Fig. 1. Typical electrophoresis strip of fresh red beet sap in 0.1 M citrate buffer at pH 5.5. Paper: Munktell 20/150; 220/35 volts/cm; 3 hours at room temperature. Visible zones: a: *red, very weak;* b: *red, weak;* c: *orange, very weak;* d: *red, very strong;* e: *orange, weak;* f: *yellow, strong;* g: *yellow, very weak.*

At pH values below 2, a weak tendency to migrate towards the cathode can be observed, but observation is made difficult by the rapid destruction of the beet pigments in strongly acid solution. Thus, the pigments seem to have an isoelectric point at about pH 2. The exact position of the isoelectric point has not been determined, but it seems to be about the same for all the coloured fractions. In their behaviour during electrophoresis, the beet pigments differ from the common anthocyanins, which form positively charged ions except in alkaline solution. The extremely low value of the isoelectric point indicates that the molecule is dominated by strongly acidic groups, such as carboxyls. From methylation experiments, previous workers have concluded that the "betanin" molecule must contain one or two carboxyl groups [2,4].

The results obtained on electrophoresis have been confirmed by experiments with ion exchange resins. The red colour of beet

sap is firmly adsorbed on an anion exchanger, but rather little on a cation exchanger. Anthocyanins from fruits or berries behave in the opposite way.

In practice, paper electrophoresis can be used to detect the addition of red beet sap to fruit juices, as only the beet pigments migrate towards the anode in weakly acid solution. An addition of 10 % of red beet sap is easily detected.

Electrophoresis on cellulose columns has been used with some success in attempts to isolate the beet pigments. A very simple apparatus built after the same principle as that described by Porath [7] was used. The buffer solutions were volatile, consisting of 0.1 M formic acid and 0.1 M pyridine in varying proportions. The separation was generally carried out at a pH about 3.5, because the pigments then can be separated from most proteins and amino acids, which move in the opposite direction. The "main red zone" was eluted from the electrophoresis column and further purified by adsorption on a talc column [6]. Lyophilisation (evaporation from a frozen solution) was generally used for concentration of the solutions, since the pigments are easily changed even during vacuum distillation at low temperature. The dark red solid fractions obtained by this method are at present being further investigated.

The author is indebted to Mrs. G. Ageby for skilful experimental assistance.

The Cuprous Salts of some N,N-Disubstituted Dithiocarbamic Acids and their Degree of Polymerisation

STIG ÅKERSTRÖM

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

Among the cuprous salts of the N,N-disubstituted dithiocarbamic acids, only the diethyl compound is mentioned in the literature. It was first prepared by Cambi and Coriselli [1]. They treated the sodium salt of diethyldithiocarbamic acid in inert atmosphere with cuprous oxide, stirring for about twelve hours; the salt was recrystallized from chloroform + petroleum ether. Fredga [2] prepared cuprous diethyldithiocarbamate by shaking thiuramdisulphide with copper bronze in chloroform solution, at room temperature. The compound isolated by him consisted of yellow, glistening needles, with a molecular weight of about 1 000 (determined in boiling chloroform). At about the same time, Tamminen and Hjelt [3] obtained a mixture of the cupri- and cuprous compounds, by boiling tetraethylthiuramdisulphide in benzene solution with metallic copper.

It was the author's intention to synthesize more of such compounds, and examine their polymerity. An X-ray examination of the cuprous diethyldithiocarbamate was begun in The Inorganic Department of this Institute by Hesse [4]; about the same time a molecular weight determination in boiling carbon disulphide was made, and later, an ultracentrifugation according to Archibald's method. It appeared that the true molecule consists of four formula units. The determination of the structure of the complex now completed, evidently shows that the molecule is tetrameric and that the four copper atoms are situated in the corners of a tetrahedron.

When the cuprous dithiocarbamates were prepared, the thiuramdisulphide was shaken with an excess of copper bronze in carbon disulphide until the colour of the solution became yellow or yellow-brown. After the copper bronze had settled, the solution was filtered and the cuprous complexes were isolated by means of their different solubilities. Several

solvents were examined as a reaction medium for the above mentioned reaction. However, carbon disulphide proved to be the most suitable. As the cuprous compounds are easily oxidized in solution, and also have a tendency to absorb various impurities on the surface of the newly-formed crystals, repeated recrystallisation is required for their purification.

The compounds hitherto prepared are listed in Tables 1 and 2, together with some data. As seen from these tables, some of the compounds are postulated tetrameric

Table 2.

Substance No.	Cu (calc.)	Cu (found)	H (calc.)	H (found)	C (calc.)	C (found)
3	* 21.21	21.25	4.88	4.44	30.06	30.00
			** 5.66	5.49	34.32	34.13
4	23.72	23.37				
5	21.47	21.10				
10	—	—	4.20	3.99	53.62	53.46
12	28.40	28.33	4.5	4.0	32.20	32.50

and some are postulated trimeric. The latter may possibly be built up of copper triangles. Preliminary data from a recently commenced X-ray examination [4] of one of the postulated trimeric compounds, $(nC_4H_9)_2NCS_2Cu$, seem to support the postulate of its trimerity. It should also be observed here, that several of these trimeric cuprous compounds crystallized with solvents (see Table 1). These solvents could be removed by careful heating *in vacuo* without the crystals being deformed, as far as could be seen. Obviously, these trimeric compounds are so packed that a crystal structure with "hollow spaces" could be well imagined. These "hollow spaces" can thus, partly or entirely, be filled out by the organic carbon chains, provided that these chains are large enough (*e. g.* $(nC_4H_9)_2NCS_2Cu$). They can also be filled by solvents (*e. g.* $(nC_3H_7)_2NCS_2Cu.1/2\ CHCl_3$).

It is remarkable that a change from a tetrameric to a trimeric structure takes place in the series of cuprous *n*-dialkyl-dithiocarbamates if the carbon chain is increased by one carbon atom. It should be observed that the only trimeric copper compounds which, up to this time, have been published, are some esters of phosphoric acid [5] (*e. g.* $CuClP(OPr\text{-}iso)_3$). The cuprous di-*iso*propyl-dithiocarbamate may possibly be high polymeric.

Determination of Small Amounts of Deuterium Oxide in Water by Infra-red Spectroscopy

ULLA BERGLUND-LARSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

In studies of isotope effects it was of interest to know the absolute deuterium concentration of various deuterium substituted organic compounds. For that reason the compounds were burned to water and the deuterium content of the water was determined by means of infra-red spectroscopy. A method, similar to that of Thornton and Condon [1], but more accurate, has been worked out.

Table 2.

Determination of Small Amounts of Deuterium Oxide in Water by Infra-red Spectroscopy

ULLA BERGLUND-LARSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

In studies of isotope effects it was of interest to know the absolute deuterium concentration of various deuterium substituted organic compounds. For that reason the compounds were burned to water and the deuterium content of the water was determined by means of infra-red spectroscopy. A method, similar to that of Thornton and Condon [1], but more accurate, has been worked out.

Experimental. The measurements were carried out on a Perkin-Elmer infra-red spectrometer, model 112, with a NaCl-prism. The cell thickness was about 0.05 mm and its windows were made of CaF_2. The slit width used was 0.050 mm. A number of standard samples were made from deuterium water containing 99.84 % D_2O, $d_4^{20} = 1.10521$ (Norsk Hydro), and ordinary distilled water. Care was taken to prevent undue dilution by exchange with atmospheric moisture.

At each determination, the whole absorption band at 3.98 μ (2 513 cm^{-1}) was recorded to eliminate a possible error in the wavelength setting, but the reading was always taken at exactly 3.98 μ. The absorption of ordinary distilled water in the same cell was always checked between the analyses. After each recording the cell was washed with acetone and dried by blowing dry nitrogen through it. No memory effect was found in the cell even when the D_2O concentration exceeded 5 % D_2O.

A calibration curve was drawn and a straight line was obtained by the method of least squares. As there will always be an error both in the determination of the absorption of ordinary water, I_0, and in that of the sample, I, the line need not pass the origin but has a small intercept on the ordinate. The equation of the line was found to be:

$$\log \frac{I_0}{I} = 0.3174c - 0.0034$$

where c is the concentration measured in per cent by weight. In Table 1 we see the true concentrations compared with those calculated from the equation. $\Delta = c_{true} - c_{found}$; e = mean error in a single determination $= \sqrt{\frac{\Sigma\Delta^2}{n-2}} = 6 \times 10^{-3}$ wt %.

Table 1. Weighed out quantities of D_2O (wt %) in ordinary water, c_{true}, compared with the values obtained from the equation, c_{found}. $\Delta = c_{true} - c_{found}$.

c_{true}	c_{found}	$\Delta 10^{-3}$
0.0163	0.0107	+5.6
0.3053	0.3091	—3.8
0.5466	0.5436	+3.0
0.8707	0.8804	—9.7
1.1161	1.1130	+3.1
1.3515	1.3547	—3.2
1.6497	1.6442	+5.5

Corrections were made for the natural occurrence of heavy water in distilled water assuming [2] its concentration to be 0.0163 wt %.

In the present investigation, Beer's law is obeyed and a straight line is obtained when plotting optical density against concentration. In a work of Gaunt [3], Beer's law was not obeyed since he used a too large slit width. This also caused some overlapping from the absorption band of the carbon dioxide at 4.25 μ (2 353 cm^{-1}). Under these conditions the accuracy of Gaunt's experiments cannot be as high as 1 % as he claimed, even if he included only concentrations up to 0.8 % D_2O. With the method of least squares (straight line), the mean error in his experiments is found to be 2 %. The assumption of a straight line was made as all the points up to concentrations of about 0.6 % fall on a straight line, but at concentrations higher than this the curvature begins, and after 0.8 % it will be appreciable.

In the present work the absorption band of HOD at 3.98 μ was well separated from other absorbtion bands and no overlapping could be observed. The absolute mean error in a single determination is found to be ± 0.006 wt % for concentrations up to 1.3 % D_2O.

The author is indebted to Docent Lars Melander for his kind interest in this investigation. The *Swedish Natural Science Research Council* has contributed to the acquirement of the infra-red spectrographic equipment.

The Configuration of the *aa'*-Dimethylpimelic Acids

ARNE FREDGA and BÖRJE ÖSTMAN

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

The diastereomeric *aa'*-dimethylpimelic acids melting at 81–81.5° and 76–76.5° have been investigated by several authors. They have been designated as the *para*- and *anti*-form, respectively, but no attempts to determine the configuration have been reported [1,2,3]. The present authors have found that the *low-melting* acid can be resolved into optically active forms using strychnine. On the other hand, the *high-melting* form gives a strychnine salt, from which the inactive compound can be regenerated with unchanged m. p. This indicates that the latter acid is the pure *meso*-form.

The separation of the diastereomeric acids is rather tedious and time-consuming. Kipping has performed it through the anilides [3], and in spite of extensive experiments no better method could be found. Owing to lack of material, the optical antipodes have not yet been prepared in a state of purity. The acid from the first crystallisation of the strychnine salt had $[\alpha]_D^{25} = -20°$ (abs. ethanol). In the same solvent, dimethylglutaric and dimethyladipic acid show 36.5° and 30.3° [4], respectively. The maximum activity of the dimethylpimelic acid can be assumed to be somewhat lower, probably near 25°. The strychnine salt thus gives a fairly good resolution.

Experimental. The inactive acids were prepared according to Kipping [3].

0.250 g of the *low-melting* acid and 0.445 g of strychnine were dissolved together in hot dilute ethanol. After standing for several days, the salt was filtered off and the acid liberated. M. p. of the crude acid 67–68°. 0.0235 g dissolved in abs. ethanol to 10.00 ml: $2\alpha_D^{25} = -0.09°$. $[\alpha]_D^{25} = -20°$.

The mother liquor from the strychnine salt was evaporated to dryness and the acid liberated. 0.0293 g dissolved in abs. ethanol to 10.00 ml: $2\alpha_D^{25} = +0.105°$. $[\alpha]_D^{25} = +18°$.

Levorotatory aa'-dimethylglutaric acid was prepared according to Möller [5]. 0.4586 g dissolved in abs. ethanol to 10.00 ml: $2\alpha_D^{25} = -3.345°$. $[\alpha]_D^{25} = -36.5°$.

Iron Transport through the Lymph Stream

G. von EHRENSTEIN

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

In the course of one hour about 30 μg of iron leaves the circulation of the rabbit. Most of this iron is ultimately utilized in the formation of hemoglobin, but a fraction before doing so is lead into the "depots" and utilized at a later stage only.

The iron circulating in the plasma is bound to β_1-globulin and has prior to passing the capillary wall to be split off from that compound [1].

The writer found the thoracic lymph of the rabbit to contain 73 μg/100 ml of iron (range 40–115 μg/100 ml, S.D. 27 μg/100 ml), all this iron being bound to β_1-globulin. It is probable that the same is the case for the iron of the whole extracellular fluid. The iron of the depots and that of the extracellular fluid has to enter the vascular bed prior to reaching the hemopoetic organs, and thus the problem occurs in which way these fractions reach the circulation.

Thirty minutes after injecting intraperitoneally or subcutaneously labelled iron-β_1-globulin to the rabbit, 1 ml of thoracic lymph was found by the writer to contain more than 150 times as much labelled iron than does 1 ml of plasma. This observation suggests that much of the iron of the interspaces and thus also the iron released from the depots, as far it is bound to β_1-globulin, is transported into the circulation with the lymph stream.

To test this conclusion, the influx of a large part of the lymph stream into the

Table 1. Change of iron content of the plasma of rabbits with ligated thoracic duct and of sham operated rabbits.

		Iron content, μg / 100 ml	
		Time 0	after 4 h
Seven rabbits with ligated thoracic duct	mean	196±17 *	151±12 *
	range	115—260	95—197
	S. D.	45	32

	range	145—210	112—208
	S. D.	27	35

* Standard deviation of the mean.

circulation was obstructed by ligating the thoracic duct and the *truncus jugularis sinister*. The effect of this obstruction on the iron content of the plasma of operated and of sham operated rabbits was then determined. The results of these experiments are seen in Table 1. They show a significant decrease of the iron content of the plasma following obstruction of much of the lymph flow.

Thus ligation of much of the lymph stream reduces the influx of iron into the plasma by 3.8 μg/h. The total iron loss by the plasma amounts to 30 μg/h. Thus 1/8 of the total iron loss by the plasma is compensated by iron lead into the circulation by the lymph stream. The share of iron carried by the lymph stream in the iron replacement is, however, much larger, if we consider the amount of iron lead from the depots into the circulation alone. This amounts to 4.5 μg/h. Thus the amount of iron lead into the plasma by the lymph stream makes out a very appreciable part of the iron carried from the depots into the circulation.

From the decrease of the plasma iron content due to obstruction of the lymph flow and from the iron content of the lymph we can calculate the volume of lymph lead hourly into the circulation. We arrive at a volume of up to 5.2 ml/kg body weight. This compares with the values of 1.4—6.8 ml/kg/h found by Forker *et al*,[2] for the rat, and 0.2—3.0 ml/kg/h measured by Paine *et al.*[3] in the dog.

As the lymph iron is bound to β_1-globulin we have to expect that a corresponding amount of β_1-globulin, making out 2.8 %/h of the total plasma content, will reach the circulation with the lymph stream as well. This is about in the case of the rat (2.8 % / h) and of the dog (2 % / h) [2,4]. Forker *et al.*[2] found, that at least about half of the plasma proteins of the dog are daily replaced by the lymph proteins. A result which suggests, among other things, that about 2.8 % of the plasma iron passes the capillary wall without being dissociated.

Three experiments carried out with growing pigs also brought out the fact, that ligation of the thoracic duct appreciably depresses the plasma iron level.

The author wishes to express his thanks to Professor George de Hevesy for the promoting interest taken in this work.

The Configuration of the *aa'*-Dimethylpimelic Acids

ARNE FREDGA and BÖRJE ÖSTMAN

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

The diastereomeric *aa'*-dimethylpimelic acids melting at 81–81.5° and 76–76.5° have been investigated by several authors. They have been designated as the *para*- and *anti*-form, respectively, but no attempts to determine the configuration have been reported [1,2,3]. The present authors have found that the *low-melting* acid can be resolved into optically active forms using strychnine. On the other hand, the *high-melting* form gives a strychnine salt, from which the inactive compound can be regenerated with unchanged m. p. This indicates that the latter acid is the pure *meso*-form.

The separation of the diastereomeric acids is rather tedious and time-consuming. Kipping has performed it through the anilides [3], and in spite of extensive experiments no better method could be found. Owing to lack of material, the optical antipodes have not yet been prepared in a state of purity. The acid from the first crystallisation of the strychnine salt had $[\alpha]_D^{25} = -20°$ (abs. ethanol). In the same solvent, dimethylglutaric and dimethyladipic acid show 36.5° and 30.3° [4], respectively. The maximum activity of the dimethylpimelic acid can be assumed to be somewhat lower, probably near 25°. The strychnine salt thus gives a fairly good resolution.

Experimental. The inactive acids were prepared according to Kipping [3].

0.250 g of the *low-melting* acid and 0.445 g of strychnine were dissolved together in hot dilute ethanol. After standing for several days, the salt was filtered off and the acid liberated. M. p. of the crude acid 67–68°. 0.0235 g dissolved in abs. ethanol to 10.00 ml: $2\alpha_D^{25} = -0.09°$. $[\alpha]_D^{25} = -20°$.

The mother liquor from the strychnine salt was evaporated to dryness and the acid liberated. 0.0293 g dissolved in abs. ethanol to 10.00 ml: $2\alpha_D^{25} = +0.105°$. $[\alpha]_D^{25} = +18°$.

Levorotatory aa'-dimethylglutaric acid was prepared according to Möller [5]. 0.4586 g dissolved in abs. ethanol to 10.00 ml: $2\alpha_D^{25} = -3.345°$. $[\alpha]_D^{25} = -36.5°$.

Iron Transport through the Lymph Stream

G. von EHRENSTEIN

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

In the course of one hour about 30 μg of iron leaves the circulation of the rabbit. Most of this iron is ultimately utilized in the formation of hemoglobin, but a fraction before doing so is lead into the "depots" and utilized at a later stage only.

The iron circulating in the plasma is bound to β_1-globulin and has prior to passing the capillary wall to be split off from that compound [1].

The writer found the thoracic lymph of the rabbit to contain 73 μg/100 ml of iron (range 40–115 μg/100 ml, S.D. 27 μg/100 ml), all this iron being bound to β_1-globulin. It is probable that the same is the case for the iron of the whole extracellular fluid. The iron of the depots and that of the extracellular fluid has to enter the vascular bed prior to reaching the hemopoetic organs, and thus the problem occurs in which way these fractions reach the circulation.

Thirty minutes after injecting intraperitoneally or subcutaneously labelled iron-β_1-globulin to the rabbit, 1 ml of thoracic lymph was found by the writer to contain more than 150 times as much labelled iron than does 1 ml of plasma. This observation suggests that much of the iron of the interspaces and thus also the iron released from the depots, as far it is bound to β_1-globulin, is transported into the circulation with the lymph stream.

To test this conclusion, the influx of a large part of the lymph stream into the

On the Complex Chemistry of the Uranyl Ion

VIII. The Complexity of Uranyl Fluoride

STEN AHRLAND, RAGNAR LARSSON and KJELL ROSENGREN

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The complexity of the uranyl fluoride system has been determined by measurements of $[H^+]$ in fluoride buffers. A perchlorate medium of ionic strength 1 M was used at a temperature 20° C. In the concentration range investigated ($C_M \leqq 100$ mM; $C_A \leqq 400$ mM) a strong mononuclear complex formation takes place between UO_2^{2+} and F^-, with $UO_2F_4^{2-}$ as the upper limit (Table 7). Neither polynuclear complexes, nor complexes containing HF_2^- seem to exist in this range. — The constants of the hydrogen fluoride system in the present medium were also obtained.

In the systems of complexes investigated so far, the uranyl ion is usually able to coordinate with not more than three ligands. This is the case for the acetate [1], chloroacetate [2] and glycolate [3] systems in aqueous solution and also for the nitrate systems in ketonic solvents [4]. These results are also corroborated by the existence of compounds in the solid state evidently containing groups such as $UO_2(CH_3 \cdot COO)_3^-$ and $UO_2(CO_3)_3^{4-}$ (*e. g.* Ref. [5, p. 158]).

The only exception seems to be the fluoride system, where a complex $UO_2F_4^{2-}$ has been reported in solution [6]. The same group is moreover present [7] in solid $K_3UO_2F_5$. As has already been reported [8] preliminarily, the present measurements confirm that four F^- can be taken up as ligands. In fact four should most probably be regarded as the maximum coordination number of the uranyl ion as this number would be displayed by the fluoride system on account of the high stability of the complexes and the small size of the ligand.

CALCULATION OF THE COMPLEXITY CONSTANTS FROM MEASUREMENTS OF $[H^+]$ OF FLUORIDE BUFFERS

A good method for investigating systems of strong complexes is the determination of the free ligand ion concentration [A], with subsequent calculation

of the complex formation function * $\bar{n} = f([A])$. From this function the complexity constants and the composition of the system for a given value of [A] can always be calculated according to established methods [2] using the function X, here denoted X_M.

In a system like the present one where the ligand is the anion of a weak acid, [A] can be found from potentiometric measurements of $[H^+]$ in a buffer solution of the ligand and its corresponding acid. This method has also been used for the aqueous uranyl systems mentioned above. For these systems, the connection between $[H^+]$ and [A] is very simple, for the fluoride system it is somewhat more complicated owing to the peculiar property of F^- to form HF_2^- and possibly also H_2F_2 beside HF. Moreover HF_2^- may be able to form complexes with UO_2^{2+}, thus competing with the complex formation of F^-.

On the other hand no hydrolytic reactions are likely to occur under the conditions chosen for the present measurements. Those solutions which contained only little fluoride were so acid that no hydrolysis was possible and as the pH gradually rose to fairly high values, ≈ 5, with increasing concentration of fluoride, UO_2^{2+} was probably well protected by the simultaneous strong complex formation with F^- (*cf.* Ref.[1]). This was confirmed experimentally since the formation function was independent of $[H^+]$ (see p. 713).

The measurements were carried out as titrations (*cf.* Ref. [9, p. 383]). Portions of a fluoride solution were added to a certain volume of perchloric acid solution and $[H^+]$ of the resulting solution measured by means of the quinhydrone electrode. In the main series, the solutions also contained a uranyl concentration C_M, but measurements had also to be performed with solutions free from uranyl ions. As in the previous parts of this series, all solutions had a constant ionic strength $I = 1$ M, sodium perchlorate being used as the supplementary neutral salt. The temperature was also the same as before, 20° C.

The half-cell containing buffer was connected with the same reference electrode RE as used before [9]. The emf of the cell thus formed is given by

$$E = E_d + \frac{RT}{F} \ln \frac{[H^+]_0}{[H^+]} \tag{1a}$$

In the initial perchloric acid solution before the addition of fluoride, $[H^+] = C_H$. For this special case eqn. (1 a) becomes

$$E^{(i)} = E_d^{(i)} + \frac{RT}{F} \ln \frac{[H^+]_0}{C_H} \tag{1b}$$

Hence

$$E - E^{(i)} - E_d + E_d^{(i)} = E_H = \frac{RT}{F} \ln \frac{C_H}{[H^+]} \tag{2}$$

As the difference of the liquid junction potentials $E_d - E_d^{(i)}$ can be estimated in separate experiments (p. 711), eqn. (2) permits the calculation of $[H^+]$ (or $C_H/[H^+]$). Hence [A] is calculated in the following way.

If all complexes which are mentioned above are considered as possibly existing, C_H can be written as

$$C_H = [H^+] + [HA] + [HA_2] + 2[H_2A_2] + \sum_{q=1}^{Q} q\,[M(HA_2)_q]$$

* Unless stated otherwise, the same symbols are used as in the previous parts I—VII of this series.

where $A = F^-$ and $M = UO_2^{2+}$. Introducing

$$[HA] = \delta_1[H^+][A] \quad (3) \qquad [HA_2] = \delta_2[H^+][A]^2 \quad (4)$$

$$[H_2A_2] = \delta_2''[H^+]^2[A]^2 \quad (5) \qquad [M(HA_2)_q] = \eta_q[M][H^+]^q[A]^{2q} \quad (6)$$

we obtain

$$C_H/[H^+] = 1 + \delta_1[A] + \delta_2[A]^2 + 2[H^+]\delta_2''[A]^2 + [M]\sum_{q=1}^{Q} q \cdot \eta_q[H^+]^{q-1}[A]^{2q} \quad (7)$$

The function experimentally determined from eqn. (2) thus generally depends upon [A], $[H^+]$ and [M]. If complexes containing HF_2^- do not exist in perceptible amounts, then the function will be independent of [M], and [A] can be calculated from eqn. (7) provided the constants δ are known.

Still more complicated complexes could be conceived, *e. g.* mixed complexes containing both F^- and HF_2^- as ligands, or polynuclear HF_2^--complexes. But this would introduce no new variable and therefore no further essential complication. The function (7) may thus be regarded as the general case.

If on the other hand values of [A] are calculated from eqn. (7) on the assumption that HF_2-complexes do not exist and they in fact do, then the computed values of [A] will be in error. However, the error will decrease as [M] (i. e. C_M) decreases and will finally disappear when $C_M \to 0$. It should therefore in any case be possible to obtain the right values of [A] by a method of extrapolation.

From the values of [A] found, the corresponding values of the ligand number of the metal ion $\bar{n}_M$, *i. e.* the complex formation function of the UO_2^{2+}—F^- system, are calculated according to

$$\bar{n}_M = \frac{C_A - [A] - \bar{n}_H \cdot C_H}{C_M} \quad (8)$$

where $\bar{n}_H$ is the ligand number of the hydrogen ion. This quantity, defined as the mean number of fluoride ions bound by each hydrogen ion is generally given by:

$$\bar{n}_H = \frac{\delta_1[A] + 2\delta_2[A]^2 + 2[H^+]\delta_2''[A]^2 + 2[M]\sum_{q=1}^{Q} q \cdot \eta_q [H^+]^{q-1}[A]^{2q}}{1 + \delta_1[A] + \delta_2[A]^2 + 2[H^+]\delta_2''[A]^2 + [M]\sum_{q=1}^{Q} q \cdot \eta_q [H^+]^{q-1}[A]^{2q}} \quad (9)$$

Thus the same condition applies to the calculation of $\bar{n}_H$ from eqn. (9) as to that of [A] from eqn. (7): if no HF_2^--complexes exist $\bar{n}_H$ may be calculated directly, if on the contrary such complexes exist, eqn. (9) gives the correct values of $\bar{n}_H$ when $C_M \to 0$. When [A] and $\bar{n}_H$ are known, $\bar{n}_M$ can be calculated from (8).

Therefore, if no HF_2^--complexes exist, all values of C_M will give the correct complex formation function, and if such complexes really do exist the correct values can in any case be calculated when $C_M \to 0$. In such a case however, we will find the complex formation function dependent on C_M when formally calculated on the assumption that $\eta = 0$.

As has been repeatedly pointed out before, even the true complex formation curve is dependent upon C_M, if polynuclear complexes exist [10, 11, 9]. Therefore if the function is found to depend upon C_M there may be two different reasons. On the other hand if it is found to be independent of C_M we may safely conclude that neither complexes of HF_2^- nor polynuclear ones exist as it is most improbable that these two factors would just compensate each other over the whole ranges of [A] and C_M used.

The constants δ necessary for the calculation of [A] and $\bar{n}_H$ are determined by separate titration series with solutions containing no uranyl ions. The symbols referring to those are denoted by primes in the following. For a solution of the same C_H as above, the emf, E_H', corresponding to E_H of eqn. (2) is given by

$$E'—E^{(i)} — E_d' + E_d^{(i)} = E_H' = \frac{RT}{F} \ln \frac{C_H}{[H^+]'} \tag{10}$$

In this case we obtain

$$C_H/[H^+]' = 1 + \delta_1[A]' + \delta_2([A]')^2 + 2[H^+]'\delta_2''([A]')^2 \tag{11}$$

The function $C_H/[H^+]'$ determined experimentally is thus generally dependent upon [A]' and $[H^+]'$. If however H_2F_2 does not exist in the solution, $C_H/[H^+]'$ will be a function of [A]' only. In any case, this will be true when $C_H \to 0$ and, consequently, $[H^+] \to 0$. Thus the limiting function will be

$$\lim_{C_H \to 0} C_H/[H^+]' = 1 + \delta_1[A]' + \delta_2([A]')^2 = X_H \tag{12}$$

When corresponding values of $(C_H/(H^+]')_{C_H=0}$ and [A]' are known δ_1 and δ_2 can be calculated from eqn. (12) (*cf.* Ref.[2, p. 787]).

The determination of the limiting function (12) is carried out by the Fronaeus' method [11 p. 18], *i. e.* corresponding values of E_H' and C_A for series of different values of C_H are plotted and the resulting family of curves is cut at a number of values of E_H'. The corresponding values of C_H and C_A thus found are now plotted with E_H' as parameter. The resulting lines when extrapolated to $C_H = 0$ give $C_A = [A]'$ corresponding to $(C_H/[H^+]')_{C_H=0}$ for each line. Moreover, this value of (A]' will remain constant along the line of constant E_H' (*i. e.* constant $C_H/[H^+]'$) if H_2F_2 does not exist, as seen from eqns. (10) and (11). The ligand number $\bar{n}_H'$ of these solutions free from uranyl ions is, according to the definition of p. 707 given by the formula

$$\bar{n}_H' = (C_A — [A]')/C_H \tag{13}$$

and if H_2F_2 does not exist it is connected with [A]' according to (*cf.* eqn. (9))

$$\bar{n}_H' = \frac{\delta_1[A]' + 2\delta_2([A]')^2}{1 + \delta_1[A]' + \delta_2([A]')^2} \tag{14}$$

Therefore $\bar{n}_H'$ is constant too along a line of constant [A]'. The C_A, C_H lines of constant E_H' will therefore in such a case be straight ones with the slope $k_E = \bar{n}_H'$, as evident from eqn. (13).

If on the other hand H_2F_2 really exists in perceptible amounts then neither [A]' nor $\bar{n}_H'$ are constant along a line of constant E_H'. The slope k_E will then

not be $\bar{n}_H'$, but another quantity $< \bar{n}_H'$ (*cf.* Fronæus [11, p. 21]). A comparison between the values of $\bar{n}_H'$ calculated from eqn. (14) using the values of δ_1 and δ_2 found from eqn. (12) and the slope k_E of the C_A, C_H lines will therefore reveal if H_2F_2 really does exist. In fact it does not, and in the following calculations of $\bar{n}_M = f([A])$ the terms referring to this complex are therefore omitted.

It is however necessary to exercise some care when using the values of δ_1 and δ_2 so found for calculating [A] in the way described on p. 707. Unfortunately, δ_1 and δ_2 vary perceptibly as the medium is altered by the exchange of perchlorate for fluoride. The values of δ_1 and δ_2 found apply to a perchlorate medium, and are therefore not sufficiently exact when C_A is high, especially as [A] must be determined as precisely as possible at high C_A on account of the gradual decrease of the difference C_A—[A] relative to [A] which always makes the computation of high values of $\bar{n}_M$ rather uncertain (*cf.* Refs.[1, 3]).

Therefore high values of [A] should be calculated using values of δ valid at these [A]. It is however not necessary to carry out a formal calculation of these values, instead [A] may be found by an appropiate modification of the method used previously [1-3] for simple acid systems.

From eqns. (10) and (2) the difference E_A is given by

$$E_H' - E_H = E_A = \frac{RT}{F} \ln \frac{[H^+]}{[H^+]'} \tag{15}$$

Combining eqns. (15) and (4) and setting $[HA_2]/[HA_2]' = \alpha_2/\alpha_2'$ ($\alpha_2 = [HA_2]/C_H$ and $\alpha_2' = [HA_2]'/C_H$, *cf.*[2]) we obtain

$$2\ln \frac{[A]'}{[A]} = \frac{E_A}{RT/F} + \ln \frac{\alpha_2'}{\alpha_2} \tag{16}$$

Combining eqns. (15) and (3) we obtain analogously

$$\ln \frac{[A]'}{[A]} = \frac{E_A}{RT/F} - \ln \frac{\alpha_1}{\alpha_1'} \tag{17}$$

where $\alpha_1 = [HA]/C_H$ and $\alpha_1' = [HA]'/C_H$. At high values of [A], $[H^+]$ is negligible compared with [HA] and $[HA_2]$. Therefore

$$\alpha_1 + \alpha_2 = 1 \tag{18}$$

Moreover the following connection exists (*cf.* eqn. (14))

$$\alpha_1 + 2\alpha_2 = \bar{n}_H \tag{19}$$

Hence $\alpha_2 = \bar{n}_H - 1$ and $\alpha_1 = 2 - \bar{n}_H$ which when combined with eqns. (16) and (17) give

$$2\ln \frac{[A]'}{[A]} = \frac{E_A}{RT/F} + \ln \frac{\bar{n}_H' - 1}{\bar{n}_H - 1} \tag{20}$$

and

$$\ln \frac{[A]'}{[A]} = \frac{E_A}{RT/F} - \ln \frac{2 - \bar{n}_H}{2 - \bar{n}_H'} \tag{21}$$

Hence [A] can be calculated by a series of approximations utilizing the fact that $[A]' = C_A - \bar{n}_H' \cdot C_H \approx C_A$ at high values of C_A. A sufficiently good value of [A]′ can therefore be found by successive approximations using values of $\bar{n}_H'$ obtained from eqn. (14) with the values of δ calculated previously. As [A] is not too far from [A]′, $\bar{n}_H \approx \bar{n}_H'$ and an approximate value of [A] can thus be calculated from eqn. (20) (if $\bar{n}_H' > 1.5$) or eqn. (21) (if $\bar{n}_H' < 1.5$). From this value of [A] a better value of $\bar{n}_H$ is obtained. Inserted in eqns. (20) or (21) the new $\bar{n}_H$will yield a better value of [A] and so by successive approximations the true value of [A] will finally be found.

In practice all values of [A] are first calculated according to the method first mentioned and then, starting with highest ones, recalculated by the more laborious method of E_A using eqns. (20) and (21) until this method gives a value of [A] identical with that found from δ_1 and δ_2.

EXPERIMENTAL

Chemicals: Uranyl perchlorate was prepared as before [9]. Its purity was proved by the fact that the solution had an extinction curve identical to that of the carefully purified preparation used before. The exact concentration of the stock solution (C_M = 334 mM) was determined cerimetrically.

The excess of perchloric acid in the present preparation was determined potentiometrically. A sample of the stock solution, suitably diluted, was titrated with a perchloric acid solution, and $[H^+]$ of the solutions thus obtained was measured by means of a quinhydrone electrode connected with the usual reference electrode RE of $[H^+]_0$ = 10.06 mM. As I = 1 M throughout the cell $[H^+]$ can be calculated directly from the emfs measured provided a correction is applied for the liquid junction potentials between solutions of different $[H^+]$ (*cf.* p. 711). The differences between the values of $[H^+]$ thus found and those stoichiometrically calculated from the amounts of perchloric acid added will give the acid content of the uranyl salt, provided the hydrolysis of the uranyl ion is negligible. This is the case [9] when $[H^+] > 10$ mM and in fact a constant difference = 8.3 ± 0.3 mM was found in the present titration where the value of $[H^+]$ measured increased from 8.2 to 67.2 mM while C_M was kept constant = 33.4 mM. The amount of free acid in the stock solution is thus 83 mM. This method of determining free acid in the presence of the fairly acidic uranyl ion is much more satisfactory than the method of potentiometric titration with alkali used previously.

Perchloric acid was of analytical grade and *sodium perchlorate*, Ciba *purum*, was purified and tested as described before [9].

Sodium fluoride: First a preparation "Bakers analyzed", lot No 3593, was used. A stock solution with C_A = 600 mM and I = 1 M was prepared. Such a solution should have pH ≈ 8.4. The present one contained excess alkali and perchloric acid was therefore added until phenolphtalein was decolourized. The solution was kept in a polythene bottle where its pH remained constant. (The pH soon rose perceptibly when the solution came into contact with glass.) During the measurement the fluoride solution had to be added from a glass burette. The titrations therefore had to be completed within about two hours; during this time no perceptible increase of pH had occurred. By use of this stock solution series of titrations with C_H = 5, 10, 15, and 25 mM, with no uranyl ions present, were first performed in order to investigate the hydrogen fluoride system. After that three uranyl ion titrations were carried out with C_M' = 10 mM, C_H = 10 mM; C_M' = 25 mM, C_H = 10 mM; and C_M' = 25 mM, C_H = 25 mM respectively * yielding three sets of values of the formation function $\bar{n}_M$ = f([A]).

At this stage it became desirable to extend the search for polynuclear complexes by using higher values of [M]. Another preparation of sodium fluoride "Baker analyzed", lot No. 5093, had then to be used. As a check, the uranyl free titrations of C_H = 10 and

* C_M' = initial value of C_M in a series of measurements (*cf.* p. 711).

25 mM were repeated with a stock solution of this preparation. In spite of the fact that this solution did not contain any free alkali, as shown by its pH, perceptibly higher values of E_H were found than before, especially for the lower value of C_H = 10 mM. The difference became greater with increasing C_A, finally reaching ≈ 3.5 mV for C_H = 10 mM. Evidently the presence of a base much stronger than F^- must be suspected but on the other hand it cannot be very strong as shown by the pH of the solution. A potentiometric titration of the fluoride stock solution also revealed that it possessed a buffering region around pH 7. The amount of the foreign base could be estimated as ≈ 0.4 mole %. This prompted us to investigate a sample left of the first stock solution, and we found that it also contained the same basic impurity but in only about half the amount. It could therefore be assumed that E_H and hence the constants of the hydrogen fluoride system are slightly in error as determined by use of the first stock solution. The figures of the uranyl system on the other hand should not be much affected as they are calculated from the difference between two series of measurements of the same C_H, one with and the other without uranyl ions, which both ought to contain the same error in their emfs.

The foreign basic substance is evidently connected with the hydrolysis of the fluosilicate, present as an impurity in the fluoride preparations. It should however be possible to remove its influence by repressing this hydrolysis in advance. In fact the titration curve of the stock solution shows a minimum of buffer capacity at pH ≈ 6.3. An adjustment of pH to this value will therefore prevent further consumption of H+ by the fluosilicate, while F^- is still left unaffected by H^+.

When the check titrations of C_H = 10 and 25 mM were repeated with such a solution, E_H had in fact decreased and moreover to a value lower than that found with the first stock solution, as could be expected. This difference is at most only 2 mV and the new constants of the hydrogen fluoride system are therefore only slightly different from those previously determined. Series of measurements were then made with uranyl solutions of C_M = 50 and 100 mM, both having C_H = 25 mM. As expected the formation function $\bar{n}_M$ = f ([A]) hence obtained does not deviate essentially from that found by the previous measurements (*cf.* p. 713).

Apparatus: The electrode vessel used for the fluoride buffers was made from methacrylate plastic (»plexiglas»). The stems of the electrodes, the burette tips and other parts which might come into contact with these solutions were also made from plastic (»perspex» tubing). These plastics are completely resistant towards the solutions used. The plexiglas especially has a good transparancy and both are moreover easily worked. The solutions are mixed by a stream of nitrogen gas free from oxygen [9], and the gas inlet tube could also be used to remove the last drop from the burette tips.

Procedure: To a known volume of a solution of known C_M and C_H present in the electrode vessel initially fluoride stock solution was added from one burette and perchloric acid was added from another, in order to keep C_H of the buffer constant during the titration. In the later measurements, the acid solution of the second burette also contained uranyl ions so as to keep also C_M constant. This is not necessary but simplifies the calculations somewhat.

The potentials measured were reproducible within ±0.2 mV and they attained their final values almost at once.

MEASUREMENTS

The solutions are so acid at the outset that perceptible liquid junction potentials must exist. Approximately these potentials are determined merely by $[H^+]$. They may therefore be determined by separate titrations of 1 M

Table 1. The liquid junction potential E_d *as a function of* E. $[H^+]_0$ = *10 mM.*

sodium perchlorate with a perchloric acid solution. The difference between the emfs found and those calculated stoichiometrically are considered to be liquid junction potentials, the activity conditions assumed to be constant as usual. In Table 1, smoothed values of E_d (or E_d') for some round E (or E') are tabulated together with the corresponding values of $[H^+]$. From these figures all resulting liquid junction potentials for the calculation of E_H (or E_H') are easily found (*cf.* eqns. (2) and (10)).

The measurements of the hydrogen fluoride system then performed are tabulated in Table 2 A for the first fluoride preparation and in Table 2 B for the second one. The C_H, C_A function of Table 2 A are straight lines, the slopes of which agree fairly well with the ligand number $\bar{n}_H'$ calculated from (14) Fig. 1. In fact k_E is for some reason even a little higher than $\bar{n}_H'$. Thus H_2F_2 does not exist at the concentrations used here. The constants found are slightly higher for the first preparation than for the second one. For δ_1, the

difference is within the experimental error, but for δ_2 it is just beyond. For reasons mentioned above the second set is thought to be the best one. As the series with the two preparations were so close together, measurements with the second one were confined to the two values of C_H already mentioned. The values of k_E obtained from the lines through the two points at each E_H agree however tolerably well with the $\bar{n}_H'$ calculated from δ_1 and δ_2, Fig. 1. — For the same medium Sundén [12] has found $\delta_1 = 840$ M^{-1} and $\delta_2 \approx 1700$ M^{-2}.

The three uranyl series performed with the first stock solution are tabulated in Tables 3 and 4. Table 3 contains the series of the same $C_H = 10.17$ mM having $C_M = 10$ and 25 mM at the outset. The formation functions, shown in Fig. 2, coincide completely within the experimental errors (which are most marked at high [A], *cf.* p. 709). This proves that neither polynuclear complexes nor complexes containing HF_2 exist in the solutions measured (*cf.* p. 708). Table 4 contains the series of $C_H = 25.43$ mM, $C_M = 25$ mM. The formation function found coincides with those already obtained, Fig. 2, thus proving that no noticeable hydrolysis exists in the solutions [1].

The two uranyl titrations performed with the second stock solution have both $C_H = 25.00$ mM. They are tabulated in Table 5 and the values of $\bar{n}_M$ and [A] are plotted in Fig. 2. The formation function of $C_M = 50$ mM coincides very well with that of lower C_M. Perhaps a slight deviation downwards could be traced for the very lowest values of [A]. For the series of $C_M = 100$ mM a deviation for low [A] is quite perceptible, but nevertheless the coincidence is complete for this series also as soon as [A] > 0.2 mM.

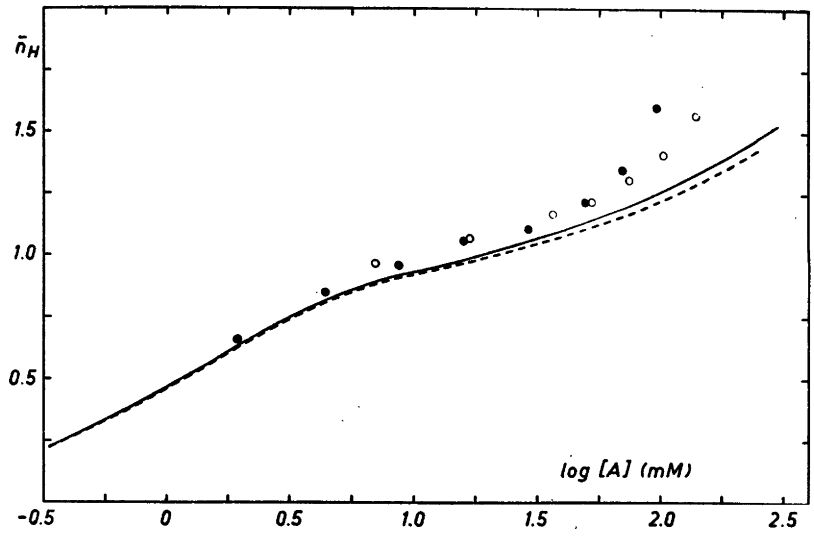

Fig. 1 Complex formation function of the hydrogen fluoride system. —

Curves calculated from (14) with the values of δ_1 and δ_2 found, circles obtained from the slopes k_E of the C_H, C_A-lines of constant E_H'. First fluoride preparation: fulldrawn curve and filled circles; second preparation: dashed curve and open circles.

This deviation at high C_M cannot be attributed to a formation of polynuclear complexes as this would cause the formation curve to move upwards instead of downwards as here (*cf.* Refs.[9, 11, p. 16]). The most probable explanation is a considerable change in the activity conditions caused by the high uranyl concentration since the uranyl salt is responsible for 1/3 of the ionic strength of the solution. Alternatively a small change in the liquid junction potentials might be the cause. E_H is <3.5 mV in this region and a quite small systematic error in the emf measured will therefore have a very marked effect.

Thus a mononuclear complex formation between UO_2^{2+} and F^- is the only reaction involving UO_2^{2+} which takes place in the present solutions. From the bend of the complex formation curve towards $\bar{n}_M = 4$ it is plain that $UO_2F_4^{2-}$ is the upper limit of this complex formation, at least within the range investigated here ([A] $<$ 300 mM).

From the complex formation function thus found the complexity constants were calculated [2], Table 6. As $\bar{n}_M/[A]$ increases very rapidly for low [A] a finite value $[A]_0 = 0.04$ mM was chosen as the lower limit of integration when $X_M([A])$ was computed. The values of β found are given in Table 7 together with the ligand number and the composition of the system calculated [2] for some values of [A]. The formation curve thus found is introduced in Fig. 2 (full-drawn). As seen it fits the experimental points very well *.

Table 7 also contains the consecutive constants [3] b and the ratios b_n/b_{n+1}. Especially the first and third ratios have unusually high values [3, 10, 11] indicating a remarkable stability of the first and third complexes. Consequently the maximum values of α_1 and α_3 (at $\bar{n}_M = 1$ and 3) are unusually high. High values of b_n/b_{n+1} seems to be a common feature of many strong fluoride systems, (for ref. see [13]) but it is quite contrary to that displayed by other uranyl systems [3], especially the acetate.

COMPARISON WITH PREVIOUS WORK

The strong complexity of uranyl fluoride was recognized during the early work on atomic energy but the first quantitative investigation is due to Kraus [14], who found $\beta_1 = 2.1 \times 10^4$ M^{-1} by an ion exchange method in an ionic medium not stated. The spectrophotometric work of Blake, Lowrie and Brown [6] gave $\beta_1 \approx 3 \times 10^5$ M^{-1} and moreover evidence was found for $UO_2F_4^{2-}$, with a value of $\beta_4 \approx 10^8$ M^{-4}. The method used was not very accurate nor was a constant ionic medium maintained. The results are therefore very approximate, and the authors themselves give the uncertainty as one power of ten. Day and Powers [15] have investigated the fluoride complexes in perchlorate medium at several temperatures and ionic strengths by means of TTA-extraction. Owing to the strong complexity a conveniently measurable partition was obtained only for low C_A. Only the first constant $[UO_2F^+][H^+]/[UO_2^{2+}][HF]$ can therefore be computed. For 20° C, $I = 1$ M a value ≈ 34 is found by inter-

* The values of β given here deviate slightly from those of the preliminary note [8]. It has been found that the formation curve obtained from the present values gives a somewhat better fit to the experimental points than did the curve from the previous ones.

this does not exclude the formation of such complexes in more concentrated uranyl solutions. The result that this dimerisation is increasing when excess fluoride is added is however very surprising. One would have expected that an increase of [A] would have favoured the formation of complexes richer in A, such as $UO_2F_3^-$ and $UO_2F_4^{2-}$. As shown above these complexes are in fact the predominating species of solutions which are not very different from those investigated by Johnson, Kraus and Young.

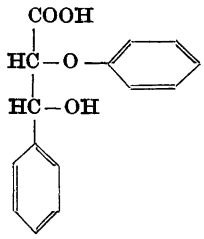
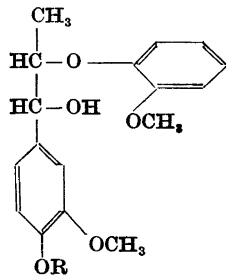
Die Einwirkung von Hypochlorit auf β-Guajacyläther von Guajacylpropaneinheiten wurde kinetisch untersucht. Das Verhalten dieser Modellsubstanzen dürfte die Auffassung stützen, dass im Lignin entsprechende Gruppierungen in grösserer Menge vorkommen.
Die Synthese einiger Modellsubstanzen wird beschrieben.

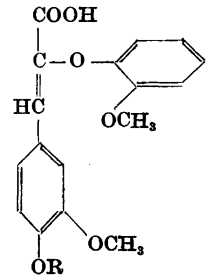


In zwei vorangehenden Mitteilungen [1,2] wurde über das Verhalten von Lignin bzw. von einer grösseren Anzahl von Ligninmodellsubstanzen gegen Hypochlorit berichtet. Diese Modellsubstanzen unterschieden sich im wesentlichen dadurch, dass sie einen Guajacolrest phenolätherartig an das α-, β- oder γ-Kohlenstoffatom einer 4-Propylguajacol- bzw. einer 4-Propylveratroleinheit gebunden enthielten. Unter diesen Modellsubstanzen zeigten einige mit einem in α-Stellung gebundenen Guajacolrest — insbesonders der von K. Freudenberg und Hübner [3] dargestellte Dehydrodiconiferylalkohol — insofern eine recht gute Übereinstimmung mit dem Verhalten des Lignins, als nicht nur der phenolische Rest, sondern auch ein Teil des phenolätherartig gebundenen Guajacolrestes durch Hypochlorit oxydiert wurde. Während in der Gruppe der β-Äther bisher nur solche von Propylveratroleinheiten auf ihr Verhalten gegen Hypochlorit geprüft wurden, wird in der vorliegenden Mitteilung nun auch der Abbau von β-Äthern von Guajacylpropanderivaten beschrieben.

Die Gruppe der β-Äther gewann in den letzten Jahren gesteigertes Interesse, nachdem Adler und Yllner [4] die Ähnlichkeit solcher Verbindungen mit dem Lignin in Bezug auf Sulfitierung und Alkoholyse erkannt und nachdem Freudenberg und Mitarbeiter [5] bei der enzymatischen Dehydrierung von Coniferylalkohol den β-Äther VII isoliert und als wichtiges Zwischenprodukt bei der Bildung der ligninähnlichen Dehydrierungspolymerisate des Coniferylalkohols erkannt hatten.

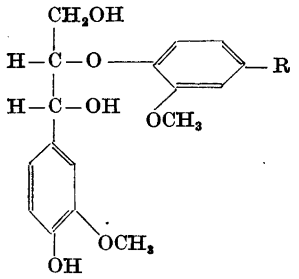


Von den untersuchten Verbindungen erwies sich die nach Stoermer und Kippe [6] dargestellte Verbindung I als ziemlich stabil gegen Hypochlorit bei 90°. Wie aus der folgenden Figur hervorgeht, ist der Hypochloritverbrauch von I so gering, dass der Ätherrest in β-Stellung sicher nur sehr langsam abge-

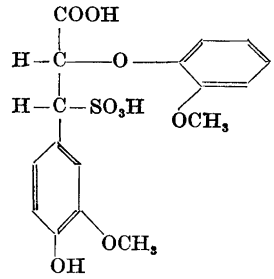


spalten werden kann. Immerhin konnte beim Abbau eine geringe Menge Benzoesäure nachgewiesen werden. Ein Vergleich des Verhaltens der phenolischen Verbindung II und ihres Methyläthers III, welche beide von Adler und Delin [7] dargestellt wurden, zeigt, dass III analog zu I nur relativ wenig Hypochlorit verbraucht. Dagegen ist bei II der Verbrauch mit 11 Mol Hypochlorit pro Mol innerhalb von 40 Min. so gross, dass bei II ausser dem phenolischen Rest auch schon der ätherartig gebundene Guajacolrest in gewissem Umfang oxydiert werden muss.

I



II: R = H
III: R = CH_3



IV: R = H
V: R = CH_3

In der Verbindung IV, welche durch Kondensation von Vanillinacetat mit 2-Methoxyphenoxyessigsäure dargestellt wurde, werden beide Kerne bei einem Verbrauch von etwa 14 Mol Hypochlorit innerhalb von 20 Min. rasch abgebaut. Dass tatsächlich beide Kerne angegriffen werden, geht aus der Bestimmung der abgespaltenen Methanolmenge hervor. Aus einem Ansatz von 14 Mol Hypochlorit pro Mol IV lassen sich 1,7—1,8 Mol Methanol abdestillieren. Die IV entsprechende, methylierte Verbindung V — durch Kondensation von Veratrumaldehyd mit dem Natriumsalz der 2-Methoxyphenoxyessigsäure dargestellt — verbraucht im Verlauf von 60 Min. weniger als 3 Mol Hypochlorit. Es findet demnach nur ein langsamer Abbau des ätherartig gebundenen Guajacolrestes statt, wobei eine geringe Menge Veratrumsäure gebildet wird.

Ganz analog werden beim β-Guajacyläther des Guajacylglycerins (VI) beide Kerne rasch abgebaut. Auch in der Sulfosäure VIII werden die beiden Kerne rasch abgebaut. Nach einem Hypochloritverbrauch von etwa 14 Mol im Verlauf von 30 Min. erhält man 1,5—1,6 Mol Methanol. Die Sulfosäure lässt sich durch Erhitzen von IV mit neutraler Sulfitlösung auf 135° herstellen und wurde als Bariumsalz isoliert. Auch V lässt sich in gleicher Weise sulfitieren. Das UV-Absorptionsspektrum des Bariumsalzes von VIII zeigt Maxima bei 225 und 277 mμ sowie ein Minimum bei 253 mμ. Die Sulfosäure VIII zeigt keine Tendenz, beim Kochen ihrer wässrigen Lösung Guajacol abzuspalten.

VI: R = H
VII: R = CH : CH · CH_2OH

VIII

Aus den Kurven des Hypochloritverbrauchs geht klar hervor, dass in den Verbindungen IV, VI und VIII die ätherartig gebundenen Guajacolreste rasch und ziemlich vollständig abgebaut werden. Diese Modellversuche stehen demnach in gutem Einklang mit der Vermutung, dass ein wesentlicher Teil der Lignineinheiten durch derartige Ätherbindungen an der β-Stellung der Guajacylpropanseitenkette miteinander verknüpft sind.

Herrn Prof. E. Adler danken wir für die freundliche Überlassung einiger Präparate. Frau S. Safwat danken wir für die Ausführung der Methanolbestimmungen.

EXPERIMENTELLER TEIL

α-(2-Methoxyphenoxy)-ferulasäure (IV). 9,7 g Vanillinacetat, 10,2 g gut getrocknetes Natriumsalz der 2-Methoxyphenoxyessigsäure und 50 ml Essigsäureanhydrid werden unter Rühren 24 Stunden auf 105—110° erwärmt. Nach dieser Zeit wird ein Teil des

Essigsäureanhydrids im Vacuum abdestilliert und der Rückstand in Wasser gegossen. Das sich zuerst ölig ausscheidende Reaktionsprodukt erstarrt allmählich und wird abgenutscht. Nun wird das Rohprodukt mehrmals mit Äther ausgezogen, wobei das Acetat von IV in Lösung geht, während die Hauptmenge der als Nebenprodukt gebildeten Acetylferulasäure ungelöst zurückbleibt. Der Ätherlösung wird das Acetat von IV durch Ausschütteln mit Sodalösung entzogen, welche in verdünnte Salzsäure gegossen wird. Das kristallin ausfallende Produkt wird durch Umkristallisieren aus Benzol rein erhalten. Schmp. 164—166°. Ausbeute 1,6 g. (Gef. C 63,76; H 5,57; OCH_3 16,82. Ber. für $C_{19}H_{18}O_7$ (358,3): C 63,69; H 5,06; OCH_3 17,30.)

Nach dreistündigem Erwärmen des Acetats mit N Natronlauge erhält man beim Ansäuern IV, welches nach Umkristallisieren aus Benzol bei 152—153° schmilzt. (Gef. C 64,50; H 5,30; OCH_3 19,13. Ber. für $C_{17}H_{16}O_6$ (316,3): C 64,55; H 5,10; OCH_3 19,60.)

Sulfitierung von IV. 2,04 g IV werden mit 40 ml neutraler Natriumsulfitlösung (10 % Schwefeldioxyd, pH 6,4) 25 Stunden auf 135° erhitzt. Aus der Reaktionslösung wird eine kleine Menge öliger Substanz mit Äther ausgeschüttelt. Nach längerem Stehen scheiden sich aus der wässrigen Lösung 0,68 g des Natriumsalzes der gebildeten Sulfosäure ab, welches in das Bariumsalz übergeführt wurde. Aus der Mutterlauge wurde nach Katjonenaustausch, Entfernung der schwefligen Säure und Neutralisation mit Bariumcarbonat eine weitere Menge Bariumsalz erhalten. Die Ausbeute an reinem Bariumsalz betrug 1,49 g (44 % der Theorie). (Gef. S 6,18; OCH_3 11,24. Ber. für $C_{17}H_{16}O_9SBa$ (533,7): S 6,01; OCH_3 11,63).

α-(Methoxyphenoxy)-3,4-dimethoxyzimtsäure (V). Wird analog der bei IV beschriebenen Kondensation aus Veratrumaldehyd und dem Natriumsalz der 2-Methoxyphenoxyessigsäure erhalten. Schmilzt nach Umkristallisieren aus verdünntem Alkohol bei 199—201°. (Gef. OCH_3 28,41. Ber. für $C_{18}H_{18}O_6$ (330,3): OCH_3 28,19).

The Stability of Metal Halide Complexes in Aqueous Solution

I. The Stability of Metal Halide Complexes in Relation to the Position of the Metal in the Periodic System

STEN AHRLAND

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

With respect to the strength of their halide complexes central ions may be divided into two groups. The first group shows decreasing stability in the order $F^- \gg Cl^- > Br^- > I^-$, the second one in the reversed order $F^- \ll Cl^- < Br^- < I^-$. The extension of the two groups within the Periodic System is discussed.

As pointed out previously by Ahrland and Larsson [1] central ions may be divided into two distinct groups with respect to their ability to form halide complexes. The ions of the first group form fluoride complexes which are much stronger than the complexes formed with the heavier halide ions. The strength of these decreases in the order $Cl^- > Br^- > I^-$. On the contrary, the ions of the second group form fluoride complexes which are much weaker than the complexes formed with the heavier halide ions. Moreover the strength of these always increases in the order $Cl^- < Br^- < I^-$.

The strength of the halide complexes is thus completely reversed between the two groups. In both cases however, the complexity varies monotonicly with the atomic number of the halogen and there is moreover always a difference in the order of magnitude between the complexity of the fluoride and that of the other halide ions.

The first group is the more numerous one. It certainly contains * H^+, Ce^{3+}, U^{4+}, UO_2^{2+}, Zr^{4+}, Fe^{3+}, and In^{3+}, most probably also Be^{2+}, Th^{4+}, Pu^{4+}, Cu^{2+}, Zn^{2+}, Al^{3+}, and Sn^{2+}. In the latter cases many desirable data are admittedly still lacking but the trend nevertheless seems obvious. In the case of Be^{2+} and Al^{3+} where only the fluoride systems have been quantitatively measured supplementary evidence is provided by the fact that the chlorides [9, 10, p. 573] are typical strong electrolytes, quite unlike the fluorides. This is also the case for aluminium bromide [11].

* A very comprehensive list of references has been compiled by Carleson and Irving [2]. Further references: U^{4+}, see [3]; Be^{2+}, see [4]; Pu^{4+}, see [5,6]; Hg^{2+}, see [7]; Pb^{2+}, see [8].

The less numerous second group certainly contains Pt(II), Cu^+, Ag^+, Cd^{2+}, Hg^{2+} and Pb^{2+}. The complexes of Pt(II) are as a rule inert and their equilibria therefore difficult to measure. In the olefin complexes however, the bond *trans* to the olefin position becomes labilised [12] and measurements of equilibria involving this ligand are therefore feasible, as shown by Leden and Chatt [13]. These measurements prove definitely that Pt(II) belongs to the second group and this could also be expected from preparative data known previously. Thus Pt(II) forms very stable chloro and bromo salts while the corresponding fluoro compounds do not even seem to exist [14]. For Pb^{2+}, the order $Cl^- < Br^-$ has recently also been confirmed by ion exchange measurements [15].

Most probably Pd(II), Pd(IV), Pt(IV), Au(III), and Tl^{3+} also belong to the second group. For Pd(II), Pd(IV) and Au(III) this conclusion is based on preparative data similar to those quoted for Pt(II) above (*cf.*[16,17] and references quoted therein). For Pt(IV), semi-quantitative measurements of Schlesinger and Palmateer [18] unequivocally indicate the second group order $Cl^- < Br^- < I^-$ of complex stability.

Now the striking fact is that all the central ions of the second group are derived from neighbouring elements around the end of the transition series. Moreover these elements seem to form a roughly triangular figure with the apex at Cu and the base stretching from somewhere to the left of Pt to the right of Pb.

The right borderline of the triangle seems fairly well established. It certainly runs between the pairs Cu—Zn, Zn—Cd, Cd—In, In—Tl, and Sn—Pb; only the last part of its course is still unknown.

On the other hand the left borderline is only roughly known at present. Fe is definitely outside the triangle and there is no doubt that the border runs between Cu and Ni, as the heavy halides of Ni^{2+} are typical strong electrolytes. Thus the activity coefficients of nickel chloride resemble those of barium and calcium chlorides [10, p. 423] and the absorption spectrum of the solution is practically identical with that of nickel perchlorate [19], both solutions evidently containing the same absorbing species, Ni^{2+}. Thus Cu^+ is the only central ion of the 4th period belonging to the second group, and the triangular area has an apex at copper. Unlike Cu^+, Cu^{2+} belongs to the first group. Copper is the only element where different valency states have been found to belong to different groups. It would be interesting if a method of investigating halide complexes of Ag(II) could be found, to see whether silver behaved analogous to copper in this respect. As to the further course of the left borderline, it may be supposed that the remaining platinum metals are also inside the triangle on account of their resemblance to Pd and Pt. However, it is not known at present if there is a further extension to the left of the second group area. The known facts are that Zr^{4+} and Ce^{3+} (and certainly the other lanthanides as well) are outside it, as are also the actinides of the 7th period.

The relative strength of the halide complexes of central ions belonging to the first group, outside the triangle, is just the one which would be expected if the complex formation is due to essentially electrostatic forces. In such a case strong bonds should be formed by ligands combining slight polarizability with small ionic radius. These quantities both decrease monotonicly from

I^- to F^-, but F^- occupies a unique position as the differences between F^- and Cl^- are much greater than those between the heavy halides. Therefore the sequence of halide complexity should be $F^- \gg Cl^- > Br^- > I^-$ as is also found for the first group.

The strength of the complex formation will also depend upon the central ion, and strong electrostatic bonds should be formed by central ions of high ionic charge and small radius. As pointed out by Connick and Tsao [20] the strength of the fluoride complexes just follow this pattern thus indicating their essentially electrostatic character.

The reversal of the relative strength of the halide complexes for the central ions within the triangle has been explained by Leden and Chatt [13] as being due to a formation of partial double bonds of an essentially covalent character between the metal ion and the heavy halide donor. In their penultimate shells, the elements at the end of the transition series have filled d-orbitals of an energy close to that of the ordinary valency hybrids. These orbitals might therefore be incorporated in the bond system of the complex provided the ligand is able to accomodate the extra bonding electrons thus offered. The three heavier halides have vacant d-orbitals in their outer shells and are therefore able to participate in a double bond while the fluoride ions has no such orbitals and thus cannot form any double bond. If the strength of the complexes is determined by a covalent double bond formation, the fluoride complexes should therefore be much weaker than those of the heavier halide ions. The order between these will be determined by their donating properties, which show a smooth increase from Cl^- to I^-. The expected order will therefore be $F^- \ll Cl^- < Br^- < I^-$, or just the one found within the second group.

Leden and Chatt [13] also point out that those metals which show a strong complexity of the chloride relative to the fluoride are also characterized by the much greater stability of thio-ether complexes relative to ether complexes, and trialkylphosphine complexes relative to trialkylamine complexes. In these cases too the formation of strong complexes might be attributed to the formation of double bonds with those ligands which possess vacant d-orbitals in their outer shells.

The existence of multiple metal to ligand bonds involving d-orbitals of the metal was first postulated by Pauling [21] in order to account for the remarkable stability of carbonyl, nitrosyl and cyano complexes of the later transition metals. In these cases it was assumed that the additional bonding electrons are accommodated in the ligand by means of an electronic rearrangement leading to a decrease in bond order of the internal ligand bond. Later Dewar [22] and Chatt [23, 24] have explained the formation of olefin complexes along similar lines. In all those cases there is also strong physical evidence (from measurements of bond lengths and infrared stretching frequencies) that the bonds of the complexes are really of the orders postulated by the multiple bond theory. Evidence of that kind is admittedly still lacking for the halide complexes.

Measurements on further halide systems are now in progress in order to see whether they all fit into the above scheme. In the first hand systems on the supposed borderlines are being investigated as they will give the information required about the exact extension of the triangular area. Such systems will possibly also show some interesting transitional properties.

This work is part of an investigation supported by *Statens naturvetenskapliga forskningsråd (Swedish Natural Science Research Council)*. My thanks are due to Dr. J. Chatt, Dr. Sture Fronæus, Dr. Ido Leden and Dr. F. J. C. Rossotti for interesting discussions and useful comments.

The Stability of Metal Halide Complexes in Aqueous Solution

II. The Fluoride Complexes of Divalent Nickel, Copper, and Zinc

STEN AHRLAND and KJELL ROSENGREN

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The stabilities of the fluoride complexes of Ni^{2+}, Cu^{2+}, and Zn^{2+} have been determined. In the solutions studied ($[F^-] \leqq 200$ mM; $C_M \leqq 100$ mM; perchlorate medium of ionic strength 1 M at 20° C) only the first mononuclear complex exists in appreciable concentrations. The following values of the constant $\beta_1 = [MF^+] / [M^{2+}] [F^-]$ have been found:

Ni^{2+}: 4.6 ± 0.5 M^{-1}; Cu^{2+}: 9 ± 1 M^{-1}; Zn^{2+}: 5.9 ± 0.6 M^{-1}

The stability order of these complexes, as well as their strength relative to the complexes formed by the same metal ions with the other halide ions is in accordance with the views advanced in the first paper [1] of this series.

According to the views developed in part I of this series of papers [1], the fluoride complexes of Ni^{2+}, Cu^{2+}, and Zn^{2+} should be much stronger than the complexes formed by these ions with the other halides. However, even the fluoride complexes will be of moderate strength as the central ions are only divalent and do not have especially small ionic radii. The stability of the fluoride complexes will vary inversely with the ionic radii, *i. e.* in the order $Ni^{2+} < Cu^{2+} > Zn^{2+}$ (*cf.* Connick and Tsao [2]).

The aim of the present investigation was to test these views experimentally. The systems were studied in the same way as the uranyl fluoride [3] system. The ionic medium (perchlorate of ionic strength $I = 1$ M) and the temperature (20° C) were also the same as in the previous measurements.

From the emf E_H obtained experimentally * by means of the quinhydrone electrode the free ligand concentration [A] may be calculated using the equation

* The same symbols are used as in the paper on uranyl fluoride [3].

$$\text{antilog}\ \frac{E_H}{RT/F} = \frac{C_H}{[H^+]} = 1 + \delta_1\,[A] + \delta_2\,[A]^2 = X_H \qquad (1)$$

where the constants δ_1 and δ_2 of the hydrogen fluoride system have been determined previously [3]. Then the ligand number $\bar{n}_M$ can be calculated from the relationship

$$\bar{n}_M = \frac{C_A - [A] - \bar{n}_H \cdot C_H}{C_M} \qquad (2)$$

where the value of $\bar{n}_H$ corresponding to the appropriate value of [A] is found from the known [3] complex formation function of the hydrogen fluoride system. Once the complex formation function $\bar{n}_M = f([A])$ has thus been found, the complexity constants can be calculated in the usual way [4].

The calculation of [A] and $\bar{n}_H$ described above presupposes however that neither the dimer H_2F_2 nor metal complexes with HF_2^- as ligand exist in the range of concentration used. It has previously [3] been shown that no H_2F_2 is formed and that HF_2^- does not compete appreciably with F^- in the formation of complexes with UO_2^{2+}. It was therefore assumed in the first instance that no complexes with HF_2 are formed by the present cations. This assumption may be tested experimentally in the same way as for UO_2^{2+}, *viz.* by determining the formation function for different values of total concentration of metal C_M. If this function is independent of C_M it may be concluded not only that no complexes of HF_2^- exist but also that the complex formation is entirely mononuclear [3].

It is well known that the present cations are not hydrolysed at low pH. This is also confirmed by the analysis performed (p. 729) in order to check if the preparations of perchlorates used contain any free perchloric acid. No buffering due to Cu^{2+} could be detected below a pH of 4 or 5; and the hydrolysis of Zn^{2+} and Ni^{2+} becomes perceptible only at still higher pH. Nevertheless series of measurement were performed at two different values of total concentration of acid, C_H, in order to ensure that complex formation is really independent of $[H^+]$ (*cf.* Ref.[3]).

The calculation of the complex formation function from δ_1 and δ_2 also presupposes that the values of these constants do not change appreciably in the range of C_A used. To judge from previous measurements this is true for $C_A \lessapprox 200$ mM. For $C_A \gtrapprox 200$ mM a fairly tedious method of calculation must be used in order to find $\bar{n}_M = f([A])$. For the present systems however no measurements are performed in this upper range, as they are not likely to give further information justifying the work involved. The systems are so unstable that only the first complex MF^+ can be shown to exist with certainty when $C_A \lessapprox 200$ mM. Even at the highest value of C_A, ≈ 400 mM, which can be reached by adding a fluoride solution almost saturated with respect to NaF, the concentration of the second complex must therefore be low. In view of the further uncertainty inherent in the change of the medium, a calculation of the stability constant of this complex is not really possible even if the measurements are extended to $C_A = 400$ mM.

EXPERIMENTAL

Chemicals. The preparations of *nickel perchlorate* and *copper perchlorate* were the same as used by Fronæus [5,6]. *Zinc perchlorate* was prepared by adding the equivalent amount of a solution of sodium hydroxide (EKA *puriss*) to a solution of zinc nitrate (Bakers analyzed), washing the precipitate free from nitrate ions and then dissolving it in a slight excess of perchloric acid (Bakers analyzed). When excess water was driven off nice crystals of the zinc perchlorate hexahydrate were obtained.

Stock solutions of the perchlorates, of an ionic strength I = 1 M, were prepared and their exact concentrations then determined by electroanalysis (according to the methods described by Vogel [7]).

The amounts of free perchloric acid possibly present in the stock solutions were determined by adding a known amount of acid to a sample which was then titrated potentiometrically with alkali. The metal ions present are all so weakly acidic that they do not interfere with the determination of the free acid. The stock solutions of Ni^{2+} and Zn^{2+} did not contain any free acid. For Cu^{2+} a small concentration of acid was found (= 1.0 % of the total perchlorate concentration) and taken into account when solutions were mixed for the fluoride titrations.

Table 1. Determination of the complex formation function of the nickel fluoride system.

A. C_M = 50 mM; C_H = 10 and 25 mM.

C_H mM →	10				25

The *sodium fluoride* was of the second preparation used for the uranyl fluoride measurements [3]. The *other chemicals* were also the same as used in this investigation.

Procedure. For each central ion three titrations were performed, the first two with C_M = 50 mM and C_H = 10 and 25 mM, the third with C_M = 100 mM and C_H = 10 mM. The values of C_M and C_H were kept constant throughout every titration. The titrations were all performed with the same reference electrode RE (with $[H]_0$ = 10 mM) as was used before [3].

The quinhydrone electrode functioned well in the present solutions. Even at the highest concentrations of metal ions used, C_M = 100 mM, the potentials differed only slightly from the values calculated from known values of $[H^+]$. Thus the emf $E^{(i)}$ measured initially which should be zero for the series of C_H = 10 mM is found to be 1—2 mV for C_M = 100 mM. This deviation may be caused by several factors which probably co-operate. The changes of the ionic medium may produce changes in the activity coefficients and the liquid junction potentials and some complex formation between the metal ion and the hydroquinone may occur. These slight deviations certainly have very little influence on the calculation of [A] (and $\bar{n}_M$) as E_H is the emf of a cell with the same value of C_M in both half-cells. The potentials measured reached equilibrium almost at once and as a rule they could be reproduced within 0.2 mV.

RESULTS

The complex formation functions are given in Tables 1—3 and plotted in Figs 1 and 2. For the three ions measured, this function is seen to be independent of both C_M and C_H within the experimental errors. It must be remembered that the errors are fairly large when weak complexes are determined by measurements of [A]. Thus no polynuclear complexes, no complexes containing HF_2^- and no hydroxo complexes exist in perceptible amounts in the solutions investigated. The mononuclear complex formation between metal ion and F^- is therefore the only process which need be considered.

The complexity constants are calculated from the complex formation functions in the same way as before [4]. When integrating the function $\bar{n}_M/[A]$ in order to find X_M it is suitable to choose [A] = 10 mM as the lower limit of integration. The results are in Table 4. As seen the function X_{1M} is virtually constant over the whole range of [A] for all the systems measured, with the

β_1 M^{-1} →	4.6 ± 0.5		9 ± 1		5.9 ± 0.6	

exception of the highest values of Cu^{2+}, where a slight upward trend is found. Thus the first complex MF^+ is the only one existing in measurable amounts in the present solutions. Therefore the value of β_1 is taken for each ion as the mean of the values of X_{1M} over the whole range of [A] (with the highest values for Cu^{2+} left out). The values of β_1 thus found are given in Table 4, with the random errors indicated.

As could be foreseen from their charge and ionic radii, Ni^{2+}, Cu^{2+}, and Zn^{2+} form only weak fluoride complexes with the stability order $Ni^{2+} < Cu^{2+} > Zn^{2+}$. Nevertheless the fluoride complexes are all, as expected, much stronger than the complexes formed by the other halides. Thus in the case of Cu^{2+} and Zn^{2+}, β_1 of the fluoride system is 10 times greater than β_1 of the next strongest system, the chloride [8,9]. In the case of Ni^{2+}, there are no quantitative data about the other halides, but they are typical strong electrolytes (*cf.*[1] and references therein). From the sequence of ionic radii one would rather expect them to be less stable than the corresponding complexes of Cu^{2+}.

The results of this investigation thus agree in all respects with the predictions made on the basis of the views put forward in I. Moreover the ions Ni^{2+}, Cu^{2+}, and Zn^{2+}, which were previously considered as only probable members of the first group of central ions (as defined in I), are now shown as certainly belonging to this group.

This investigation has been generously supported by *Statens naturvetenskapliga forskningsråd (Swedish Natural Science Research Council)*. We are further indebted to Dr. Sture Fronæus for the gift of the preparations of nickel and copper perchlorate.

Synthesis of Compounds Related to Muscarufin I

HOLGER ERDTMAN and MARTIN NILSSON

Organisk-kemiska institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The synthesis and properties of 2,5-dimethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (II), 2,5-bis-(2-carbomethoxyphenyl)-benzoquinone (III) and some related compounds is reported. These compounds embrace parts of the structure proposed by Kögl and Erxleben for muscarufin (I).

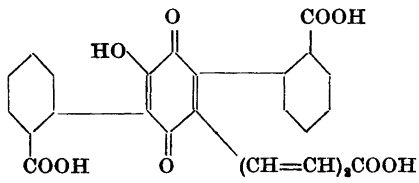
From the common fly-agaric, *Amanita muscaria*, Kögl and Erxleben [1] isolated in 1930 a red pigment muscarufin for which, as a result of elegant degradative work carried out with very small quantities of material, they were able to advance structure I. This formula appears to have met with general acceptance.

Other products of fungal metabolism which exhibit structural relationships to muscarufine include polyporic acid [2], atromentin [3] and leucomelone [4] which all possess the terphenyl system in common with muscarufin. The unsaturated side chain of muscarufin recurs in the widespread fungus and lichen pigment telephoric acid [5] and is somewhat reminiscent of polyenoid pigments of fungal origin, *e. g.* corticrocin [6], cortisalin [7], fumigallin [8] and limocrocin [9]. Among natural products from higher plants compounds of the piperic acid type are worthy of mention.

Some of these compounds have been synthesised and the bis-phenyl-dihydroxybenzoquinones in particular have been the subject of a number of investigations.

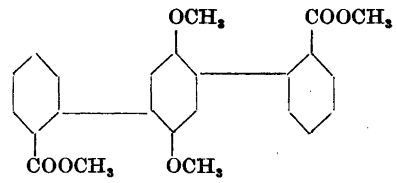
Since the work of Kögl and Erxleben, however, no further publications on muscarufin have appeared and a synthetic confirmation of the proposed structure is still lacking.

In order to obtain information about the synthetic pathways to, and the properties of, 2,5-bis-(2-carboxyphenyl)-benzoquinone and related compounds the present investigation was undertaken.



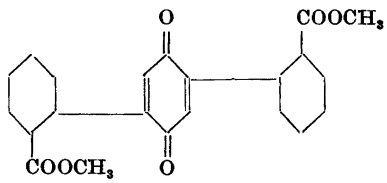
In view of the successful application of the Ullmann reaction for the preparation of tri- and tetraquinone [10] we have explored this approach for the synthesis of muscarufin-like substances.

The mixed Ullmann coupling of methyl 2-bromobenzoate and 2,5-diiodohydroquinone dimethylether afforded 2,5-dimethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (II) in good yield (50 %). On treatment with nitric acid it furnished the yellow 2,5-bis-(2-carbomethoxyphenyl)-benzoquinone (III).



We have investigated the possibilities of introducing various substituents into the central nucleus of these terphenyl systems. All attempts to brominate the terphenyl derivative II failed and the reaction between the quinone III and hydrogen bromide afforded the dilactone IV (R = H); the hydrogen bromide thus simply reduced the quinone. The same dilactone resulted from demethylation of II with pyridinium chloride and was even obtained on attempted reductive acetylation of the quinone. This fact is of interest since Kögl and Erxleben report that muscarufin under similiar conditions did not undergo lactonisation but yielded a *triacetate*. The addition of hydrogen chloride to III was more successful but lactonisation again occurred with formation of the chlorodilactone (IV, R = Cl). These lactones are very high melting, sparingly soluble substances and it is therefore sometimes difficult to isolate them in a state of complete purity. They can be dissolved in hot, strong alkali but on acidification the dilactones are recovered. Repeated treatment of the dilactone IV (R = H) with potassium hydroxide and methyl iodide afforded the monolactone methyl ether methyl ester (V).

Thiele acetylation of the quinone III using sulphuric acid as a catalyst failed. However, when perchloric acid was employed a complex reaction product was obtained, from which 2,3,5-triacetoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (VI) could be isolated although in poor yield. This compound contains all the characteristic features of *leuco*-muscarufin except the unsaturated side chain.



Further work on this subject is in progress and will be published shortly in this journal.

EXPERIMENTAL

All melting points are uncorrected. Melting points above 300° were determined by dropping a few crystals on a preheated bloc; the very strong sublimation of the substances in question prohibited the use of ordinary methods.

2,5-Dimethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (II). 2,5-Diiodohydroquinone dimethylether (25 g, 0.1 mole) and methyl 2-bromobenzoate (84 g, 0.4 mole) were heated in a 300 ml flask until a homogeneous solution was obtained. This was thoroughly mixed with copper bronze (240 g) and then slowly heated in a salt bath. At *ca.* 200° a considerable heat of reaction developed and the temperature rose to *ca.* 300°. After cooling to room temperature the hard mass was desintegrated and exhaustively extracted with chloroform in a Soxhlet apparatus. The solvent was removed and the residual oil (A) distilled *in vacuo* yielding a small amount of methyl benzoate, dimethyl diphenate and an oily fraction b. p. 200—285° (1 mm) the bulk of which passed over at about 240°. On trituration with methanol the fraction b. p. 200—285° crystallised (12 g, 48 %). Alternatively methanol (50 ml) was added to the crude oil (A) and after keeping in the refrigerator overnight most of the terphenyl derivative crystallised leaving the dimethyl diphenate in the mother liquors. Recrystallisation from glacial acetic acid gave the pure compound as small colourless prisms, m. p. 174—175°. (Found: C 70.9; H 5.5; CH_3O 30.9. Calc. for $C_{24}H_{22}O_6$: C 70.9; H 5.5; CH_3O 30.5.)

2,5-Bis-(2-carbomethoxyphenyl)-benzoquinone (III). 2,5-Dimethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (10 g) was slowly added to nitric acid (150 ml, *d* 1.42). The initial dark colouration rapidly disappeared and nitrous fumes were evolved. The suspension was allowed to stand for 15 minutes and was then poured into water (500 ml). After standing overnight the yellow precipitate was collected and recrystallised from methyl-ethyl ketone giving the pure quinone as yellow prisms, m. p. 188—189°. (Found: C 70.0; H 4.4; CH_3O 16.2. Calc. for $C_{22}H_{16}O_6$: C 70.2; H 4.3; CH_3O 16.5.)

2,5-Dihydroxy-1,4-bis-(2-carboxyphenyl)-benzene dilactone (IV, R = H). (a). The quinone III (0.20 g) was dissolved in chloroform (20 ml) and a rapid stream of hydrogen bromide passed into the solution. After an initial dark coloration white crystals began to separate. When the precipitation appeared complete the crystals were collected (0.19 g) and recrystallised from diacetone alcohol giving needles, m. p. *ca.* 410°, subliming readily above 390°. Qualitative tests showed the abscence of bromine.

(b). Attempted reductive acetylation of III using acetic anhydride, zinc dust and a trace of pyridine or fused sodium acetate led to the formation of a white flocculent precipitate, which was separated from excess zinc by decantation. Recrystallisation from very large volumes of acetic anhydride afforded small white needles, m. p. *ca.* 410°, alone or in admixture with the substance obtained in experiment (a). Determination of the acetyl content (about 2 %) indicated the almost complete abscence of acetoxyl groups.

(c). Treatment of the terphenyl derivative II with excess pyridinium chloride at 200° for 2 h resulted in the formation of the same dilactone as in experiments (a) and (b) as shown by melting point and mixed melting point determinations. (Found: C 75.9; H 3.2. Calc. for $C_{20}H_{10}O_4$: C 76.4; H 3.2.)

2,5-Dihydroxy-3-chloro-1,4-bis-(2-carboxyphenyl)-benzene dilactone (IV, R = Cl). The quinone III (0.25 g) was dissolved in chloroform and a stream of hydrogen chloride passed into the solution. The product soon separated as white crystals (0.16 g), which were recrystallised from diacetone alcohol (needles), m. p. *ca.* 385°. (Found: C 68.2; H 2.6; Cl 10.7. Calc. for $C_{20}H_9O_4Cl$: C 68.9; H 2.6; Cl 10.2.)

2-Hydroxy-5-methoxy-1-(2-carboxyphenyl)-4-(2-carbomethoxyphenyl)-benzene lactone (V). The dilactone IV (R = H) (0.9 g), potassium hydroxide (0.9 g) and methanol (10 ml) were heated on a water bath until a clear solution was obtained (0.5 h). Methyl iodide (4.3 g) was added and the mixture refluxed for 6 h. Additional quantities of potassium hydroxide (0.1 g) and methyl iodide (1 g) were introduced and the heating continued for a further 6 h. The solvent was removed and the solid residue (A) extracted several times with boiling chloroform. The extract was evaporated to dryness and the product (0.4 g) recrystallised from methanol (small needles), m. p. 197—198°. (Found: C 73.5; H 4.6. Calc. for $C_{22}H_{16}O_5$: C 73.3; H 4.5.) From the chloroform insoluble part of A unchanged starting material was recovered.

2,3,5-Triacetoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (VI). Perchloric acid (15 ml, *d* 1.67) was slowly added to acetic anhydride (300 ml), cooled in an ice bath. The temperature of the solution was then allowed to rise to *ca.* 20° and the quinone III (7.4 g) introduced with stirring. After about 5 h it had dissolved giving a brownish red solution, which was kept overnight and then poured onto ice (1 kg). Water (2 l) was added and the suspension stirred for 24 h. The dried precipitate (A) (8.5 g) was dissolved in benzene (a small amount of insoluble amorphous material being removed by filtration), and the solution evaporated to a small volume. On standing some crystalline material was deposited (B), which was, however, found to be a difficultly resolvable mixture. (M. p. of the components *ca.* 160° and *ca.* 180°.) The mother liquor was *rapidly* (compare below) passed through a column of activated alumina (15 × 2 cm), which was then thoroughly washed with benzene. Evaporation of the purified solution yielded an oil, which on treatment with benzene afforded unchanged starting material. Addition of ligroin to the mother liquor precipitated a yellowish mixture of crystals yielding on fractional crystallisation from methanol and benzene-ligroin mixtures small amounts of starting material, a mixture of higher melting compounds (B) and the desired product (*ca.* 2 g). The last named formed colourless prisms finally purified by recrystallisation from methyl *cyclo*hexane, m. p. 144—146°. (Found: C 64.1; H 4.5. Calc. for $C_{28}H_{24}O_{10}$: C 64.6; H 4.6.)

If the reaction was carried out at a slightly elevated temperature (30°) or for a prolonged time the amount of starting material recovered decreased, the amount of triacetate remained approximately constant but that of the higher melting unidentified compounds (B) increased.

In preliminary experiments the crude reaction product (A) was treated with dimethyl sulphate and alkali giving, in poor yield, a compound which according to its properties and the analytical result was a *dilactone of 2,3,5-trihydroxy-1,4-bis-(2-carboxyphenyl)-benzene methyl ether* (*e. g.* IV, R = OCH_3). On recrystallisation from acetic anhydride the dilactone was obtained as needles, m. p. *ca.* 310°. (Found: C 73.2; H 3.3; CH_3O 9.8. Calc. for $C_{21}H_{13}O_5$: C 73.4; H 3.5; CH_3O 9.0.) In another experiment A was subjected to acid methanolysis affording again in poor yield a compound, m. p. *ca.* 355°, after recrystallisation (needles) from acetic acid. This substance apparently was a *dilactone of 2,3,5-trihydroxy-1,4-bis-(2-carboxyphenyl)-benzene, e. g.* IV, R = OH). (Found: C 72.9; H 3.2. Calc. for $C_{20}H_{10}O_4$: C 72.7; 3.1.) Attempts were also made to separate the components of A by chromatography on activated alumina but on prolonged contact with the alumina the triacetate was apparently hydrolysed and the product strongly adsorbed.

The Action of Enterokinase on Trypsinogen *

IKUO YAMASHINA

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden, and Department of Physiological Chemistry, University of Lund, Lund, Sweden

Using Edman's phenyl*iso*thiocyanate method, valine and *iso*leucine were identified as the N-terminal amino acids of trypsinogen and of trypsin formed by autoactivation, respectively.

The activation of trypsinogen by enterokinase was followed by determining the N-terminal amino acids. *Iso*leucine was detected in increasing quantity during the course of the activation, the amount being directly related to the appearance of tryptic activity.

Enterokinase seems to be a peptidase with a high specificity for trypsinogen.

By means of kinetic studies Kunitz [2] showed that enterokinase is an enzyme which activates trypsinogen to trypsin. No studies have, however, been carried out on the chemical nature of the reaction.

Davie and Neurath [3] investigated the mechanism of autoactivation, the activation by trypsin itself, and showed that a valylpeptide was split off, the amount being proportional to the tryptic activity developed. Thus trypsinogen is activated to trypsin by means of a limited hydrolysis giving rise to a new N-terminal amino acid.

As to the N-terminal amino acids of trypsinogen and of trypsin formed by autoactivation, Rovery, Fabre and Desnuelle [4] have identified valine as the N-terminal amino acid of trypsinogen by using Sanger's dinitrofluorobenzene method, and *iso*leucine as that of DIP-trypsin (di*iso*propylphosphoryl trypsin) by using both Sanger's method and Edman's phenyl*iso*thiocyanate method.

Thus, if enterokinase acts as a peptidase on trypsinogen as trypsin does, the reaction may be followed by determining free amino groups which are liberated during the hydrolysis of peptide bonds. The present paper will show that this is the case.

In the first instance, the N-terminal amino acids of trypsinogen and of trypsin formed by autoactivation were determined by Edman's method and results were obtained which confirm the findings already mentioned. The

* A short communication [1] was presented at the meeting of the Swedish Biochemical Society, January 27, 1956.

activation by enterokinase was then followed by determining the N-terminal amino acids. *Iso*leucine was detected in increasing amount paralleling the appearance of tryptic activity.

EXPERIMENTAL

Trypsinogen was prepared from beef pancreas according to the method of Northrop and Kunitz [5]. The crystalline product was purified further by treatment with trichloroacetic acid. Enterokinase was prepared from swine duodenal fluid contents according to the author's method [6,7]. It has an activity of 2 000 units per mg dry substance, which indicates a high degree of purity. The estimation of the tryptic activity was performed according to Anson's hemoglobin method [5].

The N-terminal amino acid of trypsinogen. Rovery, Fabre and Desnuelle [4] have detected valine as the N-terminal amino acid of trypsinogen by using the dinitrofluorobenzene (DNFB) method. However, alkaline conditions under which the coupling between protein and DNFB takes place are quite favourable to the autoactivation and autodigestion due to an unavoidable trace of trypsin present in the trypsinogen preparation.

Several amino acids including valine and *iso*leucine were in fact detected when a non-denatured and soluble trypsinogen preparation was used instead of the denatured and insoluble one used by the French workers. The pre-treatment of the trypsinogen preparation by di*iso*propyl fluorophosphate (DFP) eliminated amino acids other than valine.

The use of Edman's method simplified the situation. By this method, both DFP-treated and non-treated trypsinogen preparations gave, due to the rapid reaction between phenyl*iso*thiocyanate and the terminal amino group as demonstrated by Edman [8,9], only one single amino acid, identified as valine.

The N-terminal amino acid of trypsin formed by autoactivation. The trypsinogen preparation was activated at 0° C and pH 5.6 using 0.1 M triethylammonium acetate buffer which contains 0.05 M $CaCl_2$. 10 mg of trypsinogen was dissolved per ml, giving a concentration of trypsin of 0.05 mg per ml without any further addition of pure trypsin. Under these conditions 100 % activation could be obtained after 22 hours. The reaction mixture was then adjusted to pH 2.5 by the addition of 1 N HCl. Aliquots were taken, diluted with water and to these solutions an equal volume of pyridine was added. To 2 ml of the pyridine-water solutions containing trypsin corresponding to 4 mg trypsinogen, 20 μl of phenyl*iso*thiocyanate was added with vigorous stirring. The pH was then adjusted to 9.0 by the addition of a few drops of triethylamine. The reaction was allowed to continue for two hours at room temperature with occasional stirring and the further addition of triethylamine in order to keep the pH between 8.5 and 9.0. After the completion of the coupling, the reaction mixture was washed with benzene (3 × 5 ml) in order to remove pyridine and an excess of phenyl*iso*thiocyanate. To the aqueous layer, 8 ml of acetone was added and the precipitate of phenylthiocarbamyl derivatives was collected by centrifugation and dried *in vacuo*. The dried material was then suspended in 1 ml of 1 N HCl and heated for one hour in boiling water with occasional stirring. The phenylthiohydantoin derivatives of the amino acids were then extracted with ethyl acetate (3 × 2 ml) and the combined extracts were washed with 0.8 ml of water. 2.0 ml of the extract was diluted to 5 ml with 95 % ethanol and the ultraviolet absorption measured. From the shape of the curve, the formation of phenylthiohydantoin derivatives of amino acids was confirmed. The yield, referred to the amount of trypsinogen, was 170 % based on the optical density at 269 mμ. For the molecular weight of trypsinogen and the molecular extinction coefficient of phenylthiohydantoin derivatives of the amino acid, 23 800 and 16 000 were used, respectively.

The rest of the extract was evaporated to dryness, dissolved in ethylene chloride and aliquots used in the identification experiments.

For this purpose paper chromatography was used according to the directions of Sjöquist and Edman [10,11]. A starch-treated Whatman No. 1 paper was dipped into a mixture of acetone and formamide (3 : 1 by volume) and dried at room temperature until the acetone had evaporated. The test solution was then applied to the paper and developed with xylene. Two spots, derived from valine and *iso*leucine, were observed either by

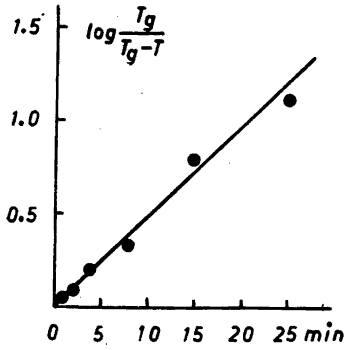

Fig. 1. Reaction of enterokinase at high trypsinogen concentration. T_g: Initial concentration of trypsinogen. T: Tryptic activity at any time. The line shows the theoretical relationship for a first order reaction and the points are the experimental values obtained.

ultraviolet absorption with the aid of a fluorescence screen or by spraying with the KI-NaN_3 reagent. Since no spots other than these two were observed, it is evident that *iso*leucine is an N-terminal amino acid of trypsin formed by autoactivation.

The N-terminal amino acid of trypsin formed by the action of enterokinase. The experimental conditions cause some difficulties in the study of the activation of trypsinogen by means of enterokinase. The standard conditions for the estimation of enterokinase activity established by Kunitz are quite inconvenient for the present purpose because of the extremely low concentration of trypsinogen (65 μg per ml). The use of a high concentration of trypsinogen is accompanied by autoactivation, autodigestion or formation of inert protein due to trypsin. In this case, the kinetics do not correspond to those of a first order reaction as has been thoroughly demonstrated by Kunitz [5].

These disadvantages could be overcome by the use of a high concentration of enterokinase together with the use of triethylammonium acetate buffer which seems to stabilize trypsin. In a series of test tubes, 5 mg of trypsinogen and 0.8 mg of enterokinase preparation having an activity of 2 000 units per mg were dissolved in 12.5 ml of 0.1 M triethylammonium acetate buffer (pH 5.6). The reaction was carried out at 0° C. Under these conditions it corresponds to a first order reaction as shown in Fig. 1, which indicates that there are no appreciable signs of autoactivation or autodigestion.

The activation was stopped at intervals by adding 1 ml of 1 N HCl to 12.5 ml of reaction mixture. To this acid solution an equal volume of pyridine, containing phenyl-*iso*thiocyanate in a concentration of 50 μl per ml was added. The pH was then adjusted to 9.0 by the addition of a few drops of triethylamine.

As to the stability of trypsin in pyridine-water (1:1) in which the coupling reaction takes place, it was found that 60 % of the activity is recovered after 2 hours at room temperature. When both trypsinogen and trypsin were present in an equal concentration of 0.1 mg per ml in this solvent, corresponding to 50 % activation where the autoactivation shows the highest velocity, 20 % of trypsinogen was converted to trypsin after 2 hours at room temperature. However, when phenyl*iso*thiocyanate was present in the above-mentioned concentration, tryptic activity was very quickly blocked, 95 % of the activity being lost 5 min. after the addition of pyridine containing phenyl*iso*thiocyanate. Consequently, the risk of autodigestion or autoactivation due to trypsin under the coupling conditions could be excluded.

The coupling was continued for 2 hours at room temperature, the pH being maintained between 8.5 and 9.0 by occasional addition of triethylamine. The reaction mixture was then washed with benzene (5 × 20 ml) and the aqueous layer was then lyophilized. The dried material was suspended in 3 ml of 1 N HCl and heated at 100° C for one hour. The phenylthiohydantoin derivatives of the amino acids were extracted with ethyl acetate (3 × 2 ml). The combined extracts were then washed by 0.8 ml of water and evaporated to dryness. The residue was dissolved in 40 μl of ethylene chloride and 5 μl of the solution was used for a single paper chromatography run.

The paper chromatogram which was prepared as described above and made visible by spraying with KI-NaN_3 reagent is shown in Fig. 2. In this figure, the amount of valine

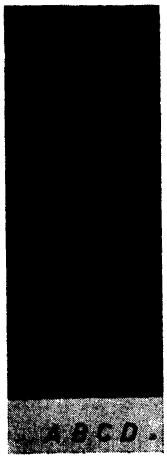

Fig. 2. Paper chromatogram demonstrating the development of isoleucine *as a new N-terminal amino acid during the activation. A: Standard substances, phenylthiohydantoins of valine and* isoleucine. *B: Zero time activation. C: 38 % activation after 4 minutes. D: 79 % activation after 15 minutes.*

remains almost constant throughout the whole course of activation whereas the amount of *iso*leucine increases with the progress of activation. The spots localized at the original point and those of low R_F values were considered to have no relation to the activation reaction.

For the quantitative evaluation of the developed spots on the chromatogram, the elution technique was applied. Thus, the spots identified by ultraviolet absorption with the aid of a fluorescence screen were cut off, eluted with 1 ml of 95 % ethanol for one hour at room temperature and the ultraviolet absorption at 269 mμ determined. The amount of valine was practically constant and that of *iso*leucine increased throughout the activation process. Since the phenylthiohydantoin derivatives of valine, *iso*leucine and alanine can be eluted just as effectively (about 80 % of the substance applied on the paper [12]), the amounts of *iso*leucine were corrected with reference to those of valine in each run. In Fig. 3, the percentages of *iso*leucine found and corrected are shown at each step of activation.

It could be concluded that there is a quantitative relationship between the degree of the activation of trypsinogen caused by enterokinase and the amount of *iso*leucine appearing as N-terminal amino acid.

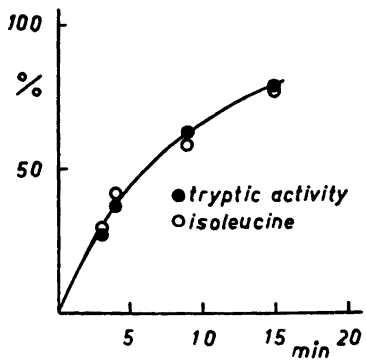

Fig. 3. Relation between the percentages of isoleucine *as referred to valine and those of activation.*

DISCUSSION

Since valine and *iso*leucine are the N-terminal amino acids of trypsinogen and trypsin, respectively, as found by Rovery *et al.*[4] and by the present author, the appearance of *iso*leucine as N-terminal amino acid and the constant presence of valine suggest that enterokinase acts as a peptidase splitting off a valylpeptide from the amino end of trypsinogen, a reaction similar to that in the case of autoactivation. The good agreement of the percentages of *iso*-leucine referred to valine and those of activation throughout the whole activation process excludes the possibility of a transitory formation of an active form of trypsinogen.

Although enterokinase acts as a peptidase in this respect its action is highly specific. Since trypsin acts on esters of lysine and arginine, the activity of the enterokinase preparation was tested on tosylarginine methyl ester and lysin ethyl ester. A slight activity was observed at a pH of between 6 and 9. Judging from the low activity and the peak of the activity curve at pH 7.5 it is very likely that the activity was caused by a contamination by trypsin.

This work was made possible by a research grant to Professor Erik Jorpes from the *Swedish State Medical Research Council.* The author's thanks are also due to Dr. Pehr Edman for his help during the progress of the work.

Apparatus for Simple Laboratory Batch Distillation

NIELS CLAUSON-KAAS

Department of Chemistry, Israel Institute of Technology, Haifa, Israel
and
FRANZ LIMBORG

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

A rugged and versatile setup for distillation of charges up to 5 liter volume is described. The setup is intended mainly for work in organic chemical and biochemical laboratories. It has been in daily use for seven years and has been tested in four different laboratories. All simple laboratory distillations, at pressures above 0.1 mm, can be carried out in this, or one of the two other setups, described previously by us (*Acta Chem. Scand.* 8 (1954) 1579).

This communication describes a distillation setup intended for (a) the purification of solvents (b) the removal of solvents and (c) the distillation of amounts larger than 100 ml of liquid organic compounds.

The setup (Fig. 1), which is mounted at the end of a laboratory bench, is especially simple and rapid to operate. After putting the distillation flask in place, outside of the water bath, the steel support rod is lifted, and the whole apparatus turned, so that the distillation flask may be immersed in the bath. *Since the three clamps supporting the glass part of the apparatus are directly aligned, there is no risk of breakage, or of leakage at the ground joints, being caused by the strain of mounting.*

Owing to the large diameter of the tube leading from the distillation flask to the condenser, distillations can be carried out rapidly and at low pressure. Table 1 shows three representative distillations illustrating the capacity of the setup.

The construction and use of the setup is described in detail below.

The distillation and the receiver flasks have either glass hooks (sizes 100, 250, 500 and 1 000 ml) or metal holders (sizes 2, 3 and 5 liters) permitting attachment of springs. When distilling under vacuum no springs are used to hold the distillation flask, but the flask is held by hand until immersed in the water bath. When solvents are distilled

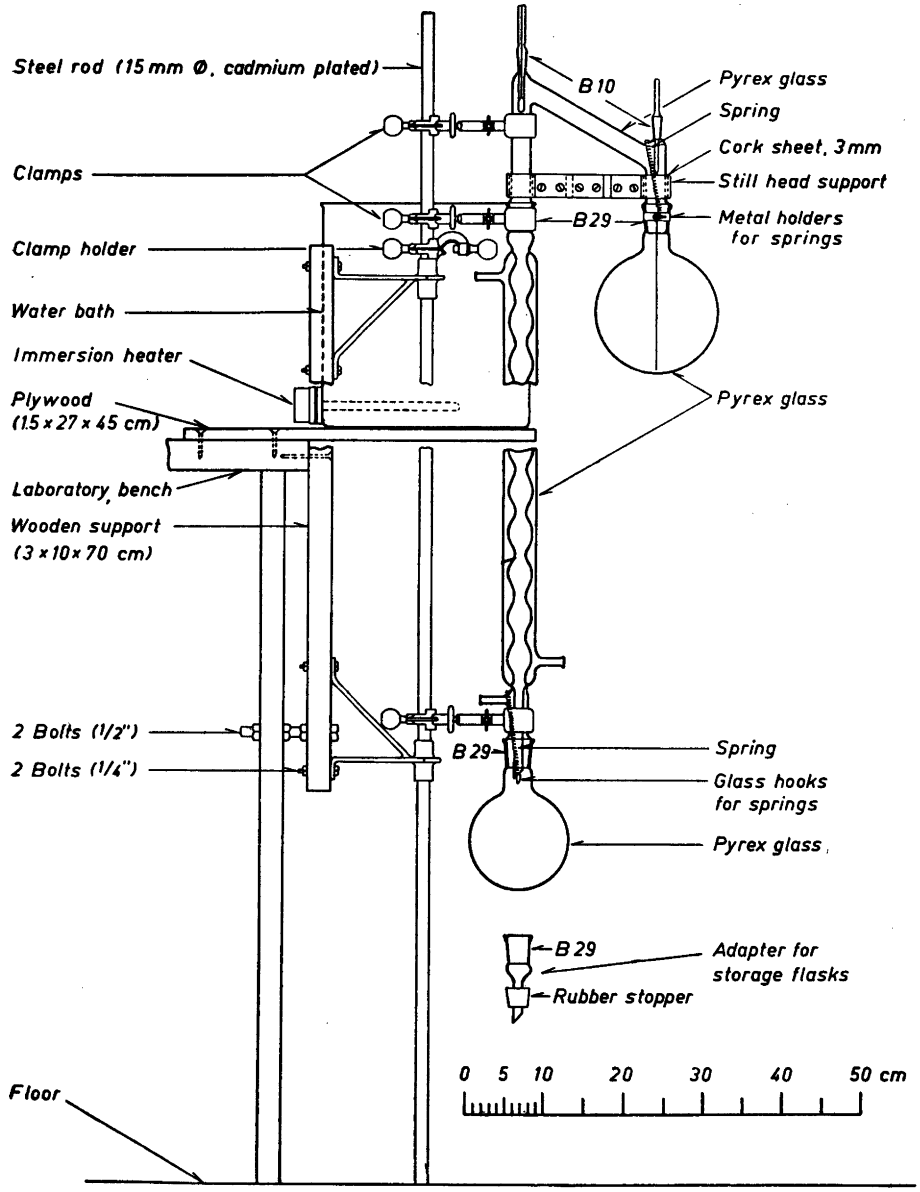

Fig. 1. Setup for simple distillation of up to 5 liters, viewed from rear.

under atmospheric pressure directly into storage flasks, an adapter as shown in Fig. 1 should be used.

The still support (3 mm iron or brass) is made of three parts to prevent breakage of the head due to strain. It is fixed to the glass by first tightening the two pairs of screws

Table 1. Representative distillations. In the case of the distillation of water, the still head was insulated with a cloth and the receiver flask cooled with ice.

Compound	B. p. at 760 mm °C	Charge ml	Yield of distillate ml	Distillation temp. °C	Bath temp. °C	Back pressure mm Hg	Distillation time min.
Acetone, crude	56	2 000	1 974	55–61	81–94	757	72
Water	100	1 000	940	36–38	75–78	26–29	64
1-Methyl-naphthalene	245	100.0	98.2	58–59	87	0.1	22

at the ends, and then the pair in the middle. The still head can carry a distillation flask weighing 5 kg without its breaking.

Suitable clamps for supporting the glass part of the setup are utility clamps (large size, rubber sleeve) from *Fisher Scientific Company*, Pittsburgh, U.S.A.

The water bath is designed for distillation flasks up to 5 liters. It is heated by a 1 500 watt immersion heater connected with the network through a bimetal regulator. In order to minimize evaporation of water, the bath is covered with a lid, slotted to receive the neck of the distillation flask. The height of the distillation flask is adjusted by use of the clamp holder, which is attached directly above the upper support for the steel rod. In general, the distillation flask should be immersed up to its neck in the water bath in order to prevent foaming. If required, the flask can easily be shaken by hand while in the bath during a distillation.

For the distillation of very high-boiling liquids, the water bath is replaced by some other heating device.

The supports for the steel rod are 40 mm wide and screwed symmetrically on to the wooden support. The wooden support is fixed to the laboratory bench in such a way that the center line of the support is 42 cm from the front of the bench. The plywood plate carrying the water bath is fixed in line with the front of the bench.

Rubber tube connections to cooling water and vacuum pumps should be mounted so that they do not disturb the lifting and turning of the apparatus.

Cleaning of the still head and the condenser is best accomplished by sucking a suitable solvent once or twice from a 50 ml beaker through the socket of the joint on to which the distillation flask fits.

Reactions between Carbon Dioxide and Amino Alcohols

III. Diethanolamine

ERIK JØRGENSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

When carbon dioxide reacts with diethanolamine in aqueous solutions the product formed is a mixture of carbamate and monoalkyl carbonate. The previous conclusion of carbamate being the main product was verified for not too alkaline solutions. In strongly alkaline solution, however, the amount of monoalkyl carbonate formed was big enough for evaluating velocity constants for the formation and decomposition.

For the determination of carbonate a complexometric method was used, which was based on the reaction between barium ion and versenate ion.

1. Carbon dioxide reacts with amino alcohols containing primary and secondary amino groups to yield carbamate and monoalkyl carbonate. Previous experiments [1] show that carbamate is the main product in the case of ethanolamine and diethanolamine.

The present paper reports additional experiments with diethanolamine in order to disclose the formation of monoalkyl carbonate.

2. The method of analysis was in principle as in previous investigations. Added barium chloride precipitates carbonate, but not carbamate or monoalkyl carbonate. The barium carbonate is separated by centrifugation. In the previous method the supernatant was heated until the carbamate and monoalkyl carbonate had been decomposed and been precipitated as barium carbonate, which was titrated acidimetrically. In the numbered experiments of this publication a slightly modified method was used.

To make the separation faster, the electric centrifuge was replaced by a hand-driven one and the sample size was diminished from 100 to 8 ml. The possibility of titrating barium ion [2] with reasonable accuracy suggested the determination of excess barium ion in the supernatant. The details are as follows:

8.00 ml of the specimen is run into a centrifuge tube (15 ml) containing 1.000 ml 0.25 M barium chloride. To mix the contents the tube is inverted twice before centrifugation. 5.00 ml of the supernatant are run into 15.00 ml 0.01 M sodium versenate + 10

drops of phthaleinpurpur-I. To neutralize the sodium hydroxide a slight excess of ammonium chloride is added. After an addition of 10 ml concentrated ammonia and 50 ml 96 % ethanol the excess of versenate is titrated with 0.005 M barium chloride.

The method is tested by titration of carbonate in solutions of potassium bicarbonate in 0.2 N sodium hydroxide. To make sure that diethanolamine does not enhance supersaturation this substance was added to some of the solutions. The results are in Table 1.

The precision of the method is comparable to the precision of the previous method, maybe slightly less, which, however, is amply compensated by the increased speed. 30 seconds suffice to separate the barium carbonate from the liquid.

Table 1. Complexometric determination of carbonate.

mM CO_3^{--}/litre	found				mean	deviation

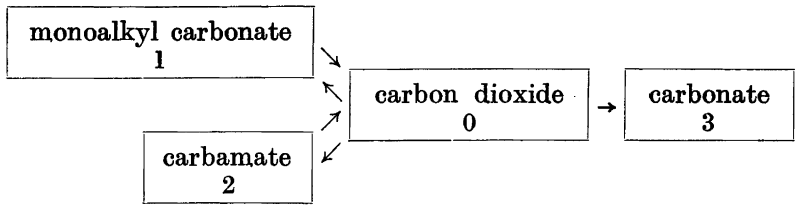
15.17	15.17	15.28	15.15	15.26	15.22	+0.05
24.29	24.38	24.32	24.20	24.11	24.25	−0.04

3. The problem of simultaneous formation of carbamate and monoalkyl carbonate is attacked in two ways.

One is to determine, how the carbon dioxide is shared instantaneously between carbonate and non-carbonate, when it is dissolved in aqueous solutions of varying concentration of sodium hydroxide and diethanolamine. The term, non-carbonate, stands for the sum of monoalkyl carbonate and carbamate.

A second is to determine the rate of the decomposition of the non-carbonate. Monoalkyl carbonates usually decompose with a higher rate and deviation from a first order reaction should be expected.

4. The experiments were carried out at 0° and 18° C. Velocity constants are calculated by means of Briggs' logarithms, which shall be thus understood: In the integrated expressions the base e is substituted by 10 without any compensation. As in previous publications the velocity constants are to be multiplied by $\log_e 10$ for correction. As the reactions take place between neutral molecules or neutral molecules and monovalent ions disregard of activity coefficients is used as a working approximation.



5. To simplify the necessary calculations the velocity constants previously used are substituted by symbols introduced by Christiansen [3].

When carbon dioxide reacts with alkaline solutions of amine and alcohol and during the decomposition of the non-carbonate formed the following processes compete:

$$CO_2 + RO^- \rightleftharpoons ROCOO^- \quad (01)$$
$$CO_2 + RNH_2 \rightleftharpoons RNHCOOH \rightleftharpoons RNHCOO^- + [H^+] \quad (02)$$
$$CO_2 + OH^- \rightarrow HCO_3^- \rightarrow CO_3^{--} + [H^+] \quad (03)$$

RO^- and RNH_2 meaning alcoholate ion and amine, respectively. The hydrogen ions are removed by hydroxyl ions.

The reactions may diagrammatically be represented by:

x_0, x_1, x_2, x_3 and x will be used for the concentrations of carbon dioxide, monoalkyl carbonate, carbamate, carbonate and non-carbonate, respectively.

The velocities are:

$$s_{10} = x_1 \cdot w_{10} - x_0 \cdot w_{01}$$
$$s_{20} = x_2 \cdot w_{20} - x_0 \cdot w_{02}$$
$$s_{03} = x_0 \cdot w_{03}$$

where, introducing the previously used symbols

$$w_{01} = k_{CO_2 \cdot RO^-} \cdot c_{RO^-} = k' \cdot c_{ROH} \cdot c_{OH^-}$$
$$w_{02} = k_{CO_2 \cdot Am} \cdot c_{RNH_2}$$
$$w_{03} = k_{CO_2 \cdot OH^-} \cdot c_{OH^-}$$
$$w_{10} = k_{ROCOO^-}$$
$$w_{20} = k_{RNHCOO^- \cdot H^+} \cdot c_{H^+}$$

ADDITION OF CARBON DIOXIDE TO SOLUTIONS OF DIETHANOLAMINE

1. The carbon dioxide introduced is shared between non-carbonate and carbonate within a small fraction of a second. The reactions (10) and (20) may be disregarded and thus the quotient non-carbonate: carbonate is equal to $(w_{01} + w_{02})$: w_{03}.

w_{01} and w_{03} are proportional to the concentration of hydroxyl ion while w_{02} is independent.

$$\frac{w_{01}+w_{02}}{w_{03}} \text{ multiplied by } \frac{c_{OH^-}}{c_{\text{amino alcohol}}}$$

gives us

$$\frac{k'}{k_{CO_2 \cdot OH^-}} \cdot c_{OH^-} + \frac{k_{CO_2 \cdot Am}}{k_{CO_2 \cdot OH^-}}$$

This expression being linearly dependent on the concentration of hydroxyl ion, we can calculate k' and $k_{CO_2 \cdot Am}$ from two experiments with different concentration of hydroxyl ion (log $k_{CO_2 \cdot OH^-}$ being fixed at 4.39 and 5.02 at 0° and 18° C, respectively).

2. A preliminary experiment (4) is performed on a solution, which besides sodium hydroxide contains an amine (diethylamine) without alcohol groups and an alcohol (triethanolamine) without primary or secondary amino groups.

In Table 2 this experiment (4) is compared with experiments (1—3) where only one of the compounds is present in the alkaline solution. From the velocity constant calculated from the experiments 1—3, it was calculated that 21.9 % monoalkyl carbonate and 39.8 % carbamate should be formed. The sum agrees reasonably with the found percentage of non-carbonate.

Table 2. Carbon dioxide in amine + alcohol + NaOH. 18°.

	0.3	0.0203	65.9	1.89	4.99	4.33	36.8	27.8
				Mean:	4.94	4.28		

[1] Calculated from the mean of the first three determinations.
[2] Calculated from the mean of k'.

Evidently a fairly high proportion of monoalkyl carbonate is found.

In judging the velocity constants found one must, however, as previous work [5] on the subject has shown, bear in mind that the experimental results are to no small extent dependent on the way in which carbon dioxide has been added. In all the experiments present, atmospheric air, of which 30 % was substituted by carbon dioxide, has been applied. In a 1-litre flask, containing 250 ml of the reaction mixture, 250 ml of the gas phase were substituted by carbon dioxide from a gasometer. The flask was immediately shaken vigorously for about one minute.

It should be noticed that the fifth column of Table 3 shows for constant concentration of hydroxyl ion a slight increase with an increasing concentration of diethanolamine, which might be due to a perceptible amount of hydroxyl ions being consumed by the alcohol groups of diethanolamine. Glass electrode measurements on 0.04 N NaOH and various amounts of diethanolamine, ranging from 0.0 to 0.3 M, showed no difference in potential, however.

THE CONVERSION: NON-CARBONATE → CARBONATE

1. Before mentioning the experiments on the velocity of decomposition the mathematical and calculatory aspects should be examined.

The following differential equations:

$$s_{10} = -\mathrm{d}x_1/\mathrm{d}t = x_1 \cdot w_{10} - x_0 \cdot w_{01}$$
$$s_{20} = -\mathrm{d}x_2/\mathrm{d}t = x_2 \cdot w_{20} - x_0 \cdot w_{02}$$

combined with the stationarity condition for the free carbon dioxide

$$s_{10} + s_{20} = s_{03} = x_0 \cdot w_{03}$$

yield solutions of the form

$$\begin{aligned} x_1 &= a_1 \cdot \exp(-k_1 \cdot t) + b_1 \cdot \exp(-k_2 \cdot t) \\ x_2 &= a_2 \cdot \exp(-k_1 \cdot t) + b_2 \cdot \exp(-k_2 \cdot t) \\ \hline x = x_1 + x_2 &= A \cdot \exp(-k_1 \cdot t) + B \cdot \exp(-k_2 \cdot t) \end{aligned}$$

$-k_1$ and $-k_2$ being roots in the auxiliary equation

$$R^2 + \frac{w_{10} \cdot (w_{02} + w_{03}) + w_{20} \cdot (w_{01} + w_{03})}{w_{01} + w_{02} + w_{03}} \cdot R + \frac{w_{10} \cdot w_{20} \cdot w_{03}}{w_{01} + w_{02} + w_{03}} = 0$$

The solution is

$$k_1 = \frac{w_{10} \cdot (w_{02} + w_{03}) + \varepsilon}{w_{01} + w_{02} + w_{03}} \qquad k_2 = \frac{w_{10} \cdot w_{20} \cdot w_{03}}{w_{10} \cdot (w_{02} + w_{03}) + \varepsilon}$$

where ε is a root in

$$\varepsilon^2 + [w_{10} \cdot (w_{02} + w_{03}) - w_{20} \cdot (w_{01} + w_{03})]\, \varepsilon - w_{10} \cdot w_{20} \cdot w_{01} \cdot w_{02} = 0$$

Now the assumption is made:

$$w_{10} \cdot w_{0i} >> w_{20} \cdot w_{0j} \text{ (i and j = 1, 2 or 3)}$$

i. e. the monoalkyl carbonate is decomposed very fast compared with the carbamate, and w_{01}, w_{02} and w_{03} are of the same order of magnitude. This assumption is supported by the fact that the experiments clearly reveal the presence of two processes, k_1 and k_2 thus differing in order of magnitude.

Choosing ε as the positive root of the above equation, the following inequalities hold:

$$0 < \varepsilon < w_{20} \cdot (w_{01} + w_{03}) \ll w_{10} \cdot (w_{02} + w_{03})$$

When the total carbon dioxide concentration is C the initial

$$x_1 = \frac{w_{01}}{w_{01} + w_{02} + w_{03}} \cdot C \text{ and } x_2 = \frac{w_{02}}{w_{01} + w_{02} + w_{03}} \cdot C$$

Inserting these concentrations as boundary conditions we get for A and B:

$$A = \frac{w_{10} \cdot w_{01} \cdot w_{03} - w_{20} \cdot w_{01} \cdot (w_{01} + w_{02} + w_{03}) + \varepsilon \cdot (w_{01} + w_{02})}{(w_{01} + w_{02} + w_{03}) \cdot [w_{10} \cdot (w_{02} + w_{03}) - w_{20} \cdot (w_{01} + w_{03}) + 2\,\varepsilon]} \cdot C$$

$$B = \frac{w_{10} \cdot w_{02} \cdot (w_{01} + w_{02} + w_{03}) - w_{20} \cdot w_{02} \cdot w_{03} + \varepsilon \cdot (w_{01} + w_{02})}{(w_{01} + w_{02} + w_{03}) \cdot [w_{10} \cdot (w_{02} + w_{03}) - w_{20}\,(w_{01} + w_{03}) + 2\,\varepsilon]} \cdot C$$

Disregarding ε and $w_{20} \cdot w_{0i}$ in sums and differences of $w_{10} \cdot w_{0j}$ reduces k_1, k_2, A and B to

$$k_1 \sim w_{10} \cdot \frac{w_{02} + w_{03}}{w_{01} + w_{02} + w_{03}}$$

$$k_2 \sim w_{20} \cdot \frac{w_{03}}{w_{02} + w_{03}}$$

$$A \sim \frac{w_{03}}{w_{02} + w_{03}} \cdot \frac{w_{01}}{w_{01} + w_{02} + w_{03}} \cdot C$$

$$B \sim \frac{w_{02}}{w_{02} + w_{03}} \cdot C$$

The significance of the approximated expressions is directly seen from the diagram, imagining the monoalkyl carbonate being quickly decomposed partly to carbamate and partly to carbonate while the carbamate slowly decomposes to carbonate. k_1 is a fraction of w_{10} corresponding to the carbon dioxide from 10 not reverting along 01. k_2 is a fraction of w_{20} corresponding to the carbon dioxide from 20 not reverting along 02 and neglecting the reaction 01. A is the fraction of the initial monoalkyl carbonate, which is temporarily not converted to carbamate. B is the amount of carbamate that was formed initially when no alcohol groups were present.

w_{03} ($= k_{CO_3} \cdot {}_{OH^-} \cdot c_{OH^-}$) is known, hence B, A, k_2 and k_1 give us w_{02}, w_{01}, w_{20} and w_{10}, successively.

To get the parameters A, B, k_1 and k_2 of each experiment, the results are subjected to a linear regression analysis in two steps. From the experimental values where the contribution of $A \cdot \exp(-k_1 \cdot t)$ is vanishing, $\log x$ is taken as

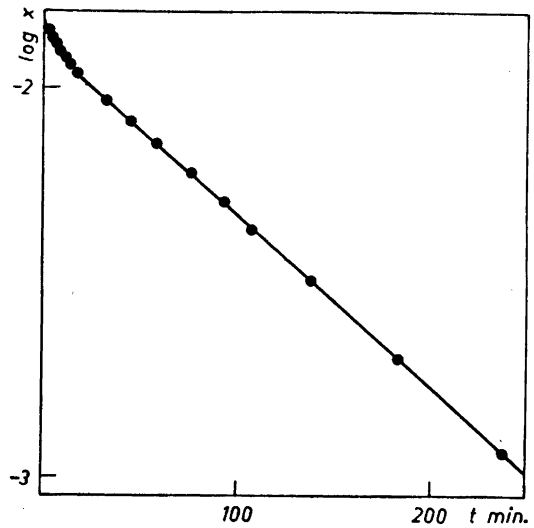

Fig. 1. The decomposition of the non-carbonate from solution 4.

the dependent variable and t as the independent variable. We then have an estimate of B and k_2. The contribution from the term $B \cdot \exp(-k_2 \cdot t)$ is extrapolated back to the first values and the differences are formed. The differences are subjected to a similar analysis and we have an estimate of A and k_1.

We proceeded on the lines laid down by A. Hald [6]. x is assumed to have a normal distribution with constant variance. Hence the variance on log x is inversely proportional to the square of x. Therefore, to each value of x a weight has been ascribed proportional to the square of the value.

2. The decomposition of the non-carbonate in the solutions from Table 2 is investigated. The three first solutions which either contain alcohol groups or amino groups give a first order rate as expected. The last, however, containing both alcohol groups and amino groups, deviates distinctly in the beginning of the experiment, *cf.* Fig. 1.

Potentiometric Study on the Formation of Perboric Acids

P. J. ANTIKAINEN

Institute of Chemistry, University of Helsinki, Helsinki, Finland

The influence of hydrogen peroxide on the ionization of boric acid in aqueous potassium chloride solutions at 25° C has been studied by means of a potentiometric method. Apparently mainly two different peracids exist in solutions of boric acid and hydrogen peroxide. The complex formation constants of these perboric acids in potassium chloride solutions of different concentrations were calculated. The corresponding thermodynamic complex formation constants and the parameters of the Debye-Hückel equation have also been determined.

The formation of perboric acid in solutions containing boric acid and hydrogen peroxide has been the object of only few investigations. According to Menzel [1] conductivity measurements show that the complex acid $H_3BO_3 \cdot H_2O_2$ or $(H_3BO_3 \cdot H_2O_2)_2$ exists in solutions of this kind, the equilibrium constants for the reactions

$$\text{a)} \quad H_3BO_3 + H_2O_2 = H^+ + (H_2BO_3 \cdot H_2O_2)^- \qquad (1)$$
$$\text{b)} \quad 2H_3BO_3 + 2H_2O_2 = H^+ + (H_2BO_3 \cdot H_3BO_3 \cdot 2H_2O_2)^-$$

being of the order of 10^{-8}—10^{-7}. On the other hand, pH measurements carried out by Edwards [2] do not confirm the assumption that the peroxide complex is a definite compound. The author of this paper has in a recent preliminary study [3] reported a potentiometric method and its application to the investigation of perboric acid formation. The object of the investigation to be reported here was to complete this preliminary work.

EXPERIMENTAL

The potentiometric titrations were carried out at 25° C, employing a differential potentiometric method [4]. A tube potentiometer Type PHM 3 manufactured by Radiometer and a Beckmann Glass Electrode Type 4990—83 were used. The reading accuracy of the apparatus was about 0.2 mV. The measurements were carried out in 0.1—1.5 M potassium chloride solutions, the concentrations of boric acid and hydrogen peroxide being varied between 0.025—0.1 M and 0.1—8.0 M, respectively. Other details of apparatus and measurement technique have previously [5] been described. All reagents used were of reagent grade. The concentration of boric acid stock solutions was determined by titration with sodium hydroxide using mannitol and phenolphthalein [6]. The hydrogen peroxide stock solutions were titrated with permanganate.

THEORY

Recent investigations [5,7-9] have shown that boric acid in its dilute solutions can be considered as a weak monobasic acid. Since according to cryoscopic measurements carried out by Menzel [1] it is apparent that the amount of any peracid formed is very small, the concentrations of boric acid and hydrogen peroxide in the solutions of boric acid-hydrogen peroxide can be exchanged for the corresponding stoicheiometric concentrations C_1 and C_2, respectively, especially when it is noted that the insignificiant ionization of boric acid does not affect conditions. Thus for the apparent ionization constant K^* of boric acid in solutions containing hydrogen peroxide an equation

$$K^* = K_1' \cdot K_k \cdot C_2^n + K_1 = K_m \cdot C_2^n + K_1 \quad (2)$$

can be derived on the basis of the experimental method [4] and its applications to boric acid [5] and telluric acid [10-11]. In this equation K_1' denotes the first ionization constant of perboric acid, here considered as a monobasic acid, and K_k the equilibrium constant of the following assumed reaction:

$$H_3BO_3 + nH_2O_2 \rightleftharpoons H_3BO_3 \cdot nH_2O_2 \quad (3)$$

In addition K_1 is the first ionization constant of orthoboric acid. Further, the value of n is the number of hydrogen peroxide molecules, which combine with each molecule of boric acid. If in this case several complexes occur, n then indicates the average of this number. In such cases it is often possible to calculate the two main complex formation constants using the equation [12]

$$K^* = k_1 \cdot C_2^{n_1} + k_2 \cdot C_2^{n_2} + K_1 \quad (4)$$

where k_1 and k_2 are the complex formation constants corresponding to K_m in eqn. (2), where it is assumed that the value of n is the average of two different values. For the determination of the constants k_1 and k_2 in eqn. (4) it is necessary to know the values of the apparent ionization constants at least two different concentrations of hydrogen peroxide. Further, the most obvious values of n_1 and n_2 should be used in these calculations as shown in a recent investigation [12] concerning the complex formation of boric acid with mannitol.

RESULTS

In Table 1 the values for the apparent ionization constants of boric acid are given at constant ionic strength and different concentrations of hydrogen peroxide. Using these results the average value of n and the complex formation constant K_m can be calculated using eqn. (2). If a complex acid really exists the values of $p(K^*—K_1)$ as a function of log C_2 should lie on a straight line with the slope n. This line should intersect the $p(K^*—K_1)$-axis at the point pK_m. However, as can be seen from Fig. 1 the linearity is only approximate and two different limiting slopes for this curve can be obtained. Here the value 8×10^{-10} for the constant K_1 has been used when the concentration

0.09802	8.930	43.30	5.034

of potassium chloride is about 0.1 M and that of boric acid [5] 0.1 M. Consequently one might assume that mainly two different peracids exist in these solutions. Furthermore, it appears that the most obvious values of n_1 and n_2

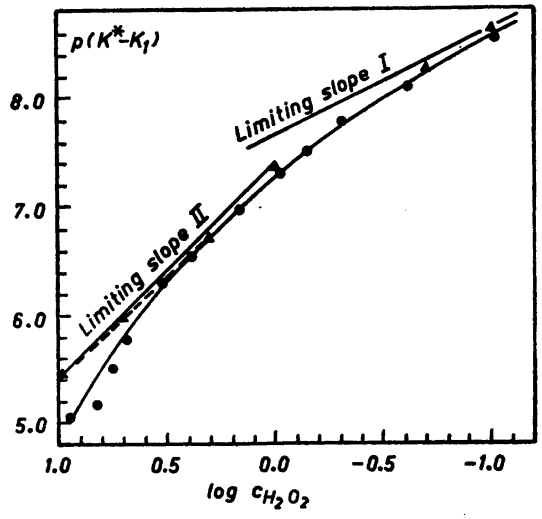

Fig. 1. The dependence of the apparent ionization constant of boric acid on the concentrations of hydrogen peroxide in about 0.1 M potassium chloride solutions. ● *Experimental results.* ▲ *Values calculated from the observed values of* pk_1 *and* pk_2 *using the theoretical eqn. (4).*

Table 2. Determination of the complex formation constants k_1 *and* k_2 *of perboric acids in about 0.0996 M potassium chloride solutions using the interpolated values from Table 1 at 25° C (*cf. *p. 757 and Eqn. 4).*

C_2'	C_2''	$K' \times 10^9$	$K'' \times 10^7$	pk_1
0.2	3.0	6.32	5.02	7.665
0.2	2.0	6.32	2.24	7.644
0.2	1.5	6.32	1.20	7.627
0.2	1.0	6.32	0.632	7.624
0.4	3.0	15.8	5.02	7.703
0.4	2.0	15.8	2.24	7.660
0.4	1.5	15.8	1.20	7.605
0.4	1.0	15.8	0.632	7.624

Average $pk_1 = 7.645 \pm 0.025$
$pk_2 = 7.40$

in eqn. (4) are 1 and 2, respectively. Using these values it is possible to calculate the corresponding complex formation constants for reactions (1a) and

$$H_3BO_3 + 2H_2O_2 \rightleftharpoons H^+ + (H_2BO_3 \cdot H_2O_2)^- \qquad (5)$$

as already has been stated. The results of these calculations are given in Table 2. Thus the corresponding values for pk_1 and pk_2 are about 7.645 and 7.40, respectively, in about 0.1 M potassium chloride solution. In this connection it should be noted that owing to the slight apparent ionization of boric acid the electrolyte concentration of this acid can be neglected. In Table 3 the values for pk_1 and pk_2 in potassium chloride solutions of different concentrations are calculated using the corresponding values for the apparent ionization constants of boric acid in these solutions. Thus the values 7.914 ± 0.04 and 7.71 ± 0.04 for the thermodynamic complex formation constants $pk_{1,0}$ and

Table 3. Determination of the complex formation constants k_1 *and* k_2 *of perboric acids in different potassium chloride solutions at 25° C (*cf. *p. 757 and Eqn. 4).*

$I^{\frac{1}{2}}$	C_2	pK^*	$(K^* - K_1) \times 10^8$	pk_1	pk_2
0.333	—	—	—	7.645	7.40
0.706	0.0800	8.393	0.305	7.472	7.22
0.705	0.9640	7.059	8.64		
1.181	0.0800	8.378	0.311	7.467	7.28
1.168	0.8802	7.119	7.50		

The average thermodynamic pk-values $pk_{1,0} = 7.914 \pm 0.04$
$pk_{2,0} = 7.71 \pm 0.04$

$pk_{2,0}$ were obtained. The values for the parameters of the Debye-Hückel equation were also calculated using the values in Table 3, with the following results:

pk_1: $\alpha = 0.525$ and $B = 0.160$
pk_2: $\alpha = 0.450$ and $B = 0.200$

CONCLUSIONS

It should be noted that the results obtained agree very well with eqns. (1a) and (5). Only the values for the apparent ionization constants measured at high concentrations of hydrogen peroxide differ markedly from the theoretically calculated values. This might be due to the formation of the next complex peracid in very concentrated hydrogen peroxide solutions, but more likely it is caused by the great variations of the dielectric constants of such solutions, which recent investigations have revealed [13]. According to these observations it can be assumed that the variation of the dielectric constants in less than 3 M H_2O_2 solutions is so small that it does not affect results (*cf.* Tables 2 and 3). On the other hand the existence of a complex acid formed according to eqn. (1b) seems most unlikely, since in this case the values of the apparent ionization constants should vary with the concentration of boric acid (*cf.* eqn. 2 and Table 1).

Using the above-mentioned values for the complex formation constants the thermodynamic complex formation constants $K_{n,1,0}$ and $K_{n,2,0}$ of the reactions

$$\begin{aligned} &\text{a)} \quad H_2BO_3^- + H_2O_2 \rightleftharpoons (H_2BO_3 \cdot H_2O_2)^- \\ &\text{b)} \quad H_2BO_3^- + 2H_2O_2 \rightleftharpoons (H_2BO_3 \cdot 2H_2O_2)^- \end{aligned} \tag{6}$$

can also be calculated [5,10,11]. Thus we get

$$\begin{aligned} &\text{a)} \quad K_{n,1,0} = \frac{c_{(H_2BO_3 \cdot H_2O_2)^-}}{c_{H_2BO_3^-} \cdot c_{H_2O_2}} = \frac{k_{1,0}}{K_{1,0}} = 21.1 \\ &\text{b)} \quad K_{n,2,0} = \frac{c_{(H_2BO_3 \cdot 2H_2O_2)^-}}{c_{H_2BO_3^-} \cdot (c_{H_2O_2})^2} = \frac{k_{2,0}}{K_{1,0}} = 33.6 \end{aligned} \tag{7}$$

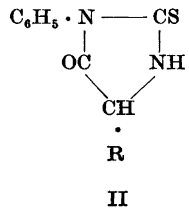
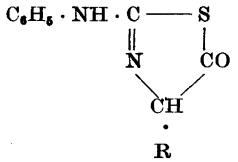
On the Mechanism of the Phenyl *Iso*thiocyanate Degradation of Peptides

PEHR EDMAN



Department of Physiological Chemistry, University of Lund, Lund, Sweden

A study of the reaction mechanism has revealed that the N-terminal amino acid is split off in the form of its 2-anilino-5-thiazolinone derivative. The latter is very unstable and can be converted along two different routes — thermal or hydrolytic — to the isomeric 3-phenyl-2-thiohydantoin derivative. The bearings of these findings on the degradation method are discussed.



A formal analogy has earlier been assumed for the phenyl *iso*cyanate [1,2] and the phenyl *iso*thiocyanate [3,4] degradation of peptides. However, some observations and in particular the great difference in the rate of formation of phenyl thiohydantoin (PTH) in aqueous [5,6] and non-aqueous media [4,7] indicated a peculiarity in the mechanism of the phenyl *iso*thiocyanate degradation which required closer investigation. With the introduction of the paper chromatographic procedure for the identification of phenyl thiohydantoins [8] this became possible.

$C_6H_5 \cdot NH \cdot CS \cdot NH \cdot CHR \cdot CO \cdot NH \cdot CHR' \cdot COOH$

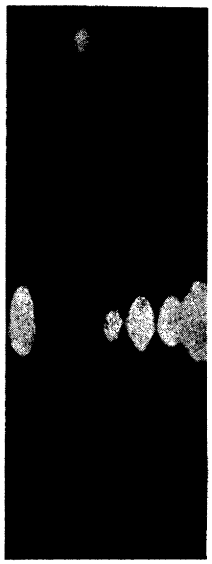

Fig. 1. Paper chromatogram of products resulting from the cleavage of PTC-leucylglycine in nitromethane-hydrogen chloride. From left to right: PTH-leucine, "crude product", PTC-leucylglycine, 1st, 2nd and 3rd fraction of recrystallised product, PTH-leucine. Solvent A.

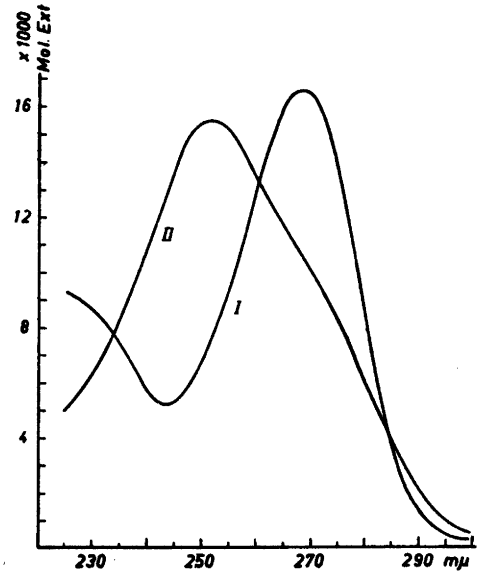

Fig. 2. Ultraviolet absorption curves of 5-isobutyl-3-phenyl-2-thiohydantoin (I) and 2-anilino-4-isobutyl-5-thiazolinone (II) in ethanol.

Paper chromatography of the reaction mixture resulting from cleavage of phenyl thiocarbamyl (PTC)-DL-leucylglycine (I; R = $CH_2 \cdot CHMe_2$; R′ = H) in nitromethane-hydrogen chloride, revealed a hitherto unobserved substance, whereas the expected PTH-leucine (II; R = $CH_2 \cdot CHMe_2$) was lacking (Fig. 1). However, on mere recrystallization the new compound was completely transformed into PTH-leucine. Obviously the N-terminal amino acid of the peptide was split off in the form of a labile derivative which was easily convertible to the phenyl thiohydantoin. The nature of this intermediate and the conditions for its conversion have been studied.

Avoiding heat and moisture the intermediate could be recrystallized as its salt with strong acids. Elementary analyses showed it to be an isomeride of the corresponding phenyl thiohydantoin from which it however differed in paper chromatographic behaviour (Fig. 1) and in ultraviolet absorption (Fig. 2).

It could be demonstrated that two different ways are open for the conversion of the intermediary compound into the corresponding phenyl thiohydantoin. At elevated temperature the transformation takes place as an intramolecular rearrangement (Figs. 3 and 4). On the other hand, in the presence of water, the intermediate compound is rapidly hydrolysed to the correspond-

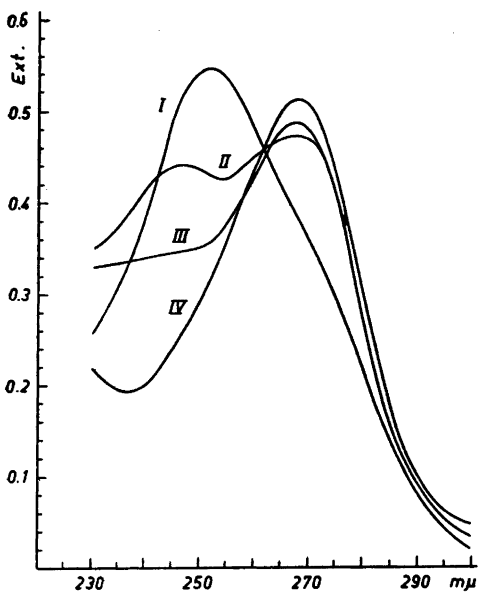

*Fig. 3. Conversion of 2-anilino-4-*isobutyl*-2-thiazolinone hydrochloride into PTH-leucine in the dry state at 115° C. Ultraviolet absorption curves of samples at zero time (I) and after 10 min. (II), 25 min. (III) and 60 min. (IV).*

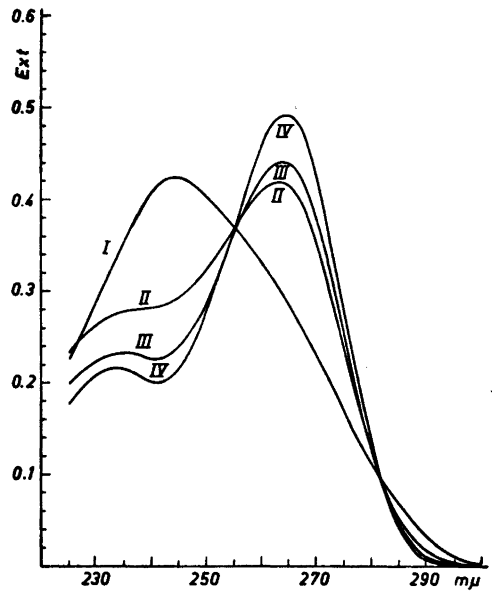

*Fig. 4. Conversion of 2-anilino-4-*isobutyl*-5-thiazolinone hydrochloride into PTH-leucine in glacial acetic acid at 93° C. Ultraviolet absorption curves of samples at zero time (I) and after 10 min. (II), 19 min. (III) and 39 min. (IV).*

ing PTC-amino acid which then slowly undergoes ringclosure to the PTH-amino acid (Fig. 6). The rate of this ringclosure was followed at pH 3 and the temperatures 30° C and 50° C (Fig. 5).

A striking similarity exists between these reactions and those displayed by S-acylated thioureas. The latter have been extensively investigated by Dixon and his coworkers [9–11]. They obtained the hydrochloride of S-acetyl-N-phenyl thiourea * (IV; R = Me) by reacting phenyl thiourea with acetyl chloride in the cold. On heating, this compound was rapidly converted first to the N-acetyl-N-phenyl thiourea (V; R = Me) and later to the N′-acetyl-N-phenyl thiourea. On the other hand water hydrolysed the thiolester linkage with the formation of phenyl thiourea and acetic acid. By analogy our intermediate should then be formulated as a 2-anilino-5-thiazolinone (III).

Several attempts were made at an independent synthesis of the labile intermediate compound but of these only an approach analogous to the one used by Dixon *et al.* for preparing the open-chain S-acylated thioureas was successful. The acid chloride of phenyl thiocarbamyl-L-leucine was prepared and

* Dixon *et al.*[10] prefer to formulate these compounds as sulfonium chlorides.

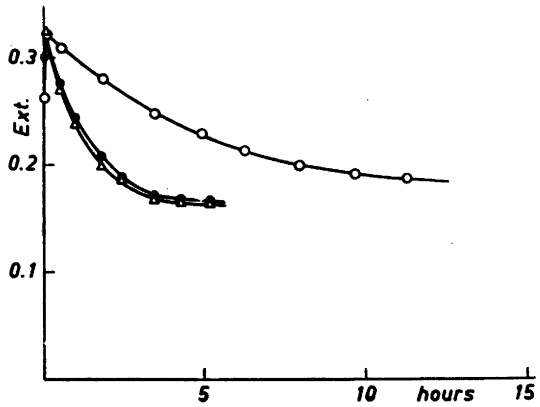

*Fig. 5. Conversion of 2-anilino-4-*isobutyl*-5-thiazolinone hydrochloride* via *PTC-leucine (initial rapid rise) into PTH-leucine in aqueous solution at pH 3 and 30° C (—○—○—) and 50° C (—●—●—) followed through change in extinction at 243 mμ. For comparison the conversion of PTC-leucine into PTH-leucine at pH 3 and 50° C (—△—△—).*

this spontaneously converted itself to the hydrochloride of 2-anilino-4-*iso*-butyl-5-thiazolinone:

$$C_6H_5 \cdot NH \cdot CS \cdot NH \cdot CH(CH_2 \cdot CHMe_2)COONa \xrightarrow{POCl_3} [C_6H_5 \cdot NH \cdot CS \cdot NH \cdot CH(CH_2 \cdot CHMe_2)COCl]$$

$$\longrightarrow C_6H_5 \cdot NH \cdot C(=S) \cdot N(CH)(CO) \cdot CH(CH_2 \cdot CHMe_2) \quad Cl^-$$

EXPERIMENTAL

Elementary analyses (except micro-Kjeldahl) were made at the Analytical Laboratory, Department of Chemistry, University of Lund, and at the Chemical Laboratory, University of Copenhagen.

Melting points were determined on a heating block (Fisher-John) and are uncorrected.

Paper chromatography was carried out as described by Sjöquist [8].

*Cleavage of phenyl thiocarbamyl-*DL*-leucylglycine in nitromethane-hydrogen chloride.* Phenyl thiocarbamyl-DL-leucylglycine [4] (200 mg) was suspended in dry nitromethane (10 ml) saturated with dry hydrogen chloride. The reaction mixture was left at room temperature for 15 min. and the crystals of glycine hydrochloride were filtered off. The mother liquor was evaporated *in vacuo* to dryness without heating. The crude, crystalline product (157 mg) was subjected to paper chromatography in solvent A (Fig. 1) and the U.V.-absorption was measured in abs. ethanol * where a broad absorption with a maximum at 252 mμ ($\varepsilon_{252} = 59$; $C = 1$ g/l) was observed.

Part of the crude product (70 mg) was dissolved in abs. ethanol (1 ml) and a small insoluble residue filtered off. The preparation was then fractionally crystallized in the cold by the gradual addition of petroleum ether. Melting points, R_F-values in solvent A (Fig. 1) and U.V.-absorption curves were determined on the separate fractions (Table 1).

Table 1.

	M. p.	R_F-value in solvent A	Abs. max.
Crude product	126—135°	0.80	$\varepsilon_{252} = 59$
Fract. I (10 mg)	178°	0.59	$\varepsilon_{268} = 63$
Fract. II (31 mg)	178°	0.59	$\varepsilon_{268} = 63$
Fract. III (4 mg)	140—144°	0.59	$\varepsilon_{268} = 59$
PTH-leucine	178°	0.59	$\varepsilon_{268} = 64$

*Cleavage of phenyl thiocarbamyl-*DL*-leucylglycine in glacial acetic acid-hydrogen chloride* [7]. Phenyl thiocarbamyl-DL-leucylglycine (0.65 g) was dissolved in glacial acetic acid saturated with hydrogen chloride (5 ml). Almost immediately crystals began to appear and they were filtered off after a few minutes (0.21 g). Paper chromatography in pyridine-amyl alcohol [12] and in acetic acid-butanol [13] showed identity with glycine.

To the mother liquor ten vols. of dry ethyl ether were added. Needleshaped crystals were collected (0.47 g). Recrystallization from glacial acetic acid — hydrogen chloride and ethyl ether. M. p. 128—31°. For U.V.-absorption curve see Fig. 2. (Found: N 9.64. $C_{13}H_{17}ON_2ClS$ requires: N 9.83).

The product was taken up in a small volume of glacial acetic acid-sulfuric acid (1 M) and ethyl ether added to crystallization. The crystals melted at 133° C. (Found: C 44.4; H 5.30; N 8.03; S 18.2. $C_{13}H_{18}O_5N_2S_2$ requires: C 45.0; H 5.25; N 8.08; S 18.5).

*Sodium salt of phenyl thiocarbamyl-*L*-leucine.* L-Leucine (2.7 g) was dissolved in pyridine-water (3:2, 50 ml) and 2 N sodium hydroxide added to pH 9. Phenyl *iso*thiocyanate (5 ml) was added and pH was kept at 9 during the reaction by the continuous addition of sodium hydroxide. After one hour the reaction mixture was extracted several times with equal volumes of benzene and finally with ethyl ether and the extracts discarded. A small insoluble residue was filtered off and pH was again adjusted to 9 with sodium hydroxide. The solution was concentrated *in vacuo* to a thick syrup. This was repeatedly

* Since the 5-thiazolinone slowly reacts with ethanol all measurements were made immediately after dissolution.

extracted first with acetone and then with ethyl ether and finally dried *in vacuo* (4.95 g). (Found: N 9.15. $C_{13}H_{17}O_3N_2SNa \cdot 1\ H_2O$ requires: N 9.15).

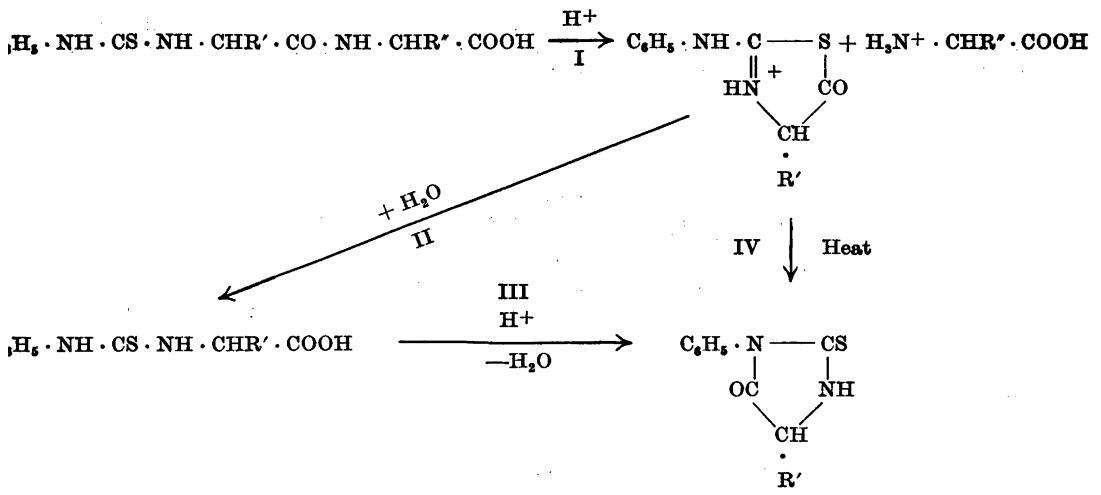
2-Anilino-4-isobutyl-5-thiazolinone. The sodium salt of PTC-L-leucine (2.3 g) was suspended in ethylene chloride (10 ml). Phosphorus oxychloride (0.6 ml) was added slowly under cooling in ice and the reaction mixture then left for two hours at room temperature. The precipitated salts were removed and the solvent then evaporated in a current of dry air. To the oily residue several vols. of dry ethyl ether were added and a stream of hydrogen chloride passed through the solution for a short while. Crystals appeared which were filtered off and recrystallized three times in quick succession from glacial acetic acid-sulfuric acid (1 M) and ethyl ether (0.8 g). M. p. 133°. R_F-value in solvent A and U.V.-absorption curve identical with that of the initial product obtained from the degradation of PTC-leucylglycine (see above). (Found: C 44.5; H 5.30; N 8.02; S 18.3. $C_{13}H_{16}O_2N_2S_2$ requires: C 45.0; H 5.25; N 8.08; S 18.5).

Attempted conversion of 5-isobutyl-3-phenyl-2-thiohydantoin into 2-anilino-4-isobutyl-5-thiazolinone. 5-*iso*butyl-3-phenyl-2-thiohydantoin (0.25 g) was dissolved in dry nitromethane (10 ml) and the solution saturated in the cold with dry hydrogen chloride. After 15 min. the solvent was removed *in vacuo*. Paper chromatography in solvents A and B and U.V.-absorption showed that the original product had been recovered unchanged.

Conversion of 2-anilino-4-isobutyl-5-thiazolinone into 5-isobutyl-3-phenyl-2-thiohydantoin by heat. Dry samples of 2-anilino-4-*iso*butyl-5-thiazolinone hydrochloride were heated at 115° C for varying times. The products were then dissolved in abs. ethanol and the U.V.-absorption measured (Fig. 3).

A solution of 2-anilino-4-*iso*butyl-5-thiazolinone hydrochloride (1 mg/ml) in glacial acetic acid was heated at 93° C. At intervals samples were diluted with abs. ethanol (1:100) and the U.V.-absorption measured (Fig. 4).

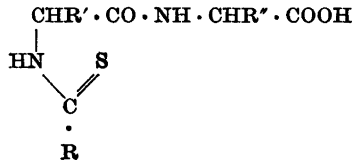
Conversion of 2-anilino-4-isobutyl-5-thiazolinone into 5-isobutyl-3-phenyl-2-thiohydantoin in aqueous acid. Solutions of 2-anilino-4-*iso*butyl-5-thiazolinone hydrochloride in acetone (10 mg/ml) were diluted with 4 N hydrochloric acid (1:10). Paper chromatograms in solvent A were run on samples taken after various times along with authentic samples of PTC-leucine and of PTH-leucine *. Already after 1 min. the spot corresponding to the 5-thiazolinone had almost completely disappeared and been substituted by a strong spot corresponding to PTC-leucine. After 5 min. a spot corresponding to PTH-leucine began to appear. The latter spot grew at the expense of the other spots and it was the only one to persist after 90 min.



Solutions of 2-anilino-4-*iso*butyl-5-thiazolinone hydrochloride and PTC-leucine (approx. 10 mg/ml) were made up in dry acetone. These solutions were diluted (1:1 000) with water previously adjusted to pH 3 and equilibrated at 30° and 50° C. The change in the U.V.-absorption at 243 mμ was then followed. The results were recalculated for equimolar concentrations (Fig. 5).

Cleavage of phenyl thiocarbamyl-DL-leucylglycine in aqueous acid. Solutions of PTC-DL-leucylglycine (15 mg/ml) in acetone were diluted with 4 N hydrochloric acid (1:10). Paper chromatograms in solvent A were run on samples withdrawn after various times along with authentic samples of PTC-leucylglycine, 2-anilino-4-*iso*butyl-5-thiazolinone, PTC-leucine and PTH-leucine (Fig. 6) *. After 1 min. a strong spot corresponding to the 5-thiazolinone and a weak spot corresponding to PTC-leucine were visible, after 15 min. PTH-leucine began to appear and this was the only substance present after 80 min.

DISCUSSION



The reaction sequences observed can be summarized in the following way:

* The 5-thiazolinone tends to react with the paper at the point of application and it was therefore necessary to develop the chromatogram without delay.

This reaction mechanism helps to clarify several hitherto obscure points. Thus the considerable difference in the rate of cleavage of PTC-peptides in nonaqueous [4,7] and in aqueous solution [5,6] is only apparent since the reactions observed were not the same. In the former case only reaction I was followed whereas in the latter instance measurements were made on the reaction sequence I—II—III of which reaction III is by far the slowest (Fig. 5). Furthermore, the frequently noted appearance of multiple spots on paper chromatograms as the result of a single step in the degradation has most likely often been due to the presence of intermediates. For the same reason the extent of cleavage of the peptide may have appeared low if calculated from the yield of thiohydantoin.

A unified aspect can be laid on several of the reactions for the degradation of peptides from the N-terminal. The reactive N-substituted peptide derivatives can be formulated:

where R represents various substituents such as C_6H_5NH- [3,4], HS- [14] or alkoxy groups [15] and the cleavage of the peptide bond ensues on the establishment of the —CO—S— linkage.

It is interesting to note that in aqueous medium the —CO—S-linkage has only a transient existence since the thiocarbamyl configuration is rapidly reestablished through hydrolysis after fission of the peptide bond. One may therefore be justified in designating the role of the thioketonic grouping (or its enolic form) as catalytic. Apparently, the nature of the neighboring R group greatly influences this catalytic activity.

This investigation has been supported by a grant from the Eli Lilly and Company which is gratefully acknowledged. The author is also indebted to Mr. K. Lauber for his skilful assistance in the experimental work.

The Mechanism of the Exchange Reaction between Cerium(III) and Cerium(IV) at Platinum Surfaces

STURE FRONÆUS and CARL OTTO ÖSTMAN

Department of Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The heterogeneous electron exchange reaction between cerium(III) and cerium(IV) at platinum surfaces under equilibrium electrode potential is investigated in a perchlorate ionic medium by means of a radioactive tracer. A general relationship for the combination of rates of consecutive steps in exchange reactions is given. From the kinetic law obtained in the present case it is established that at 0° C and in approximately 3 M perchloric acid the resultant rate of the reaction is controlled both by the electron transfer step and by the diffusion of cerium(IV) up to the interface.

The measurements indicate that the uptake of electrons from platinum by cerium(IV) takes place *via* a dimer of cerium(IV). Thus this species together with the corresponding mixed cerium(III)—cerium(IV) product, operating in the reverse process, are directly potential adjusting, although the concentrations of both species are very low in comparison with the total concentrations of cerium.

The mechanism proposed is discussed in connection with other facts about some homogeneous redox reactions in which cerium is involved.

Few kinetic investigations on the mechanisms of electrode reactions of inorganic redox systems have been reported in the literature, and electrical methods alone have been used in these studies. In some cases, *e. g.* the redox systems Fe^{3+} / Fe^{2+}, Mn^{3+} / Mn^{2+}, and Ce(IV) / Ce(III), it has been found [1–4] that the electron transfer step and the over-all electrode reaction are the same, while for other systems [5], *e. g.* Mn^{4+}/Mn^{3+}, they may be different, even though the over-all electrode reaction is very simple.

In the investigation of the cerium(IV) / cerium(III) system Vetter [4] used sulphuric acid as an additional electrolyte. However, it is known that both the cerium(III) ion (Fronæus [6]) and especially the cerium(IV) ion (Hardwick and Robertson [7]) can form three mononuclear sulphate complexes and that the hydrolysis of cerium(IV) is suppressed by this complex formation. For this reason it is probable that the electron transfer step found [4] in sulphuric acid refers to sulphate complexes.

On the other hand it has been shown by Hardwick and Robertson [8] that hydrolysis of the cerium(IV) ion occurs in perchloric acid solutions, partly with the formation of a dinuclear species. Furthermore, Gryder and Dodson [9] found that the rate of the homogeneous exchange reaction between cerium(III) and cerium(IV) is a linear function of the reciprocal of the perchloric acid concentration.

It was therefore to be expected that the electron transfer step of the heterogeneous exchange reaction in perchloric acid at platinum surfaces would be less simple than in sulphuric acid solutions. Thus the present investigation was started with the aim of elucidating the mechanism of this exchange reaction by the use of a radioactive cerium isotope.

In those cases where the electron transfer step is not very rapid in comparison with the rate of diffusion of the exchanging species up to the interface, the radioactive tracer method can give the rate of the first-mentioned step at equilibrium potential. The method has the advantage over electrical methods of being uninfluenced by small amounts of other redox systems present as impurities or formed from the solvent, and which are in redox equilibrium with the main system. The tracer method has been successfully employed by us in a previous investigation [10] of an electrode reaction of a different type.

THEORETICAL

The following notation is used for total concentrations.

c_a, q_a = concentrations of radioactive cerium(IV) and cerium(III).

c_i, q_i = concentrations of inactive cerium(IV) and cerium(III).

$c = c_a + c_i$

$q = q_a + q_i$

The kinetic law for the electron transfer step

According to Hardwick and Robertson [8] cerium(IV) is present as a mixture of Ce^{4+}, $CeOH^{3+}$, and a dimer, denoted Ce_2O^{6+}, in perchlorate solutions containing perchloric acid. Thus, to make a general treatment of the over-all electrode reaction

$$Ce(IV) + e^- \text{ (electrode)} \rightleftharpoons Ce(III) \tag{1}$$

we must presuppose that we have a set of simultaneous one-electron transfer steps of the type

$$\overset{IV}{Ce}_j(OH)_n^x + e^- \text{ (electrode)} \rightleftharpoons \overset{III\ IV}{CeCe}_{j-1}(OH)_n^{x-1} \tag{2}$$

combined with the hydrolytic equilibria

$$\overset{IV}{Ce}_j(OH)_n^x + nH^+ \rightleftharpoons jCe^{4+} + nH_2O \tag{3}$$

$$\overset{III\ IV}{CeCe}_{j-1}(OH)_n^{x-1} + nH^+ \rightleftharpoons Ce^{3+} + (j-1)Ce^{4+} + nH_2O \tag{4}$$

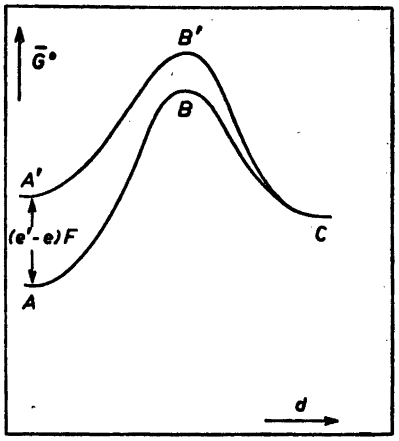

Fig. 1. The standard electrochemical free energy $\bar{G}^\circ$ during the electron transfer as a function of the distance d of the electron from the electrode surface.

Here $n \geqq 0$ for $j = 1$ and $n \geqq 2$ for $j = 2$. Within a limited range of values of q and c and at a fixed value of the perchloric acid concentration we can assume that the rates $\vec{r}$ and $\overleftarrow{r}$ of one of the reactions of type (2) predominate, and then these rates are practically equal to the total rates of the electron transfer in both directions. It should be emphasised that the concentrations of the species responsible for the electron transfer may be very small in comparison with q and c (*cf.* Fronæus and Östman [10]).

In Fig. 1 the standard electrochemical free energy during the electron transfer, $\bar{G}^0$, is represented as a function of the distance d of the electron from the electrode surface. The value of $\bar{G}^0$ at A refers to the left-hand side of (2) at a fixed value e' of the electrode potential while the value at C is that of the right-hand side of (2) just outside the rigid part of the electrode double layer. The steepness of the curve AB depends upon the so-called image force between the electrode and the electron(*cf.* Pitzer [11]).

When the electrode potential is decreased from e' to e the new energy barrier A'B'C is obtained, the increase in $\bar{G}^0$ at A being $(e'—e)F$ and for the activated state $\alpha(e'—e)F$, where $0<\alpha<1$. Thus it is evident that the electrochemical free energy of activation of the forward reaction of (2) decreases by the quantity $(1—\alpha)\ (e'—e)F$ and that of the reverse reaction increases by the quantity $\alpha(e'—e)F$. Then if e is the equilibrium electrode potential we have $\vec{r} = \overleftarrow{r} = r_0$ and for r_0 the following expressions are obtained

$$r_0 = k_1\ [\overset{IV}{Ce}_j(OH)_n^s]\ \exp\left\{\frac{(1—\alpha)\ (e'—e)\ F}{RT}\right\} \tag{5}$$

$$r_0 = k_2\ [\overset{III\ IV}{CeCe}_{j-1}(OH)_n^{s-1}]\ \exp\left\{-\frac{\alpha(e'—e)\ F}{RT}\right\} \tag{6}$$

where k_1 and k_2 denote the specific rates of the forward and reverse reactions at the electrode potential e'. For a survey of deductions of equations of the types (5) and (6) in the literature the reader is referred to a paper by Vetter [12].

