be due to the difficulty of obtaining cells free from medium constituents tending to precipitate at the harvest.

Table 4. The glycogen-glucose content of E. coli B, *varying the size of the culture, the initial cell concentration and the composition of the medium.*

Exp.	Time after inoculation in minutes	Number of cells × 10^{-6} per ml	Glycogen-glucose in per cent of dry weight
C	0	1.0	2.1
	60	1.1	14.2
	360	—	2.2
D	0	10.5	2.1
	90	12.1	9.2
E	70	5.1 *	11.3
F	0	0.9	2.4
	60	0.9	8.0
	360	66.7	1.6
G	0	1.4	6.2
	60	1.8	12.1
	360	12.0	4.7

The cultures C, D, and E were performed in Friedlein's lactate medium. The size of the culture was 5 litres in exp. C and D. In exp. E the culture volume was 70 litres. This culture was performed in a stainless steel tank. Culture F was performed in a broth medium, culture G in a glucose medium. The culture volumes in both F and G was 5 litres.

The influence of cell concentration and culture volume on the increase in glycogen during the lag phase. The culture volume did not affect the increase in glycogen during the lag phase. Cultures performed in 5, 40, and 70 litres (Expts. A—E) all showed a glycogen increase of the same magnitude during the lag phase.

The initial cell concentration did not affect the increase in glycogen during the first 60 to 90 minutes after inoculation (Table 4, expts. C, D and E).

DISCUSSION

The observation that glycogen had accumulated in lactate, glucose as well as in broth cultures during the lag phase of growth, and that in all these media the glycogen decreased during the log phase, shows that the changes in glycogen were not due to specific actions of the various carbon sources. As shown in Table 2 and Fig. 2 there was a decrease in total glycogen during the first part of the log phase, coinciding with high rates of synthesis of the nitrogen-containing cell constituents. The lag phase may in respect of the glycogen be pictured as an endergonic phase of growth and the first part of the log phase as an exergonic phase.

During the last part of the log phase there was an increase in total glycogen, but there was no significant increase in the low amount of glycogen per cell.

* The initial cell concentration was 5.3 × 10^6 cells per ml as estimated from the cell concentration in the praeculture.

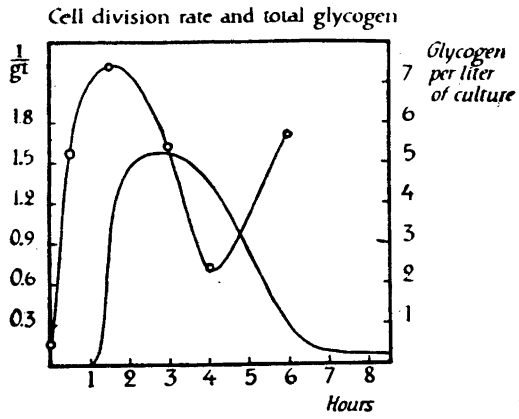

Fig. 2. The cell division rate was estimated by taking the reciprocal value of the mean generation time in hours (gt). Samples for counting were taken every 15 minutes until 6 hours after inoculation. After that the intervals were 40 minutes. The glycogen-glucose (in mg) per litre of culture is shown by the open circles. The rate of formation of nitrogen-containing compounds showed its maximum at the same time as the cell division rate was at its maximum.

It might be suggested that the small residual amount of glycogen left in the cells be considered as a primer for glycogen synthesis.

Hershey and Bronfenbrenner [12], observing the uptake of oxygen in relation to the phase of growth in *E. coli*, found that the uptake of oxygen per hour and gram of bacterial nitrogen was constant during all phases of growth. No observations were made during the first 150 minutes of growth. It is, however, evident that the oxygen uptake per unit weight of bacterial nitrogen and hour was the same at the beginning of the log phase as at the end of this phase. This means that the oxygen uptake was the same whether the synthesis of nitrogen-containing compounds proceeded at a high rate or at a low rate. It seems justifiable to conclude that the aerobic mechanisms functioned at the same rate throughout all phases of growth. Since the high rate of synthesis of nitrogen-containing compounds during the first part of the log phase was not accompanied by a high rate of oxygen consumption, the energy, necessary for these syntheses, may partly have been made available by anaerobic breakdown of carbohydrate. An auxiliary source of this carbohydrate was the glycogen accumulated during the lag phase.

The experiments C and D (Table 4) were performed in order to rule out the possibility that the decrease in glycogen during the first part of the log phase was caused by anaerobic conditions in the medium. Anaerobic or semi-anaerobic conditions might have been induced by high cell concentrations. If a high cell mass per unit volume of culture were to produce oxygen deficiency in the medium, this would cause an inhibition of the glycogen synthesis from lactate. No significant lowering of glycogen per unit weight of bacteria was observed, even though the initial cell concentration was increased ten times. Furthermore, preliminary experiments have shown that it was possible to diminish the aeration to 100 ml per minute and litre of culture, without any changes in

the length of the lag phase and the mean generation time occurring. These results seem to exclude the possibility that the decrease in glycogen during the first part of the log phase was caused by oxygen deficiency in the medium.

Roberts *et al.*[13], observing the incorporation of ^{14}C from various sources, concluded that in the case of proliferating *E. coli* cultures, the tricarboxylic acid cycle furnishes 50 % of the carbon required for protein synthesis, but is relatively unimportant as an oxidative mechanism. They express the view that the function of the tricarboxylic acid cycle is mainly a synthetic one[14] in this case. It might be suggested that the energy derived from the oxidative breakdown is sufficient for the syntheses during the lag phase, but that the capacity of the cycle is insufficient to furnish the carbon for the syntheses and the energy required during the first part of the log phase. The energy output from the cycle may be less at this time, due to the disappearance of considerable amounts of tricarboxylic acid components in the form of nitrogen containing compounds. This would imply that less energy-rich bonds were produced by the cycle, and consequently the situation would be favourable for the formation of these compounds by means of glycolysis. It should however not be overlooked that there may be other ways of oxidative breakdown in *E. coli* than that of the tricarboxylic acid cycle.

An attempt was made to get some more information about the oxygen consumption of cells in the lag phase by the Warburg "indirect" manometric method. No reproducible results could be obtained.

In the experiment performed in ^{14}C-lactate medium, the specific activity of the glycogen carbon showed a very sharp increase during the lag phase and thereafter remained at a level of about one-third of the specific activity of the lactate carbon in the medium. If every glucose molecule in the glycogen had been synthesized from two lactate molecules only, the specific activity of the glycogen carbon would have shown a still sharper increase during the lag phase, and would have reached approximately the same specific activity during the log phase as that of the medium lactate. The dilution of the glycogen carbon during the lag phase may at least in part be ascribed to dilution from cellular carbon already present at the moment of inoculation. That such was the case is indicated by the results presented in Table 3, which show that glycogen was synthesized to some extent, even when there was no carbon source except CO_2 in the medium. Hammarsten, Palmstierna, Reio and Åqvist[15] have shown that the glycogen in cells praecultured for 18 hours in β-labeled ^{13}C-lactate medium contained increasing amounts of ^{13}C during the lag phase when cultivated in a medium free from ^{13}C. This proves that the glycogen carbon was diluted by carbon of cellular origin during this phase.

A synthesis of glycogen from internal carbon sources was made probable also by the experiments described in Table 3. The role of carbon dioxide in this synthesis was also made evident. If carbon dioxide was available a synthesis of glycogen from cellular carbon sources occurred (expt. J), in this case in the absence of the organic carbon source. No such synthesis occurred if both carbon dioxide and the organic carbon source were excluded, indicating that the mechanism of the synthesis of glycogen from cellular carbon was sensitive to carbon dioxide deficiency. The result that the glycogen synthesis

was uninhibited if lactate but no carbon dioxide was provided, may be explained by a production of carbon dioxide from lactate-carbon (expt. L).

Ehrensvärd and Palmstierna [16] have shown that certain amounts of ^{14}C were incorporated into bacterial glycogen when the culture was aerated with $^{14}CO_2$-containing air. This finding agrees with the results obtained by Hastings *et al.*[17] when working with rats. The incorporation of CO_2-carbon does not explain the low specific activity of this substance when grown on β-labeled lactate, since the CO_2 was incorporated into C_3 and/or C_4. The β-carbon from lactate may be expected in the positions C_1 and C_6.

The observation that glycogen had accumulated to an approximately equal extent in lactate, glucose or broth cultures during the lag phase, and that in all of these media the glycogen decreased during the first part of the log phase, shows that the changes in glycogen were not due to a specific action of the lactate.

Changes in Glycogen and Nitrogen-containing Compounds in *Escherichia coli B* during Growth in Deficient Media

I. Nitrogen and Carbon Starvation

T. HOLME and H. PALMSTIERNA

Bacteriological Department and Chemical Department I, Karolinska institutet, Stockholm, Sweden

When *Escherichia coli B* was cultivated in media deficient either in the nitrogen or in the carbon source, there was no increase in the nitrogen-containing compounds in the cells during the phase of constant cell concentration, which was caused by exhaustion of the limiting factor.

During this starvation phase an increase of glycogen in the cells was observed.

During the phase of rapid cell division following the addition of the limiting factor in the nitrogen-deficient culture with sodium lactate as the carbon source, the glycogen per litre of culture decreased rapidly.

When the cells were cultivated in nitrogen-deficient media, substances causing an absorption in the ultra-violet region poured into the medium. During the period of growth following the addition of the nitrogen source, the ultra-violet absorption of the culture fluid decreased rapidly.

In earlier experiments it was shown that the total glycogen in *Escherichia coli B* cultures increased considerably during the lag phase of growth, and decreased abruptly when the cells began to divide[1]. By the use of a synthetic medium deficient in one essential nutrient it is possible to arrest cell division after a certain number of generations in the logarithmic phase of growth[2]. In this paper experiments are described in which this technique is used in order to obtain additional information regarding glycogen synthesis in non-dividing cells. The experiments also include the addition of the limiting factor after a certain period of starvation, as well as observations concerning the phase of cell division that followed.

METHODS

Media. The medium used in all experiments but one was Friedlein's synthetic sodium lactate medium [3]. In one experiment a medium with glucose as the carbon source was used [4]. The nitrogen source was ammonium chloride in all experiments. Praecultures were grown in these media. In the final cultures, media of the same composition as in the praecultures were used, except that they were deficient either in the carbon or in the nitrogen source. In the experiments in which the nitrogen source was the limiting factor, the initial concentration of ammonium chloride was 0.75×10^{-3} M. In the experiment with the carbon source as the limiting factor, the initial sodium lactate concentration was 1.67×10^{-2} M.

Cultivation technique. Praecultures were grown as previously described [1]. The final cultures were inoculated with an amount of cells sufficient to give a concentration of about 10^{8} cells per ml. Prior to inoculation the cells were washed once with the deficient medium. One and a half hour after the cells had ceased dividing in the nitrogen-deficient cultures, and four hours later in the carbon-deficient one, a quantity of the limiting factor was added in order to give approximately the same concentration of those factors as in the complete media, *e. g.* 0.02 M in respect of ammonium chloride and 0.1 M in respect of sodium lactate. In all other respects the techniques were the same as previously described.

Chemical methods. The isolation of glycogen and the estimation of the glycogen-glucose were performed as described in a preceding article [1]. The trichloro-acetic acid (TCA) extractions were performed according to Schneider [5]. The "hot TCA"-extraction was always performed on the material already TCA-extracted in the cold. The micro-Kjeldahl method was used for the nitrogen determinations.

The cells were washed with fresh medium free of the nitrogen source. TCA: trichloro-acetic acid.

RESULTS

Nitrogen starvation. In the nitrogen-deficient cultures (expts. A, C and D), the lag phase was of the same duration as in the complete media. After an initial multiplication period, the cells ceased dividing on account of the deficiency in the medium (Fig. 1, Tables 1, 3 and 4).

In order to obtain a cell concentration of about 5×10^8 cells per ml during the starvation phase, the initial concentration of ammonium chloride in the medium had to be 0.75×10^{-3}M.

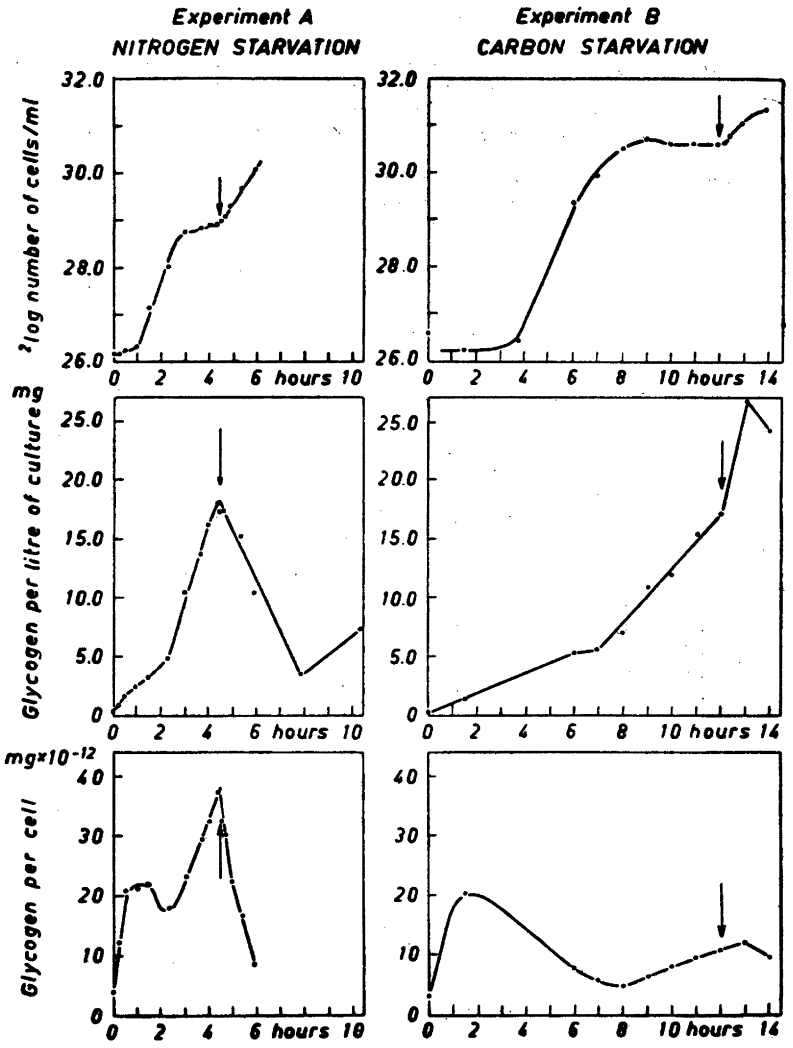

Fig. 1. Experiments A (nitrogen starvation) and B (carbon starvation). The arrows indicate the moment when ammonium chloride and sodium lactate respectively were added.

In one experiment (D, Table 4) it was noted that the glycogen content of the cells had reached a value near maximum in about two hours from the beginning of the starvation phase.* Consequently, when the starvation phase had lasted for that period in expts. A and C, ammonium chloride was added to obtain a concentration of 0.02 M, in order to initiate a second multiplication phase with the cells loaded with glycogen.

After the addition of ammonium chloride, the cells began to divide immediately (Fig. 1).

Glycogen per cell. The glycogen per cell increased during the lag phase and decreased during the first part of the logarithmic phase of growth in the same way as when the cells were cultivated in a complete medium (Fig. 1). However, when the division rate began to decrease, the glycogen per cell increased again. This increase continued linearly during the starvation phase until ammonium chloride was added. In experiment A, where lactate was the carbon source, the glycogen per cell increased from 17.9 to 37.2 $\times 10^{-12}$ mg (Table 1). The same course of development was noted in expt. C, with glucose as the carbon source, and the corresponding figures for the glycogen increase per cell were 26.0 and 75.7 $\times 10^{-12}$ mg, respectively, showing as in earlier experiments that the amount of glycogen was higher in cultures with glucose as the carbon source (Table 3). In both experiments (A and C) the addition

* After 200 minutes the number of cells remained constant at 2.8 × 10^6 cells per ml.

of ammonium chloride caused an immediate and rapid decrease in glycogen per cell.

T o t a l g l y c o g e n. In experiments performed in complete media, glycogen per dry weight and litre of culture (total glycogen) began to decrease two hours after inoculation. In the deficient cultures the starvation phase had already begun at the time when this decrease was expected and the total glycogen began instead to increase at this point. This increase was linear and continued during the starvation phase.

After the addition of ammonium chloride the total glycogen decreased rapidly in the culture with lactate as its carbon source, showing that the glycogen synthesis was too small to compensate for the utilization. The lowest figure was noted at the beginning of the stationary phase (3.5 mg per litre o culture). The slight increase in total glycogen that followed in this experiment was primarily due to the increase in the cell mass (Table 1). The culture with glucose as its carbon source (expt. C) did not show the same immediate decrease in total glycogen after the addition of ammonium chloride, but the rate of increase slowed down (Table 3).

The protein-nitrogen per cell decreased slightly at the beginning of the starvation phase, and then remained constant (Table 1).

Ultra-violet absorption of the culture fluid. In cultures grown in an unmodified Friedlein's medium, the UV absorption of the cell-free culture fluid never exceeded an extinction of 0.15 at 260 mμ (read against fresh medium, 1 cm cuvettes). The case was the same in the carbon-starved culture (expt. B). In nitrogen-starved cultures grown in lactate medium, as described above (expt. A), substances poured from the cells into the medium, causing an absorption in the UV region (Figs. 2 and 3). At 260 mμ the absorption increased from 0.15 at 90 min. after inoculation to 0.6 at 5 hours after inoculation. By that time the starvation phase had lasted for about 2 hours (Fig. 2). When the ammonium chloride was added, the UV absorption of the culture fluid decreased rapidly. The same results were obtained in three different experiments, two in 5 litre cultures, and one in a 200 ml culture.

Carbon starvation. One carbon-deficient culture (expt. B) was also investigated (Fig. 1, Table 2). In lactate-deficient media there was a considerable increase in the duration of the lag phase when the sodium lactate concentration

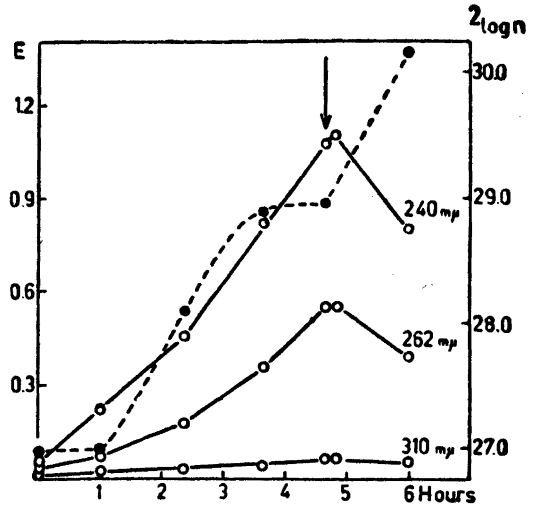

Fig. 2. Ultra-violet absorption of the cell-free medium in a nitrogen-starved culture. Broken curve: ^{2}log number of cells per ml. Unbroken curves: specific absorption (E) of the medium. The arrow indicates the moment when ammonium chloride was added.

was lower than 3.0×10^{-2} M. The initial concentration of lactate in expt. B was 1.67×10^{-2} M, giving a lag phase of about three hours' duration. The cell concentration during the starvation phase reached rather a high level, 1.6×10^9 bacteria per ml, which was about three times as much as the cell concentration during this phase in the nitrogen-starved cultures. The period of constant cell

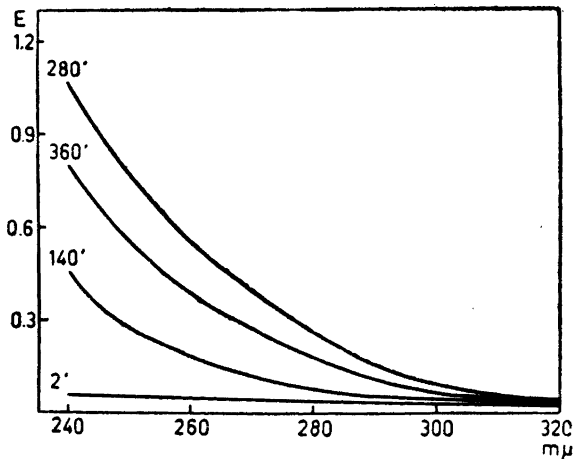

Fig. 3. The same experiment as in Fig. 2. Absorption curves obtained at different times, indicated by the figures at the end of each curve. The extinction was determined at intervals of 5 mμ except in the region 250—270 mμ, where the intervals were 2 mμ.

* Difficult to count in the Buerker chamber because of the scanty contrast.

concentration due to starvation in experiment B was not interrupted as early as in the nitrogen-starved cultures. The time chosen in each case corresponded roughly to that of the lag phase.

After the addition of sodium lactate (12 hours after inoculation) there was a short lag before the cells began to divide (Fig. 1). The increase in cell numbers was small, and the division rate low, during the period of multiplication that followed, probably because the cell concentration was near its maximum value in the medium used. Two hours after the addition, the cell concentration was 2.6×10^9 bacteria per ml.

Glycogen per cell. The glycogen per cell reached a value of about 20×10^{-12} mg during the lag phase (Table 2). During the logarithmic phase it decreased to a minimum value of 4.7×10^{-12} mg eight hours after inoculation. At this point the division rate slowed down, due to the deficiency in the medium, and the glycogen began to increase again. Compared with the nitrogen-starved cultures, this increase proceeded at a very slow rate, the glycogen per cell amounting twelve hours after inoculation to 10.7×10^{-12} mg. Since the dry weight per cell was constant during the whole starvation phase, the same rate of increase was found in glycogen per mg of dry cells. During the first hour after the addition of sodium lactate, the glycogen per cell showed a slight increase, followed by a decrease.

The "per cell" values do not of course account for different types of cells that may be present in a culture. No attempt has been made as yet to study more closely the differences between cells belonging to the same population.

Total glycogen. Glycogen per dry weight and litre of culture increased throughout the lag, logarithmic, and starvation phases in approximately the same way as in the nitrogen-starved cultures. The rate of increase, however, was much slower (Fig. 1).

In spite of the low content of glycogen in the carbon-starved cells, the values of total glycogen are similar to those in the nitrogen-starved cultures. This is due to the fact that the dry weight of cells per unit volume during the starvation phase was about 2.5 times greater in the carbon-starved culture (B) than in the nitrogen-starved cultures.

After the addition of lactate in expt. B, the total glycogen increased considerably within the first hour, followed by a decrease during the second hour.

Influence of carbon dioxide. Carbon deficient cultures (lactate starvation) were aerated with an air-CO_2-mixture. One per cent CO_2 increased the rate of glycogen synthesis 1.8 times and 4 per cent CO_2 increased the rate 2.5 times that in experiment B (aerated with common air).

DISCUSSION

Several authors have reported experiments dealing with the chemical composition of bacteria cultivated in deficient media[6-8]. When cultivated in media with high carbohydrate and low nitrogen content, *Escherichia coli* and *Aerobacter aerogenes* showed a high polysaccharide content in the stationary phase[7].

Dagley and Dawes[8] determined the total polysaccharides of *E. coli* cells cultivated in deficient media. The interpretation of their results is rendered difficult because of the inhomogeneity of the substances determined. Evidently the polysaccharide material that accumulates during prolonged nitrogen starvation represents different kinds of carbohydrates which may be more or less actively participating in the metabolism.

In a later article, Dagley, Dawes and Morrison[9] describe experiments with *Aerobacter aerogenes*, in which pyruvate was determined in the medium under different conditions of growth.

As reported previously[1], the glycogen accumulation and utilization seems to be correlated to the synthesis of the nitrogen-containing compounds in the

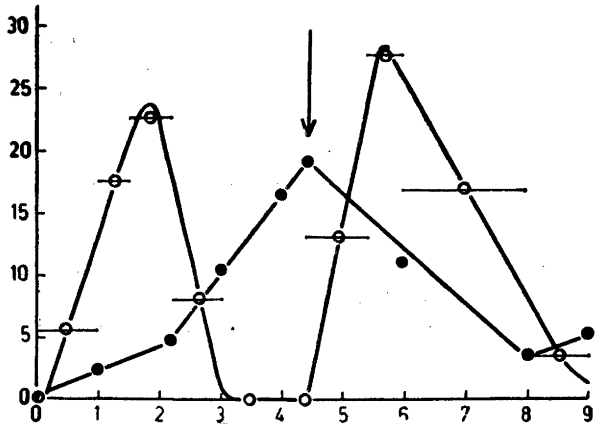

Fig. 4. Total glycogen and rate of protein synthesis in a nitrogen-starved culture. Abscissa: Time in hours. Ordinate: Glycogen per litre of culture in mg and *per cent increase in protein-nitrogen per litre of culture in 10 minutes. The arrow indicates the moment when ammonium chloride was added. The net synthesis of protein was arrived at by estimating the increase in protein nitrogen per litre of culture in per cent of the preceding value. The curve* O——O *was drawn through the midpoint of these time intervals. The curve* ●——● *represents the glycogen per litre values in mg. The curves show that the glycogen increased relatively slowly during the time when the net synthesis of protein showed its first maximum, and that the net synthesis of glycogen increased at a higher rate when there was no protein synthesis due to nitrogen starvation. After the addition of ammonium chloride, the net synthesis of protein increased very rapidly. The glycogen decreased sharply at the same time.*

cells. This view is supported by our present results. In the experiments presented in this paper, as well as in those previously reported a low net synthesis of nitrogen-containing compounds was accompanied by a high net synthesis of glycogen. During a phase of growth in which the synthesis of nitrogen-containing compounds was limited by nitrogen starvation (the starvation phase), glycogen accumulated rapidly.

The high rate of synthesis of nitrogen-containing compounds observed immediately after the addition of ammonium chloride was accompanied by a sharp decrease in the total glycogen in the culture, which also lends support to the view expressed. (Fig. 4.) In one experiment described by Dagley *et al.*[9], the addition of the nitrogen source to a nitrogen-starved culture caused an arrest in the pyruvate production from the cells. This may be explained by a high rate of utilization of the pyruvate, presumably for the synthesis of protein.

The fact that there was no lag before the cell concentration began to increase logarithmically after the addition of ammonium chloride shows that the cells were well prepared for cell division.

The material that poured into the medium during nitrogen starvation causing an absorption in the UV region (Fig. 2), was probably not of protein or nucleic acid origin. The fact that these compounds were dialysable to at least 90 % as measured by the absorption, showed that the UV absorption in the medium was not caused by non-dialysable protein or polynucleotides from autolysed cells. Furthermore, no maximum in the absorption at 260 mμ was recorded (Fig. 3), which would have been the case if cellular material of nucleic acid origin had been released to the medium.

The immediate decrease in the UV absorption in the medium after the addition of ammonium chloride shows that as soon as a nitrogen source was available, the cells were able to take up, or possibly, destroy the substances causing the absorption.

During the starvation phase in the carbon-deficient culture (expt. B) there was no increase in nitrogen-containing compounds (cold and hot TCA fractions, and protein). There was in fact a slight decrease (Table 2). In spite of the low concentration of the carbon source in the medium, there was still an accumulation of glycogen. The reactions involved in cell division and in the synthesis of the nitrogen-containing compounds are apparently more sensitive to a lowering of the concentration of the organic carbon source than is the synthesis of glycogen.

Studies on Pyrazolones

X. Reactions of Pyrazole Blue with Cyanoacetamide and Malononitrile

GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden

Cyanoacetamide and malononitrile add to pyrazole blue by normal Michael additions with formation of compounds V and VII. The malononitrile derivative (VII) rearranges readily to the cyclic compound VI.

In a previous paper [1] it was shown that ethyl cyanoacetate reacts with pyrazole blue (I) with the formation of two different adducts (II and III). Both adducts were readily hydrolysed by alkali with the formation of IV.

In the present investigation, one adduct only, a monobasic acid for which the structure V is proposed, was obtained from the reaction of pyrazole blue with cyanoacetamide. Compound V showed no tendency to ring closure and in this behaviour resembled IV and contrasted with II. The UV absorption curve of V (Fig. 1) showed a striking resemblance to the corresponding curves of II and IV.

Addition of malononitrile to pyrazole blue in the presence of a small amount of piperidine furnished mainly a product, which was obviously the iminolactone VI (a, b, c), since it had a neutral reaction and a UV absorption very similar to that of III [1]. In the absence of a catalyst, a mixture of VI and a dibasic acid was obtained. The same dibasic acid was formed on treatment of VI with excess of dilute alkali at room temperature. It had a UV absorption curve quite analogous to the corresponding curves of II, IV and V (Fig. 1). Hence structure VII is proposed for this compound.

As in the case of II, VII could be easily transformed into the corresponding cyclization product. Thus a solution of VII in ethanol was slowly isomerized to form VI. The transformation was rapid when a small amount of piperidine was added. Dry hydrogen chloride reacted with VII in ether solution with the formation of a hydrochloride of VI.

The IR spectrum of V showed a distinct C≡N stretching band at 2 240±15 cm^{-1}, whereas in VII the nitrile band was very weak in spite of the two C≡N

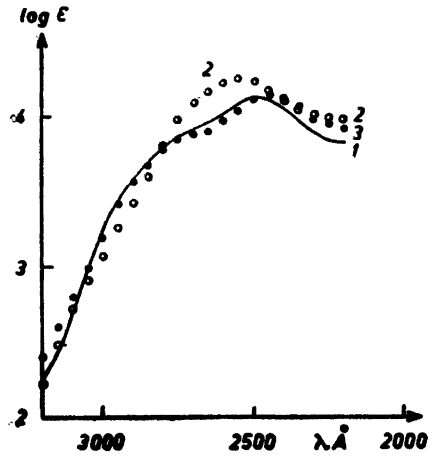

Fig. 1. UV absorption curves of compound V (1), VI (2) and VII (3) in ethanol solutions.

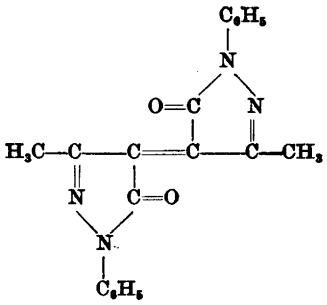
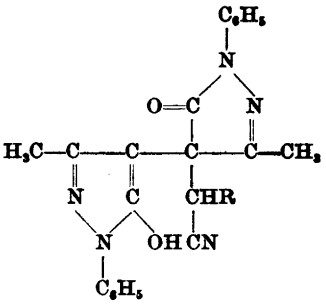


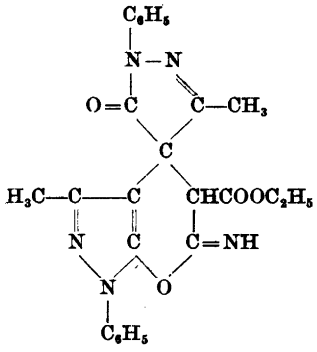
groups present in the molecule. A similar weakening of a C≡N band was described in 1952 by Kitson and Griffith [2], particularly in molecules with oxygen-containing groups. With compound IV the same effect was observed [1].

The spectrum of VI exhibited an intense C≡N absorption. The band was, however, situated at 2 190±15 cm^{-1}. This indicates that the C≡N group is in conjugation and hence that the structure of VI is essentially that of VI b. According to Kitson and Griffith the IR absorption of a nitrile group in conjugation with an olefinic double bond is found at 2 225±8 cm^{-1}. Thus the extension of the resonance to the free electron pairs of the oxygen and nitrogen atoms in the β-position of the cyano group in VI b gives rise to a marked shift of the nitrile band towards longer wavelengths.



The acidic strength of the hydrogen atoms in the α-position of the cyano groups in II, IV, V and VII is rather different. In ethanol-water solution using alizarine yellow indicator the α-hydrogen atom is neutral in compounds IV and V. In II it can be titrated with barium hydroxide solution (alizarine yellow indicator), though with a very poor end point. It is possible, however, to titrate compound VII with a sharp end point using thymolphthalein indicator. Thus in II and VII the acidifying effect of the bispyrazolonyl group, which is electron attracting and hence stabilizes the carbanion, is striking, for ethyl cyanoacetate exhibits very weakly acidic properties under the above conditions, and the ionization constant of malononitrile is 6.5×10^{-12} according to Pearson and Dillon [3].

In dimethylformamide solution, using azo violet indicator, the effect of the bispyrazolonyl group is not noticeable on titration with sodium methoxide [4]. Both malononitrile, ethyl cyanoacetate and their bispyrazolonyl derivatives are accurately titrated. Cyanoacetamide and compound V can be titrated, though with a very poor end point. In cyanoacetic acid as in compound IV the α-hydrogen has no acidic properties on titration.



Thus compounds II and VII differ from IV and V both in their greater tendency to ring closure and in the greater acidity of the hydrogen atoms in the α-position of the nitrile groups. One reason for these properties is the grea-

ter resonance interaction with conjugated groups or free electron pairs of the carbethoxy group of II and still more of the cyano group of VII, compared to the carboxyl and amide groups of IV and V. The resonance causes stabilization of the ring compounds III b and VI b. It also stabilizes the anions of II and VII.

EXPERIMENTAL

Preparation of compound V from pyrazole blue and cyanoacetamide. A mixture of cyanoacetamide (4.0 g), pyrazole blue (16.2 g), chloroform (70 ml), ethanol (10 ml) and piperidine (0.4 ml) was shaken overnight. The colourless precipitate formed was filtered off and washed with ethanol. Yield of air-dried product: 20.0 g. It was purified by crystallization from ethanol. The compound adsorbed the solvent strongly. It was dried at 0.1 mm Hg, 78°, over phosphoric anhydride and was afterwards hygroscopic. (Found: C 64.0; H 4.6; N 19.4; equiv. wt. 430. $C_{23}H_{20}N_6O_3$ requires C 64.5; H 4.7; N 19.6; equiv. wt. 428.5.) For UV absorption curve, see Fig. 1.

Preparation of VI from pyrazole blue and malononitrile. Malononitrile (3.15 g), pyrazole blue (15.6 g), chloroform (90 ml) and piperidine (0.3 ml) were mixed together. Decolorization took place in a few minutes, and crystals of VI separated. After cooling with iced water, the precipitate was filtered off and washed with cold ethanol. Yield: 17.2 g of air-dried product. It was purified by recrystallization from ethanol and dried *in vacuo* (0.1 mm Hg) at 100°, m. p. about 240° (decomp.). The product was rapidly isomerized into VII even by 0.1 N alkali solution. (Found: C 67.1; H 4.5; N 20.5. $C_{23}H_{16}N_6O_2$ requires C 67.3; H 4.4; N 20.5.) UV absorption curve see Fig. 1.

Transformation of VI into VII by addition of alkali. A mixture of compound VI (7.0 g), ethanol (35 ml) and 2.5 N sodium hydroxide solution (35 ml) was kept overnight and then poured into N hydrochloric acid. The product which separated (6.9 g) was collected by filtration, washed with water and air-dried. After extraction of impurities with ethyl acetate it was dried under reduced pressure (0.1 mm Hg) at 78° over phosphoric anhydride. The product melted at 230–240° (decomp.). (Found: C 67.3; H 4.5; N 20.4; equiv. wt. 203. $C_{23}H_{16}N_6O_2$ requires C 67.3; H 4.4; N 20.5; equiv. wt. 205.) The UV absorption curve is seen in Fig. 1.

Transformation of VII into VI using piperidine as a catalyst. A solution of compound VII (0.85 g) and two drops of piperidine in ethanol (25 ml) was kept overnight at room temperature. The product formed was precipitated by addition of N hydrochloric acid and water, filtered and washed with water. It was purified by crystallization from ethanol. The neutral product obtained was easily hydrolysed by alkali in a similar manner to compound VI. UV absorption curve and analyses were identical with the data of VI.

Transformation of VII into VI by hydrogen chloride. A suspension of VII in ether was treated with dry hydrogen chloride, and the resulting salt was filtered off and washed with ether. (Equiv. wt. of the air-dried product on titration using bromophenolblue indicator: 470. Calc. for $C_{23}H_{16}N_6O_2$, HCl: 447.) The free base was isolated by precipitation of the ethanol solution of the salt with water. According to analyses, UV absorption curve and melting point, it was identical with compound VI.

The analyses were performed by Miss M. Westerdahl, Department of Analytical Chemistry, University of Lund. Dr. Andreas Rosenberg, University of Uppsala, carried out the IR measurements.

The author wishes to thank *Statens naturvetenskapliga forskningsråd* for financial support.

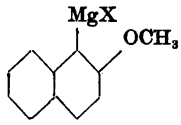
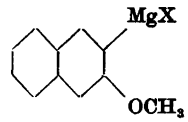
Methoxy Substituted Naphthylmagnesium Halides and Carbon Dioxide

GUST.-AD. HOLMBERG



Institutet för organisk kemi, Åbo Akademi, Åbo, Finland

The rules for the anomalous reactivity of *o*-methoxy substituted phenylmagnesium bromides are also valid for methoxy substituted naphthylmagnesium halides, if the condensed ring is considered to be a substituent.



If the rules which are valid for the anomalous reactivity of *o*-methoxy substituted phenylmagnesium bromides [1] also are valid for the corresponding naphthalene derivatives, it may be expected that 1-methoxy-2-naphthylmagnesium halide (I) and 2-methoxy-1-naphthylmagnesium halide (II) will react with carbon dioxide to give only the corresponding acid, while 3-methoxy-2-naphthylmagnesium halide (III) under the same conditions will give both the corresponding acid and the corresponding ketone.

I

II

III

These predictions were fulfilled when the Grignard reagents prepared from 1-bromo-2-methoxynaphthalene, 2-iodo-1-methoxynaphthalene, and 3-iodo-2-methoxynaphthalene were allowed to react with carbon dioxide.