Variations in the ζ-potential are suppressed in the presence of perchloric acid at a high and constant concentration as an additional electrolyte [13], and then the concentrations of the electron transferring species in the diffuse double layer are proportional to the corresponding concentrations in the bulk of the solution. Then if the latter concentrations are introduced in (5) and (6) the coefficients k_1 and k_2 should still be constants, provided, of course, that the state of the electrode surface is reproducible.

Furthermore, if, as usual, we presuppose that the inner potential in the solution phase varies linearly with d through the rigid part of the double layer, the transfer coefficient α should be a constant and, in the case of a symmetrical energy barrier, have the value 0.5.

Eliminating $e' - e$ from (5) and (6) we get

$$r_0 = \text{constant} \cdot [\overset{\text{IV}}{\text{Ce}}_j(\text{OH})_n^x]^{\alpha} \; [\overset{\text{III IV}}{\text{CeCe}}_{j-1}(\text{OH})_n^{x-1}]^{1-\alpha} \tag{7}$$

Then we apply the law of mass action to the equilibria (3) and (4), and the expressions obtained are combined with (7) giving

$$r_0 = \text{constant} \cdot [\text{Ce}^{4+}]^{j-1+\alpha} \; [\text{Ce}^{3+}]^{1-\alpha} \tag{8}$$

since $[\text{H}^+]$ is kept constant.

From the known effect of temperature on the equilibrium constants of the hydrolytic reactions [8] of Ce^{4+} it can be calculated that the concentration of the dimer is $\leqq 2.5$ % of c at 0° C, in 2.82 M perchloric acid as ionic medium, and at c-values $\leqq 8.5$ mM (the conditions for the measurements in the present investigation). The concentration of $\overset{\text{III IV}}{\text{CeCe}}(\text{OH})_n^{x-1}$ is also certainly very small, since an extinctiometric investigation by King and Pandow [14] indicates that the system cerium(III)/cerium(IV) in perchloric acid solutions does not exhibit "interaction absorption".

Thus the mononuclear species predominate, and we have $[\text{Ce}^{4+}] \approx 0.86\, c$ throughout the measurements at our acid concentrations. Furthermore, since no hydrolysis of Ce^{3+} occurs in perchloric acid solutions [6] $[\text{Ce}^{3+}] = q$, and introducing these expressions into (8) we finally obtain

$$r_0 = k_0 \; c^{j-1+\alpha} q^{1-\alpha} \tag{9}$$

where k_0 is a constant.

The resultant rate of the heterogeneous reaction

The rate r of the heterogeneous reaction is composed of the rates of at least three consecutive steps; the rate r_1 of the diffusion of cerium(III) to and from the electrode surface, the rate r_0 of the electron transfer in both directions, and the rate r_2 of the diffusion of cerium(IV) to and from the electrode, expressed in moles per unit surface area and unit time.

Of r_1 moles of cerium(III) diffusing to the electrode surface only r' moles take part in the electron transfer reaction. Now, since the fraction $r_0/(r_0+r_1)$

of all cerium(III) appearing and disappearing at the electrode is due to the electron transfer reaction we have the relation $r'/r_1 = r_0/(r_0 + r_1)$ or

$$\frac{1}{r'} = \frac{1}{r_0} + \frac{1}{r_1} \tag{10}$$

Evidently r' is the rate of transfer of cerium(III) from the solution outside the diffusion layer to cerium(IV) at the electrode surface. As the deduction is independent of the mechanisms of the two steps, the resultant rate r can be obtained by combination of r' and r_2 in the same way, and we get

$$\frac{1}{r} = \frac{1}{r_0} + \frac{1}{r_1} + \frac{1}{r_2} \tag{11}$$

If the reversible reactions (3) and (4) are not extremely rapid these steps must also be taken into consideration, and the reciprocals of their rates added to the sum on the right side of (11). Thus the reciprocals can be treated as kinetic resistances.

Obviously this fundamental law for the combination of rates of consecutive steps is *generally* applicable to exchange reactions, where all concentrations are independent of time and consequently for every step the rates are equal in both directions. For heterogeneous reactions (not exchange reactions) composed of a diffusion step and a reaction at an interface it has been shown previously [15,16] that a law of the type (10) is valid in the simplest case with a first order surface reaction.

For the diffusion rates r_1 and r_2 we have the following expressions

$$r_1 = \frac{D_1\, q}{\delta} \tag{12}$$

$$r_2 = \frac{D_2\, c}{\delta} \tag{13}$$

where δ is the thickness of the diffusion layer and D_1 the diffusion coefficient of the cerium(III) ion. D_2 is an average diffusion coefficient [17] of cerium(IV) valid at the fixed concentration ratios of the mononuclear cerium(IV) species.

EXPERIMENTAL

Chemicals. Radioactive cerium(III) perchlorate (containing some ^{141}Ce from Harwell, England) and inactive cerium(III) and cerium(IV) perchlorate solutions were prepared and analysed in the way described in previous papers [6,18]. All the stock solutions used were 2.82 M with respect to perchloric acid. The concentration of cerium(IV) was redetermined every day since the solution of cerium(IV) perchlorate was not stable but slowly oxidized water.

A 4.5 M solution of nitric acid was freed from oxides of nitrogen by bubbling air through for some hours at 60—80° C, and it was checked that the solution had no reducing effect on cerium(IV).

Diethyl ether was distilled once and stored in contact with sodium.

Exchange measurements. Cerium(III) perchlorate, cerium(IV) perchlorate and perchloric acid were mixed and tempered in a thermostat at 0° C. 15 ml of the mixture were introduced into a reaction vessel, which could be shaken in the thermostat, and 1.00 ml of the radioactive cerium(III) perchlorate solution was added quickly. After a certain

time, varying from 2 to 30 minutes, 10 ml of the solution were withdrawn and added to a mixture of 25 ml 4.5 M nitric acid and 50 ml ether. In the presence of the nitric acid cerium(IV) is rapidly extracted into the ether and this is a satisfactory and convenient method for the separation of the exchanging species, given by Gryder and Dodson [9]. After extraction the ether phase was washed once with 25 ml of the nitric acid, and the cerium(IV) was reduced with 10 ml aqueous hydrogen peroxide, causing a re-extraction of all the cerium into the aqueous phase. The gamma radioactivity of a fixed volume of the last-mentioned phase was determined with a scintillation detector (Tracerlab P-20) under reproducible geometry.

For every set of values of c and q two series of measurements were performed, one in the absence of platinum, giving the rate of the homogeneous exchange, and another with a platinum wire of 40 cm^2 surface area in the reaction vessel. In the last-mentioned case the solution was shaken so that the diffusion layer at the electrode had a fixed thickness throughout the measurements. Furthermore, the platinum wire was heated in an alcohol flame just before use, since it was very important to have the surface of the electrode in a reproducible state.

The radioactivity of cerium(IV) when approximate equilibrium with respect to isotopic mixing had been attained was determined on separate solutions, where the homogeneous exchange had proceeded for at least ten half reaction times, by the procedure described above.

It should be mentioned here that the reaction between cerium(IV) and water is so slow at 0° C, even in the presence of platinum, that it could have no influence on the exchange measurements during the reaction times used.

THE EXPERIMENTAL OVER-ALL RATE OF EXCHANGE

The differential equation for the total radioactive exchange

$$\overset{*}{\mathrm{Ce}}(\mathrm{III}) + \mathrm{Ce}(\mathrm{IV}) \rightleftharpoons \overset{*}{\mathrm{Ce}}(\mathrm{IV}) + \mathrm{Ce}(\mathrm{III}) \tag{14}$$

has the following general form [10]

$$\frac{\mathrm{d}c_a}{\mathrm{d}t} = \left(\frac{sr}{v} + R\right)\frac{c_i q_a - c_a q_i}{c\,q} \tag{15}$$

where s (= 40 cm^2) is the surface area of the platinum, v (= 16 ml) the volume of the reaction mixture, and R the rate of the homogeneous exchange reaction. If the measured radioactivity of cerium(IV) is denoted x at time t and x_∞ when the isotopic mixing has attained equilibrium the fraction exchanged will be equal to x/x_∞. If we further note that c_i and q_i are practically equal to the total concentrations c and q, integration of (15) gives

$$\ln\left(1-\frac{x}{x_\infty}\right) = -\left(\frac{sr}{v} + R\right)\cdot\frac{c+q}{qc}\cdot t \tag{16}$$

When $\ln(1-x/x_\infty)$ is plotted against t a straight line should be obtained, from the slope of which the value of R (in the absence of platinum) or $sr/v+R$ can be calculated. Since the separation with ether was performed in exactly the same way for all the solutions in a series of measurements, corresponding

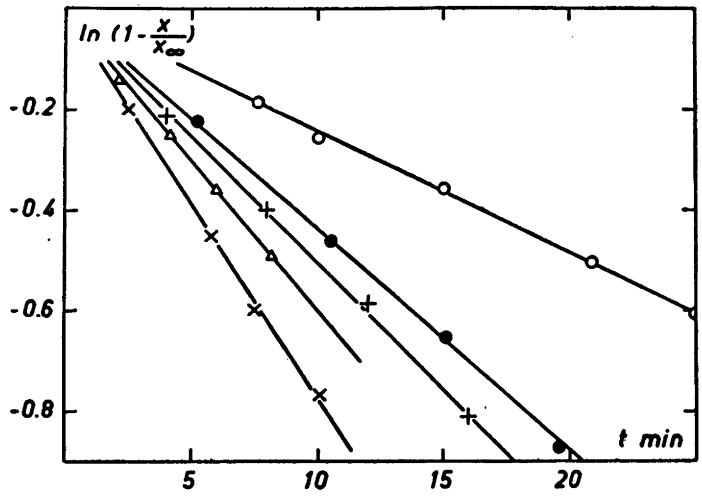

Fig. 2. $\ln(1-x/x_\infty)$ as a function of t in the homogeneous exchange for various values of c and q. —— *c = 2.18 mM, q = 2.18 mM (○); c = 2.18 mM, q = 5.43 mM ●; c = 2.18 mM, q = 10.34 mM (×); c = 4.25 mM, q = 6.14 mM (+); c = 8.21 mM, q = 4.85 mM (△).*

to fixed values of c and q, the fraction x/x_∞ should be independent of any slight incompleteness in the separation of cerium(IV).

The graphs in Fig. 2 represent the measurements of R for different values of c and q. An extrapolation of the straight lines obtained shows that $x = 0$ for $t = 0$, proving that the separation procedure does not induce any exchange. In passing it can be mentioned that R/q is a linear function of c, as found also by Gryder and Dodson [9]. The measurements with platinum in the reaction solution are represented in Figs. 3 and 4. Straight lines are also obtained in this case if very small values of t are not used in the runs corresponding to the lowest values of the rate r of the heterogeneous exchange.

It was necessary to keep $c \cdot q < 4 \times 10^{-5}$ M² in order to make the exchange rate conveniently measureable. On the other hand, the specific activity of the radioactive cerium(III) preparation available set the lower limit to the ranges of values of c and q.

Introducing the expressions (9), (12), and (13) for r_0, r_1, and r_2 into (11) we get the following relationship

$$\frac{q}{r} = \frac{q^a}{k_0\, c^{j-1+a}} + \frac{\delta}{D_1} + \frac{\delta\, q}{D_2\, c} \qquad (17)$$

From (17) it is evident that for $j = 1$ the quantity q/r should be a function of q/c only and increase monotonicly for increasing values of q/c. However, an inspection of Table 1, where the results from the exchange measurements are given, shows that this is not the case under the experimental conditions used. There remains the alternative $j = 2$, and the possibility of determining

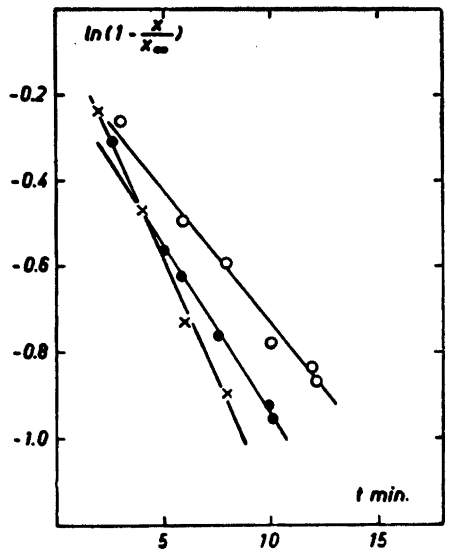

Fig. 3. $\ln(1-x/x_\infty)$ as a function of t in the mixed heterogeneous and homogeneous exchange for c = 2.18 mM and various values of q. —— q = 2.18 mM (○); q = 5.43 mM (●); q = 10.34 mM (×).

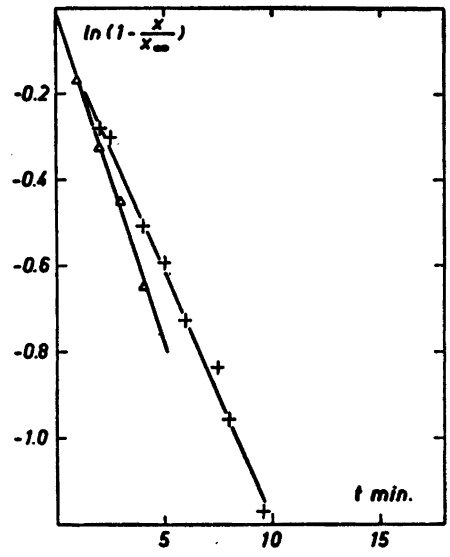

Fig. 4. The same function as in Fig. 3 for various values of c and q. —— c = 4.25 mM, q = 6.14 mM (+); c = 8.21 mM, q = 4.85 mM (△).

values of the parameters k_0, α, δ/D_1, and δ/D_2 by this approach will be investigated.

At the highest value of c and the lowest value of q/c the ratio q/r becomes so small that we can conclude that the constant term δ/D_1 is negligible. In a perchloric acid medium, where no complexing anions are present, the cerium (IV) ion is more strongly hydrated than the cerium(III) ion. Thus the difference between D_1 and D_2 should be greater than *e. g.* in a sulphuric acid medium [4], where complex formation certainly reduces the hydration of especially the cerium(IV) ion.

Table 1. The rates R and r of the homogeneous and heterogeneous exchange reactions for different values of the total cerium (III) and cerium (IV) concentrations.

c mM	q mM	$\frac{q}{c}$	R mM. min^{-1}	$\frac{sr}{v}+R$ mM · min^{-1}	$r \times 10^8$ mole · cm^{-2}.min^{-1}	$\frac{q}{r}$ cm^{-1} · min	$\frac{q}{r_{calc}}$ cm^{-1}.min
2.18	2.18	1.00	0.026	0.067	1.65	130	130
2.18	5.43	2.49	0.068	0.125	2.30	235	235
2.18	10.34	4.75	0.137	0.205	2.70	380	370
4.25	6.14	1.45	0.129	0.285	6.25	98	107
8.21	4.85	0.59	0.185	0.470	11.4	42.5	39.5

The following procedure was applied to determine the other parameters. For different values of α between 0 and 1, the quantities k_0 and δ/D_2 were calculated from corresponding values of q/r, c, and q in the first two lines of Table 1. With every set of parameters, q/r was calculated for the other c- and q-values, and it was found that the best fit with all the measurements was obtained for $\alpha = 0.50 \pm 0.05$. Then the relationship

$$\frac{1}{r} = \frac{211}{c^{1.5}\, q^{0.5}} + \frac{33}{c} \tag{18}$$

is obtained when c and q are expressed in mM and r in mM · cm · min^{-1}. In the last column of Table 1 the values of q/r have been calculated from this formula, and it is seen that they are in good agreement with the measured values. It is easily checked that no fit with all measurements can be obtained for $j > 2$. At the lowest cerium(IV) concentrations used $r_0 < r_2$, and for the highest c-values r_0 and r_2 are practically equal. Thus r_0 has a considerable influence on the resultant rate r.

We further obtain $D_2/\delta = (0.50 \pm 0.10) \times 10^{-3}$ cm · sec^{-1} from the measurements. A value of the average diffusion coefficient D_2 in the acid medium used is not known, but we can presuppose it to be of the order of magnitude 10^{-6} cm^2 · sec^{-1} (*cf.* Vetter [4]), giving us $\delta \approx 10^{-3}$ cm. This is a very plausible δ-value [19] at low relative velocities between the platinum and the solution, and there is nothing in the measurements that indicates an influence of the rates of the reactions (3) and (4) upon the total rate of the heterogeneous exchange.

DISCUSSION

We arrive at the following conclusions from the results of the present investigation.

(a) Within the concentration ranges of cerium(III) and cerium(IV) used and in approximately 3 M perchloric acid as an ionic medium the rate of the heterogeneous exchange reaction is controlled both by the electron transfer step and by the diffusion of cerium(IV), whereas the diffusion of cerium(III) seems to be too rapid to influence markedly the rate of exchange. Thus the tracer method is very suitable for the investigation of the mechanism of the electrode reaction.

(b) The hydrated cerium(IV) ion and its mononuclear hydrolysis products do not take up electrons appreciably from the platinum. This process takes place solely by way of a *dinuclear hydrolysis product*, although its concentration is only between 0,5 and 2.5 % of the total cerium (IV) concentration. As mentioned above the concentration of the corresponding mixed cerium(III)—cerium(IV) hydrolysis product, formed as an intermediate in the taking up of one electron and operating in the reverse process, must also be very low. The two dinuclear hydrolysis products mentioned are evidently the cerium species *directly* involved in the adjustment of the equilibrium electrode potential.

The results of some investigations of homogeneous reactions make conclusion (b) above very plausible. Thus Heidt and Smith [20] have investigated

the photochemical oxidation of water by cerium(IV) perchlorate in perchloric acid solutions and Kolp and Thomas [21] have studied the corresponding thermal reaction, and in both cases the measurements indicate that the oxidation is caused by a reactive dimer of cerium(IV).

It should also be mentioned that in a previous work by the present authors [18], dealing with the reaction between cerium(III) and persulphate, it was found that the rate of electron transfer is increased considerably by the coordination of sulphate ions to the cerium(III) ion. From the results of the present investigation it is evident that the coordination of a mononuclear hydrolysis product of cerium(IV) to the cerium(III) ion with the liberation of hydrogen ions has a similar effect in the electrode reaction studied. Also here the effect may be caused by a decrease in the energies of hydration (*cf.* Ref.[18]) or by a promotion of the 4*f* electron to a higher energy level. In this way we obtain a plausible explanation of the difference between the mechanisms of the electrode reactions in sulphuric acid [4] and in perchloric acid.

This investigation has been supported by a grant from the *Swedish Natural Science Research Council* which is gratefully acknowledged. We are most grateful to Dr. F. J. C. Rossotti for his revision of the English text in this paper.

Studies on the Hydrolysis of Metal Ions

XV. Partition Equilibria in the System ^{114}In/TTA/benzene

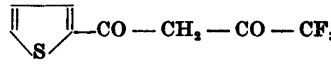
F. J. C. ROSSOTTI and HAZEL ROSSOTTI

Department of Inorganic Chemistry, the Royal Institute of Technology, Stockholm 70, Sweden *

The mononuclear hydrolysis constants of indium have been determined by studying the distribution of tracer concentrations of the indium-TTA complex, InL_3, between benzene and aqueous 3M (sodium) perchlorate solutions at 25° C. When allowance was made for TTA complexes in the aqueous phase, the data could be approximately explained in terms of the single hydroxo-complex $In(OH)_2^+$. However, agreement is improved by also taking into account the first hydrolysis product, $InOH^{2+}$. The best values of the hydrolysis constants so obtained

$$\varkappa_1 = [InOH^{2+}]\,[H^+] / [In^{3+}] = 10^{-4.4}$$

$$\varkappa_2 = [In(OH)_2^+][H^+]^2 / [In^{3+}] = 10^{-8.8}$$



are in very satisfactory agreement with those obtained potentiometrically by Biedermann [7].

Although the potentiometric method is the most accurate for studying the hydrolysis of metal ions, it can only be used for total concentrations of metal between 10^{-1} M and 10^{-3} or 10^{-4} M. Since many metal ions form predominantly polynuclear hydrolysis products in this concentration range [1,2], it may be difficult, or even impossible, to obtain reliable values of mononuclear hydrolysis constants from potentiometric measurements.

A number of stability constants have recently been measured by studying the influence of a secondary ligand on the distribution of a metal chelate between an organic and an aqueous phase. Since the partition equilibria may often be followed radiometrically using tracer concentrations of metal, the method would seem to be suitable for the determination of mononuclear hydrolysis constants. Although the effect of hydrogen ion concentration on the partition of *e. g.* 2-thenoyltrifluoroacetone (TTA, I) complexes of zirconium [3,4], thorium [5] and neptunium (IV) [6] has led to qualitative deductions about the hydrolysis of these ions, no hydrolysis constants were calculated.

* Present address: Department of Chemistry, University of Edinburgh, Scotland.

The possibility of using the method to determine mononuclear hydrolysis constants was therefore tested by studying the ^{114}In / TTA / benzene system under the same conditions as were used by Biedermann [7] in his potentiometric investigation.

I.

LIST OF SYMBOLS

a	number of hydrogen atoms in the species $H_aInL_n^{(3+a-n)+}$, $(n>1)$; negative values refer to hydroxyl groups
A	value of a for complex in organic phase
$\overline{A}$	mean value of A
C_I	initial concentration of TTA in benzene
C_M	initial concentration of indium in aqueous phase
E	measured potential in mV
E_o	$= E - 16.5\ h - 59.16 \log h$ (equation 4)
f_p	$= \varkappa_p + \sum_{n=1} K_{n-p,n} L^n$ (equation 22)
h	concentration of free hydrogen ions
J	$= \sum_{a \gtrless 0} \sum_{n=1} K_{a,n} h^{a-n} L^n$ (equation 17)
k	equilibrium constant for the reaction $H^+ + L^- \rightleftharpoons HL$
$K_{a,n}$	$= \beta_{a,n} k^{-n} (P_{HL} + 1)^{-n}$ (equation 9)
K_w	ionic product of water
l	concentration of free L^- ions in the aqueous phase
L	sum of concentrations of uncomplexed TTA in both phases (equations 6 and 7)
M	mole / l
n	number of TTA groups in species $H_aInL_n^{(3+a-n)+}$ (> 1)
$\overline{n}$	mean value of n
N	value of n for complex in organic phase
$\overline{N}$	mean value of N
p	number of hydroxyl groups in species $In(OH)_p^{(3-p)+}$
$P_{A,N}$	partition coefficient, $[H_AInL_N]_o$ / $[H_AInL_N]$
P_{HL}	partition coefficient $[HL]_o$ / $[HL]$
q	distribution ratio of indium (equations 3 and 5)
R	counting rate of equilibrated aqueous phase
R_i	counting rate of initial aqueous phase
R_o	counting rate of equilibrated organic phase
X	normalised log h, defined by equations (14) and 14a)
y, y_0, y'	defined by equations (12), (13) and (20)
Y	normalised y, y_0 and y', defined by equations (15) and (15a)
$\beta_{a,n}$	equilibrium constant for the reaction $aH^+ + In^{3+} + nL^- \rightleftharpoons H_aInL_n^{(3+a-n)+}$
$\varkappa_p$	equilibrium constant for the reaction $In^{3+} + pH_2O \rightleftharpoons In(OH)_p^{(3-p)+} + pH^+$
K_p	equilibrium constant for the reaction $In(OH)_{p-1}^{(4-p)+} + OH^- \rightleftharpoons In(OH)_p^{(3-p)+}$
Λ	radiometric absorption ratio (equation 2)
τ	$\varkappa_1 \cdot \varkappa_2^{-\frac{1}{2}}$ (equation 16) or $f_1 \cdot f_2^{-\frac{1}{2}}$ (equation 16a)
[ ]	equilibrium concentration in aqueous phase
[ ]$_o$	equilibrium concentration in organic phase

All species may be combined with sodium or perchlorate ions, or with molecules of benzene or water. Concentrations and equilibrium constants will be expressed using the molar scale.

METHOD

The variation of the distribution ratio

$$q = \frac{\text{total concentration of indium in organic phase}}{\text{total concentration of indium in aqueous phase}}$$

with the concentration, h, of free hydrogen ions was studied at 25° C for a number of initial concentrations of TTA (C_L) in benzene and of indium (C_M) in the aqueous phase in the range $-2.7 > \log h > -4.5$, $-2.3 > \log C_L > -3.0$ and $-5.24 > \log C_M > -5.65$. The aqueous phase was made 3 M with respect to the perchlorate ion, by the addition of sodium perchlorate. Since the combined concentrations of indium, hydrogen and ligand ions never exceeded 0.1 % of the concentration of perchlorate ions, the activity coefficients of all species in the aqueous phase may be assumed to remain constant [8]. King and Reas [9] have shown that the activity coefficient of TTA in benzene is effectively constant if $C_L \leq 10^{-2}$ M. Huffman and Iddings [10] have found that the solubility (and hence the activity coefficient) of the uncharged TTA complex of zirconium in benzene is independent of C_L if $C_L \leq 0.08$ M, and it is probable that the activity coefficient of the corresponding indium complex in benzene is also constant in the ranges of concentration studied. Thus it may be assumed that there is no variation of activity coefficients in either phase, and that true stoichiometric equilibrium constants may be calculated from the partition measurements.

The distribution ratio, q, was obtained radiometrically, using ^{114}In. Since equal phase volumes were used throughout, and no volume changes occurred on equilibration,

$$q = \Lambda R_o / R \qquad (1)$$

where R_o and R are the counting rates of the equilibrated organic and aqueous phases, and

$$\Lambda = \frac{\text{absorption of } ^{114}\text{In radiation in benzene}}{\text{absorption of } ^{114}\text{In radiation in 3M } NaClO_4}$$

Assuming 100 % mass balance

$$\Lambda = (R_i - R) / R_o \qquad (2)$$

(*cf.* Ref.[11]) where R_i is the counting rate of the initial aqueous phase, and the initial organic phase is not radioactive. Values of q and Λ were calculated from the measured values of R_i, R_o and R, using the relationship

$$q = (R_i - R) / R \qquad (3)$$

and eqn. (2). The standard deviation in the value of Λ is a measure of the standard deviation in the overall mass balance (*cf.* p. 783).

The equilibrium hydrogen ion concentration in the aqueous phase was obtained using a glass electrode in combination with the half-cell

$$RE = Ag \,/\, 0.01 \text{ M } AgClO_4,\ 2.99 \text{ M } NaClO_4 \,/\, 3 \text{ M } NaClO_4$$

For the cell

$$RE \,/\, h \text{ M } HClO_4,\ (3 - h) \text{ M } NaClO_4 \,/\, \text{Glass} \qquad 25° \text{ C}$$

the relationship between the measured potential, E (in mV), and the concentration of free hydrogen ions is given by

$$E = E_0 + 16.5\ h + 59.16 \log h \qquad (4)$$

where the term E_0 includes the standard potentials of the electrodes and the asymmetry potential of the glass electrode. The term 16.5 h represents the liquid junction potential [12]. Before each measurement, the glass electrode was immersed in two standard solutions of perchloric acid ($h = 0.231$ M and $h = 0.023$ M); the two values of E_0 which were calculated from the measured potentials by means of equation (4) always agreed within 0.1 mV. The distribution experiments were carried out at such low acidities ($h < 0.002$ M) that $E_0 \gg 16.5\ h$, and log h could be directly calculated from the expression

$$\log h = (E - E_0) / 59.16 \qquad (4a)$$

The partition measurements are given in Table 1, and are plotted in the form log q $(\log h)_{C_L}$ in Fig. 1.

EXPERIMENTAL DETAILS

Indium perchlorate. Indium—114 (half-life 49 days) was obtained by irradiation of a known weight of "Specpure" indium wire (Johnson Matthey, Ltd.) at A.E.R.E., Harwell. The irradiated wire was dissolved in warm 3M perchloric acid, to which a drop of hydrogen peroxide had been added to prevent the formation of chloride or chlorate ions [13]. The solution was boiled to decompose the excess of hydrogen peroxide, cooled, and diluted to a known volume.

Solutions of *sodium hydroxide, perchloric acid, sodium perchlorate* and *silver perchlorate* were prepared and standardised as described elsewhere [12, 14].

TTA. The reagent obtained from Dow Chemical Company was not purified further, as the melting point (43.5° C) was the same as that given by Day and Powers [5]. Known weights of the solid were dissolved in benzene (Merck *p. a.*) which had been presaturated with aqueous 3 M perchlorate. This ensured that the equilibrium concentration ($\sim$ 10 %) of the keto-hydrate was present [16] and reduced the time required for partition equilibrium. The solutions were stored in the dark, over a small volume of 3 M perchlorate to remove any traces of trifluoroacetic acid formed by decomposition of the TTA.

Apparatus

The radioactivity was assayed using a 20th. Century Electronics Ltd. M6 liquid counter, in conjunction with a Tracerlab scalar.

The hydrogen ion concentrations were measured in a 25 ml beaker, using a Radiometer glass electrode (type G 202 B), which had been tested as described before [14]. The reference half-cell, RE, and the valve potentiometer, were the same as used in previous work [14].

Procedure

The equilibrations and measurements were carried out in a room thermostated at 25° $\pm$ 1° C. All aqueous solutions were made 3 M with respect to the perchlorate ion by the addition of sodium perchlorate, and were presaturated with benzene.

For each distribution experiment, a known volume of a solution of radioactive indium perchlorate ($\sim 1.6 \times 10^{-5}$ M) in perchloric acid ($\sim 2 \times 10^{-4}$ M) was diluted to 25.0 ml, using sufficient perchloric acid ($\sim 1.5 \times 10^{-2}$ M) or sodium hydroxide ($\sim 2 \times 10^{-4}$ M) to give the required hydrogen ion concentration. 15.0 ml of this solution, and 15.0 ml of a solution of TTA (concentration C_L) in benzene were pipetted into a 50 ml centrifuge tube. The remaining initial aqueous solution was acidified with one drop of concentrated perchloric acid to prevent adsorption losses on the glass. The centrifuge tube was closed with a ground glass stopper, which was wetted with a solution of collodion in ether and placed firmly in position. The tube was shaken mechanically at 30 revolutions per minute for 16 hours, which had been shown to be sufficient for equilibration, even at the lowest acidities studied ($\log h \sim -4.5$). After centrifugation, the two phases were carefully separated by pipetting.

10 ml portions of the initial aqueous solution, and of the two equilibrated phases, were assayed radiometrically. The counting rates were corrected for the background activity ($\sim$ 15 counts min.$^{-1}$). Correction for the paralysis time of the counting assembly was found to be unnecessary at the counting rates used ($\leqslant$ 10 000 counts min.$^{-1}$) and no correction was needed for the decay of the 49-day indium, as aliquots from any one experiment were assayed consecutively. Whenever possible, the duration of the counting was chosen to give a standard deviation of $\pm$ 1 %. The mean value of the absorption ratio, A, was calculated using eqn. (2) and found to be 0.90; the standard deviation in this value, and hence in the overall mass balance (including statistical variations, and fluctuations in the counting efficiency), was $\pm$ 6.3 %.

The hydrogen ion concentration in the aqueous phase was determined after the radioactivity of the solution had been measured.

At values of $\log h < -4.5$, or of $\log C_L < -3.0$, low mass balances ($\leqslant$ 80 %, assuming $A = 0.90$) were obtained, and it is possible that some invisible precipitate was present. When $\log h \leqslant -5$, a visible precipitate collected at the phase boundary.

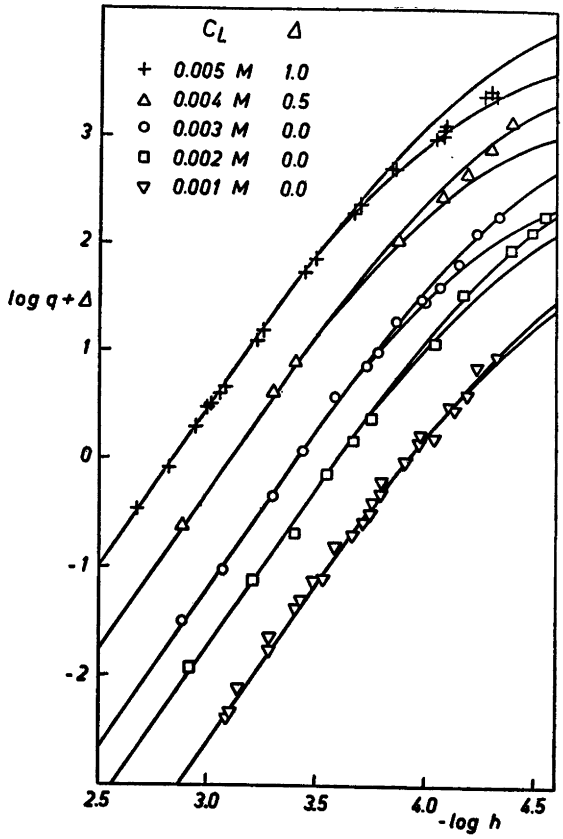

Fig. 1. Log q *as a function of log* h. +, △, ○, □ *and* ▽ *are experimental points for different initial concentrations,* C_L, *of TTA; points for different initial concentrations of metal in the range* $-5.24 \leqslant \log C_M \leqslant -5.65$ *are not differentiated. INTERPRETATION OF THE DATA

Since the distribution curves shown in Fig. 1 are independent of the total concentration, C_M, of indium, the system is homonuclear; and as $C_M \leqslant 6 \times 10^{-6}$ M, it may be assumed that only mononuclear complexes are present in appreciable amounts. If the species H_AInL_N are present in the organic phase

$$q = \sum_{A \gtrless 0} \sum_{N=1} [H_AInL_N]_o \,/\, \{[In] + \sum_{p=1} [In(OH)_p] + \sum_{a \gtrless 0} \sum_{n=1} [H_aInL_n]\}$$

$$= \sum_{A \gtrless 0} \sum_{N=1} P_{A,N}\beta_{A,N}h^A l^N \,/\, \{1 + \sum_{p=1} \varkappa_p h^{-p} + \sum_{a \gtrless 0} \sum_{n=1} \beta_{a,n} h^a l^n\} \qquad (5)$$

where charges are omitted, and [ ]$_o$ and [ ] refer to concentrations in the organic and aqueous phases respectively; l is the concentration in the aqueous

phase of the anion L derived from TTA (HL), and $P_{A,N}$, $\varkappa_p$ and $\beta_{a,n}$ are defined by

$$P_{A,N} = [H_A InL_N]_o\,[H_A InL_N]^{-1}$$
$$\varkappa_p = [In(OH)_p]h^p\,[In]^{-1}$$
and
$$\beta_{a,n} = [H_a InL_n]\,[In]^{-1}\,h^{-a}l^{-n}$$

Values of a and A will be negative for mixed TTA-hydroxo-complexes.

For equal volumes of the phases at equilibrium, the sum of the concentrations of uncomplexed TTA in both phases is given by

$$L = C_L - \sum_{A \gtrless 0} \sum_{N=1} N[H_A InL_N] - \sum_{a \gtrless 0} \sum_{n=1} n[H_a InL_n] \quad (6)$$

As the last term is negligible compared with C_L under the experimental conditions used (see p. 788)

$$L = C_L - \overline{N}[H_{\overline{A}} InL_{\overline{N}}]_o = C_L - \overline{N}C_M q(q+1)^{-1} \quad (6a)$$

where $\overline{A}$ and $\overline{N}$ are the average numbers of hydrogen and TTA groups attached to each indium ion in the organic phase. In this work, $\overline{N}[H_{\overline{A}} InL_{\overline{N}}]_o \leqslant 0.02\,C_L$. Now

$$L = [HL]_o + [HL] + l = l\{kh(P_{HL} + 1) + 1\} \quad (7)$$

where
$$k = [HL]h^{-1}l^{-1}$$

and
$$P_{HL} = [HL]_o\,[HL]^{-1}$$

If $k \sim 10^6$ (Ref.[3]) and $P_{HL} \sim 40$ (Ref.[9]), then $kh(P_{HL}+1) \gg 1$ at values of $h > 10^{-5}$ M, and

$$l = L\,/\,kh(P_{HL}+1) \quad (7a)$$

Combining eqns. (5) and (7a)

$$q = \sum_{A \gtrless 0} \sum_{N=1} P_{A,N}K_{A,N}h^{A-N}L^N\,/\,\{1 + \sum_{p=1} \varkappa_p\,h^{-p} + \sum_{a \gtrless 0} \sum_{n=1} K_{a,n}\,h^{a-n}L^n\} \quad (8)$$

where
$$K_{a,n} = \beta_{a,n}\,k^{-n}(P_{HL}+1)^{-n} \quad (9)$$

At high acidities, no indium complexes will be formed in the aqueous phase, and moreover, $L \to C_L$; then [3,17]

$$\lim_{h \to \infty} (\partial \log q\,/\,\partial \log h)_{C_L} = \overline{A} - \overline{N} \quad (10)$$

$$\lim_{h \to \infty} (\partial \log q\,/\,\partial \log C_L)_h = \overline{N} \quad (11)$$

From the data $\log q$ $(\log h)_{C_L}$ shown in Fig. 1, it was found that $\overline{A}-\overline{N} = -3.0$. Values of $\log q$ at given values of $\log h$ were interpolated from Fig. 1, and the function $\log q$ $(\log C_L)_h$ is plotted in Fig. 2; whence a value of $\overline{N} = 3.0$ was obtained.

Since $\overline{A} = 0.0$ and $\overline{N} = 3.0$, InL_3 is the sole species extracted, and the function

$$y = \log q - 3\log L + 3\log h = \log P_{0,3}K_{0,3} - \log\{1 + \sum_{p=1} \varkappa_p\,h^{-p} + \sum_{a \gtrless 0} \sum_{n=1} K_{a,n}h^{a-n}L^n\} \quad (12)$$

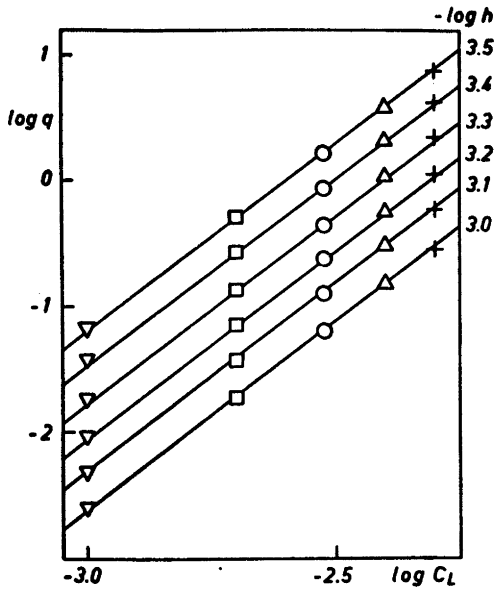

Fig. 2. Interpolated values of log q *as a function of log* C_L *for different values of log* h, *together with the best straight lines of slope 3.0. The symbols are those used in Fig. 1.*

derived from eqn. (8) will have a constant value, log $P_{0,3}K_{0,3}$, if all the metal in the aqueous phase is in the form of free indium ions. If hydroxo-complexes, but no TTA complexes, are present, y will be a function of h only, and independent of L, while if TTA complexes are formed, y will be a function of both h and L.

At hydrogen ion concentrations $> 7 \times 10^{-4}$ M, y is constant (-2.60 ± 0.03) within the experimental error, confirming that InL_3 is the species extracted. At lower acidities, the curves y (log $h)_{C_L}$ are not coincident, indicating that TTA complexes are formed in the aqueous phase. Approximate values of the hydrolysis constants, $\varkappa_p$, may be obtained by extrapolating the term y to zero concentration of TTA, and used to calculate preliminary values of the constants $K_{a,n}$; both sets of constants may then be refined by successive approximations, using eqn. (12).

Preliminary values of the hydrolysis constants. Smooth curves were drawn through the points y(log $h)_{C_L}$ and, for each value of C_L, values of y were interpolated at a number of values of h. Curves y $(C_L)_h$ were then plotted, and extrapolated to $C_L = 0$ to give values of

$$y_0 = \log P_{0,3}K_{0,3} - \log \{1 + \sum_{p=1} \varkappa_p h^{-p}\} \qquad (13)$$

which are given in Table 2 and Fig. 4. The extrapolated function y_0(log h) lies only slightly above the points y (log h) for $C_L = 10^{-3}$ M.

Table 2. Values of y_0 as a function of log h.

-log h	3.50	3.60	3.70	3.80	3.90	4.00	4.10	4.20	4.30	4.40	4.50
$-y_0 \pm 0.04$	2.59	2.63	2.64	2.69	2.74	2.78	2.84	2.89	2.96	3.02	3.13

If the uncharged complex $In(OH)_3$ is not present in appreciable amounts, preliminary values of the hydrolysis constants $\varkappa_1$ and $\varkappa_2$ may conveniently be obtained by superimposing the family of theoretical curves [18] $Y(X)_\tau$ on the extrapolated function $y_0(\log h)$. The normalised variables X and Y are given by

$$X = \log h - \tfrac{1}{2} \log \varkappa_2 \qquad (14)$$

$$Y = y_0 - \log P_{0,3}K_{0,3} = -\log (1 + \tau\, 10^{-X} + 10^{-2X}) \qquad (15)$$

where $$\log \tau = \log \varkappa_1 - \tfrac{1}{2} \log \varkappa_2 \qquad (16)$$

The required value of τ is that used to calculate the theoretical curve of the same shape as the experimental function, and the values of $\log P_{0,3}K_{0,3}$ and $\frac{1}{2} \log \varkappa_2$ are obtained from the corresponding co-ordinates of the theoretical and experimental curves, in the position of best fit (equations 14 and 15). Within the limits of experimental error, the data $y_0(\log h)$ could be described by the curve $Y(X)$ calculated for $\tau = 1$ (see Fig. 4). Thus there is no evidence for the presence of $In(OH)_3$, as would be expected from its low solubility [19]. The best fit was obtained with $\log P_{0,3}K_{0,3} = -2.6$ and $\frac{1}{2} \log \varkappa_2 = -4.45$; whence $\log \varkappa_1 = -4.45$ (eqn. 16) and $\log \varkappa_2 = -8.9$.

Final values of the constants. Substituting the preliminary values of $P_{0,3}K_{0,3}$, $\varkappa_1$ and $\varkappa_2$ into eqn. (12), values of

$$J = P_{0,3}K_{0,3} \cdot 10^{-y} - \{1 + \sum_{p=1} \varkappa_p h^{-p}\} = \sum_{a \gtrless 0} \sum_{n=1} K_{a,n} h^{a-n} L^n \qquad (17)$$

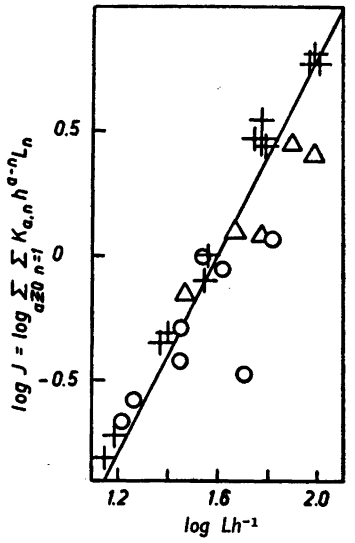

Fig. 3. Log J = log $\sum_{a \gtrless 0} \sum_{n=1} K_{a,n} h^{a-n} L^n$ as a function of log $L\,h^{-1}$. The symbols are those used in fig. 1 and the straight line is of slope 2.0 and of intercept −3.2.

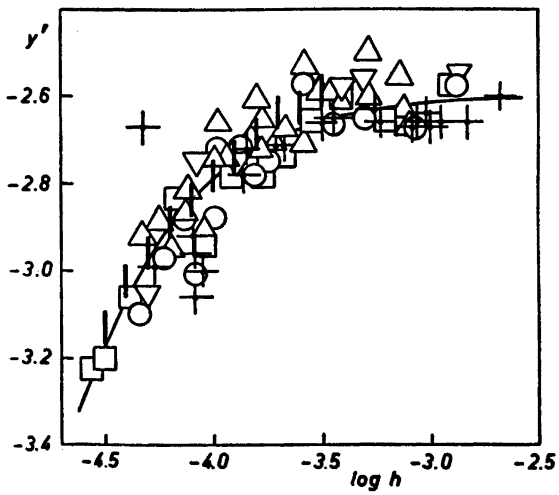

Fig. 4. Values of y′ *(points) and* y_0 *(vertical lines) as a function of log* h. *The symbols are those used in Fig. 1. The full curve is that calculated for log* $\tau = 0$, *in the position corresponding to log* $P_{0,3}K_{0,3} = -2.60$ *and* $\frac{1}{2}$ *log* $\varkappa_2 = -4.4$.

were calculated for each point $y(h,L)$. If the TTA complexes in the aqueous phase are all of the type InL_n (i.e. $a = 0$), J will be a function of Lh^{-1} only, and

$$\mathrm{d}\ \log\ J\ /\ \mathrm{d}\ \log\ Lh^{-1} = \bar{n} \qquad (18)$$

where $\bar{n}$ is the average number of TTA groups in the complex InL_n ($n > 1$). Log J is plotted as a function of log Lh^{-1} in Fig. 3; within the limits of experimental error, the points for $C_L > 3 \times 10^{-3}$ M can be represented by the equation

$$\log\ J = 2\ \log\ Lh^{-1} - 3.2 \pm 0.2 \qquad (19)$$

indicating that InL_2^+ is the predominant TTA complex in the aqueous phase in the range $1.2 < \log\ Lh^{-1} \leqslant 2.0$, and that $\log\ K_{0,2} = -3.2 \pm 0.2$. Thus the assumption that $\sum_{a \gtrless 0} \sum_{n=1} n[H_aInL_n] \ll C_L$ (see p. 785) is justified. If $\log\ k(P_{HL} + 1) \sim 7.8$ (refs.[3,9]), then from eqn. (9) the overall stability constant of InL_2^+, $\beta_{0,2} \sim 12.4$.

Values of

$$y' = \log\{qh^3L^{-3} - P_{0,3}K_{0,3}K_{0,2}^{-1}h^2L^{-2}\} = \log P_{0,3}K_{0,3} - \log\{1 + \sum_{p=1} \varkappa_p\ h^{-p}\} \qquad (20)$$

were calculated for each experimental point $q(h,L)$ using the values of $P_{0,3}K_{0,3}$ and $K_{0,2}$ given above, and are shown in Table 1 and Fig. 4. Within the experimental error (± 0.1 log unit), the function $y'(\log\ h)$ is independent of L, and is coincident with the function $y_0(\log\ h)$ obtained by extrapolation to $L = 0$ (eqn. 13). Thus no refinement of the constants is necessary. The limits of error in $\varkappa_1$, $\varkappa_2$ and $P_{0,3}K_{0,3}$ were obtained by curve-fitting using the set of

normalised $Y(X)_\tau$ curves, as described above. Although the data could be approximately explained in terms of the single hydroxo-complex $In(OH)_2^+$, represented by the curve for $\log \tau = -\infty$ and $\frac{1}{2} \log \varkappa_2 = -4.2$, the agreement is more satisfactory if the first hydroxo-complex, $InOH^{2+}$ is also taken into account. The best fit was obtained with $\log \tau = 0.0 \pm 0.1$ and $\log P_{0,3}K_{0,3} = -2.60 \pm 0.03$; for this case, $\frac{1}{2} \log \varkappa_2 = -4.4 \pm 0.1$.

The step stability constant of the species $In(OH)_p$ is given by

$$K_p = [In(OH)_p][In(OH)_{p-1}]^{-1} [OH]^{-1} = \varkappa_p / \varkappa_{p-1}. K_w \qquad (21)$$

Values of K_p were calculated assuming that the ionic product of water, $K_w = 10^{-14.22}$ in a 3 M (sodium) perchlorate medium [20].

Table 3. Equilibrium constants.

	$\log \varkappa_1$	$\log \varkappa_2$	$\log K_1$	$\log K_2$	$\log P_{0,3}K_{0,3}$
This work	-4.4 ± 0.1	-8.8 ± 0.3	9.8	9.8	-2.60 ± 0.03
Biedermann [7]	-4.42 ± 0.05	-8.3 ± 0.1	9.80	10.3	—

Curves $\log q$ ($\log h)_{C_L}$ were calculated by successive approximations, using eqns. (7) and (12), the values of the equilibrium constants given in Table 3, and the two extreme possible values of $K_{0,2}$. The calculated curves, which are shown in Fig. 1, are in very good agreement with the experimental data.

ALTERNATIVE TREATMENT OF THE DATA

The above interpretation of the data was checked using a method of curve-fitting developed by Sillén [21]. Eqn. (12) may be rewritten

$$y = \log P_{0,3}K_{0,3} - \log \{1 + (\varkappa_1 + K_{0,1}L + K_{1,2}L^2 \cdots)h^{-1} + (\varkappa_2 + K_{-1,1}L + K_{0,2}L^2 \cdots)h^{-2} \cdots\}$$

$$= \log P_{0,3}K_{0,3} - \log \{1 + \sum_{p=1} f_p h^{-p}\} \qquad (12a)$$

where

$$f_p = \varkappa_p + \sum_{n=1} K_{n-p,n}L^n \qquad (22)$$

Provided that $p \leqslant 2$, the parameter $P_{0,3}K_{0,3}$ and the coefficients f_1 and f_2 may be found by comparing the experimental data $y(\log h)_L$ with the family of normalised curves $Y(X)_\tau$. In this case (*cf.* Ref.[18])

$$X = \log h - \tfrac{1}{2} \log f_2 \qquad (14a)$$

$$Y = y - \log P_{0,3}K_{0,3} \qquad (15a)$$

and

$$\log \tau = \log f_1 - \tfrac{1}{2} \log f_2 \qquad (16a)$$

As before, it was found that the value of $\log P_{0,3}K_{0,3}$ (-2.60 ± 0.03) was independent of L, indicating that InL_3 is the extracted species. Since the value of f_1 obtained ($< 10^{-4}$) is independent of L within the experimental error, it may be assumed that this term represents only the first hydrolysis constant

$\varkappa_1$. The term f_2 is a function of L, indicating that at least one indium-TTA complex, $H_{n-2}InL_n$, is present in the aqueous phase. If $n<2$, the function $\log f_2(\log L)$ may also be analysed by curve-fitting [18]. Although the presence of appreciable concentrations of $In(OH)L^+$ cannot definitely be excluded, the variation of f_2 with L may best be explained in terms of the two species $In(OH)_2^+$ ($\log \varkappa_2 = -8.7 \pm 0.3$) and InL_2^+ ($\log K_{0,2} = -3.2 \pm 0.2$). These conclusions are in satisfactory agreement with those reached above.

DISCUSSION

The hydrolysis constants given in Table 3 may be obtained by extrapolating the experimental data to zero concentration of TTA, and are almost independent of any assumption about the nature of the TTA complexes in the aqueous phase. However, from the variation of extraction with the concentration of reagent, it appears that InL_2^+ ($\log K_{0,2} = -3.2 \pm 0.2$, corresponding to $\log \beta_{0,2} \sim 12.4$) is the predominant TTA complex present under the experimental conditions used. No polynuclear complexes could be detected, as would be expected, since the total concentration of metal in the aqueous phase, $C_M(q+1)^{-1}$, never exceeded 3×10^{-6} M in the range $\log h < -3.5$ in which hydrolysis occurs (*cf.* Ref. [7]).

Previous work on the hydrolysis of indium. As the molar fraction of benzene in the aqueous phase was less than 1.8×10^{-3}, the present hydrolysis constants should be strictly comparable with those obtained potentiometrically by Biedermann [7] (see Table 3). The best value of $\varkappa_1$ obtained from the partition data is in excellent agreement with Biedermann's value, and the difference between the two values of $\varkappa_2$ is not surprising in view of the limited accuracy both of the radiometric measurements and of the potentials of indium amalgam electrodes [7] in solutions of indium $\sim 5 \times 10^{-4}$ M.

Earlier work on the hydrolysis of indium was restricted to measurements of the pH of solutions of indium salts at different concentrations. Hepler and Hugus [22] calculated

$$\varkappa_1 = \lim_{C_M \to 0} (C_M - h)\, h^{-2} \sim 10^{-3.9}$$

from Moeller's data for the indium halides [23], and the same value at infinite dilution may also be obtained from Hattox and De Vries' and Moeller's data [24, 25] for indium sulphate. Since the measurements were made in the concentration range where indium forms predominantly polynuclear hydrolysis products [7], this value is probably unreliable. However, a decrease in the hydrolysis constant with increasing ionic strength is in accordance with the extended Debye-Hückel equation, and has also been observed for iron(III) [26] and scandium [27]. The difference in the values of $\log \varkappa_1$ at infinite dilution and in a 3 M perchlorate medium is the same (0.5 log unit) for indium as that reported for iron(III) [26].

Comparison with other trivalent metals. Mattock [2] has shown that the stability constants, K_1, of the hydroxo-complexes often follow the same order as the ratios of the negative heats of hydration, $-\Delta H_{aq}$ of the metal ions, to their characteristic co-ordination numbers, N. The same correlation is valid for the Group III B metals.

	Ga^{3+}	In^{3+}	Tl^{3+}
log K_1 (medium)	11.4 (μ = O) [a]	9.8 (3 M $NaClO_4$)	13.08 (3 M $NaClO_4$) [29]
Δ H_{aq} / N [b]	187.3	165.8	246.0
χ [c]	1.6	1.5	1.9

[a] Ref.[28] and refs. therein [b] values taken from Refs. [30, 31] [c] Ref.[32]

The stabilities of the hydroxo-complexes follow the same order (Tl>Ga>In) as Pritchard and Skinner's "best" values, χ, of the electronegativities [32].

When $P_{HL} \gg 1$ and $\bar{A} = 0$, $P_{A,N}K_{A,N}$ approximates to the extractability constant [33], $\boldsymbol{K} = [MeL_N]_o\,[H]^N / [Me][HL_o^N]$. Although values of $\boldsymbol{K}$ for the extraction of TTA complexes of trivalent metals into benzene have been obtained under different experimental conditions, it seems that indium is extracted less readily than iron(III) and scandium, but more readily than bismuth, aluminium, thallium(III), americium, yttrium, dysprosium, praeseodynium, lanthanum and actinium (Ref[34]. and refs. therein, Refs.[35–37]).

The choice of a chelating ligand for studies of hydrolysis. Although it has been shown that the partition method may be used for quantitative investigation of the hydrolysis of metal ions, the difficulty of obtaining accurate distribution measurements, and the introduction of unknown parameters associated with the extracting reagent, lowers the precision of the hydrolysis constants obtained. Even if a suitable radionuclide is available, the choice of a chelating ligand may be somewhat restricted. In studies of many other types of complexes (*e. g.* if the secondary ligand is the conjugate base of a strong acid, or is an anion which may be added to a strongly acidic solution in the form of the corresponding weak acid) the concentration of the secondary ligand may be varied almost independently of h, and hence of the concentration, l, of chelating ligand; but if the secondary ligand is the hydroxyl ion, its concentration, $K_w h^{-1}$, cannot be varied independently of l (*cf.* eqn. 8). As accurate values of the distribution ratio may only be obtained radiometrically if $2.5 \geqslant \log q \geqslant -2.5$, the reagent and solvent should be chosen so that

$$\log P_{A,N}K_{A,N} = (N - A) \log h - N \log C_L \pm 2.5 \qquad (23)$$

(assuming H_AMeL_N is the only species extracted, *cf.* eqn. 9). If possible, measurements should be made over the whole range of hydrogen ion concentration in which hydrolysis occurs, and also at somewhat higher acidities, so that a reliable value of log $P_{A,N}K_{A,N}$ can be obtained. In order to detect, and correct for, the presence of chelate complexes in the aqueous phase, series of experiments should be carried out using different concentrations of reagent (*cf.* eqn. 12). However, even within the limits imposed by eqn. (23), it is not always desirable to vary this quantity over a very wide range; at high values of C_L, the activity coefficient of the reagent in the organic phase may vary with concentration [9] and at low concentrations such that $C_L < 10\,N\,C_M$, uncertainties in the distribution measurements may result in appreciable uncertainties in the total concentration, L, of the uncomplexed reagent (*cf.* eqn. 7). Thus the TTA / benzene system could not be used to study the polynuclear hydrolysis of indium. A reagent / solvent system for which log $P_{0,3}K_{0,3} \sim -8$ would be

necessary, since measurements would be required for $C_M \leq 5 \times 10^{-2}$ M and $h \leq 10^{-2}$ M (*cf.* Ref. [7]).

We are grateful to Professor Lars Gunnar Sillén for his helpful comments on the manuscript, and to the *Swedish Atomic Energy Commission* and the *Swedish Natural Science Research Council*, for financial assistance.

A method for the reduction of the aldehyde groups in apurinic acid derived from sodium deoxyribonucleate and the chemical and dissociation properties of the reduced apurinic acid are described. Comparison of the titration curves of this material with that of the sodium deoxyribonucleate from which it was derived has enabled the dissociation ranges of the titratable groups in the deoxyribonucleate to be estimated.

Apurinic acid has been obtained from deoxyribonucleic acid by removal of its purine bases but with retention of an unchanged proportion of pyrimidines and has proved to be a useful substance for the study of the chemical structure of the original deoxyribonucleate. When apurinic acid was degraded by alkali [1] a decrease was observed in the intensity of the colour produced in the Dische test, probably because the sugar moieties containing free aldehyde groups were partly destroyed by the alkali. Hence it seemed likely that if the aldehyde groups in apurinic acid could be reduced, a more stable product would result. A suitable reducing agent would have to leave the pyrimidine bases unchanged and preliminary experiments with sodium borohydride showed that it did not reduce thymidine. In the following the reduction of the free aldehyde groups of apurinic acid to primary alcoholic groups by sodium borohydride is described together with the chemical and dissociation properties of the reduced apurinic acid so obtained. The greater stability of this reduced form made it particularly useful for titration purposes. Comparison of the titration curves of the reduced apurinic acid, which contained only thymine and cytosine bases, with those of the parent deoxyribonucleate, which in addition contained adenine and guanine, has enabled the dissociation ranges of the various groups in the deoxyribonucleate to be elucidated.

EXPERIMENTAL

Materials and preparations. Sodium deoxyribonucleate was isolated both from herring and cod roes. The herring sample used in this investigation has been described elsewhere [2] and has also been employed in concurrent titration studies [3,11]. Two samples of apurinic acid were prepared from the herring deoxyribonucleate by treatment with an acidic ion exchange resin, as previously described [4,11]. The first sample (APA—H1) of apurinic acid was isolated as the free acid by drying in the frozen state. A second sample (APA—H2) was first neutralized and isolated as the sodium salt, again by drying in the frozen state. Reduced apurinic acid (RAPA—H2) was then prepared in the form of its sodium salt from APA—H2 and was isolated after dialysis and drying in the frozen state. A second reduced apurinic acid sample (RAPA—C) was similarly obtained from apurinic acid (APA—C) which had been prepared from cod roe deoxyribonucleate by the resin method. Ribonucleoprotein was removed from the cod roes by extraction with 0.14 M sodium chloride solution. Deoxyribonucleoprotein was obtained by extraction with a stronger salt solution (1 M sodium chloride) followed by precipitation with 96 % ethanol. The protein was then removed by the use of chloral hydrate [5]. The sodium deoxyribonucleate was precipitated with ethanol, dissolved in water, dialysed against water and finally dried in the frozen state.

Reduction of apurinic acid. The course of the reduction of apurinic acid by the borohydride was studied in the following way. Apurinic acid (0.1 g of APA—C) was dissolved in distilled water (5 ml) and small amounts (0.05 ml and 0.025 ml) of this solution were withdrawn for use in the Schiff's and Dische test, respectively. Weighed amounts of solid sodium borohydride were then added successively. After each addition the mixture was shaken and half an hour was allowed to elapse before further samples were withdrawn for Dische and Schiff's tests. From these experiments (reported in Fig. 1) the following procedure for reducing apurinic acid was deduced. Apurinic acid (0.052 g of APA—H2) was dissolved in water (2 ml) and sodium borohydride (0.01 g) was added. The mixture was left at room temperature for nearly 4 hours. The absence of aldehyde groups in the product was always confirmed by Schiff's test, since control experiments showed that there was a linear relation between the amount of apurinic acid and the intensity of Schiff's colour. After reduction, the mixture which had a pH of 9 was neutralized with dilute hydrochloric acid and dried in the frozen state. Ethanol (10 ml, 96 %) was added to the white residue and the mixture was left to stand at room temperature for several days. The solid was separated by centrifugation, dried with ether, dissolved in distilled water (20 ml, pH 6.8) and dialysed at 2 °C against distilled water (300 ml). The dialysed solution was dried in the frozen state to yield the reduced apurinic acid (0.038 g). The ultraviolet absorption at 260 mμ of the dialysate indicated that negligible amounts of apurinic acid had passed through the dialysis tubing.

Chromatographic analysis. The purine and pyrimidine contents of the materials under examination were determined by hydrolysis of the samples (5 mg), previously dried at 110° C, with anhydrous trifluoroacetic acid (0.2 ml) [6] at 155° C for 1 hour, separation of the bases on paper chromatograms using *iso*propanol-hydrochloric acid [7] as the solvent system, elution of the spots and corresponding blanks with 0.1 N hydrochloric acid (5 ml) at 37° C for 12 hours, followed by examination of their ultraviolet absorption *. To obtain a more correct ultraviolet absorption of the bases at peak absorption the following formula was used [8]

$$\varepsilon_{net} = \text{net reading of base extinction} = \varepsilon_{\text{Spot at peak of base}} - \left[\varepsilon_{\text{Blank at peak}} \times \frac{\varepsilon_{\text{Base Spot at 320 m}\mu}}{\varepsilon_{\text{Blank at 320 m}\mu}} \right]$$

ε_{net} was used for the calculation of the amounts of bases present in the eluates.

Schiff's test. Schiff's reagent was prepared according to Tobie [8]. To a sample (0.05 ml) of the reduction mixture were added 0.1 N hydrochloric acid (0.05 ml), to destroy

* Eluates of spots and blanks were examined against 0.1 N hydrochloric acid in a Beckman Spectrophotometer DU.

excess borohydride, water (3 ml) and Schiff's reagent (1 ml). The mixture was left at room temperature for 135 minutes and its extinction at 560 mμ was measured in a Coleman spectrophotometer.

Dische test. The reagent was prepared according to Dische [9]. Water (2 ml) containing the material to be tested was heated with Dische reagent (5 ml) in a boiling water bath for 15 minutes. After cooling its extinction at 600 mμ was measured in a Coleman spectrophotometer.

Ultraviolet absorption measurements. The ultraviolet spectra of apurinic and reduced apurinic acid were determined at pH 7.0 in phosphate buffer and at pH 1.0 in 0.1 N hydrochloric acid. The phosphorus contents of the solutions were obtained by analysis according to the method of Jones *et al.*[10]

Titration methods. The procedures used were the same as those employed in parallel studies on the nucleic acids [11]. Solutions of the apurinic or reduced apurinic acids were prepared by dissolving the air-dry samples in sodium chloride (usually 0.05 M) and were titrated at 25 °C with acid and alkali using a cell consisting of a "Doran" Alkacid glass electrode and a saturated calomel electrode connected by a saturated potassium chloride bridge. During the titration hydrogen was passed through the cell in order both to stir the solution and to keep out carbon dioxide. The pH was measured with a Cambridge pH meter, previously standardized with 0.05 M potassium hydrogen phthalate (pH = 4.008) and 0.05 M sodium borate decahydrate (pH = 9.18) to give readings on the "saturated calomel scale" of Hitchcock and Taylor [12]. The determination of pH and of the number of equivalents of acid bound per 4 g-atoms of phosphorus had maximum errors of ± 0.01 and ± 0.03, respectively. "Water corrections" were made by the usual blank titrations.

RESULTS AND DISCUSSION

A. The preparation and properties of reduced apurinic acid

The decrease in Schiff's colour on the addition of increasing amounts of sodium borohydride continued until a total of about 20 mg of this reagent had been added to every 100 mg of apurinic acid (APA—C, Fig. 1). After this no Schiff's colour could be obtained so the aldehyde groups of the apurinic acid must have been completely reduced *. It is noteworthy that addition of 5 % of the total apurinic acid to an acidified reaction mixture could be detected by the Schiff's test. The completion of the reduction was further confirmed by the following tests. Spraying of a solution of *m*-phenylene diamine dihydrochloride on to a spot of the reaction product (400 μg) on filter paper failed to produce any fluorescence [13] in ultraviolet light as it did with apurinic acid, 20 μg of which could be readily detected by this method. Furthermore, Tollen's reagent [14], which could detect 20 μg of apurinic acid, produced a negative result with 500 μg of the reaction product, which must therefore be regarded as reduced apurinic acid. Apurinic acid in amounts of 1 mg is strongly reduced upon heating with Fehling solution. Under corresponding conditions, reduced apurinic gave only a very slight reduction. In quantities of 3 mg there was somewhat more reduction but considerably less than that given by 1 mg apurinic acid. The absence of reducing aldehyde groups is amply demonstrated by the other chemical tests and this latter observation is probably explained by the breakdown at 100° C of the 2-deoxy-D-ribitol moieties to reducing fragments by the very strong alkali in the Fehling solution. This latter view

* We have also reduced apurinic acid prepared by Chargaff's method.

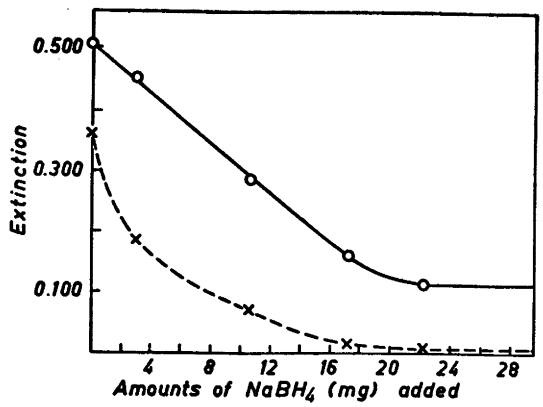

Fig. 1. Reduction of cod roe DNA (APA—C) with $NaBH_4$. The dotted line shows the decrease in the intensity of the colour produced by Schiff's reagent when added after various amounts of $NaBH_4$. The continuous line shows the decrease in the colour produced in the Dische test.

was confirmed by the fact that in a more concentrated Fehlings solution the reduction by reduced apurinic acid was greater.

On reducing apurinic acid (APA—C) there is a drop in the intensity of the colour developed with Dische's reagent. This is seen from Fig. 1 which gives the Dische colour of the reaction mixture following the addition of increasing amounts of reducing agent. It is noticeable that a constant Dische colour is obtained at a point where a negative Schiff's test indicates a complete reduction. The absorption spectrum of the Dische colour produced with reduced apurinic acid is identical with that given by apurinic acid. Comparative values (based on equal amounts of phosphorus) with cod roe sodium deoxyribonucleate, apurinic acid (APA—C) and reduced apurinic acid (RAPA—C) were 100, 83 and 15, respectively.

Chargaff [1] reported that the free aldehydo sugar in apurinic acid was unstable towards alkali, the Dische colour, for example, falling to 7 % of its original value after treatment with 2 N sodium hydroxide at 37° C for 24 hours. The reduction of the aldehydo group renders the sugar moiety stable to alkali for the Dische colour of reduced apurinic acid was almost unchanged after treatment with 2 N sodium hydroxide at 37° C for 24 hours.

Since the reduction of apurinic acid takes place in slightly alkaline solution (pH not above 9) a control experiment was carried out by keeping apurinic acid at room temperature in 0.01 M NaOH. The Dische colour of the solution was tested before and after three days and found to be the same. Thus the very slight alkalinity of the reduction mixture could not have affected the aldehydo sugar in apurinic acid.

The ultraviolet absorption spectra of apurinic and reduced apurinic acid from cod roe deoxyribonucleate are given in Fig. 2. The minima and maxima of absorption occurred at the same wavelengths. In Table 1 are given ε_{268} (P) for the different preparations. These data suggest that the reduction of apurinic acid with sodium borohydride does not affect the pyrimidines. This

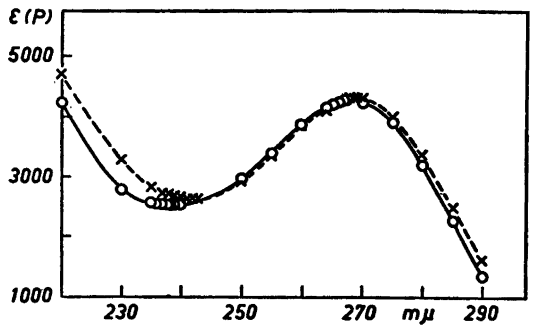

Fig. 2. The ultraviolet absorption spectra of apurinic acid (dotted line) and reduced apurinic acid (drawn line) from cod roe DNA at pH 7.

is further confirmed by the chromatographic analyses, which show no significant difference in cytosine and thymine content between a reduced apurinic acid and the apurinic acid from which it was obtained (*e. g.*, Table 2, 2nd and 4th columns).

B. The dissociation of apurinic and reduced apurinic acids

Typical titration curves in 0.05 M sodium chloride of herring apurinic and reduced apurinic acid are shown in Fig. 3 together with the reversible back titration of the herring sperm deoxyribonucleate from which they were derived [11]. The ordinate represents the acid or alkali bound by a unit amount of these substances containing 4 g-atoms of phosphorus so that, in spite of varying molecular weights, direct comparison between the curves is possible. No titration "anomaly" of the type found with sodium deoxyribonucleate was observed with either the apurinic or reduced apurinic acid, the forward and back titration curves being identical. All hydrogen bonds involving titratable groups must therefore have been ruptured in the course of the preparations.

Comparison of the apurinic and reduced apurinic acids. Comparison of the titration curves of these two substances is best effected by subtracting the alkali bound along the reduced apurinic acid curve (II) from that bound at the same pH's along the apurinic acid curve (I). The resulting comparison curve

Table 1. Ultraviolet absorption of apurinic and reduced apurinic acids. Extinctions (ε_{268}(P)) per g-atom of phosphorus per litre at λ = 268 mμ.

Source	Apurinic acid	Reduced apurinic acid
Cod roes	5 000 (APA—C)	5 100 (RAPA—C)
Herring roes	4 270 (APA—H 2)	4 290 (RAPA—H 2)

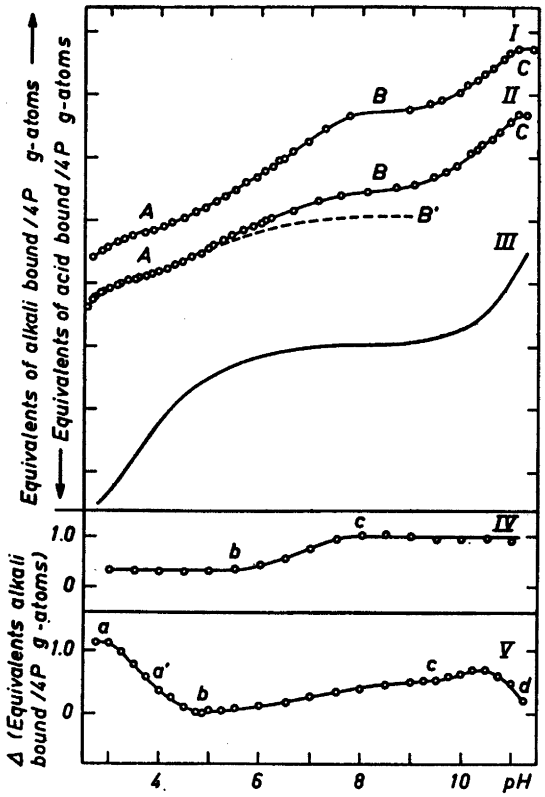

Fig. 3. Titration curves of herring apurinic, reduced apurinic and deoxyribonucleic acids. At 25° C in 0.05 M sodium chloride.

I. Herring apurinic acid (APA—H 2). Circles-experimental points.
II. Herring reduced apurinic acid (RAPA—H 2). Circles-experimental points.
III. Back titration curve of herring sodium deoxyribonucleate (from Ref. 11). Divisions on ordinate scale for curves I, II, III represent one equivalent of acid or alkali bound per 4 P g-atoms. Curves I, II, III separated vertically for clarity. Comparison curves:
IV. Alkali bound by apurinic acid, APA—H 2, along I, minus alkali bound by reduced apurinic acid, RAPA—H 2, along II.
V. Alkali bound by reduced apurinic acid, RAPA—H 2, along II, minus alkali bound by sodium deoxyribonucleate along III.

(IV) shows that only over the pH range 5.5—8.5 (*bc*) is there any significant difference in the number of titratable groups in the two derivatives. The groups titrating in this pH range are secondary phosphoryl end groups ($pK_a' = 6$—7) [15] and cytosine 6-amino groups ($pK_a' = 4.6$ according to Hurst *et al.*[15], but see below where $pK_a' = 5.0$ in 0.05 M salt is suggested). Since the analytical evidence (Table 2) indicates that the cytosine contents (in moles/4 P g-atoms) of apurinic and reduced apurinic acids are almost identical, and

equal to that of the original deoxyribonucleate, the shape of curve IV must be attributed to a larger proportion of titratable end groups in the apurinic acid than in the reduced form. This may well arise because smaller fragments, which would contain a higher proportion of end groups, were removed from the reduced apurinic acid preparation by dialysis but not from the apurinic acid preparation. In confirmation of this some of the APA—H 2 sample did appear to be dialysable after long storage.

The curves I, II and IV therefore show that in the reduction of apurinic acid there has been no structural modification of the molecule which affects the cytosine and thymine components.

Comparison of titration and analytical results. The chromatographic analytical evidence (Table 2) shows that the method of preparation of apurinic acid has entirely eliminated the purine bases, guanine and adenine, from the original nucleate structure, leaving only cytosine and thymine in the same ratio as before. Hence the titration curves I and II of apurinic and reduced apurinic acids must be interpreted in terms of the dissociations of the following groups only: primary phosphoryl groups ($pK_a' = 1—2$) [15]; cytosine 6-amino groups ($pK_a' = 4.6—5.0$, see above); secondary phosphoryl end groups ($pK_a' = 6—7$); and the —NH—CO-systems of thymine ($pK_a' \sim 10$)[15].

Curves I and II (Fig. 3) exhibit inflexion points at A (pH = 3.7), B (pH = 8.5) and an incipient one at C (pH = 11). In view of the evidence given above, the groups titrating in the various regions must be: below pH 3.7, the primary phosphoryl groups only; between pH 3.7 and 8.5 (AB), the cytosine amino groups and secondary phosphoryl groups; and between pH 8.5 and 11 (BC), the —NH—CO-systems of thymine. The difference between the alkali bound at the inflexion points B and C should be equal to the number of thymine

Table 2. Comparison of analytical and titration data. The numbers are the composition in moles or equivs/4 P—g atoms.

Preparation	Herring DNA	RAPA—H 2 [c]		APA—H 2	APA—H 1

residues per 4 P g-atoms since there is only one —NH—CO-dissociation in each thymine molecule. The proportion of thymine residues so deduced from the titration curves is in good agreement with that obtained from chromatographic analysis (Table 2) both for the samples whose titration curves are given in Fig. 3 and for APA—Hl, which was titrated in 0.15 M sodium chloride solution.

It has recently been concluded [11,16] that the modern analytical and titration data show evidence for the presence in the original herring sodium deoxyribonucleate of no more than a negligible proportion of secondary phosphoryl end groups. Hence the difference curve (V) between the titration curve of reduced apurinic acid and of the original nucleate in the region of pH 5—8.5 (*bc*) must be entirely due to the (extra) secondary phosphoryl groups in the former. The estimates in Table 2 of the proportion of these end groups were obtained in this way.

If these arguments are valid, the curve (dotted line AB′, Fig. 3) obtained by subtraction of the alkali bound along *bc* of curve V from AB of curve II should be the dissociation curve of the cytosine amino groups in the reduced apurinic acid. The difference in the alkali bound at the inflexion points A and B′ should then be equal to the number of cytosine residues per 4 P g-atoms. The agreement between the amount of cytosine so determined from titration and that given by direct analysis is very satisfactory (Table 2, 2nd and 3rd columns of numbers) and demonstrates the validity of this method of deduction from the titration data.

Comparison of reduced apurinic acid and sodium deoxyribonucleate and the pK_a' *values of the dissociable groups.* Since there is no titration anomaly with the reduced apurinic acid, comparison must be made with the titration curve of non-hydrogen bonded deoxyribonucleate, *i. e.*, with its back titration curve (III). It has already been concluded that in the difference curve V (obtained by subtracting the alkali bound along III from that bound along II) the section *bc* represents the dissociation of the (extra) secondary phosphoryl groups in the reduced apurinic acid. No cytosine amino groups are involved in *bc* since analysis shows the same number of these groups in the two materials (Table 2) and therefore they cancel out in the subtraction which gives V. The section *ab* of V represents extra groups titrating in the deoxyribonucleate which are not present in the reduced apurinic acid and must be attributed to the amino groups of guanine and adenine in the former. The part *a′b* of V must be predominantly the dissociation of the adenine group and, knowing the amount of adenine present the deoxyribonucleate (1.09 moles/4 P g atoms) an estimate of the pK_a' of this group can be made. Similarly, the pK_a' of cytosine 6-amino groups in a polynucleotide can be obtained from AB′ of II, that of secondary phosphoryl groups from bc of IV and V, and that of the thymine —NH—CO-system from BC of II. Reliable values for the pK_a' of the guanine —NH—CO-group cannot be obtained from cd of V since its shape suggests some difference in pK_a' of this group as between curves II and III. The pK_a' values derived for the other groups in 0.05 M sodium chloride are given in Table 3 together with the values of some other authors [15–17]. The pK_a' for the cytosine amino group appears to increase slightly with its degree of dissociation. This may be due to the cumulative errors of the above

Table 3. pK_a' in 0.05 M sodium chloride of the dissociable groups of herring roe deoxyribonucleate. Obtained by comparison with the corresponding reduced apurinic acid.

Degree of acid dissociation of the group in 0.05 M NaCl	pK_a' values			
	Thymine —NH—CO—	Cytosine Amino	Adenine Amino	Secondary Phosphoryl
0.20	10.1	4.95	3.65 (approx.)	6.75 (approx.)
0.30	10.1	4.98		
0.50	10.1	5.10		
0.75	10.1	5.19		
0.80	10.1	5.20		
In deoxyribonucleotides, absence of salt (Ref. 15)	10.0	4.6	4.4	6.5
From analysis of DNA titration curves, at zero ionic strength.[a] (Table 1, Ref. 16)		4.85	3.65	6.0 [b]
From spectrophotometric back titration curves at ionic strength of 0.008 (Table 1, Ref. 17) [c]		5.3		

(a) DNA concentration of 0.139 mgm P/ml = 0.001125 equiv. 4P/l.

(c) The other figures quoted in Table 1, Ref. 17, refer to the forward titration curve of DNA, which corresponds not to a reversible dissociation but to a simultaneous ionisation and irreversible denaturation.

procedure but, on the other hand, it may also be a genuine decrease of acidity consequent upon the increasing negative charge of the deoxyribonucleate anion. However the change of pK_a' is much less than that observed with synthetic polyacids (*e. g.*, changes [18] of pK_a' of the order of 0.8 units over the degree of dissociation range of Table 3; this relative suppression of the polyelectrolyte effect by the sodium gegenions has been discussed elsewhere [11]). The mean value for the pK_a' of the cytosine amino group (*viz.*, 5.0 in 0.05 M salt) is higher than would have been expected from earlier data [15] and this has important consequences [11, 19] for the interpretation of the deoxyribonucleate titration curve over pH 5.5—9. It accords with the value of 5.3 in 0.008 M salt obtained by spectrophotometric titration of thymus DNA [17]. The values obtained by Jordan *et al.*[16] (and quoted in Table 3 for comparable conditions) are more open to doubt since they depend on an analysis of the back titration curves of thymus DNA where the dissociation ranges of various groups overlap and the allocation of pK_a' values is more ambiguous [3] than in the spectrophotometric method [17], and the method reported here.

C. Conclusion

The titration results indicate that the same proportion of pyrimidine dissociable groups are present in the apurinic and reduced apurinic acid. The reduction of the free aldehyde groups in apurinic acid by sodium borohydride has therefore been effected with no major structural change and has increased the stability of the sugar ring to alkali. The proportion of end groups is relatively high in both derivatives and suggests that considerable degradation has occurred relative to the original deoxyribonucleic acid. The apurinic acid (APA—H2, undialysed) contained 1 secondary phosphoryl group for every 4 phosphorus atoms, which implies that it was on the average about 4 nucleotides long, assuming every fragment carried one secondary phosphoryl group. The reduced apurinic (RAPA—H2, dialysed) contained 1 secondary phosphoryl group every 10 phosphorus atoms, implying an average chain length of 10 nucleotides. These are lower in molecular weight than the apurinic acid obtained by Tamm *et al.* which were thought to contain about 45 nucleotides but whose titration behaviour and end-group content were not obtained *. Any difference may arise not only because different preparative reactions were employed but also because the preparation of Tamm *et al.* was carried out under conditions of continuous dialysis during the acid hydrolysis, thereby concurrently removing all except the larger fragments.

One of us (S. G. L.) wishes to thank the *Rockefeller Foundation* for financial support.

Some Graphical Methods for Determining Equilibrium Constants. IV. On Methods for Three-Variable Data $w(x, y)$

LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The treatment in part II [1] is extended to indicate graphical methods of determining a number of unknown constants (parameters) $p_1, p_2 \ldots$ from a set of three-variable data (w, x, y) when the function $w(x, y, p_1, p_2 \ldots)$ is known.

Sometimes, by transformation of variables a true reduction to a two-variable problem is possible. In other cases the function can be transformed to $w(x, f_1(y), f_2(y) \ldots)$. By considering sections at constant values of y, the parameters may then be found by two successive two-variable treatments. The method is illustrated by application to extraction equilibria of complexes of the general formula $B(HA)_p(H)_{-n}$.

When a reduction to two variables is not possible, methods of "surface-fitting" may be applied, if the parameters can be eliminated by normalizing the variables. For instance, with two variables and two parameters one may fit a calculated projection map $Y(X)_w$ to an experimental projection map $y(x)_w$. Convenient normalized variables are given for a system with species B, AB, and A_PB_Q, as an example.

Applications will be given in following papers on hydrolysis equilibria.

In part II of this series [1] various ways were discussed of treating two-variable experimental data, *i. e.* data that can be represented by a planar diagram $y(x)$, where y and x are functions that can be obtained directly from the experimental data.

More complicated cases arise if the experimental points are sets of three variables. For example, in the study of polynuclear complexes formed between two reagents A and B, the average number of A bound per B, Z, is often measured together with a, the concentration of free A, and B, the total concentration of B, so that each experimental point is a set (Z, a, B). The data can thus be represented by a curved surface in three-dimensional space, $Z(a, B)$.

We shall consider a general case where the variables determined experimentally are w, x, and y (we shall not use the symbol z to avoid confusion with Z), and the constants to be determined (parameters) are denoted by p_1, p_2 ... . We know in advance the function

$$w = w(x,\ y,\ p_1,\ p_2 \ldots) \tag{1}$$

relating the experimental variables with the parameters. As in part II, w, x, and y need not be the quantities directly determined, although it should be possible to calculate them from the data; nor need the p_i be the constants ultimately required. The most suitable functions w, x, y and parameters p_i for each case may not be immediately obvious.

SYMBOLS

a, b	concentrations of free A and B
B	total concentration of B
c	concentration of free HA (5)
f_i, f_n	functions (2), (8)
h	concentration of H^+ (5)
j	constant (16)
K_{pn}, K_{11}, K_{PQ}	equilibrium constants (3), (12)
L_{pN}	distribution constants (4)
N	charge of metal ion B^{N+}
n, p, P, Q	integer numbers (3), (12)
p_1, p_2, p_3	unknown constants (parameters) to be determined
q	over-all distribution ratio of B between organic and aqueous phase
u, v	auxiliary functions (15), (16)
w, x, y	variables determined experimentally
W, X, Y	normalized values for w, x, y
x_0, y_0	values for x and y coinciding with $X = 0$, $Y = 0$ at best fit (18, 19)
Z	average number of A bound per B

subscript)$_x$ indicates that x is constant

REDUCTION TO A TWO-VARIABLE PROBLEM

True reduction

In some cases an analysis of the data shows that one may definitely reduce the problem to one with only two variables. Three simple examples will be given.

In the formation of mononuclear complexes A_nB by a central group B and a ligand A, the experimental variables may be, for instance, (Z, a, B) or (a, b, B). Now, if only mononuclear complexes are formed, it is easily shown (N. Bjerrum [2]) that both Z and bB^{-1} are functions of a only. (Also for "homonuclear" complexes [3] Z (but not bB^{-1}) is a function of a only.) So the total concentration B is eliminated, and we are left with the two-variable problem of finding the equilibrium constants from the functions $Z(a)$ or bB^{-1} (a). For refined mathematical treatment, further transformations of the variables are usually necessary [1,4].

If, again, all complexes formed are polynuclear and can be written in the "core + links" form, $B(A_tB)_n$, then Z and bB^{-1} can be written [3,5] as functions of the single variable $x = t \log a + \log B$.

Another example is the distribution of a metal ion B, between an aqueous solution and an organic solvent, in the presence of an acid HA, forming complexes like A_nB. We shall denote by q the ratio between the total concentrations of B in the organic and aqueous phases. One might first consider this as a problem of four variables, say q (the distribution ratio), B (the total concentration of B in the aqueous phase), and the concentrations of free H^+ and HA in the aqueous phase. If only mononuclear complexes are formed, the total concentration B should, however, have no influence on $q([H^+], [HA])$. If, moreover, all complexes in the aqueous phase are of the form A_nB and only the uncharged A_NB is extracted, then q should be a function of the concentration of free A only, $a = [A] = [HA][H^+]^{-1}K_a$, so that we really have the two-variable problem [6,7] of studying $q(a)$. If, on the other hand, not A_NB but a single complex $A_NB(HA)_{p-N}$ is extracted, then $q[HA]^{N-p}$ is a function of a only.

For each of these cases, one may apply the methods for two-variable data given in part II [1].

Reduction to two-variable sections

Sometimes it proves impossible by any transformation, truly to reduce three-variable data (w, x, y) to two variables. However one may cut sections at constant values of y (say) and treat each of these as a two-variable problem. Suppose that we can transform equation (1) to the form

$$w = w(x, f_1(y), f_2(y), \ldots) \tag{2}$$

where the functions $f_i(y)$ contain the variable y, and usually a number of unknown constants. If a section $w(x)_y$ at a constant value of y is considered, the functions f_i are constants, which can be found by some method for two-variable problems given in part II[1]. Thus one may determine the values of f_1, f_2 *etc.* for a number of values of y. Finally, the functions $f_i(y)$ are treated separately; each of these functions contains one or more parameters, which can now be determined by some two-variable method.

As an example, we shall consider a case previously treated somewhat differently by Rydberg [8]. A metal ion B is distributed between an aqueous solution and an organic solvent, in the presence of an acid HA, which may form complexes with B. All those complexes present may be written in the form $B(HA)_p(H)_{-n}$, since their content of organic solvent, water or ions from the ionic medium cannot be determined by equilibrium measurements. (We replace Rydberg's symbols x and y by p and n to avoid confusion in the present paper.)

If the charge of the ion B is N^+, it is reasonable to assume that only uncharged complexes, with $n = N$, are extracted by the organic solvent. We may then write, assuming only mononuclear complexes:

$$[B(HA)_p(H)_{-n}]_{aq} = [B][HA]^p[H]^{-n}K_{pn} = bc^p h^{-n}K_{pn} \tag{3}$$

$$[B(HA)_p(H)_{-N}]_{org} = [B][HA]^p[H]^{-N}K_{pN}L_{pN} = bc^p h^{-N}K_{pN}L_{pN} \tag{4}$$

where K_{pn} are the formation constants, and L_{pN} the distribution constants of the complexes, and

$$c = [HA] \text{ and } h = [H^+] \tag{5}$$

The over-all distribution ratio q is given by

$$q = \frac{\Sigma[B(HA)_p(H)_{-N}]_{org}}{\Sigma\Sigma[B(HA)_p(H)_{-n}]_{aq}} = \frac{\Sigma c^p h^{-N} K_{pN} L_{pN}}{\Sigma\Sigma c^p h^{-n} K_{pn}} \tag{6}$$

Thus $q(c, h)$ is a function of c and h. We may, however, obtain two-variable sections by studying instead the variable

$$q^{-1}h^{-N} = \frac{\Sigma\Sigma h^{-n} c^p K_{pn}}{\Sigma c^p K_{pN} L_{pN}} = \Sigma h^{-n} f_n(c) \tag{7}$$

$$f_n(c) = \frac{\Sigma c^p K_{pn}}{\Sigma c^p K_{pN} L_{pN}} \; ; \; f_0(c) = \frac{\Sigma c^p K_{p0}}{\Sigma c^p K_{pN} L_{pN}} \tag{8}$$

If c is kept constant, (7) gives a polynomial in h^{-1}. Each section can thus be used to find the values for the functions $f_n(c)$ at the value of c chosen. Rydberg [8] has used a single "sweep" [1], with successive linear extrapolations. However, it may be preferable to study the function $w(x)_c$

$$w = \log(q^{-1}h^{-N}) = \log \Sigma h^{-n} f_n; \; x = \log h \tag{9}$$

and find the best values of $f_n(c)$ by use of the curve-fitting methods for polynomials, described in part II [1].

The treatment of the data $f_n(c)$ so obtained, will depend on the accuracy of the data and the range of concentrations studied.

It seems a reasonable assumption [8] that complexes $B(HA)_p^{N+}$ can be neglected, so that $K_{p0} = 0$ for $p \neq 0$. By definition, $K_{00} = 1$. Then, as indicated by Rydberg (whose symbols are slightly different), it is profitable to study the functions

$$f_0^{-1}(c) = \Sigma K_{pN} L_{pN} c^p \tag{10}$$

$$f_n(c) f_0^{-1}(c) = \Sigma K_{pn} c^p \tag{11}$$

To find the individual * constants K_{pn} and L_{pN} one may use the curve-fitting methods for polynomials, for instance preparing plots of $\log f_0^{-1}$ (or, say, $\log(c^{-N} f_0^{-1})$), and $\log f_n f_0^{-1}$ (or, say, $\log(c^{-n} f_n f_0^{-1})$, as functions of $\log c$, and comparing them with families of normalized curves for polynomials [1]. Such methods seem preferable to linear plots, for the same reasons as given in part II [1]. Hök-Bernström [9] has recently applied this method to extraction data for UO_2^{2+}.

As a rule, partition data will allow an independent determination of only a few equilibrium constants, and it may be wise to start by searching for the *smallest set* of complexes $B(HA)_p(H)_{-n}$ needed to explain the data. With the curve-fitting methods given, one may compare the same graphical representa-

* If $[A_pBH_{p-N}]$ is important in the organic phase but negligible in the aqueous solution, only the product $K_{pN}L_{pN}$ may be obtained.

tion of the data with curves for a number of possible combinations. One may then judge — more directly than with linear plots — which combinations can be excluded, which are just compatible with the data, and which will give the best fit.

METHODS WITHOUT REDUCTION

Elimination

If one is not successful in reducing a three-variable problem to two-variable plots, the problem becomes slightly more complicated. A survey of the possible methods is given in Table 1, which is analogous to Table 1 of part II [1].

With only one parameter, p_1, a value for this parameter is obtained by inserting the coordinates of each experimental point (w, x, y) into eqn. (1). To test for the spread and any trend in the values of p_1, one would need a three-dimensional diagram (x, y, p_1), which could be given in the form of curves $p_1(x)_y$. If p_1 is really a constant, then these curves will all coincide in a single horizontal line.

Similarily, with two or three parameters, the graphs will not be more complicated than for two-variable data with two or three parameters, provided one does not want to test for a trend. With two parameters, one may for instance use curves $p_2(p_1)_{x,y}$.

Normalized graphs

With three variables, more serious complications occur in using normalized graphs, as indicated in Table 1. For instance, with two parameters, and two normalized variables, one can no longer use a single curve $Y(X)$ to compare with the data $y(x)$, but must instead compare a curved surface in space $w(x, y)$ with another, $w(X, Y)$. In practice this is done by preparing a *projec-*

tion map with $Y(X)_w$ curves for a number of values of w, and comparing it with the experimental data, given as curves $y(x)_w$ with the same values for w. The additional work involved should be a strong incentive to reduce the problem to a two-variable one. However, it will be shown in subsequent papers that if necessary such "surface-fitting" operations may be carried through successfully.

With three variables, a problem with one parameter and one normalized variable also requires the "surface-fitting" of a projection map $y(x)_w$ of the data and a normalized one $y(X)_w$ with calculated curves.

With three parameters and three normalized variables, one should fit a normalized surface $W(X, Y)$ to the plot $w(x, y)$ of the experimental data. This could possibly be carried out on three-dimensional models. When one tries to find the best fit of two-dimensional projections $Y(X)_W$ for a number of values of, W and $y(x)_w$ for a number of values of w, a difficulty arises: in the best fit, the experimental points may in general fall somewhere midway between the calculated curves. It might be practical to use a constant spacing of w in the experimental plot, and draw a set of thicker calculated curves with the same spacing in W; between these one may insert a series of thinner calculated curves for intermediate values of W (Fig. 1).

The other types of systems in Table 1 lead us to consider four-dimensional or five-dimensional super-surfaces, so that successive approximations and "sweeping" must be resorted to [1].

Application to systems with two equilibrium constants

As a simple example, let us assume that the reagents A and B form the two complexes AB and A_PB_Q, where P and Q are known, and that we want to determine the formation constants K_{11} and K_{PQ} from experimental data $Z(a, B)$.

From the definitions of B and Z, and the law of mass action we have

$$B = [B] + [AB] + Q[A_PB_Q] = b + abK_{11} + Qa^Pb^QK_{PQ} \quad (12)$$

$$BZ = [AB] + P[A_PB_Q] = abK_{11} + Pa^Pb^QK_{PQ} \quad (13)$$

Now, it is convenient to use the experimental variables

$$w = Z;\ x = \log\ a;\ y = \log\ B \quad (14)$$

and the normalized variables

$$X = x + p_1;\ Y = y + p_2 \quad (15)$$

Let us first introduce the auxiliary variables

$$u = 10^X = a \cdot 10^p;\ v = bj \quad (16)$$

where j is a constant. We wish to give such values to p_1, p_2 and j that all equilibrium constants are removed from (12) and (13), thus

$$Y = \log(v + uv + Qu^Pv^Q) \quad (12a)$$

$$Y + \log\ w = \log(uv + Pu^Pv^Q) \quad (13a)$$

Comparison with equations (12) to (16) gives us

$$p_1 = \log\ K_{11};\ p_2 = \frac{1}{Q-1}\ (\log\ K_{PQ} - P\ \log\ K_{11}) = \log\ j \quad (17)$$

The procedure is then to construct a map $Y(X)_w$ for a series of values of w, using (12a), (16), and (13a), and to plot the experimental data $y(x)_w$, *i. e.* $\log\ B(\log\ a)_Z$, for the same values of w. The plots are moved parallel to the coordinate axes until the best fit is found. One may then read the coordinates of the point (x_0, y_0) coinciding with $(X = 0, Y = 0)$, which give us

$$x_0 = -p_1 = -\log\ K_{11} \quad (18)$$

$$y_0 = -p_2 = -\frac{1}{Q-1}\ (\log\ K_{PQ} - P\ \log\ K_{11}) \quad (19)$$

The curve $Y(X)_w$ may be calculated in two ways. One may plot curves $w(v)_u$ and $Y(v)_u$ inserting a series of values for u and v into (12a) and (13a). Then, for each value of w considered one may take sets of corresponding values $v(u)_w$, and insert them into the

Y plot which gives $Y(u)_w$ or $Y(X)_w$ since $X = \log u$ (16). One may also eliminate v from (12a) and (13a), which gives

$$(Q-1)Y = (Q-1)\log(P+u(P-Q)) + \log(w+uw-u) - Q\log(P-Qw) - P\log u \quad (20)$$

Thus for each set of values of w and $X = \log u$ one may calculate Y directly.

If experimental data (a, b, B) are available instead, we may use the same experimental, normalized and auxiliary variables as in (14, 15, 16, 17) with the exception of w:

$$x = \log a;\ X = x + p_1;\ p_1 = \log K_{11} \quad (21)$$

$$y = \log B;\ Y = y + p_2;\ p_2 = \frac{1}{Q-1}(\log K_{PQ} - P \log K_{11}) \quad (22)$$

$$u = 10^X = a \cdot 10^{p_1};\ v = bj = b \cdot 10^{p_2} \quad (23)$$

$$Y = \log(v + uv + Qu^P v^Q) \quad (12a)$$

As the third experimental variable it is convenient to use the dimensionless quantity $\log(Bb^{-1})$ denoted by η in previous papers [3,5]. From (22), (23), and (12a)

$$w = \log \frac{B}{b} = y + p_2 - \log v = Y - \log v \quad (24)$$

$$w = \log(1 + u + Qu^P v^{Q-1}) \quad (25)$$

The normalized curve $Y(X)_w$ may be constructed by inserting a series of values of $X = \log u$ and w into (25); this gives v immediately, and Y is obtained from (24): $Y = w + \log v$.

The projection map $y(x)_w$ of the experimental data is then moved parallel to the axes until the best fit with the normalized projection map $Y(X)_w$ is found, which gives p_1 and p_2, and thus K_{11} and K_{PQ}.

One may proceed similarily for any set of equilibria with only two equilibrium constants, thus either free B and two complexes, or three complexes and a negligible concentration of free B. With four species containing B, thus three equilibrium constants, one may draw a series of projection maps, in each of which the ratio between two equilibrium constants (or some other suitable expression) is kept constant.

An advantage of the choice (14; 21, 22, 24) of $\log a$ and $\log B$ as planar coordinates and Z or $\log \frac{B}{b}$ as "height" in the experimental maps is that several alternative explanations may be compared directly on the same plot of experimental data.

Examples will be given in subsequent papers on hydrolysis equilibria.

This paper is part of a program supported by *Atomkommittén (Swedish Atomic Energy Committee)* and *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)*. I wish to thank my friends George Biedermann, David Dyrssen, Brita Hök-Bernström, Hidetake Kakihana, Gösta Lagerström, Hazel Rossotti, Francis Rossotti, and Jan Rydberg for many valuable discussions.

Anionic Silver Iodide Complexes in Aqueous Solutions

IDO LEDEN

Departments of Inorganic and Nuclear Chemistry, Chalmers Institute of Technology, Göteborg, Sweden

The reaction between solid silver iodide and iodide ions was studied by solubility measurements at 25° C and at an ionic strength of 4 M ($NaClO_4$). The results have been interpreted by assuming that the mononuclear species AgI_n^{1-n} (n = 1, 2, 3, and 4) and the polynuclear species $Ag_2I_6^{4-}$ and $Ag_3I_8^{5-}$ were formed. At the highest iodide concentrations the saturated solutions also contained other more highly charged species. Their composition could not be determined exactly, but they are of the form $(AgI_2^-)_m$ or closely similar, most probably $Ag_mI_{2m+2}^{(m+2)-}$, with rather high average values of m (~10).

Earlier measurements of the solubility, l, of silver iodide have been summarized by Sillén [1], and a survey of equilibrium constants for the silver iodide system is given by Kratohvil, Težak, and Vouk [2]. King, Krall, and Pandow [3] are the only authors who have used a constant ionic strength (2 M $NaClO_4$). Their method was a direct titration analysis, which could only be used when $l > \sim 10^{-4}$. Their results can be described by eqn. (2) below. The constants in this equation have been calculated by the author for the range of their data, *vide* Table 2. They agree, after making a reasonable allowance for the difference in ionic strength, with those I have now determined.

The solubility of silver iodide in the solvent c_{NaI} M NaI + $(4 - c_{NaI})$ M $NaClO_4$, where c_{NaI} ranged from 5×10^{-4} to 4, was determined in the following ways: by electroanalyses after addition of sodium cyanide, when $l > 10^{-3}$; by potentiometric microtitrations with bromide (*vide* Ref.[4]) in the range $10^{-6} < l < 10^{-2}$; and by a radio assay technique, with silver iodide labelled with ^{110}Ag (from Harwell), when $l < 10^{-4}$. The solubility equilibria were in all cases established in less than one day. Experimental details are given elsewhere (Refs.[5-8]). The results are collected in Table 1. The accuracy has been judged from the reproducibility of the experiments. Every solubility given in Table 1 has been determined at least three times, several of them more than five times. The poor accuracy at low solubilities depends mainly on the small specific activity. When the solubility could be determined by two methods they were always in agreement. The original concentrations of sodium iodide in the solvent were corrected for the change in volume at saturation. This correction became significant at the highest solubilities measured.

Table 1. The solubility, s (in M), of silver iodide in aqueous sodium iodide. Ionic strength of the solvent 4 M ($NaClO_4$) except in the last one (6 M NaI).

* In these 7 solutions the concentration of free iodide ions could be determined by e. m. f. measurements, which gave the following results for $[I^-]$: 0.49_5, 0.78, 0.95, 1.11, 1.35, 1.50, 1.7 respectively.

** Calculated from eqn. (5).

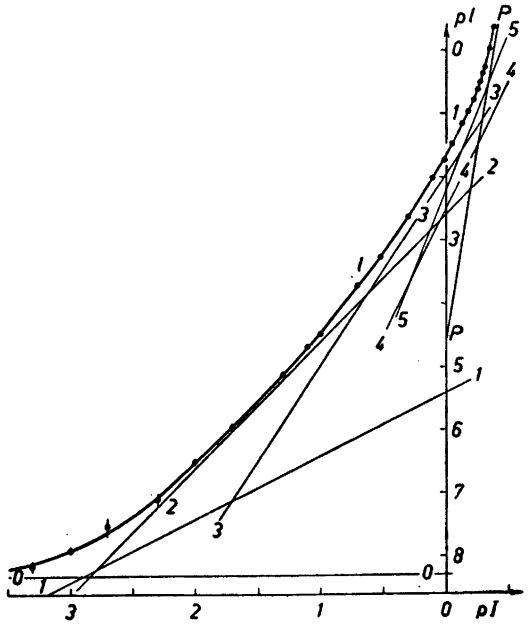

Fig. 1. The solubility, s, of silver iodide in aqueous sodium iodide. The numbered straight lines give the concentration of silver in the respective complexes as follows: 0:AgI, 1:AgI_3^-, 2:AgI^{2-}, 3:AgI_4^{3-}, 4:$Ag_2I_6^{4-}$, 5:$Ag_3I_8^{5-}$. P signifies the entire silver contents in species of ionic weight greater than $Ag_3I_8^{5-}$. Ionic strength 4 M ($NaClO_4$).

The dissolution of solid silver iodide in aqueous sodium iodide depends on reactions of the type

$$m\ \mathrm{AgI(s)} + n\ \mathrm{I^-} \rightleftharpoons \mathrm{Ag}_m\mathrm{I}_{m+n}^{n-} \qquad (1)$$

where m and n are integers to be determined by experiment. Hence the solubility is described by (*cf.* Ref.[4])

$$l = \sum_{n=-1}^{N} K_n\,[\mathrm{I^-}]^n \qquad (2)$$

If there is only one species of charge $-n$, it follows that

$$K_n = m \cdot k_{m,n} \qquad (3)$$

where $k_{m,n}$ is the equilibrium constant for reaction (1). If there are several species with the same charge, eqn. (3) would become $K_n = \sum_{m=1}^{M} m \cdot k_{m,n}$.

Computation of the constants K_n. K_0 has been determined previously from measurements of the solubility of silver iodide in aqueous silver perchlorate at 25° C and at an ionic strength of 4 M ($NaClO_4$), Ref.[8]; the value $K_0 = (6 \pm 1) \times 10^{-9}$ was found. This value ought to be confirmed by corresponding measurements with ^{110}Ag at low iodide concentrations, but the maximum specific activity of the silver obtainable at Harwell, is just insufficient to measure concentrations in the range 10^{-9} M with the apparatus at my disposal. The first term, $K_{-1}/[\mathrm{I^-}]$, of eqn. (2) is negligible in all solutions studied in this paper as the solubility product $K_{-1} = 4.5 \times 10^{-17}$ (*cf.* Refs. [8,9]).

In the range $5 \times 10^{-3} \leq [\mathrm{I^-}] \leq 5 \times 10^{-2}$, l is rather well described by a straight line of slope 2 in a logarithmic diagram (*vide* Fig. 1), which means that the term $K_2[\mathrm{I^-}]^2$ of eqn. (2) is dominant. Hence $K_2 = (25 \pm 1) \times 10^{-4}$ is immediately found. When $[\mathrm{I^-}] < 10^{-2}$, $l \simeq K_0 + K_1[\mathrm{I^-}] + K_2[\mathrm{I^-}]^2$ is a very good approximation to eqn. (2) and, as K_0 and K_2 are known, one value of K_1 can be computed from every value of l determined in this range. For K_0

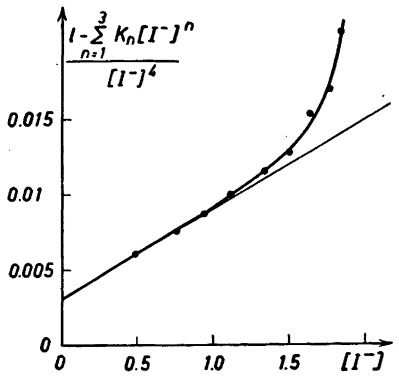

Fig. 2. The computation of K_4 *and* K_5.

the value 5×10^{-9} has been used, as this gives a better constancy to K_1 than does the mean value, 6×10^{-9}, from Ref.[8]. $K_1 = (4 \pm 2) \times 10^{-6}$ is thus obtained. Analogously, $l \simeq K_2[I^-]^2 + K_3[I^-]^3$ in the range $0.05 < [I^-] < 0.3$ and hence one value of K_3 can be calculated from every determination of l; a mean value, $K_3 = (11 \pm 1) \times 10^{-4}$, was found. In all solutions hitherto mentioned the solubility is so small that $[I^-] \simeq c_{NaI}$ with sufficient accuracy.

The equilibrium constants $k_{1,2}$ and $k_{1,3}$ have been determined recently by e.m.f. measurements (Ref.[9]). These values are compared with the values of K_n above in Table 2, from which it is evident that $K_2 = k_{1,2}$ and $K_3 = k_{1,3}$ within experimental error. Hence it follows that the only significant silver iodide species with the charges —2 and —3 are AgI_3^{2-} and AgI_4^{3-}.

When the iodide concentrations are greater than 0.3 M, the solutions contain anionic species which have charges larger than 3 and are no longer negligible in quantity. In order to determine the coefficients of the corresponding terms of degree higher than 3 in eqn. (2), $(l - \sum_{n=1}^{3} K_n[I^-]^n) / [I^-]^4$ is plotted as a function of $[I^-]$ for numerators >15 % of l (*vide* Fig. 2). As is seen from the graph, this function is very well described by a straight line in the range $0.5 \leq [I^-] \leq 1.5$. The slope of this line gives $K_5 = (6 \pm 1) \times 10^{-3}$, and its intersection with the ordinate axis gives $K_4 = (3 \pm 1) \times 10^{-3}$. These values have been compared with $k_{2,5}$ and $k_{2,4}$ from the e.m.f. measurements in unsaturated solutions (Ref.[9]) in Table 2. It is evident that $k_{2,4} = \frac{1}{2}K_4$ and $k_{3,5} = \frac{1}{3}K_5$ within experimental error, as required by eqn. (3) when there is only one species with each sharge. As the e.m.f. measurements have been made in a range $0.003 < c_{Ag} < 0.1$ corresponding to the range $0.002 < l < 0.1$, where the curve in Fig. 2 is with good approximation a straight line, it is evident that the only polynuclear complexes significant at these silver concentrations are $Ag_2I_6^{4-}$ and $Ag_3I_8^{5-}$, which thus are the only species in the saturated solutions with the charges —4 and —5.

In this range the solubility is no longer negligible compared with the concentration of sodium iodide. The concentration of free iodide ions had therefore to be determined from the e.m.f. (E mV) of the following cell:

+ Ag, AgI	0.3 M NaI 3.7 M $NaClO_4$	4 M NaI	c_{NaI} M NaI $(4-c_{NaI})$ M $NaClO_4$	Ag, AgI −

where the right hand solutions are those listed in Table 1 with $c_{NaI} > 0.3$. The concentration, $[I^-]$, of free iodide in these solutions can be calculated from Nernst's formula

$$E = 59.16 \log \frac{[I^-]}{0.3} \tag{4}$$

In order to confirm that the results from eqn. (4) are in accordance with the known concentrations of sodium iodide, $[I^-]$ was recalculated by inserting the values of $[I^-]$ from eqn. (4) in the right hand member of eqn. (5).

$$[I^-] = c_{NaI} - 2K_2[I^-]^2 - 3K_3[I^-]^3 - 2K_4[I^-]^4 - \frac{5}{3}K_5[I^-]^5 - [P] \tag{5}$$

The negative terms of this equation represent the concentration of iodide used in the formation (1) of the complexes, if these are AgI_3^{2-}, AgI_4^{3-}, $Ag_2I_6^{4-}$, and $Ag_3I_8^{5-}$, as has been found by e.m.f. measurements (Ref.[9] and see above). The term —[P], discussed below, is negligible, when $[I^-]<1.5$. The results from eqns. (4) and (5) (*vide* Table 1) agree, when the solubility is less than 0.2 M. At higher silver concentrations eqn. (4) gives absurdly high values of $[I^-]$, *e. g.* $[I^-] = 2.83$ for $c_{NaI} = 3.85$, in all probability because of increasing liquid junction potentials and changed activity factors.

At higher iodide concentrations the curve of Fig. 2 becomes increasingly steeper, which means that anionic complexes are formed with charges higher than 5. To analyse this region, it is again necessary to compute values of $[I^-]$, which can no longer be determined by e.m.f. measurements (see above). This computation has been done as follows. It can be deduced (*vide* Ref.[10]) from Erber's [11] determinations of the solubility of silver iodide in highly concentrated solutions of hydrogen iodide that the complexes formed, either have the composition $Ag_mI_{2m}^{m-}$ (with a rather high value of m, say at least 8), or a composition which comes close to this, *e. g.* $Ag_mI_{2m+2}^{(m+2)-}$ for large values of m. Erber himself claimed that the ion $Ag_2I_6^{4-}$ predominates in his concentrated solutions, but he arrived at this false conclusion by assuming that $c_{NaI} = [I^-]$ within the accuracy of his experiments. Erber, however, used this approximation for very high solubilities where it does not hold, *e. g.* for $c_{NaI} \simeq 7$ and $l \simeq 5$ (hence $[I^-] \simeq 2$, *i. e.* $[I^-]^4 \ll c^4_{NaI}$). Hence it follows that the concentration of free iodide ions must be calculated from eqn. (5), where [P] means the concentration of silver, present in complexes with ionic weights larger than that of $Ag_3I_8^{5-}$. The solubility is described by

$$l = \sum_{n=2}^{5} K_n[I^-]^n + [P] \tag{6}$$

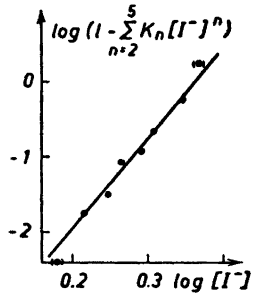

Fig. 3. The concentration, $[P] = l - \sum_{n=2}^{5} K_n [I^-]^n$, *of silver present in species of ionic weight greater than* $Ag_3I_8^{5-}$.

in this range. Values of [P] and [I^-], which satisfy both eqn. (5) and eqn. (6) are easily found for each known pair of l and c_{NaI}. The resulting values of [I^-] are given in Table 1. This approach ought to give rather good values of [I^-], as, according to Erber's measurements, the highly condensed complexes, dominant when [P] is large, are either exactly of the form $Ag_mI_{2m}^{m-}$ or very close to it, which means that the amount of iodide ions used in the formation of these complexes (*vide* reaction (1)) is equal to [P], as required by eqn. (5). On the other hand, when [P] is less, the iodide bound in complex species is presumably a little larger than [P], as the complexes are probably of the form $Ag_mI_{2m+2}^{(m+2)-}$. Fortunately in this case [P] is such a small correction term in eqn. (5), that it does not matter that this term ought strictly to be replaced by the slightly greater term $\frac{m+2}{m} \cdot [P]$, $(m \geq 4)$.

The result of the computation is shown in Fig. 3. Log [P] is seen to be a rectilinear function of log [I^-] with the slope 12 in the whole range, where [P] is sufficiently large to be calculated from eqn. (6). This connection is approximately valid even for the last solution of Table 1, in spite of the change in ionic strength from 4 M to 6 M.

SURVEY OF THE SILVER IODIDE SYSTEM

A. *Uncharged and cationic complexes.* These have been studied by the dissolution of silver iodide in aqueous solutions of silver perchlorate [8]. The complexes are probably of the form Ag_nI^{n-1} with $n = 1$, 2, 3, and 4. At high concentrations of silver perchlorate small amounts of complexes containing more than one iodide ion are probably formed. King, Krall, and Pandow [3] came to the same conclusion, because their measurements of the light absorption at the wave length 300 mμ showed that Beer's law is not obeyed exactly in solutions of silver perchlorate, undersaturated with silver iodide.

B. *Mononuclear complexes,* AgI_n^{1-n}. The existence of the species AgI_3^{2-} and AgI_4^{3-} has been shown both by e.m.f. measurements and solubility determinations. The two methods gave complexity constants, which were in agreement. The solubility measurements have also given evidence of species of charge 0 and —1. These species exist in noticeable concentration only when the solubility is small ($\sim 10^{-8}$ M), which makes it rather probable that these

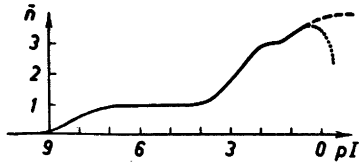

Fig. 4. The formation curves, $\bar{n}$, for saturated solutions of AgI (dotted curve) and for solutions containing so little silver, that polynuclear complexes can be neglected (dashed curve). When these two curves coincide they have been full-drawn.

species are mononuclear, *i. e.* of the form AgI and AgI_2^-. This cannot, however, be established by e.m.f. measurements because of the small total silver concentrations. The formation curve, $\bar{n}$, of the mononuclear complexes is shown in Fig. 4. A remarkable feature is the relatively high stability of the first and — to a less extent — of the third complex of the series.

This is in accordance with the idea of a dative π-bond between transition metals with filled d-orbitals and ligands with vacant d-orbitals of suitable size and energy level, as discussed by Chatt [12,13] and Chatt and Wilkins [14], who also give further literature. That the co-ordination number of silver can sometimes be 3 with strongly bound ligands containing a donor atom with vacant d-orbitals has been shown by Ahrland and Chatt [15] in their study of some complexes of silver ion with a tertiary phosphine. In the silver iodide case the strength of the first complex, AgI, relative to the second, AgI_2^-, is even still more pronounced than in the phosphine complexes studied by Ahrland and Chatt. There is a distinct "stop" in the formation curve of Fig. 4 at $\bar{n} = 3$, though the complex formation continues to the 4th complex at high iodide concentrations. This could perhaps mean that the species, written above as AgI_3^{2-}, actually has this formula and the possible fourth co-ordination place is not occupied by a molecule of water. This accords with Strock's [16] study of the high temperature form of solid silver iodide, α-AgI. Strock claims that α-AgI contains as well as two-, three- and four-co-ordinated silver ions in its iodide lattice.

In the silver thiocyanate [7] and azide systems [17] the complex AgA_2^- is more stable than the other members of the mononuclear series. From Fig. 4 it is evident that AgI_2^- is the least stable intermediate species. It is known [5,6] from the other silver halides that the activity factors at high ionic strength do not favour AgA_2^- relative to the other mononuclear species. It seems probable, therefore, that an $\bar{n}$-curve for the iodide system at zero ionic strength would show a "stop", *i. e.* a point of inflexion with a low slope of the tangent, at $\bar{n} = 2$, too. This means that the equilibrium constants, $b_{1,n}$, of the successive steps (Table 3) will differ markedly from the thermodynamic constants. In spite of this, however, the silver iodide system seems to be rather abnormal ($b_{1,1} / b_{1,2}$ being very great even after a correction for the activity factors) and this might suggest that different types of bonding occur at the different steps.

C. *Polynuclear anionic complexes.* The existence of $Ag_3I_8^{5-}$ is conclusively shown by the agreement between the results of the e.m.f. and solubility measurements. There can be little doubt about $Ag_2I_6^{4-}$, even if the silver present in this species never exceeds 20 % of the total silver concentration. It is reasonable to suppose that the two species are formed by the two condensations reactions written at the bottom of Table 3. This would indicate that the silver ion is four-co-ordinated in these species just as it is in the normal solid silver iodide, γ-AgI. The solubility measurements have shown that anionic

Table 3. The step reactions, their equilibrium constants, $b_{m,n}$, *and their over-all complexity constants,* $\beta_{m,n} = k_{m,n}/K_{-1}$. *Ionic strength 4 M* ($NaClO_4$). *Temperature 25° C.*

$Ag^+ + I^-$	$\rightleftharpoons AgI$	$b_{1,1} \gtrsim 10^{8}$	$\beta_{1,1} \gtrsim 10^{8}$
$AgI + I^-$	$\rightleftharpoons AgI_2^-$	$b_{1,2} \gtrsim 10^{3}$	$\beta_{1,2} \gtrsim 10^{11}$
$AgI_2^- + I^-$	$\rightleftharpoons AgI_3^{2-}$	$b_{1,3} \gtrsim 600$	$\beta_{1,3} = (6 \pm 1) \times 10^{13}$
$AgI_3^{2-} + I^-$	$\rightleftharpoons AgI_4^{3-}$	$b_{1,4} \gtrsim 4$	$\beta_{1,4} = (21 \pm 2) \times 10^{13}$
$2\ AgI_4^{3-}$	$\rightleftharpoons Ag_2I_6^{4-} + 2\ I^-$	$b_{2,6} \gtrsim 15$	$\beta_{2,6} = (6 \pm 2) \times 10^{29}$
$AgI_4^{3-} + Ag_2I_6^{4-}$	$\rightleftharpoons Ag_3I_8^{5-} + 2\ I^-$	$b_{3,8} \gtrsim 250$	$\beta_{3,8} = (24 \pm 2) \times 10^{45}$

complexes are formed with (negative) charges larger than 5. As is shown by Fig. 3 the solubilities can be interpreted assuming that only one such species, *viz.* $Ag_{12}I_{24}^{12-}$, is formed. It does not prove that this is the only highly condensed species in these concentrated solutions or that this particular species exists at all. It merely shows that $Ag_{12}I_{24}^{12-}$ can be regarded as a summarizing mean of the anionic complexes with high ionic weight. (For criticism of the propensity for selecting rather arbitrary species to describe complex systems, *vide* Hietanen and Sillén [18], Sillén [19], or Ahrland, Hietanen, and Sillén [20].) In the range where e.m.f. measurements [9] have been carried out, the silver concentration of the complexes, summarized as [P], *i. e.* formally $12[Ag_2I_{24}^{12-}]$, in Fig. 3, would be quite negligible, in agreement with the fact that no other species than $Ag_2I_6^{4-}$ and $Ag_3I_8^{5-}$ were needed to describe the potentiometric measurements.

An attempt [10] to describe the solubility measurements by assuming an infinite series of complexes, $Ag_mI_{2m+2}^{(m+2)-}$, formed by condensation reactions, of which all, except the first one, had the same equilibrium constant, accommodated all except the two last determinations of Table 1. E. m. f. measurements in the silver iodide system [9] might also be described by assuming an infinite series of complexes, $Ag_mI_{2m+2}^{(m+2)-}$, but the equilibrium constants calculated from the e. m. f.s on this assumption did not agree very well with those calculated from the solubility measurements. A quantitative description of the higher condensation products by such an infinite series was therefore abandoned. The most probable hypothesis is that the condensation reactions continue to some rather high value of m in $Ag_mI_{2m+2}^{(m+2)-}$, but with increasing charge the reaction with new AgI_4^{3-} becomes more difficult. It is also possible that a reaction, *e. g.* a ring-closure,

$$Ag_mI_{2m+2}^{(m+2)-} \rightleftharpoons Ag_mI_{2m}^{m-} + 2I^- \qquad (7)$$

occurs at some condensation step. It would be very difficult to decide between an infinite series and a series, cut off by a reaction such as (7) with a high value of m. In the former case the curve $\log l = f(\log[I^-])$ would have a vertical asymptote, in the latter one an asymptote with the large slope m. Perhaps the structure of the species with high ionic weights can be obtained from an X-ray analysis of solutions of silver iodide. A concentrated aqueous solution of lithium iodide, saturated with silver iodide gives X-ray photograms with distinct refraction patterns, which show that the polynuclear complexes are built up by tetrahedral AgI_4-links (Nilsson [21]). Chains of such links sharing corners have been found in solid K_2AgI_3 (Brink and Kroese [22]) and double chains of the same links sharing edges in $CsAg_2I_3$ (Brink, Binnendijk, and van de Linde [23]).

Although it has not been possible to determine the composition of the species, summarized as P above, certain forms can be excluded. They cannot be dinuclear, $Ag_2I_4^{2-}$—$Ag_2I_7^{5-}$, as Bodländer and Eberlein [24] have claimed, as

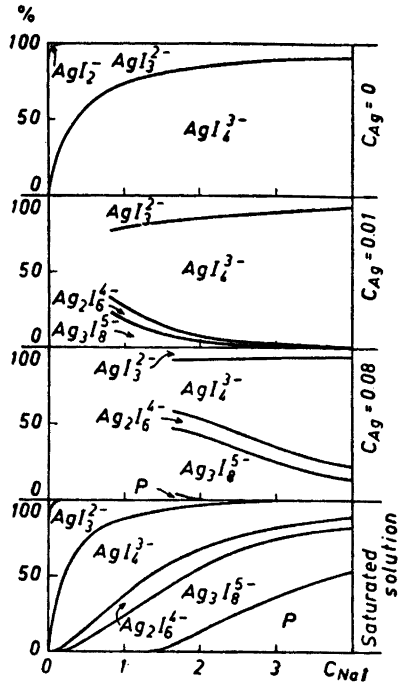

Fig. 5. The distribution of silver in anionic species in saturated solutions, in solutions containing a constant total silver concentration $c_{Ag} = 0.08$ *or* $0.01\ M$ *respectively, and in the limiting case* $c_{Ag} = 0$.

all species with the charges —2 to —5 have been quantitatively determined both by e.m.f. and solubility measurements. Similarly $Ag_4I_6^{2-}$, which Mackor [25] has found in a solvent of acetone and water is excluded. The silver iodide system seems to be completely different in organic solvents because AgI_2^- appears to be the limit of mononuclear complex formation both in acetone (Mackor [25]) and in ether (Alin, Evers, and Sillén [26]).

There is an obvious difference between the condensation reactions above and the corresponding "core + link"-description used by Sillén's school in studying hydrolysis of metal ions, as the link is uncharged in those hydrolyses — except in that of thorium — where an infinite series of hydrolysis products is formed. (The hydrolysis of bismuth seems to be under revision, *vide* Hietanen and Sillén [18,p.1622]. Hence the ionic charges of hydrolysis products do not increase with increasing ionic weight (*cf.* Rossotti and Rossotti [27]).

Data relating to the anionic complexes are summarized in Table 3, which contains the most probable values of the equilibrium constants for the stepwise formation of the complexes. Fig. 5 shows the distribution of silver in the different complexes, in saturated as well as in unsaturated solutions containing 0.08 or 0.01 M silver. In the two latter cases the curves cannot be continued to the left because the point of saturation has been reached. The figure also shows the distribution of silver at such low silver concentrations that polynuclear complexes are not formed. The calculation of the curves and directions for reading the diagrams are described elsewhere [4,7,8]. The distribution

of silver at low iodide concentration can be judged from Fig. 4. An $\bar{n}$-curve for saturated solutions for iodide concentrations higher than 0.1 M, drawn in larger scale than that of Fig. 4, is to be seen in Fig. 3 of Ref.[9]. This latter curve would be only slightly changed (and at the highest iodide concentrations only), if an infinite series of complexes were used instead of the description above. The equilibrium constants of the cationic complexes and the distribution of silver among these are given elsewhere [8].

The author is grateful to Dr. J. Chatt for valuable discussions, and to him and Dr. G. A. Gamlen for their efforts to make my manuscript readable. E. Berne and R. Nilsson carried out the G. M.-measurements and L. E. Marthén assisted at all stages of the experimental work. *Statens Naturvetenskapliga Forskningsråd* gave liberal financial support.

Kinetics of the Hydrolysis and Formation of Dimethylmaleic Anhydride in Solvent Mixtures

JOUKO KOSKIKALLIO

Institute of Chemistry, University of Helsinki, Finland

In a study of the rate of attainment of the equilibrium between dimethylmaleic anhydride and the acid in various acetone-water mixtures it has been established that the molecularity with respect to water is about three for the hydrolysis of the anhydride and about two for the reverse reaction. The rate of anhydride formation from dimethyl maleic acid has been investigated also in non-aqueous solvents as in acetone, dioxan and various diethyl ether-benzene mixtures. In benzene the rate was more than a thousand times as fast as in pure ether. The reaction was kinetically of second order and the rate constant was found to vary approximately as $1/c^2_{ox}$, where c_{ox} is the molar concentration of the solvent component which contains oxygen. The value of the rate constant obtained in dioxan fulfils the same relation fairly well if c_{ox} is taken to be equal to half the molar concentration of dioxan.

The activation energy for the hydrolysis reaction 13.4 kcal in 50 vol. % acetone-water is smaller than that for the reverse reaction, 16 kcal, and the hydrolysis reaction is exothermic by 2.6 kcal. The entropies of activation are for the hydrolysis -30.2 cal/degree and for the anhydride formation -18.7 cal/degree. These large differences in the entropies more than counterbalances the difference in the activation energies, and hence the rate of hydrolysis is smaller than the rate of the reverse reaction, and the equilibrium lies more on the side of the anhydride.

In a previous paper [1] are given data of the equilibrium constant for the reaction

$$\text{Dimethylmaleic acid} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Dimethylmaleic anhydride} + \text{Water} \qquad (1)$$

in various acetone-water mixtures. The composition of the solvent was found to influence the equilibrium only slightly. On the other hand, previous work [2] had shown that the rates of hydrolysis of acetic, succinic, and glutaric anhydrides decrease considerably when acetone is added to water. For com-

parison, kinetic measurements on the formation and hydrolysis of dimethylmaleic anhydride have been performed in acetone-water and diethyl ether-benzene mixtures and in dioxan.

EXPERIMENTAL

The dimethylmaleic anhydride was prepared as described previously [1]. The disodium-salt of dimethylmaleic acid was obtained by shaking a concentrated acetone solution of the anhydride with an approximately 20 % aqueous sodium hydroxide solution. The precipitated salt was washed with acetone and dried *in vacuo*.

For the kinetic experiments, a weighed quantity of the disodium salt was dissolved in a small volume of water, the solution cooled to 0°, and slightly less than the calculated amount of 30 % hydrochloric acid added. The liberated dimethylmaleic acid was dissolved in a small volume of one of the solvent components used in the kinetic experiments. After shaking with anhydrous sodium sulphate, the nearly anhydrous solution was warmed to 20° and pipetted to the solvent mixture previously temperated to 20° to make the mixture desired. The disadvantage of the method was that, in spite of the drying with sodium sulphate, small amounts of water were still present in the reaction mixture (especially when acetone and dioxan were used). Experiments made with diethyl ether saturated with water showed an about 5 % increase in the rate at 60° as compared with experiments made in previously dried ether solution. The values of the rate constants given in Table 5 are therefore probably all higher than the values for the corresponding dry solvents, but in no case more than about 1—2 %.

In all the organic solvents and their mixtures the conversion of dimethylmaleic acid into anhydride went to completion. Samples were titrated with 0.05 N sodium methylate, the consumption of which decreases as the acid is converted into anhydride because the anhydride consumes only one equivalent of methylate (anhydride + MeONa → monoester salt), whereas the acid consumes two equivalents. When titrated with baryta, both the acid and the anhydride consume two equivalents of base, and at the end of the reaction the consumption should be twice the methylate value if the reaction goes to completion. This was found to be the case in the dry organic solvents. Second-order kinetics were obeyed, and the rate constants were calculated from the following equation

$$k_2 = \frac{100}{at}\left(\frac{1}{100-\mathrm{p}} - \frac{1}{100}\right) \qquad (2)$$

where a is the initial concentration of the acid, t time in seconds and p the percentage of the acid changed into anhydride. Table 1 shows an example of a typical kinetic run.

In water, the hydrolysis of dimethylmaleic anhydride was followed conductometrically. In order to calculate the concentration of the acid, the conductances of the acid at various dilutions had to be measured separately. In aqueous solution the anhydride is

in equilibrium with the acid. This equilibrium is disturbed on dilution since the concentration of unionized acid is changed, and hence the values of conductances had to be extrapolated to zero mixing time. The conductances thus obtained are proportional to the acid concentrations, and the concentrations required in calculating the rate constants may be obtained with the aid of a graph. Because of the acid-anhydride equilibrium, rate constants were calculated using the following equations

$$k_1 + k_{-1} = \frac{2.303}{t} \log \frac{c_o - c_{eq}}{c_t - c_{eq}} \tag{3}$$

$$K = \frac{k_1}{k_{-1}} = \frac{c_o - c_{eq}}{c_{eq}} \tag{4}$$

where k_1 and k_{-1} are the first-order rate constants (see eqn. 1), t the time and c_o, c_t, c_{eq} the concentrations of acid at the beginning of the experiment, at time t, and at equilibrium, respectively. The conductances of different dilutions of a stock solution con-

taining 19.8×10^{-4} mole/l of acid and anhydride are given in Table 2. With aid of these values, using a graph, the conductances obtained in a kinetic run may be converted into concentrations, and values for the sum of rate constants are obtained. An example of a typical kinetic run is given in Table 2. The mean of the sum of rate constants is 16.9×10^{-4} sec^{-1} and when the value $K = 2.6$ taken from the previous paper [1] is used, it is found that $k_{-1} = 12.2 \times 10^{-4}$ and $k_1 = 4.7 \times 10^{-4}$ sec^{-1}. As already mentioned the acid concentrations and conductances given in Table 2 are only values proportional to the true values. The constancy of the sum $k_1 + k_{-1}$ in this typical run indicates that first-order kinetics are well obeyed.

In the case of all acetone-water mixtures, the samples were analysed as in the previous work [1] by titrating with 0.05 N sodium methylate and 0.02 N baryta. The experimental data for acetone-water mixture containing 90 vol. % acetone were not found to fit either first-order or the second-order rate equation. The reaction does not proceed to completion and at equilibrium at 20° 95 % of acid has been converted into anhydride. In order to simplify the calculations, the reverse reaction was disregarded and the constants were calculated by assuming two reactions, one of first-order and one of second-order to occur simultaneously:

$$-\frac{dx}{dt} = k_1 (a-x) + k_2 (a-x)^2 \qquad (5)$$

which gives on integration

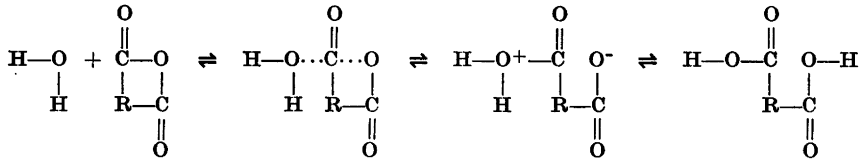
$$k_1 = \frac{2.303}{t} \log \frac{a-\beta x}{a-x} \; ; \; \beta = \frac{k_1 + ak_2}{ak_2} \qquad (6)$$

where a is the initial acid concentration, x the reacted amount of acid, t time in seconds and β a constant.

Rate constants calculated in different ways, from the rate equation for an overall first-order reaction disregarding the equilibrium (Table 3, column 6), from the first-order rate equation taking into account the equilibrium (Table 3, column 7, eqn. 3), from the second-order rate equation disregarding the equilibrium (column 8, eqn. 2) and from the rate equation for simultaneous first-order and second-order reactions assuming the value 0.5 for β (column 9, eqn. 6). Only in this last case are fairly good constants obtained. In pure acetone, the reaction is solely of the second-order, and thus a transition from first-order into second-order kinetics occurs in the acetone-water mixture containing about 90 % acetone.

RESULTS AND DISCUSSION

The rate constants obtained are summarized in Tables 4 and 5. The hydrolysis of dimethylmaleic anhydride in aqueous solution is considerably slower than the hydrolysis of maleic anhydride [2], the respective first-order rate constants at 0° being 4.7×10^{-4} and 34.3×10^{-4} sec^{-1}, but somewhat faster than the hydrolysis of succinic anhydride [2] for which the first-order rate constant at 0° is 3.34×10^{-4}. The hydrolysis of maleic anhydride is only slightly faster than the hydrolysis of methylmaleic anhydride [3]: the rate constants at 25° are 26.6×10^{-4} and 17.6×10^{-4} sec^{-1}, respectively. These differences in the rates are in the direction predicted by steric and inductive effects [6].

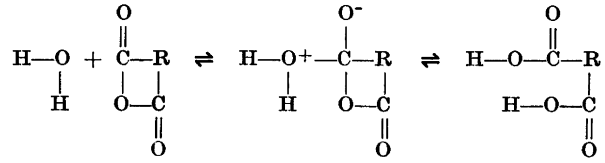


In acetone-water mixtures, the hydrolyses of all anhydrides studied previously [2] and the conversion of dimethylmaleic acid into anhydride are greatly retarded as the acetone content of the aqueous solvent is increased (Table 4). When log k is plotted against log c_{H_2O}, fairly constant slopes are obtained for the cyclic anhydrides, but not for acetic anhydride [2] (Table 6). For succinic, glutaric and dimethylmaleic anhydrides, the slope is about three, while for acetic anhydride the slope decreases continously from about four to one.

In 99.93 wt.% dioxan-water the hydrolysis of acetic anhydride is of the first-order with respect to water [2]. The rate of conversion of dimethylmaleic acid into anhydride is approximately proportional to the second power of the water concentration, while the rate of hydrolysis varies as the third power of the water concentration. Similar solvent effects are found for reactions occurring by the S_N2 mechanism [4].

It is interesting to note that the equilibrium constant

$$K = \frac{[\text{dimethylmaleic anhydride}]\ [\text{water}]}{[\text{dimethylmaleic acid}]} = \frac{k_1}{k_{-1}} \qquad (7)$$



remains fairly constant in acetone-water mixtures, at least up to the 90 vol.% acetone-water mixture [1]. Thus both k_1 and k_1/c_{H_2O} should decrease to about the same extent in acetone-water mixtures as is also obtained. Consequently the reactants and products should be similar, and in this case neutral molecules. The S_N2 mechanism usually written for the hydrolysis of anhydrides gives as the primary reaction products two ions of opposite charge which are formed from the anhydride and water [6,2]. Thus the hydrolysis of the anhydride should be retarded when acetone is added to water, but the reverse reaction should simultaneously be greatly accelerated.

(8)

In this equation R denotes the group $CH_3\dot{C}{=}\dot{C}CH_3$, while for monocarboxylic acids and their anhydrides R denotes two alkyl groups, *e. g.* two methyl groups in the case of acetic anhydride.

A mechanism analogous to the Lowry mechanism for the ester hydrolysis would give better agreement with the solvent effects observed in the reversible hydrolysis of dimethylmaleic anhydride:

(9

The main difference between these mechanism is that in eqn. (8) the proton shift does not occur simultaneously as the C—O bond is broken, whereas in eqn. (9) the proton shift occurs at the same time as the C—O bond is broken, *i. e.* in the rate-determining slow step. The addition of a water molecule to the carbonyl carbon involves a loosening of the O—H bonds in the water molecule, and it can be assumed that a kind of hydrogen bond is developed between one of the protons of the water and the "etheral oxygen" atom of the an-

hydride. The breaking of the C—O bond will thus occur more easily and the reaction products will not carry any charges. The acid formed may of course ionize later. About the transition state between reactants and products, it can only be said that it is more polar than either the reactants or products because both the hydrolysis and the reverse reaction are retarded in solvents of low ionizing power (acetone).

In acetone, diethyl ether and dioxan and their mixtures with benzene, dimethylmaleic acid is, as far as can be determined, spontaneously and completely changed into its anhydride, and it is not possible to measure the position of the equilibrium. The rate of reaction is slow in all solvents but benzene which, when added to ether, increases the rate more than a thousand times. The reaction is of second order with respect to the acid in all the nonaqueous solvents studied, but of first order with respect to the acid in acetone-water mixtures containing less than 90 vol. % acetone. The conversion of dimethylmaleic acid into anhydride is thus probably acid-catalysed in solvents containing no, or only small amounts of, hydroxylic solvents. The hydrolysis of succinic anhydride is catalysed by acids in acetone-water mixtures containing

small amounts of water, as is also the case for the ethanolysis in ethanol-benzene mixtures containing small amounts of ethanol [2]. The hydrolysis and alcoholysis of acetic anhydride was found to be slow in acetone, dioxan and ether, but fast in benzene [2]. Thus the solvent effects are very similar to those found in the present study (Table 5).

In Fig. 1, log k_2 (second order rate constant for the conversion of dimethylmaleic acid into anhydride) is plotted against log c_{ox} the molar concentration of the oxygen-containing solvent component, (in the case of dioxan the molar concentration divided by two). A linear relationship is found in mixtures containing less than 90 % benzene. The values for the pure solvents acetone, ether and dioxan fit the same curve too, but in case of dioxan only when the molar concentration is divided by two in order to take into account the two oxygen atoms in the molecule. The slope of the linear part of the curve is slightly less than two. All these effects suggest that the reactant, the acid molecule, forms an addition product with the oxygen-containing solvent molecules by hydrogen bond formation [5], which retards the rate of reaction:

$$\text{Acid} + \text{solvent} = \text{addition product} \tag{10}$$

$$c_{\text{free acid}} = K' \frac{c_{\text{add. prod.}}}{c_{\text{solvent}}} \tag{11}$$

$$-\frac{dc}{dt} = k_2 \cdot c^2_{\text{free acid}} = k_2 K'^2 \frac{c^2_{\text{add. prod.}}}{c^2_{\text{solvent}}} \tag{12}$$

In solvent mixtures containing a high proportion of the oxygen-containing solvent the addition of solvent to acid molecules may be regarded as complete and $c_{\text{add. prod.}}$ equals the total acid concentration (in curve 1 the linear part up to 90 vol. % benzene). In pure benzene the association between acid molecules and the solvent can be neglected, and hence a limiting value will be obtai-

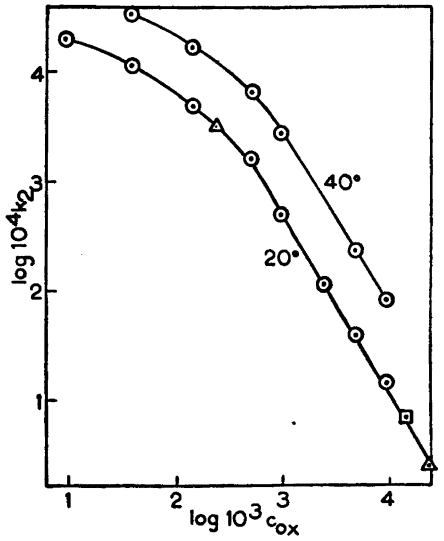

Fig. 1. Graphs showing the correlation between log k_2 *(the second-order rate constant of anhydride formation from dimethylmaleic acid) and log* c_{ox} *(the concentration of the oxygen-containing solvent component in moles per liter). ned for the rate constant. According to eqn. (12), the rate constant k_2 should vary inversely as the square of the concentration of the oxygen-containing solvent component; this is approximate true for the different solvents studied.

The high activation energy found in ether (16.5 kcal, Table 5) is partly due to the heat of addition or to the variation of K' in eqn. (10) with temperature. The activation energy, 10.1 kcal, found in 99.6 vol % benzene-ether, should be fairly close to the true activation energy. The reaction mechanism for the acid catalysed hydrolysis and the reverse reaction can be written in the same manner as for the uncatalysed reaction (eqn. (9)) with the difference that an additional proton is attached to the "etheral oxygen" of the anhydride before reacting. That the reaction is not acid catalysed in hydroxylic solvents may be due to hydrogen bonding at the "etheral oxygen" of the anhydride which has a similar catalysing effect as a proton addition.

From the differences in the activation energies for the hydrolysis and the reverse reaction in 50 vol. % acetone-water (13.4 and 16 kcal, respectively, calculated from the values in Table 4) and also from the equilibrium data published previously [1], it is seen that the hydrolysis is an exothermic reaction. In spite of this, the anhydride form is favoured because of the greater effect of the entropy factor. The first-order frequency factors of the hydrolysis and the reverse reaction in the same solvent mixture are log $A_{-1} = 6.61$ and log $A_1 = 9.12$. The activation entropies calculated [7] from frequency factors by means of the following eqn. (13)

$$A = e \frac{kT}{h} e^{\Delta S^*/R} \qquad (13)$$

are $\Delta S_{-1} = -30.2$ and $\Delta S^*_1 = -18.7$ e.u. The hydrolysis reaction is probably bimolecular, and by writing $k_{-2} = k_{-1}/c_{H_2O}$ an even more negative value is obtained for the entropy of activation, *viz.* $\Delta S^*_{-2} = -37.4$ e.u. In the for-

mation of anhydride from dimethylmaleic acid, the entropy increases by 18.7 e.u., and therefore the equilibrium lies more on the side of the anhydride in spite of the fact that this reaction is endothermic. From the difference in the activation entropies, it can be deduced that the geometry of the transition state between reactants and products is closer to that of the acid than of the anhydride form. From the great differences between both ionization constants of maleic and methylmaleic acids and from other facts, it is deduced that the two carboxyl groups are situated close to each other. The additional methyl group in dimethylmaleic acid should still effect a decrease of the distance between carboxyl groups. The high rate of conversion of dimethylmaleic acid into anhydride is due to the closely situated carboxyl groups and the resulting greater entropy of activation, which makes the anhydride form unusually stable against hydroxylic reagents. The rates and the energies and entropies of activation of the hydrolysis reaction are, however, of the same order as those found for other anhydrides [2].

Incorporation of Radioactive Phosphate into Thiamine Phosphates in Yeast

KARL-HEINZ KIESSLING

Institute of Zoophysiology, Uppsala, Sweden

The incorporation of radioactive phosphate into thiaminetri-, di-, and monophosphate in baker's yeast has been examined. Yeast containing only its natural content of thiaminephosphates was used as well as yeast made rich in these compounds by preincubation with excess of thiamine.

In both cases radioactive phosphate was incorporated to a higher degree into thiamine triphosphate than into the other thiamine phosphates. The incorporation into thiamine triphosphate was localized especially to the terminal phosphate.

No appreciable synthesis of thiamine phosphates was going on during incorporation. Therefore the high turnover rate of radioactivity in the terminal phosphate of thiamine triphosphate with glucose as a substrate has been interpreted as caused by the compound in question taking part in the phosphate transport in the metabolism.

Yeast has a considerable ability of transforming added thiamine into thiamine diphosphate * (cocarboxylase) [1-4].

The role of TDP has long been known to be that of a decarboxylating coenzyme. Moreover Kiessling and Lindahl [5] found a turnover of the phosphate groups in TDP with a liver cyclophorase system when pyruvate was the substrate. Bartley [6] could not verify these results when using a kidney system and adding TDP, differing thereby from our experiments without added TDP. In a paper by Ogata *et al.*[7], however, it was shown that a rapid transfer of phosphate occurred from ^{32}P labelled TDP into ATP by a rat liver homogenate as well as by a cyclophorase system.

In 1954 it was shown that baker's yeast synthesizes besides TDP also thiamine triphosphate [8]. TTP exists likewise in yeast not preincubated with an excess of thiamine, but to a very small extent as compared with TDP.

* Abbreviations: T thiamine, TMP thiamine monophosphate, TDP thiamine diphosphate, TTP thiamine triphosphate, ATP adenosine triphosphate, ADP adenosine diphosphate, DPN diphosphopyridine nucleotide, Pi inorganic phosphate.

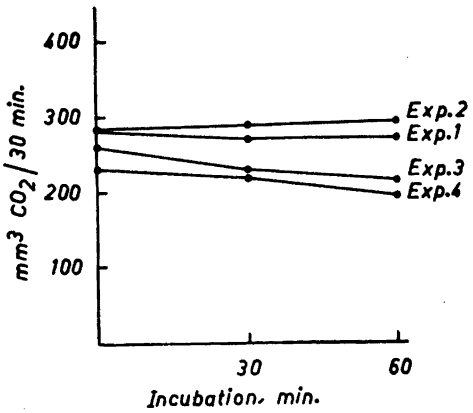

Fig. 1. TDP content of yeast during incubation with glucose and ^{32}P. The yeast had been preincubated with excess of thiamine.

Samples of 2 ml were taken at 0, 60 and 120 minutes, and added to 5 ml 0.1 M HCl at 100°, boiled for 1 minute, cooled, and centrifuged. The clear extracts were neutralized to pH 6, and TDP determined according to Westenbrink *et al.* with the Warburg method [13].

The question soon arose whether TTP could replace TDP in a decarboxylating system. Up to now only a system decarboxylating pyruvate has been examined. It has been shown by Gertrudes de la Fuente [9] * that chemically synthesized TTP, and by Kiessling [10] that both chemically synthesized TTP and TTP isolated from baker's yeast could not replace TDP as a coenzyme in this enzyme system from yeast.

In the present paper the incorporation of radioactive phosphate into yeast TTP is studied and compared with that into TDP, TMP, and ATP. The experiments have been carried out partly with yeast containing only its natural amount of thiamine phosphates, partly with yeast enriched in thiamine phosphates by preincubation with thiamine.

EXPERIMENTAL

Special chemicals. TDP and T were commercial samples (Roche products Ltd.). TMP was prepared by 20 minutes' hydrolysis of TDP at 100°. Paper chromatography proved all TDP to be transformed into TMP.

Chemical estimations. Phosphate was determined according to Berenblum and Chain [11] in a Beckman spectrophotometer. Measurements of radioactivity were made on samples of the diluted, wet ashed material. A M-6 liquid counter (20th Century Electronics) was used.

Enzyme preparation. Potato apyrase was prepared by Dr. W. Bartley according to Lee and Eiler [12].

* Recently a paper appeared by Rossi-Fanelli *et al.* (*Arch. Biochem. Biophys.* **58** (1955) 237) where the results of de la Fuente were confirmed.

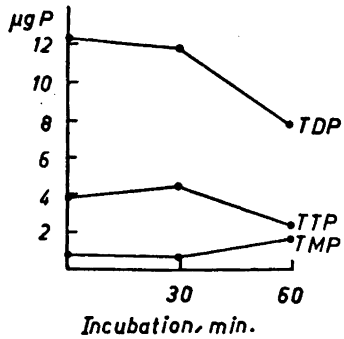

Fig. 2. TTP, TDP, and TMP in yeast rich in thiamine phosphates during incubation with glucose and inorganic phosphate.

Samples were taken at 0, 30 and 60 minutes, the thiamine phosphates isolated, and the phosphate determined after wet ashing.

Preparation and incubation of the particulate suspensions. The content of TTP in biological material in general is very low, but yeast is in my experience a better source than animal tissues. Furthermore, the TTP content of yeast can be very much increased. Preliminary experiments by the present author with animal tissues (liver, heart, brain) never showed any analogous accumulation. Thus yeast has been used in this investigation **. The first part of this paper deals with the naturally occurring TTP in yeast with regard to its capacity of incorporating radioactive phosphate. But even when starting with large amounts of yeast (1 kg) the content of TTP was so small that never sufficient TTP could be isolated to allow an enzymatic analysis of the incorporation of ^{32}P into its different phosphate groups. Thus for the carrying out of such analyses as is treated in the later part of this paper, yeast was used which by preincubation with an excess of T had been made rich in TTP and of course also in TDP and TMP [10]. This preincubation was allowed to go on for 20 hours, after which only a very slow synthesis of thiamine phosphates still occurred. To eliminate this remaining synthesis, the yeast was centrifuged down, mixed with NaCl (20 %), and washed once with succinate buffer pH 5 and twice with distilled water. The NaCl treatment was intended to cause a slight destruction of the cell surface. Excess of T could thus be washed away from the cells, and when yeast pretreated in this way with glucose and phosphate at 27° was incubated in a succinate buffer pH 6, no synthesis of TDP took place (Fig. 1). On the contrary a slight breakdown occurred. The purpose of eliminating the synthesis was to make sure that a possibly occurring incorporation of ^{32}P during the following incubation was not caused by further synthesis of thiamine phosphates from thiamine.

The concentration of TTP, TDP, and TMP throughout an experiment can be seen in Fig. 2. Phosphate was determined after wet ashing. During the first 60 minutes the concentrations are rather constant, but between 60 and 120 minutes TTP and TDP are decomposed (in this experiment TDP was decomposed more rapidly than in the experiments of the same type shown in Fig. 1), and a slight accumulation of TMP takes place.

When examining the incorporation of ^{32}P into the different phosphate groups of the thiamine phosphates 200 g of yeast pretreated as described above was incubated with 0.5 mC inorganic radioactive phosphate and 4 g glucose. Samples containing 50 g yeast were taken at 0, 10, 30, and 60 minutes, and trichloroacetic acid added to a final concentration of 9 %. Then TTP, TDP, and TMP were isolated according to Kiessling [10], and ATP and Pi according to Krebs *et al.*[15]

** The yeast was a baker's yeast from Uppsala Ångkvarn Ltd, Sweden.

When studying the incorporation of ^{32}P into TTP in yeast only containing its natural amount of TTP, fresh baker's yeast was used without adding T and treating it with NaCl, but otherwise with the same additions as to the NaCl treated yeast.

Paper chromatographic separation of thiamine phosphates. For the separation of TTP from other phosphates different paper chromatographic methods have been developed, and the author considers one using *iso*butyric acid-ammonia-versene the most suitable [10]. However, during the first part of this investigation, *viz.* that with yeast only containing its natural amount of TTP, this solvent was not yet known to separate also TTP from other compounds. Instead the method described by Siliprandi and Siliprandi [14] was used. Here ATP and ADP have the same R_F value as TTP, and had to be eliminated prior to chromatography. This was done by adsorbing the thiamine phosphates on Fuller's earth at pH 6, as described before [10]. No ATP, ADP, or other nucleotides then contaminated the thiamine phosphates as was proved by using a paper chromatographic method of Burrows *et al.*[16], separating nucleotides from thiamine phosphates, but not TTP, TDP, and TMP from each other (Fig. 3 A).

Enzymatic hydrolysis of γP and βP from TTP. Lee and Eiler [12] found that a potato apyrase, when incubated with ATP at 0° only splits off the γP, and at 40° both γ and βP. When incubating TTP with this enzyme, Kiessling demonstrated that TTP was attacked in the same way [10]. This enzyme was therefore used in the present investigation to split off the different phosphate groups from TTP in order to compare the incorporation of ^{32}P into them.

RESULTS

Incorporation of ^{32}P into thiamine phosphates in yeast not preincubated with thiamine

In fresh baker's yeast incubated with glucose and radioactive inorganic phosphate the incorporation into TTP, TDP, and TMP is clear from chromatograms reproduced in Fig. 3 B.

It is obvious that the incorporation of ^{32}P into TTP is much more rapid than that into TDP or TMP. No synthesis of TDP occurred during the incubation as evidenced by measurements with the Warburg manometric method.

The incorporation into TTP was dependent on the presence of a substrate. In the experiment shown in Fig. 3 B no substrate was added before the lapse of 20 minutes, and the incorporation of ^{32}P into TTP was very slow. At 20 minutes glucose was added, and the incorporation rate increased immediately.

Hydrolysis of TTP to TDP and TMP. When keeping a TTP sample at room temperature it decomposes only slowly to TDP and TMP. After 15 minutes in N HCl at 100° C it is nearly completely broken down to TMP, but shorter hydrolyzing times give mixtures of TDP and TMP.

A TTP sample isolated from yeast which had been incubated as described above was put as two spots on a chromatogram. A drop of diluted HCl was then added to one of the spots, and dried with hot air. This was repeated until total hydrolysis of the TTP of the spot was supposed to have taken place. Fig. 3 C shows the results. TTP was hydrolyzed, and in its place TDP and TMP spots were formed. The radioactivity of the TDP spot was low, and no appreciable activity was found of the TMP spot. On the other hand the ^{32}P was recovered as inorganic phosphate. From Fig. 3 C it appears that chiefly the γP of TTP becomes radioactive during 20 minutes incubation with substrate.

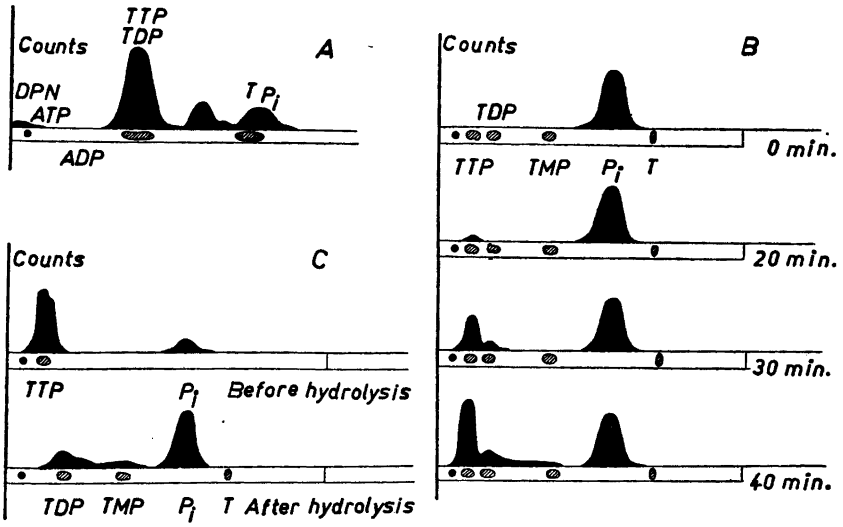

Fig. 3 A. Paper chromatographic separation of thiamine phosphates after removal of ATP, ADP, and DPN.

The chromatographic method is one described by Burrows *et al.*[16] in a solvent containing 60 vol. acetone and 40 vol. 35 % v/v formic acid. The chromatogram shows the absence of radioactivity in the spots corresponding to the R_F-values of the nucleotides. Moreover, when examinating the chromatograms in UV-light 260 mμ no dark spots could be seen. The thiamine phosphates could, however, be detected easily in UV-light after spraying the chromatograms with alcaline $Fe(CN)_6^{3-}$. They are marked out as dark spots in the figure.

B. Paper chromatographic separation of TTP, TDP, TMP, and Pi from yeast.

The yeast was incubated with ^{32}P and glucose in a succinate buffer pH 6. Glucose was not added until after the lapse of 20 minutes. Samples were taken at 0, 20, 30, and 40 minutes, and the thiamine phosphates separated. The paper chromatographic method is one described by Siliprandi and Siliprandi [14]. The thiamine compounds were made visible in UV-light as described in fig. 3 A, and marked out as dark spots.

C. TTP from a yeast sample taken after 40 minutes incubation as described in Fig. 3 B before and after hydrolysis.

As seen from the upper figure this gives only a single spot without hydrolysis. The lower figure shows the same, only here the TTP was hydrolyzed on the paper chromatogram with HCl in hot air before starting the second chromatography. TTP is transformed into TDP and TMP, and the radioactivity is mainly recovered as inorganic phosphate.

The determination of radioactivity on the strips was done according to Lindberg and Hummel [17].

A rough analysis of the radioactivity per μg P was made on TTP and ATP collected from several chromatograms (Table 1). The radioactivity of TTP was about half that of ATP.

Incorporation of ^{32}P into thiamine phosphates in yeast preincubated with an excess of thiamine

In order to obtain in the yeast an amount of TTP sufficient for a real analysis of ^{32}P in the different phosphate groups preincubation with an excess

Table 1. Radioactivity of TTP and ATP from yeast incubated with radioactive phosphate and glucose in a succinate buffer pH 6. The yeast contained only its natural amount of thiamine phosphates, i. e. *no preincubation with thiamine had been carried out before the addition of ^{32}P and substrate. TTP was isolated by paper chromatography (Siliprandi and Siliprandi)* [14], *and ATP according to Krebs and Hems* [15]. *After wet ashing of the isolated compounds radioactivity was determined, and expressed as counts / μg P.*

Exp. 1.	TTP	1 717
	ATP	3 145
Exp. 2.	TTP	1 350
	ATP	3 480

of T was started with, as described above. This preincubation was carried on until no appreciable synthesis occurred, and the thiamine not yet used up was then washed out of the cells. Thereafter the yeast, rich in TTP, TDP, and TMP, was incubated in the same way as described for the fresh yeast containing only its naturally occurring TTP. Glucose was, however, present from the beginning. Fig. 4 shows the ^{32}P per *ug* acid hydrolysable phosphate in TTP and TDP at different intervals. The incorporation into TDP was slow, and ceased after 30 minutes. Into TTP it was much more rapid, and even at 60 minutes ^{32}P was still being incorporated.

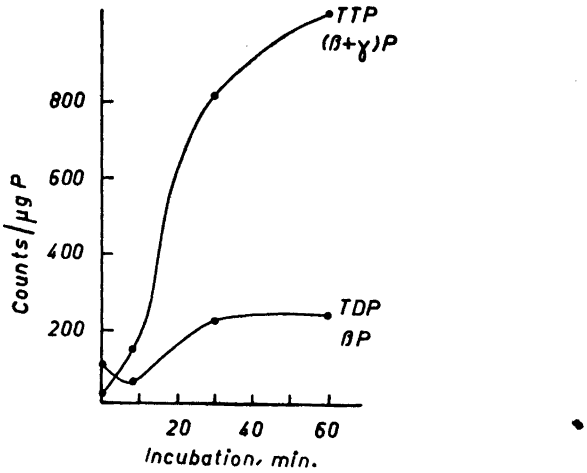

Fig. 4. Radioactivity of hydrolysable phosphate in TTP and TDP from yeast after incubation with ^{32}P and glucose in a succinate buffer pH 6.

The content of thiamine phosphates in the yeast was very high as the yeast had been incubated with an excess of thiamine for 20 hours before ^{32}P and glucose were added. The values are given as counts / μg P, and for TTP this means both βP and γP together, for TDP only βP.

Table 2. Radioactivity of α, β, and γ P of TTP and ATP from yeast after incubation with glucose and radioactive phosphate. Before the addition of ^{32}P and glucose the yeast had been preincubated with excess of thiamine, and thus was very rich in thiamine phosphates during the following incubation. The different phosphate groups were split off by means of a potato apyrase, except for ATP in exp. II, where βP and γP are determined together after acid hydrolysis. The values are given as counts / μg P.

Exp.	Time of incubation (minutes)	TTP			ATP		P_i
		αP	βP	γP	βP	γP	
I	0	0	0	0	0	0	6 310
	10	16	128	280	—	—	—
	30	250	1 102	1 860	3 290	3 820	—
	60	960	1 140	2 400	3 260	2 865	4 070
					(β + γ)P		
II	0	0	0	0	0		39 360
	30	600	1 200	7 320	17 800		—
	60	2 080	2 432	6 992	16 480		20 143

Enzymatic hydrolysis of TTP. When TTP is incubated with potato apyrase at 0° only the γ P is split off, at 40° both the γ and the βP[10]. TTP isolated from samples taken at different intervals of the ^{32}P-incubation was treated with apyrase, and then analyzed for radioactive phosphate (Table 2). In expt. I, Table 2 also ATP is treated in the same way as TTP. In expt. 2, Table 2 β P and γ P from ATP are determined together after acid hydrolysis. Also TDP and TMP (Table 3) were analysed for ^{32}P by acid hydrolysis and wet ashing.