The iodine compounds were used since they can be more easily transformed into the corresponding Grignard reagents. The fact that different halogen compounds have been used has scarcely any significance, because the nature of the halogen does not seem to influence the anomalous reactivity. This I have found to be true in the case of *o*-methoxyphenylmagnesium bromide and *o*-methoxyphenylmagnesium iodide.

Table 1. Yields of naphthoic acids and neutral substances.

Naphthalene derivative	Acid isolated				Neutral substances g
	g	M. p.	*p*-Nitrobenzyl ester Calc. N 4.15		
			M. p.	Found N	
1-Bromo-2-methoxy-	0.84	175–176	117–118	4.25	2.35
2-Iodo-1-methoxy-	1.26	123–125	93–94	4.28	3.42
3-Iodo-2-methoxy-	1.07	131–133	123–124	4.20	2.48

EXPERIMENTAL

1-Bromo-2-methoxynaphthalene was prepared according to Franzen and Stäuble [2] through bromination of β-naphthol and methylation of the resulting 1-bromo-2-naphthol.

2-Iodo-1-methoxynaphthalene. α-Naphthylamine was nitrated and the reaction product was treated with potassium hydroxide according to Burkhardt and Wood [3]. The crude potassium 2-nitro-1-naphthoxide thus obtained was treated with methyl sulphate according to Clemo, Cockburn, and Spence [4] in order to give 2-nitro-1-methoxynaphthalene. This compound was reduced to the corresponding amine by stannous chloride in the way previously used in the synthesis of 5-amino-3-bromoveratrole [5]. The yield of 1-methoxy-2-naphthylamine after distillation under reduced pressure at 158–159°/9 mm was 71.5 %. This amine was converted into 2-iodo-1-methoxynaphthalene according to Clemo, Cockburn, and Spence. The crude product was, however, finally purified by distillation under reduced pressure. The yield of material boiling at 166–167°/10 mm and melting after recrystallization from ethyl alcohol at 41–42° was 81.4 %.

3-Iodo-2-methoxynaphthalene. 3-Hydroxy-2-naphthoic acid was successively converted into 3-methoxy-2-naphthoic acid, ethyl 3-methoxy-2-naphthoate, 3-methoxy-2-naphthoic hydrazide, ethyl 3-methoxy-2-naphthylcarbamate, and 3-methoxy-2-naphthylamine according to Jambuservala, Holt and Mason [6]. From the last mentioned substance, 3-iodo-2-methoxynaphthalene was prepared according to Clemo and Spence [7]. The yield of material boiling at 186–189°/10 mm and melting, after recrystallization from methyl alcohol, at 64.5–65.5° was 39.5 %.

The reactions between Grignard reagents and carbon dioxide were examined as has previously been described [1]. Because the halomethoxynaphthalenes used are not volatile with steam, the steam distillation was omitted. The neutral substances thus contain unreacted halomethoxy compound and perhaps methoxynaphthalenes derived from Grignard reagent that has not reacted with carbon dioxide. The results are collected in Table 1.

Only unreacted halogen compounds could be isolated from the neutral substances obtained in the experiments with Grignard reagents prepared from 1-bromo-2-methoxynaphthalene and 2-iodo-1-methoxynaphthalene. No ketone was detected.

When the neutral substances isolated from the experiment with Grignard reagent prepared from 3-iodo-2-methoxynaphthalene were treated with ether, di-3-methoxynaphthylketone was isolated. After recrystallization from ethyl alcohol, it melted at 154–155°. (Found: C 80.45; H 5.45. Calc. for $C_{23}H_{18}O_3$: C 80.68; H 5.30). Its 2,4-dinitrophenylhydrazone melted at 240–241°. (Found: N 10.87. Calc. for $C_{29}H_{22}O_6N_4$: N 10.72.)

A solution of *o*-methoxyphenylmagnesium iodide was prepared by reacting *o*-iodoanisole [8] (4.68 g) with magnesium (0.49 g) in dry ether (30 ml). Carbon dioxide was led into the solution, and when the reaction products were isolated, *o*-methoxybenzoic acid (0.55 g) and 2,2'-dimethoxybenzophenone (2.27 g) were obtained.

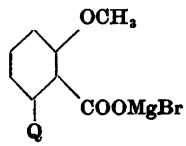
The Effect of Different Alkoxy Groups on the Anomalous Reactivity of *o*-Alkoxyphenylmagnesium Bromides

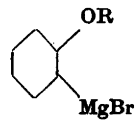
GUST.-AD. HOLMBERG

Institutet för organisk kemi, Åbo Akademi, Åbo, Finland

The reactions between carbon dioxide and 2-alkoxy-5-methylphenylmagnesium bromides containing ethoxy, *n*-propoxy, *n*-butoxy, *iso*propoxy, and *iso*butoxy groups as alkoxy groups have been studied. As in the case of the methoxy homologue both the corresponding acids and the corresponding ketones are formed in these reactions, the yield of ketone being the lowest in the case of 2-*iso*propoxy-5-methylphenylmagnesium bromide. This fact is associated with steric effects that probably cancel the anomalous reactivity of *o*-methoxyphenylmagnesium bromides with a methyl group, methoxy group or a condensed benzene ring in the ortho position relative to the original methoxy group.

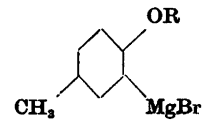


Some time ago the author proposed a reaction mechanism to explain the anomalous reactivity of *o*-methoxyphenylmagnesium bromides [1]. The mechanism in question involves an intramolecular ring formation by replacement of one of the two "etherate" ether molecules of the Grignard reagent by the methoxy group. The strained rings were expected to favour the polarization of the carbon-to-magnesium bonds:



The anomalous reactivity of the *o*-methoxyphenylmagnesium bromides is cancelled by a methyl or methoxy group in the ortho position relative to the magnesium or oxygen atom [2,3]. The same rule is also valid in the naphthalene series if the condensed ring is considered to be a substituent [4]. In the former case, *i. e.* when the substituent is in the ortho position relative to the magnesium atom, it is believed that the first reaction product (I) is sterically hindered in the same way as certain mesityl derivatives. A molecular study of the

latter case (the substituent and the oxygen atom in the ortho position relative each other) shows that the methoxy group is unable to rotate freely. It may thus be prevented from occupying the proper position for ring formation. If this is right, it may be expected that the anomalous reactivity would even be cancelled when the steric effect is produced in another way.



A substance with the required properties is 2-*tert.*-butoxyphenylmagnesium bromide (IIg). Unfortunately, 2-*tert.*-butoxybromobenzene, which is needed for its preparation, is very difficult to synthesize. For this reason other substances had to be used although they were not as well adapted. In 2-*iso*propoxyphenylmagnesium bromide (IIe) the rotation of the alkoxy group is not quite prevented, but is nevertheless obstructed to some extent. In this case a decrease in the yield of the corresponding ketone may be expected.

I

II

III

Q = —CH_3 or —OCH_3 R = (a) —CH_3, (b) —CH_2CH_3, (c) —$CH_2CH_2CH_3$, (d) —$CH_2CH_2CH_2CH_3$ (e) —$CH(CH_3)_2$, (f) —$CH_2CH(CH_3)_2$, or (g) —$C(CH_3)_3$

o-Alkoxyphenylmagnesium bromides with a primary carbon atom attached to the oxygen ought to possess an anomalous reactivity of about the same order as that of the methoxy homologue, although substances in which the β carbon atom in the alkoxy group is secondary as in 2-*iso*butoxyphenylmagnesium bromide (IIf) should perhaps give a somewhat lower yield of the corresponding ketone.

For the preparation of the 2-alkoxyphenylmagnesium bromides the corresponding 2-alkoxybromobenzenes are required. These substances are most conveniently obtained through alkylation of *o*-bromophenol, which, however, is very difficult to purify. Consequently 3-bromo-4-hydroxytoluene was chosen as the starting material, because it is easily prepared and purified [5], and because the methyl group, at least in the methoxy derivative (IIIa) did not cancel the anomalous reactivity. The bromocresol was alkylated to give the ethoxy, *n*-propoxy, *n*-butoxy, *iso*propoxy, and *iso*butoxy derivatives (IIIb, c, d, e, and f). From the latter the corresponding Grignard reagents were then prepared and reacted with carbon dioxide.

The formation of an acid in the reaction between a Grignard reagent and carbon dioxide is considered to be the normal reaction. In the formation of one molecule of the corresponding ketone, one molecule of the Grignard reagent reacts normally to form a derivative of an acid (I or its homologue). Another molecule of the Grignard reagent then reacts with this first reaction product. This latter reaction is considered a consequence of the anomalous reactivity of the Grignard reagent. According to this the number of moles of the Grignard reagent, which react normally, is equal to the sum of the moles of acid and

ketone which have been formed during the reaction. The number of moles which react anomalously is equal to those of the ketone. In order to obtain comparable values, the ratios

$$\frac{\text{moles of ketone}}{\text{moles of ketone} + \text{moles of acid}}$$

have been calculated and used as a measure of the anomalous reactivity. From Table 1 in which these values have been collected it is to be seen that the anomalous reactivity of the *iso*propoxy homologue is considerably, and that of the *iso*butoxy derivative slightly lower than those of the other Grignard reagents. Also in the series methoxy, ethoxy, *n*-propoxy, and *n*-butoxy a slight decrease of the anomalous reactivity can be observed.

Table 1. The anomalous reactivity of 2-alkoxy-5-methylphenylmagnesium bromides.

Alkoxy group	$\frac{\text{Moles of ketone}}{\text{Moles of ketone + moles of acid}}$
Methoxy	0.46 [a]
Ethoxy	0.47
n-Propoxy	0.44
n-Butoxy	0.41
*Iso*propoxy	0.07
*Iso*butoxy	0.32

[a] According to previously published results [2]

The results show that the anomalous reactivity of *o*-alkoxyphenylmagnesium bromides is influenced by steric effects which prevent or restrict the free rotation of the alkoxy group, *i. e.* which prevent the alkoxy group from occupying the proper position for the formation of a complex bond between the oxygen and magnesium atoms.

EXPERIMENTAL

3-Bromo-4-ethoxytoluene was prepared by alkylation of 3-bromo-4-hydroxytoluene with ethyl *p*-toluenesulphonate in the following way. Sodium (3.85 g) was dissolved in absolute ethyl alcohol (77 ml) and to this solution 3-bromo-4-hydroxy-toluene (31.33 g) was added. After cooling, a solution of ethyl *p*-toluenesulphonate (33.50 g) in ethyl alcohol (30 ml) was gradually added. When the addition was complete, the mixture was heated on a boiling water bath for 1 hour. The solvent was then evaporated under reduced pressure and the residue was treated with a mixture of water and ether. The ether phase was separated and washed with a dilute solution of sodium hydroxide and finally with water. After drying with anhydrous sodium sulphate, the solvent was evaporated and the residue was distilled under reduced pressure. The yield of 3-bromo-4-ethoxytoluene, b. p. 117–118.5°/11 mm, was 87.8 % (31.62 g). Found: Br 37.10; Calc. for $C_9H_{11}OBr$: Br 37.15).

Table 2. Yields, boiling points, and analyses of 3-bromo-4-alkoxytoluenes.

Alkoxy group	Yield, %	B. p.	Br	
			Found	Calc.
n-Propoxy	82.4	121.5—122.0°/11 mm	34.80	34.88
n-Butoxy	63.7	139.0—140.0°/12 mm	32.70	32.87
*Iso*propoxy	62.8	108.0—109.0°/ 8 mm	34.81	34.88

[a] Not sufficiently pure.

3-Bromo-4-isobutoxytoluene was prepared in the same way using *iso*butyl bromide as alkylating agent except that the reaction mixture was heated 4.5 hours on the boiling water bath. The yield of pure 3-bromo-4-*iso*butoxytoluene, b. p. 124.5—125.5°/8 mm, was 48.9 %. (Found: Br 32.81; Calc. for $C_{11}H_{15}OBr$: Br 32.87).

3-Bromo-4-n-propoxytoluene, *3-bromo-4-isopropoxytoluene*, and *3-bromo-4-n-butoxytoluene* were prepared in the same way using the corresponding bromides as alkylating agents. In these cases the reaction mixture was heated in an autoclave to 120—130° for one hour. The yields, boiling points, and analyses are collected in Table 2.

The Grignard reagents were prepared from 0.02 equivalents of magnesium and 3-bromo-2-alkoxytolene in dry ether (30 ml).

The reaction between Grignard reagents and carbon dioxide were examined as previously described [2]. The results are collected in Tables 3 and 4.

The Crystal Structure of $U(SO_4)_2 4H_2O$

PEDER KIERKEGAARD

Institute of Inorganic and Physical Chemistry, University, Stockholm, Sweden

$U(SO_4)_2 4H_2O$ has an orthorhombic unit cell containing four formula units and with the dimensions

$$a = (14.674 \pm 0.005)\ \text{Å}$$
$$b = (11.093 \pm 0.005)\ \text{Å}$$
$$c = (5.688 \pm 0.005)\ \text{Å}$$
$$V = 925.8_9\ \text{Å}^3$$

A structure is proposed with atomic positions in the space group No. 62 *Pnma*. The positions of the uranium and sulphur atoms were determined with Fourier methods. The parameters of the oxygen atoms were deduced from geometrical considerations, using interatomic distances from previously determined structures. The crystals are built up of layers parallel to the *yz* plane and formed by uranium atoms and sulphate groups. The layers are held together by water molecules, so that each sulphate tetrahedron has two oxygen atoms linked with hydrogen bonds to adjacent water molecules. Every uranium atom is in contact with four sulphate groups and four water molecules, so that the coordination of oxygen atoms around uranium is eightfold in the shape of a square Archimedean antiprism.

Uranium(IV)sulphate-tetrahydrate was first prepared by Ebelmen [1] by a photochemical reduction of U_3O_8 in the presence of ethanol and diluted sulphuric acid.

Meyer and Nachod [2] obtained the salt as a green crystalline precipitate when concentrated sulphuric acid was added slowly to a uranium(IV)-solution, keeping the temperature between 0 °C and 70 °C. The crystals formed star-shaped needles and were according to Ebelmen [1] and Kohlschütter [3] insoluble in ethanol and ether and were not reactive towards the water vapor and oxygen of the air.

The crystallographic results are summarized by Groth [4] as: orthorhombic bipyramidal, $b:a:c = 0.7563:1:0.3805$ (with the orientation of the axes in agreement with the present investigation).

PREPARATION OF THE CRYSTALS

A saturated solution of uranium(IV)sulphate in 1.0 M H_2SO_4 was prepared. When 30 ml of this solution was sealed and heated in a thick-walled glass tube (Pyrex) to 90° C in an oven for about a week, good crystals for X-ray work were obtained. (The method according to Lundgren [5]). After cooling, the glass tube was opened and the crystals were filtered off, washed with water and dried in air.

The crystals were dark green and most of them formed rather thin plates about 0.05—0.2 mm in length. Some crystals of more needle-shaped form were however also obtained and sometimes the crystals had grown together into clusters of varying appearance.

Analysis. A sample was dissolved in hot nitric acid (1:1) and the *uranium* was precipitated with 8-hydroxyquinoline according to Hecht and Donau [6]. The precipitate was filtered off, washed with water, ignited and weighed as U_3O_8. The amount of *sulphate* in the filtrate was determined gravimetrically by precipitation as $BaSO_4$.

The *water* was determined by Hartwig-Bendig's [7] modification of Brush [8] and Penfield's [9] method.

The *density* of the crystals was determined from the loss of weight in benzene.

	Calculated for $U(SO_4)_2 4H_2O$	Found	
% UO_2	53.77	53.9	54.0
% SO_3	31.87	32.0	31.9
% H_2O	14.36	14.2	14.0
Density	3.60	3.6_3 *	3.59

The density is calculated for 4 formula units per cell.

UNIT CELL AND SPACE GROUP

From rotation and Weissenberg photographs (zero, first and second layer), taken with CuK-radiation, of two small crystals of different shapes, (one needle rotated around the needle axis, [001], and one plate rotated around a diagonal in the plane of the plate, [010]), it was concluded that the crystals are orthorhombic and that the dimensions of the unit cell are about 14.5_5 Å, 10.9_7 Å and 5.6_4 Å.

The reflections were recorded photographically with the multiple film technique and the relative intensities were estimated visually by comparison with an intensity scale obtained by photographing a reflection with different exposure times. The values of F^2 were then calculated by division with the expression $(1 + \cos^2 2\Theta)/\sin 2\Theta$.

More accurate values for the unit cell dimensions were calculated from a powder photograph, taken with monochromatized Cu$K\alpha$-radiation in a focussing camera of Guinier type, *cf.* Table 1.

$$a = (14.674 \pm 0.005) \text{ Å}$$
$$b = (11.093 \pm 0.005) \text{ Å}$$
$$c = (5.688 \pm 0.005) \text{ Å}$$
$$V = 925.8_9 \text{ Å}^3$$

The value (3.60) found for the density gives 4 formula units in the unit cell.

* This density determination was made with small amounts of substance and thus this value is more uncertain than the second one.

The reflections systematically absent are

$$hk0 \text{ with } h = \text{odd}$$
$$0kl \text{ with } k+l = \text{odd}$$

This is characteristic of the two space groups No. 62 *Pnma* and No. 33 $Pn2_1a$. At first only the space group of higher symmetry (*Pnma*) was considered and since it was possible to find a plausible structure assuming this space group, the low-symmetrical ($Pn2_1a$) was not taken into account.

In No. 62 *Pnma* the following point positions are possible

4(*a*): 000; $0\frac{1}{2}0$; $\frac{1}{2}0\frac{1}{2}$; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$; 4(*b*): $00\frac{1}{2}$; $0\frac{1}{2}\frac{1}{2}$; $\frac{1}{2}00$; $\frac{1}{2}\frac{1}{2}0$;

4(*c*): $\pm(x,\frac{1}{4},z)$; $\pm(\frac{1}{2}+x,\frac{1}{4},\frac{1}{2}-z)$

8(*d*): $\pm(x,y,z)$; $\pm(\frac{1}{2}+x,\frac{1}{2}-y,\frac{1}{2}-z)$; $\pm(\bar{x},\frac{1}{2}+y,\bar{z})$; $\pm(\frac{1}{2}-x,\bar{y},\frac{1}{2}+z)$.

Table 1. Powder photograph of $U(SO_4)_2 4H_2O$. CuKa-radiation. $\lambda_{CuK\alpha} = 1.5418$ Å.

The powder photograph has been measured and interpreted to $\sin^2\Theta = 0.48$.
Reflections systematically absent in space group no. 62 *Pnma* have been omitted.

POSITIONS OF THE URANIUM ATOMS

In order to find the four uranium positions, the Patterson functions $P(uvp)$ and $P(upw)$ were calculated (Figs. 1 and 2).

The four uranium atoms in the unit cell must occupy one of the fourfold positions, *i. e.* 4(*a*), 4(*b*) or 4(*c*). If they were situated in 4(*a*) or 4(*b*), $P(uvp)$ should have high peaks at $u = 0$, $v = \frac{1}{2}$, at $u = \frac{1}{2}$, $v = 0$, and at $u = \frac{1}{2}$, $v = \frac{1}{2}$, and $P(upw)$ should have high maxima at $u = 0$, $w = 0$, and at $u = \frac{1}{2}$, $w = \frac{1}{2}$. $P(uvp)$ has, however, no maximum at $u = 0$, $v = \frac{1}{2}$ and $P(upw)$ has no maximum at $u = \frac{1}{2}$, $w = \frac{1}{2}$. Thus the uranium atoms are situated in 4(*c*).

In the point position 4(*c*) the U—U distances would be

$$\pm (\tfrac{1}{2},0,\tfrac{1}{2} \pm 2z)$$
$$\pm (\tfrac{1}{2} \pm 2x,\tfrac{1}{2},\tfrac{1}{2})$$
$$\pm (\pm 2x,\tfrac{1}{2},2z)$$

The Patterson projections on the *uv* and *uw* plane would thus show (besides the origin maxima) the following maxima

in the uv *plane*		*in the* uw *plane*	
I. $\pm (\frac{1}{2},0)$	weight 4	IV. $\pm (\frac{1}{2},\frac{1}{2}-2z)$	weight 2
II. $\pm (\frac{1}{2}-2x,\frac{1}{2})$	weight 2	V. $\pm (\frac{1}{2}-2x,\frac{1}{2})$	weight 2
III. $\pm (2x,\frac{1}{2})$	weight 2	VI. $\pm (\pm 2x, 2z)$	weight 1

Now there are two high peaks in $P(uvp)$ at $u = 0.15_8$, $v = \frac{1}{2}$ (A in Fig. 1) and at $u = 0.34_2$; $v = \frac{1}{2}$ (B in Fig. 1) and one peak at $u = \frac{1}{2}$, $v = 0$, whose height is about double that of the other two. (All maxima have been located by the interpolation table given by Booth [10]). These maxima certainly correspond to the U—U vectors I, II, and III and if the peak A corresponds to the vector II above (and B to III) we get $x_U = 0.17_1$. However, if the peak A corresponds to the vector III (and B to II) we get $x_U = 0.07_9$. (It is sufficient to consider the range $0 \leq x \leq \frac{1}{4}$, $0 \leq z \leq \frac{1}{4}$).

The projection $P(upw)$ must have one high peak at $w = \frac{1}{2}$ (corresponding to the vector V above) and if $x_U = 0.17_1$ this maximum should be at $u = 0.15_8$ or if $x_U = 0.07_9$ at $u = 0.34_2$. Now the projection $P(upw)$ has a pronounced peak at $u = 0.15_8$, $w = \frac{1}{2}$ (C in Fig. 2) and a considerably lower maximum at $u = 0.33_1$, $w = \frac{1}{2}$ (3 in Fig. 2). Of these two peaks, the first one (C) has the correct height in comparison with the other maxima in this projection (see below) and with the calculated weights above, and thus certainly corresponds to the vector V above. (In fact, the lower peak (3) was found to correspond to a U—S vector, see p. 605). Thus we conclude $x_U = 0.17_1$.

Moreover the projection $P(upw)$ has two more peaks, one at $u = \frac{1}{2}$, $w = 0.25_4$ (D in Fig. 2) and one at $u = 0.34_2$, $w = 0.25_4$ (E in Fig. 2). If we identify the vectors IV and V with the high maxima D and C (giving the coordinates $x_U = 0.17_1$, $z_U = 0.12_3$), the projection must have one peak at

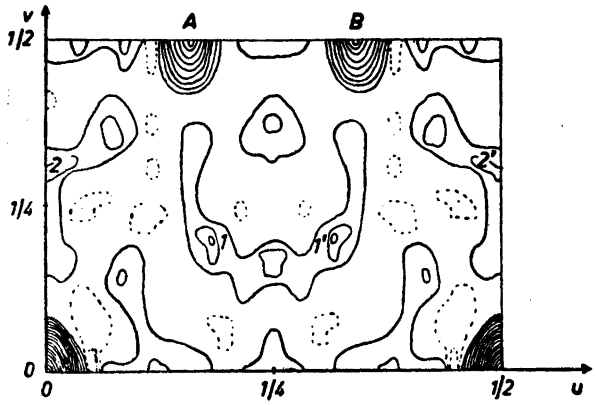

Fig. 1. The Patterson function P (uvp) *for* $U(SO_4)_2 4H_2O$. *Dotted lines indicate negative values. The figures 1,1', 2 and 2' denote peaks due to U—S vectors (see text p. 602).*

$u = 0.34_2$, $w = 0.25_4$ (corresponding to the vector VI above), whose height should be half that of the other two. Since the height and the position of E correspond to these calculated values we thus conclude:

4 U in No. 62 *Pnma* 4(*c*) with $x \approx 0.171$, $y = \frac{1}{4}$, $z \approx 0.123$.

POSITIONS OF THE SULPHUR ATOMS

Electron density projections. For a salt like $U(SO_4)_2 4H_2O$ the electron density projections could rather easily be calculated, since the signs of all the *F*-values could be determined from the contributions given by the uranium atoms, because of their dominant scattering factors. In this way, $\varrho(xyp)$ and $\varrho(xpz)$ were calculated and the results are given in Figs. 3 and 4.

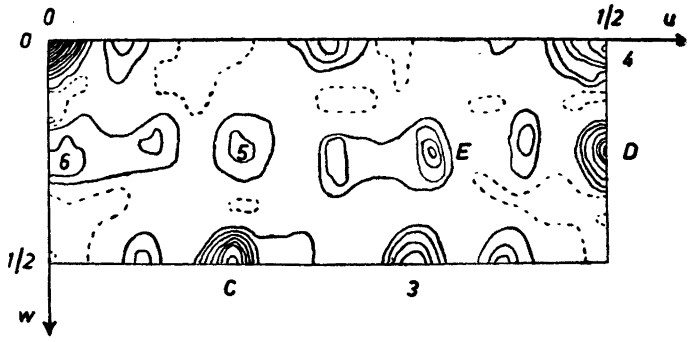

Fig. 2. The Patterson function P (upw) *for* $U(SO_4)_2 4H_2O$. *Dotted lines indicate negative values. The figures 3—6 denote peaks due to U—S vectors (see text p. 602).*

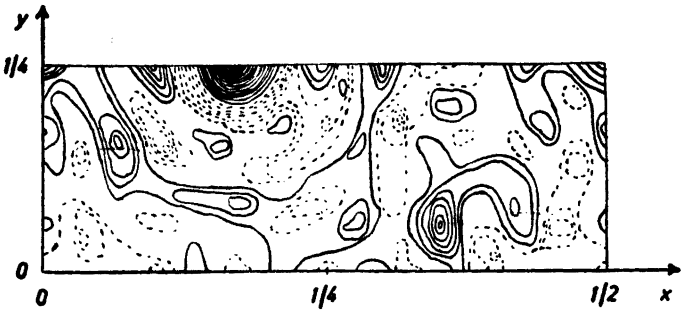

Fig. 3. Electron density of $U(SO_4)_2 4H_2O$ projected on the xy *plane. Dotted lines indicate negative values. In the uranium peak only every second contour has been marked out.*

From Fig. 3 we see, that there is, besides the very high maximum at $x = 0.171$, $y = 0.250$ giving the position of the uranium atom at this quadrant, a lower one at $x = 0.35$, $y = 0.05$. The electron density projected on the xz plane (Fig. 4) also shows, apart from the uranium maximum at $x = 0.171$, $z = 0.121$, a quite high peak at $x = 0.15$, $z = 0.37$. If the lower peaks in these projections are real maxima and not false formed by errors, diffraction effects or errors in the observed intensities due to absorption in the crystal [11], the only atoms, which could give peaks of this height, are the sulphur atoms.

In order to find out, if the lower maxima from $\varrho(xyp)$ and $\varrho(xpz)$ really correspond to sulphur positions in the unit cell, the uranium atoms were subtracted from the Fourier maps in Figs. 3 and 4 and thus two new electron density projections were calculated by the expressions

$$\varrho_s(xyp) = \sum_h \sum_k F_{\mathrm{obs}(hk0)} \cdot \cos 2\pi\,(hx + ky) - \sum_h \sum_k F_{\mathrm{U}(hk0)} \cdot \cos 2\pi\,(hx + ky)$$

$$\varrho_s(xpz) = \sum_h \sum_l F_{\mathrm{obs}(h0l)} \cdot \cos 2\pi\,(hx + lz) - \sum_h \sum_l F_{\mathrm{U}(h0l)} \cdot \cos 2\,(hx + lz)$$

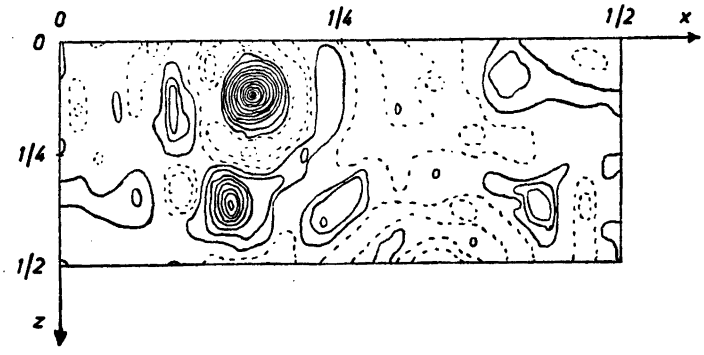

Fig. 4. Electron density of $U(SO_4)_2 4H_2O$ projected on the xz *plane. Dotted lines indicate negative values. In the uranium peak only every second contour has been marked out.*

In these new electron density projections, F_{obs} are the observed structure factors and F_U are the calculated uranium contributions to the structure factors normalized by multiplication

with the constant $\dfrac{\sum_{h,k} |F_{obs(hk0)}|}{\sum_{h,k} |F_{calc\ U(hk0)}|}$ at $\varrho_s(xyp)$ and

with the constant $\dfrac{\sum_{h,l} |F_{obs(h0l)}|}{\sum_{h,l} |F_{calc\ U(h0l)}|}$ at $\varrho_s(xpz)$.

The effect of the temperature factor, calculated by the ordinary procedure, was found to be negligible.

From Fig. 5, which shows $\varrho_s(xyp)$, we see that the uranium atoms have disappeared and that there is a rather distinct maximum at $x = 0.351$, $y = 0.054$, which should give the position of the sulphur atom. In the unit cell there are eight sulphur atoms and, with the parameters above, they must occupy the point position 8(*d*), if they belong to the space group No. 62 *Pnma* which was presumed, when $\varrho_s(xyp)$ was calculated. Since this projection really shows distinct maxima, this assumption seems to be very probable.

If the sulphur atoms are situated in 8(*d*), two sulphur maxima overlap in the *xz* projection of the electron density, and thus we get a ratio between the heights of the sulphur and the uranium peaks of about twice the ratio of the sulphur and uranium maxima obtained from the electron density projected on the *xy* plane. Fig. 6 shows $\varrho_s(xpz)$ and, as is seen, the uranium atom and most of its diffraction effects have disappeared, but there is, however, a pronounced maximum at $x = 0.149$, $z = 0.379$, which could be ascribed to sulphur atoms, and moreover this peak has the correct height corresponding to eight sulphur atoms in No. 62 *Pnma* 8(*d*).

Thus from the electron density projections the following set of parameters could be obtained

4 U in No. 62 *Pnma* 4(*c*) with $x = 0.171$, $y = \frac{1}{4}$, $z = 0.121$

8 S in No. 62 *Pnma* 8(*d*) with $x = 0.351$, $y = 0.054$, $z = 0.879$

Using these parameters, the U—S distances were calculated and the remaining maxima in the Patterson projections (Figs. 1—2) were compared with the U—S vectors. They were found to correspond to the maxima 1,1′, 2 and 2′ in *P*(*uvp*) and to 3, 4 and 5 and 6 in *P*(*upw*) and moreover the heights of the peaks also corresponded to the calculated weights. The remaining maxima in the Patterson projections may correspond to U—O vectors but, since the peaks due to some U—S and all U—O vectors are of about the same height as the false maxima [11], the remaining peaks were not considered.

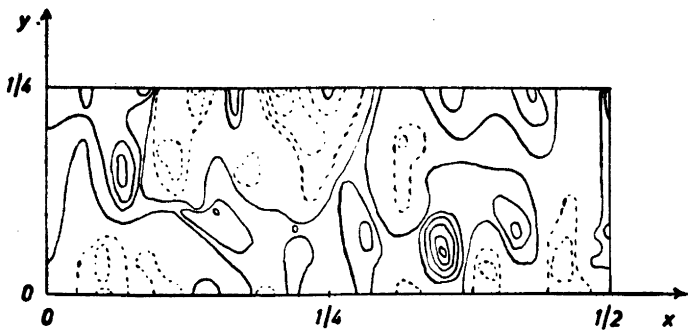

Fig. 5. Electron density of $U(SO_4)_2 4H_2O$ projected on the xy plane and with the uranium atom substracted. Dotted lines indicate negative values.

POSITIONS OF THE OXYGEN ATOMS

General remarks. The light hydrogen and oxygen atoms do not make any appreciable contribution to the intensities of the reflections and their positions had thus to be found from considerations of the interatomic distances. The following assumptions were then made

1. The U—O distance was assumed to be not less than that found[12–14] in UO_2, *i. e.* 2.3_6 Å.

2. The sulphate ion was considered to be a regular tetrahedron with the sulphur atom situated at its centre and with the bond lengths S—O = 1.4_7 Å and O—O = 2.4_0 Å. These distances are mean values of those published[15,16] for S—O and O—O in SO_4^{2-} and also in $S_2O_5^{2-}$ and $SO_3NH_2^-$.

3. The distance between two oxygen atoms, not belonging to the same sulphate group, was assumed to be not less than 2.6_0 Å.

With these assumptions the space free for oxygen atoms will be reduced as follows.

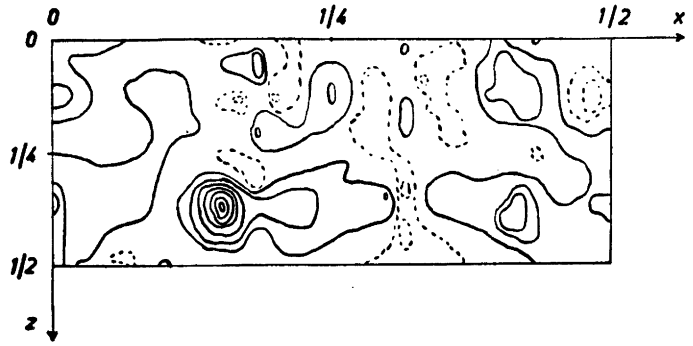

Fig. 6. Electron density of $U(SO_4)_2 4H_2O$ projected on the xz plane and with the uranium atom subtracted. Dotted lines indicate negative values.

There are two symmetry planes in the unit cell at $y = \pm \frac{1}{4}$. If an oxygen atom is not situated exactly in a symmetry plane, it must be at a distance of at least 1.3_0 Å from it. Accordingly, the y coordinates of the atoms should be either $y = \frac{1}{4}$ and $y = \frac{3}{4}$ or within the limits: $-0.13_3 \leq y \leq 0.13_3$, $0.36_7 \leq y \leq 0.63_3$. Moreover there are eight symmetry centres per unit cell (the point positions 4(*a*) and 4(*b*)). If an oxygen centre does not coincide with a symmetry centre, it must be situated outside a sphere of radius 1.3_0 Å around it. For the same reason spheres, of radii 2.6_0 Å around each oxygen atom which has been located and of radii 2.3_6 Å around each uranium atom, enclose domains forbidden for the centres of other oxygen atoms.

Positions of the sulphate oxygen atoms. For the sulphate oxygen atoms it seems probable that they are strongly attracted by the highly charged uranium ions. With the assumptions made above, the distance U—S should be $\leq 3.8_3$ Å, if a sulphate oxygen atom is in contact with a uranium atom. Now, in the structure found above, the uranium atoms are surrounded by four sulphur atoms at a distance of 3.6_9 Å, and each of the sulphur atoms has two uranium atoms at the same distance (Fig. 7). The angle, U—S—U, between the sulphur and the two neighbouring uranium atoms is 128°. Thus it is possible for at most two sulphate oxygen atoms, belonging to the same sulphate group, to be in contact with two different uranium atoms. Assuming this, which seems to be very probable, and regarding the sulphur positions as definite, we obtain an approximate position of the sulphate tetrahedron according to the following:

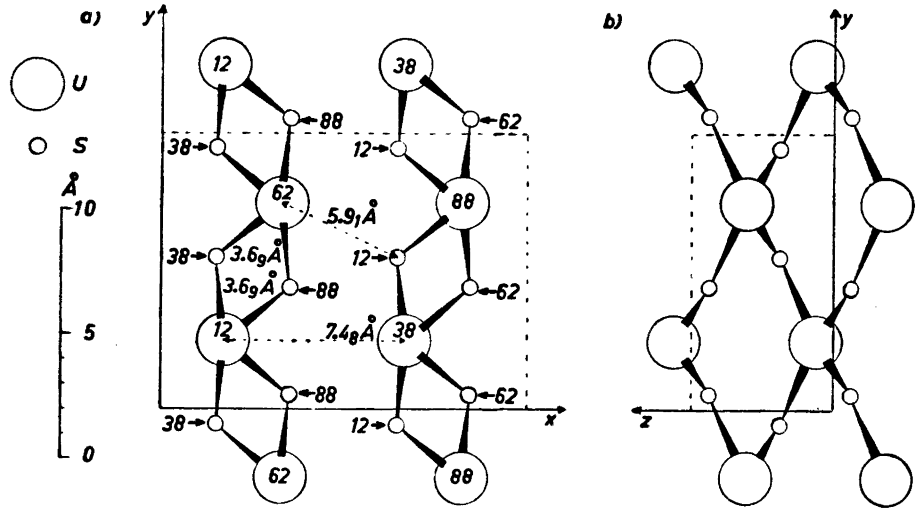

Fig. 7. Contacts (via oxygen atoms, which have not been indicated) between the uranium and the sulphate ions. a) Projection on the xy *plane. The figures denote the height of the atoms in percentages of* c. *b) Projection on the* yz *plane showing the contact in the* $U(SO_4)_2$*-layers. Only one layer has been indicated, i. e. uranium and sulphur atoms with* x *parameters between* 0 *and* $\frac{1}{2}$.

8 O_1 in 8(d) in contact with uranium; *i. e.* the oxygen centre should be situated on a circle with radius 0.5_6 Å and with the centre at $x = 0.28_4$, $y = 0.12_7$ and $z = 0.96_9$.

8 O_2 in 8 (d) in contact with uranium; *i. e.* the oxygen centre situated on a circle with radius 0.5_6 Å and with the centre at $x = 0.34_3$, $y = 0.94_1$, $z = 0.78_3$.

8 O_3 and 8 O_4 in 8(d).

However, there are 16 more oxygen atoms in the unit cell and to determine the positions of the sulphate groups more exactly, it seemed necessary at this state of the investigation to determine the positions of these non-sulphate oxygen atoms using the sulphate group position concluded above.

Positions of the non-sulphate oxygen atoms. For the non-sulphate oxygen we note, as before for the sulphate oxygen atoms, that they must be strongly attracted by the tetravalent uranium ions and consequently should be situated as close to them as possible.

Now, we have found contacts U—4O, *i. e.* four sulphate oxygen atoms in contact with each uranium, and if all of the non-sulphate oxygen atoms are in contact with uranium, we obtain the coordination U—8O. Now, in UO_2, which has CaF_2 structure [17] every uranium is surrounded by eight oxygen atoms and this is also to be expected for ions of this radius ratio [18]. It seems thus reasonable that the coordination U—8O also occurs in $U(SO_4)_2 4H_2O$ and hence we investigate the possibility that all of the non-sulphate oxygen atoms in the unit cell are in contact with uranium. This will eliminate the point positions 4(a) and 4(b) for the non-sulphate oxygen atoms and a careful survey shows that the only possibility of obtaining contact between uranium and all of the non-sulphate oxygen atoms is with

4 O_5 in 4(c)
4 O_6 in 4(c)
8 O_7 in 8(d).

Now we have to find the position of O_7. It is situated in an eightfold position and, with the assumptions made (see p. 606), reasonable interatomic distances were only obtained assuming:

8 O_7 in 8(d); $x = 0.08_3$, $y = 0.12_4$, $z = 0.87_5$.

In order to determine the x and z coordinates of O_5 and O_6 the section $y = \frac{1}{4}$ in the unit cell was drawn and domains forbidden for oxygen atoms were marked out (Fig. 8). From the figure we see that there are only two small arcs of the U—O circles, left free for the centres of O_5 and O_6. The coordinates of these oxygen atoms would then be

4 O_5 in 4(c); $x = 0.04_2$, $y = \frac{1}{4}$, $z = 0.36_8$.

4 O_6 in 4(c); $x = 0.30_0$, $y = \frac{1}{4}$, $z = 0.36_8$.

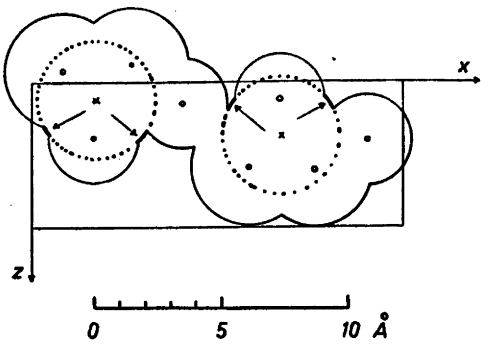

Fig. 8. Section at y = ¼ *through the unit cell showing the areas forbidden for the non-sulphate oxygen atoms* (O_5 *and* O_6) *in this plane. Thick circles indicate U—O contacts and thin circles enclose domains forbidden around the sulphate oxygen atoms and the oxygen atoms* O_7. *The arrows point out the only arcs of the U—O circles left free for the centres of* O_5 *and* O_6.
+ = *centre of uranium* ○ = *centre of oxygen*

Thus for the non-sulphate oxygen atoms we conclude

4 O_5 in No. 62 *Pnma* 4(*c*) with $x = 0.04_2$, $y = \frac{1}{4}$, $z = 0.36_8$

4 O_6 in No. 62 » 4(*c*) with $x = 0.30_0$, $y = \frac{1}{4}$, $z = 0.36_8$

8 O_7 » » 62 » 8(*d*) with $x = 0.08_3$, $y = 0.12_4$, $z = 0.87_5$.

FINAL POSITIONS OF THE LIGHT ATOMS

Now, when the positions of the atoms O_5—O_7 had been determined, the parameters of the sulphate oxygen atoms could be obtained from space considerations. It was concluded above that two of the four oxygen atoms in a sulphate group are in contact with uranium. We had also found that the centres of these two oxygen atoms (O_1 and O_2) should be situated on two circles with radii and centres given above. In fact, we can get their position still more exactly, if we notice that the distance O_1—O_2 shall be 2.4_0 Å and that the y coordinates of each of the sulphate oxygen atoms shall be within the limits $-0.13_3 \leq y \leq 0.13_3$ or $0.36_7 \leq y \leq 0.63_3$. Since the parameters of the non-sulphate oxygen atoms (O_5, O_6 and O_7) are known, it is easy to determine the orientations of the regular sulphate tetrahedra so that all O—O distances (oxygen atoms not belonging to the same sulphate group) are $\geq 2.6_0$ Å and so that U—O_1 = U—O_2 = 2.3_6 Å. In this way the coordinates of the oxygen atoms O_1 and O_2 were obtained. Finally the positions of the remaining sulphate oxygen atoms in SO_4 tetrahedra follow immediately from the parameters for S, O_1 and O_2. Thus we obtain

8 O_1 in No. 62 *Pnma* 8(*d*) with: $x = 0.26_5$ $y = 0.12_4$ $z = 0.89$
8 O_2 » » 62 » 8(*d*) with: $x = 0.33_0$ $y = 0.92_1$ $z = 0.88$
8 O_3 » » 62 » 8(*d*) with: $x = 0.40_4$ $y = 0.08_1$ $z = 0.09$
8 O_4 » » 62 » 8(*d*) with: $x = 0.40_2$ $y = 0.08_4$ $z = 0.66$

The oxygen positions are not free from assumptions. Thus we have assumed that the oxygen atoms belong to the space group No. 62 *Pnma*, but since the uranium and sulphur atoms really belong to this group, it seems plausible to assume the same for the oxygen atoms. Moreover, the positions of the uranium and sulphur atoms cannot be far from the truth and this will make the determination of the positions of the sulphate groups rather probable. The remaining non-sulphate oxygen atoms were concluded to be in contact with uranium and the positions were obtained from space considerations. This will give a coordination figure, the square Archimedean antiprism, which is found in previously determined crystal structures of uranium salts [19-23] (see below, p. 611).

Now, there are in the unit cell four uranium atoms, eight sulphur atoms and forty-eight oxygen atoms. The signs of the structure factors were determined from the uranium contributions, but of course, the magnitudes will be influenced by the sulphur and oxygen contributions. Table 2 shows some reflections, where this influence is more pronounced and it will appear that the sulphur and the oxygen contributions lead to better agreement between observed and calculated structure factors and this is noticeable with most of the reflections, when the scattering power of these atoms was taken into account.

Table 2. Comparison between calculated and observed structure factors of some reflections from Weissenberg photographs of $U(SO_4)_2 4H_2O$ CuK-radiation.

Thus it seems probable that the sulphur and oxygen coordinates concluded above are correct.

In the unit cell there are also thirty-two hydrogen atoms, which must be situated at the oxygen atoms O_5, O_6 and O_7, *i. e.* H_2O molecules. The structure would otherwise be built up of UO_2 or $U(OH)_4$ groups and neutral H_2SO_4 molecules (or HSO_4^--ions), which does not seem very probable. The hydrogen atoms may then form hydrogen bonds with the neighbouring sulphate oxygen atoms. However, it is not possible to determine the parameters of the hydrogen atoms.

FINAL STRUCTURE PROPOSITION

The following structure is thus proposed for $U(SO_4)_2 4H_2O$. Space group: No. 62 *Pnma*. 4 formula units per unit cell.

		x	y	z
4 U	in 4(*c*)	0.171 ± 0.003	¼	0.121 ± 0.003
8 S	in 8(*d*)	0.351 ± 0.005	0.054 ± 0.005	0.879 ± 0.005
8 O_1	in 8(*d*)	0.27	0.12	0.89
8 O_2	in 8(*d*)	0.33	0.92	0.88
8 O_3	in 8(*d*)	0.40	0.08	0.09
8 O_4	in 8(*d*)	0.40	0.08	0.66
4 O_5 (H_2O)	in 4(*c*)	0.04	¼	0.37
4 O_6 (H_2O)	in 4(*c*)	0.30	¼	0.37
8 O_7 (H_2O)	in 8(*d*)	0.08	0.12	0.88

4(*c*): $\pm(x, \frac{1}{4}, z)$; $\pm(\frac{1}{2}+x, \frac{1}{4}, \frac{1}{2}-z)$

8(*d*): $\pm(x,y,z)$; $\pm(\frac{1}{2}+x, \frac{1}{2}-y, \frac{1}{2}-z)$; $\pm(\bar{x}, \frac{1}{2}+y, \bar{z})$; $\pm(\frac{1}{2}-x, \bar{y}, \frac{1}{2}-z)$

The accuracy of the oxygen parameters is estimated to be about ±0.01, the *z* parameters being perhaps a little more uncertain. Using these parameters the structure factors for *hk*0, *hk*1 and *h*0*l* were calculated and compared with the observed structure factors from the corresponding Weissenberg photographs (Table 3). Taking into account that, in spite of the choice of two crystals with different longitudinal directions, there is an absorption effect [11] in the reflections, the agreement between observed and calculated intensities is rather good.

DESCRIPTION OF THE STRUCTURE

In the structure of $U(SO_4)_2 4H_2O$ the uranium atoms are surrounded by eight oxygen atoms, a coordination, which is to be expected for ions of this radius ratio [18]. The coordination figure is a somewhat distorted square Archimedean antiprism, which according to Pauling [18] gives a more satisfactory ionic coordination than the cube. The same configuration around uranium is also found in $U(OH)_2SO_4$ [19] and $U_6O_4(OH)_4(SO_4)_6$ [20] and further around thorium in $Th(OH)_2CrO_4H_2O$ [21] and $Th(OH)_2SO_4$ [22] and around cerium in $CeOSO_4H_2O$ [23].

In the crystals of $U(SO_4)_2 4H_2O$ every uranium ion is in contact with four sulphate ions and every sulphate ions with two uranium ions, *i. e.* the crystals

Table 3. Comparison between calculated and observed structure factors from Weissenberg photographs of $U(SO_4)_2 4H_2O$. Cu-K radiation.

are built up of $U(SO_4)_2$-layers parallel with the *yz* plane (Fig. 7 b). Between these layers there is water of crystallization, so that every uranium atom is in contact with four water molecules and each of them is in contact with one uranium atom. The two sulphate oxygen atoms (O_3 and O_4), which are not bound to uranium, are in contact with the water oxygen atoms (O_5, O_6 and O_7). These O—O distances vary between 2.7 and 2.9 Å, and are similar to

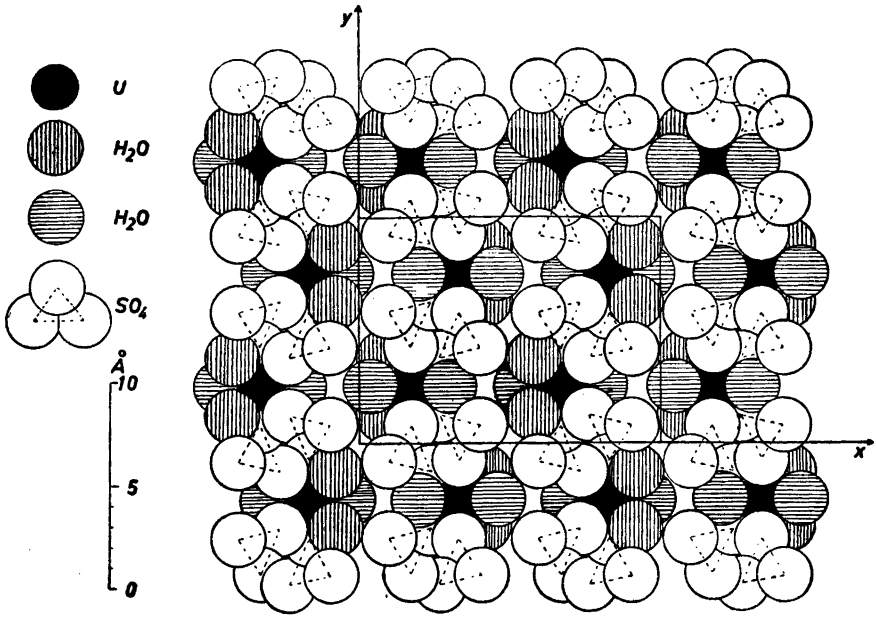

Fig. 9. Projection on the xy *plane of the structure of* $U(SO_4)_2 4H_2O$.

those found in several hydrates of oxy-salts containing O—H—O-bonds [24]. It seems therefore very probable that the layers, mentioned above, are joined by hydrogen bonds between the water oxygen atoms and the sulphate oxygen atoms O_3 and O_4.

The *xy* projection of the structure is shown in Fig. 9.

The distances U—O, S—O and O—O (within a sulphate group) were assumed to be 2.3_6 Å, 1.4_7 Å and 2.4_0 Å. The distances between the oxygen atoms, not belonging to the same sulphate group, will be (in Å)

A Protease Inhibitor in Ox Lung Tissue

TAGE ASTRUP and AGNETE STAGE

Biological Institute, Carlsberg Foundation, Copenhagen, Denmark

Procedures are described for the isolation and partial purification of a protease inhibitor from ox lung tissue. The active compound has a characteristic thermostability. It is most stable at acid reaction, and is destroyed at neutral and alkaline reaction. The inhibitor differs from heparin and shows similarity with pancreatic trypsin inhibitors.

Ox lung tissue inhibits the proteolytic effect of a number of proteases [1]. The present paper describes the isolation of a powerful protease inhibitor from ox lung tissue. The inhibitor differs from heparin and appears similar to the trypsin inhibitor present in pancreatic tissue. The active compound has been termed *pulmin* [2].

EXPERIMENTAL

1. *Estimation of inhibitory effect.* Trypsin (crystalline, Armour, containing less than 50 % $MgSO_4$) was used in estimating the inhibitory effect. The proteolytic activities of appropriate mixtures of enzyme solution (1 vol.) and inhibitor dilutions (1 vol.) were estimated by the fibrin plate method and recorded as the products in mm^2 of two diameters of the lysed zones (average of 3 determinations) [3]. In the first part of this work [4] the activity was estimated at pH 6.5 or 7.2 and at 32°. Later when the improved fibrin plate method (pH 7.8; 37°) was available [7], this was used.

Though the form of the inhibition curves does not allow a precise quantitative estimation of the inhibitory activity at low concentrations of inhibitory compounds, the fibrin plate method has important advantages in preparative work. The presence of salts at different concentrations, of dissolving or precipitating agents, of small amounts of alcohol, or even of solid matter in suspension, does not significantly interfere with the estimations. This makes the estimation of the inhibitory effects of the preparations obtained very simple. Thiocyanate (1 M) had no influence on the trypsin activity or on the inhibitory effect, and was therefore preferred as dissolving medium in the estimation of the activity of the preparations. In order to increase the accuracy of the estimations during the final steps of the purification procedure, the inhibitory effect towards chymotrypsin (crystalline, Armour) was also measured, because the curves obtained here were more suitable for interpolation. The yields given below are approximate. They vary from batch to batch of crude material, and the amount of total substances in a given preparation is not always easily estimated (see later).

2. *Crude material.* The ox lung tissue was freed from water-soluble proteins by repeated treatment of the ground tissue with 0.9 % NaCl and water, followed by dehydration with acetone [1]. The aqueous phase was removed through gauze instead of by centrifug-

ing, and the final treatment with ether was omitted. One kg of ground lung tissue produced about 70 g of dried tissue containing about 13.3 % N. The inhibitory effects of these preparations were compared by shaking a trypsin solution with varying amounts of the dried tissue, followed by estimation of the protease activity retained in the solution [1]. Larger amounts, prepared according to our description, were kindly placed at our disposal by the *Løvens kemiske Fabrik*, Copenhagen.

3. *Crude extract.* Extraction of the inhibitory compound was accomplished with thiocyanate, as used by Snellman, Jensen and Sylvén [14], in the isolation of heparin. Because of considerable swelling of the lung tissue an amount of 5 g dried tissue per 100 ml solution was found most convenient.

The dried tissue (100 g) was stirred for 2 hours at room temp. with 2 000 ml M potassium thiocyanate and then passed through a double layer of gauze, yielding about 1 650 ml extract. The nitrogen content was estimated to 0.2 mg/ml (Micro-Kjeldahl) after removal of thiocyanate by dialysis (discarding a small inactive sediment). This gave about 350 mg N in the extract from 100 g dried tissue.

Low yields were obtained in extraction experiments with secondary phosphate (M), NH_4OH, sodium salicylate (50 %), dextrose (50 %), thiosulphate (M) and pyridine (5 %). Urea (50 %) gave potent solutions but inconsistent results. Treatment with NaOH yielded very potent solutions, but produced also an extreme swelling of the lung tissue, resulting in poor yields. Potassium thiocyanate (M) produced potent solutions without too much swelling. Treatment for 2, 6 and 20 hours (at room temp.) gave the same potencies of the extracts, but the content of impurities increased with time. Best yields were obtained with 0.5—1.0 M potassium thiocyanate. Extraction at room temp. produced slightly higher activity than at 0°, but also a higher N content. The turbid thiocyanate extract could be clarified without loss of activity by passing through a Seitz clarification filter (asbestos filter pad). Dialysis produced a slight, inactive sediment and from the resulting solution the active compound could be precipitated with acetone or ethanol. Repeated treatment of the lung tissue with thiocyanate did not significantly increase the yield of soluble inhibitor, though a certain amount of inhibitor effect still remained in the lung tissue. Extraction of the washed lung tissue before dehydration yielded inferior results because of an immense swelling of the tissue, and because of the presence of large amounts of inert material in the resulting solution. The activity and N content of the crude extract varied considerably with the sample of lung tissue used.

4. *Fractional precipitation.* Large amounts of inactive proteins could be removed by means of sulphosalicylic acid whereafter the inhibitory fraction could be precipitated by addition of tungstic acid. The procedure finally adopted was as follows:

Five ml of 0.1 M sodium sulphosalicylate was added to each 100 ml of undialyzed thiocyanate extract. The mixture was stirred mechanically, and N HCl was added until pH 2.8 was attained. An inactive precipitate (amounting to 150 mg N per 100 g dried tissue) was removed by centrifugation. 10 ml of 0.1 M sodium tungstate were added to each 100 ml of the supernatant followed by 10 ml N HCl (mechanical stirring). The pH was now about 1.3. After standing in the icebox for 2 hours for complete sedimentation, the mixture was centrifuged and the inactive supernatant discarded. The precipitate could be redissolved in about 100 ml H_2O per 100 g tissue by addition of solid sodium bicarbonate to neutral reaction. The solution had about 200 mg N per 100 g of tissue, and contained most of the activity of the crude extract. The methods used in this fractional precipitation were derived from previous studies on the precipitation of proteins with anions [5,6]. If the precipitation was carried out on a dialyzed extract the precipitate with sulphosalicylic acid contained the active material.

5. *Acetone precipitation.* When the solution containing the dissolved tungstic acid precipitate was dialyzed against tap water (24 hours), a precipitate containing part of the inhibitory activity was formed. In order to retain this substance in solution it was found necessary to add an equal volume of 1 M potassium thiocyanate to the dialyzed mixture. Some insoluble matter (amounting to 50 mg N per 100 g tissue) was removed by centrifugation and discarded. The supernatant was still turbid and had to be clarified by passing through a thin layer of diatomaceous earth (Kieselguhr) in a Büchner funnel. After this treatment the solution contained about 125 mg N per 100 g tissue. After dialysis against tap water (24 hours) and addition of a few drops of saturated NaCl solution an active precipitate was obtained in the cold with 3 volumes of acetone. After treatment with acetone and ether it amounted to about 1 g (~ 120 mg N) per 100 g tis-

sue. This preparation was soluble in water after addition of alkali and contained almost the total activity of the crude extract.

Further purification was attempted by fractionation with ethanol. The thiocyanate solution of the tungstic acid precipitate was clarified and dialyzed as described. Then 0.6 vol. of 96 % ethanol and a few drops of saturated NaCl solution were added. An active precipitate was isolated by centrifugation, and dried with ethanol and ether (*pulmin I*). It amounted to about 0.9 g per 100 g tissue. A re-precipitation was performed by dissolving pulmin I in 0.9 % NaCl (16 mg per ml) and adding 0.5 vol. of 96 % ethanol. The centrifugate was again inactive, and the active precipitate was dried with abs. ethanol and ether *(pulmin II)*. It amounted to about 250 mg per 100 g tissue.

6. *Purification of the thiocyanate solution.* The good solubility of the precipitates in M thiocyanate suggested a fractional precipitation of such solutions.

100 mg of an ethanol precipitated product (pulmin II) was dissolved in 20 ml M potassium thiocyanate and precipitated with 50 ml of 96 % ethanol. The precipitate was inactive and was discarded. The centrifugate was freed from ethanol by evaporation *in vacuo*, diluted to the original volume with water, and 6 g solid ammonium sulphate per 10 ml solution was added. The active precipitate obtained was extracted twice by stirring for half an hour with a mixture of 12.5 ml ethanol and 5 ml H_2O per 10 ml original volume. The united extracts were freed from ethanol *in vacuo* and the resulting solution dialyzed for a short time against 0.9 % NaCl in a rapid dialyser. The solution was precipitated slowly by addition to 10 volumes of abs. ethanol, and the precipitate was washed and dried with ethanol and ether *(pulmin III)*.

This procedure was based on preliminary experiments about which the following could be stated: The solubility of the ethanol precipitated product (pulmin II) in thiocyanate solutions is of great advantage, because the presence of thiocyanate completely changes the order of precipitation. Without thiocyanate active components precipitate at low ethanol concentrations (see Section 5). In the presence of thiocyanate considerable amounts of inert matter (80 % of the material) could be precipitated at low ethanol concentration. However, the subsequent separation of the active components was not possible even with excess of ethanol. The removal of thiocyanate was difficult. Dialysis of the solutions produced a considerable loss of activity. Slight losses had also been observed in the preparation of the previous products, but had been thought to be caused by losses during the procedures. With the more pure preparations the losses were so large that they could not be accounted for in this way. Dialysis against a number of different solutions was tried. Apparently the loss only depended upon time, and some activity could be recovered from the outer fluid. Best results were obtained by rapid dialysis in a dipping dialyser. These results suggest that the inhibitor has a fairly low molecular weight, and this possibility has to be taken into consideration when preparing larger quantities. Losses were not encountered during storage of the solutions.

Because of the difficulties involved in removing thiocyanate by dialysis without losing inhibitor activity, other ways were sought for the isolation of active compounds. It was found that the solution could be evaporated to dryness *in vacuo* (bath temp. $<50°$) without losing activity. Complete removal of thiocyanate by extraction of the residue with ethanol could not be accomplished without loss of activity. Removal of free thiocyanic acid was attempted by addition of glacial acetic acid and water during the evaporation. No loss in activity was encountered, but difficulties arose in the subsequent removal of potassium acetate. After evaporation of ethanol *in vacuo* the active components in the thiocyanate solution could be precipitated by addition of ammonium sulphate. Addition of 6 g solid ammonium sulphate per 10 ml solution produced a precipitate containing all activity in addition to inorganic components. Most of the activity could be extracted with a mixture of ethanol and water in the proportion 25:10. After removal of ethanol *in vacuo* and concentration to a smaller volume, a short dialysis could be performed and an active precipitate obtained by dropwise addition to 10 vol. abs. ethanol.

The yields during these last steps were not high. Losses were encountered during dialysis as already mentioned, and the extraction of the ammonium sulphate precipitate was far from quantitative. However, the precipitates as finally obtained (pulmin III) were extremely potent powders.

7. *Properties.* The experiments described above have revealed some interesting properties of the active component. It is extremely stable at acid reaction, tolerating treatment for several days at a pH between 1 and 2. The active substance appears to have

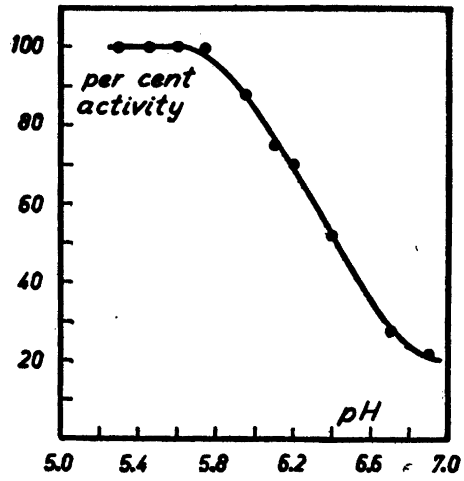

Fig. 1. Thermostability of ox lung inhibitor. (Acetone precipitated preparation). Appropriate solutions were made in a dilute maleic acid buffer. After heating in a boiling water bath for 1 hour the activity against trypsin was estimated on fibrin plates, and read on a dilution curve of the inhibitor. A b s c i s s a: pH during heating. O r d i n a t e: Remaining activity in per cent of untreated solution.

a fairly low molecular weight, disappearing slowly by diffusion during dialysis. This ability to diffuse appears to be especially pronounced in more pure preparations. Less pure preparations do not dialyze. In these solutions proteins probably combine with the active substance, preventing diffusion. When a dialysis is incorporated into the procedure, a certain loss is therefore encountered in all excepting the first few steps. The necessity of using thiocyanate solutions makes it impossible to follow the purification steps accurately by nitrogen estimations and the amount of dry matter isolated at different steps has to be used as an approximate measure of the total amount of substance present. In the first steps the amounts of nitrogen have been estimated after dialysis; the figures recorded represent a good estimate of the compounds present, because the active, dialysable component in these steps is only a small fraction of the total amount of solid matter. Because of the high solubility of the active components in alcohol-water mixtures, it was impossible in all intermediate steps to isolate the products quantitatively as a dry powder.

The preparation isolated as pulmin I contained about 11 % N and 6 % P. Pulmin II contained about 10 % N and 5 % P. The preparation isolated as pulmin III contained a large amount of inorganic salts so that the nitrogen content was reduced. It contained also thiocyanate if the dialysis had not been sufficient. The inactive product removed during the step leading to pulmin III (fractional precipitation of the thiocyanate solution with ethanol) contained about 12 % N and 7 % P, which by re-precipitation could be increased to about 8.9 % P. Measurements of ultraviolet absorption of solutions of this compound indicated that it consisted mainly of nucleic acids. Because of the high salt content in pulmin III, the solutions were analysed for N and P and the proportion P/N compared with that obtained from other products. For pulmin I and pulmin II P/N (mg/mg) was between 0.4 and 0.5. For pulmin III it was below 0.01 because of removal of most of the phosphorus. A rough idea of the degree of purification could be obtained from the amounts of nitrogen in the different preparations which produced complete inhibition of a chymotrypsin solution. One mg of chymotrypsin was inhibited by the following amounts: pulmin I, 0.9 mg N; pulmin II, 0.3 mg N; pulmin III, <0.1 mg N.

The lung inhibitor is a rather stable compound. Solutions of pulmin heated for 2 hours at 56° (pH between 1.6 and 9.7) did not lose activity. At acid reaction the com-

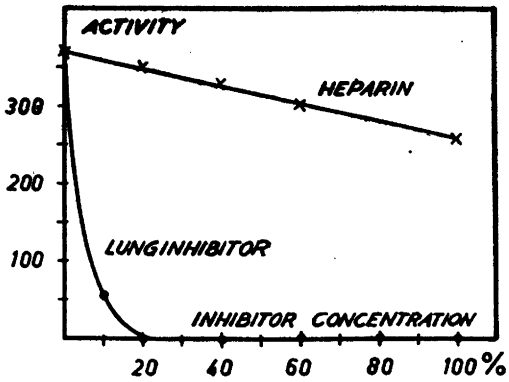

Fig. 2. Inhibitory effect of heparin and the ox lung inhibitor on streptokinase activated human globulin. In each case 20 mg substance were dissolved in 10 ml physiol. NaCl. Dilutions of the inhibitors were prepared and samples added to equal volumes of the active solution. The resulting activities were estimated by means of the fibrin plate method at pH 7.2 and 32°. A b s c i s s a: Concentration of inhibitor in per cent of stock solution. O r d i n a t e: Fibrinolytic activity recorded as the product of two diameters of the lyzed zones. The lung inhibitor was an acetone precipitated preparation (Section 5).

pound tolerates heating for 1 hour at 100°, but at neutral and alkaline reactions it is destroyed (see the thermostability curve, Fig. 1).

A comparison was made between the inhibitory effects of heparin (obtained from Løvens kemiske Fabrik, Copenhagen) and the acetone precipitated lung inhibitor on a solution of human globulin activated by streptokinase. This solution contains plasmin as well as an activator of plasminogen. The results are presented in Fig. 2. It can be seen that the lung inhibitor is a much more powerful inhibitor of fibrinolysis than heparin.

DISCUSSION

The method described here for the isolation and preparation of a protease inhibitor from ox lung tissue makes it possible to obtain this antiproteolytic agent as a stable, watersoluble dry powder of high potency. The losses encountered during dialysis indicate that the inhibitor is not a protein, but that it has a rather low molecular weight, possibly less than 10 000. The heat stability curve shows a characteristic optimum at rather acid reaction and in this respect the compound resembles trypsin inhibitors isolated from pancreas and colostrum (Laskowski and Laskowski, Jr.[13]). The yield of inhibitory compounds from the pancreas is low. Green and Work [11] mention a figure of 1 mg pure inhibitor per kg of fresh pancreas, and they obtained only 10 g of a product about 50 % pure from 100 kg dried pancreas residues. The results with ox lung show that this organ is extremely rich in inhibitory substance. Apart from the pancreas it is the only organ in the animal organism, which has been found to contain large amounts of a protease inhibitor, though it may be mentioned that urine contains an inhibitor of apparently similar nature (Astrup and Sterndorff [8]). It is of interest that the inhibitor is absent from the lungs of most other mammalian species, including man. Lung tissue is usually a

potent plasminogen activator. Even calf embryo lung is a potent plasminogen activator and does not contain the inhibitor.

Ox lung serves as a source for the production of heparin (Charles and Scott [10]; Kuizenga and Spaulding [12]). Initially we thought that the substance might contain heparin bound to protein. We have tried to prepare heparin from the lung inhibitor after methods devised by Charles and Scott [9] and Wilander [15] for the extraction of heparin from tissues. Only traces were obtained. A search for sulphuric acid residues after hydrolysis with HCl revealed only insignificant amounts. The comparison in Fig. 2 of heparin with a purified lung inhibitor shows definitely that the inhibitor is different from heparin, and we have therefore suggested the term *pulmin* for the ox lung inhibitor. Larger amounts of this compound are being prepared in order to study its properties and physiological effects.

The participation of A. S. in this work was made possible by means of a fellowship from *Det teknisk-videnskabelige Forskningsraad*, Copenhagen. It was also aided by a grant from the *Josiah Macy Jr. Foundation*, New York. Mr. Chr. Pedersen, M. Sc., and Mrs. Alice Kjær, M. Sc., assisted in some of the experiments.

Studies on Vanadium Oxides

II. The Crystal Structure of Vanadium Dioxide

GEORG ANDERSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of VO_2 has been investigated by X-ray methods. It has been found to belong to the space-group $P2_1/c$. The unit cell dimensions and the parameters of the metal and oxygen atoms are given. The structure is shown to be of a deformed rutile type with the metal atoms within the strings of VO_6 octahedra occurring in doublets as in the MoO_2 structure type. The interatomic distances and angles in the VO_6 octahedra are compared with those in the TiO_6 octahedra (rutile).

In a recent report [1] on a phase analysis of the vanadium-oxygen system carried out at this Institute it was stated that the crystal structure of the dioxide is not of the simple rutile type proposed by Goldschmidt [2] but constitutes a monoclinic deformation of this structure type. The unit cell dimensions obtained from powder photographs in a Guinier focussing camera using Cr$K\alpha$ radiation and sodium chloride, added as an internal standard (a_{NaCl}= 5.640 Å), were thus found to be

$$a = 5.743 \text{ Å}, \; b = 4.517 \text{ Å}, \quad c = 5.375 \text{ Å}, \quad \beta = 122.61°$$

The observed density of 4.65 corresponds to a cell content of 4 formula units of VO_2 (calculated density 4.67).

The dimensions of the rutile type cell reported by Goldschmidt [2] were

$$a_r = 4.54 \text{ Å}, \quad c_r = 2.88 \text{ Å}$$

Evidently the following relations exist between the monoclinic cell and the rutile type subcell:

$$\underline{a} = 2c_r, \quad \underline{b} = a_r, \quad \underline{c} = a_r - c_r$$

Crystals grown by heating vanadium trioxide-vanadium pentoxide mixtures of the gross composition $VO_{2.00}$ in evacuated sealed silica tubes at 900° C for about a week were used for the single crystal X-ray investigations. The blue-black crystals showed prismatic form elongated along the *a* direction.

MoK radiation was used throughout for the single crystal photographs. Weissenberg diagrams were registered with the prism axis as rotation axis (layer lines $h = 0$—6). The intensity scales of these photographs were correlated by means of precession photographs of the layer lines $h0l$, $h1l$ and $h2l$ taken with a Buerger camera.

The intensities of the reflections were estimated using a calibration scale of reflections of known relative intensities. The structure factor values were derived using the curves of Lu [3] for the Weissenberg photographs and those of Waser [4] and of Burbank *et al.*[5,6] for the precession diagrams.

All reflections $h0l$ with l odd were found to be absent while reflections $0k0$ were only observed for k even. This is characteristic of the space-group $P2_1/c$ (No. 14), the symmetry of which thus is very likely to be that of vanadium dioxide.

The crystal structure of the isomorphous dioxides of molybdenum and wolfram are known to be of deformed rutile type [7]. Their unit cell dimensions are similar to those of vanadium dioxide and show the same relation to the basic rutile-type subcell as does the latter. This observation suggested the possibility of structural similarities between vanadium dioxide and the MoO_2-type. However, due to the lower symmetry [$P2_1$ (No. 4)] observed for the latter the structure problem for vanadium dioxide was attacked without postulating the existence of such a structural relation.

DETERMINATION OF THE STRUCTURE

The space-group $P2_1/c$ contains a general point position 4(e): x, y, z; $\bar{x}$, $\bar{y}$, $\bar{z}$; $\bar{x}$, $\frac{1}{2}+y$, $\frac{1}{2}-z$; x,$\frac{1}{2}-y$,$\frac{1}{2}+z$ and four sets of twofold point-positions corresponding to the symmetry centers of the cell. The occurrence of the glide plane and the twofold screw axis in this space-group suggested that the Harker sections $P(0v\frac{1}{2})$ and $P(u\frac{1}{2}w)$ should be investigated. The former was found to contain only one major maximum ($v=\frac{1}{2}$) which shows that all the metal atoms are situated close to the planes $y = 0$ and $y = \frac{1}{2}$. The latter section shows a heavy maximum in $u = 0$, $w=\frac{1}{2}$ and peaks of about half the height of the maximum in $u = 0.48$, $w = 0.55$ and $u = 0.52$, $w = 0.45$ and in addition a few maxima of considerably lower magnitude. This observation excludes the possibility of the vanadium atoms occupying specialized point positions. An arrangement of four vanadium atoms in 4(e) with y close to 0 (and $\frac{1}{2}$), however, requires the following maxima in the section $P(u\frac{1}{2}w)$:

(1)	$u = 2x$,	$w = 2z + \frac{1}{2}$	(weight = 1)
(2)	$u = -2x$,	$w = -(2z + \frac{1}{2})$	(weight = 1)
(3)	$u = 0$,	$w = \frac{1}{2}$	(weight = 2)

This immediately gives the approximate arrangement of the vanadium atoms

4 V in 4(e): $x \approx 0.24$, $y \approx 0$, $z \approx 0.025$.

After deriving the signs of the structure factors $F(h0l)$ from these vanadium positions the projection parallel to the b axis of the electron density function was calculated. It was found to show high peaks very close to the positions

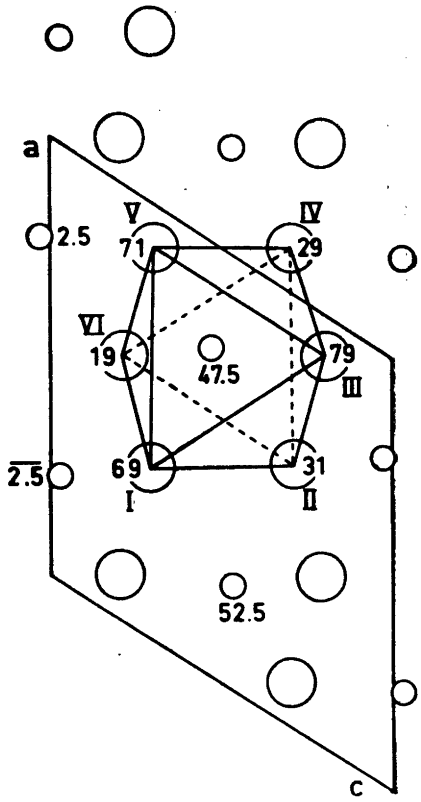

Fig. 1. VO_2. Projection of the structure on (010). The large circles denote O atoms and the small circles V atoms. The arabic numerals give the levels of the atoms in per cent of b. *One VO_6 octahedron is marked out and its O atoms are denoted with roman numerals (*cf. *Table 2).*

assumed for the vanadium atoms and minor maxima, the heights and arrangement of which suggested that they corresponded to the oxygen atoms. The oxygen atoms were found to have no influence on the signs of the structure factors $F(h0l)$.