DISCUSSION

This work was started with yeast containing only its natural amount of TTP, *i. e.* no thiamine was added after the yeast left the factory. From yeast TTP could be isolated in amounts detectable on a paper chromatogram. With the chromatographic method used in this part of the investigation only small amounts of yeast extract could be added on the paper to allow a good separation of TTP and TDP. After collecting TTP from several chromatograms it was, however, possible to make preliminary analyses as seen from Table 1. When hydrolyzing the TTP directly on the chromatogram it could be transformed into TDP and TMP. Thus TTP isolated from yeast incubated with ^{32}P and glucose in a succinate buffer gave a spot on the chromatogram which was rather radioactive, whereas the TDP and TMP formed by hydrolysis gave spots exhibiting only very feeble radioactivity (Fig. 3 B and C). It thus seems as if during the comparatively short incubation only the γP of TTP was exchanged. Glucose is necessary for this exchange as is shown in Fig. 3 B. Here no substrate was added until after 20 minutes, and TTP did not incorporate any noteworthy amount of ^{32}P until glucose was present.

Table 3. Radioactivity of α and βP of TDP and αP of TMP from yeast after incubation with glucose and radioactive phosphate. The yeast was the same as that used for investigating TTP and ATP (Table 2). The phosphate groups were split off by acid hydrolysis and wet ashing. The values are given as counts / μg P.

Exp.	Time of incubation (minutes)	TDP		TMP
		αP	βP	αP
II	0	0	0	0
	30	324	490	301
	60	332	408	482

When yeast is incubated with an excess of thiamine in a pyrophosphate buffer a strong synthesis of thiamine phosphates occurs [10]. TTP accumulates to a greater extent in this buffer than for example in a succinate or monophosphate buffer. After about 24 hours the synthesis has almost ceased, and on the removal of most of the remaining thiamine it comes to an end. The use of yeast rich in thiamine phosphates, especially TTP, has certain advantages with regard to the investigation into the rate of incorporation of ^{32}P into the different phosphate groups during the metabolism of glucose. A much greater amount of TTP can be isolated making possible an enzymatic hydrolysis of the different phosphate groups. From Tables 2 and 3 and Fig. 4 it is seen that there is a higher turnover rate of phosphate in TTP than in TDP or TMP. When incubating only for a short time (10 or 30 minutes) mainly the two terminal phosphate groups of TTP are radioactive, and γP in a higher degree than βP. After 60 minutes the radioactivity of αP nearly equals that of βP (Table 3). From this it can be concluded that TTP takes part in the phosphate transport during the metabolism, and this mainly by the turnover of its terminal phosphate. The radioactivity of the most active phosphate group of TTP, the γP, never reaches that of inorganic phosphate or ATP. This may be explained by the hypothesis that during the preincubation with excess of thiamine, the yeast synthesizes more TTP than can take a share in the phosphate transport. This is not the case when using yeast containing only its natural source of TTP. In Table 1 the values of TTP are about half those of ATP, but as is seen from the chromatograms in Fig. 3 C, only γP exhibits a remarkable radioactivity after 20 minutes' incubation. In ATP both βP and γP are nearly equally labelled after this incubation time. Consequently the terminal P of TTP and ATP may be labelled to about the same extent.

Acknowledgements. I am indebted to Prof. P. E. Lindahl for the kind interest he has shown in my work, to Dr. W. Bartley for the preparation of potato apyrase, and to Mrs. M. Aunver for valuable technical assistance.

This work was made possible by a grant from the *Swedish Natural Science Research Council.*

The Infra-Red Absorption Spectra of Some Amino Acid-Metal Chelates at Liquid Air Temperature

ANDREAS ROSENBERG

Institute of Biochemistry, Uppsala, Sweden

A method for obtaining infra-red absorption spectra at low temperatures is described. The infra-red spectra of some amino acid-metal chelates are examined and evidence presented in support of the concept that the carboxyl groups and the metal ions in certain chelates tend to form bonds of different, probably more covalent, character than the usual ionic carboxyl-metal ion linkage.

The use of infra-red (IR) absorption measurements for the investigation of coordination compounds has been scarce. Recently, however, a number of investigations on metal chelate compounds have been published. In these studies changes in IR absorption have been used in order to gain information about the behaviour of chelate forming groups in the molecule and thus even about the nature of the bond with the metal ion. Such spectral changes have also been used as a means of distinguishing between different geometrical isomers of the same chelate. Thus, for example, Bryant, Parriaud and Fernelius [1] have studied the effect of metal ions on the position of the carbonyl frequency of tropolone and its derivatives. They have observed shifts of about 20 cm^{-1} towards lower wavenumbers for the carbonyl frequency after chelate formation. On the other hand differences between shifts caused by various metal ions were negligible. This seems to confirm the conclusion arrived at by Bellamy and Branch [2] from investigations on the metal chelates of diketones. They found that the values for the carbonyl frequency of acetylacetone chelates are essentially the same for all the metals investigated. The shift in carbonyl frequency in this case is probably mostly influenced by an increase in the resonance effects of the *p*-diketone molecule and not by any difference in the type of linkage with the metal ion. That this kind of behaviour is not general is shown by the same authors with salicylaldehyde. The chelates of this compound with different metal ions do show significant differences in the position of the carbonyl frequency. A slightly different way of applying IR absorption was used by Merrit and Wiberley [3] who showed that differences exist in IR absorption between *cis* and *trans* isomers of Co^{+++} chelates.

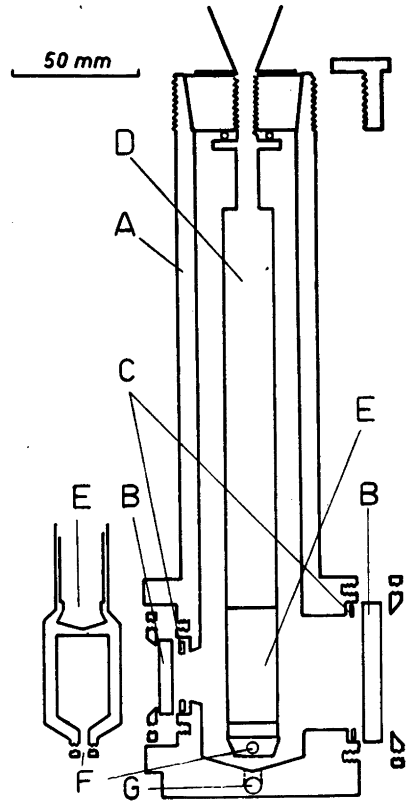

Fig. 1. Low-temperature cell. For explanations, see the text.

The aim of the present study was to examine the possibilities of using the IR methods for investigating biochemically interesting metal chelates. The investigation of complicated compounds can only be successful provided that the behaviour of the important chelate forming groups, such as NH_2, has been studied in simple molecules with established configurations. Previously Lenormant [4] has published some IR curves for such compounds and recently Sen *et al.*[5] have studied Cu^{++} and Ni^{++} chelates of glycine. The present investigation of amino acid-metal chelates was carried out as a necessary introduction to further studies of metal-ion peptide complexes. Pt^{++}, Cu^{++} and Ni^{++} were used since these ions form chelates of the same square-planar type[6].

EXPERIMENTAL

A Perkin-Elmer model 21 spectrophotometer equipped with a CaF_2 prism was used for the IR measurements. The substances, all in the solid state, were mixed with powdered KBr and pressed to transparent discs according to the method developed by Schiedt and Reinwein [7]. Earlier investigations [5] and preliminary experiments made here showed that the changes in the spectra were such that the NaCl prism was not able to give the required resolution. The important regions around 3 and 6 μ showed broad absorption

bands strongly influenced by the presence of the water of crystallization. Even with the use of a CaF_2 prism the resolution was not always sufficient. In search for a method giving still better resolution, the low-temperature approach seemed to be most promising. In recent years low-temperature IR spectroscopy has been the subject of some controversy. It is generally accepted that cooling a substance so that it changes its state of aggregation, causes changes in its IR absorption. On the other hand the effects produced by continued cooling of a given crystalline phase are open to discussion. King, Hainer and Mc Mahon [8], for example, have investigated a number of high-molecular-weight substances and conclude that very little is gained by the use of low temperatures. However, work reviewed by Hornig [9] indicate that the low-temperature method is very effective when used for low-molecular-weight substances. The main difficulty encountered in the present work was to obtain definite bands from regions with broad non-specific absorption. Thus even if the results obtained by low-temperature measurements were only caused by an increased transparency giving new peaks in the region of non-specific absorption, the use of low temperatures would be justified. The next step was the construction of a simple low-temperature cell suitable for work with crystalline substances. The main obstacle in low-temperature work with crystals is the heat transfer from the substance to the refrigerant. For this reason the KBr-disc method was utilized. The crystals investigated were mixed with powdered KBr and pressed to rectangular plates which were firmly attached to metal frames. The only problem of heat transport was thus the transfer from the metal frame to the metal reservoir containing liquid air and this was easily solved. Fig. 1 shows a schematic drawing of the cell. The outer case (A) is made of Perspex. The windows (B) are standard Perkin Elmer cell windows made of NaCl which are tightened with rubber washers (C). The metal container (D) for the liquid air is made of brass. Its lower part (E) is formed as a holder for the metal frame of the KBr disc. Good contact between the frame and the holder is obtained by tightening with a screw at (F). The cell is connected to a vacuum pump *via* (G). When the pressure was maintained below 0.5 mm Hg, no fogging of the windows could be detected after approximately 100 runs. The following procedure was used to control the effectiveness of the cell. A copper-constantan thermocouple was embedded in powdered KBr and pressed into the disc. When liquid air was introduced in the container by means of a siphon the temperature sank rapidly reaching an equilibrium value of $-170°$ after approx. 8 minutes and it remained constant as long as the reservoir contained liquid air.

Cu^{++} and Ni^{++} chelates were prepared by mixing aqueous solutions of Na salts of amino acids with solutions of $CuCl_2$ and $NiCl_2$, respectively. The water-soluble chelates were recrystallized from water, the insoluble chelates washed extensively with water and alcohol. The Pt^{++} chelates were prepared from K_2PtCl_4 and glycine according to Refs [11,12]. The *cis* and *trans* forms were separated by fractional crystallization.

RESULTS OF THE ABSORPTION MEASUREMENTS

In order to illustrate the effect of low temperature on the IR absorption, the IR spectra of a group of substances were recorded both at room temperature and at —170°. The substances were deliberately chosen among those closely related to the compounds which were to be investigated. The effects obtained vary with different substances. Figs. 2 and 3 show two possibilities

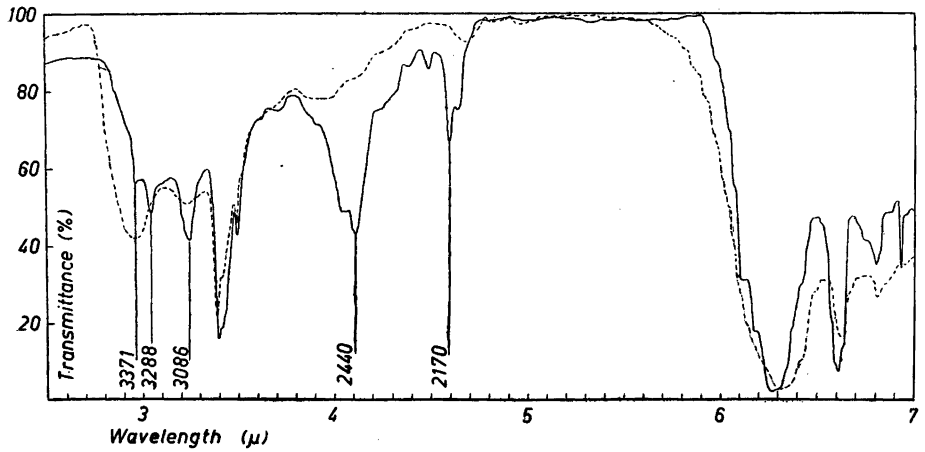

Fig. 3. IR absorption of Na+ leucine.
..... *at 25°*
——— *at —170°*

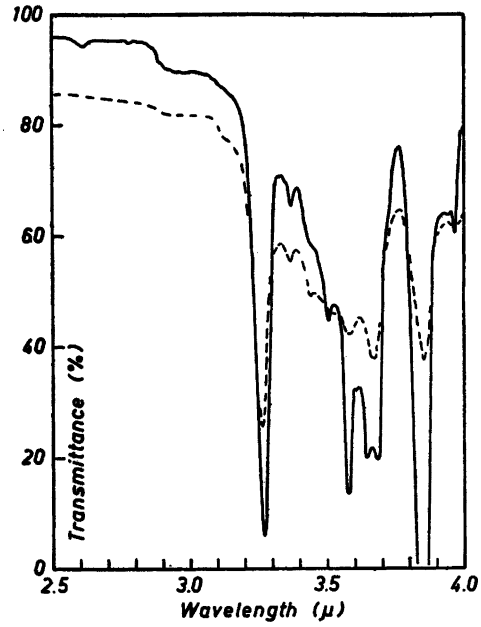

Fig. 4. IR absorption of DL-*alanine.*

..... *at 25°*
——— *at −170°*

of an extreme nature. $EDA_2Cu \cdot CuCl_4$ (Fig. 2), prepared according to Chattaway and Drew [10], shows a simple and well-defined spectrum already at normal temperatures. The only effects obtained by the low temperature were the splitting of one band into two at 3 129 cm^{-1} (3.196 μ) and 3 114 cm^{-1} (3.211 μ) besides the narrowing of the 1 567 cm^{-1} (6.380 μ) band. In sharp contrast stands the behaviour of Na DL-leucine (Fig. 3) where the effects are considerable. The NH_2 bands at 3 371 cm^{-1} (2.966 μ) and 3 288 cm^{-1} (3.041 μ) emerge from a broad band of continuous absorption. The bands at 3 086, 2 440 and 2 170 cm^{-1} (3.240, 4.10 and 4.61 μ) are most likely due to water molecules present in the crystals as these bands vanish completely after heating to 120° over P_2O_5. The NH_2 bands remain unperturbed with the exception of a slight shift. That the effects obtained by the low temperature are not entirely due to the presence of water molecules is shown by Figs. 4 and 5, displaying the IR absorption spectra of DL-alanine and glycylglycine from 2.5 μ to 4 μ. In this connection it is of interest to note that while the absorption bands due to the NH_3^+ group of glycylglycine at 3 047 cm^{-1} and 2 990 cm^{-1} (3.282 and 3.344 μ) scarcely show any shifts due to the temperature change, the band at 3 296 cm^{-1} (3.034 μ) ascribed to the NH of the amid linkage shows a shift of approximately 25 cm^{-1} towards lower wavenumbers.

Before further discussion some words ought to be said about the effects due to moisture. As it is difficult to keep KBr powder absolutely dry and as

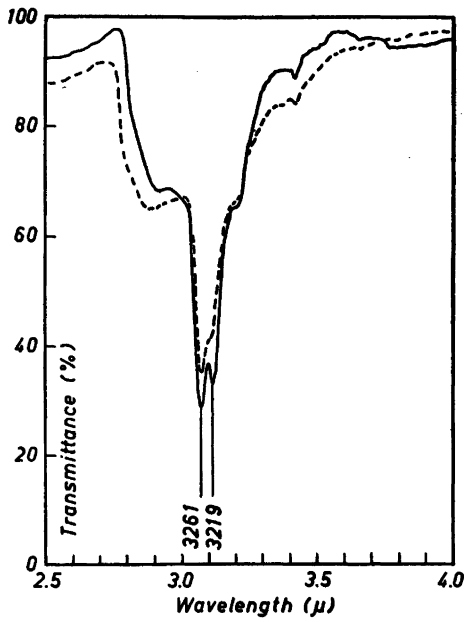

Fig. 6. IR absorption of $KPt^{++}Cl_2$ glycine.
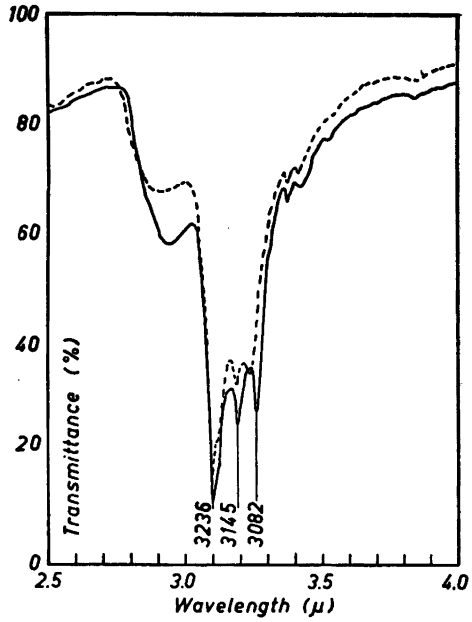
..... *at 25°*
——— *at −170°*



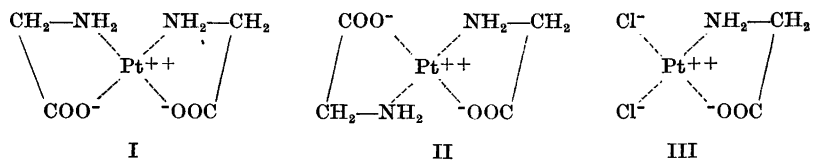


Fig. 7. IR absorption of Pt^{++} glycine$_2$(cis).
..... *at 25°*
——— *at −170°*

during the low-temperature run a certain amount of water vapour condenses on the KBr disc, a relatively weak and broad absorption appears at 2.95 μ (3 400 cm^{-1}). This kind of absorption has very little effect on the sharp and well defined bands of NH_2 and no special effort was made to compensate for it.

In general all the metal-amino acid chelates investigated showed different and highly individual absorptions in the "fingerprint region" (8—15 μ). As the purpose of this investigation was to study the behaviour of NH_2 and COOH groups the discussion is limited to the regions around 3 and 6 μ where well-defined absorption bands of these groups appear. The first question to be answered was if the difference between geometric isomers of the same chelate has any influence on the IR absorption of NH_2 and COOH vibrations. For this purpose the three possible forms of Pt^{++} glycine chelates were prepared according to Grünberg and Pitzyn [11] and Ficken and Ley [12]. Figs. 6—8 show the IR absorption in the 3 μ region of Pt^{++} glycine$_2$*cis* (I), Pt^{++} glycine$_2$*trans* (II) and $KPt^{++}Cl_2$-glycine (III).

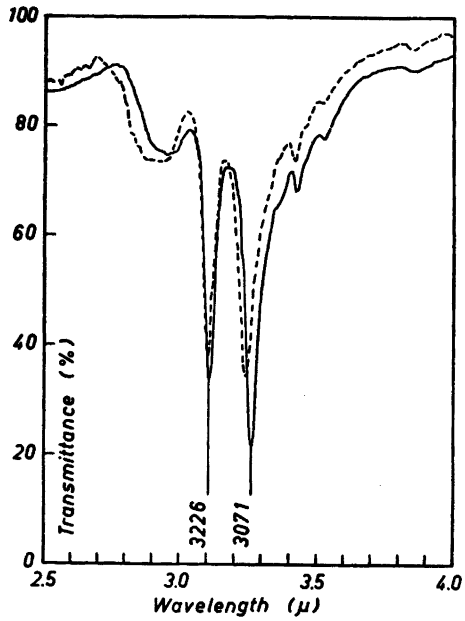

Fig. 8. IR absorption of Pt++ glycine$_2$ (trans).
..... *at 25°*
——— *at −170°*

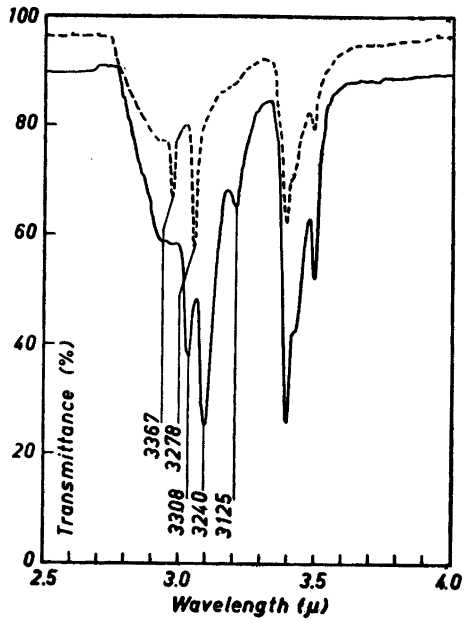

Fig. 9. IR absorption at −170° of
..... *Ni++ leucine$_2$*
——— *Cu++ leucine$_2$*

Low-temperature values are given in Table 2 as the absorption curve of monoglycine shows inadequate resolution at normal temperatures.

Table 2.

	NH_2 frequencies in wavenumbers (cm^{-1})		
$KPt^{++}Cl_2$-glycine	3 261	3 219	
Pt^{++}-diglycine *cis*	3 236	3 145	3 082
Pt^{++}-diglycine *trans*	3 226	3 071	

The same kind of differences are present in the 6 μ region. Here both the *mono* and *trans* chelates display a well-defined absorption band of great intensity at 1 655 cm^{-1} (6.04 μ) and 1 644 cm^{-1} (6.08 μ), respectively. These bands are naturally not as sharp as those in the NH region so that an uncertainty of $\pm$ 5 cm^{-1} must be taken into account. They can with certainty be ascribed to the carboxyl group. The NH bending mode is found at 1 582 cm^{-1} (6.321 μ) for the *mono*chelate and at 1 608 cm^{-1} (6.220 μ) for the *trans* isomer of the dichelate. The *cis* form displays a broad band of overlapping carbonyl frequencies with distinct maxima at 1 681 (5.95 μ) 1 661 cm^{-1} (6.02 μ) and 1 639 cm^{-1} (6.10 μ). The region of NH bendings also shows two peaks at 1 610 cm^{-1} (6.208 μ) and 1 570 cm^{-1} (6.370 μ), respectively. These perturbations in the

spectrum are not due to the presence of water molecules since the spectrum remains unchanged after the substance is dried at 120° over P_2O_5. The same conclusion can be drawn from the analytical data. The next step was to investigate the influence of different metal ions on the NH_2 and COOH frequencies. The presence of water molecules in most of the Cu^{++} and Ni^{++} chelates greatly complicates the spectra. Although these effects can be reduced by drying it seemed advisable to avoid such complications in the beginning. For this reason the salts of DL-leucine with Na^+, Ni^{++} and Cu^{++} were compared. Both the Cu^{++} and Ni^{++} chelates of leucine contain no water, the spectrum remaining unchanged after heating over P_2O_5. Fig. 9 presents the IR absorption of Ni^{++} and Cu^{++} chelates of DL-leucine. The NH_2 frequencies of Ni^{++}, Cu^{++} and a dried sample of Na^+ leucine are presented in Table 3.

All the values in Table 3 are low-temperature values. As the low temperature curves of Ni^{++} and Cu^{++} chelates showed no shifts of absorption bands when compared to the curves at normal temperature, Fig. 9 shows only one, the low-temperature curve of each substance. The IR spectra of glycine and alanine chelates in this region are rather complicated due to hydration. That water molecules itself may possess, well defined and sharp bands in the neighbourhood of 3 μ can conveniently be demonstrated by the IR absorption spectrum of KMg-nitrilotriacetic acid prepared according to Schwarzenbach [13]. This salt of a substituted amino acid has no NH or OH groups of its own. But as it crystallizes with several molecules of water the IR spectrum shown in Fig. 10 has several sharp absorption peaks reminding of the frequencies of NH_2. The different absorption curves of Cu^{++} $glycine_2$ are shown in Fig. 11. It is difficult to decide without further investigations if the absorption maximum at 3 333 cm^{-1} (3.000 μ) being NH frequency is shifted to 3 248 cm^{-1} (3.045 μ) after drying or if this frequency belongs to the water of hydration. The behaviour of Cu^{++}DL-$alanine_2$ is analoguous. The spectra of dried substances, however, show the same kind of differences with varying metal ions as leucine chelates. For exampel Ni^{++} $alanine_2$ has its NH_2 frequencies at 3 361 cm^{-1} (2.975 μ) and 3 284 cm^{-1} (3.045 μ) whereas the Cu^{++} chelate of alanine shows

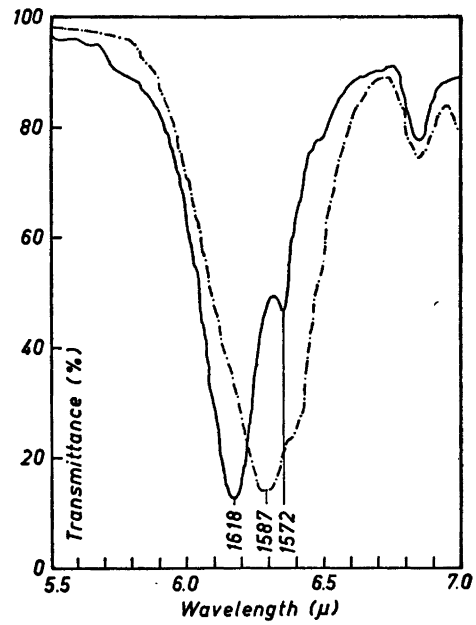

Fig. 14. IR absorption at −170° of Cu^{++} *alanine*$_2$ ———— Ni^{++} *alanine*$_2$ —·—·—·

two strong bands at 3 263 and 3 231 cm^{-1} (3.065 and 3.095 μ) with an additional weak band at 3 145 cm^{-1} (3.180 μ).

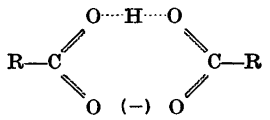
The behaviour of the carboxyl frequencies at about 6 μ of different salts of DL-leucine is demonstrated by Fig. 12. The general picture resembles that of NH_2 stretchings. The Ni^{++} chelate shows a frequency practically identical with the frequency of the Na^+ salt whereas the carboxyl absorption band of the Cu^{++} chelate is shifted towards higher wavenumbers. The water of crystallization in Ni^{++} and Cu^{++} chelates has an effect, even more pronounced than in the 3 μ region. Fig. 13 shows the absorption bands of Cu^{++} glycine$_2$ before and after drying. The four distinct peaks present yield when the chelate is dried a single intense band at 1 618 cm^{-1} (6.18 μ) with a shoulder at 1 582 cm^{-1} (6.32 μ) probably due to the NH bending. These changes are reversible and the original spectrum can be restored through recrystallization from water. These water effects were probably the reason why Sen *et al.*[5] only observed one broad band between 1 639 and 1 563 cm^{-1} (6.10 and 6.40 μ) for Cu^{++} and Ni^{++} chelates of glycine. The differences between Ni^{++} and Cu^{++} chelates are further illustrated by Fig. 14 which shows the spectra of dried chelates of DL-alanine. The behaviour of the carboxyl frequencies of Na salts and water-free chelates is summarized in Table 4.

Table 4. The carboxyl frequency in wavenumbers (cm^{-1}).

Na^+ leucine	1 590	Na^+ glycine	1 588	Na^+ alanine	1 590
Ni^{++} leucine$_2$	1 590	Ni^{++} glycine$_2$	1 587	Ni^{++} alanine$_2$	1 587
Cu^{++} leucine$_2$	1 618	Cu^{++} glycine$_2$	1 618	Cu^{++} alanine$_2$	1 618

The Cu^{++} chelates of valine, sarcosine, proline and serine showed the same position of the carboxyl frequency which confirms the conclusion that the shift to 1 618 cm^{-1} seems to be characteristic of Cu^{++} chelates.

The frequencies of NH_2 and COOH were unchanged when L-amino acids were used instead of DL-acids.



DISCUSSION

When compared to the NH_2 frequencies of Na glycine at 3 400 and 3 360 cm^{-1} (2.941 and 2.975 μ) all the chelates of Pt^{++} show a definite shift towards lower wavenumbers. The slight trend of NH_2 frequencies from *mono* to *trans* form can be explained by the assumption that the *trans* form is most favourable for the formation of a symmetric bond structure. Another feature of interest here is the fact that the *cis* form shows a far more complicated spectrum than the *trans* form. There is more than one plausible explanation for this. In the first place the stretching vibrations of NH_2 groups may be coupled due to a rigid structure and as the *trans* form is more symmetrical some of its vibrations may be IR-inactive. Another possibility is that due to the unsymmetrical position of the chelate forming groups the bonds formed by the two NH_2 groups with the metal ion are not identical. Even a change in the system of hydrogen bonds between NH_2 and the oxygen of the carboxyl group between different molecules of the chelate may render a possible explanation. The existence of such a system of hydrogen bonds has been demonstrated by Stosick [14]. The NH_2 groups of Cu^{++} and Ni^{++} chelates show differences in position of frequencies resembling those of the different forms of Pt^{++} glycine chelates. The NH_2 frequencies of Cu^{++} chelates are found at lower wavenumbers than the frequencies of Ni^{++} chelates. This, together with the fact that Pt^{++} chelates have their NH_2 frequencies at still lower wavenumbers, may indicate that the magnitude of the shift towards lower wavenumbers is dependent on the strength of the covalent linkage between nitrogen and metal ion. The pattern of NH_2 frequencies together with the single and well-defined carboxyl group frequency when compared with the different forms of Pt^{++} glycine, support the conclusion from the X-ray work of Stosick [14] that the Cu^{++} and Ni^{++} chelates with amino acids are the *trans* forms of the coplanar structure. This conclusion is naturally valid only for the dehydrated forms of glycine and alanine chelates. The behaviour of the carboxyl frequency is of special interest. Previous investigators [5] came to the conclusion that the carboxyl group retains its ionic character and does not partake in bond formation with the central metal ion. If this were the case the carboxyl frequency should lie unchanged at approx. 1 590 cm^{-1} as in salts with alkali metals. This is the case with Ni^{++} chelates. Cu^{++} and Pt^{++} chelates, on the other hand, do show a definite shift. The behaviour of the carboxyl frequency with different metals can be summarized for glycine chelates.

Na^{+} glycine 1 590 cm^{-1}, Ni^{++} $glycine_2$ 1 590 cm^{-1}, Cu^{++} $glycine_2$ 1 618 cm^{-1}, Pt^{++} $glycine_2$ (*trans*) 1 644 cm^{-1}. This gives a shift of 28 cm^{-1} for the Cu^{++} chelate and of 54 cm^{-1} for the Pt^{++} chelate.

It is suggested that a shift of this magnitude and direction can be correlated with covalent bond formation. A parallel case is that of K acetate and

acetic acid. K acetate and acetic acid form, when present in equimolar amounts a wellknown addition compound. For this investigation the addition compound between chloroacetic acid and K chloroacetate was used as the acid in this case is crystalline and the separation of the addition compound is simple. Pure chloroacetic acid shows a carboxyl frequency at 1 735 cm^{-1} and the K-salt the normal frequency for ionized carboxyl at 1 590 cm^{-1}. The addition compound showed no trace of either of these bands. The only band present in this region was an intense band at 1 645 cm^{-1}. It is doubtful that the structure in question may be represented by a configuration involving a symmetrical H-bond (IV),

IV

but that the carboxyl groups in this case are connected through covalent bonds with a H atom is very plausible. Thus it seems probable that the shift of the carboxyl group frequency observed with Cu^{++} and Pt^{++} chelates really indicates that the carbonyl group partakes in bond formation with the central metal ion, while in the Ni^{++} chelates it shows no such tendency. This is naturally restricted to the crystalline state as the situation in aqueous solutions may be different due to the fact that the water molecules can to a certain extent replace the carboxyl groups in bond formation with the central ion. Likewise it is clear that the results are valid only for the waterfree chelates as the role played by water molecules is not sufficiently elucidated.

The Crystal Structure of Mercury(II)oxide Studied by X-Ray and Neutron Diffraction Methods

KARIN AURIVILLIUS

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden; Joint Establishment for Nuclear Energy Research, Kjeller, Norway

The crystal structure of mercury(II)oxide has been investigated by X-ray and neutron diffraction methods. The symmetry has been found to be *Pnma* (No. 62) and the unit cell twice the one reported by previous authors. The positions of the mercury and oxygen atoms have been determined. The structure is built up of infinite, planar zig-zag chains —O—Hg—O— running parallel to the *a*-axis and lying in the *ac* plane. Within the chains the Hg—O distance is 2.03 ± 0.10 Å and the angles O—Hg—O and Hg—O—Hg 179° ± 3° and 109° ± 1°, respectively.

In connection with studies of the crystal chemistry of mercury in various mercury oxide halides [1], knowledge of the mercury-oxygen distance was of fundamental importance for the discussion of the spatial arrangement of the atoms. No exact value of this distance could be obtained from the literature and it was thus found appropriate to undertake a detailed investigation of the crystal structure of mercury(II)oxide.

A previous study of this substance carried out in 1927 by Zachariasen [2] by means of X-ray powder photographs indicated an orthorhombic structure with the unit cell dimensions $a = 3.303$ Å, $b = 3.520$ Å, $c = 5.515$ Å.

The following positions of the mercury atoms were given:

Space group *Pmmn*, No. 59 *, 2 Hg in 2(*a*): 0, 0, z; $\frac{1}{2}$, $\frac{1}{2}$, $\bar{z}$; $z \sim \frac{1}{4}$
or space group $Pmn2_1$, No. 31*, 2 Hg in 2(*a*): 0, y, z; $\frac{1}{2}$, $\bar{y}$, $\frac{1}{2}+z$; $y \sim \frac{1}{4}$ $z = \frac{1}{4}$

Three possible arrangements for the oxygen atoms were discussed but it was not possible to decide between them. The mercury-oxygen distances were 2.15 Å for two of the alternative structures and 2.41 Å for the third.

The considerable difference in scattering power for X-rays between mercury and oxygen makes it almost a hopeless enterprise to locate the latter atoms in mercury(II)oxide. On the other hand the relative scattering power

* Notations rearranged to conform with *International Tables for X-ray Crystallography*, Birmingham 1952.

of the two elements for neutrons is much more favourable. The author was thus very happy in having the privilege of performing a neutron diffraction study at the *Joint Establishment for Nuclear Energy Research*, Kjeller, Norway, in addition to the X-ray investigation performed at the University of Stockholm.

X-RAY DIFFRACTION STUDIES

For the X-ray studies, three samples of various origins were used, *viz.* commercial mercury(II)oxide (Baker's Analysed), a sample obtained by carefully heating mercury(II)nitrate in air and naturally occurring montroydite from Terlingua, Texas. All the samples gave identical powder photographs. Tiny rods and thin plates were observed in the samples of the synthetic materials while the natural substance showed only rods. The registering of single crystal reflexions was accompanied by considerable difficulties, due to the extreme delicacy of the crystals. The very slight mechanical stress applied when mounting the crystals often gave rise to serious damage noticeable by the occurrence of multiple spots or even powder lines in the Weissenberg photographs. In some cases, however, it was possible to register the diffraction patterns of obvious single crystals and all calculations were based on data obtained in this way.

CELL DIMENSIONS AND SPACE-GROUP

The powder photographs were taken in a Guinier focussing camera of 80 mm diameter using monochromatic Cu-$K\alpha_1$ radiation and potassium chloride ($a = 6.2930$ Å[3]) added as an internal standard. The powder pattern is given in Table 1. Normally exposed photographs (30 minutes) were found to be in fair agreement with that given by Zachariasen but, in amply exposed ones (3 hours), several extra lines were found which were also observed in single crystal photographs (see below). The unit cell was thus found to have the dimensions $a = 6.612_1$ Å, $b = 5.520_1$ Å, $c = 3.521_3$ Å, corresponding to a doubling of the a axis of the orthorhombic cell reported by Zachariasen.

The observed density of 11.3 indicates a cell content of 4 formula units of HgO per unit cell. The calculated density is 11.2.

Cu-K radiation was used for the single crystal photographs. Rotation diagrams were taken around all the three axes and also Weissenberg photographs registering the reflexions $h0l$—$h3l$, $0kl$—$3kl$, $hk0$—$hk3$. Weak interspacing layer lines in the rotation photograph around [100] showed the a axis to be twice that reported by Zachariasen. This was confirmed by the powder patterns (see above) and by the Weissenberg photographs. The layer line $1kl$ showed no less than 4×18 reflexions.

The Laue symmetry mmm was confirmed. The following spectra were systematically missing: $0kl$ with $k+l =$ odd and $hk0$ with $h =$ odd, which is characteristic of the space groups No. 33, $Pn2_1a$ * and No. 62, $Pnma$.

* Orientation analogous to that of No. 62 but different from that given in the *International Tables*.

* $I_{calc} = 6.25 \cdot 10^{-3}(pF^2)_{calc}$.

The intensities of the reflexions, which were visually estimated, were considerably influenced by the high absorption in the crystal. Unfortunately, a source of harder radiation than Cu-K radiation was not available at that time. Attempts to cut or grind the crystals to a cylindrical form were not successful due to the extreme delicacy of the material (*cf.* above). However, the absorption was minimized by using as small crystals as possible.

POSITIONS OF THE MERCURY ATOMS

The projections *P(pvw)*, *P(uvp)* and *P(upw)* of the Patterson function were calculated on the basis of F^2 values derived in the usual way. The maps thus obtained were of a rather simple appearance, indicating the existence of the heavy maxima listed in Table 2.

Table 2. Observed maxima in the Patterson functions.

u	v	w	Relative weight obs.	calc.
$\frac{1}{2}$	0	0	2.0	2
$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{2}$	2.0	2

In the space-groups $Pn2_1a$ and *Pnma*, the following positions are possible for the four mercury atoms:

$Pn2_1a$: 4(a): $x, y, z;\ \bar{x}, \frac{1}{2}+y, \bar{z};\ \frac{1}{2}-x, \frac{1}{2}+y, \frac{1}{2}+z;\ \frac{1}{2}+x, y, \frac{1}{2}-z$

Pnma: 4(a): 0,0,0; $0,\frac{1}{2},0$; $\frac{1}{2},0,\frac{1}{2}$; $\frac{1}{2},\frac{1}{2},\frac{1}{2}$

4(b): $0,0,\frac{1}{2}$; $0,\frac{1}{2},\frac{1}{2}$; $\frac{1}{2},0,0$; $\frac{1}{2},\frac{1}{2},0$

4(c): $x,\frac{1}{4},z;\ \bar{x},\frac{3}{4},\bar{z};\ \frac{1}{2}-x,\frac{3}{4},\frac{1}{2}+z;\ \frac{1}{2}+x,\frac{1}{4},\frac{1}{2}-z$

All the maxima of Table 2 are undoubtedly due to mercury-mercury interactions. This excludes the possibility that the positions 4(a) and 4(b) in *Pnma* are the sites of the metal atoms.

If the mercury atoms occupy the point positions 4(a) in $Pn2_1a$ or 4(c) in *Pnma*, the following set of interatomic vectors will occur in the Patterson function in addition to the trivial peak at the origin (Table 3).

Table 3. Expected maxima in the Patterson functions.

u	v	w	Relative weight
$\pm 2x$	$\frac{1}{2}$	$\pm 2z$	1
$\pm(2x \pm \frac{1}{2})$	$\frac{1}{2}$	$\frac{1}{2}$	2
$\frac{1}{2}$	0	$\pm(2z \pm \frac{1}{2})$	2

A comparison of this set of vectors with the Patterson function derived from experimental data immediately gives the following approximate parameter values:

$Pn2_1a$: 4 Hg in 4(a): $x = \frac{1}{8}$ and $z = \frac{1}{4}$

Pnma: 4 Hg in 4(c): $x = \frac{1}{8}$, $y = \frac{1}{4}$, $z = \frac{1}{4}$.

The y parameter for the former space-group may be arbitrarily chosen equal to $\frac{1}{4}$ — the two possibilities will thus become identical, making possible the use of the second space group with its higher symmetry.

The approximate arrangement of the metal atoms thus derived is actually bodycentered with the symmetry identical with that proposed by Zachariasen [2]. However, it does not account for several reflexions observed in the Weissenberg diagrams, *e. g. hkl* with $h = 2n + 1$ and $h0l$ with $\frac{h}{2} + l = 2m + 1$ (n, m are integers). The F^2 values of these reflexions are too high to be ascribed only to the influence of the oxygen atoms. The parameters of the mercury atoms must thus be somewhat different from the values given above. By trial methods it was found that a slight shift of the metal atoms to the position (I) with $x = 0.115$ and $z = 0.245$ (or, which is equivalent, (II) with $x = 0.115$ and $z = 0.255$) was enough to give a better agreement between observed and calculated X-ray intensities (*cf.* Table 4). The former alternative (I) was arbitrarily chosen as giving the sites of the mercury atoms.

NEUTRON DIFFRACTION STUDIES

A comparison of the coherent scattering amplitudes of the mercury and oxygen atoms for neutrons and for X-rays shows the great advantage in investigating mercury(II)oxide by neutron diffraction.

Scattering amplitude (10^{-12} cm)[4]

	Neutron	X-ray ($\Theta = 0°$)
Hg	1.31	22.5
O	0.58	2.25

While the amplitude values for neutrons are independent of the scattering angle, those for X-rays decrease with Θ—relatively more so for oxygen than for mercury.

Due to the relatively low neutron flux of the pile, which was run at an effect of 200—250 kW, it was necessary to use a large single crystal. A beautiful crystal of montroydite ($1.5 \times 1.5 \times 14$ mm) from Terlingua in Texas was kindly lent by Drs. W. F. Foshag and G. Switzer, Smithsonian Institution, U.S. National Museum, Washington, D. C. The absorption of the radiation in the crystal was neglected for the wavelength of 1.01 Å applied. X-Ray photographs confirmed that this specimen is a single crystal.

The crystal was mounted in a thinwalled glass capillary tube to prevent mechanical injury and oriented on the spectrometer table with rotation around the longest edge (the a direction). With the strongest reflexion 020 as a starting point, the diffraction peaks of the reflexions $0kl$ were measured at counter intervals of 0.5° scattering angle. The monitor counter serving as a measure of the incident monochromatic beam intensity was set at 40 000 counts for the weaker reflexions and 20 000 for the stronger ones. The ap-

pearance of the curves obtained by plotting the intensities against the angles is given in Fig. 1. The observed intensities obtained by measuring the areas under the peaks with a planimeter and corrected for the Lorentz factor are given in Table 5. Because of the mechanical arrangement of the

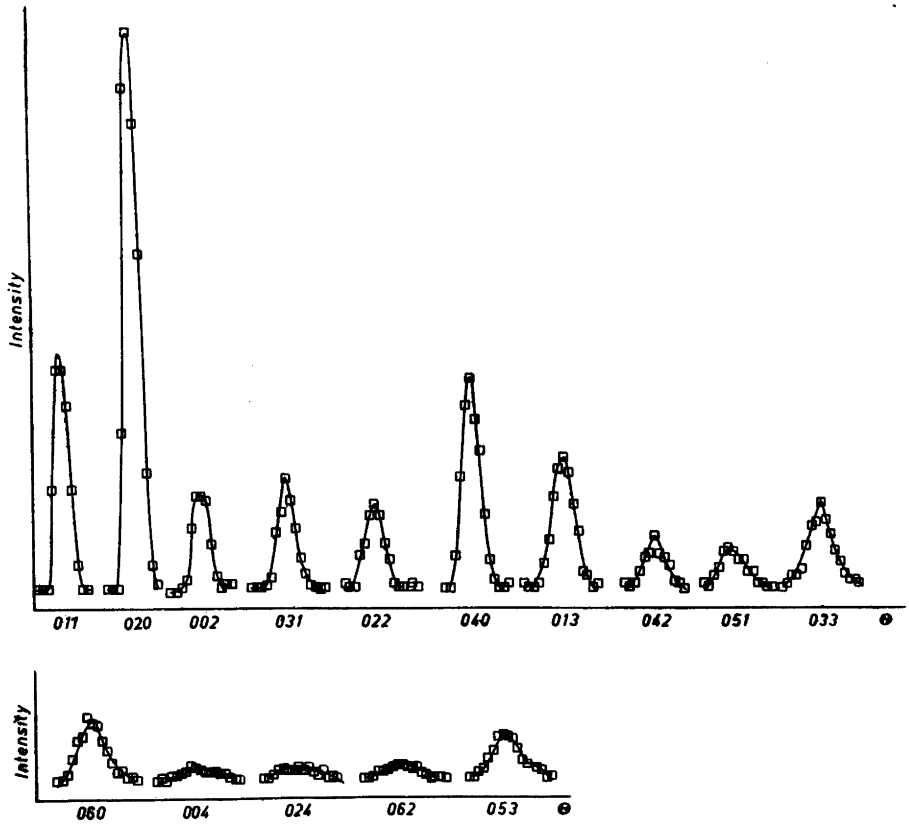

Fig. 1. Neutron reflexions 0kl *from the single crystal investigation. Counts for angular intervals of 0.5°.*

apparatus it was only possible to measure the intensities of the reflexions of the 0*kl* layer line.

Neutron diffraction powder diagrams were also taken using both a cylindrical and a flat container for the sample.

Positions of the oxygen atoms

On the basis of the neutron reflexions 0*kl* from the single crystal diagram, the projection $P(pvw)$ of the Patterson function was calculated. As the degree of mosaic character of the crystal was not known, the two extreme possibilities, *viz.* that the observed intensities are proportional to F^2 or to $|F|$, were considered. The Patterson functions derived from these two assumptions were, however, found to be of a closely similar character. The positions of the maxima were thus exactly the same in both cases and the relative heights were only moder-

ately different. The appearance of $P(pvw)$ calculated on the basis of $F^2(0kl)$ is given in Fig. 2. The mercury-mercury vector is superimposed on the origin maximum in this picture. The discussion of the oxygen arrangement is based on the positions of the mercury atoms derived from the X-ray investigation described above. The following sets of projections of the mercury-oxygen vectors correspond to the possible arrangements of the four oxygen atoms in the space-groups $Pn2_1a$ and $Pnma$.

	Mercury-oxygen vectors v	w	Relative weight obs.	calc.
$Pn2_1a$: 4 O in 4(a):	$\frac{1}{4}-y$	$\pm(0.245-z)$	1	1
	»	$\pm(0.255-z)$	1	1
	$\frac{3}{4}-y$	$\pm(0.245+z)$	1	1
	»	$\pm(0.255+z)$	1	1
Pnma: 4 O in 4(a) or 4(b):	$\frac{1}{4}$	$\pm$ 0.255	—	1
	»	$\pm$ 0.245	—	1
	$\frac{3}{4}$	$\pm$ 0.255	—	1
	»	$\pm$ 0.245	—	1
Pnma: 4 O in 4(c):	0	$\pm(0.245-z)$	1	1
	»	$\pm(0.255-z)$	1	1
	$\frac{1}{2}$	$\pm(0.245+z)$	1	1
	»	$\pm(0.255+z)$	1	1

Since the maxima of $P(pvw)$ only occur at $v = 0$ and $\frac{1}{2}$, the y parameter of the oxygen atoms must be $\frac{1}{4}$ which excludes alternatives *Pnma*, 4(a) and 4(b) for the arrangement of the oxygen atoms. It also makes the two alternatives

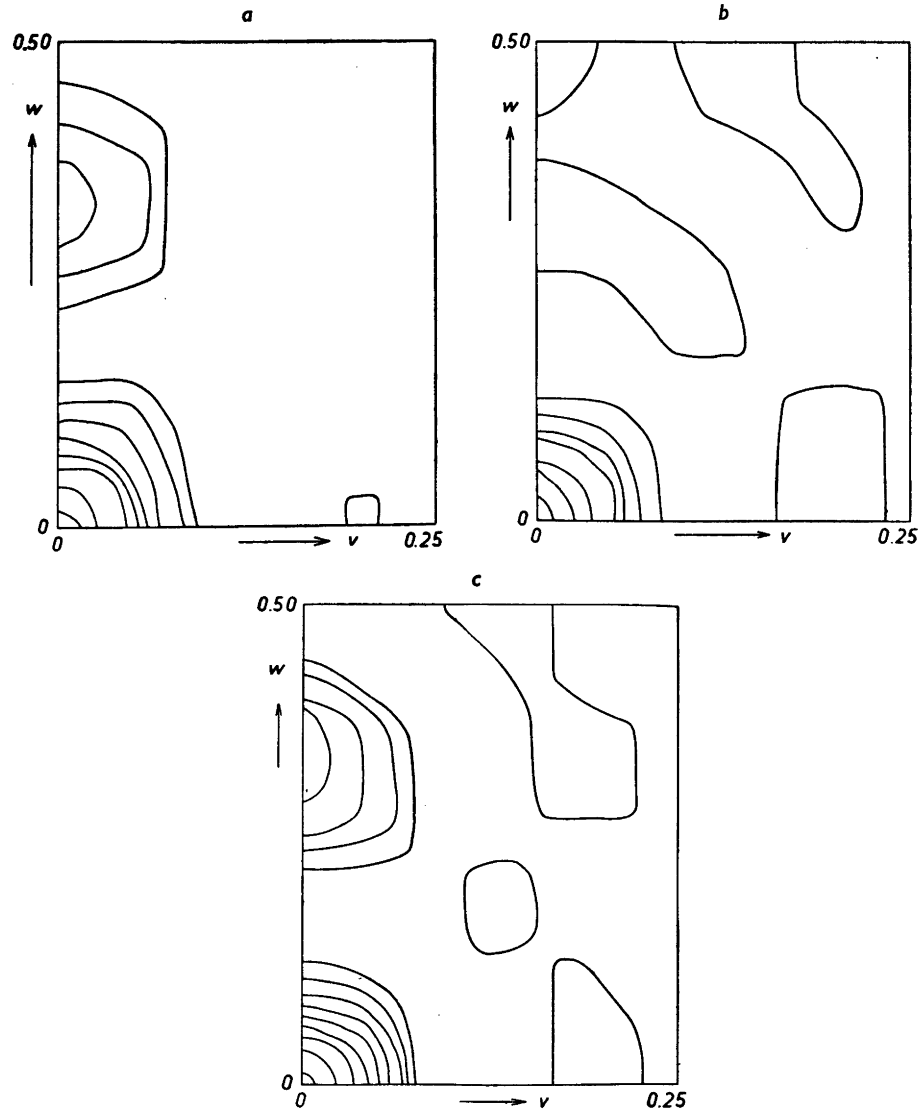

Fig. 2. a) The Patterson function P(pvw) *based on observed neutron intensities* 0kl, *b)* P(pvw) *based on calculated values* $(A_{Hg} \cdot b_{Hg})^2$, *c)* P(pvw) *based on calculated values* $(A_{Hg} \cdot b_{Hg} + A_O \cdot b_O)^2$ (cf. *Ref. 4)*

$Pn2_1a$, 4(*a*) and *Pnma*, 4(*c*) coincide and evidently shows that the structure of mercury oxide has the symmetry *Pnma* at least as far as can be judged from the present experimental data.

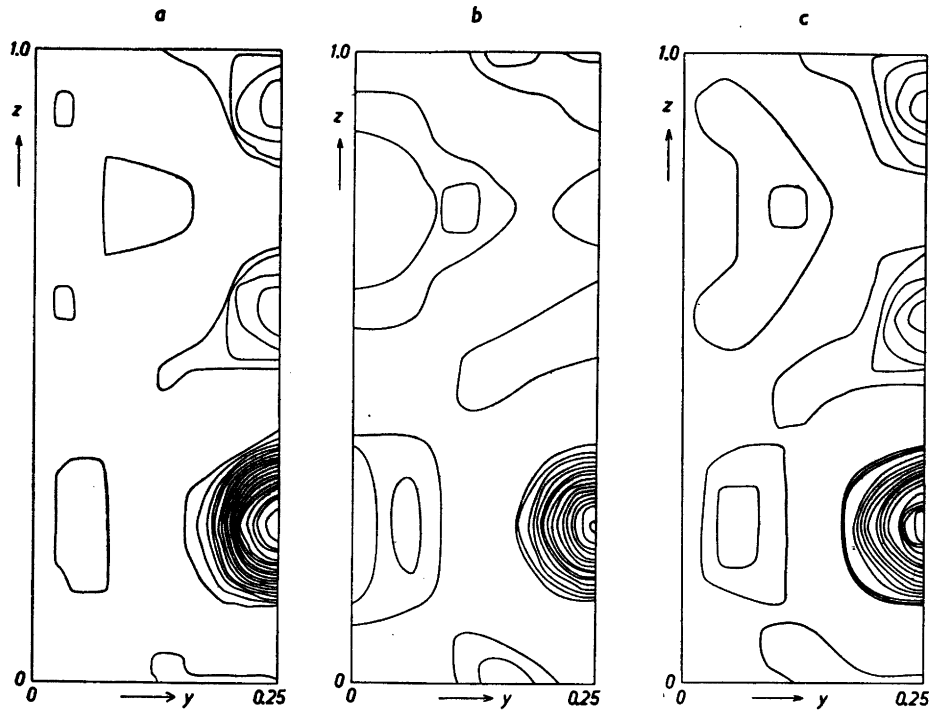

Fig. 3. a) The Fourier projection ϱ(pyz) *based on neutron intensities* 0kl *(the observed intensity considered proportional to* F^2*),*
b) ϱ(pyz) *based on calculated values* $A_{Hg} \cdot b_{Hg}$,
c) ϱ(pyz) *based on values* $A_{Hg} \cdot b_{Hg} + A_O \cdot b_O$.

The mercury-oxygen peaks in $P(pvw)$ at $v = 0$, $w = \frac{1}{3}$ give the following two alternatives for the arrangement of the oxygen atoms:

$$A: \quad 4\ \mathrm{O}\ \text{in}\ 4(c): \quad x,y = \tfrac{1}{4},\ z = 0.58$$
$$B: \quad 4\ \mathrm{O}\ \text{in}\ 4(c): \quad x,y = \tfrac{1}{4},\ z = 0.92$$

Due to the slight displacement of the mercury atom positions from ($x = \frac{1}{8}$, $y = \frac{1}{4}$, $z = \frac{1}{4}$) with $|\Delta x| = 0.010$ and $|\Delta z| = 0.005$, these two alternatives are not identical. However, the difference between them is not big enough to affect the signs of the structure factor values $F(0kl)$ for neutron diffraction. The projection of the electron density function $\varrho\ (pyz)$ thus derived, on the assumption that the observed intensity is proportional to F^2, is represented in Fig. 3. The mercury maximum in this projection (corresponding to two superimposed atoms) appears in $y = 0.250$, $z = 0.250$ and the oxygen maxima in $y = 0.250$, $z = 0.585$ and $z = 0.915$ respectively. Functions $P(pvw)$ based on F^2 $(0kl)$ values and $\varrho\ (pyz)$ based on $F(0kl)$ values calculated for the mercury atoms only and also for both the mercury and oxygen

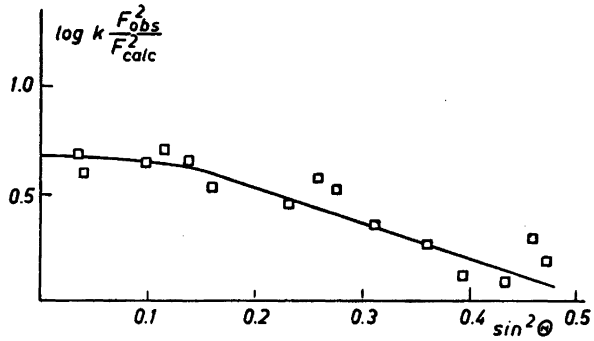

Fig. 4. Temperature correction curve. Log $k \frac{F^2_{obs}}{F^2_{calc}}$ *plotted against* $\sin^2\Theta$.

atoms in the positions derived above are of reasonable appearance with the heights and positions of the various maxima in accordance with those of the experimentally derived functions (*cf.* Figs. 2 and 3).

Calculated and observed neutron intensities $0kl$ are given in Table 5. For each reflexion a temperature factor correction was calculated from the curve in Fig. 4. The reliability index

$$R = \frac{\Sigma \| F_{obs}| - |F_{calc} \|}{\Sigma |F_{obs}|}$$

was calculated to be 6.8 %.

CORRELATION OF X-RAY AND NEUTRON DIFFRACTION DATA

The intensities of the $1kl$ X-ray reflexions were found to be greatly influenced by the oxygen atom positions and allowed a decision to be made between the two alternatives *A* and *B* for the oxygen atom arrangement. As a matter of fact, only *A* was found to be compatible with the arbitrarily chosen position I for the mercury atoms. However, the structure thus obtained was identical with the combination of the mercury arrangement II with the oxygen arrangement *B*.

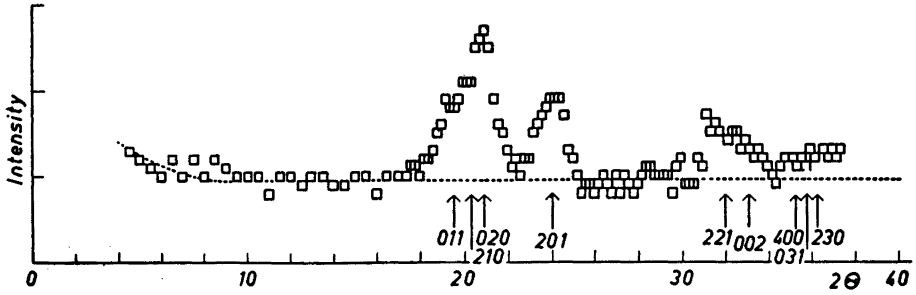

Fig. 5. Neutron diffraction powder diagram of a sample of HgO in a flat container.

Table 6. Observed and calculated neutron intensities of a few reflexions from a powdered sample of HgO.

I. Flat sample. II. Cylindrical sample.

Calculations according to G. E. Bacon, *Neutron Diffraction*, Oxford 1955.

hkl	I		II	
	F^2_{obs}	F^2_{calc}	F^2_{obs}	F^2_{calc}
011	58	35	114	75
210		16		34
020	49	50	103	108
201	49	55	118	118

The accuracy of the resolution of the area under the first observed peak into its components, the reflexions 011, 210, and 020 may be rather low. The separate intensities have not been used for any further calculation.

Systematic variation of the x parameter of the oxygen atom position gave the best agreement between observed and calculated structure factor values for adjacent reflexions of comparable absorption when x_O was equal to 0.36 ± 0.02 (*cf.* Table 4).

The spots in the Weissenberg photograph $3kl$ were highly elongated. It was not possible to estimate their intensities with the accuracy needed for quantitative calculations.

Due to the considerable absorption for several reflexions, the R-index for the X-ray data lacks significance.

The atomic positions thus derived are in accordance with the neutron diffraction powder diagrams. The low resolution of the latter, however, makes these diagrams less reliable than the X-ray data for the determination of the parameter values (*cf.* Fig. 5 and Table 6).

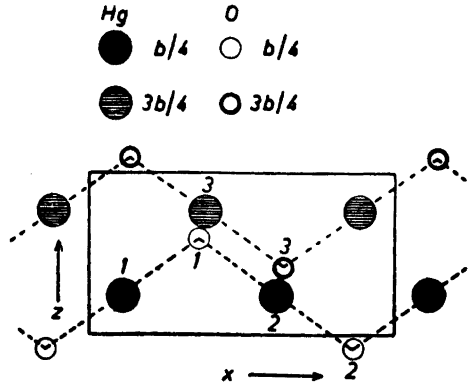

Fig. 6. xz *projection of the structure of HgO. The diagram shows the coordination of the atoms. The small circles show the O atoms and the larger ones the Hg atoms. The distances Hg→Hg, Hg→O and O→O are listed in the text. The dotted lines indicate the bonds of one zig-zag chain.*

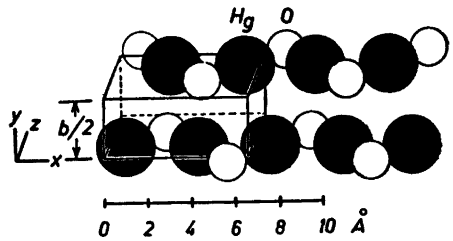

Fig. 7. Diagram showing the infinite zig-zag chain —O—Hg—O— lying in the ac plane and running parallel to the a axis.

DESCRIPTION OF THE STRUCTURE

The following structure of mercury(II)oxide has thus been arrived at:

Cell content: 4 HgO
Space group: *Pnma*, No. 62
4 Hg in the point position 4(*c*): $x,\frac{1}{4},z;\ \bar{x},\frac{3}{4},\bar{z};\ \frac{1}{2}-x,\ \frac{3}{4},\ \frac{1}{2}+z;\ \frac{1}{2}+x,\frac{1}{4},\frac{1}{2}-z$
$x = 0.115,\ z = 0.245$
4 O in the point position 4(*c*): $x = 0.36_5,\ z = 0.58_5$

The structure is built up of infinite, planar zig-zag chains —O—Hg—O— running parallel to the *a* axis and lying in the *ac* plane (*cf.* Figs. 6 and 7).

The distances and angles within the chains are:

Hg(1) — O(1)	2.03 ± 0.10 Å
Hg(2) — O(1)	2.03 ± 0.10 Å
Hg(1) — Hg(2)	3.30 Å
The angle Hg(1) — O(1)—Hg(2)	109° ± 1°
The angle O(1) — Hg(2)—O(2)	179° ± 3°

The distances between the chains are:

Hg(3) — O(1)	2.82 Å
Hg(2) — O(3)	2.82 Å
Hg(2) — Hg(3)	3.59 Å
O(1) — O(3)	3.39 Å

The distance from a mercury atom to an adjacent oxygen atom should be [5,6]:

for ionic bonds 2.18 Å (coordination number 2)
for covalent sp^3 bonds 2.16 Å
for covalent sp bonds 2.0_1 Å

The Hg—O distances, actually found within the chain, 2.03 Å, and the values of the angles suggest that the bond between Hg and O within the chains is mainly homopolar. Between the chains, the forces are far weaker since the interatomic distances are considerably longer than those within the chains. The chains probably support each other by means of the Hg—O contacts.

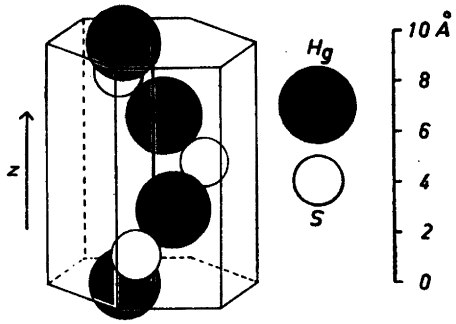

Fig. 8. Diagram showing one spiral chain —S—Hg—S— of the cinnabar structure. The spiral chain extends indefinitely through the crystal in a vertical direction.

A comparison between the structures of mercury(II)oxide and the hexagonal modification of mercury(II)sulphide (cinnabar) [7] (*cf.* Figs. 7 and 8) indicates the existence of similar building principles in these two structures. The infinite zig-zag chains —O—Hg—O— of the former correspond to infinite spiral chains —S—Hg—S— running parallel to the *c* axis of the latter. The angles —X—Hg—X— do not differ much from 180° in either case. The decrease in the angle Hg—X—Hg when going from oxygen (109° ± 1°) to sulphur (105° ± 2°) is in analogy to previously reported structural data.

A recent report by Roth [8] on an X-ray and neutron diffraction study of mercury(II)oxide gives a structure considerably different from that found in the present investigation. The doubling of the *a* axis and thus also the primitive character of the unit cell were not observed. The oxygen atom arrangement suggested by Roth and leading to a different system of Hg—O chains and to O—Hg—O angles of 105° is likewise inconsistent with the experimental data obtained by the present author.

The author wishes to thank Professor A. Ölander for his kind interest in this work. The author is also much indebted to Dr. A. Magnéli for many valuable discussions. Thanks are also due to Dr. G. Randers, head of the *Joint Establishment for Nuclear Energy Research*, Kjeller, Norway, for his kind hospitality and to Dr. J. A. Goedkoop, head of the Neutron Physics Department and to Dr. A. F. Andresen for very valuable help in the neutron diffraction work.

These studies form part of a research program on metal oxides and fluorides financially supported by the *Swedish Natural Science Research Council.*

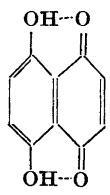
Short Communications

A Preliminary X-Ray Investigation of Naphthazarin

O. BORGEN

Institutt for teoretisk kjemi, Norges Tekniske Høgskole, Trondheim, Norway



Naphthazarin has been isolated in three modifications at room temperature. Two of these have been reported previously by Palacios and Salvia [1] and Rogers [2].

Our approximate X-ray data are as follows:

Modification	I	II	III
a (Å)	3.81	8.09	5.46
b (Å)	7.63	7.27	6.35
c (Å)	14.52	15.26	11.71
β (°)	97.2	115	91.5
Space group	$P2_1/c$	$P2_1/c$	$P2_1/c$
Molecules in unit cell	2	4	2
Colour	green metallic lustre	red	dark red

The physical properties, especially the colours, of the various modifications are appreciably different. An investigation has therefore been commenced in order to study the influence of intermolecular forces and molecular orientation.

The structure of naphthazarin, based on chemical evidence, is given as 5,8-dihydroxy-1,4-naphthoquinone.

The space group of the modifications I and III is $P2_1/c$, and the unit cells contain 2 molecules. The molecules therefore have a centre of symmetry. This is incompatible with the above formula.

There exist a number of possible explanations, of which we may mention some.

1) The compound may be of the form 4,8-dihydroxy-1,5-naphthoquinone, in spite of certain chemical evidence.
2) The hydrogen bonds may be symmetrical, although such bonds are not known in any organic compound.
3) The protons of the hydrogen bonds may change positions between neighbouring oxygen atoms, giving a quasi-centrosymmetric structure.
4) The benzo- and keto-parts of the molecules may be statistically distributed in the lattice, giving a quasicentrosymmetric structure.

In the three later cases we would expect to find the four C—O distances equal.

The electron-density projection of naphthazarin I on (100) is shown in Fig. 1. The signs of the structure amplitudes have been determined from a model based on a Patterson projection.

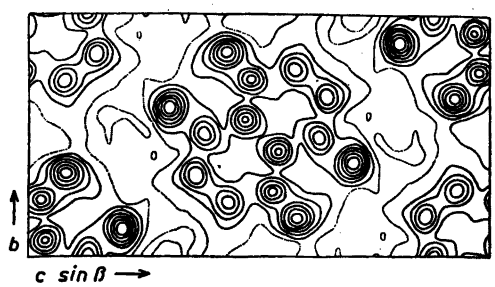


Fig. 1. Electron-density projection on (100) of naphthazarin I.

The molecules are oriented nearly parallel to the (100) plane, and a rough calculation of the atomic positions indicates short intramolecular O—H...O distances and rather close intermolecular approach. The length of the hydrogen bond is of great interest in connection with the recent studies of the infrared spectra of hydroxy-quinones [3-5], but further discussion will have to await the final refinements of the calculations.

X-Ray Crystallographic Data on Sodium and Potassium Thiosulphonates

OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

A study of unit cells and space groups of some alkali methane- and *p*-toluenethiosulphonates has been made, with the following results. The axial lengths, from oscillation and Weissenberg photographs taken with copper radiation, $\lambda(CuK\alpha) = 1.542$ Å, are probably correct to within 0.5 %. Densities were determined by a flotation method.

Sodium methanethiosulphonate monohydrate, $CH_3SO_2SNa \cdot H_2O$. Orthorhombic, $a = 6.49$ Å, $b = 5.55$ Å, $c = 16.23$ Å. Four formula units per unit cell; density, calc. 1.73, found 1.72 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. These absences are characteristic of the space groups, $D_{2h}^{16}-Pnma$ and $C_{2v}^{9}-Pn2_1a$. If the former is the correct one, the carbon and both sulphur atoms of the methanethiosulphonate ion lie in a crystallographic mirror plane of symmetry.

From water, the salt crystallized as plates {001} with plate edges parallel to the a and b axes. There is perfect cleavage along the plate face, and also a pronounced tendency of cleavage along another, not identified plane parallel to the a axis.

Potassium methanethiosulphonate, CH_3SO_2SK. Monoclinic prismatic, $a = 8.76$ Å, $b = 8.12$ Å, $c = 7.42$ Å, $\beta = 92°$. Four formula units per unit cell; density, calc. 1.89, found 1.88 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^{5}-P2_1/c$.

The salt crystallized from water or methanol as thick plates {100} bounded by {011}, {010} and occasionally {111}. There is perfect cleavage along the plate face.

Potassium p-*toluenethiosulphonate monohydrate*, $C_7H_7SO_2SK \cdot H_2O$. Monoclinic, $a = 8.56$ Å, $b = 9.67$ Å, $c = 13.01$ Å, $\beta = 95°$. Four formula units per unit cell; density, calc. 1.51, found 1.49 g/cm³. Systematic absences, hkl when $h + k$ is odd. The monoclinic prismatic morphology [1,2] of the crystals points to the centrosymmetric space group, $C_{2h}^{3}-C2/m$, the correctness of which would imply that the *p*-toluenethiosulphonate ion possesses mirror plane symmetry in the crystals.

The salt was first prepared by Blomstrand [3] and Wahlstedt [4], and by these authors noted to crystallize particularly well. Brugnatelli [1,2] described the crystals as monoclinic prismatic, with $a : b : c = 0.8854 : 1 : 1.5436$ and $\beta = 119° 52'$. Transforming according to the matrix, 100/010/$\bar{1}0\bar{1}$, these data become $a : b : c = 0.8854 : 1 : 1.344$; $\beta = 94.9°$, as compared with $a : b : c = 0.8853 : 1 : 1.345$; $\beta = 95°$ from the X-ray data.

There is perfect cleavage along the c plane.

Sodium p-*toluenethiosulphonate*, $C_7H_7SO_2SNa$. Monoclinic, $a = 7.36$ Å, $b = 9.72$ Å, $c = 12.96$ Å, $\beta = 93°$. Four formula units per unit cell; density, calc. 1.51, found 1.51 g/cm³. Systematic absences, hkl when $h + k$ is odd.

Except for the length of the a axis, the cell dimensions are close to those found for potassium *p*-toluenethiosulphonate monohydrate. The systematic absences are the same, and the intensity distribution of the $0kl$ reflections of the two salts are very similar. It appears likely that the space group of the sodium salt is that of the potassium salt, and thus probably $C_{2h}^{3}-C2/m$.

Crystallized from 96 % ethanol above room temperature, the salt occurred as

The molecules are oriented nearly parallel to the (100) plane, and a rough calculation of the atomic positions indicates short intramolecular O—H...O distances and rather close intermolecular approach. The length of the hydrogen bond is of great interest in connection with the recent studies of the infrared spectra of hydroxy-quinones [3-5], but further discussion will have to await the final refinements of the calculations.

X-Ray Crystallographic Data on Sodium and Potassium Thiosulphonates

OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

A study of unit cells and space groups of some alkali methane- and *p*-toluenethiosulphonates has been made, with the following results. The axial lengths, from oscillation and Weissenberg photographs taken with copper radiation, $\lambda(CuK\alpha) = 1.542$ Å, are probably correct to within 0.5 %. Densities were determined by a flotation method.

Sodium methanethiosulphonate monohydrate, $CH_3SO_2SNa \cdot H_2O$. Orthorhombic, $a = 6.49$ Å, $b = 5.55$ Å, $c = 16.23$ Å. Four formula units per unit cell; density, calc. 1.73, found 1.72 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. These absences are characteristic of the space groups, $D_{2h}^{16}-Pnma$ and $C_{2v}^{9}-Pn2_1a$. If the former is the correct one, the carbon and both sulphur atoms of the methanethiosulphonate ion lie in a crystallographic mirror plane of symmetry.

From water, the salt crystallized as plates {001} with plate edges parallel to the a and b axes. There is perfect cleavage along the plate face, and also a pronounced tendency of cleavage along another, not identified plane parallel to the a axis.

Potassium methanethiosulphonate, CH_3SO_2SK. Monoclinic prismatic, $a = 8.76$ Å, $b = 8.12$ Å, $c = 7.42$ Å, $\beta = 92°$. Four formula units per unit cell; density, calc. 1.89, found 1.88 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^{5}-P2_1/c$.

The salt crystallized from water or methanol as thick plates {100} bounded by {011}, {010} and occasionally {111}. There is perfect cleavage along the plate face.

Potassium p-*toluenethiosulphonate monohydrate*, $C_7H_7SO_2SK \cdot H_2O$. Monoclinic, $a = 8.56$ Å, $b = 9.67$ Å, $c = 13.01$ Å, $\beta = 95°$. Four formula units per unit cell; density, calc. 1.51, found 1.49 g/cm³. Systematic absences, hkl when $h + k$ is odd. The monoclinic prismatic morphology [1,2] of the crystals points to the centrosymmetric space group, $C_{2h}^{3}-C2/m$, the correctness of which would imply that the *p*-toluenethiosulphonate ion possesses mirror plane symmetry in the crystals.

The salt was first prepared by Blomstrand [3] and Wahlstedt [4], and by these authors noted to crystallize particularly well. Brugnatelli [1,2] described the crystals as monoclinic prismatic, with $a : b : c = 0.8854 : 1 : 1.5436$ and $\beta = 119° 52'$. Transforming according to the matrix, 100/010/$\bar{1}0\bar{1}$, these data become $a : b : c = 0.8854 : 1 : 1.344$; $\beta = 94.9°$, as compared with $a : b : c = 0.8853 : 1 : 1.345$; $\beta = 95°$ from the X-ray data.

There is perfect cleavage along the c plane.

Sodium p-*toluenethiosulphonate*, $C_7H_7SO_2SNa$. Monoclinic, $a = 7.36$ Å, $b = 9.72$ Å, $c = 12.96$ Å, $\beta = 93°$. Four formula units per unit cell; density, calc. 1.51, found 1.51 g/cm³. Systematic absences, hkl when $h + k$ is odd.

Except for the length of the a axis, the cell dimensions are close to those found for potassium *p*-toluenethiosulphonate monohydrate. The systematic absences are the same, and the intensity distribution of the $0kl$ reflections of the two salts are very similar. It appears likely that the space group of the sodium salt is that of the potassium salt, and thus probably $C_{2h}^{3}-C2/m$.

Crystallized from 96 % ethanol above room temperature, the salt occurred as

fatty leaves or thin plates {001}. There is perfect cleavage along (001) and along planes parallel to the *ab* diagonals.

Sodium p-toluenethiosulphonate dihydrate, $C_7H_7SO_2SNa \cdot 2H_2O$. Monoclinic prismatic, $a = 13.59$ Å, $b = 6.47$ Å, $c = 12.95$ Å, $\beta = 91\frac{1}{2}°$. Four formula units per unit cell; density, calc. 1.44, found 1.43 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^5 - P2_1/c$.

The dihydrate [3,5] was obtained by crystallization from 96 % ethanol at low room temperature, and occurred as plates {100} which were often prismatic along the *b* axis. There is a pronounced tendency of cleavage along the plate face. In air, the crystals keep well at temperatures below 10° C, but give off the water of crystallization rapidly above 20° C.

A salt, originally [6] listed as sodium *p*-toluenethiosulphonate dihydrate but later [2] reported to be the monohydrate, was described by Weibull [2,6] as monoclinic prismatic with $a : b : c = 0.8869 : 1 : 2.774$ and $\beta = 103° 52'$. With the transformation, $\bar{1}00/0\bar{1}0/\frac{1}{2},0,\frac{1}{2}$, Weibull's data become $a : b : c = 0.8869 : 1 : 1.351$; $\beta = 94.6°$, which do not agree with the X-ray data for the dihydrate nor the anhydrous salt. A monohydrate has not been observed in the present work. Weibull's transformed data are almost identical with those which apply to potassium *p*-toluenethiosulphonate monohydrate.

Further work on the crystal structures of some of the salts will be made, with a view of determining the length of a thiosulphonate sulphur-sulphur bond. As pointed out earlier [7], this bond is probably a predominantly double bond.

Structure of Thiuret Hydroiodide

OLAV FOSS and OLAV TJOMSLAND

Chemical Institute, University of Bergen, Bergen, Norway

Thiuret hydroiodide, or 3,5-diimino-1,2,4-dithiazolidine hydroiodide, occurs on oxidation of dithiobiuret with iodine [1], and is a five-membered cyclic disulphide [1,2].

The unit cells and space groups of some simple 1,2,4-dithiazolidine derivatives, including thiuret hydroiodide, were reported by one of us in a preceding note [3]. The preliminary results of a complete crystal structure determination of thiuret hydroiodide are given here. The disulphide group has been found to lie across a crystallographic mirror plane of symmetry, and is thus exactly planar. This appears to be the first crystal structure determination reported for a cyclic disulphide, and the first recorded instance of a planar disulphide group.

Open-chain disulphides, X—S—S—X, have always been found to be non-planar *cf.*[4] with a dihedral angle of about 90° between the X—S—S and S—S—X planes, there being a barrier to internal rotation about an S—S bond of from 10 to 14 kcal/mole [5-7]. The formation of a five-membered cyclic disulphide requires the rotation of the S—S bond to a dihedral angle of nearly 0°, where the barrier probably has its highest value. The nevertheless relatively high stabilities of unsaturated five-membered cyclic disulphides, such as 1,2-dithiacenaphthene [8] and the trithiones [9,10], and of 1,2,4-dithiazolidine derivatives with double-bonded substituents in the 3 and 5 positions, must be due to some extent to resonance stabilization of the ring, a resonance involving the unshared *p* electron pairs of the sulphur atoms. The barrier to internal rotation about an S—S bond being thought to be due principally to the mutual repulsion of these electron pairs [11], one on each sulphur atom, their participation in π bonding with the adjacent carbon atoms would tend to lower the barrier height.

The yellow crystals of thiuret hydroiodide, $S_2(C{:}NH)_2NH \cdot HI$, occur as prisms, bounded by {001} and {011} and showing perfect cleavage along the *c* plane. The four-molecule unit cell has the dimensions [3], $a = 5.38$ Å, $b = 9.24$ Å, $c = 13.98$ Å, and the space group is $D_{2h}^{16} - Pnma$. The intensities of the $0kl$ reflections were

fatty leaves or thin plates {001}. There is perfect cleavage along (001) and along planes parallel to the *ab* diagonals.

Sodium p-toluenethiosulphonate dihydrate, $C_7H_7SO_2SNa \cdot 2H_2O$. Monoclinic prismatic, $a = 13.59$ Å, $b = 6.47$ Å, $c = 12.95$ Å, $\beta = 91\frac{1}{2}°$. Four formula units per unit cell; density, calc. 1.44, found 1.43 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^5 - P2_1/c$.

The dihydrate [3,5] was obtained by crystallization from 96 % ethanol at low room temperature, and occurred as plates {100} which were often prismatic along the *b* axis. Structure of Thiuret Hydroiodide

OLAV FOSS and OLAV TJOMSLAND

Chemical Institute, University of Bergen, Bergen, Norway

Thiuret hydroiodide, or 3,5-diimino-1,2,4-dithiazolidine hydroiodide, occurs on oxidation of dithiobiuret with iodine [1], and is a five-membered cyclic disulphide [1,2].

The unit cells and space groups of some simple 1,2,4-dithiazolidine derivatives, including thiuret hydroiodide, were reported by one of us in a preceding note [3]. The preliminary results of a complete crystal structure determination of thiuret hydroiodide are given here. The disulphide group has been found to lie across a crystallographic mirror plane of symmetry, and is thus exactly planar. This appears to be the first crystal structure determination reported for a cyclic disulphide, and the first recorded instance of a planar disulphide group.

Open-chain disulphides, X—S—S—X, have always been found to be non-planar *cf.*[4] with a dihedral angle of about 90° between the X—S—S and S—S—X planes, there being a barrier to internal rotation about an S—S bond of from 10 to 14 kcal/mole [5-7]. The formation of a five-membered cyclic disulphide requires the rotation of the S—S bond to a dihedral angle of nearly 0°, where the barrier probably has its highest value. The nevertheless relatively high stabilities of unsaturated five-membered cyclic disulphides, such as 1,2-dithiacenaphthene [8] and the trithiones [9,10], and of 1,2,4-dithiazolidine derivatives with double-bonded substituents in the 3 and 5 positions, must be due to some extent to resonance stabilization of the ring, a resonance involving the unshared *p* electron pairs of the sulphur atoms. The barrier to internal rotation about an S—S bond being thought to be due principally to the mutual repulsion of these electron pairs [11], one on each sulphur atom, their participation in π bonding with the adjacent carbon atoms would tend to lower the barrier height.

The yellow crystals of thiuret hydroiodide, $S_2(C{:}NH)_2NH \cdot HI$, occur as prisms, bounded by {001} and {011} and showing perfect cleavage along the *c* plane. The four-molecule unit cell has the dimensions [3], $a = 5.38$ Å, $b = 9.24$ Å, $c = 13.98$ Å, and the space group is $D_{2h}^{16} - Pnma$. The intensities of the $0kl$ reflections were

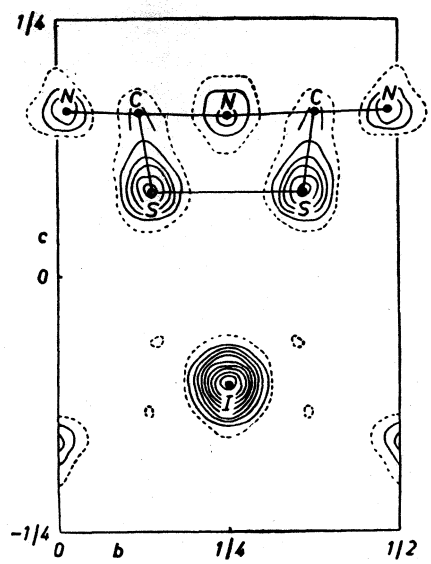

Fig. 1. Electron density projection of thiuret hydroiodide along the a *axis, showing two asymmetric units. The 4-electron line is dashed. Contour intervals: 10 e · Å^{-2} for the iodide ion, 4 e · Å^{-2} for the sulphur atoms and 2 e · Å^{-2} for the carbon and nitrogen atoms.*

estimated visually from zero layer Weissenberg photographs about the *a* axis. A crystal with cross-section 0.07 × 0.08 mm was used, and copper radiation. A Patterson synthesis based on the 0*kl* data gave the *y* and *z* coordinates of the iodide ion and the sulphur atom of the asymmetric unit, and subsequent Fourier syntheses lead to the electron density map reproduced in Fig. 1.

At the present stage of refinement, the *y* and *z* coordinates are as listed in Table 1. These coordinates, with appropriate temperature and scale factors, give a reliability factor of $R = 14.4$ % for the 0*kl* reflections.

The sulphur *y* coordinate and the iodide *z* coordinate give a S—S bond length of 2.05 Å and a closest I—I approach of 4.82 Å, respectively. The former of these distances agrees well with the S—S bond length in orthorhombic sulphur [12], 2.04 Å, and the latter is 0.5 Å larger than twice the ionic radius of iodine [13].

Table 1. Atomic coordinates, in fractions of corresponding cell edges. Origin at a centre of symmetry.

	y	*z*
I	0.250	—0.107
N_1	0.250	0.156
S	0.139	0.081
C	0.120	0.160
N_2	0.014	0.162

The 1,2,4-dithiazolidine ring is intersected by a crystallographic mirror plane, which passes through the nitrogen atom and midway between the sulphur atoms, and it follows that the disulphide group, including the two sulphur atoms and the adjacent carbon atoms, is planar. The ring as a whole, however, need not be planar, and as far as can be judged from the 0*kl* electron density map, the nitrogen atom of the 1,2,4-dithiazolidine ring is displaced from the plane of the sulphur and carbon atoms.

The work will be continued, and details published later. Also, it is intended to study the crystal structures of 1,2-dithiacyclohepta-3,6-diene derivatives [14,15], with a view of determining the degree of planarity of the disulphide group in unsaturated seven-membered rings.

Note added in proof, Sept. 3, 1956. — Refinement by difference syntheses of the *a* axis projection of thiuret hydroiodide has led to a reliability factor of $R = 7.6$ % and a S—S bond length of 2.09 Å.

X-Ray Crystallographic Data on Certain Five-membered Cyclic Disulphides

OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

A survey has been made of unit cells and space groups of some simple 1,2,4-dithiazolidine derivatives. The compounds studied are, xanthan hydride [1-3] (3-imino-1,2,4-dithiazolidine-5-thione), rhodan hydrate [4,5] (3-imino-1,2,4-dithiazolidine-5-one), and three thiuret (3,5-diimino-1,2,4-dithiazolidine) hydrohalides. The latter compounds are oxidation products of dithiobiuret; the hydrochloride [6] and hydroiodide [7] have been mentioned in literature earlier, but apparently not the hydrobromide. The hydrobromide and hydroiodide used in the present work were obtained by adding an excess of aqueous potassium bromide or iodide to a warm aqueous solution of the hydrochloride.

Oscillation and Weissenberg photographs were taken using copper radiation, $\lambda(CuK\alpha) = 1.542$ Å. The axial lengths given below are believed to be correct to within 0.5 %. Densities were determined by flotation in bromoform-carbon tetrachloride mixtures.

Xanthan hydride, $S_2(C{:}NH)(C{:}S)NH$. Monoclinic prismatic, $a = 4.05$ Å, $b = 10.59$ Å, $c = 12.78$ Å, $\beta = 97°$. Four molecules per unit cell; density, calc. 1.83, found 1.84 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^5-P2_1/c$.

From 60 % acetic acid the compound crystallized as long prisms, extended along the a axis and flattened along the b axis.

Rhodan hydrate, $S_2(C{:}NH)(C{:}O)NH$. Monoclinic, $a = 12.50$ Å, $b = 5.24$ Å, $c = 14.67$ Å, $\beta = 95\frac{1}{2}°$. Eight molecules per unit cell; density, calc. 1.86, found 1.87 g/cm³. Systematic absences, hkl when $h + k$ is odd, $h0l$ when l is odd. The space group is thus either C_{2h}^6-C2/c or C_s^4-C/c.

From water, the compound crystallized as flat prisms, extended along the b axis and with {100} predominant. There is perfect cleavage along (001). The morphology of the crystals indicates the presence of a twofold axis and thus the correctness of the centrosymmetric space group, C_{2h}^6-C2/c.

Thiuret hydrochloride, $S_2(C{:}NH)_2NH \cdot HCl \cdot \frac{1}{2}H_2O$. Monoclinic, $a = 19.58$ Å, $b = 5.47$ Å, $c = 14.34$ Å, $\beta = 114\frac{1}{2}°$. Eight formula units per unit cell; density, calc. 1.70, found 1.71 g/cm³. Systematic absences, hkl when $h + k$ is odd, $h0l$ when l is odd. Space group, C_{2h}^6-C2/c or C_s^4-C/c.

The density, and the statement by Preisler and Bateman [6] that 5 % water remain after drying over calcium chloride, point to the presence of half a mole of crystal water per mole of hydrochloride.

From water, the compound crystallized as prisms extended along the b axis. As in the case of rhodan hydrate, the morphology is in favour of the former of the two possible space groups. The water molecules would then lie on twofold axes.

Thiuret hydrobromide, $S_2(C{:}NH)_2NH \cdot HBr$. Monoclinic prismatic, $a = 5.11$ Å, $b = 12.76$ Å, $c = 10.47$ Å, $\beta = 110°$. Four formula units per unit cell; density, calc. 2.22, found 2.22 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^5-P2_1/c$.

The compound crystallized from water as large plates {010} or as prisms extended along the a axis with, also here, {010} predominant.

Thiuret hydroiodide, $S_2(C{:}NH)_2NH \cdot HI$. Orthorhombic bipyramidal, $a = 5.38$ Å, $b = 9.24$ Å, $c = 13.98$ Å. Four formula units per unit cell; density, calc. 2.50, found 2.49 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. Of the two space groups compatible with these absences, the centrosymmetric one, $D_{2h}^{16}-Pnma$, has been found to be the correct one through Patterson and Fourier projections along the a axis [8]. The thiuret-H^+ ion lies across a crystallographic mirror plane of symmetry, and also the iodide ion is located in the mirror plane.

From water, the compound crystallized as prisms extended along the a axis and bounded by {001} and {011}. There is perfect cleavage along (001), and a rather pronounced tendency of irregular growth and twinning.

Further work on the crystal structures of some of the compounds will be made.

X-Ray Crystallographic Data on Certain Five-membered Cyclic Disulphides

OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

A survey has been made of unit cells and space groups of some simple 1,2,4-dithiazolidine derivatives. The compounds studied are, xanthan hydride [1-3] (3-imino-1,2,4-dithiazolidine-5-thione), rhodan hydrate [4,5] (3-imino-1,2,4-dithiazolidine-5-one), and three thiuret (3,5-diimino-1,2,4-dithiazolidine) hydrohalides. The latter compounds are oxidation products of dithiobiuret; the hydrochloride [6] and hydroiodide [7] have been mentioned in literature earlier, but apparently not the hydrobromide. The hydrobromide and hydroiodide used in the present work were obtained by adding an excess of aqueous potassium bromide or iodide to a warm aqueous solution of the hydrochloride.

Oscillation and Weissenberg photographs were taken using copper radiation, $\lambda(CuK\alpha) = 1.542$ Å. The axial lengths given below are believed to be correct to within 0.5 %. Densities were determined by flotation in bromoform-carbon tetrachloride mixtures.

Xanthan hydride, $S_2(C{:}NH)(C{:}S)NH$. Monoclinic prismatic, $a = 4.05$ Å, $b = 10.59$ Å, $c = 12.78$ Å, $\beta = 97°$. Four molecules per unit cell; density, calc. 1.83, found 1.84 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^5-P2_1/c$.

From 60 % acetic acid the compound crystallized as long prisms, extended along the a axis and flattened along the b axis.

Rhodan hydrate, $S_2(C{:}NH)(C{:}O)NH$. Monoclinic, $a = 12.50$ Å, $b = 5.24$ Å, $c = 14.67$ Å, $\beta = 95\frac{1}{2}°$. Eight molecules per unit cell; density, calc. 1.86, found 1.87 g/cm³. Systematic absences, hkl when $h + k$ is odd, $h0l$ when l is odd. The space group is thus either C_{2h}^6-C2/c or C_s^4-C/c.

From water, the compound crystallized as flat prisms, extended along the b axis and with {100} predominant. There is perfect cleavage along (001). The morphology of the crystals indicates the presence of a twofold axis and thus the correctness of the centrosymmetric space group, C_{2h}^6-C2/c.

Thiuret hydrochloride, $S_2(C{:}NH)_2NH \cdot HCl \cdot \frac{1}{2}H_2O$. Monoclinic, $a = 19.58$ Å, $b = 5.47$ Å, $c = 14.34$ Å, $\beta = 114\frac{1}{2}°$. Eight formula units per unit cell; density, calc. 1.70, found 1.71 g/cm³. Systematic absences, hkl when $h + k$ is odd, $h0l$ when l is odd. Space group, C_{2h}^6-C2/c or C_s^4-C/c.

The density, and the statement by Preisler and Bateman [6] that 5 % water remain after drying over calcium chloride, point to the presence of half a mole of crystal water per mole of hydrochloride.

From water, the compound crystallized as prisms extended along the b axis. As in the case of rhodan hydrate, the morphology is in favour of the former of the two possible space groups. The water molecules would then lie on twofold axes.

Thiuret hydrobromide, $S_2(C{:}NH)_2NH \cdot HBr$. Monoclinic prismatic, $a = 5.11$ Å, $b = 12.76$ Å, $c = 10.47$ Å, $\beta = 110°$. Four formula units per unit cell; density, calc. 2.22, found 2.22 g/cm³. Systematic absences, $h0l$ when l is odd, $0k0$ when k is odd. The space group is thus $C_{2h}^5-P2_1/c$.

The compound crystallized from water as large plates {010} or as prisms extended along the a axis with, also here, {010} predominant.

Thiuret hydroiodide, $S_2(C{:}NH)_2NH \cdot HI$. Orthorhombic bipyramidal, $a = 5.38$ Å, $b = 9.24$ Å, $c = 13.98$ Å. Four formula units per unit cell; density, calc. 2.50, found 2.49 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. Of the two space groups compatible with these absences, the centrosymmetric one, $D_{2h}^{16}-Pnma$, has been found to be the correct one through Patterson and Fourier projections along the a axis [8]. The thiuret-H^+ ion lies across a crystallographic mirror plane of symmetry, and also the iodide ion is located in the mirror plane.

From water, the compound crystallized as prisms extended along the a axis and bounded by {001} and {011}. There is perfect cleavage along (001), and a rather pronounced tendency of irregular growth and twinning.

Further work on the crystal structures of some of the compounds will be made.

The author wishes to express his thanks to the American Cyanamid Company, New York, for a sample of thiuret hydrochloride.

Kinetics of the Heterogeneous Reaction of Calcium Bicarbonate Formation, with Special Reference to Copper Ion Inhibition

O. ERGA and S. G. TERJESEN

Chemical Engineering Laboratory, Technical University of Norway, Trondheim, Norway

The system $CaCO_{3(s)}-CO_{2(g)}-H_2O_{(l)}$ is of considerable geological, physiological and technical importance. The reaction between solid calcium carbonate and aqueous carbon dioxide has therefore been discussed extensively in literature [1]. However, the published papers deal mainly with the thermodynamics of the reaction whereas the kinetic aspects seem to have been largely neglected.

Calcite of natural origin was used in the present investigation. When giving the ground material a repeated treatment with aqueous carbon dioxide, the reactivity of the calcite particles used for the experiment, did not change from one run to another. The experiments were carried out at 25° C in an agitated vessel made of stainless steel and designed to keep the solid particles well suspended in the liquid during the runs. The carbon dioxide-air mixture was blown into the suspension of calcite particles, and the reaction was followed by conductivity measurements.

The reaction was found to be strongly inhibited by very small amounts of copper ions. In Fig. 1 are shown the results of three runs, all carried out with 100 g of calcite suspended in 10 litres of distilled water. The particle size was 295—422 μ, corresponding to a surface area of approximately 125 cm² per g². The carbon dioxide pressure was 0.95 atm. In the first experiment traces of copper inevitably present in the solution were screened by adding 4×10^{-5} moles per litre of disodium - ethylenediamin - tetraacetic acid (EDTA) [2]. The middle curve shows that less than 2×10^{-7} moles per litre of copper ions, accidentally present due to contamination of the surface of the particles and the distilled water, has a significant effect on the reaction rate. The third run was carried out in the presence of 10^{-5} moles per litre of cupric chloride. The inhibition was now so strong that the reaction gave the appearance of approaching a new equilibrium concentration, 20—30 % below the real one.

With the object of investigating whether the bulk of the added copper ions was adsorbed on the calcite surface or remained dissolved in the water, the following experiment was carried out: Initially, the liquid contained 10^{-5} moles per litre of cupric chloride, but when the concentration of calcium bicarbonate reached c_1 in Fig. 1, the experiment was stopped, the liquid decanted and used for another run with a fresh portion of calcite. The concentration then continued to rise along the lower curve. At c_2 this experiment was stopped, the solution removed by decantation and

a new experiment started with the same particles but with fresh water. The reaction now followed the middle curve. These experiments strongly indicate that the copper was present mainly in the bulk of the liquid and that very little could have been adsorbed at the surface of the particles.

The inhibition by copper ions provides a reasonable explanation for the difficulties encountered by many investigators in reaching a final state of equilibrium. Frear and Johnston [4] found it necessary to allow weeks and Shtermina and Frolova [5] even months for the establishment of equilibrium. It is shown here that this excessive delay can be eliminated by additions of small quantities of EDTA, an expedient which might prove useful also in other cases involving solid calcium carbonate.

In Fig. 2, the rate of reaction is plotted against the concentration of calcium bicarbonate for partial pressures of carbon dioxide of 0.952, 0.664, 0.392 and 0.135 atm. The amount and size of the calcite particles were exactly as for the runs shown in Fig. 1, and 4×10^{-5} moles per litre of EDTA was added. Except for a short period after the start of the experiments, the relation between the concentration of calcium bicarbonate and the rate of reaction is linear. Furthermore, the points of intersection of these lines with the abscissa, give the respective equilibrium concentrations. These are 6.2 to 9.8 % lower than

▲: p_{CO_2} = *0.664* »
●: p_{CO_2} = *0.392* »
×: p_{CO_2} = *0.135* »

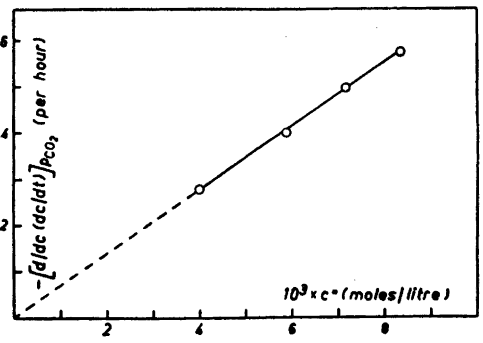

Fig. 3. A plot of the slope of the rate-concentration lines of Fig. 2 against the respective equilibrium concentrations.

the values reported by Frear and Johnston [4], who used finely powdered material, but 4 to 0 % higher than those of Miller [1], obtained with coarser crystalline aggregates of natural calcite.

The slope of the lines in Fig. 2 have been plotted against the corresponding equilibrium concentrations in Fig. 3, and it can be seen that the relationship is a straight line through origo. This means that the results of the experiments without inhibition can be described by the following kinetic equation:

$$\frac{dc}{dt} = k \cdot c^* \ (c^* - c)$$

where c^* = concentration of calciumbicarbonate at equilibrium in moles per litre; c = concentration of calciumbicarbonate at a time t after start of the reaction; k = a constant, independent of c^*, but shown below to be proportional to the surface area of the particles per unit volume of suspension.

In an attempt to localise the rate determining steps, experiments were carried out with various gas velocities, intensities of agitation and quantities of particles, but with the same particle size as above and with a partial pressure of carbon dioxide of 0.95—0.97 atm. The rate of reaction was found to be strictly proportional to the surface area of the particles, but independent of the gas velocity in the range investigated. This shows that the rate of reaction is affected neither by the transfer of carbon dioxide from the gas to the liquid, nor by any chemical reaction in the bulk

of the liquid. Consequently, the rate determining steps are localised at the solid-liquid interface or in the liquid film in immediate contact with it.

The effect of the rate of stirring can be expressed by the coefficient of stirring, a, defined by the relationship: dc/dt proportional to $(\text{r.p.m.})^a$. The average value of this coefficient was found to be 0.22 over the range investigated, *i. e.* 280—555 r.p.m. This is much smaller than the value of 0.5—1.0 generally reported for heterogeneous processes controlled by diffusion [4], indicating that chemical reactions are among the rate determining steps.

Further work is in progress in an endeavour to elucidate the reaction mechanism both in the absence and presence of inhibiting metal ions.

Action of Ionizing Radiation on Insulating Plastics

L. EHRENBERG and K. G. ZIMMER

Institute for Organic Chemistry and Biochemistry, University, Stockholm, Sweden, and Max-Planck-Institut für physikalische Chemie, Göttingen, Germany

The action of ionizing radiation on insulating plastics is of great interest from various points of view, such as (i) the selection of most suitable materials for the construction of measuring equipment, (ii) the elucidation of the mechanism of induced conductivity and also (iii) as a model for the action of radiation on biologically important macromolecules [1,2]. By making use of a new experimental method [3] it has been possible to demonstrate that induced conductivity during beta irradiation (from Ce-Pr-144) as well as the so called after-effects are generally very different when part of the volume only is irradiated (leaving the insulating surface completely untouched by radiation) or when directing the radiation on the insulating surface [4]. From a theoretical point of view volume effects seem more interesting but for practical purposes surface effects are sometimes very important. They are often so pronounced as to make an otherwise excellent insulator practically useless. It seemed of interest, therefore, to investigate these surface effects somewhat further.

Insulating surfaces are in most cases in contact with atmospheric air and we thought it likely that, amongst other things, the deterioration might be caused by oxidation under the action of radiation. Oxidation would be expected to lead to the formation of hydrophilic groups and, consequently, to an increase in wettability. This would tend to decrease the usefulness of any insulator as small changes of temperature will always occur and may, on a wettable surface, enable a continuous and conducting layer of water to be formed. The formation of hydrophilic groups we were able to demonstrate in several ways:

(a) Specimens of insulating plastics were exposed to gamma-radiation from a ^{60}Co source of 70 Curies and the contact angle of small drops of 0.1 N NaOH measured on freshly machined surfaces. For machining we used a tool carefully washed in benzene and alcohol, for measuring a simple device made from a microscope. The data compiled in Table 1 show a considerable decrease of contact angle (increase in adhesion [5]).

(b) The formation of hydrophilic groups can be demonstrated very easily using liquid paraffin which has been shown to undergo much the same change of properties under irradiation as does polyethylene [6]. A drop of a paraffin of standard weight put onto a clean surface of 0.1 N aqueous NaOH forms a lens with a well defined diameter [7] which increases due to increased number of hydrophilic groups as the material is irradiated by ionizing radiation (previous to putting drops onto the aqueous alkali). We used 180 kV X-rays for irradiation in this case. A series of measurements is shown in Fig. 1.

(c) The effect can also be demonstrated in another way, lending itself more easily

Action of Ionizing Radiation on Insulating Plastics

L. EHRENBERG and K. G. ZIMMER

Institute for Organic Chemistry and Biochemistry, University, Stockholm, Sweden, and Max-Planck-Institut für physikalische Chemie, Göttingen, Germany

The action of ionizing radiation on insulating plastics is of great interest from various points of view, such as (i) the selection of most suitable materials for the construction of measuring equipment, (ii) the elucidation of the mechanism of induced conductivity and also (iii) as a model for the action of radiation on biologically important macromolecules [1,2]. By making use of a new experimental method [3] it has been possible to demonstrate that induced conductivity during beta irradiation (from Ce-Pr-144) as well as the so called after-effects are generally very different when part of the volume only is irradiated (leaving the insulating surface completely untouched by radiation) or when directing the radiation on the insulating surface [4]. From a theoretical point of view volume effects seem more interesting but for practical purposes surface effects are sometimes very important. They are often so pronounced as to make an otherwise excellent insulator practically useless. It seemed of interest, therefore, to investigate these surface effects somewhat further.

Insulating surfaces are in most cases in contact with atmospheric air and we thought it likely that, amongst other things, the deterioration might be caused by oxidation under the action of radiation. Oxidation would be expected to lead to the formation of hydrophilic groups and, consequently, to an increase in wettability. This would tend to decrease the usefulness of any insulator as small changes of temperature will always occur and may, on a wettable surface, enable a continuous and conducting layer of water to be formed. The formation of hydrophilic groups we were able to demonstrate in several ways:

(a) Specimens of insulating plastics were exposed to gamma-radiation from a ^{60}Co source of 70 Curies and the contact angle of small drops of 0.1 N NaOH measured on freshly machined surfaces. For machining we used a tool carefully washed in benzene and alcohol, for measuring a simple device made from a microscope. The data compiled in Table 1 show a considerable decrease of contact angle (increase in adhesion [5]).

(b) The formation of hydrophilic groups can be demonstrated very easily using liquid paraffin which has been shown to undergo much the same change of properties under irradiation as does polyethylene [6]. A drop of a paraffin of standard weight put onto a clean surface of 0.1 N aqueous NaOH forms a lens with a well defined diameter [7] which increases due to increased number of hydrophilic groups as the material is irradiated by ionizing radiation (previous to putting drops onto the aqueous alkali). We used 180 kV X-rays for irradiation in this case. A series of measurements is shown in Fig. 1.

(c) The effect can also be demonstrated in another way, lending itself more easily

Table 1. Contact angles of drops of aqueous alkali on various plastics before and after irradiation.

Material	Contact angle after irradiation with 0 Mrad	8 Mrad	16 Mrad
Polyethylene * ("Alkathene")	85°	76°	75°
Polysterene ("Trolitul")	98°	86°	77°
Polymethylmethacrylate ("Plexiglas")	84°	72°	52°
Polytetrafluorethylene ("Teflon")	90°	86°	82°
Polymonochlortrifluorethylene ("Kel F")	74°	55°	50°
Polyethyleneterephthalate ("Melinex")	71°	62°	55°

* Paraffin wax was measured for comparison. A dose of 2 Mrad gave a change of contact angle from 100° to 95°.

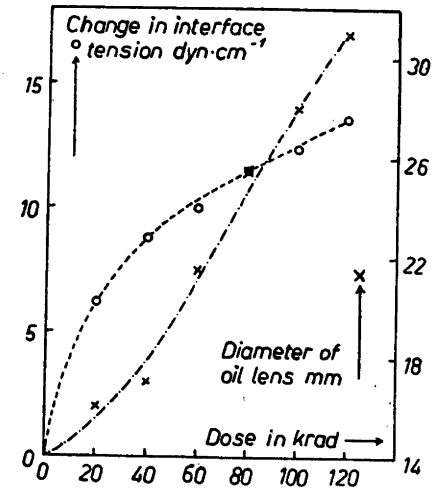

Fig. 1. Equilibrium values of interfacial tensions (24 hours) and oil lens diameters (10 mins. after surface contact). Latter values average 10 measurements. 20° C.

to quantitative evaluation, by measuring the interfacial tension between liquid paraffin and water by means of a Du-Noüy-balance (Fig. 1).

Another series of irradiations was conducted in an atmosphere of purified nitrogen admitted after prolonged evacuation of the vessels containing the specimens of plastic. Contact angles were measured by method (a) in air. They showed a decrease of the same order as had been found after irradiation in air. Though this result seems to disagree with the above explanation it must be kept in mind that irradiation of many substances in the absence of air produces long lived radicals which react with oxygen rapidly as soon as the latter becomes available [8].

The fact that the materials studied were of technical grade has to be borne in mind. This does not detract from the practical value of the results though side effects due to unspecified additions cannot be excluded.

On the Presence of Phosphoproteins in Erythrocyte Ghosts

GUNNAR ÅGREN and LORENTZ ENGSTRÖM

Institute of Medical Chemistry, University of Uppsala, Sweden

In a previous paper it has been demonstrated that the main part of the phosphoproteins in *E. coli* cells are located in the cell wall preparations [1]. It was therefore of interest to carry out a similar investigation with some animal cells. The erythrocytes seemed to offer a suitable material. This paper deals with the isolation of phosphoserine from erythrocyte ghosts.

After some preliminary work with earlier methods the ghosts were finally prepared in the following manner. 500 ml samples of blood were washed with cold physiological sodium chloride solution at least twice in a centrifuge taking 4 liters. After each washing the leucocytes were removed by decantation and suction. 3 volumes of cold distilled water were added. After haemolysis the remaining leucocytes were removed by centrifugation in a Spinco centrifuge with rotor 21 at 6 000 r.p.m. for 20 min. The suspension of erythrocyte ghosts was decanted and centrifuged for 20 min. at 18 000 r.p.m. in the same rotor. The voluminous precipitate was washed once with distilled water and at least 3 times with a 0.1 % sodium chloride solution.

The ghosts were suspended to a final volume of 100 ml in 0.1 M Tris (tris-(hydroxymethyl)aminomethane) at pH 7.4, and in the presence of 0.01 M $MgCl_2$. 5 mC ^{32}P was added and the incubation was finished after different times by the addition of trichloroacetic acid to a final concentration of 10 %. Lipids and nucleic acids were removed as previously described [2]. The residue from this treatment, taken as the Schneider protein fraction weighed about 2 g. This fraction was partially hydrolysed according to Lipmann [3]. Radioactive phosphoserine could be isolated both from pig and human erythrocyte ghosts in the same manner as previously described [4].

A ghost suspension was quickly heated to and kept at 80° C for about 1 minute, followed by rapid cooling. After incubation with ^{32}P it was not possible to detect more than traces of activity in the isolated phosphoserine fractions. A similar result was obtained when the ghosts were incubated with ^{32}P in the presence of monoiodoacetate to a final concentration of 0.01 M.

For the determination of the specific activity the effluents from the Dowex 50−8X columns were run through Dowex 1−X2 columns according to Busch *et al* [5]. The specific activity of the pure phosphoserine isolated from pig erythrocyte ghosts incubated with ^{32}P for 20 min. at room temperature was 3 550 cpm per μg P. It may be of interest that the specific activity of the pure phosphoserine isolated in earlier experiments [7] from rat liver fractions was about 4 500 cpm per μg P.

The trichloroacetic acid centrifugate from the reaction mixtures of erythrocyte ghosts and ^{32}P were run through Dowex 1−X2 formate columns according to Siekevitz and Potter [7]. Several peaks of radioactivity could be observed, but so far they have not been identified. Ultraviolet absorbing peaks could not be found in the eluates.

These experiments demonstrate that the ghosts contain phosphoproteins which may be active in the phosphorus metabolism of the erythrocytes. A metabolic pontential of erythrocyte ghosts has recently been recorded by Lionetti [8]. He used ghost plasma suspensions and studied the effect of adenosine on plasma inorganic phosphorus.

This investigation was supported by grants from *the Swedish Medical Research Council* and *the Wallenberg Foundation.*

On the Phosphorus Linkage in a Muscle Phosphorylase Preparation

LORENTZ ENGSTROM and GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

Recently we reported the isolation of ^{32}P-labeled phosphoserine from a yeast hexokinase preparation [1] incubated with radioactive adenosinetriphosphate or glucose-6-phosphate. It was concluded that hexokinase was a phosphoprotein functioning as a phosphotransferring enzyme with an incorporation of phosphate from the substrate to the enzyme molecule or an exchange between substrate and enzyme phosphate.

This paper deals with the isolation of ^{32}P-labeled phosphoserine from a muscle phosphorylase preparation incubated with glycogen and radioactive ^{32}P. The following different types of experiments were carried out with the same amount of enzyme in each experiment.

100 mg of a commercial muscle phosphorylase preparation (Delta Chemical Works, Inc.) and 150 mg of glycogen (Merck) were dissolved in 5 ml of a freshly prepared cysteine-glycerophosphate buffer [2]. 5 mC carrierfree ^{32}P was added. The solution was kept at room temperature. After 30 minutes the enzyme was precipitated with trichloroacetic acid to a final concentration of 10 %. The protein was hydrolyzed according to Lipmann [3]. ^{32}P-labeled phosphoserine was identified as previously described [1]. The specific activity calculated as cpm per μg P was 72 186. This is the highest value so far recorded by us for any phosphorylated amino acid isolated from animal or plant tissue proteins. When glycogen was present the addition of 5 mg of adenosinemonophosphate (AMP) did not seem to increase the incorporation of radioactive phosphate into the enzyme molecule. The specific activity of the isolated phosphoserine was 32 977.

Next the enzyme was incubated with ^{32}P without the addition of glycogen. The phosphoserine was isolated in the usual way. It was only slightly labeled. The specific activity was 182. Finally when the enzyme was incubated with ^{32}P and AMP the specific activity of the isolated phosphoserine was 2 626 cpm per μg P.

The results seem to indicate that muscle phosphorylase is a phosphoprotein according to our definition, since we have been able to isolate phosphoserine from the partially hydrolysed enzyme. In the enzyme reaction there is probably an exchange between enzyme and substrate phosphate. Glycogen appears to play an essential role in this mechanism. The small exchange which takes place when no polysaccharide is added to the system may depend on traces of glycogen present in the enzyme preparation.

The bearing of our results to those obtained by Sutherland and coworkers [4] is difficult to discuss at present time. The possibility of an exchange with glucose-1-phosphate without addition of glycogen will be examined later. When possible, the results will also be controlled by repeated experiments with a more purified enzyme preparation.

This investigation was supported by grants from *the Gustav and Tyra Svenssons Memorial Foundation* and *the Wallenberg Foundation.*

On the Presence of Phosphoproteins in Baker's Yeast

LORENTZ ENGSTROM and GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

In previous reports from this laboratory it has been demonstrated that phosphoproteins are present in several microorganisms [1,2]. It has now been possible to demonstrate the presence of phosphoproteins in yeast.

The cells were washed twice in distilled water and cultured in the medium of Juni *et al.*[3] for different times. Non-labeled inorganic phosphate was excluded from the

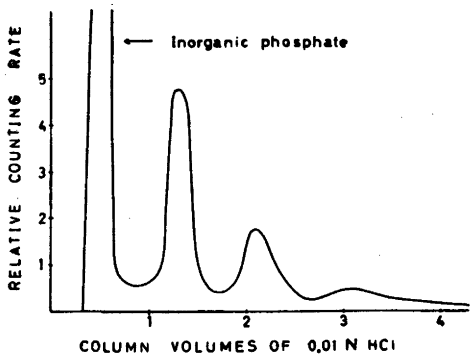

Fig. 1. Radioactivity curve from the hydrolysate of baker's yeast.

medium. About 2—3 mC radioactive phosphate per liter medium was added at the beginning of each experiment. Very heavy inocculum was used in order to obtain large amounts of phosphorylated products. At the end of the experiments trichloroacetic acid was added to a final concentration of 10 %. After centrifugation the precipitate was washed twice with 5 % trichloroacetic acid at 90° C for 15 minutes and hydrolyzed in the usual way [4].

The acid hydrolysate was run through a Dowex 50—X8 column with 0.01 N HCl. In Fig. 1 the first part of a typical elution curve is demonstrated.

A small part of the material from the first peak after the inorganic phosphate was run through a Dowex 1—X2 formate column according to Busch *et al.*[5] with the addition of non-labeled phosphoserine. The main part of the activity run parallel with the non-labeled phosphoserine. Two small peaks containing peptides of phosphoserine were also isolated from the eluate. In this way about 80 mg of crystalline radioactive phosphoserine was obtained from about 4 kg of fresh yeast cultured for about two hours at 37° C in the presence of 2 mC radioactive phosphate per liter of medium. The X-ray powder diagram of the crystals was identical with a sample isolated from casein.

The crystalline precipitate was analyzed. (Found: C 21.4; H 3.91; N 7.50; P 16.30. Calc. for $C_3H_8O_6NP$: C 19.5; H 4.32; N 7.57; P 16.76.)

Altogether about 10 column volumes of effluent from the Dowex 50 column were analyzed for radioactivity. Only one rather high peak immediately after the phosphoserine peak could be observed. In this respect the elution curve is of the same type as previously reported in experiments with partial hydrolysates of animal tissues [6], and in contrast to the findings in other microorganisms where other peaks of phosphorylated amino acids and peptides are dominating the diagram [7,2]. The peak following the phosphoserine peak is at present purified for further analysis. In hydrolysates from animal tissues the corresponding peak contains phosphothreonine.

On the Phosphorus Linkage in a Muscle Phosphorylase Preparation

LORENTZ ENGSTROM and GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

Recently we reported the isolation of ^{32}P-labeled phosphoserine from a yeast hexokinase preparation [1] incubated with radioactive adenosinetriphosphate or glucose-6-phosphate. It was concluded that hexokinase was a phosphoprotein functioning as a phosphotransferring enzyme with an incorporation of phosphate from the substrate to the enzyme molecule or an exchange between substrate and enzyme phosphate.

This paper deals with the isolation of ^{32}P-labeled phosphoserine from a muscle phosphorylase preparation incubated with glycogen and radioactive ^{32}P. The following different types of experiments were carried out with the same amount of enzyme in each experiment.

100 mg of a commercial muscle phosphorylase preparation (Delta Chemical Works, Inc.) and 150 mg of glycogen (Merck) were dissolved in 5 ml of a freshly prepared cysteine-glycerophosphate buffer [2]. 5 mC carrierfree ^{32}P was added. The solution was kept at room temperature. After 30 minutes the enzyme was precipitated with trichloroacetic acid to a final concentration of 10 %. The protein was hydrolyzed according to Lipmann [3]. ^{32}P-labeled phosphoserine was identified as previously described [1]. The specific activity calculated as cpm per μg P was 72 186. This is the highest value so far recorded by us for any phosphorylated amino acid isolated from animal or plant tissue proteins. When glycogen was present the addition of 5 mg of adenosinemonophosphate (AMP) did not seem to increase the incorporation of radioactive phosphate into the enzyme molecule. The specific activity of the isolated phosphoserine was 32 977.

Next the enzyme was incubated with ^{32}P without the addition of glycogen. The phosphoserine was isolated in the usual way. It was only slightly labeled. The specific activity was 182. Finally when the enzyme was incubated with ^{32}P and AMP the specific activity of the isolated phosphoserine was 2 626 cpm per μg P.

The results seem to indicate that muscle phosphorylase is a phosphoprotein according to our definition, since we have been able to isolate phosphoserine from the partially hydrolysed enzyme. In the enzyme reaction there is probably an exchange between enzyme and substrate phosphate. Glycogen appears to play an essential role in this mechanism. The small exchange which takes place when no polysaccharide is added to the system may depend on traces of glycogen present in the enzyme preparation.

The bearing of our results to those obtained by Sutherland and coworkers [4] is difficult to discuss at present time. The possibility of an exchange with glucose-1-phosphate without addition of glycogen will be examined later. When possible, the results will also be controlled by repeated experiments with a more purified enzyme preparation.

This investigation was supported by grants from *the Gustav and Tyra Svenssons Memorial Foundation* and *the Wallenberg Foundation.*

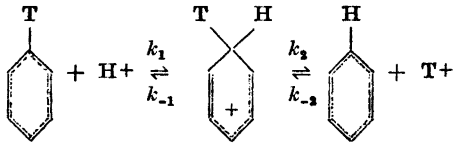
On the Presence of Phosphoproteins in Baker's Yeast

LORENTZ ENGSTROM and GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

In previous reports from this laboratory it has been demonstrated that phosphoproteins are present in several microorganisms [1,2]. It has now been possible to demonstrate the presence of phosphoproteins in yeast.



The cells were washed twice in distilled water and cultured in the medium of Juni *et al.*[3] for different times. Non-labeled inorganic phosphate was excluded from the

Kinetic Isotope Effect in Isotopic Exchange. Electrophilic Exchange of Hydrogen in Benzene and Toluene

LARS MELANDER and STIG OLSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

The existence of two heavy isotopes of hydrogen, deuterium and tritium, offers the possibility of determining the kinetic isotope effect in hydrogen exchange. As the reaction is symmetric except for the mass of the hydrogen, it is believed to be useful for examining the mechanism of electrophilic aromatic substitution [1]. If the reaction is represented by

and the intermediate is assumed to be present in a very small amount, the rate factor

$$\frac{k_2}{k_{-1} + k_2} = \frac{1}{k_{-1}/k_2 + 1}$$

will determine the isotope effect in the forward reaction. This holds irrespective of whether a hydrogen acceptor is involved in reactions -1 and 2 and also irrespective of whether the reaction proceeds *via* a low-stability intermediate of the π-complex type as assumed by Gold and Satchell [2]. If the σ-complex intermediate shown above behaves like an ordinary molecule, the ratio k_{-1}/k_2 could be supposed to be of the order of 7—10 for the tritium-protium and 4—6 for the deuterium-protium exchange. Consequently the following observable isotope effect could be expected

$$\frac{k_T}{k_D} = \frac{(k_{-1}/k_2)_D + 1}{(k_{-1}/k_2)_T + 1} \approx 0.6$$

This is indeed found.

As in previous experiments [3] 3 ml of the labelled hydrocarbon was shaken with 20 ml of aqueous sulphuric acid (this time

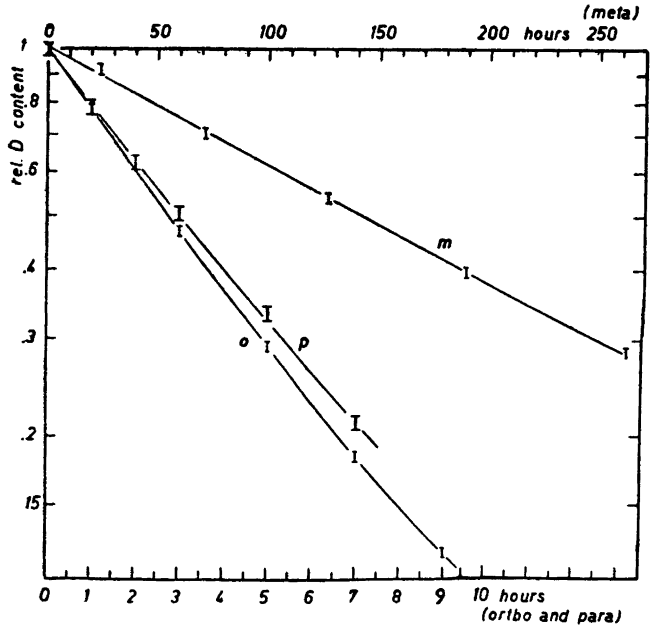


Fig. 1. Semilogarithmic plot of relative deuterium content of toluene-2-t (o), -3-t (m), and -4-t (p) as a function of time (note different time scales). For conditions, see the text.

80.8 %) at 25° C for different time intervals. In special experiments it was checked that the shaking frequency was without measurable influence on the observed rate, that the reaction took place in the acid phase, and that sulphonation was negligible. The deuterium derivatives were present in a few percent and the tritium derivatives in tracer concentrations, and the exchange of both isotopes was studied in the same experiments in each other's presence. In the analytical procedures (infrared spectrography and Geiger-Müller counting, respectively) the isotopes did not interfere. Fig. 1 shows the exchange curve for deuterium in the three nuclear positions of toluene. The limits of error were slightly less in the case of tritium. The exchange rates were determined from the initial slopes of the semilogarithmic curves [4].

The relative exchange rates for tritium in the individual positions of toluene are *o:m:p* = (47 ± 2):(1.00 ± 0.04):(41 ± 2) and for deuterium (51 ± 2):(1.00 ± 0.04):(46 ± 3). The former result differs from that obtained earlier [3] owing to insufficient shaking speed in the preliminary experiments. The results with deuterium are in agreement with similar and somewhat more approximate results obtained by Gold and Satchell in a homogeneous system (private communication).

Experiments on benzene have also been carried out in this laboratory, but the partial rate factors for the toluene positions cannot be obtained from these heterogeneous systems until the relative solubilities of the hydrocarbons have been determined.

It is seen that the directive influence of the methyl group is not exactly the same for the two exchange reactions, *i. e.* the isotope effect is not the same in the three positions. In Fig. 2 the initial slopes are represented on a reduced time scale such that all deuterium curves coincide. The results for benzene have also been included. The slopes of the tritium curves relative to the single deuterium curve give the isotope effects. The results are given in Table 1, and an idea of the accuracy could be obtained from a comparison of Fig. 2 with the typical experimental curve in

Table 1. Isotope effects in hydrogen exchange for different aromatic positions. For conditions, see the text.

Position	k_T/k_D
Toluene, *ortho*	0.53
Toluene, *meta*	0.59
Toluene, *para*	0.52
Benzene	0.65

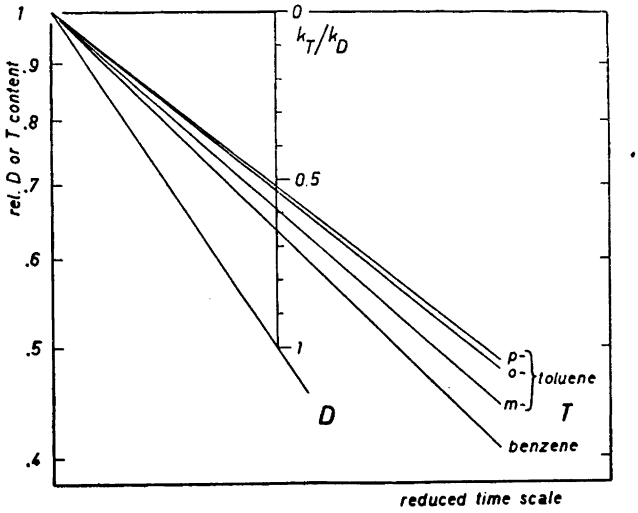

Fig. 2. Isotope effect in hydrogen exchange for different aromatic positions, cf. the text.

Fig. 1. All differences between the isotope effects except that between the *ortho* and *para* positions in toluene are believed to be significant. Differences in solubility between isotopic molecules are believed to be negligible and without importance for the present conclusions.

From the work privately communicated by Gold and Satchell it is evident that the *meta* position in toluene is somewhat more reactive than a single position in benzene, just as with the common electrophilic substitutions. Thus, it appears that the ratio k_T/k_D increases with decreasing reactivity, but whether this is a general rule cannot, of course, be inferred from the present very limited experimental material.

Open Peptide Chains in Chymotrypsinogen and α-Chymotrypsin

BODIL MEEDOM

Carlsberg Laboratorium, Copenhagen, Denmark

The principle of breaking S—S linkages in proteins by oxidation has been used extensively and with considerable success in the study of the chemical constitution of the peptide chains in these substances [1].

Upon the suggestion of M. Ottesen the author has applied this method to the study of α-chymotrypsin and chymotrypsinogen. Part of this work was reported in a paper read at a meeting in Uppsala in January 1956 [2] and in the following the further development of these investigations is briefly described.

The opening of the disulfide bridges by oxidation [3] causes the α-chymotrypsin molecule to fall apart essentially into three peptides which were separated as follows:

The oxidized enzyme was dissolved in alkali and pH brought down to 6 whereby a precipitate (fraction B) was formed. The supernatant was placed on a small Dowex 50 column (H^+ form). By elution with water, fraction A was collected, and by subsequent elution with NH_4OH, fraction C was obtained.

Fractions A, B, and C could also be separated by dialysis (removal of A) followed by free electrophoresis at pH-values higher than 7.5 (separation of B and C).

Amino acid analysis and end-group determinations were carried out on the fractions using the Sanger method [4] for amino-endgroup determination and digestion by carboxypeptidase [5] for the carboxyl-end-group estimation. The results were as follows:

Fraction A is a peptide composed of 13 amino acids, *viz.* 1 cysteic acid, 1 serine, 1 glutamic acid, 1 alanine, 2 glycine, 2 valine, 1 *iso*leucine, 2 leucine, and 2 proline. The N-terminal amino acid is cysteic acid and the C-terminal leucine.

Fraction C is a larger peptide containing about 50 amino acids. Of the species present in chymotrypsin only histidine and arginine are missing in C. Alanine is the N-terminal amino acid and tyrosine the C-terminal.

Fraction B seems to be a long peptide chain with an N-terminal *iso*leucine and a C-terminal tyrosine.

It is rather surprising that all three separated peptides are attacked by carboxypeptidase inasmuch as native α-chymotrypsin only contains two C-terminal end-groups as estimated by degradation with this enzyme [5].

The higher susceptibility of oxidized α-chymotrypsin to the action of carboxypeptidase may be due to an "unmasking" of a group which, although it conforms to the specific requirements of the enzyme, is inaccessible to it in native α-chymotrypsin under normal conditions.

The same effect would naturally be observed if a peptide bond had been broken during the oxidation procedure, but we feel justified in ruling out this possibility since no new N-terminal group seems to be formed.

The presence of a hidden C-terminal group in α-chymotrypsin suggests that of an identical group in chymotrypsinogen.

Oxidized, dialyzed chymotrypsinogen was therefore incubated with carboxypeptidase and the reaction mixture analyzed for free amino acids in the usual way.

Fig. 1. All differences between the isotope effects except that between the *ortho* and *para* positions in toluene are believed to be significant. Differences in solubility between isotopic molecules are believed to be negligible and without importance for the present conclusions.

From the work privately communicated by Gold and Satchell it is evident that the *meta* position in toluene is somewhat more reactive than a single position in benzene, just as with the common electrophilic substitutions. Open Peptide Chains in Chymotrypsinogen and α-Chymotrypsin

BODIL MEEDOM

Carlsberg Laboratorium, Copenhagen, Denmark

The principle of breaking S—S linkages in proteins by oxidation has been used extensively and with considerable success in the study of the chemical constitution of the peptide chains in these substances [1].

Upon the suggestion of M. Ottesen the author has applied this method to the study of α-chymotrypsin and chymotrypsinogen. Part of this work was reported in a paper read at a meeting in Uppsala in January 1956 [2] and in the following the further development of these investigations is briefly described.

The opening of the disulfide bridges by oxidation [3] causes the α-chymotrypsin molecule to fall apart essentially into three peptides which were separated as follows:

The oxidized enzyme was dissolved in alkali and pH brought down to 6 whereby a precipitate (fraction B) was formed. The supernatant was placed on a small Dowex 50 column (H^+ form). By elution with water, fraction A was collected, and by subsequent elution with NH_4OH, fraction C was obtained.

Fractions A, B, and C could also be separated by dialysis (removal of A) followed by free electrophoresis at pH-values higher than 7.5 (separation of B and C).

Amino acid analysis and end-group determinations were carried out on the fractions using the Sanger method [4] for amino-endgroup determination and digestion by carboxypeptidase [5] for the carboxyl-end-group estimation. The results were as follows:

Fraction A is a peptide composed of 13 amino acids, *viz.* 1 cysteic acid, 1 serine, 1 glutamic acid, 1 alanine, 2 glycine, 2 valine, 1 *iso*leucine, 2 leucine, and 2 proline. The N-terminal amino acid is cysteic acid and the C-terminal leucine.

Fraction C is a larger peptide containing about 50 amino acids. Of the species present in chymotrypsin only histidine and arginine are missing in C. Alanine is the N-terminal amino acid and tyrosine the C-terminal.

Fraction B seems to be a long peptide chain with an N-terminal *iso*leucine and a C-terminal tyrosine.

It is rather surprising that all three separated peptides are attacked by carboxypeptidase inasmuch as native α-chymotrypsin only contains two C-terminal end-groups as estimated by degradation with this enzyme [5].

The higher susceptibility of oxidized α-chymotrypsin to the action of carboxypeptidase may be due to an "unmasking" of a group which, although it conforms to the specific requirements of the enzyme, is inaccessible to it in native α-chymotrypsin under normal conditions.

The same effect would naturally be observed if a peptide bond had been broken during the oxidation procedure, but we feel justified in ruling out this possibility since no new N-terminal group seems to be formed.

The presence of a hidden C-terminal group in α-chymotrypsin suggests that of an identical group in chymotrypsinogen.

Oxidized, dialyzed chymotrypsinogen was therefore incubated with carboxypeptidase and the reaction mixture analyzed for free amino acids in the usual way.

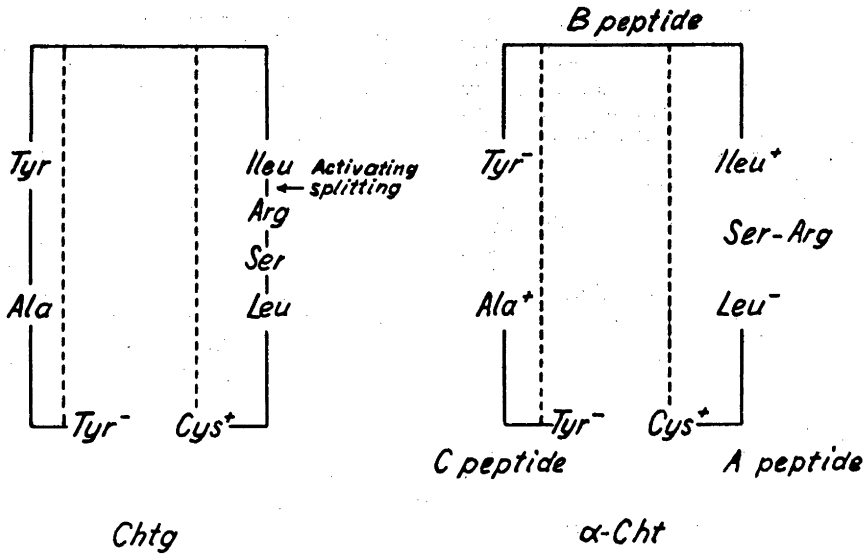

Fig. 1. Schematic drawing of chymotrypsinogen and α-chymotrypsin. The S—S bridges which link the peptide chains together are symbolized by the dotted lines. The A peptide is arbitrarily connected to the B peptide.

Paperchromatograms revealed that tyrosine and leucine were released as the first two amino acids, followed by valine, alanine, and serine.

Also in this case oxidation produced no new N-terminal groups in stoichiometrically significant amounts and in agreement herewith only one boundary was formed in free electrophoresis of the oxidized protein.

In an attempt to unmask the C-terminal group in a milder way than by oxidation, carboxypeptidase was allowed to act on chymotrypsinogen in 6 M urea [6]. In one of the experiments 0.8 mole of tyrosine, 0.7 mole of leucine, and 0.4 mole of valine were liberated per mole of chymotrypsinogen together with smaller quantities of phenylalanine, serine, and alanine (quantitative estimation by chromatography on Moore and Stein columns [7]).

On the basis of these experiments it may be stated with considerable certainty that the third C-terminal group found in oxidized α-chymotrypsin is not formed by rupture of a peptide bond during oxidation but is a hitherto not identified terminal group in chymotrypsinogen.

This result together with Bettelheim's discovery of the N-terminal half cystine [8] establishes chymotrypsinogen as an open peptide chain with a C-terminal tyrosine. This fact is easily brought in relation to previous considerations concerning the structure of α-chymotrypsin and its precursors [3,5]. This is seen in Fig. 1. It will be observed that in the model assumed here the activating splitting should take place at a distance of 15 amino acids from the N-terminal group (peptide A + ser-arg).

A more detailed report of the experiments will appear in *Comptes Rendus des Travaux du Laboratoire Carlsberg.*

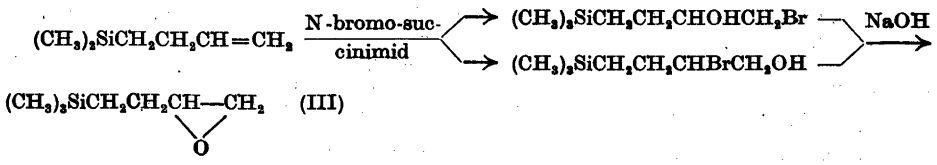
The Synthesis of Some Organosilicon Alcohols.

SUNE BRYNOLF

Chemical Institute of the University, Department of Organic Chemistry, Lund, Sweden



In order to prepare some organosilicon alcohols with their hydroxyl groups attached to carbon atoms the reaction between epichlorohydrin and trimethylsilylmethylmagnesium bromide was investigated. The only silicon-containing alcohol (A) that could be isolated was 4-trimethylsilyl-1-chlorobutanol-2. The constitution of this compound was proved by transforming it into the corresponding epoxy-compound, 4-trimethylsilylbutylene-1,2-oxide, which was compared with an authentic sample.

The two chlorohydrins that theoretically may be obtained from epichlorohydrin and trimethylsilylmethylmagnesium bromide must have either constitution (I) or (II)

$(CH_3)_3SiCH_2CH_2CHOHCH_2Cl$
(I)

$(CH_3)_3SiCH_2CH(CH_2Cl)CH_2OH$
(II)

The obtained chlorohydrin (A) must have the constitution (I) because it gave on alkaline hydrolysis an oxide (B), identical with the oxide (III) that was obtained from 4-trimethylsilylbuten-1, prepared by Hauser and Hance [1], on interaction with N-bromosuccinimide and alkali, analogously to a method described by Guss and Rosenthal [2]. The synthesis may be described by the following formulas:

$(CH_3)_3SiCH_2CH_2CH{-}CH_2$ (III)
O

The identity between (B) and (III) was demonstrated by the fact that the crystalline amine alcohols resulting from interaction between the oxides and aniline had the same melting points.

Oxide	Addition product with aniline. M. p.	B.p. 20 mm Hg
(B)	52.5—53° *	58—59°
(III)	53 —53.5°	58—60°

(A) was characterized as its phenylurethan.

Experimental. 4-Trimethylsilyl-1-chlorobutanol-2 (A). 92.5 g (1.0 mole) of epichlorohydrin were dropped with stirring into the Grignard reagent prepared from 83.5 g (0.5 mole) of bromomethyltrimethylsilane, 12.0 g magnesium and 100 ml of absolute ether in a 1-litre flask equipped with a stirrer, a reflux condenser and a dropping funnel, and immersed in an ice-bath. When all the oxide had been added the ice-bath was removed, whereupon the temperature of the mixture generally rose enough to cause boiling. When this ceased the mixture was warmed on a water bath (45—46°) for 5—6 hours. The reaction mixture was decomposed with ice-water. Simultaneously the ether and tetramethylsilane were distilled over. *Ca.* 10 g (0.13 mole) of tetramethylsilane could be recovered from the distillate by dropping it into concentrated sulphuric acid, cooled in an ice-and-salt bath.

The magnesium hydroxide precipitated by hydrolysis was dissolved by adding a sufficient quantity of dilute hydrochloric acid. The organic layer was separated and the water layer extracted with ether. The combined ether solutions were washed with a small quantity of water and dried with anhydrous sodium sulphate. After removal of the ether, fractionation at 20 mm Hg yielded 49 g (0.39 mole) of glyceroldichlorohydrin at 74—75°, 34 g (0.20 mole) glycerolchlorobromohydrin at 88—89° and 45.5 g (0.25 mole) 4-trimethylsilyl-1-chlorobutanol-2 at 103—104°. Practically no higher boiling products were obtained. $n_D^{20} = 1.4562$, $d_4^{20} = 0.9790$. (Found: C 46.4; H 9.6; Si 15.3, MR_D 50.2; equiv. wt 180.* Calc.

* mixed m. p. with (III). 53—53.5°.

for $C_7H_{17}OClSi$: C 46.5; H 9.5; Si 15.5; MR_D 50.5; equiv.wt. 181).

N-Phenylurethan. 2.3 g (0.019 mole) of phenyl *iso*cyanate and 2.6 g (0.015 mole) of (A) were warmed for 5 minutes on a boiling water bath. The mixture was allowed to stand at room temperature until crystallization occurred. The crystal cake was boiled with 10 ml of petroleum ether (b.p. 100—110°) and the insoluble diphenylurea removed by filtration. The filtrate was cooled in ice and the obtained crystals were collected on a filter and recrystallized from petroleum ether. The yield of crystals melting at 77.5—78° was 3.2 g (0.011 mole). (Found: C 56.3; H 7.4; Si 9.3; equiv.wt. 298 *. Calc. for $C_{14}H_{22}O_2ClNSi$: C 56.1; H 7.4; Si 9.3; equiv.wt. 300.)

4-Trimethylsilylbutylene-1,2 oxide (B) from (A). 100 g (0.55 mole) of (A) were dissolved in 200 ml of ether and refluxed for 3 h with 80 g (2.0 moles) of finely powdered sodium hydroxide. The mixture was filtered and the precipitate washed several times with ether. The ether was removed by distillation and the residue was fractionated at 20 mm Hg. 56 g (0.39 mole) of 4-trimethylsilylbutylene-1,2-oxide were collected at 58—59°. $n_D^{20} = 1.4276$, $d_4^{20} = 0.8452$. (Found: C 58.2; H 11.3; Si 19.0; MR_D 43.9. Calc. for $C_7H_{16}OSi$: C 58.2; H 11.2; Si 19.5; MR_D 43.9.)

Addition product with aniline. 2.0 g of (B) dissolved in 30 ml of ethanol were dropped into a stirred solution of 14.0 g of freshly distilled aniline in 50 ml of ethanol and 15 ml of water. The mixture was allowed to stand for 3 days. The ethyl alcohol was distilled off until two layers were formed. After cooling to room temperature the organic layer was separated and the water layer extracted with ether. The ether and the remaining ethanol were removed from the combined ether layers by distillation at ordinary pressure and the excess of aniline at 2 mm Hg. The residue solidified on cooling and was crystallized four times from petroleum ether (b. p. 30—50°). 2.0 g (60 %) of crystals melting at 52.5—53° were obtained. (Found: C 64.8; H 9.7; Si 11.8. Calc. for $C_{13}H_{23}NOSi$: C 65.8; H 9.8; Si 11.8.)

4-Trimethylsilylbutylene-1,2-oxide from 4-trimethylsilylbutene-1. (III). 16.2 g (0.091 mole) of N-bromosuccinimide and 11.6 g (0.091 mole) of 4-trimethylsilylbutene-1 were shaken with 100 ml of water until all the N-bromosuccinimide had dissolved. The solution was extracted with ether and the combined ether portions were treated with alkali according to the method above. 4.2 g (0.030 mole) of (III) were obtained.

The *addition product with aniline* was prepared in the same way as above for the oxide (B). M. p. 53—53.5°.

The author wishes to express his appreciation to Professor Erik Larsson for his kind interest in this work.

Corrected Heats of Combustion of Organic Iodine Compounds

LENNART SMITH

Chemical Institute, University of Lund, Sweden

In his dissertation [1] Karlsson * has shown convincingly that combustion in a calorimetric bomb of iodine containing compounds forms only elemental iodine besides carbon dioxide and water **. He further estimated that the heats of sublimation and solution of the iodine under his experimental conditions (liquid phase in the bomb 20 ml water) were very small (0.05 and 0.1 cal, respectively) and considered them negligible. For the heats of solution of the carbon dioxide appropriate corrections, however, were not applied, since the method of calculation of these was worked out and described after the publication of Karlssons dissertation (Smith *et al.*[3]).

Owing to the experimental conditions used by Karlsson, and the iodine compounds chosen by him, the last mentioned corrections are mostly very small as will be shown below. Thus his values of combustion are more accurate than should be expected from the considerable quantity of water present in the bomb during the

The filtrate was cooled in ice and the obtained crystals were collected on a filter and recrystallized from petroleum ether. The yield of crystals melting at 77.5—78° was 3.2 g (0.011 mole). (Found: C 56.3; H 7.4; Si 9.3; equiv.wt. 298 *. Calc. for $C_{14}H_{22}O_2ClNSi$: C 56.1; H 7.4; Si 9.3; equiv.wt. 300.)

4-Trimethylsilylbutylene-1,2 oxide (B) from (A). 100 g (0.55 mole) of (A) were dissolved in 200 ml of ether and refluxed for 3 h with 80 g (2.0 moles) of finely powdered sodium hydroxide. The mixture was filtered and the precipitate washed several times with ether. The ether was removed by distillation and the residue was fractionated at 20 mm Hg. 56 g (0.39 mole) of 4-trimethylsilylbutylene-1,2-oxide were collected at 58—59°. $n_D^{20} = 1.4276$, $d_4^{20} = 0.8452$. (Found: C 58.2; H 11.3; Si 19.0; MR_D 43.9. Calc. for $C_7H_{16}OSi$: C 58.2; H 11.2; Si 19.5; MR_D 43.9.)

Addition product with aniline. 2.0 g of (B) dissolved in 30 ml of ethanol were dropped into a stirred solution of 14.0 g of freshly distilled aniline in 50 ml of ethanol and 15 ml of water. The mixture was allowed to stand for 3 days. The ethyl alcohol was distilled off until two layers were formed. After cooling to room temperature the organic layer was separated and the water layer extracted with ether. The ether and the remaining ethanol were removed from the combined ether layers by distillation at ordinary pressure and the excess of aniline at 2 mm Hg. The residue solidified on cooling and was crystallized four times from petroleum ether (b. p. 30—50°). 2.0 g (60 %) of crystals melting at 52.5—53° were obtained. (Found: C 64.8; H 9.7; Si 11.8. Calc. for $C_{13}H_{23}NOSi$: C 65.8; H 9.8; Si 11.8.)

4-Trimethylsilylbutylene-1,2-oxide from 4-trimethylsilylbutene-1. (III). 16.2 g (0.091 mole) of N-bromosuccinimide and 11.6 g (0.091 mole) of 4-trimethylsilylbutene-1 were shaken with 100 ml of water until all the N-bromosuccinimide had dissolved. The solution was extracted with ether and the combined ether portions were treated with alkali according to the method above. 4.2 g (0.030 mole) of (III) were obtained.

The *addition product with aniline* was prepared in the same way as above for the oxide (B). M. p. 53—53.5°.

The author wishes to express his appreciation to Professor Erik Larsson for his kind interest in this work.

Corrected Heats of Combustion of Organic Iodine Compounds

LENNART SMITH

Chemical Institute, University of Lund, Sweden

In his dissertation [1] Karlsson * has shown convincingly that combustion in a calorimetric bomb of iodine containing compounds forms only elemental iodine besides carbon dioxide and water **. He further estimated that the heats of sublimation and solution of the iodine under his experimental conditions (liquid phase in the bomb 20 ml water) were very small (0.05 and 0.1 cal, respectively) and considered them negligible. For the heats of solution of the carbon dioxide appropriate corrections, however, were not applied, since the method of calculation of these was worked out and described after the publication of Karlssons dissertation (Smith *et al.*[3]).

Owing to the experimental conditions used by Karlsson, and the iodine compounds chosen by him, the last mentioned corrections are mostly very small as will be shown below. Thus his values of combustion are more accurate than should be expected from the considerable quantity of water present in the bomb during the

* Now Karrman.

** Concerning other investigations of this problem, see Ref.[2].

combustion. It may be mentioned here that his values are not published elsewhere than in his dissertation.

For the recalculation of his data I have applied eqn 2 in Ref.[3]. This equation, the result of experiments with chlorine compounds, in which a HCl-containing bomb solution is formed, was nevertheless used even here, as considered exact enough for the very small corrections occurring in this case.

In Karlssons *calibration* experiments also the above mentioned quantity of water was present in the bomb. The standard being benzoic acid and almost all the compounds burnt aromatic, the errors in the heat equivalent and in the heats of combustion of the compounds tend to cancel. Among the aromatic compounds the iodotoluenes have the maximum-correction (0.4 cal/g). For the only non-aromatic compound, iodo*cyclo*hexane, the correction has been calculated to 0.7 cal/g.

In Table 1 developed heat is considered *positive*, as done in the dissertation. Notations in the table: In the first column "No." refers to the table numbers in Ref.[1]; in the second the names of the compounds are given, "l" = liquid, "s" = solid, and in the third the heats of combustion (cal/g; const. volume) determined by Karlsson. In the fourth column "Corr.CO_2" denotes the calculated correction (cal/g) for the heat of solution of carbon dioxide; the fifth contains the correction to weight in vacuum ("Corr. vac.") and the sixth ("Heats of comb, corr.") the final corrected heats. Temperature 20°. — For computing the heats of combustion in the gaseous state of the compounds, the heats of vaporization and sublimation in Ref.[1], Tables 89 and 90, can be used.

Compounds, which are liquid at 20°, were burnt with cellophane cover. This method gives too low results (see Ref.[3], p. 79). The resulting errors will of course diminish with rising boiling points of the compounds (see also Ref.[4], p. 196).

The table shows that the corrections caused by the heat of solution of carbon dioxide, especially for the solid compounds, are very small and negligible, this, as already mentioned, depending on the fact that the errors in the determination of the heat equivalent and the heat of combustion of the compounds mostly almost cancel.

Table 1. Heats of combustion of iodine compounds.

[a] Not corrected to weight in vacuum.

[b] These corrections are given by Karlsson only for the heat of combustion per mole.

Compounds with an appreciable carbon dioxide correction are in the liquid state and Karlssons values (see above) of the heats of combustion are certainly somewhat too low (perhaps except for α-iodonaphthalene with a very high boiling point). The plus-correction in the heats for the liquid compounds thus will diminish the error in question.

Comparative Crystal Field Studies II. Nickel(II) and Copper(II) Complexes with Polydentate Ligands and the Behaviour of the Residual Places for Co-Ordination

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The complexes of nickel(II) and copper(II) with ethylenediaminetetraacetate, nitrogentriacetate and β,β',β''-tris(ethylamino)amine have one or more residual places left for co-ordination. The absorption spectra of such complexes containing either water, ammonia, ethylenediamine, glycinate or cyanide were determined. The wavenumbers of the bands illustrate the regular behaviour of paramagnetic octahedral nickel(II) complexes, whereas the intensities vary. Some copper(II) complexes are much more tetragonally distorted than others. The "chelate" effect in formation constants is not only due to the different dependence on dilution of the degree of formation of polydentate ligands' complexes, but can be estimated from the spectra in some cases to contain actual stabilization energies. The different crystal field strength of six nitrogens in nickel(II) amine complexes is further illustrated, *e.g.* by 1,3-diaminopropane. The bonding of cyanide in paramagnetic complexes is not very strong and the complexes slowly react to form yellow, diamagnetic nickel(II) and colourless copper(I) cyanides. β,β',β''-tris(ethylamino)amine does not form a tetrahedral complex with nickel(II), since the water in *cis*-position of the octahedral complex can be exchanged with ammonia, ethylenediamine or glycinate. The last complex has a very hypsochromic spectrum corresponding to a high stabilization energy. The absorption spectra of nickel(II) complexes demonstrate intermediate coupling and decreased values of the Racah parameters of electrostatic interaction between d-electrons, relative to the gaseous ion.

The first paper of this series [1] treated nickel(II) complexes with increasing crystal field strength, corresponding to yellow, green, blue, purple and red colours. The four strongest absorption bands can be interpreted as transitions from the groundstate $^3\Gamma_2$ (F) to $^1\Gamma_3$ (D), $^3\Gamma_5$ (F), $^3\Gamma_4$ (F) and $^3\Gamma_4$ (P) in the notation of Bethe [2]. It was shown that the singlet state $^1\Gamma_3$ (D) is intermixed with $^3\Gamma_5$ (F) and $^3\Gamma_4$ (F) by effects of intermediate coupling. In the present paper, nickel(II) is studied in different environments, supplied partly by polydentate ligands. Further, characteristic properties of copper(II), compared to nickel(II) complexes will be discussed [1].

Empirically, the absorption spectra of mixed complexes have led to the idea of averaged environment. For example, except for very small solvent effects, the six atoms in the first co-ordination sphere of an octahedral complex determine the absorption spectrum. The position of the absorption bands can be predicted mainly from one parameter, expressing the average of the positions of the ligands in the spectrochemical series. Thus, Mead [3] studied mixed ethylenediamine- and oxalate complexes of chromium (III) and cobalt(III); Tsuchida [4] investigated many complexes of the same two metals, *e.g.* acido-pentammines. Mathieu [5] investigated the influence of amino-acids on the two residual places in *cis*-bis(ethylenediamine)cobalt(III) ions. Linhard and Weigel studied the halogenopentammines [6] and the *cis*- and *trans*-tetrammines and pentammines of cobalt(III) with carboxyl groups on the residual places [7]. Copper(II) complexes with ethylenediamine and other ligands have been studied by Jonassen *et al.*[8], copper(II) bis(acetylacetonate) with different solvents by Belford [9] and cobalt(III) complexes by Basolo, Ballhausen and Bjerrum [10]. In some cases crystal fields of pronounced tetragonal symmetry produce new bands by splitting as in *trans*-Co $en_2Cl_2^+$. In the second and third transition group, Delépine's complexes of rhodium(III) and iridium(III) exhibit similar behaviour [11]. Since water is exchanged without change of the co-ordination number, the consecutive uptake of six ammonia molecules to nickel(II), studied by J. Bjerrum [12], or of three ethylenediamine molecules, measured by Ballhausen [13], can also be cited as examples of mixed complexes with water as one of the ligands.

Table 1 gives the absorption spectra measured here of nickel(II) complexes and Table 3 of copper(II) complexes. Table 2 collects the band maxima of nickel(II) and gives also the results of the first paper [1].

The following abbreviations will be used for the ligands:

en	= ethylenediamine = 1,2-diaminoethane
tn	= trimethylenediamine = 1,3-diaminopropane
bdn	= 1,3-diaminobutane
ptn	= 1,2,3-triaminopropane
tren	= β,β',β''-tris(ethylamino)amine
trien	= triethylenetetramine
den	= diethylenetriamine
tetren	= tetraethylenepentamine
temeen	= C,C,C′,C′-tetramethyl-ethylenediamine
dip	= α,α'-dipyridyl = 2,2′-bipyridine
phen	= *o*-phenanthroline = 1,10-phenanthroline
gly^-	= glycinate = aminoacetate
ata^{-3}	= ammoniatriacetate * = nitrilotriacetate = nitrogentriacetate
$enta^{-4}$	= ethylenediaminetetraacetate.

NICKEL(II) ETHYLENEDIAMINETETRAACETATES

Schwarzenbach [14] studied the colour reactions of Ni $enta^{---}$ with NH_3, en and CN^-. He pointed out that the formation constant of Ni $enta^{---}$ is so large that the other ligands do not decompose this complex. While this has a somewhat limited validity in the case of Ni $enta^{---}$ + en, as discussed below, the ligands must be assumed to exchange with the water present in the first co-ordination sphere of Ni enta, H_2O^{---}. The latter complex has a free carboxyl group, which can take up protons[15] with $pK = 3$, forming Ni enta H, H_2O^{--}. In Table 1, two forms are given of nickel(II) ethylenediaminetetraacetate, denoted α and β. The latter form corresponds to the intermediate form which is observed [1] during the slow formation reactions. However, at low pH $\sim$ 3,

* As proposed by Martell and Calvin in *The Chemistry of the Metal Chelate Compounds*, New York 1952. Professor K. A. Jensen has proposed the name "nitrogentriacetate".

Table 1. Absorption bands of nickel(II) complexes. Wavelength λ_n, wavenumber ν_n and molar extinction coefficient ε_n of the maxima; δ (−) and δ (+) the half-width towards lower and higher wavenumbers, and P *the oscillator strength for each band.*

the β-form is stable and can be formed by addition of acids to the α-form. This cannot be due to a partly decomposition to hexaaquo ions, since the fourth band of the β-form is higher and shifted towards higher wavenumbers than of the α-form, while the other three bands show a different behaviour *. Since two isomers are possible [1] for the complex Ni enta (H_2O), with water in *cis*- or *trans*-position to one of the nitrogen atoms, α- and β-may represent two

* Plumb, Martell and Bersworth [58] measured the spectra of some enta^{-4}-complexes. The height of the first band indicate the β-structure of their Ni enta^{--}.

different equilibrium mixtures, where the equilibrium is changed by the formation of Ni enta H, H_2O^-. But the change might also be due to a variable number of water molecules in the environment. An anhydrous complex analogous to Co enta$^-$, would be promoted by high pH and might thus participate in the α-form.

It is seen from Table 1 that the enormously high intensity of the first band of α-Ni enta^{--} decreases for the addition compounds of NH_3, en and CN^-, while the other bands show mainly increasing intensities. The fourth band of Ni enta en^{--} is not high, but rather broad. This may be ascribed to tetragonal splitting [16] or to the presence of more isomers. Although enta^{-4} probably occupies only four co-ordination positions in this complex, the question might be raised as to whether one or two NH_3 are bound in the ammonia complex. If ammonia is added to 0.1 M Ni enta^{--} the ε values of the fourth band are, respectively:

α-Ni enta^{--}	12.6
β-Ni enta^{--}	13.8
1 NH_3: 1 Ni	16.0
2 NH_3: 1 Ni	18.1
3 NH_3: 1 Ni	19.5
10 NH_3: 1 Ni	20.2

This suggests a formation constant for Ni enta NH_3^{--} of about 20, leaving 0.05 M free NH_3 at its 50 % formation. The small band-width (Table 1) does not suggest the presence of more complexes, but this can of course not be excluded. The intensity demonstrates that the decomposition to enta-free ammonia complexes cannot be advanced. log $K = 1.3$ resembles much the average value [12] in the nickel(II)-ammonia system, *viz.* log $K_{av} = 1.43$, whilst log $K_6 = 0.01$.

If 1 M potassium cyanide is gradually added to 0.1 M Ni enta$^-$, a more intense blue-violet colour is observed. The colour becomes distinctly more lilac at the ratio 3 CN^-: 1 Ni. These solutions do not change for several weeks at room temperature. They are, however, slightly decomposed due to local excess concentrations during the preparation as shown by the high absorption in the ultraviolet due to ~1 % Ni $(CN)_4^{--}$. Therefore, the fourth absorption band can only be observed as a shoulder. Solutions in the ratio 5 CN^-: 1 Ni decompose in a few seconds to the yellow colour of diamagnetic nickel(II). The formation constants of the paramagnetic, violet forms are not exceedingly large, as shown by the slow variation of the spectrum with the ratio x CN^-: 1 Ni. A similar behaviour was found by Schwarzenbach [14] for Co enta SCN^{-3} which has the formation constant $K = 0.7$.

NICKEL(II) NITROGENTRIACETATES

Schwarzenbach and Biedermann [17] found two nitrogentriacetate complexes of several metal ions, *e. g.* Ni ata$^-$ and Ni ata$_2^{-4}$ with log $K_1 = 11.26$ (as later determined by Schwarzenbach and Freitag [59]) and log $K_2 = 4.7$. As seen in Table 1, the first band of blue-green Ni ata$^-$ is not as high as that of Ni enta^{--} and the band intensities of the violet-blue Ni ata$_2^{-4}$ are low, suggesting the presence of a centre of inversion [10,18]. It is not known whether ata^{-3} functions

as a tri- or tetradentate ligand, but this will not be of great importance to the spectra, since H_2O and $RCOO^-$ are nearly adjacent in the spectrochemical series. In the Ni ata_2^{-4}, one would for symmetry reasons expect bonding of one nitrogen and two carboxyl groups from each ligand. The two nitrogen atoms may be in *cis*- or *trans*-configuration. The *cis*-form does not seem very likely, since the intensity relations are different from Ni $enta^{-2}$ with two *cis*-nitrogens. The fourth band of Ni ata_2^{-4} has a shoulder on the side of high wavenumbers, and the second band a less pronounced shoulder towards the lower wavenumbers. This may be ascribed to tetragonal effects (of the rare "compressed" type [11,16] in the *trans*-complex) or to the presence of different isomers.

The uptake of ammonia and ethylenediamine in Ni ata^- does not lead to very high displacements towards higher wavenumbers (Table 1) whereas glycinate in Ni ata gly^- has a stronger effect. The first absorption band is particularly difficult to move, and the direction of change is even opposite to that expected for Ni ata en^-. Ni ata^- decomposes very rapidly upon addition of CN^- probably due to more positions for "attack" than in Ni $enta^-$. Ni ata den^- has broad bands with relatively very high wavenumbers.

NICKEL(II) tren-COMPLEXES

Cox and Webster [19] investigated the crystal structure of Ni $tren(SCN)_2$, which could either be a *cis*-octahedral or a tetrahedral complex. Mr. C. J. Ballhausen and the present author have a year ago measured the spectrum of Ni $tren^{++}$ which is similar to that of Ni en_2^{++}, strongly supporting the *cis*-diaquo configuration. Mr. S. E. Rasmussen has kindly presented me with a sample of anhydrous Ni $tren(SCN)_2$ which in 0.03 M aqueous solution has an identical spectrum. In solution, the thiocyanate ions are thus exchanged with water.

Data in Table 1 show that Ni $tren^{++}$ reacts with dilute NH_3 and one mole of en with a slight displacement of the bands towards lower wavenumbers, as expected for the exchange of H_2O by NH_3 and en in an octahedral complex. Most surprising is the behaviour of the purplish red Ni tren gly^+, which is much more hypsochromic than either Ni $tren^{++}$, Ni gly_3^- or Ni_2 $tren_3^{+4}$. This deviation from the rule of average environment can be ascribed to an actual chelate effect, or to the electrostatic effect of binding one glycinate and thus decreasing the external charge. On the other hand Ni en_2 gly^+ is not so strongly hypsochromic.

With excess tren, Ni $tren^{++}$ forms the complexes $Ni_2tren_3^{+4}$ or Ni $tren_2^{++}$ with a crystal field strength similar to that of Ni en_3^{++}. Similar behaviour was found by Jonassen and Douglas [20] for nickel(II) complexes of triethylenetetramine = trien. The spectra found for Ni $trien^{++}$ and Ni_2 $trien_3^{++}$ have the absorption bands at almost the same wavenumbers as do Ni en_2^{++} and Ni en_3^{++}, respectively. Jonassen and Douglas [20] have measured the double band, corresponding to the intermixing [1] of ${}^1\Gamma_3$ (*D*) and ${}^3\Gamma_5$ (*F*), but did not draw the curves through the points. In the case of Hg $tren^{++}$, Prue and Schwarzenbach [42] demonstrated the existence of mixed complexes with chloride and bromide ions on the residual places. *Cf.* also the observations by Mann [66] of hexaco-ordinated Pt $trenI_2$ and Pt ptn_2^{++}.

NICKEL(II) COMPLEXES OF ETHYLENEDIAMINE AND GLYCINATES

Ballhausen [13] determined the spectra of Ni en$(H_2O)_4^{++}$ and Ni $en_2(H_2O)_2^{++}$ from the observed spectra of Ni^{++}-en-mixtures treated by the method of J. Bjerrum [12]. However, Ballhausen did not observe the weak singlet transition ^{1} to $^1\Gamma_3$ (D). In mixtures of 1 Ni : 1 en, a narrow band can be distinguished at 734 mμ with an effective $\varepsilon = 2.1$. Since the mixed spectrum of Ni^{++} + Ni en_2^{++} is approximately a horizontal line in this wavelength range [13], the measured band occurs at the same place for pure Ni en^{++} as it does for the mixture (18 % each of Ni^{++} and Ni en_2^{++} and 64 % Ni en^{++} at $\bar{n} = 1$).

Ni en_2 gly^+ was measured (Table 1) for comparison with Ni tren gly^+. The spectrum of Ni en_2 gly^+ is not changed noticeably with excess of gly^-. However, the formation constants with en are so large [12] relative to glycinate [21] that no appreciable disproportionation occurs.

Further the spectrum of Ni en gly_2 was determined in solution (Table 1), which for similar reasons does not deviate much from that of the pure complex. The spectra agree well with the interpolation between Ni en_3^{++} and Ni gly_3^-.