Atoms situated in the planes $y = 0$ and $y = \frac{1}{2}$ do not contribute to the intensities of reflections $0kl$ with $k + l =$ odd. As several reflections of this type were found with too high intensities to be accounted for by mere influence of the oxygen atoms, it was concluded that the y parameter of vanadium was slightly different from zero. The signs of the structure factors $F(hkl)$ were thus calculated from a y_V value of —0.02 obtained by a rough trial and error estimation. The values of the y parameters of vanadium and oxygen were then finally obtained from the bounded projection $\varrho_{12}(y,z) = \int_{x_1}^{x_2} \varrho(x,y,z) a \, dx$ evaluated between the planes $x_1 = 0$ and $x_2 = \frac{1}{2}$.

In this way the following structure was arrived at:

Space-group: $P2_1/c$ (No. 14)

Unit cell content: 4 VO_2

4 V in 4(*e*): $x, y, z;\ \bar{x}, \bar{y}, \bar{z};\ \bar{x}, \frac{1}{2}+y, \frac{1}{2}-z;\ x, \frac{1}{2}-y, \frac{1}{2}+z$
$x = 0.242, \quad y = 0.975, \quad z = 0.025$
4 O in 4(*e*): $x = 0.10, \quad y = 0.21, \quad z = 0.20$
4 O in 4(*e*): $x = 0.39, \quad y = 0.69, \quad z = 0.29.$

The oxygen-oxygen vectors required by this atomic arrangement will give rise to maxima in the Patterson function with v not far from $\frac{1}{2}$ and u and w values close to those of the minor maxima found in the section $P(u\frac{1}{2}w)$.

The agreement between observed and calculated structure factor values is illustrated in Table 1. The reliability factor $R = \frac{\Sigma||F_{obs}| - |F_{calc}||}{\Sigma|F_{obs}|}$ for all observed reflections was found to be 0.10.

DISCUSSION OF THE STRUCTURE

The structure thus derived corresponds to reasonable interatomic distances throughout (*cf.* Table 2). The vanadium-oxygen distances of 1.76—2.05 Å are comparable with those found in, *e. g.*, paramontroseite (a metastable, naturally occurring form of VO_2) 1.88—2.13 Å [8], in V_6O_{13} 1.85—2.50 Å [9], and in V_2O_5 1.54—2.02 Å [10].

The structure of vanadium dioxide may be described as built up of distorted VO_6 octahedra joined by edges to form strings, which are mutually connected by corners to a three-dimensional network of deformed rutile type. As in the MoO_2 structure type the metal atoms within the strings are grouped pairwise to form doublets. The fundamental analogy between the structures of vanadium dioxide and molybdenum dioxide and the higher symmetry of the former suggest that the vanadium dioxide structure be considered as representing the idealized form of the "MoO_2 structure type", which also comprises the dioxides of wolfram, technetium and rhenium [11].

The metal-metal atom distances within the strings of octahedra are 2.959 Å in titanium dioxide (rutile), 2.65 and 3.12 Å in vanadium dioxide and 2.50 and 3.10 Å in molydebdenum dioxide. The sequence 2.959, 2.65 and 2.50 Å demonstrates the influence of the number of valence electrons of the metal on the formation of metal atom doublets (*cf.* Ref. [11]).

Table 2 gives a survey of the geometry of the MeO_6 octahedra of titanium dioxide (rutile) [12] and vanadium dioxide. The vanadium-oxygen distances are

Table 2. Interatomic distances (Å) and angles in MeO_6 octahedra of VO_2 and TiO_2 (rutile) [12].

Me—O	VO_2	TiO_2	O—O	VO_2	TiO_2	∧(OMeO)	VO_2	TiO_2

—O_{IV}	1.86	1.944	O_I —O_{VI}	2.73	2.780	O_I MeO_{VI}	93°	90.0°
—O_V	1.87	1.944	O_{II} —O_{III}	2.62	2.780	O_{II} MeO_{III}	80°	90.0°
—O_{VI}	1.76	1.988	O_{II} —O_{IV}	2.84	2.959	O_{II} MeO_{IV}	94°	99.2°
			O_{II} —O_{VI}	2.74	2.780	O_{II} MeO_{VI}	93°	90.0°
			O_{III}—O_{IV}	2.72	2.780	O_{III}MeO_{IV}	88°	90.0°
			O_{III}—O_V	2.71	2.780	O_{III}MeO_V	87°	90.0°
			O_{IV} —O_V	2.62	2.520	O_{IV} MeO_V	89°	80.8°
			O_{IV} —O_{VI}	2.66	2.780	O_{IV} MeO_{VI}	95°	90.0°
			O_V —O_{VI}	2.77	2.780	O_V MeO_{VI}	99°	90.0°

probably correct within ±0.05 Å while the oxygen-oxygen distances are likely to be better than ±0.08 Å. The error in the interatomic angles is estimated to a few degrees.

It is evident that the shapes of the oxygen octahedra of titanium dioxide (rutile) and vanadium dioxide differ little in spite of the distortion of the rutile type of the latter structure. Thus the oxygen atoms forming the edge common to the two VO_6 octahedra of a metal atom pair are somewhat forced apart. The corresponding distance in molybdenum dioxide is considerably longer, *viz.* 3.1 Å which is accounted for by the very close molybdenum-molybdenum contact. The conservation of the fairly regular arrangement of the oxygen atoms implies that the metal atom in vanadium dioxide is somewhat removed from the center of gravity and approaching one face of the VO_6 octahedron.

Acknowledgements. The author wishes to express his thanks to Professor G. Hägg for the facilities placed at his disposal. Thanks are also due to Dr. A. Magnéli for valuable discussions and continued interest in this investigation. A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged.

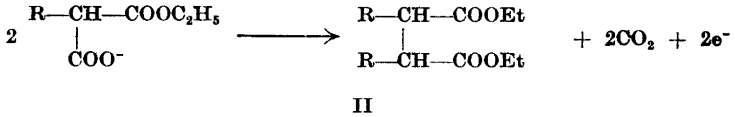
The Synthesis of Some Aliphatic Organosilicon Dicarboxylic Acids. III *

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden



The preparation of α,α′-bis-[trimethylsilylmethyl]-succinic acid by electrolysis of monoethyl trimethylsilylmethylmalonate is described. The acid is found to exist in two forms, corresponding to the *meso* and racemic forms.

During attempts to prepare α,α′-bis-[trimethylsilylmethyl]-succinic acid by the following sequence of reactions

it was found [1] that the intermediate tetraester (I) could not be hydrolyzed under conditions which did not cause cleavage of methyl groups from the silicon atoms.

Another method for the preparation of α,α′-dialkylsubstituted succinic acids is the Crum Brown-Walker modification of the Kolbe electrolytic synthesis [2], namely the electrolysis of a half ester of an alkylmalonic acid according to the formula

II

* Part II: see Ref.[1].

In this paper the application of this reaction to monoethyl trimethylsilylmethylmalonate will be described.

The half ester was readily obtained in the crude state by half saponification of the corresponding diester, but could not be purified by distillation on account of its thermal instability. When heated to a temperature above 120° it decomposed into ethyl β-trimethylsilylpropionate, similarly to other monoethyl alkylmalonates. Attempts to purify the half ester by conversion into its calcium salt and recrystallization were not successful, as there was considerable loss of material during this procedure. However, the use of the crude ester in the electrolyses gave reasonably good yields and therefore no other purification methods were tried.

The electrolysis was carried out in anhydrous methanolic solution, where the conditions for optimum yields are not so critical as in aqueous solution. In water solution the yield of diester was much smaller, and besides which large amounts of polymeric material were obtained. The latter was probably polyacrylic ester, which could be formed by β-elimination of an intermediate radical. The presence of this polymer made the separation of the reaction products very difficult. In methanolic solution the reaction proceeded smoothly and a 40 % yield of the diester (II), R = $(CH_3)_3Si—CH_2$-, was obtained. (II) was then readily hydrolyzed by boiling with ethanolic potassium hydroxide to give a mixture of the *meso* and racemic forms of α,α'-bis-[trimethylsilylmethyl]-succinic acid. The separation of the diastereoisomers was easily affected by a simple crystallization from acetone, in which the high-melting acid was rather insoluble. The acids were finally recrystallized from 70 % acetic acid, giving the pure isomers of the melting points 241—244° (decomp.) and 160—162°, respectively.

The two forms could readily be converted into their anhydrides by boiling them with acetyl chloride. The anhydride of the high-melting acid melted at 74—76°, while the other was obtained as an oil, which did not crystallize. The anhydrides were hydrolyzed by boiling aqueous sodium hydroxide to form the corresponding acids. The above-mentioned decomposition of the high-melting acid at its melting point was found to be due to an elimination of water with the formation of the anhydride of the *low*-melting acid. The low-melting acid, in turn, on heating to 80—100° above its melting point gave its own anhydride. This was in line with the behavior of other α,α'-dialkyl-substituted succinic acids, *e. g.*, α,α'-diethylsuccinic acid [3].

With the preparation of these two acids the series of α,α'-bis-[trimethylsilylmethyl]-substituted *n*-dicarboxylic acids from the succinic to the suberic acid derivative has been completed. The work on these acids is now being continued to determine which of the forms can be resolved into optically active acids.

EXPERIMENTAL

Monoethyl trimethylsilylmethylmalonate. 49.2 g (0.2 mole) of diethyl trimethylsilylmethylmalonate was added to a solution of 11.2 g (0.2 mole) of potassium hydroxide in 250 ml of absolute ethanol, and the mixture was allowed to stand at room temperature for two hours. Then 100 ml of water was added and the ethanol was distilled off on a water-bath. The aqueous solution was extracted four times with 30 ml portions of ether

to remove unreacted diester and then acidified with concentrated hydrochloric acid with cooling in an ice-bath. (The recovered diester amounted to 7.2 g, 14 %). The organic layer was taken up in ether and the ether solution was washed twice with water, the ether distilled off and 100 ml of benzene was added. By distilling the benzene the contaminating water was removed from the half ester and a dry product was obtained. During the distillation the temperature of the flask content was not allowed to exceed 100° in order to prevent decarboxylation. The yield of crude ester was 85 % (based on unrecovered material) and it could be used directly in the electrolysis experiments.

Diethyl α,α'-bis-[trimethylsilylmethyl]-succinate. 21.8 g (0.1 mole) of monoethyl trimethylsilylmethylmalonate and 2 g of potassium hydroxide were dissolved in 100 ml of dry methanol. The solution was placed in a cell consisting of a 200 ml beaker fitted with a platinum spiral anode (surface area 3.0 cm²), a platinum net cathode (total surface area *ca.* 50 cm²), and a thermometer reaching into the liquid. The cell was cooled by immersion in an ice-bath (internal temperature of cell was kept all the time about 30°) and a current of 1.5 amp. was passed until the electrolyte became approximately neutral. This required *ca.* 20 % longer time than that calculated on the basis of the current and the amount of half ester employed.

The product was isolated by dilution of the cell contents with water, distilling off the methanol on a water-bath and taking up the organic layer in ether. The extract was washed with very dilute (2 %) sodium hydroxide solution to remove small amounts of starting material, then with water and finally dried with anhydrous magnesium sulphate. After evaporation the remaining oil was distilled in *vacuo*, b.p. 136—138°/4 mm, n_D^{20} 1.4448, d_4^{20} 0.9363, yield 6.9 g (40 %). (Found: C 55.3; H 9.8; Si 16.0; r_D 0.2841. Calc. for $C_{16}H_{34}O_4Si_2$: C 55.4; H 9.9; Si 16.2; r_D 0.2843.)

α,α'-Bis-[trimethylsilylmethyl]-succinic acid. 5.1 g (0.015 mole) of the above diester was hydrolyzed by boiling with excess 10 % ethanolic potassium hydroxide for 24 hours. The solution was diluted with water and the ethanol distilled off on a water-bath. Acidification with 5 N hydrochloric acid precipitated the mixture of the diastereoisomers. The crystals were filtered, washed thoroughly with water and air-dried. They were dissolved in 100 ml of boiling acetone, filtered to remove insoluble matter and left to crystallize. A yield of 1.4 g melting at 235° (decomp.) was obtained. The filtrate was evaporated to a volume of 10 ml and then gave an additional 0.4 g with the same melting point. The two fractions were combined and recrystallized from 70 % acetic acid giving a product, m. p. 242—244° (decomp.), which was not increased by further recrystallization. Yield 1.5 g.

The mother-liquor from the second filtration was evaporated to dryness and the residue recrystallized twice from 70 % acetic acid to give 1.4 g of the low-melting acid, m. p. 160—162°. The yields of the pure isomers were 34 and 32 %, respectively. (Found for the high-melting acid: C 49.3; H 9.1; Si 19.2; equiv. wt. 145.2. Found for the low-melting acid: C 49.8; H 9.1; Si 19.3; equiv. wt. 145.0. Calc. for $C_{12}H_{26}O_4Si_2$: C 49.6; H 9.0; Si 19.3; equiv. wt. 145.3.)

Preparation and hydrolysis of the anhydrides. I. 0.5 g of the high-melting acid was boiled with 3 ml of acetyl chloride until the crystals had completely dissolved, which required about 20 hours. Evaporation of the excess acetyl chloride and the acetic acid formed gave a residue which soon solidified, m. p. 71—76°, yield 0.4 g. The crude product was recrystallized from petroleum ether, to give the m. p. 74—76°. Upon hydrolysis with hot sodium hydroxide solution the high-melting acid was quantitatively recovered.

II. After treating the low-melting acid in the same manner as above an oil was obtained which did not solidify. It was vacuum-distilled, b. p. 130—135°/12 mm. The product gave the low-melting acid on hydrolysis as before. (Found for the anhydride, m. p. 74—76°: C 52.7; H 8.8; Si 20.6. Found for the liquid anhydride: C 52.9; H 8.8; Si 20.5; Calc. for $C_{12}H_{24}O_3Si_2$: C 52.9; H 8.9; Si 20.6.)

Anhydrization of the acids by heat. 160 mg of the high-melting acid was heated in a small test-tube to 250° in an oil-bath for 15 minutes. The crystals melted and drops of water condensed in the upper end of the test-tube. The product was liquid and consisted of the anhydride of the low-melting acid, as identified by its almost quantitative conversion into the low-melting acid by hydrolysis. (150 mg, m. p. 159—162°).

The low-melting acid on the same treatment gave exclusively its own anhydride.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work.

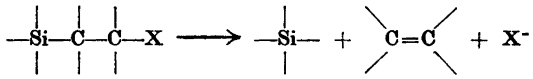
ACTA CHEMICA SCANDINAVICA 10 (1956) 633—637



On Diethyl Trimethylsilylmethylhalogenomalonates

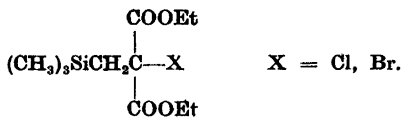
LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

The diethyl trimethylsilylmethylchloro- and bromomalonates have been prepared and the chemical properties of the bromo compound have been studied in some detail. It has been allowed to react with aqueous base, ethanolic base, diethyl sodiomalonate, and bromine, and subjected to pyrolysis. In the first three reactions it has been found that β-elimination is wholly or partially absent, whereas in the last two reactions β-elimination occurs.

Organosilicon compounds in which a halogen atom is situated on the carbon atom β to the silicon atom have received much attention [1–13]. Their most important chemical property is the so-called β-elimination which occurs more or less readily under the influence of various reagents (alcoholic bases, aqueous alkali, water, methyl magnesium bromide, bromine, silver nitrate, anhydrous aluminium chloride, and heat alone) according to the formula

A few general rules of the influence of structure upon β-elimination have been established.



1. Electronegative substituents, *e. g.*, halogen, situated on the silicon atom give an increased rate of the reaction [6].

2. The β-elimination is hindered by alkyl substituents on the β carbon atom [11,13].

3. The order of reactivity of the β halogen is I>Br>Cl [13].

4. β-Halovinylsilanes do not undergo β-elimination [9].

This communication is a report of the preparation and the investigation of some chemical properties of the chloro and bromo derivatives of diethyl trimethylsilylmethylmalonate (I).

X = Cl, Br.

I

This type of β-haloalkylsilanes is substituted by two carbethoxy groups on the β-carbon and it was of interest to investigate if the presence of these groups has any remarkable influence on the β-elimination reaction. No β-haloalkylsilane simultaneously containing functional groups other than halogen on the β-carbon atom has hitherto been investigated.

When diethyl trimethylsilylmethylmalonate was boiled with an excess of sulphuryl chloride the chloroester (I), X = Cl, was obtained in a 62 % yield. The corresponding bromoester was prepared by adding one mole of bromine dropwise with stirring to one mole of diethyl trimethylsilylmethylmalonate. The reaction was started by adding a few ml of bromine and heating the mixture to 40—50 °. When the reaction once had begun each new drop of bromine reacted almost instantaneously. The stirring had to be very efficient to avoid partially high bromine concentrations in the reaction mixture (see below).

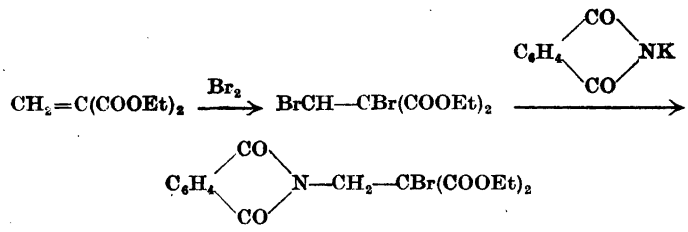
Diethyl trimethylsilylmethylbromomalonate was quite stable towards aqueous bases. Thus, it could be boiled with 10 % aqueous potassium hydroxide without being affected. However, when treated with 10 % ethanolic potassium hydroxide, in which the compound was soluble, the bromine atom was rapidly split off as bromide ion and there were formed small amounts of hexamethyldisiloxane together with an alkali-soluble silicon-containing polymer. The minute amount of hexamethyldisiloxane formed and the fact that the polymer contained silicon indicated that β-elimination was only a side-reaction under these conditions. The nature of the polymer was not further investigated.

On reaction with diethyl sodiomalonate the bromoester behaved like other alkylbromomalonic esters [14], *i. e.*, diethyl trimethylsilylmethylmalonate and tetraethyl ethylenetetracarboxylate were formed according to the formula

$$2\ (CH_3)_3Si{-}CH_2{-}\underset{\displaystyle COOEt}{\overset{\displaystyle COOEt}{\overset{|}{\underset{|}{C}}}}{-}Br\ +\ 2\ NaCH(COOEt)_2 \longrightarrow$$

$$2\ (CH_3)_3Si{-}CH_2{-}CH(COOEt)_2\ +\ (EtOOC)_2C{=}C(COOEt)_2\ +\ 2\ NaBr$$

No traces of products which could have resulted from a β-elimination could be detected. The relative stability of (I) against β-elimination in the above reaction might be ascribed to the tendency of dissociating into a positive bromine ion and a negative diethyl trimethylsilylmethylmalonate ion [15].



$$(CH_3)_3Si{-}CH{-}CBr(COOEt)_2 \longrightarrow (CH_3)_3Si{-}CH{-}C^{-}(COOEt)_2\ +\ Br^{+}$$

This ion is stable under the conditions employed.

Decomposition of I by heat occurred at 190—200° with the formation of trimethylbromosilane and diethyl methylenemalonate.

$$(CH_3)_3Si{-}CH_2{-}CBr(COOEt)_2 \xrightarrow{Heat} (CH_3)_3SiBr\ +\ CH_2{=}C(COOEt)_2$$

The diethyl methylenemalonate was identified by addition of bromine and reaction of the resulting dibromoester with potassium phthalimide [16].

The product did not depress the melting point of an authentic sample.

Diethyl trimethylsilylmethylbromomalonate reacted with bromine with the formation of trimethylbromosilane and diethyl bromomethylbromomalonate according to

$$(CH_3)_3Si—CH_2—CBr(COOEt)_2 + Br_2 \longrightarrow (CH_3)_2SiBr + BrCH_2—CBr(COOEt)_2$$

The last-mentioned compound was identified as before.

Preliminary experiments in order to brominate the free trimethylsilylmethylmalonic acid were not successful, as the bromination product was very unstable and decomposed rapidly on standing. Likewise the bromination of β-trimethylsilylpropionic acid gave decomposition products, among which trimethylbromosilane could be identified. The residue was probably a complex mixture of polybrominated propionic acids.

EXPERIMENTAL

Chlorination of diethyl trimethylsilylmethylmalonate. In a 100 ml flask equipped with a reflux condenser and a dropping funnel there was placed 24.6 g (0.1 mole) of diethyl trimethylsilylmethylmalonate. A few ml of freshly distilled sulphuryl chloride were added and the solution was heated to 60°. When the reaction had started as indicated by the evolution of hydrogen chloride the rest of the sulphuryl chloride (total amount 13.5 g) was added during a period of 30 minutes. The reaction was completed by heating at 70—80° for two hours. Then excess sulphuryl chloride and dissolved gases were evaporated under reduced pressure at room temperature and at last the residue was fractionated *in vacuo*. From this was obtained 17.3 g (0.062 mole) of diethyl trimethylsilylmethylchloromalonate, b. p. 131—133°/11 mm, n_D^{20} 1.4463, d_4^{20} 1.0553. (Found: C 47.1; H 7.6; Cl 12.4; Si 10.0; r_D 0.2528. Calc. for $C_{11}H_{21}O_4ClSi$: C 47.1; H 7.5; Cl 12.6; Si 10.0; r_D 0.2516.)

Bromination of diethyl trimethylsilylmethylmalonate. In a 250 ml flask equipped with an efficient stirrer, a reflux condenser, and a dropping funnel 98.4 g (0.4 mole) of diethyl trimethylsilylmethylmalonate was heated with a few ml of bromine to *ca.* 40°. The reaction soon began and the bromine colour disappeared. Bromine (a total of 64 g = 0.4 mole) was then added so slowly that the solution never assumed more than a faint brown colour. The stirring was rapid to avoid partially too high bromine concentrations. The hydrogen bromide evolved was absorbed in alkali. After the gas evolution had ended the reaction mixture was washed twice with water, once with saturated sodium carbonate solution, and with water again. After drying with anhydrous calcium chloride the product was fractionated under reduced pressure. From this was obtained 99.0 g (0.304 mole) of diethyl trimethylsilylmethylbromomalonate, b. p. 118—120°/4 mm, n_D^{20} 1.4597, d_4^{20} 1.2033, a yield of 76 %. (Found: C 40.4; H 6.5; Br 24.6; Si 8.5; r_D 0.2275. Calc. for $C_{11}H_{21}O_4BrSi$: C 40.6; H 6.5; Br 24.6; Si 8.6; r_D 0.2261.)

Reactions of diethyl trimethylsilylmethylbromomalonate. A. With aqueous base. 3.25 g of the bromo compound (0.01 mole) was boiled for 30 minutes with 20 ml of 10 % aqueous

potassium hydroxide. Only traces of bromide ion could be detected in the aqueous layer after cooling and extraction with ether. The ether solution was dried with anhydrous calcium chloride and gave upon distillation nearly all the starting material in recovery.

B. With ethanolic base. To a solution of 6.7 g (0.12 mole) of potassium hydroxide in 3 ml of water and 10 ml of ethanol was added 6.5 g (0.02 mole) of diethyl trimethylsilylmethylbromomalonate. The mixture was gradually heated and suddenly a violent reaction occurred. The flask was cooled in ice water, when necessary. At last the solution was heated under reflux for three hours, after which time it was acidified with hydrochloric acid and 50 ml of water was added. The organic layer was taken up in ether and the ether solution washed thoroughly with water to remove ethanol. After drying with anhydrous sodium sulphate fractionation gave 0.2 g of hexamethyldisiloxane, b. p. 99°, n_D^{20} 1.3774, a 12 % yield. None of the other lowboiling products contained silicon. The residue (3.3 g) was a very viscous, alkali-soluble polymer, which on titration with standard alkali solution showed an equivalent of 172. The silicon content was 10.5 %, corresponding to 62 % of the silicon present in the starting material.

C. With diethyl sodiomalonate. In a 25 ml three-necked flask equipped with a stirrer, a reflux condenser, and a dropping funnel 0.46 g (0.02 mole) of sodium was dissolved in 10 ml of absolute ethanol, followed by 3.2 g (0.02 mole) of diethyl malonate. 6.50 g (0.02 mole) of the bromoester was added cautiously. This was followed by refluxing for one hour, after which time the mixture was slightly acidified with glacial acetic acid and the ethanol distilled off. The residue was poured into 20 ml of water and worked up as usual. From this was obtained 3.0 g of diethyl trimethylsilylmethylmalonate (0.012 mole) and 1.8 g of tetraethyl ethylenetetracarboxylate (0.0057 mole), m. p. after recrystallization from ligroin 52—53°, mixed m. p. with an authentic specimen 52—53° [17].

The diethyl trimethylsilylmethylmalonate was identified by conversion into its diamide according to the method of Russell [18]. The authentic compound which was prepared from diethyl trimethylsilylmethylmalonate prepared otherwise melted at 161—162°. It contained one mole of water of crystallization which was removed by heating the compound before being analyzed in air at 110° for 20 hours. (Found C 45.5; H 8.7; Si 14.9; Calc. for $C_7H_{16}O_2N_2Si$: C 45.6; H 8.7; Si 14.9.)

D. Decomposition by heat. In a 25 ml flask equipped with a short column and a thermometer reaching into the flask there was placed 8.1 g (0.025 mole) of diethyl trimethylsilylmethylbromomalonate. The flask was slowly heated. When the temperature of the liquid reached 190° the compound began to decompose and a liquid distilled over, b. p. 75—77°. It was redistilled and was found to be trimethylbromosilane, b. p. 78—80°, 3.0 g, a yield of 79 %. (Found: Br 52.0. Calc. for C_3H_9BrSi: Br 52.2.)

The residue in the reaction flask was a dark oil with the characteristic odour of diethyl methylenemalonate, which was distilled at atmospheric pressure, b. p. 195—198°, 3.0 g, a yield of 70 %. For identification it was dissolved in 10 ml of carbon tetrachloride, 2.8 g of bromine was slowly added, the solvent was evaporated, and at last 3.2 g of potassium phthalimide was added. This mixture was heated at 150° for two hours, and then cooled. The solid mass was washed with water and finally recrystallized twice from ethanol, giving beautiful crystals, m. p. 135.5—136.5° undepressed on admixing with an authentic sample [16].

Reaction with bromine. To 8.1 g (0.025 mole) of diethyl trimethylsilylmethylbromomalonate 4.0 g (0.025 mole) of dry bromine was slowly dropped. The mixture warmed and soon began to reflux. After standing for an hour the trimethylbromosilane formed was distilled over, b. p. 76—78°, 3.1 g, a yield of 81 %. It was redistilled over a small amount of red phosphorus in order to remove traces of bromine. (Found: Br 52.1. Calc. for C_3H_9BrSi: 52.2.)

The residue was distilled under reduced pressure. From this was obtained 6.7 g of diethyl bromomethylbromomalonate, b. p. 125—126/5 mm, n_D^{20} 1.4838, d_4^{20} 1.6268, a yield of 80 %. It was identified as in the foregoing experiment.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work.

The Identification of Organic Compounds

I. The Preparation of *p*-Bromophenacyl Esters of Carboxylic Acids

JØRGEN BERGER

Department of Organic Chemistry, Royal Danish School of Pharmacy, Copenhagen, Denmark

The melting points of twenty *p*-bromophenacyl esters are given. The melting points taken from the literature of the *p*-bromophenacyl esters of formic acid (92° C, 99—100 °C, 134.5° C, 135.2° C and 140° C), oxalic acid (242° C) and fumaric acid (197° C) are discussed and revised by the author to 101° C, 244—245° C and 256—257° C, respectively. Further, the melting point of the oxalate and the fumarate determined on Koflers Heizbank are found to 256° C and 266° C, respectively. An improved method for the preparation of the *p*-bromophenacyl formate and the *p*-bromophenacyl oxalate is given.

It is known to be convenient to identify carboxylic acids as their esters of *p*-halogenophenacyl alcohol and in this paper and in a subsequent paper some new esters will be reported. Judefind and Reid [1] have prepared the *p*-bromophenacyl esters of many acids but they found that some acids did not give derivatives, such as oxalic acid and formic acid. However, Moses and Reid [2] later prepared the *p*-bromophenacyl formate with m. p. 135.2° C. Hurd and Christ [3] reported the m. p. as 140° C, which was confirmed by Summerbell and Bauer [4].

In 1950 Kubota and Matsuura [5] pointed out that the compound widely used as a derivative for the identification of formic acid was the *p*-bromophenacyl alcohol and not the ester, and in addition they found that the *p*-iodophenacyl and the *p*-chlorophenacyl formate reported by Moses and Reid [2] were also the corresponding alcohols. They reported the m. p. of the *p*-bromophenacyl formate as 99—100° C, but they recommended the use of another derivative for the identification of formic acid.

Similary Grove and Suter [6] in 1950 found the m. p. to be 99° C for the formate, but they could only obtain the pure derivative after chromatography of a benzene solution on activated alumina. In 1952 Neish and Lemieux [7] stated that the *p*-bromophenacyl formate had a m. p. of 92° C. The ester was

prepared by refluxing equivalent amounts of the reactants in ethanol for 30 minutes giving a yield of 80 %. By refluxing longer the ester was hydrolysed and the derivative was the alcohol with m. p. varying from 137° C to 142° C depending on the rate of heating.

In order to explain some of these discrepancies we have prepared the *p*-halogenophenacyl formates and the m. p. were 87° C, 101° C and 124° C for the *p*-chloro-, *p*-bromo- and *p*-iodophenacyl ester, respectively; these values are in accordance with those given by Kubota and Matsuura [5]. The special procedure used is described in the experimental part; the *p*-bromo phenacyl formate is recommended as an excellent derivative of formic acid.

We found that the derivative, prepared according to the method of Neish and Lemieux [7] had a m. p. of 92° C, but this was increased to 101° C by repeated recrystallisation from ethanol. The derivative is extremely difficult to purify because of the presence of *p*-bromophenacyl alcohol and unconverted *p*-bromophenacyl bromide.

In 1951 Erickson, Dechary and Kesling [8] described a new method for the preparation of the *p*-bromophenacyl esters; the acid being converted by *p*-bromo-*α*-diazoacetophenone in dioxan solution. Apparently this procedure also gives the *p*-bromophenacyl alcohol, as they reported the m. p. of the formic ester as 134.5° C.

Hydrolysis of the p-*bromophenacyl esters.* Neish and Lemieux [7] state that the hydrolysis of the formic ester appears to be catalysed by salts of carboxylic acids and that in general it is to be recommended for the preparation of *p*-substituted phenacyl esters that equivalent amounts of reactants should be used and that the reaction time should be kept to a minimum. Procedures in many textbooks for the preparation of the derivatives, prescribe the use of about equal amounts (weight/weight) of the acid and the *p*-bromophenacyl bromide and consequently there will usually be an excess of the salt and this might cause hydrolysis of the ester formed.

However, we have found that by using an excess of the salt — two or three times the equivalent amount — a pure derivative was always obtained after recrystallisation. Furthermore, the refluxing period has been varied and again a pure derivative was isolated after recrystallisation even if the reaction mixture was refluxed for four hours. Certainly a hydrolysis occurs but the crude product can be purified. This hydrolysis can be observed for those derivatives which melt below the melting point of the *p*-bromophenacyl alcohol (143° C) as a derivative contaminated with the *p*-bromophenacyl alcohol only melts partially near the expected m. p. and on further heating it melts completely in the proximity of 143° C. The conclusion must be that in general it is advisable to keep the refluxing period below four hours.

An extensive hydrolysis of a derivative only occurs in carboxylic acids of which the esters are known to be highly sensitive to hydrolytic conditions; for example formic acid. Also in the preparation of the *p*-bromophenacyl oxalate some alcohol appears and has been isolated (see later).

It was also observed that in order to obtain a pure derivative it is essential that the reaction mixture should be adjusted to a pH of approximately 5 or below. At higher pH values the reaction mixture acquires a more intense yellow to red colour. The further addition of 10—15 drops of 0.5 N hydro-

chloric acid after the red colour of the indicator has disappeared is therefore suggested in the general procedure given in the experimental part.

The p-*bromophenacyl oxalate.* Mowry and Brode [9] have prepared the oxalate, the m. p. of which was 242° C (decomp.); this was determined by using a thermometer of the Anschütz type. However, it is very difficult to prepare this derivative according to Mowry and Brode and we have worked out a special procedure. Due to a decomposition the m. p. was found to be highly dependent on the time in which the substance is in the silicone bath before melting. By introducing the capillary tube into the bath at *ca.* 235° C, the m. p. is found to be 244—245° C (rate of heating: 1—2° C per minute). Determined on Kofler Heizbank the m. p. was 256° C ± 2° and no decomposition was observed when it melted; destruction occurred after some seconds.

The p-*bromophenacyl fumarate.* The melting point of this derivative is given in the textbook by Shriner and Fuson [10,p.225] as 197° C but is has not been possible to find it in the original literature or in other textbooks on organic analysis; only the phenacyl fumarate is found (m. p. 197° C) [11,p.80]. We have now prepared the fumarate by the general method, given later in the text, and the m. p. was found to be 256—257° C (decomp.). On Kofler Heizbank no decomposition of the melt was observed, and the m. p. was 266° C ± 2°.

Melting points and microanalysis of twenty *p*-bromophenacyl esters are given in Table 1.

Table 1. Corrected capillary melting points of p-*bromophenacyl esters.*

Acid	Melting point, °C	Formula	% C		% H	
			calc.	found	calc.	found
Formic	101	$C_9H_7BrO_3$	44.47	44.40	2.90	2.96
Vinylacetic	60.5	$C_{13}H_{11}BrO_3$	50.90	50.87	3.92	3.79

3-Nitrophthalic	166	$C_{24}H_{15}Br_2NO_8$	47.63	47.50	2.50	2.67
3,4,5-Trimethoxybenzoic	129	$C_{18}H_{17}BrO_6$	52.83	52.84	4.19	4.23
1-Naphthylacetic	112.5	$C_{20}H_{15}BrO_3$	62.68	62.72	3.95	3.99

EXPERIMENTAL PART *

The capillary melting points are determined in an electrically heated silicone bath with mechanical stirrer. The temperature at which the compound melts completely are registered. The thermometers used were of the Anschütz type calibrated in 0.1 of a degree. The results are corrected melting points to about 0.5° C. Rate of heating *ca.* 1° C/per minute; it is found that generally the melting points are almost independent of the rate of heating. The derivatives have been recrystallised to constant melting points.

Preparation of the *p*-bromophenacyl esters

The procedure used for the preparation of the esters given in Table 1, except the ester of formic acid and oxalic acid, is that given by Judefind and Reid [1] with some modifications. The detailed description is given below.

Procedure. An amount corresponding to 0.004 equivalents of the acid is dissolved in 5 ml of ethanol (by heating if necessary). The solution is neutralised with 2 N sodium hydroxide to phenolphthalein as indicator. To this solution is added 3 ml of water and 0.5 N hydrochloric acid to remove the red colour and then further 10—15 drops hydrochloric acid. It is important that the solution of the sodium salt is faintly acid in order to prevent the formation of coloured by-products in the subsequent reaction. 1 g of *p*-bromophenacyl bromide, 5 ml of ethanol and some porous plate are added and the solution is heated under reflux for one or two hours according to whether the acid is mono- or dibasic.

If the reaction mixture is not clear on heating to boiling, a little more ethanol is added (10—30 ml). After boiling for 5—10 minutes a precipitate sometimes is formed but the boiling is continued nevertheless.

The solution is immediately cooled under the tap; if an appreciable amount is not precipitated by cooling a little water is added. The ester is removed by suction and washed on the filter with a few ml of ethanol (*ca.* 50 %). Generally the yield of the crude product is 60—80 %, and this is satisfactory as the aim is purity rather than large yields.

The derivative is recrystallised from ethanol or from aqueous ethanol (*ca.* 50 %). Usually one or two recrystallisations are sufficient. If the ester is insoluble in ethanol, glacial acetic acid should be used.

The p-*bromophenacyl formate.* The procedure above is followed except that the refluxing period is reduced to 30 minutes. The crude product melts at *ca.* 90° C; it should be recrystallised one to three times from ethanol. The *p*-chloro- and the *p*-iodophenacyl formate can be prepared in the same way.

The p-*bromophenacyl oxalate.* The procedure above could not be used; after refluxing for two hours unreacted sodium oxalate and *p*-bromophenacyl bromide were the main products. Other solvents were tried (dioxan, methyl cellosolve and butyl cellosolve) and by using methyl cellosolve the preparation of the oxalate was successful. The method above is modified so that the oxalic acid is dissolved in 5 ml of methyl cellosolve and the solution is adjusted as above. 1 g of *p*-bromophenacyl bromide, 15 ml of methyl cellosolve and some porous plate are added and the reaction mixture is refluxed for only one hour. After cooling under the tap, the ester is removed by suction and washed on the filter with a little ethanol (50 %). A pure derivative usually is obtained; it can be recrystallised from glacial acetic acid (sparingly soluble).

The *p*-bromophenacyl oxalate is readily hydrolysed to the *p*-bromophenacyl alcohol. By varying the refluxing period it is found that the largest yield of the *p*-bromophenacyl oxalate was obtained by refluxing for about one hour (yield *ca.* 40 %). Also by heating for 30 minutes the oxalate was obtained in good yield but unreacted *p*-bromophenacyl bromide was recovered. By boiling for two hours the yield of the oxalate was about 30 % and the main product was the *p*-bromophenacyl alcohol; this was precipitated by addition of water to the filtrate (yield 50—60 %; m. p. 143° C Kofler Heizbank). When the reaction mixture was boiled for only one hour the filtrate did not give an immediate precipitation upon dilution with water.

* Microanalysis by Mr. W. Egger or Mr. P. Hansen, Department of Organic Chemistry, University of Copenhagen, Denmark.

The author is greatly indebted to the Head of the Department, Professor, Dr. H. Baggesgaard Rasmussen.

Kinetics of the Splitting of Hyaluronic Acid by Streptococcal Hyaluronidase

JOHN GRAAE and C. E. JENSEN

Københavns Universitets Fysisk-kemiske Institut, Copenhagen, Denmark

The splitting of hyaluronic acid by streptococcal hyaluronidase was investigated viscometrically. This degradation can be described by either of the following two expressions:

$$Et = A(1/y-1) + B(1/y^3-1) \quad (1)$$
$$Et = C(e^{D/y}-e^{D}) \quad (2)$$

where y is a measure of the remaining viscosity, and E the total enzyme concentration. These expressions are of the same form as those previously found for the splitting of hyaluronic acid by a preparation of testicular enzyme. In the present case expression (2) by insertion of the experimental values yields a closer fit than expression (1), the constant D being 0.165.

The source of streptococcal hyaluronidase was a strain of group A hemolytic streptococcus type 24 (A. 24 N.W.).

The solution of enzyme was prepared by Dr. Viggo Faber, Statens serum-institut, Copenhagen, in the following way:

0.1 ml of an 18 hours culture was inocculated into 1 l of Todd-Hewitt substrate [1]. After incubation for 24 hours at 37°C the culture was centrifuged, the supernatant Seitz-filtered, and the pH adjusted to 6.0. The solution was stored at —20° C until use. This solution contains 25 turbidity-reducing units per ml as measured with a modification of the turbidity-reducing method described by Faber [2].

The experimental conditions of the kinetic investigations reported here were identical with those used by Andersen and Graae [3], with the only exception that the substrate concentration was lowered to 0.2 %.

The stability of the enzyme was checked as described by Andersen and Graae [3]. The result was that the enzyme was stable at 20 °C for more than 4 hours.

It was established that the time necessary to reach a given degree of reaction varies approximately inversely proportional to the enzyme concentration. A similar result was obtained by Hale [4], Madinaveitia and Quibell [5], and in this laboratory [3].

Table 1. a means degree of reaction; t_1, t_2 and t_3 times necessary to reach the given degree of reaction for three different enzyme concentrations. Times are determined by graphical interpolation from the measured figures indicated in Tables 2 and 3.

a	t_1 min	t_2 min	t_3 min	t_2/t_1	t_3/t_1	t_3/t_2
0.491	(4.7)	7.9	12.5	(1.68)	(2.65)	1.58
0.564	(6.3)	11.0	17.4	(1.75)	(2.76)	1.58
0.636	(8.9)	15.0	24.8	(1.69)	(2.79)	1.65
0.709	12.0	22.0	36.5	1.83	3.04	1.66
0.781	19.5	36.5	60	1.87	3.08	1.64
0.854	39.0	73.5	122	1.88	3.13	1.66

Mutually interdependent values of time and degree of reaction for three different enzyme concentrations, are recorded in Table 1. The figures given in parenthesis are estimated to be erroneous, because the time is determined under the wrong condition that a linear relationship exists between time and decrease in viscosity [3]. The constant value of the proportions seems to indicate that the chronometric integral is of the ordinary form $Et = f(y)$. The directly measured values are recorded in Table 2.

Table 2. The table gives the measured values of time and the difference Δ between the flow time for the solution and the flow time for water (45.0 sec.).

Expt. 1		Expt. 3

173.28	25.9	0.0938	−19.71	1.24
211.97	24.0	0.0870	−37.03	−5.17
244.78	22.6	0.0819	−50.46	−6.49
255.07	22.0	0.0797	−51.24	−0.60
1 181	13.7	0.0496	−707	−175

As will be seen from Table 3, the two expressions earlier found [3], fit in this case too. These were

$$Et = A(1/y - 1) + B(1/y^2 - 1) \quad (1)$$

and

$$Et = C(e^{D/y} - e^{D}) \quad (2)$$

In the experiment calculated in Table 2 the values of the constants are: A = 5.05, B = 0.93, C = 37.71 and D = 0.165. It is obvious from these experiments that expression (2) is the best one. It should be noticed that it could be expected that the constant D only depends of the nature of the enzyme and neither of enzyme nor substrate concentration.

The amount of reducing sugar liberated from a given substrate is much greater with pneumococcal hyaluronidase than with testicular hyaluronidase as enzyme [6]. Other bacterial hyaluronidases, especially streptococcal enzymes, show a similar behaviour, *cf.* Rapport, Linker and Meyer [6].

The fact that chronometric integrals of the same form fit both testicular and streptococcal hyaluronidases strongly suggests that the pathways of the reactions are the same. However, in a viscometric investigation it is impossible to distinguish between a reaction resulting in a disaccharide as endproduct and one resulting in other oligosaccharides as endproducts. Therefore the experimental results reported here do not necessarily contrast those obtained by Rapport *et al.*[6]

We wish to thank professor J. A. Christiansen for his interest and help in this investigation.

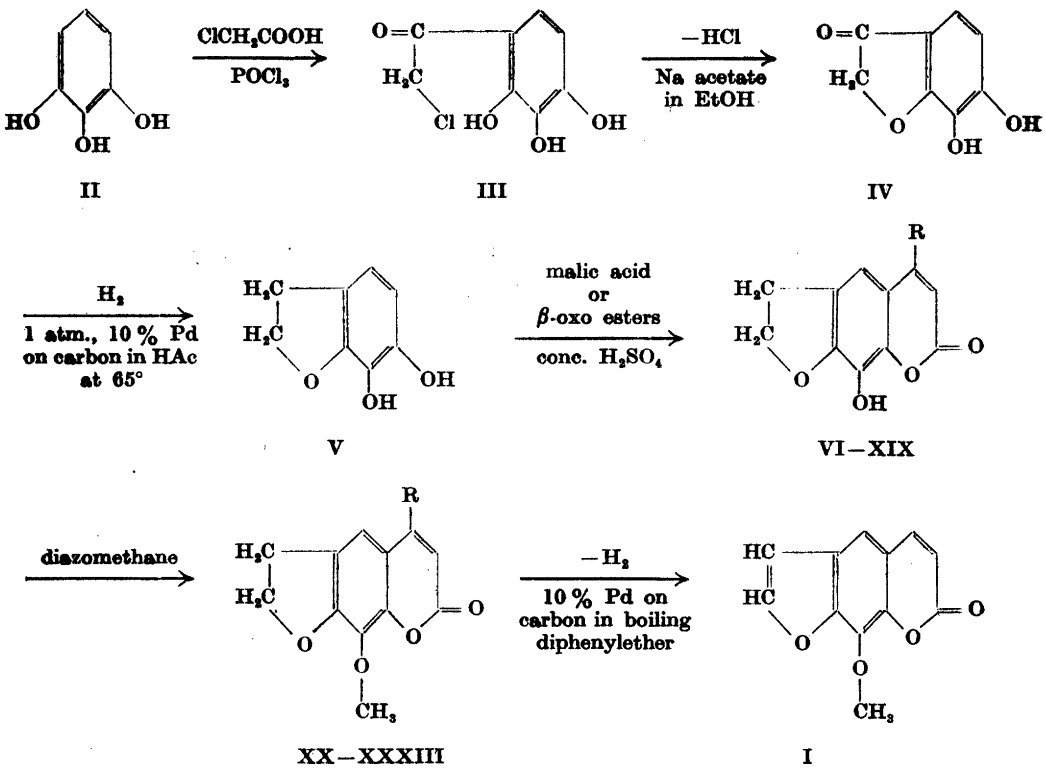
Dihydrofurocoumarins

Synthesis of some Long Chain 4-*n*-Alkyl Substituted Dihydroxanthotoxins, 4-Phenyl-dihydroxanthotoxin and Methyl 8-(Dihydroxanthotoxin-4)-*n*-octanoate



CARL LAGERCRANTZ

Institute of Medical Chemistry, University of Uppsala, Sweden

A number of long chain 4-*n*-alkyl substituted dihydroxanthotoxols and dihydroxanthotoxins have been synthesized together with some other substituted dihydroxanthotoxols and dihydroxanthotoxins. Xanthotoxin has been prepared by a modification of the method described by Späth and Pailer [4].

Since old times in Egypt a drug obtained from the plant *Ammi majus* L. has been used as treatment for *leucoderma idiopathicum*. The active principle of this drug was crystallized by Fahmy and Abushady [1] and was shown by Schönberg and Sina [2] to be identical with the methoxyfurocoumarin xanthotoxin (I) previously isolated by Thoms [3] from the fruits of *Fagara xanthoxyloides*. The total synthesis of xanthotoxin was performed by Späth and Pailer [4].

For the knowledge of the etiology of *leucoderma idiopathicum*, it would seem important to study the effect of furocoumarins and related compounds on the pigment metabolism. In this connection a number of new derivatives of dihydroxanthotoxin has been prepared. This report describes the synthesis of some 4-alkyl substituted dihydroxanthotoxols and dihydroxanthotoxins, 4-phenyl-dihydroxanthotoxol and 4-phenyl-dihydroxanthotoxin and methyl 8-(dihydroxanthotoxin-4)-*n*-octanoate. Xanthotoxin was prepared according to Späth and Pailer [4] with some minor modifications of the original method. The accompanying chart shows the route by which the synthesis of xanthotoxin and the derivatives of dihydroxanthotoxin were carried out.

In this chart R is equal to: VI and XX = H, VII and XXI = methyl, VIII and XXII = ethyl, IX and XXIII = *n*-pentyl, X and XXIV = *n*-hexyl, XI and XXV = *n*-heptyl, XII and XXVI = *n*-octyl, XIII and XXVII = *n*-nonyl, XIV and XXVIII = *n*-hendecyl, XV and XXIX = *n*-tridecyl, XVI and XXX = *n*-pentadecyl, XVII and XXXI = *n*-heneicosyl, XVIII and XXXII = phenyl, XIX and XXXIII = *n*-heptyl-7-methoxycarbonyl.

Späth and Pailer [4] carried out the conversion of 6,7-dihydroxy-coumaran-3-one (IV) to the corresponding 6,7-dihydroxy-coumaran (V) by low pressure hydrogenation at elevated temperature using a palladium on carbon catalyst. The calculated amount of hydrogen was absorbed, but the yield of (V) was only about one third of the theoretical one, indicating that other reactions than conversion of the carbonyl group to a methylene group took place. Attempting to convert 6-hydroxy-coumaran-3-one to 6-hydroxy-coumaran, Horning and Reisner [5] completely failed to isolate the desired product, and they noted that an excess of about 40 % hydrogen was absorbed in the reaction. After acetylation of the free hydroxy group, however, 6-acetoxy-coumaran was obtained in nearly quantitative yield, indicating that the free hydroxy group is involved in these side reactions. However, reduction of the carbonyl group

of hydroxy-coumaran-3-ones and their acetoxy derivatives is perhaps still more complex. Davies and Deegan [6] have shown that acetylation of 6,7-dihydroxy-coumaran-3-one (IV) with acetyl chloride in ethyl acetate solution gives two different products, *i. e.* 6,7-diacetoxy-coumaran-3-one and 3,6,7-triacetoxy-coumarone. The last compound was successfully hydrogenated to give 6,7-diacetoxy-coumaran. Thus, in this case acetylation involves an enolization on the carbonyl group with introduction of a double bond in the heterocyclic ring prior to the hydrogenation reaction. Similar conditions seem to be valid for the acetylated product of 6-hydroxy-coumaran (Davies *et al.*[7]).

When converting 6,7-dihydroxy-coumaran-3-one (IV) to 6,7-dihydroxy-coumaran (V), the overall yield appears to be about the same, either direct hydrogenation is used, or the route is followed which includes acetylation of IV, hydrogenation of the acetylated product and finally deacetylation of the hydrogenated compound. Consequently, the present author preferred to carry out the reaction in one step. In order to avoid poisoning of the catalyst, it is essential that the 6,7-dihydroxy-coumaran-3-one is very pure (recrystallization several times with active carbon), and that efficient stirring is employed when dissolving the substance in the acetic acid used as solvent in the hydrogenation reaction. With these precautions fulfilled, the theoretical amount of hydrogen is rapidly absorbed on hydrogenation at 65° and one atmosphere pressure with 10 % palladium on carbon as catalyst. Very constant yields are obtained, which are somewhat higher than those reported by Späth and Pailer [4].

The condensation of 6,7-dihydroxy-coumaran with malic acid in the presence of concentrated sulphuric acid at 114° gives dihydroxanthotoxol (VI). In this reaction the present author obtained a yield of about 38 % of the theoretical in good agreement with the result reported by Späth and Pailer [4]. In this connection it may be remarked that condensation of phenols with malic acid generally gives lower yields than those obtained when condensating the same phenols with a β-oxo ester as ethyl acetoacetate (*cf.* Sethna and Phadke[8]). Horning and Reisner [5] got pure dihydropsoralene only in a yield of 11 % condensing 6-hydroxy-coumaran with malic acid.

Condensation of phenols with β-oxo esters in the presence of sulphuric acid almost always produces coumarins (*cf.* Sethna and Phadke [8]) and consequently γ-substituted β-oxo esters form coumarins substituted in position 4. Long chain β-oxo esters do not seem to have been used for such condensation to any large extent. The reactivity of the β-oxo esters is generally assumed to decrease with increasing length of the carbon chain. When condensing 6,7-dihydroxy-coumaran (V) with a number of β-oxo esters, which have straight chains of a length varying from four to twenty-four carbon atoms, however, 4-*n*-alkyl substituted dihydroxanthotoxols (VII—XVII) were obtained as crystalline products in rather good yields. The condensation between 6,7-dihydroxy-coumaran and the higher β-oxo esters were generally carried out as follows. After dissolving the phenol and the β-oxo ester in each other by heating, the solution was slowly poured into concentrated sulphuric acid and the mixture was kept at room temperature for three to five days before the product was isolated. Condensing methyl 3-oxo-hendecane-1, 11-dioate with 6,7-dihydroxy-coumaran yielded 8-(dihydroxanthotoxol-4)-*n*-octanoic

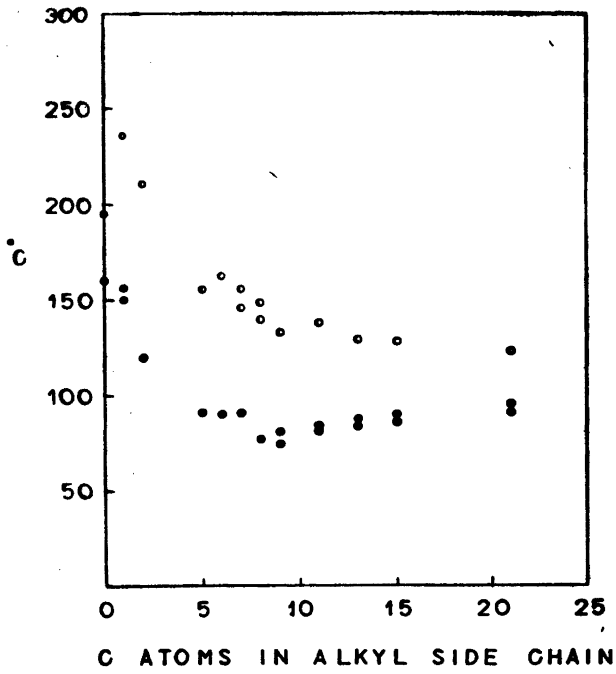


Fig. 1. Melting points of 4-n-alkyl substituted dihydroxanthotoxols, O, and 4-n-alkyl substituted dihydroxanthotoxins, ●, as a function of the number of carbon atoms in the side chain.

acid together with the corresponding methyl ester (XVIII) due to partial hydrolysis during the condensing reaction.

Methylation of the phenolic hydroxy group with diazomethane converted the dihydroxanthotoxols to the corresponding dihydroxanthotoxins (XX—XXXIII). Many of the alkyl substituted dihydroxanthotoxols and dihydroxanthotoxins are dimorphous and possess two melting points. Fig. 1 gives the melting points of these substances as a function of the number of carbon atoms in the alkyl side chain. The melting points of the alkyl substituted dihydroxanthotoxols are generally much higher than the corresponding dihydroxanthotoxins and decrease with increasing length of the side chain. An increase of the alkyl side chain of the dihydroxanthotoxins to about eight carbons continously depresses the melting points. With further lengthening of the side chain the melting points are slowly raised in a rather regular manner.

The last step in the preparation of xanthotoxin involves a dehydrogenation of the dihydrofuran ring. By heating a mixture of dihydroxanthotoxin and a palladium catalyst at 170° Späth and Pailer [4] carried out this reaction with a yield of about 10 % of the theoretical one. Horning and Reisner [9] successfully dehydrogenated dihydropsoralene (2′,3′-dihydrofurocoumarin) to psoralene with a yield of about 50 % by refluxing the substance during four hours together with a 5 % palladium on carbon catalyst in a high boiling medium,

viz. diphenyl ether (b. p. 259°). By employing this technique, the present author could dehydrogenate dihydroxanthotoxin to xanthotoxin in a yield of 37 % of the theoretical. An attempt to dehydrogenate 4-methyl-dihydroxanthotoxin (XXI) with the same technique was unsuccessful. The corresponding xanthotoxin could not be isolated and the starting material had almost completely decomposed. When mesitylene (b. p. 165°) was used as an indifferent medium, only an almost quantitative recovery of 4-methyl-dihydroxanthotoxin was obtained.

EXPERIMENTAL *

6,7-Dihydroxy-coumaran-3-one (IV) was prepared by the method of Davies and Deegan [9]. In the reaction leading to ω-chloro-gallacetophenone (III), a minimum of tarry products was obtained when the temperature was kept below 61° (Davies and Deegan give 60—70°). The overall yield of 6,7-dihydroxy-coumaran-3-one crystallized twice (charcoal) from water was about 16 % of the theoretical calculated on the pyrogallol used.

6,7-Dihydroxy-coumaran (V). 6,7-Dihydroxy-coumaran-3-one (36 g) was dissolved in hot acetic acid (850 ml) with careful stirring. The yellow solution was transferred to a hydrogenation vessel previously filled with hydrogen and containing 15 g 10 % palladium on carbon (*Organic Syntheses*, Vol. 26, method D). The vessel, which was placed in a large flask shaker, was equipped with a jacket through which water maintained at 65° was circulated from a thermostat. The gas burette and other devices for supply of hydrogen gas were of a construction similar to those described by Parrette [10]. The theoretical amount of hydrogen was absorbed in about two hours, but in some runs it was necessary to add more catalyst in order to complete the reaction. After removal of the catalyst and evaporation of the acetic acid, the residue (a brown oil) was distilled at 125—132° at 0.05 mm pressure to give a nearly colourless oil (25 g) that immediately solidified on cooling. This material was redistilled to give a colourless substance (24 g) that was further purified by crystallization from a mixture of light petroleum (b. p. 20—40°) and benzene (1:1 by volume) as follows. The finely powdered substance was extracted with 500 ml light petroleum-benzene by refluxing with stirring for 15 minutes. The liquid was decanted off and discarded. The remaining amount of substance was dissolved in about 3 000 ml light petroleum-benzene. After being kept at —8° overnight, 6,7-dihydroxy-coumaran (16.8 g) crystallized as long beautiful needles. Melting point 112° (Kofler "Heizbank"). The yield was about 50 % of the theoretical.

Dihydroxanthotoxol (VI) (*cf.* Späth and Pailer [4]). A mixture of 6,7-dihydroxy-coumaran (5 g), malic acid (5 g), and concentrated sulphuric acid (25 ml) was kept at 114° in an oil bath with constant stirring until foaming stopped (about 7 minutes). After cooling the mixture was poured with stirring into 250 ml of cold water to give a dark tarry product suspended in the aqueous layer. After extraction with eight 100 ml portions of chloroform, the combined organic solutions were dried over anhydrous sodium sulphate and the solvent evaporated to yield 3.5 g of a yellow powder. Crystallization from water (charcoal) gave 2.3 g (38 % of the theoretical) of slightly yellow long beautiful needles. The melting point was 195° (Kofler "Heizbank", odour of coumarin) and could not be raised after sublimation *in vacuo*. Späth and Pailer [4] reported a melting point of 202°.

4-n-Alkyl-dihydroxanthotoxols (VII—XVII) and 4-phenyl-dihydroxanthotoxol (XVIII). 6,7-Dihydroxy-coumaran was condensed with a number of β-oxo esters in the presence of concentrated sulphuric acid. The data of these preparations are collected in Table 1. Generally the condensation was performed as follows.

* If not otherwise stated, the melting points up to about 200 °C recorded in this paper were taken in sealed capillary tubes using calibrated Anschütz type thermometers completely immersed in a well stirred bath of silicon oil (DC 710 Fluid, Dow Corning Co.). The heating was carried out very slowly (1° per 3 minutes). The melting points over 200 °C were taken by use of a Kofler type hot stage microscope.

* When crystallized from aqueous methanol, one mole of substance VII contains one mole of water that could be quantitatively removed after drying overnight at 120°.

A mixture of 6,7-dihydroxy-coumaran and an excess (10—20 %) of the β-oxo ester was dissolved by heating. The solution was poured into concentrated sulphuric acid with constant stirring. The mixture was kept standing at room temperature for one hour to five days (see Table 1) and was then slowly poured with stirring into ice water. The precipitate formed was collected and suspended in water. The excess of ester was removed by steam distillation. The material collected was recrystallized several times from acetone and from methanol (charcoal).

Ethyl 3-oxo-pentanoate was prepared as described by Brändström [11]. The higher β-oxo esters were those prepared by Mrs. Ställberg-Stenhagen (Ställberg-Stenhagen [12]).

Methyl 8-(dihydroxanthotoxol-4)-n-octanoate (XIX). 6,7-Dihydroxycoumaran (5 g) was dissolved by heating in methyl 3-oxo-hendecane-1,11-dioate (10 g, prepared by the author as described by Ställberg-Stenhagen [12]) and was poured with stirring into 25 ml of concentrated sulphuric acid. The reaction mixture was kept at room temperature for three days. Proceeding as usual gave 3.65 g (about 30 % of the theoretical) of a crystalline material melting between 80 and 95° (recrystallized once from acetone, twice from methanol, charcoal). This substance is most likely a mixture of the ester and the corresponding free acid. No attempts were made to separate the substances.

Derivatives of dihydroxanthotoxin. The 4-substituted dihydroxanthotoxols were converted to the corresponding dihydroxanthotoxins by methylation with diazomethane in a mixture of methanol and ether (1:1 by volume). The solutions were chilled to about +15° before an excess of cold solution (−5°) of diazomethane in ether was added. The reaction mixtures were kept at room temperature overnight. After evaporating the solvent, the methylated products were recrystallized from methanol. The yields were in general between 70 and 85 % of the theoretical. The analytical figures and the melting points of these substances are collected in Table 2. After methylation the mixture of free acid and ester (XIX) was converted to a homogeneous substance, methyl 8-(dihydroxanthotoxin-4)-*n*-octanoate of m. p. 71.8—73.2° and 76.6—77.8° (for analytical figures see Table 2 XXXIII).

Xanthotoxin (I) (*cf.* Späth and Pailer [4]). A mixture of dihydroxanthotoxin (XX) (0.165 g) (m. p. 160.4—161.2°, obtained by methylating VI), 10 % palladium on carbon catalyst (0.165 g), and diphenyl ether (11 g) was heated under reflux for four hours. The catalyst was removed by filtration and washed with hot diphenyl ether (20 g). After removing the diphenyl ether with steam distillation, the hot aqueous solution was filtered. Crystalline xanthotoxin was obtained from the chilled solution as slightly yellow needles. Recrystallization from methanol (charcoal) yielded 0.061 g (37 % of the theoretical) of colourless needles of m. p. 145.7—146.2° in good agreement with that given by Späth and Pailer [4] (146°).

4-Methyl-xanthotoxin. 4-Methyl-dihydroxanthotoxin (XXI) (0.3 g), 10 % palladium on carbon catalyst (0.3 g), and diphenyl ether (17 g) were heated under reflux with mechanical stirring for four hours. Proceeding as just described only 0.08 g of a substance could be isolated that was identical with the starting material. When the same procedure was performed with mesitylene as an indifferent solvent, only a nearly quantitative yield of the starting material was obtained.

Acknowledgements. The author is very much indebted to Mrs. Stina Ställberg-Stenhagen and Professor Einar Stenhagen for the long chain β-oxo esters used in the synthesis described, and to Miss Ulla-Britt Dahlberg in the microanalytical laboratory of this institute for the analyses.

The author would like to thank Notarie S. Haeger and *Statens Medicinska Forskningsråd* for financial support.

The Isotopic Exchange between Hydrogen and Water on Platinum. Relative Rates of Exchange of Isotopic Hydrogen Molecules

KÅRE HANNERZ

Department of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

The isotopic exchange between deuterium- and tritiumcontaining hydrogen and ordinary water vapor on platinum has been investigated using mass spectrometric and radiotracer techniques. A certain amount of HD is formed when D_2 exchanges with deuterium-free water vapor. The rate of HD formation shows that the exchange cannot be due to the interaction of a D_2 molecule, from the gas phase or from the van der Waals layer, with a chemisorbed hydrogen atom or hydroxyl radical. It is necessary to assume that both the hydrogen molecule and the water undergo a dissociative chemisorption on the surface. The ratio of the rates of chemisorption of HD and D_2 has approximately the value given by the simple collision theory for a reaction without activation energy. This points to the possibility that hydrogen is chemisorbed without activation energy on bare dual sites on the surface, formed by the desorption of water or hydrogen.

The isotopic exchange between water and hydrogen has been studied by a large number of investigators. Most of the work has been done with liquid water with a view to elucidating the phenomena involved in the electrolytic discharge of molecular hydrogen. During the war, the exchange reaction between water vapor and hydrogen acquired technical importance as the basis for a method of producing heavy water. The mechanism of the exchange reaction was extensively studied by Farkas in the middle of the thirties [1,2]. From a comparison of the rates of the exchange reaction and the *para-ortho*-hydrogen conversion, Farkas concluded that the exchange must involve a dissociative chemisorption of the hydrogen as atoms. Later, doubts were cast on the correctness of this mechanism, based mainly on the high heats of chemisorption of hydrogen on clean metal surfaces, which seemed to preclude the occurrence of desorption near room temperature. Eley suggested a mechanism where the interaction of a hydrogen molecule from the gas phase or the van der Waals layer with a chemisorbed hydroxyl or hydrogen atom was responsible for the exchange [3]. Recently, the validity of the early measurements of the heat of adsorption of hydrogen on clean metal surfaces has been questioned,

and Rideal and Trapnell have been able to show that the heat of adsorption on tungsten falls to quite low values at full coverage of the surface, in contradiction to previous results [4]. Recent considerations of the effect of the electric double layer formed in chemisorption predict a large variation in heat of adsorption with coverage to be quite common, independent of any neighbour interactions [5]. These new findings make the arguments against Farkas's original mechanism appear less serious.

In the early work with deuterium exchange, heat conductivity measurements were generally used for the determination of deuterium. Since then, the mass spectrometer has become generally available. With it, much more detailed and accurate information about the composition of the hydrogen can be obtained than was possible before. The discovery of the radioactive tritium provides another important tool for investigations of this kind.

With these new experimental resources at hand, an investigation of the exchange reaction has been made in an attempt to test the correctness of the different mechanisms proposed. The rate of the tritium exchange has been used as a measure of the activity of the catalyst, thereby making it unnecessary to assume that the activity of the catalyst is unchanged between successive experiments. In this way the ratio of the exchange rates of D_2 and HD has been obtained, and this in turn makes possible a determination of the amount of HD formed when D_2 exchanges with an excess of light water. As shown below this provides important information about the mechanism of the exchange.

EXPERIMENTAL

Reaction apparatus

The exchange reaction was studied in a static system. To eliminate any influence of diffusion on the reaction rate the reacting gas was circulated over the catalyst. The apparatus is shown in Fig. 1. It contains about 50 ml of specially purified water and has a total volume of about 2 l. During an experiment, most of the water is at A in the figure. From A, the water flows through a capillary constriction to a heated piece of asbestos at B, where it is evaporated without risk for explosive boiling. The vapor passes to the jet at C, which it leaves with a high velocity, thus circulating the gas in the rest of the apparatus. Thermostated water circulates through the condensers. Most of the excess water vapor is condensed on the downward path of the gas and only a little in the lower part of the upward condenser. In the upper part of the latter, there is a constriction. Any water condensing above this constriction would have therefore been visible. The fact that no water was observed shows that the water vapor pressure of the gas, when it left the condensers, was the equilibrium pressure corresponding to the temperature of the water circulating through the condensers. After leaving the condensers, the gas enters the bulb D, which constitutes most of the volume of the reaction apparatus. It is inserted in a thermostat set at a temperature higher than that of the gas circulating through the condensers. On its way out from the bulb the gas comes into contact with the platinized platinum catalyst at E. A thermocouple inside the glass tube carrying the catalyst indicates the temperature at which the exchange reaction takes place. The stopcock F and the ground joint G are lubricated with apiezon L high vacuum grease which is considered to have an immeasurably low vapor pressure at room temperature. Before being installed, the reaction apparatus was heated in oxygen in an oven to 550 °C to burn out any organic impurities. The efficiency of the gas circulation was checked by cooling at E when the apparatus was running with about equal pressures of hydrogen and water vapor. A very rapid condensation took place and continued as long as the cooling was applied. This could not have been due to diffusion of water vapor through the hydrogen, but showed that the circulation in the apparatus was very efficient.

Materials

The catalyst consisted of a piece of platinum foil, 20 × 10 × 0.05 mm, platinized by 60 mA, 2—3 min. After platinizing, the foil was purified using cathodically evolved hydrogen in a dilute sulfuric acid bath, carefully rinsed with distilled water and kept in doubly distilled water overnight before use.

The water used for the exchange experiments was purified by double distillation, and finally the vapor was passed through a quartz tube kept at 800° C to destroy any volatile organic impurities.

Commercial cylinder hydrogen was used and purified before use by passing through a pyrex tube filled with platinized asbestos at 500 °C and a liquid air trap.

Deuterium was prepared by electrolysis of 99.6 % heavy water and purified as the hydrogen above. Deuterium was circulated over the platinized asbestos for three hours before the gas from the electrolysis cell was sent to the deuterium storage bulb.

Tritium, about 0.1 mC as hydrogen gas, was obtained from A.E.R.E., Harwell, England.

Determination of deuterium

Deuterium was determined in a 90°, Nier type mass spectrometer. The pressure before the leak was kept constant during all analyses. The spectrometer was calibrated with gas samples of known composition. These were prepared by diluting deuterium gas from the storage bulb with hydrogen. An aliquot of the gas was analyzed in the mass spectrometer and another part burned in dry oxygen and the deuterium content in the resulting water

determined by means of the gradient-tube method. In this way a calibration for D_2 was obtained. Still another part of the gas mixture was equilibrated over a glowing platinum wire, previously outgassed by prolonged heating in a high vacuum, and then analyzed in the spectrometer. This gave a calibration curve for HD. There was very little mass 2 background in the spectrometer, and background on masses 3 and 4 from previous samples was never observed. In the range of HD and D_2 percentages used it was found that peak heights and percentages were always proportional within experimental errors, when the 2 peak was corrected for background, so that there was no fractionation in the spectrometer. The percentage of HD and D_2 was consequently obtained directly from the peak heights on the recorder diagram. When the HD content of a sample was below 0.5 %, the value obtained was discarded and not used in the calculation of the reaction rate constant, since the spectrometer was not calibrated below this percentage. The standard deviation obtained when making repeated measurements on several samples taken from the same storage bulk was 3 % of the measured HD or D_2 percentage.

Determination of tritium

Tritium analyses were made in a proportional counter. The counter consisted of a 20 mm diam. copper tube, enclosed in a pyrex tube. The anode was a 0.05 mm tungsten wire. It hung freely and was stretched by a 20 g weight at the lower end, and could thus easily be removed. The distance between the sleeves, *i. e.* the active length of the wire, was 25 cm. The total volume of the counter was 200 ml. The high voltage was supplied by an EKCO power unit type 1033/7. The pulses were amplified in an EKCO amplifier type 1008 and counted with an EKCO scaler type 1009 A. The counter had a plateau with a slope of 4 % per 100 volt between 1 900 and 2 100 volt. When measurements were made, the sample gas was first allowed to expand into the previously evacuated counter. Ordinary hydrogen was then added to a total pressure of 40 mm Hg. Finally, methane was added to a total pressure of 200 mm Hg. The counter was left for 15 min. to allow the gases to mix completely. Counting was made at 4 to 5 different voltages with each sample. The precision of the method was tested by counting ten different mixtures of a gas of known activity and ordinary hydrogen. These samples underwent exactly the same treatment as the samples taken during exchange experiments. The standard deviation of the activity of the original T-containing gas was obtained as 3 % of the mean value. The counter did not show any detectable memory effects. After some use, the plateau became steeper and narrower, probably as a result of the deposition of hydrocarbon residues from the methane on the anode, caused by the discharges [6]. Replacement of the anode wire restored the original plateau.

Procedure

Before each experiment, the whole apparatus was evacuated by means of a mercury diffusion pump to less than 10^{-5} mm Hg. The water in the reaction apparatus was frozen in a solid CO_2 bath during the evacuation.

The stopcock leading to the reaction apparatus was closed, and the water heated and distilled to position A (Fig. 1). A constant flow of water passed through the capillary and entered the heated zone, where it was evaporated. When the vapor jet circulation was working, the predetermined mixture of tritium, deuterium and hydrogen was admitted *via* a liquid air trap. The mixing of the gases was performed in a special bulb and if desired the mixture could be equilibrated over a glowing platinum filament. After admission of the gas, the total pressure in the reaction apparatus was measured on a mercury manometer placed outside the apparatus while the stopcock was kept open. As mentioned above the water vapor pressure could be taken as the saturation pressure corresponding to the temperature of the water circulating through the condensers. The hydrogen pressure was obtained as the difference. The number of moles of water taking part in the exchange reaction was about 2 000 times the number of moles of hydrogen, so that the increase in deuterium and tritium content of the water after completed exchange could be neglected.

The exchange reaction was allowed to go on for 5 min. during which the liquid air trap (volume about 20 ml) was evacuated. Then the first sample was taken. After the

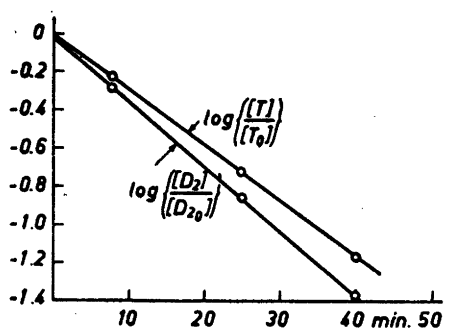

Fig. 3. Reaction of hydrogen containing tritium and a few per cent D_2 with light water vapor. (Exp. 6).

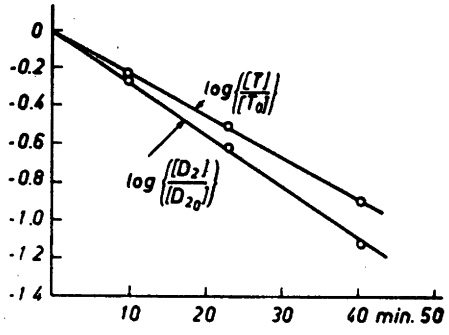

Fig. 4. Reaction of tritium containing, D_2-rich hydrogen with light water vapor. (Exp. 4).

water vapor had been frozen out, the sample was sent to a storage bulb *via* a Toepler pump. Four or five samples at intervals of about 10 min. were taken in each experiment.

From the sample storage bulb, part of the gas was forced into an ampoule, which was removed from the apparatus, and the gas contained submitted to mass spectrometric analysis.

The rest of the gas was forced into a gas burette by means of the Toepler pump, and the mercury adjusted to a constant marked level (Fig. 2). The pressure of the gas was then measured on the other arm of the manometer by means of a cathetometer. The temperature at the gas burette was noted. The gas was then allowd to expand into the counter, and the mercury level in the Toepler pump adjusted to the lower end of the outlet tube (B, Fig. 2). When corrected for temperature variations, the amount of hydrogen in the counter was thus proportional to the pressure of the gas in the burette. Counting was then done as described, and gave the relative specific activity of the gas. Absolute determination of the specific activity was of course not necessary.

RESULTS

All measurements were made at a water vapor pressure of 14 mm Hg, a hydrogen pressure of 22 mm Hg and a reaction temperature of 25 °C.

All successful experiments are reported in Table 1, where the apparent monomolecular reaction constants of the different hydrogen molecules are given. The plot of the logarithm of the tritium content in the hydrogen against time generally gave excellent straight lines, showing that the reaction was of first order. When a gas mixture containing a few per cent D_2 and very little HD was exchanged, the plot of log (D_2) *vs.* time was also strictly linear (Fig. 3). When hydrogen with a high D_2 content was exchanged, however, there seemed to be a tendency for the half life to decrease slightly as the deuterium content of the hydrogen decreased (Fig. 4). The number of samples taken is too small to allow anything more than a qualitative observation of this effect.

In a few experiments, first order kinetics were not obtained, instead the exchange tended to become slower with time. This was attributed to some impurity in the reaction gas, which caused poisoning of the catalyst. When this was observed, the reaction apparatus was heated in an oven to 500 °C for several hours to burn out any impurities, and the catalyst replatinized.

The D_2, HD and HT concentrations were generally observed over a range of 10 or more. If four points are taken on each curve, and the logarithm of a concentration value is considered as derived from a sample taken from a normal distribution of concentration values with a coefficient of variation of 3 %, the ratio of the reaction constants of HD and D_2 is obtained from six experiments (5—10) with a coefficient of variation of 4 %. This means that in present case, where the ratio is near unity, there is only one chance in twenty that the obtained ratio is in error by more than 0.08.