NICKEL(II) COMPLEXES OF VARIOUS AMINES

In the first paper [1], several nickel(II) complexes were studied with six nitrogen atoms surrounding the central ion, *viz.* Ni$(NH_3)_6^{++}$, Ni en_3^{++}, Ni dip_3^{++} and Ni $phen_3^{++}$. The crystal field strength (E_1—E_2) varies from 10 800 to 12 200 cm^{-1} in this series. Since the groundstate is stabilized 1.2 (E_1—E_2) by the $\gamma_5^6\gamma_3^2$-configuration [22], this represents a considerable range of energy differences, relative to (E_1—E_2) = 8 500 cm^{-1} in Ni$(H_2O)_6^{++}$. J. Bjerrum and the present author pointed out [23] that these stabilizations actually can be found in the values of ΔG for formation of nickel(II) complexes, compared with the similar values of Ca^{++}, Mn^{++} and Zn^{++} without crystal field stabilization. There has been much discussion [24] as to whether the large formation constants for complexes with chelates are only due to effects of entropy, leaving ΔH nearly constant, or if a real "chelate effect" exists also in the bond strength. Since the absorption spectra demonstrate stronger stabilization of ethylenediamine than of ammonia complexes, the chelate effect according to I. Poulsen and J. Bjerrum [25] must be partly real in the complexes with unfilled d-shells, while it may be due to entropy alone in complexes with closed shells. I. Poulsen and J. Bjerrum [25] also investigated ΔG and ΔH of nickel(II) and copper(II) complexes with tn. Trimethylenediamine was found to be distinctly weaker bound to these metal ions than ethylenediamine. As seen from Tables 1 and 2 the place of tn in the spectrochemical series is between NH_3 and en, and rather near to NH_3. Except for the first absorption band of Ni tn_3^{++}, the bands are higher than that of Ni en_3^{++}, as often found by increasing size of the organic ligand [18].

Similar behaviour is found in Ni bdn_3^{++}, as by C-methylsubstituted ethylenediamine complexes studied by F. Basolo. The position of bdn in the spectrochemical series is between tn (of which it is the methyl substitute) and en.

Table 2. The four strong absorption bands in nickel(II) complexes, classified according to the number of nitrogen atoms in the first co-ordination sphere. Wavenumbers of maxima in cm^{-1}.

Prue and Schwarzenbach [26] have studied the complex formation with 1,2,3-triaminopropane. It is found here that at least two complexes are formed in solutions with up to three moles ptn per nickel ion. The purple complex finally formed (presumably Ni ptn_2^{++}) has about 1 % higher value of $(E_1—E_2)$ than Ni en_3^{++}, but has lower band maxima. The upper limit of $(E_1—E_2)$ for aliphatic amines does not seem to be more than 1 % higher than that of en, as exemplified by tren, trien and ptn, while larger alkyl radicals and larger chelate rings, as in tn and to a lesser degree in bdn have an decreasing influence on bonding strength.

Another aliphatic amine with a high crystal field strength is C,C,C′,C′-tetramethyl-ethylenediamine of which Basolo, Chen and Murmann report [27] diamagnetic, planar yellow ions Ni temeen$_2^{++}$ (with only one absorption maximum [27] at 23 000 cm^{-1}, while the reflection spectrum of the salmon-pink [16] solid [Ni en$_2$] [AgBrI]$_2$ shows a band at 20 800 cm^{-1}). Basolo and the present author observed that solid [Ni temeen$_2$] Cl$_2$ reacts with concentrated aqueous ammonia to a violet solution *. It was obvious to suppose the existence of a paramagnetic ion Ni temeen$_2$ (NH$_3$)$_2^{++}$. However, the solution shows bands at nearly the same place as Ni (NH$_3$)$_6^{++}$, and a solution, 0.05 M Ni^{++}, 6 M NH$_3$, 0.12 M temeen, which contains less than 2 % of the yellow form, is decomposed by addition of 50 volume % 0.4 M temeen to a mixture of about 60 % Ni temeen$_2^{++}$ and 40 % of the violet form. It is not a reasonable behaviour for a mixed ammonia complex, but is rather caused by the sudden break-down of the chelate complex at increasing ammonia concentration, as discussed below. Basolo, Chen and Murmann [27] found that Ni temeen$_3^{++}$ cannot be formed, due to steric hindrance; and Ni temeen$_2$ Cl$_2$ has the same absorption spectrum in water and absolute ethanol, showing no tendency of solvation or association of chloride ions in the first co-ordination sphere. Neither has it been possible to identify a purple *cis*-Ni temeen$_2$ en^{++} in mixed solutions.

Although the heterocyclic diamines as α,α'-dipyridyl and *o*-phenanthroline have even larger crystal field strengths [1] than ethylenediamine, the heterocyclic monamine pyridine has a smaller crystal field strength than ammonia. It is not easy to identify the hypothetical Ni py$_6^{++}$ in solution. The solutions of nickel(II) nitrate in pyridine with a small water content may still contain nitrato complexes [28], which perhaps also were important in the system *n*-butylamine-water-copper(II) nitrate, studied by Bjerrum and Lamm [23]. Robust complexes of cobalt(III) and rhodium(III) are only known with at most four molecules of pyridine. Nevertheless, the results in Table 1 and 2 demonstrate a low crystal field strength of pyridine, compared to other amines agreeing well with the observed weak tendency to complex formation [51].

Table 1 gives also the spectra of Ni den$_2^{++}$, Ni tetren^{++}, and Ni tetren NH$_3^{++}$, demonstrating the regular behaviour of nickel(II), compared to copper(II), of which Table 3 gives Cu den^{++}, Cu den NH$_3^{++}$, Cu den$_2^{++}$, and Cu tetren^{++}. The latter series of complexes resembles much the spectra of Cu(NH$_3$)$_n$ (H$_2$O)$_{6-n}^{++}$ with n = 3, 4, 6, and 5, respectively, exhibiting pentammine effect in the two last cases [32]. Haendler [67] measured the absorption spectra of Cu^{++} and Ni^{++} with 1 and 2 moles of den. While K_1/K_2 is so large in the first case that Cu den^{++} disproportionates only to the extent $10^{-5.4}$, 5 % each of Ni^{++} and Ni den$_2^{++}$ occur for n = 1. The complex formation with the "guirlande" chain amines den, trien, tetren with H$_2$O and NH$_3$ on the residual places will be discussed later.

* However, Basolo isolated a violet solid from the action of liquid ammonia. Since this solid returns to the original yellow complex upon standing in the air, Basolo assumes the solid to be the mixed complex [Ni temeen$_2$ (NH$_3$)$_2$]Cl$_2$. *(Private communication).*

Table 3. Absorption bands of copper(II) complexes. Notation as in Table 1.

COPPER(II) ETHYLENEDIAMINETETRAACETATES

It was shown above that the absorption spectra of paramagnetic nickel(II) complexes can be described roughly by only one parameter, which may be identified with the energy difference (E_1—E_2) between γ_3- and γ_5-electrons in a regularly octahedral complex [13,16,30,31]. In copper(II) complexes, one further parameter is necessary to describe the relative tetragonality [2] varying from a regular octahedron to square planar complexes with decreasingly weaker ligands on the perpendicular axis. Empirically, the ratio ν_{Cu}/ν_{Ni} between the principal band of the copper(II) complex and the first band of the corresponding nickel(II) complex is proposed [1]. This ratio is roughly 1 in copper (II) complexes with cubic symmetry, increasing to about 1.8 in the most extremely tetragonal cases.

J. Bjerrum, Ballhausen and the author [32] discussed previously the ligands ammonia and ethylenediamine, which form the distinctly tetragonal planar complexes $Cu(NH_3)_4^{++}$ and $Cu\ en_2^{++}$ with two weakly bound water molecules, resulting in $\nu_{Cu}/\nu_{Ni} = 1.7$. If stronger bound ligands such as ammonia, replace water on the z-axis, a pentammine effect is observed to decrease the value of this ratio. Recently Linford [9] studied the solvates of copper(II) bis(acetylacetonate) and similar planar complexes with chloroform, acetone, dioxan, alcohols, pyridine and piperidine solvates, arranged according to increasing z-axis contribution. Most of the results obtained are readily explained except for the absorption band of $Cu\ en_2^{++}$ which is shifted 800 cm^{-1} in the wrong direction by solvation with ethanol [33]. This effect is much larger than the solvation effects of the second co-ordination sphere, studied by J. Bjerrum, Adamson, and Bostrup [34].

A series of copper(II) complexes with much lower values of ν_{Cu}/ν_{Ni} have been investigated [1]. The behaviour of amines as ligands is rather capricious,

some form "cubic" and some "tetragonal" complexes without conspicuous regularities. The polydentate amino-acids, however, form only weakly tetragonal copper(II) complexes whenever, of steric reasons, the carboxyl groups cannot be bound in the plane of four strongly bound atoms. In the case [1] of Cu enta$(H_2O)^{--}$ we have $\nu_{Cu}/\nu_{Ni} = 1.36$.

Bonnett and Schmidt [35] found that the less coloured Cu enta$(OH)^{-3}$ is formed with pK = 11.35 in 1 M Na_2SO_4 and with higher pK at lower ionic strength. Schwarzenbach and Heller [36] found pK = 7.39 for the acidity of Cr enta$(H_2O)^{-}$ and 7.49 for the first proton of Fe enta$(H_2O)^{-}$. It is known from pK of $Cu(H_2O)_6^{++}$ and from the formation [32] of $Cu(NH_3)_3OH^{+}$ that copper(II) complexes generally are more acidic than those of nickel(II) and zinc(II). Even though the external charge and the oxidizing power (the intermixing of electron transfer states stabilizes perhaps the groundstate of the hydroxo complexes) make an important contribution to the acidity, there is, *inter alia*, an evident effect of deviation from cubic symmetry for metal ions with unfilled d-shells [22]. This is especially evident for the tetragonal d^4- and d^9-systems.

Data in Table 3 show that the band of Cu entaNH_3^{--} has much lower intensity than that of Cu entaH_2O^{--}. This cannot be ascribed to the formation of Cu enta OH^{--} in aqueous ammonia, since addition of a large amount of NH_4NO_3 has no effect on the spectrum. The maximum in Cu entaNH_3^{--} is only shifted 2 % towards higher wavenumbers, relative to Cu entaH_2O^{--}. Thus, the ammonia molecule must be placed on the axis, perpendicular to the plane containing the two *cis*-nitrogen atoms of enta $^{-4}$.

Upon addition of KCN to 0.02 M Cu enta^{-3}, the maximum at 734 mμ is displaced to 719 mμ with 1 CN^- : 1 Cu and to 706 mμ with 3 CN : 1 Cu. The corresponding violet colours can be changed even further towards brownish purple. Such solutions are very unstable (the lowest maximum measured is 695 mμ) and change in a minute to colourless copper(I) cyanide complexes. It is interesting to note that a high electron transfer spectrum in the violet is present in the intermediate copper(II) complex. Representative values of the effective ε are 16 at 400 mμ, 75 at 375 mμ and 280 at 350 mμ, while the decomposed solution has only $\varepsilon = 9$ at 350 mμ and $\varepsilon = 20$ at 325 mμ. Also Cu enta^{--} has an electron transfer spectrum [1] with $\varepsilon = 46$ at 350 mμ, and similar values are found for Cu enta NH_3^{--}.

Thus, the intrinsic tendency of a redox process in Cu enta$(CN)^{-3}$ is depicted by the electron transfer spectrum, as is also the case of $CuCl_4^{--}$ and $CuBr_4^{--}$. Duke and Courtney [37] demonstrated the strong colour produced in copper(II) solutions in ammonia water by CN^-, which contained rather stable complexes of the type $Cu(NH_3)_3CN^+$. Analogously, Cu en^{++} forms purple and reddish intermediate complexes with CN^-, probably corresponding to high values of the tetragonality. The position of CN^- is at the extreme end of the spectrochemical series. For example the first band of tris(ethylenediamine) complexes of cobalt(III), rhodium(III) and iridium(III) [38] has 1.30 times as large a wavenumber as in the corresponding hexaaquo ions. The similar ratio is 1.96 for $Co(CN)_6^{---}$.

Pfeiffer and Schmitz [39] maintain the existence of enta-complexes with two metal ions in the solid compound Ca Cu enta, 3.5 H_2O. Although such complexes would be very

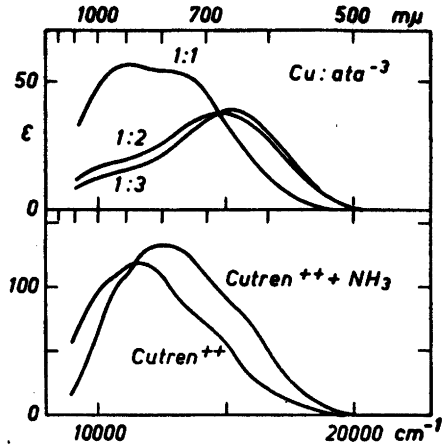

Figure 1. Upper part: Absorption spectra, demonstrating the consecutive formation of Cu ata⁻ and Cu ata₂⁻⁴. The solutions measured were:
0.04 M Cu++, 0.04 M ata⁻³
0.04 M Cu++, 0.08 M ata⁻³
0.04 M Cu++, 0.12 M ata⁻³

Lower part: Absorption spectra of the two complexes Cu tren $(H_2O)_3$++ and Cu tren $(NH_3)_2$++ (or perhaps Cu tren $(NH_3)(H_2O)$++) from solutions:
0.01 M Cu++, 0.01 M tren
0.01 M Cu++, 0.01 M tren. 1 M NH_3

interesting it would not appear that there is any good evidence for their existence. Pfeiffer and Schmitz [39] found that $Cu(OH)_2$ is precipitated with NaOH from CaCu enta, while Na_2Cu enta is not decomposed. But this may be a consequence of the presence of calcium ions, removing enta⁻⁴ from the equilibria by formation of Ca enta⁻⁻ with log $K = 10.59$, while Cu enta⁻⁻ has log $K = 18.4$. Mixtures of Ni enta⁻⁻ and Ni++ do not react, according to the spectra, and in alkaline solution, Ni $(OH)_2$ is precipitated. The second formation constant of Ca $enta_2^{-6}$ is [61] less than 20, but the investigation is rendered difficult by the relatively low value of $pK = 11.39$ for formation of Ca(OH) enta⁻³. The intention of Pfeiffer and Schmitz [39] to prepare isomeric enta-salts, differing only in the free metal ion, is more apt to occur with robust species, *e.g.* $[Cr(H_2O)_6]_2$ [Ni enta]$_3$ and $[Ni(H_2O)_6][Cr\ enta]_2$.

COPPER(II) NITROGENTRIACETATES

The robin-egg's blue Cu ata⁻ reacts with an excess of ata⁻ to form darker blue complexes. It is seen from Fig. 1 that the formation of Cu ata_2^{-4} is not totally complete at the ratio 2 ata⁻³ : 1 Cu^{+2} but the spectrum is a linear combination of that of Cu ata⁻ with the new complex.

The intensity of Cu ata_2^{-4} is much lower than of Cu ata⁻, analogous to the nickel(II) complexes. Since ν_{Cu}/ν_{Ni} goes from 1.25 for Cu ata⁻ to 1.45 for Cu ata_2^{-4}, the two nitrogens in the latter complex determine the tetragonal plan. The development has the opposite direction [1] in Cu gly_2 with $\nu_{Cu}/\nu_{Ni} = 1.60$, which decreases in Cu gly_3^-. The complex formation necessitates in the latter case relatively large free concentrations of the ligand.

Cu ata$^-$ has two absorption bands (Table 3) with a distance of 1 500 cm^{-1} between the maxima, while Cu ata$_2^{-4}$ has only an extreme large half-width towards the infra-red. The former phenomenon resembles Cuphen$_2$(H$_2$O)$_2^{++}$ and Cudip$_2$(H$_2$O)$_2^{++}$, both of which are presumed to have *cis*-configuration [1]. R. Linn and Geneva Belford [9] assume that the broad bands of copper (II) complexes can be resolved into three Gaussian curves [40] with three different half-widths, but with $\delta(-) = \delta(+)$ for each band [40]. While the existence of three bands may be theoretically justified [9], the determination of their positions is certainly near to the limits of experimental uncertainty. However, at least two bands are constituents of most of the spectra of copper(II) complexes [1,32], and three are observed in Fig. 1 of Cu tren $^{++}$.

COPPER(II) tren-COMPLEXES

Cu tren^{++} is sea-blue with the same tint as the hexaaquo ion and the high band is displaced to 860 mμ, compared to Cu(H$_2$O)$_6^{++}$ at 790 mμ. Hence the crystal field is strong in Ni tren (H$_2$O)$_2^{++}$, ν_{Cu}/ν_{Ni} is only = 1.08, the lowest value found in any copper(II) complex. Thus, a *cis*-diaquo configuration for Cu tren(H$_2$O)$_2^{++}$ can be proposed. In aqueous ammonia a flat maximum is obtained at 785 mμ. This increases the ratio ν_{Cu}/ν_{Ni} only slightly to 1.11.

Thus, the tendency of forming cubic copper(II) complexes is not restricted to heterocyclic diamines, but can also be found in aliphatic amines with steric resistance against formation of planar complexes. However, in the discussion of copper(II) complexes of polydentate ligands a special precaution must be taken: Contrary to most calculational assumptions [9,16], the six atoms in an octahedral complex are not bound to the axes of a Cartesian co-ordinate system, but instead may have a triclinic symmetry. Geometrically a *cis*-complex MA$_4$B$_2$ with loosely bound B can smoothly transform to a tetrahedral complex MA$_4$, first of non-regular and later of regular symmetry. During this process, the cubic contribution [16] will change in sign, and the energies of the five d-orbitals, if calculated from the electrostatic model [41] will cross in a very complicated way. The most stable configuration is obtained when the average energy of the d-electrons is relatively low and the interaction energies of the ligands low, while the highest d-orbital has a relatively high energy. The latter orbital contains only one electron in Cu^{++}. A further complication arises, because the regularly tetrahedral symmetry of copper(II) is unstable, due to the Jahn-Teller effect [22]. Actually, bonding of tren to Cu^{++} is rather strong: Prue and Schwarzenbach [42] determined log K = 14.65 for Zn tren^{++}, 18.8 for Cu tren^{++} and 14.8 for Ni tren^{++}. Contrary to this behaviour, the heterocyclic diamines have their formation constants in the order [23] Ni>Cu>Zn. However, the profound analogy (Fig. 1) between the spectra with two shoulders at nearly the same place strongly supports the *cis*-configuration of mainly octahedral Cu tren(H$_2$O)$_2^{++}$ and Cu tren(NH$_3$)$_2^{++}$ (or Cu tren(NH$_3$)(H$_2$O)$^{++}$).

COPPER(II) COMPLEXES WITH ALIPHATIC DIAMINES

I. Poulsen and J. Bjerrum [25] found the formation heats for copper(II) amine complexes for the four first co-ordination places the series NH_3<tn <en. As seen from Table 3, ν_n of Cu tn_2^{++} occurs between that of Cu $(NH_3)_4^{++}$ and Cu en_2^{++} and ν_{Cu}/ν_{Ni} is therefore ~1.7. The stabilization energy is probably also roughly proportional to the wavenumber of the principal band in tetragonal complexes.

The highest wavenumber observed yet in a copper(II) complex occurs in Cu $temeen_2^{++}$ (Table 3), 1/2 % larger than that of Cu en_2^{++}. The diamagnetism of Ni $temeen_2^{++}$ corresponds to an even higher tendency of tetragonality [27] with the highly destabilized orbital γ_{t3} which is empty [16].

The tridentate ptn does not utilize the possibility of forming a nearly cubic, hexa-coordinated copper(II) complex such as dip and phen. On the other hand Cu ptn_2^{++} is dark violet with $\nu_{Cu}/\nu_{Ni} = 1.6$ and must be assumed to bind only four nitrogen atoms, as already proposed by Mann and Pope [65]. It would be interesting to know, if the residual amine group has affinity to silver ions, forming perhaps the bi-nuclear complex Cu ptn_2 Ag^{+3} with linear environment of the silver [12,60].

While the tridentate amines ptn and den (of which the latter has one secondary amine group) form similar nickel(II) complexes, is Cu den_2^{++} distinctly hexa-(or penta-)co-ordinated, and has high intensity of the double band, as also Cu $tetren^{++}$ has.

The band intensity of Cu ptn_2^{++} is of the same magnitude as for Cu en_2^{++}, while Cu $temeen_2^{++}$, Cu tn_2^{++}, and Cu bdn_2^{++} are much stronger coloured. In the bis(diamine) complexes, the absorption band vanishes in the infra-red. the values of ε being:

	800 mμ	900 mμ	1 000 mμ
Cu en_2^{++}	2.7	0.7	0.3
Cu tn_2^{++}	13.0	4.1	1.4
Cu ptn_2^{++}	7.2	3.4	1.5
Cu $temeen_2^{++}$	9.6	4.0	2.4
Cu bdn_2^{++}	19.6	6.0	2.0
Cu den^{++}	11.5	3.4	1.0

CHELATE STABILIZATION EFFECTS

In Table 2, the wavenumbers of the four strong absorption bands of paramagnetic nickel(II) complexes are classified, according to the number of nitrogen atoms in the first co-ordination sphere. The formulae of Ni py_6^{++}, Ni $ata(NH_3)_2^-$, Ni $enta(NH_3)^{--}$ and Ni enta CN^{-3} are tentative.

The last complex is classified as a system with three N.

It is a rather good approximation except for the highly polarizable anions as SCN^-, NO_2^-, and CN^- to write the spectrochemical series according to the elements alone as:

$$Br < Cl < F < O < N$$

In the amino-acid complexes, the active atoms in the first co-ordination sphere are O from carboxyl groups and water and N from the amine groups. The oxygen atoms are not very different. The oxalate ion is nearly coincident

with water in the spectrochemical series [4], but has a similar position among carboxyl groups as ethylenediamine has among the amines. The other carboxyl groups are slightly bathochromic, as found by Linhard and Weigel [7] and for nickel(II) propionates etc. by Pestemer and Alslev-Klinker [44]. The results reported in this paper show the following spreading of the amines in the spectrochemical series:

$$py < NH_3 < tn < bdn < \left\{ \begin{matrix} en \\ temeen \\ trien \\ tren \end{matrix} \right\} < den < ptn < dip < phen.$$

Already Russell, Cooper and Vosburgh [57] found empirically that the formation constants of nickel(II) amine complexes increase with the hypsochromic effect of the ligand.

It is easily seen from Table 2 that the polydentate amino-acids generally are further removed in the spectrochemical series than interpolated directly from the rule of average environment. Thus, one N in Ni ata^- and two N in Ni $enta^{-2}$ function as 2.5 NH_3 and 4.5 NH_3, respectively, if the visible band is compared to the spectra of Ni $(NH_3)_n$ $(H_2O)_{6-n}{}^{++}$ found by J. Bjerrum [12]. Since the crystal field strength is roughly proportional [9,41,45,46] to R^{-5}, where R is the distance to the negative charge of the ligand, this observation can easily be explained by a slightly tighter bonding. It is interesting [1] that even the anhydrous Co $enta^-$ is 2.5 % hypsochromic in the first band, compared to Co enta H_2O^-. As seen from the method of preparation [14], the latter complex must be highly thermodynamically unstable in aqueous solution.

Even if ΔG and ΔH cannot be calculated from the spectrochemical series, ignoring the many unknown factors in the case of closed-shells as Zn^{++}, considerable correlation can be found between the relative values for ΔG and ΔH. For example, the differences between negative and neutral ligands are particularly large. The exchange with water of chloride ions has formation constants slightly below 1, whereas the relative crystal field strength [38] of Cl^- and H_2O is 0.76 and the corresponding ratio for amines and H_2O is $\sim$1.3. Thus, the high formation constants for $enta^{-4}$-complexes are partly due to electrostatic effects.

J. Bjerrum and the author [23] discussed the ethylenediaminetetraacetates of the divalent ions of the first transition group, log K varies [15] from 10.96 for Ca^{++} over 14.04 for Mn^{++} to 16.50 for Zn^{++}. If Ni^{++} had a closed d-shell, log K would extrapolate 15.5 instead of the observed value 18.62. The stabilization of 2.8 in log K corresponds to 3.8 kcal/mole = 1 300 cm^{-1}. Analogously, the formation constants for lanthanide-enta complexes vary smoothly from log K = 15.50 for La $enta^-$ over 17.37 for Gd $enta^-$ to 19.83 for Lu $enta^-$. These half- and closed shell structures represent the standard state of electrostatic behaviour while all the other complexes are stabilized between 0.2 and 0.3 units in log K, due to the smaller influence of the crystal field on f- than on d-electrons.

In Table 4, a series of stabilization energies are compiled for Fe^{++}, Co^{++}, Ni^{++} and Cu^{++}, when the non-stabilized values of log K_n are assumed to vary linearly with the number of d-electrons between Mn^{++} and Zn^{++}. Most examples are taken from the article of Schwarzenbach [24] on the chelate effect,

Table 4. Crystal field stabilization of complexes of the second half of the first transition group. Most formation constants refer to 20° C and the ionic strength ~0.1. ϱ is the stabilization parameter [22] valid for regularly octahedral complexes, viz. energy decrease = 0.2 ϱ (E_1—E_2). Ref. 63 considers N-substituted iminodiacetates $RN(CH_2COO^-)_2$, here denoted Rada. The consecutive formation constants are considered in cases, where the formulae indicate the binding of the second or the third ligand.

Ref. No. Ligands beside water	log K_n		Stabilization found from the hypothesis of linear variation of log K_n with the number of d-electrons from 5 to 10			
	Mn++	Zn++	Fe++	Co++	Ni++	Cu++

63 $(HOC_2H_4ada)_2$	3.76	3.69	—0.53	0.46	1.25	1.31
63 $NH_2C_2H_4$ada	7.71	11.93	1.25	2.37	3.50	4.82
ϱ =	0	0	2	~4	6	3

and from the recent measurements by Schwarzenbach, Anderegg, Schneider and Senn [63] on substituted iminodiacetates $R(CH_2COO^-)_2 \equiv$ R ada. It is seen that the stabilization for iron(II), cobalt(II), and nickel(II) complexes are roughly proportional to the stabilization parameter [22]ϱ, *viz.* 2, 4 and 6. In some cases, *e. g.* the third en or the second HOC_2H_4ada the steric conditions for bonding are better in Mn^{++} than in Zn^{++}, but here also the evolution of stabilization energies is rather regular. On the other hand, the strong tendency of tetragonal distortion in copper(II) complexes produces an enormous stabilization of ligands on the four planar places, *e. g.* in en_2 and trien. The effective value of ϱ for Cu^{++} in Table 4 can exceed the value 10, whereas values ~3 ν_{Cu}/ν_{Ni} ~5 might have been expected.

In nickel(II) complexes the crystal field stabilization can be compared to the theoretical value 1.2 (E_1—E_2). However, as seen from Table 2, the value of (E_1—E_2) cannot be found accurately from the absorption spectra, since the relative positions of the bands vary some hundred cm^{-1} in an irregular way. If the energies of the two lowest levels are defined:

$$^3\Gamma_2\ (F) = -1.20\ (E_1-E_2)$$
$$^3\Gamma_5\ (F) = -0.20\ (E_1-E_2)$$

then the Orgel diagram of nickel(II) complexes [1] can be approximately described by the three other lines in the range of our interest:

$$^3\Gamma_4\ (F) = 2\,800\ cm^{-1} + 0.155\ (E_1-E_2)$$
$$^3\Gamma_4\ (P) = 15\,100\ cm^{-1}$$

and after correction for the intermixing of triplet character:

$$^1\Gamma_3\,(D) = 16\,500 \text{ cm}^{-1} - 1.55\,(E_1 - E_2)$$

These equations demonstrate that either are the term distances to ^3P, ^1D, and ^1G decreased from the values, found from the gaseous ion, or other electron configurations are intermixed in the states of the complexes. The former alternative explanation is discussed below in the last section.

If $(E_1 - E_2)$ is assumed to be the wavenumber of the first band 10 100 cm^{-1} in α-Ni enta^{-1} and 8 500 cm^{-1} in $Ni(H_2O)_6^{++}$ the predicted stabilization is 1 900 cm^{-1}. The similar numbers are:

Ni ata$^-$	1 200 cm^{-1}	3.4 kcal/mole	2.5 units in log K
Ni gly$_3^-$	1 900	5.4	4.0
$Ni(NH_3)_6^{++}$	2 700	7.7	5.7
Ni tn$_3^{++}$	3 300	9.3	6.9
Ni tren^{++}	2 900	8.2	6.1
Ni en^{++}	3 700	10.5	7.8
Ni phen$_3^{++}$	4 400	12.5	9.3
Ni en$_2$gly$^+$	3 100	8.8	6.5
Ni tren gly$^+$	3 800	10.8	8.0

It must be remembered that these quantities are found from the spectra by subtraction of the even larger stabilization of the hexaaquo ion, relative to the free Ni^{++} *in vacuo*. This quantity is 10 200 cm^{-1} ≡ 29 kcal/mole ≡ (log K = 22). Orgel [47] pointed out that this stabilization can actually be observed as a part (~ 5 %) of the absolute heat of hydration of metal ions. I. Poulsen and J. Bjerrum [25] found ΔH = 21.0 kcal/mole for $Ni(NH_3)_6^{++}$, 21.3 kcal/mole for Ni tn$_3^{++}$ and 27.9 kcal/mole for Ni en$_3^{++}$. If these values are corrected for the stabilization mentioned above, the residual "closed shell" case gives 13.3, 12.0 and 17.4 kcal/mole, respectively, for $Ni(NH_3)_6^{++}$, Ni tn$_3^{++}$ and Ni en$_3^{++}$. Besides the d-orbital stabilization, the σ-bonding of even γ_1 and odd γ_4-electrons[48-50] may be stronger in the ethylenediamine complexes where the ligands have comparatively smaller distances due to the γ_3-bonding.

The entropy effects in chelate complexes are rather peculiar, inducing the irregular behaviour of ΔG, compared to ΔH. The discussion that follows is concerned only with the importance of chelating number L in reactions of a complex with a polydentate, *viz.* of the type

$$\text{Ni enta}^{--} + 6\ NH_3 \rightleftharpoons Ni(NH_3)_6^{++} + \text{enta}^{-4}$$

It is seen from the mass action law that this process is half complete when

$$\frac{[NH_3]^6}{[\text{enta}]} = \frac{K_{\text{Ni enta}}}{K_{\text{Ni (NH}_3)_6}}$$

Thus, if a buffer concentration of free [enta] = 0.01 M is maintained, the free [NH_3] will be 20 M. If a similar experiment is performed with [enta] = 0.01 M and the nickel complex is destroyed with tn or en, respectively, [tn] = 28 M and [en] = 0.24 M are necessary for 50 % decomposition to Ni tn$_3^{++}$ or Ni en$_3^{++}$. Any formation of mixed complexes, as Ni enta NH_3^{--} and Ni enta en^{--} studied above, will of course delay the actual destruction of the bonding between Ni^{++} and enta^{-4}.

Even though log $K_{1\text{-}3}$ = 12.0 for Ni tn$_3^{++}$, and log $K_{1\text{-}6}$ = 8.6 for Ni $(NH_3)_6^{++}$, it is seen that tn and NH_3 in high concentrations are nearly equally effective for decomposing Ni enta^{--}. This is a result of the occurrence of a sixth power term in the mass action law for NH_3, but only a third power term for tn. Roughly speaking, a dilute solution of a polydentate amine resembles "coarsegrained" aqueous ammonia. The prob-

ability of finding a high number of amine groups (L groups per molecule) within reach of a certain metal ion is very high, and it is proportional to C^{-1}, whereas, in a monodentate amine like NH_3, the corresponding probability is proportional to C^{-L}.

Inversely, a polydentate complex is affected very little by dilution of the free ligand. Although 0.01 M free enta^{-4} encountered 20 M free NH_3 above, 10^{-5} M free [enta] will still afford 6 M free NH_3 for half decomposition of Ni enta^{--}, and $10^{-9.6}$ M enta^{-4} is sufficient against 1 M NH_3. Now, it is easily understood why the yellow diamagnetic Ni temeen$_3^{++}$ suddenly breaks down at a rather high ammonia concentration:

$$\text{Ni temeen}_3^{++} + 6\ NH_3 \rightleftharpoons Ni(NH_3)_6^{++} + 2\ \text{temeen}$$

with the constants [27] log $K_{1-3} = 14.68$ for Ni temeen$_3^{++}$ and log $K_{1-6} = 8.6$ for $Ni(NH_3)_6^{++}$, 50 % decomposition is predicted at $[NH_3] = 4.8$ M when [temeen] = 0.1 M. At slightly higher ammonia concentration, the decomposition is practically complete, owing to the sixth power dependence.

Reversely, the presence of a mixed complex Cu tren en^{++} can definitely be proven by the absorption spectrum of a solution, 0.001 M Cu, 0.001 M tren, 0.8 M en, which shows the presence of only ~50 % of the copper as Cu en$_3^{++}$. From the formation constants of Cu en$_3^{++}$ and Cu tren^{++}, the constant for the reaction en + Cu tren^{++} → Cu tren en^{++} can be estimated to ~4.10^4.

By comparison of ligands with different chelating number L, it might be reasonable to choose a scale of apparent activity, proportional to C^3/L. Since the standard state of chemical compounds is often chosen as the pure compounds, the formation constants referring to 1 M solutions are from this point of view exaggerated for polydentate ligands. For instance, tren is less affected by dilution than is NH_3. J. Bjerrum [51] pointed out for monodentate ligands that the exchange with water might be treated by defining $[H_2O] = 55$ M in the dilute solutions. Adamson [43] later demonstrated that most of the ΔS by chelate formation [24] vanishes, if a new $\Delta G'$ is defined

$$\Delta G' = \Delta G + \Delta \mu\, RT \ln 55$$

when $\Delta\mu$ is the number of produced moles minus reacted moles, except of the solvent. Actually, the activities of different ligands in dilute solution, compared to the pure compounds, ought to be determined by partial vapour pressures. Adamson's proposal [43] is equivalent to the assumption of activities, proportional to the mole fraction. An alternative proposal will be the molar concentration of the ligand in solution divided with the molar concentration of the pure ligand. In ideal gas mixtures, the two concepts based on number and partial volumes, are identical, and in dilute solutions the two concepts are only different by a proportionality constant, characteristic for the solvent and the ligand. In stronger solutions, the two proposals may differ somewhat. The molar concentration of the anhydrous, liquid amines at 25° C are 38 M NH_3, 15 M en and 12 M tn. Thus the formation constants of nickel(II) complexes can be corrected by the factors 38^6, 15^3, and 12^3, respectively, resulting in log $K'_{1-6} = 18.1$ for $Ni(NH_3)_6^{++}$, log $K'_{1-3} = 21.8$ for Ni en$_3^{++}$ and log $K'_{1-3} = 15.3$ for Ni tn$_3^{++}$. By this method, there appear small residual entropy effects [25], and the crystal field stabilization in ΔH will of course still subsist in the values of $\Delta G'$, corresponding, *e.g.*, to the predicted difference 2.1 between log K_{1-6} for $Ni(NH_3)_6^{++}$ and log K_{1-3} for Ni en$_3^{++}$.

THE INTERMIXING OF SINGLET AND TRIPLET LEVELS BY INTERMEDIATE COUPLING

The validity of sharply defined total spin S and total angular moment L in the free atoms and ions, corresponding [2] to S and Γ_n in crystal fields, is weakened by increasing values [52] of Landé's multiplet factor ζ_{nl}. In systems in crystal fields, states with the same Γ_J (found from the internal vector product [16] of $C(S)$ and $C(\Gamma_n)$) are intermixed with nondiagonal elements of energy

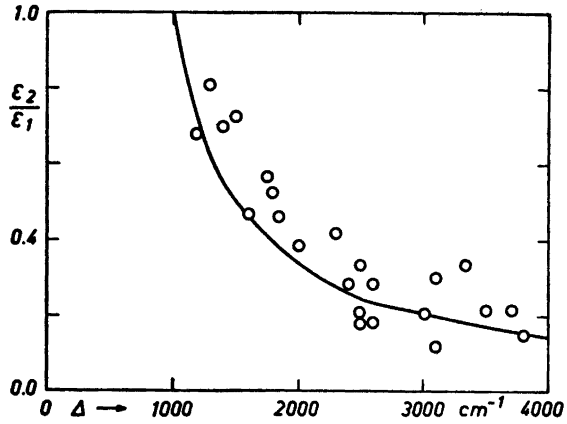

Figure 2. The ratio $\varepsilon_2/\varepsilon_1$ between the directly observed heights of the two first absorption bands of nickel(II) complexes as function of the difference Δ between the wavenumbers of the two maxima. The curve represents the function $\frac{a}{1-a}$ with $a = \frac{500\ cm^{-1}}{\Delta}$ discussed in the text.

$= k\,\zeta_n$, where the constants k are not very different from 1. Thus, the usual description of levels in d^n-systems as having definite S and Γ_n breaks down, when $k\,\zeta_{nl}$ is sufficiently large [1] and the distance Δ between the interacting levels small. The intermixing in the squares of the wavefunctions is approximately $\left(\frac{k\,\zeta_{nl}}{\Delta}\right)^2$.

The most conspicuous case [1] of intermixing of S in the nickel(II) complexes occurs between the lowest singlet level $^1\Gamma_3(D)$ and the two lowest excited triplet levels $^3\Gamma_5(F)$ and $^3\Gamma_4(F)$ with the values of $k\,\zeta_{nl} = 500$ cm^{-1} and 800 cm^{-1}, respectively. The numerical results of Tables 1 and 2 are used in Fig. 2 to estimate the former intermixing. The oscillator strength P is divided between the two interacting levels proportional to their triplet character ($S = 1$) since the groundstate for the transition has $S = 1$ to a high degree of precision. But the ratio between the values of P for the two components is not easily accessible from the measurements. Rather, it is assumed that the observed maximum ε_n is proportional to the numerical value of intermixing a, *viz.*

$$\frac{\varepsilon_2}{\varepsilon_1} = \frac{a}{1-a} \text{ with } a = \frac{k\zeta_{nl}}{\Delta}$$

This is equivalent to assume the half-widths of the bands to be also proportional to ε_n. This is a good approximation, since the pure singlet bands $^1\Gamma_3(D)$ are very narrow.

Fig. 2 gives the ratio $\varepsilon_2/\varepsilon_1$ as function of the distance Δ between the two maxima. Further the curve for the function $\frac{a}{1-a}$ with $k\,\zeta_{nl} = 500$ cm^{-1} is given. It is seen to represent the somewhat scattered points reasonably well.

The influence of the second triplet level $^3\Gamma_4(F)$ is important for large values of Δ (over 2 000 cm^{-1}) raising the degree of intermixing. On the other side, the non-vanishing half width for $\alpha \rightarrow 0$ should decrease the position of the right-hand side points.

The statistical distribution of the points of mixed complexes demonstrates that no particular deviation from cubic symmetry is necessary for making $k\zeta_{nl}$ large. Fig. 2 demonstrates also the lower limit of $\Delta = 2\ k\ \zeta_{nl}$. The two bands are actually repulsed from each other by this impenetrable barrier. Mr. C. E. Schäffer [53] has found a similar variation of relative intensities of quartets and doublets with Δ in chromium(III) complexes. Also iridium(III) complexes [38] prove that $k\ \zeta_{nl}$ is rather invariant (= 2 000 cm^{-1}) in so different ions as $IrBr_6^{---}$, $IrCl_6^{---}$, $Ir(NH_3)_5Cl^{++}$, Ir en_3^{+++} but here Δ is nearly constant (= 7 000 cm^{-1}) as function of the crystal field strength, because the singlet and triplet level belong to the same electron configuration [31] of γ_n.

The other singlet levels of nickel(II) give much lower intensities to the bands. Therefore, it is necessary to measure strong solutions of pure complexes, and the detection is often impossible in the ranges of the triplet bands. Besides $^1\Gamma_3$ (D), the two levels $^1\Gamma_5$ (D) and $^1\Gamma_1$ (G) should be the next excited singlets, as discussed by Tanabe and Sugano [54], Ballhausen and Klixbüll Jørgensen [16], and Orgel [49]. $^1\Gamma_3(D)$ and $^1\Gamma_1$ (G) have the configuration $\gamma_5^6\gamma_3^2$ common [31] with the groundstate $^3\Gamma_2$ (F) and thus should produce narrow bands [54,55], while $^1\Gamma_5$ (D) analogous to $^1\Gamma_4$ (G), $^3\Gamma_5$ (F) and $^3\Gamma_4$ (F) in strong crystal fields are $\gamma_5^5\gamma_3^3$ with broader transitions from the groundstate. The concept of a single distribution of electrons in molecular orbitals seems nevertheless to be rather inadequate [50] for the description of a given level (S, Γ_n).

Already Gielessen [56] found a great number of small bands in solid salts of $Ni(H_2O)_6^{++}$. In solutions, small bands are found [49] at 18 400 cm^{-1} and 22 000 cm^{-1}. In Ni en_3^{++}, a weak band can be distinguished at 24 000 cm^{-1} in Ref. 40, Fig. 5. It is not easily decided from the half-widths, which band is the "narrow" $^1\Gamma_1(G)$, but there is some evidence that it is the band at 18 400 cm^{-1} in the hexaaquo ion, contrary to primitive electrostatic calculations [16]. It can interact [1] by intermediate coupling with $^3\Gamma_4$, but not with $^3\Gamma_5$. While most of the absorption bands in Table 1 are very regular, and do not exhibit signs of tetragonal splitting except the fourth band of Ni ata_2^{-4}, there is a tendency of the third band to have a shoulder towards lower wavenumbers (see the half-widths in Ni $en\ gly_2$, Ni enta NH_3^{---}, α-Ni $enta^{---}$, Ni ata gly^{---} and Ni ata^{---}). While this may very well depend on tetragonal splitting and in a few cases be due to presence of more isomers, it is quite suspicious that the phenomenon prevails in a narrow range of the Orgel diagram near $(E_1—E_2)$ = 10 000 cm^{-1}. It cannot be excluded that $^1\Gamma_1$ (G) is going down in the Orgel diagram along a line of the type 23 000 cm^{-1}—1.7 $(E_1—E_2)$.

THE DECREASE OF THE PARAMETERS OF ELECTROSTATIC INTERACTION BETWEEN d-ELECTRONS IN COMPLEXES

For a complex with regularly octahedral configuration, the energy levels can be given in the Orgel diagram as function of the crystal field strength $(E_1—E_2)$. Tanabe and Sugano [54] and Owen [48] emphasized that term differen-

Table 5. Crystal field strength (E_1-E_2) and effective term distances for various nickel(II) complexes. The value of (E_1-E_2) is derived from ν_1 and the energies (^3P) and $\frac{4}{7}$ (^1D) + $\frac{3}{7}$ (^1G) from $\nu_3 + \nu_4$ and ν_2, respectively. In all cases, the values of ν_n from Table 2 are corrected for effects of intermediate coupling (important for ν_1 and ν_2) and for asymmetry of the bands (usually significant for ν_3). Finally are given the calculated and observed values of the perturbation energy ΔE between $^3\Gamma_4$ (F) and $^3\Gamma_4$ (P), as defined p. 908. All the energies are given in the unit cm^{-1}.

Complex	(E_1-E_2)	$(^3P) = 15\,B$	$\frac{4}{7}(^1D)+\frac{3}{7}(^1G)$ $=8B+2C$	ΔE, calc.	ΔE, obs.

ces might also change in complexes from the values for the gaseous ion. Thus, it might be necessary to apply more than one parameter in the Orgel diagram. Actually, the agreement with observed absorption bands can be highly improved by the assumption of decreased term distances in the complexes. Especially, the decrease is larger for many anion complexes than for complexes with neutral ligands.

The energy differences between multiplet terms of a given d^n-configuration can be expressed as multipla of the Slater-Condon-Shortley [52] parameters F_2 and F_4. Racah [64] applies the linear combinations $B = F_2 - 5F_4$ and $C = 35F_4$. In nickel(II)complexes, the distance from the ground term ^3F to the other triplet term ^3P is $15B$. Table 5 gives this distance inferred from the diagonal sum rule:

$$\nu_3 + \nu_4 = 3(E_1 - E_2) + (^3P)$$

The wavenumbers ν_3 and ν_4 of the third and fourth absorption band are corrected for asymmetry by taking the average of $\nu_n - \delta(-)$ and $\nu_n + \delta(+)$ from Table 1. It is seen from Table 5 that B actually decreases to ~70 % of the original value, but not as a monotoneous function of $(E_1 - E_2)$. Since three excited triplet levels occur in paramagnetic nickel(II)complexes, it is of interest to see whether the two parameters $(E_1 - E_2)$ and B are sufficient for their description. The two $^3\Gamma_4$ levels have energies, which are the roots E_a and E_b of the secular determinant [49]:

$$\begin{vmatrix} E_{33}-E & E_{34} \\ E_{34} & E_{44}-E \end{vmatrix} = 0$$

with $E_{33} = 0.6\ (E_1-E_2)$; $E_{44} = (^3P)$; and $E_{34} = 0.4\ (E_1-E_2)$.

We define the perturbation energy ΔE by $E_a = E_{33}-\Delta E$ and $E_b = E_{44} + \Delta E$. The observed and calculated values of ΔE are seen to agree except for the ethylenediaminetetraacetate complexes.

Finally, Table 5 gives the values of $\frac{4}{7}(^1D) + \frac{3}{7}(^1G) = 8B + 2C$, which is the asymptotical[16,54] energy of $^1\Gamma_3\ (D)$ above $^3\Gamma_2\ (F)$. The wavenumber ν_2 is corrected for the influence of intermediate coupling. It is seen that C decreases slightly more than B in the complexes. This can be interpreted as an expansion of the 3d-wavefunction into a larger volume. For isomorphous wavefunctions, both F_2 and F_4 are inversely proportional to the average radius; whereas in the case of spreading from, *e. g.*, the concentration on a spherical surface, F_2/F_4 increases with resulting decrease of the ratio C/B. Owen[48] assumes that the decrease of B in complexes is caused by covalent bonding. However, it is not easily decided if this is the only possible explanation. It is interesting to compare nickel(II) with other metal ions. Thus, Schäffer[53] investigates many chromium(III) complexes, where the distance $\sim 12B$ between $^4\Gamma_5\ (F)$ and $^4\Gamma_4\ (P)$ implies values of B in the range 500—750 cm^{-1} while $B = 950\ cm^{-1}$ in Cr^{+++}. The distance $\sim 16B$ between $^1\Gamma_4$ and $^1\Gamma_5$ of cobalt(III) complexes[54] gives slightly smaller values of B. Diamagnetic d^6-systems of the two next transition groups[38] have even smaller values of B: $RhCl_6^{-3}$ has 310 cm^{-1}, $Rh(NH_3)_6^{+++}$ and $Rhen_3^{+++}$ both 400 cm^{-1}, and $IrCl_6^{-3}$ has $B = 250\ cm^{-1}$. On the other hand, manganese(II) complexes have values of B and C, which are not much less than the values for Mn^{++}. Thus, only 7 % decrease is observed[55] in $Mn(H_2O)_6^{++}$ and 11 % in Mn enta^{--}, as will be discussed in the third paper of this series. While it might seem somewhat unsatisfactory to describe four absorption bonds of nickel(II) complexes by three parameters, (E_1-E_2), B, and C, ten bands of manganese(II) can also be described by the three parameters. The crystal field theory can be applied to all d^n-systems, giving a much more unified picture than earlier sharp distinctions between "ionic" and "covalent" complexes.

EXPERIMENTAL

The absorption spectra were measured in the range 800—325 mμ with a Cary recording spectrophotometer at room temperature, 20° C, and in the range 800—1 080 mμ with a Beckman DU spectrophotometer. 1 cm absorption cells were always used, and the measurements in the infra-red performed with a maximum interval of 20 mμ.

1.07 M $Ni(NO_3)_2$ (AnalaR) and 0.050 M $CuSO_4$ were transferred to measuring flasks with a Krogh's 1.00 ml syringe pipette. The ligands were added in solutions from microburettes, and finally diluted with water. In cases of rarer ligands, 10 ml measuring flasks were shown to be sufficiently precise for the measurement of the spectra.

H_4enta (complexon II) and H_3ata (Prof. Schwarzenbach's sample and complexon I) were dissolved in water with 2 and 1.5 moles of Merck's Na_2CO_3 per mole amino-acid, respectively, and diluted.

tren H_3Cl_3, ptn H_3Cl_3 and temeen$_2H_2Cl_2$ were weighed off and dissolved in stoichiometric amounts of NaOH solution.

H gly was dissolved with 1 equiv. of KOH in water.

Dilute solutions of ammonia and ethylenediamine (Merck's No. 946) were titrated. tn and bdn were supplied by Shapley Co. den was purified from the commercial product by fractional distillation and tetren by standing two weeks of the 1 M solution with norite coal, removing the yellow colour. Cu den NH_3^{++} was measured in 0.4 M NH_3 and Ni tetren NH_3^{++} in 1 M and 2 M NH_3.

Redistilled pyridine was kindly furnished by Mr. F. Woldbye.

The concentration of nickel(II) was usually 0.107 M, but more dilute solutions (0.02 M) were made of Ni enta^{--} and addition compounds for measurement of the high first band.

The concentration of copper(II) solutions varied between 0.04 M and 0.01 M.

Acknowledgments. I am very much indebted to Professor Jannik Bjerrum for his interest in the work. Further, I thank Mr. C. E. Schäffer for valuable discussions and information about the analogies with absorption spectra of chromium(III) and cobalt(III) complexes. Finally, I express my gratitude to Professor G. Schwarzenbach, Zürich, for samples of H_2ata, ptnH_3Cl and tren H_3Cl_3, and to Professor Fred Basolo, Northwestern University, Evanston, Illinois, for samples of temeen H_2Cl_2, Ni temeen$_2Cl_2$ and of tren H_3Cl_3, and to Dr. F. G. Mann, Cambridge, for samples of Ni ptn$_2SO_4$ and several tren-complexes presented to this study of energy levels.

Chromatographic Separation of Anomeric Glycosides

III. Crystalline Methylfuranosides of L-Fucose, D-Ribose, and L-Rhamnose

INGVALD AUGESTAD and ENDRE BERNER

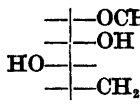
Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

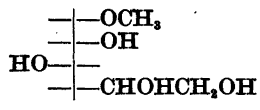
Three crystalline methylfuranosides of L-fucose, D-ribose, and L-rhamnose, respectively, have been prepared by column chromatography. The rates of hydrolysis of these and some previously prepared furanosides have been measured at 20° in N hydrochloric acid. The rule seems to exist that furanosides having *cis*-configuration at C_1 and C_2 are more easily hydrolyzed than the anomeric forms with *trans*-configuration.

Since the publication of part II [1] of this series Watkins [2] has described the isolation of crystalline α-methyl-L-fucofuranoside. Already before his publication appeared we had obtained the same crystalline fucoside, but although our results agree with those of Watkins we find it appropriate to include them here. Barker and Smith [3] have described the chromatographic separation on a column of "Solkafloc" of the four isomeric methyl-D-ribosides, but they did not obtain any of the furanosides in the crystalline state. Using a similar procedure as described in part II of this series we succeeded in isolating the crystalline β-methyl-D-ribofuranoside. By the same method we have also prepared the crystalline α-methyl-L-rhamnofuranoside. The melting points and rotations of the new crystalline furanosides are as follows:

α-Methyl-L-fucofuranoside	M.p.	126°	$[\alpha]_D^{20}$	−111.4° (in water)
β-Methyl-D-ribofuranoside	"	80°	"	− 49.8° "
α-Methyl-L-rhamnofuranoside	"	62°	"	− 98.6° "

The rates of hydrolysis of the furanosides in N hydrochloric acid at 20° have been calculated from measurements of free sugar. As the rates of hydrolysis given in part II were measured only at room temperature we have redetermined them at exactly 20°. For comparison the rates of hydrolysis of a few other methylfuranosides have been included. The results are collected in





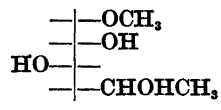


Table 1 in which the rate constants are calculated from the equation $k = 1/t \cdot \ln(a/a—x)$ with time in minutes. As some authors, *e. g.* Riiber and Sørensen [4] and Isbell and Frush [5] have calculated the rates of hydrolysis of glycosides from the equation $k_{10} = 1/t \log (a/a—x)$, we have also given the figures for k_{10}.

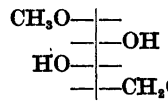

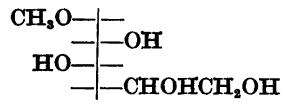

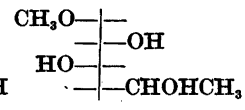

Table 1. Rates of hydrolysis in N HCl at 20°.

	$[\alpha]_D^{20}$	k	k_{10}	Half life

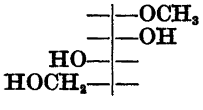
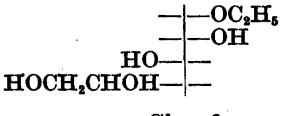
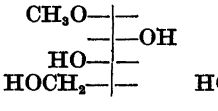
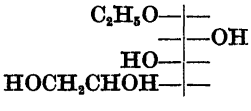
As the ring in the furanosides is most probably plane a relationship between configuration and physical constants is more likely to be found for these glycosides than in the case of the pyranosides in which the six-membered ring may have different conformations (see, *e. g.*, the discussion recently by Edward [6]). In the following consideration of this question we have, besides our own experimental data, made use of the figures for rotation and hydrolysis of the α- and β-ethyl-D-glucofuranosides determined by Haworth, Porter, and Waine [7]. Their values for k were measured at 55—60° in 0.01 N hydrochloric acid.









Using the periodic oxidation method Jackson and Hudson [8] have shown that, in the case of the methylpyranosides of aldopentoses and aldohexoses, the α-forms of D-sugars in all cases investigated have the same configuration at C_1, *viz.* the methoxyl group falling to the right in the conventional projection formulae. In a single case they oxidized a furanoside, *viz.* α-methyl-D-arabofuranoside, and found that also this glycoside had the same configuration at C_1 as the α-pyranosides. Assuming now that this hold for the other α-furanosides as well, it will be seen from the simplified projection formulae below that the anomeric form having *cis*-configuration at C_1 and C_2 always is more easily hydrolyzed than the corresponding anomer with *trans*-configuration. In the case of D-fucose it is assumed that enanthiomeric glycosides have the same rate of hydrolysis and that their optical rotations differ in sign only. The molecular rotation given are calculated in the usual way as one hundreth of the product of specific rotation and molecular weight.

			
	β-L-Arabofurano-side	α-D-Galactofurano-side	α-D-Fucofurano-side
$[M]_D$	+194°	+202°	+198°
$k^{20°}$	0.00140	0.00104	0.00049

			
	α-L-Arabofurano-side	β-D-Galactofurano-side	β-D-Fucofurano-side
$[M]_D$	−209°	−218°	−201°
$k^{20°}$	0.000206	0.000123	0.00015

The molecular rotations of the configurationally corresponding methylosides of the three sugars are as will be seen very nearly the same, indicating that the influence on the optical rotation of the size of the substituent at C_4 is insignificant.

In the case of the methyl-D-xylo- and the ethyl-D-glucofuranosides again the anomers having *cis*-configuration at C_1 and C_2 are hydrolyzed more easily than those with *trans*-configurations, although the ratio *cis*:*trans* is considerably less than by the three sugars above. The latter fact might be due to the different configuration at C_4. In the case of D-xylose and D-glucose the furanosides which are more easily hydrolyzed have *trans*-configurations of the substituents at C_1 and C_4, while in the case of the three other sugars the more easily hydrolyzable furanosides have the groups at C_1 and C_4 in *cis*-position.

				
	α-D-Xylofuran-oside	α-D-Glucofuran-oside	β-D-Xylofuran-oside	β-D-Glucofuran-oside
$[M]_D$	+299°	+210°	−146°	−179°
$k^{20°}$	0.0128	$k^{60°}$ 0.0230	$k^{20°}$ 0.0075	$k^{60°}$ 0.0124

The experimental material is still too small for a further discussion of these questions, and it must be hoped that additional data will soon be available.

Added in proof: The α- and β-methyl-D-mannofuranosides have been isolated by means of column chromatography, the β-form, however, only as a syrup. The rates of hydrolysis in N hydrochloric acid at 20° were found to be in agreement with the results in the case of the other anomeric furanosides described above: α-Methyl-D-mannofuranoside, m. p. 120°, $[\alpha]_D^{20} = +109°$, $k = 0.000327$ ($k_{10} = 0.000142$), half life 35 h 21 m. β-Methyl-D-mannofuranoside (syrup) $[\alpha]_D^{20} = -86.5°$, $k = 0.00471$ ($k_{10} = 0.00205$), half life 2 h 27 m.

EXPERIMENTAL

Methyl-L-fucofuranosides

Watkins [2] using the method described by us succeeded in preparing crystalline α-methyl-L-fucofuranoside with m. p. 125—126° and $[\alpha]_D$ −108° (c = 2 in water). The corresponding β-furanoside was obtained as a clear syrup with $[\alpha]_D$ +113°.

In the present case a 2 % solution of L-fucose in methanol containing 0.014 % HCl (0.0039 N) was refluxed for 2 hours. After removing the hydrogen chloride with silver carbonate the solution was evaporated to a syrup. On leaving the syrup from 3.1 g fucose in a vacuum desiccator for a week some crystalline material (0.37 g) had separated which was found to be α-methyl-L-fucopyranoside having m. p. 156° and $[\alpha]_D$ −190° (water). This separation of the α-pyranoside was found to be advantageous for the subsequent separation on the cellulose column. As mobile phase was used a mixture of butanol-1, methyl ethyl ketone, and water (1:1:1) and the effluent was collected automatically in tubes. At certain intervals paper chromatograms were run (using methyl ethyl ketone saturated with water) in order to check the degree of separation. The pyranosides necessary for this purpose were prepared according to Minsaas [9]. The tubes 1—19 contained only β-furanoside, and the solution on evaporation gave a clear syrup (1.08 g) which has not yet crystallized; $[\alpha]_D^{20}$ +113° (c = 2 in water). From the tubes 28—39 was obtained the pure α-methyl-L-fucofuranoside (0.5 g) which recrystallized from ethyl acetate had m. p. 126° and $[\alpha]_D^{20}$ −111.4° (c = 3 in water). (Found: C 47.33; H 7.71. Calc. for $C_7H_{14}O_5$: C 47.19; H 7.92.)

β-Methyl-D-ribofuranoside

Barker and Smith [3] prepared a mixture of the four ribosides by treatment of ribose at room temperature with methanol containing 1 % hydrogen chloride. The separation of the ribosides was effected on a column of cellulose using butanol-water as eluant. The ribosides finally distilled in a high vacuum were obtained as syrups except in the case of the β-pyranoside which had also previously been prepared in the crystalline state.

In the present investigation a syrup rich in furanosides was obtained by refluxing for 70 min. a methanolic solution containing 2.6 % D-ribose and 0.0108 % HCl (0.003 N). Under these conditions the sugar was transformed completely into glycosides. After removing the hydrogen chloride in the usual way and evaporating the methanol a clear syrup was obtained. The syrup (4.04 g) dissolved in a small quantity of the eluant was placed on top of a column of powdered cellulose and eluted with a mixture of ethyl acetate, propanol-1, and water (5:3:2) which left the column at a rate of 28 ml per min, 7 ml being collected in each tube. The following fractions were obtained:

Fraction	Tube No.	Weight
A	2—12	1.44 g
B	13—18	1.30 »
C	19—25	0.73 »
D	26—46	0.40 »
		3.87 g (95 % recovered)

On a new column, using butanol-1 saturated with water as eluant, fraction A was separated into two fractions A_1 and A_2 of 0.73 and 0.57 g respectively. Fraction A_1 was dissolved in 30 ml dry ethyl acetate, treated for one hour at room temperature with charcoal, filtered and then 25 ml of the solvent was removed by distillation. After the concentrated solution had been kept for a few days above calcium chloride at −20° the β-methyl-D-ribofuranoside had crystallized. On inoculating A_2 with the new crystalline riboside also this fraction crystallized. Fractions B and C were each fractionated a second time on cellulose columns, using butanol-1 saturated with water as eluant. In both cases

the first fractions on inoculation gave some crystalline β-furanoside. The yield of crystalline β-furanoside was in all 2.34 g (58 %). After recrystallization from ethyl acetate, m. p. 80° and $[\alpha]_D^{20}$ −49.8° (c = 4.2 in water).

The second fractions of B and C had the specific rotations +100° and +121°, respectively, but the quantities were too small for further treatment.

α-Methyl-L-rhamnofuranoside

Of the L-rhamnosides the α- and β-pyranosides have been known in the crystalline state since the days of Emil Fischer. They also represent the pair of anomeric glycosides which was for the first time separated by a chromatographic method; see Hough, Jones, and Wadman [10]. In the present case a mixture of methylrhamnosides rich in furanosides was prepared by refluxing for 4 1/2 hours a solution of anhydrous L-rhamnose (10 g) in methanol (500 ml) containing 0.02 % hydrogen chloride (0.0055 N). After treatment first with lead carbonate and then with silver carbonate the solvent was evaporated at room temperature. The syrup was redissolved in some methanol and shaken with charcoal in order to remove traces of colloidal silver. Finally the filtered clear solution on evaporation in a vacuum above calcium chloride gave a syrup with $[\alpha]_D$ −39° (in water).

The first fractionation of the syrup (10 g) was carried out on three columns of powdered cellulose, each loaded with about 3 g. The eluant was a mixture of butanol-1, ethyl acetate, and water (7:5:2) and the general procedure by the separation as described before. As an example may serve the fractionation in one of the columns:

Fraction	Tube No.	Weight
A	1—15	1.92 g
B	16—20	0.27 »
C	21—25	0.15 »
D	36—60	0.29 »
E	61—71	0.07 »

Paper chromatograms showed that A contained mainly α-furanoside, and actually the tubes 1—6 from one of the columns on evaporation gave a syrup which crystallized spontaneously. In order to achieve a better separation the rest of fraction A from the same column and the whole of the fractions A from the other two columns were put together and the syrup obtained from them fractionated for a second time on a column. The new first fraction (AII) together with the above tubes 1—6 gave 3.05 g which were dissolved in ethyl acetate (20 ml), treated with charcoal and filtered. After distilling off half of the solvent the solution was placed at −20° overnight and then inoculated whereby the glycoside separated in crystals. On recrystallization from benzene this new α-methyl-L-rhamnofuranoside was obtained in needles with m. p. 62° and $[\alpha]_D^{18}$ −98.6° (c = 3.8 in water). A paper chromatogram gave a single spot only.

The fractions B and C from the first and BII and CII from the second fractionation contained mixtures of the other rhamnosides. The fractions D were rich in β-pyranoside and on evaporation crystallized partly. In order to obtain more of the β-pyranoside all fractions B and C were collected and their content subjected to a new fractionation. The β-methyl-L-rhamnopyranoside thus isolated was recrystallized from ethyl acetate and obtained in needles with m. p. 138° and $[\alpha]_D^{22}$ +96.4° (c = 2.2 in water). On the paper chromatogram a single spot only appeared.

On Vitamins in Sewage Sludge

IV. Isolation of New Vitamin B_{12}-like Factors

HALINA Y. NEUJAHR

Royal Institute of Technology, Division of Food Chemistry, Stockholm, Sweden

Of eleven vitamin B_{12}-like factors isolated from digested sewage sludge three behave as nucleotide-containing compounds and show considerable activity towards *Ochromonas malhamensis*. One of them (the most abundant) has been identified as cyanocobalamin, another may be identical with Factor III (Bernhauer) but the third has not, as yet, been identified with any known factor.

Eight of the isolated factors show behaviour typical of the factors lacking a nucleotide component. Three of them have considerable activity towards *E. coli* and one of these factors has been identified as factor B; the other two, or at least one of them, are probably identical with factor C. The microbiological activity of the remaining five factors is practically negligible.

Some properties of the isolated factors are given, and their behaviour during the isolation process discussed.

The abundance and variety of known vitamin B_{12}-like factors has increased considerably during the last two years. In particular, faecal sources — raw faeces of different animals and treated sewage sludges — have been found to contain many new factors suggesting that hitherto unknown forms of this vitamin may occur in nature..

At the same time there arose the problem of a rational method of nomenclature. At present several authors use individual systems of their own invention when describing factors isolated by them — a fact which complicates the naming of new factors when isolated by other workers. In previous work on vitamin B_{12}-activity in sewage sludge [1–3] the present author adapted the terminology of the Reading-[4–7] and Glaxo-[8,9] groups, and of Pfiffner *et al.*[10] who isolated a series of vitamin B_{12}-like factors from the faeces and rumen contents of certain ruminants. The factors found in sewage sludge (in addition to cyanocobalamin) were designated A, B, C, (C_1 and C_2) and pseudovitamin B_{12} after their identification by bioautography and paper electrophoresis with samples of the respective factors kindly provided by the above mentioned authors. Such identification was in most cases performed on crude sludge extracts or concentrates.

Armitage and co-workers [11] have described two series of vitamin B_{12}-like factors obtained by the hydrolytic cleavage of cyanocobalamin and have shown that those factors lacking a nucleotide component form stable *violet* * dicyanocomplexes at pH 6.5, while those containing a nucleotide component factors yield *red* monocyanocomplexes at this pH. Bernhauer and co-workers [12,13] have used this property and have characterized factors isolated from sewage sludge as "complete" (containing nucleotide) or "incomplete" (lacking nucleotide). Among several vitamin B_{12}-like factors isolated by them from sewage sludge was the previously unknown Factor III ("complete") which was later shown by two independent groups [14,15] to differ from cyanocobalamin in containing 5(6)-hydroxybenzimidazole instead of 5,6-dimethyl-benzimidazole. Bernhauer and co-workers [12] have also isolated from sewage sludge a substance, originally called "Factor V", which on electrophoresis was resolved into five different factors ** corresponding to the five nucleotide-lacking carboxylic acids described by Armitage *et al.*[11] (*cf.* Bernhauer [12]).

From portions of digested sewage sludge totalling 100 l (containing 10 % dry solids) 11 vitamin B_{12}-like factors of which three are red and eight violet in the presence of cyanide at pH 6.5, have now been isolated together with an orange substance of similar R_F-value to the slow moving vitamin B_{12}-like factors. Thus repeated chromatographic and electrophoretic separations have shown "factor A + pseudovitamin B_{12}"[1-3] to be a mixture of six factors with R_F-values close to those of factor A and pseudovitamin B_{12} but differing in their microbiological activities and spectrophotometric characteristics. Since most of these substances have not, as yet, been identified with known factors they may be conveniently described as: factor B, cyanocobalamin, factors V and W, factors X1, X2, X3 and X4, factors Z1, Z2, Z3, and factor Y which is not, however, a vitamin B_{12} factor. The investigation of the nature of these factors is continued with a view to their identification with similar substances isolated from other sources. Factor Z3 appears to be identical with factor C [6,7]. In the earlier stages of purification by chromatography, it behaved as factor C_2[1,2] (or B_{12s} [18,19]), while after numerous chromatographic and electrophoretic separations its behaviour changed to that of factor C_1[1,2].

EXPERIMENTAL

Isolation of factors

2–3 l portions of digested sludge (10 % total solids) were diluted (4:1) with water boiled at pH 6 for 15 min. in the presence of KCN (100 mg/l) and centrifuged. The combined supernatants (1 % total solids) were subjected to absorption on activated charcoal (Norit. 2 % w/v) at pH 6 and 3° C for 2 hours in 10 l portions. The charcoal suspension (together with 2 % w/v filteraid (Hyflo-Super Cel)) was removed by filtration through

* The term "violet" as used in this paper corresponds to the term "purple" used by the above mentioned authors.

** The electrophoretic separation of these factors was performed by the author in Professor Bernhauers laboratory, using the two zone electrophoresis apparatus described by Flodin [16] and Carlsson [17].

filteraid layers of 2—3 cm thickness in large Büchner funnels and then washed with a 5 % (w/v) solution of phenol in water. Considerable amounts of brown impurities, but negligible amounts of vitamin B_{12}-active material, were removed by the washing. Every filtercake was washed with 2—3 l of the phenolic solution. The washed filtercakes were boiled for 5 minutes under reflux with a volume of 70 % ethyl alcohol equal to about four times that of the filtercake and quickly filtered. This operation was repeated four times. The filtrates were cooled rapidly and the alcohol distilled *in vacuo*. The remaining liquid was concentrated by further evaporation *in vacuo* and the precipitated material was removed by filtration at 80° C with some filteraid. The red-brown liquid was then extracted with an equal volume of *iso*propanol containing 30 % $(NH_4)_2SO_4$ and the emulsions and precipitates formed were reextracted until the solution was only very slightly coloured and showed negligible vitamin B_{12} activity. The combined purple extracts were concentrated *in vacuo* in order to remove *iso*propanol and about half the water and the concentrate was subjected to a series of extractions with *p*-chlorophenol solutions the vitamin B_{12} activity being finally precipitated on kieselguhr as described by Bernhauer [12]. Each extraction was repeated until the red material passed completely into the extracting phase and until microbiological tests (mainly cup plate assay with *E. coli* 113—3) showed the almost total absence of vitamin B_{12} activity in the extracted phase. In some cases as many as 10—15 extractions were necessary.

For the final stages of purification and separation of the different factors the vitamin B_{12} preparation was subjected to partition chromatography on cellulose powder columns and on Whatman 3MM filterpaper using, as solvents, water saturated *sec.* and *n*-butanols containing 0.01 % KCN and saturated with $KClO_4$ [20]. The height of the columns varied between 8—12 cm; the filter paper sheets were 50 cm long and 20 cm broad.

Although in earlier experiments the vitamin B_{12} material was dissolved in few ml of the eluting solvent and applied directly to the top of the column it was later found more convenient to apply the kieselguhr concentrate itself as described by Friedrich and Bernhauer [20].

The first stage of chromatography was performed with *sec.* butanol on cellulose columns when the vitamin B_{12} material resolved into four bands. The fastest, a violet band (I), was followed by a red band (II) which in turn was followed by a very slow violet band (III) and another, almost immobile, violet band (IV). The degree of separation was poor and considerable amounts of yellow and brown impurities could be seen in the column moving both faster than (I) and as slow as or slower than (IV). The kieselguhr layer on the top of the column retained a large amount of brown immobile material. Although (I) and (II) could easily be eluted and collected in two distinctly separated fractions the bands (III) and (IV) could not be eluted even after an extended period of time. The cellulose column was then extruded and the two violet bands cut off, extracted with water, evaporated to small volumes in *vacuo* and the vitamin B_{12} activity precipitated on kieselguhr as before. The remainder of the column including the kieselguhr layer was cut in sections and analyzed for vitamin B_{12} activity. Only that extract corresponding to the top of the column, including the kieselguhr layer, contained noteworthy amounts of vitamin B_{12}-activity. This extract was evaporated to dryness and rechromatographed several times on thick Whatman paper using, respectively, *sec.* and *n*-butanol but the separation of the vitamin B_{12} activity from the yellow and brown impurities was not successful (*cf.* p. 926). The four kieselguhr preparations were then rechromatographed on cellulose columns with *n*-butanol. All four preparations contained besides the main band smaller amounts of the three other bands and of brown or yellow impurities which could be separated from the vitamin B_{12}-active substances; (III) divided into two poorly separated violet bands (IIIa) and (IIIb). Again (I) and (II) could be easily eluted, while (IIIa), (IIIb) and (IV) were cut from the columns and treated as before. After repeated precipitation on kieselguhr the five fractions were rechromatographed on cellulose columns using *n*-butanol for (I), (II) and (IIIa) and *sec.* butanol for (IIIb) and (IV). After this third fractionation (I) appeared to have divided into two bands, one of which was a weak violet, faster-moving band (Ia) poorly separated from the main violet band (I). Fraction Ia was collected but could not be thoroughly investigated due to an accident. Its R_F value (relative to that of cyanocobalamin) was about 1.5 while the corresponding R_F-value of (I) was 1.35 and on mixed bioautograms the two fractions appeared as distinct zones. In the following, fraction Ia will be referred to as factor B1. When fraction (I) was again chromatographed on thick Whatman paper with *n*-butanol it appeared as a

single violet band free of yellow impurities. Ionophoretic test confirmed the homogeneity of the fraction but an attempt to crystallize it from aqueous acetone gave only a precipitate. It could be identified by bioautography and paper electrophoresis as factor B, its other properties can be seen in Tables 1 and 2 referred to as factor B.

Fraction II appeared as a distint single red band on the column but to ensure its purity it was rechromatographed on thick Whatman paper with *n*-butanol. It was then crystallized from aqueous acetone and identified as cyanocobalamin.

Fraction (IIIa) appeared as a broad violet band which could be removed from the column only by protracted elution. Spectrophotometric measurements of the eluate fractions indicated the presence of three different factors in this band but repeated chromatography on thick Whatman paper did not lead to a satisfactory separation. On paper electrophoresis at pH 3.0 (0.5 N HAc containing 0.01 % KCN) the mixture separated into three zones: one basic (X2), one neutral (W) and one strongly acidic (X1). The degree of separation of zones X2 and W was not quite satisfactory but could be improved by electrophoresis at pH 6.5 (phosphate, $\mu = 0.1$). The three factors thus obtained were rechromatographed on thick Whatman paper with *n*-butanol. Factor W appeared as a single distinct red band, while factors X1 and X2 moved as violet zones. Considerable amounts of factor B separated from each of these two latter factors.

Fraction IIIb appeared on the column as a broad violet band. Spectrophotometric measurements of the eluate fractions gave no indication of its heterogeneity but to ensure its purity it was rechromatographed on thick Whatman paper with *n*-butanol. After a considerable time it appeared to separate into three very close zones but a satisfactory separation of the factors could not be obtained. Paper electrophoresis of the mixture at pH 3.0 led to separation into one neutral (V) and two basic zones (X3 and X4) and the three factors were rechromatographed on thick Whatman paper with *n*-butanol. Factor V gave a single, rather wide pink zone while factors X3 and X4 appeared as distinct violet bands. As in the case of the factors isolated from (IIIa) considerable amounts of factor B could be separated from factors X3 and X4 during this final purification.

Fraction (IV) appeared on the column as a very broad violet band and the presence of several factors was confirmed by spectrophotometric measurements of the eluate fractions. The degree of separation was very poor and the band appeared to contain considerable amounts of yellow substances. Paper-electrophoresis at pH 6.5 followed three times by chromatography on thick Whatman paper with *n*-butanol resulted in the isolation of three violet factors (Z1, Z2 and Z3) and one orange factor (Y). Again, considerable amounts of factor B could be separated at the same time.

All chromatographically pure factors were tested for their homogeneity by paper electrophoresis and further purified in that way if necessary. Attempts to crystallize the isolated factors were unsuccessful except in the case of cyanocobalamin. The amounts isolated were in most cases too small to be weighed and they are listed in Table 2 on the basis of the optical density of their solutions. The factors were desalted and kept in 70 % EtOH at $-20°$ C.

Characterization of factors

Absorption spectra. For determination of spectra appropriate amounts of the alcoholic solutions were evaporated to dryness and dissolved in 5 ml water. 1 drop of 0.1 % KCN solution was added and the pH adjusted to 6.5 with HAc or NH_4OH; in most cases these additions were negligible. The pH of the solution was also measured after each determination and in no case did the pH change exceed 0.2 pH units. The measurements were performed on a Beckman Spectrophotometer Model DU. Although the spectrophotometric data on the non-crystalline factors listed in Table 2 must be taken with reserve, it is hoped that they can help to elucidate the relationships between these factors and those previously identified.

Partition coefficients were determined in the solvent pair 20 % *p*-chlorophenol in trichloroethylene-water. The amount of vitamin B_{12}-like factor in each phase was measured spectrophotometrically.

Paper electrophoresis was performed with two buffer systems; at pH 3 with HAc and at pH 6.5 with $K_2HPO_4-KH_2PO_4$, both containing 0.01 % KCN and having an ionic strenght of 0.1. Voltage gradients of 10 V/cm at $+4°$ C during 18 hours were standard experimental conditions using LKB Paper Electrophoresis Apparatus Type 3276 B.

Both the bioautographic technique using *E. coli* 113—3 and the technique with visible spots were used in detection.

Microbiological tests were performed with *E. coli* 113—3 in both cup plate and tube assays and with *Ochromonas malhamensis*. Using Ford's technique most tests were repeated on 3—5 different days and the values listed in Table 2 are averages of all determinations. The microbiological potency of the factors is calculated on the basis of the optical density of their solutions at λ = 361 mμ for the red and at λ = 367 mμ for the violet factors.

Bioautography was used to determine the R_F-values of the factors and in certain cases visible spots were chromatographed for comparison. Chromatograms (descending technique) were run for 48 h at 21° C in water-saturated *sec.* butanol containing 3 % HAc and 0.01 KCN, and developed on *E. coli* 113—3 plates; authentic specimens were run as standards. The R_F-values listed in Table 1 are calculated in relation to that of cyanocobalamin and will be referred to as R_c-values. Mixtures of known and unknown factors as well as of groups of unknown factors were chromatographed but usually little information was obtained regarding the relationships between different factors (Table 1). The R_c-values appeared to be influenced by the impurities present in the samples and usually increased with the degree of purity.

RESULTS AND DISCUSSION

The factors isolated are listed in Table 1 and are grouped vertically according to their ability to form violet (di)cyano complexes at neutral pH, and horizontally according to their R_c-values. The horizontal arrangement yields four main groups (left column in Table 1), with R_c-values 1.6—1.3 (I), 1.0 (II), 0.7—0.6 (III) and 0.5—0.4 (IV), respectively. The R_c-values of the factors within each group have been determined at least six times in each case giving variations of up to $\pm$0.05. Although the values listed in Table 1 agree

Table 1. Vitamin B_{12} factors isolated from sewage sludge. (Behaviour at pH 6.5 in the presence of CN^-.)

solvent: 20 % *p*-chlorophenol in trichloroethylene.

fairly well with the order in which the factors moved on chromatograms during the isolation procedure (*cf.* p. 920) it is evident that R_c-values are of limited use in the characterization of these factors unless they are well differentiated. It is possible that group III can be divided into two subgroups with R_c-values 0.70—0.65 (IIIb), respectively.

Some properties of these factors are listed in Table 2. The four main groups (left column in Table 1) are in full agreement with earlier findings [1] (*cf.* right column in Table 1) except in the case of "factor C_2".

Factors "Z". The presence in sewage sludge of a virtually immobile B_{12}-like factor ($R_c = 0.0$) has been noted in this laboratory before [1-3]. In the present isolation experiment such a factor was detected by bioautography in the original sludge and after repeated purification by chromatography it appeared as a very distinct, immobile, violet band at the top of the column (*cf.* p. 919). Its behaviour was similar to that of "factor C_2" or B_{12a} [18,19] and was unchanged after being twice chromatographed on

min B_{12} factors from sewage sludge.

cellulose powder columns although there was then some indication that this factor was, in fact, not homogeneous. After further chromatography (on thick Whatman paper) and electrophoresis this factor could be separated into three violet factors (Z1, Z2, Z3) and one orange factor (Y), all of which had R_c values within the range 0.5—0.4. This R_c range corresponds to "factor C_1" (*cf.* right column in Table 1). The explanation of this fact is not yet known. It appears that the immobile violet factor has been transformed to other violet forms during the extended time of isolation.

Similarly it is difficult to decide whether the orange factor (Y) was initially present in the sludge or merely formed during the transformation of the original immobile violet material into the violet factors of R_c 0.5—0.4. The slight microbiological activity of this factor may be due to traces of impurities; its absorption spectrum indicates that it is not a vitamin B_{12}-like factor. The "intermediate" character of "factors C_2" and "C_1" which are present only in

the initial stages of bacterial fermentation, "factor C_2" being the first one to disappear, has already been noted [2]. Assuming that "Fraction IV" (p. 920), the source of the three factors "Z", corresponds to the "factor C_2" of bioautograms then the present investigation offers further confirmation of the labile nature of this factor. Similarly the labile nature of "factor C_1" may be confirmed by the separation of considerable amounts of factor B at each of the numerous chromatographings of "Fraction IV" (*cf.* p. 920).

It is difficult to decide which, if any, of the factors "Z" most closely resembles factor C but on the basis of microbiological activity it cannot be Z1 whose activity for *E. coli* is insignificant and probably due only to traces of the other two factors "Z" still present.

Earlier information on the electrophoretic behaviour of factor C (C_1 and C_2) or B_{12s} concerns mostly crude extracts or concentrates. Holdsworth [21] reports the mobility of factor C in 0.5 N acetic acid containing KCN; as -1.4×10^{-5}. According to Ericson [19] vitamin B_{12s} should move to the anode under these conditions as should factors C_1 and C_2. Brown and coworkers have determined the acidic character of factor C by electrophoresis in neutral and alkaline buffers [9].

As can be seen in Table 2 all three factors "Z" show acidic electrophoretic behaviour at pH 6.5 but at pH 3.0 factor Z3 is neutral while factors Z1 and Z2 behave as bases. This corresponds to the findings of Brown and coworkers [9] on factor C but is contrary to the earlier information [19] on the electrophoretic behaviour of this factor at pH 3.0.

However, it should be remembered that some determinations were carried out on crude extracts whose content of salts and other impurities may have influenced the electrophoretic behaviour of the B_{12}-like factors. Again if "factor C" has "changed" during the isolation procedure, this would explain its changed electrophoretic behaviour. (*cf.* p. 923).

It is, therefore, probably factor Z3 which most closely resembles the earlier description of factor C (C_1), both in its microbiological activity and in its chromatographic and electrophoretic behaviour.

Factors X. The four violet factors of R_c values 0.7—0.6 occurred together with two red factors V and W on the bioautograms (see Table 2). On mixed chromatograms (bioautograms) with standard substances — factor A, ψ B_{12}, and factor III — they gave in most cases single spots. In a few cases the spots were oval suggesting the presence of at least two components. It is evident, therefore, that this method of identifying B_{12} factors must be used only with very great caution. The "incomplete" character of these factors is shown by their ability to form violet (di)cyano complexes at neutral pH. Not only is their R_c range distinct from that of "factors C" but their microbiological activity for *E. coli* is also extremely low — this slight activity, together with the low activity for *O. malhamensis*, may be explained by the presence of traces of factors V and W (*cf.* Table 2). Although the electrophoretic behaviour of factors X2, X3 and X4 resembles that of factors Z, insofar as they are acidic at pH 6.5 and basic at pH 3.0; factor XI differs markedly from the rest of the group in being strongly acidic at both pH's although much less so at pH 6.5. (*cf.* Table 2).

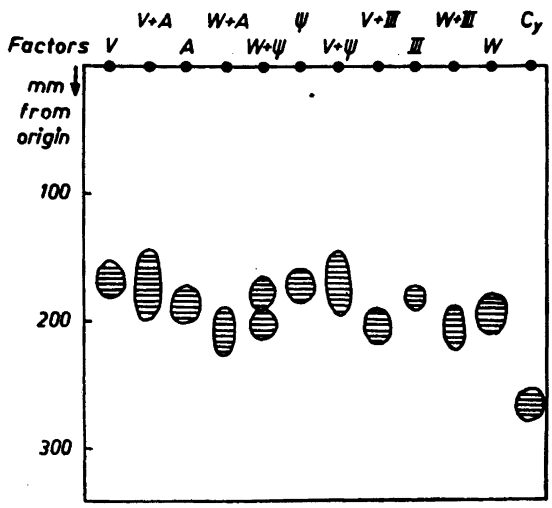

Fig. 1. Mixed bioautograms of factors W and V with known factors. Solvent system: water satur. sec. BuOH containing 3 % HAc and 0.01 % KCN; 21° C, 48 h. run. Developed with E. coli 113—3.

ψ = pseudovitamin B_{12}
C_y = cyanocobalamin

Factors V and W. These two red factors with R_c-values 0.7—0.6 have absorption spectra closely resembling that of cyanocobalamin. They are neutral at pH 3.0 and slightly basic at pH 6.5 (*cf.* Table 2). In order to establish their identity with known factors, bioautography, electrophoresis and, in the case of Factor III, spectrophotometric measurements were carried out several times on mixed solutions in order to compare them with known standards.

Since a mixture of factor W and ψ B_{12} is resolved by paper chromatography (Fig. 1) it is obvious that the two substances are not identical. Although other mixed solutions gave single spots these have a markedly oval shape, except in the case of V+III, while the single spots of pure solutions are more circular. It seems likely therefore that factor W is not identical with any of the three factors A, ψ B_{12}, and III available for comparison, while factor V is possibly identical with Factor III.

It was not possible to identify the factors V and W with the above mentioned known standards by electrophoresis or by spectrophotometric measurements. The spectrophotometric data for ψ B_{12} were unavailable. The band at 295 mμ characteristic for the monocyano complex of Factor III could not be detected in either factor W or V but the monocyano complexes of these factors showed, instead, bands at 275 mμ and 278 mμ, respectively. The absence of a band in this region may not be incompatible with the postulate of a relationship to Factor III, since the measurements were performed on a non-crystalline product. Moreover factor V resembles Factor III in its microbiological activity towards *E. coli* by both the cup plate and tube methods. The activity towards *O. malhamensis* is about 40 % of that of cyanocobalamin.

Factor W shows a strikingly high microbiological activity towards *E. coli* in plate assay. Its activity towards *E. coli* in tube assay is of the same order as that of cyanocobalamin. Although Factor H, isolated by Brown and coworkers [9] also has a very high activity towards *E. coli* in plate assay its activity in tube assay is lower than that of factor W and the activity towards *O. malhamensis* is very small. Further differences between these two factors are found in their absorption spectra [9] (*cf.* Table 2).

GENERAL CONSIDERATIONS

Violet factors. Of the 8 violet factors only three (B, Z2 and Z3) have a pronounced microbiological activity (Table 2) while the remaining five factors (X1, X2, X3, X4 and Z1) can be considered as inactive, (*cf.* p. 924). They form violet (di)cyanocomplexes at pH 6.5 which show the characteristic maxima at 367—368, 540 and 580 mμ. They exhibit acidic properties upon electrophoresis at the same pH. When acidified to pH 4.0 the colour of the solutions changes rapidly to orange, presumably due to the formation of hydroxo (or aquo) compounds.

The microbiologically active factors Z2 and Z3 (as well as factor B) were identical with the inactive factors in the formation of (di)cyano and hydroxyforms, respectively, and in their electrophoretic behaviour (*cf.* Table 2 and p. 924). In cup-plate assay with *E. coli* these factors showed characteristically *diffuse* growth zones which may account for their high microbiological potencies when calculated by this method. The phenomenon was much more pronounced in the case of factors Z2 and Z3 than in the case of factor B.

Behaviour of the different factors during some isolation steps. It is possible that the inactive factors, like the violet factors (Z2 and Z3) of high activity, tended to remain in precipitates, emulsions *etc.* during extraction. For this reason the solutions were exhaustively extracted beyond the point judged necessary by the behaviour of the red-brown substances (*cf.* p. 919) but constant microbiological testing is essential if the yellow hydroxo (or aquo) compounds formed by the active violet factors at pH 4.0—5.0 are not to be mistaken for "impurities" (most of which are also yellowish) and lost during the isolation procedure. Although these factors can be easily detected in solution by the violet colour formed immediately upon addition of CN^- this may not be the case in emulsions and precipitates. However, such extended extractions may give impure preparations necessitating repeated chromatography in later purification. It is not clear, whether the microbiological activity contained in the "kieselguhr layer" (p. 919) was due to still another factor or to the "tail" of the immobile violet factor which later resolved into factors Z1, Z2 and Z3 (*cf.* p. 919). Furthermore, the factors apparently differ in their ability to form the phenolic complexes described by Bernhauer since they behaved in different ways during extractions with phenolic solutions; some preliminary values for partition coefficients in one solvent system are given (Table 2). Unfortunately in many cases the amount of material available was insufficient to allow a thorough investigation of the problem.

It has been pointed out above (*cf.* p. 920) that considerable amounts of factor B could be separated from the violet factors upon repeated chromato-

graphy. This phenomenon suggests the possibility that the violet factors (or some of them) correspond merely to some different cyanide complexes of factor B. However, the relatively stable character of these factors during the process of determination of their spectrophotometric and electrophoretic properties rather points against this possibility. The problem was not further investigated.

Acknowledgements. The author wishes to thank Professor H. Lundin, Head of the Division, for his encouraging interest and valuable advice in performing this work. The author is grateful to Professor Dr. K. Bernhauer, Aschaffenburger Zellstoffwerke, Stockstadt/Main, Germany, for the stimulating experience acquired during her stay in his laboratory in the summer of 1954 and for samples of factor III and factor B, and to Dr. E. Lester Smith, Glaxo Laboratories, England, for spectrophotometric data on factor B. Valuable information on electrochromatography was given by Dr. L. Carlsson, King Gustaf V:s Research Institute, Stockholm, and Dr. P. Flodin, The Institute of Biochemistry, Upsala.

Thanks are due to Mrs. M. Jonason, Mr. I. T. Okine, and Mr. Th. Kirsipuu for technical assistance. The financial support of *Statens Tekniska Forskningsråd* is gratefully acknowledged.

Reversible Enzymatic Synthesis of Guanosine Diphosphate Mannose from Guanosine Triphosphate and Mannose-1-Phosphate

AGNETE MUNCH-PETERSEN

Universitetets cytofysiologiske Institut, Copenhagen, Denmark

From brewer's yeast an enzyme is isolated and purified, which catalyzes a pyrophosphorylation of guanosine diphosphate mannose. This reaction is demonstrated spectrophotometrically, and the reversibility of the process is proved by means of paper chromatography. Separation of guanosine diphosphate mannose from uridine diphosphate glucose on a cellulose column is described.

A number of enzyme systems, catalyzing processes which involve guanosine compounds have recently been demonstrated [1–4] and guanosine nucleotides have been isolated from liver, brain, tumor and muscle tissue [5,6]. An interesting compound, guanosine diphosphate mannose (GDPM) *, was isolated from yeast and identified by Leloir and Cabib [7]. This compound is probably identical with the mannose-containing nucleotide, noticed by Buchanan *et al.*[8] in their investigations of phosphorus compounds as intermediates in photosynthesis.

In the present paper the existence of an enzymatic pathway for the synthesis of GTP from GDPM and P—P is reported, and the reversibility of the process is proved. The reaction consists in a pyrophosphorolytic cleavage of GDPM according to the following equation:

$$\text{GDPM} + \text{P—P} \rightleftharpoons \text{GTP} + \text{M—1—P} \qquad (1)$$

and the process seems analogous to the earlier described pyrophosphorolytic cleavages of DPN [9], UDPG [10] and UDPAG [11].

* The following abbreviations are used: GDPM for guanosine diphosphate mannose; GMP, GDP, GTP for guanosine mono-, di- and triphosphate; DPN, TPN for di- and triphosphopyridine nucleotide; UMP, UDP, UTP for uridine mono-, di- and triphosphate; UDPG for uridine diphosphoglucose; UDPAG for uridine diphosphate N-acetyl glucosamine; AMP, ADP, ATP for adenosine mono-, di- and triphosphate; M-1-P for mannose-1-phosphate; G-6-P for glucose-6-phosphate and Tris for tris(hydroxymethyl)aminomethane.

The enzyme, for which the name GDPM pyrophosphorylase is proposed, has been prepared and purified from brewer's yeast, and its presence has been demonstrated in a number of microorganisms. A preliminary report of the work has appeared earlier [12].

EXPERIMENTAL

M-1-P was prepared synthetically according to Colowick [13]. Hexokinase, G-6-P dehydrogenase and nucleoside diphosphokinase were obtained as previously described [14].

GTP, isolated from muscle tissue, was a gift from Dr. Adam Deutsch, University of Lund, Sweden.

GDPM was prepared from baker's yeast using a method similar to the one described by Cabib and Leloir [7] with a few modifications in the column technique. Baker's yeast, 10 kg, was used as starting material, and the solution of nucleotides obtained by decomposition of the mercury salts (*cf.* Ref.[7]) was run through a Dowex-1 anion exchange column, which was eluted according to the principle described by Alm *et al.*[15], by gradually increasing the concentration of the eluting agent.

The column used for this purpose had a length of 25 cm and a bed volume of 64 cm^3. About 2 000 μmoles (200 ml) of the nucleotide mixture was applied in a run, and after rinsing with 25 ml H_2O the column was subjected to gradient elution. The apparatus was similar to that described by Hurlbert *et al.*[16], starting with 250 ml H_2O in the mixing flask and 800 ml 0.03 M HCl, containing 0.03 M NaCl, in the reservoir. Under these conditions nucleosides, AMP, UMP and ADP were eluted from the column. When the reservoir was empty, elution was continued by adding 500 ml 0.03 M HCl, containing 0.3 M NaCl, to the reservoir without changing the content of the mixing flask. During this step GDPM, UDPAG, UDPG, UDP and finally the nucleoside triphosphates are eluted from the column. The identity of the different peaks mentioned here was established by adsorption of each fraction on norite followed by paper chromatography together with known compounds. The eluted fractions were concentrated by adsorption on norite and subsequent elution with 50 % ethanol.

By this method GDPM is obtained, contaminated with varying amounts of UDPAG and UDPG. Complete separation of these nucleotides is difficult to accomplish on a Dowex-1 column, whereas paper chromatography in the ethanol-ammonium acetate solvent [17] at pH 7.5 yields a good separation. Separation of the compounds on a somewhat

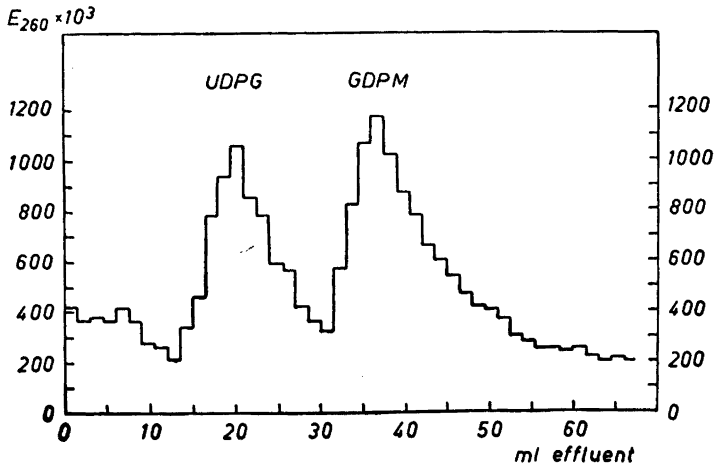

Fig. 1. Separation of GDPM from UDPG on a cellulose column.
Eluting agent: 1 M ethanol-ammonium acetate, pH 7.5 (17).

larger scale was obtained by using a cellulose column (standard grade Whatman cellulose powder), 20 cm high, with a bed volume of 22 cm^3. A solution of 10–15 μmoles of nucleotides in a volume of about 100 μl was placed on top of the column, and the column was washed with 2–3 ml ethanol. Elution was effected with 1 M ethanol-ammonium acetate, pH 7.5, the same solvent as used for paper chromatography [17]. Fig. 1 shows the separation of GDPM from UDPG by this method. The peaks were identified by paper chromatography.

The combined eluates containing the GDPM were evaporated to a small volume, and this solution was used directly in the enzymatic experiments. A salt free solution, if desired, was obtained by treating the mixture once more with norite, and subsequent elution of the norite. The technique used for adsorption of the nucleotides on norite and elution with 50 % ethanol was as earlier described [14].

Assay of enzyme activity. During the purification procedure enzyme activity was estimated by determining the GTP formed in reaction (1). The method is similar to the one used [14] for determination of UTP by pyrophosphorylation of UDPG or UDPAG. In the assay system the following reactions take place:

GDPM + P–P ⇌ GTP + M–1–P	(GDPM pyrophosphorylase)
GTP + ADP ⇌ GDP + ATP	(nucleoside diphosphokinase)
ATP + glucose ⇌ ADP + G–6–P	(hexokinase)
G–6–P + TPN + H_2O ⇌ 6-phosphogluconic acid + TPNH + H+	(G–6–P dehydrogenase)

and the reduction of TPN is followed in the Beckman spectrophotometer at 340 mμ. 1 ml quartz cells were used, and the components of the system were as follows: 100 μl GDPM, 0.002 M; 800 μl Tris, 0.05 M, pH 7.3; 5 μl $MgCl_2$, 1 M; 20 μl ADP (0.002 M); 25 μl glucose (0.01 M); 25 μl hexokinase (12 mg/ml protein); 15 μl TPN (10 mg/ml); 15 μl G–6–P dehydrogenase (1 mg/ml protein) and 5–10 μl GDPM pyrophosphorylase. 10 μl P–P (0.1 M) was added to start the reaction (*cf.* Fig. 4).

A unit of enzyme activity was defined as the amount causing the splitting of 0.1 μmole/min. Specific activity is defined as units per mg protein. A rise in extinction of 0.622 per 0.1 μmole at 340 mμ was used as basis for the calculation [18].

Protein determinations were carried out according to Bücher [19].

RESULTS

Purification of enzyme. 50 g of dried brewer's yeast (A/S Tuborgs Fabriker) was autolyzed and extracted overnight with 200 ml 0.07 M $(NH_4)_2HPO_4$ at 25° C. After centrifugation the proteins in the supernatant (150 ml) were precipitated by addition of 280 ml saturated ammonium sulphate. The mixture was left for 30 min. at 2° C before centrifugation. The supernatant was discarded, and the precipitate was dissolved in 75 ml chilled H_2O, and pH adjusted to 7.5 (volume 90 ml). To this was added 150 ml saturated ammonium sulphate. After 30 min. at 2° C the precipitate was collected by centrifugation, dissolved in 25 ml 0.02 M phosphate buffer, pH 7.5, and subjected to ethanol fractionation.

Table 1. Purification of GDPM pyrophosphorylase from brewer's yeast.

	Total units	volume ml	specific activity units / mg protein
Crude extract	145	150	0.01
Ammonium sulphate at pH 7.5	96	90	0.02
Ethanol fractionation	53	35	0.11
Calcium phosphate gel eluate	21	5	0.50

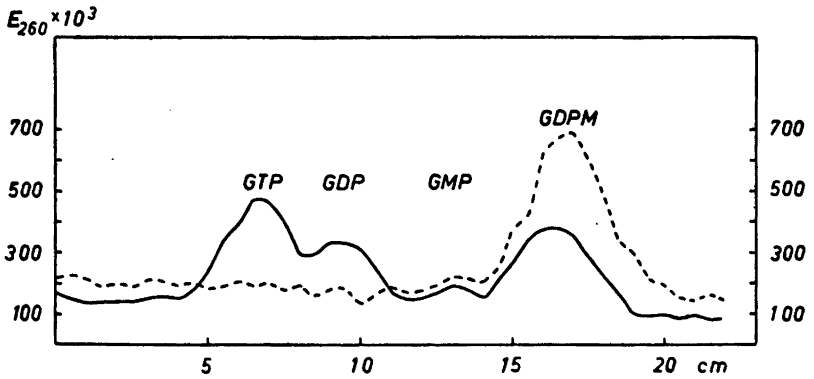

Fig. 2. Diagram of paper chromatogram from GDPM pyrophosphorylase digest.

Reaction mixture: 0.3 μmoles GDPM; 2 μmoles P—P (8 280 cts/min/μmole); 1 ml Tris; 0.05 M, pH 7.3; 0.5 μmoles $MgCl_2$.
Control: same without P—P
After 60 min. incubation the digest was acidified, adsorbed on norite and eluted with 50 % ethanol. Chromatographed 22 hours. Chromatogram scanned in the Beckman spectrophotometer at 260 mμ.

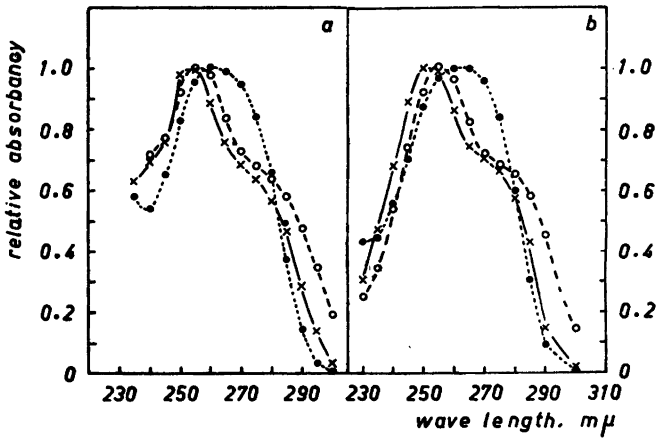

Fig. 3a. Ultraviolet absorption curves for GTP eluted from paper chromatogram.

For comparison with Hotchkiss' data [20] the relative absorbing value is used (maximum absorbancy taken as equal to 1). The values were corrected for absorption originating from the paper.

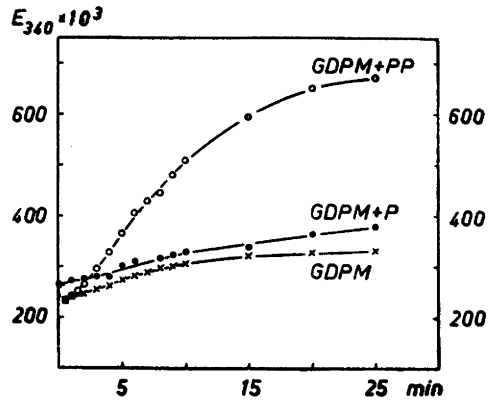

Fig. 4. Spectrophotometric demonstration of the GTP formed by pyrophosphorylation of GDPM.

Reaction mixture O—O—O: 50 µl GDPM, 0.002 M; 20 µl ADP, 0.002 M; 25 µl glucose, 0.01 M; 25 µl hexokinase (12 mg/ml); 15 µl TPN (10 mg/ml); 15 µl G—6—P dehydrogenase (0.5 mg/ml); 10 µl pyrophosphorylase; 10 µl P—P, 0.1 M and 800 µl Tris, 0.05 M, pH 7.3; 5 µl $MgCl_2$, 1 M.
Control 1 ×—×—× same without P—P.
Control 2 ●—●—● same with 2 µmoles inorganic P instead of P—P.

To 40 ml solution, cooled to —1° C were added dropwise 80 ml 50 % ethanol. During this addition the solution was stirred mechanically, and the temperature of the surrounding bath was gradually lowered to —12° C. The mixture was centrifuged 5 min. at —15° C in a previously cooled centrifuge. The supernatant was left 20 min. at —15° C and centrifuged again. The last precipitate contained the bulk of activity and was stored overnight at —20° C.

Next morning the precipitate was dissolved in 35 ml chilled Tris buffer, 0.001 M, pH 7.3, 35 ml calcium phosphate gel (16 mg/ml dry weight) was added, and the solution thoroughly mixed. After centrifugation and removal of the supernatant the precipitate was treated with 50 ml 0.05 M phosphate buffer, pH 7.2. The mixture was spun, and to the supernatant was added 80 ml ammonium sulphate. The mixture was left overnight at 2° C, and the precipitate collected by centrifugation. Stored at —20° C, this preparation retained its activity for several weeks. The preparation was soluble in 0.05 M Tris buffer. The activity was about 40 times that of the crude extract, and the overall yield was 14 % (Table 1).

The purified preparation showed no pyrophosphorolytic activity towards UDPG, but contained traces of UDPAG pyrophosphorylase.

Pyrophosphorolysis of GDPM. If GDPM, prepared from yeast, as described in Methods, was incubated with ^{32}P-labelled pyrophosphate and the enzyme, paper chromatography of the reaction mixture showed that a new ultraviolet absorbing substance had appeared (Fig. 2). The new spot was eluted with H_2O, and the ultraviolet absorption spectrum of the substance in neutral, alkaline and acid solution was determined, as presented in Fig. 3. The curves

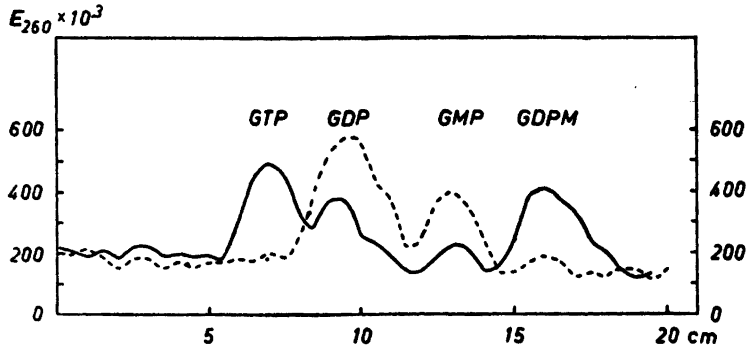

Fig. 5. Diagram of paper chromatogram from GTP—M—1—P pyrophosphorylase digest.

Reaction mixture (solid line): 0.2 μmoles GTP; 0.4 μmoles M—1—P; 1 ml Tris, 0.05 M, pH 7.3 and 25 μl GDPM pyrophosphorylase.
Control mixture (broken line): same as above, except that 0.2 μmoles GDP is substituted for GTP. After 60 min. incubation the digests were acidified and treated as described in Fig. 2.

are almost identical to those found for guanosine by Hotchkiss [20], and the changes in acid and alkaline solution are the same.

Aliquots of the solution were deposited on planchets, dried and counted in a Geiger-Müller counter. Counts per min. per μmole of the new compound (μmoles calculated from the absorption value at 257 mμ) and of the ^{32}P-labelled pyrophosphate used in the experiment were 7 800 and 8 270, respectively, and thus agree with the assumption that a pyrophosphorolysis of GDPM has occurred with simultaneous formation of GTP. The GTP formed in the reaction may be demonstrated spectrophotometrically as described in Methods (Fig. 4). As seen in Fig. 4 addition of inorganic phosphate instead of pyrophosphate causes no formation of GTP.

Reversibility of the reaction. Incubation of GTP with M-1-P and the enzyme results in formation of a compound which moves on the paper chromatogram with the same rate as known GDPM (Fig. 5). Incubation of GDP with the same M-1-P solution yields a very faint spot at the GDPM site. It is possible that a reaction exists by which GTP and GMP are formed from GDP, but this possibility has not been further investigated.

Judging from the curves in Figs. 2 and 5 the equilibrium of the reaction is at around 50 % conversion, similar to what is found for the UDPG pyrophosphorylase [14].

DISCUSSION

Nucleotidyl transferases, the group of enzymes to which the GDPM-pyrophosphorylase belongs, have been demonstrated in a number of tissue and in several microorganisms, and it is assumed that their role in the cell is the synthesis of nucleoside diphosphate glycosyl compounds from nucleoside triphosphates and glycosyl phosphates.

The function of the nucleoside diphosphate glycosyl compounds as donors of glycosyl groups has been experimentally demonstrated in the case of

UDPG[21–23] and UDPGlucuronic acid [24]. GDPM has been suggested to be active in the synthesis of mannan in the yeast cell-walls [7], but no proof of this hypothesis has so far been obtained. The abundance of mannose-containing polysaccharides in brown algae suggests these as a suitable material for further investigations on the function of GDPM.

On the Instantaneous Polarographic Current

I. Automatic Recording of Selected Parts of the Current-time Curve of the Individual Mercury Drop

ERIK WÅHLIN and ÅKE BRESLE

Royal Institute of Technology, Stockholm, Sweden

A method of measuring the instantaneous polarographic current within an accuracy of ± 0.2 per cent is described. The apparatus includes a polarograph, a recording potentiometer and a device with the double purpose of knocking off the mercury drops and of periodically connecting the recording pen.

In polarography calculations are usually based, not on the instantaneous diffusion current, but on a mean value, evaluated in some way. This seems satisfactory for analytical purposes, but it is a serious drawback in theoretical studies. A method which gives the instantaneous current must, however, also have great advantages in analytical work. The correct evaluation of a polarographic curve is often very difficult and for practical reasons the recording instrument is damped. However the damping often conceals small polarographic waves and thus the sensitivity is reduced. Furthermore Lingane [1] has pointed out that the damping of the polarographic current results in a registered mean current; the deviation from the theoretical current depends on the degree of damping. In analytical work there is also a tendency to use shorter drop times in order to get smoother curves, but the gain in simplicity of evaluation is lost on account of interference from other sources.

In an earlier communication [2] Wåhlin has given a short description of an apparatus which makes it possible to measure a selected part of the diffusion-time curve. The present paper describes the apparatus fully and gives some tests of its performance.

List of Symbols used

C = concentration of depolarizer, millimoles liter^{-1}
D = diffusion constant, cm^2 sec^{-1}
$\bar{i}$ = mean diffusion current, microamperes

i_τ = instantaneous current, microamperes
i_t = instantaneous current immediately before the drop falls
K = a constant in eqn. (1)
n = number of faradays of electricity required per mole of electrode reaction
m = rate of flow of mercury from the capillary, mg sec^{-1}
τ = age of drop, sec
t = τ_{max}, sec
h = the distance between the upper and lower mercury surface (cm).

APPLICATIONS

The characteristic features of our apparatus make it suitable for measurements of the following types.

1. Checking the revised Ilkovic equations

The measurements on which the polarographic theory is based are mostly done with the mean diffusion current method. It would be more logical and closer to facts to use the instantaneous polarographic current for checking the modified Ilkovic equation[3,4]. Several investigators are of the opinion that the formula is as follows:

$$i_\tau = 709\ nD^{\frac{1}{2}}Cm^{2/3}\tau^{1/6} + KnDC(m\tau)^{1/3} \qquad (1)$$

The mean diffusion current is derived from eqn. (1) and is only valid if eqn. (1) is correct

$$\bar{i} = 607\ nD^{\frac{1}{2}}Cm^{2/3}t^{1/6} + \frac{3}{4}KnDCm^{1/3}t^{1/3} \qquad (2)$$

However the theoretical value of the constant K is still discussed in the literature[3-6], and furthermore Hans *et al.*[7] do not consider K a constant, but a function of τ and t. Sufficiently accurate measurements of i_τ are still very rare and therefore it is natural that values of the constant K as different as 17 and 39 may be found in the literature. Precision measurements of the instantaneous current are only given by Hans, Henne and Meurer [7], Taylor, Smith and Cooter [8], and Khalafalla [9]. The lack of data is due to the difficulty of making measurements of the complete course of the instantaneous current/time curve, owing to the discontinuity of the polarographic current obtained when the mercury drop falls and the rapid increase of current during the first second after the formation of a new drop.

Oscillographic measurements are of course quick enough, but the accuracy is only around ± 2 % which means that the second term of eqn. (1) can only be determined within approximately ± 20 %. Some research has also been done with undamped galvanometers. These instruments are, however, very delicate, and according to Strehlow [10] the results obtained are subject to certain limitations.

The fact that the polarographic current during the life-time of an individual mercury drop is approximately proportional to $\tau^{1/6}$ means that while the age of the drop increases from 0 to 1 second the current increase is 76 units, but from 4.0 to 5.0 seconds the increment is only 3.5 units. A polarograph cannot record this complete curve with its sharp discontinuity when the drop falls, but records instead some kind of "damped" curve, which is sometimes undesirable. Especially at long drop times the conventional polarograph gives curves with big oscillations and it is doubtful whether these curves have any relation to the true polarographic current.

Accurate measurements of the later parts of the current-time curve can be used for investigating the symbol K. Our method is well adapted for supplying such data and furthermore the measurements can be made very quickly.

2. Analytical precision polarography

For analytical polarography it may seem satisfactory to measure the mean diffusion current, but experience in this field has shown that correct evaluation of the curves requires a skilled analyst. As mentioned above the curves obtained with our apparatus are undamped and still very easy to evaluate (Fig. 1)

When prewave compensation is used on conventional polarographs, the results are not very accurate because of the big oscillations. With the present method straight lines are obtained, and the results are much more reproducible.

3. Extending the lower limit in analytical polarography

When determining micro quantities of depolarizer with the mean current method the diffusion controlled part of the measured current is only a minor constituent beside the main component, the condenser current. This restricts the possibility of determining very small quantities of depolarizer with any reasonable degree of accuracy. As the diffusion current increases with the

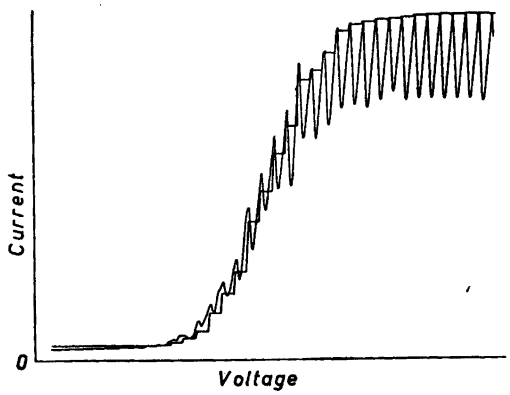

Fig. 1. Polarograms obtained in the conventional way (lower curve) and with the apparatus described in the text (upper curve).

age of the drop, while the condenser current decreases, the most favourable conditions for determining small diffusion currents occur immediately before the drop falls. Thus, if the instantaneous current is measured in this way the accuracy is increased and the lower limit of detection is depressed.

APPARATUS

1) *Capillary.* Length: 253 mm, drop time: 5.2 seconds in 0.1 M potassium chloride solution at a mercury pressure of 60 cm and at 0.90 volts *vs* the silver anode. The capillary was made from Pyrex glass rod [11].

2) *Polarographic vessel* including de-aerating tube and a tube to keep the oxygen out by blowing nitrogen gas over the surface. The nitrogen was purified by passing it over activated copper absorbed on diatomaceous earth according to Meyer and Ronge [12]. In this way the partial pressure of the oxygen was reduced to less than 3×10^{-4} mm of mercury.

3) *Anode,* a silver sheet of 8 cm^2. This anode proved to be much more convenient to handle than the conventional calomel electrode [13,14].

4) *Hammer for knocking off the mercury drops* at predetermined intervals. The hammer was actuated by an electromagnet [15] and the intervals were timed with an accuracy of ± 0.01 seconds by a rotating cam.

5) *Disconnector and interval selector for balancing motor.* The intervals were timed in the same way as above with the exception that the circuit could be also connected for longer periods. The cams were both attached to the same shaft, driven by a constant speed electric motor.

6) *Potentiometer recorder,* Speedomax Type G, Model S, Leeds and Northrup Comp. USA. The essential part of the recorder for this application is a phase sensitive balancing motor, which moves the pen to its correct position.

7) *Polarograph,* both an electronic polarograph, LKB Type 3266 B LKB-produkter, Fabriks AB, Sweden, and a Heyrovsky type polarograph, Polarograph 38, F. Leybold Nachfolger, Germany. Both types contain damping capacitors, which were disconnected in order to obtain the correct value of the polarographic current.

OPERATING PRINCIPLES

Fig. 2 illustrates the construction of the apparatus schematically and Fig. 1 shows a typical current/voltage curve. The operating principle of the apparatus is as follows:

The mercury drop is knocked off by the hammer for example every 5.02 seconds. The current is recorded while the age of the drop increases from *e.g.*, 4.5 to 5.0 seconds. Immediately before the drop falls the balancing motor circuit is broken and so the pen rests in the 5.0 second position until the next drop is 4.5 seconds old, and the same process is then repeated. In this way it is possible to record accurately the instantaneous value of the diffusion current (not the mean diffusion current), as a mean value from a suitable number of drops.

Especially at long drop times, the i/V curves of this apparatus will be smooth and easily evaluated. During the periods when the polarographic curve is not being recorded calibrated resistors may be connected in place of the polarographic cell, and the resulting current can be measured. This provides calibration of the polarograph.

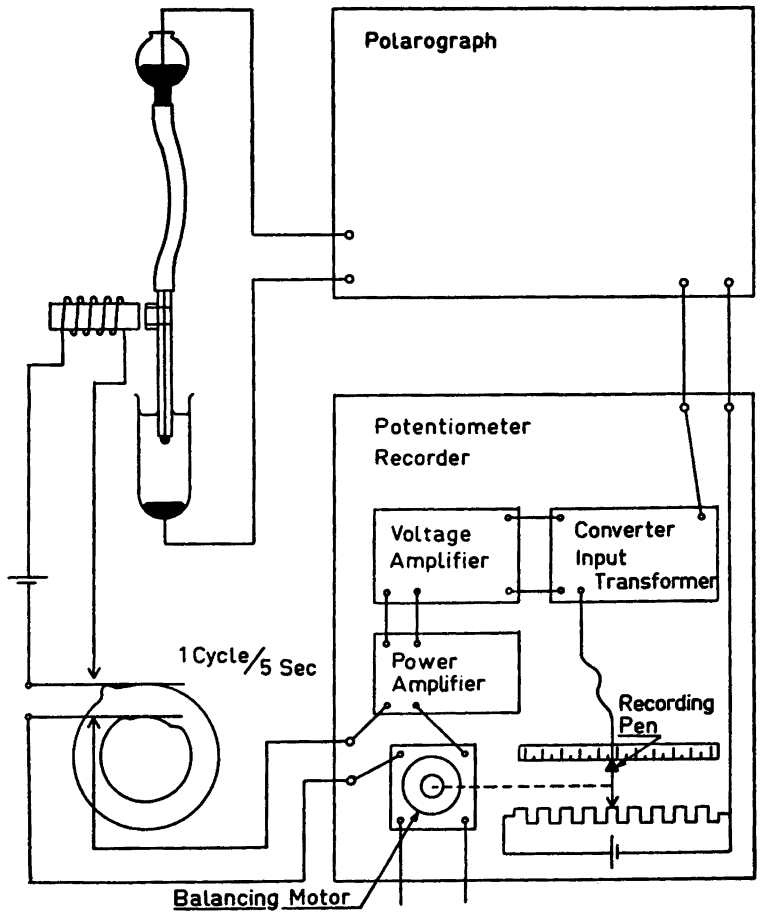

Fig. 2. Diagram of the assembly used in the experiments.

TESTS

1. It is essential to prove that the apparatus really records the true current. The following experiments were carried out in order to demonstrate that the recording pen always moves to its correct position.

A deaerated cadmium solution in potassium chloride was polarographed at constant voltage (−0.90 volts *vs* the silver anode). The mercury drops were knocked off every 5.0 seconds and the recorder was first connected during the whole drop life a) in Fig. 3. At b) the recorder was disconnected at a pen position corresponding to 4.7 seconds. As the timer had been adjusted to have the pen connected between 2.0—2.2 seconds, the pen moved downwards a small distance every time it was connected and reached its final position after about 4 drops. Then the paper was wound back and the pen was placed in a position

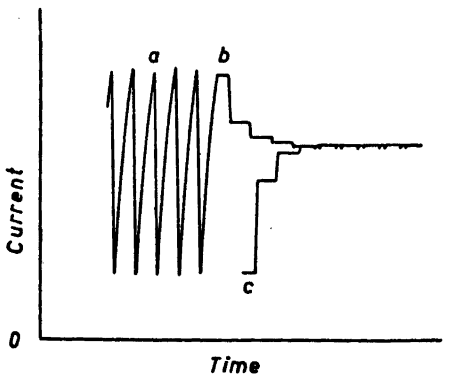

Fig. 3. Precision polarogram obtained at a constant potential. For explanation of a) b) and c) see p. 939.

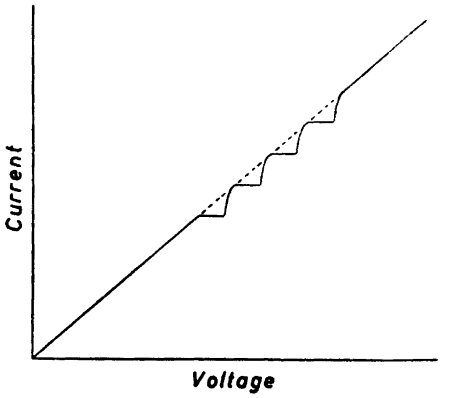

Fig. 4. Current-voltage diagram showing the ability of the apparatus to give a definite current for the short period of operation of the recorder.

corresponding to $\tau = 0.9$ sec, c) in Fig. 3. When connected, the pen now moved up to the same final value as before. This experiment proves that the apparatus records a definite current value corresponding to every value of τ during the drop life independently of the initial pen position.

2. In order to check the ability of the apparatus to record the true instantaneous current the following experiment was carried out. The polarographic cell was replaced by a resistor, and the voltage was increased at constant rate beginning at 0 volt. Under these conditions the recorded current should be a straight line. (Fig. 4). At the beginning the recorder was connected registering a straight line. Then the timer was started making the recorder to be connected and disconnected at predetermined intervals. Fig. 4 shows that when connected only 0.5 sec of a 5.0 sec period the pen moves to a position that coincides with the straight line. Of course this is only true when the i/V curve is not too steep, but the experiment shows that the apparatus is quick enough for the present investigation.

3. All revised formulae suggested for the polarographic current agree on one point, *viz.* the proportionality between current and concentration of depolarizer. All precision measurements up to now have proved this to be true within very close limits [16]. It was therefore considered important to use this well-known fact as a method of testing the apparatus. The following experiments were carried out: The timer was adjusted to give the undamped, instantaneous current after about 4.0 seconds. Drop time 5.2 sec. The cadmium concentration was varied according to Table 1. Background solution was 0.1 molar potassium chloride and 0.009 % gelatine. The height of the mercury reservoir was 60 cm above the capillary orifice and the temperature was 25.0 ± 0.1 °C.

Table 1 shows that our measurements of i_τ / C are constant within ±0.24 %, which lies within the experimental errors.

Table 1. The linear correlation between the diffusion current and the depolarizer concentration.

mM Cd	μA	μA_{corr}	μA_{corr} / mM Cd
0.000	0.041	0.000	—
0.892	7.410	7.369	8.261
1.115	9.240	9.199	8.250
1.337	11.08	11.04	8.257
1.783	14.78	14.74	8.267
2.229	18.44	18.40	8.255
2.786	23.11	23.07	8.280

Mean value: μA_{corr} / mM Cd = 8.26 ± 0.02.

4. In order to get a comparison between the polarographic current obtained from an electronic and from a non-electronic polarograph a polarogram was taken from the same solution with Polarograph LKB and Leybold Polarograph 38. The result is shown in Table 2. Under LKB is listed the instantaneous current obtained with the electronic polarograph and under LEYBOLD the same is given for the non-electronic instrument. The symbol Δ % is the percentage deviation of the current from the calculated mean value. As can be seen, the difference never exceeds 0.2 %.

Table 2. Comparison between currents obtained with an electronic and a non-electronic polarograph.

Sec	μA		Δ %
	LKB	LEYBOLD	
3.12	10.570	10.542	0.13

On the Instantaneous Polarographic Current

II. Measurements of the Rate of Flow of Mercury

ÅKE BRESLE

Institute of Inorganic and Physical Chemistry, University, Stockholm; Royal Institute of Technology, Stockholm, Sweden

The variation of the rate of flow of mercury from a polarographic capillary during the lifetime of a drop is given. The results are based upon measurements of the instantaneous rate of flow obtained by a special technique described earlier. The agreement between the experimental data and those calculated from the theoretical formula is shown, the deviation being about 0.3 %.

The polarographic diffusion current is a function of the age of the mercury drop, the rate of flow of mercury through the capillary and some characteristics of the electrolyzed solution, *i. e.* the concentration, the valency and the diffusion constant of the depolarizer. In ordinary polarographic work, for instance in analytical polarography where the mean diffusion current is measured, the mean value of the rate of flow of mercury is determined, but in investigations on the instantaneous current it is necessary to know the corresponding instantaneous value of the rate of flow.

As a part of an investigation on the instantaneous polarographic current data concerning the flow of mercury were collected and the theoretical and experimental results were compared.

List of symbols

m = instantaneous rate of mercury flow at the time τ (mg · sec $^{-1}$)
$\overline{m}$ = mean value of the rate of mercury flow, measured from the time zero to τ (mg · sec^{-1})
M = constant rate of mercury flow obtained when the capillary tip is immersed in mercury (mg · sec^{-1})
τ = age of the drop at a certain moment (sec)
r = radius of the drop at the time τ (cm)
r_c = inner radius of the capillary (cm)

l = length of the capillary (cm)
d = density of mercury (g · ml^{-1})
η = viscosity coefficient of mercury (dynes · sec · cm^{-2})
σ = interfacial tension between mercury and the electrolyte (dynes · cm^{-1})
h = distance between the upper and lower mercury surfaces (cm)
P_{tot} = total applied pressure (dynes · cm^{-2})
P_{eff} = effective pressure (dynes · cm^{-2})
P_b = back pressure (dynes · cm^{-2})
ω = weight of the drop at the time τ
k_1, k_2, k_3, α, β = constants

THEORETICAL

When mercury flows through a capillary and forms a growing drop at the capillary tip, the rate of flow varies during the life of the drop. The relation between the dimensions of the drop and the variables m and τ is expressed by the equation

$$\frac{4}{3}\pi r^3 = \frac{\overline{m}\,\tau}{d} = \frac{\omega}{d} \tag{1}$$

or

$$r = k_1 \cdot (\overline{m}\,\tau)^{1/3} = k_1 \cdot \omega^{1/3} \tag{2}$$

and the rate of flow is given by the Poiseuille relation

$$m = \frac{\pi\, r_c^4 d\, P_{eff}}{8\, l\, \eta} = k_2\, P_{eff} \tag{3}$$

Owing to the back pressure, produced by the interfacial tension at the surface of the growing drop, the effective pressure varies during the life of the drop. The back pressure [1] is related to the geometry of the drop by the equation

$$P_b = \frac{2\,\sigma}{r} \tag{4}$$

and the effective pressure can be written

$$P_{eff} = P_{tot} - P_b \tag{5}$$

If eqns. (2), (3), (4), and (5) are combined the instantaneous rate of flow is given by

$$m = k_2 P_{tot} - \frac{2\, k_2\, \sigma}{k_1\, (\overline{m}\,\tau)^{1/3}} = M - \frac{k_3}{(\overline{m}\,\tau)^{1/3}} \tag{6}$$

This equation cannot be tested experimentally as the rate of flow is not explicitly expressed. It may, however, be transformed. The instantaneous and mean rates of flow are related to the weight of the drop by the equations

$$m = \frac{d\omega}{d\tau} \tag{7}$$

and

$$\overline{m} = \frac{\omega}{\tau} \tag{8}$$

After substituting these equations into eqn. (6) and solving for ω and differentiating the following expression is obtained [2]

$$m = M - \frac{2}{3} \cdot \frac{1.5\ M^{2/3}\ \delta\ \tau^{-1/3}}{172.7\ h} - \frac{1}{3} \cdot \frac{1.5\ M^{1/3}\ \sigma^2\ \tau^{-2/3}}{(172.7\ h)^2} \tag{9}$$

The corresponding formula of the mean rate of flow is

$$\overline{m} = M - \frac{1.5\ M^{2/3}\ \sigma\ \tau^{-1/3}}{172.7\ h} - \frac{1.5\ M^{1/3}\ \sigma^2\ \tau^{-2/3}}{(172.7\ h)^2} \tag{10}$$

In these equations the first term on the right hand side is equal to the rate of flow obtained when there is no back pressure. It can be measured by determining the rate of flow when the capillary tip is immersed in a pool of mercury [3]. The quantities M, σ, τ and h in the equations are known, or can easily be determined. With a technique described below the instantaneous rate of flow can be measured, thus making it possible to check eqn. (9) experimentally.

Table 1. Comparison between measured and calculated values of the instantaneous rate of flow of mercury.

EXPERIMENTAL

The method of determining the rate of flow is as follows.

For a given capillary and at a constant mercury pressure the weight of mercury droplets falling naturally from the dropping mercury electrode can be determined in a well-known manner. If now the individual droplets are disengaged from the capillary at a moment shortly before the natural drop time is reached, the difference between the weights of a natural and forced drop gives a mean value of the rate of flow during this last interval of the life of the drop. If this interval is chosen to be sufficiently short, the mean rate of flow can be taken as the instantaneous value during the interval.

This process is repeated for other selected intervals of the life of the drop, giving the instantaneous rate of flow of mercury from the capillary for any time.

The mercury drops are disengaged using an electromagnetically operated hammer described in a previous paper in this series [4]. The solution used in the experiments was 0.1 M potassium chloride with 0.009 % of gelatine, deaerated with purified nitrogen [5]. The anode consisted of a silver sheet and the applied potential, constant during each experiment, was varied from 0.8 to 1.2 volts *vs* the silver anode. The vessel and apparatus used for collecting the mercury drops has been described by Lingane and Kolthoff [6]. The temperature was held at 25 ± 0.1° C, the height of the upper mercury level above the capillary orifice was 57.0 cm and for M a value of 1.776 mg mercury per second was obtained.

With the technique described above a series of experiments has been carried out and the results are given in Table 1, where the measured values of m are listed together with those calculated according to eqn. (9). The values of the interfacial tension used in the calculations have been taken from Grahame [7].

The empirical results show a very good agreement with those calculated. The deviation of the measured value from the calculated value does not exceed 0.3 %, a figure that is of the same order of magnitude as for example the accuracy of the measurements of the age of the drop. Thus, eqn. (9) is shown to give a correct value of the instantaneous rate of flow of mercury from the measured data.

On the Instantaneous Polarographic Current

III. Accurate Measurements of the Residual Current

ÅKE BRESLE

Institute of Inorganic and Physical Chemistry, University, Stockholm; Royal Institute of Technology, Stockholm, Sweden

With an apparatus described by Wåhlin and Bresle the instantaneous residual polarographic current has been measured. Data from these measurements are presented in this paper. The measured values show that the residual current can quantitatively be divided into a condenser and a faradaic current. From the condenser current the capacity constant is calculated giving the value of 19.7 ± 0.2 microfarads · cm^{-2}.

The instantaneous diffusion current is not a primary quantity found experimentally, but is a calculated difference between the measured limiting current and the measured residual current. The accuracy of the calculated diffusion current, as a consequence, depends on the accuracy of measurement of these quantities. Several theoretical considerations on the form of the mathematical expression for the diffusion current are to be found in the literature, but there are few accurate experimental data on the instantaneous currents.

This paper gives experimental data and calculations on the instantaneous residual current obtained in a common electrolyte under ordinary polarographic conditions. The measurements are intended to be used later in presenting instantaneous values of the diffusion current from measurements of the limiting current.

THEORETICAL

The instantaneous condenser current produced by the dropping mercury electrode can be written [1]

$$i_c = k \cdot \frac{dF}{d\tau} \cdot \Delta E \qquad (1)$$

where F is the area of the drop at the time τ, ΔE the potential difference between the electrocapillary maximum and the actual constant potential for the experiment, τ the age of the drop, and k the capacity constant. If the

drop is assumed to be spherical [2,3], the area can be expressed using the symbols m (the rate of flow of mercury from the capillary in mg per sec) and τ, eqn. (1) being transformed to

$$i_c = k \cdot 0.0057 \cdot m^{2/3}\ \tau^{-1/3}\Delta E \qquad (2)$$

As it is very difficult to remove the last traces of oxygen and mercury ions from the solution [4] the current obtained is always a sum of the condenser current and a faradaic current, i_F, caused by the reduction of the above-mentioned elements and sometimes of other impurities. Thus the measured current i_{res} can be written

$$i_{res} = i_c + i_F \qquad (3)$$

or, as the condenser current is proportional to $\tau^{-1/3}$ and the faradaic current is proportional to $\tau^{1/6}$

$$i_{res} = A\tau^{-1/3} + B\tau^{1/6} \qquad (4)$$

This can be transformed to

$$\frac{i_{res}}{\tau^{1/6}} = A\tau^{-\frac{1}{2}} + B \qquad (5)$$

The value of the true condenser current is obtained graphically if the experimental data, $i_{res}/\tau^{1/6}$, are plotted against $\tau^{-\frac{1}{2}}$ and the constant A is evaluated.

EXPERIMENTAL

The apparatus used in the experiments was Polarograph Type 3266 B, LKB-Produkter Fabriks AB, Sweden, furnished with a device for knocking the mercury drop off the capillary, described earlier by Wåhlin and Bresle [5].

The solution was 0.1 M potassium chloride with 0.09 % of gelatine in ion-free water. Deaeration was carried out for two hours with oxygen-free nitrogen gas, purified according to Meyer and Ronge [6]. The chemicals used, mercury, potassium chloride, and gelatine, were of Polaritan reagent grade in all experiments. The temperature was 25 ± 0.1 °C. The mean rate of flow of mercury from the capillary was measured and the corresponding instantaneous value was calculated as described in a previous paper in this series [7]. The calculations justified the use of a constant value of m for the last 2/3 of the life of the drop without any great error. The potential at the electrocapillary maximum was obtained by evaluating the maximum drop time from observed values of the drop time at different potentials. The value thus obtained was −0.45 ± 0.02 volts *vs* the silver anode. The potential in all the experiments was −0.94 volts *vs* the silver anode.

The rates of flow of mercury in the experiments are given in Table 1 and corresponding values of time and residual current in Table 2. With the aid of eqn. (5) the constants A and B are calculated [8] and listed in Table 3 together with the values of the capacity constant, calculated according to eqn. (2). Table 4, finally, gives a comparison between the residual current measured directly, and the calculated as the sum of a condenser and a faradaic current using Table 3 and eqn. (4).

CONCLUSIONS

The reproducibility of the measurements can be studied in Table 2. The experiments number 1 and 2 listed in this table are made under the same conditions. The values of the residual current differs somewhat, those in expt. 1

5	0.0647	0.0111	20.1

always exceeding those in expt. 2 by about 4 %. The explanation for this difference is given in Table 3, where it can be seen that the condenser current part in these two experiments is the same, as the values of A are practically identical. The different values of the constant B, however, indicate that the faradaic component, due to impurities, is somewhat smaller in the latter experiment.

The capacity constant of the expanding mercury drop calculated from values of the current for different rates of flow assumes the value of 19.7 ± 0.2 microfarads $\cdot$ cm^{-2}. The value given by other authors obtained by different methods are: Philpot [9], 21.8 microfarads $\cdot$ cm^{-2}; Ilkovic [1], 22.3 microfarads $\cdot$ cm^{-2}.

There is good agreement between the measured residual current, and that calculated on the assumption that this current can be divided into a condenser part and a faradaic part. The deviation is about 1 % at the beginning of the life of the drop, but is then diminished to some tenths of a per cent, as can be seen from Table 4.

On the Instantaneous Polarographic Current

IV. Measurements of the Diffusion Controlled Current

ÅKE BRESLE

Royal Institute of Technology, Stockholm, Sweden

The instantaneous diffusion current has been measured by means of a special method which makes use of an externally controlled drop time of the dropping mercury electrode. The results are shown to be very reproducible. Attempts to correlate the experimental data with the revised Ilkovic relationship support the assumption this equation is inadequate in its present form.

It is well-known that the Ilkovic formula gives a relatively clear picture of the mathematical relationship between the fundamental polarographic variables. However, more quantitative attempts to correlate the empirical values of the diffusion current using the Ilkovic formula have lead to the addition of a correction term to this expression, based upon theoretical considerations neglected in the original formula. The nature of this correction term has been widely discussed in the literature. As there are few sufficiently accurate measurements of the instantaneous diffusion current, the different proposals cannot be rigorously checked.

Such precise diffusion current data can only be obtained from reliable measurements of the following polarographic quantities, *viz.* the instantaneous rate of flow of mercury from the capillary, the instantaneous residual current and the instantaneous limiting current.

Using a method, described by Wåhlin and Bresle [1], the rate of flow of mercury [2] and the residual current [3] have been investigated. The results obtained show that it is possible to measure values of these variables with an accuracy of the same order of magnitude as the accuracy of, *e. g.*, the temperature constancy and the measurements of the concentration of the depolarizer in the experiments.

The instantaneous limiting diffusion current of cadmium ions in potassium chloride solution has been determined with the techniques mentioned above. This paper gives results of these measurements together with some calculations of the diffusion current according to the revised Ilkovic formula. The results are compared with those obtained by other investigators.

EXPERIMENTAL

The measurements were made with the same apparatus and the same techniques as described earlier [3]. The depolarizer was cadmium sulphate of ANALAR quality. A stock solution of this reagent was made and standardized with the aid of an ion exchanger resin (Dowex 50). Potassium chloride and gelatine were added to known volumes of this solution which was then diluted to give the final solutions used in the experiments.

For the calculations the value of the diffusion constant of cadmium ions in 0.1 M potassium chloride was assumed to be 7.17×10^{-6} cm^2 sec^{-1}, a value determined experimentally by v. Stackelberg *et al* [4].

THE REPRODUCIBILITY OF THE MEASUREMENTS

In order to check the reproducibility of the measurements some experiments have been repeated under identical conditions. The values of the currents measured in three experiments are given under No. 1, No. 2, and No. 3 in Table 1. The two first experiments are made with an electronic polarograph and the last with a non-electronic instrument. The deviation from the calculated mean of these values of the current is about 0.2 % indicating that there is no significant difference in the results obtained using the two types of polarograph.

List of symbols

i_{lim} = instantaneous limiting current microamps
i_τ = instantaneous diffusion current microamps
τ = age of the drop, sec
n = number of electrons taking part in the electrode reaction
D = diffusion constant, cm^2 · sec^{-1}
m = rate of flow of mercury from the capillary, mg · sec^{-1}
C = concentration of the depolarizer, millimoles · liter^{-1}
K,α = constants

THE RELATION BETWEEN i AND C

According to the fundamental polarographic law

$$i_\tau = \alpha \cdot C \qquad (1)$$

the ratio of the instantaneous diffusion current and the concentration of the depolarizer is a constant for fixed values of m and τ. Using values of the residual instantaneous current [3] published earlier and of the limiting instantaneous current, given in Tables 1 and 2 in this paper, this ratio has been calculated.

The results are given in Table 3, together with the mean value and the percentage deviation of the three measurements for every value of τ.

The divergence from the mean value is about 1 % up to the first second of the life of the drop; it gradually diminishes as the drop grows older and is only some tenths of a per cent at the later part of the life of the drop. There is a slight increase of the ratio α with increasing concentrations of the depolarizer; this is probably due to some contribution of the migration current in the total measured current in the experiments with the highest depolarizer concentration.

MATHEMATICAL INTERPRETATION OF THE MEASURED DIFFUSION CURRENT

The revised Ilkovic equation can be written according to v. Stackelberg-Strehlow [5], Lingane-Loveridge [6] and Kambara *et al.*[7]

$$i_\tau = 709\ n\ D^{\frac{1}{2}}\ C\ m^{2/3}\ \tau^{1/6} + KnDC\ m^{1/3}\ \tau^{1/3} \qquad (2)$$

where different values are given to the symbol K by the various investigators. Eqn. (2) may be rewritten in a form more easily handled and more suitable for studying the symbol K:

$$i_\tau - 709\ n\ D^{\frac{1}{2}}\ C\ m^{2/3}\ \tau^{1/6} = P = KnDCm^{1/3}\ \tau^{1/3} \qquad (3)$$

$$K = \frac{P}{nDC\ m^{1/3}\ \tau^{1/3}} \qquad (4)$$

Taking the available values of the diffusion current given by Taylor *et al.*[8], Khalafalla [9], Hans *et al.*[10] and in Table 3 in this paper, K has been calculated and the different values are presented in Table 4. The variation of K with time can be studied in Fig. 1. The agreement between the results obtained from the data of the different investigators shows the term K to be a function of τ. It has large negative values in the beginning of the life of the drop, passes through the value zero when the drop is about 1 second old and then increases, more and more slowly, until the maximum drop time is reached. This indicates that the revised Ilkovic equation in the form given in eqn. (2) does not describe the experimental data exactly. The variation of i_τ with m has been studied in experiments Nos. 1, 7, 8, and 9 given in Tables 1 and 2. According to eqn. (2) the diffusion current for fixed values of C and τ should depend on

Table 4. Comparison between different calculated values of the symbol K in the revised Ilkovic equation.

the rate of flow, m, raised to a power of between one third and two thirds, or mathematically expressed

$$\frac{1}{3} < \left(\frac{\delta \log i_\tau}{\delta \log m}\right)_{c,\tau} < \frac{2}{3} \qquad (5)$$

The plot of log i_τ *vs* log m (not reproduced here) for values obtained in the experiments described above, shows that the individual points lie very well together, but, somewhat surprisingly on a straight line of slope 0.7 rather than

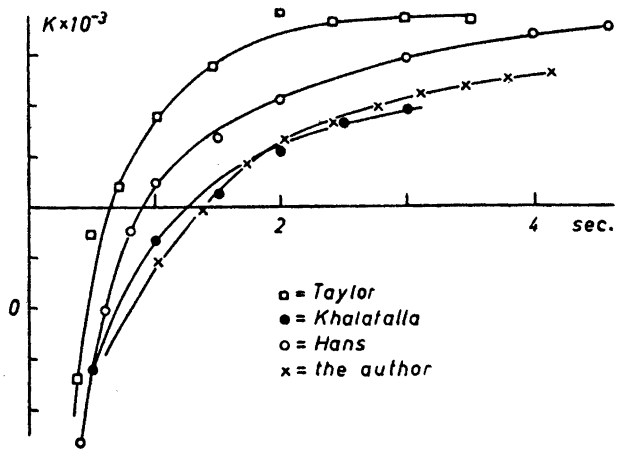

Fig. 1. The variation of the symbol K *in the revised Ilkovic equation.*

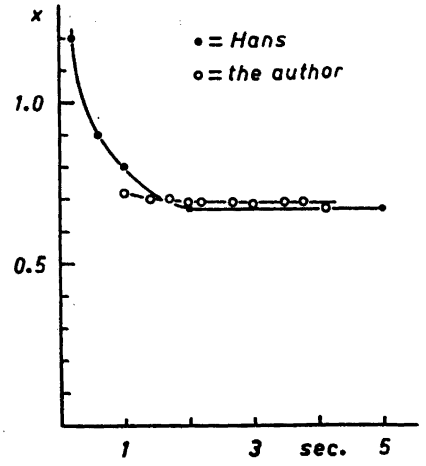

Fig. 2. The slope of the line log $i_\tau = x \log \tau + \log A$ *for different values of the age of the drop.*

on a curve. For a comparison the corresponding values from the measurements of Hans *et al.*[10] have been studied, and the same result was obtained: for fixed values of C and τ, log i_τ can be expressed as a linear function of log m. In Fig. 2 the slopes of these lines are plotted *vs* the age of the drop. The result indicates that the diffusion current is a function of m raised to a power, not between 1/3 and 2/3, but greater than 2/3, or approaching it asymptotically. To explain this fact it is necessary to reconsider whether the best revision of the Ilkovic equation is to add a correction term as done by the authors cited above, or whether the theoretical principles underlying the original Ilkovic equation should be critically re-examined.

The author wishes to acknowledge his great gratitude to Dr. Axel Johansson for his interest and encouragement and to Dr. Erik Wåhlin for many valuable discussions.

Equilibrium Studies of Polyanions

I. Isopolyvanadates in Acidic Media

F. J. C. ROSSOTTI and HAZEL ROSSOTTI

Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden *

The following equilibria have been assigned to the isopolyvanadate system in the range $-0.5<\mathrm{pcH}<6.5$, on the basis of spectrophotometric and potentiometric measurements (with glass electrodes) made in perchlorate media at 25°C:

$10VO_2^+,\mathrm{aq.} + 8\,H_2O \rightleftharpoons H_2V_{10}O_{28}^{4-},\mathrm{aq.} + 14\,H^+$; $\varkappa_{14,10}$

$H_2V_{10}O_{28}^{4-},\mathrm{aq.} \rightleftharpoons HV_{10}O_{28}^{5-},\mathrm{aq.} + H^+$; $K_{15,10}$

$HV_{10}O_{28}^{5-},\mathrm{aq.} \rightleftharpoons V_{10}O_{28}^{6-},\mathrm{aq.} + H^+$; $K_{16,10}$

The cation $VO_2^+,\mathrm{aq.}$ is the sole species in solutions $-0.5<\mathrm{pcH}<1.3$ (for a 1 M perchlorate medium in which sodium is the predominant cation), and the isoelectric point is given by:

$$\mathrm{pcH} = 0.803 - 0.643 \log B \text{ and}$$
$$\mathrm{pcH} = 0.715 - 0.643 \log B$$

for 1 M and 3 M perchlorate media, respectively. The values of the equilibrium constants are evaluated as:
$\log \varkappa_{14,10} = -6.75 \pm 0.15$; $\log K_{15,10} = -3.6 \pm 0.3$; and $\log K_{16,10} = -5.8 \pm 0.1$ in the 1 M medium, and $\log \varkappa_{14,10} = -5.5 \pm 0.15$; and $\log K_{15,10} = -3.5 \pm 0.3$ in the 3 M medium. The application of the "core + links" treatment to the data is indicated in an appendix.

PREVIOUS WORK ON THE HYDROLYSIS OF VANADIUM(V)

Considerable uncertainty exists as to the nature of the orange-yellow vanadium(V) species which occur in acidic solution. The existence of the cation, VO_2^+, is well established, but it is not clear if less hydrolysed cations also exist. The nature of the polyvanadates in acidic media appears to be completely in doubt.

Düllberg [1] demonstrated the existence of cationic species by transport measurements in strongly acidic solutions, and the redox potentials between vanadium(V) and (IV) were first interpreted in terms of an equilibrium between

* Present address: Department of Chemistry, University of Edinburgh, Scotland.

VO_2^+ and VO^{2+} by Foerster and Böttcher [2]. Although this interpretation has been confirmed by many other workers (*cf.* Hart and Partington [3] and refs. therein) several authors have mentioned the possible existence of species less hydrolysed than VO_2^+. The existence of VO^{3+} has been discussed by Meyer and Pawletta [4], Britton and Welford [5] and Jander and Jahr [6]. More recently, the existence of VO^{3+} has been proposed by Trujillo and Rios [7] and of $V(OH)_3^{2+}$ by Ramsey, Colichman and Pack [8], in order to explain the kinetics of reduction of vanadium(V) by iodide ions. The diffusion data of Jander and Jahr [6] indicate that the cations, whatever they may be, are not polymerised. No distinction can be made between alternative formulae such as VO_2^+ or $V(OH)_4^+$ by conventional equilibrium methods, but LaSalle and Cobble [9] have recently shown that the former formula is more probable on the basis of structure-entropy considerations. For simplicity, all formulae will be written here in a form stripped of the maximum possible number of molecules of water.

An isoelectric point [6,10] occurs in the region of pcH = 2 *. The orange-yellow *iso*polyvanadic acid which is then formed has been variously considered to contain 2, 4, 5, 6 and 10 vanadium atoms. The main experimental support for most of these formulations has been the occurrence of a point of inflexion in pH titration curves, or a break in conductimetric titration curves in the region $3<\text{pcH}<6$. Thus Ducret [10] considers that the inflexion corresponds to the uptake of one hydroxyl ion per molecule of V_2O_5, and that the orange-yellow colour is due to $H_3V_2O_7^-$. Düllberg [1] had realised that this evidence alone cannot give the degree of polymerisation of the acid, and chose instead the formula $HV_6O_{17}^{3-}$ on the basis of molecular weight determinations and by analogy with an orange solid $Na_4V_6O_{17}$, aq. However, solid vanadates corresponding to a wide variety of ratios of $Na_2O:V_2O_5$ are claimed (see p. 978), and the molecular weights determined by a combination of cryoscopic and conductivity measurements are of doubtful validity. Nevertheless, the existence of hexavanadic acid has been supported by Bray and Tihenko [12], Carpéni and Souchay [13,14], and by Trujillo [15] mainly on the basis of the point of inflexion obtained in titration curves.

However, Britton and Robinson [16], Britton and Welford [5], and Hazel, McNabb and Santini [17] consider that the point of inflexion corresponds to the uptake of only 0.8 hydroxyl ions per molecule of V_2O_5, and formulate the species in solution as $V_{10}O_{27}^{4-}$. This choice was also supported by the existence of the salt $Na_4V_{10}O_{27}$, aq. Although the interpretation of Robinson and Sinclair's vapour pressure measurements [18] is not unequivocal, the data indicate that the molecular weight of the polyvanadate ion existing in acidic solutions is of the order of 1 000, and point to a degree of polymerisation greater than 6 and of the order of 10.

Jander and Jahr [6] assumed that the stable polyvanadate at pcH$\sim$3 is $Na_2H_4V_5O_{16}^-$, by analogy with a salt which was considered to be a pentatantalate [19], but which Lindqvist and Aronsson have subsequently shown to be a hexatantalate [20]. This erroneous assumption forms the basis of Jander and Jahr's interpretation of diffusion data for the polyvanadate system [6] in terms

* The symbol pcH denotes $-\log h$, where h is the free concentration of hydrogen ions *cf. Ref.* [11].

of Riecke's law, which is itself of doubtful validity in these systems [21]. Moreover, as Carpéni and Souchay [14] have pointed out, Jander and Jahr's titration data [6] do not, in fact, appear to support these authors' interpretation of the diffusion data. Ottar [22] has recently reinterpreted the diffusion data on the basis of a kinetic theory, and has obtained the formula $V_4O_{13}^{6-}$ for the polyvanadates existing in acidic solutions. This interpretation is based on the supposition that all polyvanadates consist of chains of VO_4^{3-} tetrahedra, which share one corner, (see p. 978), and involves assumptions about the formation of hydrogen bonds between solute and solvent. Consequently, the diffusion data must still be considered to be of only qualitative interest.

It appears to be generally agreed [17] that the polyvanadates stable in acidic media depolymerise with increasing pcH to trimeric or tetrameric metavanadates, $(VO_3^-)_n$; pyrovanadates, $V_2O_7^{4-}$; and finally to monomeric orthovanadates, VO_4^{3-}. These equilibria, however, are outside the scope of the present work.

List of symbols

A		Total concentration of A
a		concentration of free A
A_s		optical absorbancy
B		total concentration of B, or of metal
$\boldsymbol{B}$		normalised variable defined by (25) or (31)
b		concentration of free B
c_j	=	$[B(A_{st}B_s)_j]$ (51)
E		measured potential in mV
E_j		liquid junction potential
E_0	=	$E - E_j - 59.16 \log h$ (2)
g	=	$\Sigma\ K_j u^{sj}$ (48)
H		total concentration of hydrogen ions, assuming all vanadium to be in the form VO_2^+ (4)
H'		total concentration of hydrogen ions, assuming all vanadium to be in the form V^{5+} (3)
h		concentration of free hydrogen ions
$\boldsymbol{h}$		normalised variable, variously defined by (13), (28) and (36)
j		variable number of polynuclear links, $(A_{st}B_s)$, per complex $B(A_{st}B_s)_j$
$\bar{j}$		average number of polynuclear links per complex, $B(A_{st}B_s)_j$
K_j		equilibrium constant for $(1 + sj)B + sjt\ A \rightleftharpoons B(A_{st}B_s)_j$ (49)
k_0, k		parameters defined by $K_j \rightleftharpoons k_0 k^{sj}$ (54)
$K_{p,q}$		equilibrium constant for $(VO_2)_q(OH)_p^{(p-q)-} + H_2O = (VO_2)_q(OH)_{p+1}^{(p+1-q)-} + H^+$
K_w	=	$[H^+][OH^-]$
l	=	$K_{16,10}K_{15,10}^{-1}$ (29)
M		mole/l
N		unique value of n
n		variable number of mononuclear links, (A_tB), per complex $B(A_tB)_n$
P		unique value of p
p		number of hydroxyl groups in complex $(VO_2)_q(OH)_p$
pcH	=	$-\log h$
Q		unique value of q
q		number of VO_2^+ groups in complex $(VO_2)_q(OH)_p$
s		smallest integer such that product st is also integral
t		number of A groups per B group in mononuclear link (A_tB)
u	=	bh^{-t} (48)
V	=	v^s (55)

v = ku (56)
$V_{\frac{1}{2}}$ = value of V corresponding to $y = \frac{1}{2}$
$X^{\frac{1}{2}}$ normalised variable defined by (60)
x = $\log B - t \log h$ (7)
$x_{\frac{1}{2}}$ = value of x corresponding to $y = \frac{1}{2}$
y = Zt^{-1} (8)
Z average number of hydroxyl groups per VO_2^+ group = $(h-H)B^{-1}$ (1)
Z_q = $\Sigma\, p[A_pB_q] \,/\, q\,\Sigma\,[A_pB_q]$ (19) and (34)
$\boldsymbol{Z}$ = ZZ_{10}^{-1}
$\alpha_{p,q}$ = $100q[A_pB_q]B^{-1}$ (42) and (43)
$\beta_{p,q}$ = $[A_pB_q]a^{-p}b^{-q}$ (41)
ε = $\frac{1}{9}(1 + \log \varkappa_{14,10} - 14 \log K_{15,10})$ (30)
η = $\log \frac{B}{b}$ (45)
ϑ = $P\varkappa_{P,Q}b^{Q-1}h^{-P}$ (12)
$\varkappa_{p,q}$ equilibrium constant for $q\ VO_2^+ + pH_2O \rightleftharpoons (VO_3)_q(OH)_p^{(p-q)-} + p\ H^+$

METHOD

A series of potentiometric titrations of vanadium(V) perchlorate solutions of differing concentrations, in an excess of perchloric acid, was carried out at 25° C. In each titration, the total concentration of metal, B, was held constant, and the hydrogen ion concentration was varied by additions of sodium hydroxide or sodium hydrogen carbonate. In the main series of titrations, all solutions were made 1 M with respect to perchlorate ions by the addition of sodium perchlorate. Preliminary titrations were also made in a 3 M perchlorate medium. As the concentration of metal ions and hydrogen ions never exceeded 2 % and 10 %, respectively, in the former medium, and 0.33 % and 3.3 %, respectively, in the latter medium, it may be assumed that the activity coefficients of all species remain constant. Although McKay has questioned this type of assumption [23], the simplest explanation of Biedermann and Sillén's results [24] appears to be that the activity coefficients remain constant, within the experimental error, for changes in the medium of this order of magnitude. Accordingly, it has been assumed that true stoichiometric equilibrium constants may be calculated from the measurements in each medium.

Since the hydrolysis of vanadium(IV) in a 3 M perchlorate medium has previously been reported [25], the possibility exists of interpreting vanadium (IV/V) redox equilibria as a function of hydrogen ion concentration in terms of the hydrolysis of vanadium(V). Unfortunately, equilibrium values of the redox potential could not be achieved in periods of up to 30 hours, using a number of different platinum, palladium and gold electrodes in conjunction with various potential mediators (*cf.* Refs.[3,26]). Therefore, only the equilibrium hydrogen ion concentration, h, was measured. Although this quantity may often be determined most accurately with hydrogen or quinhydrone electrodes, these cannot be used in vanadium(V) solutions [27]. A glass electrode was therefore used in combination with the reference half-cells, RE_1 or RE_3, where

RE_1 = Ag/0.01M $AgClO_4$ + 0.99M $NaClO_4$/1.00M $NaClO_4$

for titrations in 1 M perchlorate media, and

RE_3 = Ag/0.01 M $AgClO_4$ + 2.99M $NaClO_4$/3.00M $NaClO_4$

for titrations in the 3 M medium. Since equilibrium was achieved in 2 to 15 minutes with these cells (see below), it is considered that the failure to attain equilibrium redox potentials was due to some cause other than a slow hydrolysis reaction.

The average number of hydroxyl ions bound per central group may be calculated for each point of titration, using the relationship

$$Z = (h—H) / B. \quad (1)$$

where H is the total analytical concentration of hydrogen ions, defined by eqn. (4). Thus both H and B are known from the analyses of stock solutions. The data for Z as a function of log h at different total concentrations of metal were analysed by number of methods.

The potentiometric study was supplemented by a spectrophotometric investigation of the species existing in strongly acidic solution.

EXPERIMENTAL

Reagents

Vanadium (V) perchlorate solutions were prepared by dissolving vanadium pentoxide in perchloric acid. One batch of the pentoxide was prepared by dissolving sodium vanadate (*p.a.*) in hot water, and acidifying with perchloric acid. After the solution had stood overnight, more pentoxide was precipitated by evaporating the solution to half its bulk. The product was washed by decantation, centrifuged, and washed free from sodium ions. In other cases, commercial pentoxide (*p.a.*) which had been shown by analysis for vanadium(V) to be >99.9 % pure, was used. The solubility of vanadium pentoxide in perchloric acid is very low (*e.g.* ~0.06 M in 0.2 M acid), and equilibration is slow, *cf.* Ref. [9]. An excess of the oxide was allowed to stand in contact with ~0.2 M perchloric acid for about 4 weeks, and the yellow solution filtered through a very fine sintered glass disc. The concentration of vanadium(V) in the stock solution was determined as described previously [25]. The total concentration of perchlorate ions was found by titrating the eluate of aliquots passed through the hydrogen form of the resin Amberlite IR 120. Acidic solutions of vanadium(V) are reduced during passage through cation exchange resins [28] and the results were not reproducible. Accordingly, vanadium(V) was reduced to vanadium(IV) before passing aliquots through the ion-exhange column. Hydrogen sulphide was passed into the hot solution, excess of the gas expelled and sulphur coagulated by boiling, and the solution filtered.

Sodium hydroxide was freed from carbonate by allowing a 50 % solution of AnalaR grade reagent to stand for 4 weeks in a polythene bottle. Under nitrogen, the solution was filtered through a fine sintered glass disc, diluted with carbon dioxide-free water, and stored in polythene bottles. These solutions were standardised by potentiometric titration with perchloric acid, using Gran's method for calculating the end-point [29].

Sodium perchlorate solutions. One batch was prepared as described elsewhere [25]. A further stock solution was made by filtering a solution of the G. F. Smith Co. product, which had been shown to be free from iron, chlorate, hypochlorite and chloride ions. The solutions were analysed as described previously [25].

Other reagents were prepared and standardised by methods described elsewhere [25].

Procedure

The titration vessel, liquid junction, electrodes and potentiometer have also been described elsewhere [25]. The correct functioning of the Blomgren glass electrode was also tested by comparison with the quinhydrone electrode [25]. For the cell

$$RE/HClO_4 + NaClO_4/glass$$

at 25°C the relationship between the measured potential, E (in mV), and the concentration, of free hydrogen ions is given by

$$E = E_0 + E_j + 59.16 \log h \qquad (2)$$

The term E_0 includes the standard potentials of the electrodes, and the asymmetry potential of the glass electrode. E_j is the liquid junction potential, which was found to be a linear function of h in the range of acidity studied ($h \leq 0.1$ M) and in a given medium. The values of E_0 and of $E_j(h)$ were determined for each titration in the region where no hydrolysis of the ion VO_2^+ occurs (see below), and where h is identical to H.For each point, H is known from the analyses of the solution so that ($E - 59.16 \log h$) may be plotted as a function of h. The values of E_j so found

$$E_j = -16.5h \pm 0.5 \text{ mV/mole in 3 M perchlorate}$$
$$E_j = -63h \pm 2 \text{ mV/mole in 1 M perchlorate}$$

are in good agreement with the values of Biedermann and Sillén [24] and of Biedermann (quoted by Hietanen) [30].

In preliminary work, values of E_0 and of $E_j(h)$ for each titration were found by first titrating acid and base in the absence of metal. However, a change of $\lesssim 0.5$ mV in E_0 usually occurred when some of the acid-base mixture was withdrawn from the titration vessel and metal solution added.

When E_0 and $E_j(h)$ are known, values of h corresponding to the measured potentials E can be found by successive approximation, using eqn. (2).

Measurements were carried out at 25.0 ± 0.1°C in a paraffin oil thermostat placed in a room also thermostated at 25°C. In a particular titration, 18.0 ml of a solution A, containing 0.04 M vanadium(V) perchlorate and 0.12 M perchloric acid was added to 18.0 ml of 0.08 M perchloric acid. This mixture was titrated with equal volumes of 0.2 M sodium hydroxide, and of solution A. (All these solutions were 1 M with respect to perchlorate ions.) Thus, the total concentration of vanadium was 0.02 M throughout the titration. A total volume of 32 ml of each titrant was added stepwise. A value of $E_0 = -314.6$ mV was obtained from the points corresponding to the addition of the first 5.0 ml of each solution. Lower concentrations of perchloric acid and of sodium hydroxide were used for measurements with lower concentrations of vanadium. Series of titrations were carried out at least in duplicate with vanadium concentrations of 0.02, 0.01, 0.005 and 0.0025 M in a 1 M perchlorate medium. Titrations at the three lowest concentrations of metal were repeated in a 3 M perchlorate medium. Higher concentrations of metal could not be used, as vanadium pentoxide is precipitated from initial solutions ($h \sim 0.1$ M) in this medium. The equilibrium hydrogen ion concentration was varied from 10^{-1} to $10^{-6.5}$ M by additions of sodium hydroxide in the 1 M medium ,and of sodium hydrogen carbonate in the 3 M medium. Local excesses of hydroxyl ions were avoided by the use of the latter reagent, and it was shown by alternately bubbling nitrogen and carbon dioxide [31] that the measurements were not invalidated by complex formation between carbonate and vanadium(V) ions. The similarity between the $\bar{Z}$ $(\log h)_B$ data obtained in the two media using the different bases provides a further indication of the absence of such an effect.