DISCUSSION

Before undertaking a discussion of the mechanism of the exchange reaction it must be shown that the kinetics are not obscured by the influence of diffusion.

The adsorption of water on a blank platinum surface has been examined by Bowden and Throssell [7]. At the relative saturation of the water vapor used in the present experiments, they have found an adsorbed amount corresponding to as much as 50 molecular layers. By means of an optical method they found that the water was not uniformly distributed but must have been localized as microscopic droplets on certain contaminated parts of the surface. On almost the whole surface the adsorbed layer was only about 2 molecules thick. If it is still assumed for the moment that the water is adsorbed as a layer 50 molecules thick, the diffusion through this layer would approximately account for the observed reaction rates with a roughness factor of unity for the surface. However, from the measurements of Bowden and Rideal [8], confirmed by numerous polarization measurements, it is evident that the roughness factor of platinized platinum is of the order of 10^3. It is thus quite clear that diffusion through the adsorbed layer of water cannot have influenced the reaction rate in any way. As mentioned earlier the mixing of the reaction gases was very rapid, so that the gas could at all times be regarded as homogeneous and the water vapor as deuterium-free.

The various mechanisms proposed for the exchange reaction will now be discussed in the light of the experimental findings.

I. The fact that HD is formed during the exchange of D_2 with H_2O shows at once that the deuterium atoms are not transferred simultaneously to the water, so that the reduction of a surface oxygen atom by a hydrogen molecule cannot be responsible for the exchange.

II. The electrolytic mechanism proposed for the hydrogen electrode

$$H_2O + H—M \rightarrow M^- + H_3O^+ \qquad (1)$$

where M means a surface metal atom, cannot be expected to occur in such a thin water layer as was present in these experiments. The incomplete solvation of the ions would increase the activation energy for the process considerably above the value in the presence of liquid water [1].

III. Rideal and Eley have suggested a mechanism for the *para-ortho*-hydrogen conversion where the interaction of a hydrogen molecule from the van der Waals layer and a chemisorbed hydrogen atom is the rate determining step [9]

$$p\text{-}H_2 + H—M \rightarrow o\text{-}H_2 + H—M \qquad (2)$$

Table 1.

Experiment No.	Initial content in hydrogen			k_{D_2}	k_{HD}	k_T	$\frac{k_{D_2}}{k_T}$	$\frac{k_{HD}}{k_T}$
	% D_2	% HD	% H_2	min $^{-1}$	min $^{-1}$	min $^{-1}$		
1	74.7	10.2	15.1	0.122		0.097	1.26	
2	83.4	7.5	9.1	0.063		0.051	1.23	
3	65.3	15.1	19.6	0.136		0.099	1.37	
4	66.6	13.9	19.5	0.099		0.078	1.27	
5	6.3	0.31	93.4	0.157		0.123	1.27	
6	4.7	0.26	95.1	0.081		0.066	1.24	
7	4.1	0.21	95.7	0.118		0.083	1.30	
8	0.03	3.0	96.9		0.187	0.163		1.15
9	0.04	3.9	96.1		0.085	0.078		1.09
10	0.04	3.8	96.2		0.094	0.083		1.14

It has been shown by Farkas [1] that the *p-o*-conversion and the exchange of deuterium occur with similar rates under conditions such as used here; the small difference in rate seems to be due to an isotopic effect. Therefore, if the *p-o*-conversion proceeds at all according to eqn. (2) it must be assumed that the chemisorbed D atom produced according to the same mechanism:

$$D_2 + H—M \rightarrow HD + D—M \quad (3)$$

is rapidly transferred to the water. The chemisorbed hydrogen atoms would then consist exclusively of light hydrogen.

In experiments 8—10 (Table 1), the ratio of the following two reaction constants were measured:

$$HD + H_2O \rightarrow HDO + H_2,\ k_2 \quad (4)$$
$$HT + H_2O \rightarrow HTO + H_2,\ k_3 \quad (5)$$

In experiments 5—7 the ratio k_1/k_3 was measured:

$$D_2 + H_2O \rightarrow HDO + HD,\ k_1 \quad (6)$$

In these experiments there must be very little chemisorbed deuterium on the surface, and according to the above mechanism the reaction constants represent the rate of reaction of HD, HT and D_2 with chemisorbed H atoms.

If it is now assumed that the surface is free from chemisorbed deuterium even when pure D_2 is undergoing exchange, it is easy to calculate the concentration of HD in the hydrogen in terms of the remaining D_2 from the formulae for consecutive reactions, because the ratio of their reaction constants is known from experiments 5—10.

In experiment 4 (Fig. 4) the rate constant for D_2 is taken from the slope of the straight line of best fit for the experimental values of log (D_2). In Fig. 5 are shown the curves for the calculated (curve I) and actually observed (curve II) HD concentration. Curve III would be obtained if no HD formation

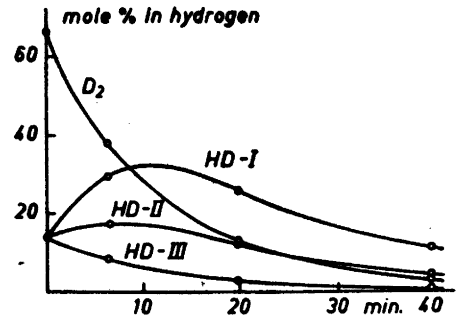

Fig. 5. The formation of HD in the exchange of D_2 with H_2O (Exp. 4).

from D_2 occurred. Clearly much smaller amounts of HD are formed than those required by the postulated mechanism.

If chemisorbed D atoms are actually present on the surface, the rates of D_2 and HD disappearance are governed by the following expressions:

$$\frac{-\mathrm{d(D_2)}}{\mathrm{d}t} = k_1(\mathrm{D_2})\,\sigma_\mathrm{H} - k_4\,(\mathrm{HD})\,\sigma_\mathrm{D} \qquad (7)$$

$$\frac{-\mathrm{d(HD)}}{\mathrm{d}t} = k_2\,(\mathrm{HD})\sigma_\mathrm{H} + k_4(\mathrm{HD})\sigma_\mathrm{D} - k_1(\mathrm{D_2})\sigma_\mathrm{H} - k_5(\mathrm{H_2})\sigma_\mathrm{D} \qquad (8)$$

Here σ_D = fraction of deuterium among the chemisorbed hydrogen atoms, σ_H = that for light hydrogen, σ_T = that for tritium.

$$\sigma_\mathrm{H} + \sigma_\mathrm{D} + \sigma_\mathrm{T} = 1 \qquad (9)$$

where, of course, $\sigma_\mathrm{T} \ll 1$.
The ratio

$$\frac{-\mathrm{d(HD)}/\mathrm{d}t}{\mathrm{d(D_2)}/\mathrm{d}t} = \frac{k_1(\mathrm{D_2})\sigma_\mathrm{H} - k_4(\mathrm{HD})\sigma_\mathrm{D} + k_5(\mathrm{H_2})\sigma_\mathrm{D} - k_2(\mathrm{HD})\sigma_\mathrm{H}}{k_1(\mathrm{D_2})\sigma_\mathrm{H} - k_4(\mathrm{HD})\sigma_\mathrm{D}} \qquad (10)$$

is seen to have its lowest value for $\sigma_\mathrm{D} = 0$, which gives the above-mentioned curve I in Fig. 5. Consequently, for $\sigma_\mathrm{D} > 0$, the HD concentration must at all times be *higher* than that given by curve I. The fact that the experimental curve is considerably below curve I definitely rules out a Rideal-Eley mechanism as the preliminary step in the exchange of molecular hydrogen with water.

IV. A mechanism suggested by Eley [3] involves interaction between a D_2 molecule and a chemisorbed OH radical

$$\mathrm{D_2 + HO{-}M \rightarrow HDO + D{-}M} \qquad (11)$$

which must be followed either by

$$\mathrm{H_2O + D{-}M \rightarrow HD + HO{-}M} \qquad (12)$$

or

$$\mathrm{H_2O + D{-}M \rightarrow H_2 + DO{-}M} \qquad (13)$$

In eqn. (13) the D atom in the hydroxyl group can then exchange rapidly with the water. If reaction (12) occurs, it gives rise to the same kinetics as mechanism III above and is thus excluded for the same reasons. The correct rate of HD formation from D_2 could, however, result if reactions (12) and (13) occurred simultaneously. As they must involve quite dissimilar transition states this is very unlikely. Besides, reaction (13) seems improbable as such, since it involves the simultaneous breaking and formation of three bonds. It is also unable to explain the exchange between hydrogen and alcohols, which occurs with about the same rate as with water [1].

V. Finally, Farkas has presented evidence for a mechanism in which the hydrogen is chemisorbed as hydrogen atoms on the platinum surface [1].

If the exchange occurs *via* chemisorption of hydrogen it is necessary that the chemisorption of water is also reversible. It is now generally agreed that chemisorption of simple hydrides involves a splitting of the bond between the central atom and a hydrogen atom [3]. In the case of water this leads to formation of hydroxyl radicals on the surface. If the hydroxyls are irreversibly adsorbed, they will eventually cover the surface completely if they are mobile, and the exchange comes to a standstill. If they are immobile on the surface, some isolated hydrogen atoms will be left which could be active in mechanisms III and IV but not in the one discussed here. As the former mechanisms have been shown to be inapplicable, the dissociative chemisorption of water must necessarily be reversible. It is then reasonable to assume that the chemisorbed hydrogen atoms are transferred to the water *via* desorption of a hydrogen atom and an adjacent hydroxyl radical. The disappearance of the various hydrogen molecules is then governed by the following equations:

$$\frac{-\mathrm{d}(\mathrm{D_2})}{\mathrm{d}t} = k_1(\mathrm{D_2}) - k'_1\sigma_{\mathrm{D}}^2 \tag{14}$$

$$\frac{-\mathrm{d}(\mathrm{HD})}{\mathrm{d}t} = k_2(\mathrm{HD}) - k'_2\sigma_{\mathrm{H}}\sigma_{\mathrm{D}} \tag{15}$$

$$\frac{-\mathrm{d}(\mathrm{H_2})}{\mathrm{d}t} = k_3(\mathrm{H_2}) - k'_3\sigma_{\mathrm{H}}^2 \tag{16}$$

$$\frac{-\mathrm{d}(\mathrm{HT}+\mathrm{DT})}{\mathrm{d}t} = k_4(\mathrm{HT}) + k_5(\mathrm{DT}) - k'_4\sigma_{\mathrm{H}}\sigma_{\mathrm{T}} - k'_5\sigma_{\mathrm{D}}\sigma_{\mathrm{T}} \tag{17}$$

The above equations involve two assumptions:

a) That the amount of chemisorbed hydrogen is independent of the isotopic composition of the molecular hydrogen. In view of what is now known about the generally occurring large variation in heat of adsorption with coverage it is very unlikely that the necessarily small difference in heat of adsorption between the different isotopes can give rise to any noticeable change in coverage.

b) That surface diffusion of the adsorbed hydrogen atoms is rapid compared with desorption, so that the composition of the desorbed hydrogen is statistically governed by the amount of the different hydrogen isotopes chemisorbed on the surface.

It is evident that by choosing a suitable value of the ratio k'_2/k_1, this mechanism can be made to account for any observed rate of HD formation.

Using the above equations and some additional ones describing the chemisorption and desorption of the water on the surface, Farkas has calculated the composition of the adsorbate from a comparison of the rates of *p*-*o*-hydrogen conversion and deuterium exchange [1]. He then had to assume that $k_1 = k_2 = k_3$ and $k'_1 = k'_2 = k'_3$.

If the preliminary step is the chemisorption of hydrogen molecules as atoms, and the exchange is made with water containing only light hydrogen, it is obviously correct to write:

Rate of transfer of chemisorbed deuterium to the water = net rate of exchange $= k_D\sigma_D$ (18)

whilst that for tritium $= k_T\sigma_T$ (19)

From eqns. (15) and (17) it is seen that, in the exchange of HD and HT with light water, first order kinetics will always be obtained since the amount of chemisorbed deuterium and tritium will be proportional to the fraction of HD and HT, respectively, in the hydrogen gas. In the exchange of D_2 with light water, on the other hand, eqn. (14) shows that the kinetics will not be simple first order. The deviation from first order kinetics depends on the ratio k'_1/k_1. In all cases where the exchange of hydrogen with a high D_2 content was observed, there is in fact a slight downward curvature of the log (D_2) *vs.* time lines, as required by eqn. (14) (Fig. 4). However, the number of samples taken in each exchange experiment is too small to permit an evaluation of the σ_D^2-term.

If a mixture of small amounts of almost HD-free D_2 with H_2 is undergoing exchange the disappearance of D_2 represents directly the rate of chemisorption of D_2 if assumption b) above is correct.

If HD in low concentration is present in the hydrogen, on the other hand, some HD will desorb from the surface. The probability of escape to the hydrogen gas of a chemisorbed D-atom will be constant as long as σ_D is small, resulting in first order kinetics. When the deuterium in the hydrogen gas is present as D_2 this probability is determined by measuring the rate of formation of HD. In experiments 5 to 7, the rate of HD formation was obtained from a knowledge of the mean value of the ratio of the reaction constants of D_2 and HD, obtained from experiments 5 to 10 as 1, 14. The probability of desorption of a D atom as HD enters the calculations as a parameter. If this probability is given the value 0.23, the experimental points give the best agreement with the theoretical curve. Evidently, then, the rate of chemisorption of HD is 1/1—0.23 = 1.30 times larger than the actual rate of disappearance of HD. The ratio of the rates of chemisorption of HD and D_2 at equal concentration is then 1.30/1.14 = 1.14.

If it is assumed for the moment that the probability of escape to the hydrogen as HT of a chemisorbed tritium atom is the same as that for deuterium as HD at low D concentrations, the relative rates of chemisorption of HD, D_2 and HT are obtained as 1.14:1:1.03. It is interesting to note that this is quite close to what would be expected from the simple collision theory for a process without activation energy (1.16:1:1).

It is now known that hydrogen is chemisorbed immeasurably fast on many clean metal surfaces even at liquid air temperatures, so that the energy of activation of the adsorption must be very low. This process may therefore well be a case where the assumption of equilibrium between reactants and activated complex in the theory of absolute reaction rates is not valid. The ratio of the adsorption velocities of different isotopic hydrogen molecules may then be expected to be equal to the ratio of the collision frequencies with the surface. If this is true the obtained ratios of adsorption velocities seem to indicate that the chemisorption of a hydrogen molecule on a bare dual site occurs without appreciable energy of activation even when the surface is largely covered with adsorbate.

If the relative rate of chemisorption of H_2 can be obtained analogously from the simple collision theory, the *p-o*-conversion of light hydrogen can be calculated to proceed 1.8 times faster than the deuterium exchange. Farkas [1] generally obtained a conversion rate 2—3 times higher than the exchange rate. If the disagreement is real, the explanation may be that there is a certain probability that a hydrogen molecule adsorbed on a dual site may desorb before the atoms are separated by surface diffusion. Assumption b) is then no longer valid, and the arguments based on it break down. Whether such an immediate desorption actually occurs could have been tested by observing the *ortho-para*-conversion of the unexchanged deuterium in the experiments with D_2-rich gas.

In conclusion it has been shown that of the mechanisms so far suggested for the isotopic exchange between hydrogen and water vapor on platinum, the only one in agreement with the reported experimental results involves a simultaneous dissociative chemisorption of both hydrogen and water on the surface. This is followed by desorption of the same molecular species. The hydrogen is chemisorbed as atoms, the water as a hydrogen atom and a hydroxyl radical. The chemisorption of hydrogen probably occurs without any appreciable activation energy and its rate is governed by the production of bare dual sites on the surface by the desorption of water or hydrogen.

A consequence of this mechanism is that in order for a metal to be an efficient catalyst for the isotopic exchange between hydrogen and water, the heat of adsorption of hydroxyl radicals must be low. The heat of adsorption of hydroxyl should run roughly parallel to the tendency of the metal to combine with oxygen. Among the metals commonly used in hydrogen catalysis, platinum has the lowest affinity for oxygen, and it is thus not surprising to find that it is by far the most efficient catalyst for the exchange reaction [10-12].

Infrared Spectroscopic Investigations of some Hydrazides

J. BUUR JENSEN*

Leo Pharmaceutical Products, Copenhagen, Denmark

The infrared spectra of some hydrazides in the solid state and in chloroform solution have been investigated in the 6 μ region. Characteristic frequencies in the solid state are found at 1 630—1 660 cm^{-1}, 1 620 cm^{-1} and between 1 570 and 1 530 cm^{-1}. Corresponding bands in the solutions are found around 1 670, 1 620 and 1 500 cm^{-1}. The assignment of the bands to different group frequencies is discussed. Investigations in the 3 μ region on phenylacetic acid hydrazide make it evident that hydrogen bonding takes place in the solid state and in concentrated solutions.

Furthermore it is shown, that the spectrum of cinnamic acid hydrazide synthesized by Godtfredsen and Vangedal [1] is in agreement with the spectra of the other hydrazides, while the spectrum of the compound which Muckermann [2] believed to be cinnamic acid hydrazide shows essential differences.

In a recent publication from this laboratory Godtfredsen and Vangedal [1] have proved, that the compound synthesized by Muckermann [2] was 3-phenyl-5-pyrazolidone and not, as hitherto believed, cinnamic acid hydrazide. This observation caused the author to investigate the infrared spectra of some hydrazides. The present publication deals mainly with the spectra in the 6 μ region, but measurements in the 3 μ region are also reported.

Only few spectra of hydrazides are found in the literature; thus Lenormant [3] in a work on amides has recorded the spectrum of acetic acid hydrazide, while Mattu and Pirisi [4] have recorded that of *iso*nicotinic acid hydrazide.

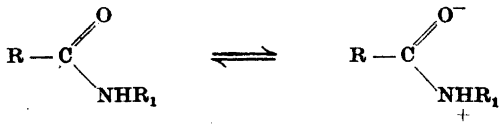
EXPERIMENTAL

All spectra are absorption spectra measured on a Beckman infrared spectrophotometer model IR 2 equipped with rock salt optics and automatic recorder. A computing device, as described by Foreman and Jackson [5] was used for the purpose of eliminating background absorption. Spectra of solids were recorded in KBr-discs. The KBr employed was prepared as described by Clauson-Kaas *et al.*[6] The discs contained 0.5 % hydrazide, weighed about 0.2 g and were prepared in a pressing device and under experimental

* Present address: Specialitetskontrollen, Copenhagen, Denmark.

conditions as described elsewhere [7]. Spectra of chloroform solutions were recorded in rock salt cells. The employed chloroform was Merck a.g.

All the hydrazides were synthesized in this laboratory. With the exeption of cinnamic acid hydrazide, which was synthesized by the method of Godtfredsen and Vangedal [1], they were all prepared by the reaction of the corresponding ethyl ester with hydrazine. Melting points agreed with those found in the literature.



RESULTS AND DISCUSSION

Figs. 1 and 2 show, respectively, the spectra of the solid hydrazides and those of the chloroform solutions. In addition the spectrum of 3-phenyl-5-pyrazolidone is given. Among the spectra of the solids acetic acid hydrazide is absent, as it was impossible to prepare a sufficiently transparent disc with this compound, presumably due to its low melting point. However, the spectrum given by Lenormant [3] is in comparatively good agreement with those given in Fig. 1.

One observes at once that the transition from the solid state to dilute solution is associated with distinct changes in the spectra. In the solid state the hydrazides absorb strongly between 1 630 and 1 660 cm^{-1}, while this absorption in chloroform solution is shifted to frequencies about 20 cm^{-1} higher. Likewise the hydrazides in the solid state show medium absorption in the region around 1 530—1 570 cm^{-1}. This absorption is found in the solutions at essentially lower frequencies around 1 500 cm^{-1}. The absorption of the phenyl groups can be observed [8] around 1 500 and 1 600 cm^{-1}, and finally is a medium to strong band found in the neighbourhood of 1 620 cm^{-1} in the spectra of the dissolved hydrazides. In the spectra of the solid hydrazides this absorption may be overlapped by the strong band at 1 630—1 660 cm^{-1}, but the absorption pattern makes it evident, that this band also is present in the spectra of the solid hydrazides.

In the following it is attempted to assign the absorption bands to different groups in the molecule. It should be noted at once that the spectra of the hydrazides resemble those of the N-monosubstituted amides. Considerable contribution to the understanding of the spectra of the amides is offered by among others Richards and Thompson [9], Lenormant [3] and latest by Gierer [10].

The strong absorption of the hydrazides around 1 650 cm^{-1} in the solid state and 1 670 cm^{-1} in chloroform solution in analogy with the N-monosubstituted amides must be ascribed to the carbonyl group. Normally one would expect its absorption at a somewhat higher frequency around 1 710 cm^{-1}. The reason for the low frequency is explained by a weakening of the double bond, due to the following resonance:

In the spectra of the N-monosubstituted amides Richards and Thompson [9] observed, that the absorption of the carbonyl group is dependant on the state

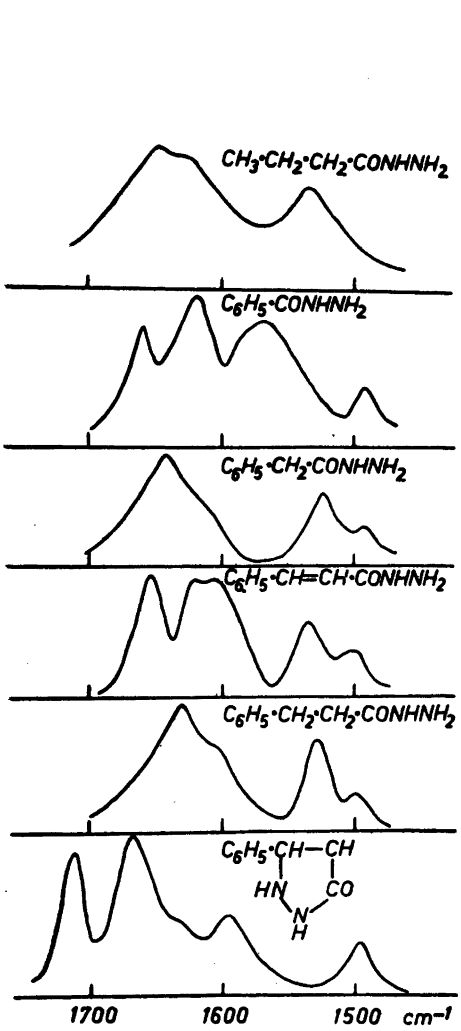


Fig. 1. I.R.-spectra of solid hydrazides (KBr discs containing 0.5 % hydrazide).

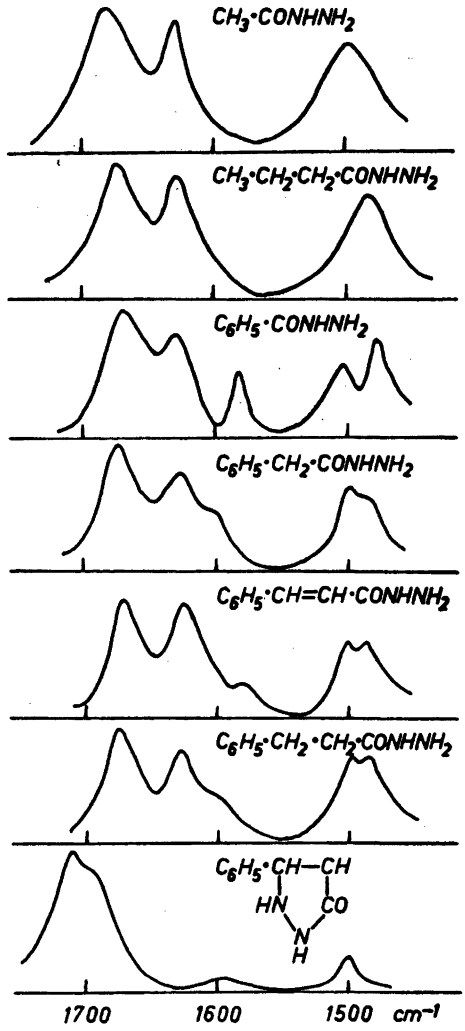

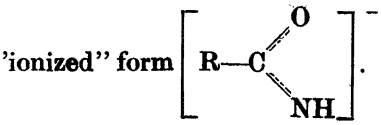

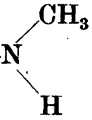

Fig. 2. I.R.-spectra of hydrazides (1 % in $CHCl_3$)

in the same manner as here observed for the absorption of the carbonyl group in the hydrazides.

The medium band observed between 1 530 and 1 570 cm^{-1} in the solid hydrazides is also found in the spectra of solid N-monosubstituted amides [9], and in both cases this absorption is shifted to lower frequencies in the spectra of the solutions [9]. There are yet different opinions on the causes of this absorption. In the N-monosubstituted amides Richards and Thompson assign this absorption to NH deformation frequency, while Lenormant is of the opinion that

the absorption can be attributed to an "ionized" form  .

Finally Gierer assigns the band in N-metylacetamide to a deformation of the group  . A final explanation of this problem is still missing, and it will only be brought to attention, that the spectra of the hydrazides also on this point resemble the N-monosubstituted amides.

Absorption around 1 600 cm^{-1} and 1 500 cm^{-1} is found in the hydrazides containing a phenyl group, and must be due to this [8]. Only the assignment of the medium or strong band around 1 620 cm^{-1} is remaining. Absorption at this frequency is due most often to C=C stretching, C=N stretching or NH_2 deformation [8]. As absorption of the carbon-carbon double bond is most often weak, and as only cinnamic acid hydrazide contains this bond, absorption can not originate here. If the absorption is assigned to a C=N group it must involve a ketone-enol equilibrium in the solid state, which is most unlikely. It is therefore most reasonable to assign the absorption around 1 620 cm^{-1} to a NH_2 deformation frequency in conformity with what is observed in primary amines [8]. This assignment may be further evidenced by the fact, that this band is absent in the spectra of the hydrohalides [3].

From Figs. 1 and 2 it is seen that the spectrum of cinnamic acid hydrazide synthesized by the method of Godtfredsen and Vangedal [1] is in exact agreement with the spectra of the other hydrazides, while 3-phenyl-5-pyrazolidone, which Muckermann [2] believed to be cinnamic acid hydrazide, differs in essential degree. This may be regarded as a further proof of the structure determinations of these compounds accomplished by Godtfredsen and Vangedal [1].

The variations mentioned in the spectra on passing from dilute chloroform solution to solids may be ascribed to association of the molecules in the solid state under the formation of hydrogen bonds. A concrete proof of this can be derived from the spectra in the 3 μ region, as it is well established that free —NH-groups give rise to narrow bands in the region 3 500—3 300 cm^{-1} while the bonded groups give rise to broader bands at somewhat lower frequencies [8]. The employed rock salt optics, however, are not suitable for measurements in this region due to low resolution, and the experimental technique in recording the spectra of solids is complicated by scattering.

For this reason, reference is made only to the measurements which are performed on phenylacetic acid hydrazide. Although they cannot be regarded as exhaustive, they form a basis sufficient to verify that association takes place in concentrated solutions and in the solid state.

Figs. 3 and 4 show the spectra of phenylacetic acid hydrazide in the solid state and in chloroform solution, respectively. The spectrum of the chloroform solution shows a narrow band of high intensity at approximately 3 450 cm^{-1}, and a weaker broad one at approximately 3 340 cm^{-1}. An eventual absorption at lower frequency is difficult to measure due to the background absorption of the chloroform. The spectrum of the solid substance lacks ab-

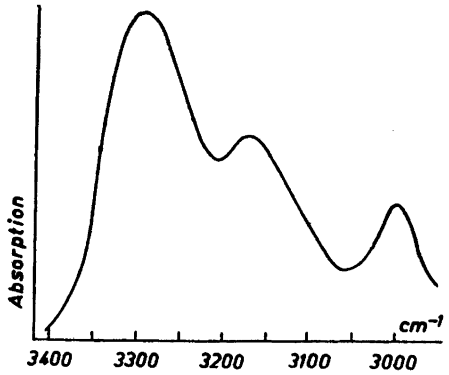

Fig. 3. I.R.-spectrum of phenyl acetic acid hydrazide in the solid state (0.5 % in KBr).

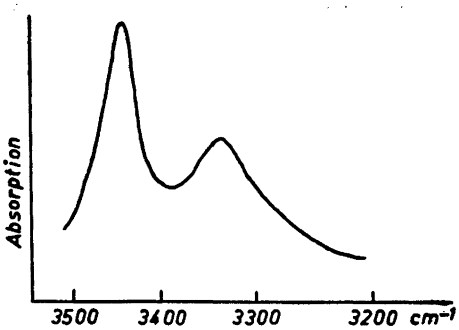

Fig. 4. I.R. spectrum of phenylacetic acid hydrazide (1 % in $CHCl_3$).

sorption at 3 450 cm^{-1}, instead an intense band is found centered around 3 300 cm^{-1}, a weaker broad band around 3 175 cm^{-1}, and furthermore a weak band at approximately 3 000 cm^{-1}. There is no doubt that a complete association takes place in the solid state, as the narrow band in the solution must be assigned to a free —NH-group, while the broad band in the spectrum of the solid substance is due to a bonded —NH-group.

The absorption at 3 340 cm^{-1} found in the chloroform solution may consist of two bands unresolved by the available spectrograph. However, the absorption at this frequency increases more rapidly at increasing concentrations than the absorption at 3 450 cm^{-1}. This fact may be explained by association in concentrated solutions.

On the basis of the measurements carried out here it is, however, difficult to determine in which form association takes place. It may be mentioned that during the time this work was done, a publication by Jensen [11] on X-ray crystallographic investigations of *iso*nicotinic acid hydrazide appeared, in which the author claims the existence of hydrogen bonds of the type NH---N. However it seems most unreasonable not to consider hydrogen bonds of the NH---OC type, solely because the frequency of the carbonyl group in the 6 μ region is displaced significantly to higher frequencies when passing from the solid state to dilute solutions.

Acknowledgment. The author is indebted to W. O. Godtfredsen and I. S. Vangedal for supplying the compounds, and to L. Fleischer-Olsen and G. Bay-Christiansen for assistance in recording the spectra.

X-Ray Investigations on Uranyl Hydroxides

I. The Crystal Structure of β-$UO_2(OH)_2$

GUNILLA BERGSTRÖM and GEORG LUNDGREN

Research Institute of National Defence, Dpt. 1, Sundbyberg 4; Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70; Institute of Inorganic and Physical Chemistry, University, Stockholm, Sweden

β-$UO_2(OH)_2$ has a face-centered orthorhombic cell with the dimensions $a = 6.295 \pm 0.005$ Å, $b = 5.636 \pm 0.005$ Å, and $c = 9.92_9 \pm 0.01$ Å. The unit cell contains four formula units. The atomic positions can be described by the space group No. 69 *Fmmm* as given on p. 678. The structure is built up of pseudotetragonal layers connected by van der Waals contact between the UO_2^{2+} groups. Every uranium atom is joined through four atoms to its neighbouring U atoms. The positions of the oxygen atoms were inferred from geometrical arguments and considerations of the strength of the U—O bonds.

In connection with an X-ray investigation of "uranates" undertaken at these institutes by Bergström and Sillén [1], it was of interest to know the crystal structure of a pure uranyl hydroxide. However, in the literature only a preliminary structure determination of a uranyl hydroxide, *viz.* α-$UO_2(OH)_2$, has been published (Zachariasen) [2]. The positions of the uranium atoms in the unit cell are given, but the parameters of the oxygen atoms are not discussed. Other investigations [2] are mainly concerned with the identification of different phases of $UO_2(OH)_2(H_2O)_x$. Thus, since no complete structure determination seems to have been published, we thought that an investigation of such a structure would be worth while.

In Gmelin's Handbuch some papers on the preparation of crystalline uranyl hydroxides are cited. The best of the methods described seemed to be thermal hydrolysis of uranyl acetate solutions [3,4]. In this way we were able to prepare some different uranyl hydroxides in a crystalline form suitable for single crystal X-ray work. The structure determination of one of them is dealt with here. It has been called β-$UO_2(OH)_2$ for reasons to be given at the end of this paper. Structure studies on some of the other phases will be published in subsequent papers.

PREPARATION OF THE CRYSTALS

A solution of uranyl acetate containing 1 g $UO_2(CH_3COO)_2$ in 100 ml water was heated in a sealed glass tube at 105—110° C for about 120 hours, after which a yellow, crystalline precipitate had formed. The crystals were filtered off and dried in air. Under the microscope they proved to be either yellow, transparent, six-sided plates or yellow needles about 0.1—0.2 mm in length. They often grew together in clusters.

X-ray powder photographs were taken with focussing cameras of the Phragmén type, first of the original mixture of plates and needles, and then only of picked-out plates. The same patterns were obtained. However, on comparing the observed values of $\sin^2\Theta$ with those calculated from the cell dimensions obtained from single crystal photographs, we found that some of the weaker lines of the powder photograph did not fit in. As no indication of a superstructure was found in the single crystal photographs, we concluded that the preparation contained one or more phases as impurities. We also tried to index the extra lines assuming the impurity to be α-$UO_2(OH)_2$ [2], but the attempt was not successful.

Analysis. Since the crystals were prepared from a solution of uranyl acetate we tested them for acetate ions with lanthanum nitrate and iodine before they were analysed quantitatively [5]. The result was negative and we concluded that the compound contained only uranium, oxygen, and hydrogen. The uranium content was determined by igniting the sample at 750° C and weighing the residue as U_3O_8. The water was determined by Brush [6] and Penfield's [7] method, described by Kolthoff and Sandell [8].

	Found		Calculated for $UO_2(OH)_2$
% UO_2	93.0	93.2	94.08
% H_2O	5.9	6.1	5.92
Density	5.72	5.72	5.73

The analyses indicate the formula $UO_2(OH)_2$. Since, however, the powder photographs show that the preparation contains more than one phase the analytical data alone do not allow a definite conclusion. As will be shown below, the geometrical arguments for the positions of the oxygen atoms also support the formula $UO_2(OH)_2$.

UNIT CELL AND SPACE GROUPS

A crystal was set with the longest diagonal of the plate as rotational axis; it was called the a axis. Using CuK radiation, rotation and the following Weissenberg photographs were taken: $0kl$ (with 4 × 23 reflections registered), $1kl$ (with 4 × 16 reflections registered) and $2kl$ (with 4 × 19 reflections registered). From these photographs the following approximate cell dimensions of the orthorhombic unit cell were found: $a = 6.2_9$ Å, $b = 5.6_3$ Å, and $c = 9.9_3$ Å. The c axis is perpendicular to the plate. Rotation and Weissenberg photographs were also taken of the needles, which proved to have the same cell dimensions and symmetry as the plates. The axis of the needles was [110].

From the powder photographs (*cf.* Table 1) more accurate cell dimensions were calculated:

$$a = 6.295 \pm 0.005 \text{ Å}$$
$$b = 5.636 \pm 0.005 \text{ Å}$$
$$c = 9.92_9 \pm 0.01 \text{ Å}$$
$$V = 352.4 \text{ Å}^3$$

All reflections hkl with $h + k$ = odd or $k + l$ = odd are systematically absent. This is characteristic of the space groups No. 69 $Fmmm$, No. 42

Table 1. Powder photographs of β-$UO_2(OH)_2$. CrK radiation $\lambda_{CrK\alpha} = 2.2909$ Å.

The horizontal lines mark the boundaries between the angular ranges of the three different focussing cameras used. Reflections systematically absent in the space group *Fmmm* have been omitted. Reflections coinciding with β reflections are given in brackets. Reflections having no corresponding $\sin^2\Theta$ are assumed to belong to the phase not investigated. In the powder photographs there is an absorption and orientation effect favouring reflections with high *l* indices.

*Fmm*2, and No. 22 *F*222. The reflections recorded in the Weissenberg photographs were all strong and of much the same intensity, apart from the general decrease in intensity always found with increasing Θ.

Positions of the uranium atoms

The plausible space groups demand that there should be $4n$ uranium atoms in the unit cell (where n is an integer). From the volume of the cell we can calculate that, for $n = 1$, $d_{calc} = 5.73$ (assuming the formula as $UO_2(OH)_2$). As the observed density is 5.72 and as the major part of the preparation seems to consist of the phase investigated, we could then safely say that there are

4 U atoms per unit cell. We may arbitrarily choose their positions as 4(*a*) in *Fmmm*, 4(*a*) in *F*222 or 4(*a*) with $z = 0$ in *Fmm*2. All these positions have the coordinates 000; $\frac{1}{2}\frac{1}{2}0$; $\frac{1}{2}0\frac{1}{2}$; $0\frac{1}{2}\frac{1}{2}$, corresponding to a face-centered uranium lattice.

Previous data on uranium-oxygen coordination

In addition to the uranium atoms there are oxygen and hydrogen atoms in the unit cell. The positions of these light atoms could not be determined from the intensities of the reflections, and thus they had to be inferred from considerations of the interatomic distances and the bond strength of the U—O bond.

All oxygen compounds of U(VI) hitherto studied by X-ray methods, except α-UO_3, seem to contain uranyl ions UO_2^{2+}. In the "uranates" investigated ($CaUO_4$, $SrUO_4$, $BaUO_4$, Li_2UO_4, Na_2UO_4, K_2UO_4, $MgUO_4$) [9-11], the uranium atoms are connected by oxygen bridges forming $(UO_2O_2)_\infty^{2n-}$-layers or chains perpendicular, or almost perpendicular, to the uranyl groups.