A steady potential was usually reached between 2 and 15 minutes after the addition of alkali; the longer times were required for high values of d $\bar{Z}$/d log h. When a steady potential had been obtained, the same value was always found when measured again after an interval of 3 hours. Individial titrations appeared to be reversible. Thus, the pcH of a 0.01 M solution of vanadium(V) was raised from ~1.0 to ~4.3 during the course of 6½ hours. After an interval of 1 hour, the pcH was lowered stepwise to pcH ~1. Points for $\bar{Z}(\log h)_B$ lay on the same curve for the forward and backward titration (*cf.* Fig. 2). For this reason, it is considered that the failure to achieve an equilibrium redox potential was due to some cause other than a slow hydrolytic reaction. Britton and Welford [5] have previously found that equilibrium is rapid below, but slow above, pcH ~5, *cf.* Ref. [17].

The spectrophotometric measurements were made at 25 ± 1°C with a Beckman DU Spectrophotometer, using matched 1.00 cm silica cells, and minimum slit widths.

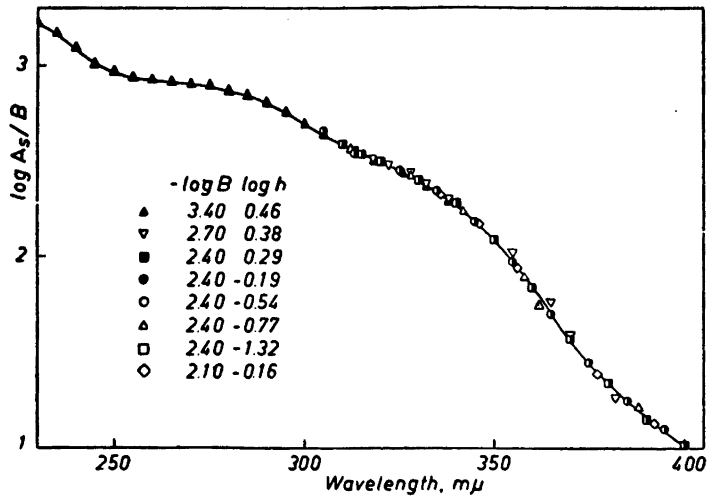

Fig. 1. Absorption spectrum of vanadium(V) perchlorate in acidic solutions 3 M with respect to perchlorate ion.

VANADIUM(V) PERCHLORATE IN STRONGLY ACIDIC SOLUTION

The total analytical hydrogen ion concentration, H', in the stock solution of vanadium(V) perchlorate and perchloric acid was first calculated assuming that all the vanadium(V) was unhydrolysed. Then

$$H' = [ClO_4^-] - 5\ B \qquad (3)$$

Preliminary titrations based on this assumption indicated that 4 hydroxyl ions are bound to each metal atom in the range 0.1 M$\geq h \gtrsim$0.04 M (for 0.01 M vanadium in the 3 M perchlorate medium), *i. e.* the species present is $[V(OH)_4^+]_x$ or $[VO_2^+]_x$.

The effect of higher acidities on the nature of this species was investigated for a range of metal concentrations by comparing the optical absorbancy, A_s, of a series of solutions, 3 M with respect to perchlorate ion. It was found that the plot of A_s/B against wavelength was independent of B in the range 0.008 M$\geq B \geq$0.0004 M, and of h in the range 2.89 M$\geq h \geq$0.048 M. The spectrum (see Fig. 1) is substantially the same as that recently obtained in ~0.2 M perchloric acid by LaSalle and Cobble [9]. As the ratio A_s/B is independent of the value of B, the vanadium cation may be assumed to be the monomeric species, VO_2^+,aq.

It is therefore convenient to discuss subsequent results in terms of the combination of hydroxyl ions to a central VO_2^+ group. H is now defined as the total analytical concentration of hydrogen ions, assuming all the vanadium to be in the form VO_2^+. Thus for the stock solution of vanadium (V) perchlorate

$$H = [ClO_4^-] - B \qquad (4)$$

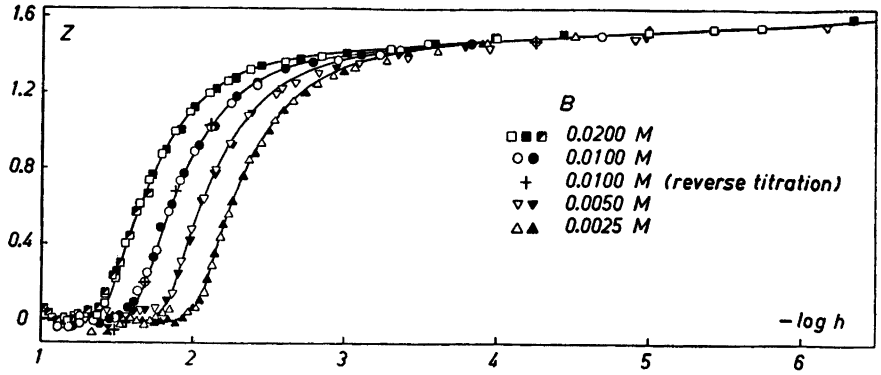

Fig. 2. The average number of hydroxyl groups, Z, bound to each VO_2^+ ion as a function of pcH for different total concentrations of vanadium, B. The lines represent theoretical formation curves calculated for: $\varkappa_{14,10} = 10^{-6.75}$, $K_{15,10} = 10^{-3.6}$ and $K_{16,10} = 10^{-5.8}$

Similarly, Z is now defined as the average number of hydroxyl ions bound to, or protons dissociated from, the VO_2^+ ion.

THE HYDROLYSIS OF THE VO_2^+ ION

Identification of the initial product of hydrolysis

In the first instance, discussion will be restricted to the potentiometric measurements made in the 1 M perchlorate medium. The data $Z(\log h)_B$ calculated for ten titrations using eqns. (1), (2) and (4) are shown in full in Fig. 2. The data for four representative titrations at different total metal concentrations, B, are also given in Table 1.

The upper limit of 0.02 M for the metal concentrations used was imposed by the limited solubility of vanadium(V) in the perchlorate medium; and the lower limit of 0.0025 M by the limited accuracy of the glass electrode in solutions of $0.1\ M \geqslant h \geqslant 0.05\ M$. The random scatter about $Z = 0$ at the base of the curves lies within the experimental error of $\pm$ 0.2 mV.

As the curves referring to different values of B are not coincident, it is apparent that at least one polynuclear complex, $(VO_2)_q(OH)_p^{(q-p)+}$ is formed. The curves pass through an isoelectric point (represented by $Z = 1.0$), and each VO_2^+ ion evidently combines with a maximum of $\sim$1.6 hydroxyl ions in the range studied (pcH$<$6.5). The high values of $(-\partial Z/\partial \log h)_B$ for $Z<1.0$ indicate the formation of polynuclear species which contain a relatively high number of vanadium atoms, *cf.* Fig. 1 in Ref.[32]. For $Z \gtrsim 1.5$, and pcH$>$4, the system is again homonuclear, since curves for different values of B are coincident.

For values of $Z \lesssim 1.2$, the curves $Z(\log h)_B$ appear to be parallel, so that Sillén's "core + links" hypothesis [32,33] may be applied. In this range, the complex, or complexes, $(VO_2)_q(OH)_p$ may be written in the form

Table 1. $Z(\log h)_B$ for four representative titrations. The symbols are those used in Fig. 2.

$B = 2\times10^{-3}$ M		$B = 10^{-3}$ M		$B = 5\times10^{-3}$ M		$B = 2.5\times10^{-3}$M

$VO_2((OH)_t(VO_2))_n$, where t is a constant (not necessarily integral) and where n may be a unique integer, N, or a series of integers such that the product nt is also integral. Charges are omitted for clarity. Hence, the parameter t is defined by

$$t = p/(q-1) \tag{5}$$

and p is a linear function of q. Sillén [33] has shown that

$$t = (\partial \log B / \partial \log h)_Z \tag{6}$$

The function $\log B\ (\log h)_Z$, which is derived from the data in Fig. 2, is plotted in Fig. 3, and it is found that $t = 1.50 \pm 0.07$. Accordingly, the different $Z(\log h)_B$ curves may be made to coincide by transforming the $\log h$ axis to

$$x = \log B - t \log h \tag{7}$$

For convenience, the Z axis is simultaneously transformed to

$$y = Z / t \tag{8}$$

The plot of $Z/1.5$ against $(\log B - 1.5 \log h)$ is not reproduced here, but as in the similar plot shown in the Appendix (Fig. 8), all points lie on a single curve, within experimental error. Now a curve $y(x)$ is analogous to the

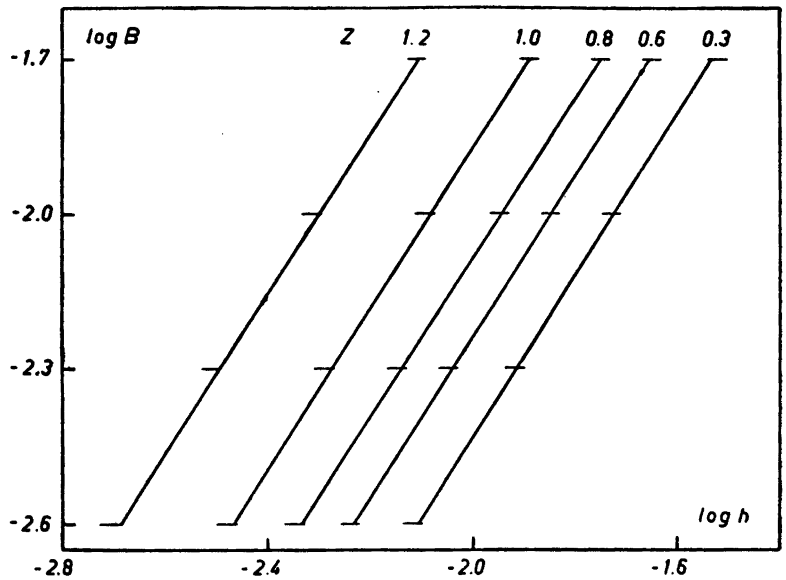

Fig. 3. Log B *as a function of log* h *for different values of* Z. *The lines are calculated for* $\varkappa_{14,10} = 10^{-6.75}$.

single curve $Z(\log h)$ which obtains for a system of mononuclear hydroxyl complexes. Thus, as a first approximation, the products of the reaction between VO_2^+ ions and hydroxyl ions may be represented by the formula $VO_2((OH)_{1.5}(VO_2))_n$.

By comparing the experimental curve $y(x)$ with families of normalised curves $y(X)$ calculated for certain simplifying assumptions, the value or values of n may be found, and the formation constants for the system described in terms of two parameters. Sillén [32] has given a number of normalised curves calculated on the assumptions that:

I, no soluble complexes are formed, but an insoluble complex precipitates,
II, a unique complex $B(A_tB)_N$ is formed in solution,
III, a series of complexes $B(A_tB)_n$ is formed in solution, with values of n ranging from unity to infinity.

Although the curves given elsewhere [32] for hypotheses I and II are valid irrespective of whether t is integral or non-integral, the curves given for hypothesis III are only valid for integral values of t (*cf.* Appendix).

For $y \lesssim 0.5$, the curve $y(x)$ was found to fit in with the family of normalised curves for hypothesis II, with a value of $N = 8$ or 10 (odd values of N are excluded from consideration, since the product $Nt = P$ must be integral). It could therefore be tentatively inferred that the initial reaction product is a single polynuclear species $VO_2^+((OH)_{1.5}VO_2)_8^{4-}$ or $VO_2^+((OH)_{1.5}VO_2)_{10}^{5-}$, and that this species undergoes some further reaction. Even if the value of t is not exactly 1.5, it is likely that the above formulae approximate to the com-

position of the complex. Other possible combinations of values of t (within the range 1.5 ± 0.07) and of N were found by trial and error, and are given in Table 2, together with the two combinations discussed above.

Table 2. Possible initial reaction products, $(VO_2)_Q(OH)_P$ or $VO_2((OH)_2(VO_2))_N$

t	N	Q	P	Range fitted by hypothesis II
1.444	9	10	13	$Z \lesssim 0.6$
1.455	11	12	16	0.6
1.500	8	9	12	1.0
1.500	10	11	15	1.1
1.545	11	12	17	0.8
1.556	9	10	14	1.3

Now for the reaction

$$Q\ VO_2^+ + P\ H_2O \rightleftharpoons (VO_2)_Q(OH)_P^{(P-Q)-} + P\ H^+ \quad (9)$$

$$B = b + Q\ [(VO_2)_Q(OH)_P] \quad (10)$$

$$\text{and } BZ = P\ [(VO_2)_Q(OH)_P] \quad (11)$$

where b is the concentration of free VO_2^+ ions. Introducing the following auxiliary variables into eqns. (10) and (11)

$$\vartheta = Q\ [(VO_2)_Q(OH)_P]\ b^{-1} = Q\varkappa_{P,Q} b^{Q-1} h^{-P} \quad (12)$$

where $\varkappa_{P,Q}$ is the equilibrium constant for reaction (9) and

$$\log h = \frac{1}{P} \log Q\varkappa_{P,Q} + \frac{Q-1}{P} \log B - \log h = \frac{1}{P} \log \vartheta + \frac{Q-1}{P} \log (1+\vartheta) \quad (13)$$

it may be shown that

$$Z = \frac{P}{Q} \frac{\vartheta}{1+\vartheta} \quad (14)$$

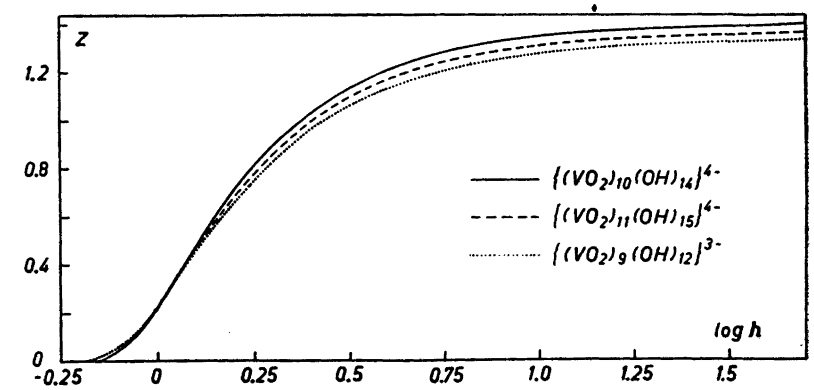

Fig. 4. Normalised curves $Z(\log h)_B$ for the single species $(VO_2)_Q(OH)_P$

Thus a normalised set of $Z(\log h)_B$ curves may be calculated using eqns. (12) and (13), together with the values of P and Q given in Table 2, and compared with the experimental data shown in Fig. 2. Some of the normalised curves are shown in Fig. 4. A good fit could be obtained, within the limits of experimental error, with all the curves, for values of Z less than those listed in column 4 of Table 2. None of the curves fitted particularly well for values of $Z<0.05$, but this is to be expected from the large experimental error in this region. For values of $Z\lesssim 0.8$, the data appear to be consistent with the formation of $(VO_2)_9(OH)_{12}^{3-}$, $(VO_2)_{10}(OH)_{14}^{4-}$, $(VO_2)_{11}(OH)_{15}^{4-}$ or of $(VO_2)_{12}(OH)_{17}^{5-}$, and there seems to be no reliable criterion for distinguishing with certainty between these possibilities with the present data. However, since the data are consistent with the existence of $(VO_2)_{10}(OH)_{14}^{4-}$ over the biggest range of values of Z ($\lesssim 1.3$), the simplest and most likely explanation of the hydrolysis of the VO_2^+ ion may be given in terms of the initial formation of this species.

The hydrolysis constant of $(VO_2)_{10}(OH)_{14}^{4-}$

The equilibrium constant $\varkappa_{14,10}$ for the initial reaction

$$10\ VO_2^+ + 14\ H_2O \rightleftharpoons (VO_2)_{10}(OH)_{14}^{4-} + 14\ H^+ \qquad (9a)$$

may be calculated in many ways from the data in the range where no further reaction is detectable.

(a) *Direct curve fitting.* Values of $\varkappa_{14,10}$ may be obtained directly from corresponding coordinates of experimental and theoretical curves $Z(\log h)_B$ placed in the position of best fit in the region $Z<1.3$ (*cf.* Figs 2 and 4). When the right hand side of eqn. (13) is zero,

$$\log \varkappa_{14,10} = 14\ \log h - 9\ \log B - \log 10 \qquad (13a)$$

whence is obtained $\log \varkappa_{14,10} = -6.75 \pm 0.15$

(b) *Linear extrapolation.* It has been shown elsewhere [25] that

$$\log\{P^{Q-1}Z(P-QZ)^{-Q}\} = (Q-1)\ \log B - P\ \log h + \log \varkappa_{P,Q} \qquad (15)$$

for reaction (9). The data for 26 titration points in the range $0.1<Z<1.3$, but otherwise selected at random, were plotted in the form of $\log\{14^9 Z(14-10Z)^{-10}\}$ against $(9\ \log B - 14\ \log h)$; *cf.* Table 3. Since the points lie on a straight line (not reproduced here) of unit slope, and of intercept -6.8 ± 0.1, the data are consistent with the initial formation of $(VO_2)_{10}(OH)_{14}^{4-}$ with a hydrolysis constant of $\log \varkappa_{14,10} = -6.8 \pm 0.1$.

(c) *Methods based on the "core + links" hypothesis.* Values of

$$\log \varkappa_{14,10} = -6.75 \pm 0.03$$
$$\text{and} \qquad -6.75 \pm 0.07$$

were obtained by integration, and by curve fitting, respectively, of the plot of $Z/1.556$ against $(\log B - 1.556\ \log h)$. Discussion of the application of the "core + links" hypothesis [32] to the present data will be deferred to an appendix to this paper.

Table 3. Data for determining $\varkappa_{14,10}$ by linear extrapolation according to eqn. (15).

$-\log B$	$-\log h$	Z	$\log\{14^9 Z(14-10Z)^{-10}\}$	$9\log B - 14\log h$

	2.14	0.356	−0.32	6.60
	2.20	0.508	0.52	7.34
	2.32	0.764	2.16	9.12
	2.49	0.998	4.28	11.40
	2.59	1.11	5.70	12.87
	2.73	1.20	7.37	14.85

Straight lines of unit slope are also obtained in certain ranges for plots using the other values of P and Q listed in table 2. However, the data may be represented by equation (15) over the biggest range of values of Z ($\leqslant 1.3$) with $P = 14$ and $Q = 10$.

The secondary products of hydrolysis

If $(VO_2)_{10}(OH)_{14}^{4-}$ were the sole product of hydrolysis of VO_2^+, the plots $Z(\log h)_B$ would coincide at $Z = 1.4$, and $dZ / d\log h$ would then be zero. On the contrary, the curves do not coincide until $Z > 1.4$, and Z increases to approximately 1.6 in the range $3 \leqslant pcH \leqslant 6.5$. Within the accuracy of the experimental measurements, it appears possible to describe the upper parts of the Z $(\log h)_B$ curves mathematically in one of two ways:

(a) further hydrolysis of $(VO_2)_{10}(OH)_{14}^{4-}$ to $(VO_2)_{10}(OH)_{15}^{5-}$ and $(VO_2)_{10}(OH)_{16}^{6-}$, or

(b) formation of a series of more condensed isopolyvanadates, $(VO_2^+)_q(OH^-)_p$ where $q > 10$.

The former explanation is preferable on grounds of simplicity and in view of recent preliminary crystallographic studies of isopolyvanadates, which will be discussed later.

If $(VO_2)_{10}(OH)_{16}^{6-}$ is the ultimate decavanadate, the three isopolyvanadates may arbitrarily be assigned the formulae $H_2V_{10}O_{28}^{4-}$, aq., $HV_{10}O_{28}^{5-}$, aq., and $V_{10}O_{28}^{6-}$, aq. The dissociation constants of the first two species may be denoted

by $K_{15,10}$ and $K_{16,10}$, and the overall hydrolysis constants of the last two species by $\varkappa_{15,10}$ and $\varkappa_{16,10}$. Thus

$$\varkappa_{15,10} = \varkappa_{14,10} \cdot K_{15,10} \tag{16a}$$

$$\varkappa_{16,10} = \varkappa_{15,10} \cdot K_{16,10} \tag{16b}$$

Accordingly, for a system consisting of VO_2^+, $H_2V_{10}O_{28}^{4-}$, aq., $HV_{10}O_{28}^{5-}$, aq. and $V_{10}O_{28}^{6-}$, aq. in equilibrium

$$B = b + 10b^{10} \sum_{p=14}^{p=16} \varkappa_{p,10} h^{-p} \tag{17}$$

and

$$h - H = BZ = 10b^{10} Z_{10} \sum_{p=14}^{p=16} \varkappa_{p,10} h^{-p} \tag{18}$$

where Z_{10}, the average number of additional hydroxyl groups per VO_2 group in the decavanadates is defined by

$$Z_{10} = \frac{\sum_{p=14}^{p=16} p[(VO_2)_{10}(OH)_p]}{10 \sum_{p=14}^{p=16} [(VO_2)_{10}(OH)_p]} \tag{19}$$

where charges are omitted for clarity. Now

$$Z = \frac{10\varkappa_{14,10} b^{10} h^{-14} \ (1.4 + 1.5K_{15,10}h^{-1} + 1.6K_{15,10}K_{16,10}h^{-2})}{b + 10\varkappa_{14,10} b^{10} h^{-14} \ (1 + K_{15,10}h^{-1} + K_{15,10}K_{16,10}h^{-2})} \tag{20}$$

so that the function $Z(\log h)_B$ may be described in terms of the two variables b and h and the three parameters $\varkappa_{14,10}$, $K_{15,10}$ and $K_{16,10}$. Moreover

$$Z_{10} = \frac{1.4 + 1.5K_{15,10}h^{-1} + 1.6K_{15,10}K_{16,10}h^{-2}}{1 + K_{15,10}h^{-1} + K_{15,10}K_{16,10}h^{-2}} \tag{21}$$

so that Z_{10} (log h) may be described in terms of the single variable h and the two parameters $K_{15,10}$ and $K_{16,10}$. Combining eqns. (17) and (18)

$$\frac{b}{B} = \frac{Z_{10} - Z}{Z_{10}} \tag{22}$$

whereby b may be eliminated from eqn. (18). Thus

$$Z = 10B^9 \ (Z_{10} - Z)^{10} (Z_{10})^{-9} \sum_{p=14}^{p=16} \varkappa_{p,10} h^{-p} \tag{23}$$

By introducing auxiliary variables into this equation, it is possible to calculate theoretical (or normalised) curves, which may be superimposed on the experimental data. The required equilibrium constants are found from the differences between the coordinates of these curves in the position of best fit. This approach is analogous to that used by Lagerström and Sillén for interpreting measurements of equilibria in silicate solutions [34].

Evaluation of the decavanadate hydrolysis constants

(a) *Normalised curves log B (log Z).*

Introducing the auxiliary variables

$$\log Z = \log Z - \log Z_{10} \tag{24}$$

and

$$\log B = \log B + \frac{1}{9}\left(1+\log \sum_{p=14}^{p=16} \varkappa_{p,10} h^{-p}\right) \tag{25}$$

eqn. (23) may be rewritten in the form

$$\log B = \frac{1}{9} \log Z - \frac{10}{9} \log (1-Z) \tag{26}$$

The normalised curve log B (log Z) may be calculated from eqn. (26) and fitted to each of the experimental curves log B (log $Z)_h$ by movement parallel to the axes, *cf.* Fig. 5. Then, for each particular value of h, the differences between the coordinates of the theoretical and experimental curves give values of Z_{10} and $\sum_{p=14}^{p=16} \varkappa_{p,10} h^{-p}$ according to eqns. (24) and (25). The internal consistency of the values so obtained may be checked since it may be shown from eqn. (21) that

$$\frac{\mathrm{d} \log \sum_{p=14}^{p=16} \varkappa_{p,10} h^{-p}}{\mathrm{d} \log h} = -10 Z_{10} \tag{27}$$

The equilibrium constants may be found from the functions $\sum_{p=14}^{p=16} \varkappa_{p,10} h^{-p}$ (h) or $10 Z_{10}(h)$ by standard methods, *cf.* Ref.[35] and parts (c) and (d) of this section.

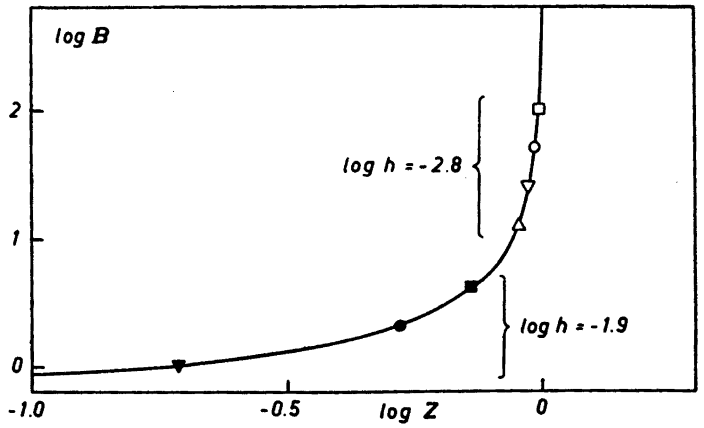

Fig. 5. Normalised curve log B (log Z) for the series of complexes $(VO_2)_{10}(OH)_p$. The lower and upper groups of experimental points show log B$(\log Z)_h$ *for* h = $10^{-2.8}$ *and* $10^{-1.9}$ *M in the positions of best fit.*

In the present case, reliable experimental data for log $B(\log Z)_h$ can only be derived from the data log Z (log $h)_B$ in the range $1.6 \leqslant \text{pcH} \leqslant 2.8$. Throughout this range it is found that

$$Z_{10} = 1.4$$
$$\text{and } \log \varkappa_{14,10} = -6.7 \pm 0.2$$

In the range $2.8 \leqslant \text{pcH} \leqslant 4.0$, d log B/d log $h \to \infty$ so that experimental curves cannot be obtained, and fitted to the normalised curves, with any great accuracy. Nevertheless, it is evident that Z_{10} increases from 1.4 to 1.5 in this region.

(b) *Normalised curves log B (log h)$_{Z,l}$.*

Alternatively, the following auxiliary variables and parameters may be introduced into eqn. (23):

$$\log \boldsymbol{h} = \log K_{15,10} - \log h \tag{28}$$

$$\log l = \log K_{16,10} - \log K_{15,10} \tag{29}$$

$$\log \varepsilon = \frac{1}{9}(1 + \log \varkappa_{14,10} - 14 \log K_{15,10}) \tag{30}$$

$$\log \boldsymbol{B} = \log B + \log \varepsilon \tag{31}$$

and it may be shown that

$$\log \boldsymbol{B} = \log Z + \log (1.4 + 1.5\boldsymbol{h} + 1.6\ \boldsymbol{h}^2 l) - \frac{14}{9} \log \boldsymbol{h} - \frac{10}{9} \log [(1.4 - Z) + (1.5 - Z)\ \boldsymbol{h} + (1.6 - Z)\boldsymbol{h}^2 l] \tag{32}$$

A family of normalised curves log $\boldsymbol{B}$ (log $\boldsymbol{h})_{Z,l}$ may be calculated from eqn. (32) for a number of values of Z ($\leqslant 1.42$). For each family of curves, it is also necessary to assume some value of l, defined by eqn. (29), *cf.* Fig. 6. The experimental curves log B (log $h)_Z$ are moved over the families of normalised curves, calculated for different values of l. In the position of best fit, the differences between the coordinates of the experimental and normalised curves give log $K_{15,10}$ according to eqn. (28), and

$$\log \boldsymbol{B} - \log B = \frac{1}{9}(1 + \log \varkappa_{14,10} - 14 \log K_{15,10}) \tag{33}$$

according to eqns. (30) and (31). Log $K_{16,10}$ is found from eqn. (29).

Comparison of the experimental data log B (log $h)_Z$ with families of normalised curves calculated for a few different values of l indicated that the best fit could be obtained with values of $l < 0.01$, *i.e.* in the range $Z < 1.4$, the species $V_{10}O_{28}^{6-}$,aq. is scarcely detectable. Hence a simplified form of eqn. (32) was used, with $l = 0$. From the coordinates in the position of best fit, the following equilibrium constants were evaluated: —

$$\log \varkappa_{14,10} = -6.75 \pm 0.15$$
$$\log K_{15,10} = -3.6 \pm 0.3$$

Moreover, log $K_{16,10} < -5.6$

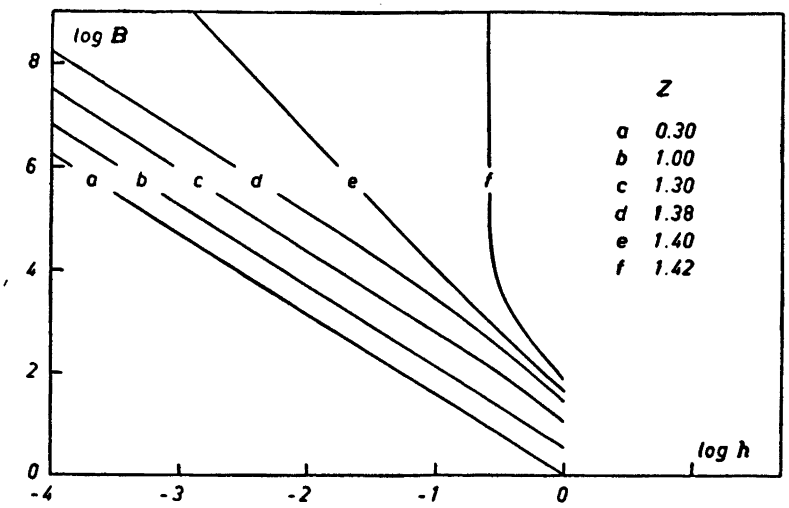

Fig. 6. Normalised curves log B $(\log h)_{Z,l}$ for $l = 0$.

(c) *Normalised curves* $10Z_{10}$ $(\log h)_l$

For a system consisting of a metal ion Me and of two mononuclear complexes MeOH and $Me(OH)_2$

$$Z_1 = \frac{\sum_{p=1}^{p=2} p\varkappa_{p,1}h^{-p}}{\sum_{p=0}^{p=2} \varkappa_{p,1}h^{-p}} \tag{34}$$

where $\varkappa_{0,1} = 1$.

Similarly, for the species $H_2V_{10}O_{28}^{4-}$ and its dissociation products $HV_{10}O_{28}^{5-}$ and $V_{10}O_{28}^{6-}$, eqn. (21) may be rewritten

$$10Z_{10}-14 = \frac{K_{15,10}h^{-1} + 2K_{15,10}K_{16,10}h^{-2}}{1 + K_{15,10}h^{-1} + K_{15,10}K_{16,10}h^{-2}} \tag{21a}$$

Thus, eqn. (21a) is of the same form as eqn. (34). The family of curves $10Z_{10}(\log h)_{K_{15,10}/K_{16,10}}$ will be the same shape as the formation function Z_1 $(\log h)_{K_{1,1}/K_{2,1}}$ for a mononuclear system, but will be displaced 14 units up the ordinate axis. As $b \to 0$ in the homonuclear range pcH>4, Z_{10} may be obtained as the value of Z in this region.

Introducing the auxiliary parameters and variables

$$\gamma = \tfrac{1}{2}\ (\log\ K_{15,10} + \log\ K_{16,10}) \tag{35}$$

$$l\ = K_{16,10}\ /\ K_{15,10} \tag{29a}$$

$$\log\ h = \gamma - \log\ h \tag{36}$$

into eqn. (21a)

$$10Z_{10} - 14 = \frac{l^{\frac{1}{2}}h + 2h^2}{1 + l^{\frac{1}{2}}h + h^2} \tag{37}$$

Normalised curves $10Z_{10}$ (log h)$_l$ were calculated for a number of values of $l^{\frac{1}{2}}$, using eqn. (37) (*cf.*[36]), and fitted to the experimental function $10Z_{10}$(log h), by movement along the log h axis. The parameter l is that value used to calculate the curve of appropriate shape, and γ is obtained from the differences between the coordinates, according to eqn. (36). The following values of the dissociation constants of $H_2V_{10}O_{28}^{4-}$ and $HV_{10}O_{28}^{5-}$ were obtained

$$\log K_{15,10} = -3.6 \pm 0.3$$

$$\log K_{16,10} = -5.8 \pm 0.1$$

(d) *Linear Extrapolation.*

Eqn. (17) may be rewritten as

$$\frac{B-b}{10b^{10}h^{-14}} = \varkappa_{14,10} + \varkappa_{15,10}h^{-1} + \varkappa_{16,10}h^{-2} \tag{17a}$$

or

$$\frac{B-b}{10b^{10}h^{-16}} = \varkappa_{16,10} + \varkappa_{15,10}h + \varkappa_{14,10}h^2 \tag{17b}$$

Hence, if the concentration of free VO_2^+ ions, b, were known, the equilibrium constants could be found by successive extrapolations, *cf.* Ref.[35]. In the absence of direct measurements of b, this quantity may be calculated. Hedström [37] has shown that

$$\left(\frac{\partial \ln b}{\partial \ln h}\right)_B = \left(\frac{\partial H}{\partial B}\right)_h \tag{38}$$

Combining eqns. (1) and (38), it may be shown that

$$\ln\frac{B}{b} = \left[\int\left\{Z + \left(\frac{\partial Z}{\partial \ln B}\right)_h\right\}\mathrm{d}\ln h\right]_B \tag{39}$$

for a system which is mononuclear at the lower limit of integration, *cf.* Lagerström and Sillén [34]. Values of $\left(\frac{\partial Z}{\partial \log B}\right)_{h,B}$ were obtained by graphical differentiation of plots of Z (log B)$_h$, and the right hand side of eqn. (39) was evaluated by graphical integration of plots of $\left\{Z + \left(\frac{\partial Z}{\partial \log B}\right)_h\right\}_B$ against log h. Corresponding values of B, b and h were substituted into eqns. (17 a) and (17 b) and the polynomials plotted both as a function of h and of h^{-1}. The following mean values of the overall hydrolysis constants were obtained:

$$\log \varkappa_{14,10} = -\ 6.82 \pm 0.17$$

$$\log \varkappa_{15,10} = -\ 9.9\ \pm 0.6$$

$$\log \varkappa_{16,10} = -\ 15.7\ \pm 0.6$$

Hydrolysis constants found: $\log \varkappa_{14,10} = -6.8$, $\log \varkappa_{15,10} = -9.3$, $\log \varkappa_{16,10} = -15.07$.

The large errors associated with $\varkappa_{15,10}$ and $\varkappa_{16,10}$ arise from a systematic drift in the values of the left hand side of eqns. (17a) and (17b) obtained using different total concentrations of vanadium, B. Such discrepancies are scarcely surprising as high powers of b and h are involved, and neither of these variables can be obtained very accurately from measurements made with a glass electrode of high resistance.

POTENTIOMETRIC TITRATIONS IN A 3 M MEDIUM

The preliminary titrations (like the spectrophotometric work) were carried out in a 3 M perchlorate medium in which sodium was the predominant cation, and in the region $1 < \text{pcH} < 4$, only. This work was discontinued owing to the limited solubility of vanadium(V) perchlorate in the medium. The curves, Z ($\log h)_B$, (not reproduced here) were of the same shape as those obtained in the 1 M medium, but for identical vanadium concentrations were displaced by —0.1 pcH units. Assuming the same products of reaction as in the 1 M medium the following equilibrium constants were obtained for this medium:

$$\log \varkappa_{14,10} = -5.5 \pm 0.15$$
$$\log K_{15,10} = -3.5 \pm 0.3$$

DISCUSSION

Potentiometric and absorptiometric studies indicate that vanadium(V) exists as the VO_2^+, aq. ion in the range of acidity 2.9 M$> h >$0.05 M. No evidence was found of less hydrolysed cations, which have been suggested by

previous investigators [4–8]. Although the interpretation of the potentiometric data in the range $1.3<\text{pcH}<6.5$ is not unequivocal, these data are clearly incompatible with the formation of hexavanadates [1,12–15], pentavanadates [6], or other smaller polyanions [10,22], which have also been proposed by earlier workers, and which are described in contemporary text-books. The present data may most simply be explained by assuming that the decavanadates $H_2V_{10}O_{28}^{4-}$, aq., $HV_{10}O_{28}^{5-}$, aq., and $V_{10}O_{28}^{6-}$, aq. are successively formed in solution from VO_2^+, aq. The species $H_2V_{10}O_{28}^{4-}$ corresponds to $V_{10}O_{27}^{4-}$, which has been suggested by Britton and Welford [5], and by Hazel, McNabb and Santini [17], although this species has now been shown to give rise to further decavanadates. The present data provide no evidence for the equilibrium

$$VO_2^+ \rightleftharpoons (VO_2^+)_q(OH^-)_p \rightleftharpoons V_{10}O_{27}^{4-} \text{ (where } q>10)$$

suggested by the latter workers. At higher vanadium concentrations than have been used in the present work, the pentoxide precipitates in the region of the isoelectric point, which is given by

$$\text{pcH} = 0.803—0.643 \log B \quad \text{and} \tag{40a}$$

$$\text{pcH} = 0.715—0.643 \log B \tag{40b}$$

in 1 M and 3 M (sodium) perchlorate media, respectively.

Since few quantitative studies of step-equilibria of the type

$$10VO_2^+, \text{ aq.} + 8H_2O \rightleftharpoons H_2V_{10}O_{28}^{4-}, \text{ aq.} + 14H^+ \qquad \varkappa_{14,10}$$

$$H_2V_{10}O_{28}^{4-}, \text{ aq.} \rightleftharpoons HV_{10}O_{28}^{5-}, \text{ aq.} + H^+ \qquad K_{15,10}$$

$$HV_{10}O_{28}^{5-}, \text{ aq.} \rightleftharpoons V_{10}O_{28}^{6-}, \text{ aq.} + H^+ \qquad K_{16,10}$$

have been reported, values of the equilibrium constants have been obtained using a variety of methods, and are given below.

Table 5. Hydrolysis constants valid at 25°C in a 1 M perchlorate medium, in which sodium is the predominant cation.

Proposed values		6.75±0.15	3.6±0.3	5.8±0.1

The hydrolysis of vanadium(V) is somewhat greater in a 3 M (sodium) perchlorate medium than in a 1 M medium, and the following equilibrium constants have been obtained;

$$\log \varkappa_{14,10} = —5.5 \pm 0.15$$

$$\log K_{15,10} = —3.5 \pm 0.3$$

The overall stability constant, $\beta_{q,p}$, for the hydroxo-complex $Me_q(OH)_p$ is related to the corresponding hydrolysis constant, $\varkappa_{q,p}$, by the expression

$$\beta_{q,p} = \frac{[Me_q(OH)_p]}{[Me]^q[OH]^p} = \varkappa_{q,p}K_w^{-p} \tag{41}$$

where K_w is the ionic product for water. Using values $K_w = 10^{-13.8}$ and $10^{-14.22}$ (Ref. 38) $\log \beta_{14,10} = 186$ and 194 in the 1 M and 3 M media, respectively. An increase in the overall hydrolysis constant of $Fe_2(OH)_2^{4+}$ with increasing ionic strength has recently been reported by Milburn and Vosburgh [39].

In order to calculate the proportions of the various species present in solution, it is convenient to combine eqn. (17) with the auxiliary variables defined by eqns. (29) and (30).

$$\frac{100\ [VO_2]}{B} = 100\left[1 + 10\varkappa_{14,10}B^9h^{-14}\left(1 - \frac{Z(1+h)}{1.4+1.5\ h}\right)^9\ (1+h)\right]^{-1} \tag{42}$$

$$\frac{100\ [H_{16-p}V_{10}O_{28}]}{B} = \frac{10^3\varkappa_{14,10}B^9h^{-p}\left(1 - \frac{Z(1+h+lh^2)}{1.4+1.5\ h+1.6lh^2}\right)^9}{1 + 10\varkappa_{14,10}B^9h^{-14}\left(1 - \frac{Z(1+h+lh^2)}{1.4+1.5h+1.6lh^2}\right)^9(1+h+lh^2)} \tag{43}$$

The proportions of the different species, $\alpha_{p,q}$, have been calculated as percentages of the total vanadium present for the highest (2×10^{-2} M) and lowest (2.5×10^{-3} M) vanadium concentrations used in the 1 M medium. These are plotted as functions of pcH in Fig. 7. The curves for VO_2^+ and $H_2V_{10}O_{28}^{4-}$, which are in heteronuclear equilibrium, are unsymmetrical. However, the curves $\alpha_{p,10}$ (pcH) for $HV_{10}O_{28}^{5-}$ and $V_{10}O_{28}^{6-}$, which are substantially in homonuclear equilibrium, are symmetrical (*cf.* mononuclear systems).

Polyvanadates in the solid state

Orange polyvanadates crystallise from solutions of pcH<7. The analytical ratios Me(I)/V(*V*) reported in the literature [40] include; 5/6, 4/5, 5/8, 2/3, 3/5, 4/7, 1/2, 3/7, 2/5, 1/3, 1/4, 2/9. Previous formulae suggested for the polyvanadates have been in accordance with one or other of these ratios. If solid vanadates of the VO_2^+ ion can be obtained from acidic solutions, as Jahr and Jander [41] have suggested, a number of these ratios may represent distinct compounds. However, in the absence of further evidence, it is somewhat doubtful whether all these ratios can represent different compounds.

Lindqvist [42], and Evans, Mrose, and Marvin [43] have recently examined crystallographically a number of orange polyvanadates, which were crystallised at pcH ~ 6.5. Analytical data were in good agreement with the formulae listed in Table 6, and the salts have all been shown to contain ten, or multiples of ten, vanadium atoms per unit cell.

Table 6. Polyvanadates examined structurally.

Analytical formula	V atoms per unit cell.	Ref.
$(NH_4)_6V_{10}O_{28},6H_2O$	20	Lindqvist[42]
$K_6V_{10}O_{28},9H_2O$	20	Evans, Mrose & Marvin [43]
$K_6V_{10}O_{28},10H_2O$	40	»
$Ca_3V_{10}O_{28},16H_2O$ (pascoite)	20	»
$K_2Mg_2V_{10}O_{28},16H_2O$ (hummerite)	10	»
$K_2Zn_2V_{10}O_{28},16H_2O$	10	»

Although attempts to solve these structures have so far failed [42,43], it seems likely that anions which contain ten vanadium atoms exist in the solid phase.

The coordination number of vanadium(V) may be 4, 5 or 6, in solid vanadates depending upon the pcH at which the compound is obtained. Vanadium pentoxide (which precipitates at pcH ~ 2) is considered to consist of chains of distorted trigonal bipyramids (Byström, Wilhelmi and Brotzen [44]) or of distorted octahedra (Magnéli and Oughton [45]). Metavanadates, $(VO_3)_n^{n-}$, crystallise from solutions of 6.5<pcH<8.0, and for KVO_3, H_2O, Christ, Clark and Evans [46] have shown that the basic structural unit is again the trigonal bipyramid. The metal-oxygen coordination is octahedral in the polyanions $Nb_6O_{19}^{8-}$ (Lindqvist [47]) and $Ta_6O_{19}^{8-}$ (Lindqvist and Aronsson [20]). Since, moreover, tetrahedral coordination [48] is only found in the orthovanadates, $MeVO_4$, which crystallise at pcH> 10, it is probable that vanadium is coordinated to 5 or 6 oxygen atoms in the decavanadates, which are obtained at pcH ~ 6.5 (however, *cf.* Ottar [22]).

APPENDIX

The experimental data obtained in the 1 M medium are now discussed with reference to the "core + links" hypothesis [32,33]. When the parameter t is non-integral, the basic formulae [32] are still valid, but those concerned with continuous polymerisation (hypothesis III) must be modified, since some terms in the summation are now equal to zero. The "core + links" complexes

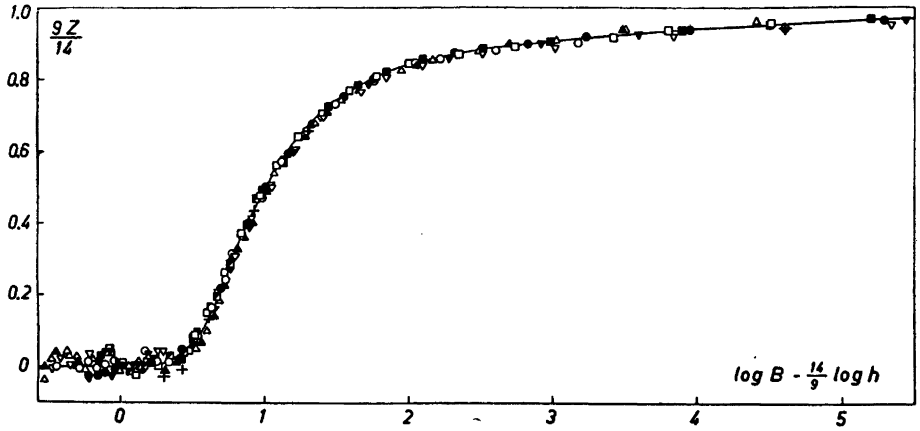

Fig. 8. y(= Z/*1.556*) *as a function of* x(= *log* B − *1.556 log* h). *The symbols are those used in Fig. 2. The curve is calculated from equations (59) and (60) with the two parameters, log* k_0 = *2.0 and 9 log* k = −*8.75.*

$B(A_tB)_n$ only have a physical meaning when the product nt is also integral. If s is the smallest positive integer such that the product st is also integral, the possible complexes may be written as $B(A_{st}B_s)_j$, where j is either a single integer or a series of integers, and

$$n = sj \tag{44}$$

The spacing of the curves Z (log $h)_B$ indicates that the predominant complexes may be written in the form $VO_2((OH)_tVO_2)_n$, and it has been shown that the best value of t (within the experimental limit of 1.50 ± 0.07) is 14/9, or 1.556. By plotting the data in the form $y(x)$, where

$$y = 9\ Z\ /\ 14 \tag{8a}$$

and

$$x = \log\ B - \frac{14}{9} \log\ h \tag{7a}$$

the separate curves may be made to coincide (see Fig. 8). Hence $s = 9$, and the system may be considered as a series of complexes $VO_2((OH)_{14}(VO_2)_9)_j$. The points for $x < 2.5$ fit the curve calculated for the first complex with $sj = N = 9$ (hypothesis II, Ref. [32]) in a position corresponding to log $\varkappa_{14,10} = -6.75 \pm 0.07$ for the complex $(VO_2)_{10}(OH)_{14}$. This conclusion has been reached by other methods; but the upper part of the curve $y(x)$ with $x > 2.5$ could now be interpreted in terms of continuous polymerisation.

Integration of the curve $y(x)$

Combining eqns. (5a), (8a) and (14) in Ref. [32], it may be shown that

$$\eta = \log \frac{B}{b} = \int_{-\infty}^{x} y\ dx + y\ \log\ e \tag{45}$$

The function $y(x)$ may be used to calculate

$$\log\ (1 + g) = \log\ (1 - y) + \eta \tag{46}$$

and

$$\log\ u = x - \eta \tag{47}$$

Here

$$g = \Sigma\ K_j u^{sj}, \qquad u = bh^{-t} \tag{48}$$

and K_j is the equilibrium constant for the reaction

$$(1 + sj)\ \mathrm{B} + sjt\mathrm{A} \rightleftharpoons \mathrm{B}(\mathrm{A}_{st}\mathrm{B}_s)_j \tag{49}$$

The average number, $\bar{j}$, of polynuclear links, $(\mathrm{A}_{st}\mathrm{B}_s)$, per complex is given by

$$\bar{j} = \frac{\Sigma\ j\ c_j}{\Sigma\ c_j} = \frac{\bar{n}}{s} = \frac{1}{s} \cdot \frac{\mathrm{d}\ \log\ g}{\mathrm{d}\ \log\ u} \tag{50}$$

$$\text{where } c_j = [\mathrm{B}(\mathrm{A}_{st}\mathrm{B}_s)_j] \tag{51}$$

As an alternative to finding $\bar{j}$ by graphical differentiation of the function $\log\ g$ ($s\ \log\ u$), it may be shown that

$$\bar{j} = \frac{y}{s\ (1 - y - 10^{-\eta})} \tag{52}$$

A smooth curve was drawn through the experimental points of Z / 1.556 plotted against ($\log B - 1.556\ \log h$), and a set of values of $\int_{-\infty}^{z} y\,dx$ was obtained by graphical integration. The residual integral $\int_{-\infty}^{0.35} y\,dx$ was assumed to be zero *cf.* Fig. 8. Corresponding values of $\log\ g$ and $\log\ u$ were calculated using eqns. (46) and (47), and are given in Table 7, together with values of $\bar{j}$, calculated from eqn. (52). The function $\bar{j}(x)$ is plotted in Fig. 9.

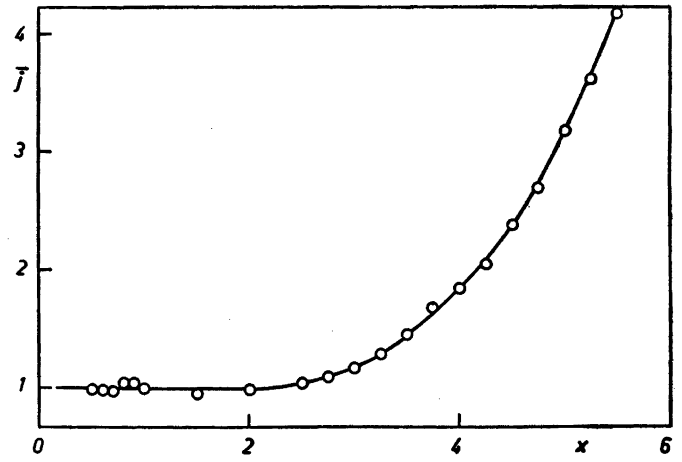

Fig. 9. The average number $\bar{j}$ *of* $((OH)_{14}(VO_2)_8)$ *links per complex as a function of* x.

Table 7. Integration of the smoothed curve $y(x)$.

3.75	0.936	2.427	1.629	0.917	1.67
4.00	0.942	2.661	1.827	0.930	1.83
4.25	0.948	2.898	2.022	0.940	2.04
4.50	0.955	3.136	2.201	0.949	2.38
4.75	0.960	3.375	2.393	0.958	2.68
5.00	0.966	3.616	2.566	0.964	3.17
5.25	0.970	3.858	2.802	0.970	3.60
5.50	0.974	4.101	2.939	0.976	4.17

Since $\bar{j}$ is approximately unity for $x<2.5$, the single complex $VO_2((OH)_{14}(VO_2)_9)$ predominates in this region. From eqn. (48)

$$\log K_1 = \log g - 9 \log u \tag{53}$$

whence the value

$$\log K_1 = \log \varkappa_{14,10} = -6.75 \pm 0.03$$

was obtained, in good agreement with values obtained by other methods.

Curve fitting of the function $y(x)$

It is evident from Fig. 9 that $\bar{j}$ increases to values >4 at $x = 5.5$ (corresponding to pcH $\sim$ 5 for 5×10^{-3} M vanadium). Thus within the accuracy that the data may be represented by a single curve $y(x)$, the "core + links" treatment would indicate that polymers containing at least 37 vanadium atoms are formed. This system may be described in terms of two parameters k_0 and k, provided that some assumption is made about the ratio of successive hydrolysis constants. For simplicity, attention is restricted to the hypothesis (IIIa, Ref.[32]) that this ratio is constant, and that complexes with all positive integral values of j may be formed. Sillén's treatment may be modified by defining

$$K_j = k_0 k^{sj} \tag{54}$$

and

$$V = v^s \tag{55}$$

where

$$v = ku = ka^t b \tag{56}$$

On the reasonable assumption that $|V| < 1$, then

$$g = k_0 \Sigma V^j = k_0 V (1-V)^{-1} \quad (57)$$

and

$$v \frac{dg}{dv} = sV \frac{dg}{dV} = sk_0 V (1-V)^{-2} \quad (58)$$

The coordinates of normalised curves $y(X)$ are found by substituting eqns. (57) and (58) into eqns. (8a) and (9a) of Ref.[32]. For convenience, the X coordinate is defined so that the family of curves $y(X)$ passes through the point (log 2, $\frac{1}{2}$). Then

$$y = sk_0 V [(1-V)^2 + k_0 V (1 + s - V)]^{-1} \quad (59)$$

$$X = x + \log 2 - x_{\frac{1}{2}}$$

$$= \frac{1}{s} \log V + \log [(1-V)^2 + k_0 V (1 + s - V)] - 2 \log (1-V) - \log sk_0$$

$$- (1 + \frac{1}{s}) \log V_{\frac{1}{2}} + 2 \log (1-V_{\frac{1}{2}}) \quad (60)$$

where

$$x_{\frac{1}{2}} = \log 2sk_0 - \log k + (1 + \frac{1}{s}) \log V_{\frac{1}{2}} - 2 \log (1-V_{\frac{1}{2}}) \quad (61)$$

and $V_{\frac{1}{2}}$ is given by eqn. (59) when $y = \frac{1}{2}$.

Hence the value of log k may be found from the x coordinate of the point ($x_{\frac{1}{2}}$, $\frac{1}{2}$) of the experimental curve $y(x)$, when the normalised curve $y(X)$ of the same shape has been found. The value of k_0 is that used to calculate the appropriate curve $y(X)$.

It would thus be incorrect to compare experimental curves $y(sx)$ for systems with non-integral values of t and in which continuous polymerisation is suspected, with normalised curves calculated on the assumption that t was integral. This procedure was inadvertantly used in an earlier paper on the hydrolysis of aluminium [49]. Families of curves are required for different values of s; when $s = 1$, eqns. (59), (60) and (61) reduce to equations given previously by Sillén [32]. As $k_0 \to 0$, the curves for all values of s tend to the limiting curve calculated [32] assuming that precipitation occurs, but that no complexes are detectable in solution (hypothesis I). As $k_0 \to \infty$ then each family of curves tends to a limiting curve calculated [32] assuming that a single species is present in solution (hypothesis II, $N = s$).

The normalised curve $y(X)$, calculated using eqns. (59) and (60) with $s = 9$ and $k_0 = 100$, is shown in the position of best fit in Fig. 8. From eqn. (61) the value of 9 log $k = -8.75$ is obtained, and hence from eqn. (54), log $K_1 = -6.75$, log $K_2 = -15.5$, log $K_3 = -24.25$ . . . . . The large value of k_0 implies that the formation of the first complex with $j = 1$ dominates the first stages of the reaction.

If more accurate experimental data in the range $Z > 1.3$ were available, it might be possible to distinguish between the hypothesis of a further hydrolysis of the first decavanadate ion $(VO_2)_{10}(OH)_{14}^{4-}$, and that of a repeated "core + links" mechanism. The former would give a single curve Z (log h), indepen-

dent of B, and the latter would give a single curve $y(x)$, also independent of B, in the region $1.4 \leq Z \leq 1.6$. However, although the repeated mechanism cannot be excluded with the present data, it appears to be physically much less plausible.

The authors are indebted to Professor Lars Gunnar Sillén for helpful discussions, to Professor Sillén and Civ.ing. Gösta Lagerström for communicating to them some methods of evaluating equilibrium constants prior to publication; to Docent Ingvar Lindqvist of Uppsala University and Dr. Howard T. Evans, Jr. of the U.S. Geological Survey for crystallographic data and to the *Swedish Natural Science Research Council* for financial assistance.

Studies on the Hydrolysis of Metal Ions

XVI. The Hydrolysis of the Beryllium Ion, Be^{2+}

HIDETAKE KAKIHANA* and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of the ion Be^{2+} has been studied by electrometric titrations at constant ionic medium (3 M ClO_4^-), using quinhydrone and hydrogen electrodes. A mathematical analysis was made of the curves Z (log h)$_B$ giving Z, the average number of OH bound per Be, as a function of log h, at various total beryllium concentrations B. It was concluded that the main product is $Be_3(OH)_3^{3+}$; for the equilibrium constant of the reaction $3Be^{2+} + 3H_2O \rightleftharpoons Be_3(OH)_3^{3+} + 3H^+$, $\log K_{33} = -8.66 \pm 0.03$ was obtained. No evidence was found of the complexes $(BeOH)_2^{2+}$ and $(BeOH)_4^{4+}$ proposed by previous workers.

Deviations at low values of B and Z indicate the presence of Be_2OH^{3+} and $Be(OH)_2$. The best value for the equilibrium constants were: $2Be^{2+} + H_2O \rightleftharpoons Be_2OH^{3+} + H^+$, $\log K_{12} = -3.24 \pm 0.02$; $Be^{2+} + 2H_2O \rightleftharpoons Be(OH)_2 + 2H^+$, $\log K_{21} = -10.9 \pm 0.2$. Slight deviations at $Z > 0.9$ where equilibrium is achieved very slowly may be due to precipitation or to higher complexes.

Solutions of beryllium salts are acidic, and Berzelius [1] noticed that a solution of beryllium sulfate can dissolve considerable quantities of beryllium hydroxide. Thus the existence of beryllium hydroxo or oxo complexes seems very probable. Several quantitative investigations of the hydrolysis of Be^{2+} have been reported. Most workers agree [2-10] that clear solutions can be obtained up to $Z = 1.0$ (Z = average number of OH^- bound per Be^{2+}). At higher values of Z, precipitation begins. With halogenide ions [2] it is completed by $Z = 2.0$. With other ions precipitation is complete by $Z = 1.8$ to 1.9, which indicates that in these cases the precipitate is not pure $Be(OH)_2$ but contains sulfate [2,8], nitrate [7] or perchlorate [7] ions as well.

The fact that the precipitate appears only when Z exceeds 1.0 suggests the formula $(BeOH)_n^{n+}$ for the soluble complexes. The main reaction would then be (*cf.* eqn. 4 below)

$$n\ Be^{2+} + n\ H_2O \rightleftharpoons (BeOH)_n^{n+} + n\ H^+;\ K_{nn} = [(BeOH)_n^{n+}]\ h^n[Be^{2+}]^{-n} \quad (1)$$

* Associate professor of chemistry, University of Nagoya, Japan

Prytz [2-4] has compared pH titrations carried out with different beryllium concentrations in the presence of various anions. Testing for $n = 1$ and $n = 2$, she found a variable value for K_{11} whereas K_{22} seemed to be fairly constant. The average value of 10^7 K_{22} was 1.4 for sulfate [2], 1.7 for chloride [2], 5.9 for bromide [3], and 4.4 for iodide [3] solutions. According to Prytz, the complex would then not be $BeOH^+$ but $(BeOH)_2^{2+}$ or Be_2O^{2+}; as usual, equilibrium data cannot distinguish between species containing different amounts of the solvent.

In connection with his work on metal ammine complexes, J. Bjerrum [5, p. 173] studied solutions containing Be^{2+} and NH_3 in 2 M NH_4NO_3. He concluded that his data should rather be explained by the formation of OH complexes than of NH_3 complexes. Following Prytz, he also assumed the equilibrium (1) with $n = 2$, but since his values of K_{22} varied, he suggested that in addition to Be_2O^{2+} also Be_2OH^{3+} and small amounts of a trimer are present.

From pH titration curves for total beryllium concentrations from 10 to 100 mM, and with the ionic medium 1 M $NaClO_4$ or 1 M KNO_3, Schaal and Faucherre [6,7] concluded that n should rather be 4. Teyssèdre and Souchay [8] made a mathematical analysis of the titration curves of 200 and 40 mM Be in 1 M Na_2SO_4 between $Z = 1.0$ (clear solution) and 1.9 (complete precipitation). They also concluded that $n = 4$ in the solution with $Z = 1$. Souchay [9] titrated $BeSO_4$ with NaOH in a solution saturated with Na_2SO_4, and measured the change in temperature of formation of solid $Na_2SO_4(H_2O)_{10}$. From these data he also concluded that $n = 4$. Faucherre [7] studied the depression of the NH_4NO_3-ice eutectic point in the presence of beryllium hydroxo complexes; no figures seem to be given, but he claims that the tetramer, with $n = 4$, is formed. Thus, according to the French workers, the predominant complex would be $(BeOH)_4^{4+}$ or $Be_4O_2^{4+}$.

The existence of ions $(BeOH)_n^{n+}$ is confirmed by the finding of Puche and Josien [10] that $Be(OH)_2$ dissolves in $Be^{2+}SO_4^{2-}$ solutions until the ratio OH/Be becomes 1, and by the thermometric titration of Haldar [11]. Ion exchange data obtained by Honda [12] were explained in terms of the species $(BeOH)_2^{2+}$ in solution. However, Honda's data may equally well be explained by assuming the presence of any species $(BeOH)_n^{n+}$.

Diffusion and conductivity measurements by Heukeshoven and Winkel [13] give an almost linear transition from Be^{2+} to the region with one OH per Be; these data give no evidence for complexes with less than one OH group per Be.

Using a glass electrode, Mattock[14] made "static" titrations of $Be(ClO_4)_2$ solutions of concentration from 1 mM to 30 mM, with NaOH using the ionic medium 1 M $NaClO_4$. He seems to have had considerable difficulties with irreversible equilibria, and his data differ in some respects from those obtained by ourselves and other workers. His conclusions are that there are rapid equilibria up to $Z = 0.5$ whereas the equilibria between $Z = 0.5$ and 1.0 are reached only after about two months at 25°C. Equilibrium constants are given for the formation of $BeOH^+$ and Be_2OH^{3+}: $[BeOH^+][H^+][Be^{2+}]^{-1} = (3 \pm 1) \cdot 10^{-7}$; $[Be_2OH^{3+}]\,[H^+][Be^{2+}]^{-2} = (3.1 \pm 0.6) \cdot 10^{-4}$.

From all other data, including our own, it seems that equilibrium is established very rapidly, as long as a clear solution is obtained. When a precipitate of $Be(OH)_2$ has already been formed, *e.g.* by local high pH, it can only be redissolved rather slowly, and the attainment of equilibrium is retarded. Mattock's equilibrium constants were calculated from data in the lowest pH region, where equilibrium was rapidly obtained, and his value for log K_{12} (−3.5) is in fair agreement with ours (−3.24).

The present work was carried out to throw a little more light on the hydrolysis of Be^{2+}, using the techniques previously developed in this laboratory [15-31].

Symbols

B	total concentration of Be
$\mathbf{B}$	normalized value of B (29)
b	concentration of free Be^{2+} (9a)
c_{pq}; c_n	concentration of complex $Be_q(OH)_p$ (4); of n:th complex (10)
E	emf; E_0 constant, E_j liquid junction emf (2)
F, F_r, F_q	functions of experimental data (7), (19), (22), (23)
g	defined in (9b)
H	total (analytical) excess concentration of H^+
h	concentration of free H^+
j	constant in $E_j = -jh$
k, k_0	constants in hypotheses "II" and "IIIa" (14) and ff
K_{nn} K_{pq},	equilibrium constants (1) (4)
k_n	$= K_{tn,\ n+1}$, equilibrium constants (9)
N	singular value of n in (1) or (9c); (14)
n	integer (1); number of links in "core + links" complex (9c)
$\bar{n}$	average number of links (10)
p_1, p_2	constant parameters to be determined (29)
p, q	integers: number of OH and Be in complex (4)
r	integer (19)
s_n	constants (18)
t	number of OH in "link" (5)
u	auxiliary functions (9a), (17) or (30)
X, Y	normalized x and y (29)
x, y	experimental functions (6a, b) or (28)
Z	average number of OH bound per Be
α	auxiliary function (29), (30)
δ	residual integral in (12)

In the calculations and especially in the equilibrium constants, M (mole/l) is used as unit throughout. Sometimes in the text or headings, however, the convenient unit mM (millimole/l) is used.

METHOD

The present investigation consisted of a series of potentiometric titrations at 25° C. In each titration, the total concentration of beryllium, B, was kept constant, while the total concentration of acid in the system was varied. All solutions were made to contain 3 M ClO_4^- by the addition of $NaClO_4$. Since the concentrations of hydrogen and beryllium ions were low, Be at most 48 mM, H^+ usually much less, compared with the concentrations $\approx$ 3 000 mM of Na^+ and ClO_4^-, it can be assumed with good approximation that the activity factors of all reacting species remain constant [17], and hence that true stoichiometric constants may be calculated from the measurements.

It would be desirable to know the concentrations of both free H^+ and free Be^{2+}. However, no electrode reversible to Be^{2+} is known, so the titrations were followed only by measuring h, the free hydrogen ion concentration. A quinhydrone electrode was used, in combination with the reference electrode

$$SE// = Ag \,/\, 0.01\ M\ AgClO_4,\ 2.99\ M\ NaClO_4 \,/\, 3\ M\ NaClO_4$$

To check that no error is introduced by the use of quinhydrone, the hydrogen electrode was used in a few titrations.

Thus the cells for measuring h may be written:

$$\mathrm{SE//H^+}\ (h),\ \mathrm{QH_2},\ \mathrm{Q/Pt} \qquad (25^\circ\,\mathrm{C})$$

or

$$\mathrm{SE//H^+}\ (h)\ /\ \mathrm{H_2(g)},\ \mathrm{Pd} \qquad (25^\circ\,\mathrm{C})$$

For each of these cells, the measured emf, E, is related to h by

$$E = E_0 + E_j + 59.16\ \log\ h \qquad (2)$$

Here E_0 is a constant, different for each type of cell, and E_j is the liquid junction potential [17], which is approximately given by $E_j = -jh$, where j is a constant, around 0.018 ± 0.001 mV $\mathrm{mM^{-1}}$. The values for E_0 and j were checked for each titration, either by a preliminary acid-base titration in the absence of beryllium, or by titration in the presence of a small amount of beryllium ($B = 1.00$ or 2.56 mM) in the range $0.1\ \mathrm{M} > h > 0.01\ \mathrm{M}$, where the hydrolysis is negligible.

When E_0 and j are known, and E is measured, h can be obtained from equation (2). From the composition of the solution, the total beryllium concentration B is known, and the analytical excess of hydrogen ions H can be obtained (assuming all beryllium to be present as $\mathrm{Be^{2+}}$). Z, the average number of OH per Be, may then be calculated for any point of the titration:

$$Z = (h - H)\ B^{-1} \qquad (3)$$

(part 8[20], eqn. 6; $[\mathrm{OH^-}]$ is negligible in all beryllium solutions studied here).

The data may conveniently be discussed in terms of the variation of Z with $\log h$.

EXPERIMENTAL DETAILS

Reagents

Beryllium perchlorate solutions were prepared as follows: Beryllium carbonate (Kebo puriss) was moistened with water and dissolved in dilute HCl, and sufficient water was added to make $[\mathrm{Be^{2+}}] \approx 0.1$ M and $[\mathrm{H^+}] \approx 0.1$ M. The solution was passed through a column containing the $\mathrm{H^+}$ form of the cation exchange resin, Amberlite IR-120. In the effluent beryllium was obtained completely free from impurities such as aluminium, iron and calcium, which have a far stronger affinity for the cation exchange resin than beryllium ion [33]. An excess of dilute $\mathrm{NH_3}$ was added dropwise to the effluent. The precipitate was centrifuged, dissolved in dilute $\mathrm{HNO_3}$ (p.a.), and reprecipitated with dilute $\mathrm{NH_3}$, freshly prepared from $\mathrm{NH_3}$ gas. This precipitate was again centrifuged, washed free from $\mathrm{NO_3^-}$ ions, and dried at 300°C for 12 hours. Each batch of the porous oxide contained about 2 % of water; it was divided into three portions.

The purity of the first portion was checked by the alizarin drop test for aluminium and the thiocyanate test for iron [33]; both tests were negative. The second portion was weighed and ignited at 1 200°C for 8 hours; the accurate content of BeO in the batch was obtained from the constant weight. The third portion was weighed and dissolved in a weighed excess of perchloric acid. The clear solution was completely transferred into a standard flask, and made up to a known volume. The concentration of beryllium in the solution was checked by gravimetric determination as BeO. The result agreed with the expected value within the experimental error. Dilute solutions of $\mathrm{Be(ClO_4)_2}$ for titration were prepared by weight.

Perchloric acid solutions were prepared from perchloric acid (p.a.) and standardized against potassium hydrogen carbonate (Merck p.a.) which was free from $\mathrm{Na^+}$, and had been dried in an atmosphere of $\mathrm{CO_2}$.

Sodium hydrogen carbonate solutions were prepared from the p.a. product of Merck. The concentrations were determined against standard $\mathrm{HClO_4}$, both by potentiometric titration using Gran's method for calculating the end-point [34], and by visual titration to the methyl-red end-point.

Sodium perchlorate was prepared by neutralising a solution of $HClO_4$ with $NaHCO_3$. The solutions were analysed by evaporating and drying to constant weight at 125°C. No chloride, chlorate, aluminium or iron could be detected in the product.

Silver perchlorate solutions were prepared by adding an excess of Ag_2O to a boiling solution of $HClO_4$. The solution was filtered, and the concentration of Ag^+ determined by Volhard's method.

Quinhydrone (Merck p.a.) was used without purification since no positive reaction was found for acid, alkali, or iron.

Apparatus

The titration cell was of the "Wilhelm" type described by Forsling, Hietanen, and Sillén [16]. It was kept in a paraffin oil thermostat, 25.0 ± 0.1°C, which was placed in a room thermostated at approximately 25°C.

In the cells with quinhydrone, a Pt foil was used as the inert electrode. It was first cleansed in HNO_3 (1:1), washed with water, and ignited in an alcohol flame. The hydrogen electrodes were lightly palladinated Pt foil [35]. The silver reference electrodes were first prepared as recommended by Brown [36] and then coated with AgCl by electrolysis for half an hour in 0.1 M HCl with a current of 0.3 mA per electrode. The emfs (E) were measured with a Jensen compensator, type 10A, or a Vernier potentiometer. Hundredths of a mV were estimated in each case.

The solutions were introduced into the titration cell from burets which had been calibrated by weighing, using 3 M $NaClO_4$ solution. When a quinhydrone electrode was used, the titration solution was stirred by means of nitrogen which had passed through 10 % H_2SO_4, 10 % NaOH, and 3 M $NaClO_4$ solutions. When a hydrogen electrode was used, the solution in the cell was stirred by a stream of hydrogen which had passed through a column filled with activated copper [37], and then through 10 % H_2SO_4, 10 % NaOH, and 3 M $NaClO_4$ solutions.

Titration procedure

In the following it will be tacitly understood that all solutions contained 3 M ClO_4^-, and in addition Na^+.

Preliminary titrations with NaOH (0.1 M) showed that local precipitation occurred. To avoid this, $NaHCO_3$ (Hedström [19]) was used as the base. To get preliminary values for E_0 and j (eqn. 2), 25.0 or 50.0 ml of 24.92 or 99.43 mM $HClO_4$ was titrated with 100.65 mM $NaHCO_3$. In the main experiments, eleven titrations were made with B = 48.7_4, $19{,}2_7$, 10.02_5, 5.05_7, 2.56_0, and 1.00 mM.

Almost all titrations were carried out as follows: 25.0 ml of "neutral medium" (3 M $NaClO_4$), or of 24.92 mM $HClO_4$ was added to 25.0 ml of a solution T_1, containing Be^{2+} (concentration 2 B) and H^+. This mixture, solution S, was titrated, always adding equal volumes of 100.65 or 30.25 mM $NaHCO_3$(T_2), and of solution T_1. In a few cases, the experiment was continued with a back titration, adding equal volumes of 24.92 mM H^+ and of solution T_1, to confirm that equilibrium had been obtained (see below). The total concentration of beryllium, B, always remained constant throughout the titration.

For the highest value of B, 48.7_4 mM, a different procedure was adopted. To 25.0 ml of a solution T_1, containing Be^{2+} (concentration 2 B) and 113.5 mM H^+, 25.0 ml of 100.65 mM $NaHCO_3$(T_3) was at first added in portions. This mixture was titrated with equal volumes of 264.0 mM $NaHCO_3$(T_3) and solution T_1.

At the end of one titration, with 10 mM Be, the equilibrium emf was noted, and the stream of nitrogen replaced by a stream of CO_2. The system was left for an hour, and then nitrogen was bubbled through the solution for two minutes. The emf was the same as before, indicating that the measurements are not invalidated by complex formation between beryllium and carbonate ions.

A steady E was usually attained within half an hour for $Z \leqq 0.8$, thus in the main part of the range studied. When hydrolysed solutions (with $Z \leqq 0.8$) were back-titrated with acid, the points $Z(\log h)$ fell on the same curve as points obtained by forward titration with HCO_3^-, indicating that the equilibria are reversible in this region. (Fig. 1, 19 mM and 48 mM). In solutions with $0.8 < Z < 0.9$, equilibrium was reached more slowly. A steady E was obtained within one or two hours, and remained constant for at least four

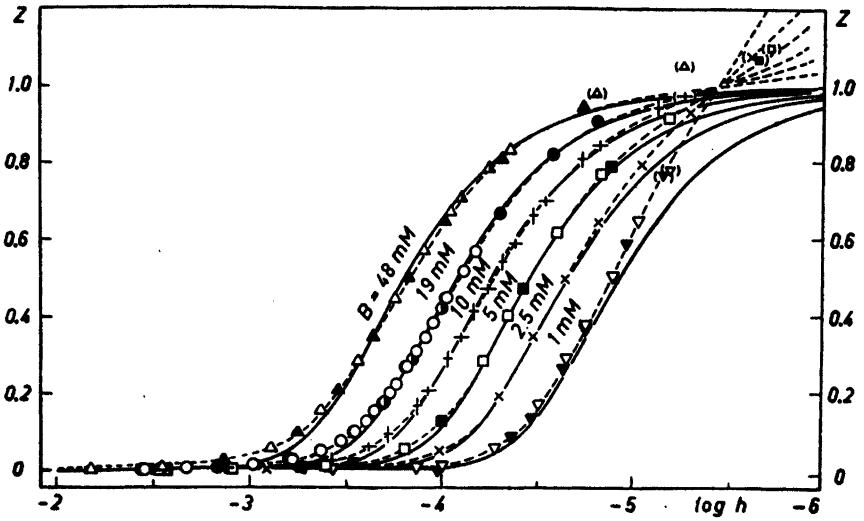

Fig. 1. Average number, Z, of OH bound per Be, as a function of log h. *All experimental points are given. Filled or open symbols represent points from different titrations, half-filled symbols from backtitrations. Total Be concentration B:* ▲ Δ ◭ *48.7, mM;* ● ○ ◑ *19.2, mM;* + *10.0, mM;* ■ □ *5.05, mM;* × *2.5, mM;* ▼ ▽ *1.00 mM. Hydrogen electrode used for* ● *and* ■, *quinhydrone for other symbols. Full curve: calculated for* $K_{21} = K_{12} = 0$, $\log K_{22} = -8.66$. *Broken curves: calculated for* $\log K_{12} = -3.25$, $\log K_{21} = -10.87$, $\log K_{22} = -8.66$.

hours. With $Z \geq 1$, E was always unsteady, even before a visible precipitate appeared, so that titration was discontinued. With the lowest metal concentration, $B = 1$ mM, a steady emf was only obtained up to $Z = 0.6$; with higher values of Z, E kept drifting even after three hours; it seems practically impossible to get accurate values in this region.

With hydrogen electrodes, the $Z(\log h)$ curves for $B = 19$ and 5 mM agreed, within 0.15 mV, with those obtained with quinhydrone electrodes throughout the whole region of hydrolysis (see Fig 1). Hence, there is no reason to assume an appreciable error due to beryllium-quinhydrone complexes.

THE MAIN PRODUCT OF HYDROLYSIS

Fig. 1 gives the data $Z(\log h)_B$, calculated from the potentiometric measurements, using eqns. (2) and (3). Table 1 gives the values of $\log h$ and Z for one titration at each of the six values of B, and for one titration with a hydrogen electrode. If only mononuclear complexes were formed, Z would be a function of h only, and all points would lie on the same Z ($\log h$) curve, regardless of the value of B. As this is not the case, at least one polynuclear hydroxo complex must be formed.

The polynuclear species may be written in the general form $Be_q(OH)_p^{(2q-p)+}$, where p and q are positive integers; we shall by K_{pq} denote the equilibrium constant of the reaction

$$pH_2O + qBe^{2+} \rightleftharpoons Be_q(OH)_p^{(2q-p)+} + pH^+, \quad K_{pq} = c_{pq}h^p b^{-q} \qquad (4)$$

* Values of back-titration.
** Hydrogen electrodes were used. ( ) no steady potential obtained.

A quite general method for computing the various K_{pq}, which has been suggested by Hedström [27] could not be used in the present work, since the data have not the extreme accuracy needed. Therefore, two other approaches were attempted: the "core + links" approach and the assumption that all complexes are $(BeOH)_n^{n+}$. When the main product of hydrolysis had thus been determined, the secondary products were considered.

"Core + links" approach

It has previously been found that the main hydrolysis products of a number of metal ions [20-23] may be written in a general "core + links" form $Me((OH)_tMe)_n$, where t is a constant, and n is a constant or variable integer; then $p = t\,(q-1)$. If all the complexes present in appreciable amounts can be written in such a "core + links" form, a set of parallel $Z(\log h)_B$ curves should be obtained [25, 20], and the value of t is given by

$$t = (\partial \log B / \partial \log h)_Z \qquad (5)$$

Indeed, the data in Fig. 1 for the hydrolysis of Be^{2+} seem to lie on parallel curves $Z\,(\log h)_B$, in the range $0.1 < Z < 0.8$. In Fig. 2, $\log B$ is plotted against $\log h$ for values of Z between 0.05 and 0.8. From the slope, and (5), a value of $t = 1.5$ may be obtained, neglecting the slight deviations at high and low values of Z.

Again, if only "core + links" species $Be((OH)_tBe)_n$ are formed, all experimental points should lie on the same curve $y\,(x)$ with the coordinates [26, 20]

$$x = \log B - t \log h; \quad y = Z / t \qquad (6a, b)$$

The experimental plot of $y = Z/1.5$ against $x = \log B - 1.5 \log h$ is shown in Fig. 3. It is seen that the points for 48 mM $\geqq B \geqq$ 5 mM lie on a single curve except these for very low values of Z. Small deviations are observed for the lowest values of B, 2.5 and 1 mM, which may indicate the presence of mononuclear complexes.

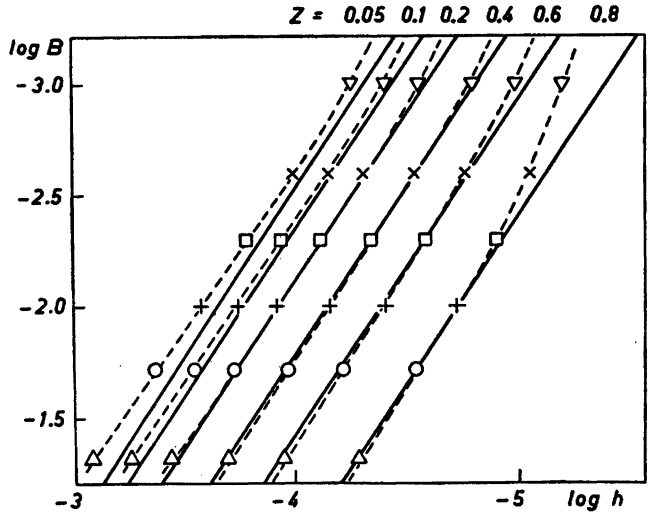

Fig. 2. Log B *as a function of log* h, *for different values of* Z. *Full lines are calculated for log* $K_{33} = -8.66$, *and no other complexes than* $(BeOH)_3^{3+}$. *Broken curves are calculated for same set of constants as in Fig 1; they also represent the best fit with the "normalized projection map" (29).*

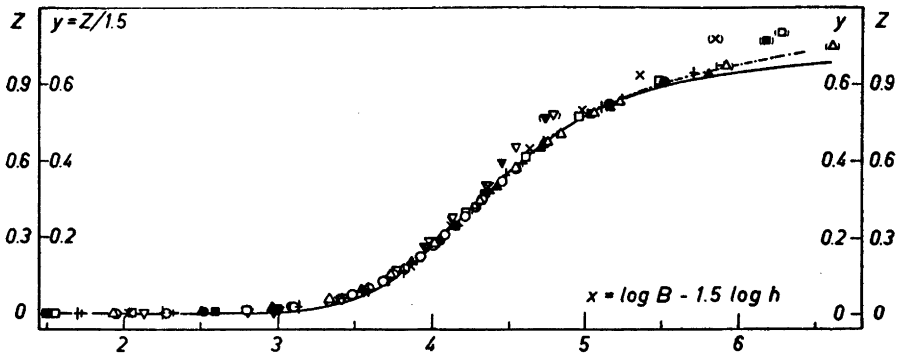

Fig. 3. Z, *or* y = Z/*1.5, as a function of* x = *log* B − *1.5 log* h. *All experimental points are shown using the same symbols as in Fig. 1. Full curve: calculated for log* $K_{33} = -8.66$; *dot-dash curve: calculated for log* $K_{33} = -8.68$, *log* $K_{56} = -19.14$ *etc (IIIa,* $k_0 = 60$).

Although these deviations for low values of Z or B seem to be beyond the experimental errors, it seems reasonable to postpone a discussion of them, and to start by discussing the main reaction in the range where the y (x) curves coincide for $t = 1.5$.

To test for the other values of t, plots were made of $Z/2$ against (log B − 2 log h), of $3Z/5$ against (log $B - \frac{5}{3}$ log h) and of $3Z/4$ against (log $B - \frac{4}{3}$ log h). With $t = 2$, the spread of the points was too severe. With $t = \frac{5}{3}$ and $\frac{4}{3}$, the spread of the points was not so bad as with $t = 2$, but far worse than with $t = 1.5$.

With $t = 1.5$, the complexes formed in appreciable amounts would be of the type $\mathrm{Be}((\mathrm{OH})_{1.5}\mathrm{Be})_n^{(2+0.5n)+}$. To decide whether n is a constant or a variable, the curve y (x) must be investigated further.

Direct analysis of the curve y (x)

It may be shown (AB II [26], eqns. 14 and 15) that from data y (x) one can calculate

$$\log F = y \log e + \int_{-\infty}^{x} y \, dx \qquad (7)$$

$$u = 10^x F^{-1}; \qquad g = F(1-y)-1; \qquad (8a, b)$$

where in our case

$$u = [\mathrm{Be}^{2+}]h^{-1.5} = bh^{-1.5}; \quad g = \Sigma k_n u^n \qquad (9a, b)$$

and k_n is the equilibrium constant for the reaction

$$(n+1)\mathrm{Be}^{2+} + 1.5\,n\,\mathrm{H_2O} \rightleftharpoons \mathrm{Be}((\mathrm{OH})_{1.5}\mathrm{Be})_n^{(2+0.5n)+} + 1.5\,n\,H^+; \quad k_n = K_{1.5n,n+1} \qquad (9c)$$

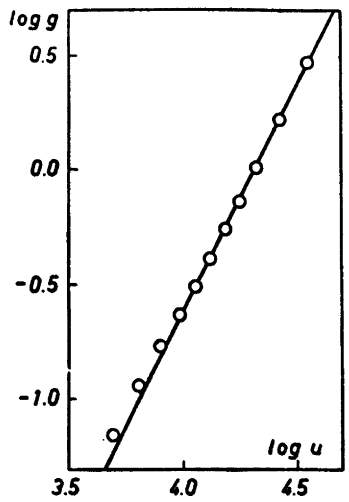

Fig 4. Direct analysis of the curve y(x) *in Fig. 3: log* g *as a function of log* u*, together with the best straight line of slope 2.*

(In passing we may note that $\log F = \log \frac{B}{b}$ and is thus identical with the quantity that has been denoted by η in other papers [20, 25 etc]).

The average number of $((OH)_{1.5}Be)$ links per complex is defined by

$$\bar{n} = \Sigma n c_n / \Sigma c_n \qquad (10)$$

where c_n is the equilibrium concentration of the complex with n links. One may calculate $\bar{n}$ either by differentiating log g (log u), or directly [29] from y and F:

$$\bar{n} = \frac{\mathrm{d}\ \log\ g}{\mathrm{d}\ \log\ u} = \frac{y}{1 - y - F^{-1}} \qquad (11a,\ 11b)$$

A smooth curve was drawn through the experimental points (y, x); where deviations occurred at low y, the lowest value of y was always used for each

value of x. By graphical integration from $x = 2$ and using (7), (8), and (11 b), the values of F, log g, log u and $\bar{n}$ in Table 2 were calculated. The residual integral

$$\delta = \int_{-\infty}^{2.0} y \mathrm{d}x \tag{12}$$

was assumed to be zero. In Fig. 4, log g is plotted against log u; a straight line of slope 2.0 was obtained in almost the whole range, which according to (11a) means that only the complex with $n = 2$, *i. e.* $Be_3(OH)_3^{3+}$, is formed. The same conclusion is drawn from the values for $\bar{n}$ calculated directly and given in Table 2. If the residual integral δ is assumed to be —0.05, a still better constancy of $\bar{n}$ is obtained. (Last two columns of Table 2). Since at low values of x there are also secondary reactions, we need not be surprised at a negative value of δ.

If higher complexes were formed, the slope d log g/d log u should increase with increasing log u; however, no such curvature can be observed in the region with $y \leqq 0.6$ ($Z \leqq 0.9$). In the range $y \leqq 0.25$, where $\bar{n}$ is very sensitive to small errors in y, a slight deviation from the straight line is observed, which may be due to the presence of other complexes.

If only the complex with $n = 2$ is formed, then from equation (9b)

$$\log g - 2 \log u = \log k_2 \tag{13}$$

and a value of log k_2 can be obtained for each point (log g, log u) from eqn. (13). The average values

$$\log k_2 = \log K_{33} = -8.64 \pm 0.02 \text{ (for } \delta = 0)$$
$$= -8.67 \pm 0.03 \text{ (for } \delta = -0.05)$$

were obtained using points in the range $0.25 \leqq y \leqq 0.60$ (Table 2).

Comparison with simple mechanisms

Following AB II [26] and part 8 of this series [20], the experimental curve $y(x)$, Fig. 3, was compared with families of cures $y(X)$, calculated for the simple mechanisms I—III. With hypothesis I (no soluble complex, precipitate formed), no agreement was found.

With hypothesis II (only one complex formed, with $n = N$), only $N = 2$ gave an acceptable agreement in the main part of the curve (even then small deviations were seen for high and low values of y) (Fig. 3). This agreement again makes it very probable that the main complex is $Be_3(OH)_3^{3+}$. Thus we may apply AB II[26], eqn. (24).

$$x_{\frac{1}{2}} = \log 2 - \log k + \log N - (1 + N^{-1}) \log (N - 1) = \log 4 - \log k \tag{14}$$

From the value $x_{\frac{1}{2}} = 4.93 \pm 0.015$, where $y = \frac{1}{2}$, eqn. (14) gives log k = —4.33 ± 0.015. Since the equilibrium constant $k_2 = k^2$, we find

$$\log k_2 = \log K_{33} = -8.66 \pm 0.03$$

With a repeated mechanism like IIIa, the equations in AB II[26] must be modified because n must be even to give an integral number of atoms per complex. Curves were constructed of the $y(X)$ functions calculated for the modified hypothesis IIIa and various values of k_0. Suitable equations are given in the appendix of a paper of Rossotti and Rossotti [31]. For $k_0 \approx 60$, the agreement for high values of y was improved (dot-dash curve in Fig. 3). For $y < 0.53$ ($Z < 0.8$) the curve practically coincides with the full curve for a single complex; the first complex $Be_3(OH)_3^{3+}$ would predominate over all the following complexes $Be((OH)_3Be_2)_{\frac{1}{2}n}^{(\frac{1}{2}n+2)+}$, with $n = 4$, 6 etc. Since the equilibria are very slow for high Z, we do not consider the existence of the higher complexes as certain. The value obtained for log K_{33}, -8.68 ± 0.03, is the same as with other methods.

Although they do not give coincident curves, the experimental diagrams $y(x)$, assuming $t = \frac{4}{3}$ and $\frac{5}{3}$, were also compared with calculated curves for mechanisms I, II and IIIa. No agreement could be found.

Approach assuming polymers $(BeOH)_n^{n+}$

It is remarkable that the present work has indicated $(BeOH)_3^{3+}$ as the main product, whereas previous workers have decided upon either $(BeOH)_2^{2+}$ (Prytz [2-4]), or $(BeOH)_4^{4+}$ (Faucherre [6,7], Souchay [8,9]). It thus seemed worthwhile to test the assumption that all complexes formed are of the general formula $(BeOH)_n^{n+}$. This approach might give an independent check on our conclusion about the main complex ($n = 3$), and also test to what extent complexes $(BeOH)_n^{n+}$ with $n = 2$ or 4 might be formed. (These complexes would not be covered by the "core + links" formula with $t = 1.5$.)

We shall develop this approach along lines given in AB I[25], p. 313. If we have a series of equilibria

$$n\ Be^{2+} + n\ H_2O \rightleftharpoons (BeOH)_n^{n+} + n\ H^+;\ [(BeOH)_n^{n+}] = K_{nn}b^n h^{-n} \quad (1)$$

we find

$$BZ = \Sigma\, nK_{nn}b^n h^{-n};\quad B = b + \Sigma\, nK_{nn}b^n h^{-n} \quad (15)$$

hence

$$b = B\ (1 - Z) \quad (16)$$

We introduce the auxiliary variable u and a series of constants s_n:

$$u = bh^{-1};\ s_n = nK_{nn} \quad (17)$$

From (15), (16) and (17) we obtain

$$BZ = \Sigma\, s_n u^n;\quad u = B(1-Z)h^{-1} \quad (18)$$

We may find the constants s_n by the aid of a family of functions F_r which can be obtained from the experimental data:

$$F_r = BZu^{-r} = BZ[B(1-Z)h^{-1}]^{-r} = \Sigma\, s_n u^{n-r} \quad (19)$$

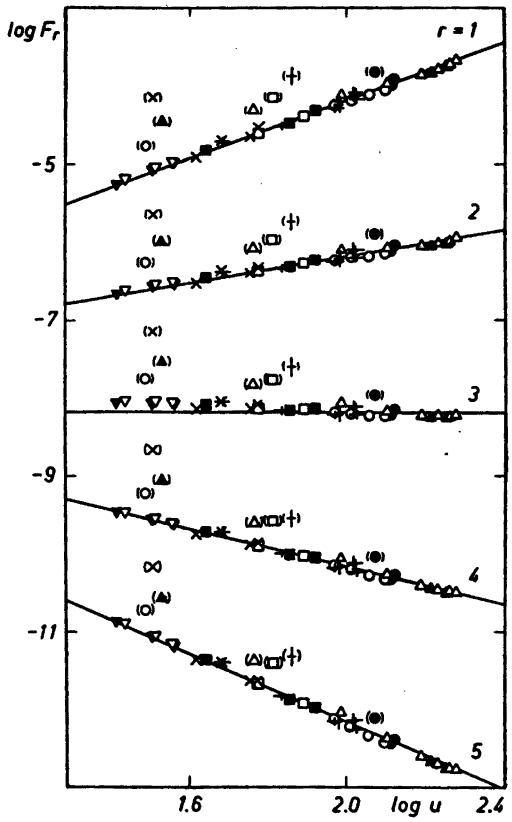

Fig 5. Log F_r, *eqn (19), for* r = *1 to 5, as functions of log* u, *eq (18), and best lines of slope 3 — N. About one half of the experimental points, which were chosen at random, are given.*

If only one complex $(BeOH)_N^{N+}$ is formed, log $F_N(\log u)$ should be a horizontal line at log $F_N = \log s_N$.

Fig. 5 gives plots of log F_1 to log F_5 against log u. Indeed, log F_3 gives a horizontal line, indicating that the main complex formed in the solution is $(BeOH)_3^{3+}$, but not $(BeOH)_2^{2+}$ or $(BeOH)_4^{4+}$. If the two latter complexes were present in appreciable amounts, (19) would give $F_3 = s_2u^{-1} + s_3 + s_4u$. One would then expect the log F_3 plot to form a single curve, independent of B, with upward bends at one or both ends. This is, however, not observed. There are deviations at $Z < 0.15$ and $Z > 0.9$, but they are not independent of B and should be due either to experimental errors (the function in rather sensitive to small errors) or to other complexes than the polymers $(BeOH)_n^{n+}$.

From the constant value of log $F_3 = \log 3 + \log K_{33}$ we obtained

$$\log K_{33} = -8.68 \pm 0.05$$

Likewise, from the straight lines log $F_1 = \log s_3 + 2 \log u$ and log $F_2 = \log s_3 + \log u$, the same value was obtained from both lines

$$\log K_{33} = -8.66 \pm 0.05$$

Conclusion on K_{33}

For the main reaction, $3\ Be^{2+} + 3\ H_2O \rightleftharpoons Be_3(OH)_3^{3+} + 3\ H^+$, the equilibrium constant K_{33} has been found by a number of methods, which give values that agree very well:

Method	log K_{33}	
Direct analysis	-8.64 ± 0.02	($\delta = 0$); -8.67 ± 0.02 ($\delta = -0.05$)
Curve-fitting	-8.66 ± 0.03	(hyp. II); -8.68 ± 0.03 (IIIa, $K_0 = 60$)
Polymer approach	-8.66 ± 0.05	(F_1 or F_2); -8.68 ± 0.05 (F_3)
Normalized proj.map (see below)	-8.65 ± 0.03	

As an average we may use the value log $K_{33} = -8.66 \pm 0.03$.

THE SECONDARY REACTIONS

Although the main part of the Z (log $h)_B$ curves is compatible with the existence of a single complex $Be_3(OH)_3^{3+}$, there are deviations, especially at low values of Z and B, indicating the presence of secondary products. To find the formulas of these products we shall use a method which will be discussed by Kakihana [38] in a subsequent paper.

Formulas of complexes

Let us first assume that besides $Be_3(OH)_3^{3+}$ there is only one more complex, $Be_q(OH)_p$, and try to find the values of p and q. The equilibrium constants of formation are K_{pq} and K_{33} and

$$B = [Be^{2+}] + q[Be_q(OH)_p] + 3[Be_3(OH)_3] = b + qh^{-p}b^qK_{pq} + 3h^{-3}b^3K_{33} \quad (20)$$

$$BZ = ph^{-p}b^qK_{pq} + 3h^{-3}b^3K_{33} \quad (21)$$

For small values of Z, where the deviations are most pronounced, we may approximately set $b \approx B$ in (21) and study the function

$$F = Zh^3B^{-2} - 3K_{33} \approx ph^{3-p}B^{q-3}K_{pq} \quad (22)$$

Fig. 6 gives a plot log h(log $F)_B$ calculated using log $K_{33} = -8.66$. As h increases the curves tend to straight lines with d log F/d log $h = 3 - p = 2$;

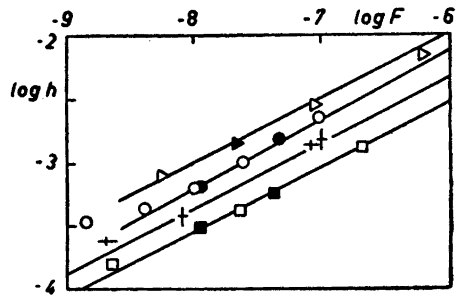

Fig 6. Log F, *eqn.* (22) versus *log* h. *Straight lines of slope* ½, *calculated with log* $K_{11} = -3.25$. *All experimental points are given within the range shown.*

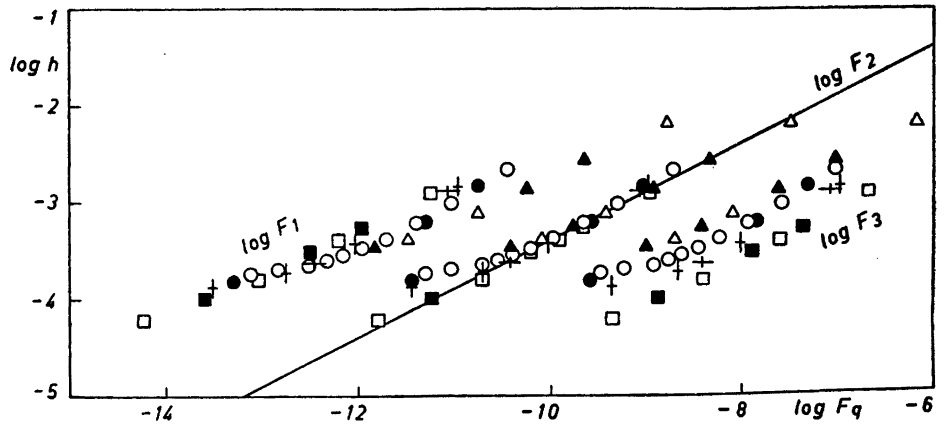

Fig 7. Log F_1, *log* F_2, *and log* F_3, *eqn. (23)* versus *log* h. *Straight line: log* h (*log* F_2) *calculated using log* $K_{12} = -3.25$. *All experimental points are given within the range shown.*

from the spacing between the lines for various values of B, between 48.74 and 5.06 mM, we may calculate $q - 3 = -1.0$. Changes in log K_{33} by $\pm$ 0.03 do not affect the values obtained for p or q.

We might then conclude that the most important complex in this range, next to $Be_3(OH)_3^{3+}$, is Be_2OH^{3+}; from the position of the curves in Fig. 6 we may calculate log $K_{12} = -3.25 \pm 0.07$.

To check this result we may try another approximation in (21), namely $b \approx B(1-Z)$; in fact in most of our solutions $B > b > B(1-Z)$. We may then study the function

$$F_q = [Z(1-Z)^{-3}h^3B^{-2} - 3K_{33}][B(1-Z)]^{3-q} \approx pK_{pq}h^{3-p} \qquad (23)$$

We have inserted in turn $q = 1, 2, 3$ and used the data to plot in Fig. 7 log F_q *versus* log h. With $q = 2$ the data with B between 5 and 48 mM fitted a straight line with d log F_2/d log $h = 3$ — $p = 2.0$. With $q = 1$ or 3, points with different values of B spread out considerably. Thus we once more conclude $p = 1$ and $q = 2$; the position of the line gives log $K_{12} = -3.25 \pm 0.05$.

It still remains to explain the deviations as to the two lowest values of B, 2.56 and 1.00 mM. The only reasonable explanation (besides experimental errors) would be the presence of one or more mononuclear complexes $Be(OH)_n$. We would then have

$$BZ = \Sigma n[Be(OH)_n] + [Be_2OH] + 3[Be_3(OH)_3] = \Sigma nh^{-n}bK_{n1} + h^{-1}b^2K_{12} + 3h^{-3}b^3K_{33} \qquad (24)$$

Again, we may approximately set $b \approx B(1-Z)$ in (24) and calculate the function $F = Z(1-Z)^{-1} - K_{12}(1-Z)h^{-1}B - 3K_{33}(1-Z)^2h^{-3}B^2 \approx \Sigma nK_{n1}h^{-n}$ (25)

Inserting the previously determined values of log $K_{33} = -8.66$ and log $K_{12} = -3.25$, in (25) log F was calculated as a function of log h (Fig. 8).

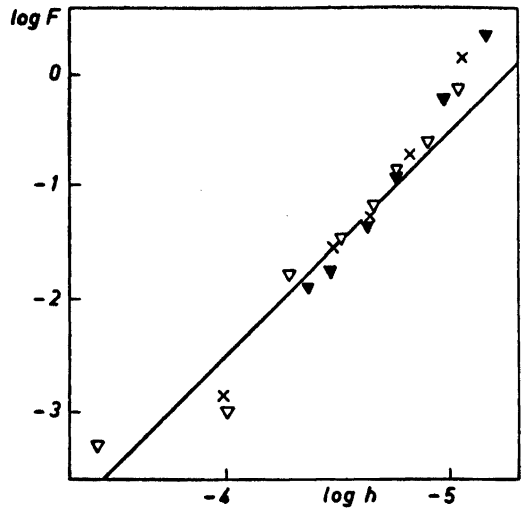

Fig 8. Log F, *eqn. (25), as a function of log* h. *Straight line: calculated for* $K_{11} = 0$, *log* $K_{21} = -10.8$.

Even up to $Z \approx 0.65$, the points seem to fall on a straight line of slope —2, in a position corresponding to log $K_{21} = -10.8$. We may conclude that the main mononuclear complex formed is $Be(OH)_2$; however, the spread of the data certainly does not permit one to exclude the presence of small amounts of $BeOH^+$.

This is not so surprising. For several ions, mercury(II) [15], thallium(III) [18], iron(III) [19], indium(III) [23, 24] the intermediate complex MOH has a remarkable tendency to split up to M and $M(OH)_2$, in marked contrast to the intermediate ion of most dibasic acids.

Calculation of equilibrium constants with normalized projection maps

Now that the formulas of the main and secondary products of hydrolysis were known, we set out to refine the values of the constants, using the method of normalized projection maps for three-variable data [30, 28].

In the present case, the quantities directly measured are h, B, and Z. We have

$$B = b + K_{21}h^{-2}b + 2K_{12}h^{-1}b^2 + 3K_{33}h^{-3}b^3 \tag{26}$$

$$BZ = 2K_{21}h^{-2}b + K_{12}h^{-1}b^2 + 3K_{33}h^{-3}b^3 \tag{27}$$

It is convenient to compare projection maps $y(x)_Z$ of the experimental variables

$$x = -\log h; \qquad y = \log B \tag{28}$$

with calculated normalized projection maps $Y(X)_z$ of the normalized variables

$$X = \log a = -\log h + p_1; \quad Y = \log B = \log B + p_2 \tag{29}$$

From the best fit of the maps one may obtain $X—x = p_1$ and $Y—y = p_2$. We shall introduce the auxiliary variables ("normalized h^{-1} and b")

$$a = h^{-1} \cdot 10^{p_1}; \quad u = b \cdot 10^{p_2} \tag{30}$$

In order to get simple formulas for calculation, we want to choose the constants p_1 and p_2 so that all equilibrium constants are eliminated except for a constant k, which replaces the smallest correction term K_{21}. We thus set

$$B = B \cdot 10^{p_2} = u + ka^2u + 2au^2 + 3a^3u^3 \tag{31}$$

$$BZ = 2ka^2u + au^2 + 3a^3u^3 \tag{32}$$

Inserting (30) into (31) and comparing with (26) we find

$$\log K_{33} = 3p_1 + 2p_2; \quad \log K_{12} = p_1 + p_2; \quad \log K_{21} = 2p_1 + \log k \tag{33}$$

To construct the necessary graphs $Y(X)_Z$ we used the formulas, derived from (31) and (32).

$$(2—Z)B = u(2 + 3au + 3a^3u^2) \tag{34}$$

$$Z = 2 - (2 + 3au + 3a^3u^2)\ (1 + ka^2 + 2au + 3a^3u^2)^{-1} \tag{35}$$

Auxiliary diagrams were constructed: $\log [(2—Z)B]$ $(\log u)_a$ which is independent of k, and Z $(\log u)_a$ for a number of different values of k. From these diagrams, $Y(X)_Z$ or $\log B$ $(\log a)_Z$ was constructed for various values of k, namely $10^7k = 0$, 2, 3, 5 and 10.

The best agreement was found for $k = 3.10^{-7}$, thus $\log k \approx -6.5_3$. In the position of the best fit, the parameters were

$p_1 = \log a + \log h = -2.17 \pm 0.01$; $p_2 = \log B - \log B = -1.07 \pm 0.01$; $\log k = -6.5_3 \pm 0.2$

whence with (33)

$\log K_{33} = 3p_1 + 2p_2 = -8.65 \pm 0.03$.
$\log K_{12} = p_1 + p_2 = -3.24 \pm 0.02$
$\log K_{21} = 2p_1 + \log k = -10.9 \pm 0.2$.

The value for $\log K_{33}$ agrees well with the average —8.66 obtained by several methods in the previous sections. Also the values for $\log K_{12}$ and $\log K_{21}$ are in good agreement with the values obtained from the diagrams in Figs. 6—8. We shall accept the values for $\log K_{12}$ and $\log K_{21}$ from the projection maps as our final values.

The dashed curves Z $(\log h)_B$ in Fig. 1 were calculated with $\log K_{33} = -8.66$, $\log K_{12} = -3.25$ and $\log K_{21} = -10.87$, thus practically the final set of constants K_{33}, K_{12} and K_{21}. The agreement seems to be as good as can be expected except in the region with $Z > 0.9$. However, in this region the equilibrium emf was obtained much more slowly than for lower values of Z, which may be explained by the presence of either higher species (*e. g.* according to hypothesis IIIa above), or of an invisible precipitate; both might give rise to

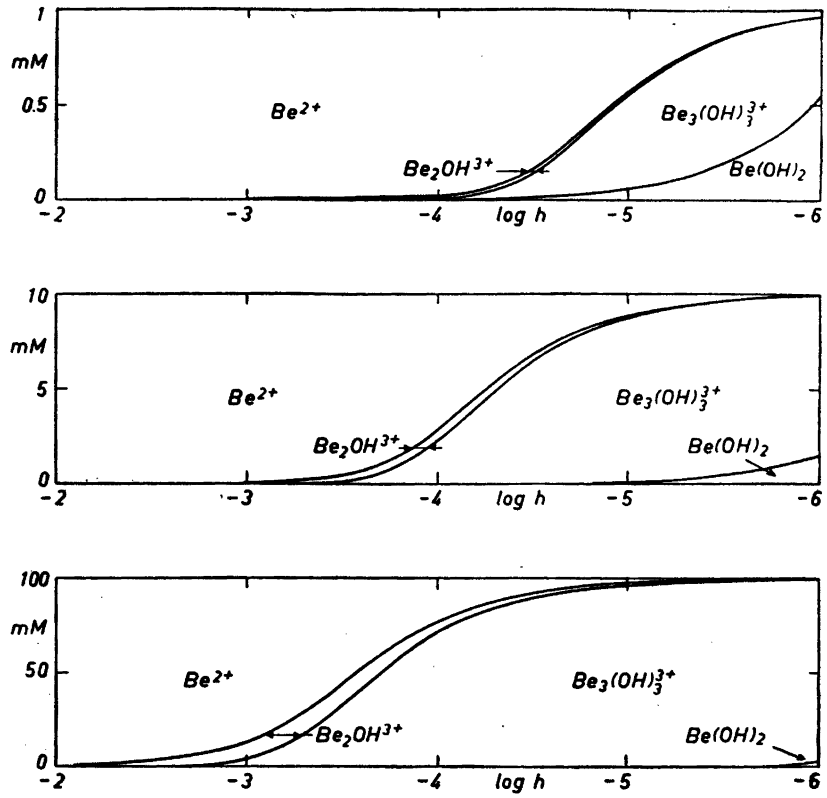

Fig 9. Distribution of complexes for total beryllium concentration B = 1, 10, and 100 mM, as a function of log h. *If a vertical line is drawn for a given value of* h, *the segment of this line falling in a certain area, e.g.* Be_2OH^{3+}, *represents the concentration of Be present as this complex in the solution at equilibrium.*

the slight positive deviation in the observed value of Z. The accuracy of the present work does not permit any certain conclusion.

Fig. 9 shows the distribution of the total beryllium over the various species, as a function of log h, for the total concentrations B = 1 mM, 10 mM and 100 mM, assuming the equilibrium constants obtained here.

ON THE STRUCTURE OF THE COMPLEXES

Four-coordination of Be^{2+}

Two- or three-coordinated beryllium occurs in some organoberyllium compounds like $Be(C_6H_5)_2$ and $Be(C_6H_5)_3^-$, but with O and F, the coordination always appears to be tetrahedral. The proof of this is to be found in certain simple crystal structures, since beryllium is light and thus rather difficult

to locate with X-ray methods. For complicated structures, it has generally been taken for granted that Be is in the centre of a BeO_4 or BeF_4 tetrahedron.

Phenakite, Be_2SiO_4, has a rhombohedral structure built up of SiO_4 and BeO_4 tetrahedra [39]; Be_2GeO_4 is isomorphous [40]. The structure of hambergite, Be_2BO_3OH, is built up of BO_3 triangles and BeO_3OH tetrahedra, sharing corners [41]. In β-$Be(OH)_2$, each Be is surrounded [42] by a somewhat distorted tetrahedron of 4 OH. The structure of $BeSO_4(H_2O)_4$, is built up [43] of tetrahedra $Be(H_2O)_4^{2+}$ and SO_4^{2-}. The stable complexes with organic acids, $Be_4O(OCOR)_6$, where R = CH_3, C_2H_5, C_6H_5 etc., have a symmetrical structure [44] with a central O surrounded by 4 Be. Each Be is in contact with the central O, and with 3 O from three different RCOO groups. The two oxygen atoms of a RCOO group are parallel with an edge of the Be_4 tetrahedron and in contact each with one Be.

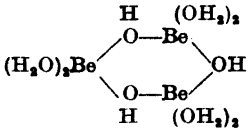
With the exception of these volatile substances, which are rather rapidly hydrolysed by water, with the formation of RCOOH, and the rather special Be_2BO_3OH, no structures of beryllium hydroxo- or oxo-compounds seem to be known that would give an easy clue to the structure of the soluble complexes.

In the fluoride complexes, Be and F are very often found to give compounds isomorphous to corresponding compounds with Si and O. For instance, BeF_2 seems to be isomorphous with cristobalite [45], $BaBeF_4$ with $BaSO_4$ [46], the five forms of Na_2BeF_4 with different forms of Ca_2SiO_4 (Thilo and Liebau [47]), and $NaBeF_3$ with β-$CaSiO_3$ [48]. It may thus be expected that the structures contain BeF_4 tetrahedra connected by sharing corners (but not edges), just like the SiO_4 tetrahedra in the corresponding silicon compounds.

Similarly, in Be-OH complexes one may expect the BeO_4 tetrahedra to share corners but not edges.

In the older literature, a number of "basic" beryllium salts have been described. Later work has thrown considerable doubt on their existence as well-defined compounds [49]. Slavvo [50] has recently prepared halogenomercurates as hygroscopic crystals. In addition to $Be(H_2O)_5HgCl_4$ and $Be(H_2O)_5HgBr_4$, he also prepared crystalline $BeOH(H_2O)_2HgCl_3$, $BeOH(H_2O)_2HgBr_3$, and $Be_3(OH)_3(H_2O)_6Hg_2I_7$. It is interesting to note that the three last mentioned salts may all contain the ringshaped complex $Be_3(OH)_3(H_2O)_6^{3+}$ proposed below.

Possible structure of the hydrolysis products



From what is known on the structure of other beryllium compounds it seems reasonable that the complex Be_2OH^{3+} consists of two BeO_4 tetrahedra, sharing a corner, which is very probably OH. The complex would thus be: $(H_2O)_3BeOHBe(OH_2)_3$

The mononuclear complex $Be(OH)_2$ is probably also a tetrahedron, $(H_2O)_2Be(OH)_2$. There is, however, a possibility that the molecule may be linear, forming *sp* bonds: HOBeOH. Alternation between tetrahedral to linear coordination may occur in some Hg^{2+}-complex systems [51] and might be related to the unusually small stability of the complex with one ligand.

The equilibrium constant for the formation of the main complex, $Be_3(OH)_3^{3+}$ from the mono- and dinuclear complexes is

$Be_2OH^{3+} + Be(OH)_2 \rightleftharpoons Be_3(OH)_3^{3+}$; $K_{33}K_{12}^{-1}K_{21}^{-1} = 10^{5.5}$.

The very high value of this constant, and the predominance of $Be_3(OH)_3^{3+}$ make it extremely unlikely that this complex would have an open chain structure. The most likely structure seems to be a six-membered ring, three tetrahedra being linked by sharing OH corners:

If the tetrahedra are filled out with water, one would get the formula $Be_3(OH)_3(OH_2)_6^{3+}$, which corresponds very well to the formulas of the halogenomercurates prepared by Slavvo [50].

This work is part of a program, financially supported by *Statens Naturvetenskapliga Forskningsråd* (*Swedish Natural Science Research Council*) and *Atomkommittén* (*Swedish Atomic Energy Committee*). We are indebted to Dr. George Biedermann for valuable advice, to Dr G. Mattock for giving us access to his primary data, to Drs. Francis and Hazel Rossotti for discussions of the manuscript and to Mr Frans Ericson for practical aid in many ways.

The Reaction between Phenols and Orthoesters. A New Synthesis of Aryl Alkyl Ethers

BENGT SMITH

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

It has been shown that alkyl orthocarbonates and phenols react under very mild conditions with the formation of aryl alkyl ethers. The reaction between phenols and ethyl orthoacetate and ethyl orthoformate was also studied in some detail. Only by the former reaction were aryl alkyl ethers formed as the ultimate products.

In an attempt to prepare some carbon analogues of the phenoxyalkoxysilanes from alkyl orthocarbonates and phenol it was found that the reaction produced phenyl alkyl ethers, dialkyl carbonates, and alcohols instead of the expected phenyl alkyl orthocarbonates.

$$(RO)_4C + C_6H_5OH \rightarrow C_6H_5OR + (RO)_2CO + ROH \quad (1)$$

This reaction seems, with certain exceptions, to be a general one for phenols. The yield of ethers from phenol is good (80—90 %), but methyl groups in the *ortho* position to the hydroxyl group diminish the yield appreciably. In the case of 2,6-di-*tert.*-butyl-*p*-cresol no reaction took place. This is certainly caused by the shielding of the hydroxyl group by the butyl groups.

Among the dihydric phenols investigated resorcinol reacted regularly yielding the mono- and diethers while no ethers were formed in the reaction between pyrocatechol and methyl orthocarbonate. Instead *o*-phenylene dimethyl orthocarbonate resulted.

$$C_6H_4(OH)_2 + (CH_3O)_4C \rightarrow C_6H_4\begin{smallmatrix}O\\ \diagup\ \diagdown\\ O\end{smallmatrix}C(OCH_3)_2 + 2CH_3OH \quad (2)$$

The mode of reaction between phenols and some other types of orthoesters was also examined in some detail. Phenol and ethyl orthoacetate reacted with the formation of phenyl diethyl orthoacetate

$$CH_3C(OC_2H_5)_3 + C_6H_5OH \rightarrow CH_3C(OC_6H_5)(OC_2H_5)_2 + C_2H_5OH \quad (3)$$

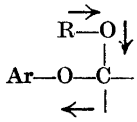
and a small amount of diphenyl ethyl orthoacetate. Depending on the conditions used for the synthesis smaller or larger amounts of decomposition products were also formed.

Phenyl diethyl orthoacetate was previously prepared by McElvain and Kundiger [1] from ketene diethyl acetal and phenol. They reported that it decomposed on distillation at atmospheric pressure yielding phenetole and phenyl acetate *. The phenetole and the ethyl acetate probably originate from the reaction **.

$$CH_3C(OC_6H_5)(OC_2H_5)_2 \rightarrow C_6H_5OC_2H_5 + CH_3COOC_2H_5 \quad (5)$$

The particular reactions by which the ethyl alcohol, phenol and phenyl acetate are formed are obscure as yet. The reaction between *p*-nitrophenol and ethyl orthoacetate furnished directly *p*-nitrophenetole in fair yield. This result is in accordance with the observation made by McElvain and Kundiger [1] that aryl alkyl ethers were formed in high yields from ketene diethyl acetale and phenols with negative substituents, while no aryl diethyl orthoacetates could be isolated.

Phenol reacted with ethyl orthoformate in much the same way as with ethyl orthoacetate; the main product being phenyl diethyl orthoformate. Contrary to the decomposition of phenyl diethyl orthoacetate the phenyl diethyl orthoformate yielded no phenetole on distillation at atmospheric pressure. Only ethyl formate, ethyl alcohol, and a black brittle resin were isolated.



The course of the reaction between phenols and ethyl orthoacetate throws some light on the related reaction between phenols and alkyl orthocarbonates. It must be assumed that a labile phenyl alkyl orthocarbonate is formed,

$$C_6H_5OH + (RO)_4C \rightarrow [C_6H_5OC(OR)_3] + ROH \quad (6)$$

which decomposes according to eqn. 7 ***

$$[C_6H_5OC(OR)_3] \rightarrow C_6H_5OR + (RO)_2CO \quad (7)$$

The instability of a structure containing one aryloxy group and three alkoxy groups bonded to a carbon atom must be due mainly to the presence of the aryloxy group since alkyl orthocarbonates are quite stable compounds at moderate temperatures. The resonance in the aryloxy group is likely to originate an electron displacement in the manner denoted by the arrows in the following formula,

* No mention is made in the cited paper of the simultaneous formation of ethyl alcohol, phenol, and ethyl acetate. (See the experimental part).

** In an attempt to prepare ketene acetals by thermal decomposition of orthoesters at 250—300°, Staudinger and Rathsam [2] observed the following reaction

$$RC(OC_2H_5)_3 \rightarrow C_2H_5OC_2H_5 + RCOOC_2H_5 \quad (4)$$

for ethyl orthoformate, ethyl orthoacetate and ethyl orthopropionate.

*** In 1911 Einhorn and Rothlauf [3] snowed that certain aryl alkyl ethers could be prepared from the corresponding aryl alkyl carbonates (ArOCOOR) by heating them to 200—300° for long periods.

thereby causing the decomposition according to eqn. 7. The proximity of the R-group and the oxygen atom of the aryloxy group is probably also of significance for the decomposition. The existence of phenyl diethyl orthoacetate and the corresponding orthoformate shows that the stability increases when a methyl group or a hydrogen atom is substituted for an ethoxy group in the hypothetic phenyl triethyl orthocarbonate. This fact can be ascribed to the increased electron density at the central carbon atom, whereby the electron withdrawal from the R-group is opposed. Again, the presence of a *p*-nitro group on the benzene ring enhances the pull exercised by the aryloxy group on the electrons, thus making the *p*-nitrophenyl alkyl orthoester (*e. g.* orthoacetate) more susceptible to decomposition.

Orthoesters and especially alkyl orthocarbonates might be valuable in certain instances as alkylating agents for phenols because of the mild conditions under which the reaction proceeds. The orthocarbonates may be prepared conveniently from thiocarbonylperchloride (Cl_3CSCl) and sodium alkoxides [4].

It is interesting to note the difference in their reaction with phenols of alkyl orthocarbonates and the corresponding organosilicon compounds, the tetraalkoxysilanes. In the latter case quite stable aryloxyalkoxysilanes are formed; no thermal decomposition of these compounds has been observed [5]. A contributive reason for this circumstance is, undoubtedly, the non-existence of compounds with silicon-oxygen double bonds [6].

EXPERIMENTAL

Phenol and methyl orthocarbonate. A mixture of methyl orthocarbonate (27.2 g, 0.2 mole) and phenol (18.8 g, 0.2 mole) was slowly heated at atmospheric pressure. An azeotrope (10.2 g) mixture of methyl alcohol and dimethyl carbonate was distilled over between 62–64°, $n_D^{20} = 1.348$. Further distillation yielded dimethyl carbonate (9.7 g) b.p. 90–91°, $n_D^{20} = 1.369$, and a mixture (5.6 g) of the latter compound and methyl orthocarbonate b.p. 91–113°, $n_D^{20} = 1.377$. The residue, after removal of some phenol by alkali, was distilled under vacuum yielding *anisole* (18.8 g, 87 %) b.p. 46° (12 mm). (Found: OCH_3 28.4. Calc. for C_7H_8O: OCH_3 28.7).

Phenol and ethyl orthocarbonate. Ethyl orthocarbonate (38.5 g, 0.2 mole) and phenol (18.8 g, 0.2 mole) yielded on treatment as above a mixture (10.0 g) of ethyl alcohol and a small amount of diethyl carbonate, b.p. 78–79°, $n_D^{20} = 1.368$, and diethyl carbonate (20.1 g) b.p. 125–126°, $n_D^{20} = 1.384$. From the residue, after removal of some phenol, was obtained *phenetole* (20.7 g, 85 %) b.p. 55° (10 mm) $n_D^{20} = 1.507$. (Found: OC_2H_5 36.7. Calc. for $C_8H_{10}O$: OC_2H_5 36.9).

Alkylation of various phenols using methyl orthocarbonate. The general procedure for the alkylation of phenols using methyl orthocarbonate was the following. The phenol and methyl orthocarbonate were mixed in the molar ratio 1:1.2 for monohydric phenols and 1:2.5 for dihydric phenols. Gentle heating of the mixture was continued as long as any methyl alcohol was being distilled after which the dimethyl carbonate and residual methyl orthocarbonate were distilled rapidly. The residue was taken up in ether and this solution extracted with dilute sodium hydroxide to remove any phenol. After drying the solution and distilling the ether, the residue was fractionated under vacuum.

In this way there was obtained: From *o*-cresol (10.8 g, 0.1 mole) o-*cresyl methyl ether* (6.6 g, 54 %) b.p. 68° (18 mm). (Found: OCH_3 25.3. Calc. for $C_8H_{10}O$: OCH_3 25.4.). From *m*-cresol (10.8 g, 0.1 mole) m-*cresyl methyl ether* (7.0 g, 57 %) b.p. 71–72° (17 mm). (Found: OCH_3 25.5. Calc. for $C_8H_{10}O$: OCH_3 25.4). From 2,6-xylenol (12.2 g, 0.1 mole)

2,6-xylyl methyl ether (3.0 g, 22 %) b.p. 72° (15 mm). (Found: OCH_3 22.8. Calc. for $C_9H_{12}O$: OCH_3 22.8). From resorcinol (11.0 g, 0.1 mole) *resorcinol monomethyl ether* (2.0 g, 16 %) b.p. 137° (18 mm). (Found: OCH_3 25.0. Calc. for $C_7H_8O_2$: OCH_3 25.0) and *resorcinol dimethyl ether* (9.1 g, 66 %) b.p. 103° (18 mm). (Found: OCH_3 44.8. Calc. for $C_8H_{10}O_2$: OCH_3 44.9). The last two ethers were separated by extracting the former with alkali. No reaction could be traced between methyl orthocarbonate and 2,6-di-*tert.*-butyl-*p*-cresol.

Pyrocatechol and methyl orthocarbonate. Pyrocatechol (11.0 g, 0.1 mole) and methyl orthocarbonate (34.0 g, 0.25 mole) were treated in the usual way. There was obtained methyl alcohol (6.4 g) b.p. 64—65°, n_D^{20} = 1.334 and methyl orthocarbonate (18.4 g) b.p. 111—113°, n_D^{20} = 1.384. Further fractionation under vacuum yielded *o-phenylene dimethyl orthocarbonate* * (16.5 g, 91 %) b.p. 115—116° (19 mm), n_D^{20} = 1.4978, d_4^{20} = = 1.1959, MR_D = 44.64. (Found: OCH_3 33.6, H 5.61, C 59.4. Calc. for $C_9H_{10}O_4$: OCH_3 34.0, H 5.53, C 59.33). Guaiacyl methyl carbonate which has the same composition as *o*-phenylene dimethyl orthocarbonate might also be formed in the reaction above. The proof that *o*-phenylene dimethyl orthocarbonate was actually obtained was given by the hydrolysis of the reaction product in a mixture of dilute hydrochloric acid and methyl alcohol to yield pyrocatechol quantitatively. Furthermore the refractive index of guaiacyl methyl carbonate is reported as $n_D^{15.7}$ = 1.51736.[7]

Phenol and ethyl orthoacetate. A mixture of phenol (18.8 g, 0.2 mole) and ethyl orthoacetate (32.4 g, 0.2 mole) was heated to 70—110° at 70 mm pressure. A liquid (7.8 g), distilled over between 26 and 49°. It was composed mainly of ethyl alcohol but also contained some ethyl acetate and ethyl orthoacetate. On continuation of the distillation at 15 mm there was obtained a fraction (8.9 g) boiling between 50 and 100° and comprising unchanged starting materials and decomposition products. The main fraction, phenyl diethyl orthoacetate (24.2 g, 58 %), distilled at 104—105° (15 mm), n_D^{20} = 1.4801, d_4^{20} = = 1.0099, MR_D = 59.16. (According to McElvain and Kundiger [1] n_D^{25} = 1.4783). Found: Equiv. wt.** 35.0. Calc. for $C_{12}H_{18}O_3$: Equiv. wt. 35.04). A small amount of diphenyl ethyl orthoacetate * (3.5 g, 7%) was obtained at 135—136° (4 mm), n_D^{20} = 1.5369, d_4^{20} = 1.0934, MR_D = 73.77. (Found: OC_2H_5 17.1, equiv.wt. * 21.9. Calc. for $C_{16}H_{18}O_3$: OC_2H_5 17.4, equiv. wt. 21.5).

A better yield of phenyl diethyl orthoacetate was obtained if the ethyl orthoacetate was used in excess. In a synthesis performed as above but with phenol and ethyl orthoacetate in the molar ratio 1:3 the yield of phenyl diethyl orthoacetate was 92 %.

When the initial stage of the reaction between phenol and ethyl orthoacetate was allowed to proceed at atmospheric pressure instead of at 70 mm, the yield of phenyl diethyl orthoacetate dropped to about 30 % as the higher bath temperature (140—160°) caused an increased decomposition of the latter compound.

Thermal decomposition of phenyl diethyl orthoacetate. The thermal decomposition of this compound was previously studied by McElvain adn Kundiger [1] who reported the formation of phenetole and phenyl acetate. Here it was of principal interest to determine the amount of phenetole formed.

Phenyl diethyl orthoacetate (21.0 g, 0.1 mole) was heated to 170—180°. A mixture of ethyl alcohol and ethyl acetate (6.0 g), n_D^{20} = 1.370, containing about 80 % of the latter distilled between 72—78°. Further heating afforded a mixture (10.2 g) of phenetole, phenyl acetate and some phenol all boiling at about 170°. On redistillation under vacuum it distilled between 63—86° (13 mm), n_D^{20} = 1.510. Boiling this fraction with ethanolic sodium hydroxide produced pure phenetole (7.6 g, 62 %) b.p. 62° (15 mm), n_D^{20} = 1.507.

As phenyl diethyl orthoacetate under favourable conditions may be prepared in about 90 % yield from phenol and ethyl orthoacetate it appears that the overall yield of phenetole from phenol by this method is at best about 50 %.

---

* New compound.

** Titration with 0.1 N bromide-bromate solution.

p-*Nitrophenol and ethyl orthoacetate.* *p*-Nitrophenol (13.9 g, 0.1 mole) and ethyl orthoacetate (24.3 g, 0.15 mole) were heated together to 140—160°. A liquid (13.5 g) containing principally ethyl alcohol and ethyl acetate distilled at 77°. Further distillation under vacuum afforded, along with other products, *p*-nitrophenetole (11.2 g, 67 %) b.p. 112—115° (3 mm). After recrystallization from light petroleum m.p. 59—60°. (According to Jaeger [8] m.p. 60°. Found: OC_2H_5 27.0. Calc. for $C_8H_9NO_3$: OC_2H_5 26.96).

Phenol and ethyl orthoformate. A mixture of phenol (18.8 g, 0.2 mole) and ethyl orthoformate (29.6 g, 0.2 mole) was heated at 140—170° until 9.2 g of a liquid boiling at 78—79° had distilled. It was composed mainly of ethyl alcohol, but contained also some ethyl formate. By continued fractionation under vacuum there was obtained unchanged starting materials and phenyl diethyl orthoformate * (22.4 g, 57 %), b.p. 111° (11 mm), n_D^{20} = = 1.4799, d_4^{20} = 1.0185, MR_D = 54.72. (Found: Equiv. wt. ** 32.7, H 8.28, C 67.4 Calc. for $C_{11}H_{16}O_3$: Equiv. wt. 32.71, H 8.22, C 67,32). A small amount of a black resin remained in the distillation flask.

Thermal decomposition of phenyl diethyl orthoformate. Phenyl diethyl orthoformate (18.5 g, 0.094 mole) was heated to about 200°. A mixture (6.9 g) of ethyl alcohol and ethyl formate distilled over between 53 and 73°. At the end of the heating period carbon dioxide and other gases were evolved. A black brittle resin (9.3 g) remained in the distillation flask. The losses amounted to 2.3 g.

If the heating were discontinued before all of the material in the distilling flask had resinified, fractions boiling between 40 and 80° at 10 mm could be isolated. They were composed mainly of ethyl orthoformate and phenol. No phenetole was found.

On Equilibria in Systems with Polynuclear Complex Formation

IV. The Transition from Polynuclear to Mononuclear Products

GEORGE BIEDERMANN and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The behavior of Z (average number of A bound per B) as a function of log a and log B is discussed for a system, where both mononuclear complexes A_tB and polynuclear "core + links" complexes $B(A_tB)_n$ exist. At high values of B, the family of curves $Z(\log a)_B$ are parallel with a constant spacing. With decreasing values of B they approach to a limiting curve $Z(\log a)$, the "mononuclear wall". The transition range from a predominantly polynuclear to a predominantly mononuclear mechanism may be only about two units in log B.

"Normalized projection maps" and numerical methods are given for finding the first or first two mononuclear constants. The corresponding treatment of the function η is indicated.

In our studies of hydrolysis equilibria [1], the data have often indicated the formation of "core + links" complexes, *i. e.* complexes that can be written in the general form $B(A_tB)_n$, where t is a constant and n may have one or several values. For B = cation, and A = OH^-, examples of this type of complex are $UO_2((OH)_2UO_2)_n^{2+}$ and $In((OH)_2In)_n^{(3+n)+}$. The occurrence of such complexes was one reason for treating them rather thoroughly in the papers "AB I"[2] and "AB II"[3]; in the following we shall use, as a rule, the notation of these papers. (See "Symbols" below).

When "core + links" complexes of the type $B(A_tB)_n$ predominate, the curves $Z(\log a)_B$ are parallel, and Z (the average number of A bound per B) is a function of (AB I, eqn. 26)

$$x = t \log a + \log B \qquad (1)$$

A plot of Z against log a^tB may thus be used as an experimental test of this type of mechanism; if the correct value of t has been chosen, the points should fall on a single curve, irrespective of the value of B.

In several systems, the data for high values of B are explained by a "core + links" mechanism, within the experimental accuracy, whereas for low values

of B deviations are observed which might be explained by the formation of species richer in A than $B(A_tB)_n$, such as $AB(A_tB)_n$ and $B(A_{t+1}B)_n$.

If B is made sufficiently low, one may always expect that the concentrations of *mononuclear complexes* A_iB will become appreciable in comparison with those of polynuclear complexes, and finally predominate completely. The aim of the present paper is to discuss the behavior of the experimental quantities Z and $\eta = \log (B\, b^{-1})$ in a transition range where both mononuclear and polynuclear "core + links" complexes exist in comparable amounts, and to indicate methods for the evaluation of data from such a transition range.

Symbols

a, b	concentrations of free A and B
B	total concentration of B
$\mathbf{B}$	normalized B (12)
$g(v)$	function for polynuclear complexes (7)
i	number of ligands in mononuclear complex A_iB (3)
k	constant, ratio k_{n+1}/k_n with hypothesis IIIa (18)
k_0	constant, k_1/k in hypothesis IIIa (18)
k_n	equilibrium constant (2)
l	$\beta_2\beta_1^{-2}$ (27)
n	number of links in polynuclear complex $B(A_tB)_n$ (2)
t	number of A in link A_tB
u	auxiliary function, a^tb (2a)
v	$= ka^tb$ (6)
X, Y	normalized values for x and y, particularly (13), (14)
x, y	variables determined experimentally, particularly (1), (15)
Z	average number of A bound per B
α	normalized a (10)
β_i	equilibrium constant for mononuclear complexes (3)
η	$= \log B - \log b$

General equations

Let us assume that A and B form two series of complexes: polynuclear species $B(A_tB)_n$ and mononuclear species A_iB, and that the equilibrium constants of their formation are k_n and β_i, thus

$$nt\ \mathrm{A} + (n+1)\ \mathrm{B} \rightleftharpoons \mathrm{B(A_tB)_n};\quad [\mathrm{B(A_tB)_n}] = bk_nu^n \tag{2}$$

$$u = a^tb \tag{2a}$$

and

$$i\ \mathrm{A} + \mathrm{B} \rightleftharpoons \mathrm{A_iB};\qquad [\mathrm{A_iB}] = b\beta_ia^i \tag{3}$$

The total concentration of B, and the concentration of A bound to B, will be expressed by

$$B = [\mathrm{B}] + \Sigma[\mathrm{A_iB}] + \Sigma(n+1)\,[\mathrm{B(A_tB)_n}] = b(1 + \Sigma\beta_ia^i + \Sigma(n+1)k_nu^n) = b10^\eta \tag{4}$$

$$BZ = \Sigma i\ [\mathrm{A_iB}] + \Sigma nt\ [\mathrm{B(A_tB)_n}] = b\ (\Sigma i\beta_ia^i + t\ \Sigma nk_nu^n) \tag{5}$$

Introducing from AB II [3] the symbols

$$v = ku = ka^tb \tag{6}$$

$$g(v) = \Sigma\ k_nu^n;\qquad v\frac{\mathrm{d}g}{\mathrm{d}v} = vg' = \Sigma\ nk_nu^n \tag{7}$$

we obtain from (4) and (5)

$$B = b\ (1 + \Sigma\beta_i a^i + g + vg') \tag{8}$$

$$BZ = b\ (\Sigma i\beta_i a^i + tvg') \tag{9}$$

In AB II[3], expressions for $g(v)$ have been derived for a few simple hypotheses: I (no soluble complex, precipitate formed), II (a single complex formed, with $n = N$), and III (complexes with all values of n are formed, three different simple assumptions about the k_n). In the following we shall treat the simple cases, where only one or two mononuclear complexes are formed, and shall calculate diagrams for the additional simple assumption that the polynuclear complexity constants follow "hypothesis IIIa" [3], with an integer t. On these assumptions it seems possible to explain approximately the experimental data for the hydrolysis of scandium(III)[4,5] and uranium(IV)[6]. Even in more complicated cases the behavior should be analogous, and a similar mathematical treatment could be applied.

ONLY ONE MONONUCLEAR COMPLEX

If only one mononuclear complex, AB, is formed, all $\beta_i = 0$ except β_1. To eliminate the constant β_1 we introduce the auxiliary "normalized" variable

$$\alpha = \beta_1 a \tag{10}$$

Then (8) and (9) take the form

$$B = b\ (1 + \alpha + g + vg'); \qquad BZ = b\ (\alpha + tvg') \tag{8a, 9a}$$

Hence

$$Z = \frac{\alpha + tvg'}{1 + \alpha + g + vg'} \tag{11}$$

Multiplying B by $k\,\beta_1^{-}$ we obtain a new function, $\mathcal{B}$, which like Z is a function of v and α only and does not contain the constants k and β_1 (8a, 10, 6):

$$\mathcal{B} = B\ k\ \beta_1^{-t} = v\ \alpha^{-t}\ (1 + \alpha + g + vg') \tag{12}$$

If the constant t and the function $g(v)$ (including constants like k_0 below) are known, one may use (11) and (12) and suitable values of the auxiliary variable v to calculate corresponding values of α and $\mathcal{B}$ for a series of fixed values of Z. These figures may be used for plotting projection maps $Y(X)_Z$, for the variables

$$X = \log\ (B\ a^t) = \log\ B + t\ \log\ a + \log\ k = x + \log\ k \tag{13}$$

$$Y = \log\ \mathcal{B} = \log\ B + \log\ k\ -\ t\ \log\ \beta_1 = y + \log\ k - t\ \log\ \beta_1 \tag{14}$$

As seen from (13) and (14) X and Y are normalized variables [7,8] corresponding to the experimental variables

$$x = \log\ B + t\ \log\ a; \qquad y = \log\ B \tag{15}$$

Fig. 1 and Fig. 2. Variation of Z with other variables for a system A—B with a single mononuclear complex AB, and polynuclear "core + links" complexes $B(A_2B)_n$, hypothesis IIIa, $k_0 = 5$.

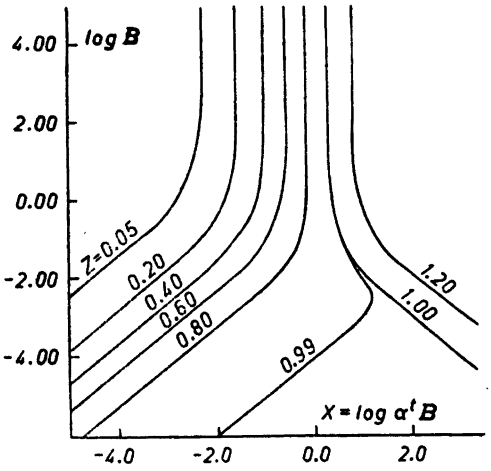

Fig. 1a. Projection map of $Y(X)_Z$, with $Y = \log B$ and $X = \log(\alpha^t B)$.

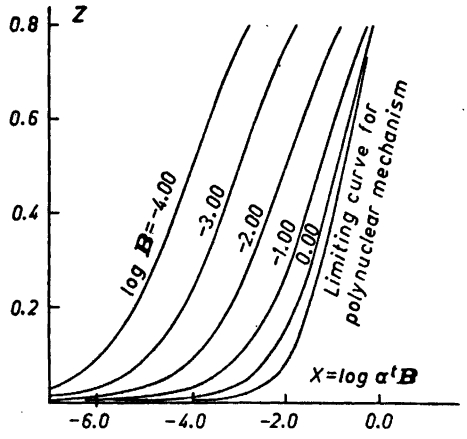

Fig. 1b. Family of curves $Z(X)_B$. For $\log B > 1$, the curves practically coincide with the limiting curve.

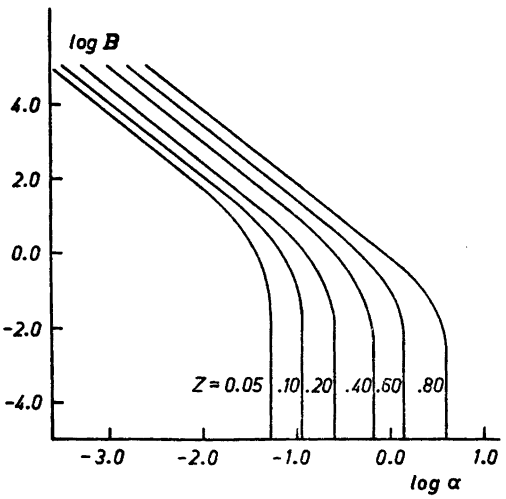

Fig. 2a. Projection map log $B(\log \alpha)_Z$.

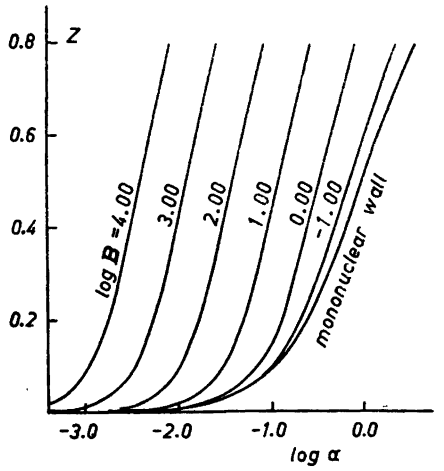

Fig. 2b. Family of curves $Z(\log \alpha)_B$. For $\log B < -1.5$, the curves practically coincide with the limiting curve, the "mononuclear wall".

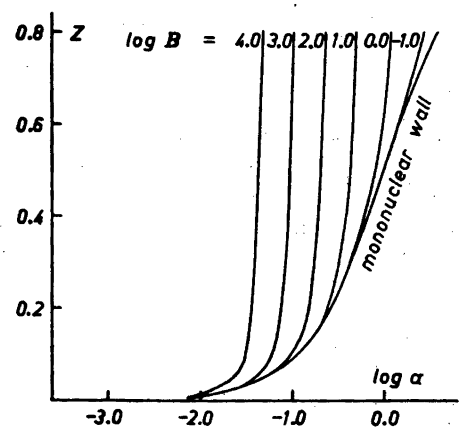

Fig. 3. Family of curves $Z(\log \alpha)_B$ *calculated for single mononuclear complex + polynuclear "IIIa" complexes with* $t = 3$, $k_0 = 0.06$.

The following formulas are useful for the calculations, (11, 12, 13)

$$\alpha = \frac{Z}{1-Z}(1 + g + v\,g') - \frac{t\,v\,g'}{1-Z} \tag{16}$$

$$X = \log v + \log [1 + g - v\,g'\,(t-1)] - \log (1-Z) \tag{17}$$

Diagrams for single mononuclear complex + hypothesis IIIa

In Fig. 1a, a projection map is given of $\log B(X)_Z$ calculated using (13, 14, 16, 17) assuming "hypothesis IIIa" [3],

$$k_n = k_0\,k^n \tag{18}$$

with $t = 2$ and $k_0 = 5$. These values give a good agreement with the data for scandium(III) [4,5].

Hypothesis IIIa with integer t would give (AB II[3], eqn. 31)

$$g(v) = k_0 v\,(1-v)^{-1}; \qquad vg'(v) = k_0 v(1-v)^{-2} \tag{18a}$$

The irregular shape of the curves for $Z = 0.99$, 1.00, and 1.20 in Fig. 1a should be disregarded. It is due to the fact that with the reactions assumed, the mononuclear complex can give at most $Z = 1$, whereas with polynuclear complexes, higher values of Z can be achieved. The case of a non-integer t has been treated by Rossotti and Rossotti [9].

The same values of t and k_0 have been used to construct the diagrams $Z(X)_B$ (Fig. 1b), $\log B(\log \alpha)_Z$ (Fig. 2a), and $Z\,(\log \alpha)_B$ (Fig. 2b). When considering these diagrams one should remember that the normalized variables $X = \log (\alpha^t B)$, $\log B$, and $\log \alpha$ differ from the experimental variables $x = \log (a^t B)$, $\log B$, and $\log a$, only by constant terms (13, 14, 10).

For high total concentrations B, the polynuclear complexes predominate and Z is a function of x only (vertical lines in upper part of Fig. 1a, limiting curve $Z(X)$ to the right of Fig. 1b, constant spacing in Fig. 2b). For very low

values of B, on the other hand, the polynuclear complexes become negligible in comparison with the mononuclear complexes. Then Z is effectively a function of a only (vertical lines in lower part of Fig. 2a, lines of slope 1 in lower part of Fig. 1a). The limiting curve $Z(\log a)$ is referred to as the "mononuclear wall", (Fig. 2b), since with decreasing B the curves Z $(\log a)_B$ approach to it indefinitely but never pass it. For intermediate values of B there is a transition range, of a breadth of 2—3 units in log B. This range of transition from a practically mononuclear reaction (within ordinary experimental errors) to a practically pure "core + links" reaction may seem surprisingly narrow, which may partly be due to the fact that in Fig. 2b the polynuclear and mononuclear curves have a rather similar shape.

Fig. 3 shows $Z(\log a)_B$ calculated for $t = 3$ and hypothesis IIIa with $k_0 = 0.06$; these values describe approximately the hydrolysis of uranium(IV)[6]. Here the polynuclear curves are steeper, and the transition range in log B is much broader.

Similar behavior would be expected for the function $Z(\log a)_B$ on transition between a mononuclear reaction and polynuclear reactions of other types, and also for the function $\eta(\log a)_B$, where $\eta = \log \frac{B}{b}$ (see (4)).

Evaluation of data by normalized projection map

In very favorable systems, the experiments cover a range of B such that at low values of B the mononuclear, at high values of B the polynuclear processes predominate. Then approximate equilibrium constants for both processes can be calculated separately, and refined values may be obtained by considering, at each end, the other process as a small disturbance. Such a procedure was possible for the hydrolysis of iron(III) (Hedström[10]) and indium(III) (Biedermann[11]). These cases were additionally favorable in that both the free concentrations a and b could be measured.

In other systems, the polynuclear process certainly predominates at high values for B, so that one may use the methods in AB II[3] to find a mechanism that gives a good agreement, and an approximate value for log k. At low values for B, deviations from the "core + links" curve are observed; however, the mononuclear process is too small a disturbance to be treated independently.

In such cases, the accuracy of the data may not allow one to determine more than one equilibrium constant for the mononuclear reactions; it has seemed reasonable to start by assuming that the first mononuclear complex AB is formed and testing this assumption by "surface-fitting", using projection maps.

To find the formation constant β_1 for this complex, and a refined value of log k, one may plot the experimental data in the form $y(x)_Z$, (15), and move this projection map parallel with the axes on a calculated normalized plot $Y(X)_Z$, (13, 14), until the best agreement is found. From the coordinates $x_0 = x—X$ and $y_0 = y—Y = \log B—\log B$ of the points coinciding with the point $X = 0$, $Y = 0$, one may then find the best values for log k and log β_1, using (13) and (14). An example is given in Fig. 4a, where the experimental values of Kilpatrick and Pokras[4] (dots) are shown in the position of best fit with calculated

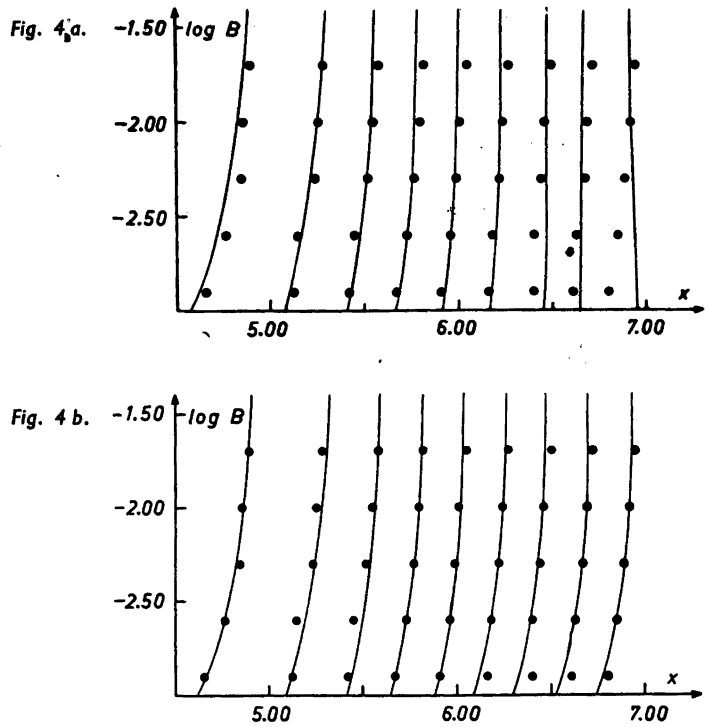

Fig. 4. "Surface-fitting" of Kilpatrick's and Pokras' data for scandium(III) hydrolysis [4] *(dots), plotted as log* $B(\log h^{-2} B)_Z$. *Curves :projection map log* $B(X)_Z$ *in best fit; a) only one mononuclear complex,* $k_0 = 5$: $\log \beta_1 = -5.02$ *and log* $k = -6.85$. *The curves are the same as in Fig. 1a but on a larger scale. b) two mononuclear complexes* $1 = 1$: $\log \beta_1 = -5.1$, $\log \beta_2 = -10.2$ *and log* $k = -6.87$.

curves for a single mononuclear complex + hypothesis IIIa with $k_0 = 5$. In this case, $x_0 = 6.85$ and $y_0 = -3.15$, which give $\log k = -6.85$ and $\log \beta_1 = -5.0$.

Numerical approach

One may use a numerical approach to find β_1 if the equilibrium constants k_n of the polynuclear reactions are known, or, which is the same, if k and $g(v)$ are known. If there is only one mononuclear complex, one may conveniently start with (8a), (9a) and (6) and eliminate b and a to find

$$a^t B(1-Z) = k^{-1}v(1 + g-(t-1)vg') \qquad (19)$$

Thus $a^t B$ $(1-Z)$ is a function of v only. Using the known k and $g(v)$ one may calculate and plot the expression to the right of (19) as a function of v. For each experimental point one may then calculate $a^t B$ $(1-Z)$ from the experim-

ental data, read off the value of v from the plot of (19), and use it to calculate (9a, 6)

$$\beta_1 = a^{-1}\,(a^i\ B\ Z\ k\ v^{-1}\text{—}t\ v\ g') \tag{20}$$

This can be done for a series of experimental points, and the average value of β_1 is taken. This method was used in the study of the Cu^{2+} hydrolysis [12].

Treatment of data (a, b, B)

If both a and b are measured and t is known, one may calculate $u = a^i b$ for each point. Now from (4)

$$\eta = \log \frac{B}{b} = \log\ (1 + \Sigma\ \beta_i\ a^i + \Sigma(n+1)\ k_n\ u^n) \tag{21}$$

In this case, one may also treat mechanisms with more than one mononuclear complex in a comparatively simple manner. Assuming, however, that we need consider only one mononuclear complex, AB, (21) takes the form

$$\eta = \log\,(1 + \alpha + g + v\ g') \tag{22}$$

If $g(v)$ is known, one may easily calculate a normalized projection map $\log v(\log \alpha)_\eta$ for a set of values of η and $\log v$. This could be fitted to an experimental diagram $\log u(\log a)_\eta$. The position of best agreement gives (6, 10)

$$\log k = \log v\text{—}\log u; \qquad \log \beta_1 = \log \alpha\text{—}\log a \tag{23}$$

Alternatively one may calculate $X(\log \alpha)_\eta$ and compare with the experimental $x(\log a)_\eta$. From (13), and (8)

$$X = \log v + \eta = x + \log k; \qquad \alpha = 10^\eta\text{—}(1 + g + vg') = \beta_1 a \tag{24}$$

So, by keeping η constant and varying v we may obtain sets of corresponding values for X and α.

To construct $\log u(\log a)_\eta$ one may draw the primary graphs $\eta(\log a)_B$ and $\log u(\log a)_B$, read the $\log a$ values for round values of η in the first diagram, mark out these points on corresponding curves in the second diagram, and finally join the points with the same η values in the latter diagram. The plot $x(\log a)_\eta$ is constructed in an analogous way.

TWO MONONUCLEAR COMPLEXES

Graphical method

If, in addition to AB, the second mononuclear complex A_2B must also be considered, there will be an additional term $b\beta_2 a^2$ in (8) and $2\,b\beta_2 a^2$ in (9). Defining the normalized functions α and B as before, (10, 12), we find from (8) and (9)

$$B = v\alpha^{-t}(1 + \alpha + l\ \alpha^2 + g + vg') \tag{25}$$

$$BZ = v\alpha^{-t}(\alpha + 2\ l\ \alpha^2 + tvg') \tag{26}$$

$$l = \beta_2\beta^{-2} \tag{27}$$

We may construct one normalized projection map log $B(X)_Z$ for each value of l to be tested, and search for the best fit with the experimental data log $B(x)_Z$, or alternatively construct log B (log $a)_Z$ and compare it with log B (log $a)_Z$.

Elimination of B from (25) and (26) leads to a second-degree equation in a, from which we get an explicit expression for $a(v,Z)$. Inserting this into (25) we find explicit expressions for $B(v,Z)$ and $X = \log Ba^l(v,Z)$. If the values of these functions are calculated for a series of values of v and Z, one may obtain the plots log $B(X)_Z$ and log $B(\log a)_Z$.

Alternatively we may construct intermediate plots of curves $X = \log Ba^l(v)_Z$, log $B(v)_a$ and $Z(v)_a$, by means of (25) and (26), and read off corresponding values of B, Z, and X or a.

Fig. 4 gives the projection map log $B(X)_Z$ for $k_0 = 5$ and $l = 0$ (Fig. 4a) or $l = 1$ (Fig. 4b) and the data for scandium(III). The agreement is improved by introducing the second complex.

It is true that we will have to construct as many projection maps as we want to test values for l. On the other hand, once this work is done, the "surface fitting" has several advantages over other methods (such as successive approximation) which might be devised. The normalized projection maps may be compared with a plot of experimental data, like log $B(\log a)_Z$, where one may still retain a feeling for the influence of experimental errors, so that one may see whether a certain agreement is satisfactory or not. It is an important advantage with this method that the same experimental plot log $B(\log a)_Z$ may also be used for testing other mechanisms that might be considered. One may then see where the significant differences between the various mechanisms arise, and whether the data suffice to make a certain decision between them.

This work is part of a program supported by *Atomkommittén (Swedish Atomic Energy Commission)* and *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)*. We are indebted to Dr. Sirkka Hietanen and Dr. Gösta Lagerström for valuable discussions in the course of our work and to Drs. Francis and Hazel Rossotti for reading and discussing the manuscript.

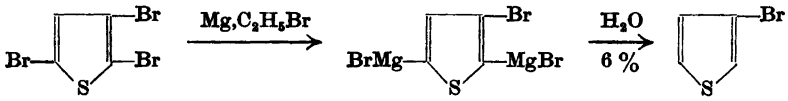
Dehalogenation of Bromothiophenes with Butyllithium

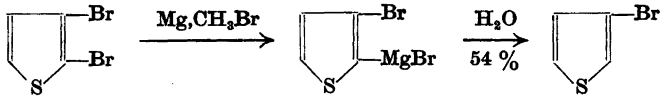
SVEN-OLOV LAWESSON



Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

Two new methods of preparing 3-bromothiophene and the preparation of a new compound, 3,5-dibromo-2-thiophencarboxylic acid, are described.

A possible route to 2,4-dibromothiophene is outlined.



The author, who is investigating thiopheneboronic acids, needs as intermediates all isomers of the bromothiophenes. Some of these are troublesome to synthesize and the identity and purity of the product are not certain and, therefore, some preliminary experiments have been made in order to work out better methods. This paper deals with the preparation of 3-bromothiophene and 2,4-dibromothiophene.

As early as 1934, Steinkopf [1] prepared 3-bromothiophene according to the following reaction:

(Method I)

The yield was very low, but he did not abandon the method, neither did he try to improve it, strange to say. Instead, he prepared 3-bromothiophene by reacting 2,3-dibromothiophene with methylmagnesium bromide [2], *viz.*

(Method II)

Gronowitz [3] has recently improved both the methods of Steinkopf. By refluxing 2,3,5-tribromothiophene with magnesium for 49 hours, using ethyl bromide as entraining agent and then hydrolysing the Grignard reagent, he got 3-bromothiophene in a yield of 51 %. Using Steinkopf's method II, Gronowitz got 3-bromothiophene in a good yield.

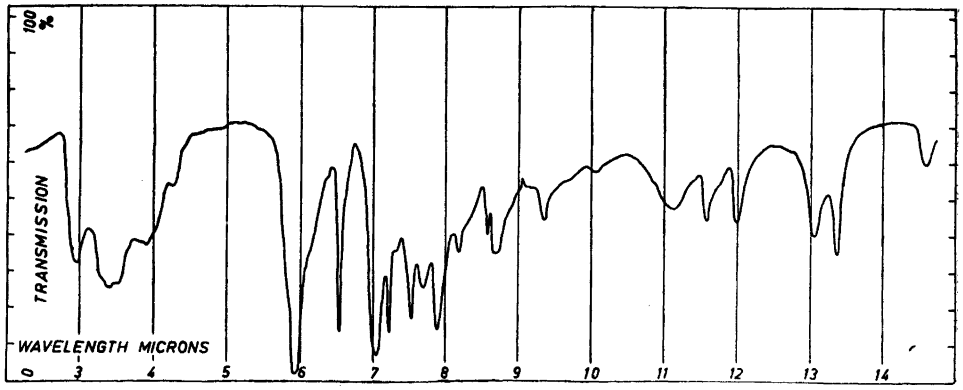


Fig. 1. The infrared spectrum of 4,5-dibromo-2-thiophenecarboxylic acid (in pressed KBr).

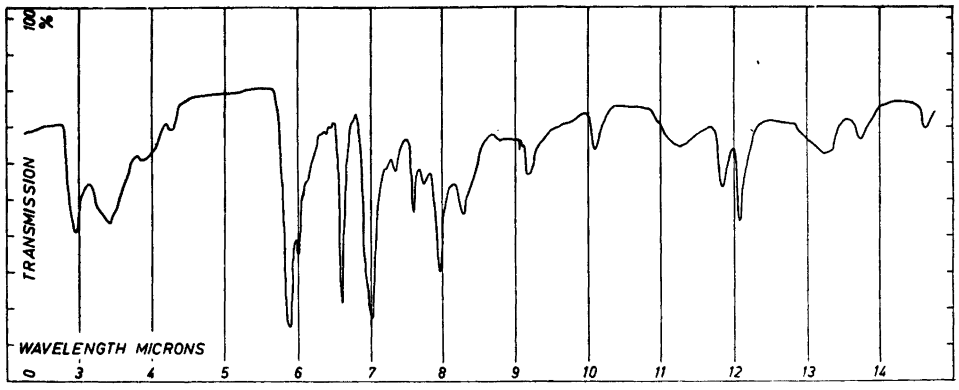

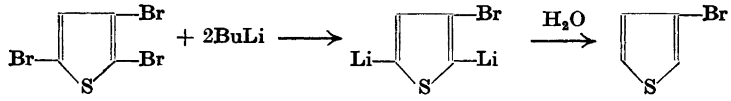

Fig. 2. The infrared spectrum of 3,5-dibromo-2-thiophenecarboxylic acid (in pressed KBr).

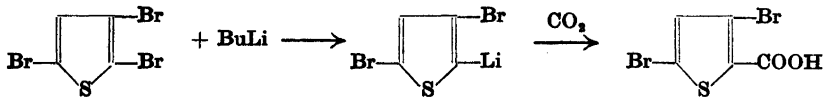
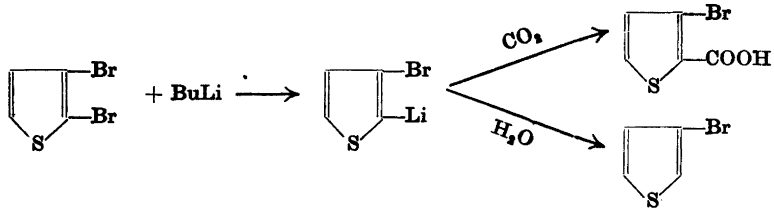


All these methods seem to be tedious and very time-consuming. We have instead brought together one mole of 2,3,5-tribromothiophene [4] and two moles of butyllithium [5] and obtained, after hydrolysing the lithium compound, 3-bromothiophene, through the reaction:

(Method III)



If the reaction was carried out with a 1 : 1 molar ratio of the 2,3,5-tribromothiophene and the butyllithium, at —70°, we obtained, after pouring the solution onto dry ice, a substance with a melting point 15° lower than that of 4,5-dibromo-2-thiophenecarboxylic acid [1]. The IR spectra (Figs. 1 and 2) showed

great differences in the finger-print region between 4,5-dibromo-2-thiophenecarboxylic acid, prepared by brominating 2-thiophenecarboxylic acid, and the new compound. Even in chloroform solution the differences remained, and consequently, the possibility of polymorphism is excluded. As a matter of fact, the occurrence of the following reaction is proposed:

From this it is seen that if instead of pouring the monolithium reagent on dry ice, we hydrolyse it, 2,4-dibromothiophene should be obtained. Investigation in this field is in progress at this Institute.

By treating 2,3-dibromothiophene[6] with an equimolar amount of butyllithium, 3-bromothiophene was obtained in good yields after hydrolysis. If the lithium reagent was poured onto dry ice, 3-bromo-2-thiophenecarboxylic acid[1] was isolated, as a result of the reaction:

(Method IV)

The infrared spectra were recorded with a Perkin-Elmer spectrophotometer (model 21) equipped with NaCl optics.

EXPERIMENTAL

3-Bromothiophene (*Method III*). A solution of 0.2 mole of butyllithium in 250 ml dry ether was added dropwise, over a period of 90 minutes, to an ice-cold solution of 2,3,5-tribromothiophene (32 g, 0.1 mole) in 200 ml of dry ether. The reaction was carried out under nitrogen, with stirring. The resulting yellow suspension was poured into ice-water. The organic layer was separated off and the water phase shaken several times with ether. The combined extracts were washed once with water, dried over sodium sulfate, and then concentrated. The residue was distilled, yielding 10.5 g of 3-bromothiophene, b.p. 58°/20 mm Hg, (identified by means of the IR spectrum), and 2 g of dibromothiophenes, b.p. 94°–96°/15 mm Hg. Yield of 3-bromothiophene: 65 %.

3,5-Dibromo-2-thiophenecarboxylic acid. 21 ml of 1.5 M butyllithium in dry ether was added, in a slow stream, to 10 g of 2,3,5-tribromothiophene in 100 ml of ether, at −70°. The solution was stirred for 5 minutes and then treated all at once with an excess of powdered solid carbon dioxide. After the dry ice had evaporated, the mixture was hydrolysed with water, the organic layer separated off, the water solution extracted with ether, and the combined ether layers extracted with dilute sodium hydroxide. Upon acidification of the alkaline solution, a white powder precipitated; this, after recrystallisation from water-ethanol solution, yielded small, faintly yellow-coloured, needles. Weight: 3.2 g, yield 36 %. M.p. 210–212°C.

Anal Subst. 44.30 mg; 3.11 ml of 0.0495 M NaOH
27.60 mg; 9.88 ml of 0.00978 M $Hg(NO_3)_2$
$C_5H_2Br_2O_2S$ Calc. Equiv. wt. 285.95 Br 56.19
Found » » 288.0 Br 55.98

3-Bromothiophene (*Method IV*). Butyllithium (0.09 mole) in 150 ml of dry ether was added with stirring over a 45-minute period to 20 g (0.083 mole) of 2,3-dibromothiophene in 150 ml of ether at 0°C. The solution was hydrolysed, and after being worked up as usual was distilled, giving 7.9 g of 3-bromothiophene (b.p. 44°—46°/11 mm Hg). Yield 58 %.

The yield ought to be better, but the optimum conditions have not been worked out, since this method is inferior to method III and more time-consuming.

3-Bromo-2-thiophenecarboxylic acid. Into 10 g of 2,3-dibromothiophene in 50 ml of ether, at −40°, was poured 23 ml of 1.5 M butyllithium. The reaction was carried out under nitrogen, with stirring; after 7 minutes, the solution was poured onto dry ice and worked up in the usual way. Recrystallisation from water-ethanol solution gave white needles with m.p. 193°—195°C. Weight: 6 g; yield 70 %.

Anal. Subst., 24.30 mg; 2.37 ml of 0.0495 M NaOH. Equiv. wt. Calc. 207.1; Found 207.2.

Indebtedness is expressed to Professor A. Fredga for his kind interest, and to Dr. A. Rosenberg for taking the IR spectra.

A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged.

Enzymic Synthesis of Carbamylaspartate from Citrulline in Extracts from Rat Liver Mitochondria

LLOYD H. SMITH JR.* and PETER REICHARD

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

The formation of carbamylaspartate from citrulline and aspartate has been demonstrated to proceed in at least two steps. First, carbamylphosphate was formed from the carbamyl group of citrulline and ATP. Secondly, carbamylphosphate and aspartate formed carbamylaspartate. The formation of carbamylphosphate from citrulline required ATP, acetylglutamate and Mg^{++}. Ornithine was identified as the second product of the reaction. The reaction was very strongly inhibited by ornithine.

The carbamyl group of citrulline was found to be utilized for the biosynthesis of polynucleotide pyrimidines in pigeon liver by Schulmann and Badger [1]. These authors could not demonstrate the specific incorporation of this group into polynucleotide pyrimidines of the rat. Later work indicated, however, that rat liver slices formed orotic acid-^{14}C from carbamyl labeled citrulline [2]. Since orotic acid is formed from aspartic acid *via* CA-aspartate ** in rat liver slices [4], it seemed likely that the utilization of citrulline took place by a transfer of its carbamyl moiety to aspartic acid. The possibility of such a mechanism has been considered earlier and argininosuccinate [4,5] was suggested as an intermediate in the formation of CA-aspartate from citrulline and aspartate.

The enzymic formation of CA-aspartate in rat liver has recently been shown to proceed in at least two steps[6-8]:

$$(1)\ NH_3 + CO_2 + ATP \xrightarrow[\text{acetylglutamate}]{Mg^{++}} \text{Compound X} + ADP$$

$$(2)\ \text{Compound X} + \text{L-aspartate} \longrightarrow \text{L-carbamylaspartate} + \text{phosphate}$$

* Fellow of U. S. Public Health Service. Present address: Mass. General Hospital, Boston, Mass. USA. Requests for reprints should be addressed to Stockholm.

** The following abbreviations are used in this paper: CA = carbamyl; CAP = carbamylphosphate; ATP, ADP and AMP = adenosine tri-, di- and monophosphate, respectively; PGA = 3-phosphoglyceric acid; MP = muscle protein fraction for regeneration of ATP from ADP + PGA[15]; PCA = perchloric acid; P_i = inorg. phosphate.

Reaction (1) has been described earlier by Grisolia and Cohen [9] as the first step in citrulline synthesis, the second being:

(3) Compound X + ornithine ⟶ Citrulline + phosphate

The recent work of Jones *et al.*[10] has demonstrated the identity of compound X with carbamylphosphate in reaction (3).

The investigations described here were carried out to determine if CA-aspartate could be formed from citrulline through these known enzymic mechanisms. Using preparations from rat liver mitochondria, evidence has been obtained for a reaction by which carbamylphosphate (CAP) and ornithine are formed from citrulline and ATP in the presence of acetylglutamate and Mg^{++}:

$$\text{(4) Citrulline} + \text{ATP} \xrightarrow[\text{acetylglutamate}]{Mg^{++}} \text{carbamylphosphate} + \text{ornithine (+ADP)}$$

When aspartate was included during the reaction the formation of CA-aspartate could be demonstrated. Some of these experimental results have been briefly published earlier [11,12].

MATERIALS AND METHODS

L-*Citrulline-carbamyl-*^{14}C was synthesized according to Smith [13]. *CAP* was prepared according to Jones *et al.*[10] and L-*acetylglutamate* according to Karrer *et al.*[14] ATP, ADP, AMP and PGA were commercial products (Schwartz and Sigma). A muscle protein fraction [15] was prepared for the regeneration of ATP from ADP and PGA. ATP-^{32}P (labeled in the two terminal phosphate groups) was prepared from AMP through oxidative phosphorylation [16].

Ion exchange chromatography of CAP was carried out by gradient elution at 5°. Two columns of Dowex-2-formate (0.8 cm^2 × 10 cm) were connected with a 1 000 ml mixing flask, containing water, which received 2.25 M ammonium formate, pH 5.0, from a reservoir flask. P_i (10 column volumes), CAP (15 column volumes), ADP (34 column volumes) and ATP (45 column volumes) were completely separated (*cf.* also Ref.[8]).

Preparation of enzymes. The enzymes carrying out the overall synthesis of CA-aspartate from citrulline and aspartate were prepared by freezing and thawing rat liver mitochondria in 0.1 M $NaHCO_3$[7].

The enzyme preparation which was used for the study of reaction (4) was made in a slightly different manner. Mitochondria from *ca.* 40 g rat liver were prepared in 0.25 M sucrose-0.01 M versene (*cf.* Ref.[6]) suspended in 50 ml of distilled water, and quickly frozen in dry ice. The frozen mass was lyophilized directly, and the dry powder stored in a desiccator at 0°. Immediately before use the powder was extracted with 0.02 M glycylglycine buffer, pH 8.0, for 5 minutes in an ice bath and centrifuged at 20 000 g for 15 minutes at 0°. The supernatant was used for the experiments. The lyophilized powder could be stored for several days with a slow decrease of activity. When in solution the enzyme deteriorated in a few hours, even at 0° and despite the addition of glutathione.

Assay of enzyme activity. The *over all reaction* (formation of CA-aspartate) was determined by the isotope dilution method as described earlier [6,8].

Reaction (4). A convenient determination of CAP formation was based on its decomposition to release free CO_2 in the presence of a strong mineral acid. The amount of CAP formed during an experiment was calculated from the total radioactivity of the liberated $^{14}CO_2$ and the specific activity of the precursor citrulline-carbamyl-^{14}C. Incubations were carried out in stoppered 25 ml Warburg vessels, containing 0.5 ml of 12 N H_2SO_4 in the side arm, and 0.5 ml of 6 N NaOH in the center well. At the end of the experiment 100 μmoles of $NaHCO_3$ were added to the incubation mixture, the flask was

stoppered again, and the sulfuric acid added from the side arm. The flask was then shaken at 37° for 30 minutes, during which time all of the CAP was decomposed and the liberated CO_2 was collected in the center well. The completeness of CO_2 collection under these conditions was established in model experiments with radioactive CAP.

The carbonate in the center well was precipitated with saturated $Ba(OH)_2$, washed twice with hot water, filtered on to a paper disk of standard size, and counted as an infinitely thick sample in an end window Geiger-Müller counter. The number of μmoles $^{14}CO_2$ liberated could then be calculated from an experimentally determined conversion factor.

In this way all CAP formed during the experiment (including CAP broken down to CO_2 during the incubation) was determined. The assay method, of course, also determined any $^{14}CO_2$ formed from citrulline without the intermediate formation of CAP. Under the proper conditions this "background formation" of CO_2, however, did not amount to more than 10—15 % of the total amount of CO_2 formed from citrulline (*cf.* Fig. 1).

RESULTS

Over-all formation of CA-aspartate from citrulline

The over-all reaction was first demonstrated in rat *liver slices*. The conditions were the same as those described for orotic acid synthesis [3] except for the use of 200 μmoles of citrulline-carbamyl-^{14}C and a carrier of 100 μmoles of non-labeled CA-aspartate. From the isotope content of the reisolated CA-aspartate it was calculated that approximately two μmoles of CA-aspartate had been formed during the 4-hour incubation period.

In liver homogenates CA-aspartate synthesis from citrulline could also be demonstrated, though only to a small and varying extent. The homogenates were centrifuged at 100 g for 10 minutes at 0° to remove most of the cell nuclei and then for 15 minutes at 15 000 g (*cf.* Ref. [6]). Activity for CA-aspartate formation from citrulline per mg nitrogen was roughly five times larger in the sediment (mitochondria) than in the supernatant (cell sap + microsomes). All subsequent experiments were carried out with mitochondrial preparations.

Non-involvement of free CO_2. It has previously been shown [7] that the carbamyl carbon of CA-aspartate is derived from CO_2. Rat liver preparations contain a "citrullinase" which liberates CO_2 from the carbamyl group of citrulline, possibly unrelated to CAP formation [17] (see also below). It was possible, therefore, that "free CO_2" released from citrulline by this enzyme was then incorporated into CA-aspartate *via* the known enzymic pathways described as reactions (1) and (2) above. Experiments were therefore designed to test whether the carbamyl carbon of citrulline equilibrated with bicarbonate in the system or was transferred to CA-aspartate over a "closed circuit". For this purpose the synthesis of ^{14}C-labeled CA-aspartate by mitochondria was compared in tightly stoppered flasks containing either (a) citrulline-^{14}C + non-labeled $KHCO_3$, or (b) $KHCO_3$-^{14}C + non-labeled citrulline. At the end of the incubation CO_2 was liberated by the addition of PCA and collected and counted as $BaCO_3$ at infinite thickness. The amount of CA-aspartate-^{14}C formed from the respective ^{14}C precursors was then measured by the isotope dilution technique. The results summarized in Table 1 demonstrate that considerably more CA-aspartate was formed from citrulline-^{14}C than from bicarbonate-^{14}C, even though the specific activity of the bicarbonate at the end of the incubation in experiment 1 (citrulline-^{14}C) was only about one tenth as great as that in

Table 1. Non involvement of "free CO_2" in CA-aspartate synthesis from citrulline-CA-^{14}C.

Experimental conditions	+ acetylglutamate		no acetylglutamate	
	specific activity of $BaCO_3$	μmoles ^{14}CA-aspartate formed	specific activity of $BaCO_3$	μmoles ^{14}CA-aspartate formed
Citrulline-^{14}C $KHCO_3$ Phosphate buffer	13 400	0.16	7 700	0.09
Citrulline $KHCO_3$-^{14}C Phosphate buffer	142 000	0.02	132 000	0.00
Citrulline-^{14}C $KHCO_3$ Glycylglycine buffer	2 300	0.24		

Each vessel contained 100 μmoles of citrulline, 300 μmoles of L-aspartate, 1 000 μmoles of buffer, pH 7.4, 180 μmoles of succinate, 10 μmoles of ATP, 100 μmoles of $MgSO_4$, 200 μmoles of $KHCO_3$ and KCl to give isotonicity. Where indicated the vessels contained 100 μmoles of L-acetylglutamate. Volume 16 ml. Incubation for 60 minutes at 37° with rat liver mitochondria (8.7 mg nitrogen). The carbamyl labeled citrulline contained 60 000 ct/min/μmole; $KH^{14}CO_3$ contained 8 000 ct/min/μmole.

experiment 2 (bicarbonate-^{14}C). When glycylglycine was used instead of phosphate buffer (to decrease the phosphorolysis of citrulline) the specific activity of the bicarbonate at the end of the experiment was considerably decreased, but the formation of ^{14}CA-aspartate was not materially affected. When acetylglutamate was excluded from the reaction mixture there was a decrease of ^{14}CA-aspartate formation. This effect will be described more fully below.

The same general results were obtained when extracts of mitochondria were used rather than intact mitochondria. In these experiments the influence of increasing amounts of non-labeled ammonium carbonate on the formation of ^{14}CA-aspartate from labeled citrulline was studied. No dilution effect was observed.

Table 2. Requirements over-all reaction.

	μmoles CA-aspartate formed
Complete	0.26
no acetylglutamate	0.07
no aspartate	0.00
no ATP, PGA and MP	0.05
no phosphate	0.23

The complete system contained 20 μmoles of citrulline-^{14}C, 15 μmoles of L-aspartate, 10 μmoles of ATP, 60 μmoles of PGA, 2 mg MP, 40 μmoles of $MgCl_2$ and 100 μmoles of potassium phosphate buffer, pH 7.4. Volume = 3 ml. Incubation for 60 minutes at 37° with 40 mg of a lyophilized mitochondrial extract.

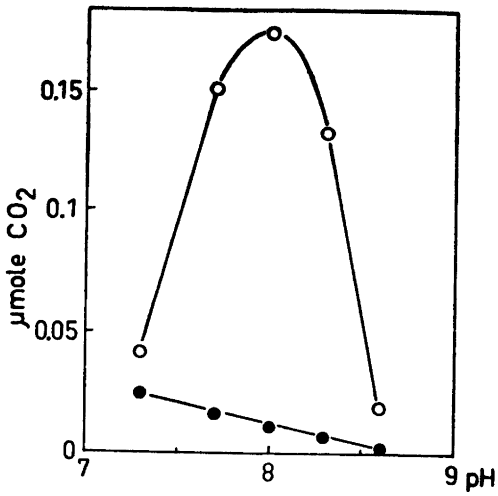

Fig. 1. pH curve of $^{14}CO_2$ formation from citrulline-^{14}C.

5 µmoles of citrulline-^{14}C, 5 µmoles of ATP, 30 µmoles of PGA, 5 mg MP, 50 µmoles of $MgSO_4$, 250 µmoles of glycyl-glycine buffer and 20 µmoles of acetyl glutamate were incubated with enzyme (1.1 mg nitrogen) for 20 minutes at 37° at pH values indicated (open circles). The full circles represent experiments where acetyl glutamate was excluded.

Requirements for over-all reaction. After the enzyme was brought into solution by freezing and thawing the rat liver mitochondria in 0.1 M $NaHCO_3$, the requirements for the over-all reaction were established (Table 2). CA-aspartate formation from citrulline was dependent on the presence of L-aspartate, and was strongly stimulated by acetylglutamate*, Mg^{++}, and ATP (and an ATP regenerating system). The addition of phosphate was not necessary. The strong stimulation by acetylglutamate suggested the intermediate formation of CAP, which in liver preparations requires the presence of acetylglutamate.

Formation of CAP from citrulline

Since it was demonstrated that free CO_2 was not involved in the reaction, CAP could not be formed from citrulline by way of reaction (1), described above. This suggested a direct transfer of the carbamyl group from citrulline to a phosphate group to form CAP. This reaction was studied directly in soluble extracts from lyophilized mitochondria by the omission of aspartate from the system. The enzyme assay was based on the measurement of the acetylglutamate dependent release of $^{14}CO_2$ from citrulline-carbamyl-^{14}C, following the addition of strong acid to break down CAP. In confirmation of the work of Krebs *et al.*[17] it was found that our enzyme preparation contained a "citrullinase" which released CO_2 from the carbamyl group of citrulline inde-

* Stimulation by acetyl glutamate was much more pronounced in mitochondrial extracts than in intact mitochondria. The amount of stimulation varied considerably with different preparations.

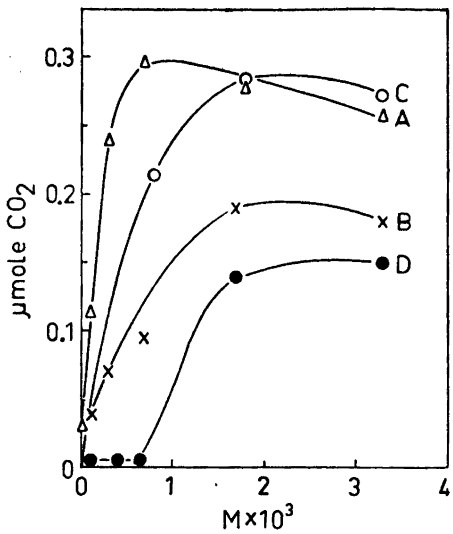

Fig. 2. Dependence of CAP formation on citrulline (curve A), acetylglutamate (curve B) and ATP (curves C and D).

Incubation for 20 minutes at 37°. 50 µmoles of $MgSO_4$ and 250 µmoles of glycylglycine buffer, pH 8.0, in a volume of 3.0 ml for each curve.

Curve A: 10 µmoles of ATP, 20 µmoles of acetyl glutamate, enzyme (1.1 mg nitrogen) and citrulline-^{14}C as indicated on abscissa.

Curve B: 10 µmoles of ATP, 5 µmoles of citrulline-^{14}C, enzyme (0.9 mg nitrogen), and acetyl glutamate as indicated.

Curve C: 5 µmoles of citrulline-^{14}C, 20 µmoles of acetyl glutamate, enzyme (1.1 mg nitrogen), 30 µmoles of PGA, 5 mg MP, and ATP as indicated.

Curve D: 5 µmoles of citrulline-^{14}C, 20 µmoles of acetyl glutamate, enzyme (1.1 mg nitrogen), and ATP as indicated.

All values are given for one experimental point in each curve.

pendent of acetylglutamate concentration. This background release of CO_2 was greatly diminished by the exclusion of phosphate from the system, which did not affect CAP formation. The citrullinase activity was furthermore sharply decreased by carrying out the reaction at pH 8.0, the pH optimum for CAP formation from citrulline (Fig. 1). The pH optimum for citrullinase is 6.8 [17]. The closed circles in Fig. 1 represent the release of carbamyl-CO_2 from citrulline in the absence of added acetyl glutamate, *i.e.* the maximum value for citrullinase in the present system under our experimental conditions.

Requirements of the reaction. Fig. 2 demonstrates the dependence of the reaction on acetylglutamate, citrulline, and ATP. As the different curves were not obtained with the same enzyme preparation, no significance should be attached to the absolute height of the curves, with the exception of curves C and D. These two curves show that the presence of an ATP regenerating system gives better synthesis than ATP alone, presumably because of the presence of ATP-ases. The S-shaped curve D was observed in several experi-

Table 3. Comparison of ATP, ADP, AMP and phosphate in the synthesis of CAP from citrulline-^{14}C.

Additions	μmoles of $^{14}CO_2$ formed	
	+ acetylglutamate	no acetylglutamate
None	0.008	—
20 μmoles of phosphate	0.006	0.011
20 μmoles of ATP	0.105	0.002
20 μmoles of ADP	0.033	0.004
20 μmoles of AMP	0.001	0.001
20 μmoles of ATP + 30 μmoles of PGA + 5 mg MP	0.163	—

5 μmoles of citrulline-^{14}C, 50 μmoles of $MgSO_4$, 250 μmoles of glycyl-glycine buffer, pH 8.0 and additions as indicated were incubated with enzyme (1.3 mg nitrogen) in 3 ml volume for 20 minutes at 37°.

ments and maximum synthesis was sometimes not achieved below 3×10^{-3} M concentration of ATP.

The reaction was also found to be dependent on the presence of Mg^{++}. Enzyme saturation was achieved between 6×10^{-3} — 3×10^{-2} M concentration of $MgSO_4$ without apparent inhibition at higher concentration. Some "versene" was always left in the enzyme (from the preparation of the mitochondria) and undoubtedly influenced the amount of Mg^{++} necessary for optimum synthesis.

The specific requirement for ATP is also demonstrated by Table 3. A small amount of synthesis was observed also with ADP (myokinase action), while AMP or phosphate were without effect. Best synthesis was obtained when ATP was regenerated by addition of PGA and a muscle enzyme fraction.

Fig. 3 represents a time curve of the reaction. The dependance on the amount of enzyme is shown in Fig. 4.

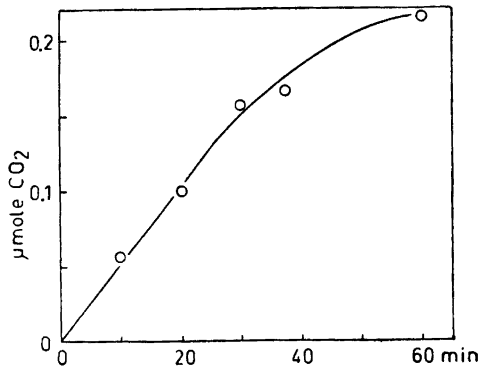

Fig. 3. Time curve of CAP formation.

Substrate and conditions as in Fig. 1 (pH 8.0). 1.1 mg of enzyme nitrogen.

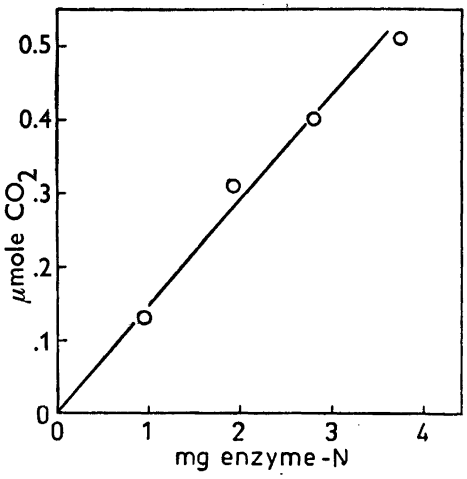

Fig. 4. Dependence of CAP formation on the amount of enzyme. Substrate and conditions as in Fig. 1 (pH 8.0).

Products of the reaction. The presence of CAP at the end of an experiment was demonstrated by the enzymic formation of CA-aspartate after addition of an excess of L-aspartate and aspartate carbamyl transferase from *E. coli* [8]. This enzyme catalyzed the formation of CA-aspartate from CAP and aspartate, but was incapable of forming CA-aspartate from citrulline + aspartate. From several such experiments it was calculated that a minimum of one fourth to one half of the $^{14}CO_2$ released by the addition of acid in the enzyme assay corresponded to CAP present at the end of the incubation. The rest of the $^{14}CO_2$ corresponded presumably to CAP broken down chemically and enzymically [18] during the course of the incubation.

Further evidence for the formation of CAP was obtained by paper chromatography and paper electrophoresis. Citrulline-^{14}C (750 000 ct/min/µmole in the carbamyl group) was incubated under the conditions described in Fig. 3. At the end of the incubation the reaction mixture was chilled and 20 µmoles of synthetic CAP were added as carrier. All subsequent steps were carried out at 0—5°. Protein was precipitated by the addition of 0.5 N PCA to pH 1—2 and the supernatant after centrifugation was neutralized to pH 8.0 with M NaOH (phenolphthalein). Then 0.5 ml of M barium acetate were added and the resulting precipitate was discarded after centrifugation. Two volumes of alcohol were added and the Ba-CAP was centrifuged and dried.

The barium salt was extracted with 0.25 ml of water + 0.05 ml of M sodium sulfate in the cold. After centrifugation aliquots of 0.01 ml of supernatant were subjected to paper electrophoresis[12] (saturated sodium tetraborate containing 0.01 M versene, 4 hours at 0°, 12 volts/cm) and ascending paper chromatography with three different solvents (methanol: 2 M NH_3: versene [19], 7:3:0,01;

5 % K_2HPO_4: *iso*amyl alcohol [20]; propanol: water; conc. NH_3: versene [21], 6:1:3:0.01). After drying the paper strips were scanned for radioactivity.

In all four solvents the CAP obtained by the carrier technique from the citrulline-^{14}C incubation showed a radioactive spot which coincided with that obtained from synthetic CAP (*cf.* Ref. [8]). When acetylglutamate or ATP was not included during the incubation no radioactivity appeared in the chromatograms at the place of CAP. The best separation was obtained by paper electrophoresis and results with this method have been published in a preliminary communication [12]. After paper electrophoresis one more radioactive spot was observed whose presence depended on the inclusion of acetylglutamate and ATP during the incubation. This compound moved faster towards the anode than CAP and it could also be obtained from carbamylglutamate-^{14}C. It was therefore suggested that the compound was CAP bound to a glutamic acid derivative [12].

The incorrectness of this idea has now been demonstrated by experiments in which CAP was formed in the presence of ^{32}P labeled ATP and ^{32}P labeled inorganic phosphate, respectively (conditions as in Fig. 3, but including 100 μmoles of K_2HPO_4 and excluding PGA and MP). When added carrier CAP was reisolated and subjected to electrophoresis as described above no radioactivity was found in the position of the fast moving band.

Ion exchange chromatography of the reisolated CAP showed that this substance had received ^{32}P from ATP while in the experiment with labeled inorganic phosphate only a very small incorporation of isotope into CAP was observed (*ca.* 12 % of that found in the ATP experiment).

Ornithine was demonstrated as a product of the reaction by ion exchange chromatography by the method of Hirs *et al.*[22] In one experiment when 0.80 μmoles of $^{12}CO_2$ were liberated after acid treatment (corresponding to CAP), 1.04 μmoles of ornithine were formed, thus demonstrating a rough stoichiometry for the two products of the reaction. In the absence of acetylglutamate ornithine formation was negligible.

Ornithine was a very potent inhibitor of CAP formation from citrulline and ATP. At 1.7×10^{-3} M concentration of citrulline a 50 % inhibition of the reaction rate was observed at *ca.* 0.7×10^{-4} M concentration of ornithine. No similar inhibition was observed with CAP.

DISCUSSION

It is evident from the present investigation that the utilization of citrulline for the biosynthesis of pyrimidines in rat liver represents a relatively small fraction of the total pyrimidines formed. In liver slices it was found that only 0.14 μmoles of orotic acid were synthesized from citrulline-CA-^{14}C under conditions that permitted synthesis of 3—5 μmoles of orotic acid from ammonia. This low rate of pyrimidine synthesis from citrulline was the reason why in earlier experiments with citrulline-CA-^{15}N it was concluded that the utilization of ammonia for pyrimidine synthesis did not proceed *via* citrulline.[6]

The present experiments demonstrate that in rat liver preparations the carbamyl group of citrulline can be utilized for the synthesis of CA-aspartate. This process could be separated into at least two enzymic steps. In the first

step the CA-group of citrulline gave rise to CAP, which in the second step reacted with aspartate to form CA-aspartate. Since the second step has been described earlier [6-8], this paper is mainly concerned with the first step, *i.e.* the formation of CAP.

Using intact mitochondria and comparing the utilization of labeled bicarbonate and citrulline for CA-aspartate synthesis it could be clearly demonstrated that the carbamyl group of citrulline was used relatively directly and not after breakdown to ammonia and CO_2 (Table 1). The dilution experiments with non-labeled ammonium carbonate — which in solution is in equilibrium with ammonium carbamate — also made the participation of free carbamate in the reaction unlikely.

In addition to citrulline the formation of CAP required ATP, acetylglutamate, and Mg^{++}. Addition of phosphate either did not influence or slightly decreased CAP formation as measured in our enzyme assay. This fact, together with the specific requirement for ATP and the pH optimum of 8.0, makes it unlikely that the phosphorolytic cleavage of citrulline [17], which might represent a reversion of reaction (3), was involved in the formation of CAP from citrulline *.

The requirement for acetylglutamate also differentiates this enzyme system from citrullinase. Acetylglutamate, or a similar compound, was previously shown to be required by rat liver preparations for CAP synthesis from CO_2, NH_3 and ATP. The function of acetylglutamate in CAP formation is not understood at the present time. Our earlier evidence for the existence of an intermediate compound, containing CAP bound to acetylglutamate [12] has been invalidated by the present finding that the proposed compound does not contain phosphate.

Two of the products of the reaction have been identified as CAP and ornithine. It seems likely that ADP was also formed but the presence of ATP-ase and myokinase in the mitochondrial extracts made it impossible to demonstrate the specific formation of ADP. Because of the unusual instability of the enzyme activity attempts to purify the enzyme by ammonium sulfate precipitation were not successful.

CAP formation from citrulline in other rat organs than liver could not be demonstrated **. The apparent low activity in mitochondrial extracts together with the high inhibition by ornithine would seem to indicate that the formation of CAP from citrulline in the rat is of minor quantitative importance for pyrimidine biosynthesis.

Acknowledgement. This investigation has been supported by grants from *Riksföreningen för Kräftsjukdomarnas bekämpande.*

The authors gratefully acknowledge the valuable technical assistence of Miss B. Carlsson and Mr. G. Hanshoff.

* *Added in proof:* We have recently extensively purified ornithine carbamyl transferase (the enzyme catalyzing reaction (3)) from rat liver and found that the citrullinase of Krebs *et al.*[17] in all probability is identical with this enzyme. Reversal of reaction (3) therefore represents an alternative way for CAP formation from citrulline which — unlike the reaction demonstrated in this paper — does not involve the participation of acetyl glutamate or ATP.

** An acetylglutamate stimulated release of $^{14}CO_2$ from citrulline-carbamyl-^{14}C was, however, observed with washed cells of *E.coli*.

Short Communication

Synthesis of Racemic Methyl C_{27}-Phthienoate. Part II.

CECILE ASSELINEAU*, JEAN ASSELINEAU* **, and STINA STÄLLBERG-STENHAGEN

and

EINAR STENHAGEN

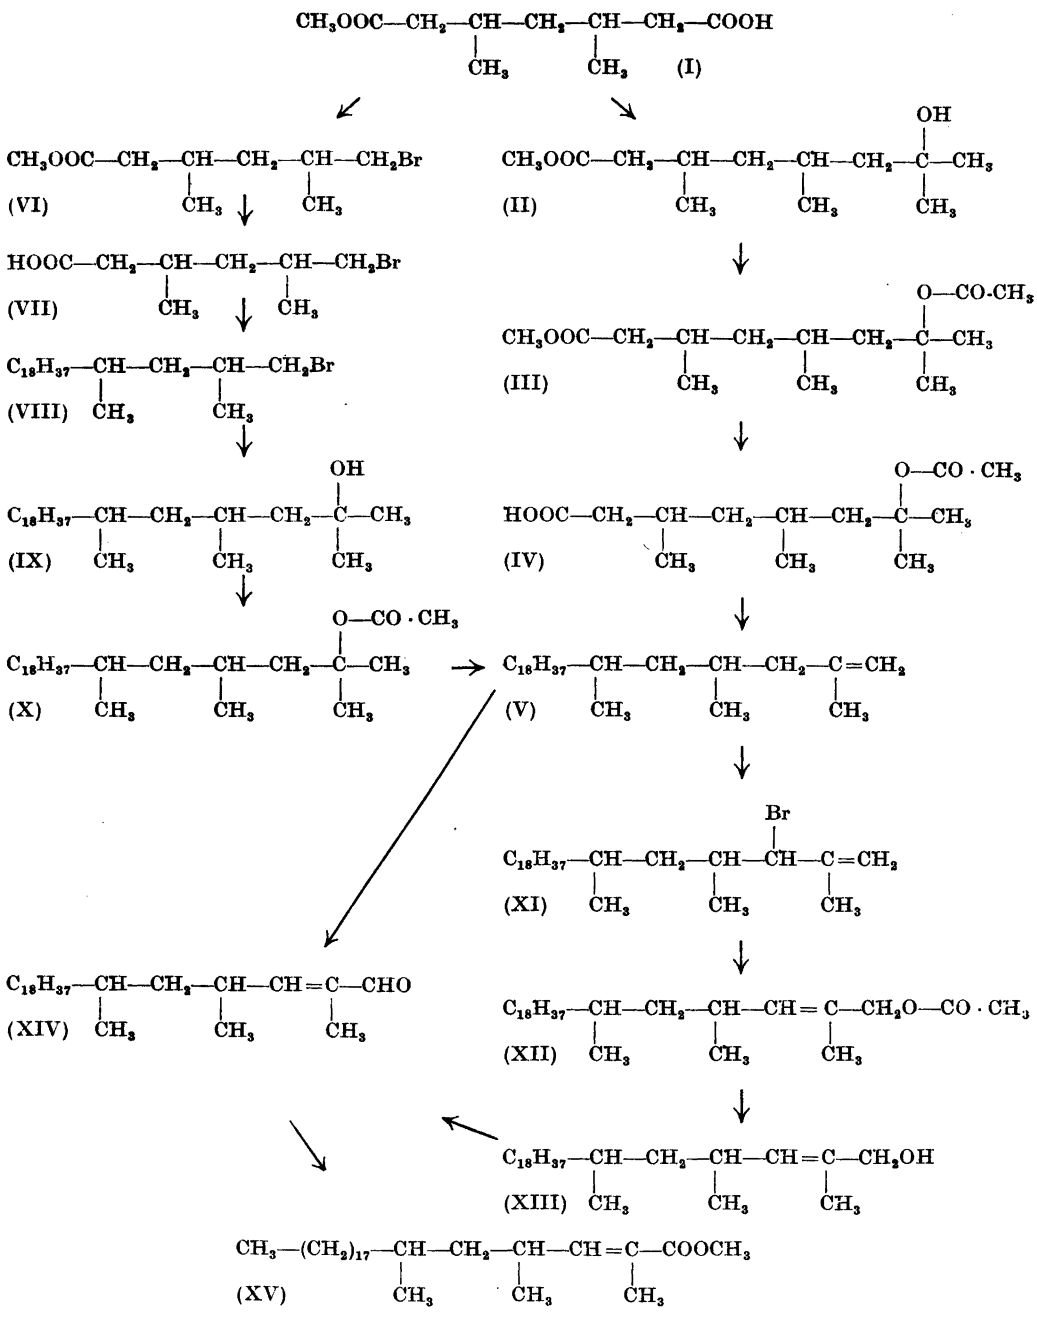
Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

A synthesis of racemic methyl *erythro*-2,4,6-trimethyl-$\Delta^{2:3}$-tetracosenoate was described in a previous communication [1]. The route which was used gave, as major product, the *cis*-isomer. The *trans*-isomer also obtained had the same infra-red absorption curve as the methyl ester of C_{27}-phthienoic acid isolated from tubercle bacilli [2,3].

In the present communication, a new method of synthesizing racemic methyl *erythro*-2,4,6-trimethyl-$\Delta^{2:3}$-tetracosenoate is described, which gives almost solely the *trans*-isomer. The starting material, the monomethyl ester of *meso*-3,5-dimethylpimelate (I), is the same as that used in the previous synthesis [1]. The sequence of reactions involved is shown in the following chart.

The acid chloride of (I) was treated with the calculated amount of CH_3MgI in the cold, and the neutral product obtained (II) was acetylated by boiling with acetic anhydride: methyl 3,5,7-trimethyl-7-acetoxyoctanoate (III) was isolated as a colourless liquid, b. p. 92—94°, 0.2 mm, $n_D^{25} = 1.4358$, $d_4^{25} = 0.965$. By cautious saponification, the acid (IV) was obtained. Kolbe reaction [4] of 3,5,7-trimethyl-7-acetoxyoctanoic acid (IV) with stearic acid and isolation of the reaction products by distillation gave 2,4,6-trimethyltetracosene-1 (V), m. p. 10.2—10.6°, $n_D^{20} = 1.4549$, $d_4^{20} = 0.811$ ($C=CH_2$ I.R. out of plane deformation vibration at 11.26 μ).

The formation of the unsaturated hydrocarbon (V) (instead of the expected long-chain acetoxy-compound) is due to thermal decomposition of an intermediary trimethyltetracosanyl-2 stearate arising from a transesterification of trimethyltetracosanyl-2 acetate (X) when distilled in the presence of free stearic acid. 2,4,6-Trimethyl-2-acetoxytetracosane (X) can be distilled without decomposition, whereas slow distillation of a mixture of the same acetoxy-compound (X) together with free stearic acid gives trimethyltetracosene-1 in excellent yield.



The same hydrocarbon (V) was also prepared from methyl hydrogen 3,5-dimethylpimelate (I) by bromine degradation of its silver salt according to Hunsdiecker [5], hydrolysis of the bromo-ester (VI) thus obtained to the bromo-acid (VII) (colourless liquid, $n_D^{21} = 1.4750$, $d_4^{21} = 1.298$), and transformation of this bromo-acid through Kolbe reaction with stearic acid * into 2,4-dimethyldocosanyl bromide (VIII) (colourless liquid, $n_D^{20} = 1.4635$, $d_4^{20} = 0.950$). 2,4-Dimethyldocosanyl magnesium bromide was obtained in low yield by the

* In a recent paper [10], the behaviour of straight chain ω-halogenocarboxylic acids in the Kolbe reaction was studied; it was concluded that "only with a chain length of eleven or greater did normal coupling occur". In our case, the main chain consisted of only six carbon atoms.

CH3OOC—CH2—CH(CH3)—CH2—CH(CH2)—CH2—COOH (I)
CH3OOC—CH2—CH(CH3)—CH2—CH(CH2Br)—CH3 (VI)
HOOC—CH2—CH(CH3)—CH2—CH(CH2Br)—CH3 (VII)
C18H37—CH(CH3)—CH2—CH(CH3)—CH2Br (VIII)
C18H37—CH(CH3)—CH2—CH(CH3)—CH2—C(OH)(CH3)—CH3 (IX)
C18H37—CH(CH3)—CH2—CH(CH3)—CH2—C(O—CO·CH3)(CH3)—CH3 (X)
CH3OOC—CH2—CH(CH3)—CH2—CH(CH3)—CH2—C(OH)(CH3)—CH3 (II)
CH3OOC—CH2—CH(CH3)—CH2—CH(CH3)—CH2—C(O—CO·CH3)(CH3)—CH3 (III)
HOOC—CH2—CH(CH3)—CH2—CH(CH3)—CH2—C(O—CO·CH3)(CH3)—CH3 (IV)
C18H37—CH(CH3)—CH2—CH(CH3)—CH2—C(=CH2)—CH3 (V)
C18H37—CH(CH3)—CH2—CH(CH3)—CHBr—C(=CH2)—CH3 (XI)
C18H37—CH(CH3)—CH2—CH(CH3)—CH=C(CH2O—CO·CH3)—CH3 (XII)
C18H37—CH(CH3)—CH2—CH(CH3)—CH=C(CH2OH)—CH3 (XIII)
C18H37—CH(CH3)—CH2—CH(CH3)—CH=C(CHO)—CH3 (XIV)
CH3—(CH2)17—CH(CH3)—CH2—CH(CH3)—CH=C(COOCH3)—CH3 (XV)

method of Geiger-Berschandy [6] and after reaction with acetone, 2,4,6-trimethyltetracosanol-2 (IX) was isolated (m. p. 23.1—24.1° and 27.5—29.0° (dimorphism)), $n_D^{24} = 1.4554$, $d_4^{24} = 0.842$. 2,4,6-Trimethyl-2-acetoxytetracosane (X) (m. p. 8.6—9.2°, $n_D^{23} = 1.4498$, $d_4^{23} = 0.853$) was prepared by boiling the free alcohol with acetic anhydride. Distillation of this acetate with stearic acid gave 2,4,6-trimethyltetracosene-1 (V) ($n_D^{23} = 1.4533$, $d_4^{23} = 0.808$).

Allylic bromination of the unsaturated hydrocarbon (V) with N-bromo-succinimide [7] gave a bromo-compound (XI) which was transformed into 2,4,6-trimethyl-1-acetoxytetracosene (XII) under conditions which favoured the allylic transposition. The free primary alcohol (XIII) was obtained after $LiAlH_4$ reduction of its acetate. CrO_3-pyridine oxidation [8] gave the unsaturated aldehyde (XIV) (phthienoic aldehyde) (crude product: λ_{max} 225 mμ, $\varepsilon = 7\,280$ in hexane; I.R. spectrum: aldehydic C—H stretching vibration at 3.72 μ and C=O stretching vibration at 5.92 μ). Silver oxide oxidation [9] of the unsaturated aldehyde and chromatographic purification of the acidic fraction as methyl ester gave the *trans*-isomer of methyl *erythro*-2,4,6-trimethyl-$\Delta^{2:3}$-tetracosenoate (XV) (m. p. 14.1—14.6°, $n_D^{25} = 1.4598$, λ_{max} 216 mμ, $\varepsilon = 12\,850$ in hexane); no *cis*-isomer could be detected.

The transformation of 2,4,6-trimethyltetracosene-1 (V) into C_{27}-phthienoic aldehyde (XIV) was also directly performed by SeO_2 oxidation [11]; the α,β-unsaturated aldehyde chromatographically purified had m. p. 29.5—35.0°, λ_{max} 225 mμ, $\varepsilon = 15\,550$ (hexane). Silver oxide oxidation lead to a sample of slightly impure *trans*-isomer of methyl *erythro*-2,4,6-trimethyl-$\Delta^{2:3}$-tetracosenoate (XV): m. p. 16.8—17.6°, $n_D^{25} = 1.4597$, λ_{max} 217 mμ, $\varepsilon = 11\,900$ in hexane.

The infra-red absorption curves of both preparations of the *trans*-form of racemic methyl *erythro*-2,4,6-trimethyl-$\Delta^{2:3}$- tetracosenoate described in the present paper are identical with that of the *trans*-isomer described previously [1], and with that of the methyl ester of naturally occurring C_{27}-phthienoic acid.

In this synthetic route, the carboxyl group of phthienoic acid is introduced on the side of the free acid group of the methyl hydrogen 3,5-dimethylpimelate (I) whereas in the route previously described [1] it is introduced on the ester side of the half ester (I). For the synthesis of the optically active natural acid it is therefore necessary to start with different enantiomorphs of (I) in the two routes.

We are indebted to Dr. I. Fischmeister for the infra-red spectra. The expenses involved in this work were defrayed by grants from *the Swedish Medical Research Council* to S. Ställberg-Stenhagen.

Structural Factors Involved in the Reduction of External DPN * by Mitochondrial Systems

L. Ernster and F. Navazio **

The Wenner-Gren Institute for Experimental Biology, Stockholm, Sweden

Previous studies [1] of the mitochondrial organization of DPN-linked oxidative systems have indicated the involvement of reversibly alterable structural factors in the availability of external DPN for intramitochondrial dehydrogenase reactions. The present report constitutes a complement to these studies, dealing with the effects of aging and subsequent structural reconstruction by ATP and Mn^{++} on the capacity of mitochondria to oxidize glutamate with external DPN as the terminal hydrogen acceptor.

Twice washed mitochondria from one rat liver, prepared in 0.25 M sucrose, were suspended in 20 ml 0.15 M KCl, containing 24 mg AMP, 174 mg K_2HPO_4 and 216 mg glucose (pH 7.5); the suspension was supplemented with 0.6 ml 0.1 M $MgCl_2$ and an excess of hexokinase, and diluted with 0.25 M sucrose to 30 ml. The suspension was aged at 30° C in a 200 ml Erlenmeyer flask under shaking in the presence of air. 0.2 ml aliquots were removed before and during aging and transferred to Beckman cuvettes containing 1.1 ml 0.05 M potassium phosphate buffer (pH 7.5), including 2.7 μmoles DPN, 1 μmole KCN and other additions to be tested. Silica plungers, reducing the light path to 1 mm, were placed in the cuvettes and optical density was measured at 340 mμ. After the zero time reading, 0.2 ml 0.1 M glutamate was added and the readings repeated each minute. The increase, proportional to the formation of DPNH, was virtually linear during the first five minutes. The blank contained all components but glutamate, which was replaced by 0.2 ml 0.05 M phosphate buffer.

In experiments entailing a determination of respiration and phosphorylation, 1.5 ml aliquots of the mitochondrial suspension were transferred to Warburg vessels and supplemented with 0.2 ml 0.1 M glutamate, as well as desired individual additions, to a final volume of 2 ml. The analytical procedures have been described elsewhere [2]. All experiments were performed at 25° C.

Table 1 shows that the rate of DPNH formation markedly increases upon aging and reaches a maximum after about 80 minutes. This increase can be prevented by Mn^{++} (Table 2), or reversed to the level prevailing in the intact system by the addition of ATP

and Mn++ (Table 3). In the latter case, Mn++ alone is without effect, while ATP alone or, to a lesser extent, ADP, but not AMP, may exhibit a certain action.

In the experiment presented in Table 4, it is shown that the effect of ATP and Mn++ is not due to an inhibition of the oxidation of glutamate, but rather to a structural reconstruction of the mitochondrial system, also involving a restoration of the phosphorylative ability.

The results support the previous postulate [1] that the availability of cytoplasmic DPNH is controlled by the structural state of the mitochondria.

The Effect of Thyroxine on Mitochondrial Stability

Robert E. Beyer*, Hans Löw and Lars Ernster

Wenner-Gren's Institute, Stockholm, Sweden

It has been demonstrated repeatedly that thyroxine, either administered *in vivo* [1-3] or applied *in vitro* [1,2,4-8], may lower the P/O ratio of isolated rat liver mitochondria. The action of thyroxine applied *in vitro* can be obliterated by Mg++, and more efficiently [7] by Mn++. These ions had been shown previously to protect mitochondria against the action of calcium [9,10]. Using phosphorylative ability [10] and optical density [11] as criteria, it has been shown that under suitable conditions the stability of the enzymic and morphological integrity of isolated mitochondria is an inverse function of the concentration ratio of Ca++/Mg++ and/or Ca++/Mn++ in the system. It was therefore visualized that the action of thyroxine may be reflected primarily in a labilization of mitochondria rather than in a direct action on oxidative phosphorylation. Optical density studies of liver mitochondrial preparations derived from normal and thyroxine treated rats have lent support to this concept [8]. A labilization of the system has been demonstrated to occur even at doses of thyroxine where a direct effect on oxidative phosphorylation could not be ascertained.

All rats used were of the Wistar strain weighing between 125 and 150 g. Hyperthyroidism

was induced by intraperitoneal injections of 0.1 mg DL-thyroxine (F. Hoffmann-La Roche and Co. A. G., Basel) for five days, thyrotoxicosis by intraperitoneal injections of 2 mg of DL-thyroxine for various periods. Control animals were injected with suitable sodium chloride solutions. Mitochondria were prepared essentially after Schneider and Hogeboom [12] and suspended in the Mg^{++} free aging medium of Ernster and Löw [10]. Optical density measurements were performed as previously described [11] at room temperature. Phosphorylation was determined according to a modification [13,14] of the Martin and Doty [15] method. Succinate oxidation was measured by the conventional Warburg technique.

Since the *potential* phosphorylative ability of a mitochondrial system may be studied by following the optical density loss during aging in a Mg^{++} free, substrate free, incubation medium supplemented with hexokinase [11], such experiments were performed on liver mitochondria derived from thyrotoxic and control rats. Mitochondria from a thyrotoxic rat liver swell more rapidly than control mitochondria, *i. e.* the former mitochondria become swollen at an earlier stage of the aging process. When the "aging index" is expressed as the time required for 1/2 minimum optical density to be attained, the mean value of 12 experiments for the thyrotoxic mitochondria is 6.5 minutes, for the control, 17.8. The probability that this difference will occur through chance alone is 14 in 10 000. Preliminary data indicate that liver mitochondria from hyperthyroid rats have an aging index intermediate between the control and the thyrotoxic. Further preliminary experiments indicate that the phosphorylation coupled to the oxidation of succinate in mitochondria from thyrotoxic rats possesses a greater sensitivity to calcium ions than does the normal preparation. Table 1 presents an experiment illustrating this point. Phosphorylation became uncoupled from oxidation at the 0.5 mM level in the thyrotoxic series while the P/O ratio remained above 1 at considerably higher levels of calcium in the control flasks. It may also be seen that no uncoupling of oxidative phosphorylation occurred in the thyrotoxic flask when calcium was not added. Unpublished experiments indicate that a preincubation, or equilibration period, may cause a preferential uncoupling of oxidative phosphorylation in the thyrotoxic system, and that this effect may be restored by the addition of ATP and Mn^{++}.

These data are interpreted as follows: Thyroxine, or its active principle, renders the mitochondria, *in vivo*, more susceptible to factors or mechanisms which may lower their phosphorylative efficiency. Upon isolation of the particles and incubation in routinely employed medium this increased susceptibility may elude detection since the incubation media used in studies of oxidative phosphorylation have been systematically developed with the highest possible phosphorylative efficiency as a goal. The lability of the mitochondria, or the potential aging capacity, remains, however. Thus, aging under controlled conditions [10,11], *i. e.* supplying artificial regulatory mechanisms, reveals that the difference between the thyroxine treated and normal animals is the *degree of lability* of the oxidation-phosphorylation systems.

The Action of a Mitochondrial Protein Fraction on Mitochondrial ATP-ase and Oxidative Phosphorylation

Robert E. Beyer* and John Glomset

Wenner-Gren's Institute, University of Stockholm, Stockholm, and Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

A protein fraction has been extracted from rat liver mitochondria which stimulates "latent" mitochondrial ATP-ase activity without exhibiting ATP-ase itself and which stimulates the oxidation of succinate in a mitochondrial system containing AMP as the terminal phosphate acceptor. The fraction, in 0.1 M Tris (tris(hydroxymethyl)aminomethane), pH 7.4, has its spectroscopic peak in the Soret region at 414 mμ; in the visible region at 548 mμ and 576 mμ. The mitochondrial ATP-ase stimulating activity is proportional to the concentration of the fraction added.

The mitochondrial fraction (fraction 60) is prepared as follows. Rat liver mitochondria are prepared essentially according to Schneider and Hogeboom [1] using 0.25 M sucrose-0.001 M versene, pH 7.4, as the homogenizing medium. The mitochondrial pellet is washed twice in 0.25 M sucrose and then suspended in Na_2CO_3 which has been adjusted to pH 8.4 with HCl and diluted to 0.1 M. The suspension is then shaken for 12—18 hours at 0—4° C, followed by centrifugation in a Spinco Model L Centrifuge for 7 979 400 *g*-minutes (3 hours, 21 000 RPM, head $\neq$21). The resulting pinkish-yellow supernate is then adjusted to pH 6.5 with acetic acid. The slight cloudy precipitate which forms is centrifuged down. Chilled acetone is added to the supernate in a dropwise fashion with constant stirring to 10 % and maintained in an acetone-dry ice bath made by producing a thick slurry of 9 % acetone and powdered dry ice. The precipitate is spun down in an International Refrigerated Centrifuge at the temperature of the acetone-dry ice bath. Additional fractions are collected at 20, 30, 40 and 60 % acetone, adjusting the acetone-dry ice bath to 19, 29, 39 and 59 % acetone at each subsequent precipitation. The centrifuge is also adjusted accordingly until its lower limit is reached. The pink precipitate resulting from the 40—60 % fraction, called fraction 60, is completely soluble in Tris buffer, pH 7.4, resulting in a cherry red solution. From approximately 100 g of rat liver 10 ml of a solution with an optical density reading at 280 mμ (Beckman DU spectrophotometer) of 1.7 through a 1 cm path length have been obtained. Preliminary experiments indicate that fraction 60 may also be prepared by the above method from "acetone mitochondria" which have been stored *in vacuo* at —15° C for several weeks.

The preparation of a mitochondrial fraction with an action on mitochondrial ATP-ase processes provides a basis for hypotheses which implicate the fraction in oxidative phosphorylation. A protein factor, called mitochrome-I, has been reported briefly [2-4] which appears to have an action similar to fraction 60. Attempts to prepare mitochrome-I, however, have not been successful in our hands. Furthermore, since the only datum of a chemical nature reported for mitochrome-I is its approximate molecular weight, a direct comparison of the two factors has been impossible.

It must be added that fraction 60 is probably not homogeneous. Attempts are in progress to further purify the active principle of fraction 60 by zone electrophoresis and chromatography on cellulose ion exchange columns, as well as to gain some insight into its role in the transfer of high energy phosphate.

Enzymic Synthesis of Xanthosine- and Guanosine-5-phosphate

Ulf Lagerkvist

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Extracts of pigeon liver acetone powder catalyze the following reactions: [1]

$$\text{Inosine-5-phosphate} \xrightarrow{\text{DPN}^*} \text{Xanthosine-5-phosphate} \quad (1)$$

$$\text{Xanthosine-5-phosphate} \xrightarrow[\text{L-glutamine}]{\text{ATP}} \text{Guanosine-5-phosphate} \quad (2)$$

Abrams and Bentley [2] have independently demonstrated the occurrence of reactions (1) and (2) in extracts of rabbit bone marrow while Gehring and Magasanik found reaction (1) in *Aerobacter aerogenes* [3].

* The following abbreviations are employed: ATP = adenosine triphosphate, DPN = diphosphopyridine nucleotide, DEAE = diethylaminoethyl.

The enzyme (or enzymes) catalyzing reaction (2) has been purified by fractionation with ammonium sulfate, adsorption on Cγ gel and chromatography on DEAE-cellulose according to Peterson and Sober *et al.* [4,5]. The stoichiometry and mechanism of reaction (2) will be discussed.

Incorporation of Radioactive Phosphate into Thiamine Phosphate in Yeast

Karl-Heinz Kiessling

Zoophysiological Institute, Uppsala, Sweden

Besides thiamine diphosphate yeast contains small amounts of thiamine triphosphate. When incubating yeast with an excess of thiamine under special conditions the amount of thiamine triphosphate can be considerably increased. The incorporation of ^{32}P into thiamine triphosphate in yeast has been studied and compared with that into thiamine di- and monophosphate and adenosine triphosphate. The experiments have been carried out partly with yeast containing only its natural amount of thiamine phosphates, partly with yeast enriched in thiamine phosphates. In both cases ^{32}P was incorporated to a higher degree into thiamine triphosphate than into the other thiamine compounds. The incorporation into thiamine triphosphate was localized especially to the terminal phosphate.

Studies on a Thrombin-coagulable Protein in Blood Platelets

Kristian Grette

The Physiological Institute, University of Oslo, Norway

Reports on the effect of thrombin on washed platelet suspensions and platelet extracts indicate the presence of a thrombin-coagulable protein [1,2].

A preliminary report is given of experiments in which these observations were verified. Extraction and partial purification of the coagulable material is described, together with observations of some of its characteristics. The effects of thrombin on intact blood platelets are discussed in relation to these results.

A detailed report will be published later.

Nucleotide Metabolism in the Surviving Rat Diaphragm

Aa. Rye Alertsen, O. Walaas and E. Walaas

Institute of Physiology, University of Oslo, Norway

The metabolism of acid-soluble nucleotides in the isolated rat diaphragm has been studied by aid of ion exchange chromatography on Dowex-1 Resin according to the method of Hurlbert *et al.*[1]. 9 major compounds have been isolated, the predominant nucleotides being AMP, ADP, ATP and DPN. In incubation experiments the interconversion of nucleotides within the diaphragm and the liberation of nucleotides to the medium have been studied. Experiments under aerobic and anaerobic conditions have been performed. The effect of 2,4-dinitrophenol, insulin and adrenaline on nucleotide metabolism has been studied. The mechanism of glucose uptake by muscle is discussed.

The Interaction of Rat Muscle Hexokinase with the Mg-ATP Complex

E. Walaas and O. Walaas

Institute of Physiology, University of Oslo, Norway

In experiments on partly purified rat muscle hexokinase the role of Mg^{2+} and ATP on the enzyme activity have been studied. The effects of cations, anions, inorganic pyrophosphate, ITP, UTP, GTP and CTP on the rate of the reaction have been investigated. Indication of the nature of the Mg-ATP complex with hexokinase has been obtained.

The Breakdown of Adenosine Triphosphate in Human Blood

Søren Jørgensen

Department of Pharmacology, University of Copenhagen, Denmark

Using an enzymic spectrophotometric method elaborated according to Kalckar's principles, the concentrations of the adenosine mononucleotides ATP, ADP and AMP were followed in shed human blood during standing.

In freshly withdrawn blood the total concentration of these three nucleotides was about 600 μmole per liter of blood; 85 % of this was ATP. The amount of ADP was higher than AMP. During storage at 37° C the ATP decreased gradually and had disappeared in 24 hours. ADP and AMP showed an intermittent 2—5 fold increase compared to the initial concentration. During the 24 hours storage the concentration of hypoxanthine and xanthine increased about 100 fold from 5 to 500 μmole/l. The total molar sum of the adenine nucleotides, hypoxanthine and xanthine, was nearly constant during the whole period.

In mechanically haemolysed blood the ATP disappeared completely within 4 hours. In the same period the ADP and AMP increased about 3 and 10 fold, respectively, and disappeared from the blood within 8 hours. The concentration of hypoxanthine and xanthine showed a concomitant increase from 5 to 500 μmole/l. In this case also, the sum of all the measured compounds remained constant.

By adding ATP, AMP and IMP (inosinic acid) to blood these nucleotides were degraded into hypoxanthine with increasing velocity in the mentioned sequence. Adenosine and inosine were transformed with greater but uniform velocity.

The breakdown of added ATP in whole blood takes place extracellularly and consists of a stepwise dephosphorylation. From the course of the curves for ATP, ADP and AMP in the plasma of the whole blood, it is concluded that the splitting off of all three phosphate groups is catalysed by one and the same enzyme mainly localised on the blood cells.

In plasma without blood corpuscles the breakdown of ATP takes place with a much smaller velocity than in whole blood.

The breakdown of AMP and IMP is initiated by a dephosphorylation.

Hypoxanthine formation in plasma takes place with equal velocity from added AMP, IMP, adenosine and inosine. It is therefore concluded that the splitting of inosine is the velocity determining reaction.

Biosynthetic Preparation of ^{14}C-labelled 2-Deoxy-D-ribose and Thymidine by Means of *Thiobacillus denitrificans*

K. Baalsrud and S. Laland

Institute of Marine Biology and Biochemistry Department, University of Oslo, Norway

In connection with studies on the metabolism of 2-deoxy-D-ribose and thymidine, it became desirable to perform experiments with labelled material. The possibility of obtaining ^{14}C uniformly labelled DNA as a source for these substances has been considered. It was concluded that the use of an autotrophic organism like *Thiobacillus denitrificans* which can be grown in the dark on a large scale in deep culture under controlled conditions, would offer a simple and satisfactory solution. The strain of *Thiobacillus denitrificans* used was isolated from the fresh water mud of an Oslo lake. The medium and technique used for the large scale cultivation of this organism has been described previously [1]. The organism was grown in the presence of $Na_2{}^{14}C\,O_3$ and utilized 98 % of the total activity present. The cells were harvested from a 50 % ethanol solution and the supernatant contained 20 % of the total activity. The cell residue was treated with 96 % ethanol and, after drying, extracted twice with 10 % NaCl at 100° C. The nucleic acids were precipitated with ethanol, redissolved in 10 % NaCl and reprecipitated. From 17 g of dried cells, 26 mg DNA (as estimated by the Dische test) and 58.4 mg RNA (as estimated by the Euler and Hahn test) were obtained. DNA was separated from RNA by treatment with KOH and acid precipitation. 2-Deoxy-D-ribose and thymidine were isolated from DNA by a method described previously [2]. The mixture of labelled thymidine and 2-deoxy-D-ribose was separated by paper chromatography and isolated by the elution of the appropriate areas of the chromatogram. There was isolated 0.625 mg thymidine (2.58 μM) and 0.347 mg (2.59 μM) of 2-deoxy-D-ribose, with a total activity of 0.93×10^6 c/min and 0.51×10^6 c/min, which corresponds to an activity of 0.36×10^5 c/min/μM carbon and 0.32×10^5 c/min/μM carbon respectively. The total activity of 2-deoxy-D-ribose and thymidine together represented 0.2 % of that taken up by the cell residue.

Kinetics of Fatty Acid Dehydrogenation

J. G. Hauge

Central Institute for Industrial Research, Blindern, Oslo, Norway

Four flavoproteins are involved in the first dehydrogenation step of the fatty acid cycle in pig liver [1-3]. Some of the kinetic properties of this system have now been investigated with 2,6-dichlorophenolindophenol as electron acceptor. From these studies the following three step mechanism of reaction appears likely: Electrons are passed from substrate to a primary dehydrogenase; thence to a specific electron transferring flavoprotein; and finally to indophenol. The interaction of the two enzymes concerned with their respective substrates, *i. e.* fatty acyl CoA and reduced primary dehydrogenase, follows Michaelis-Menten behaviour. In the primary dehydrogenation reaction a pronounced product inhibition was observed. The pH optima ranged from 7.6 to 8.4 for the three primary dehydrogenases, when these enzymes were rate limiting. When the transfer step was rate limiting, the optimum was at pH 6.8.

Theoretical considerations reveal that oxidation enzyme systems with tightly bound prosthetic groups, such as the system studied, have special kinetic properties. Michaelis constants and turnover numbers of these enzymes cannot be obtained when overall reactions are measured. The observed apparent Michaelis constants and turnover numbers give the kinetic characteristics of the total substrate-enzyme-acceptor system.

The Fractionation of the Phosphorus-containing Proteins of Rat Liver Cell Sap

John Glomset

Institute of Medical Chemistry, Uppsala, Sweden

The occurrence of phosphoserine and phosphothreonine in partial hydrolysates of liver protein has been demonstrated in previous reports from this laboratory [1,2]. Moreover, phosphoserine was also found in hydrolysates of rat liver nuclear, mitochondrial, microsomal and supernatant protein. Attempts are now in progress to isolate the native, phosphorus-containing proteins of these liver cell fractions. The fractionation of the proteins of the rat liver supernatant fraction is the subject of this communication.

2—4 hours after the intraperitoneal injection of radioactive phosphate into non-fasted male, Wistar rats, the animals were sacrificed by cervical dislocation. The livers were perfused with ice-cold isotonic saline followed by 0.25 M sucrose *via* the hepatic portal vein. The pH of both solutions had been adjusted to 7.4 and both contained 0.01 M versene. After mincing and homogenizing the livers in the versene-sucrose solution the supernatant fraction was prepared essentially according to Hogeboom [3]. The proteins of this fraction were then subjected to a preliminary fractionation by precipitation with either a modification of the method of Cohn *et al.*[4] or with ammonium sulfate. The various precipitates were subsequently dissolved in tris buffer (tris hydroxymethyl aminomethane) pH 7.8, dialyzed at 0—1° for 1—2 hours and then further fractionated by zone electrophoresis in tris buffer according to Porath [5] on 100—150 cm cellulose powder columns. After the completion of the electrophoresis the effluent from the column was followed by spectrophotometric reading at 260 and 280 mμ and by measurement of the ^{32}P content of the effluent tubes. The identity of the phosphoprotein fractions was established by hydrolysis followed by the chromatographic isolation of phosphoserine using the methods described previously [1,2]. A detailed paper will be published shortly.

Partition Chromatography of some C_{27}-Steroids

H. Danielsson

Department of Physiological Chemistry, University of Lund, Lund, Sweden

With reversed-phase partition chromatography using *iso*propanol/water (165/135 ml) as mobile and chloroform/heptane (10/40 ml) as stationary phase, it is possible to separate hydroxy- and keto-C_{27}-steroids. Substances with hydroxyls in the 3-, 7- and 12-position and 3-ketones have been used and are separated into groups of compounds containing 3, 2 and 1 hydroxyl, respectively, and one with 3-ketones. Those with a double bond in the 5,6-position can be separated from the saturated ones. Furthermore, by increasing the content of water in the mobile phase a separation of 3α,7α-dihydroxy from 3α,12α-dihydroxy coprostane is obtained.

Table 1 shows the result of a run with the phases mentioned above. 4 ml of the stationary phase was supported on 4.5 g of Hyflo Supercel, made completely hydrophobic with dichlorodimethylsilane [1].

Compound	Appearance of compound Beginning	Peak	End
3α,7α,12α-Trihydroxy-coprostane	17	22	26
7α-Cholesterol	22	28	38
3α,7α-Dihydroxy-coprostane	36	45	70
3α,12α-Dihydroxy-coprostane	36	48	70
Cholesterol	75	89	110
Cholestenone	118	132	143
Cholestanone	150	175	200

Some other separations will be discussed.

The Conjugation of 2-Aminoethanesulfinic Acid (Hypotaurine) with Cholic Acid by Rat Liver Microsomes

Lorentz Eldjarn and Jon Bremer*

Norsk Hydro's Institute for Cancer Research, Det Norske Radiumhospital, Oslo, Norway

Hypotaurine seems to be the main immediate precursor of taurine in the organism [1]. Taurine is conjugated with cholic acid by an enzyme system in rat liver microsomes [2]. In the present report we have demonstrated that hypotaurine as well is conjugated with cholic acid by this enzyme system, with the formation of "hypotaurocholic acid".

Hypotaurine-^{35}S was synthesized according to Eldjarn, Pihl and Sverdrup [3]. The preparation of rat liver microsomes and the incubation experiments were performed as earlier described [2].

The reaction was stopped and the proteins precipitated by adding 0.15 ml N perchloric acid to the vessels, followed by 0.15 ml N KOH. The reaction mixture was extracted with 0.6 ml *n*-butanol. Aliquots of the butanol extract were plated for radioactivity measurements or chromatographed on paper according to Sjövall [4].

* Fellow of the Norwegian Cancer Society, Oslo.

The paper chromatography showed that mainly taurocholic acid (R_F 0.25) had been formed after incubation of hypotaurine with cholic acid, but in addition a radioactive compound with R_F 0.75 was found. This presumably was hypotaurocholic acid, since no radioactivity was found at this R_F when hypotaurine was incubated without cholic acid. The identity of the unknown compound was confirmed by the following experiment: The radioactive compound at R_F 0.75 was eluted from the paper with ethanol. The eluate was made alkaline with a few drops of N KOH and stored for 24 hours at 37° C. The eluate was then brought to dryness and the residue was extracted twice with 0.1 ml ethanol. The eluate was again chromatographed according to Sjövall [4]. Approximately 60 % of the radioactivity of the unknown compound at R_F 0.75 reappeared at the R_F of taurocholic acid after this treatment, *i. e.* the hypotaurocholic acid had been oxidized to taurocholic acid.

As the sulfinic groups is a less polar group than the sulfonic group, the coefficient:

$$\frac{\text{concentration in butanol phase after extraction}}{\text{concentration in } H_2O \text{ before extraction}}$$

of hypotaurocholic acid presumably is greater than the coefficient of taurocholate which is known [5] to be 2.0. As a coefficient of 3.5 corresponds to quantitative extraction, the coefficient of hypotaurocholate was presumed to be 3.0. From this coefficient, the extractable radioactivity and from the radioactivity on the paper chromatograms the results of Table 1 were calculated.

The table shows that addition of taurine almost completely abolished the formation of

Table 1.

Substrates	Net counts/min/ 0.05 ml butanol extract	µmole taurocholate formed per vessel	µmole hypotaurocholate formed per vessel
0.5 µmole hypotaurine-^{35}S = 340 000 c/min	0	0	0
0.5 µmole hypotaurine-^{35}S + 1 µmole cholate	4 150	0.082	0.019
0.25 µmole hypotaurine-^{35}S = 170 000 c/min + 1 µmole cholate	3 905 3 660	0.075	0.014
0.25 µmole hypotaurine-^{35}S + 2.4 µmoles inactive taurine + 1 µmole cholate	460 400	—	0.001
0.8 µmole taurine-^{35}S = 105 000 c/min + 1 µmole cholate	2 330 2 220	0.307	0
0.8 µmole taurine-^{35}S + 2.4 µmoles inactive hypotaurine + 1 µmole cholate	1 960 1 820	0.275	—

Microsomes from approximately 500 mg rat liver per vessel, CoA 0.001 M, ATP 0.006 M, KF 0.15 M, sucrose 0.05 M, potassium phosphate buffer (pH 7.4) 0.033 M. Gas phase air, incubation time 90 min., temp. 37° C, total volume 1.5 ml.

hypotaurocholate, whereas addition of hypotaurine had no significant effect on the taurocholate formation. Our experiments therefore show that rat liver microsomes can conjugate hypotaurine with cholic acid, but that taurine is preferred as substrate in the reaction. Since rat liver is known to contain great amounts of free taurine [5], the conjugation with hypotaurine can only be of limited physiological importance in the rat.

Whether the conversion of hypotaurine to taurine is enzymatic or spontaneous in our system is not known.

Formation of Itaconic Acid from the Krebs Cycle Tricarboxylic Acids by Extracts of *Aspergillus terreus*

Elizabeth Brigham Jenssen, Helge Larsen and John G. Ormerod

Department of Biochemistry, The Technical University of Norway, Trondheim, Norway

Evidence has been presented that citric acid [1,2] and *cis*-aconitic acid [3] are intermediates and close precursors to itaconic acid in the formation of itaconic acid from sugars by *Aspergillus terreus*.

Cell-free extracts of *A. terreus* can be prepared by crushing rapidly frozen mycelium in the Hughes' bacterial press and extracting the paste with water. Such extracts, when prepared from itaconic acid producing mycelia (*i. e.*, mycelia grown under acid conditions [4]), will catalyze a conversion of citric, *cis*-aconitic and *iso*citric acids to itaconic acid and carbon dioxide. *cis*-Aconitic acid is by far the most readily converted; citric and isocitric acids were in some experiments converted to itaconic acid only to a negligible extent. The optimum pH is about 5.7. Molecular oxygen does not affect the conversions. Extracts prepared from mycelia grown under neutral conditions (*i. e.*, mycelia not producing itaconic acid from sugars [4]), will not catalyze a conversion of the aforementioned tricarboxylic acids to itaconic acid. This finding is in agreement with the previously presented hypothesis that the itaconic acid forming enzyme system is dependent upon acid conditions for its formation [4].

Active extracts decarboxylate 1 mole of *cis*-aconitic acid to give close to 1 mole of carbon dioxide and 1 mole of itaconic acid. Correspondingly, the yield of carbon dioxide from citric acid is close to 1 mole per mole of citric acid converted, whereas the yield of itaconic acid is usually much lower, *viz.* 0.3—0.6 moles per mole of citric acid converted.

Synthetic monofluorocitrate in a concn. of 10^{-4} M causes an appreciable inhibition in the rate of itaconic acid production from citric acid and a slight inhibition in the rate of itaconic acid production from isocitric acid. 10^{-4} M fluorocitrate does not inhibit the rate or lower the yield of itaconic acid formation from *cis*-aconitic acid; there is rather a slight stimulation. Aconitase has been shown to be present in the extract. Assuming the aconitase to be fluorocitrate sensitive [5], the results would indicate that itaconic acid is formed by decarboxylation of *cis*-aconitic acid.

The reversibility of the decarboxylating system has been tested by incubating itaconic acid producing extracts in the presence of *cis*-aconitic acid and $^{14}CO_2$ at pH 5.3. Itaconic acid and residual *cis*-aconitic acid were isolated and tested for radioactivity. Both compounds were found to be non-radioactive. The lack of radioactivity in the *cis*-aconitic acid does not necessarily imply that the conversion is irreversible; it might equally well indicate an extreme slowness in the mixing of the *cis*-aconitic acid supplied and its biologically activated counterpart [6].

The work was supported by grants from the *Royal Norwegian Council for Scientific and Industrial Research*. We are indebted to Professor R. A. Peters for a gift of synthetic tri sodium monofluorocitrate.

On the Isolation of Gangliosides

Lars Svennerholm

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

Gangliosides in a high yield have been isolated on a small scale by partition chromatography on cellulose columns [1]. A disadvantage with the method is the low capacity. When larger amounts of lipids are applied to the column, part of the gangliosides is eluted together with the main bulk of other lipids. Other methods have therefore been tried. Reversed phase chromatography on hydrophobic kieselguhr did not separate gangliosides from the other lipids. Zone electrophoresis in a capillary system with pyridinium-formic acid buffer in 80 % methanol was suitable only for preparations containing 50 % or more of gangliosides. A good separation was achieved on anion exchange resins. Radin, Lavin and Brown [2] have in a recent work used the same type of resins for the separation of cerebrosides from other glycolipids.

Chloroform-methanol extracts of brain lipids were passed on a strong cation exchanger in hydrogen form (Amberlite IR-120 or Dowex 50-X8, 50—100 mesh). The solution was then percolated through a column packed with a weak anion exchange resin in hydroxyl form (Duolite A-7, 40—60 mesh) or through a strong one in bicarbonate form (Dowex 1, 50—100 mesh). Cerebrosides, cholesterols and part of the phospholipids passed through the column. The rest of the phospholipids, cerebroside sulphuric acid and gangliosides were taken up by the resin and eluted with 0.1—1.0 N formic acid in chloroform--methanol mainly in the order mentioned. The fractions containing gangliosides were evaporated to a small volume. Formic acid and contaminating lipids were removed by partition dialysis as described by Folch *et al* [3]. The anion exchange resins are capable to bind considerable amounts of gangliosides. A Duolite column of the dimensions 25 × 250 mm removed about 90 % of the gangliosides from a total lipid extract of one kilogram of fresh brains.

Determination of Glycolipids in Plasma

Elisabet Svennerholm and Lars Svennerholm

Departments of Medical Clinic II and Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

Only few quantitative estimations of the glycolipids in plasma have earlier been performed [1,2]. They have been based on the determination of the reducing power of a lipid extract before and after hydrolysis. The difference has been attributed to cerebroside sugar, but no attempt has been made to isolate the corresponding lipid. Large variations in the cerebroside content (0—167 mg/100 ml) have been reported. The methods used are unsatisfactory because other reducing substances than sugars are released during the hydrolysis. If gangliosides occur in addition to cerebrosides they will be included in the cerebroside value.

In the method worked out the lipid extract is purified through partition between chloroform and methanol-water. Cerebrosides will go into the chloroform phase, while gangliosides and low molecular contaminants will go into the methanol-water phase.

Experimental. Blood is drawn into a centrifuge tube containing sodium citrate. Plasma is separated from blood cells in a refrigerated centrifuge at 0° and lyophilized. The lipids are extracted with chloroform-methanol (2:1, v/v) under reflux boiling. After evaporation *in vacuo* the lipids are redissolved in the same solvent and quantitatively filtered down into a volumetric cylinder. 1/4 volume of 0.1 % sodium chloride in water is added and the cylinder is shaken thoroughly. On the resulting two phases hexose is determined in the chloroform phase with an orcinol method and sialic acid from gangliosides is determined in the methanol-water phase with Bial's reagent. The mean value of 8 normals was for cerebrosides 4.8 mg/100 ml (range 3.5—5.7) and for gangliosides 2.5 mg/100 ml (range 2.0—3.8). Cerebrosides were isolated from the chloroform phase by the method of Klenk and Leupold [3].

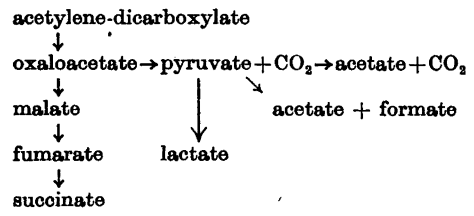
Bacterial Dissimilation of Acetylene Dicarboxylic Acid

Kjell Eimhjellen*

Department of Biochemistry, The Technical University of Norway, Trondheim, Norway



Very little is known about the biological conversion of acetylenic compounds. As part of an investigation of the biosynthesis and dissimilation of organic compounds containing acetylenic bonds, a facultative anaerobic bacterium has been isolated from sewage. The bacterium has been identified as a member of the family of *Enterobacteriaceae*. The organism grows on acetylene dicarboxylic acid as the only carbon source and ammonium-N as the only nitrogen source.

Acetylene dicarboxylic acid is converted by resting cell suspensions under anaerobic conditions to CO_2, lactate, succinate, acetate, formate and ethanol; the latter compound is produced in relatively small amounts. H_2 is hardly detectable. Occasionally fumarate will accumulate. The fermentation of glucose leads to the same end products, but relatively larger amounts of ethanol and H_2 are produced.

The non-gaseous products of the fermentations have been isolated either in the pure state or as the derivatives of *p*-bromophenacylbromide. The volatile products have been further identified by Duclaux distillation, ethanol as acetic acid after oxidation by chromic acid.

When the CO_2-evolution from acetylene dicarboxylic acid by resting cell suspensions is followed manometrically, a sharp break in reaction velocity is observed, at which time pyruvate can easily be detected. The pyruvic acid has been isolated and characterized as the 2,4-dinitrophenylhydrazone.

The results indicate that acetylene dicarboxylic acid is dissimilated by this bacterium according to the following scheme:

* Fellow of the Technical University of Norway.

Fumarate and malate are fermented anaerobically by resting cells with CO_2 production in correspondance with the above scheme.

The CO_2 output from acetylene dicarboxylic acid is completely inhibited by 2×10^{-2} M KF. Lower concentrations of KF, *viz.* 10^{-3}—10^{-2} M, cause a greater total output of CO_2 from the same substrate, concomitantly with a smaller total production of succinate.

In view of the above results it would appear that the initial reaction in the metabolism of acetylene dicarboxylic acid is a conversion to oxaloacetate followed by known pathways of metabolism of the latter substance.

The Mechanism of Formation of Bile Acids from Cholesterol

S. Bergström and S. Lindstedt

Department of Physiological Chemistry, University of Lund, Lund, Sweden

A short review of recent work on the transformation of cholesterol into bile acids will be given.

Recent results have brought further support to the view that the steroid ring system is modified before the side chain degradation is completed [1], thus 3α,7α-dihydroxycoprostane is transformed into both cholic and chenodesoxycholic acid in the rat [2], whereas earlier work [3] has shown that chenodesoxycholic acid cannot be 12α-hydroxylated into cholic acid.

Furthermore 7α-hydroxycholesterol has been found to give rise to cholic acid as well as to chenodesoxycholic acid [4].

In this connection results obtained in studies on hydroxylated coprostanic acids and their possible role as intermediates in the formation of bile acids from cholesterol will be discussed [5,6].

Carbon Dioxide Fixation in *Rhodospirillum rubrum*

J. G. Ormerod*

Department of Microbiology, The University, Sheffield 10, England

Rhodospirillum rubrum is a photosynthetic bacterium which uses simple organic compounds as electron donors in photosynthesis. During the oxidation of these compounds under anaerobic conditions in the light, CO_2 may be fixed in the photosynthetic process, but at the same time CO_2 may be produced as a result of the oxidation of the electron donor. Depending on the state of oxidation of these substrates the net result of these processes may be an uptake or an output of CO_2. In either case, it is impossible to determine by manometric methods alone the actual amounts of CO_2 fixed or produced. An attempt was therefore made to measure the CO_2 fixation by washed suspensions in the presence of various organic compounds as electron donors by means of $^{14}CO_2$.

In the light the endogenous incorporation of isotopic CO_2 proceeds at a fairly high rate and corrections were therefore made for this. With acetate as substrate the amount of $^{14}CO_2$ incorporated was less than in the control without substrate, indicating that acetate inhibits the endogenous fixation of CO_2 (*cf.* Glover and Kamen [1]). Butyrate was the only substrate which caused a $^{14}CO_2$ incorporation equal in amount to the CO_2 fixation as measured manometrically. It seems likely that no CO_2 is produced in the photometabolism of this substrate. The quantity of $^{14}CO_2$ incorporated with propionate was more than twice as great as the net fixation measured manometrically. It is possible that the photometabolism of propionate involves carboxylation to succinate as in the green sulphur bacterium *Chlorobium thiosulphatophilum* [2]. When succinate was the substrate the $^{14}CO_2$ incorporation was the same as expected on theoretical grounds [3]. Malate, fumarate and lactate all gave results higher than expected on the basis of theory. Manometric measurements showed that there was a net output of CO_2 with each of these substrates. A possible explanation of these discrepancies is that certain substrates may stimulate exchange reactions involving CO_2, leading to an incorporation of isotope but without affecting the net fixation of CO_2. In view of the probable occurrence of these reactions methods involving isotopic CO_2 are not suitable for measuring CO_2 fixation in photosynthetic systems of this type.

Sulfhydryl Groups in Serum Proteins During Influence of Cortisone

B. Larsen

Rheumatic Research Laboratory, University Institute for Pathological Anatomy, Copenhagen, Denmark

It has previously been shown that cortisone restores the lowered sulfhydryl values in patients with polyarthritis [1]. Several investigations seem to indicate that cortisone when it acts inhibitively on cell activity and protein synthesis does so through the mediation of sulfhydryl dependent systems [2].

These investigations have been continued in experiments *in vitro*. The sulfhydryl determinations are carried out by means of amperometric methods, using a rotating platinum electrode and mercuric acetate as the titrator.

The results so far reached show that cortisone is capable of increasing sulfhydryl values in albumin by 15—20 % depending on incubation conditions.

Work is in progress and a detailed paper is in preparation.

Quantitative Determination of Bile Acids in Human Bile

Jan Sjövall

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The methods used for the determination of bile acids in bile have usually been based on different colour reactions. These methods have mostly been limited to the determination of only one or a few of the bile acids in the bile. Since the different bile acids under various conditions may be excreted independently of each other it is desirable to have a method where all the bile acids can be determined simultaneously.

Synthetic mixtures of bile acids can be determined after separation by paper chromatography [1]. A preliminary note on the application of this method to bile acids in bile has been published [2]. The method has been used for the determination of bile acids in rat bile [3] and has now been adapted to the determination of bile acids in gall-bladder bile, fistula bile and duodenal contents of man.

The fluid to be analyzed is applied directly on the starting line of the chromatogram as described for synthetic bile acids [1]. Bile from the gall-bladder usually has to be diluted.

Taurine conjugated bile acids are separated with ascending chromatography. *Iso*amyl acetate:heptane 85:15 saturated with an equal volume of 70 % (v/v) formic acid is used as moving phase. The papers are equilibrated for 1/2 hour in the atmosphere of the moving phase. The chromatograms are then run for 20 hours. This procedure gives well defined spots of the bile acids even when large amounts of other bile constituents are present.

After localization the spots are cut out and eluted [1]. Taurocholic acid (TC) is determined in 65 % sulfuric acid as described [1]. Since taurodeoxycholic (TD) and taurochenodeoxycholic (TDC) acids often occur together in human bile and since they do not separate in these chromatograms they are determined as the sum TD+TCD. This is done by heating the acids 15 minutes at 50° C in 65 % sulfuric acid when TD and TCD show the same molar extinction at their maximum at 305 mμ. This is reproducible within ±5 % with synthetic acids and the acids follow Beer's law singly and in mixtures.

Bile constituents other than bile acids (mainly bile pigments) also contribute to the light absorption of the samples in sulfuric acid. When this contribution is between 10 and 20 % of the total light absorption it can be corrected for by subtracting the light absorption of a corresponding sample in 80 % ethanol where bile acids have no absorption at the wave lengths used.

Glycine conjugated bile acids are separated with descending chromatography using ethylene chloride:heptane 50:50 as moving phase [4]. The filter paper used for the chromatography is cut as described but since the bile acids travel different distances on the different strips in descending chromatography one strip on each side of the strip to be eluted has to be sprayed in order to localize the bile acids. Glycocholic (GC), glycochenodeoxycholic (GCD) and glycodeoxycholic (GD) acids are separated and can be eluted and determined. Synthetic mixtures of GCD and GD are determined within ±5 %. Except in cases with extraordinarily large amounts of bile pigments no ethanol correction has to be made.

Within the errors of the method (approximately ±15 % for each bile acid in biological material) the ratio of glycine to taurine conjugation was the same for trihydroxy- as for dihydroxycholanic acids. In most human samples the glycine conjugated bile acids dominated. No free bile acids were detected It has been confirmed that cholic and chenodeoxycholic acids are the main hydroxycholanic acids in human bile. In several bile samples no conjugated deoxycholic acid could be found. With the method used glycodeoxycholic acid would have been detected when present as 2 % of the total amount of bile acids.

Quantitative Aspects of Bile Acid Formation in Man

Sven Lindstedt

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Our knowledge of the amount of bile acids taking part in the enterohepatic circulation is incomplete and based on determinations of concentration of bile acids in bladder or fistula bile. For a review see Josephson [1].

We have attempted to determine the total amount of circulating cholic acid by an isotope dilution *in vivo*. By determining the fall of specific activity with time information has been gained on the rate of formation of this compound. 3—4 μC of cholic acid-24-^{14}C was given orally as sodium salt to healthy male medical students. At different time intervals bile was obtained through a duodenal tube after administration of 1—3 mg of a purified pancreozymine-cholecystochinine preparation (kindly supplied by Professor Erik Jorpes, Stockholm). Cholic acid was isolated and the specific activity determined. A bile sample was used for a quantitative determination with a paperchromatographic technique of the concentration of various bile acids. These determinations were kindly carried out by Dr. J. Sjövall [2]. By the use of the figures thus obtained the total amount of circulating acids was calculated. In the table the results obtained in three subjects are given:

Subject	Cholic acid g	Total amount of of bile acids g	"Half-life" of cholic acid in days
B	0.575	1.85	1.2
P	0.92	3.65	2.5
S	1.29	3.55	3

On the Metabolism of Bile Acids in Germ-free Rats

B. Gustafsson, S. Bergström, S. Lindstedt and A. Norman

Section of research on germ-free animals, Department of Histology and Department of Physiological Chemistry, University of Lund, Lund, Sweden

The bile of rats contains taurocholic and taurochenodeoxycholic acids [1]. With the aid of 24-^{14}C-labelled acids it has been shown that these acids are extensively modified during the passage down the intestinal tract [2]. When the fecal acids were chromatographed these modifications were found to include:

1) a splitting of the peptide bond,
2) an attack on the bile acid moiety leading to a variety of mostly less hydrophilic compounds.

It has been found [3] that in rats treated with intestinal chemoterapeutics no such modifications occur making it highly probable that microbial enzymes are responsible for the reactions. Furthermore several strains of bacteria that can split the conjugated bile acid *in vitro* have been isolated from the rat intestine [4]. We have earlier reported on the turnover of bile acids in normal rats and in animals treated with chemoterapeutics [5]. The half-lives were found to be about 2.5 and 6—7 days, respectively. In order to study the importance of intestinal microorganism for the elimination of bile acids we have administered 24-^{14}C-labelled cholic acid to germ-free rats and to a rat that had been infected with *Aspergillus niger* and then further with *Clostridium perfingens* type E. The rats were reared with slight modifications in the technique of Gustafsson [6]. The time course of excretion was followed and the acids in the feces fractionated with chromatography. One rat was finally transferred from the apparatus to normal environments and the elimination rate investigated.

The germ-free rats were found to excrete unchanged taurocholic acid in their feces. This was also the case in the rat infected with the mould. When the same rat was also infected with the *Clostridium* strain, however, about 25 % of the labelled acids appeared in the feces in the free form, mainly as cholic acid. The chromatographic pattern was in this case similar to that found after *in vitro* incubation of taurocholic acid with the same strain of bacterium [4].

In all rats studied the excretion rate was quite slow with a half life-time of about 7 days. It may be concluded that the state of the intestinal flora greatly influences the rate of elimination from the enterohepatic circulation. As, however, neither the mould nor the peptide bond-splitting *Clostridium* increases the excretion rate it seems probable that other microorganisms are of importance for the rate of elimination of bile acids.

Synthetic mixtures of bile acids can be determined after separation by paper chromatography [1]. A preliminary note on the application of this method to bile acids in bile has been published [2]. The method has been used for the determination of bile acids in rat bile [3] and has now been adapted to the determination of bile acids in gall-bladder bile, fistula bile and duodenal contents of man.

The fluid to be analyzed is applied directly on the starting line of the chromatogram as described for synthetic bile acids [1]. Bile from the gall-bladder usually has to be diluted.

Taurine conjugated bile acids are separated with ascending chromatography. *Iso*amyl acetate:heptane 85:15 saturated with an equal volume of 70 % (v/v) formic acid is used as moving phase. The papers are equilibrated for 1/2 hour in the atmosphere of the moving phase. The chromatograms are then run for 20 hours. This procedure gives well defined spots of the bile acids even when large amounts of other bile constituents are present.

After localization the spots are cut out and eluted [1]. Taurocholic acid (TC) is determined in 65 % sulfuric acid as described [1]. Since taurodeoxycholic (TD) and taurochenodeoxycholic (TDC) acids often occur together in human bile and since they do not separate in these chromatograms they are determined as the sum TD+TCD. This is done by heating the acids 15 minutes at 50° C in 65 % sulfuric acid when TD and TCD show the same molar extinction at their maximum at 305 mμ. This is reproducible within ±5 % with synthetic acids and the acids follow Beer's law singly and in mixtures.

Bile constituents other than bile acids (mainly bile pigments) also contribute to the light absorption of the samples in sulfuric acid. When this contribution is between 10 and 20 % of the total light absorption it can be corrected for by subtracting the light absorption of a corresponding sample in 80 % ethanol where bile acids have no absorption at the wave lengths used.

Glycine conjugated bile acids are separated with descending chromatography using ethylene chloride:heptane 50:50 as moving phase [4]. The filter paper used for the chromatography is cut as described but since the bile acids travel different distances on the different strips in descending chromatography one strip on each side of the strip to be eluted has to be sprayed in order to localize the bile acids. Glycocholic (GC), glycochenodeoxycholic (GCD) and glycodeoxycholic (GD) acids are separated and can be eluted and determined. Synthetic mixtures of GCD and GD are determined within ±5 %. Except in cases with extraordinarily large amounts of bile pigments no ethanol correction has to be made.

Within the errors of the method (approximately ±15 % for each bile acid in biological material) the ratio of glycine to taurine conjugation was the same for trihydroxy- as for dihydroxycholanic acids. In most human samples the glycine conjugated bile acids dominated. No free bile acids were detected It has been confirmed that cholic and chenodeoxycholic acids are the main hydroxycholanic acids in human bile. In several bile samples no conjugated deoxycholic acid could be found. With the method used glycodeoxycholic acid would have been detected when present as 2 % of the total amount of bile acids.

Quantitative Aspects of Bile Acid Formation in Man

Sven Lindstedt

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Our knowledge of the amount of bile acids taking part in the enterohepatic circulation is incomplete and based on determinations of concentration of bile acids in bladder or fistula bile. For a review see Josephson [1].

We have attempted to determine the total amount of circulating cholic acid by an isotope dilution *in vivo*. By determining the fall of specific activity with time information has been gained on the rate of formation of this compound. 3—4 μC of cholic acid-24-^{14}C was given orally as sodium salt to healthy male medical students. At different time intervals bile was obtained through a duodenal tube after administration of 1—3 mg of a purified pancreozymine-cholecystochinine preparation (kindly supplied by Professor Erik Jorpes, Stockholm). Cholic acid was isolated and the specific activity determined. A bile sample was used for a quantitative determination with a paperchromatographic technique of the concentration of various bile acids. These determinations were kindly carried out by Dr. J. Sjövall [2]. By the use of the figures thus obtained the total amount of circulating acids was calculated. In the table the results obtained in three subjects are given:

Subject	Cholic acid g	Total amount of of bile acids g	"Half-life" of cholic acid in days
B	0.575	1.85	1.2
P	0.92	3.65	2.5
S	1.29	3.55	3

On the Metabolism of Bile Acids in Germ-free Rats

B. Gustafsson, S. Bergström, S. Lindstedt and A. Norman

Section of research on germ-free animals, Department of Histology and Department of Physiological Chemistry, University of Lund, Lund, Sweden

The bile of rats contains taurocholic and taurochenodeoxycholic acids [1]. With the aid of 24-^{14}C-labelled acids it has been shown that these acids are extensively modified during the passage down the intestinal tract [2]. When the fecal acids were chromatographed these modifications were found to include:

1) a splitting of the peptide bond,
2) an attack on the bile acid moiety leading to a variety of mostly less hydrophilic compounds.

It has been found [3] that in rats treated with intestinal chemoterapeutics no such modifications occur making it highly probable that microbial enzymes are responsible for the reactions. Furthermore several strains of bacteria that can split the conjugated bile acid *in vitro* have been isolated from the rat intestine [4]. We have earlier reported on the turnover of bile acids in normal rats and in animals treated with chemoterapeutics [5]. The half-lives were found to be about 2.5 and 6—7 days, respectively. In order to study the importance of intestinal microorganism for the elimination of bile acids we have administered 24-^{14}C-labelled cholic acid to germ-free rats and to a rat that had been infected with *Aspergillus niger* and then further with *Clostridium perfingens* type E. The rats were reared with slight modifications in the technique of Gustafsson [6]. The time course of excretion was followed and the acids in the feces fractionated with chromatography. One rat was finally transferred from the apparatus to normal environments and the elimination rate investigated.

The germ-free rats were found to excrete unchanged taurocholic acid in their feces. This was also the case in the rat infected with the mould. When the same rat was also infected with the *Clostridium* strain, however, about 25 % of the labelled acids appeared in the feces in the free form, mainly as cholic acid. The chromatographic pattern was in this case similar to that found after *in vitro* incubation of taurocholic acid with the same strain of bacterium [4].

In all rats studied the excretion rate was quite slow with a half life-time of about 7 days. It may be concluded that the state of the intestinal flora greatly influences the rate of elimination from the enterohepatic circulation. As, however, neither the mould nor the peptide bond-splitting *Clostridium* increases the excretion rate it seems probable that other microorganisms are of importance for the rate of elimination of bile acids.

Conjugation of Cholic Acid in Human Liver Homogenates

Urs Gloor and Per-Hugo Ekdahl

Department of Physiological Chemistry and Department of Surgery, University of Lund, Lund, Sweden

Cholic acid is the end-product of cholesterol metabolism, that is, no further oxidation of the steroid nucleus takes place. We therefore used it as a model substance for conjugation studies. In liver homogenates human bile acids are conjugated with taurine and glycine in different proportions [1].

We have now developed this procedure further both as a macro and a micro method for homogenizing human liver biopsies. For macro experiments we used 1 ml 20 % homogenate in a medium similar to that described by Bucher [2] containing 11 g KH_2PO_4, 4 g KOH (85 % pure), 1 g $MgCl_2$, $6H_2O$ and 3.7 g nicotinamide per liter. The pH was 7.4. A loose fitting pestle and a short homogenisation time are essential. We used a gap between tube and pestle of 1 mm, a motor of 1 500 RPM and 1 min homogenisation time. To 1 ml medium we added 100 μg (= 40 000 counts per minute, end window tube) cholic acid-24-^{14}C and 2 mg adenosine triphosphate (crystalline, Pabst Laboratories, Milwaukee 5, Wisc.) and incubated in air for 2 hours at 37° after which time we stopped the reaction by adding 5 volumes of ethanol and proceeded as described earlier [3]. The time between surgical operation and incubation of the homogenate should not exceed 2 hours and care has to be taken that no part of the liver piece becomes dry. For micro experiments, that is liver pieces obtained by punction through the abdominal wall, we used the same buffer solution and 15 μg cholic acid + 200 μg adenosine triphosphate in a total of 0.25 ml. The liver (20—40 mg) was transferred directly from the biopsy needle into the homogenisation tube where all further operations were performed. We proceeded with methods similar to those described earlier [3].

Some results are compiled in Table 1. Glyco- + tauro-conjugation = 100 %. The variations of the extent of conjugation (1—50 %) had no influence on the ratio between glycine and taurine coupling.

The patients in all three of the groups had different clinical test values and exact diagnosis may result in a further specification. Yet, the values for patients with cirrhosis are much lower than for the other groups. In this group a deficiency of glycine could be at least a partial explanation. In two experiments glycine and taurine (5 mole per mole acid) alone or together were added. In the case of single additions glyco- respectively tauro-conjugation was increased, whereas with both together the ratio between the conjugates did not differ from that without amino acids added.

Table 1. Per cent glyco-cholic acid formed of total conjugated acids from 1 ml 20 % human liver homogenate with different patients.

Diagnosis		
Liver cirrhosis shunt operations	Gall-bladder and bile duct diseases	Ulcus duodeni Ulcus ventriculi
10	43	57
18	43	35
25	40	54
16	25	54

Studies on the Formation of Mixed Disulphides of Biological Importance

L. Eldjarn and A. Pihl

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo

Previously we have shown that cystamine interacts *in vivo* as well as *in vitro* with the free SH groups of proteins and other body constituents to form considerable amounts of mixed disulphides [1-3]. This raises the question as to the chemistry of mixed disulphide formation in general.

A study has now been made of the chemical kinetics of the reaction of cystamine and cysteamine with various thiols and disulphides. A method has been worked out for the direct determination of the mixed disulphide formation. Use is made of the fact that the disulphide-thiol interaction is negligible below pH 2. ^{35}S-labeled cystamine or cysteamine is incubated with the thiol or disulphide, the reaction stopped by acidification, the mixed disulphide separated by rapid paper electrophoresis at pH 2, and the amount of mixed di sulphide measured by direct counting on paper.

In general the reaction proceeds according to the equations:

$$\mathrm{XSH} + \mathrm{R{-}SS{-}R} \underset{v_2}{\overset{K_1\ v_1}{\rightleftharpoons}} \mathrm{XSSR} + \mathrm{RSH} \qquad K_1 \qquad \text{I}$$

$$\mathrm{XSSR} + \mathrm{XSH} \underset{v_4}{\overset{v_3}{\rightleftharpoons}} \mathrm{XSSX} + \mathrm{RSH} \qquad \text{II}$$

When XSH = glutathione and RSH = cysteamine a rapid and extensive formation of mixed disulphide takes place. The $K_4 = K_2/K_3$ has been found to be greater than 130. This high K_4 value makes difficult the accurate determination of K_2 and K_3 from equilibrium data. The equilibrium values for the mixed disulphide were found to be independent of temperature (0 to 37° C), and of pH (5 to 7.4).

The velocity constants k_{v_1} and k_{v_4} were measured separately. Their pH dependence showed that $-S^-$ is the reactive form of the thiol. With equimolar amounts of the reactants, equilibrium at pH 7.4 and 37° C is attained in less than 45 seconds and 3 minutes in reactions I and II respectively.

The striking fact emerging from the present experiments is that at equilibrium nearly 80 % of glutathione (and of cysteine) exist as the mixed disulphide when incubated, in the absence of oxygen, with equimolar amounts of cystamine at 37° C, pH 7.4. Recently Kolthoff *et al.*[4] have calculated, from cystine solubility data, the equilibrium constants for the reactions of cystine with reduced glutathione and thioglycolic acid respectively. It can be calculated from these constants that in equimolar concentrations and under conditions comparable to ours, 41 % of the glutathione exist as mixed disulphides at equilibrium.

The rapid reaction velocities demonstrated in the present study and the high equilibrium values for the mixed disulphides would seem to have considerable interest with regard to the chemistry of protein sulphur groups. We have previously studied the formation of mixed disulphides between protein SH groups and cystamine [1-3]. In recent experiments we have found that cysteamine, as expected, forms mixed disulphides with accessible protein SS groups (serum albumin, desoxyribonuclease, cytochrom c).

Our data strongly suggest that the accessible protein SH and SS groups exist in a dynamic equilibrium with the thiols and disulphides of the surrounding medium. Thus, depending on the conditions, one particular protein sulphur group may conceivably exist either as a free SH group, in a mixed disulphide with a smaller compound, in an intramolecular disulphide, or occasionally in a protein-SS-protein linkage. Accordingly, the number of titratable SH groups of a protein may depend on the exact conditions of its pretreatment with thiols and/or disulphides (pH, temperature, chemical nature, concentrations). This view might offer an explanation of the numerous controversies concerning the number of free SH groups of various proteins.

It is suggested, on the basis of the above evidence, that the accessible sulphur groups of a protein should be classified as a) single SH groups, b) adjacent sulphur groups capable of forming intramolecular disulphides. It seems probable that in the case of proteins, the formation of intermolecular disulphides is of minor significance.

Influence of Thyroid Hormone on the Formation of Bile Acids

Sten Eriksson

Department of Physiological Chemistry, University of Lund, Lund, Sweden

It has long been recognized that an inverse relationship exists between plasma cholesterol level and thyroid activity [1]. As the bile acids have been shown [2,3] to be the main metabolic end-products of cholesterol in the rat we have studied the influence of thyroid activity on the excretion of bile acids in bile fistula rats. Thompson and Vars [4] studying the same problem found lower values of cholic acid in the hyperthyroid and hypothyroid rats than in the euthyroid animals. In their experiments they did not determine taurochenodesoxycholic acid, the second bile acid of quantitative importance in the rat [5]. In the present work taurocholic and taurochenodesoxycholic acids have been determined with the technique used in a previous work from this laboratory in which the quantitative excretion of bile acids in normal bile fistula rats were studied [6]. The rats were made hyper- and hypothyroid by including 0.4 % thyroid or 0.5 % propyltiouracil, respectively, in the diet. The bile was collected for five days following operation. In Table 1 are given the values obtained for the excretion of taurocholic and taurochenodesoxycholic acids during the time of collection. In the hypothyroid group there is a large reduction of the total excretion of bile acids. In the hyperthyroid group the total excretion remains unchanged as compared to the control rats. In the hypothyroid group the excretion of taurochenodesoxycholic acid is less than 10 % of the total excretion, whereas the normal rats had about 20 %. On the other hand in the hyperthyroid group taurochenodesoxycholic acid constitutes between 70 and 80 % of the total excretion. Thus the excretion of bile acids in hyperthyroid rats is not decreased but the composition is changed in that taurocholic acid is markedly decreased but taurochenodesoxycholic acid increased.

Further data will be presented.

The Incorporation of Methyl and Carboxyl Labelled Acetate into the Purine-Bound Sugars of Nucleic Acids in Liver Slices

S. Laland and I. Smith-Kielland

Biochemistry Department, The University, Oslo

The incorporation of carbon-labelled acetate into ribose has been the subject of several investigations. Thus it was shown that in chicks carboxyl labelled acetate was incorporated into the purine-bound ribose of RNA [1]. Löw [2] using rats found that when given $^{13}CH_3$ $^{14}COOH$ both isotopes were present in the ribose of RNA and that the methyl carbon was incorporated to a considerable greater extent than the carboxyl. However, studies on the incorporation of labelled acetate into the purine-bound 2-deoxy-D-ribose has not been reported. The present study concerns this problem together with an investigation of the simultaneous incorporation of isotope into the purine-bound ribose. Liver slices obtained from regenerating rat liver were incubated in Krebs-Hensleit medium at pH.7.4 containing glucose together with labelled sodium acetate for 3 hours at 37° C. The nucleic acids were isolated from the liver slices by the method of Brown *et al.*[3] The purine-bound 2-deoxy-D-ribose was isolated from the DNA by a slight modification of a method described previously[4]. The sugar was finally purified by paper chromatography, eluted, estimated and counted. D-Ribose was isolated from the RNA after acid hydrolysis, followed by passage of the hydrolysate through a column of mixed resins (IR 120(H) and IR4B(OH)) and finally paper chromatography. The sugar was eluted from the chromatogram, estimated and counted. In both cases results obtained from three different chromatographic solvent systems were found to agree satisfactorily and the figures quoted in the table below represent the mean of the three figures.

Acetate incubated	2-Deoxy-D-ribose c/min/μmole	D-Ribose c/min/μmole
$^{14}CH_3COONa$	147	790
$CH_3{}^{14}COONa$	292	300

It thus appears that in regenerating liver slices both the methyl and carboxyl carbon of acetate can be incorporated into the purine-bound 2-deoxy-D-ribose. Experiments performed with liver slices from non regenerating liver showed as expected no incorporation of carboxyl labelled acetate. Furthermore it is seen that in the case of the methyl labelled acetate the incorporation of isotope is 5 times as large in the case of the purine-bound D-ribose, as for the purine-bound 2-deoxy-D-ribose. With carboxyl-labelled acetate there is however the same degree of incorporation of isotope.

Studies on the Regulation of Bile Acid Formation in Bile Fistula Rats

S. Bergström, H. Danielsson and U. Gloor

Department of Physiological Chemistry, University of Lund, Lund, Sweden

When a bile fistula is made in a rat the excretion of bile acids increases 20—40 fold over the normal daily synthesis to 40—60 mg per day!

In order to study the influence of the bile acids in the enterohepatic circulation on the bile acid production in the liver, we have used two experimental approaches.

We have prepared fistula rats as normal but also inserted a cannula into the lower part of the severed bile duct and continuously injected 0.5 ml of saline per hour containing the synthetic bile salt investigated.

In order to follow the taurocholic acid production we have injected sodium-taurochenodesoxycholate. It is known that this substance does not give rise to cholic acid but to relatively small amounts of higher hydroxyla-

ted compounds, that can be differentiated from cholic acid by partition chromatography [2,3]. The amount of cholic acid in the hydrolysed bile was then calculated from the titration values of the cholic acid band.

It was found, that the injection of 2.5 mg of sodium-taurochenodesoxycholate per hour scarcely influenced the cholic acid production, 5 mg per hour reduced the daily production to about 4 mg, whereas 10 mg per hour caused a reduction down to the normal daily synthesis of 1—2 mg.

If the amount of bile salts in a 200 g rat is about 15 mg the bile acids have to circulate 15—20 times per day in the enterohepatic circulation to maintain a concentration in the portal blood similar to that in the last mentioned experiment.

The daily formation of 40—60 mg of bile acids corresponds to about three times the amount cholesterol present in the liver. We have therefore injected ^{14}C-acetate intraperitoneally and followed the appearance of ^{14}C in the secreted bile.

In a typical experiment about 1 mg of sodium acetate (1.9×10^6 c.p.m.) in 1.5 ml of saline was injected intraperitoneally into fistula rats at the time indicated after the operation. The percentage of the administered isotope that was recovered in the bile during the following 6 hours is shown in the second column below.

Hours after operation	% injected isotope recovered in bile
16	0.13
64	0.61
112	1.41

According to paper chromatography about 80 % of the isotope was contained in the bile salts.

The correlation of data of this type with the bile acid formation will be exemplified and discussed. The method has been found useful for studying the regulation of the synthesis of bile acids under different experimental conditions.

Increase of Cholinesterase Content in Mouse Liver Homogenates after Incubation

Karl Håkon Skramstad

The Norwegian Defence Research Establishment, Toxicological group, Kjeller, Norway

The rate of hydrolysis of acetylcholine by mouse liver homogenates increases by about 100 % when the homogenates are left either overnight at room temperature (20° C) or two to three hours at 37° C.

Of the organs investigated (brain, kidney, plasma, erythrocytes and liver) only the liver presented a real "autoactivation". This increase in activity takes place in liver homogenates from mice of different ages and both sexes, but seems to be more progressive in the female. There seems to be a greater "activation" in liver homogenates from infantile mice than mature ones, although there are large fluctuations.

The "activation" does not disappear with dialysis and seems to be localized to the particles of the liver cell upon "high speed" centrifuging. Calcium ions have no influence, neither is the increase in activity dependent on the isotonicity of the medium.

Kinetic experiments with a selective inhibitor of "pseudo"-cholinesterase [1], Nu 683, suggest that one and the same enzyme, *viz.* a "pseudo"-cholinesterase, is responsible for the major part of the activity with acetylcholine as substrate, both prior to and after the "activation".

The increase of hydrolysis takes place with acetylcholine and butyrylcholine as substrates, while deactivation results when tributyrin and benzoylcholine are employed. With acetyl-β-methyl-choline the rate of hydrolysis is quite slow, but has a slight tendency to increase with time; too small, however, to be of any experimental significance. These experiments indicate that we are dealing with a butyrocholinesterase [2].

Benzoylcholine, often used as a specific substrate for "pseudo"-cholinesterase [3], is not hydrolysed at an increased rate after incubation. On the contrary, the hydrolysis decreases with time. Thus there might perhaps be two "pseudo"-cholinesterases in the mouse liver; one butyrocholinesterase and one "benzoylcholinesterase". As known, "benzoylcholinesterases" are occasionally found in the plasma of rabbits [4] and in the liver of guinea pigs [5,6].

The Incorporation of Methyl and Carboxyl Labelled Acetate into the Purine-Bound Sugars of Nucleic Acids in Liver Slices

S. Laland and I. Smith-Kielland

Biochemistry Department, The University, Oslo

The incorporation of carbon-labelled acetate into ribose has been the subject of several investigations. Thus it was shown that in chicks carboxyl labelled acetate was incorporated into the purine-bound ribose of RNA [1]. Löw [2] using rats found that when given $^{13}CH_3$ $^{14}COOH$ both isotopes were present in the ribose of RNA and that the methyl carbon was incorporated to a considerable greater extent than the carboxyl. However, studies on the incorporation of labelled acetate into the purine-bound 2-deoxy-D-ribose has not been reported. The present study concerns this problem together with an investigation of the simultaneous incorporation of isotope into the purine-bound ribose. Liver slices obtained from regenerating rat liver were incubated in Krebs-Hensleit medium at pH.7.4 containing glucose together with labelled sodium acetate for 3 hours at 37° C. The nucleic acids were isolated from the liver slices by the method of Brown *et al.*[3] The purine-bound 2-deoxy-D-ribose was isolated from the DNA by a slight modification of a method described previously[4]. The sugar was finally purified by paper chromatography, eluted, estimated and counted. D-Ribose was isolated from the RNA after acid hydrolysis, followed by passage of the hydrolysate through a column of mixed resins (IR 120(H) and IR4B(OH)) and finally paper chromatography. The sugar was eluted from the chromatogram, estimated and counted. In both cases results obtained from three different chromatographic solvent systems were found to agree satisfactorily and the figures quoted in the table below represent the mean of the three figures.

Acetate incubated	2-Deoxy-D-ribose c/min/μmole	D-Ribose c/min/μmole
$^{14}CH_3COONa$	147	790
$CH_3{}^{14}COONa$	292	300

It thus appears that in regenerating liver slices both the methyl and carboxyl carbon of acetate can be incorporated into the purine-bound 2-deoxy-D-ribose. Experiments performed with liver slices from non regenerating liver showed as expected no incorporation of carboxyl labelled acetate. Furthermore it is seen that in the case of the methyl labelled acetate the incorporation of isotope is 5 times as large in the case of the purine-bound D-ribose, as for the purine-bound 2-deoxy-D-ribose. With carboxyl-labelled acetate there is however the same degree of incorporation of isotope.

Studies on the Regulation of Bile Acid Formation in Bile Fistula Rats

S. Bergström, H. Danielsson and U. Gloor

Department of Physiological Chemistry, University of Lund, Lund, Sweden

When a bile fistula is made in a rat the excretion of bile acids increases 20—40 fold over the normal daily synthesis to 40—60 mg per day!

In order to study the influence of the bile acids in the enterohepatic circulation on the bile acid production in the liver, we have used two experimental approaches.

We have prepared fistula rats as normal but also inserted a cannula into the lower part of the severed bile duct and continuously injected 0.5 ml of saline per hour containing the synthetic bile salt investigated.

In order to follow the taurocholic acid production we have injected sodium-taurochenodesoxycholate. It is known that this substance does not give rise to cholic acid but to relatively small amounts of higher hydroxyla-

ted compounds, that can be differentiated from cholic acid by partition chromatography [2,3]. The amount of cholic acid in the hydrolysed bile was then calculated from the titration values of the cholic acid band.

It was found, that the injection of 2.5 mg of sodium-taurochenodesoxycholate per hour scarcely influenced the cholic acid production, 5 mg per hour reduced the daily production to about 4 mg, whereas 10 mg per hour caused a reduction down to the normal daily synthesis of 1—2 mg.

If the amount of bile salts in a 200 g rat is about 15 mg the bile acids have to circulate 15—20 times per day in the enterohepatic circulation to maintain a concentration in the portal blood similar to that in the last mentioned experiment.

The daily formation of 40—60 mg of bile acids corresponds to about three times the amount cholesterol present in the liver. We have therefore injected ^{14}C-acetate intraperitoneally and followed the appearance of ^{14}C in the secreted bile.

In a typical experiment about 1 mg of sodium acetate (1.9×10^6 c.p.m.) in 1.5 ml of saline was injected intraperitoneally into fistula rats at the time indicated after the operation. The percentage of the administered isotope that was recovered in the bile during the following 6 hours is shown in the second column below.

Hours after operation	% injected isotope recovered in bile
16	0.13
64	0.61
112	1.41

According to paper chromatography about 80 % of the isotope was contained in the bile salts.

The correlation of data of this type with the bile acid formation will be exemplified and discussed. The method has been found useful for studying the regulation of the synthesis of bile acids under different experimental conditions.

On the Question of a Cysteinyl-glycinase Activity of RNA

G. Semenza

Institute of Biochemistry, University of Uppsala, Sweden

Binkley [1] reported that cysteinyl-glycinase should be a protein-free RNA and put forward the hypothesis that RNA should interfere in protein synthesis through this activity.

Because of the remarkable implications of these statements (among others, that an enzyme should be non-protein in nature), an attempt was made at purifying further the cysteinyl-glycinase (through chromatography on calcium phosphate, Dowex 2 and DEAE cellulose) and at studying some of its chemical properties.

A separation of cysteinyl-glycinase activity from RNA was achieved, and Folin-positive, orcinol-negative, P-negative, chloroform-sensitive preparations of enzyme were obtained, showing a maximum in UV absorption spectrum at about 280 mμ.

A Method for the Isolation of 2-Deoxy-D-ribose from Thymidine

S. Laland and E. Roth

Biochemistry Department, The University, Oslo

It has always been assumed that the sugar component of thymidine is in analogy with the purine nucleosides 2-deoxy-D-ribose. Good evidence in support of this assumption has recently been provided [1-3], although the conclusive chemical proof was lacking. The present work describes the isolation of crystalline 2-deoxy-D-ribose from thymidine, and also provides a very convenient micro-method for the isolation of this sugar for tracer studies, which was the main purpose of this work. Thymidine is reduced by 3 % NaHg in aqueous solution at room temperature. The reduction mixture was shown by paper electrophoresis to contain two acidic 2-deoxy-D-ribosyl components formed by breakage of the reduced pyrimidine ring under the prevailing alkaline conditions. Removal of alkali in the reduction mixture with Amberlite IR 120(H) followed by gentle acid hydrolysis with dilute sulphuric acid and passage through a column of weakly basic resin such as Amberlite IR 4B(OH) afforded crystalline 2-deoxy-D-ribose. The yield was almost 100 %. For tracer work it is advisable to purify it by recrystallization or paper chromatography.

Glucose Inhibition of Respiration in Ascites Tumor Cells

Elling Kvamme

Ullevål Sykehus, Centrallaboratoriet, Oslo, Norway

Glucose exerts a pronounced inhibitory effect upon the respiration of ascites tumor cells, a phenomenon also called the Crabtree effect. In an attempt to approach this problem the glycolysis and the tricarboxylic acid cycle of the ascites tumor cells were studied under various conditions.

Ascites cells (30—40 mg protein) incubated in phosphate buffer for 1 h at 37° with excess glucose as substrate were found to accumulate 1—2 μM of a barium insoluble fructose ester, assumed to be fructose-diphosphate.

In the presence of glucose (10 μM/ml), the removal of inorganic phosphate (20 μM/ml) from the medium increased the oxygen uptake by 25—50 % and decreased the glucose uptake

as well as the lactic acid formation by 30—50 %, while the blank respiration was unaffected. In this experiment the cells were incubated in trisbuffer with and without phosphate, and special care was taken to maintain the same ionic concentrations of sodium and potassium. The oxygen uptake was measured in a Warburg apparatus for 1 h at 37°. This experiment is in apparent contrast to the results reported by Ibsen, Mc Carty and Mc Kee [1]. These authors operated with glucose concentrations of less than 3 μM/ml and measured the oxygen uptake during a 3 h period. The small glucose concentrations employed may explain the discrepancy, because in the presence of phosphate (20 μM/ml) more than twice as much glucose was taken up after 1 h by the cells (13—15 mg protein) in our experiments.

In iodoacetate (10^{-4} M) treated cells phosphate on the contrary slightly stimulated the respiration and exerted no appreciable effect upon glucose uptake or lactic acid formation.

Increasing amounts of iodoacetate (0—1.5×10^{-4} M final concn.) successively enhanced the oxygen uptake of ascites cells incubated with glucose as substrate in a way fairly parallel to the normalization of the pH, while the blank respiration decreased slightly. Judged from the glucose uptake and the formation of fructose-diphosphate and lactic acid, an excess of adenosinediphosphate is likely to be formed extramitochondrially in IAA poisoned cells. The still existent Crabtree effect may be explained in accordance with Rackers shuttling theory [2] if one presumes a rate difference as to the permeation of adenine nucleotides in and out of the mitochondria.

Dinitrophenol (DNP, 10^{-4} M) increased the glucose uptake and lactic acid formation markedly. DNP initially stimulated the oxygen uptake more than the blank when glucose was substrate, but fell off earlier.

Excess fumarate completely abolished the glucose inhibition of the respiration in malonate treated cells. The oxygen uptake was also unaffected by malonate in the presence of glucose and fumarate. Glucose did not appreciably affect the citrate formation from fumarate in these cells. Glucose increased the concentration of α-ketoglutarate and reduced the formation of succinate when the cells were incubated in the presence of excess citrate and malonate. Under similar conditions glucose markedly inhibited the oxygen uptake in the presence of excess citrate or α-ketoglutarate.

Hence there was found no evidence for an inhibition of the tricarboxylic acid cycle between fumarate and citrate by glucose. The results may be explained by assuming a partial block of the cycle between α-ketoglutarate and succinate and that this step is rate limiting of the overall mitochondrial respiration in the presence of glucose.

Estimation of Corticosteroid Metabolites in Urine

L.-O. Plantin, E. Diczfalusy and G. Birke

King Gustaf V:th Research Institute and Hormone Laboratory, The Womens Clinic, Karolinska sjukhuset, Stockholm 60, Sweden

During the last decade the importance of adequate methods for evaluation of the adrenocortical function has been more clearly recognized. We have compared the methods most used for corticosteroid determinations in urine and related them to the structure of the steroid hormones and their metabolites. We have worked especially with the method developed by Norymberski and coworkers which we think is superior to other methods [1,2]. This method converts, by an oxidation with sodium bismuthate, corticosteroids of certain types called 17-ketogenic steroids (17-KGS) to 17-ketosteroids (17-KS). Apart from the desired oxidative effect of the sodium bismuthate on the side chain at carbon atom 17, other effects appear which can cause faulty results. That is especially the case with dehydro*epi*androsterone, which is almost completely transformed to other products by the combined effects of sodium bismuthate and acid hydrolysis. The bismuthate probably causes an oxidation to the 5,6-epoxide which is then further rearranged by the acid hydrolysis. This deleterious effect can be minimised by using short oxidation time and it can be completely avoided by using the modification proposed by Appleby *et al.*[3]

A system has been worked out for the separation and estimation of the different more important corticosteroid metabolites in urine. It employs enzymatic hydrolysis of the corticosteroid conjugates with β-glucuronidase, oxidation of corticosteroids to 17-KS with sodium bismuthate, reduction of ketonic groups to

The Amino Acid Composition of a Melanophore-expanding Peptide from Pig Pituitary Gland

PAUL ROOS

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

The amino acid composition of a melanophore-expanding peptide isolated from pig pituitaries has been investigated by chromatography on Dowex 50 columns. Tryptophan was determined spectrophotometrically. The analyses indicate the following 18 amino acid residues in the molecule (mol. wt. 2176):

Asp_2 Glu_2 Gly_2 Ser Met Pro_2 Phe Tyr Try His Lys_2 Arg.

In a previous communication [1] the isolation from acetone-dried pig posterior lobe powder, of an electrophoretically homogeneous fraction, a peptide, possessing a high melanophore-expanding activity, has been reported. Isolation and amino acid analysis of a melanophore-expanding hormone from pig pituitary gland have also been reported by Lerner and Lee [2], and by Benfey and Purvis [3]. Their substances differed considerably in the amino acid composition, and this disagreement prompted the publication of the present investigation.

In the following experiments acid hydrolysates of the peptide have been analyzed by chromatography on columns of Dowex 50—X4 and of Dowex 50—X8, using the methods of Moore and Stein [4,5]. The concentrations of the amino acids in the effluent fractions were in all experiments determined by the modified reagent described by Moore and Stein [6]. Tyrosine and tryptophan have been determined spectrophotometrically according to Goodwin and Morton [7], and the occurrence of cystine and cysteine have been tested by paper electrophoresis of a sample previously oxidized with performic acid according to Thompson [8] and then hydrolyzed with 6 N hydrochloric acid.

The investigation was started with chromatography on columns of Dowex 50—X4. This method, however, did not give satisfying separations of all the present acids, and, furthermore, difficulties arose in the determination of the correct base-line (caused by ammonia) in the vicinity of the lysine and histidine peaks. Complementary analyses were therefore performed according to the older method of Moore and Stein on Dowex 50 of the stronger crossed-linked type. All the methods mentioned above have given a satisfactory determination of the amino acid composition.

EXPERIMENTAL

From a pure specimen, dried over phosphorus pentoxide *in vacuo*, samples weighing about 2 mg were taken for analysis. The peptide was dissolved in 1.0 ml 6 N hydrochloric acid and hydrolyzed in a sealed Pyrex tube. The hydrolytic conditions were varied (see Table 1) in order to make sure that all peptide linkages were split and in order to obtain indications of the reaction orders of the amino acids being decomposed. The hydrolysate was quantitatively transferred to a small beaker (5 ml) and the hydrochloric acid removed over sodium hydroxide pellets in a vacuum desiccator. The dry residue was dissolved in 1 ml buffer solution, according to the directions given by Moore and Stein. When using Dowex 50-X4, the column was 0.9 × 150 cm; for the separations on Dowex 50-X8, the column used for the acidic and neutral acids was 0.9 × 115 cm; and that used for the basic amino acids was 0.9 × 15 cm. The fractions were collected by means of an automatic fraction collector and analyzed for the amino acids with ninhydrin. The optical density readings were made with a Beckman B spectrophotometer. The integration for each amino acid was performed by simple addition of the ninhydrin color values (in leucine equivalents in micromoles), after subtracting the base-line value near the amino acid peak. With the modified ninhydrin reagent an investigation of the color yields of the amino acids was carried out. The acids were dissolved in the buffer solutions, in which they emerge from columns of Dowex 50—X4 and of Dowex 50—X8 in the current chromatographic procedures. The found values agree, within the experimental errors, with those which have been given by Moore and Stein [6] when using the buffers described by them for Dowex 50—X4.

The substances in the different peaks of the column chromatograms were identified by paper chromatography, paper electrophoresis, or specific reactions, according to the following procedure. In order to locate the different peaks, 0.5 ml of every other fraction (1 ml) was boiled with ninhydrin. All fractions which belonged to the same peak were then desalted on ion exchange resin according to Drèze, Moore and Bigwood [9], using columns of 0.9 × 10 cm. The salt-free eluates were then evaporated to dryness. For the identification of the acidic and neutral amino acids paper chromatography was used, and for that of the basic amino acids paper electrophoresis was used. In addition, the Pauli test, modified according to Sanger and Tuppy [10], and the reaction of Sakaguchi, as described by Jepson and Smith [11], gave an additional identification method for histidine and arginine respectively.

The presence of methionine could only be demonstrated in one of the methods of Moore and Stein [4,5], and therefore it was necessary to confirm the presence of this amino acid by an independent method. One sample of the intact hormone and one of methionine were oxidized with performic acid according to Thompson [8]. The oxidized hormone, free from hydrogen peroxide, was hydrolyzed for 30 hours at 120° with 6 N hydrochloric acid. A first separation of the acids was achieved by paper electrophoresis in 0.05 M borate buffer (pH = 8.7), when using an apparatus constructed by Porath and Jerstedt [12], which permits electrophoresis in one direction and succeeding chromatography in the perpendicular direction. After the electrophoresis the paper was dried, the oxidized methionine was put on near the edge of the paper as a reference, and the acids were separated by descending chromatography in a system of eighty parts of pyridine and twenty parts of the 0.05 M borate buffer.

An independent investigation of the occurrence of cysteine and cystine was also made. One sample of the peptide and one of cystine were simultaneously oxidized with performic acid according to Thompson. The peptide hydrolysate was subjected to paper electrophoresis at pH 4.9, using 0.1 M pyridine-acetic acid buffer. The oxidized cystine and a mixture of cysteic acid, aspartic acid, glutamic acid, and lysine were used as references.

For the analysis for tyrosine and tryptophan [7], 1.5 mg of the peptide was dissolved in 5 ml 0.1 M NaOH. Readings of the ultraviolet absorption at 280 and 294.5 mμ were made with a Beckman DU spectrophotometer using 1 cm quartz cells. The molar extinction coefficients for tyrosine and tryptophan were determined at the same wave-lengths, and from the measurements it was possible to calculate the molar ratio of tyrosine to tryptophan.

In order to find out if the ammonia in the total hydrolysate originated from amide nitrogen or from another source, the amide nitrogen of the peptide was determined by the Conway microdiffusion technique. The Conway vessels were provided with a liquid seal according to Öbrink [13], and the procedure was essentially the same as that of Hirs, Stein and Moore [14]. 3.28 mg of the peptide was dissolved in 1.00 ml of 1 N H_2SO_4. The solution was divided into two equal parts and heated in sealed Pyrex tubes at 100°, one tube for 4 hours, the other for 8 hours. 0.2 ml aliquots were transferred from the tubes to the Conway vessels containing 0.4 ml of 0.02 N H_2SO_4 in the inner chamber. The sample in the outer chamber was brought to pH 10 to 11 by addition of 1 ml of the alkaline solution (see Hirs *et al.*[14]), which was also used in the seal of liquid. After standing overnight at room temperature, 0.15 ml aliquots from the inner chamber were analyzed for NH_3 with the modified ninhydrin reagent [6]. The technique was checked on an electrophoretically homogeneous preparation of asparagine.

RESULTS AND DISCUSSION

The elution curve obtained from a run on a column of Dowex 50—X4 is presented in Fig. 1. The time of hydrolysis was 30 hours at 120°. The separation of the acids was not as good as was expected. This was especially the case for tyrosine and phenylalanine, which emerged together as one symmetric peak. There was no separate ammonia peak, but ammonia caused an elevated base-line color in the region of lysine and histidine, which made the exact determination of these acids difficult. The ninhydrin-positive peak X, only given by this method and not by the Dowex 50—X8 method, could not be identified as one of the common amino acids.

A two-dimensional chromatogram run with a hydrolysate of the peptide prepared under identical conditions to those mentioned above gave no spot which could account for X. The system used was *n*-butanol-acetic acid-water, followed by phenol, pH 9.3 borate buffer [15].

In Figs. 2 and 3 the results obtained, respectively, with a long and short column of Dowex 50—X8 are shown. The time of hydrolysis was 40 hours at 120°. The amino acids were all completely separated except tyrosine and phenylalanine. A peculiarity, however, was that this method did not give any methionine.

The check of methionine as methionine sulfone (see Experimental) gave a distinct spot, which in color and position agreed with the only spot given by the simultaneously oxidized methionine. The occurrence of methionine was further confirmed by the sulphur content and by the absence of cysteine and cystine. The peptide was found to contain 1.47 % S, which corresponds to one gram atom sulphur per mole (molecular weight approximately 2 500, as obtained by a recent determination at this Institute by the method of Archibald [16]), and as the test of cysteine and cystine gave a negative result (see Fig. 4), the total sulphur must come from methionine.

In Table 1 the analytical data from various experiments on Dowex 50 columns are collected. From the values in the table it appears that 15 hours at 115° is too short a time for complete hydrolysis, and that a hydrolysis for 50 hours at 120° is rather long. Especially serine is decomposed to a large extent.

The runs on short columns of Dowex 50—X8 gave a separate ammonia peak (Fig. 3). If the ammonia values in the table are corrected for ammonia

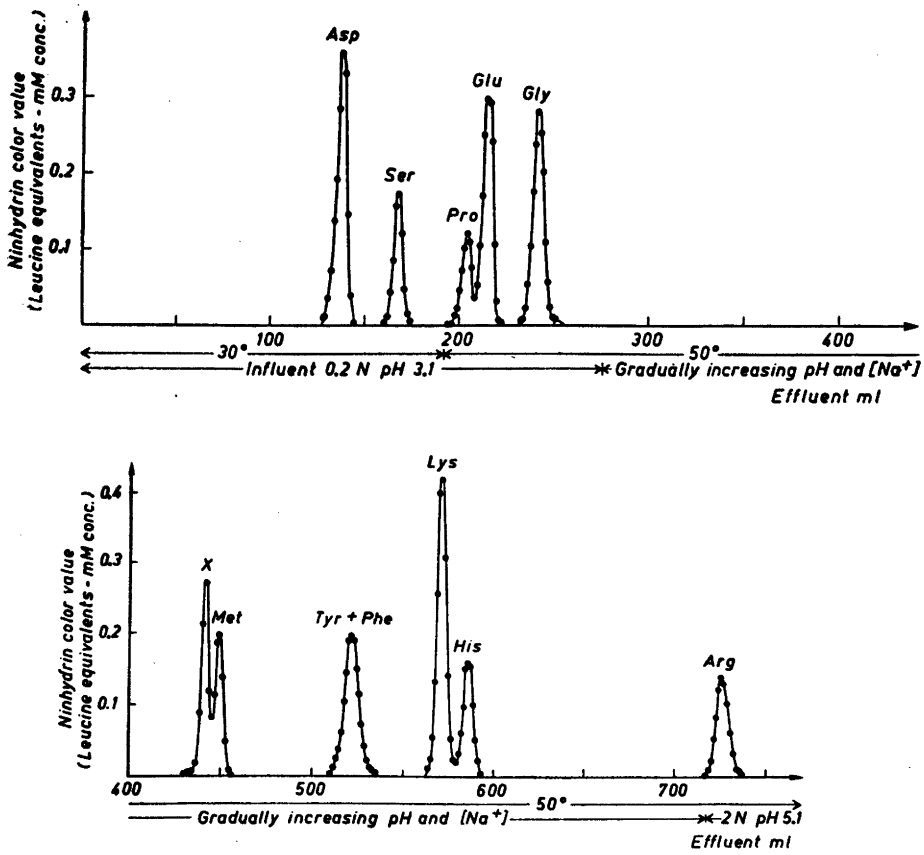

Fig. 1. Elution curve for a 30 hour hydrolysate of the peptide at 120° on a 0.9 × 150 cm column of Dowex 50—X4. For the run shown 1.874 mg of peptide hydrolysate was used.

from the destruction of serine, they indicate the presence of one amide group in the molecule. When using the Conway microdiffusion technique, however, the found ammonia values, after 4, respectively 8 hours of hydrolysis, were 3.8 and 4.4 μmoles per 100 mg of the peptide, which is only about 0.1 amide group per molecule. The check of the method on asparagine gave after 4 hours of hydrolysis 1.0 ± 0.1 amide group per molecule. Thus it seems necessary to assume another source of the ammonia in the total hydrolysate than amide nitrogen.

The molar ratio of tyrosine to tryptophan was found to be [7] 1.07, and this together with the values in the table give the following empirical formula of the peptide:

$$Asp_2\ Glu_2\ Gly_2\ Ser\ Met\ Pro_3\ Phe\ Tyr\ Try\ His\ Lys_2\ Arg.$$

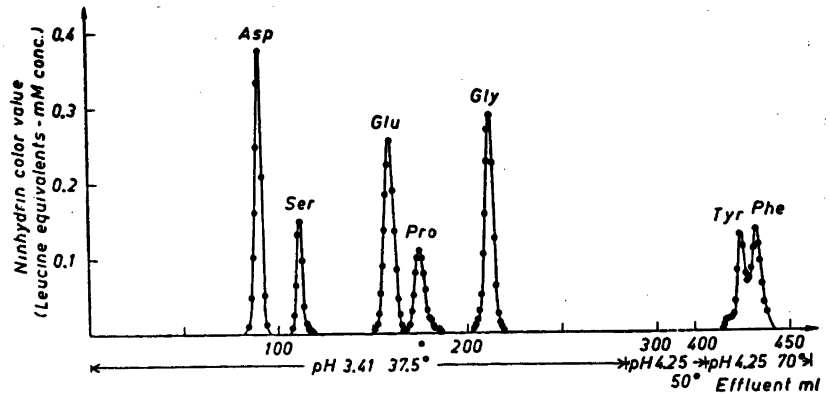

Fig. 2. Elution curve for the determination of the acidic and neutral amino acids on a 0.9 × 115 cm column of Dowex 50—X8. The time of hydrolysis was 40 hours at 120°. For the run illustrated 1.990 mg of peptide hydrolysate was used.

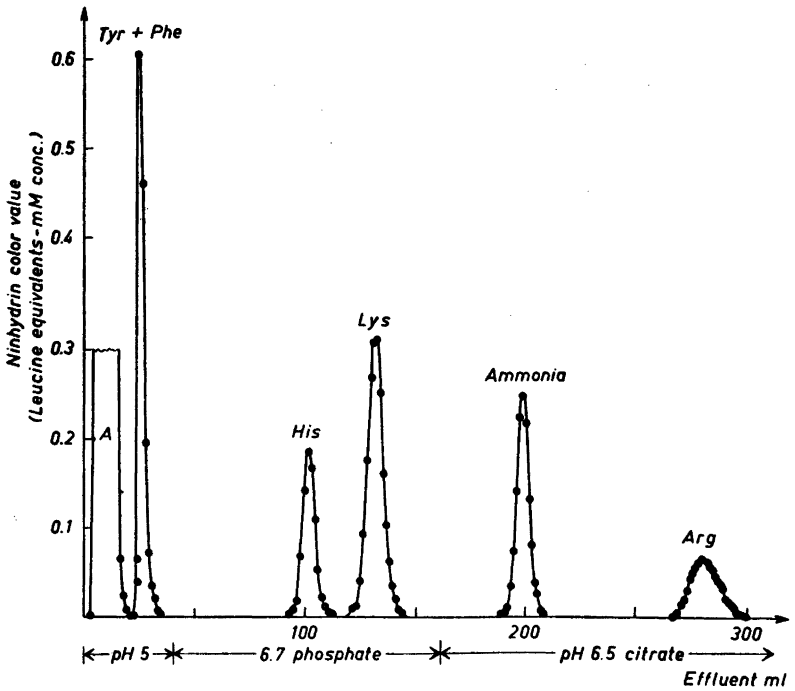

Fig. 3. Elution curve for the determination of the basic amino acids and ammonia on a 0.9 × 15 cm column of Dowex 50—X8. The time of hydrolysis was 40 hours at 120°. For the run illustrated 1.851 mg of peptide hydrolysate was used. The large peak, A, comprised all the amino acids emerging before tyrosine and phenylalanine.

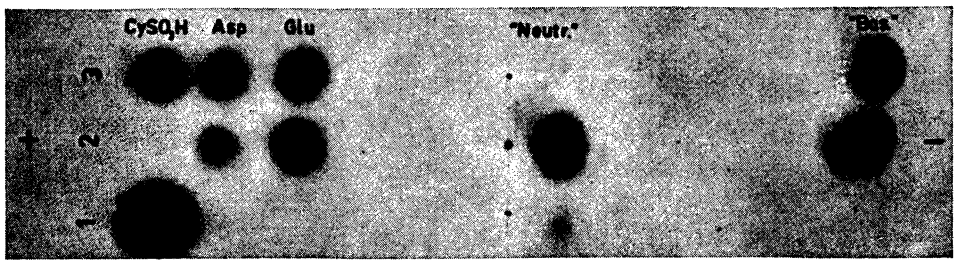

Fig. 4. Electrophoretic patterns of 1) cystine oxidized according to Thompson, 2) the active peptide oxidized according to Thompson and then hydrolyzed for 20 hours at 120°, 3) a mixture of cysteic acid, aspartic acid, glutamic acid, and lysine.

The results in this analysis differ considerably from those given by Lerner and Lee [2], who reported the presence of alanine, valine, cystine, leucine and threonine, which were not found in this investigation. Furthermore, they did not find histidine and did not analyze for methionine. Benfey and Purvis [3] reported the same amino acids as found in this work, but their minimum number of residues per molecule were twice those in Table 1 for all acids except glycine, methionine and proline.

Table 1. Analytical data from various experiments on Dowex 50 columns.

Ion exchange	Dowex 50−X4			Dowex 50−X8				Calculated integral numbers of residues for mol. wt. 2 500 *
Dimension of the column	0.9 × 150 cm			0.9 × 115 cm		0.9 × 15 cm

Ammonia						53.2	69.0	

* The approximative value found in the ultracentrifuge. The molecular weight calculated on the basis of the integral numbers of residues including the tryptophan residue, amounts to 2 176.

The author wishes to thank Professor A. Tiselius for kind interest in this work. The author is also indebted to Dr. J. Porath for advice and encouragement.

This work has been supported by a grant from the *Swedish Natural Science Research Council.*

Added in proof: Since this manuscript was submitted for publication the amino acid analysis has been repeated on a Dowex 50—X4 column. The results obtained were in complete agreement with those reported in the text, except that in this case the unidentified component X did not appear. The author is indebted to Mr. M. Rees, Department of Biochemistry, Cambridge, for his assistance in carrying out this analysis.

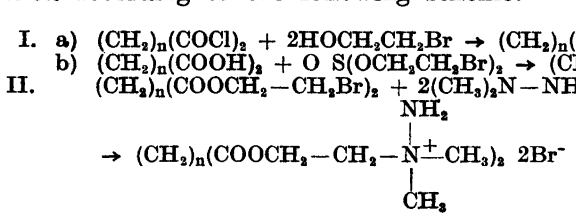
Syntheses of Dimethylhydrazoniumethyl Esters of Aliphatic Dicarboxylic Acids



L.-E. TAMMELIN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The choline analogue N′,N′-dimethyl-N′-hydroxyethylhydrazonium bromide has been prepared.

The bis-(ω-bromoethyl)-esters of oxalic, malonic, succinic, glutaric and adipic acids have been prepared. It is shown that these esters, except the oxalic ester, react with unsym. dimethylhydrazine in ether at 25° C yielding a product which is a bis quaternary ammonium compound of the N′,N′-dialkyl-N′-amino-ammonium type. The compounds are analogous to choline esters and have neuro-muscular blocking effects.

It has been shown by Renouf[1] that unsym. dimethylhydrazine reacts with alkyl halogenides to form N′,N′-dimethyl-N′-alkyl-N′-amino-ammonium halogenides, compounds having most of the properties of ordinary tetra alkyl ammonium compounds. An analogue of the acetylcholine has been synthesized by Schuler *et al.*[2] which contains the N′,N′-dimethyl-N′-amino-ammonium group. The purpose of this paper is to report methods of syntheses of similar analogues of succinylcholine and its homologues. The synthesis was performed according to the following scheme:

I. a) $(CH_2)_n(COCl)_2 + 2HOCH_2CH_2Br \rightarrow (CH_2)_n(COOCH_2CH_2Br)_2 + 2HCl$

b) $(CH_2)_n(COOH)_2 + O\ S(OCH_2CH_2Br)_2 \rightarrow (CH_2)_n(COOCH_2CH_2Br)_2 + H_2SO_3$

II. $(CH_2)_n(COOCH_2-CH_2Br)_2 + 2(CH_3)_2N-NH_2 \rightarrow$

$\rightarrow (CH_2)_n(COOCH_2-CH_2-\overset{NH_2}{\underset{CH_3}{\overset{|}{\underset{|}{N^+}}}}-CH_3)_2\ 2Br^-$

According to II the resulting product is analogous to a choline ester, except that choline is substituted for N′,N′-dimethyl-N′-hydroxyethyl-hydrazonium bromide. This compound was also synthesized.

EXPERIMENTAL

Bis-(ω-bromoethyl) esters of the aliphatic dicarboxylic acids

Unsym. dimethylhydrazine was prepared according to H. H. Hatt [3].

a) The bis-(ω-bromoethyl)esters of oxalic, malonic, succinic, glutaric and adipic acids were prepared as follows. 1 Mole of acid dichloride in 500 ml of benzene was added to 3 moles of ethylenebromhydrine and 1 mole of potassium carbonate in 500 ml of benzene. Nitrogen was bubbled through the reaction mixture and the reaction vessel was fitted with a reflux condenser and sealed with calcium chloride to eliminate moisture. The reaction was complete in 2 hours after which the potassium chloride was filtered off, the solution treated with calcium chloride, filtered again and finally fractioned by distillation. The esters were distilled *in vacuo*. For data see Table 1.

b) *A method according to Voss and Blanke* [4] was also tested for the preparation of bromoethyl esters of aliphatic dicarboxylic acids. The esters of oxalic and glutaric acids were prepared. For data see Table 1.

Table 1.

ω-Bromo-ethyl-ester of	Formula	M	Method of preparation	b. p. °C/mm Hg	m. p. °C	n_D^{20}	d_4^{20}	MR		% Br		Yield calc. on acid in %

Bis-(ω-bromoethyl) ester of oxalic acid. 3.3 Moles of bis-(ω-bromoethyl)sulfite and 1 mole of oxalic acid [$(COOH)_2$, $2H_2O$] were mixed and heated on a steam bath for two hours. The reaction mixture was extracted with ether and the ether solution washed twice with water and finally with a sodium bicarbonate solution. The solution was dried with sodium sulfate and fractionated by distillation. The ester was distilled *in vacuo*. For data see Table 1.

Bis-(ω-bromoethyl) ester of glutaric acid. 1.1 Moles of bis-(ω-bromoethyl)sulfite, 1 mole of glutaric acid and one drop of conc. sulfuric acid were mixed and heated for two hours on a steam bath. The reaction mixture was extracted with ether and the ether solution was washed twice with water and finally with a sodium bicarbonate solution. The solution was dried with sodium sulfate and fractionated by distillation. The ester was distilled *in vacuo*. For data see Table 1.

Dimethyl-hydrazoniumethyl esters of the aliphatic dicarboxylic acids

1 Mole of the bis-(ω-bromoethyl)ester and 2.2 moles of unsym. dimethylhydrazine were mixed with about eight volume parts of dry ether in a glass stoppered round bottomed flask. After three weeks at 25° C a crystalline or viscous precipitate was filtered off from the ether. When viscous products occurred the preparation was stored for a few

Table 2.

Acid esterified by N′,N′-dimethyl-N′,-hydroxyethyl hydrazonium bromide	Formula	M	m. p. °C	% Br		% C		% H		Yield in % of theoretical
				calc.	found	calc.	found	calc.	found	
Malonic acid	$C_{11}H_{26}O_4N_4Br_2$	438.2	80—100	36.5	35.9	30.2	30.2	6.0	6.0	55

days in a desiccator for crystallization. The compounds were recrystallized from ethanol. For data see Table 2.

N′,N′,-dimethyl-N′-hydroxyethylhydrazonium bromide

1 Mole of ethylenebromhydrine and 1.1 moles of unsym. dimethylhydrazine were mixed with about eight volume parts of dry ether in a glass stoppered round bottomed flask. After three days the colourless precipitate was filtered off. (Yield 76 %; m. p. < 50°, hygroscopic). (Found: C 25.8; H 7.0; Br 43.6. Calc. for $C_4H_{13}N_2OBr$ (185.1) C 25.9; H 7.1; Br 43.2).

The ω-bromo-ethyl esters of the aliphatic dicarboxylic acids have been shown to react with unsym. dimethylhydrazine with the formation of N′,N′-dimethyl-N′-amino-ammonium-ethyl ester bromides, although the reaction does not seem to be possible with the oxalic ester, yielding precipitates which differ in composition from the end product of reaction II. The esters of malonic, succinic, glutaric and adipic acids are all colourless crystalline compounds of salt character. They are easily soluble in water and the bromine content has been determined by means of directly applied argentometric titration. Since this was possible the compounds are completely dissociated in bromine ions and the organic cations. By means of pH-measurements and potentiometric titrations the amino groups have been shown to fail in protolytic properties in ordinary water solutions and seem even in this respect to correspond to the third methyl group in choline. A report on the pharmacological properties of these compounds will be given elsewhere.[5] It might be worth mentioning, however, that they possess neuromuscular blocking activity, but are less potent than the corresponding choline esters.

My sincere thanks are due to the Director of this Institute, Professor G. Ljunggren, for his kind interest in this work.

Determination of the Distribution Constant of a Compound Reacting with One of the Phases

LENNART LARSSON

Research Institute of National Defence, Dept 1, Sundbyberg 4, Sweden

A formula has been deduced for calculation of the distribution constant of a compound which reacts with one of the phases according to a first order reaction. The application of the formula is illustrated by the distribution of 2-methoxy-ethyl nicotinate between xylene and water. Another formula has been deduced in the case of association of the compound in one phase in addition to its decomposition in the other.

The distribution constant of a compound which reacts with one of the phases can be accurately determined if the concentrations of the solute are determined in each phase. Distribution constants, however, are generally evaluated from determinations of the concentration of the solute in one phase, the concentration in the other being obtained as a difference. In the case of reaction between the compound and one of the phases the total amount of compound is reduced ,and an erroneous concentration in the unanalysed phase is obtained. Hence the error of the distribution constant will be considerable. In this investigation it has been found that the distribution constant of a compound can also be calculated from measurements of its reaction rate in the phase in question.

Let us consider the concentrations in the two phases of a compound distributed between an organic solvent and water, when the compound hydrolyses in the aqueous phase according to a first order reaction.

The following symbols will be used:

$[\ ]_{aq}$ or $[\ ]_{org}$ = concentrations in aqueous and organic phases, respectively;
α = slope of the line, when log $[A]_{aq}$ is plotted against t;
A = unhydrolysed compound;
A_2 = double molecule of A;
D = optical density;
k = reaction rate constant of A in water;
k_{ass} = association constant of A in organic phase;
k_d = distribution constant of A between organic and aqueous phase;

P = one of the hydrolysis products;
t = time;
v = phase volume.

Assuming that at a given moment the concentration of the hydrolysis product is

$$[P]_{aq} = \int_0^t k \cdot [A]_{aq} dt \tag{1}$$

Then the total amount of the compound and its hydrolysis product is

$$v_{org}[A]_{org} + v_{aq}[A]_{aq} + v_{aq}[P]_{aq} = \text{const.} \tag{2}$$

Further the distribution constant is

$$k_d = \frac{[A]_{org}}{[A]_{aq}}$$

On differentiating eqn. (2) we obtain

$$v_{org}d[A]_{org} + v_{aq}d[A]_{aq} + v_{aq}d[P]_{aq} = 0 \tag{4}$$

and on substitution of $d[P]_{aq}$ which according to eqn. (1) is

$$d[P]_{aq} = k \cdot [A]_{aq} dt \tag{5}$$

in eqn. (4), we get

$$\frac{v_{org}}{v_{aq}} \cdot \frac{d[A]_{org}}{dt} + \frac{d[A]_{aq}}{dt} = -k \cdot [A]_{aq} \tag{6}$$

From eqn. (3) we obtain on differentiating with respect to time

$$\frac{d[A]_{org}}{dt} = k_d \frac{d[A]_{aq}}{dt} \tag{7}$$

On introduction of this expression into eqn. (6) we get

$$\frac{d[A]_{aq}}{dt}\left(\frac{v_{org}}{v_{aq}} k_d + 1\right) = -k \cdot [A]_{aq} \tag{8}$$

When this equation is integrated, we obtain

$$\frac{k \cdot t}{\frac{v_{org}}{v_{aq}} k_d + 1} = \ln \frac{[A]^0_{aq}}{[A]_{aq}} \tag{9}$$

where $[A]^0_{aq}$ is the concentration of A in the aqueous phase at distribution equilibrium, at which time no hydrolysis is assumed to have occurred.

By plotting log $[A]_{aq}$ against t we get a straight line the slope of which is

$$|\alpha| = \frac{0.4343 \cdot k}{\frac{v_{org}}{v_{aq}} k_d + 1} \tag{10a}$$

or

$$k_d = \frac{v_{aq}}{v_{org}}\left(\frac{0.4343 \cdot k}{|\alpha|} - 1\right) \tag{10b}$$

If the compound is associated to some extent into double molecules in the organic phase, a straight line would not be obtained. On the assumption that such an association occurs, the distribution constant can be calculated from eqn. (11) which can be deduced analogously to eqn. (9).

$$k \cdot t = \left(\frac{v_{org}}{v_{aq}}\, k_d + 1\right) \overline{\ln} \frac{[A]^0_{aq}}{[A]_{aq}} + 4k_{ass} \cdot k_d^2 \frac{v_{org}}{v_{aq}} ([A]^0_{aq} - [A]_{aq}) \qquad (11)$$

where $k_{ass} = \dfrac{[A_2]_{org}}{[A]^2_{org}}$

EXPERIMENTAL

The application of the method is illustrated by determination of the distribution constant of 2-methoxy-ethyl nicotinate between xylene and a buffer solution at pH 9.15. At this pH the nicotinic ester may be regarded as completely unionized. The two phases are nearly insoluble in each other. Hydrolysis of the ester proceeds as a first order reaction, when the pH remains constant. In order to verify the result obtained with this method the distribution constant was also determined in the conventional manner from the concentrations of the ester in the aqueous phase before and after shaking to equilibrium. The hydrolysis of this compound is negligible during the time required for this experiment.

Materials. 2-Methoxy-ethyl nicotinate: To 17.7 g (0.10 mole) of the hydrochloride of nicotinyl chloride, prepared from nicotinic acid and thionyl chloride [1], was gradually added 22.8 g (0.30 mole) of 2-methoxy-ethanol. The reaction mixture was refluxed for two hours in a water bath. After cooling, the mixture was neutralized with a saturated solution of potassium carbonate and extracted three times with ether. After drying of the ether extract overnight the ether was evaporated, and the ester was distilled under reduced pressure; b.p. 80–83°/0.20–0.25 mm Hg. A solid, colourless product was obtained which was recrystallized from acetone. Yield 11.0 g (61 %). (Found: C 59.5; H 6.0, Calc. for $C_9H_{11}O_3N$: C 59.7 ;H 6.1.)

Buffer solution: A borax buffer solution with pH 9.15 was used. It was standardized at 25°C against 0.05 M solution of potassium hydrogen *o*-phthalate, pH 4.01[2], with a Radiometer pH-meter, type 3.

Xylene: Reagent grade; b.p. 139–140°; $n_D^{20} = 1.4957$.

Procedure I. All experiments were carried out in a thermostat at 25°C. Each series of experiments consisted of 6–8 samples with the same concentration. The 2-methoxy-

ethyl nicotinate was dissolved in xylene; in this way a smaller amount of the compound came into contact with water, before equilibrium was attained, than if the compound was dissolved in buffer solution. The buffer solution was added at zero time. The mixtures were shaken mechanically in sealed ampoules which were withdrawn from the thermostat at annotated times. After separation and filtration, the concentration of unhydrolysed ester in the aqueous phase was determined colorimetrically with the method reported by Hestrin [3]. The colour intensities of the samples were measured in a 10 mm cell at 5 200 Å with a Beckmann B Spectrophotometer. In the different series both the concentration of ester and the ratio of the volumes of xylene to buffer solution were varied as shown in Table 1. The total volume of each sample was 30 ml. Preliminary mutual saturation of the immiscible layers was unnecessary, since it was found to have no effect on the distribution constant. The pH of the solutions was determined at the beginning and end of hydrolysis, and was found to remain constant within 0.01 pH unit. Because Beer's law was obeyed, the logarithm of the optical density rather than that of the concentration of unhydrolysed ester was plotted against time. This is illustrated in Fig. 1. From the slope of the line obtained the distribution constant was calculated by means of eqn. (10b).

The rate constant of hydrolysis of the ester in buffer solution alone was determined colorimetrically as described above and calculated from the first order equation

$$k = \frac{1}{t} \ln \frac{D^\circ}{D} \qquad (12)$$

			Mean value	4.28 ± 0.11

where $D°$ and D are the optical densities at zero time and t time, respectively. The values obtained are given in Table 2.

Procedure II. Buffer solutions in which the ester was dissolved, were shaken with xylene for about 5 minutes. The concentration of ester and the ratio of the volumes were varied as in the previous experiment. The concentration of ester in the aqueous phase before and after shaking was determined colorimetrically as described in procedure I. The unshaken buffer solutions had to be diluted four times before they were analysed. The values of the optical density, D', given in Table 3 have been converted for this dilution. Mixtures shaken for 3, 6, 9, and 12 minutes showed that equilibrium was already attained after 3 minutes. As Beer's law proved to be valid, the distribution constant was calculated from

$$k_d = \frac{[A]_{org}}{[A]_{aq}} = \frac{v_{aq}}{v_{org}} \cdot \frac{D'-D}{D} \qquad (13)$$

where D' and D are the optical densities before and after shaking, respectively.

RESULTS AND DISCUSSION

From Tables 1 and 3 it will be seen that the distribution constant calculated from kinetic data is in close agreement with that obtained from analysis of the aqueous phase before and after shaking, and that the precision of the two methods is approximately the same. When the logarithm of the optical density is plotted against time (Fig. 1), straight lines are obtained, indicating that no appreciable association occurs in the xylene phase. Further confirmation of this is that the distribution constant is independent of concentration.

The kinetic method is of course more time-consuming than the other, but it is far more reliable. Eqn. (9) is, however, not exactly valid, because no account has been taken of the distribution rate of the solute. The internal controlling factor in this process is the rate of solute diffusion across the interfacial stationary films [4], but the thicknessses and surfaces of the interfacial films vary considerably with the experimental conditions. The rate of distribution will consequently be very difficult to determine. However, since equi-

librium is generally attained very rapidly [5], the method can be applied in all cases where the reaction rate is relatively low, or where the concentration of the solute in the indifferent phase is high compared to that of the reacting phase. The assumption made in eqn. (9) concerning $[A]^0_{aq}$, on the other hand, does not influence the accuracy, because zero time can just as well be taken as the moment when equilibrium is attained.

The method described may also be used in the study of rapid reactions, for the reaction rate can be reduced appreciably by adding a suitable solvent which must be immiscible with the reacting phase and readily dissolve the solute. One must consider that errors may arise from neglecting the rate of distribution and, in this case, from $[A]^0_{aq}$ too, if this value is used for determination of the distribution constant.

My thanks are due to the Director of the Research Institute of National Defence, Dept. 1, Professor G. Ljunggren, for the kind interest he has shown in this investigation.

Chromatography of Human Serum Cholinesterase

B. G. MALMSTRÖM, Ö. LEVIN and H. G. BOMAN

Institute of Biochemistry, Uppsala, and the Research Institute of National Defence, Department 1, Sundbyberg, Sweden

Human serum cholinesterase has been purified by chromatography on calcium phosphate and on the anion exchange resin Dowex 2. One milligram of the most highly active material, obtained by calcium-phosphate chromatography alone, hydrolyzes 13 000 micromoles of acetylcholine in 1 h at 37.5°. The chromatographic experiments show that this is not a homogeneous protein but that further purification can be achieved by rechromatographing on the same adsorbents.

Several methods for the partial purification of serum cholinesterase (ChE) have been developed [1]. The most active preparation from human serum has been obtained by low-temperature alcohol fractionation according to Surgenor and Ellis [2]. In the present communication, experiments will be described showing that an additional purification of the enzyme material can be achieved by chromatography on calcium phosphate [3,4] and on an anion exchange resin (Dowex 2) [5].

MATERIALS AND METHODS

Enzyme. A partially purified preparation of human serum ChE, fraction IV-6-3 of Surgenor and Ellis [2] (prepared by AB. Kabi, Stockholm), was used as the starting material for the chromatographic experiments.

Chromatographic Techniques. The preparation of calcium phosphate (hydroxylapatite) and details of the chromatographic procedure have been described [3,4]. Sodium phosphate buffers, pH 6.83, were used in all experiments. The enzyme was adsorbed at low ionic strength and eluted with increasing buffer concentrations.

An extensive description of protein chromatography on the anion exchange resin Dowex 2 has been published recently [5]. With this adsorbent, tris(hydroxymethyl) aminomethane (THAM)-HCl buffers, pH 7.3, were used. As in the case of calcium phosphate, adsorption of the protein was effected at low ionic strength and elution by increasing buffer concentrations.

All chromatographic runs have been performed at +4°.

The protein concentration of the eluate fractions was determined by ultraviolet absorption measurements at 280 mμ in the Beckman DU spectrophotometer using 1 cm cells. The protein components of the separate fractions were identified by paper electrophoresis; the solutions were concentrated by pressure dialysis before application to the paper.

Measurement of Enzyme Activity. For determining the ChE activity of the fractions, an indicator method was used. The substrate mixture employed had the following composition: (a) 0.01 M Na barbital; (b) 0.02 M KH_2PO_4; (c) 0.3 M KCl; (d) 0.0014 M HCl; (e) 0.05 M butyrylcholine iodide; and (f) 0.005 % bromothymol blue. To 3 ml of this solution, 0.1 ml of the sample was added, and the optical density at 610 mμ was immediately determined in a Beckman B spectrophotometer using 1 cm cells. The solution was then allowed to stand at 22° for 30 min. after which time the optical density was read again. The measured change in optical density allowed the estimation of the activity from a standard curve constructed by carrying serial dilutions of a solution of fraction IV-6-3 through the entire procedure. The activity unit was defined as the activity obtained when a solution containing 1 mg of IV-6-3/ml was used as sample.

The simplicity of the method described made it suitable for following the activity in the eluate fractions, but it could not be employed for accurate determinations of the specific activity of the starting material and purified fractions. For this purpose, the method of Hestrin [6] was used, and the activity was expressed as the number of micromoles of acetylcholine (AcCh) hydrolyzed in 1 h at 37.5° per mg of protein.

RESULTS

Fig. 1 gives part of the elution curve from an experiment with 360 mg of IV-6-3 on a column (15 × 4 cm) with 190 ml of calcium phosphate in equilibrium with 0.01 M phosphate buffer. The sample was dissolved in 35 ml of the same buffer and applied to the column. Elution was first carried out with 0.05 M buffer and fractions of about 5 ml volume were collected. The two zones that are obtained in this elution range are the ones shown in Fig. 1. They account for about 40 % of the added activity but contain only 10 % of the protein material applied. The remainder of the adsorbed proteins could be eluted with 0.3 M buffer but the specific activity in the zones obtained in this elution range was never higher than that of the starting material.

Fractions 40—44 from the experiment illustrated in Fig. 1 were combined (fraction A) and used for rechromatographing both on calcium phosphate and

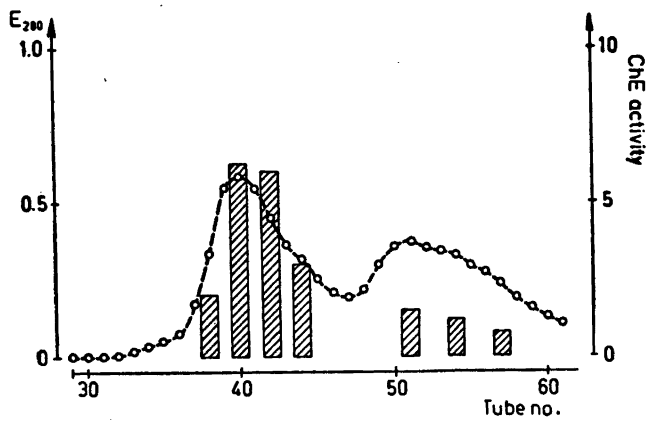

Fig. 1. The first part of a chromatogram obtained with 360 mg of IV-6-3 on a column with 190 ml of calcium phosphate. Elution was here carried out with 0.05 M phosphate buffer, pH 6.83. Open circles denote extinction at 280 mμ, and the blocks show the ChE activity.

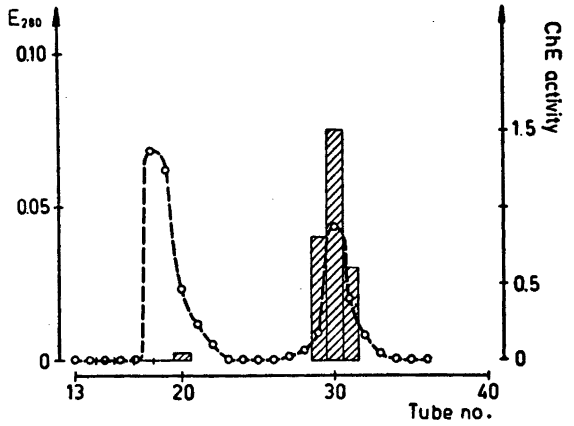

Fig. 2. Rechromatographing of fractions 40—44 from the experiment shown in Fig. 1 on a column with 7.5 ml of calcium phosphate. The first zone (tubes 18—22) was eluted with a gradient and the second one (tubes 29—32) with 0.1 M phosphate buffer, pH 6.83. Open circles denote extinction at 280 mμ, and the blocks show the ChE activity, zero acitivity being marked with a line.

on Dowex 2; the specific activity in the combined sample was about 10 times that of the starting material. The distribution of ultraviolet-absorbing material and activity seen in Fig. 1 indicate that a separation of the enzyme from contaminating proteins by step-wise elution would offer difficulties. Thus, gradient elution [7] was tried, but it was found that the enzyme zone was too wide to allow accurate measurements of concentration and activity. Instead the

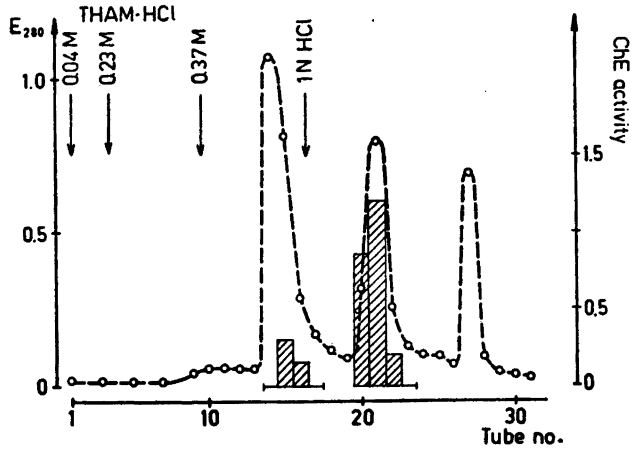

Fig. 3. Chromatography of 40 mg of IV-6-3 on a column with 180 ml of Dowex 2. The arrows indicate the start at the top of the column of the different elution agents. Open circles denote extinction at 280 mμ, and the blocks show the ChE activity, zero activity being marked with a line.