In $BaUO_4$ and $MgUO_4$ each oxygen bridge connects two neighbouring uranyl groups, resulting in pseudo-tetragonal $(UO_2O_2)_\infty^{2n-}$-layers with single oxygen bridges for $BaUO_4$ [10] and $(UO_2O_2)_\infty^{2n-}$-chains with double oxygen bridges for $MgUO_4$.[11] The distances U—O_{bridge} are 2.12—2.22 Å.

In the other "uranates" mentioned each UO_2^{2+} group is connected with its next six UO_2^{2+} neighbours by oxygen atoms, each of which is shared between three uranyl groups, and thus a pseudo-hexagonal lattice is formed. In these compounds the distances U—O_{bridge} are 2.3 Å.

In α-UO_3 the coordination uranium-oxygen is the same as in the pseudo-hexagonal "uranates". However, the "uranyl" oxygen atoms are shared between two uranium atoms forming chains of U—O—U—. . . . instead of discrete UO_2^{2+} groups.

A compilation of all observed U—O distances has been given by Zachariasen [12]. He found that they all lay on a smooth curve when they were plotted as a function of the bond strength s of the U—O bond.

Positions of the oxygen atoms

The positions of the oxygen atoms were discussed from geometrical arguments without assuming any special space group. We felt it justified to assume that the O—O distances are not less than 2.6 Å and that the distances between interacting U and O atoms are within the limits 1.6—2.5 Å (*cf.* Zachariasen [12]).

If none of the oxygen atoms were shared between two or more uranium atoms, the structure would be built up of separate molecules and every uranium should be surrounded by only four oxygen atoms. This is not very probable as the coordination number of U is 6—8. Moreover, crystals of $UO_2(OH)_2$ built up of separate molecules should be easily soluble in water, as, for instance, is H_2SO_4. The crystals are, however, very sparingly soluble in water, and from this reason too the configuration seems rather improbable. Thus it is likely that the uranium atoms are joined by oxygen (or OH^-) bridges to form infinite chains, layers, or a three-dimensional framework, as they are in the "uranates", which are difficult to bring in solution.

Now, every uranium atom is surrounded by four other uranium atoms at a distance of 4.22 Å $= \sqrt{\left(\frac{a}{2}\right)^2 + \left(\frac{b}{2}\right)^2}$, all other U—U distances being larger than 5.63 Å.

If the oxygen atoms in the bridges were to be shared between three or more uranium atoms, the U—O distances would be larger than 2.8 Å, *i. e.* too long for a U—O interaction. We thus concluded that each of them is in contact only with two uranium atoms.

The shared oxygen atoms (O_{II}) are then probably situated between the uranium atoms, 4.22 Å apart, as the U—O_{II} distances would otherwise be longer than 2.8 Å. The uranium atoms could then be joined either by double oxygen bridges leading to the formation of chains, as in $MgUO_4$[11], or by single oxygen bridges leading to the formation of pseudo-tetragonal layers, as in $BaUO_4$[10].

In the first case the distances U—O_{II} would be 2.48 Å, if the oxygen atoms were situated 2.60 Å apart. According to Zachariasen [12], this would indicate a U—O bond strength of about 0.45 units. As there are four such bonds we would have 6—4 × 0.45 = 4.2 units left for bonds to the remaining oxygen atoms O_I in the coordination polyhedron, leading to the very short bond distances U—O_I = 1.6 Å. (The shortest experimentally determined [13] distance U—O_I is 1.76 Å in $K_3UO_2F_5$ corresponding to a bond strength of 1.63. The distance U—O_I = 1.58 Å in $RbUO_2(NO_3)_3$ was estimated and is therefore very uncertain [14].)

In the second case when the uranium atoms are joined by single oxygen bridges the distance U—O_{II} would be $\frac{1}{2}$ × 4.22 Å = 2.11 Å corresponding to a bond strength of about 0.95. The bond strength left for bonds to the two remaining oxygen atoms O_I in the coordination polyhedron would then be 2.2, giving a distance U—O_I = 2.0 Å, which is close to those observed for the uranyl groups in the "uranates" mentioned above.

From these considerations the second case with single oxygen bridges seemed to be the most plausible and we concluded that the bridging oxygen atoms are situated in the following way:

8 O_{II} in *Fmmm* 8(*e*): $(0,0,0;\ 0,\frac{1}{2},\frac{1}{2};\ \frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0) \pm (\frac{1}{4},\frac{1}{4},0;\frac{1}{4},\frac{1}{4},\frac{1}{2})$

Thus the crystals contain pseudo-tetragonal layers similar to those in $BaUO_4$.

In all the "uranates" previously determined there are UO_2^{2+} ions with U—O = 1.76—2.08 Å, and thus it is plausible that our crystals also contain uranyl groups, perpendicular, or almost perpendicular, to the sheets. As we have found the unit cell to contain four uranium atoms there must be eight uranyl oxygen atoms (O_I) in addition to the eight bridging oxygen atoms (O_{II}), the approximate positions of which we have already found. The O_I atoms should then be arranged as follows:

8 O_I in *Fmmm* 8(*i*): $(0,0,0;\ 0,\frac{1}{2},\frac{1}{2};\ \frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0) \pm (0,0,z)$ with $z = 0.20$

The parameter $z = 0.20$ was determined from the distance U—O_I = 2.0 Å expected from the bond strength $s = 1.1$ in the uranyl bond (*cf.* above).

In this way we have found the positions of 4 U and 16 O atoms in the unit cell, corresponding to the formula $UO_2(OH)_2$, as indicated by the analysis. However, since the chemical analysis was not quite conclusive as the sample contained some impurities, and since the structure seemed to be very open we concluded to investigate whether there could be more oxygen atoms present in the unit cell.

We found then that the most favourable positions for any additional O atoms (O_{III}) would be at $(0,0,0; \frac{1}{2},\frac{1}{2},0; 0,\frac{1}{2},\frac{1}{2}; \frac{1}{2},0,\frac{1}{2}) \pm(\frac{1}{4},\frac{1}{4},\frac{1}{4})$. An investigation showed, however, that even if the structure would be distorted a little some $O—O_{III}$ distances came out rather short (2.4 Å or less) and thus it did not seem probable that the unit cell contained any additional oxygen atoms at all. This also supports the conclusion made from the analytical data that the formula of the compound should be $UO_2(OH)_2$

Positions of the hydrogen atoms

As there are 4 O atoms per U(VI) atom electrical neutrality demands 2 H atoms per U, and thus the cell must contain 8 H. They can be situated close to the uranyl oxygen atoms (O_I) or close to the bridging oxygen atoms (O_{II}). From the considerations of the bond strength of the U—O bond the first seems to be rather plausible as the total bond strength for O_I is 1.1 when the total bond strength for O_{II} is 1.9. On the other hand, investigations on the hydrolysis of uranyl ions [15,16] show that UO_2^{2+} groups do not seem to attract protons in acidic solutions, which would demand that in the crystals of $UO_2(OH)_2$ we would have the hydrogen atoms situated at the O_{II} atoms forming OH^- ions.

At present we could not say which of the two possibilities is the correct one even if the argument in the second case seems to be the most convincing.

In both cases the hydrogen atoms may form hydrogen bonds to the neighbouring oxygen atoms.

Final structure proposition

We thus consider that the crystals have the following structure:

Space group: No. 69 *Fmmm* with

$(0,0,0; 0,\frac{1}{2},\frac{1}{2}; \frac{1}{2},0,\frac{1}{2}; \frac{1}{2},\frac{1}{2},0) \pm$

4 U in 4(*a*): 0,0,0

8 O_I in 8(*i*): 0,0,*z* with $z = 0.20$

8 O_{II} in 8(*e*): $\frac{1}{4},\frac{1}{4},0; \frac{1}{4},\frac{1}{4},\frac{1}{2}$

DISCUSSION OF THE STRUCTURE

Projections of the structure on the *xy* and *xz* planes are shown in Figs. 1 and 2. The structure is built up of layers $UO_2(OH)_2$ consisting of linear UO_2^{2+} ions (perpendicular to the sheets) joined to each other through oxygen atoms, two uranyl ions sharing one O atom. The layers are perpendicular to the *c*

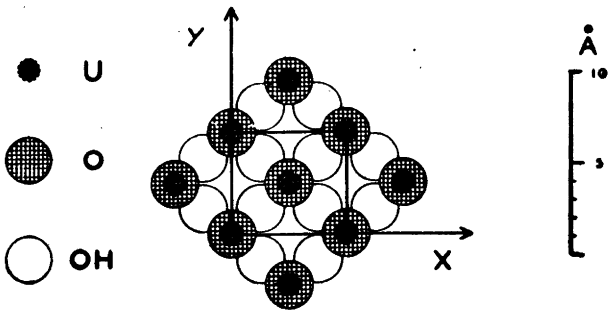

Fig. 1. Part of the structure of β-$UO_2(OH)_2$ projected on the xy *plane. Only atoms with* z *within the limits* $-0.25 \leqq z \leqq 0.25$ *have been marked out.*

axis, and they are connected to each other by van der Waals forces between the uranyl groups.

The distances between the atoms in the same layer would be:

$$\begin{aligned} &U\ -2\ O_I\ ,\ O_I\ -U && = 2.0\ \text{Å} \\ &U\ -4\ O_{II},\ O_{II}-2\ U && = 2.11\ \text{Å} \\ &O_I\ -4\ O_{II},\ O_{II}-2\ O_I && = 2.8_4\ \text{Å} \\ &O_{II}-4\ O_{II} && = 2 \times 2.82,\ 2 \times 3.15\ \text{Å} \end{aligned}$$

The layers support each other by:

$$O_I-4\ O_I = 2 \times 3.0_5,\ 2 \times 3.3_6\ \text{Å}$$

These figures are all within the normal range, showing that O—O interaction also occurs in the lattice. However, the bond lengths may be inaccurate by one or a few 0.1 Å since the positions of the oxygen atoms have been inferred from geometrical arguments.

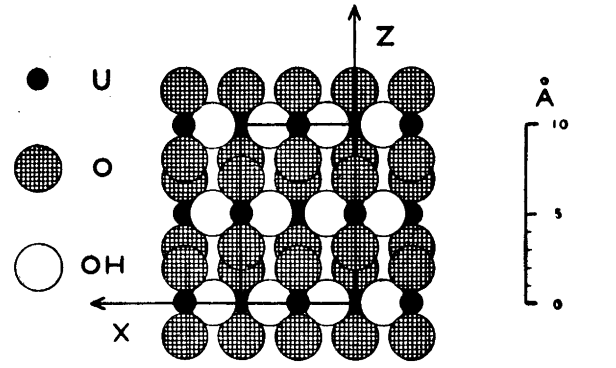

Fig. 2. The structure of β-$UO_2(OH)_2$ projected on the xz *plane.*

During the Manhattan project Zachariasen [2] made a preliminary structure determination of an orthorhombic uranyl hydroxide, α-$UO_2(OH)_2$. Its cell dimensions were found to be $a = 6.86 \pm 0.03$ Å, $b = 4.27 \pm 0.03$ Å, $c = 10.19 \pm 0.06$ Å, $V = 299$ Å^3 and the phase is thus different from ours. Zachariasen determined the positions of its uranium atoms but not those of its oxygen atoms. He found that every uranium is surrounded by six others at distances 4.05—4.27 Å in pseudohexagonal layers. Zachariasen's α-$UO_2(OH)_2$ structure then seems to resemble the hexagonal "uranates", whereas our structure is closely related to the tetragonal "uranates", where every uranium atom is surrounded by four others at the distance 4.22 Å.

In *"The Chemistry of Uranium"* [2] four phases of $UO_2(OH)_2$ are described. Two of them (α and β) are said to be orthorhombic, and as Zachariasen's crystals were called α-$UO_2(OH)_2$, the phase described in our paper should be β-$UO_2(OH)_2$. However, the data are very meagre, and the identity between our crystals and the β phase there could not be definitely stated.

We wish to thank Professor Lars Gunnar Sillén and Dr. Arne Magnéli for many valuable discussions in connection with this work. We are also very much indebted to Professor Gustaf Ljunggren, FOA 1, and Professor Arne Ölander, University of Stockholm, for their kind interest.

Short Communications

Some Differences between Solubilization in Bile Salt and Paraffin Chain Salt Solutions

PER EKWALL, ARMAS STEN and ARNE NORMAN*

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Similarly as other association colloids, the bile acid salts are good solubilizers of lipophilic substances, but there exist clear differences between the solubilization processes in solutions of the bile salts and the association colloids of the paraffin chain salt type. In both cases solubilization of hydrocarbons begins at a well-defined low colloid concentration and proceeds stepwise as the colloid concentration is increased [1-4]. The concentrations separating the solubility ranges are more or less clearly definable even when substances other than hydrocarbons are solubilized (but in some cases slightly displaced owing to the interaction between the solubilized substance and the colloid). In other respects marked differences are noted when polar-nonpolar substances such as straight-chain alcohols and fatty acids are solubilized. Whereas the solubilization of these substances begins in the bile salt solutions at the same concentration as the solubilization of hydrocarbons, in paraffin chain salt solutions the solubilization begins, although in a limited degree, at a concentration, the L.A.C., that is far below that where the hydrocarbon solubilization begins [4-6]. In the bile salt solutions the solubilization of alcohol continues until the micelles become saturated with alcohol, after which the excess of alcohol separates in the free form. In the paraffin chain salt solutions the solubilization in many cases ends when a mesomorphic phase composed of alcohol, association colloid and water separates. The added long-chain alcohols do not influence the conductances of the bile salt solutions (as far as we have investigated), but do alter the conductances of the paraffin chain salt solutions (Fig. 1 A). In the latter case even small amounts of alcohol bound by the micelles in the solutions alter the conductance, but a rapid decrease in the conductance occurs as soon as the system becomes heterogeneous [6-7]. Similar differences are also noted when fatty acids are solubilized by bile salt and fatty acid soap solutions.

The fact that the conductances of bile salt solutions are not altered by the alcohols (in any case not by small amounts of the additive) suggests that the charge distribution on the surface of the bile salt micelle does not change when alcohols are incorporated in the micelles, whereas the charge distribution is, however, altered when the alcohols are incorporated in fatty acid soap and alkyl sulphate micelles. That the mesomorphic phase does not separate from bile salt solutions may possibly be due to the fact that hydrophilic properties of the micelle surface of the bile salt micelles are not diminished to the same extent by alcohols and fatty acids as when the latter are incorporated in the paraffin chain salt micelles.

The polar-nonpolar compounds mentioned are known to increase the power of paraffin chain colloids to solubilize hydrocarbons [5,8]. This is illustrated by the curves 1 a and 1 b in Fig. 1 B which shows that the solubility of *p*-xylene in 0.04 M sodium myristate solution increases as much as 60—70 % when increasing amounts of decanol or myristic acid are added to the solution. In bile salt solutions the effect of the addition is the opposite. This is evident from curve 2 which shows the influence of added decanol on the solubility of *p*-xylene in a 0.1 M sodium cholate solution, and from curves 3 a and 3 b (in Fig. 1 B) which

show the influence of decanol, nonylic acid and heptylic acid on the solubility of *p*-xylene in 0.09 M sodium taurodesoxycholate solution. As long as the amount of polar-nonpolar additive is relatively small, the xylene solubility either remains constant or decreases slowly, but when the amount added exceeds a certain value, the solubility of xylene decreases rapidly. (In order to facilitate the comparison, the content of the polar-nonpolar compound has been expressed as a percentage of the maximum solubility of the compound in the pure colloid solution in question).

It has, as known, been concluded (above all on the basis of X-ray studies) that the solubilized hydrocarbon molecules are built in between the palisade layers of the paraffin chain colloid micelles (or in the centre of the

spherical or spheroidal micelles); the molecules of the alcohols and fatty acids are, however, incorporated between the colloid molecules in the palisade layers and thus increase the amount of micelle-forming matter. Solubilization data of the type on which curves 1 a and 1 b in Fig. 1 B are based have been considered to support this view and to prove the existence of two loci of solubilization in the micelles [8,9].

The experiments described in curves 2 and 3 in Fig. 1 B show that the alcohols and fatty acids on one hand and hydrocarbons on the other, are initially solubilized quite independently by the bile salt micelles. This can be considered to indicate that the polar-nonpolar compounds and hydrocarbons are solubilized in different loci in the bile salt micelles. A marked difference as compared with the paraffin chain colloids is, however, that the polar-nonpolar compounds are built in the bile salt micelles in such a manner that the power of the micelles to solubilize hydrocarbons is not increased; on the contrary, the incorporation of larger amounts of the polar-nonpolar compounds progressively diminishes the power to solubilize hydrocarbons. It is thus evident that the mode in which the polar-nonpolar compounds are built in the micelles differs for the bile and paraffin chain salts.

One of the present authors has called attention to the fact that the maximum amounts of fatty acids that sodium taurocholate solutions are able to solubilize are so great [3] (from about 2 moles of nonylic acid to 5 moles of caproic acid per mole of taurocholate in 0.09 M solution) that it must be assumed that the structure of the micelles is altered to such an extent that mixed micelles with completely new properties are formed. Also the maximum amounts of long-chain alcohols solubilized by bile salt micelles are fairly large (1—2 moles per mole of the bile salt). According to the data presented here altered properties of the micelles become apparent only after the mole ratio of polar-nonpolar compound and bile salt exceeds a certain value, which is about 0.14 for decanol and sodium cholate, 0.34 for decanol and sodium taurodesoxycholate, and 0.8 for nonylic and 1.3 for heptylic acid and sodium taurodesoxycholate. A change in micellar structure apparently occurs only after these values of the ratio are exceeded.

All the above mentioned data show that there exist important differences in the solubilization mechanism in the case of bile salts and paraffin chain salts, particularly in regard to the location of solubilized molecules in the micelles and the interaction between the solubilizer and solubilizate. This is evidently connected with essential differences in the structures of the micelles of the two types of association colloids.

Can Micelles be Treated as Ideal Mixtures of Ions and Neutral Molecules?

JÜRI SEIM, LARS GUNNAR SILLÉN and ULF ULFVARSON

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

In the last few years, attempts have been made in this Institution to study equilibria involving micelles of carboxylic acids such as lauric acid, $C_{11}H_{23}COOH$ = HL, and amines like dodecyl amine $C_{12}H_{25}NH_2$ = D. Emf titrations have been made (using glass or hydrogen electrodes, sometimes Ag, AgL electrodes) with a practically constant ionic medium, in order to keep the activity factors constant. In each titration, the total concentration $B = [HL]_t + [L^-]_t$ or $[D]_t + [DH^+]_t$ has been kept constant, and the data have been given in the shape of a plot $Z(\log h)_B$,

spherical or spheroidal micelles); the molecules of the alcohols and fatty acids are, however, incorporated between the colloid molecules in the palisade layers and thus increase the amount of micelle-forming matter. Can Micelles be Treated as Ideal Mixtures of Ions and Neutral Molecules?

JÜRI SEIM, LARS GUNNAR SILLÉN and ULF ULFVARSON

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

In the last few years, attempts have been made in this Institution to study equilibria involving micelles of carboxylic acids such as lauric acid, $C_{11}H_{23}COOH$ = HL, and amines like dodecyl amine $C_{12}H_{25}NH_2$ = D. Emf titrations have been made (using glass or hydrogen electrodes, sometimes Ag, AgL electrodes) with a practically constant ionic medium, in order to keep the activity factors constant. In each titration, the total concentration $B = [HL]_t + [L^-]_t$ or $[D]_t + [DH^+]_t$ has been kept constant, and the data have been given in the shape of a plot $Z(\log h)_B$,

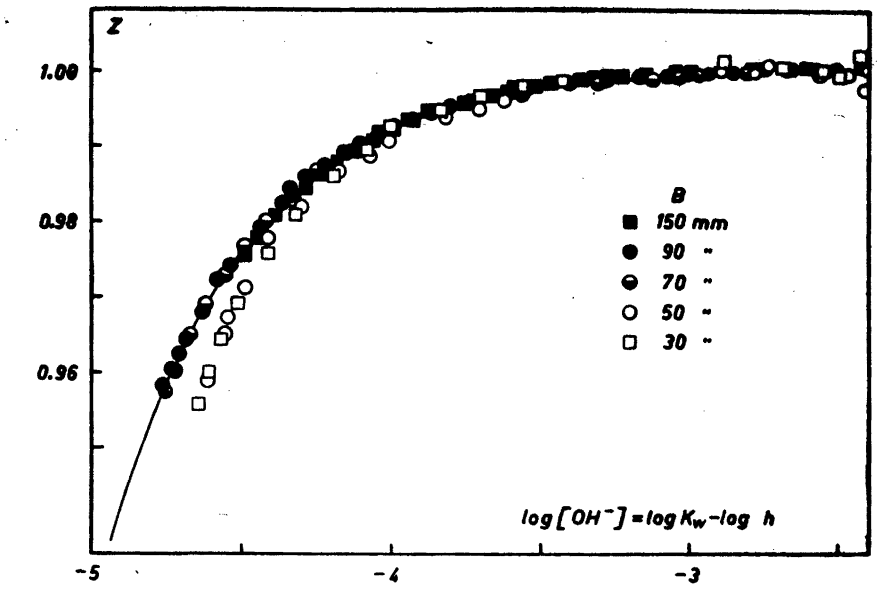

Fig. 1. Z (log K_w *—log* h)$_B$ *for potassium laurate solutions in 1 m* KNO_3 *at 25° C. Points: experimental points for five total concentrations. Curve: calculated for monoprotic acid with* $pK_w - pK_a = 6.11$.

where $h = [H^+]$ and Z is the average charge per unit, thus $BZ = [L^-]_t$ or $[DH^+]_t$. These experiments have met with many difficulties and are still in progress. We would however like to draw attention to one of the results obtained.

Fig. 1 gives the data $Z(\log h)_B$ for lauric acid, obtained by one of us (J.S.). Ionic medium 1 m $K^+(NO_3^-)$, 25° C, glass electrode. The abscissa is really $\log [OH^-] = \log K_w - \log h$. In the range $Z = 1.0$ to 0.95, reversible equilibria were achieved since the same curves were obtained when HNO_3 or KOH was added; for lower values of Z, precipitates appeared which dissolved but slowly on addition of KOH. For lower values of B, there were also difficulties with the equilibria.

In the concentration range given, 30 to 150 mm, the major part of the laurate groups would be present in the form of micelles. Using the method of Ekwall and Harva [1], we found the maximum concentration of free L^- to be about 6 mm at 50° C. From data of Corrin and Harkins [2], one may estimate the critical concentration to be about 2.5 mm.

One may calculate what the shape of $Z(\log h)_B$ would have been under various simple assumptions concerning the phases and dissolved species present. At equilibrium between two solid phases of constant composition, such as KL(s) + HL(s), or KL(s) + KHL_2(s), $\log h$ would be constant. If the main reaction is equilibrium between L^- in solution and KHL_2(s) or HL(s), the slope of $Z(\log h)$ would also have been much steeper than that actually found. Moreover, the curve would have shifted with varying values of B.

Assuming equilibrium between KL(s) and HL or HL_2^- in solution, one would get curves of the right shape, but the curves would have been shifted with an amount equal to the shift in log B. According to experiment, the points for 70, 90, and 150 mm practically coincide, and the deviations for 30 and 50 mm are only about 0.1 units, whereas log 150/30 = 0.7. Thus, none of these assumptions is valid.

However, a very good fit is found with the simple curve $Z = K_a h^{-1} (1 + K_a h^{-1})^{-1}$, calculated for the dissociation of a monoprotic acid, with $pK_w - pK_a = 6.11$. Assuming $pK_w \approx 13.7$ one obtains $pK_a \approx 7.6$. The simple explanation that the solution

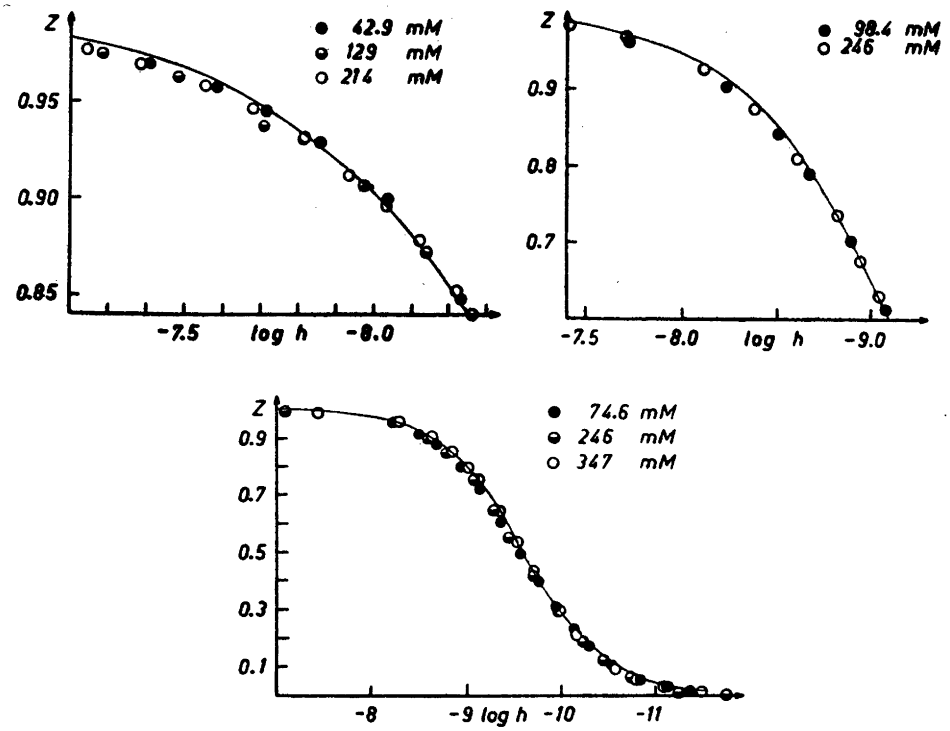

Fig. 2 a—c. $Z(\log h)_B$ *for dodecyl ammonium chloride solutions in 0.5 M NaCl at 25° C with a) 1.70, b) 4.75, c) 6.78 M* C_2H_5OH. *Curves: calculated for simple equilibrium* $DH^+ \rightleftharpoons D + H^+$, *with a)* $pK_a = 8.97$, $pK_w = 13.96$; *b)* $pK_a = 9.27$, $pK_w = 14.03$; *c)* $pK_a = 9.62$, $pK_w = 14.09$.

would contain only single molecules HL and L^- is ruled out already by the fact that, for lower values of B, the curves $Z(\log h)_B$ break away from the curve in Fig. 1. Nor would it be consistent with what is known about the micellar behavior.

The simplest way of expressing our results is perhaps treating the micelles formally as a separate phase, a mixture of L^- and HL (perhaps also K^+, NO_3^-, and H_2O from the ionic medium). Then our results would imply that, in the range where this phase is stable ($x_{HL} = 0$ to 0.05), it is approximately an ideal mixture of L^- and HL. A similar picture has been given by Stainsby and Alexander [3]; at that time it was supported only by measurements of the hydrolysis of pure soap solutions with varying ionic strength.

One might speculate on why the acid is so much less willing to give off a proton than normal carboxylic acids in aqueous solution ($pK_a = 4$ to 5). A related fact is the observation of Ekwall [4] that monolayers of myristic acid show a large ionization effect around pH ≈ 8—10.

Fig. 2 gives analogous results, obtained by one of us (U.U.), for dodecyl ammonium chloride (DH^+Cl^-). The ionic medium was 0.5 M (Na^+)Cl^-, with three different concentrations of C_2H_5OH (1.70, 4.75, and 6.78 M). For each concentration of C_2H_5OH, two or three different total concentrations B were used, all in a range in which the micelles would predominate, even without adding NaCl, according to the conductivity data of Ralston and Hoerr [4].

In this case too, the $Z(\log h)$ curves seem to be independent of the total concentration B, and to coincide surprisingly well with those calculated for a simple equi-

librium between dissolved B and BH^+, with $pK_a \approx 8.9$ to 9.6. If the previous conductivity data have been interpreted correctly, we are once more brought to the approximation of the micelle as an ideal mixture; for D and DH^+, the range of Z is moreover much wider than it was for lauric acid.

The work on lauric acid has been supported by a grant from *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)*.

Preparation of Di-*p*-nitrobenzylphosphoryl chloride *via* the Corresponding Phosphite

GEORG FÖLSCH

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

The very promising phosphorylating reagents recently introduced by Leonidas Zerwas and collaborators, *e. g.* di-*p*-nitrobenzylphosphoryl chloride, were originally synthesized by procedures involving silver salt esterifications [1]. For preparation of these reagents in large batches it seems to be preferable to use the phosphite route [2,3]. In connection with syntheses of phosphopeptides [4] we have obtained di-*p*-nitrobenzyl phosphite in good yield from *p*-nitrobenzyl alcohol and phosphorus trichloride. This phosphite gives, as expected, the desired phosphoryl chloride quantitatively by chlorination with sulphuryl chloride.

Experimental. Di-p-nitrobenzyl phosphite. To a vigorously stirred solution of 27.6 g phosphorus trichloride (1 mole) in 600 ml dry benzene of room temperature a warm solution of 61.2 g *p*-nitrobenzyl alcohol (2 moles) and 48.4 g dimethylanilin (2 moles) in 200 ml benzene was added in small portions within one hour. After an additional hour of stirring, 30.6 g *p*-nitrobenzyl alcohol (1 mole) in 200 ml benzene was added within 20 minutes. The mixture was stirred for a further two hours and then left overnight. The benzene solution was washed with water (3 × 200 ml), 5 N ammonia (2 × 200 ml), water (2 × 200 ml) and dried over anhydrous sodium sulphate. By addition of light petroleum, di-*p*-nitrobenzyl phosphite separated as white crystals. The yield was 43.5 g (62 % of the theoretical). The phosphite was recrystallized from ethanol or chloroform-cyclohexane. M. p. 75°. (Found: C 47.70; H 3.70; N 7.91; P 9.00. Calc. for $C_{14}H_{13}O_7N_2P$: C 47.70; H 3.72; N 7.96; P 8.81).

Chlorination. To a suspension of 35.3 g phosphite in 250 ml carbon tetrachloride 8 ml sulphuryl chloride was added dropwise with shaking. Dry nitrogen was slowly bubbled through the mixture and the temperature was held under 20°. After 20 minutes the solvent was removed *in vacuo* and the solid dissolved in chloroform. Addition of light petroleum gave white crystals of di-*p*-nitrobenzylphosphoryl chloride (36.0 g = 93 %) with the m. p. 107—108°. The mixed melting point with phosphoryl chloride prepared according to Zerwas [1] showed no depression. (Found: P 7.91; Cl 8.89. Calc. for $C_{14}H_{12}O_7N_2PCl$: P 8.00; Cl 9.16).

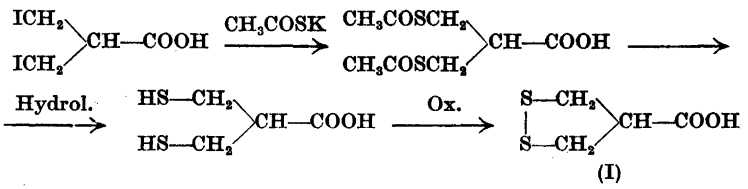
The Preparation of 1,2-Dithiolane-4-carboxylic Acid

LENNART SCHOTTE and HOLGER STRÖM

Chemical Institute, University of Uppsala, Uppsala, Sweden

In order to complete an investigation of the substituent influence on the spectral behaviour of the disulphide group in 1,2-dithiolane derivatives [1,2], it seemed important to include 1,2-dithiolane-4-carboxylic acid.

The related dimercaptan, β,β′-dimercapto-*iso*butyric acid, was first obtained in 1948 by Jansen [3] upon reduction of a sulphur-containing polymeric material isolated from asparagus juice. The mercapto acid appeared to be the first dithiol substance reported from a natural source. The structural proof involved identification of the methylated compound with authentic β,β′-di-methylmercapto-*iso*butyric acid (obtained from the related di-iodo acid and methyl mercaptan). Recently the preparation of β,β′-dimercapto-*iso*butyric acid was described by Corse and Jansen [4]. Reduction of β,β′-dibenzylmercapto-*iso*butyric acid with sodium in liquid ammonia yielded the expected substance, whereas hydrolysis of the related di-*iso*thiuronium salt was unsuccessful.



1,2-Dithiolane-4-carboxylic acid (I) has now been prepared from the mercaptan (without intermediate isolation) by oxidation with oxygen [5]. The β,β′-dimercapto-*iso*butyric acid was obtained from the corresponding di-iodo compound [3,6] and potassium thiolacetate with subsequent hydrolysis of the bis-acetyl substance formed.

The spectrochemical (UV and IR) and polarographic properties of (I) have been discussed in a previous communication [2] where also comparison was made with the 3-isomer, prepared by Claeson [7].

The presence of disulphide in asparagus juice has been qualitatively shown by Jansen. His results might suggest that the disulphide material present in asparagus is of polymeric nature but the experience of the present authors indicates that the conditions used by Jansen [3] were not mild enough to ensure the isolation of a possible monomer. As the 1,2-dithiolane system is reactive (*cf.* 6-thioctic acid) and cleavage of the S—S bond with formation of polymers readily occurs, it seems reasonable to assume the presence of (I) in the plant. In view of the properties of 6-thioctic acid it will therefore be very interesting to find out if the occurrence of the reactive ring system is in some way important for the biochemical processes in the rapidly growing asparagus.

Both the monomeric disulphide and the polymer give β,β′-dimercapto-*iso*butyric acid when reduced according to Fredga [8] with zinc in ammoniacal solution. The data of the mercapto acid coincide with those previously reported.

Experimental. 1,2-Dithiolane - 4 - carboxylic acid. 11 g (0.032 mole) of β,β′-diiodo-*iso*butyric acid was suspended in 40 ml of water and neutralized with an aqueous solution (40 ml) of 2.1 g (0.032 mole) of 86 % KOH. A solution of 5.2 g (0.0685 mole) of thiolacetic acid and 4.45 g (0.0685 mole) of 86 % KOH in 40 ml of water was added dropwise, and the mixture heated in an oil bath at 80° for 8 hours. Acidification with dilute H_2SO_4 caused precipitation of the bis-acetylmercapto acid as a heavy oil. After its separation the product

(I)

was dissolved in 100 ml of KOH water solution (containing 10 g (0.154 mole) of 86 % KOH). The mixture was kept at room temperature for 16 hours and then acidified (dil. H_2SO_4). The mercapto acid was extracted five times with ether. The substance remaining after spontaneous evaporation of the dried solvent was

The disulphide acid obtained was contaminated with polymeric material, which, however, could be removed by treatment with benzene in which the polymers are insoluble. Recrystallized from benzene-*cyclo*hexane (I) was obtained as transparent yellow prisms.

dissolved (without previous purification) in 400 ml of aqueous $NaHCO_3$ solution (containing 8.5 g (0.10 mole) of $NaHCO_3$). A small amount of $FeCl_3$ was added as a combined catalyst and indicator and oxygen bubbled through the mixture until the violet colour disappeared (about two hours). After acidification (dil. H_2SO_4) and removal of small amounts of polymeric material by filtration the product was extracted with ether (6 × 75 ml). The ether solution was dried with anhydrous Na_2SO_4 and the solvent evaporated *(in vacuo)*. 1.3 g (27 %) of crude acid (mixture of monomer and polymer) with m. p. 60—70° was obtained; after treatment with benzene for some minutes at room temperature it left an insoluble viscous substance. Evaporation of the solvent yielded 0.8 g (16.5 %) of dry acid (monomer) with m. p. 75—77°. This product was now recrystallized from benzene-*cyclo*hexane and obtained as transparent yellow prisms with m. p. 76.5—77.5°. (Found: Equiv. wt. 151.1; C 31.96; H 3.92; S 42.72; Mol.wt. 146. Calc. for $C_4H_6O_2S_2$ (150.22): Equiv. wt. 150.2; C 31.98; H 4.03; S 42.68; Mol.wt. 150).

β,β'-Dimercapto-isobutyric acid. 0.5 g of (I) or the related polymer (insoluble in benzene) was dissolved in 20 ml of 4 M ammonia, and the solution sucked through a layer of zinc powder four times. The reaction mixture was neutralized with dil. H_2SO_4 and the precipitated zinc mercaptide filtered. The acid was liberated and extracted with ether. Evaporation of the solvent gave the dimercapto acid, which crystallized after being kept for some days at —15°. M. p. 57—60°. (Found: Equiv. wt. 75.7. Calc. for $C_4H_8O_2S_2$ (152.22): 76.1).

Ein Beispiel für die Variationsmöglichkeiten in der Zusammensetzung der freien Aminosäuren in einer Pflanzenart

BARBARA BRAMESFELD und ARTTURI I. VIRTANEN

Laboratorium der Stiftung für chemische Forschung, Biochemisches Institut, Helsinki, Finnland

Im Sommer 1954 isolierten Virtanen, Uksila und Matikkala [1] α-Amino-γ-hydroxy-pimelinsäure aus *Asplenium septentrionale*. Das Pflanzenmaterial war in den Monaten Mai, Juni, Juli und August gesammelt und gesondert auf seinen Aminosäuregehalt geprüft worden. Alle Alkoholextrakte zeigten im zwei-dimensionalen Papierchromatogramm (Butanol-Essigsäure-H_2O und Phenol-Ammoniak) die in Fig. 1 A dargestellte Zusammensetzung. Vom gleichen Standort wurde im August 1955—Juni und Juli waren ausser-gewöhnlich trocken — *Asplenium septentrionale* geerntet und der Alkoholextrakt dieses Materials ergab das Chromatogramm in Fig. 1 B, auf dem zwischen Asparaginsäure und Glutaminsäure ein Ninhydrin-positiver Fleck sichtbar ist.

Die Trennung dieser Aminosäure von Asparaginsäure und Glutaminsäure gelang zum Teil an Dowex 50 (200—400 mesh) mit 0.2 M Natriumcitratpuffer pH 3,48 [2]. Die Lage der Aminosäure im Chromatogramm deutete auf die von Steward *et al.*[3] aus *Adiantum pedatum* und von Virtanen und Berg [4] aus *Phyllitis scolopendrium* isolierte γ-Hydroxy-γ-methylglutaminsäure hin.

Die Reduktion mit 66 % HJ (d = 1.9) und rotem Phosphor bei 130° C für 4 Stdn. ergab Methylglutaminsäure. Nach Oxydation mit $KMnO_4$ in saurer Lösung erhielten wir im Chromatogramm einen gelben Flecken im Bereich der neutralen Aminosäuren, den wir bisher nicht identifiziert haben. Die reine Substanz enthält Kristallwasser, welches durch Erhitzen auf 105° C für 16 Stdn. mit ½ H_2O pro Mol. bestimmt wurde. Dies stimmt mit dem von Steward nach Elementaranalyse gefundenen Wert überein.

Der Perjodat-test auf nachbarständige Hydroxy- und Aminogruppe war negativ. N-Bestimmung: gef. 8.03 %; theor. 7.53 %. Die Substanz verkohlt ab 165°. Papier-

dissolved (without previous purification) in 400 ml of aqueous $NaHCO_3$ solution (containing 8.5 g (0.10 mole) of $NaHCO_3$). Fig. 1. Zwei-dimensionale Papierchromatogramme (Butanol-Essigsäure-H_2O und Phenol-NH_3) der freien Aminosäuren in Asplenium septentrionale.

A: Sommer 1954 [1]. B: August 1955.
1 = Glycin, 2 = Alanin, 8 = Serin, 16 = Asparaginsäure, 17 = Glutaminsäure, 24 = Glutamin, 29 = γ-Aminobuttersäure, 71 = α-Aminopimelinsäure, 72 = Acetylornithin, x = 82 = α-Amino-γ-hydroxypimelinsäure, z = 83 = Lakton der α-Amino-γ-hydroxypimelinsäure, 87 = γ-Hydroxy-γ-methylglutaminsäure.

chromatographisch war die Aminosäure identisch mit der aus *Phyllitis scolopendrium* isolierten. Aus den Ergebnissen ist zu schliessen, dass es sich um γ-Hydroxy-γ-methylglutaminsäure handelt. Ein Versuch, die Aminosäure zu decarboxylieren, verlief sowohl mit *Escherichia coli* als auch mit einem Extract aus *Asplenium nidus*-Blatt negativ. Glutaminsäure wird unter gleichen Bedingungen von *Escherichia coli* quantitativ und von *Asplenium nidus*-Extrakt zum grössten Teil decarboxyliert. Wie Virtanen und Hietala [5] gezeigt haben, wird auch γ-Hydroxyglutaminsäure von *Escherichia coli* decarboxyliert.

Da keine Spuren von dieser Aminosäure im Pflanzenmaterial von Mai, Juni, Juli und August 1954 papierchromatographisch zu finden waren, scheint es, dass die Aminosäure in den *Asplenium*-Proben des Sommers 1954 entweder total fehlte oder in so kleinen Mengen vorkam, dass sie keinen sichtbaren Flecken auf dem Chromatogramm bildete. Zu bemerken ist, dass γ-Methyl-γ-hydroxyglutaminsäure bedeutend schwächere Farbe mit Ninhydrin gibt als Glutaminsäure, γ-Hydroxyglutaminsäure und γ-Methylglutaminsäure. Unsere Befunde zeigen wie vorsichtig man sein muss bei der Beurteilung der Aminosäurezusammensetzung einer Pflanzenart auf Grund der Befunde einer einzigen Wachstumsperiode.

Im Mai 1956 wurden nochmals *Asplenium septentrionale* Proben vom gleichen Standort in der Nähe Helsinkis und ausserdem eine kleine Menge *Aspl. septentrionale* aus Locarno (Schweiz) auf ihren Aminosäuregehalt untersucht. In beiden Proben liess sich γ-Hydroxy-γ-methylglutaminsäure nachweisen; es scheint also, dass γ-Hydroxy-γ-methylglutaminsäure meistens in *Aspl. septentrionale* vorkommt.

Infrared Conformational Analysis of 1,2-Dichloro-4,5-dibromo*cyclo*hexane (*a,a-e,e* ⇌ *e,e-a,a*)

K. LUNDE

Universitetets Kjemiske Institutt, Blindern — Oslo, Norway

Some years ago the compound 1,2-dichloro-4,5-dibromo*cyclo*hexane (*a, a—e, e* ⇌ *e, e—a, a*) was prepared in this laboratory [1] in order to see which of the two possible conformations, a or b (Fig. 1), would be the preferred one. According to an X-ray investigation by Hassel and Wang Lund [2] the bromine atoms are in the *e, e* position (Fig. 1a) in the solid state. Using the electron diffraction method Bastiansen and Hassel [3] demonstrated that this conformation was the only detectable also for the molecules in the vapour phase.

This latter result has now been confirmed by the present investigation, using the general assumption that no large shift in the conformational equilibrium should be expected on going from the vapour to the liquid phase. The infrared spectra of the solid compound (nujol mull) and that of the liquid (dissolved in carbon disulphide) were practically identical. Considering the very small quantities of molecular species which can be detected by infrared analysis this result seems remarkable. It indicates a much lower energy content for the free molecules of conformation a than of conformation b (Fig. 1).

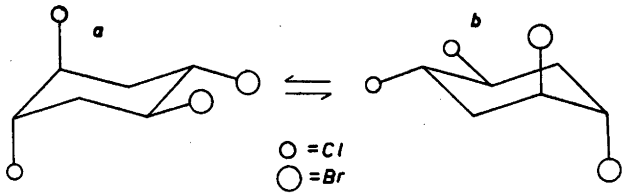

Fig. 1.

Furthermore, it is quite interesting to compare the X-ray results for the solid 1,2-dibromo-4,5-dichloro compound with a recent infrared investigation of the *trans* 1,2-dichloro- and *trans* 1,2-dibromo-*cyclo*hexane [4]. These dihalogeno*cyclo*hexanes can be regarded as the two "halves" of the 1,2-dichloro-4,5-dibromo-*cyclo*hexane molecule. They crystallize, however, according to the infrared investigation in inversed conformations: The dichloro-*cyclo*hexane has the conformation *e, e* and the dibromo-*cyclo*hexane the conformation *a, a* in the solid state. It will be seen that this is just the inverted geometrical direction of the halogen atoms in the crystalline 1,2-dichloro-4,5-dibromo*cyclo*hexane. The explanation of this phenomenon may be simple: When the energy difference between two conformations of a molecule is small, the lattice packing forces may become the determining factor. Thus, the question of which conformation is present in the crystals will be the question of which conformation gives the most favourable lattice packing.

This argument can, of course, not be used when considering the molecules in their free state. It is therefore surprising to compare the conformational equilibria of the two *trans* 1,2-dihalogeno*cyclo*hexanes with the data for the 1,2,4,5-tetrahalogeno compound. In the liquid dihalogeno*cyclo*hexanes there are almost equal quantities of the two possible conformations, whereas only *one* conformation has been observed in the case of the tetrahalogeno compound. This unexpected finding cannot be accounted for by simple considerations involving steric interactions.

The author wishes to thank *Sentralinstitutt for Industriell Forskning* for cooperation in recording the spectra and *Norges almenvitenskaplige forskningsråd* for financial support.

A Simple Method for Preparation of Glucose-3,4-^{14}C

H. PALMSTIERNA and G. EHRENSVÄRD

Chemical Department, Karolinska Institutet Stockholm; Department of Physiological Chemistry, Wenner-Grens Institut, Stockholm, Sweden

As shown before [1] *Escherichia coli B* accumulates a glycogen-like polysaccharide during the lag phase of growth. This finding could be used to label the glycogen-glucose preponderantly in the position C_3 and C_4. One way of obtaining such a labeling would be to grow the cells on lactate-1-^{14}C, expecting the pyruvate formed to enter the classical Embden-Meyerhof pathway towards glucose. Another possibility would be to circumvent the cumbersome synthesis of labeled lactate and cultivate the cells on non-labeled lactate in the presence of $^{14}CO_2$, expecting a CO_2-incorporation by way of the Wood-Werkman reaction and the tricarboxylic acid cycle to occur. Our experiments were carried out with this last assumption in mind.

Method: The cells were precultivated aerobically under shaking in a 6-litre Erlenmeyer flask containing 5 l of Friedleins lactate medium [2] (medium I) and harvested in the cold after 18 hours. About 4 g of cells (wet weight) were inoculated into a 6-litre Erlenmeyer flask containing 4 l of the medium mentioned, from which, however, the ammonium chloride had been omitted (medium II). It should be stressed that the cells must be kept in the cold until the moment of inoculation. A slight underpressure was effected in the vessel and a quantity of ^{14}C-labeled carbon dioxide was introduced corresponding to 2 g of barium carbonate. This will give an atmosphere containing about 10 % of carbon dioxide. After closing, the flask was vigorously shaken for 15 minutes before the inoculation. For practical reasons the cells were introduced by means of a syringe containing the cells suspended in 50 ml of cold medium II. The cells were allowed to grow for 60 minutes under very vigorous shaking.

Growth may either be interrupted by cooling the content of the flask to 4° or by adding formaldehyde to a final concentration of 0.5 %. The cells were harvested by centrifugation in the cold [1] and lyophilized. The glycogen was isolated and hydrolysed as previously described [1]. After purification by chromatography according to Gardell [3], the glucose was subjected to biological degradation in order to determine the ^{14}C-content in the separate carbon atoms of the glucose molecule * [4].

Results. The yield of glucose varied between 80 and 126 mg. In one experiment the distribution of the activity in the glucose obtained was as follows:

Carbon atoms 3,4	116 c.p.m. per μg
Carbon atoms 2,5	1.8 c.p.m. per μg
Carbon atoms 1,6	2.6 c.p.m. per μg

More than 95 % of the activity has thus entered carbon atoms 3 and 4. It must be stressed that the method of degradation used does not differentiate between the carbon atoms 3 and 4. Further work is in progress to find the ratio between the specific activities incorporated into C_3 and C_4. The isotope entering the positions 3 and 4 was diluted between 10 and 15 times. The specific activity of the protein carbon was in one experiment 21 c.p.m. per μg protein carbon. The specific activity of the glycogen carbon was in the same experiment 198 c.p.m. per μg of glucose carbon, showing that very little of the activity was lost to the protein. The remaining $^{14}CO_2$ in the atmosphere and the culture medium may be trapped by conventional methods and reutilized for further cultures of the same type as described, thus stepping up the actual yield of glucose-3,4-^{14}C considerably. The limiting factor is the amount of CO_2 expired by the cells. According to preliminary experiments it does not seem impossible to step up the yield to 20 %.

Difficulties at the Infrared-Spectrophotometric Identification and Estimation of Pure Compounds and Mixtures by Use of Potassium Bromide Disk Technique

BØRGE BAK and DANIEL CHRISTENSEN

Chemical Laboratory of the University of Copenhagen, Copenhagen, Denmark

Spectra of a number of biologically active compounds such as urea, D-glucose, D-fructose, amino acids etc. have been studied in the infrared, using pressed KBr-disk technique. Examples show that identification of the compounds of even simple mixtures of compounds of this type meets with difficulties of unexpected magnitude.

With the advent of the KBr-disk technique [1,2] new fields of research were opened up. Since strong, discrete spectra are obtainable from a mixture of 0.2—2.0 mg crystalline material and 500 mg KBr, evaporation residues from rather small amounts of reaction mixtures, blood serum, tissue liquids etc. can now be examined spectrophotometrically in the infrared. In this connection it is of interest to know how well-defined a KBr-disk spectrum of a *pure compound* is. Also, the spectra of *mixtures* may or may not obey the 'superposition principle' to the same extent as for mixtures of liquids and mixtures of gases. We want to illuminate these problems by practical examples from an investigation of blood serum crystalloids in which we are engaged. No complete treatment of the subject is intended.

Experimental. All our spectra were recorded on a Beckmann IR 2 instrument with NaCl optics. Water vapor and CO_2 had effectively been removed from the spectrograph by flushing with air from a liquid-air container. The quantity of sample to be mixed with 500 mg KBr never exceeded *ca.* 2 mg. Table 1 gives the results of seven experiments with glycine. The method of disk preparation marked with an '*a*' in Table 1 consisted in mixing the quantity of crystalline glycine indicated with 500 mg KBr, shaking the mixture in a conventional von Ardenne vibrator [3], and finally pressing the disk *in vacuo*. The recorded spectra were quite comparable in quality with spectra of liquids and gases. Lines in the region where the spectrograph has high resolving power (667—1 000 cm^{-1}) appear typically with a width of about 10 cm^{-1} at the 'foot' and very sharp maxima with D (optical density) = 0.3—0.4 for 1 mg samples.

In many types of experiment it is, however, impossible or impractical to use the '*a*' procedure. In such cases we dissolve 300 mg KBr in 1—2 ml of an aqueous solution of the compound(s) to be investigated, whereafter the water is removed by freeze-drying. The resulting voluminous crystalline powder is slightly compressed in order to decrease the volume, 200 mg KBr is added, a five minutes treatment in the vibrator follows and a disk is pressed (procedure *b*).

The results in Table 1 show that method *b* gives spectral lines at 894 and 912 cm^{-1} of *equal* peak intensity in contrast to the lines of *different* intensity observed with

Table 1. Optical density at maximum of some of the spectral lines observed for KBr-disks containing glycine.

Experiment number	Glycine quantity (mg)	Method of disk preparation	Optical density of disk at top of absorption line at (cm^{-1}) 700	894	912	934
1	1.170	*a*	0.25	0.32	0.26	No line
2	1.210	*b*	0.25	0.31	0.30	» »
3	1.180	*b*	0.33	0.37	0.36	» »
4	1.150	*c*	0.37	0.38	0.38	» »
5	0.818	*b*	0.21	0.27	0.26	» »
6	0.414	*b*	0.06	0.13	0.11	0.05
7	0.400	*b*	0.06	0.12	0.10	0.04

the *a* procedure. In method *c* an aqueous glycine solution (1 ml) was freeze-dried. The resulting glycine was mixed with 500 mg KBr, vibrated and pressed. The spectrum only deviates from *b*-spectra in the astonishing high intensity of the band at 700 cm^{-1}. Since the glycine particle size is probably more uniform in freeze-drying experiments (*b*) then by 'dry mixing' (*a*), freeze-drying is likely to mean a step towards a standardization of the disk-spectra. But a glance at the results in expts. Nos. 2 and 3 (Table 1) shows that no simple relationship between spectral band intensity and compound quantity exists. Expts. 3, 5 and 6 in which the freeze-drying was carried out simultaneously do show a very rough Beer's law agreement. But as will be noted, expt. 6 (successfully repeated in expt. 7) presents the surprising feature that a new line is observed! The remaining part of the glycine spectrum has the same not too well defined character but we chose the examples in Table 1 in order to speak of bands that could be observed with optimum resolving power. Since we know now with what kind of uncertainties we are dealing in the disk-spectrum of a pure compound we shall see what happens with mixtures.

Glycine and L-*alanine* form relatively well-behaving mixtures. Spectra of disks prepared by *a* and *b* procedure are almost identical. Roughly, they are a superposition of a glycine and an alanine spectrum. But the absorption intensities are wrong. For the line at 894 cm^{-1} in the spectrum of a mixture (glycine 0.87 mg; alanine 0.619 mg) we would expect $D = 0.27$ at the maximum (Table 1). We found $D = 0.20$. But inspite of similar defaults throughout the spectrum nobody would doubt that one sees the spectrum of a mixture of glycine and alanine since no bands of medium and high intensity from these components are missing and *no* extra bands are found.

In the disk-spectrum of mixtures of *urea and* D-*glucose* prepared by method *a* and *b*, *no* bands corresponding to the strong absorption at 1 481 and 1 716 cm^{-1} in urea occur (urea quantity 0.5 mg; D-glucose 1.5 mg). In return, both disks have an extra line at 1 460 cm^{-1} (which may be a displaced 1 481-band (urea)). A band, corresponding to the urea band at 1 169 cm^{-1} is observed in the 'dry' disk (proc. *a*), but hardly in the 'wet' (*b*). The freeze-dried disk has a band at 1 083 cm^{-1} neither to be found in the spectrum of pure D-glucose, nor in the urea spectrum. A superficial glance at the disk-spectrum of the urea-glucose spectrum immediately makes one suspect what the components are. But closer inspection reveals features quite incompatible with the superposition principle, even if this is reduced to being of only qualitative validity.

A third case may be mentioned in which the identification of the components is even more difficult. We studied mixtures of *glycine and* L-*aspartic acid.* Between 863 and 953 cm^{-1} glycine has bands at 894 and 912 cm^{-1}. Aspartic acid has bands at 875 ($D = 0.06$), 900 ($D = 0.11$), and 940 ($D = 0.03$) (sample quantity 1.156 mg). A 'dry-mixed' disk with 0.987 mg aspartic acid and 0.532 mg glycine roughly shows the four bands to be expected from superposition, namely, at 875; $(894 + 900)/2 = 897$; 912, and 940 cm^{-1}. If 3/5 of the disk is treated by the 'wet' procedure (*b*), a spectrum results with only one pronounced maximum at 904 cm^{-1}. Also a band at 700 cm^{-1} which would indicate the presence of glycine, is completely missing. From the spectrum of the freeze-dried disk one can probably conclude that the disk contains two or more *amino acids.* But it seems impossible to deduct that a simply glycine-aspartic acid mixture is present.

No simple explanation covers the glycine-aspartic acid case. If it is suggested that hydrogen ions are transferred from the latter (being the stronger acid) to the former this would mean that we should 'see' the ion $H_3\overset{+}{N}-CH_2-COOH$. But the spectrum of this ion we know from a study of glycine hydrochloride which has dominant lines at 807 and 859 cm^{-1} where no lines are observed by us in any glycine-aspartic acid mixture.

Discussion. Ebert and Gottlieb [4] found pronounced differences in the spectra of *polymorphic* compounds (in Nujol), but it seems impossible to assume any kind of polymorphism in our cases. Kirkland [5] has emphasized that caution must be used when attempting to apply the disk technique to systems containing solid solutions or mixed crystals, but no examples of the effect to be expected were given by him. The findings by Brockmann and Musso [6] seem more interesting in the present connection. They demonstrated that differences exist between the spectra of optical isomers and the spectrum of the racemate, provided that the optical isomer and the racemate differ sufficiently in melting

point and solubility. Also, they claim that mixtures of optical isomers can be converted to the racemate if the KBr disk technique is applied (see also Right [7]). Therefore, the optical isomers can 'find' each other inspite of the great quantity of KBr, consistent with our result on the 'dry' D-glucose-urea mixture. Brockmann and Musso state that probably hydrogen bonding is responsible for the effects they found. The same explanation may be valid here, but further experiments are undoubtedly necessary to verify this interpretation. Therefore, although KBr disk spectra are of great value to the analyst they must be used with some reservation in view of the present incomplete experimental coverage of the field and the lack of adequate theoretical insight.

On Sialic Acid in Brain Tissue

LARS SVENNERHOLM

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

Gangliosides were isolated from brains by exhausted extraction with methanol-chloroform (2:1, v/v). After evaporation of the solvent *in vacuo* and drying the residue with ethanol the lipids were redissolved in waterfree solvent of the same composition. An insoluble rest remained, and it was considerably larger when the tissue was extracted directly with methanol-chloroform without previous drying with acetone. It was composed of low molecular substances, such as amino acids, purines and salts but also substances of high molecular weight. The low molecular substances were removed by repeated dialysis against distilled water. The total amount of carbohydrates (hexose, hexosamine and sialic acid) was high (20–50 % in different samples) in the dialysed material. After hydrolysis several amino acids were also identified with paper chromatography. If strandin prepared according to procedure C of Folch, Arsove and Meath [1] was redissolved in methanol-chloroform (2:1) a substance containing hexosamine and sialic acid remained undissolved.

Only a few similar observations have been found in the literature. Klenk and Lauenstein [2] isolated a substance from methanol-chloroform extract of erythrocyte stroma which was only soluble in hot pyridine and contained a high amount of hexosamine. Rosenberg, Howe and Chargaff [3] have recently identified several amino acids after hydrolysis of strandin prepared by procedure C of Folch *et al.*

The observations described indicate that amino sugar and sialic acid are not only occurring in the lipopolysaccharides (gangliosides) but also in other substances in brain.

A quantitative estimation of sialic acid with Bial's reagent [4] in brain tissue, from which the lipids had been extracted, demonstrated that the amount of 'protein-bound' sialic acid was higher than that of lipid-bound. The amount of sialic acid was higher in old brains than in young ones and about twice as high in grey as compared with white matter. In adult brain the content was about 0.6 %, calculated on lipid-free brain tissue. N-Acetyl-sialic acid has now been isolated from lipid-free brain tissue and its X-ray diagram compared with that of sialic acid from gangliosides and serum proteins.

Analytical methods. Nitrogen was determined by the Kjeldahl micromethod. Hexose was determined with an orcinol-sulphuric acid method [5] and calculated as galactose. Hexosamine was assayed with a modified Elson and Morgan method [6], and glucosamine was separated by the procedure outlined by Gardell [7]. The determination of sialic acid was performed with Bial's reagent and calculated as N-acetyl sialic acid (mol.wt. 309) [4]. The X-ray powder diagrams were taken with a Guinier camera using copper $K\alpha$-radiation.

Materials. Brains from old people were freed from membranes and blood vessels. Grey matter was dissected free from the main part of white matter and water removed by two successive treatments with 4 vol. of acetone at 0°. The dried brain powder was extracted with

point and solubility. Also, they claim that mixtures of optical isomers can be converted to the racemate if the KBr disk technique is applied (see also Right [7]). Therefore, the optical isomers can 'find' each other inspite of the great quantity of KBr, consistent with our result on the 'dry' D-glucose-urea mixture. Brockmann and Musso state that probably hydrogen bonding is responsible for the effects they found. The same explanation may be valid here, but further experiments are undoubtedly necessary to verify this interpretation. Therefore, although KBr disk spectra are of great value to the analyst they must be used with some reservation in view of the present incomplete experimental coverage of the field and the lack of adequate theoretical insight.

On Sialic Acid in Brain Tissue

LARS SVENNERHOLM

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

Gangliosides were isolated from brains by exhausted extraction with methanol-chloroform (2:1, v/v). After evaporation of the solvent *in vacuo* and drying the residue with ethanol the lipids were redissolved in waterfree solvent of the same composition. An insoluble rest remained, and it was considerably larger when the tissue was extracted directly with methanol-chloroform without previous drying with acetone. It was composed of low molecular substances, such as amino acids, purines and salts but also substances of high molecular weight. The low molecular substances were removed by repeated dialysis against distilled water. The total amount of carbohydrates (hexose, hexosamine and sialic acid) was high (20–50 % in different samples) in the dialysed material. After hydrolysis several amino acids were also identified with paper chromatography. If strandin prepared according to procedure C of Folch, Arsove and Meath [1] was redissolved in methanol-chloroform (2:1) a substance containing hexosamine and sialic acid remained undissolved.

Only a few similar observations have been found in the literature. Klenk and Lauenstein [2] isolated a substance from methanol-chloroform extract of erythrocyte stroma which was only soluble in hot pyridine and contained a high amount of hexosamine. Rosenberg, Howe and Chargaff [3] have recently identified several amino acids after hydrolysis of strandin prepared by procedure C of Folch *et al.*

The observations described indicate that amino sugar and sialic acid are not only occurring in the lipopolysaccharides (gangliosides) but also in other substances in brain.

A quantitative estimation of sialic acid with Bial's reagent [4] in brain tissue, from which the lipids had been extracted, demonstrated that the amount of 'protein-bound' sialic acid was higher than that of lipid-bound. The amount of sialic acid was higher in old brains than in young ones and about twice as high in grey as compared with white matter. In adult brain the content was about 0.6 %, calculated on lipid-free brain tissue. N-Acetyl-sialic acid has now been isolated from lipid-free brain tissue and its X-ray diagram compared with that of sialic acid from gangliosides and serum proteins.

Analytical methods. Nitrogen was determined by the Kjeldahl micromethod. Hexose was determined with an orcinol-sulphuric acid method [5] and calculated as galactose. Hexosamine was assayed with a modified Elson and Morgan method [6], and glucosamine was separated by the procedure outlined by Gardell [7]. The determination of sialic acid was performed with Bial's reagent and calculated as N-acetyl sialic acid (mol.wt. 309) [4]. The X-ray powder diagrams were taken with a Guinier camera using copper $K\alpha$-radiation.

Materials. Brains from old people were freed from membranes and blood vessels. Grey matter was dissected free from the main part of white matter and water removed by two successive treatments with 4 vol. of acetone at 0°. The dried brain powder was extracted with

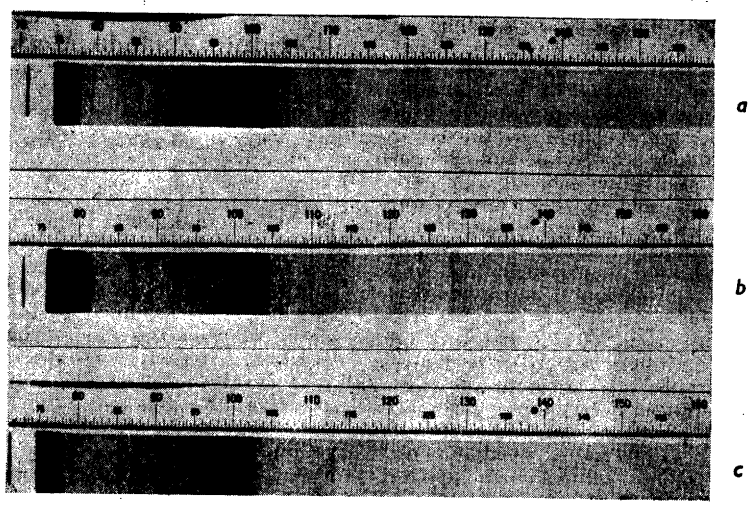

Fig. 1. X-ray powder diagram of N-acetyl-sialic acid isolated from (a) serum, (b) gangliosides and (c) lipid-free brain tissue.

methanol-chloroform (2:1, v/v) in a modified Soxhlet apparatus during 24 hours.

Gangliosides were prepared from the lipid extract by chromatography on cellulose columns [8]. Analysis of the potassium salt of gangliosides gave the following composition: nitrogen 2.70 %, chondrosamine (base) 6.45 %, hexose 27.5 %, N-acetyl-sialic acid 25.2 %.

Lipid-free substance. Portions of 100 g extracted tissue were suspended in about 3 l of 0.01 N sulphuric acid at 0° and shaken for at least 4 hrs. The liquid was filtered off and the treatment of the tissue was repeated until pH of the filtrate did not exceed 2.5. The substance was then hydrolysed as described below. *Analysis* (figures calculated on dry weight). Hexosamine 0.7 % (ratio glucosamine: galactosamine = 3:1), N-acetyl-sialic acid 0.9 %.

Serum. Pooled human serum was added four volumes of ethanol and brought to boiling. The precipitate was then treated as described for lipid-free brain substance. *Analysis* (calc. on dry weight). Hexose 1.8 %, hexosamine 1.3 % (glucosamine:galactosamine = 12:1), N-acetyl-sialic acid 1.0 %.

Isolation of N-acetyl-sialic acid. The procedure used [9] for isolation of N-acetyl-sialic acid has in the main been the same as that described by Zilliken, Braun and György [10] for the isolation of gynaminic acid from human milk.

The yield of crystalline acid was 40—50 % calculated from the quantitative estimation of N-acetyl-sialic acid with Bial's reagent on the starting material.

The isolated acids were tested by partition chromatography on Whatman paper No. 1. The solvents used were *n*-butanol-acetic acid-water (4:1:5), *sec*-butanol-acetic acid-water (4:1:5) and *sec*-butanol-acetone-acetic acid-water (3:3:1.5:2.5). After drying of the chromatograms the sialic acids were detected by spraying with [10]: orcinol-trichloroacetic acid [11]. All the crystallized acids ran as only one spot and had the same R_F-values. The X-ray diffraction patterns of the acids were identical (Fig. 1). The X-ray diagrams were also identical with that of ovine sialic acid [12].

Conclusion. N-Acetyl-sialic acid ($C_{11}H_{19}NO_9$) has been isolated from brain gangliosides and lipid extracted brain tissue.

The methods worked out for the quantitative estimation of gangliosides are based on determinations of sialic acid in lipid extracts. But a minor part of the non-lipid-bound sialic acid is extracted together with the lipids by methanol-chloroform mixtures containing some water. So when fresh tissues are extracted

directly with methanol-chloroform mixtures too high values for gangliosides are obtained.

Rittenberg, Howe and Chargaff [8] have suggested the existence of both gangliosides and mucolipids (strandin) in brain tissue, as they found that strandin contained amino acids, which was not the case of gangliosides. When strandin, prepared by the method used by them, was chromatographed on a cellulose column [9] with chloroform-methanol mixtures, gangliosides were isolated in the effluents, while on the top of the column a substance remained which gave strong positive reactions for sialic acid (Bial's reagent) and amino-acids (ninhydrin). After hydrolysis of the substance all the common amino acids were indicated by paper chromatography. A further evidence for the heterogenity of strandin is that Folch *et al.*[1] showed only amino acids in strandin prepared with the partition dialysis method (procedure C) but not in strandin prepared by two other procedures.

Until further data are given for strandin we have to consider it is a ganglioside to which other substances are associated. Gangliosides consist of a hydrophobic and a hydrophilic portion and may be able to act as protecting colloids for, *e.g.*, polypeptides in organic solvents and cerebrosides in water.

Structure of the 1:1 Compound Pyridine — Iodo Monochloride

O. HASSEL and CHR. RØMMING

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

It has been suggested that the 1:1 complexes probably present in the liquids containing pyridine and halogens are non-planar: The halogen atom directly linked to nitrogen is assumed to lie in the ring plane whereas the second halogen atom (bearing a negative charge) was expected to form an electrostatic link with the (positive) nitrogen atom and to lie outside the ring plane [1,2]. Unfortunately the yellow precipitate obtained by adding water to a solution of iodine in pyridine has been shown to contain water and the very unstable compound obtained in the absence of water does not appear to have the 1:1 composition [3]. Our X-ray work has therefore started with the iodo monochloride compound [4], the yellow, needle-shaped crystals of which (m. p. 132° C) turned out to be monoclinic — space group $P2_1/c$ — with the parameters $a = 4.25$, $b = 12.29$, $c = 14.07$, $\beta = 94.4°$. Using trial and error methods approximate y and z parameters of the iodine atoms (occupying a fourfold position) could easily be determined and signs of the structure factors evaluated which made possible a preliminary Fourier synthesis referring to the $(0kl)$-zone.

In Fig. 1a the refined electron density map is reproduced. The pyridine ring drawn in the figure is derived not from the direct synthesis but is slightly modified according to the results of a difference synthesis with subtraction of the contribution to structure factors from the halogen atoms. The $(h0l)$-synthesis in its final form is given in Fig. 1b. Here the overlapping of *two* pyridine rings forms an obstacle to a more precise determination especially of the carbon coordinates. A difference synthesis with subtraction of the contribution of the *iodine* atoms led to a z coordinate of the nitrogen atom which did not deviate more than 0.004 from the value obtained in the first projection. Neglecting not observed reflexions, the R factors for the two zones are 0.12 and 0.14, respectively.

From the above results it may safely be

From the above results it may safely be

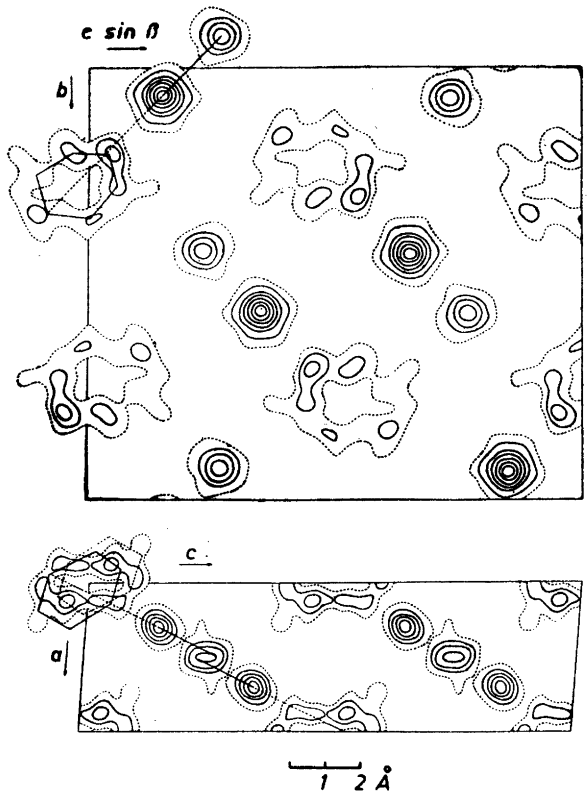

Fig. 1. a. Fourier projection along a-*axis. b. Fourier projection along* b-*axis. Approximate relative position of two overlapping pyridine rings is indicated. In both projections the ratio of contour line distances is: N(C): Cl : I = 1 : 2 : 5.*

concluded that the I, Cl and N atoms are situated at least very nearly on a straight line. The projection 1a together with considerations of ring dimensions [5] strongly suggest that the carbon atom opposite to the nitrogen atom is also situated on this line. The I, Cl and N parameters are: I(0.298, 0.068, 0.151); Cl(0.509, 0.072, 0.268) and N(0.141, 0.201, 0.047). From these values the following distances result: I—Cl = 2.51 Å, N—Cl = 2.2$_6$ Å.

Published structure analyses of addition compounds of ethers and amines with halogens [6-8] show a linear arrangement O (or N)—Hal.—Hal. in contrast to suggestions earlier made. The experimental findings do not appear to strengthen the suggestion that the "outer" halogen atom attains a strong negative charge. In the case of *ethers* a small lengthening only of the Hal.—Hal. bond is observed, whereas in the case of amines the lengthening is considerably greater. This lengthening may at least partly be due to a weakening of the double bond character [9] of the Hal.-Hal. bond present in the free molecules. The strong interaction between the oxygen (nitrogen) atom and the nearest halogen atom is evident from the short separation between these atoms, this effect being greatest in the case of nitrogen. It appears probable that electrons associated with the atoms forming an O-Hal. or N-Hal. bond are partially promoted to d orbitals.

We wish to express our sincere gratitude towards *The Rockefeller Foundation* for financial aid.

Electrophoresis of the Red Beet Pigments

GÖSTA LINDSTEDT

Food Chemistry Laboratory, National Institute of Public Health, Tomteboda, Sweden

The chemical nature of the red beet pigments is still unknown, and they have not yet been isolated in a pure state. They have been classified as "nitrogenous anthocyanins" since the pioneer investigation by Schudel [1], who discovered the nitrogen content and the glycosidic character of the pigments. Other workers have isolated different preparations of "betanin chloride", which all differ in their composition [2-5]. The formulae hitherto proposed are all based on the assumption that "betanin" really is an anthocyanin derivative. So far, there has been no proof of that assumption.

The complexity of the red beet pigments was later demonstrated by the aid of adsorption chromatography [6]. At least eleven coloured zones (yellow, orange, and red) could be observed on the column. The absorption spectra of the different components were determined, but no chemical investigations were made.

A similar separation of the red beet pigments can be effected by means of paper electrophoresis. Within the pH interval 2—7, they form relatively stable, *negatively* charged ions. A typical electrophoresis strip from fresh red beet sap is shown on Fig. 1. In a 0.1 M citrate buffer of pH 5.5, a good separation is obtained in 3—4 hours (Munktell 20/150 paper strips of size 5 × 35 cm; 220 V). At least seven coloured zones can be observed, of which one red and one bright yellow are always the strongest ones. The different zones seem to separate in roughly the same order as on an adsorption column [6]. The main yellow component is very easily destroyed and appears only in fresh beet sap. Different varieties of the red beet seem to contain the same coloured components, though differing in their relative amounts.

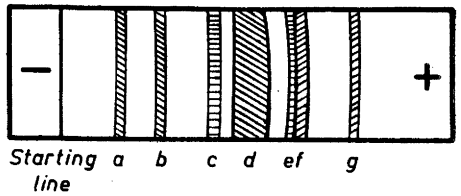

Fig. 1. Typical electrophoresis strip of fresh red beet sap in 0.1 M citrate buffer at pH 5.5. Paper: Munktell 20/150; 220/35 volts/cm; 3 hours at room temperature. Visible zones: a: *red, very weak;* b: *red, weak;* c: *orange, very weak;* d: *red, very strong;* e: *orange, weak;* f: *yellow, strong;* g: *yellow, very weak.*

At pH values below 2, a weak tendency to migrate towards the cathode can be observed, but observation is made difficult by the rapid destruction of the beet pigments in strongly acid solution. Thus, the pigments seem to have an isoelectric point at about pH 2. The exact position of the isoelectric point has not been determined, but it seems to be about the same for all the coloured fractions. In their behaviour during electrophoresis, the beet pigments differ from the common anthocyanins, which form positively charged ions except in alkaline solution. The extremely low value of the isoelectric point indicates that the molecule is dominated by strongly acidic groups, such as carboxyls. From methylation experiments, previous workers have concluded that the "betanin" molecule must contain one or two carboxyl groups [2,4].

The results obtained on electrophoresis have been confirmed by experiments with ion exchange resins. The red colour of beet