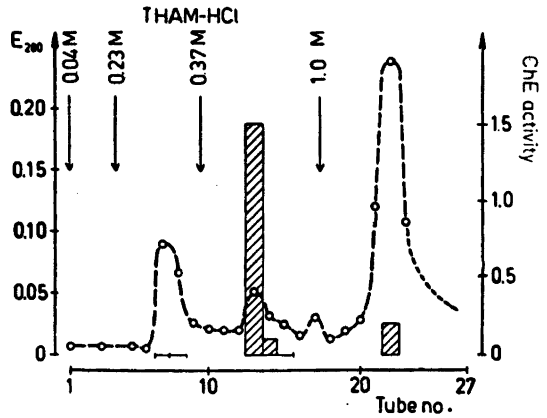

Fig. 4. Rechromatographing of fractions 40—44 from the experiment shown in Fig. 1 on a column with 34 ml of Dowex 2. The second zone (tubes 13—14), containing most of the activity, was eluted with 0.37 M THAM-HCl, pH 7.3. Open circles denote extinction at 280 mμ, and the blocks show the ChE activity, zero activity being marked with a line.

following procedure was adopted: After dialysis against 0.01 M phosphate buffer, 4.5 ml of the combined sample was applied to a column (9.5 × 1.0 cm) with 7.5 ml of calcium phosphate. Elution was first carried out with a linear gradient (discussed by Drake[7] as "case 4") between 0.03 and 0.08 M phosphate buffer, pH 6.83. The fraction volumes were 3.8 ml. When the first zone (tubes 18—22 in Fig. 2) had emerged (at about 0.04 M phosphate), the gradient was interrupted and elution with 0.1 M buffer was started. With this concentration a second zone (tubes 29—31 in Fig. 2) was eluted containing about 70 % of the activity applied. The most highly purified fraction (tube 29) was about 70 times more active than fraction IV-6-3.

Fig. 3 illustrates an experiment with 40 mg of IV-6-3 on a column with 180 ml of Dowex 2 in equilibrium with 0.04 M THAM—HCl. In this figure, as well as in Fig. 4, the arrows indicate the start at the top of the column of the different eluting agents. As can be seen, most of the material added is adsorbed at 0.04 M buffer concentration while three separate zones are obtained for the other three steps. Both the first and the second zone contain activity but most of it is present in the second one, the recovery being about 50 %.

Fig. 4 gives the results of an experiment in which ChE chromatographed once on calcium phosphate is run on Dowex 2. Five milliliters of the same solution used in the experiment in Fig. 2 were applied directly to a column with 34 ml of the resin. The first and last zone together account for about 80 % of the ultraviolet absorbing material while approximately 50 % of the activity applied was found in the second zone. The specific activity in tube 13 is approximately 40 times higher than that of IV-6-3.

The identification of the protein components is illustrated in Fig. 5, which shows a paper electrophoresis run on the starting material (denoted "0") and on material from the first two zones of an experiment similar to that in Fig. 3. The starting material is seen to be made up mainly of α_2-globulin with smaller

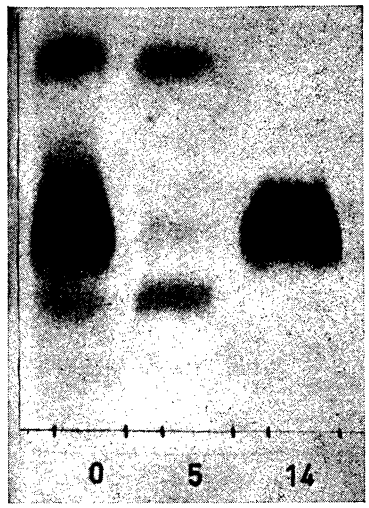

Fig. 5. Paper electrophoresis of IV-6-3 ("0") together with the first ("5") and second zone ("14") from a chromatographic experiment on Dowex 2, comparable to the one shown in Fig. 3.

amounts of albumin and β-globulin. The latter two components, with small amounts of α_2-globulin, are obviously eluted in the first zone ("5"), while most of the α_2-globulin, together with the enzyme, appears in the second zone ("14"). In the most highly purified fractions, the only protein component that could be identified had a mobility close to that of α_1-globulin. However, zone electrophoresis on cellulose columns (unpublished experiments) showed that the enzyme activity migrates somewhat slower than α_2-globulin, so that this component cannot be ChE.

Table 1 summarizes the maximum specific activities obtained in the experiments described herein.

The enzyme can also be purified directly from human serum using stepwise elution on Dowex 2 as described for the experiment illustrated in Fig. 3.

Table 1. Specific activity of ChE fractions.

Fraction	Maximum specific activity (μM AcCh hydrolyzed per mg of protein in 1 h at 37.5°)
Starting material (Cohn fraction IV-6-3)	175
One chromatographic run on calcium phosphate (tube 42, Fig. 1)	1 940
One chromatographic run on Dowex 2 (tube 20, Fig. 3)	423
Rechromatographing of "fraction A" on Dowex 2 (tube 13, Fig. 4)	7 700
Rechromatographing of "fraction A" on calcium phosphate (tube 29, Fig. 2)	13 000

The specific activity of the enzyme obtained after one chromatographic run is about 50 times that of human serum. The purification directly from serum can also be carried out by a displacement technique as described by Boman and Westlund [5].

DISCUSSION

Mutual displacement phenomena play an important role in chromatography [4,5] both on calcium phosphate and on Dowex 2. This is shown in Figs. 2 and 3, where it can be seen that the zones of the major part of the ultraviolet-absorbing material and of the enzymic activity do not coincide. This also demonstrates that even the most highly purified material is not homogeneous. The small amounts obtained prohibited the use of other purity criteria, such as electrophoresis and ultracentrifugation.

It should be stressed that the exact elution concentrations given here for the calcium phosphate experiments apply only to hydroxylapatite. Thus, the detailed directions for the preparation of the adsorbent [4] must be strictly adhered to. It is recommended that, before a new batch of calcium phosphate is used in a preparative chromatographic run, the elution concentrations are determined in an orientating experiment with a smaller column and smaller amounts of protein.

While the uneven distribution of protein and activity demonstrates inhomogeneity, it also indicates that further purification can be obtained by additional rechromatographing on these same adsorbents. On Dowex 2, ChE and α_2-globulin are eluted in the same range of THAM—HCl concentration, while these substances can be separated on calcium phosphate columns. Thus, it may be possible to use calcium phosphate alone for the purification of the enzyme, and, in any case, the procedure must start with chromatography on this adsorbent. It is, however, impossible as yet to decide which adsorbent is capable of giving the highest degree of purification on rechromatographing. A possible advantage of combining the two methods is the fact that the eluate from the calcium phosphate column can be applied directly to Dowex 2, thus obviating the need for dialysis. The main difficulty in carrying the purification further appears to be the fact that the concentration of ChE in serum is very low compared that of contaminating proteins. Thus, considerably larger amounts of starting material than those employed here would be necessary.

Acknowledgment. The authors are indebted to Professor A. Tiselius for helpful discussions. They also wish to thank Professor G. Ljunggren for his stimulating interest and generous support.

New Spectrophotometric Methods for Investigation of the Respiratorical Enzymes of Yeast

H. LUNDEGÅRDH

Penningby, Sweden

Modern photo multiplier tubes have made it possible to observe the state of oxidation-reduction of respiratorical enzymes in living objects on the basis of accurate measurements of the extinction in the whole range of the spectrum. Leading principles for the construction of a new recording spectrophotometer, especially built for this purpose, are briefly presented. A survey is also given of the corrections by means of which the obstacles arising from optical interference of the pigments and from the turbidity of the object may be eliminated. A special technique has been elaborated for the observation of rapid changes in the steady states of the respiratorical enzymes of yeast.

The results regarding observed start lags and apparent velocity constants of reduction and reoxidation elucidate the order of activation of the following enzymes: cytochromes a_3, a, c, c_1, and b, flavoprotein (FP), diphosphopyridine nucleotide (DPN) and its combination with alcohol dehydrogenase (ADH). Besides of its far-going inactivation of cytochrome b antimycin A is shown to reduce the operating activities of cytochrome c_1, FP and DPN to about 50 % but leave the group a + a_3 and c nearly unaffected. Cytochrome b and one fraction of the total FP are closely cooperating in equimolar quantities.

EXPERIMENTAL TECHNIQUE AND PROCEDURE

A new recording spectrophotometer. Sensitive recording photometers were introduced only a few years ago [1,2]. The instruments constructed by the author are primarily built for the purpose of *accurate measurements of the extinction in distinct wave-length intervals.* The figures for the reference and the sample are separately recorded. The new construction eliminates the inertia of the recording millivoltmeter and secures the attainment of precise wave-length positions, a fact of fundamental importance for accurate calculations of extinction values. One of the author's instruments is shown in Fig. 1. It automatically plots extinction values of reference beam and sample for a series of wave-lengths, the intervals of which may be chosen at will. Sufficient for most purposes are intervals of 2 mμ. A record in 2 mμ intervals of the range

between 400 and 620 mμ takes 3 to 6 minutes, a single band may be recorded in 10—20 seconds. A high degree of accuracy is attained, enabling optical resolution of bands lying 3—4 mμ apart (*cf.* Refs. [3,4]).

Rapid recording of bands. Complete records of larger spectral regions may be used for the study of more slowly changing steady states. For a more incisive analysis of the kinetics, however, still more rapidly working procedures must be applied. Some bands, *e. g.* the α-band of cytochrome c, may be measured from the difference in extinction between 550 and 546 mμ, which in the case of a difference spectrum (ε reduced-ε oxidized, *cf.* Fig. 4) corresponds to approximately 50 % of the total height. Some authors prefer to compute such measurements by means of a device implying rapid oscillation between the two wave-lengths [2]. According to my experience with yeast constant

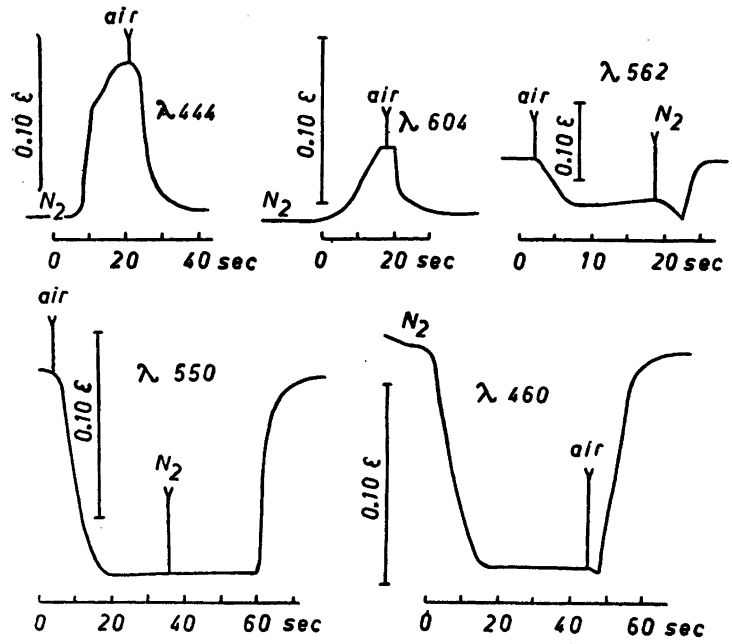

Fig. 2. Direct records of the top of the main bands of the cytochromes a_3 (444 mμ), a (604 mμ), c (550 mμ), b (562 mμ), and flavoprotein (460 mμ), at alternating reduction in N_2 and reoxidation in air.

recording of the top of the band, *viz.* in the case of cytochrome c at 550 mμ, serves the same purpose. With a sensitive and rapid millivoltmeter, *e. g.* Speedomax G supplied with A. C. 60 periods, changes in time intervals of *ca.* 0.5 seconds are within the reach of the operator (see Fig. 2).

Corrections for interfering bands. Accurate knowledge of the variations of the background of the spectrum constitutes the basis of all measurements. Baker's yeast, fortunately, lacks pigments which are interfering with the respiratorical enzymes, but the spectra of the different cytochromes and FP are partly overlapping, a fact necessitating a number of corrections. There is little hope for reliable results unless the spectral behaviour of the chosen object is thoroughly known. For successful calculation the observed spectrum has to be carefully compared with spectra of known preparations of the single enzymes, which must be recorded on the same instrument, because variations in dispersion and slit width may to some extent affect the shape of the bands. Good preparations of riboflavin, DPN and ADH are commercially available. Preparations of peroxydase and cytochrome c have been kindly afforded by Professor Keilin and Dr. Hill in Cambridge. Professor Kiese in Marburg kindly sent a preparation of cytochrome oxidase and recommended a method for the preparation of cytochrome b from beef heart. The spectrum of this preparation was carefully compared with the spectrum of the same cyto-

Fig. 3. About 30 % of cytochrome b remains reduced in aerated water or malonate, together with a few percent reduced cytochrome c. A slight curvature at 554 mμ in antimycin A marks the partial reduction of cytochrome* c_1.

chrome appearing after treatment of yeast with antimycin A. It was shown that the shape of the γ- and α-bands of reduced cytochrome b within *ca.* 5 % coincide with the shape of the corresponding bands of cytochrome c, but that oxidized cytochrome b, contrary to cytochrome c, shows low β- and α-bands, too, which are displaced a few mμ towards blue in comparison to the reduced bands (*cf.* Ref.[4]). This fact is able to complicate the *direct spectrum* (recorded with filter paper as reference substance; see Refs.[1,3]) the twobanded weak spectrum of which (in the region 520—570 mμ) is a combination between about 70 % oxidized and 30 % reduced cytochrome b, together with a few percent of reduced cytochrome c (see Fig. 3). A similar weak two-banded spectrum also appears in roots of higher plants as will be shown in a separate publication.

Cytochromes c_1 *and* b_2. These more recently studied enzymes are present in baker's yeast [4]. Cytochrome c_1 has its α-band at 554 and its γ-band at 422 mμ. Its concentration is about 50 % of that of cytochrome c. This cytochrome takes part in the normal aerobic respiration. Cytochrome b_2 has its α-band at 556 mμ and it is closely connected to an approximately equimolar quantity of FP [5,6]. This cytochrome does not participate in the aerobic respiration. Its reduced bands appear after treatment with lactate, primarily in the presence of nitrogen [4,6].

The procedure of corrections. Following the recording of the purified enzymes or coenzymes in intervals of 2 mμ the extinction values are conveniently

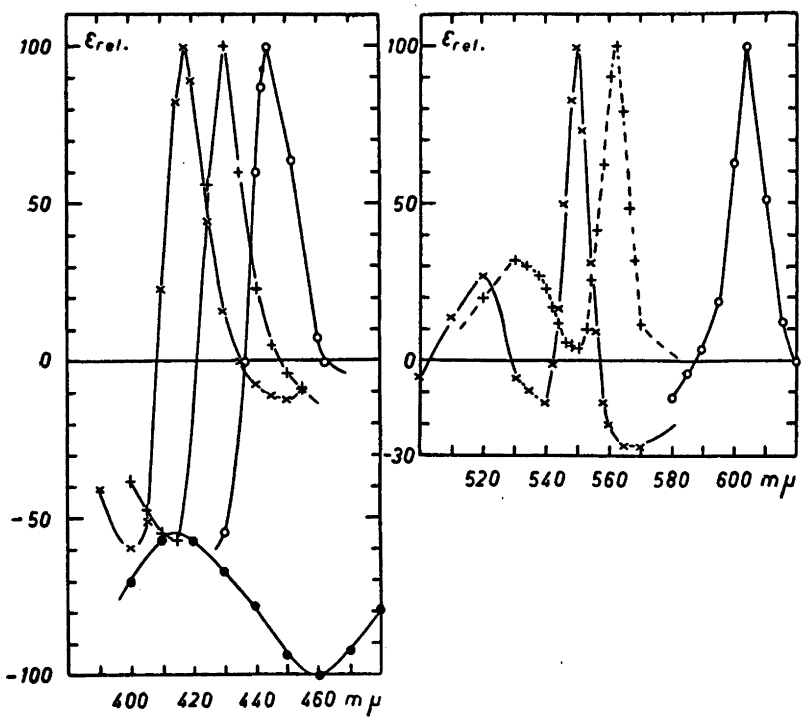

Fig. 4. Difference *curves of preparations of the cytochromes c, b and a* (a_3 + *a*), *and flavoprotein (riboflavin). The reference contains the oxidized and the sample the reduced enzyme. The extinction values are calculated for the purpose of optical analysis,* viz. *the top of the bands set at 100. See the text.*

calculated in percent of the main bands (see Fig. 4). Calculations on spectrograms of living objects ought to be made both from the *direct spectrum* (with strips of filter paper as reference substance [1,3,4]) and from the *difference spectrum* (*e. g.*, oxidized yeast as standard and O_2-free yeast as sample). The difference spectrum is extended on both sides of the zero abscissa which is traversed at the isosbestic points (Fig. 4). The difference spectrum is more convenient to handle and it ought to be mentioned that corrections of records of single band tops (see above) have to be made according to the figures of the difference spectrum (Figs. 5, 6).

Corrections for turbidity. This question has been treated in some detail in a previous communication [4]. The turbidity, *e. g.* of a suspension of yeast, generally lowers the apparent molar extinction of bands in blue and ultraviolet, whereas bands in green and red are far less influenced. The scattering of the light may be to some extent calculated [7], but the only accurate method is here direct determination of the depression of the bands of added pigments. Different objects may behave rather differently. In a suspension of 15 % yeast

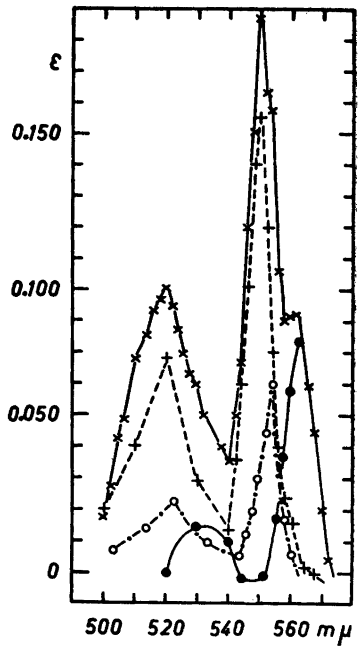

Fig. 5. Example of optical analysis of a spectrogram, according to the procedure mentioned in the text. ×———× *record of a 15 % yeast suspension aerated with nitrogen.* ●———● *spectrum of cytochrome b calculated from the difference 562—570 mμ.* +– – – – + *spectrum of cytochrome c calculated from the difference 550—546 mμ minus the value of* $\frac{1}{3}$ *b at these wave-lengths.* O·····O *spectrum of cytochrome* c_1 *calculated as the observed curve minus c minus b.*

the Soret bands are depressed about 33 % (factor 1.33). The same is true with regard to the band of FP at 450—460 mμ, whereas the values of the DPNH band at 340 mμ have to be corrected with the factor 2.3. Dilution to 5 % here lowers the correction to only 1.25.

Technique for studying rapid changes in the steady states. As shown in Fig. 3 a suspension of washed yeast in aqua dest. or 0.02 M phosphate (pH 6—7) is predominantly oxidized if aerated for some 30 minutes. According to frequent variations in the concentration of DPN the balance may be attained in less than one minute but may occasionally take several minutes. Because there is always a residual reduction of several enzymes, *e. g.* cytochrome b (Fig. 3), in aerated yeast, a fact reflecting the intensive aerobic respiration, observations of the kinetics of reduction have to start from this state as the bottom level. Addition of glucose or still more of ethanol of course moves the steady state far more to the reduced side [4].

Continuous recording of the involved enzymes now shows that reduction does not start immediately after the shifting over from air to nitrogen. As shown in Table 1 the time lag is directly influenced by the intensity of the previous aeration, *viz.* obviously by the quantity dissolved oxygen in the

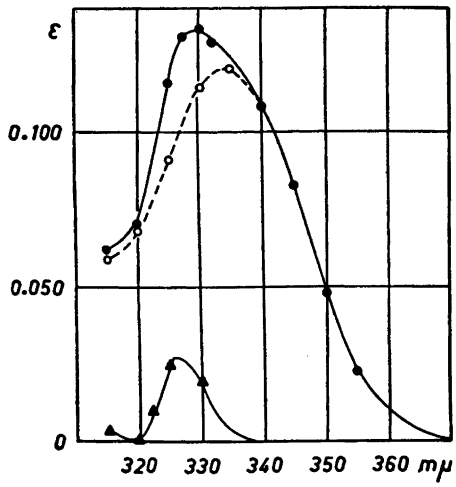

Fig. 6. Optical analysis of the spectrum of DPNH. 3 ml of the sample contained 0.1 mg DPN, 3 mg ADH (from a commercial preparation) and 0.05 ml alcohol. medium surrounding the cells. All experiments were performed in "circulation vessels", made of molten quartz and holding 18 ml (Fig. 7). According to the shape of the vessel the suspension is vigorously moved by the stream of air or nitrogen blown from the narrow tube near the bottom. No yeast is accordingly sedimented, a matter of importance for the maintaining of constant light absorption, and the gas exchange is exuberant.

As may be seen from the direct records in Fig. 2 the reduction of the enzymes, primarily those of highest oxidation potential, a + a_3 and c, starts abruptly and proceeds practically linearly, at least up to more than 50 % reduction. This sudden reduction after a comparatively long lag period supports the idea that oxygen forms an adsorption layer in close contact with

The addition of inhibitors etc. may be made through the smaller tube to the right.*

cytochrome oxidase, a layer operating as a buffer between the dissolved oxygen and the process of electron transfer. It may be tentatively assumed that the absorbed gas layer is carried by a hemoglobin-like pigment (*cf.* Ref.[8]), but it may otherwise be supposed that the apoenzyme of the oxidase adsorbs oxygen.

Preliminary experiments now showed that the lag phase of reduction remains constant within one second or less, if the two gases, air and nitrogen, are alternating in fixed intervals, provided that the gas stream is maintained at a constant value, and that the system has came to a balance. This observation together with the fact that the length of the lag phase is not identically the same for all enzymes served as the basis of a method for determination of the apparent kinetics of a complex system. The experimental outfit is shown in Fig. 7. Air and nitrogen (99.9 %) are fed to the circulation vessel *via* two electrical valves which are operated by means of a relay and a clockwork. Both gas streams are adjusted to the same speed, amounting to about 250 ml in one minute, which gives an intense bubbling in the right side of the vessel. The gas escapes through a tube leading to a flask with a layer of water above the gas outflow. The clockwork was mostly set for periods amounting to 35 seconds for the air and 75 seconds for the nitrogen. In order to obtain a precise record of the start moments the relay is provided with a guide-contact marking a line on the record each time the lever of the relay shifts position.

Apparent velocity constants. Thermodynamical velocity constants cannot be calculated for living enzyme systems, mainly for two reasons: 1) the enzymes are not in true solution but with few exceptions (DPN and possibly cytochrome c) attached to structural moieties ("mitochondria"); each enzyme

is structurally linked to at least one, frequently two or more other enzymes, a situation creating difficulties in clearly distinguishing between individual kinetics and group kinetics. An approximate estimation of the reaction velocity may be calculated from the half-time *ht* (*cf.* Ref.[9]), *viz.* the time elapsing from the start to the point of 50 % increase or decrease of the reduction. The value *ht* is inversely related to the reaction velocity. The apparent velocity constant is calculated as $K_{app} = c/ht$, where c = the apparent molar concentration, *viz.* that fraction of the actually present enzyme which partakes in the reaction.

EXPERIMENTAL RESULTS

Start lag and reaction velocity of the respiratorical enzymes.

The experiments were conducted at 20° C with 15 % baker's yeast (from Svenska Jästfabriksaktiebolaget), washed twice and resuspended in double distilled water. Aeration during 1—2 hours before start.

Table 2. Start lags and apparent reaction velocity at alternating reduction and reoxidation (35 sec. air, 75 sec. N_2). c = μmole × lit.$^{-1}$ moist yeast. Time unit seconds.

The start lags of reduction of the group a_3 + a and c show that these enzymes are the first to be "saturated by electrons" when the supply of oxygen is cut off. The slightly schematical picture of the start field in Fig. 8 clearly shows the close connection between a_3 and c, whereas a while starting as rapidly as a_3 takes a quite deviating course of reduction. In its time course it is very similar to c_1. These two enzymes are leading over to group b — FP which enzymes are starting about synchronously with the final stage of reduction of the group a_3 and c. The probably close linkage between cytochrome b and flavoprotein has been emphasized in a recent communication [4]. The existence of a lag of six to seven seconds between the first response of the groups a — c and b — FP points to the presence of a "buffer system" between these two. A member of this intermediate system is probably cytochrome c_1 and possibly also cytochrome a. The situation is complicated by side-lines which are certainly branching off from some of the enzymes, if not all of them, side-lines which imply a display of energy. Studies in the cytochrome

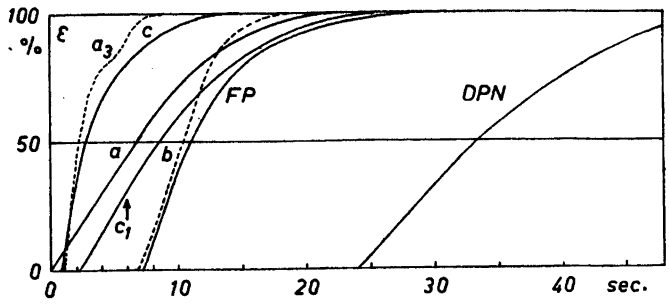

Fig. 8. Slightly schematical reproduction of the course of reduction of the respiratorical enzymes of yeast (cf. Table 6). The start lags are calculated from the moment when the reduction of cytochrome a begins. The first half-part of the reduction approximately follows a straight line, the course of the reduction above the 50 % line is somewhat more varying, but generally slightly curved. The exact position of 100 % reduction is difficult to ascertain.

system of wheat roots strongly support the assumption that the oxidation — reduction of cytochrome b is conducting synthesis of high energy phosphate. Such a coupling between processes giving off and taking up energy will, if they are reversible, act as a buffer system, too [12]. The scheme in Fig. 8, however, may possibly be significant of the pulsations of the stream of electrons, because it shows that the group b — FP does not start reduction until the group a_3 — c is nearly completely reduced, and DPN does not start reduction until the group b — FP is completely reduced. This "pulsation" of the total process cannot be taken as an argument for disruptures in the structural integrity of the total system. It is more likely to assume that it reflects a grouping of oxidation potential states. From this point of view the deviating course of the cytochromes a and c_1 is most interesting. — Certain minimum quantities of DPNH are of course present from the beginning, even in well aerated yeast, and act as a continuously working source of electrons feeding the group b — FP and so on. Electrons are fed to DPN by, among others, the alcohol and glyceraldehyde phosphate dehydrogenases. The proceeding of the reduction of ADH can be measured on the ADH · DPNH band at 323—325 mμ (Ref.[4], Fig. 6). Observations of the time course of the development of this band show that it starts considerably slower than the DPNH band, an observation alluding to the fact that a certain level of DPNH is needed before measurable quantities of the enzyme combination are formed.

Cytochromes a_3 and a. In their important work on the spectral characteristics of the cytochrome system Keilin and Hartree [13] concluded that in respect of cytochrome a "we are dealing here with two distinct but closely allied and intimately connected compounds a and a_3". There has been much discussion in the literature as to this point. One of the main difficulties is the fact that the quantitative relation $\lambda_{444}/\lambda_{604}$ remains constant irrespective of the path of reduction [10]. A fixed combination of two pigments in equimolar concentrations would, however, render a similar result. The present observation of a deviating time course of reduction and reoxidation of the two bands 444 and 604 undoubtedly corroborates the original conception of Keilin and Hartree.

The results clearly show that a_3 is the oxidase, because it reacts about four times as rapidly as a at reduction. Some peculiarities of a were emphasized above. Others are appearing under the influence of antimycin A, as will be shown below.

The actually reacting quantities. As already mentioned these are not necessarily identical with the total quantities. Previous measurements [4] pointed to equimolar total quantities of a, c and b. In the present experiments calculations of the activity of a only give *ca.* 50 % of the total quantity (see Table 3). Calculations from 444 mμ give higher values (see Table 4). Because no really pure preparation of $a + a_3$ is at hand all figures of molar concentrations are somewhat uncertain. The results, however, support the conclusion that under the conditions of the experiments the actually reacting quantities of a_3 and a are not always the same, even if the total amounts may be alike. Regarding the group b and FP the results corroborate the authors previous calculations. Experiments with N_2, lactate, and antimycin A showed [4] that cytochrome b is most probably connected to an equimolar quantity of flavoprotein. A similar close connection has actually been shown to exist [5,6] regarding cytochrome b_2. The fact that the actually reacting quantity of flavoprotein is twice as large as that of b, even if b_2 does not partake in the balance (see above), points to the existence of still another fraction of FP, which participates in the respiratorical chain but is not intimately linked to b. The following experiments with antimycin A will further elucidate this question. The high concentration of DPN in yeast is a well known fact. The experiments show that the total reacting quantity is 50—100 times as large as that of the single cytochromes and that nearly 50 % of DPNH is within 1—2 minutes bound to the alcohol dehydrogenase.

The response to antimycin A. Antimycin is claimed [11] to inhibit the transfer of electrons from cytochrome b to cytochrome c. If this antibioticum is added in increasing quantities to 18 ml of an 15 % yeast suspension (containing 2.7 g yeast) a visible reduction of cytochrome b starts at *ca.* 1 μg and an optimum

is attained at *ca.* 2.4 μg antimycin A. Larger quantities do not change the spectroscopic picture. It could, however, be shown that the initial effect of antimycin A is not exclusively confined to cytochrome b. Also cytochrome c is affected in the start period, and cytochrome c_1, too (Table 4). This intermediate reduction of cytochrome c reflects the comparatively slowly proceeding combination of antimycin A with cytochrome b, as can be observed by continued recording of the band 563 mμ. The proportions between quantities of antimycin A needed for optimal effect on b, and the enzyme itself, are about equimolar. The reaction takes at least a couple of minutes. It could furthermore be shown that the reaction stops at *ca.* 80 %, the rest may then be reduced in nitrogen. The residual quantity of noninhibited cytochrome b is possibly responsible for the residual aerobic respiration of about 5—10 %, frequently observed after treatment with antimycin A, but this observation may be explained otherwise, too (see below). The effect of antimycin is reversible. It may be abolished by treatment with some dithionite followed by aeration.

Change of activities after treatment with antimycin A. The deepgoing effects af antimycin A are illustrated in Tables 5 and 6, computed from experiments with alternating reduction and reoxidation. If attention is first paid to the

actually reacting quantities (Table 5) these are remaining practically constant as far as a and c are concerned whereas the activity of b is practically completely abolished (not shown in the table) and that of cytochrome c_1, FP and DPN reduced to 50 %. The apparent rise of the activity of a_3 may be caused either by a more far going activation of the oxidized state under the influence of the lessened effect of the dehydrogenases, or simply by some interfering effect which is still obscure. The first explanation is, however, good enough. The observed 50 % reduction of the reacting quantities of FP strongly support the idea of a close molar linkage between cytochrome b and this pigment. The other half quantity of flavoprotein is obviously cooperating with the rest of the cytochrome system probably *via* the remaining quantities of cytochrome c_1. The fact that the reacting quantity of DPN is reduced to about the same percentage as FP is difficult to understand unless we assume the existence of two different enzymes performing the transference of electrons from DPNH to FP. One of these enzymes will only react with that fraction of total flavo-

protein which is directly linked to cytochrome b. After blocking the b — FP moiety a corresponding quantity of DPN is put out of circulation.

The strongly reduced oxygen consumption (about 5—10 % of the normal) in yeast which has been treated with antimycin A is illustrated by the increase in the start lag of reduction from about 40 to about 150 seconds (Table 6). The retardation of the velocity of reduction ($K_{app\ red}$) of the cytochromes a_3 and c amounts to about 1/3 and is a consequence of the drop in DPN activity, *viz.* in the intensity of the stream of electrons, at preserved activity of the oxidase. Inversely a slower working mechanism of reduction raises the speed of reoxidation (from 1 to 3). It is significant that these reciprocal relations between K_{app} before and after the addition of antimycin A are less exaggerated with regard to flavoprotein, because the velocities are here calculated on the basis of 50 % lower activity. The residual quantity of FP must then, of course, speed up its $K_{app\ ox}$ in relation to the oxidase. We are in Table 6 again meeting the deviating response of cytochrome a, as compared with a_3 and c. Its activity is seemingly only little affected by the sharp drop in the activity of reduction of DPN. Because it is not hampered with regard to active concentration one must conclude that it is involved in some oxidation-reduction balance outside of the scope of DPN and FP, perhaps in relation to high energy phosphate. This point needs further experimental elucidation.

Alternate pathways of electron transfer. Even if antimycin A is not inactivating cytochrome b to fully 100 % it could be calculated that under the conditions quoted in Table 6 the state of oxidation and reduction of this enzyme is not visibly altered. Reduction only causes a negative response at 562 mμ

(*cf.* Fig. 2) the magnitude of which is quite in accord with the calculated depression of the extinction curves of c and c_1 at this wave-length (see Fig. 4). It must consequently be concluded that the electrons largely bypass the inhibited cytochrome b and from the residual FP go to cytochrome c, probably *via* c_1, the behaviour of which in some way resembles that of b. This would be an alternate pathway of electron transference from DPN to a_3 and oxygen. But this way offers a poor substitute for the main line through cytochrome b which normally transmits 80—95 % of the electrons conducting aerobic respiration. The sharp drop in effectivity is nevertheless surprising, because a reduction of DPN and FP to half activity would only cause a retardation of $\frac{1}{2}$. The real depression, however, approximates $(\frac{1}{2})^3$ or even $(\frac{1}{2})^4$. For explanation two possibilities present themselves. It may either be assumed that the cytochrome b, in spite of the spell under which it is held by antimycin A, still maintains a strongly reduced activity, or it may be assumed that the alternate pathway from FP to c_1 and c is far less convenient (perhaps for structural reasons) as a track for electrons. In view of what was said above of the obvious outruling of cytochrome b and of the fact that its partner, *viz.* the halfpart of the total flavoprotein, is inactivated too, the odds are obviously more in favour of the second scheme of explanation.

The investigation has been aided by a grant from *Statens Naturvetenskapliga Forskningsråd.*

Isolation of N-[D-2,3-Dihydroxy-*n*-propyl]-taurine from *Gigartina leptorhynchos*

BÖRJE WICKBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

In an investigation of the red alga *Gigartina leptorhynchos* a new internal salt was isolated. This was shown to be N-[D-2,3-dihydroxy-*n*-propyl]-taurine, for which the shorter name D-glyceryltaurine is suggested. Taurine, floridoside, glycerol and small amounts of *meso*-inositol, mytilitol and laminitol were also found.

In previous communications from this institute investigations on the occurrence of internal salts [1] and of low-molecular weight carbohydrates [2] in various algae have been reported. The present paper records the investigation of the red alga *Gigartina leptorhynchos*, *Florideae*, order *Gigartinales*, from which a new internal salt, shown to be N-[D-2,3-dihydroxy-*n*-propyl]-taurine or shortly, D-glyceryltaurine, was isolated. In addition taurine, floridoside, glycerol and small amounts of the cyclitols *meso*-inositol, laminitol and mytilitol were found.

Floridoside is a common constituent of algae belonging to *Florideae* while taurine and its N-methyl derivatives [1] are frequently met with throughout the red algae. The amounts of cyclitols found, being of the order 0.001 %, are so small that these substances could possibly derive from impurities in the material investigated.

The new internal salt was optically active $[\alpha]_D^{23}$ −21° (water) and had a much lower melting point (163.5—164.5°) than taurine and its N-methyl derivatives which all melt in the range 240—340°. On a carbon column the new compound travels at about the rate of a hexitol which is much slower than the rate observed for the other taurines. When paper chromatograms were run in ethyl acetate-acetic acid-water (3:1:1) the R_F-value of the substance was some 10 % higher than for taurine. On the chromatogram the substance could be detected with the silver nitrate-sodium ethoxide reagent and with ninhydrin. With the latter reagent rather strong heating was required and the colour produced was fainter than that observed with taurine, a behaviour which is similar to that of N-methyl taurine. The crude compound could be freed from

carbohydrates by adsorption on Amberlite resin IR 400 in the OH-state and subsequent elution with dilute acetic acid.

Analysis was in fair agreement with the composition $C_5H_{13}O_5NS$, and no solvent of crystallisation was detected. The substance was unaffected by hydrolysis in 2 N HCl for 15 h at 120°. Periodate oxidations indicated a consumption of 2 moles of oxidant with the formation of 2 moles of formaldehyde. From the oxidized material pure taurine was isolated. According to these facts the compound should have structure I. This conclusion was confirmed by the synthesis of D-glyceryl-taurine by reductive coupling of *iso*-propylidene-D-glyceric aldehyde with taurine and subsequent hydrolysis of the *iso*propylidene derivative obtained. The optical rotation, melting point and chromatographic behaviour were the same for the synthetic product as for the substance obtained from the alga, and the mixed melting point for the two preparations showed no depression. The internal salt from the alga thus possesses the D-form of structure I.

EXPERIMENTAL

The alga (320 g) was extracted with ether for 2 days and with methanol for 14 days. The methanol extract was concentrated to a syrup which was stirred with water, the mixture was filtered and the filtrate de-ionised with Amberlite IR 120 and IR 4B and concentrated to dryness. The residue (5.5 g) was dissolved in water (100 ml) and the solution added to the top of a carbon-Celite column (35 × 4.5 cm). The column was eluted with water (2 000 ml) and then with aqueous ethanol (4 000 ml) the concentration of which was linearly raised from 0 to 30 %. The eluate was fractionated and investigated by paper chromatography using as solvent ethyl acetate-acetic acid-water. The main fractions were de-ionised as before and concentrated to dryness.

Fraction No. 1 (200 mg) contained only one component and this was ninhydrin-positive. After recrystallisation from aqueous ethanol taurine (150 mg) was obtained, m. p. 320—8° * alone or admixed with an authentic sample.

Fraction No. 2 (112 mg) contained two components with the same R_F-values as *meso*-inositol and glycerol. Separation on Whatman filter paper No. 3 MM yielded *meso*-inositol (15 mg) which after recrystallisation had m. p. 222—225°, alone or admixed with authentic material. The glycerol fraction (90 mg) was benzoylated by the Schotten-Bauman procedure, yielding a benzoate (110 mg) which melted at 74—75° and gave no melting point depression with authentic glycerol tribenzoate.

Fraction No. 3 (30 mg) gave one reducing spot. Recrystallisation and acetylation yielded an acetate which crystallised in needles melting at 170—172° with simultaneous transformation into rhombic crystals melting at 184—186°. The melting points were undepressed on admixture with mytilitol hexa-acetate.

Fraction No. 4 gave a spot indistinguishable from that of laminitol. Recrystallisation yielded a substance (15 mg) a sample of which was acetylated yielding an acetate, m. p. 155—157° alone or admixed with an authentic sample of laminitol hexa-acetate.

Fraction No. 5 (580 mg) contained a substance which gave one strong spot with the silver nitrate and the ninhydrin reagents. It was adsorbed on the Amberlite resin IR 400 in OH-form and subsequently eluted with 5 % aqueous acetic acid. The crude crystalline material so obtained (420 mg) melted when heated under aqueous ethanol and was recrystallised by the careful addition of ethanol to its slightly warmed aqueous solution. M. p. 163.5—164.5°, $[\alpha]_D^{23}$ −21° (water, c = 2.0). (Found: C 30.4; H 6.68; N 6.64; S 14.7. Calc. for $C_5H_{13}O_5NS$: C 30.1; H 6.58; N 7.03; S 16.1.)

* All melting points are corrected.

Fraction No. 6 (2.3 g) contained a substance which was recrystallised from aqueous ethanol. M. p. 125—128°, $[\alpha]_D^{23}$ +152° (water, c = 2). These data and its chromatographic behaviour showed it to be floridoside.

Periodate oxidations of the internal salt from fraction 5. Periodate oxidations were carried out on a micro scale with an aqueous solution containing *ca.* 2 mg/ml of the internal salt from fraction 5.

a) *Periodate consumption.* To each sample (0.5 ml) 0.03 molar sodium metaperiodate solution (1 ml) was added. After varying times saturated sodium bicarbonate solution (1 ml), 0.1 N sodium arsenite (1 ml) and 20 % aqueous potassium iodide (0.2 ml) were added and after standing for 15 minutes the mixture was titrated with 0.02 N standard iodine solution. Within a few minutes the periodate consumed was 2.1 moles/mole substance and this value rose to 2.2 moles overnight.

b) *Formation of formaldehyde and taurine.* The sample (2 ml) was oxidized with sodium periodate and the formaldehyde formed was determined as its dimedone compound as described by Reeves [3]. The dimedone compound had m. p. 193—194°, alone or admixed with an authentic sample and the yield corresponded to the formation of 1.9 moles of formaldehyde per mole of internal salt.

The mother liquors from the dimedone precipitation were freed from excess dimedone by extraction with ether and from inorganic salts by passing the solution through Amberlite resins IR 120 and IR 4B. By evaporation of the de-ionised solution and subsequent recrystallisations from dilute methanol, pure taurine was obtained, m. p. 325—329°, alone or mixed with authentic material.

D-*Glyceryltaurine. Iso*propylidene-D-glyceric aldehyde was prepared from D-mannitol as described by Baer [4,5].

To a solution of freshly distilled *iso*propylidene-D-glyceric aldehyde (6.4 mmole, 0.83 g) and taurine (8 mmole, 1.0 g) in water (10 ml) colloidal platinum solution [6] (4 ml, 8 mg Pt) was added and the mixture shaken with hydrogen for 100 hours at room temperature and atmospheric pressure. The hydrogen uptake was 7.9 mmole. This high value may have been due to the reduction of liberated acetone, as the hydrogenated mixture was found to be slightly acid afterwards.

After hydrogenation the mixture was heated for a short while with a minute amount of hydrochloric acid to remove *iso*propylidene groups, filtered through a small amount of carbon-Celite and the filtrate concentrated and added to the top of a carbon-Celite column (170 ml carbon-Celite 1:1). The column was subjected to gradient elution (2 000 ml, 0—30 % ethanol); the appropriate fractions of the eluate were concentrated to dryness and the residue (0.9 g) was after treatment with Amberlite resins IR 120 and IR 4B recrystallised from dilute ethanol yielding a product (0.67 g, 53 % calc. on *iso*propylidene-D-glyceric aldehyde) which proved to be identical with the internal salt isolated from the alga. M. p. 163—164.5° alone or mixed with the natural product, $[\alpha]_D^{23}$ −19° (water, c = 2), CH_2O formed upon periodate oxidation: 2 moles/mole comp.

*iso*Thiocyanates XIX.* L(-)-5-Methylsulphinylpentyl *iso*Thiocyanate, the Aglucone of a New Naturally Occurring Glucoside (Glucoalyssin)

ANDERS KJÆR and ROLF GMELIN

The Chemical Laboratory of the University of Copenhagen, Denmark

The isolation of L(−)-5-methylsulphinylpentyl *iso*thiocyanate (VII) from seeds of the crucifer *Alyssum argenteum* Vitm. is described. The mustard oil is liberated from its glucosidic precursor, *glucoalyssin*, on enzymic hydrolysis and characterized as its thiourea derivatives, formed upon reaction with ammonia, aniline and benzylamine. The derivative with the last amine, (I), serves to prove the structure of (VII) by transformation into compounds of established structure. The aniline derivative (IX) is compared with a synthetic sample prepared elsewhere.

The mustard oil of glucoiberin is unambiguously proved to be L(−)-3-methylsulphinylpropyl *iso*thiocyanate (XIII). The configurational relationship of the latter, as well as (VII), with (−)-sulphorophene is pointed out. The natural occurrence of sulphoxides is reviewed.

A paperchromatographic survey of the *iso*thiocyanate glucosides in 12 species of *Alyssum* is presented. They appear to contain glucoalyssin, gluconapin, the glucoside of 4-pentenyl *iso*thiocyanate (glucobrassicanapin) and glucoberteroin in various combinations, together with one or two glucosides containing yet undetermined *iso*thiocyanates.

In a previous paper of this series[1] 5-methylthiopentyl *iso*thiocyanate (V) was proved to be the aglucone of a glucoside (glucoberteroin) *ex* the crucifer *Berteroa incana* (L.) DC. Strong, though admittedly inconclusive evidence further suggested that a second glucoside in the same species was derivable from one of the corresponding stereoisomeric sulphoxides. This surmise has now been put beyond dispute, through the isolation and characterization of L(−)-5-methylsulphinylpentyl *iso*thiocyanate (VII), present in various

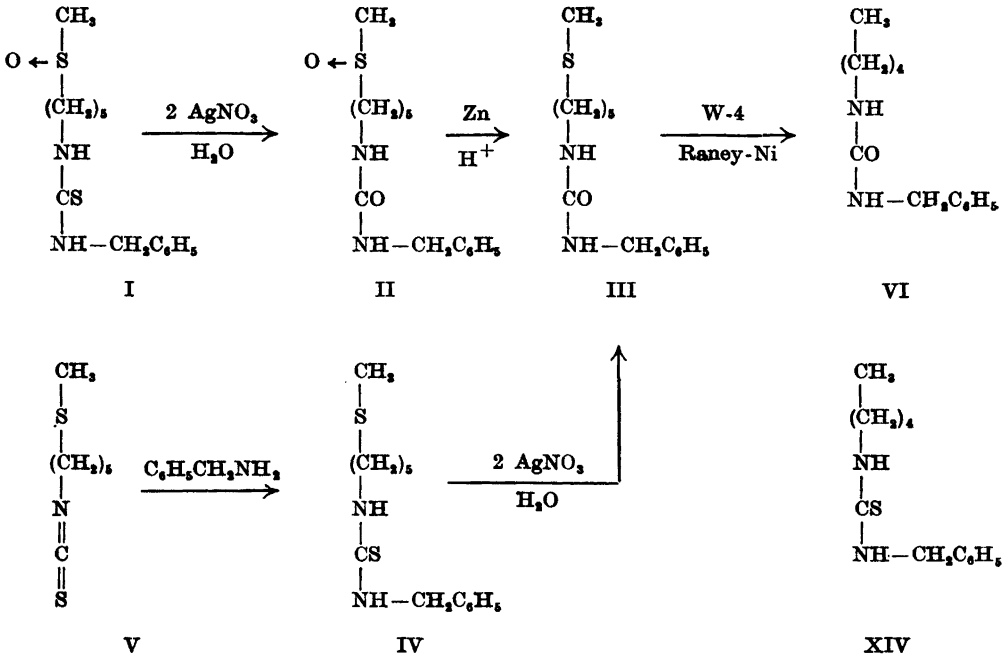
* Part XVIII of this series: *Acta Chem. Scand.* **10** (1956) 335.

species of the genus *Alyssum* as a glucoside for which the name *glucoalyssin* is proposed *.

Due to insufficient supplies of *Berteroa*, the species *Alyssum argenteum* Vitm.** was selected as a starting material for the isolation of the new *iso*thiocyanate (VII). Paperchromatographic evidence indicated that glucoalyssin is present in *B. incana* as well, the two genera being closely allied with regard to taxonomy ***. *Alyssum* species have been only incidentally quoted as sources of *iso*thiocyanates. Thus, Schultz and Gmelin [2] from paperchromatographic survey work considered sinigrin, glucocochlearin and sinalbin to be present in various species of this genus, in addition to two or three other, less certainly identified or unknown glucosides. In this laboratory, various *Alyssum* species have been subjected to glucoside chromatography by essentially the same method, yet with different conclusions as discussed below.

Glucoalyssin occurs in most *Alyssum* species investigated here (Table 2). In *A. argenteum* Vitm. the glucoside is accompanied by only a trace of glucoberteroin, a fact facilitating the purification considerably; no attempts were made, however, to isolate the glucoside in pure condition. A methanolic extract, partly purified by precipitation of impurities with lead acetate, was subjected to enzymic hydrolysis and the sulphide-*iso*thiocyanate selectively removed by ether extraction. The sulphoxide-mustard oil (alyssin) was then extracted with chloroform and obtained as a colourless, vesicant, *levo*rotatory oil which was used directly for the preparation of solid derivatives. Its rotation value was comparable to those determined by Karrer *et al.* for other sulphoxide-*iso*thiocyanates (Table 1). On reaction with ammonia, benzylamine and aniline, alyssin afforded the corresponding thioureas in good yields. The analytical data left no doubt as to the composition, $C_7H_{13}NOS_2$, for the parent mustard oil. Infra-red spectra strongly indicated the presence of a sulphoxide-grouping in the *iso*thiocyanate, the structure of which was definitely proved through the following series of reactions, starting with the *levo*rotatory benzylthiourea-derivative **** (I).

This compound was transformed into the corresponding benzylurea (II) by a modification of the method of Dixon [5], the reaction probably pro-

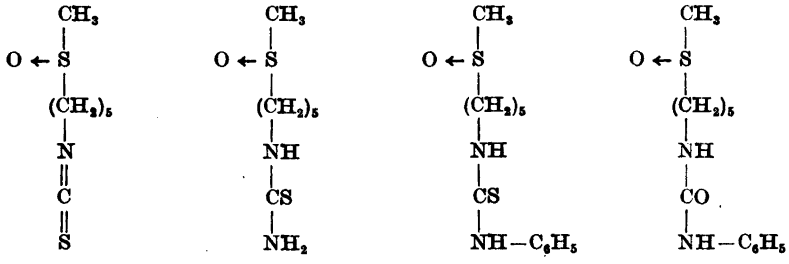


---

* *Note added in proof:* In a recent paper, submitted to publication a few weeks later than the present communication, Schultz and Wagner [27] describe the isolation from seeds of a species named *Alyssum argenteum* Allioni (*cf.* Table 2) of a crystalline tetraacetate of a glucoside, almost certainly identical with and fortuitously named as our glucoalyssin [28]. The formulation of the corresponding mustard oil as 5-methylsulphinylpentyl *iso*thiocyanate, a structure foreshadowed in a previous paper from this laboratory [1], rests solely on analysis of the acetylated glucoside, infra-red data and analogy to previously recognized *iso*thiocyanates of this type. A non-analyzed preparation of the corresponding thiourea, m. p. 112°, is further reported, yet without optical rotation data.

** The generous gift of a substantial seed sample from E. Benary, Hann.-Münden, Germany, is gratefully acknowledged.

*** *Berteroa incana* DC. was originally described by Linné (1753) as *Alyssum incanum*.



**** For reasons to be discussed in the sequel, (I) is considered to be configurationally related to *levo*-rotatory sulphoraphene, previously proposed by Schmid and Karrer [3] as a configurational reference standard for sulphoxides and arbitrarily allotted the designation L. In this paper, the substances are depicted in conformity with the convention of Karrer *et al.*[4] according to which the oxygen atom is written to the left in the projection formulae of members of the L-series, arranged with the methyl groups at the top.

V IV XIV

ceeding *via* a carbodiimide. Reduction of (II) with zinc dust in acid solution resulted in loss of optical activity, a fact pointing to the sulphoxide-grouping as the sole centre of asymmetry. The identity of the reduced product as 1-benzyl-3-(5′-methylthiopentyl)-urea (III) was established on comparison with an authentic specimen, prepared from the corresponding thiourea (IV) which was, in turn, produced from synthetic 5-methylthiopentyl *iso*thiocyanate [1] (V) and benzylamine. Ultra-violet and infra-red spectra, as well as mixed melting point determination, served as criteria of identity of the two preparations. A specimen of the heretofore unknown 1-benzyl-3-pentylurea (VI), needed in another connection, was produced by hydrogenolysis of (III) with W-4 Raney nickel and also by sulphur exchange of the corresponding thiourea (XIV).

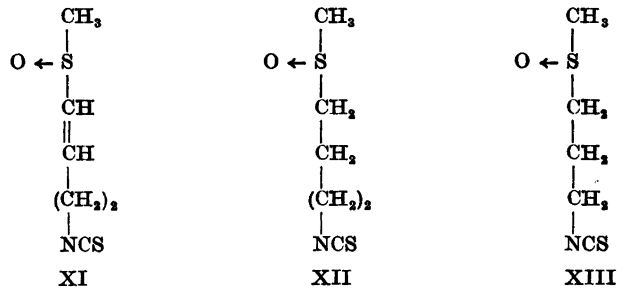
[a] *cf.* Foot-note p. 1104. [b] *cf.* Foot-note. [c] Non-analyzed specimen. [d] It has been established in this laboratory that the compound possessing the reported data does not represent authentic sulphoraphene-thiourea. [e] *cf.* Foot-note p. 1101.

The crystalline thiourea-derivatives, (VIII) and (IX), prepared by reaction of alyssin with ammonia and aniline, respectively, possessed properties comparable to those of the above benzyl-derivative. (—)-1-Phenyl-3-(5′-methylsulphinylpentyl)-thiourea (IX), with a specific rotation of —11°, was previously reported by Karrer *et al.*[6] as a reaction product of synthetic (+)-5-methylsulphinylpentyl *iso*thiocyanate (spec. rotat. +4°) and aniline. The corresponding antipodes were reported with the specific rotation values +19°* and —9° for the phenylthiourea and *iso*thiocyanate, respectively.



These values differ considerably from those determined in this laboratory for the natural mustard oil (VII) and its derivative (IX) (*cf.* Table 1) and raised doubt as to the stereochemical homogeneity of the formerly described preparations. We are indebted to Professor Karrer for a specimen of the original preparation of the (—)-phenylthiourea which, despite its deviating rotation value, showed hardly any depression of the melting point on admixture with our natural derivative. Moreover, the infra-red spectra of the two specimens were identical save for a few minor details. We are inclined to believe that in-

* A recent redetermination of the specific rotation gave a small negative value (<9°) suggesting that the antipodes had originally been interchanged. In addition, however, a partial racemization must have taken place on storing as estimated from the small numerical value (private communication from Professor Karrer).

completely resolved products account for the numerically low values reported, a suggestion supported by the fact that the rotation data for the natural *iso*thiocyanate and its derivatives are of the same order of magnitude as those found in analogous series (Table 1). In order to extend the number of compounds for comparison purposes, the sulphoxide-phenylthiourea (IX) was also transformed into the corresponding phenylurea-derivative (X).

The first sulphoxide-mustard oil recognized in nature was the *levo*rotatory sulphoraphene (XI), isolated by Schmid and Karrer [7] from seeds of *Raphanus sativus* L. var. *alba* and representing the first natural product in which optical activity was attributable solely to a sulphoxide-grouping. Therefore, (—)-sulphoraphene was proposed [3] as a configurational L-standard for sulphoxides *. The synthetic (—)-dihydroderivative (XII) has been directly related with (—)-sulphoraphene [3] and is consequently to be designated L-sulphoraphane. Comparable rotation values for (—)-3-methylsulphinylpropyl *iso*thiocyanate (XIII), as well as its derivatives afford strong evidence of the relationship also of the latter to the L-series [6]. Schultz and Gmelin [8] suggested the *iso*thiocyanate (XIII) (iberin) as the aglucone of the crystalline glucoside glucoiberin which they isolated from seeds of *Iberis amara* L. They did not succeed in isolating pure iberin and no crystalline derivatives were obtained. The proposed structure (XIII) was based mainly on the composition of the glucoside, infra-red spectra and structural analogy to the long known cheirolin (3-methylsulphonylpropyl *iso*thiocyanate) and sulphoraphene. In order to prove the structure and configurational relationship of iberin we have prepared its crystalline phenylthiourea- and benzylthiourea-derivatives. The former was compared with an authentic, synthetic specimen, generously supplied by Professor Karrer. The natural derivative had the specific rotation —54°, comparable to the reported value [6] (—43.6°) of the synthetic specimen **. Except for this minor deviation in optical rotation, the two products proved to be identical with regard to mixed melting point and infra-red spectra. It is thus established that iberin possesses the structure (XIII) and belongs, as well as alyssin (VII), to the same configurational series as (—)-sulphoraphene. Both are consequently to be designated as L-compounds.

Alyssin (VII) represents a novel addition to the steadily increasing group of naturally occurring sulphoxides. At present it comprises, besides sulpho-

* *Cf.* note added in proof p. 1109.

** A recent redetermination in Professor Karrer's laboratory gave $[\alpha]_D^{22.5}$ —45.4° (*c* 1.76, ethanol) (private communication).

raphene, iberin and alyssin, the active principle of garlic, alliin, which was shown by Stoll and Seebeck [9] to be (+)-S-allyl-L-cysteine sulphoxide; further, the corresponding (+)-S-methyl-L-cysteine sulphoxide, recently recognized as a constituent of cabbage juice [10] and turnip roots [11] by two groups of workers. (+)-Biotin sulphoxide has been isolated from milk residues [12] and the diastereoisomeric (−)-sulphoxide from cultures of *Aspergillus niger* [13]. Again, the so-called β-lipoic acid, isolated from liver residues, has been demonstrated to be a sulphoxide [14].

The recent recognition of so many sulphoxides in nature raises the question as to what extent these compounds shall be regarded as artefacts, formed as a result of secondary oxidation *in vitro*, or rather as species of individual metabolic significance. Although convincing evidence is lacking, various observations point to an independent biochemical role of the sulphoxides.

In Table 2 are summarized the results of paperchromatographic studies of the *iso*thiocyanate glucosides in seeds of several species of the genus *Alyssum*, collected from various botanical gardens *. In every case, paper chromatography of the glucosides in two solvent systems [2], combined with paper chromatography of the thioureas of the corresponding *iso*thiocyanates in several systems (see Experimental), served to make the assignments as correct as possible by this type of approach. Except for two, all species investigated so far contain glucoalyssin ** (A), often in combination with glucoberteroin (D) from which it is probably biogenetically derived by enzymic oxidation. In several species gluconapin (B), a name introduced by Ter Meulen [15], is proved to be present. The *iso*thiocyanate of gluconapin was previously identified as 3-butenyl *iso*thiocyanate in this laboratory [16] and, independently, by Ettlinger and Hodgkins [17], both groups using seed of rape (*Brassica napus* L.) as a starting material. From unpublished survey work, it appears that this mustard oil is one of rather wide distribution. On the paper chromatograms a glucoside (C) was often detectable possessing an R_F-value slightly lower than that of glucoberteroin. The corresponding *iso*thiocyanate is volatile and the glucoside only difficultly distinguishable from glucoerucin, the glucoside containing

* The seed samples have been sowed in the Botanical Garden of the University of Copenhagen with the purpose of controlling their identities. Possible corrections will appear at a later date.

** *Note added in proof:* The formation of glucose and sulphate subsequent to enzymic hydrolysis of glucoalyssin has been established in the present work. This fact, supplemented with the remarkable demonstration by Ettlinger and Lundeen [30] of a revised structural expression for the mustard oil glucosides, lends support to the following formula for glucoalyssin:

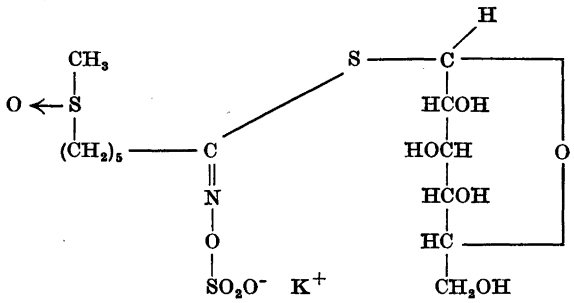


Table 2. iso*Thiocyanate glucoside pattern of seeds of various species of the genus* Alyssum *as determined by paper chromatography.*

A. alyssoides (L.) L.[a,d]				

A: Glucoalyssin. B: Gluconapin. C: Glucobrassicanapin. D: Glucoberteroin. (+): Traces only. [a] Contains an additional, not yet identified glucoside. [b] Probably identical with the species, less correctly designated as "*A. arg. Allioni*"[20] (=*Lunaria argentea* All.). [c] identical with *Lobularia maritima* Desv. (and *A. Benthamii*[20]). [d] identical with *A. calycinum* L.[20].

4-methylthiobutyl *iso*thiocyanate which we have previously identified in other species [18]. Paper chromatograms of the thiourea corresponding to (C) in special solvent systems, with synthetic 4-pentenylthiourea as a reference substance, leave little doubt, however, that (C) represents a new glucoside containing 4-pentenyl *iso*thiocyanate as the aglucone (glucobrassicanapin). Further evidence of its identity is available in this laboratory and will be presented in a forthcoming communication. It is interesting to note that 4-pentenyl *iso*thiocyanate fits well into the series of allyl and 3-butenyl mustard oil and the formally similar 3-methylthiopropyl [19], 4-methylthiobutyl [18] and 5-methylthiopentyl [1] *iso*thiocyanates. Two additional glucosides are recognized in the *Alyssum* series, the *iso*thiocyanates of which are being further studied.

After this work had been concluded, a paper by Schultz and Wagner [20] appeared, presenting paperchromatographic data for the glucosides of a long series of various plants, including 6 *Alyssum* species, 5 of which are identical with species investigated here. No allocations to specified glucosides are given, but it seems likely that the R_B-values 0.45 and 0.41 in *n*-butanol: acetic acid:water (4:1:3) and *n*-butanol:pyridine:water (6:4:3), respectively, represent glucoalyssin, the values 0.79—0.80 and 0.87—0.95, respectively, gluconapin, 1.06—1.07 (BuOH:HAc:H_2O) the 4-pentenyl *iso*thiocyanate glucoside and 1.16—1.17 (same system) glucoberteroin. Two additional glucosides are listed, one of which, at least, may be identical with one of the still unidentified types observed here (*cf.* Table 2).

The possible significance of the *iso*thiocyanate pattern of the genus *Alyssum* for taxonomical and genetic problems will be discussed in a forthcoming paper.

EXPERIMENTAL

The melting points are uncorrected and determined in capillary tubes in a slowly heated bath. All samples were dried over calcium chloride at room temperature before analysis.

Isolation of (−)-5-methylsulphinylpentyl isothiocyanate (VII). Finely ground seed (200 g) of *Alyssum argenteum* Vitm. was exhaustively extracted with hot 70 % methanol. The filtered extract was freed of methanol by evaporation *in vacuo* to a volume of about 500 ml. Impurities were precipitated by adding excess lead acetate as a 10 % solution. After filtration and removal of excess lead ions as PbS, the filtered solution was again concentrated to *ca.* 500 ml. Solid phosphates were added, in order to buffer the solution at pH 6.6, together with a myrosinase preparation (5 ml), and the mixture was set aside at room temperature for 18 hours. It was then extracted with two 50 ml portions of ether and the extract was discarded. Three extractions with 100 ml portions of chloroform removed all alyssin from the aqueous phase. The organic layer was washed twice with a sodium carbonate solution and finally with water. After drying, the solvent was removed in a vacuum, leaving (VII) as a colourless, vesicant oil (1.01 g) which was used directly for the preparation of the following derivatives. $[\alpha]_D^{24}$ −69° (*c* 4.06, $CHCl_3$).

L(−)-*5-Methylsulphinylpentylthiourea (VIII).* The mustard oil (500 mg) was dissolved in methanol, previously saturated with ammonia at 0°, and the solution kept at room temperature for 24 h in a stoppered flask. After removal of the solvent, a crystalline residue remained which was recrystallized from ethyl acetate, a slight, sticky residue being discarded. After two additional recrystallizations from the same solvent, the thiourea (281 mg) was obtained as colourless compact needles with m.p. 106.0−106.5° (*cf.* foot-note on p. 1101). $[\alpha]_D^{24}$ − 79.5° ± 1.5° (*c* 2.00, H_2O). The ultra-violet spectrum in ethanol was normal, displaying a maximum at 242 mμ (ε 14 200) and a minimum at 222 mμ (ε 3 870). (Found: C 40.28; H 7.60; N 13.29. Calc. for $C_7H_{16}N_2OS_2$: C 40.36; H 7.74; N 13.45).

The thiourea was chromatographed descendingly on Whatman paper No. 1 with the upper layer of the system *n*-butanol:ethanol:water (4:1:4) as the mobile phase, conditions which we previously found useful for certain thioureas [21]. Comparative runs with selected thioureas (Th.) gave the following R_F-values: iberin-Th. 0.44, cheirolin-Th. [22] 0.50, erysolin-Th.[23] 0.53, (VIII) 0.55 and N-methyl-Th. 0.60.

L(−)-*1-Benzyl-3-(5′-methylsulphinylpentyl)-thiourea* (I). From a solution of the mustard oil (VII) (500 mg) in chloroform, containing excess benzylamine, the benzylthiourea (I) crystallized spontaneously after about 5 minutes (616 mg). An analytical specimen was obtained as colourless rhombs after two recrystallizations from aqueous ethanol, m.p. 103.5−104.0°. $[\alpha]_D^{25}$ −58.6° ± 1.0° (*c* 1.20, 96 % ethanol). (Found: C 56.55; H 7.45; N 9.36. Calc. for $C_{14}H_{22}N_2OS_2$: C 56.34; H 7.43; N 9.39). The UV-spectrum in ethanol exhibited a maximum at 242 mμ (ε 14 050) and a minimum at 233 mμ (ε 12 120).

L(−)-*1-Benzyl-3-(5′-methylsulphinylpentyl)-urea (II).* The benzylthiourea (I) (200 mg) was dissolved in a mixture of ethanol (4 ml) and water (5 ml). A solution of silver nitrate (228 mg) in 50 % ethanol (6 ml) was added, resulting in the development of a yellow colour gradually changing to brown. The reaction mixture was heated on the steam bath for 0.5 h and kept neutral by gradual addition of a total of 2.6 ml of 0.5 N NaOH. After filtering through Celite, the solution was taken to dryness *in vacuo* and the benzylurea extracted with hot anhydrous ethanol which was again removed. The crystalline residue was recrystallized from ethyl acetate yielding clusters of small needles (120 mg). An analytical specimen was obtained after a new recrystallization from the same solvent, m.p. 105.5−106.5°. $[\alpha]_D^{24}$ −64.5° ± 1.0° (*c* 0.87, 96 % ethanol). (Found: C 59.30; H 7.51; N 9.63. Calc. for $C_{14}H_{22}N_2O_2S$: C 59.55; H 7.86; N 9.92). The UV-spectrum in EtOH displayed strong end-absorption and low benzyl-group absorption at *ca.* 250 mμ (ε *ca.* 200).

Reduction of (II) to 1-benzyl-3-(5′-methylthiopentyl)-urea (III). The sulphoxide-urea (II) (80 mg) was dissolved in glacial acetic acid (5 ml); this solution had the initial rotation −0.87°. Acid-activated zinc dust (50 mg) and two drops of conc. hydrochloric acid were added and the solution heated on the steam cone. After 4 h, the rotation had

decreased to $-0.07°$, and after standing at room temperature overnight, no optical activity was observable. On evaporation of the solvent and addition of water the reduced benzylurea crystallized (23 mg). Recrystallization from 50 % ethanol afforded the pure compound as rhombic plates, m.p. 86.5—87.5°, alone or in admixture with the synthetic preparation described below. The IR-spectra further served to establish the identity of the two specimens.

1-Benzyl-3-(5'-methylthiopentyl)-thiourea (*IV*). Previously prepared 5-methylthiopentyl *iso*thiocyanate [1] (V) (1.52 g) was gradually added to a solution of benzylamine (1.29 g) in ether (10 ml). Next day, the solvent was removed and the residue recrystallized from aqueous ethanol (1.98 g). An analytical specimen separated as colourless, rhombic plates from the same solvent, m.p. 56.0—57.0°. (Found: C 59.45; H 8.06; N 9.97. Calc. for $C_{14}H_{22}N_2S_2$: C 59.53; H 7.85; N 9.92).

1-Benzyl-3-(5'-methylthiopentyl)-urea (*III*). The benzylthiourea (IV) was transformed into the corresponding benzylurea (III), essentially as described above for the corresponding sulphoxide-derivative (yield 65 %). The reaction product separated from 50 % ethanol as colourless flat needles, m.p. 86.5—87.0°, undepressed on admixture with the specimen prepared above from the natural derivative. (Found: C 62.95; H 8.08; N 10.51. Calc. for $C_{14}H_{22}N_2OS$: C 63.11; H 8.33; N 10.52). The infra-red spectra of the two preparations were identical.

1-Benzyl-3-pentylurea (*VI*). Hydrogenolysis of the methylthio-urea (III) (266 mg) was performed by heating a stirred solution in anhydrous ethanol (30 ml) with a level teaspoon full of freshly prepared W-4 Raney nickel [24] for 2 h at 40°, followed by 2 h at 70°. After filtering, and removal of the solvent, the sulphur-free urea remained (181 mg). It separated from 50 % ethanol as thin platelets, m.p. 93.5—94.5°. (Found: C 70.80; H 9.37; N 12.65. Calc. for $C_{13}H_{20}N_2O$: C 70.88; H 9.15; N 12.72.) No depression was observed on admixture with a specimen produced by treatment of 1-benzyl-3-pentylthiourea with silver nitrate in the usual way.

1-Benzyl-3-pentylthiourea (XIV). A quantitative yield of this thiourea was obtained by reaction of benzyl *iso*thiocyanate with *n*-pentylamine. It separated as colourless, nacreous plates from aqueous ethanol, m. p. 53°. (Found: C 65.95; H 8.51; N 11.80. Calc. for $C_{13}H_{20}N_2S$: C 66.03; H 8.53; N 11.85).

Weller *et al.*[25] report the m. p. 62° for this compound, whereas the value 54° is listed for 1-benzyl-3-*iso*pentylthiourea. A specimen of the latter, prepared in this laboratory, melted at 62°, suggesting an accidental interchange of the two isomerides in the American laboratory. (Found: C 66.15; H 8.58; N 11.79. Calc.: *vide supra*).

L(−)-*1-Phenyl-3-(5'-methylsulphinylpentyl)-thiourea* (*IX*). A solution of the *iso*thiocyanate (VII) (1.00 g) and aniline (2 ml) in chloroform was kept at room temperature for 5 h. On addition of ether an oil separated which rapidly crystallized on scratching. The product separated from chloroform and petroleum ether as small needles (848 mg). An analytical sample was obtained as prisms from aqueous ethanol, m.p. 126.0—126.5° (previously recorded [6] 123°; a mixture melted at 125.0—125.5°). $[\alpha]_D^{25}$ $-61.6° \pm 2.5°$ (*c* 2.14, 96 % ethanol) (*cf.* Table 1). The UV-spectrum in ethanol exhibited a maximum at 247 mμ (ε 14 550), a minimum at 225 mμ (ε 9 000) and a plateau at 260—265 mμ (ε *ca.* 13 100). (Found: C 54.95; H 7.10; N 9.78. Calc. for $C_{13}H_{20}N_2OS_2$: C 54.89; H 7.09; N 9.85). The infra-red spectra of the natural and the synthetic derivative coincided except for a few, very small details.

L(−)-*1-Phenyl-3-(5'-methylsulphinylpentyl)-urea* (*X*). When the above phenylthiourea (IX) (285 mg) was treated with silver nitrate (340 mg) in the usual fashion, the corresponding phenylurea (X) was obtained (138 mg). The pure compound crystallized as thin, rhombic plates from ethyl acetate, m.p. 101.5—102.0°. $[\alpha]_D^{24}$ $-55° \pm 1°$ (*c* 0.76, 96 % ethanol). (Found: C 58.20; H 7.48; N 10.34. Calc. for $C_{13}H_{20}N_2O_2S$: C 58.17; H 7.51; N 10.44). (X) exhibited very intense absorption in the UV-region with maxima at 241 mμ (ε 24 100) and *ca.* 270 mμ (ε 1 700) and a minimum at 265 mμ (ε 1 360). These data are comparable to those reported for similar substances, *e.g.* 1-ethyl-3-phenylurea [25].

L(−)-*1-Benzyl-3-(3'-methylsulphinylpropyl)-thiourea.* A solution of glucoiberin [8] (1.00 g) was dissolved in water (200 ml), 1/15 M phosphate buffer solution of pH 6.6 (50 ml) and a myrosinase preparation (5 ml) were added, and the mixture set aside for 18 h at room temperature. The *iso*thiocyanate (iberin) was extracted with chloroform and the extract divided into two halves, one of which was treated with benzylamine in

the usual way to give a crystalline thiourea (151 mg). An analytical sample separated from ethyl acetate as stout, colourless prisms, m. p. 107.5—108.5. $[\alpha]_D^{24}$ −51° ± 1° (*c* 2.00, 96 % ethanol). (Found: C 53.75; H 6.40; N 10.27. Calc. for $C_{12}H_{16}N_2OS_2$: C 53.30; H 6.71; N 10.36).

L(−)-*1-Phenyl-3-(3'-methylsulphinylpropyl)-thiourea.* The other half of the above chloroform solution of iberin was allowed to react with aniline. The crystalline phenylthiourea (67 mg) separated from water in beautiful, colourless prisms, m.p. 137.0—137.5°. (A synthetic specimen prepared elsewhere [6] had m.p. 134.5—135.0° in the same bath, and a mixture of the two samples melted undepressed at 136.0—136.5°). $[\alpha]_D^{24.5}$ −54° ± 2° (*c* 1.90, 96% ethanol). (Found: C 51.40; H 6.42; N 10.99. Calc. for $C_{11}H_{16}N_2OS_2$: C 51.52; H 6.29; N 10.93). The infra-red spectra of the natural and the synthetic derivative were found to be identical.

Paper chromatography of Alyssum *species.* The seed samples were crushed in a mortar and extracted with hot methanol. Without further purification, these extracts were used for descending paper chromatography in the two solvent systems: (a) *n*-butanol: ethanol: water (4:1:4) and (b) pyridine:amyl alcohol:water (35:30:30), essentially by the method of Schultz and Gmelin [2].

Separate extracts were taken to dryness, dissolved in dilute phosphate buffer (pH 6.6) and hydrolyzed enzymically with myrosinase. The solutions were then extracted with chloroform and transformed into thioureas on treatment with ammonia at room temperature. The concentrated solutions were used for paper chromatography in water-saturated chloroform by our usual method [26], yet modified to the descending technique. Chromatograms in this system, run with suitable authentic reference samples, permitted the unambiguous identification of the thioureas of 3-butenyl and 5-methylthiopentyl *iso*thiocyanates. Also alyssin-thiourea could be clearly distinguished by comparison with an authentic specimen.

In some seed species (*cf.* Table 2) an additional glucoside spot, (C), with an R_F-value slightly lower than that of glucoberteroin, was observed. A corresponding spot appeared in the thiourea-chromatograms with an R_{Ph}-value [26] of *ca.* 0.95, intermediate between those given by benzylthiourea (0.92) and 4-methylthiobutylthiourea (0.99). It was indistinguishable, however, from a reference sample of 4-pentenylthiourea, the synthesis of which will be described in a forthcoming paper. This finding was confirmed in chromatograms, run with the upper layer of the system *n*-heptane:benzene-water (2:9:9) as the mobile phase. In this solvent, the R_F-values of benzyl- and 4-methylthiobutyl-thiourea are depressed to such an extent that they can be clearly differentiated from 4-pentenylthiourea. On the other hand, it is still possible to recognize the latter in the presence of 5-methylthiopentylthiourea. Other evidence (unpublished) is available for the natural occurrence of a glucoside of 4-pentenyl *iso*thiocyanate in nature.

Note added in proof: From a paper by Synge and Wood [10] it appears that an X-ray structural analysis of (+)-S-methyl-L-cysteine sulphoxide has been embarked upon elsewhere with the purpose of relating the sulphoxide configuration directly to that of the *a*-carbon atom, which is known, thus abolishing the need for an arbitrary sulphoxide reference compound.

Microanalyses were performed in this laboratory by Mr. P. Hansen. The technical assistance of Mrs. Dorthe Hansen (B.Sc.) is gratefully acknowledged. We are thankful to Dr. B. Hansen, the *Botanical Museum of the University of Copenhagen*, for botanical advice, and to the *Botanical Garden of the University of Copenhagen* for numerous seed samples.

The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation).*

Fungus Pigments

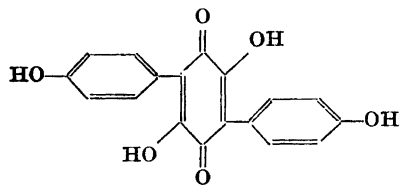
IV. * Aurantiacin, the Pigment of *Hydnum aurantiacum* Batsch

JARL GRIPENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

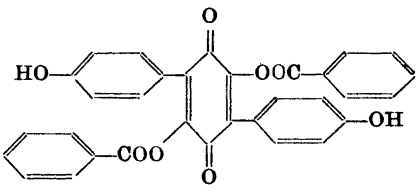
The fungus, *Hydnum aurantiacum* Batsch has yielded a red pigment, termed aurantiacin. It has been shown that aurantiacin is 2,5-bis(benzoyloxy)-3,6-bis(*p*-hydroxyphenyl)-1,4-benzoquinone, that is, a dibenzoate of the previously known fungus pigment atromentin.

Hydnum aurantiacum Batsch is a fungus growing on the ground, particularily in shady places in spruce forests. The foot of the sporophore is dark red-brown, whereas the cap is lighter in colour with darker streaks. The pigment can very readily be extracted with ether from the fresh material, and somewhat more slowly from the dried fungus. When the extraction is carried out in a Soxhlet apparatus, a red crystalline precipitate is formed in the extraction flask. This precipitate gives after purification, as described in the experimental part, aurantiacin as dark red, small needles, m.p. 285—295°. Aurantiacin gives a yellow acetate, m.p. 235—238° and a colourless leuco-acetate, m.p. 246—253°.



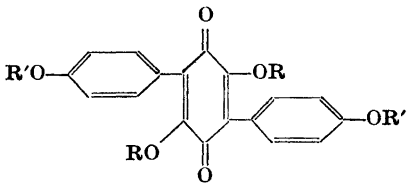
Analytical data indicated a composition $C_{32}H_{20}O_8$ for aurantiacin, $C_{36}H_{24}O_{10}$ for the acetate and $C_{40}H_{30}O_{12}$ for the leuco-acetate. The two derivatives are thus a diacetate and a dihydrotetra-acetate, respectively. Molecular weight determination gave somewhat high values, but this is not considered too important, because the low solubility of the substances necessitated working with relatively low concentrations, making the values obtained rather uncertain.

A clue to the structure of aurantiacin was obtained in an attempt to recover more of the pigment from the highly coloured ether extract. This was shaken first with sodium hydrogen carbonate and then with sodium carbonate solutions, which, however, extracted only minute amounts of material. With 2 N sodium hydroxide, on the other hand, all of the pigment could be removed from the ether solution giving a dark red-brown alkaline solution. When this was acidified and the colouring matter taken up in ether most of it could now



* Part III. *Acta Chem. Scand.* **6** (1952) 587.

be extracted with sodium hydrogen carbonate. Reprecipitation with acid gave a mixture which upon treatment with benzene was separated into two components. The benzene soluble component was identified as benzoic acid. The insoluble component formed upon recrystallisation dark brown leaflets, decomposing without melting at about 300°. This substance corresponds to the formula $C_{18}H_{12}O_6$ and gave a yellow tetra-acetate, $C_{26}H_{20}O_{10}$. This melts at 242—245°, but resolidifies and then melts at 290—294°. A colourless leuco-acetate, $C_{30}H_{26}O_{12}$, m.p. 235—240° was obtained upon reductive acetylation. The formation of these derivatives shows the presence of four hydroxyl groups and a quinone group in the compound $C_{18}H_{12}O_6$. The parent hydrocarbon is thus $C_{18}H_{14}$, which is the composition of terphenyl. Because several diphenylbenzoquinones have been found in fungi [1,2] the formulation of the compound $C_{18}H_{12}O_6$ as a tetrahydroxydiphenylbenzoquinone suggested itself. In fact the properties of this compound and its derivatives are in close agreement with those given by Kögl and Postowsky [3] for atromentin isolated from *Paxillus atrotomentosus* Batsch. The only serious difference is that Kögl and Postowsky report only a single m.p. 240—241° for atromentin tetra-acetate. Through the kindness of Professor Kögl, who sent a very generous sample of authentic atromentin, it could be shown that the compound obtained in the present work was identical with atromentin. When the m.p. of atromentin tetra-acetate was determined in the Kofler hot-stage microscope it showed the same characteristic double m.p. as observed with the acetate of our compound.



It is obvious that both the benzoic acid and the atromentin have been formed upon treatment of the extract with alkali. This suggests that they might be combined with another in aurantiacin. This was borne out by a separate experiment, where aurantiacin was dissolved in sodium hydroxide, giving atromentin and benzoic acid.

II

III ; R = OC—⟨benzene⟩ ; R′ = CH_3

IV ; R = CH_3 ; R′ = OC—⟨benzene⟩

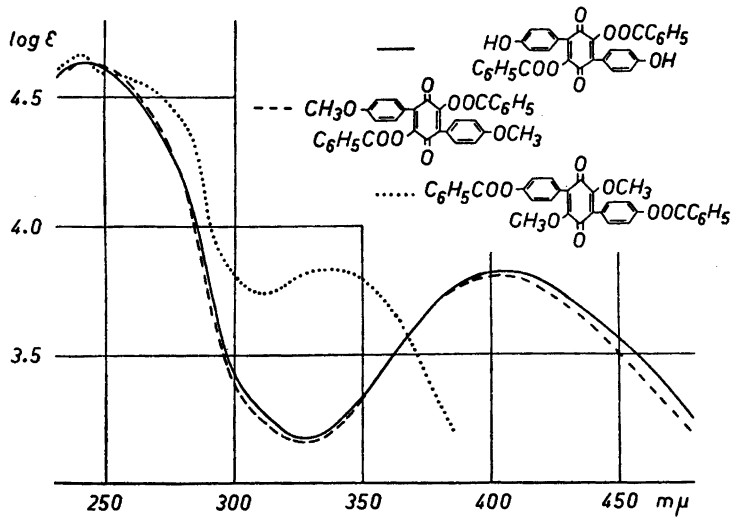

Fig. 1.

Aurantiacin is thus most probably a benzoate of atromentin, and the analyses reported above show that it is a dibenzoate. This view is further supported by benzoylation of aurantiacin to a dibenzoate. which is identical with the tetrabenzoate obtained by benzoylation of atromentin.

The structure of atromentin (I) has been established by Kögl and coworkers, both by degradation [4] and by synthesis [5]. It remains to show which of the four hydroxyl groups are benzoylated in aurantiacin. Three dibenzoates of atromentin are possible and, as will be shown below, aurantiacin must be (II)

This conclusion rests on the following observations. Aurantiacin is only a very weak acid, being insoluble in 2 N sodium carbonate, whereas atromentin is soluble even in sodium hydrogen carbonate. This shows that aurantiacin cannot have any free hydroxyl groups in the quinone ring. The almost instantaneous hydrolysis of aurantiacin, when treated with alkali also indicates that it is the hydroxyl groups in the quinone ring that are benzoylated, giving what can be considered as a vinylogous acid anhydride. Thirdly a comparison of the UV-absorption curve of aurantiacin with the absorption curves of the compounds (III) and (IV) prepared by unambiguous routes from atromentin, shows, as can be seen from Fig. 1, that the spectrum of aurantiacin is very close to that of (III), but quite different from that of (IV). (All spectra in dioxan).

Final proof of the structure (II) for aurantiacin was obtained by methylating it to its dimethyl ether, which was identical with the synthetically prepared (III). This methylation was unexpectedly difficult to achieve. Only a rather low yield (20 %) of the desired compound could be obtained. At least three other compounds were formed in the methylation but they have not been studied further.

EXPERIMENTAL

(All m.p:s have been determined on a Kofler hot-stage microscope, unless otherwise stated. The analyses have been carried out by Dr. A. Bernhardt, Mülheim.)

Isolation of aurantiacin. The finely ground sporophores of the fungus were extracted with ether in a Soxhlet apparatus and the red crystalline precipitate was filtered off. The yield was varying, one batch of 140 g giving 2.7 g, another of 170 g giving 1.7 g of crude pigment. This (100 mg) was dissolved in acetone and chromatographed on acid washed alumina (10 g). In the upper part of the column a narrow green band was formed and immediately below this a broad dark brown zone. Development with acetone caused a slow broadening of the brown zone but no clear separation from the green band could be achieved. The green band was removed from the column and the brown zone was eluated with acetone containing a few drops of acetic acid (3 drops per 40 ml). A dark red eluate was obtained. The pigment could be recovered either by evaporation of the solvent in vacuum, or by addition of water. In either case dark red crystals (85 mg) were obtained. Rechromatography of this gave only the brown zone. The pigment was recrystallised from dioxan giving small orange red needles. Upon standing they slowly turned dark red. They evidently contain dioxan of crystallisation. M.p. 285–295°. (Found: C 72.25; H 3.72; O 23.89; Mol.wt. (Rast) 610; $C_{32}H_{30}O_8$ requires C 72.18; H 3.79; O 24.04; Mol.wt. 532.5).

Aurantiacin diacetate. Aurantiacin (200 mg) was suspended in acetic anhydride (10 ml) containing two drops of pyridine. After standing overnight all the red crystals of aurantiacin had disappeared and the solution contained the yellow crystals of aurantiacin diacetate. These were filtered off (180 mg) and recrystallised from dioxan. M.p. 235–238°. (Found: C 69.61; H 3.88; O 26.85; Mol.wt. 745, 760; $C_{36}H_{24}O_{10}$ requires C 70.13; H 3.92; O 25.95; Mol.wt. 616.5).

Aurantiacin leuco-acetate. Aurantiacin diacetate (100 mg) was suspended in acetic anhydride (2 ml) to which had been added a few drops of pyridine. Zinc powder was then added and the mixture was allowed to stand. The yellow acetate disappeared rapidly and the almost colourless solution was filtered from the zinc, and poured into cold water. A white crystalline precipitate was formed (100 mg) This was recrystallised from acetic acid. M.p. 246–253°. (Found: C 68.35; H 4.50; O 27.30; $C_{40}H_{30}O_{12}$ requires C 68.46; H 4.29; O 27.25).

Aurantiacin dibenzoate. Aurantiacin (100 mg) was dissolved in pyridine (5 ml) and benzoyl chloride (0.25 ml) was added. The mixture turned warm and after some time a mixture of colourless and yellow crystals was formed. The crystals were filtered off and washed with water to remove the colourless pyridine hydrochloride. The remaining yellow aurantiacin dibenzoate was recrystallised from dioxan. M.p. 310–315°. (Found: C 74.22; H 3.93; O 22.02; $C_{46}H_{28}O_{10}$ requires C 74.59; H 3.81; O 21.60).

Treatment of the ether extract. The ether extract obtained in the extraction of one batch of fungus (170 g) was shaken successively with portions of saturated sodium hydrogen carbonate, 2 N sodium carbonate and 2 N sodium hydroxide, each time until the aqueous phase was almost colourless. The two first extracts gave upon acidification only minute amounts of precipitate, which were not further investigated, while the sodium hydroxide extract gave a large precipitate. This was taken up in ether and the extraction repeated as above. The precipitate obtained by acidification of the sodium hydrogen carbonate extract was filtered off and washed with benzene, whereby a part of it dissolved. The mother liquor from the filtration was extracted with ether, the ether was removed and the residue was divided into a benzene soluble and benzene insoluble part, which were combined with the corresponding fractions from the precipitate. 3.3 g of a brown benzene insoluble powder was thus obtained. This was extracted with hot methanol. Upon cooling 1.9 g of dark brown crystals of atromentin separated. By adding dioxan to the mother liquor a further amount (0.35 g) was obtained. Recrystallisation from methanol-dioxan mixture gave orange red crystals which rapidly darken in the air. It decomposes without melting at about 300°. (Found: C 66.68; H 3.96; O 29.54; $C_{18}H_{12}O_6$ requires C 66.67; H 3.73; O 29.60).

The benzene solution obtained above was evaporated leaving a slightly red crystalline mass. Sublimation gave colourless needles, m.p. 120–121°, identified as benzoic acid by mixed m.p.

When pure aurantiacin was dissolved in 2 N sodium hydroxide and the solution acidified a precipitate was obtained that in the same way could be separated into atromentin and benzoic acid.

Atromentin tetra-acetate was prepared from atromentin and acetic anhydride in the presence of pyridine in the same way as aurantiacin diacetate. Recrystallisation from acetic acid and then from dioxan gave yellow needles. When the m.p. was determined in a conventional m.p. apparatus a m.p. of 242—245°, not depressed by admixture of authentic atromentin tetra-acetate was observed. In a m.p. microscope the same initial m.p. was observed, but the melt recrystallised to very characteristic clusters of needles which then melted at 290—294°. The same behaviour was observed also with authentic atromentin tetra-acetate. (Found: C 63.09; H 4.06; O 32.53; $C_{26}H_{20}O_{10}$ requires C 63.41; H 4.09, O 32.49).

Atromentin leuco-acetate. Reductive acetylation in the same manner as described above for aurantiacin gave the colourless leuco-acetate, m.p. 235—240°. Kögl and Postowsky [3] report 235—236°. (Found: C 61.83; H 4.82; O 33.13; $C_{30}H_{26}O_{12}$ requires C 62.28; H 4.53; O 33.19).

Atromentin tetrabenzoate. Atromentin (100 mg) was suspended in pyridine (3 ml) and benzoyl chloride (0.5 ml) was added. The atromentin dissolved and after a short time precipitation began. After standing overnight the crystals were filtered off and washed thoroughly with water. The yellow crystals (140 mg) were recrystallised from anisole, m.p. 308—315°. Gives no depression of m.p. when mixed with aurantiacin dibenzoate. (Found: O 22.19; $C_{46}H_{28}O_{10}$ requires O 21.60).

Aurantiacin dimethylether (III). *a*) From atromentin. Atromentin was converted to its *p,p'*-dimethylether according to Kögl and Becker [4]. This (50 mg) was suspended in pyridine (2 ml) and benzoyl chloride (0.1 ml) was added. After a few hours the same amount of benzoyl chloride was added. After 24 hours the crystalline material was filtered off and washed with water. The residue, after recrystallisation from dioxan-water was obtained as orange red plates, m.p. 243—247°. (Found: C 73.09; H 4.45; $C_{34}H_{28}O_8$ requires C 72.85; H 4.32).

b) From aurantiacin. Aurantiacin (300 mg) was dissolved in dry acetone (50 ml) and dimethyl sulphate (2 ml) and potassium carbonate (3 g) were added. The mixture was boiled one day on a water bath, filtered and the acetone evaporated in vacuum. The residue was dissolved in benzene and the solution chromatographed on alumina. It formed a broad yellow, rapidly moving band and above that several narrow red to brown coloured bands. The eluate of the yellow band was evaporated under vacuum, whereby a partly crystalline residue was obtained. The crystals were filtered off (50 mg) and recrystallised from dioxan-water, giving orange red plates, m.p. 243—246°, no depression when mixed with a specimen prepared according to *a*).

Atromentin-2,5-dimethylether-p,p'-*dibenzoate* (IV). Atromentin-2,5-dimethylether was prepared from atromentin with diazomethane [3]. This (120 mg) was dissolved in pyridine (5 ml) and benzoyl chloride (0.3 ml) was added. After some time crystallisation set in and the mixture was allowed to stand for 2 days. The crystals were removed by filtration and were washed with water and benzene. The residue was recrystallised from pyridine, giving light brown needles, m.p. 278—290°. (Found: C 72.45; H 4.79; $C_{34}H_{24}O_8$ requires C 72.85; H 4.32).

The author wishes to express his indebtedness to Prof. F. Kögl, Utrecht, for a sample of atromentin. A grant from *Statens Naturvetenskapliga Kommission* is gratefully acknowledged.

Dyeing of Wool with Lichens and Lichen Substances

YNGVE JOHANNES SOLBERG

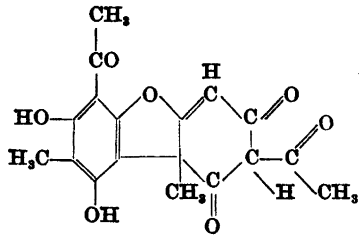
Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Experiments have been carried out in dyeing wool with lichens, lichen substances or their decomposition products and with simple aromatic aldehydes. It is suggested that the formation of azomethine linkages is responsible for the yellow colour obtained under mild dyeing conditions with aldehydic substances. By the usual, more drastic dyeing conditions, where darker colours are developed, the chemical process during dyeing may be more complex.

Some new azomethine compounds with fumarprotocetraric and salazinic acids are described.

I. INTRODUCTION AND GENERAL SURVEY

Dyeing of wool and silk on an industrial scale with lichens has been known in Europe as long as we have records about this craftsmanship, at least as early as the fourteenth century. As a part of domestic industry records may be traced at least 2 000 years further back. The only lichens still used on an industrial scale are giving the well known Orseille dyestuffs. Although the constitution of the pigment is still unknown similar shades may be obtained with other lichens known to contain orcein.



A great number of lichen species which have found use in domestic industry especially for the dyeing of wool does, however, not contain any orcein. By the dyeing procedure mostly used in domestic industry — long boiling of the whole lichens in water followed by introduction of the textiles mostly followed by further boiling — these other lichens give colours ranging from ochre through tawny to a very dull brown.

A broad review of the literature [1-17] revealed that at least 50 different lichen species have been used for dyeing purposes. When the lichens giving Orseille dyes are omitted the 35 species collected in Table 1 remain. In the same table references are given to those of the lichen constituents ("lichen acids") which most reasonably might have some connections with their dyeing properties. Usnic acid (I) one of the most common lichen acids and present in 14 of these lichens is no dyestuff for wool or silk. Most of the aromatic lichen substances are depsides (II) or depsidones (III), compare Table 2.

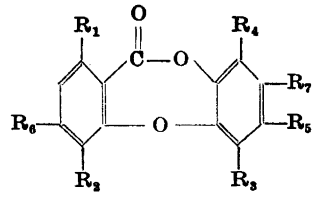
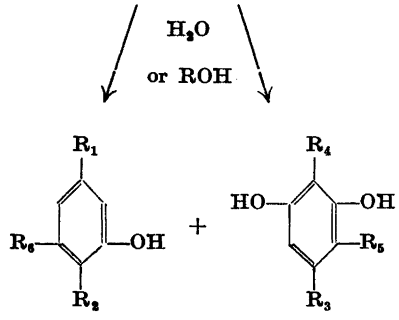
I Usnic acid



VI Barbatolic acid



Inspection of Tables 1 and 2 reveals that most of the non-Orseille lichens used for the dyeing of wool contain aromatic compounds with at least one aldehyde function. Of the 12 lichen acids with an aldehyde function in Table 2, four have been tested as pure substances for their dyestuff properties. It turned out that if these aldehydic depsides or depsidones were applied in aqueous acetone or 90 % alcohol at room temperature, the wool took on a bright yellow to yellowish brown colour, whereas boiling under reflux for 2 hours produced the much stronger reddish to brown colours which are usually obtained when dyeing with lichens. In the 2nd chapter is demonstrated that aldehydic depsides or depsidones with different amines give azomethine compounds of yellow to orange colours. Thus it seems probable that the bright colours developed on wool from solutions in organic solvents may be azo-

methine compounds formed from the aldehydic function of the lichen acids and free amino residues in the wool.

A confirmation of this hypothesis follows from the fact that evernic acid (14, see Table 2) and lobaric acid (18, see Table 2) which do not contain any aldehydic group give no colour on wool. We suppose that the closely related depsides obtusatic acid (10), barbatic acid (13), divaricatic acid (15) and the depsidones alectoronic acid (16) and physodic acid (17) will prove to be wihtout dyeing properties.

That hydroxyaldehydes take part in the dyestuff formation was demonstrated with simple aromatic compounds. Methanolic solutions of salicylic aldehyde, 2,4-dihydroxy-benzaldehyde, 4,6-dimethyl-2-hydroxybenzaldehyde and vanillin all gave strong colours on wool. Piperonal and cinnamic aldehyde, however, also developed yellow colours on wool demonstrating that free hydroxygroups may be absent.

It is well known that lichen depsides are hydrolysed by boiling water II → IV + V (Refs.[18,19]). From atranorin (2) atranol (IV: $R_1 = CH_3$, $R_2 = CHO$, $R_6 = OH$) and β-orcinol carboxylic acid methyl ester (V: $R_3 = R_4 = CH_3$, $R_5 = COOCH_3$) were prepared. The orcinol carboxylic acid methyl ester did not dye wool; atranol refluxed with water and wool gave the same colour as did atranorin (2). The strong tawny colours produced during the process used in domestic industry, could then be due not to the aldehydic lichen acids themselves, but to their decomposition products generated by hydrolysis.

The chemistry of the dyeing process is obviously more complicated in the case of a native lichen than when using the corresponding lichen substances. Experience has really shown that the colour obtained with native lichen is deeper and richer than the colour which results from treatment with the isolated lichen substances. We know to-day that the aldehydic lichen substances are present in a very great number of lichen species (atranorin or chloroatranorin has been demonstrated in more than eighty different species), and that lichens which contain one or more of them always give colour with wool.

In Table 1 *Ramalina calicaris* figures as a dye lichen. This lichen is known to contain usnic (1), evernic (14) and obtusatic acid (10), none of which contains an aldehyde group. As mentioned above usnic acid does not act as a dyestuff. Pure evernic acid (from *Evernia prunastri*) was tested and as expected was found to be negative. Since obtusatic acid is the methyl homologue of evernic acid also this lichen acid most likely is not colour-forming. Since literature gives no informations about the colour obtained with *Ramalina calicaris* dyeing experiments were carried out with the whole lichen. The wool took on a green colour. The dyeing properties of *Ramalina calicaris* thus is due to quite another type of dyestuff formation.

The dye lichens *Ramalina cuspidata* and *Haematomma ventosum* are also said to be free from aldehydic substances. Lack of material has prevented examination of these lichens.

II. NEW AZOMETHINE COMPOUNDS WITH FUMARPROTOCETRARIC ACID AND SALAZINIC ACID

It appears that comparatively few azomethine compounds of depsidone aldehydes and derivatives have been studied [20-26]. Aniline, bromoaniline, phenylhydrazine and *p*-nitrophenylhydrazine have been used as amino components. These azomethine compounds are yellow substances, easily decomposed into their components by treatment with diluted hydrochloric or sulphuric acid. Most frequently they are slightly soluble in the common organic solvents.

The synthesis of five new azomethine compounds is reported in this paper: *p*-aminobenzoic acid-N-fumarprotocetraric acid, glycine methyl ester-N-fumarprotocetraric acid, methyl anthranilate-N-fumarprotocetraric acid, methyl *m*-aminobenzoate-N-fumarprotocetraric acid and di(methyl *m*-aminobenzoate-N-)salazinic acid.

The yellow colour of these azomethine compounds resembles closely the colour obtained when wool is dyed under certain conditions with fumarprotocetraric acid, atranorin, chloroatranol and simpler aromatic aldehydes. This seems to support the suggestion put forward above that azomethine linkages are formed when fibres of wool and silk react with aromatic aldehydes. The fact, however, that the dyeing under other conditions will give darker colours (tawny, brown, redbrown) would indicate that the chemical process in such cases is more complex.

The azomethine compounds described in the experimental part are hygroscopic substances, amorphous or crystalline. They have no definite melting point, but decompose above two hundred degrees.

EXPERIMENTAL

Isolation of lichen substances

The following aldehyde depsidones have been isolated: Fumarprotocetraric acid from *Cetraria islandica* and salazinic acid from *Parmelia saxatilis*. The isolation of the depsidones was carried out mainly according to the methods described by Simon, Hesse, Zopf, Koller, Klein, Pöpl and Asahina [2, 15, 20-23, 27-34].

Preparation of azomethine compounds

I. p-*Aminobenzoic acid-N-fumarprotocetraric acid.* To 2 g of fumarprotocetraric acid, dissolved in the minimum amount of pyridine, was added an ethanolic solution of 0.6 g of *p*-aminobenzoic acid. The mixture immediately turned dark yellow. On dilution with 80 ml hot ethanol and standing, microscopic, yellow needles were precipitated. The condensation product was purified by recrystallization from acetone-petroleum ether (1:2).; Yield: 1.3 g. (Found: C 58.6; H 4.3; N 2.2; equiv.wt. 145.4. Calc. for $C_{29}H_{21}O_{13}N$: C 58.9 H 3.6; N 2.4; equiv.wt. 147.9.)

The substance was easily soluble in cold pyridine and dioxan, soluble in hot acetone and ethanol, insoluble in ether, ethyl acetate, xylene, chloroform and benzene. An ethanolic solution of the compound gave an intensely red colour with *p*-phenylenediamine. The yellow colour of the condensation product disappeared on treatment with diluted hydrochloric acid, indicating that the compound was decomposed. In diluted alkali the compound was stable for some time (5—7 min.).

II. *Glycine methyl ester-N-fumarprotocetraric acid.* Fumarprotocetraric acid (1 g), glycine methyl ester (0.5 g), dry methanol (50 ml) and dry acetone (50 ml) were shaken in a bottle at room temperature for 15 h. By evaporation of the solvents a yellow, amorphous product was precipitated. The condensation product was purified by washing with much petroleum ether and then dried at 80° for 15 h. (Found: C 55.7; H 4.4; N 2.5; CH_3O 5.8. Calc. for $C_{25}H_{21}O_{13}N$: C 55.3; H 3.9; N 2.6; CH_3O 5.7.) The condensation product was found to be easily soluble in ethanol and acetone, slightly soluble in ether, petroleum ether and benzene.

III. *Methyl anthranilate-N-fumarprotocetraric acid.* Fumarprotocetraric acid (1 g), methyl anthranilate (0.5 g), acetone (75 ml) and 96 % ethanol (75 ml) were shaken at room temperature for 15 hours. After filtration the solution was evaporated to dryness. The yellow residue was purified by treatment with petroleum ether. Before analysis the azomethine compound was dried at 60° for 15 h. (Found: C 59.4; H 4.2; N 2.4. Calc. for $C_{30}H_{23}O_{13}N$: C 59.5; H 3.8; N 2.3). The substance was soluble in acetone and ethanol, insoluble in petroleum ether and benzene.

IV. *Methyl* m-*aminobenzoate-N-fumarprotocetraric acid.* This azomethine compound was prepared in two different ways.

a) Fumarprotocetraric acid (1 g) and methyl *m*-aminobenzoate (0.7 g) were shaken with a mixture of 100 ml dry acetone and 100 ml absolute ethanol at room temperature. Yellow, transparent needles precipitated gradually. After 24 h the condensation product was filtered and treated with 75 ml ether for 20 h. Next dried at 100°. (Found: C 59.9; H 4.2; N 2.3; CH_3O 5.1. Calc. for $C_{30}H_{23}O_{13}N$: C 59.5; H 3.8; N 2.3; CH_3O 5.1.) The azomethine compound was insoluble in ether, benzene and petroleum ether, slightly soluble in acetone and ethanol, easily soluble in warm glycol monoethyl ether.

b) Fumarprotocetraric acid (1.5 g) was dissolved in 700 ml hot 80 % acetone. To this solution methyl *m*-aminobenzoate (1 g), dissolved in 150 ml 96 % ethanol, was added. The mixture immediately turned dark yellow. By evaporation of the solvents a yellow, amorphous product was precipitated. The condensation product was purified by shaking it with 50 ml ethanol for 20 h. (Found: C 60.1; H 4.2; N 2.2; CH_3O 5.6. Calc. for $C_{30}H_{23}O_{13}N$: C 59.5; H 3.8; N 2.3; CH_3O 5.1.)

V. *Di(methyl* m-*aminobenzoate-N-)salazinic acid.* Salazinic acid (2.5 g) was dissolved in 600 ml boiling 80 % acetone. Methyl *m*-aminobenzoate (4 g) dissolved in 50 ml acetone was added. The deep yellow solution was filtered and diluted with 1.2 liter cold water. Hereby the condensation product was precipitated. It was purified by recrystallization from acetone-water (1:2). Yield 2.5 g. (Found: C 62.0; H 4.3; N 4.1; CH_3O 9.5. Calc. for $C_{34}H_{28}O_{13}N_2$: C 62.4; H 4.0; N 4.3; CH_3O 9.5). This azomethine compound was easily soluble in hot acetone, slightly soluble in ethanol and insoluble in ether and benzene. An ethanolic solution gave a brown-violet colour with ferric chloride. In conc. sulphuric acid the azomethine compound dissolved with a red colour.

The First Step in the Swelling of Gelatin with Water. II

CHR. WINTHER

Photochemical Laboratory, Technical University of Denmark, Copenhagen, Denmark

On the basis of a very simple model of the structure of gelatin and of the individual layers of the Christensen-interference plate it is possible to explain the two steps of absorption of water into the interference plate and to show that the final amount of water here is the same as in the corresponding chromated gelatin plate. Moreover it is shown that the diffusion of water throught gelatin is independent of the degree of hardening.

In the first paper in this series [1] I have examined the speed of swelling of the Christensen-interference plate with water. I was thereby forced to assume that about half of the water was taken up practically momentarily, whereas the remaining water was absorbed in the course of some days.

Continued examination of this peculiar phenomenon on various other examples of the said plates has shown its general character. At the same time it has been possible to measure the first "momentary" time and to give a plausible explanation of the two different modes of swelling on the same plate.

1. THE FORMULA

In the said paper was used the formula

$$v_v - \Delta = (v_\infty - \Delta)(1 - 10^{-k \cdot t^{0.5}}) \quad (1)$$

where v_v is the momentary volume of water, Δ the "instantaneous" absorption of water, v_∞ the final absorption of water, all of them per 100 volumes of gelatin, k is a constant and t the time (in minutes) of the slow absorption.

The examination of five other plates has shown that good agreement with this formula can only be obtained if the time t is replaced by $t - t_0$, the formula therefore being

$$v_v - \Delta = (v_\infty - \Delta)(1 - 10^{-k_2(t-t_0)^{0.5}}) \quad (2)$$

and, as the time t_0 is of the order of 0.1—2.0 minutes, it must be understood as the time for the first, "momentary" swelling.

Table 1 contains the results. The 1st column shows the number of the plate. Fig. 1 refers to the upper side of the "broad band"[2], Fig. 2 to the lower side. The 2nd column shows the percentage by volume of unhardened gelatin G′, the 3rd the percentage by volume of silver bromide v_A. Next comes Δ, the first rapid absorption of water, $v_\infty - \Delta$, the second slow absorption, then the observed and calculated values of t_0, the observed and calculated values of k_2, the velocity constant of the slow absorption, and finally k_3 (see below).

Table 1.

									22.1

The quoted values are means of three independent experiments.

The plates were selected to give the greatest possible variations in properties and composition. No. 20 was watered before treatment with silver nitrate, No. 28 has a special thick coating, No. 2 a special high content of silver bromide, and the remaining two plates are more normal, but still with a marked difference in the extinctions of the original chromated gelatin plates.

2. THE STRUCTURE OF THE GELATIN LAYER

In order to penetrate into this certainly very complex subject it is necessary to use a very simplified working model. Like Sheppard, Lambert and Swinehart [3] I assume that the gelatin molecule has a length of about 100 mμ and a diameter of 0.8—0.9 mμ, and that all the polar groups are found on one side of the molecule, which is therefore hydrophilic, whereas the non-polar groups are found on the other side, which is therefore hydrophobic.

The most simplified model of this structure is shown in Fig. 1, where two hydrophilic surfaces are connected, perhaps with a thin layer of water between them, as air dryed gelatin always contains some water, about 15—20 %. The mutual attraction between these hydrophilic surfaces, with or without the layer of water, will presumably be greater than the attraction between the two adjacent, hydrophobic surfaces.

3. THE CHROMATED GELATIN

If a gelatin layer of the suggested structure is treated with a solution of a chromate, the chromate ions must necessarily be adsorbed on the hydrophilic surfaces, and by the following hardening by light the chromate-bonds must therefore be situated between these surfaces. As to the hydrophobic surfaces, there is accordingly no difference between hardened and unhardened gelatin.

4. THE DIFFUSION OF WATER

In general it is assumed that the rate of diffusion of water in gelatin is independent of the degree of hardening of the gelatin, but it has not been possible to find any literature about this problem. Therefore, I have measured the rate of diffusion directly.

For this purpose four thick layers of photographic gelatin (Stoess, middle hard) were prepared on plate glass which was covered with Zaponlack so that afterwards the layers could be removed and the Zaponlack be dissolved in amyl acetate. One of the layers was hardened with formaldehyde, another, after treatment with a chromate solution, was hardened by prolonged exposure with a mercury lamp, while the two others were not treated in any way.

The thicknesses of the layers were measured directly with a micrometer. Then they were, one at a time, pressed against a Christensen-interference plate, a little water was poured out on the gelatin and the time was measured until the first sign of colour variation on the interference plate was observed. The results are shown in Table 2.

Table 2.

Treatment	Thickness in μ	t sec	sec/μ
Unhardened	65	41	0.63
Unhardened	60	45	0.75
Hardened with formaldehyde	73	60	0.82
Hardened with chromate and light	80	45	0.56
			0.69

Table 2 shows that the rate of diffusion is independent of the degree of hardening. This result must be expected from the suggested model of the structure. The diffusing water must find its way through the lowest possible resistance, *i.e.* between the hydrophobic surfaces. As conditions here are independent of the degree of hardening, the rate of diffusion must be the same for hardened and unhardened gelatin, as was actually found.

5. THE TREATMENT WITH SILVER NITRATE

When the exposed chromated gelatin plate is treated with a solution of silver nitrate the silver ions must be adsorbed on the hydrophilic surfaces, and

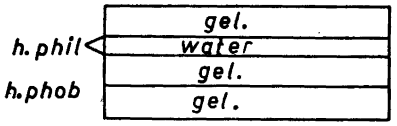

Fig. 1.

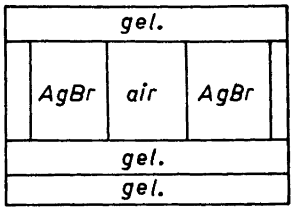

Fig. 2.

by the subsequent treatment with potassium bromide the silver bromide particles must become situated on the same places, probably linking the two adjacent surfaces together. The situation in the plate is now as shown in Fig. 2.

6. THE FIRST "INSTANTANEOUS" SWELLING

The experiments show that the amount of water hereby absorbed agrees with the formula

$$\Delta = 64 + k_3 t_0^{0.5} \tag{3}$$

The values of k_3 and the calculated values of t_0 are shown in Table 1.

The number 64, which means volume of water per 100 volumes of total gelatin, is the same for all the examined plates. As it is independent of time it must refer to the almost instantaneous diffusion of water between the hydrophobic surfaces. It must therefore be independent of the degree of hardening.

In Fig. 3 are shown my earlier measurements [4] of the amounts of water absorbed in differently exposed chromated gelatin. The four curves correspond to plates which are treated with water 2, 4, 7 and 11 days after producing the

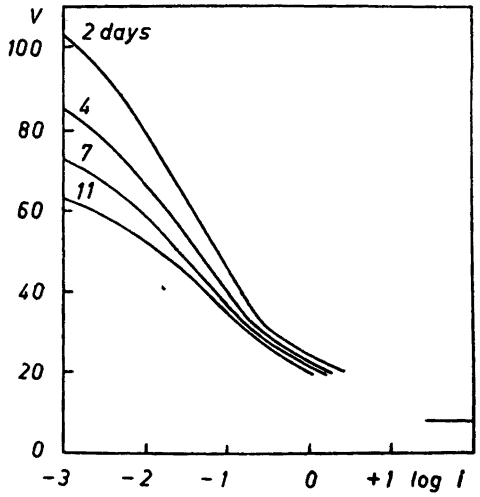

Fig. 3.

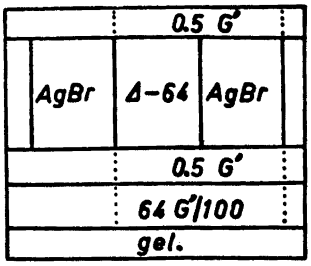

Fig. 4.

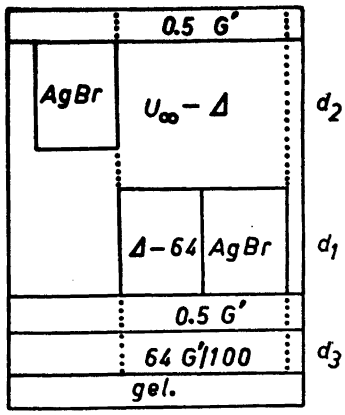

Fig. 5.

plates. The abscissae are the logarithms of the quantities of light, the ordinates the amounts of water per 20 mg of coating. Obviously the curves are not going to zero but are approaching a certain positive value. To the right is marked out the amount of water which corresponds to 64 %. These measurments therefore confirm the conclusion that the very rapid diffusion is independent of the degree of hardening.

When this rapid diffusion has finished the water proceeds to fill the interstices between the gelatin and the silver bromide particles. It is quite natural that the time for this absorption increases with the amount of absorbed water, as shown in formula (3). The measured values, 0.1—2.0 minutes, are in agreement with my earlier measurements, which have shown that the swelling of chromated gelatin is completed in less than 2.5 minutes. Further treatment with water up to 15 minutes shows no difference.

The situation is now as shown in Fig. 4.

7. THE SECOND SWELLING

In my earlier experiments with swelling of exposed layers of chromated gelatin [5] I have found that the adsorption of silver nitrate is somewhat greater than could be expected from the concentration of the solution, so that a selective adsorption of silver nitrate must take place. In other words, the forces between silver ions and gelatin are somewhat stronger than those between water and gelatin. Through the competition between the bonds water-gelatin and AgBr-gelatin, which consequently are not very much different, there will in every moment occur a number of ruptures between gelatin and silver bromide, so that there will always be a very small, but constant, number of free gelatin surfaces. This situation can be written as an equilbirium

$$\text{gel.AgBr.gel.} \rightleftharpoons \text{gel. AgBr} + \text{gel.}$$

The two "concentrations" on the right side are equal, therefore

$$\text{gel.} = K\ (\text{gel.AgBr.gel.})^{0.5}$$

Now, after the first rapid absorption water continues to enter. Thereby the process must be furthered, and the speed must be proportional to the existing free gelatin surface. In accordance herewith the experiments show that

$$k_2 = k_4 \left(\frac{v_A}{G' - \frac{64}{9.3}} \right)^{0.5}$$

The number 9.3 is the swelling factor for this particular type of gelatin [4]. For the results see Table 3 (for k_4) and Table 1 where the observed and calculated values of k_2 are compared.

Now the situation is as shown in Fig. 5. In this figure are indicated the thicknesses of

the gelatin molecule (assumed to be 0.8 mμ),
the silver bromide particle, d_1,
the layer v_∞—Δ, d_2, and
the layer "64", d_3.

These three numbers are given in absolute measure, if the thickness of the gelatin molecule is taken as 0.8 mμ. The following two lengths are only relative.

Table 3.

Plate No.	$k_4 \times 10^2$	d_1	d_2	m	n	v_1	v_2	D	k_5
20_2	3.92	2.78	2.90	13.4	3.0	4.37	5.68	11.9	2.73
20_1	3.23	2.28	1.98	12.8	6.8	5.75	4.26	11.9	2.55
$14a_2$	3.57	2.96	2.78	8.8	5.0	5.18	5.74	15.0	2.35
$14a_1$	3.27	2.62	2.24	8.8	10.1	5.75	4.86	15.0	2.36
9_2	3.45	2.64	3.16	8.2	5.6	5.18	5.80	14.8	2.45
9_1	3.40	2.28	2.60	7.8	10.0	6.27	4.88	14.8	2.52
28_2	3.08	2.36	4.28	7.8	6.0	5.07	6.64	19.3	2.10
28_1	3.08	1.68	2.74	7.4	13.9	5.96	4.42	19.3	2.28
2_2	3.55	1.80	5.52	4.2	9.6	5.18	7.32	15.8	2.06
2_1	3.51	1.80	3.90	4.2	15.0	5.76	5.70	15.8	2.12
	3.40					5.45	5.53		2.38

The length of the silver bromide particle, n, and
the length of the water filled interstice $\Delta - 64$, m.

As $$0.5\ G' = 0.8\ (m + n) \qquad (5)$$

and $$\Delta - 64 + v_A = d_1\ (m + n)$$

then $$d_1 = 1.6\ \frac{\Delta - 65 + v_A}{G'} \qquad m = \frac{\Delta - 64}{d_1} \qquad n = \frac{v_A}{d_1}$$

Further

$$d_2 = d_1 \frac{v_\infty - \Delta}{\Delta - 64 + v_A} \qquad d_3 = 1.6 \frac{64}{100} = 1.0 \text{ m}\mu$$

The last number d_3 must have a constant value as the amount 64 comprises both hardened and unhardened gelatin.

The values of the other quantities are given in Table 3.

For pure chromated gelatin with the swelling factor 9.3 the amount of water in the second slow swelling is 9.3 G′ — 64. The length $m + n$ is calculated for 0.5 G′ (see formula (5)). The amount of water per (relative) unity of length therefore is

$$v_1 = \frac{0.5(9.3\ G' - 64)}{m + n}$$

For the interference plate the corresponding quantity (see Fig. 5) must be

$$v_2 = \frac{(v_\infty - \Delta)\frac{m}{m+n} + \Delta - 64}{m} = d_1 + d_2$$

The values of v_1 and v_2 are shown in Table 3. The values of v_2 must be less exact than those of v_1 because so many different observations take part in the calculations of them, each with its own uncertainty. As a whole there can still be no doubt about the identity of the two series of numbers. The slow absorption of water, therefore, proceeds to the same end in pure chromated gelatin and in the interference plate, indicating that the elastic forces between the gelatin molecules which terminate the absorption are of the same magnitude in the two different cases.

8. THE SPONTANEOUS DRYING OF THE WET PLATE

After the measurement of the final amount of water by the swelling process the plate was with the utmost speed wiped with filter paper and then spectrographed 0.5, 1, 2 . . . minutes after wiping.

During the drying process the water does not need to overcome any elastic or other forces, but the process is a simple diffusion and evaporation. Accordingly the speed of drying must be inversely proportional to the thickness of the coating and directly proportional to the remaining amount of water. Therefore

$$-\frac{dv}{dt} = k_5 \frac{v_V}{D}$$

where D denotes the thickness of the coating in μ. Through integration it follows that

$$v_V = v_\infty\, 10^{-k_5 t/D}$$

Table 3 contains the results. It seems that the constant k_5 decreases a little with increasing thickness of the coating. It must, however be taken into account that the half period for $D = 11.9\ \mu$ is only 1.3 minutes. As the first

spectrograms were taken after 0.5 and 1 minute and the time of exposure must be at least 5 seconds, there must be a systematical error which tends to an apparent increase of the speed of drying, *i.e.* the value of k_5 in this case tends to be too great. For the greater values of D the half period increases up to 2.8 minutes and the measurements are therefore apt to be less erroneous.

After completion of this work I have learned that Bagley and Long [6] have examined a quite analogous case by the sorption of acetone vapour in cellulose acetate. Thereby they have found, first a rapid and thereafter a slow stage of sorption, and they have explained the former as due to diffusion and the latter to breaking of the interchain bonds in the polymer network, just as I have proposed.

The Diffusion of an Electrolyte Solution in a Superimposed Electric Field

OLE LAMM

Department of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

A diffusion effect in electrolyte solutions, arising from an outer field being superimposed in the diffusion direction, is discussed and, in a special case, related to the field characteristics and to the kinetics of the ionization equilibrium.

As is well known, the diffusion of salts in solution is accompanied by a macroscopic electric field, which changes with the nature of the concentration gradient and during the diffusion process. This field, and the ionic migration in it, is characteristic of the gradient diffusion of electrolytes. Phenomena within the gradient, obtained by superimposing an outer electrical field, are naturally considered in connection with the theory of electrophoresis [1], owing to the importance of knowing what happens to the gradient itself (such as sharpening or broadening effects) and of knowing how to define the migration of a boundary. It is in this case the question of a constant outer field. The literature concerning this case is rather large.

In the present article we will investigate the possible ability of the superimposed field to increase the diffusion coefficient of one component of the solution. Such an effect can be foreseen for both alternating current and direct current. In section 3 we will briefly systematize some different reasons for the occurrence of such an electrodiffusion phenomenon, irrespective of whether the order of magnitude is sufficient for an experimental demonstration or not. In sections 1 and 2 we will enter into the quantitative aspect, although only in a special case. We will assume the system to be free of thermal convections, the appearance of which sets a serious limit for the measurements and must be decisive for the choice of experimental conditions.

1. GENERAL PRINCIPLES

Owing to the fact that gegenions, which play no direct role in the above-mentioned electrodiffusion phenomenon possess the disadvantage of increasing the Joule heat, the theory is exemplified by a case with only one single electro-

lyte component *. In the simplest case, this is a weak electrolyte AB. In the ionization equilibrium the constituents A and B are present either as ions or as uncharged AB. This forms a statistical basis for a diffusion effect since the ions are not simply moving up and down as in a completely ionized, simple electrolyte. (This latter is theoretically true only if the statistical changes in the mobility of the ions are neglected. These changes appear to be too rapid for a measurable effect in ordinary cases.)

In the kinetical equilibrium $AB = A^+ + B^-$, an ion has a certain average life-time T. This may not always be the same for the two kinds of ions, $T^+ \neq T^-$. For the present we will assume that the undissociated state AB has a sufficiently long average life-time, with a statistical dispersion large enough, to make the duration of the ionic state of each single A (and B), even for short time intervals, randomly distributed on the time axis of the alternating field.

In the experiments it is not necessary to use a concentration gradient — we can instead measure the self-diffusion using isotopic labelling. Some of the possible systems (see section 3) will give an effect *only* in self-diffusion. In self-diffusion we have, with some exceptions, the disadvantage of a very small density gradient, which may cause difficulties owing to the Joule heat and convection risk **. We will, therefore, assume a real concentration gradient. This complicates the theory because of the Nernst diffusion potential.

Assuming a concentration gradient of the salt as in a differential measurement of the diffusion coefficient, we arrange electrodes at the top and bottom of the diffusion cell or use a technique as in electrophoresis work. Applying an alternating electrical field upon the gradient column, an ion A^+ will move a distance l_+ in one direction, the length of which may depend on the life-time of the ion, on the phase condition at the moment of appearance of the ionic state and on the frequency of the electric field. In addition, l_+ of course depends on the mobility of the ion and on the field strength. After an average time T^+, the ion disappears. In the next ionic state of the same A, the field direction may be the same or opposite, the correlation of phase of the electrical field at the moments of disappearance and reappearance of the ion being supposed to be low according to our suppositions. Under these circumstances, the action of the field will result in a macroscopical net displacement of the ion and the ion constituent A, and therefore also of the substance AB as a component. Thus we have an electrical diffusion effect in addition to the ordinary diffusion.

Assuming ideal statistical conditions, the electrical diffusion effect upon the cations may be expressed by a one-dimensional diffusion coefficient according to *** (see for instance the recent article [2])

$$D^+ = \nu \, l_+^2/2 \qquad (1)$$

* Two solute components is in itself a wider field for practical application. Using a real concentration gradient (mutual diffusion as distinct form self-diffusion), this case will not give an ideal gaussian gradient curve, which means a complication in the evaluation of the experiments.

** The porous disc method is often used, *e. g.* to avoid convections, but would eventually involve troubles from the Joule heat in the membrane and an electroosmotic diffusion effect which is of interest in itself but undesired as a source of error.

*** The number factor 2 is deduced assuming steps of equal length.

where ν is the number of steps per unit time. From eqn. (1) it is seen that the length of the steps (and therefore also the duration of the steps) is more important than the number of steps/sec., since the former appears as a square. As a matter of fact, the kinetical process, and the current frequency as well, has to be comparatively slow if the electro-diffusion shall compete measurably with the ordinary diffusion.

The choice of characteristics of the superimposed field is optional from both theoretical and practical viewpoints. A certain generality and simplicity is achieved by choosing a square field as in Fig. 1.

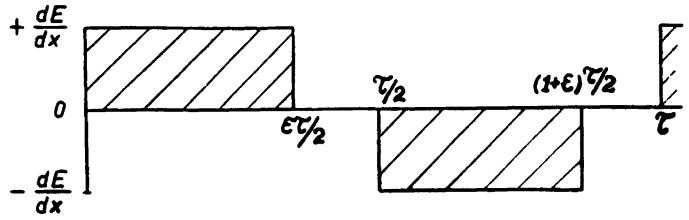

Figure 1.

The period length is τ sec and ε is the fraction of the half-period during which current is conveyed. The reason for choosing $\varepsilon \neq 1$ is that ε is an interesting variable for the magnitude of the diffusion effect. The possibility is also foreseen of using the current-free interval to measure the conductance of the diffusion column, in order to get an exact measure of the average temperature in the column.

It seems that, under certain conditions of current and kinetical characteristics, the regularity of the current variations gives rise to a lower diffusion effect than that which would be obtained if the superimposed field is given a random nature. There is no doubt that such can be experimentally arranged.

We will here treat two extreme cases, the theory for which is elementary. In both cases we assume as above that the uncharged state for A and B is of a comparatively long duration $T°$ and that the statistical dispersion of $T°$ is broad enough to eliminate any correlation between the consecutive phases (on the time axis of the field) with which an ion appears. In this way we also practically exclude the possibility that the ion can appear twice or more during the same period of the current.

The life-time of the ion being T, the two cases we are going to treat are a) $T < \varepsilon\tau/2$ and b) $\varepsilon\tau/2 < T$, $\varepsilon \ll 1$. The latter case corresponds to sudden current shocks, as experimentally used when studying the Wien-effect of electrolytes. In both cases τ is intermediate between T and $T + T°$, which means a kind of broad resonance between the field and the pulsation of the electrolyte.

a) $T < \varepsilon\tau/2$.

The length of each step is $l = \pm Tu$, $\pm u$ being the velocity of the ion in the field $\mathrm{d}E/\mathrm{d}x$. The number of ionic states/sec. is $1/(T+T°)$. Of these states

a fraction ε leads to a step, so that the number of steps/sec. is $\nu = \varepsilon/(T+T^\circ)$. Thus eqn. (1) gives for the electrodiffusion of the cations

$$D^+ = \frac{(T^+u^+)^2\varepsilon}{2(T^+ + T^\circ)} \tag{2}$$

The frequency $1/\tau$ is not directly contained in this formula, compare however the discussion of eqn. (5).

b) $\varepsilon\tau/2 < T$, $\varepsilon << 1$.

The step length is $l = \pm\, \varepsilon\tau u/2$, *i. e.* the duration $\varepsilon\tau/2$ of the step multiplied by the velocity $\pm u$. The number of steps/sec. is the product of the number of + or — shocks $2/\tau$/sec. and the probability $T/(T+T^\circ)$ that a step shall be taken at a certain current shock. Thus $\nu = 2T/\tau(T+T^\circ)$ and, for cations

$$D^+ = \left(\frac{u^+\varepsilon}{2}\right)^2 \frac{T^+\tau}{T^+ + T^\circ} \tag{3}$$

In order to compare cases a) and b), the D^+-values are divided by the Joule effect w watt/cm^3 in each case, which ratio ought to be decisive for the possibility of measuring the effect. This effect is $w = \varepsilon\varkappa(\mathrm{d}E/\mathrm{d}x)^2$, the conductance being denoted by $\varkappa$. The measurements are supposed to be made upon exactly similar diffusion columns, one according to eqn. (2) and the other according to eqn. (3). The allowed potential gradients are different in these cases, and therefore also the velocities u^+. Considering also that $u^+ = U^+\mathrm{d}E/\mathrm{d}x$, where U^+ denotes the ionic mobility, we obtain

$$(D^+/w)_{\text{eqn. (2)}} \,/\, (D^+/w)_{\text{eqn. (3)}} = T^+ \,/\, \tfrac{1}{2}\,\varepsilon\tau \tag{4}$$

Here $\varepsilon\,\tau$ belongs to the conditions of eqn. (3), for which we have assumed $\varepsilon\tau/2 < T^+$. Thus this case is comparatively unfavourable according to eqn. (4).

From eqn. (2) we obtain

$$D^+ \,/\, w = (T^+U^+)^2 \,/\, 2\,\varkappa\,(T^+ + T^\circ) \tag{5}$$

showing that the result is independent of the field characteristic ε. (τ does not enter this formula. However, the greater τ is, the greater must $T^+ + T^\circ$ be according to our suppositions.)

2. DIFFUSION THEORY

The diffusion effect on the two kinds of ions has to be combined with the ordinary diffusion of the ions and undissociated part, due regard being paid to the diffusion potential. For this purpose we first need an expression for the

diffusion of a weak electrolyte A_pB_q, with mole concentration C and degree of dissociation α according to

$$A_pB_q \underset{k'}{\overset{k}{\rightleftharpoons}} pA^{z+} + qB^{z-};\ pz^+ = qz^- \tag{6}$$

$$\begin{array}{lll} C\ (1-\alpha) & pC\alpha & qC\alpha \end{array}$$

$$(pC\alpha)^p\ (qC\alpha)^q = KC(1-\alpha) \tag{7}$$

neglecting for the present the activity coefficients. We will calculate the diffusion coefficient D_{12} using the general expression [3] for the components 1 and 2

$$D_{12} = RTN_1B_{12} / \Phi_2;\ B_{12} = \partial \ln a_2 / \partial \ln N_2 \tag{8}$$

The mole fraction N_1 of the solvent is sufficiently near 1 in the dilute solutions considered here. Φ_2 is the molar friction of the solute, a_2 its activity.

It has been previously shown [3,4] that if a component in solution exists in different forms or molecular sizes, the molar friction Φ of the component depends upon the molar frictions Φ_i of the different species according to

$$\frac{1}{\Phi} = \sum \frac{n\nu_i}{\Phi_i} \tag{9}$$

where ν_i is the fraction of the component which is present in the form i and n is the degree of association ($n = 2$ for double molecules etc.). The molecular weight of the component (necessary for defining Φ) shall correspond to $n = 1$.

Since in our present, simple case with only two kinds of ions, the ions must follow one another in the stoichiometric proportion, eqn. (6) corresponds to a simple conversion, the forms of the electrolyte being A_pB_q with the friction Φ° and ($pA^{z+} + qB^{z-}$) with the friction $\Phi^\pm$. For the friction of the solute Φ_2 we obtain from eqn. (9) simply

$$\frac{1}{\Phi_2} = \frac{1-\alpha}{\Phi^\circ} + \frac{\alpha}{\Phi^\pm} \tag{10}$$

This determines Φ_2 of eqn. (8). We will now proceed to determine B_{12} and may use the concentration of the undissociated part as a measure of the activity of the solute; $a_2 = C(1-\alpha)$. Eqns. (7) and (8) give

$$B_{12} = \frac{p+q}{p+q-\alpha(p+q-1)} \tag{11}$$

This is quite plausible, $\alpha = 0$ giving $B_{12} = 1$ (ideal solute) and $\alpha = 1$ giving $B_{12} = p + q$ (ideal solute of $p + q$ ions per mole salt). The desired expression is then for the very dilute solution ($D_{12} \rightarrow D_2$)

$$D_2 = \frac{RT\ (p+q)}{p+q-\alpha(p+q-1)} \left(\frac{1-\alpha}{\Phi^\circ} + \frac{\alpha}{\Phi^\pm} \right) \tag{12}$$

This expression will now be extended to include the specific electrodiffusion effect. For this purpose it is preferable to use the complete expressions for the stationary motion as functions of forces and frictions. The contribution k^+ of the electrodiffusion to the diffusion force must first be calculated. In the diffusion theory, this force per mole solute, is the gradient in the chemical potential, $k_2 = -RT\partial \ln a_2/\partial x$. Confining our calculation to a dilute component of concentration c_2, eqn. (8) may be written $D_2 = (-RT\partial \ln a_2 \,/\, \partial x) \,/\, (-\Phi_2 \partial \ln c_2/\partial x)$ and from this

$$k_2 = -D_2\, \Phi_2 \partial \ln c_2/\partial x \tag{13}$$

For the cations, eqn. (2) is now assumed (the sign Δ distinguishes electrodiffusion from ordinary diffusion)

$$\Delta\, D^+ = \tfrac{1}{2}\, \frac{(T^+u^+)^2\varepsilon}{T^+ + T^\circ} \tag{14}$$

The concentration is, according to eqn. (6), $pC\alpha$. Further, the velocity $u^+ = U^+ dE \,/\, dx$, U expressing mobility. The electrical force per gram-ion is $-z^+F\ 10^7 dE \,/\, dx$ (F = 1 faraday). From this, since the ratio of force to velocity equals the friction,

$$\Phi^+ = z^+F\ 10^7 \,/\, U^+ \tag{15}$$

Denoting by L the magnitude

$$L^+ = \tfrac{1}{2}\, \frac{\left(T^+ \dfrac{dE}{dx}\right)^2}{T^+ + T^\circ}\ F\ 10^7 \tag{16}$$

we finally get the diffusion force per gram-ion k^+ from equation (13) (D_2 in this case being ΔD^+, $c_2 = pC\alpha$ and $\Phi_2 = \Phi^+$) and by analogy also k^-

$$\begin{aligned} k^+ &= -L^+U^+z^+\partial \ln C\alpha \,/\, \partial x \\ k^- &= -L^-U^-z^-\partial \ln C\alpha \,/\, \partial x \end{aligned} \tag{17}$$

Let v°, v^+, and v^- be the linear velocities of AB, A^+, and B^-, respectively. Considering also the forces originating from the l o c a l potential gradient dE'/dx in the diffusion column, and denoting, as in eqn. (12), the molar friction of AB by Φ°, we obtain by equalizing the forces,

$$v^\circ\ \Phi^\circ = -RT\frac{\partial \ln C(1-\alpha)}{\partial x} \tag{18}$$

$$v^+\ \Phi^+ = -RT\frac{\partial \ln C\alpha}{\partial x} - L^+U^+z^+\ \frac{\partial \ln C\alpha}{\partial x} - z^+F10^7\ \frac{dE'}{dx}$$

$$v^-\ \Phi^- = -RT\frac{\partial \ln C\alpha}{\partial x} - L^-U^-z^-\ \frac{\partial \ln C\alpha}{\partial x} + z^-F10^7\ \frac{dE'}{dx} \tag{19}$$

We have $pz^+ = qz^-$ and, the resulting electricity transport being zero, $pz^+C\alpha v^+ = qz^-C\alpha v^-$. From this, $v^+ = v^-$, and this velocity is denoted v. Expressing the ionic friction in terms of the electrochemical mobilities (eqn. (15), the following is obtained by elimination of dE'/dx from the eqns. (19)

$$F\ 10^7 \left(\frac{1}{U^+} + \frac{1}{U^-}\right) v = -\left[RT\left(\frac{1}{z^+} + \frac{1}{z^-}\right) + (L^+U^+ + L^-U^-)\right]\frac{\partial \ln C\alpha}{\partial x} \quad (20)$$

Calculating the total flow of A_pB_q as a component, according to $J_2 = v^\circ C(1-\alpha) + vC\alpha$, we get from eqns. (18) and (20)

$$J_2 = -\left\{\frac{RT}{\Phi^\circ}\frac{\partial C(1-\alpha)}{\partial C} + \frac{RT\left(\frac{1}{z^+} + \frac{1}{z^-}\right) + (L^+U^+ + L^-U^-)}{F\ 10^7\left(\frac{1}{U^+} + \frac{1}{U^-}\right)}\frac{\partial C\alpha}{\partial C}\right\}\frac{\partial C}{\partial x} \quad (21)$$

Since eqn. (21) is Fick's first law, the expression within the brackets is the total diffusion coefficient D_2. The equilibrium expression (7) provides

$$\frac{\partial C(1-\alpha)}{\partial C} = \frac{(p+q)\ (1-\alpha)}{p+q-\alpha\ (p+q-1)} \quad (22)$$

and similary for $\partial C\alpha/\partial C$. Inserting in eqn. (21) we arrive at

$$D_2 = \frac{RT(p+q)}{p+q-\alpha\ (p+q-1)}\left[\frac{1-\alpha}{\Phi^\circ} + \frac{\alpha\left(\frac{1}{z^+} + \frac{1}{z^-}\right)}{(p+q)F10^7\left(\frac{1}{U^+} + \frac{1}{U^-}\right)}\right] + \\ + \frac{\alpha}{p+q-\alpha\ (p+q-1)}\frac{L^+U^+ + L^-U^-}{F\ 10^7\left(\frac{1}{U^+} + \frac{1}{U^-}\right)} \quad (23)$$

The analogy with eqn. (12) is evident. The last term of eqn. (23) is the contribution ΔD of the superimposed field to the diffusion coefficient of the electrolyte. Thus by eqn. (16)

$$\Delta D = \frac{\frac{1}{2}\alpha\varepsilon\left(\frac{dE}{dx}\right)^2}{p+q-\alpha\ (p+q-1)}\frac{\frac{(T^+)^2U^+}{T^+ + T^\circ} + \frac{(T^-)^2U^-}{T^- + T^\circ}}{\frac{1}{U^+} + \frac{1}{U^-}} \quad (24)$$

We have assumed a real (but small) concentration gradient and thus dE/dx is not exactly constant over the diffusion column. Measuring instead, with isotopic labelling, say AB against A*B, the theory (for the diffusion of the A constituent) is simpler but shall not be given here.

In order to complete our intention of indicating a theory for a simple case, consider the equilibrium scheme of eqn. (6). It is the question of determining average life-times (T°, T^+ and T^-) of the uncharged and the ionic states from the kinetics of the dynamical equilibrium. In a monomolecular reaction, the lifetime of a particle is the inverse of the specific reaction constant k. Assuming an uncomplicated monomolecular reaction, we simply obtain $T^\circ = 1/k$. For the reverse reaction we observe that the process of disappearance of an A^{z+} ion is not limited to a reaction with the ions existing at a certain (zero) time point. Since any A^+ and B^- ion (of equilibrium concentration) can take part, the disappearance of A^{z+} also occurs according to a monomolecular scheme

$$\frac{1}{p}\frac{dA^{z+}}{dt} = k' \, (pC\alpha)^{p-1}(qC\alpha)^q(pC\alpha - A^{z+}) \qquad (25)$$

This equation describes the disappearance of the cations which exist at a certain zero time while the equilibrium is maintained. Since p of A^{z+} must disappear simultaneously for the formation of A_pB_q, each elementary reaction includes the disappearance of a number of the original A^{z+} ions which, on an average, is proportional to the relative content of these amongst the total amount. It seems however that this is accounted for in eqn. (25). It may in this connection be pointed out that the problem is not identical with the rate of disappearance of labelled ions from an original mixture of them with unlabelled salt. In the latter problem, labelled ions successively reappear by dissociation of the molecules formed, a process which is irrelevant to the question of the life-time of an ion, with which we are here concerned.

A complete theory has to consider an eventual exchange reaction, say according to the scheme

$$A_pB_q + (A^{z+})^* \rightarrow A_{p-1}(A^*)B_q + A^{z+} \qquad (26)$$

by which the life-time of the ion, and of the undissociated state of A, are diminished.

Special reaction mechanisms might modify the statistical nature of the kinetics. The same is true in the case of an equilibrium between different states of the salt or a formation of double molecules etc.* — From eqn. (25) we obtain

$$T^+ = T^- = 1/(k'p^pq^q(C\alpha)^{p+q-1}) \qquad (27)$$

The common life-time being denoted by $T^\pm$, this leads to

$$\frac{(T^\pm)^2}{T^\circ + T^\pm} = \frac{\alpha^2}{k(1-\alpha)}; \left(\frac{T^\pm}{T^\circ + T^\pm} = \alpha\right)^{**} \qquad (28)$$

* This may modify the statistical distribution, for short time-intervals, of the life-times. This distribution may be quite abnormal and it may not be self-evident that the calculated kinetical average life-time is identical with the average life-times which are contained in the electrodiffusion eqns. (2) and (24), as is assumed here.

** This expression is directly obtained from $T^\pm/T^\circ$ = the ratio of the ion concentration (divided by the stoichiometric factor) and the concentration of the undissociated state.

Applying this result, eqn. (24) reads

$$\Delta D = \frac{\frac{1}{2}\,\alpha^3\,U^+U^-\varepsilon\left(\frac{dE}{dx}\right)^2}{k\,(1-\alpha)\,[pq\alpha]} \tag{29}$$

$$[pq\alpha] \equiv p + q - \alpha\,(p + q - 1)$$

From the experimental point of view, the current heat is a critical magnitude. Introducing the electrical effect $w = \varepsilon\varkappa\left(\frac{dE}{dx}\right)^2$ watt/cm^3 and the ionic conductances $\Lambda_0^+ \simeq FU^+$, eqn. (29) transforms to

$$\Delta D = \frac{\frac{1}{2}\,\alpha^3\,w}{(1-\alpha)\,[pq\alpha]k}\,\frac{\Lambda_0^+\Lambda_0^-}{F^2\,\varkappa} \tag{30}$$

We will from now on assume $p = q = 1$ and $z = 1$. A modification may be attained by considering $\Lambda \simeq \alpha(\Lambda_0^+ + \Lambda_0^-) = 1\,000\ \varkappa/C$. Eliminating $\varkappa$ and introducing the equilibrium constant K gives

$$\Delta D = \frac{500\,K\,(w/C)}{k(2-\alpha)CF^2}\,\frac{\Lambda_0^+\Lambda_0^-}{\Lambda_0^+ + \Lambda_0^-} \tag{31}$$

The reason for using w/C is that the permitted Joule heat w increases with the density gradient of the column, which latter may be chosen greater with increasing concentration of the salt. Thus, according to eqn. (31), the order of magnitude of a measurable diffusion effect for a given electrolyte in our case varies inversely to the molarity of the salt. Another expression for a numerical estimation is

$$\Delta D = \frac{500\alpha^2\,(w/C)}{(1-\alpha)\,(2-\alpha)kF^2}\,\frac{\Lambda_0^+\,\Lambda_0^-}{\Lambda_0^+ + \Lambda_0^-} \tag{32}$$

obtained from eqn. (31) by eliminating K.

For the present we will prefer the formula

$$\Delta D = \frac{500\alpha^4 w}{(1-\alpha)^2\,(2-\alpha)KkF^2}\,\frac{\Lambda_0^+\Lambda_0^-}{\Lambda^+ + \Lambda_0^-} \tag{33}$$

for an estimation of the electrodiffusion effect, in order to use the value $w = 0.2$ watt/cm^3 which is sometimes given as a maximum value in electrophoresis work at the temperature (approx. 4° C) of the maximum density of water. Our requirements for undisturbed diffusion ought to be greater than those in general electrophoretic work, but on the other hand the cooling of the cell has been considerably improved in our work, so we may use this value as an upper limit. Assuming $\alpha = 1/3$, $K = 10^{-3}$, and the Λ-factor = 40 (international units), we get $\Delta D = 2/3 \cdot 10^{-5}/k$ cm^2/sec. Since $2 \cdot 10^{-5}$ is the

order of magnitude of the diffusion coefficients of common electrolytes in water, the calculation shows that $k = 1/3$ / sec., *i. e.* $T^\circ = 3$ sec., would give a diffusion effect of about 100 %. The molarity is, in this example $C = 0.006$.

With regard to the current to be used (see eqn. (28) the period length is in this example between $T^\circ = 3$ sec. and $T^\circ + T^\pm = 4.5$ sec. The conditions $T^\pm < \varepsilon\tau / 2$ and $T^\pm + T^\circ > \tau$ lead to $\varepsilon > 2\alpha$, independent of k.

These calculations refer to eqn. (2), case a) above, as it was introduced in eqn. (14). The case b), eqn. (3), leads to the expressions

$$\Delta D = \frac{250\alpha\varepsilon\tau(w/C)}{(2-\alpha)\ F^2} \frac{\Lambda_0^+ \Lambda_0^-}{\Lambda_0^+ + \Lambda_0^-} \tag{34}$$

and

$$\Delta D = \frac{250\alpha^3\ \varepsilon\tau w}{(2-\alpha)\ (1-\alpha)\ KF^2} \frac{\Lambda_0^+ \Lambda_0^-}{\Lambda_0^+ + \Lambda_0^-} \tag{35}$$

From these equations it is seen that the use of current shocks leads to an electrodiffusion effect, which is i n d e p e n d e n t of the kinetics of the dynamical equilibrium. This result of the calculation can be seen directly, since sudden shocks do not give an indication of life-times which are comparatively long. The reaction rate is, however, contained in the assumptions regarding order of magnitudes, which were made in case b). A numerical estimate shows clearly that a measurable effect may be obtained also under these conditions.

3. RANGE OF SYSTEMS

If the magnitude or sign of the electric charge of at least one of the constituents changes, then an electrodiffusion effect is possible. The same is true if the mobility of an ionic constituent varies with time, *e. g.* in the case of linear macromolecular ions or longchain polyelectrolytes. The mobility is in this case a function of the actual form of the ion. Other causes are: random changes in solvation, in the instantaneous properties of the medium or in the interionic forces. The reversible formation of micelles and other colloids, the formation of complexes, electron transfers, ampholytes and protolytic systems in general, and exchange reactions within the electrolyte or with an additional component, also belong to this field. An effect upon an added nonelectrolyte or upon the solvent is possible, if this component is bound to ions or reversibly dissolved (solubilized) in micelles. An interesting case may prove to be that of carbon dioxide, say according to the scheme $CO_2 + OH^- = HCO_3^-$. The diffusion of acids, with an equilibrium between *pseudo-* and *aci-*form, belongs to the category theoretically discussed above, since we may here find the delayed kinetics which are necessary in order to provide the region of measurable conditions.

A special field is represented by the presence of a solid structure, such as diffusion in an ion exchange column, in a gel or in an adsorbent.

4. COMPLETIVE REMARKS

Experiments in a special cell, cooled by water to approximately 4° C, have shown that reproducible measurements may be made at somewhat higher electric effects than the figure 0.2 watt/cm^3 given above. We have delayed publication, awaiting experimental evidence of the special effect in question. The publication of Mysels [5,1], in which the principles are the same, although in part rather differently outlined, has now caused the publication of this article.

The connection with the kinetics of the dynamical equilibrium is of interest and may, in special cases, lead to determinations which are difficult to obtain with simpler or more direct methods. It is of special value to obtain an insight into statistical details of the kinetics, which are not revealed by other methods, if this proves to be possible.

This work has been supported by the *Swedish National Research Council.* It has been performed parallel with other investigations and with forced interruptions. The official application to the Council, dated May 1953, contains a description of the electrodiffusion principles and the connection to kinetics.

The Synthesis of Some Organosilicon Alcohols. I

SUNE BRYNOLF

Department of Organic Chemistry, Chemical Institute of the University, Lund, Sweden

In order to prepare some organosilicon compounds containing hydroxyl groups attached to carbon atoms the reaction between propylene oxide and trimethylsilylmethylmagnesium bromide was investigated. The only silicon-containing alcohol that could be isolated was 4-trimethylsilyl-butanol-2. The constitution of this compound was proved by comparing it with authentic samples of the two alcohols that theoretically could be obtained.

A widely applied method of synthesizing alcohols is to let ethylene oxides react with Grignard compounds. A review is published by Gaylord and Becker [1]. Sommer, Van Strien and Whitmore [2] applied these reactions to silicon-containing materials. The Grignard reagents from chloromethyltrimethylsilane and 3-trimethylsilyl-1-bromopropane yielded on interaction with ethylene oxide 3-trimethylsilyl-propanol-1 and 5-trimethylsilyl-pentanol-1, respectively.

During attempts to repeat the former synthesis with trimethylsilylmethylmagnesium bromide instead of chloride, as in the paper [2], a low yield of the desired alcohol and a large amount of higher boiling materials were obtained. However, when the synthesis was made with the chloride, the stated yield was obtained.

In this work the reaction between propylene oxide and trimethylsilylmethylmagnesium bromide has been studied. Theoretically one or both of the two alcohols (I) and (II) may be formed, depending upon which way the oxide ring is opened.

$(CH_3)_3SiCH_2\text{-}CH_2\text{-}CHOH\text{-}CH_3$ (I)

$(CH_3)_3SiCH_2\text{-}CH(CH_3)\text{-}CH_2OH$ (II)

The only silicon-containing alcohol (A) that could be isolated from the reaction mixture must have had the constitution (I). This was evident partly from the fact that it was non-identical with the alcohol (II) that was obtained from α-methyl-β-trimethylsilyl-propionic acid, prepared by Sommer *et al.* [3] by reduction with lithium aluminium hydride; partly from the fact that those

of its properties that were studied were identical with the corresponding properties of the alcohol (I), obtained from 4-trimethylsilyl-butanone-2 by reduction with lithium aluminium hydride according to Perklev [4]. The data of the alcohols (I), (II) and (A) and their 3,5-dinitrobenzoates are collected in Table 1.

Table 1.

Alcohol	Bp °C	n_D^{20}	d_4^{20}	Mp °C of 3,5-dinitrobenzoate
(A)	81—82°	1.4301	0.8279	65—66° *
(I)	82° **	1.4301 **	—	65.5—66°
(II)	88—89°	1.4357	0.8375	44.5—45.5°

* Mixed m. p. with (I) 65.5—66° C.
** Data recorded by Perklev [4].

EXPERIMENTAL

4-Trimethylsilyl-butanol-2 from propylene oxide (A = I)

58.0 g (1.0 mole) of propylene oxide were dropped with stirring to the Grignard reagent prepared from 83.5 g (0.5 mole) of bromomethyltrimethylsilane, 12.0 g magnesium and 100 ml of absolute ether in a 1-litre flask equipped with a stirrer, a reflux condenser and a dropping funnel, and immersed in an ice-bath. When all the oxide had been added the ice-bath was removed, whereupon the temperature of the mixture generally rose enough to cause boiling. When this ceased the mixture was warmed on a water bath (45°—46°C) for 5—6 hours. The reaction mixture was decomposed with ice-water. Simultaneously the ether, tetramethylsilane and unreacted propylene oxide were distilled over. *Ca.* 8 g (0.1 mole) of tetramethylsilane could be recovered from the distillate by dropping it into concentrated sulphuric acid, cooled in an ice-and-salt bath.

The magnesium hydroxide precipitated by hydrolysis was dissolved by adding a sufficient quantity of dilute hydrochloric acid. The organic layer was separated and the water layer extracted with ether. The combined ether solutions were washed with a small quantity of water.

In an earlier experiment the resulting silicon-containing product was found to contain some bromine, probably due to the presence of propylene bromohydrin, formed upon hydrolysis of the reaction mixture. It was difficult to separate the bromohydrin from the formed silicon-containing alcohol through distillation and, therefore, the ether solution was shaken with small portions of dilute sodium hydroxide solution until a lasting red colour with phenolphthalein was obtained.

The ether layer was separated and the water layer extracted with ether. The combined ether layers were washed with water and dried with anhydrous sodium sulphate. The ether was removed and the mixture distilled in a Claisen flask at 25 mm Hg. A viscous residue was obtained. The distillate was fractionated in an efficient column and the fraction boiling at 81—82° at 25 mm Hg, 29.0 g (0.20 mole), was collected as pure 4-trimethylsilyl-butanol-2. $n_D^{20} = 1.4301$, $d_4^{20} = 0.8279$. (Found: C 57.0; H 12.5; Si 19.2, MR_D 45.6. Calculated for $C_7H_{18}OSi$: C 57.5; H 12.4; Si 19.2, MR_D 45.8).

3,5-Dinitrobenzoate was prepared according to a method described by Vogel [5]. 2.0 g of the 4-trimethylsilyl-butanol-2 were heated with 4.0 g 3,5-dinitrobenzoyl chloride in an oil bath at 110°C until the evolution of hydrogen chloride ceased. The mixture was cooled, and 40 ml of saturated sodium bicarbonate solution was added. The resulting ester was stirred until crystallization occurred. The precipitate was filtered at the pump and washed with a little sodium bicarbonate solution followed by water. The crystals were recrystallized twice from ethanol and water. The yield of crystals melting at 65.0—66.0°C was 2.8 g (*ca.* 60 %). (Found: C 49.1; H 5.8; Si 8.1. Calculated for $C_{14}H_{21}N_2O_6Si$: C 49.4; H 5.9; Si 8.2).

4-Trimethylsilyl-butanol-2 (I) from 4-trimethylsilyl-butanone-2

A few drops of the alcohol (I) were kindly placed at my disposal by Perklev, who synthesized it from 4-trimethylsilyl-butanone-2 by reduction with lithium aluminium hydride [4].

The 3,5-dinitrobenzoate was synthesized in the same way as above for the alcohol (A). M.p. 65.5—66°.

2-Methyl-3-trimethylsilyl-propanol-1 from α-methyl-β-trimethylsilylpropionic acid

22.8 g (0.143 mole) of *a*-methyl-*b*-trimethylsilyl-propionic acid dissolved in 215 ml of absolute ether were dropped into 7.6 g (0.20 mole) of lithium aluminium hydride in 260 ml of absolute ether. When all had been added the mixture was refluxed for 3 hours. Hydrolysis with water and diluted hydrochloric acid and extraction and drying were carried out in the usual way. Fractionation of the ether solution yielded 14.2 g (0.097 mole) of the desired alcohol, b.p. 88—89°C at 25 mm Hg. (Found: C 57.2; H 12.6; Si 19.4, MR_D 45.6. Calculated for $C_7H_{18}OSi$: C 57.5; H 12.4; Si 19.2, MR_D 45.8).

3,5-Dinitrobenzoate. From 2.0 g of 2-methyl-3-trimethylsilylpropanol-1 2.3 g of the 3,5-dinitrobenzoate of m.p. 44.5—45.5° were obtained. (Yield 50 %.)

The author wishes to express his gratitude to Professor Erik Larsson for his kind interest in this work.

Studies on the Interaction of Paraffin-Chain Alcohols and Association Colloids

VII. Microscopic Investigation of the Interaction between some Liquid Alcohols and Sodium Laurate Solutions

PER EKWALL, MILAN SALONEN, INGMAR KROKFORS and INGVAR DANIELSSON

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

The formation of a mesomorphic phase as a result of the interaction between aqueous sodium laurate solutions and liquid paraffin-chain alcohols has been studied with the microscope. The first signs of this interaction occur at the L.A.C. The interaction product is predominantly hydrophilic and analyses show that it contains both alcohol and soap. The water content of this product seems to vary; the birefringence diminishes with increasing water content. When decanol interacts with laurate solutions, the molar ratio of alcohol to soap in the separated phase varies from about 1:2 to about 4-5:1, the alcohol content rising as more alcohol is added to the system. The interaction proceeds in several steps. The first amounts of alcohol added form soluble aggregates with the soap, mixed micelles or smaller aggregates. Then alcohol, soap and water separate as a mesomorphic phase. With further alcohol additions, more and more soap is transferred from the aqueous solution to the separated phase until the soap concentration of the solution decreases to a minimum value. Also after this point is reached, the separated phase takes up added alcohol. Finally this uptake reaches a limit and the alcohol appears in the free form. Soap solutions in equilibrium with the mesomorphic phase are not saturated with alcohol. Saturation is reached only when drops of free alcohol appear in the system.

As one of us has shown previously, microscopic observations can be used with advantage to study the interaction between an aqueous soap solution and fatty acid [1–4]. A method based on such observations was developed for the determination of the limiting concentration (L.A.C.) in soap solutions [3]. Subsequently the same method was found to be suitable for the study of the interaction between long-chain alcohols and association colloid solutions [5,6]. In the following we shall describe the results of further investigations in which

the same method has been used. In these investigations special attention was directed to the first stages of the interaction, but the appearance of the interaction product at later stages and its composition were also studied.

EXPERIMENTAL

Sodium laurate was prepared in the usual manner from pure lauric acid and sodium ethylate. Conductivity water with a specific conductance less than 1×10^{-6} $ohm^{-1}cm^{-1}$ was employed in the preparation of the soap solutions.

The paraffin-chain alcohols were the same as those used in the previous investigations of this series.

The concentrations of the soap solutions are given in moles per litre of solution, M.

The microscopic observations were made with a Leitz Dialux microscope equipped with phase-contrast and dark-field condensers. Some observations were made also in polarized light (between polaroid plates). While the observations were being made, care was taken to avoid evaporation from the aqueous solutions.

A. INTERACTION BETWEEN DECANOL AND SODIUM LAURATE

The first signs of interaction. The experiments were performed in such a manner that the interface between a decanol drop and the surrounding sodium laurate solution could be examined in the microscope from the moment when they came into contact with each other.

In extremely dilute solutions, when the laurate concentration is below 0.004—0.005 M, the interface between the drop and the solution remains sharply outlined and undergoes no change with time (Fig. 1 a). When the concentration exceeds 0.005—0.006 M, a pronounced change indicating inter-

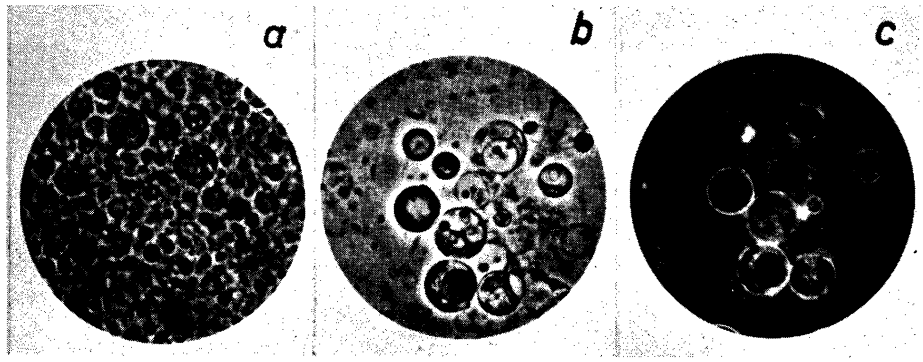

Fig. 3. Final stage of the interaction between decanol and laurate.

c) The same sample as in b. Dark field condenser. 600 ×.

action between decanol and soap is observed. This change is noted immediately after decanol comes into contact with the laurate solution. The interface becomes uneven, cavities form on the surface of the decanol drop and small particles are dislodged. With the dark-field condenser numerous bright points are seen in vigorous motion in the vicinity of the drop surface. Very soon, however, a corona of hairlike filaments grows from the drop surface (Figs. 1 b, c, d,). Later this corona becomes uneven (Figs. 1 e, f), especially in solutions of high laurate concentration (Figs. 1 g, h, i). (The initial stages of the interaction, before the corona is formed, are difficult to observe, and we have not succeeded in photographing them.)

After the layer of interaction product is formed about the decanol drop, the interaction proceeds much more slowly, particularly in dilute laurate solutions. The outer ends of the filaments in the corona swell and form sausage-shaped figures (myelinic figures) which continue to expand (Figs. 2 a, b). Ultimately the expanded outer ends are disengaged and form clusters of spherical particles which stream out (Fig. 2 c) and are gradually dispersed uniformly in the solution (Fig. 2 d). In the concentration range, 0.02—0.03 M, on both sides of the C.M.C., it is observed that the solubility of the interaction product in the soap solution increases. This has been confirmed by quantitative measurements [6-7].

The final product of interaction. A laurate solution above the C.M.C. is able to solubilize a certain amount of decanol. When an excess of decanol is added, there results a turbidity caused by the separated interaction product. Below the turbidity point, no ultramicroscopic particles are seen on dark-field illumination in decanol-containing laurate solutions, but above this point there occur particles of ultramicroscopic and larger dimensions. The degree of dispersion depends on the mode of preparation and on the decanol and laurate contents of the system. When the decanol content is low, *e.g.* when a new phase

separates on cooling from solutions that are clear at higher temperatures, all the particles are very finely dispersed, ultramicroscopic. When larger amounts of decanol are added to the laurate solutions, the new phase separates in the form of particles of different sizes. The system resembles a semi-transparent emulsion.

In order to be able to examine the final products of the interaction, the following procedure was followed.

A 0.05 M sodium laurate solution containing one mole of decanol per mole of laurate was heated in a sealed ampoule in a water-bath to 75—80°C and shaken thoroughly to

promote the interaction of decanol and the soap. While the shaking was continued, the ampoule was allowed to cool to 40°C, and shaken for two days at this temperature. It was expected that in this way the interaction would be brought to completion.

As seen in Fig. 3 a, the solution now contained an agglomerate of spherical particles of different sizes, from 5—10 μ in diameter downwards. With oil immersion and 900-fold magnification, it was established that there was no lower limit to the sizes of the particles; the number of very small particles was exceedingly large. With the dark-field condenser it could be established that the solution contained numerous ultramicroscopic particles in vigorous Brownian motion.

In some cases another procedure was followed in preparing the solutions.

For example, a 0.014 M sodium laurate solution containing 0.6 moles of decanol per mole of laurate (and 0.05 moles of sodium hydroxide per mole of laurate to suppress the hydrolysis) was thoroughly shaken in a sealed ampoule at room temperature until the decanol was dispersed into small droplets barely visible to the naked eye. The solution was then allowed to stand for two months at room temperature to permit the interaction to continue to completion.

Also in this case the product of interaction was found to consist of spherical particles, but so that smaller particles often were embedded in the larger ones; sometimes one large particle contained many small spheres (Fig. 3 b, c). The refractive index of the substance appeared to differ from sphere to sphere; it seemed as if the decanol content was not the same in all spheres. Also some small drops of unreacted decanol could be seen alongside the interaction products.

It is thus evident that this latter mode of preparation cannot guarantee a complete interaction between the decanol and soap and therefore does not yield an uniform interaction product. The local decrease in the soap concentration of the solution and the accumulation of the separated interaction product, which hinders the contact between solution and decanol, must be prevented by shaking.

0.01—0.05 M sodium laurate solutions with different decanol additions prepared in the first-mentioned manner were investigated systematically. The appearance of the interaction product varied greatly. The sizes of the particles varied from very small particles in vigorous Brownian motion and observable only in dark-field illumination to large spheres about 10^{-2} mm in diameter; the refractive power of the separated phase varied from values near to values greatly deviating from that of the surrounding aqueous solution. At lower laurate concentrations, but above the L.A.C. (*e.g.* in the 0.01—0.014 M sodium laurate solutions) the separated phase appeared as a finely dispersed substance which was indistinct with both phase contrast and dark-field illumination and as fairly large spheres or drops of different sizes which were empty in dark-field and only weakly visible in phase contrast illumination. At higher laurate concentrations, above the C.M.C., (*e.g.* in the 0.04 M sodium laurate solution) and when the decanol additions were relatively small (up to 0.48 mole of decanol per mole of laurate), the separated phase appeared partly as a very finely dispersed substance, partly as small more or less compact spheres clearly outlined in phase contrast and dark-field illumina-

tion. With somewhat higher decanol additions, also in these cases the previously mentioned large, almost invisible spheres appeared. With increasing decanol content, the number of the large spheres increased, but the smaller distinctly outlined spheres did not disappear. There is thus a clear difference in the appearance of the particles of the separated phase above the L.A.C. (up to about 0.02 M sodium laurate) and above the C.M.C. The difference diminishes to some extent when larger amounts of decanol are added.

Observations on the properties of the interaction product. The interaction product is a viscous liquid. Decanol drops covered with a filamentous layer of interaction product approach each other until the ends of the filaments touch. When the drops are pressed together the filaments give way, but when the external force is removed they straighten out again and the drops separate from each other. The filaments are thus elastic. The same applies to the coarser myelinic figures and spherical particles. Examination in polarized light between polaroid plates showed that the interaction product is birefringent (Fig. 4). We have thus a liquid in the mesomorphic state [8,5,6].

In order to determine whether the interaction product is predominantly lipophilic or hydrophilic, the decanol was coloured with a typical fat-soluble dye, Sudan Red.

When the deep-red-coloured decanol interacted in the laurate solution, the dye remained in the decanol drops and the colour of the latter intensified until finally the dye separated as small granules. After all the decanol had been used up in the interaction, small dark red granules of Sudan Red remained among the interaction products at the points where the decanol drops had been earlier.

The dye facilitated the study of the various stages of the interaction. It was now found that sometimes a thin stream of dyed decanol flowed from the decanol drops into the layer of interaction product or into the solution where it more or less rapidly reacted with the soap. Sometimes the connection between the main drop was broken and the decanol formed a new drop that reacted further.

The interaction product was undyed. (A weak rose colour sometimes noted in the layer of the filamentous product was due to minute Sudan Red particles embedded here and there which had separated when the decanol had reacted.) No signs indicating that Sudan Red dissolves in the interaction product were seen. The conclusion was drawn that the interaction product was predominantly hydrophilic.

This was confirmed by experiments in which laurate solutions were coloured with the water-soluble dyes, Azo-blue and Wollecht-violet, which are insoluble in decanol. So far as we could determine, the interaction product was coloured in this case.

The phase formed at the interface between the decanol drop and the soap solution is thus a hydrophilic liquid in the mesomorphic state, probably of the smectic type. This phase seems to swell by taking up more water or soap solution, during which the birefringence diminishes and may disappear completely. The refractive index of the new phase approaches that of the surrounding solution. As mentioned above, this is especially the case in the concentration range above the L.A.C. up to a sodium laurate concentration of about 0.02 M.

Table 1. The decanol and sodium laurate contents of the interaction products formed in 0.014 M sodium laurate solutions to which various amounts of decanol had been added.

Decanol added, moles per mole of sodium laurate	Dried separated product mg	Decanol content of the dry product mg	Sodium laurate content (corrected *) of the dry product mg	Molar ratio of decanol and sodium laurate in the water-free reaction product
0.3	9.9	2.3	7.1	(0.5 :1)
0.3	145.0	29.2	106.4	0.44:1
0.3	89.6	21.3	61.9	0.48:1

1.0	68.4	28.6	35.1	1.2 :1
1.5	46.0	19.7	16.9	1.6 :1
1.5	102.0	42.1	35.8	1.6 :1
2.0	382.0	234.5	125.8	2.6 :1
3.0	425.0	310.5	93.4	4.7 :1

* The correction is based on the assumption that all the water of the isolated product is present as occluded sodium laurate solution. A part of the water belongs, however, to the separated phase itself. The correction is therefore somewhat too large and the decanol-soap ratios in the last column are thus maximum values.

The decanol content of the interaction product. An attempt was made to isolate for analysis the interaction product that appeared as a separate phase, but a complete separation from the solution was not achieved.

A series of 0.014 M sodium laurate solutions containing different additions of decanol were prepared as described above. The solutions were left to stand one month at 40°C, during which time the lighter interaction product gradually rose to the surface from which it was collected. This concentrate was passed through a membrane filter, first under slight pressure and finally by applying suction. The remaining highly viscous product still contained some of the laurate solution that could not be removed.

This product was dried and the water content calculated. Decanol was then removed from the dry residue by distillation and its amount determined. The distillation residue was acidified and the liberated lauric acid extracted with ether. Part of the fatty acid came from the soap dissolved in the occluded laurate solution. The amount of this lauric acid was subtracted and after this correction, the composition of the interaction product was calculated; the water content of the product could not be established. The calculated values are only approximate, but do, however, give an idea of the composition of the separated interaction product.

The data in Table 1 show that the interaction product contains both decanol and sodium laurate. They suggest that in the case of small decanol additions to the solution, the molar ratio of decanol to sodium laurate is near 0.4—0.5. With higher decanol additions, the decanol content of the separating phase increases, the ratio rising to about 1.6 when the amount of added decanol increases to 1.5 moles per mole of laurate. When further amounts of decanol are added, the decanol content of the separated phase increases more rapidly.

As will be shown below, free decanol occurs in the 0.014 M sodium laurate solution only after about 2.5 moles of decanol per mole of laurate have been added.

It is thus evident that the composition of the phase containing decanol and soap is a function of the total decanol content of the system. The interaction between the soap in solution and the decanol does not end when the new phase appears at the turbidity point. The interaction progresses further, but now the decanol is not incorporated in the micelles of the solution but in the separated phase and at the same time more and more soap is removed from the solution. Only after the soap concentration of the solution is decreased to a rather low value, does the interaction with the soap in the aqueous phase end.

Previously we have come to the same conclusion on the basis of conductance measurements.[9] These measurements showed that the decanol content of the separated phase increases with the amount of added decanol at the same time as the concentration of soap in the water phase decreases. The composition of the product which separates from 0.010—0.014 M sodium laurate solutions was calculated (from conductance values) to be 0.6—0.8 mole of decanol per mole of sodium laurate at the turbidity point, but was found to increase to about 4:1 after 1.5 moles of decanol had been added per mole of laurate. (These calculations, which were made on the assumption that the separated phase does not play any part in the transport of current, thus give higher decanol contents than the analyses.)

The calculations made on the basis of conductance measurements also showed that the composition of the separated phase varies with the concentration of the soap solution in which it is formed; in 0.1—0.5 M sodium oleate solutions the composition at the turbidity point was found to be 0.5 moles of decanol per mole of oleate, but at lower oleate concentrations the decanol content increased to 1 mole or more per mole of oleate.

In this connection it may be noted that it was previously found that the mesomorphic acid soap that separates from caprate solutions when capric acid is added has the composition 1 mole of capric acid to 2 moles of sodium caprate and 13—20 moles of water [4]. These acid soaps and the decanol-soap interaction products studied here resemble each other in many of their properties.

The maximum amount of decanol that dissolves in the system. We have previously found that the conductance of the system decreases to a constant value when sufficient decanol has been added. The composition of the separated phase at this point was calculated to be 3.0—3.5 moles of decanol per mole of soap in the 0.010—0.022 M sodium laurate solutions. We have also pointed out that drops of free decanol were observed in the range where the conductance was no longer altered by added decanol.

In a series of 0.010, 0.014, 0.023, 0.030 and 0.040 M sodium laurate solutions containing 0.1—10 moles of decanol per mole of laurate, a study was made of the amount of decanol that a known volume of the soap solution can transfer to the separated mixed phase. Microscopic examinations showed that drops of free decanol occurred in these solutions when the molar ratio of decanol to soap had risen in the respective cases to 2, 2.5, 3.5, 4.0 and 4.5. Considering that only a part (C_{tot}—$C_{L.A.C.}$) of the soap takes part in the formation of the

mesomorphic phase, the ratio in the new phase increases in all cases to 4—5 moles of decanol per mole of laurate. This shows that free decanol occurs in the investigated systems soon after the conductance has decreased to a constant value; small amounts of decanol seem to dissolve in the separated phase even after the interaction with soap in the aqueous phase has gone to completion. (At higher soap concentrations, *e.g.* in the 0.1—0.3 M sodium oleate solutions, the separated phase dissolves appreciable amounts of decanol between the point where the conductance becomes constant and the point where free decanol separates).

B. INTERACTION BETWEEN SODIUM LAURATE AND LIQUID ALCOHOLS OF VARYING CHAIN LENGTH

We have employed the above-described microscopic technique in a study of the interaction of sodium laurate solutions with octanol-1, heptanol-1 and hexanol-1. Similar effects were observed with all alcohols. The solubilities of the alcohols increase, however, with decreasing chain length of the alcohols, and likewise the solubilities of the products of the interaction with soap increase. As a result of this, the interaction proceeds more rapidly and some of the phenomena observed with decanol are weaker or are not observed at all.

On the surfaces of the octanol drops the characteristic layer of filamentous structure composed of birefringent liquid phase was formed. A similar layer developed also on the surfaces of the heptanol drops but did not retard the interaction to the extent noted in the case of decanol and octanol. No continuous layers were produced round the hexanol drops; the dissolution proceeded rapidly and led to complete disappearance of the drops. The end products of the interaction assumed in all cases similar filamentous, myelinic and spherical forms as in the case of decanol.

Separate experiments were made to determine the lowest laurate concentration at which the first signs of interaction with the different alcohols could be detected at 20°C. The laurate solutions employed contained 0.1 mole of sodium hydroxide per mole of laurate to suppress hydrolysis. For decanol, the laurate concentration was found to be 0.0045—0.0055 M; for octanol 0.0055—0.0061 M; for heptanol 0.0061—0.0068 M; and for hexanol 0.0061—0.0068 M. For all alcohols the reaction thus begins in the same relatively narrow laurate concentration range extending from 0.0045 to 0.0068 M. Within this range, the concentration where the first signs of interaction are noted with the microscope varies slightly with the chain length of the alcohol; this may be primarily due to the greater solubility of the reaction product with decreasing chain length of the alcohol.

The observed lowest laurate concentration range, 0.0045—0.0068 M, where interaction with alcohols occurs is in good agreement with the results of our previously published turbidity measurements.

C. INTERACTION WITH CRYSTALLINE ALCOHOLS

Some observations were also made on the interaction between sodium laurate solutions and crystalline dodecanol-1, tetradecanol-1, hexadecanol-1 and octadecanol-1. This interaction differs in principle from that observed with

the lower liquid homologues. The alcohol crystals swell rapidly when they come in contact with the soap solution; they seem to split into thin parallel layers which appear to be held together by a semisolid substance. The alcohol layers also expand in length and breadth; small reacting crystals often move forward quite rapidly, leaving behind a wide tail of interaction product with the layers parallel to the crystal surface. One gets the impression that the soap solution penetrates into the crystal between its double layers of parallel alcohol molecules and that soap concentrates there and also penetrates into the layers of alcohol molecules. The interaction product is birefringent and the interaction with alcohol crystals occurs at rather low laurate concentrations.

The study of this interaction is being continued.

DISCUSSION

In the previously described nephelometric measurements, the first sign of interaction between soap and alcohol at the L.A.C. was the disappearance of the excess of alcohol [10,11]. In the above-described microscopic method, on the other hand, one observes the formation of the mesomorphic phase. Neither of these methods gives information of the changes occurring in the solution, but with the aid of a third method (solubility measurements) we obtain an idea of what happens in the solution; we find that the solubility of the alcohol (decanol-1) increases somewhat above the L.A.C.[6,7]. These three methods give the same value for the concentration (L.A.C.) where the interaction begins; the small differences between the values depend on the fact that the three methods register different phenomena associated with the same process.

In the microscopic observations, the interaction between alcohol and soap solution appears as a reaction taking place at the interface. No changes or processes that take place within the alcohol phase are observed, whereas one gets an idea of the solution of the alcohol in the aqueous phase and of the conditions favouring the formation of the mesomorphic phase when the alcohol concentration increases locally to a certain value. In the interface (also on the alcohol side) there must occur an adsorption of soap and a formation of palisade layers composed of parallel alcohol molecules and soap ions. The interfacial tension must be very low. An extensive dispersion into very fine particles follows ("spontaneous emulsification") and the rapid solution of the alcohol in the water phase in the vicinity of the phase boundary is facilitated. These processes make it possible for the corona to grow out from the interface. The palisade layers of alcohol and soap formed in an environnement rich in alcohol but poor in water take up more water and perhaps more soap with swelling. We refer again to the swelling of the filaments; their strong birefringence decreases and spherical drops are produced. We wish to emphasize that the formation of the mesomorphic alcohol-soap-water phase does not presuppose the presence of soap solution-alcohol interfaces in the system, even if the formation of the corona-like structures does so. This phase can be formed directly from the components in the solution, *e.g.* on cooling the homogeneous solution. Soap solutions in equilibrium with the mesomorphic phase are not saturated with respect to alcohol and the concentration of free alcohol in them is much lower than in a saturated aqueous solution of the alcohol; conditions favouring the

formation of the phase mentioned are produced when the concentrations of soap and free alcohol increase over certain limits.

In the cases we have investigated the interaction between decanol and soap solution passes through several steps. The first amounts of added alcohol (in excess of that which dissolves in the water) form soluble aggregates with the soap; the alcohol solubilizes in micelles or forms smaller soap-alcohol aggregates. When more alcohol is added, a separate phase consisting of alcohol, soap and water is formed; with increasing alcohol additions, more and more soap is removed from the water solution to form more of the separated phase until the soap concentration of the solution is decreased to a minimum value. Also after this minimum value is reached and the interaction with soap in the solution ends, the separated alcohol-soap-water phase takes up added alcohol. Finally also this uptake attains a limit, and the alcohol appears in the free form. Only at this point does the system become saturated with alcohol. In sodium laurate and sodium oleate solutions at 20°C, the system at this point consists of three phases, the aqueous solution, the alcohol-soap-water phase and free decanol.

Both the alcohol-soap ratio and the water content of the alcohol-soap-water phase seem to vary between rather wide limits. If there is a continuous transition between the different compositions and forms of this interaction product or if the product possibly forms more than one phase is not clear. See, for example, the previously described rather sharp turbidity maxima which result when decanol is added to soap solutions in increasing amounts [9].

The character and composition of the substance that separates from association colloid solutions above the L.A.C. when alcohol is added in sufficient amount seems to have been unknown to most of the investigators in this field. This had led to a misinterpretation of the results of the solubility determinations in connection with studies of the solubilization of alcohols. Already in 1947 one of the present writers [8] postulated the difference in the solubilization mechanism of nonpolar and polar compounds and called attention to the fact that a liquid-crystalline product separates from sodium oleate solutions when octanol or hexadecanol is added and that this is accompanied by a fall in the conductance. In the same paper the solubilization of terpineol was also reported and it was shown that terpineol first dissolves readily in a 0.3 M oleate solution, but then causes the system to become heterogeneous when more than 4.5 % is added. The system becomes homogeneous again when still more terpineol is added. The solution was found to be definitely saturated with terpineol only after more than 26 % had been added. At the first turbidity point the viscosity passed through a very pronounced maximum, and after adding 13—16 % terpineol a second, rather low viscosity maximum was noted; the conductance was observed to decrease rapidly above the first turbidity point, but then passed through a minimum. In the saturated systems, both the viscosity and conductance remained constant. It was reported that many other substances effect similar phenomena. Menthol and decamethylene glycol were, however, found to solubilize normally in rather high oleate concentrations, *i.e.* the excess of these substances separated in pure form [8]. These investigations showed the necessity of making observations of the nature of the separated phase in solubilization studies.

Later [5,12] it was shown that a liquid-crystalline product is generally formed when paraffin-chain alcohols interact with aqueous association colloid solutions of the paraffin-chain type (fatty acid soaps, alkyl sulphates, alkyl trimethyl ammonium salts) and that the product contains both alcohol and colloid. It was emphasized that a large part of the colloid can be precipitated in this way from the solution, by adding sufficient amounts of the alcohol. It was also shown that the mesomorphic phase forms only above the L.A.C. and that the maximum solubility of the alcohol increases slightly somewhat above this point (before the system becomes heterogeneous). The great similarities between the interaction between alcohols and association colloid solutions and the formation of acid soaps in the interaction of soap and fatty acid were stressed. Ekwall, Passinen and Danielsson [6] reported on the formation of the mesomorphic alcohol-soap-water phase in a brief survey of their experimental work conducted during 1950—53 on the solubilization of alcohols, and pointed out the differences between the solubilization of alcohols and hydrocarbons. In the present series the results of this work is thoroughly discussed. In Part I [13] it was for instance emphasized that the solubility curves for paraffin-chain alcohols are not comparable with those obtained in studies of hydrocarbon solubilization.

In 1948 Winsor also reported on the separation of birefringent "gels" in systems which, however, contained besides a hydrotropic substance, alcohol, and water, also a hydrocarbon or a mixture of hydrocarbons and thus were rather complex; only in one case did Winsor give experimental data on the formation of a "gel" in a system containing no hydrocarbon (sodium-*n*-butyrate-octanol-water) [14]. Klevens, referring to his own observations and to Winsor's work, mentioned that added polar long-chain compounds and soaps readily form viscous birefringent "gels" [15]. However, in the same paper the solubility curves for alcohols were directly compared with those obtained for hydrocarbons. Lumb investigated the phase equilibria in mixtures of alcohols and aqueous potassium butyrate and octanoate solutions and showed clearly that in some cases a mesomorphic phase composed of soap alcohol and water separates over a wide concentration range [16]. Recently. Hyde, Langbridge and Lawrence, on the basis of extensive experimental observations, primarily on aqueous Teepol-alcohol systems, discussed "soap + water + amphiphile systems" [17]. In their work the study of the formation of a liquid-crystalline phase consisting of alcohol, association colloid and water holds a central place; also the disappearance of this phase on adding greater amounts of alcohol was studied. They showed that there occur two ranges of homogeneous systems (compare Ekwall's [8] observations on the sodium oleate-terpineol systems and Lumb's [16] on the above-mentioned soap-alcohol systems). The viscosities and conductances of the Teepol-systems pass through maxima and minima (somewhat similar to those previously observed in other association colloid-alcohol systems [8,6,9,18]). Lawrence and coworkers state that a similar phase equilibrium pattern has been found to apply to all soaps and all amphiphilic additives of the long-chain type. They emphasize the serious error incurred in many earlier studies when "the initial separation of the liquid-crystalline phase was taken to be emulsion and excess of the amphiphile above saturation . . ."

Summarizing it can be said that Ekwall and coworkers have studied the changes in the aqueous association colloid solutions when alcohol is added both before and after the mesomorphic phase has formed and have attempted an exact determination of the conditions favouring the formation of this phase. They have also studied the properties and composition of this phase, but their investigations were in only a few cases extended to the addition of more than 5 moles of the alcohol per mole of the colloid. The English investigators have studied the systems from the viewpoint of the phase equilibria and have been interested also in those systems where the polar substance predominates; they have attempted to draw equilibrium diagrams for the ternary systems. Only in a few cases have the same systems been studied in these different investigations. They complement each other and give a fairly good idea of the interaction between polar substances and aqueous association colloids, even if there still are many unsolved problems in this field.

Dimethylsulphoxide, a Solvent for Hemicelluloses

ERIK HÄGGLUND, BENGT LINDBERG
and JOHN McPHERSON

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden and Institutionen för Träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

Part of the holocellulose of birch or spruce can be extracted with dimethylsulphoxide and further quantities are extracted from the swollen material by a subsequent treatment with water. The extraction is quite mild, and the fractions still contain a high percentage of the acyl groups (acetyl and formyl) originally present in the wood. Partial fractionation of the hemicellulose components is achieved by the extractions. Dimethylsulphoxide can also be used as a rather selective precipitating agent for hemicelluloses.

In a recent investigation at this Institute [1], it was found that dimethylsulphoxide (D.M.S.) was an excellent solvent for cellulosexanthates of a low D.S., in which the xanthate groups had previously been reacted with chloro-di-N-ethyl-acetamide. It was superior to other solvents, *e. g.* dimethylformamide. We therefore considered it worth while to investigate the possibilities of D.M.S. as a solvent for hemicelluloses, and in the present paper a preliminary study on this subject is reported.

A birch holocellulose, a spruce holocellulose and a spruce sulphite pulp have been investigated. They were all extracted with D.M.S. at room temperature, with cold and with hot water and finally with 18 % sodium hydroxide solution. The fractions were collected and analysed, the results being summarized in Tables 1, 2 and 3. The recovery of extracted material is not quantitative, partly because further fractionations were performed before the fractions were dried and weighed, which involved losses, and partly because the polysaccharides in some extracts were not completely precipitated. In separate experiments, however, it was shown that a good recovery could be obtained.

From the Tables 1, 2 and 3 it is evident that a considerable part of the hemicellulose is extracted with D.M.S. The cellulosic material exhibits considerable inter-micellar swelling during the extraction and this is probably the reason why so much material is extracted during the subsequent treatment with water. In the D.M.S. extract from the birch holocellulose, a high percentage of acyl groups was found, recorded as acetyl, although it is known that

formyl group are also present. One of the chief advantages of the extraction method is that hemicellulose fractions, with the original acyl groups still present, have been made available for investigation. The xylose still dominates in the D.M.S. fraction but the non-xylan polysaccharides have been considerably enriched, and the fraction is a good starting material for an investigation of these completely unknown polysaccharides. The water extract is essentially a pure xylan with high percentages of acetyl and of uronic acids. As it is possible that the acetic and formic acids in the wood are chiefly combined

with the xylans, this is an especially interesting starting material for further investigations.

The polysaccharides in conifers constitute a complicated mixture, and it is obvious that a considerable partial fractionation has been obtained by the extraction of the spruce holocellulose. There are great differences in composition between the D.M.S. extract and the water extract, xylose dominating in the first and mannose in the second. Also here the acyl groups have survived the extractions. Mannose seems to occur in two different types of polysaccharides, one easily extracted and one very insoluble, which, of course, is known also from previous investigations. It is unknown whether there are structural differences between the two types or if the different solubilities are due to morphological reasons. The two types are enriched in the D.M.S. fraction and in the extraction residue, respectively. The high percentage of arabinose in the D.M.S. fraction probably comes from an arabogalactan, which seems to be present in most conifers, and in this case most of the combined glucose-galactose of this fraction, recorded in Table 2, should be galactose.

From the spruce sulphite pulp, an almost pure xylan, with a high percentage of uronic acids, was obtained from the D.M.S. extract.

It is evident from the experiments described above that some types of polysaccharides are quite soluble in D.M.S. and others are not. One would deduce that the more highly branched or substituted polysaccharides should show the greatest solubility. It was therefore natural to investigate whether D.M.S. could be used, too, as a selective precipitating agent. The 18 % sodium hydroxide fraction from spruce holocellulose in aqueous, neutral solution was added to six times its volume of D.M.S. and after 16 hours, the precipitate was collected. The residual solution was then added to ethanol four times the volume of the original aqueous solution, when further amounts of material precipitated. The analyses of the fractions (Table 4) show that a considerable fractionation has been achieved and that chiefly the mannose-containing polysaccharides were precipitated by D.M.S.

When some of the material precipitated by D.M.S. was treated with 7 % sodium hydroxide solution at room temperature, only part of it went into solution. The insoluble material contained glucose and mannose as the only sugars, with the latter dominating. The recent work of Anthis [3] strongly indicates that at least part of the mannose in conifers is present as a glucomannan, and this fraction thus might be a homogeneous polysaccharide. The material

Table 4. Fractionation with D.M.S. as precipitating agent.

Fraction	Uronic acids, %	(Galactose + Glucose) : Mannose : Arabinose : Xylose
18 % NaOH extract, precipitated with ethanol	11.0	13.5 : 48.0 : 2.3 : 36.2
18 % NaOH extract, precipitated with D.M.S.	8.56	13.7 : 66.5 : 0.7 : 19.1
Residual solution, precipitated with ethanol	16.1	5.3 : 16.0 : 4.2 : 74.5

obtained by precipitation of the residual solution with ethanol was rich in xylose and uronic acids, contained only traces of mannose but other sugars were not detected in the hydrolysate.

When extracted but undelignified wood powder under the same conditions was treated with D.M.S. no significant amounts of carbohydrate material went into solution.

In this preliminary work, no attempts have been made to study the optimum conditions of extraction and precipitation with regard to the concentration and pH of the D.M.S. and of the temperature and duration of the treatment. The D.M.S. is a very slightly alkaline solvent obtained as a white crystalline material (M. p. 18.5° C) and shows partly an "aldehydic" and partly an unsaturated character. It is easily recoverable by distillation under reduced pressure and is miscible with many organic solvents, except the aliphatic hydrocarbons, and with water. As with dimethylformamide it is strongly hygroscopic and at 20° C has an equilibrium moisture content of 10 %. Because of these properties it should have great potentialities in the isolation of undenatured polysaccharides. Whether it effects any marked degradation in the cellulose and hemicellulose components and its exact mode of operation is not yet known. It does appear that the swelling of the pulps and holocelluloses is mainly inter-micellar from experiments on the moisture regain of the samples.

EXPERIMENTAL

The D.M.S. used in this investigation was as obtained from the manufacturer and was not further purified.

All concentrations were carried out at reduced pressure and at about 40° C. All precipitates were investigated by qualitative chromatography after total hydrolysis, using the solvent systems; ethyl acetate-acetic acid-water (3:1:1), butanol-pyridine-water (6:2:3) and butanol-formic acid-water (100:23:77). Most fractions were also investigated by quantitative paper chromatography, using the method of Saeman *et al.*[4]. As aldobiuronic acids are essentially not hydrolysed under the conditions used, the values for xylose are consistently too low.

Birch holocellulose. The birch wood used was a technical mixture of *Betula verrucosa* and *B. pubescens*. The chips were handsorted, ground in a Wiley mill and the fraction of particle size less than 0.5 mm removed by sieving. The remaining wood powder was extracted with acetone in a continous extractor for 24 h, air-dried and delignified, using the sodium chlorite method as modified by Saarnio, Wathén and Gustafsson [5]. The yield of air-dried holocellulose, based on the extracted wood, was 82.7 %, a rather high value, indicating that the delignification was not complete.

The holocellulose (146 g, calc. as oven-dried weight) was extracted with D.M.S. (1 000 ml) at room temperature for 20 h. The extraction was performed in a desiccator and by applying and releasing a vacuum a number of times a good penetration of the solvent was effected. The mixture was filtered and the residue given a further treatment with D.M.S. (760 ml) for 2 h. After this extraction the holocellulose was washed with water (1 000 ml) for five min and filtered. The residue was extracted with water (1 000 ml) at room temperature for 20 h and then with hot water (1 000 ml, 90—95°) for 4 h. To each of the extracts was added four times its volume of ethanol and a few drops of conc. hydrochloric acid and the mixtures were allowed to stand for 24 h. The cold water extract yielded no precipitate but from all the others precipitates were recovered by decantation and centrifugation. The precipitates were washed with ethanol and with benzene and dried under a vacuum, and were thus obtained as white or almost white powders.

Concentration of the residual solutions from the aqueous extracts to small volumes (~ 150 ml) and addition of large excesses of ethanol yielded further precipitates, rather

similar in composition to the first precipitate from the hot water extract. Further concentration of the mother liquors from the aqueous extracts produced no additional amounts of polysaccharide material but deep orange or brown syrups which probably contained modified lignin products. The residues from the D.M.S. extracts were not further investigated but probably contained more soluble polysaccharides.

Part of the holocellulose residue (60 g) after the extractions with D.M.S. and water was given an extraction with 18.1 % sodium hydroxide solution (1 000 ml) for 25 min at room temperature, the mixture was then diluted with water (3 000 ml), stirred for 5 min and filtered. The residue was washed with water, 10 % acetic acid and water again and air-dried in order to determine the yield. The extract was adjusted to pH 6, then to pH 2, and kept at this pH-values for several days at 4°, according to the procedure of McPherson and Rånby [6], but no substancial amounts of material were precipitated. The polysaracchides were then precipitated by addition of ethanol (9 000 ml) and the precipitate washed and dried as described above.

The analyses given in Table 1 for the D.M.S. and the water extracts refer to the first D.M.S. extract and the first precipitate from the hot water extract, but qualitative analyses indicate that they are typical for all the precipitates from the D.M.S. and water extracts, respectively.

Spruce holocellulose. Spruce wood chips were handsorted, extracted with benzene-ethanol and the air-dried extracted wood was converted to holocellulose using sodium chlorite according to the method of Wise *et al.*[7] Yield, 66.1 %. The holocellulose was then extracted and worked up analogously to the birch holocellulose. The various precipitates were divided into a number of subfractions by fractionated precipitation with ethanol. No significant fractionation into different types of polysaccharides was, however, obtained. Quite different and more efficient separations were achieved by using D.M.S. as a precipitating agent for the hemicelluloses extracted by 18 % sodium hydroxide solution, as described in the general part, where also the separation of a subfraction from this fractionation into a "glucomannan" and a xylan by partial dissolution with 7 % sodium hydroxide solution is described.

The second and third analysis given in Table 2 refer to the precipitates from the combined D.M.S. extracts and from the hot water extract, but, as mentioned above, are typical for all the precipitates from the D.M.S. and water fractions, respectively.

Spruce sulphite pulp. The preparation of the chemical grade sulphite pulp is described by McPherson and Rånby [6]. It was extracted and worked up analogously to the birch holocellulose.

Studies on Monoalkyl Carbonates

XIV. The Monoalkyl Carbonates of Sorbitol, Mannitol and Glucose

JØRN THAMSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

By addition of carbon dioxide to an aqueous solution of an alcohol and sodium hydroxide, monoalkyl carbonate and carbonate are formed as the carbon dioxide reacts with the alcoholate ion and the hydroxide ion. Sorbitol, mannitol and glucose also form monoalkyl carbonate with carbon dioxide and the velocity constant and the equilibrium constant for the formation of monoalkyl carbonate have been determined. The velocity of the decomposition of monoalkyl carbonate in strongly basic medium has also been investigated and may be explained by assuming that the decomposition is a two-stage reaction *viz.* (1) $RCO_3^- = RO^- + CO_2$; (2) $CO_2 + OH^- = HCO_3^-$

1. The present investigation deals with the equilibrium conditions and the reaction mechanism for the formation and decomposition of the monoalkyl carbonates of sorbitol, mannitol, and glucose.

2. The sorbitol was either D-sorbitol obtained from the Atlas Powder Co., stated to be of great purity, or crystalline D-sorbitol Merck. The melting point, given as 97.7° C for the stable form, was found to be 96—97° C. The mannitol was D-mannitol from the Pfanstiehl Chemical Co., stated to be pure, and had a melting point of 166—167° C. The melting point of mannitol is given as 166° C. The glucose used was 'Dextropur' from the Corn Products Co. Ltd., Copenhagen. Upon analysis it was found to contain 91.2 % glucose and 8.8 % water, thus corresponding very closely to the formula $C_6H_{12}O_6$, H_2O.

3. As it was difficult to isolate the monoalkyl carbonates themselves the solutions were prepared in the following manner: About 0.03 moles carbon dioxide were dissolved in one litre of a solution, which was 0.10—0.50 molar with regard to alcohol and 0.1 molar with regard to NaOH, thus converting about 20—60 % of the carbon dioxide to monoalkyl carbonate and the rest to ordinary carbonate.

4. The method of analysis was the same as in previous investigations, *viz.* separation of the monoalkyl carbonate from the ordinary carbonate by precipitating the carbonate with barium chloride [1]. The data presented are cor-

rected for the blank values and for decomposition as mentioned in the next section. The experiments were carried out at 0° C. The velocity constants were calculated by means of Briggs' logarithms and with the time measured in minutes.

I. ON THE FORMATION OF MONOALKYL CARBONATE FROM CARBON DIOXIDE AND ALCOHOL IN BASIC SOLUTIONS, AND ON THE REACTION $RO^- + CO_2 = RCO_3^-$

The first series of experiments was carried out by introducing 500 ml carbon dioxide gas into a 2.5 litre flask containing 1 litre of a basic solution of the alcohol and shaking vigorously for 2 minutes. As the manner in which the

* In the column 'composition of the solutions' are two sets of values. The upper one states the concentrations of hydroxyl ion OH^-, undissociated alcohol ROH, and alcoholate ion RO^- before the addition of carbon dioxide gas, and the lower set states these concentrations immediately after the addition. The lower set of values are corrected for the change in the concentration of alcohol and sodium hydroxide due to the reaction with the carbon dioxide. In further calculations the mean values of the upper and lower figures are used.

carbon dioxide was added to the solution could possibly influence the ratio between monoalkyl carbonate and carbonate (*cf.* the analogous experiments with carbamate and carbonate [2]) a second series of experiments was carried out. In these experiments 500 ml of a 0.06 M solution of carbon dioxide in water was added to 500 ml of the basic solution of alcohol with vigorous stirring. The two series of experiments disagree especially for sorbitol and mannitol. The difference could possibly be ascribed to the different concentrations of the reactants during the addition of the carbon dioxide.

Immediately after the addition of carbon dioxide the reaction solution was analysed for monoalkyl carbonate. The results are listed in the Tables 1 and 1a.

Because of the very rapid decomposition of the monoalkyl carbonate the results are corrected not only with respect to the blanks but also with respect to the decomposition taking place during the time which elapses between the start of the experiment and the separation of the precipitate and the supernatant by centrifugation. The blank values amounted to about 2—5 % of the total concentration of carbon dioxide. The other corrections appear from the tables.

The values in column 5 are computed by means of the following expression

$$\frac{c_{ROH}c_{OH^-}}{c_{RO^-}} = \frac{(a - c_{RO^-})(b - c_{RO^-})}{c_{RO^-}} = \frac{K_{H_2O}}{K_A}$$

where a and b are the total concentrations of alcohol and sodium hydroxide, respectively, thus

$$c_{ROH} + c_{RO^-} = a$$

$$c_{OH^-} + c_{RO^-} = b$$

The acid dissociation constants for sorbitol, mannitol and glucose are: $10^{-14.14}$, $10^{-14.09}$ and $10^{-12.92}$, respectively [3], and $K_{H_2O} = 10^{-14.93}$ at 0° C.

For most of the previously investigated alcohols the dissociation constants were either not known or not known with sufficient accuracy, and it was therefore convenient to compute the velocity constant k' of the gross reaction

$$ROH + OH^- + CO_2 = RCO_3^- + HOH$$

but in this case it is possible to compute the velocity constant $k_{CO_2 \cdot RO^-}$ of the reaction

$$RO^- + CO_2 = RCO_3^-$$

by means of the expression

$$\frac{\% \text{ monoalkyl carbonate}}{\% \text{ carbonate}} = \frac{k_{CO_2 \cdot RO^-} \cdot c_{RO^-}}{k_{CO_2 \cdot OH^-} \cdot c_{OH^-}}$$

where $k_{CO_2 \cdot OH^-} = 10^{+4.39}$

The mean values of $k_{CO_2 \cdot RO^-}$ corresponding to Table 1 are $10^{4.56}$, $10^{4.52}$ and $10^{3.12}$ for sorbitol, mannitol and glucose, respectively. The mean values of $k_{CO_2 \cdot RO^-}$ corresponding to Table 1a are $10^{4.16}$, $10^{4.14}$ and $10^{2.92}$ for sorbitol, mannitol and glucose, respectively.

For comparison it is convenient to state the values of the velocity constant k' computed from the expression $k' = k_{CO_2 \cdot RO^-} K_A / K_{H_2O}$, *viz.* $10^{5.35}$, $10^{5.36}$ and $10^{5.13}$, corresponding to Table 1, and $10^{4.95}$, $10^{4.98}$ and $10^{4.93}$ corresponding to Table 1a for sorbitol, mannitol and glucose, respectively.

II. THE EQUILIBRIUM OF THE REACTION $RCO_3^- + HOH = HCO_3^- + ROH$

The above equilibrium was established in aqueous solutions of alcohol, potassium hydrogen carbonate and sodium carbonate. With the alcohols studied in the present investigation the equilibrium is shifted strongly to the right, and thus the determinations of per cent monoalkyl carbonate may be attended with rather large errors as the blank values are almost of the same order of magnitude as the experimental values, and the computed K_{Eq}-values give only the order of magnitude.

a) Sorbitol. The equilibrium was established at 0° C in a solution 0.25 M with regard to sorbitol, 0.1 M with regard to $KHCO_3$ and 0.1 M with regard to Na_2CO_3.

The monoalkyl carbonate was determined in 100 ml samples and found to be equivalent to 2.35, 2.60, 2.46, 2.50 and 2.44 ml 0.1 N HCl, respectively, with a mean value of 2.47 ml. The blank values corresponded to 1.41, 1.33, 1.38, 1.30 and 1.41 ml 0.1 N HCl, with a mean value of 1.37 ml. The true quantity of monoalkyl carbonate thus corresponds to 1.10 ml 0.1 N HCl, *i. e.* $\frac{1.10 \times 100}{200} = 0.55$ % of the $KHCO_3$ is transformed to monoalkyl carbonate.

b) Mannitol. The equilibrium was established at 0° C in a solution 0.25 M with regard to mannitol, 0.1 M with regard to $KHCO_3$ and 0.1 M with regard to Na_2CO_3. In the equilibrium 0.98 % of the $KHCO_3$ is converted to monoalkyl carbonate.

The monoalkyl carbonate in the samples corresponded to 3.09, 3.30, 3.36, 3.19, 3.41, 3.19, 3.12 and 3.29 ml 0.1 N HCl, with a mean value of 3.24 ml. The blank values corresponded to 1.49, 1.40, 1.58, 1.41, 1.40, 0.98, 1.02 and 0.92 ml 0.1 N HCl, with a mean value of 1.28 ml.

c) Glucose. Equilibrium was established at 0° C in a solution 0.5 M with regard to glucose, 0.1 M with regard to $KHCO_3$ and 0.1 M with regard to Na_2CO_3. In different determinations the monoalkyl carbonate was equivalent to 1.84, 1.94, 2.31, 3.07, 1.56 and 1.52 ml 0.1 N HCl, respectively, with a mean value of 1.87 ml. The blank values were equivalent to 1.03, 0.81, 0.95, 1.05, 1.24, 1.27 and 1.32 ml 0.1 N HCl, respectively, with a mean value of 1.10 ml. In the equilibrium 0.38 % of the $KHCO_3$ is transformed to monoalkyl carbonate.

d) From the above values and

$$K_{Eq} = \frac{c_{ROH} c_{HCO_3^-} f}{c_{RCO_3^-} f}$$

K_{Eq} has the values 45, 25, and 128 for sorbitol, mannitol and glucose, respectively, but as suggested above these values only state the order of magnitude of K_{Eq}.

III. ON THE VELOCITY OF THE REACTIONS $RCO_3^- + HOH = HCO_3^- + ROH$

The solutions mentioned in the Tables 1 and 1a were all directly used for the kinetic determinations. The results corresponding to the experiments represented in the Tables 1 and 1a coincide, and therefore to save space only a limited number of the experiments corresponding to Table 1a are represented in Table 2.

Table 2. Monoalkyl carbonate in NaOH + alcohol. 0°C.

k_{mono} is the value of $\frac{1}{t} \log \frac{a}{a-x}$

In Table 2, column 2, the initial concentration of monoalkyl carbonate are computed from % RCO_3^-(corr.) in Table 1a. The initial compositions of the solutions and the compositions after the reaction is completed are given in column 3. In the kinetic experiments represented in columns 4—6, $t = 0$ corresponds to the fifth minute after the addition of the carbon dioxide.

The mechanism of these reactions is assumed to be similar to that of previously investigated decompositions of monoalkyl carbonates, *i. e.*

(1) $RCO_3^- = RO^- + CO_2$; (2) $CO_2 + OH^- = HCO_3^-$.

k_{mono} may be calculated at pH > 10 by means of the expression

$$k_{mono} = \frac{k_{CO_2 \cdot RO^-} \cdot \frac{K_{Eq} \cdot K_A}{K_{CO_2}}}{1 + \frac{k_{CO_2 \cdot RO^-}}{k_{CO_2 \cdot OH^-}} \cdot \frac{K_A}{K_{H_2O}} \cdot c_{ROH}}$$

the values of K_{CO_2} being $10^{-6.65}$, but in this case the experimental values of K_{Eq} are very uncertain, so it may be better to calculate K_{Eq} from the experimental values of k_{mono}.

By calculation of K_{Eq} by means of the mean values of $k_{CO_2 \cdot RO^-}$ from Table 1a, which may be considered as the most correct values [2], and the mean values of c_{ROH} during the experiments, the following values are obtained (Table 3).

Table 3.

	Expt. No.	K_{Eq}	
		calc.	found
Sorbitol	1	35	45
Mannitol	3	31	25
	5	29	
Glucose	7	79	128
	10	71	
	11	78	

In view of the uncertainty (*cf.* section II) in the experimental values of K_{Eq} they agree quite well with the above calculated values.

The present work has been performed in the Department of Inorganic Chemistry of the Royal Danish School of Pharmacy. The author wishes to thank the head of the department Professor Carl Faurholt for his interest in the work and his valuable advice.

Studies on Monoalkyl Carbonates

XV. The Monoalkyl Carbonates of Sucrose and Lactose

BERTEL SMIDT and JØRN THAMSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

By addition of carbon dioxide to an aqueous solution of an alcohol and sodium hydroxide, monoalkyl carbonate and carbonate are formed as the carbon dioxide reacts with the alcoholate ion and the hydroxide ion. Sucrose and lactose also form monoalkyl carbonate with carbon dioxide and the velocity constant and the equilibrium constant for the formation of monoalkyl carbonate have been determined. The velocity of the decomposition of monoalkyl carbonate in strongly basic medium has also been investigated and may be explained by assuming that the decomposition is a two-stage reaction, *viz.* (1) $RCO_3^- = RO^- + CO_2$; (2) $CO_2 + OH^- = HCO_3^-$.

1. The present investigation deals with the equilibrium conditions and the reaction mechanism for the formation and decomposition of the monoalkyl carbonates of sucrose and lactose.

2. The sucrose used was nitrogen-free sucrose from 'De danske Sukkerfabriker'. An aqueous solution of 9.995 g sucrose per 100 ml showed an optical rotation of 13.3° at 20° C in a 20 cm tube giving a value for $[\alpha]_D^{20°}$ of 66.53 which agrees with the value given in the literature. The sucrose was thus regarded as fit for use. The lactose was 'Baker's Analyzed' lactose stated to be pure. An aqueous solution of 9.994 g lactose per 100 ml showed an optical rotation of 10.5° at 20° C in a 20 cm tube. Thus $[\alpha]_D^{20°} = 52.53$ which agrees with the value given in the literature. The lactose was thus considered to be usable and corresponded very closely to the formula $C_{12}H_{22}O_{11} \cdot H_2O$.

3. The present investigation is analogous to the investigation concerning sorbitol, mannitol and glucose [1] and the experimental method being similar, it is on the whole sufficient here to state the experimental data and the calculated constants, referring for further information to the investigation of sorbitol, mannitol and glucose.

ON THE FORMATION OF MONOALKYL CARBONATE FROM CARBON DIOXIDE AND ALCOHOL IN BASIC SOLUTION, AND ON THE REACTION $RO^- + CO_2 = RCO_3^-$

The experimental results concerning the addition of carbon dioxide to sucrose and lactose are in the Tables 1 and 1a.

The acidic dissociation constants of sucrose and lactose are [2]: $10^{-13.36}$ and $10^{-12.75}$, respectively, at 0° C.

The mean values of $k_{CO_2 \cdot RO^-}$ corresponding to Table 1 are $10^{4.36}$ and $10^{3.95}$ for sucrose and lactose, respectively. The mean values of $k_{CO_2 \cdot RO^-}$ corresponding with Table 1a are $10^{3.74}$ and $10^{3.46}$ for sucrose and lactose, respectively. The mean values of k' are $10^{5.93}$ and $10^{6.13}$ corresponding with Table 1, and $10^{5.31}$ and $10^{5.64}$ corresponding with Table 1a for sucrose and lactose, respectively.

* Preceding paper [1]. Footnote, Table 1.

THE EQUILIBRIUM OF THE REACTION $RCO_3^- + HOH = HCO_3^- + ROH$

The equilibrium was established in aqueous solutions of the alcohol, potassium hydrogen carbonate and sodium carbonate.

a) Sucrose. Equilibrium was established at 0° C in a solution 0.25 M with regard to sucrose, 0.1 M with regard to $KHCO_3$ and 0.1 M with regard to Na_2CO_3. The monoalkyl carbonate was determined in 100 ml samples. In different determinations the monoalkyl carbonate was equivalent to 3.29, 3.16, 3.09, 3.06, 3.30, 3.34, 3.44 and 3.54 ml 0.1 N HCl, respectively, with a mean value of 3.28 ml. The blank values were equivalent to 1.50, 1.35, 1.37, 1.45, 1.51, 1.35, 1.50, 1.50 and 1.45 ml 0.1 N HCl, respectively, with a mean value of 1.44 ml. The true quantity of alkyl carbonate thus corresponds to 1.84 ml 0.1 N HCl, *i. e.* 0.92 % of the $KHCO_3$ is transformed to monoalkyl carbonate.

	1	24	
	6	11	

alkyl carbonate. The monoalkyl carbonate in the samples was equivalent to 2.24, 2.39, 2.29, 2.25, 2.34, 1.98, 3.00, 3.19 and 2.71 ml 0.1 N HCl with a mean value of 2.49 ml. The blank values correspond to 1.67, 1.72, 2.20, 1.66, 1.80, 1.38 and 1.62 ml 0.1 N HCl with a mean value of 1.72 ml.

Thus K_{Eq} has the values 27 and 64 for sucrose and lactose, respectively, but these values only state the order of magnitude of K_{Eq}.

ON THE VELOCITY OF THE REACTIONS $RCO_3^- + HOH = HCO_3^- + ROH$

The solutions mentioned in the Tables 1 and 1a were all directly used for the kinetic determinations. The results are given in Table 2. To save space only a limited number of the experiments corresponding to Table 1a are represented.

The initial concentration of monoalkyl carbonate computed from $\%\,RCO_3^-$ (corr.) in Table 1a are given in Table 2, column 2.

The initial compositions of the solutions and the compositions after the reaction is completed are given in column 3.

The mean values of c_{ROH} during the experiment and the mean values of $k_{CO_2 \cdot RO^-}$ from Table 1a [1] are used to calculate K_{Eq} from the experimental values of k_{mono} and the following values are obtained (Table 3).

The agreement between the calculated and the experimental values is quite good for sucrose whereas for lactose the experimental value is 3—6 times the calculated and thus not in as good agreement as to be wished.

The present work has been performed in the Department of Inorganic Chemistry of the Royal Danish School of Pharmacy. The authors wishes to thank the head of the department Professor Carl Faurholt for his interest in the work and his valuable advice.

Studies on the Interaction of Paraffin Chain Alcohols and Association Colloids

VIII. The Solubility of Decanol-1 in Soap Solutions below the C.M.C.

PER EKWALL and TUURE VITTASMÄKI

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

The solubility of decanol in dilute sodium caprate, laurate and myristate solutions at 40°C up to somewhat above the C.M.C.'s of the pure soaps has been determined with the greatest possible accuracy (maximum error ± 0.005 ml per litre). In all three cases a definite and rapid increase of the solubility begins at a concentration about 30 % lower than the C.M.C. of the pure soap. At this point a rapidly increasing formation of alcohol-soap-micelles begins; the C.M.C. of the decanol-containing soap solution is located at this concentration. The shift of the C.M.C. is caused by the facilitated association of the soap ions due to a decrease in the repulsion of their ionic groups owing to the incorporation of decanol. Below the C.M.C. the decanol solubility changes in a characteristic manner; already immediately above the L.A.C. the solubility increases slightly, passes a maximum and decreases again to a minimum value immediately below the C.M.C. These changes in solubility depend on the formation of small soap ion-decanol aggregates of relatively low solubility. The decanol-soap-water phase separating from all solutions above the L.A.C. has other properties and obviously another composition in the concentration range between the L.A.C. and C.M.C. than above the latter concentration limit. The investigation thus shows that below the C.M.C. there is in the solutions of all soaps a fairly wide concentration range where a limited association of alcohol and soap ions occurs. The degree of this association develops slowly until the critical concentration is reached.

A study has been made of the solubility of decanol in dilute sodium caprate, laurate and myristate solutions in the concentration range below the C.M.C. The solubility determinations made use of the fact that the system becomes turbid when a new phase appears. Since the solubility of decanol is very low below the C.M.C. and the turbidities in some cases were rather weak, the greatest care had to be exercised in the performance of the measurements.

MATERIALS AND METHODS

The fatty acids were purified by repeated crystallization from ethanol. The melting points of the acids were: capric acid 31—31.5°C, lauric acid 42—43°C, myristic acid 56—57°C. Soaps were prepared from the acids in the usual manner by neutralization in abs. ethanol with sodium ethylate. The decanol was purified by repeated freezing;

the melting point of the final product was −6°C. The specific conductance of the twice distilled water used in the preparation of the solutions was less than 1×10^{-6} ohm^{-1} cm^{-1}.

In most of the experiments, 100-ml cylindrical glass-stoppered Pyrex flasks (30 mm in diameter) were used both as storage vessels and as cuvettes in the turbidity measurements. Several series of solutions were prepared in each of which the soap concentration was constant but the amount of added decanol varied. The flasks were shaken 24 hours in a thermostat at 40° until all decanol had dissolved or the solutions had become saturated and the excess of decanol or separated interaction product was dispersed throughout the solutions. It was found advisable to allow the solutions to stand four hours before measuring the turbidities. The turbidities were measured at 40°C with a Zeiss nephelometer combined with a Pulfrich photometer.

All the flasks were thoroughly cleaned and then rinsed several times with distilled water, after which they were dried and stored so that they did not collect dust.

In order to avoid turbidities caused by separated hydrolytic products, 0.1 mole of sodium hydroxide was added per mole of soap to the solutions.

The decanol was added to the solutions with an Agla micrometer syringe in which the scale is divided into 0.0002 -ml divisions.

EXPERIMENTAL RESULTS

a) The variation of the turbidity with the excess of decanol

Decanol added to a soap solution in excess of the amount dissolved causes the appearance of a turbidity. The turbidity increases with the amount of decanol added but our experiments showed that the increase in turbidity effected per unit volume of decanol added varied greatly with the soap concentration. This is illustrated by the nephelometer curves relating to sodium caprate solutions reproduced in Figs. 1 a, 1 b, 1 c, 1 d.

As seen from the curves, the nephelometric value remains constant when small amounts of decanol are added, but rises when larger amounts are added. The slope of the rising part of the curve is very different in the four cases. The turbidity curve for the 0.002 M caprate solution rises rapidly as soon as decanol is added in excess (Fig. 1a). For the 0.028 M solution the increase is slow at first, but later the curve rises steeply (Fig. 1b). The turbidity curve for the 0.052 M solution rises very slowly above the breakpoint with a constant slope (Fig. 1 c). A linear increase is also seen in the curve for the 0.090 M solution, but the slope is large (Fig. 1d).

It is of interest to note that this variation of the slope of the rising part of the curve is common to all the soaps studied. This is seen in Figs. 2, 3 and 4. The abscissae of these figures give the soap concentrations and the ordinates the slopes of the turbidity curves (above the breakpoint), *i. e.* the increase in turbidity due to a unit volume of decanol in excess per litre of solution. In those cases where the slope is different for small (a) and large (b) excesses of decanol (as in Fig. 1 b), both curves are given. Figs. 2, 3 and 4 are based on all the experimental data obtained in this study. In all cases the slope of the turbidity curve is large in dilute soap solutions, but decreases to a low value as the soap concentration increases; it then remains constant over a certain concentration range and begins to increase again at higher soap concentrations. This shows that the degree of dispersion of the separating substance and/or the refractive index and the nature of the substance causing the turbidity varies in the different concentration ranges.

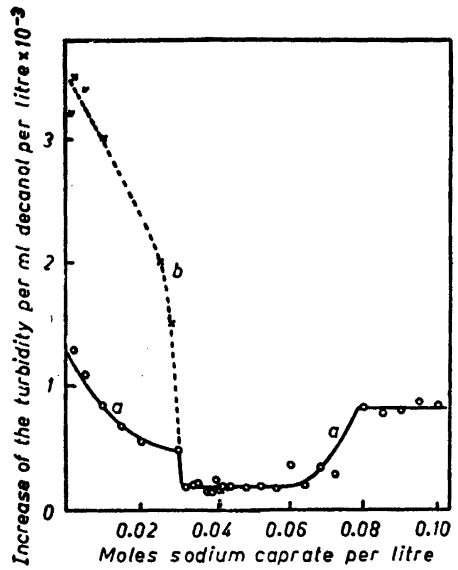

Fig. 2. The dependence of the soap concentration on the increase in turbidity due to a unit volume of decanol per litre of sodium caprate solution. a. Small excesses of decanol above the turbidity point. b. Large excesses of decanol above the turbidity point.

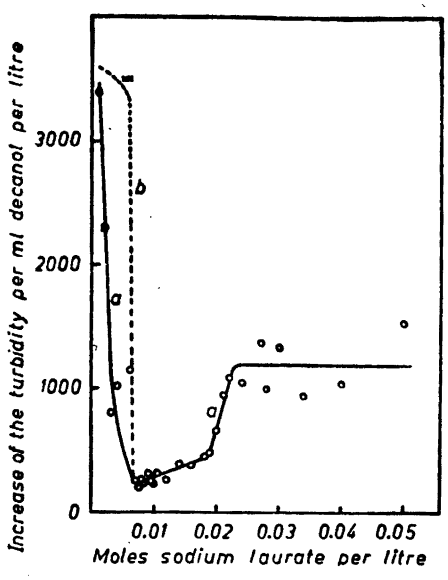

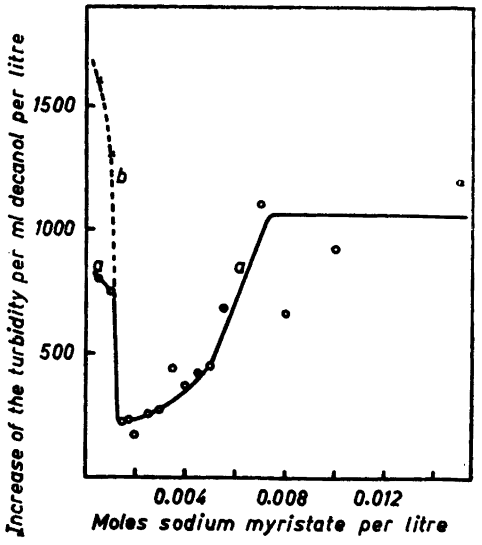

Fig. 3. The dependence of the soap concentration on the increase in turbidity due to a unit volume of decanol per litre of sodium laurate solution. a. Small excesses of decanol above the turbidity point. b. Large excesses of decanol above the turbidity point.

Fig. 4. The dependence of the soap concentration on the increase in turbidity due to a unit volume of decanol per litre of sodium myristate solution. a. Small excesses of decanol above the turbidity point. b. Large excesses of decanol above the turbidity point.

The intermediate concentration ranges, where the turbidity curves rise slowly, *i. e.* the separating substance causes only a slight turbidity, are for the various soaps: sodium caprate, from 0.030 M to 0.064 M; sodium laurate, from 0.007 to 0.019 M; sodium myristate, from 0.0015 to 0.005 M. The lower limits are very close to the limiting concentrations L.A.C., of the soaps, (0.02—0.03 M for sodium caprate, 0.005—0.006 M for sodium laurate and 0.0013—0.0015 M for sodium myristate), where, according to our previous studies, the interaction between decanol and soap begins [1-8]. Whereas the excess of decanol separates below the L.A.C. as emulsified free decanol, the separating substance above this limit is a fine-disperse semitransparent mesomorphic phase composed of decanol, soap and water. Already the turbidity-soap concentration curves reproduced in our earlier papers showed that this latter substance (separating above the L.A.C.) produces a relatively weak turbidity [1,2,5-7]. In those cases where we now found the turbidity-decanol content curves to rise slowly immediately above the turbidity point (as in Fig. 1 b) but later to exhibit a large slope, a mesomorphic phase separates at first, but when decanol is added in greater excess, free alcohol separates and is emulsified. Conductance measurements support this interpretation.

b) The solubility of decanol in the soap solutions

The solubility of decanol is given by the point where the horizontal and rising parts of the nephelometric curves intersect. We have attempted to determine in various ways the accuracy with which this point of intersection can be determined. Only in a few unfavourable cases, in which the slope of the curve was low and the nephelometric values scattered more than normally, the method of least squares gave standard deviations up to $\pm$ 0.005 ml of decanol per litre of solution. In most cases the standard deviation was less than this value.

The solubility values are shown in Tables 1, 2 and 3.

Fig. 5a shows the variation of the solubility of decanol with the soap concentration in sodium caprate solutions. From 0.065 M caprate upwards, the solubility increases rapidly and especially above the 0.08 M concentration, the solubility curve rises steeply. In pure caprate solutions the critical concentration is 0.097 M at 20° C. The solubility of decanol thus begins to increase rapidly already at a lower concentration, 0.065—0.080 M, of sodium caprate.

A very slight increase in solubility can, however, be detected at even lower concentrations; this is shown by the enlarged lower part of the curve in Fig. 5b. We observed the first signs of an increased solubility already at caprate concentrations between 0.025 M and 0.030 M. The solubility of decanol rises from 0.028 ml of decanol per litre, the solubility in pure water and in very dilute caprate solutions, to a value of 0.049 ml per litre in the 0.044 M caprate

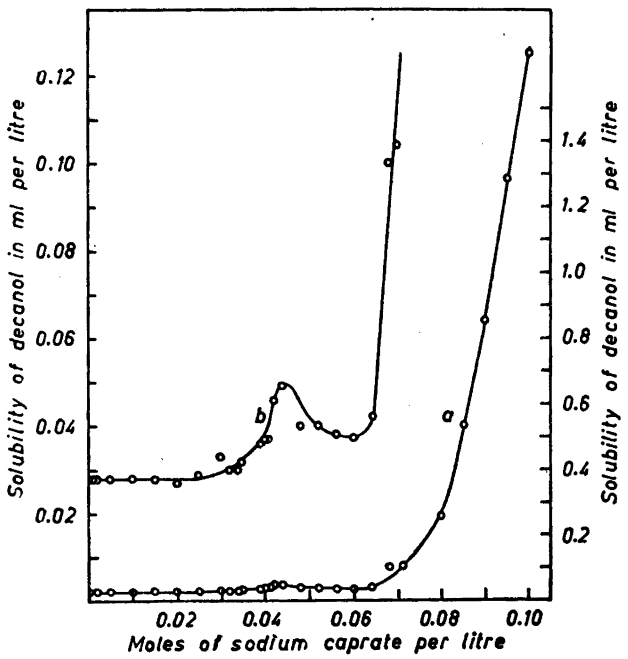

Fig. 5. The solubility of decanol in sodium caprate solutions at 40°C. a. The increase of the solubility around the C.M.C. (scale on the right). b. The solubility between the L.A.C. and the C.M.C. on an enlarged scale (scale on the left).

solutions, an increase of 75 %. At higher caprate concentrations, the solubility decreases again to a minimum in the 0.060 M caprate solution, after which the above-mentioned rapid increase begins.

The first increase in decanol solubility coincides with the limiting concentration, 0.025—0.030 M, of sodium caprate. The range in which the increase and decrease occur, 0.025—0.065 M sodium caprate, is practically the same as the range (0.03—0.064 M caprate) where the effect of the separated substance on the turbidity is especially weak. These two phenomena are thus seen to be closely connected.

Fig. 6a illustrates the variation of the solubility of decanol with the sodium laurate concentration. The solubility begins to increase when the laurate concentration exceeds 0.019—0.020 M. The critical concentration of sodium laurate is 0.028 M (20° C). Decanol thus begins to dissolve in laurate solutions at a laurate concentration somewhat below the C.M.C. of pure sodium laurate.

Also in the laurate solutions a slight increase in solubility is noted even at lower concentrations (Fig. 6b). The first signs of an increase are noted at the laurate concentrations of 0.005—0.007 M. The solubility increases to a value in the 0.008—0.009 M solution which is about 64 % higher than in water. It then undergoes a decrease to a minimum at the 0.016—0.018 M concentration, after which the rapid increase begins.

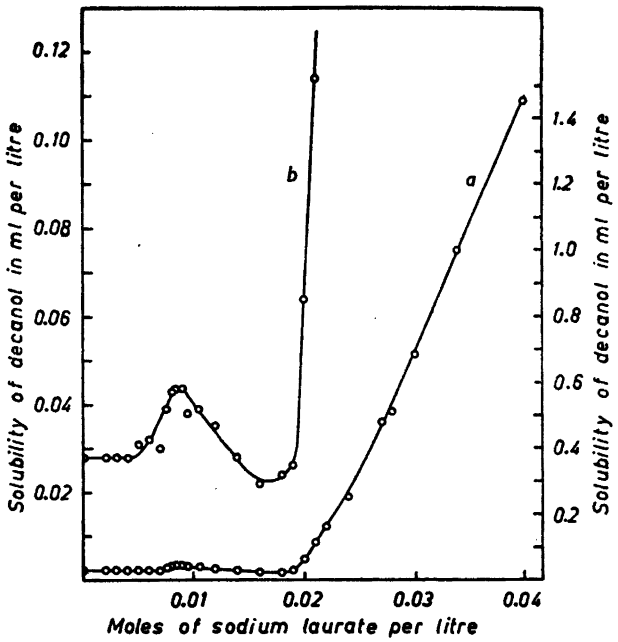

Fig. 6. The solubility of decanol in sodium laurate solutions at 40°C. a. The increase of the solubility around the C.M.C. (scale on the right). b. The solubility between the L.A.C. and the C.M.C. on an enlarged scale (scale on the left).

The first solubility increase begins at the limiting concentration of sodium laurate, 0.005—0.006 M. The solubility variations occur in the same concentration range (0.006—0.019 M laurate) where the separating substance effects only a weak turbidity.

The variation of the decanol solubility in sodium myristate solutions is shown in Fig. 7. The solubility begins to increase when the sodium myristate concentration exceeds 0.0045—0.0050 M and more rapidly when the soap concentration increases above 0.006 M. The critical concentration of sodium myristate is 0.007 M at 40° C. Thus decanol begins to dissolve at a myristate concentration definitely below the C.M.C. of pure sodium myristate. Also in the myristate solutions we have noted solubility changes at still lower concentrations (Fig. 7b). The solubility begins to increase already at the 0.001 M myristate concentration; it is about 50 % higher than the solubility in water in the 0.0015 M myristate solution, but then decreases until it is only one-third of the solubility in water in the 0.0045 M sodium myristate solution. Above this point a rapid increase in the solubility begins.

Also in sodium myristate solutions, the first increase in solubility occurs in the vicinity of the limiting concentration, which is 0.0013 M. The variations in the solubility are observed in the same concentration range (0.0015 M—0.0050 M myristate) where the separating substance effects only a weak turbidity.

c) The effect of added sodium hydroxide on the solubility of decanol

In all the above experiments, the solutions contained 0.1 mole of sodium hydroxide per mole of soap to suppress hydrolysis. We have not undertaken any systematical study of the effect of sodium hydroxide or that of the products of hydrolysis on the solubility of decanol, but certain observations throw some light on this question.

The solubility of decanol was measured in 0.008 M sodium myristate solutions containing various amounts of sodium hydroxide up to 0.14 mole per mole of soap. From Fig. 8 it is seen that the solubility is very low in the absence of alkali hydroxide, increases at first rapidly with the amount of sodium hydroxide added but attains a constant limiting value when the concentration of sodium hydroxide increases to about 0.1 mole per mole of soap. A similar increase in the decanol solubility in a 0.006 M myristate solution was also observed when 0.05 and 0.1 mole of sodium hydroxide was added per mole of soap.

The addition of 0.1 mole of sodium hydroxide per mole of soap to a 0.04 M sodium laurate solution increased the solubility of decanol only from 1.30 to 1.44 ml per litre. No increase was noted in the case of a 0.014 M laurate solution when the sodium hydroxide content was increased from 0.05 to 0.15 mole per mole of soap.

The solubility of decanol in a 0.064 M sodium caprate solution did not increase when the sodium hydroxide concentration was increased from 0.1 to 0.15 mole per mole of soap.

In the concentration range immediately above and below the C.M.C. of pure soaps, where we have observed the solubility of decanol to increase rapidly, the sodium hydroxide increases the decanol solubility; 0.1 mole of sodium hydroxide per mole of soap seems, however, to be sufficient to effect maximum solubility of decanol in most cases (in myristate solutions a slightly larger amount may be necessary). In the region above the L.A.C. where the first increase in decanol solubility occurs, sodium hydroxide does not seem to influence the solubility, but the small number of observations does not permit any definite conclusions.

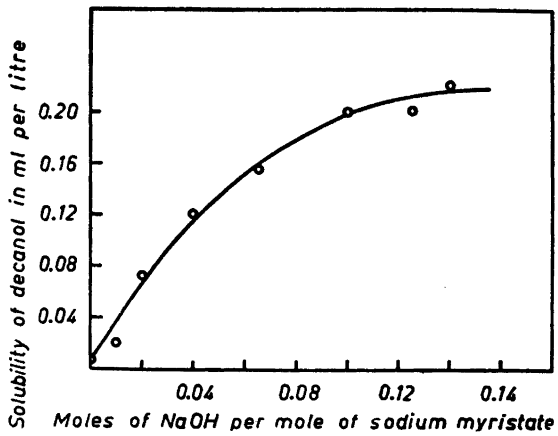

Fig. 8. The influence of added sodium hydroxide on the solubility of decanol in a 0.008 M sodium myristate solution at 40°C.

The addition of sodium hydroxide to a colloid solution generally influences the micelle formation in such a way that the C.M.C. shifts to a somewhat lower value. The effect of sodium hydroxide on the decanol solubility may be partly due to this shift. We think, however, that the results may be considered to indicate that the hydrolysis products (fatty acid, acid soap) present in solutions containing no added alkali decrease the capacity of the soap to dissolve decanol, at least in solutions in which micelle formation has not progressed very far.

d) Solubility of *p*-xylene in soap solutions containing decanol

It is known that soap solutions begin to solubilize hydrocarbons when the critical concentration is exceeded and that the solubilization of hydrocarbons is increased in the presence of long-chain alcohols. We have conducted a few experiments to determine the effect of decanol on the solubilization of *p*-xylene in sodium laurate solutions below the C.M.C. The results are given in Table 4.

The solubility of *p*-xylene in pure water is 0.20 ml per litre at 40°C. The solubility is the same also in dilute soap solutions below the C.M.C. The data in Table 4 show that the solubility is no larger in 0.003 and 0.009 M laurate solutions when these contain

Table 4. The solubilization of p*-xylene in sodium laurate solutions containing different amounts of decanol. The solutions contained 1 mole of sodium hydroxide to 10 moles of soap. 40°C.*

Sodium laurate mole/litre	Decanol ml/litre	*p*-xylene ml/litre
0.003	0.028	0.21
0.009	0.046	0.20
0.018	0.026	0.33
0.023	0.19	0.56

decanol, but a slightly higher solubility is noted in the 0.018 M solution and a definitely higher solubility in the 0.023 M solution.

These results show that solubilization of the hydrocarbon begins at about the same concentration where the solubility of decanol begins to increase rapidly. This seems to indicate that the decanol-laurate mixed micelles are of the usual spheroidal (or double-layer) type. Micelles of this type do not seem to be formed at lower soap concentrations although decanol is present.

DISCUSSION

In the case of all three soaps studied, the first signs of an increase in the decanol solubility appear in the region of the limiting concentration of the soap [1–5]. As the soap concentration is increased, the increase in solubility slows down and the solubility begins to decrease until slightly before the C.M.C. of the pure soap is reached, the solubility again begins to increase [5]. The changes in solubility below the abrupt rise are admittedly rather small, but yet considerably greater than the error of the experimental method. The changes must hence be considered significant.

The regions where these changes in solubility are observed are given in Table 5.

The second increase in the decanol solubility begins at soap concentrations that are about 30 % lower than the C. M. C.'s in pure soap solutions. Above this point the increase in solubility is very rapid. It is obvious that this increase is due to the formation of mixed micelles containing soap and decanol and that their formation progresses rapidly from the solubility minimum upwards. The minimum points thus give the C. M. C. values for soap solutions containing decanol. This is supported by the observation that the 0.018 and 0.023 M laurate solutions begin to solubilize *p*-xylene only after decanol has been added to them. These mixed micelle C. M. C. values lie only a little below the approximate values we have previously obtained for decanol-containing soap solutions by the turbidity method [6]. Our data thus give the lowest soap concentrations to which the C. M. C. can be decreased by decanol at 40° C. These values are appreciably lower than the values recently obtained by Shinoda for decanol-containing soap solutions at 10° and 18° C with the pinacyanol method [9].

Table 5. Variation of the solubility of decanol in soap solutions containing 0.1 mole of NaOH per mole of soap. 40°C.

Soap	L.A.C. M	Soap concentration (mole/l) at which		C.M.C. in pure soap solution M

On the basis of the solubility values it is possible to estimate the amount of soap bound in the mixed micelles above the critical concentration. Already from concentrations only slightly higher than the C. M. C., the solubility curves begin to rise linearly; this means that the maximum ratio of decanol to soap in the mixed micelles remains constant above this point. The ratio is found to

be 0.41 mole of decanol per mole of sodium caprate, 0.39 mole of decanol per mole of sodium laurate, and 0.33 mole of decanol per mole of sodium myristate, at 40° C. If it is assumed that the mixed micelles have the same composition down to the point of minimum decanol solubility, the values given in Figs. 9, 10 and 11 (curves a) can be calculated for the amounts of soap bound in the mixed micelles. Also the amounts of molecular soap calculated from the difference between total and micellar soap are given in the figures (curves b). The curves show that after a relatively narrow transition region, in which the proportion of micellar soap increases rapidly, there is a concentration range where all the added soap is bound in the mixed micelles and hence the concentration of free soap remains constant. This range begins already before the C. M. C. of the pure soap is reached.

For comparison also the amounts of soap present in the micellar state and in the molecular state in decanol-free soap-solutions, calculated in a corresponding manner from the data for the *p*-xylene solubilization, are given in Figs. 9, 10 and 11 (the dotted curves c and d) [11]. In these latter cases the formation of micelles begins at the C. M. C.'s of the pure soaps and proceeds at first much more slowly than in the presence of the alcohol. Though all these values are only approximate, they show clearly the effect of the polar-nonpolar substance on the micelle formation. As we have seen above, the concentration of decanol at the solubility minimum (C. M. C.) is in all cases very low compared with that of the soap (only about 0.5—1.5 % of the latter). Our calculation thus indicates that the effect of decanol is not caused by an increase in the amount of micelle-forming hydrocarbon chains in solutions, but by an increased association of the soap ions due to a decrease in the repulsion

of their ionic groups [7]. In other cases, however, when the solubility of the polar substance is greater, the former factor may play a part in lowering the C. M. C.

The first slight increase in the decanol solubility above the L. A. C. must also be caused by the formation of soluble decanol-soap aggregates. These aggregates are formed only sparingly, however. Therefore the previously (Parts V and VI) described rapid fall at the L. A. C. in the turbidity-soap concentration curves of solutions containing alcohol in excess [6,7] is due only to a minor extent to the increase in the solubility of the alcohol but for the most part to a weak turbidity of the alcohol-soap-water phase formed above the mentioned concentration limit.

It is very interesting to note that the decanol-soap-water phase separating immediately above the L.A.C. effects a much weaker turbidity per unit volume of decanol added than the corresponding phase separating above the C.M.C. This fact conforms with our microscopic observations of the different appearance of the separated phase below and above the latter concentration in sodium laurate solutions (Part VII); these observations suggested that the water content of the former product is greater than that of the latter [8]. On the other hand, we have found (Parts II and III) that the decanol content per mole of soap in the separated phase increases with decreasing concentration of the soap solution in which it is formed [10]. From all these results we conclude that both the properties and the composition of the decanol-soap-water phase formed between L.A.C. and C.M.C. differs from that formed above the latter concentration limit; in the former case the molar ratio of decanol to soap and the water content is larger and the refractive index is nearer that of the aqueous soap solution.

Our investigations thus show that in the concentration range between L.A.C. and C.M.C. the solubility of decanol is different from that in other ranges and the separating phase deviates in properties and composition from those separating in other ranges. As to the composition and properties of the soluble soap ion-alcohol aggregates existing in this range, calculations show that these aggregates are small and composed of only very few soap ions and alcohol molecules. The hydrophilic properties and thus the solubility of such small aggregates must decrease rapidly with increasing molar ratio of decanol to soap. The range of composition of these aggregates is therefore rather limited. If one assumes that two kinds of small aggregates with different decanol-soap ratios, and thus different solubilities, are formed, the course of the observed solubility curve between L.A.C. and C.M.C. with its solubility maximum and decrease to and below the value for pure water can be readily understood. We will return to this question in a later paper of this series.

Now we only wish to emphasize that the solubility measurements presented in this paper show clearly that the limiting concentration should not be confused with the critical concentration [6,7]. Below the latter there is a fairly wide concentration range in solutions of all soaps where a limited association of alcohol and soap ions occurs. The degree of this association increases slowly until the critical concentration is reached.

Short Communications

Steric Relations between α-(1-Naphthyl)-propionic Acid and α-(3-Thianaphthenyl)-propionic Acid

BERNDT SJÖBERG

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In connection with stereochemical studies on aralkyl carboxylic acids, α-(3-thianaphthenyl)-propionic acid has been prepared and resolved into its optical antipodes ($[\alpha]_D^{25} = 80.2°$ in abs. alcohol).

Several methods could be used to determine the configuration of α-(3-thianaphthenyl)-propionic acid and sterically relate it to D-glyceraldehyde. At the present time the simplest and most reliable method is perhaps that of quasi-racemates [1], provided it is possible to find some suitable structurally similar compound.

It may be assumed that the angle γ (Fig. 1) in the thianaphthene molecule ought to be between 113° and 120°, since the corresponding angle in the thiophene molecule is 113° [2] and in the naphthalene molecule

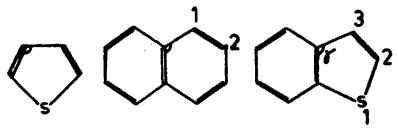

Fig. 1.

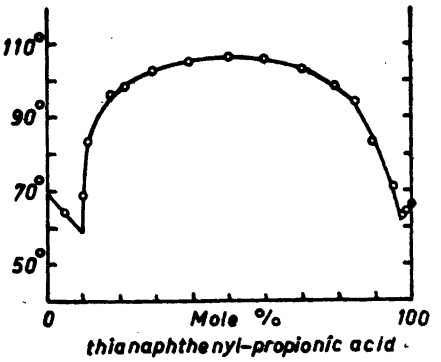
120°. The structural dissimilarity between α-(1-naphthyl)-propionic acid and α-(3-thianaphthenyl)-propionic acid should in that case perhaps be small enough to enable a quasi-racemic compound to be formed between the opposite antipodes of these two acids.

The configuration of α-(1-naphthyl)-propionic acid has already been determined by Fredga [3] and the pure antipodes of this acid have been put at my disposal.

By thermal analysis according to Kofler [4] it was shown with the aid of the contact method that a molecular compound was formed between (−)-α-(3-thianaphthenyl)-propionic acid and (+)-α-(1-naphthyl)-propionic acid. After the preliminary experiments the whole curve was determined for this two-component system. As is seen in Fig. 2, a very pronounced quasi-racemic compound is formed from the components in the ratio 1:1.



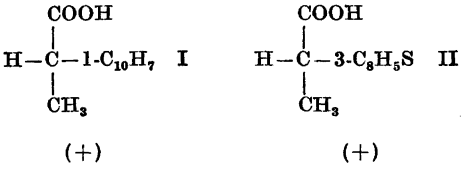


Fig. 2. (−)-α-(3-thianaphthenyl)-propionic acid and (+)-α-(1-naphthyl)-propionic acid.

The melting point curve for the system containing acids with the same direction of rotation was not investigated in detail, but preliminary experiments indicated that no molecular compound was formed.

From the results obtained the conclusion can be drawn that α-(1-naphthyl)-propionic acid and α-(3-thianaphthenyl)propionic acid with the same direction of rotation (measured in alcohol at the wave-length of the D-line) also have the same configuration.

The dextro-rotatory α-(1-naphthyl)-propionic acid has the configuration I. Consequently (+)-α-(3-thianaphthenyl)-propionic acid has a stereo formula corresponding to II.

If the 3-thianaphthenyl group is considered as a substituent on the aliphatic carbon chain, this acid must be assigned to the D-series.

The work described here is part of a stereochemical study of aralkyl carboxylic acids. Full details will be given elsewhere.

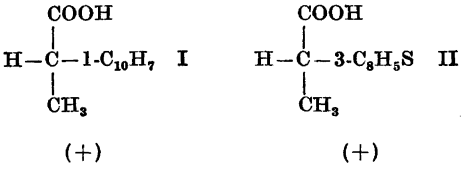
*iso*Thiocyanates XXII *. 3-Benzoyloxypropyl *iso*Thiocyanate, Present as a Glucoside (Glucomalcolmiin) in Seeds of *Malcolmia maritima* (L.) R.Br.

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark

Paperchromatographic analysis of the *iso*thiocyanate glucosides in a seed extract of the crucifer *Malcolmia maritima* (L.) R. Br. revealed the presence of two glucosides, (a) and (b), possessing R_B-values [1] of 0.34 and 1.36, respectively, in the solvent system: *n*-butanol:ethanol:water (4:1:4). In addition, traces of a third glucoside (R_B 1.03) and substantial amounts of sinapine were recognized in the seed extract, a pattern similar to that obtained elsewhere [1].



In the present work, the glucoside (a) has been unequivocally identified as glucocheirolin, furnishing cheirolin (3-methylsulphonylpropyl *iso*thiocyanate) on enzymic hydrolysis, a mustard oil formerly recognized as a constituent of *Cheiranthus cheiri* L.** and other species [2]. Crystalline thiourea derivatives have been obtained from enzymically hydrolyzed seed macerates of *M. maritima* after treatment with aniline and benzylamine, identical with reference specimens prepared from synthetic cheirolin [3]. The phenylthiourea has been described previously [2,3] whereas the benzyl derivative is a new compound, m. p. 116° (uncorr.). (Found: C 50.35; H 6.26; N 9.70. Calc. for $C_{12}H_{16}O_2N_2S_2$: C 50.31; H 6.33; N 9.78).

The component (b), for which we propose the name *glucomalcolmiin*, is obviously different from all glucosides heretofore encountered in nature. The corresponding optically inactive, non-volatile *iso*thiocyanate, liberated from a paperchromatographically purified specimen of glucomalcolmiin, displays an ultraviolet absorption spectrum indicative of the presence of a strongly chromophoric system (λ_{max} 230 mμ, λ_{min} 213 mμ in water). The new mustard oil has been characterized as a crystalline thiourea, $C_{11}H_{14}O_2N_2S$, after treatment with ammonia, m. p. 162° (uncorr.). (Found: C 55.40; H 5.91; N 11.75; S 13.59. Calc. for $C_{11}H_{14}O_2N_2S$: C 55.41; H 5.92; N 11.75; S 13.45); UV-spectrum in ethanol: λ_{max} 237 mμ (ε 19 400), λ_{min} 214 mμ (ε 11 180) and low-extinction inflections at 270—272 mμ and 278—280 mμ. authentic specimen. On paper chromatography in water-saturated chloroform, the thiourea migrates at a rate corresponding to an R_{Ph}-value [4] of 1.07.

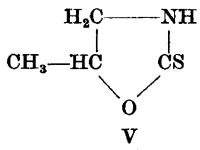
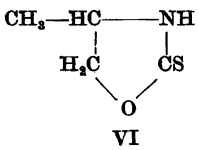
Disregarding the unlikely structures containing a hydroxyl grouping at the α-carbon atom, the alcoholic fragment of the new *iso*thiocyanatoalkyl benzoate may be represented by (I), (II) or (III), the last two structures possessing a centre of asymmetry and thence considered less likely in view of the optically inactive nature of the *iso*thiocyanate.

$HOCH_2CH_2CH_2NCS$ I



$H_3CCHOHCH_2NCS$ II

$H_3CCH(CH_2OH)NCS$ III



There are good reasons to expect (I), (II) and (III) to undergo spontaneous cyclization to (IV), (V) and (VI), respectively, the last two formulae representing a ring system formerly recognized in various substances derivable from naturally occurring β-hydroxysubstituted *iso*thiocyanates (*cf.* Ref.[5]).

IV

V

VI

$C_6H_5CO-O-(CH_2)_3NCS$ VII

When the thiourea-mixture, obtained by enzymic hydrolysis, solvent extraction and ammonia treatment of a purified seed extract of *M. maritima*, was chromatographed on paper, the pattern shown in Fig. 1 was observed. The results can be interpreted according to the following scheme, and strongly suggest that the new mustard oil is 3-benzoyloxypropyl *iso*thiocyanate (VII).

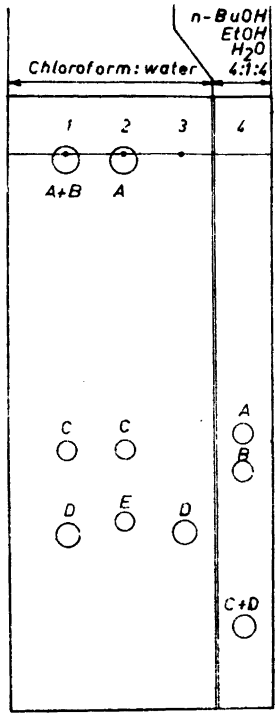


Fig. 1. Schematic, descending paper chromatograms. 1 and 4: thiourea mixture obtained from seeds of Malcolmia maritima; *2 and 3: synthetic reference samples. A: cheirolinthiourea; B: 3-hydroxypropylthiourea; C: tetrahydro-1,3-oxazine-2-thione (IV); D: 3-benzoyloxypropylthiourea; E: (±)-5-methyl-2-oxazolidinethione (V).*

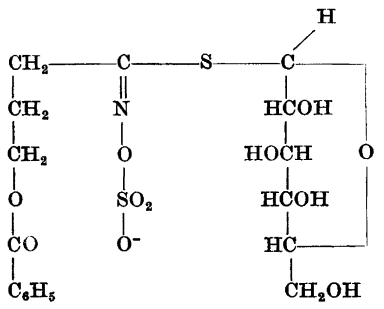
The normal thiourea formation is partly accompanied by ammonolysis of the ester linkage, resulting in the formation of (B) as well as the previously unknown tetrahydro-1,3-oxazine-2-thione (IV). An authentic specimen of the latter, prepared from 3-amino-1-propanol by the method of Hodgkins and Ettlinger [6] for the synthesis of *iso*thiocyanates, was obtained as colourless plates, m. p. 129° (uncorr.). (Found: C 41.05; H 6.21; N 11.86. Calc.



$$CH_3SO_2CH_2CH_2CH_2NCS \xrightarrow{NH_3} CH_3SO_2CH_2CH_2CH_2NHCSNH_2 \quad (A)$$

$$C_6H_5CO-O-CH_2CH_2CH_2NCS \xrightarrow{NH_3} \begin{cases} C_6H_5CO-O-CH_2CH_2CH_2NHCSNH_2 & (D) \\ HOCH_2CH_2CH_2NHCSNH_2 & (B) \\ IV & (C) \end{cases}$$

for C_4H_7ONS: C 40.98; H 6.02; N 11.95). The compound migrated on paper chromatograms at a rate definitely lower than that of a reference sample of (±)-5-methyl-2-oxazolidinethione (V) [7,8] (Fig. 1); it appears likely that the isomeride (VI) [9] will not differ markedly from (V) in its chromatographic behaviour. Synthetic experiments are now in progress to verify the structure (VII).

The possible existence in *Malcolmia* seeds of an additional glucoside, containing (B) as the aglucone and located at the site of glucocheirolin in the paper chromatogram, has been ruled out by chromatography on paper of the free *iso*thiocyanates in chloroform (spray reagent: ammoniacal silver nitrate). Only cheirolin and (VII) were detectable, both travelling near the solvent front, whereas no trace of the expected ring compound (IV) was observed. The present results explain the appearance of two spots in the low R_F-region of the paper chromatogram of *Malcolmia*-thioureas, reported by Schultz and Wagner [1]. One is attributable to cheirolinthiourea (A) whereas the other spot probably represents the artefact (B). In the present work it has been further established that our previously recorded occurrence of methyl *iso*thiocyanate in *Malcolmia* seeds [10] is incorrect.

The presence of glucose and sulphate in glucomalcolmiin has been verified by paper-chromatographic methods. The glucoside thence appears to be of the usual type. Unpublished results from this laboratory, supplemented by the conclusive work of Ettlinger and Lundeen [11] on the revised mustard oil glucoside structure, favour the following expression for the glucomalcolmiinate ion:

A detailed account of the present work will appear in this journal.

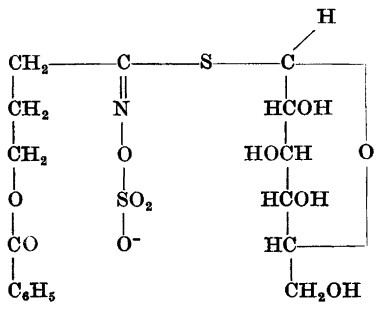
A New Modification of Titanium Monoxide

ULF KUYLENSTIERNA and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

According to Ehrlich [1], titanium monoxide has a structure of sodium chloride type with randomly distributed vacancies in both the titanium and oxygen frameworks and a very broad range of homogeneity. Samples of this phase were prepared by melting mixtures of titanium metal and titanium dioxide (both of high purity) under argon atmosphere in an electric arc furnace. The following data, which are in fair agreement with Ehrlich's results, were obtained for a few of the compositions studied.



The unit cell dimensions were obtained from powder photographs taken in a Guinier focusing camera with strictly monochromatized Cu$K\alpha_1$ radiation using potassium chloride as an internal standard.

The arc-melted samples were sealed in evacuated silica tubes, heated at 800° C for several days and quenched in water. The Guinier photographs of the preparations TiO_x ($x < 1$) then showed the pattern

for C_4H_7ONS: C 40.98; H 6.02; N 11.95). The compound migrated on paper chromatograms at a rate definitely lower than that of a reference sample of (±)-5-methyl-2-oxazolidinethione (V) [7,8] (Fig. 1); it appears likely that the isomeride (VI) [9] will not differ markedly from (V) in its chromatographic behaviour. Synthetic experiments are now in progress to verify the structure (VII).

A New Modification of Titanium Monoxide

ULF KUYLENSTIERNA and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

According to Ehrlich [1], titanium monoxide has a structure of sodium chloride type with randomly distributed vacancies in both the titanium and oxygen frameworks and a very broad range of homogeneity. Samples of this phase were prepared by melting mixtures of titanium metal and titanium dioxide (both of high purity) under argon atmosphere in an electric arc furnace. The following data, which are in fair agreement with Ehrlich's results, were obtained for a few of the compositions studied.

The unit cell dimensions were obtained from powder photographs taken in a Guinier focusing camera with strictly monochromatized Cu$K\alpha_1$ radiation using potassium chloride as an internal standard.

The arc-melted samples were sealed in evacuated silica tubes, heated at 800° C for several days and quenched in water. The Guinier photographs of the preparations TiO_x ($x < 1$) then showed the pattern

Composition	Axial length	Density	Per cent of available atomic sites occupied by titanium atoms	Per cent of available atomic sites occupied by oxygen atoms
$TiO_{0.64}$ (phase limit)	4.202 Å	5.00	96	61
$TiO_{1.00}$	4.182 Å	4.95	85	85
$TiO_{1.26}$ (phase limit)	4.169 Å	4.78	77	97

of the hexagonal α-titanium phase and a great number of extra lines. The latter also appeared in the photographs of samples TiO_x ($1 < x < 1.12$) in addition to a pattern corresponding to titanium monoxide of sodium chloride type of the approximate composition $TiO_{1.15}$. The new phase, the lines of which showed no detectable displacements in samples of different compositions, was pure in the sample $TiO_{1.00}$ and is obviously a new modification of titanium monoxide possessing a very narrow range of homogeneity. The density was found to be 4.91.

Table 1. Part of Guinier powder photograph of $TiO_{1.00}$, prepared at 800° C. CuKa_1 radiation.

I	$\sin^2\Theta_{obs}$
w	0.0191
w	0.0300
w	0.0347

The powder pattern of the new phase, listed in Table 1, is of a rather complicated appearance and probably of low symmetry. So far it has not been possible to index it. However, it shows a noticeable similarity to that of the monoxide of sodium chloride type. Thus the strong reflexions of the former appear as doublets close to those of the latter, *i. e. st* ($\sin^2\Theta = 0.1017$), *v st* (0.1358), and *v st* (0.2714). The similarity seems to indicate the existence of a structural relationship between the two phases. It might be that the structural transformation is associated with an ordering of the atomic vacancies present in the cubic phase.

These studies form part of a research program on metal oxides and related compounds financially supported by the *Swedish Natural Science Research Council*. Further studies on the titanium-oxygen system are in progress. A detailed report of the investigation will be published elsewhere.

The Synthesis of 6-Methoxy-2(3)-benzoxazolinone

PENTTI K. HIETALA and ÖRN WAHLROOS

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In this laboratory an anti-fungal substance was recently isolated from maize and wheat plants [1]. The structure 6-methoxy-2(3)-benzoxazolinone (IV) was proposed for this substance. This has now been confirmed by the following synthesis:

I II III IV

Pure *p*-benzene-azo-resorcine (I) was obtained by the method of Will and Pukall [2].

The methylation was done by the method of Bechold [3], with the following modifications: a) methyl iodide was used in the proportion 2 moles to 1 mole of the dry potassium salt of I; b) the reaction time was reduced from 6 h to 3 h (yield: 6 h, 1.5 %; 3 h, 14 % theor.).

2-Hydroxy-4-methoxy-aniline (III) is very easily oxidized wherefore the following stages were carried out in a carbon dioxide atmosphere: a) II was reduced in a boiling alcohol solution with a slight excess of a saturated solution of sodium hyposulphite in water [4], the mixture was neutralized with barium carbonate and evaporated almost to dryness (the aniline is removed with the vapour); b) III was extracted from the remaining mixture by peroxide-free ether and after evaporation of the ether it was mixed with glacial acetic acid, about ten times its weight, when the acetate of III precipitated. Phosgene was bubbled through the mixture [5] until the precipitate had dissolved.

After evaporation of the acetic acid *in vacuo*, dissolving the residue in hot water, treating with active carbon to decolourize the solution, and filtrating, IV crystallizes on cooling. Yield 15 % of the theoretical. Through recrystallization from alcohol colourless needles, m. p. 156°, were obtained.

The mixed melting point of this substance and the anti-fungal substance of wheat and maize plants showed no depression. Acetyl derivative m. p. 150° C (no depression).

UV spectra (in water): Synthetic product: Max. 229–230 mμ and 285–286 mμ; Min. 255 mμ; Log ε 286 mμ = 3.74.

Isolated anti-fungal substance: Max. 285–286 mμ; Min. 255 mμ.

On the Preparation of Alkyl Cyanides

ÅRNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

In an interesting paper Lewis and Susi [1] report that the preparation of alkyl cyanides from the corresponding primary bromides gives very good yields when ethylene glycol is used as solvent.

Glycols seem to be excellent for this reaction, being good solvents of alkali cya-

nides and easily obtainable in a sufficiently anhydrous state to prevent hydrolysis of the alkyl cyanide under the condition of the reaction. The boiling-point of ethylene glycol is, however, somewhat too low to permit easy separation of the alkyl cyanide by means of distillation. In order to eliminate this disadvantage some polymers of ethylene glycol, such as diethylene glycol and polyethylene-glycol-300, have been tried. In these experiments it was surprisingly found that, although the yields were moderate and the reaction slow when bromides were employed, the yields were excellent and the reaction rapid and sometimes vigorous when the corresponding chlorides were used. The reason for this is probably that the reaction is heterogeneous, making solubility a very important factor.

The fact that excellent yields of alkyl cyanides can be obtained from the corresponding alkyl chloride is of great value, since alkyl chlorides are readily available by the chlorination of hydrocarbons and by other methods.

When an alkyl chloride is refluxed with sodium cyanide in polyethylene glycol the temperature in the reaction-flask is at first equal to the boiling-point of the chloride. Since the alkyl cyanide has a much higher boiling-point than the corresponding alkyl chloride, the reaction-temperature will rapidly rise as long as the alkyl cyanide is being formed from the alkyl chloride. This permits an exact determination of the end-point of the reaction as the point where the temperature in the flask no longer rises. The alkyl cyanide is then easily removed from the reaction-mixture by distillation. The crude product obtained in this way contains very little by-products, and is pure enough for most purposes.

If necessary it can easily be purified by means of distillation.

Experimental. In a 5-l round-bottomed flask fitted with an efficient stirrer, a reflux condenser, and a thermometer, were placed 1.5 l of polyethylene-glycol-300, 300 g of sodium cyanide, and 5 moles of the alkyl chloride. The flask was heated by means of an electric heating-mantle so arranged that it could easily be removed if the reaction showed any tendency to become violent. The flask was heated until the temperature was practically constant. The refluxing time varied from about 15 min for *n*-octyl chloride to about 4 h for *n*-butyl chloride. The nitrile was then removed by distillation under reduced pressure as long as any product came over. A temperature of 200° at a pressure of 10 mm was often required to ensure complete removal of the nitrile from the reaction-product. Practically no polyethylene glycol distilled under these conditions. The yield of the crude product varied between 90—95 %, and the yields of the redistilled alkyl cyanides were all in the region of 85—95 % when the chlorides from *n*-butyl to *n*-octyl were employed. When the reaction tended to become violent, which was the case when chlorides higher than *n*-hexyl were used, the reaction was easily controlled by stopping the stirrer and removing the heating-mantle.

La Structure d'un Isomère du Raffinose Isolé des Racines de l'*Angélica archangélica* L. subsp. *norvégica* (Rupr.) Nordh

ALF WICKSTRØM et ANDERS BÆRHEIM SVENDSEN

Universitetets farmasøytiske institutt, Blindern-Oslo, Norvège

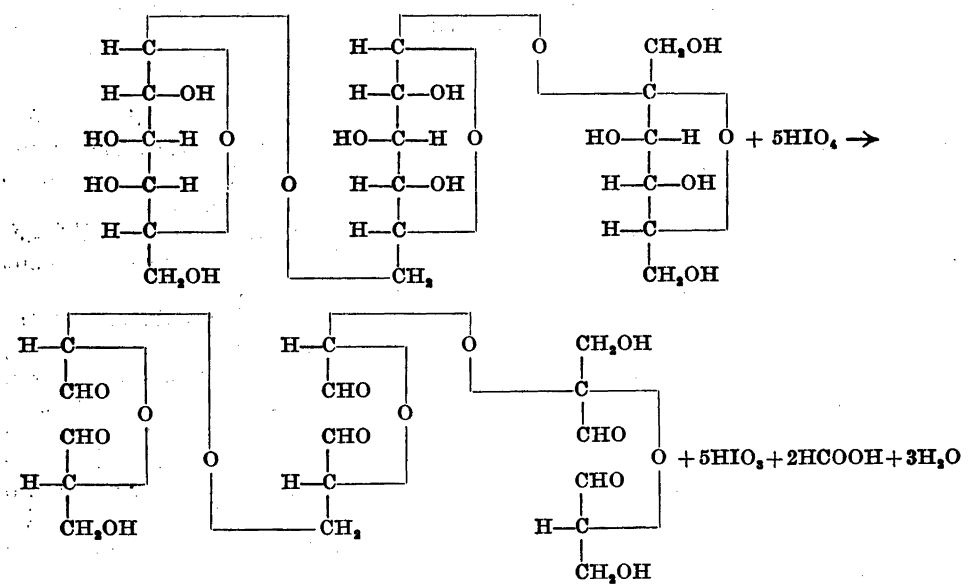
A non-reducing trisaccharide occurring in the roots of some *Umbelliferæ* has been isolated on a preparative scale from *Angelica archangelica* L. subsp. *norvegica* (Rupr.) Nordh. The trisaccharide ($[\alpha]_D^{20} = +125°$; water; on anhydrous basis) contains D-fructose, D-glucose and D-galactose, linked together in the same order as in raffinose, and, like raffinose, it yields sucrose on hydrolysis with α-galactosidase. One molecule of the trisaccharide reduces under standard experimental conditions four molecules of periodate, and one molecule of formic acid is simultaneously formed. The fully methylated trisaccharide gives by acid hydrolysis equimolecular amounts of tetramethyl-D-fructofuranose, tetramethyl-D-galactopyranose and 3,4,6-trimethyl-D-glucose. All experimental results obtained agree with the structure of a *2'-α-D-galactopyranosyl-2-α-D-glucopyranosyl-β-D-fructofuranoside*. According to this structure the trisaccharide studied is an *iso*raffinose, in the present paper, however, denoted as *umbelliferose*.

Au cours de ses recherches phytochimiques sur des ombellifères de Norvège l'un de nous [1] a trouvé dans les racines de certaines espèces de cette famille un trisaccharide qui, par quelques unes de ses propriétés, se distingue nettement des trisaccharides naturels décrits dans la littérature antérieure.

Ce sucre a été trouvé dans les racines de *Pimpinella saxifraga* L. et d'*Angélica archangélica* L. subsp. *norvégica* (Rupr.) Nordh., et il est probablement présent dans les racines de quelques autres ombellifères [1].

Le trisaccharide a été isolé en petites quantités à l'aide de chromatographie sur papier épaix. Il est composé de fructose, de glucose et de galactose, arrangés dans le même ordre que dans le raffinose: fructose-glucose-galactose.

Cependant, l'auteur cité [1] a trouvé à ce trisaccharide certaines propriétés permettant de conclure qu'il n'est pas identique au trisaccharide le plus répandu dans les plantes, le raffinose: 1) Après hydrolyse partielle on a isolé du fructose ainsi qu'un disaccharide qui, aux chromatogrammes, se sépare nettement du mélibiose, disaccharide isolé du raffinose par le même procédé. 2) Le trisaccharide nouveau est beaucoup plus résistant vis-à-vis de l'invertase que n'est le raffinose dans les mêmes conditions.



Dans le mémoire présent nous décrivons une téchnique améliorée pour l'isolement du trisaccharide des racines d'*Angélica archangélica* L. subsp. *norvégica* (Rupr.) Nordh. et nous présentons les résultats d'une étude de la structure moléculaire du sucre ainsi isolé. Nous adopterons, pour ce trisaccharide, la dénomination d'umbelliférose.

L'extraction et la purification de l'umbelliférose se trouvent décrites dans la partie expérimentale. 1 000 g de racines desséchées donnent 10 g environ de trisaccharide. Celui-ci se présente sous forme de poudre blanche, amorphe, non réductrice vis-à-vis le réactif cupro-alcalin. Son pouvoir rotatoire spécifique, déterminé sur des échantillons anhydres est de $+125°$ ($c = 2$; eau). Ce chiffre est très voisin de celui indiqué dans la littérature [2] pour le raffinose anhydre, $+123°$.

La vitesse d'hydrolyse de l'umbelliférose par l'α-galactosidase des graines de café est à peu près pareille à celle du raffinose (voir Tableau 1). Une molécule d'umbelliférose, par cette hydrolyse, donne naissance à une molécule de galactose et une molécule d'un disaccharide se composant de fructose et de glucose. Ce disaccharide a été isolé en état cristallin. Toutes ses propriétés chimiques et physiques, y compris le diagramme de diffraction aux rayons X, sont identiques à celles du saccharose (recristallisé de la même manière que le disaccharide inconnu). On en peut conclure que l'umbelliférose est un α-galactoside du saccharose. La présence dans l'umbelliférose de D-galactose sous forme pyranique étant prouvée par des études de méthylation auxquelles nous reviendrons plus bas, nous sommes en droit de conclure que l'umbelli-

SCHÉMA I.

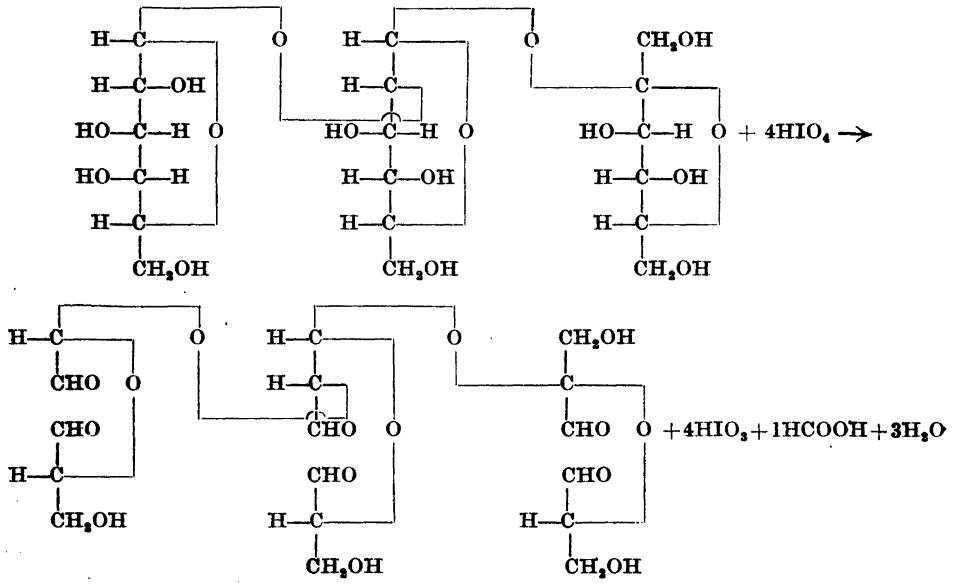
Oxydation du raffinose par l'acide periodique.

férose est un α-D-galactopyranoside du saccharose avec son galactose lié au glucose. Toutefois, cette description ne le distingue en rien du raffinose.

Cependant, l'étude quantitative de l'oxydation de l'umbelliférose par le periodate de sodium a révélé une différence de structure nette entre ce sucre et le raffinose. Le raffinose, étudié par Courtois et Wickström [3], réduit cinq molécules d'acide periodique en donnant naissance à deux molécules d'acide formique au cours de la réaction présentée ci-dessous dans le schéma I. L'umbelliférose, par contre, réduit dans des conditions expérimentales semblables quatre molécules d'acide periodique, ne produisant qu'une seule molécule d'acide formique. Ces résultats, qui se trouvent exposés dans le Tableau 2, sont interprétés de la façon suivante.

L'acide formique est libéré par l'attaque de l'acide periodique sur les trois hydroxyles libres se trouvant dans l'anneau D-galactopyranosique, qui, par conséquent, pour son ouverture, exige la réduction de deux molécules d'acide periodique. Une troisième molécule d'acide periodique est réduite par le D-fructofuranose appartenant à la partie du trisaccharide possédant la configuration du saccharose. Il s'en suit que la quatrième molécule d'acide periodique est réduite, sans libération simultanée d'acide formique, par l'unité centrale du trisaccharide: le D-glucopyranose. Celui-ci, par conséquent, doit posséder deux fonctions alcooliques libres attachées à deux atomes de carbone contigus. La réaction entre l'umbelliférose et l'acide periodique permet d'envisager, pour l'umbelliférose, deux structures différences: 1) celle d'un α-D-galactopyranoside du saccharose avec le pont galactosidique lié au carbone 4 du glucose ou 2) celle d'un α-D-galactopyranoside du saccharose avec le pont galactosidique attaché au carbone 2 du glucose.

Pour nous permettre de choisir entre ces deux possibilités, l'umbelliférose, après méthylation complète, a été soumis à l'hydrolyse et les oses méthoxylés ainsi formés ont été identifiés. Par ce procédé ont été obtenus, en quantités pratiquement égales, le tétraméthyl-D-fructofuranose, le tétraméthyl-D-galactopyranose et le triméthyl-3,4,6-D-glucose. Ce dernier a été identifié par sa réaction caractéristique, décrite par Greville et Northcote [4], avec le periodate de sodium, réaction qui permet de distinguer ce dérivé de tous les triméthyl-D glucoses ne possédant pas, comme le triméthyl-3,4,6-D-glucose, un groupement hydroxyle libre en position 2.



La réaction entre l'umbelliférose et l'acide periodique est représentée par le schema II.

Il convient de noter que l'observation du changement du pouvoir rotatoire pendant l'oxydation de l'umbelliférose par l'acide periodique nous a fourni d'un argument supplémentaire en faveur de la configuration α du carbone 1 du groupement galactopyranosique. Ce changement du pouvoir rotatoire est dû à l'élimination partielle des centres optiquement actifs, principe déjà devenue classique dans les recherches sur les hétérosides simples [5].

Herrisey, Wickstrøm et Courtois [6], étudiant l'oxydation periodique du raffinose, du gentianose et du stachyose, on démontré que la déviation au polarimètre pendant l'oxydation du raffinose et du stachyose, oligosaccharides possédant des liaisons osidiques sous forme α, est toujours positive. Le gentianose, au contraire, qui possède une liaison osidique sous forme β, est transformé par oxydation en substance lévogyre. Or, nous avons trouvé à l'umbelli-

SCHÉMA II.

Oxydation de l'umbelliférose par l'acide periodique.

férose pendant son oxydation une déviation au polarimètre positive et du même ordre de grandeur que celle du raffinose dans les mêmes conditions.

L'ensemble de nos résultats expérimentaux sont en accord avec la structure présentée ci-dessous pour l'umbelliférose:

α-D galactopyranosyl-2′-α-D glucopyranosyl-2 β-D-fructofuranoside.

D'après cette structure la seule différence entre l'umbelliférose et le raffinose se trouve dans la position du pont oxydique reliant le D-galactose au carbone 2 du D-glucose dans l'umbelliférose tandis que dans le raffinose il est lié au carbone 6; voir schéma I et II. L'umbelliférose se classe donc comme un *isoraffinose.*

PARTIE EXPÉRIMENTALE

1. Isolement et purification de l'umbelliférose

Des racines d'*Angélica archangélica* L. subsp. *norvégica* (Rupr.) Nordh. furent cultivées par Vinmonopolet A/S, Oslo, et récoltées en Septembre—Octobre de la première année de végétation.

Les racines, soigneusement lavées, puis grossièrement découpées, ont été stabilisées par l'alcohol à 96 % bouillant additionné de carbonate de calcium. Après ce traitement les racines séchées à la température ordinaire sont découpées et pulvérisées. Un kg de racines pulvérisées est extrait par dix litres d'eau distillée, saturée de toluène, pendant 24 heures à environ 20°. L'extrait aqueux est filtré; ensuite on le fait passer par des colonnes d'échangeurs d'ions, d'abord l'Amberlite IR 120 (H) et ensuite l'Amberlite IRA 400 (OH).

Il est avantageux de soumettre la solution ainsi obtenue à une purification ultérieure par la méthode classique de précipitation des acides par l'acétate de plomb.

On obtient finalement une solution jaune renfermant de l'umbelliférose, du saccharose, des traces d'hexoses et des impuretés colorées. Cette solution est concentrée sous pression réduite. Le résidu est un sirop de couleur jaune très foncé, presque solide. Rendement: 100 g.

Pour le fractionnement du sirop nous avons eu recours à la téchnique chromatographique de Whistler et Durso [7]; emploi d'une colonne de charbon actif et de celite, élution par l'éthanol à titre croissant. Avec le "Carbo activatus siccus Merck, p.a. No. 2186" nous avons obtenu une séparation des sucres aussi satisfaisante qu'avec le charbon "Darco-G-60", utilisé par Whistler et Durso.

L'adsorbant est introduit sur une hauteur d'environ 18 cm dans une colonne de 3,5 cm de diamètre, puis on ajoute 30 ml d'une solution aqueuse à 10 % du mélange saccharique. Ensuite la colonne est lavée, d'abord avec de l'eau distillée (environ 1 litre), puis avec de l'eau renferment 5 % d'éthanol (1,5 à 2 litres) pour éliminer le saccharose. Vers la fin de l'élution la solution sortant de la colonne contient des traces d'umbelliférose. Il est naturellement indispensable de contrôler, par chromatographie sur papier, que toute trace de saccharose est éliminée avant de commencer l'élution de l'umbelliférose avec de l'éthanol à 15 % (0,75 litre).

L'éluate contenant l'umbelliférose est concentré sous pression réduite. Le résidu est repris dans 5—10 ml d'eau distillée, traité par du charbon actif, filtré et concentré de nouveau sous pression réduite. On obtient finalement environ 300 mg d'umbelliférose chromatographiquement homogène, se présentant sous forme de poudre blanche, floconneuse et amorphe. Nous n'avons pas réussi à faire cristalliser l'umbelliférose.

Le pouvoir rotatoire du trisaccharide a été déterminé avec des échantillons séchés jusqu'au poids constant dans le vide en présence d'anhydride phosphorique à 60°. Le pouvoir rotatoire spécifique en solution aqueuse, observé sur plusieurs échantillons provenant de préparations différentes, a toujours été trouve entre $+121°$ et $+125°$ ($c = 2$). Il nous paraît probable que le pouvoir rotatoire le plus élévé, $[\alpha]_D^{20} = +125{,}3°$, corresponde au produit le plus pur.

Il convient à noter que l'umbelliférose est facilement séparé du raffinose par chromatographie sur papier, avec le même système solvant que nous avons utilisé pour contrôler, par chromatographie sur papier, le fractionnement sur colonne du saccharose et le l'umbelliférose. Aux chromatogrammes, réalisés par la technique descendante à 20°—22° avec le système monophasique: *iso*pentanol: 7 vol./pyridine: 7 vol./eau: 6 vol., le cheminement du saccharose au cours de 24 heures est de 24 à 28 cm. Les distance parcourues (R_S) par les trisaccharides par rapport à la migration du saccharose ($R_S = 1{,}00$) sont pour le raffinose 0,62 et pour l'umbelliférose 0,70.

2. Dosage quantitatif des hexoses libérés par hydrolyse acide de l'umbelliférose

a) *Hydrolyse complète:* Environ 50 mg de l'umbelliférose anhydre, exactement pesés, ont été dissous dans 1 ml d'acide sulfurique N/1 et chauffés en ampoule scellée à 100° pendant une heure. Neutraliser avec le carbonate de baryum, centrifuger et séparer les hexoses par chromatographie sur papier avec la phase organique du système solvant: acétate d'éthyle: 2 vol./pyridine: 1 vol./eau: 2 vol. Les hexoses séparés ont été élués à froid [8] et dosés par titration, d'après le protocôle de Hirst et Jones [9], de l'acide formique libéré par oxydation avec le metaperiodate de sodium. Les chiffres suivants, représentant des moyennes de plusieurs chromatogrammes, expriment les proportions moléculaires des hexoses dans l'hydrolysat: glucose: 1,00; galactose: 0,96; fructose: 0,89.

b) *Hydrolyse partielle:* Une solution à 1,874 % d'umbelliférose anhydre dans de l'acide sulfurique 0,01 N (3 ml) est introduite dans une ampoule scellée et chauffée à 100° pendant 40 minutes. Par ce traitement le fructose est selectivement et complètement détaché de la molécule d'umbelliférose. Pendant l'hydrolyse le pouvoir rotatoire change: $\Delta(\alpha)_D^{20}$: $-58{,}3°$, ce qui correspond à un changement du pouvoir rotatoire moléculaire ($\Delta(\alpha)_D^{20}$ x P.M. du trisaccharide) de $-$ 29 410. Ce dernier chiffre est très voisin à ceux

indiqués dans la littérature pour le changement du pouvoir rotatoire moléculaire de certains oligosaccharides, changement provoqué par la rupture d'une liaison β-D-fructofuranosidique [10].

L'hydrolysat a été neutralisé par le carbonate de baryum, puis centrifugé. Le fructose libre a été dosé, sur volumes exactement mesurés avec une micropipette, après séparation chromatographique suivant la méthode décrite ci-dessus. Analyse: Anhydrofructose, $C_6H_{10}O_5$, calc. pour $C_{18}H_{32}O_{16}$: 32,15 %, tr: 31,0 % (moyenne de plusieurs analyses).

3. Hydrolyse de l'umbelliférose par l'α-galactosidase des graines de café

a) *Vitesse d'hydrolyse comparée avec celle du raffinose dans les mêmes conditions:* Mélanger 2 ml d'une solution M/20 du sucre à analyser, avec 0,5 ml d'un tampon contenant de l'acide acétique M/1 neutralisé avec de la soude jusqu'à pH 4,8 et 0,1 ml d'une suspension à 2 % de l'α-galactosidase. Laisser en contact à 37°. Les sucres réducteurs libérés par l'hydrolyse enzymatique sont dosés par leur action réductrice sur le réactif cupro-alcalin d'après la méthode de Lehmann, mise au point par Fleury et Boutot [11]. Nos résultats sont exposés dans le Tableau 1.

b) *Isolement et identification du saccharose après l'hydrolyse enzymatique de l'umbelliférose:* 2,3 g du trisaccharide, dissous dans 10 ml du tampon acétique de pH 4,8, furent additionnés de 5 ml d'une suspension à 1 % de l'α-galactosidase dans l'eau. L'hydrolyse à 37°, en présence d'un peu de toluène, est contrôlée tous les 4 jours au moyen de chromatographie sur papier. Après 16 jours le mélange est filtré et transfert à une colonne de charbon actif-cellite (diamétre: 3,5 cm, hauteur de l'adsorbant: 20 cm). Le galactose et les sels minéraux sont élués par de l'eau distillée (3 litres). Ensuite le disaccharide est récupéré par élution avec de l'éthanol à 5 %. La solution alcoolique fut concentrée sous pression réduite en un sirop visceux et incolore (1 g). Cette substance, après avoir été séchée dans le vide en présence d'anhydride phosphorique, fut obtenu en état cristallin en suivant le procedé décrit par Courtois, Anagnostopoulos et Petek [12]. Rendement 0,47 g.

Un échantillon témoin de saccharose a été recristallisé dans un mélange d'éthanol et d'éther suivant le même protocôle. Le disaccharide formé par détachement de galactose de l'umbelliférose fournit le même diagramme de diffraction aux rayons X que l'échantillon témoin de saccharose. Il est dédoublé par l'invertase d'une vitesse voisine de celle du dédoublement du saccharose. Son point de fusion: 185—188° (déterminé au microscope avec l'appareil de Kofler) n'est pas modifié par mélange avec l'échantillon témoin du saccharose. Son pouvoir rotatoire, $(\alpha)_D^{20} = +66{,}8°$ (c = 2; eau), donc, pareil à celui du saccharose.

4. Oxydation de l'umbelliférose par l'acide periodique; comparaison avec le raffinose

50 ml d'une solution à M/500 du trisaccharide à analyser sont mélangés avec 200 ml d'une solution à M/100 de metaperiodate de sodium ($NaIO_4$). Laisser reposer à 18—20° à l'abri de lumière. Avec des prélèvements de 25 ml on fait a) un dosage de la quantité

Tableau 1. Action de l'α-galactosidase sur l'umbelliférose. Comparaison avec le raffinose.

Durée de contact à 37° (jours)	1	2	4	7
Molécules de galactose libérées par molécule de raffinose	<0,2	0,25	0,36	0,64
Molécules de galactose libérées par molécule d'umbelliférose	0,26	0,46	0,53	0,66

d'acide periodique réduite, dosage effectué d'après la méthode classique à l'anhydride arsénieux-iodure, et b) un dosage de l'acide formique libéré. Ce dosage a été fait par titration avec de la soude M/100 (rouge de méthyle-bleu de méthylène) après addition d'éthylèneglycol neutre (0,5 ml).

Les chiffres trouvé sont présenté dans le Tableau 2. Les résultats obtenus avec le raffinose en suivant la technique décrite ci-dessus sont conformes aux observations antérieures, voir Courtois et Wickstrøm [3].

Dans des essais supplémentaires l'oxydation de l'umbelliférose par l'acide periodique libre est suivie au polarimètre. A titre d'exemple nous citerons une des expériences. 116,80 mg d'umbelliférose anhydre, dissous dans 4 ml d'eau distillée, sont mélangés avec 3,6 ml d'une solution d'acide periodique libre M/2. Compléter à 10 ml et suivre l'oxydation au polarimètre à la température de 20—22°. Lectures (l = 1 dm): Après 15 min: +0,61°; après 2 h: + 0,55°; après 22 h: +0,48°. Après 22 h le pouvoir rotatoire reste constant. Le chiffre de +0,48° correspond à $[M]_D$ = 20 700. calculé en employant le poids moléculaire du polyaldéhyde résultant en théorie de l'oxydation de l'umbelliférose (schéma II). Le chiffre correspondant pour le raffinose est $[M]_D$ = 23 500[6].

Tableau 2. Oxydation de l'umbelliférose et du raffinose par le periodate de sodium.

Sucre	Durée de contact à 18°—20°	24 h	48 h	4 jours	6 jours	8 jours
Umbelliférose	Molécules [a] d'acide periodique réduites	3,57	3,90 3,97	4,06 4,02	4,13 4,17	4,16 4,17

Raffinose	Molécules [a] d'acide periodique réduites	4,87	4,98	5,03		
	Molécules [a] d'acide monovalent libérées	1,58	1,82	1,94		

[a] par molécule de trisaccharide.

5. Hydrolyse d'un umbelliférose complètement méthylé et séparation des oses méthylés libérés par l'hydrolyse

3,8 g d'umbelliférose anhydre sont traités trois fois par le diméthylsulfate en présence de soude. Ensuite le produit est traité plusieurs fois par l'iodure de méthyle en présence d'oxyde d'argent. Nous avons suivi sans modifications essentielles le procédé décrit d'une façon détaillée par Laidlaw et Wylam [13] pour la méthylation complète du stachyose.

L'umbelliférose complètement méthylé se présente sous forme de sirop. Il est légèrement jaune. Rendement: 2,35 g. Analyse: CH_3O calc. pour $C_{20}H_{34}O_{10}$: 51,8 %; tr.: 49,5 %. $[\alpha]_D^{20}$: +110° (c = 0,8; eau); $[\alpha]_D^{20}$: +133° (c = 1,2; chloroforme).

2 g du produit méthylé sont dissous dans 100 ml d'acide sulfurique N/1 et chauffés à reflux dans un bain marie bouillant. Lectures du $[\alpha]_D^{20}$: Après 2 h: +52°; après 4 h: +49°. Après chauffage ultérieur le pouvoir rotatoire spécifique reste constant. Après 5 h de chauffage l'hydrolysat est neutralisé par le carbonate de baryum (10 g). La solution est filtrée et ensuite concentrée sous pression réduite. Le résidu est un sirop légèrement jaune. Rendement: 1,5 g.

1,2 g de ce sirop qui, aux chromatogrammes, se comporte comme un mélange de trois hexoses méthylés, est fractionné par chromatographie de partage sur une colonne de poudre de cellulose d'après Hough, Jones et Wadman [14]. Le diamètre intérieur de la

colonne est de 3 cm et la poudre de cellulose (Whatman Ashless Cellulose powder, Standard grade) est introduite sur une hauteur d'environ 65 cm. La phase mobile utilisée pour l'élution des oses méthylés est un mélange de *n*-butanol et d'éther de pétrole, saturé avec de l'eau: *n*-butanol: 3 vol/light petroleum, Eb: 100—120°, B.D.H. Londres: 7 vol. Nous avons récupéré de la colonne trois fractions distinctes, chromatographiquement homogènes, obtenues, après évaporation complète du solvant sous pression reduite, sous forme de sirops incolores ou légèrement jaunes. Rendements: Fraction I: 0,30 g; Fraction II: 0,30 g; Fraction III: 0,25 g.

6. Identification des trois fractions d'hexoses méthylés

Chaque fraction est d'abord purifiée par dissolution dans l'eau, traitement à environ 60° avec un peu de charbon actif, filtration à chaud et ensuite élimination de l'eau sous pression réduite.

Les valeurs de R_G données ci-dessous pour les différentes fractions sont déterminées par chromatographie sur papier avec la phase organique du système solvant: *n*-butanol: 50 vol/éthanol: 10 vol/eau: 40 vol. R_G exprime [15] la distance parcourue par un ose par rapport à la distance parcourue par le tétraméthyl-D-glucopyranose (pour lequel R_G = 1,00), observé sur le même chromatogramme.

Fraction I (0,25 g): Analyse: CH_3O calc. pour $C_{10}H_{20}O_6$: 52,5 %; tr.: 52,0 %. $[\alpha]_D^{20}$: +30,5° (c = 1; eau) R_G: 1,00. Au chromatogrammes la fraction I ne peut être distinguée du tetraméthyl-1,3,4,6-D-fructose, ajouté comme témoin. Les taches sont développées par l'oxalate d'urée et chauffage à 130°. Elles sont de couleur noire ou grise, différente de la couleur brune des taches produites par les méthylfructoses fixés sous forme pyranique [16,17]. Les propriétés trouvées à la fraction I sont identiques à celles signalées pour le tétraméthyl-1,3,4,6-D-fructose [18].

Fraction II (0,25 g): Analyse: CH_3O calc. pour $C_{10}H_{20}O_6$: 52,5 %, tr.: 51,8%. Lectures du $[\alpha]_D^{20}$: (c = 0,8; eau) Après 30 min: +122°, après 2 h: +111°, après 3 h: + 106°. Ensuite, il reste constant. R_G = 0,90. Déméthylation [19] par chauffage avec l'acide bromhydrique à 48 % donne du galactose, caractérisé par chromatographie sur papier. La fraction II, traitée par l'aniline, fournit un anilide qui fond à 196—198° (au microscope avec l'appareil de Kofler). Ce point de fusion n'est pas modifié par mélange avec un échantillon témoin de tétraméthyl-2,3,4,6 N-phényl-D-galactopyranosylamine. Le pouvoir rotatoire spécifique de l'anilide est initialement —70° (c = 1; acétone) avec une mutarotation très lente vers le droite. L'ensemble des résultats permet de conclure que la fraction II est identique au tétraméthyl-2,3,4,6-D-galactose [20].

Fraction III (0,20 g): Analyse: CH_3O calc. pour $C_9H_{18}O_6$: 41,9 %; tr.: 41.1 %. R_G = 0,85. La déméthylation [19] par chauffage avec l'acide bromhydrique à 48 % fournit du glucose. $[\alpha]_D^{18}$: 1) +67°, 2) +73° (c = 1; méthanol anhydre avec 2 % d'acide chlorhydrique). Aucune mutarotation ne peut être décelée. Ce résultat élimine la possibilité de la fraction

Tableau 3. Oxydation de la fraction III (triméthyl-3,4,6-D-glucose) par le periodate de sodium.

Triméthyl-D-glucose ..... 0,002 M, 5 ml
Metaperiodate de sodium ..... 0,01 M, 1,5 ml

Durée de contact à 20°—22° à l'abri de lumière	30 min	60 min.	20 h	48 h
Molécules [a] de periodate réduit	0,62 [b]	0,82	0,95	0,97
Molécules [a] d'acide volatil monovalent formées			0,80	0,89

(a) par molécule de triméthyl-D-glucose.
(b) Les chiffres représentent des moyennes de plusieurs expériences.

III étant identique au triméthyl-2,3,6-D-glucose, qui est le plus souvant caractérisé par l'inversion [21] de son pouvoir rotatoire dans le méthanol en présence d'acide chlorhydrique. On peut déjà constater celle-ci après 24 h dans les conditions expérimentales précisées ci-dessus [22]. Le $[\alpha]_D^{20}$ du triméthyl-3,4,6-D-glucose, au contraire, reste constant à environ +70° (méthanol + HCl) [22].

L'oxydation de la fraction III par le periodate de sodium fut étudiée suivant le procédé de Greville et Northcote [4], qui permet de distinguer d'une façon irréfutable le triméthyl-3,4,6-D-glucose des autres triméthyl-D-glucopyranoses. Nos résultats se trouvent exposés dans le Tableau 3. D'après Greville et Northcote [4] c'est uniquement le triméthyl-3,4,6-D-glucose qui, par oxydation periodique, donne naissance à une molécule d'acide volatil (formique) et qui d'ailleurs est capable de réduire rapidement le periodate. Le triméthyl-2,3,6,-D-glucose ne le réduit point [4]. L'ensemble de nos résultats permet de conclure que la fraction III est identique au triméthyl-3,4,6-D-glucose.

Nous adressons nos plus vifs remercîments à Monsieur le professeur J.-E. Courtois, Paris, qui a bien voulu mettre à notre disposition un échantillon purifié d'α-galactosidase des graines de café.

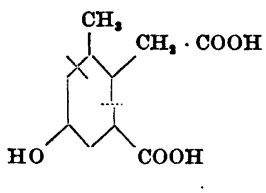
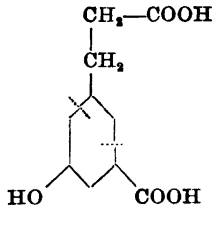
ACTA CHEMICA SCANDINAVICA 10 (1956) 1208—1214



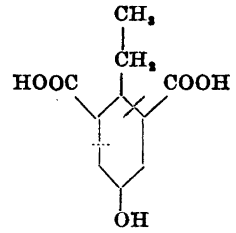
Cyclic Compounds from Acetylpyruvic Esters. Part III
Structure of the Acid $C_{10}H_{10}O_5$

ENDRE BERNER



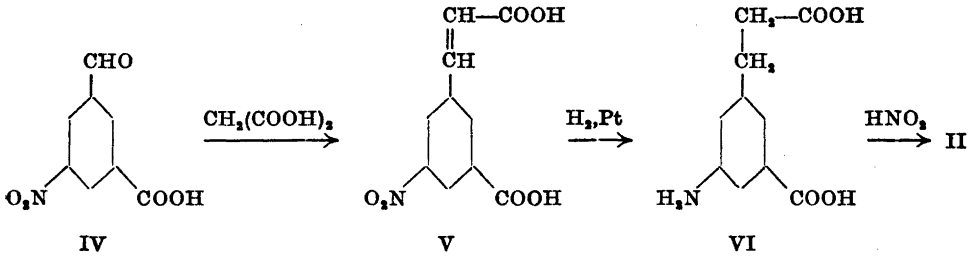
Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The following three aromatic hydroxy acids have been synthesized, a) 3-hydroxy-5-carboxyhydrocinnamic acid, b) 2-ethyl-5-hydroxybenzoic acid, and c) 2-ethyl-5-hydroxy*iso*phthalic acid. The acid c was found to be identical with the acid $C_{10}H_{10}O_5$ obtained by treatment of the hydrogenated condensation product of methyl acetylpyruvate with barium hydroxide.



In part I of this series [1] it was shown that the condensation product of methyl acetylpyruvate (in short called methyl product), first described by Claisen [2] as being an open-chained compound, actually must have a cyclic structure. Already Claisen found that the methyl product on heating with barium hydroxide split off oxalic acid and gave 3-methyl-5-hydroxybenzoic acid. Besides verifying this we found that the hydrogenated methyl product, having taken up two moles of hydrogen, on heating with barium hydroxide gave the three compounds: oxalic acid, 3-methyl*cyclo*hexanone-5-carboxylic acid, and an aromatic hydroxy-dicarboxylic acid $C_{10}H_{10}O_5$ with m.p. 267°. For the latter we found that the structural formula I would be in agreement with most of the findings, although we were unable to prove the structure by degradation, either by decarboxylation or by oxidation. Later it was found that an acid with the structure I, 5-hydroxy-3-carboxy-*o*-tolueneacetic acid, had been synthesized by Meldrum and Vaidyanathan [3]. The synthetic acid, having the m.p. 210°, was quite different from our acid, a fact which was verified by repeating the synthesis, and formula I therefore had to be abandoned.

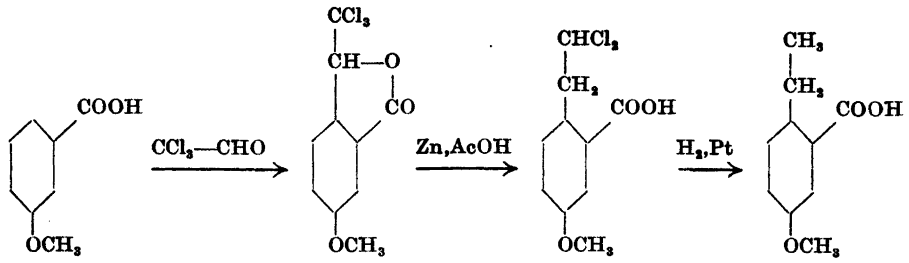
I



II

III

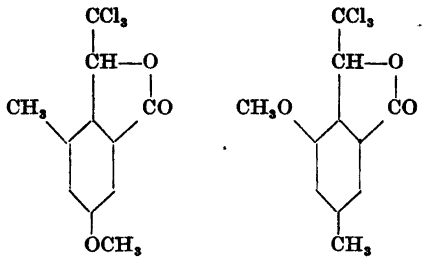
By further work on the structure of $C_{10}H_{10}O_5$ it was found that the main product obtained on decarboxylating the sodium salt by heating with calcium hydroxide was *p*-ethylphenol, a chromatographic investigation at the same time revealing that small amounts of *m*-ethylphenol and phenol were also formed during the decarboxylation. In order to explain the occurrence of the ethylphenols a structural formula II, 3-hydroxy-5-carboxyhydrocinnamic acid, for the substance $C_{10}H_{10}O_5$ was considered. A corresponding formula for the methyl product would contain the side-chain $-CH_2-CO-COOH$ and thus be able to explain that oxalic acid and 3-methyl-5-hydroxybenzoic acid are formed by treatment with barium hydroxide. The simultaneous occurrence of *p*- and *m*-ethylphenol would at any rate imply that either the ethyl or the hydroxyl group migrates during the decarboxylation. As indicated by dotted lines a skeleton as in formula II would be compatible with the formation of the methyl product from two molecules of acetylpyruvic ester. A synthesis of 3-hydroxy-5-carboxyhydrocinnamic acid (II) also showed, however, that this acid was different from our acid $C_{10}H_{10}O_5$.



The synthesis was carried out in the following way: *Iso*phthalaldehydic acid on nitration gave 5-nitro*iso*phthalaldehydic acid (IV) in which the 5-position of the nitro group was proved by oxidation of IV to the known 5-nitro*iso*phthalic acid. Condensation of IV with malonic acid gave 3-carboxy-5-nitrocinnamic acid (V). On catalytic hydrogenation the latter was transformed into 3-carboxy-5-aminohydrocinnamic acid (VI) which was diazotized to 3-carboxy-5-hydroxyhydrocinnamic acid (II), having m.p. 200—202°.

The third possibility for the structure of $C_{10}H_{10}O_5$ which suggested itself was formula III, representing the 2-ethyl-5-hydroxy*iso*phthalic acid. It is *a priori* difficult to perceive how a skeleton as in formula III could be compatible with the simultaneous occurrence of the 3-methyl*cyclo*hexanone-5-carboxylic acid when the hydrogenated methyl product was treated with barium hydroxide, and with the formation of 3-methyl-5-hydroxybenzoic acid by treament of the methyl product itself with barium hydroxide. A satisfying explanation of this difficulty has, however, been found and will be dealt with in a later communication. Our present aim is to prove the correctness of formula III for the acid $C_{10}H_{10}O_5$.

As described in part I of this series a methyl ether of the acid $C_{10}H_{10}O_5$ could easily be prepared. A partial decarboxylation of this methyl ether was achieved by heating it with copper chromite, the main product being a crystalline methyl ether of a monobasic hydroxy acid. The corresponding hydr-

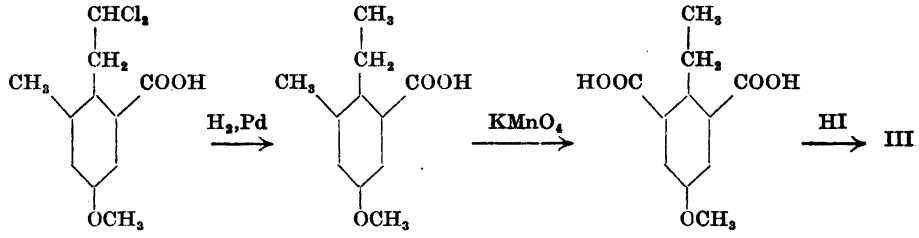


oxy acid, $C_9H_{10}O_3$, m.p. 155°, gave no colour with ferric chloride and on further decarboxylation in the usual way gave *p*-ethylphenol only. The product from the partial decarboxylation must therefore be the methyl ether of 2-ethyl-5-hydroxybenzoic acid (X) which was confirmed by the following synthesis.

VII VIII IX X

According to Fritsch [4] the main product of the reaction between *m*-methoxybenzoic acid (VII) and chloral hydrate in the presence of conc. sulphuric acid is 5-methoxy-2-trichloromethylphthalide (VIII). On heating with zinc powder and glacial acetic acid VIII was reduced to 2-β,β-dichloroethyl-5-methoxybenzoic acid (IX). The substance IX on catalytic dehalogenation gave 2-ethyl-5-methoxybenzoic acid (X) which was found to be identical with the product obtained by partial decarboxylation of the methyl ether of $C_{10}H_{10}O_5$.

Finally an acid with the structural formula III was synthesized along a similar line as that followed by the synthesis of the acid m.p. 155°. Meldrum [5] and later Meldrum and Vaidyanathan [3] showed that 5-methoxy-3-methylbenzoic acid (or its ester) reacted with chloral hydrate to give a mixture of 5-methoxy-3-methyl-2-trichloromethylphthalide (XI) and 3-methoxy-5-methyl-2-trichloromethylphthalide (XII), having m.p. 118° and 143°, respectively.



XI XII

A complete separation of the two isomers by crystallization is very difficult to achieve. On repeated crystallizations the lowest melting isomer (XI) was, however, accumulated in the mother liquors and could thus be obtained in a sufficient purity so as to ensure that it was really this isomer which formed the basis for the present synthesis. Having established this fact it was in later

experiments found to be practical to separate the isomeric trichloro-compounds only partially and to use the lower melting, more soluble fraction for the synthesis. A final separation of isomeric reaction products was then undertaken at a later stage as described in the experimental part. The structures of the two isomers XI and XII have been ascertained by Meldrum and Vaidyanathan [3] by transforming them into 5-hydroxy-3-methylphthalic acid (β-coccinic acid) and 3-hydroxy-5-methylphthalic acid (γ-coccinic acid), respectively.

The isomer XI on treatment with zinc powder in glacial acetic acid gave 2-β,β-dichloroethyl-5-methoxybenzoic acid (XIII) which was dehalogenated catalytically to 2-ethyl-3-methyl-5-methoxybenzoic acid (XIV).

XIII XIV XV

The oxidation of XIV to 2-ethyl-5-methoxy*iso*phthalic acid (XV) was effected by potassium permanganate in alkaline solution. The fact that the methyl group alone and not the ethyl group was oxidized must be due to steric hindrance. In the oxidation product itself (XV) in which both *ortho* positions to the ethyl group are occupied by carboxyl groups the steric hindrance is so pronounced that the substance cannot be oxidized at all without breaking up the molecule. The methyl ether XV on treatment with hydroiodic acid gave the corresponding hydroxy acid (III) which had the m.p. 267° and was found to be identical with the acid $C_{10}H_{10}O_5$ obtained from the hydrogenated methyl product.

As mentioned above the decarboxylation of $C_{10}H_{10}O_5$ by the classical method led mainly to *p*-ethylphenol with *m*-ethylphenol and phenol as minor products. In view of formula III the explanation of this result must be that the ethyl group migrates. In some cases it will thereby occupy the position of a carboxyl group when this is expelled, in other cases the ethyl group will not re-enter the molecule at all and phenol will be the final product.

EXPERIMENTAL

(Melting points not corrected)

3-Hydroxy-5-carboxyhydrocinnamic acid

(In part with Stud. real. Asbjørn Baklien)

m-Carboxycinnamic acid, prepared by conventional methods from *m*-nitrocinnamic acid, had m.p. 268–270°. (Found: C 62.27; H 4.21; M by titration 194; Calc. for $C_{10}H_8O_4$ (192.2): C 62.50; H 4.20.). Oxidation to *iso*phthalaldehydic acid: To a solution of *m*-carboxycinnamic acid in 50 ml N sodium carbonate and 400 ml water were added slowly

at 4—5° 80 ml 5 % potassium permanganate, stirring vigorously. The filtrate from manganese dioxide was concentrated to about 150 ml and acidified with 5 N hydrochloric acid, when a mixture of *iso*phthalaldehydic acid, isophthalic acid and unoxidized *m*-carboxycinnamic acid separated. In order to isolate the aldehydic acid, the solid mixture as well as the filtrate from it were extracted with ether in which the two last-mentioned acids are sparingly soluble. The crude *iso*phthalaldehydic acid (3.6 g) was recrystallized from water and had then m.p. 173°.

Nitration: A solution of *iso*phthalaldehydic acid (1.6 g) in conc. sulphuric acid (13 ml) was cooled to +5° and 1.23 g finely powdered potassium nitrate added in small portions. The solution was stirred until all nitrate had dissolved, keeping the temperature below 10°. During half an hour the temperature was raised to 35° and finally to 105—110° where it was kept for 15 min. Pouring the cooled solution on ice some un-nitrated substance (0.7 g) separated. The filtrate from this on extraction with ether gave the nitro*iso*phthalaldehydic acid as a yellow oil (1.0 g) which crystallized slowly when kept in a desiccator. The m.p. was not sharp, clear at 150°, but no attempt was made to recrystallize the acid. In order to prove the position 5 for the nitro group a small quantity of the substance (0.2 g) was oxidized with potassium permanganate to the corresponding nitro*iso*phthalic acid. The methyl ester of the oxidation product (prepared by means of diazomethane) had m.p. 123° and was identical with the methyl ester of the nitrated *iso*phthalic acid.

The 5-nitro*iso*phthalaldehydic acid was condensed with malonic acid, using a method given by Brand and Horn [6]: A mixture of the nitro acid (1 g), malonic acid (0.7 g), pyridine (3 ml), and piperidine (0.3 ml) was heated for half an hour to 70—80°. On raising the temperature to 100° carbon dioxide began to evolve. The temperature was finally raised to 140° and the heating discontinued after 2 ¼ hours. By addition of hydrochloric acid the 5-nitro-3-carboxycinnamic acid separated crystalline (1.2 g). It was recrystallized twice from water, using some Carbex E, and had m.p. 207—211°.

The simultaneous saturation of the double bond and the reduction of the nitro group were effected by catalytic hydrogenation. A solution of 5-nitro-3-carboxycinnamic acid (0.46 g) in methanol (25 ml) to which PtO_2 (0.1 g) had been added did not at first take up any hydrogen. Only after adding more PtO_2 (0.1 g) did the solution in the course of two hours consume 154 ml hydrogen (1 ½ atm.), calculated 160 ml. The filtered solution on evaporation left the amino acid as an oil (0.42 g) which was diazotized directly according to the following method given by Fieser and Lothrop [7]. A solution of the amino acid in 4 ml N sodium carbonate was diluted with water to 6 ml and 0.14 g sodium nitrite in 1 ml water added. The solution was cooled with ice and added slowly under stirring to a mixture of 0.8 ml conc. hydrochloric acid, 4—5 g ice and 0.25 g boric acid. On heating, first on a water-bath, later to boiling, gas evolved. By extraction of the solution with ether the 5-hydroxy-3-carboxyhydrocinnamic acid was obtained as a crystalline, slightly red-coloured mass with m.p. 200°. After recrystallizing twice from water, adding some Carbex E, the acid became practically colourless, m.p. 200—202°. It gave no colour with ferric chloride. (Found: C 57.48; H 4.82. Calc. for $C_{10}H_{10}O_5$ (210.2): C 57.14; H 4.76.)

2-Ethyl-5-hydroxybenzoic acid

3-Methoxybenzoic acid (5.0 g) and chloral hydrate (5.4 g) were dissolved in conc. sulphuric acid (25 ml) and left at room temperature for 24 hours. On dilution with ice and water an oil separated which immediately crystallized. The crystalline mass was crushed in a mortar and recrystallized from ethanol. The first fraction (5.5 g) had m.p. 139° (Fritsch [4] gave m.p. 135°) and the second fraction (1.6 g) m.p. 135—138°. A solution of the first fraction in glacial acetic acid (50 ml) was refluxed for 1 ½ hours with zinc powder (20 g). After adding water (30 ml) the refluxing was continued for half an hour. The clear solution decanted from excess of zinc powder on cooling separated needles (4.0 g) with a somewhat unsharp m.p., clear at 187°. This substance was dissolved in pure methanol (40 ml) and the solution after adding platinum oxide (0.25 g) shaken in an atmosphere of hydrogen. In the course of 1 ½ hours 1 110 ml hydrogen were absorbed. The filtrate from the platinum on evaporation in a vacuum gave a crystalline, halogen-free product (2.9 g) with m.p. about 65°, being the methyl ether of 2-ethyl-5-hydroxybenzoic acid. It was demethylated by refluxing for 3/4 hour with hydroiodic acid (10 ml,

d 1.7). The free hydroxy acid after crystallizing from water had m.p. 155° and showed no depression on mixing with the acid from the partial decarboxylation of $C_{10}H_{10}O_5$. (Found: C 64.97; H 6.05; M by titration 164. Calc. for $C_9H_{10}O_3$ (166,2): C 65.05; H 6.07.)

2-Ethyl-5-hydroxy*iso*phthalic acid

3-Methyl-5-methoxybenzoic acid (22.5 g) and chloral hydrate (22.5 g) were dissolved in conc. sulphuric acid (110 ml). The temperature rose slowly to 29° and then fell again. After standing for 24 hours at room temperature the solution was poured in ice-water. The viscous mass which separated crystallized overnight. It was crushed, filtered, washed and dried (38.7 g) and then crystallized from methanol.

Fraction	I, filtered after short time	21.6 g	m.p.	clear at	115°
»	II, filtered next day	7.8 »	»	» »	112°
»	III, after dilution with water	4.2 »	»	» »	114°

The fractions were treated separately with zinc powder in glacial acetic acid. Fraction I and zinc powder (8 g) in glacial acetic acid (45 ml) reacted on shaking and the solution became warm. In order to finish the reaction the shaking was continued for 3 hours. Afterwards some crystalline material which had separated was redissolved by heating and the solution filtered from excess of zinc. On subsequent addition of water the reduction product (IA, 15.2 g) separated crystalline. Fraction II on treatment in the same way with 3 g zinc powder gave 5.3 g crystalline product (IIA). Equivalent weight by titration 261, calc. for $C_{11}H_{12}O_3Cl_2$ 263. Fraction III on treatment with zinc gave only a partly crystalline reduction product which was discarded.

The fractions IA and IIA were combined and recrystallized from glacial acetic acid and two fractions were collected. Fraction IVA (5.5 g) which separated directly on cooling was not used for further treatment. Fraction IVB (12.8 g) obtained after dilution with water had equiv. wt. 260; it was dehalogenated in the following way. A solution of fraction IVB in 180 ml pure methanol to which had been added 105 ml 25 % methanolic KOH and 6.5 g catalyst (aluminum oxide with 5 % Pd) was shaken in an atmosphere of hydrogen for two hours when about 3 l hydrogen had been adsorbed. On diluting the filtered solution with water the dehalogenated product separated crystalline (7.5 g). It consisted of the methyl ethers of the two isomeric ethylmethylhydroxy-benzoic acids which could be separated by crystallization from petrol ether (45—68°). A solution obtained by refluxing the mixture with 200 ml petrol ether was allowed to evaporate slowly at room temperature in a beaker. The one component crystallizing in thin needles crept up the wall of the beaker. After recrystallization from dilute ethanol it had m.p. 137° and analyzed correctly for a methyl ether of ethylmethylhydroxy-benzoic acid. The other component separated mostly at the bottom of the beaker as clear prisms which could easily be collected (1.7 g). Recrystallized from dilute ethanol, m.p. 90°. (Found: C 68.11; H 7.45; OCH_3 15.98; M by titration 193. Calc. for $C_{11}H_{14}O_3$ (194.2): C 68.02; H 7.27; OCH_3 15.98.) Preliminary experiments had shown that the methyl ether m.p. 90° was derived from the lowest melting of the isomeric trichloro-compounds XI and XII. It must therefore be the 2-ethyl-3-methyl-5-methoxybenzoic acid. Oxidation: The methyl ether (1.6 g) dissolved in 12 ml N sodium hydroxide and 250 ml water was heated on the steam-bath and a solution of 3.1 *g* potassium permanganate (20 % excess) in water (60 ml) added in small portions. After 6 hours the filtrate from manganese dioxide was concentrated to 100 ml and 5 N hydrochloric acid added. The crystalline precipitate (1.2 g) was recrystallized from glacial acetic acid; m.p. 186°, no depression on admixture. It was demethylated by refluxing 1/4 hour with hydroiodic acid. The crude hydroxy acid had m.p. 267° and the m.p. was not altered either on recrystallization from water or on mixing with $C_{10}H_{10}O_5$ prepared from acetylpyruvic ester. (Found: C 57.03; H 4.82. Calc. for $C_{10}H_{10}O_5$ (210.2): C 57.14; H 4.76.)

Decarboxylation of $C_{10}H_{10}O_5$

(With Magister Odd Leander Johansen and Cand. real. Agnes Thoresen)

The sodium salt of the methyl ether of $C_{10}H_{10}O_5$ (3 g) was mixed with twice its weight of calcium hydroxide and heated in a glass tube through which nitrogen passed slowly. The distillate (0.6 ml) was demethylated by refluxing for half an hour with 3 ml hydro-

iodic acid (1.7). The free phenol was taken up in ether, the solution shaken with sodium carbonate and thiosulphate. On distillation the phenol went over at 200—220°. The following derivatives were prepared. 1) Phenylurethane, after recrystallization from petrol ether, m.p. 117—119°. (Found: C 74.98; H 6.29; N 6.20. Calc. for $C_{15}H_{15}O_2N$ (241.3): C 74.66; H 6.27; N 5.81.) The phenylurethane prepared from authentic *p*-ethylphenol had m.p. 120°, mixed m.p. 118—119°. 2) *p*-Ethylphenoxyacetic acid prepared by reaction with monochloroacetic acid and sodium hydroxide; recrystallized from benzene plus petrol ether, m.p. 94°. Prepared from authentic *p*-ethylphenol, m.p. 96—97°, mixed m.p. 96°. 3) Benzoyl derivative crystallized from dilute ethanol, m.p. 55—57°. Corresponding derivative from *p*-ethylphenol, m.p. 60°.

A chromatographic analysis of the product from the decarboxylation was later carried out according to the method of Hossfeld [8]. The product was coupled with diazotized sulphanilic acid and the dyestuffs extracted with ether. Drops of the concentrated ethereal solution were placed on a filter paper (Whatman no 1) which beforehand had been treated with sodium carbonate. For comparison coupling-products of *p*- and *m*-ethylphenol, *p*- and *m*-cresol and phenol were placed on the same paper. The mobile phase was methyl ethyl ketone saturated with water. The chromatogram showed in all five spots of which two were very weak. One yellow spot corresponded to *m*-ethylphenol, one reddish spot to *p*-ethylphenol and another yellow spot to phenol. The two spots of the ethylphenols were of about the same intensity and control experiments showed that mixtures of *m*- and *p*-ethylphenol containing only a minor quantity of the *meta* isomer (5—10 %) would give spots of about equal intensity. The two very weak spots had the same position as those of *m*- and *p*-cresol.

Partial decarboxylation of the methyl ether of $C_{10}H_{10}O_5$: The methyl ether (1.16 g) was mixed with copper chromite (0.3 g) and heated in a test tube through which a slow current of nitrogen passed. At about 290° decarboxylation set in and the temperature was finally raised to 330°. The liquid distillate (0.83 g) crystallized overnight. A sample pressed on porous tile had m.p. 65°. The rest was demethylated in the usual way. The free hydroxy acid after recrystallization from water had m.p. 154°. (Found: C 64.50; H 5.98; M by titration 165.8. Calc. for $C_9H_{10}O_3$ (166.2): C 65.05: H 6.07.)

Most of the synthetic work described in this paper was carried out during a stay in London. The author wants to express his sincere thanks to Dr. R. P. Linstead F.R.S., Rector, of the Imperial College of Science and Technology, at that time Director of the Chemistry Department, for his great kindness in receiving me as a guest in his department. Grants from *Norges Almenvitenskapelige Forskningsråd* and *Fridtjof Nansens Fond* are acknowledged. Magister Odd Leander Johansen wants to thank *A/S Lilleborg Fabrikers Jubilæumsgave* for a scholarship.

Studies on the Interaction of Paraffin Chain Alcohols and Association Colloids

IX. The Solubility of Decanol-1 in Solutions of Sodium Caprate, Laurate and Myristate above the C.M.C.

KAAPO PASSINEN and PER EKWALL

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

The maximum amounts of decanol that are solubilized by sodium caprate, laurate and myristate solutions before they become turbid have been determined at concentrations above the C.M.C. The solubility curves are linear over a wide concentration range above the C.M.C., slope upwards in a narrow range (A) and continue again as straight lines. Two concentration ranges can hence be distinguished above the C.M.C. with respect to the solubility of decanol, one from the C.M.C. to the break point A and another above this latter point. The break point A in the solubility curve shifts to lower soap concentrations as the number of carbon atoms in the soap increases in the homologous series, but also other factors operate here. The ratios of decanol to soap in the mixed micelles at the turbidity points in the different soap concentration ranges have been calculated from the slopes of the solubility curves. The maximum decanol content of the mixed micelle decreases with increasing number of carbon atoms in the hydrocarbon chain of the soap both in the range between the C.M.C. and the break point A and in the range above the latter point. The maximum decanol content of the mixed micelles depends also on the nature of the ionic group in the association colloid and on the gegenions. It is shown that in the concentration ranges where the break points A are located in the solubility curves also other changes typical of the *2nd* C.M.C. occur in the properties of the solutions. The meaning of the *2nd* C.M.C. and the factors responsible for the separation of the mesomorphic phase that causes the turbidity are discussed.

In Part VIII [1] of this series it was shown how the solubility of decanol varies with the soap concentration in dilute sodium caprate, laurate and myristate solutions. It was found that the first slight increase in solubility occurs already above the limiting association concentration, L.A.C., but that the solubility then passes through a maximum. After a minimum at a concentration about one-third of the critical micelle concentration (C.M.C.) of the pure soap, the

solubility of decanol begins to increase again, the increase being now appreciable. The C.M.C.'s of the decanol-containing soap solutions, *i.e.*, the concentrations where mixed micelles begin to form to a greater extent, are located at these points.

In the present paper data are reported on the solubility of decanol in solutions of the soaps mentioned in the concentration range above the C.M.C. The solubility discussed here is, as in Parts I [2] and VIII [1] of this series, the maximum solubility in the aqueous solution before it becomes turbid owing to the separation of a mesomorphic phase composed of decanol, soap and water. The heterogeneous system as a whole can, as we have shown previously [3-6], bring further, large amounts of decanol into solution, but the decanol is incorporated within the new phase. The solubility relationships when decanol is added in excess of the amount required to produce the turbidity are not considered in this paper.

Previous studies have shown that the micellar substance in solutions of association colloids has constant properties in a relatively wide concentration range above the C.M.C. (in the so-called small micelle range) [7,8]. The saturation capacity of the micellar substance (the solubilizing power expressed as the amount of solubilized substance per mole of micellar soap) has been found to be constant for *p*-xylene, benzene and other hydrocarbons [7,9]. In Part I [2] of this series it was shown that also the maximum amount of decanol that is incorporated in sodium oleate and sodium myristyl sulphate micelles at the turbidity point remains constant over practically the whole small micelle range. We have pointed out earlier that this is the case also for sodium caprate, laurate and myristate solutions [2,3]. The experimental evidence is presented here.

Our earlier studies [2] showed, however, that the linear course of the solubility curve of decanol in solutions of sodium oleate and sodium myristyl sulphate ends at a higher concentration; the curve bends upwards at first and then downwards. The break point is situated in approximately the same concentration range in which the solubilizing power for *p*-xylene and benzene begins to increase more rapidly than at lower concentrations [7,8] and where also many other properties of the solutions undergo a change (see Part IV [6]). Similar results have later been obtained by Markina, Posspelova and Rebinder [10] who studied the solubility of the hydrocarbons benzene, cyclohexane, octane and dodecane and of the polar-nonpolar compounds octanol and acrylonitrile in solutions of sodium oleate. These observations support the view that important changes occur in the properties of oleate (and myristyl sulphate) solutions in the concentration range in question so that one has to assume that changes also occur in the micellar structure. We have investigated whether a corresponding change can also be established in the power of concentrated caprate, laurate and myristate solutions to solubilize decanol.

MATERIALS AND METHODS

The fatty acids were products of Eastman Kodak Co., Rochester. They were recrystallized twice from absolute ethanol. The melting points of the fatty acids were 31.0–31.5°C for capric acid, 42–43°C for lauric acid and 56–57°C for myristic acid. The soaps were prepared in the usual manner by neutralizing the fatty acid with sodium

ethylate in absolute ethanol. The decanol-1 was that used in previous investigations of this series [2].

The solutions were prepared and the solubility was measured as described in Part I [2]. The temperature was 40°C. The solubility values are estimated to be accurate to about ±0.1 ml of decanol per litre of solution in most cases but are perhaps slightly less accurate for the most concentrated myristate solutions owing to the fact that these solutions are gel-like at 40°C and hence very difficult to work with.

The concentrations of the soap solutions are given in moles of soap per 1 000 g of soap solution and denoted by *M*.

EXPERIMENTAL RESULTS

The solubility of decanol has been studied in the following concentration ranges: sodium caprate 0.08—0.5 *M*, sodium laurate 0.02—0.6 *M*, sodium myristate 0.006—0.2 *M* and potassium myristate 0.01—0.06 *M*.

Figs. 1, 2 and 3 show how the solubility of decanol varies with the soap concentration. The solubility values reported in Part VIII have been marked with crosses in these figures; the curves joining the new solubility values (marked with circles) are seen to be continuations of the previously drawn curves. In the case of all soaps the solubility begins to increase definitely a little below the C.M.C. of the pure soap. The solubility curves rise steeply and exhibit a constant slope. The linear course is maintained over a comparatively wide concentration range. In the case of all three soaps there then follows a narrow range (A) where the curves bend upwards and continue as straight lines. (In the solubility curve of myristate (Fig. 3) a weak suggestion of a downward trend can be noted at still higher concentrations. The determination of the course of the curve in this region was a little uncertain owing to the

difficulty of determining the solubility of decanol in sodium myristate solutions of higher concentrations than about 0.2 *M*; both the pure and the decanol-containing solutions are very viscous in this concentration range.) Above the C.M.C. two concentration ranges can hence be distinguished with respect to the solubility of decanol: one from the C.M.C. to the break point A and another above this latter point.

It should be emphasized that the solubility of sodium myristate in water is so low at 40°C that separated sodium myristate appears in pure myristate

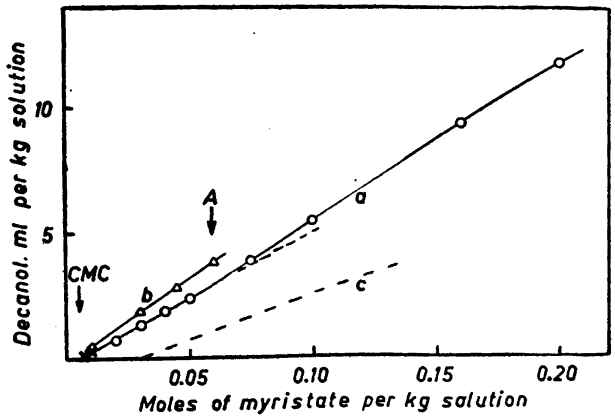

Fig. 3. The maximum amounts of decanol dissolved at the turbidity point. 40°C. a) Sodium myristate solutions, b) Potassium myristate solutions, c) Boundary line separating clear and turbid (lower right) solutions, the turbidity being caused by separated myristate.

solutions above about 0.03 *M* in concentration [11]. The solubility of the soap increases, however, when decanol is added to the system. The dotted curve in Fig. 3 has been drawn on the basis of some scattered observations; it gives the approximate amounts of decanol needed to prevent the separation of myristate. Below the dotted curve, the system is heterogenous owing to separated myristate. Between the dotted and the continuous curves, the system is homogeneous but becomes heterogeneous again above the latter curve owing to the separation (above the L.A.C.) of the decanol-myristate-water phase.

The solubility of decanol in potassium myristate solutions was determined at only four soap concentrations (Fig. 3, curve b).

With the purpose of making possible a direct comparison of the solubility curves, the curves for the three soaps and the corresponding curve for sodium oleate have been plotted in the same diagram, Fig. 4. It can be seen that the slopes of the first linear parts of the curves for laurate, myristate and oleate between the C.M.C. and the break point A decrease with increasing number of carbon atoms in the soap; the result is that the curves intersect.

DISCUSSION

The solubility of decanol and its relationship to the molecular structure of the soap and the concentration of the soap solution. It is believed that the molecules of solubilized higher alcohols enter into the palisade layers of the micelles, whereupon mixed micelles are formed. The solubility which results from the solubilization in the micelles is, however, limited by the separation of a new phase composed of decanol, soap and water. As we have already pointed out, the appearance of the new phase does not mean that the system as a whole is

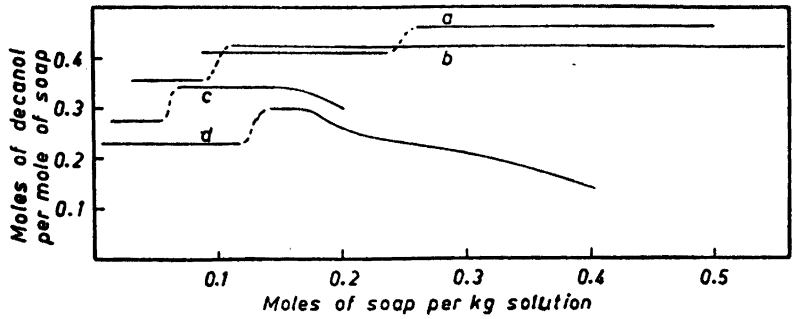

Fig. 5. The decanol content per mole of soap in the mixed micelles. 40°C. a) Sodium caprate solutions, b) Sodium laurate solutions, c) Sodium myristate solutions, d) Sodium oleate solutions.

saturated with decanol. The solubility curves drawn in the figures give only the maximum amounts of decanol which the micelles are able to dissolve before the new phase separates. Hence the solubility values measured at the turbidity point when a polar substance such as a long chain alcohol or fatty acid is solubilized are not comparable with the solubility values obtained in the solubilization of nonpolar compounds since the latter values give the real saturation points above which the pure solubilizate separates [2,7,8]. This difference has been recently stressed also by Hyde, Langbridge and Lawrence [12].

It has previously been customary to compare the solubilities of alcohols (and also hydrocarbons) at the same and often only one concentration of different soaps [13]. Since, as shown by the curves in Fig. 4, the solubility curves have different slopes for different soaps, the results of the comparison depend on the soap concentration chosen. A better survey is obtained when, as has been done in the present study, the slopes of the solubility curves are compared.

The slope of the solubility curve at a certain soap concentration, ∂(solubility)/∂(soap concentration), gives the ratio of decanol and soap in the mixed

Table 1. The compositions of the mixed micelles at the turbidity point expressed as moles of decanol per mole of micellar soap.

Association colloid	Concentration range	Composition, moles of decanol per mole of soap	Break point A	Concentration range	Composition, moles of decanol per mole of soap	Increase of the decanol content of mixed micelles above the break point A (%)
Na-caprate	0.08—0.22 *M*	0.41	0.23 *M*	0.24—0.5 *M*	0.46	12
Na-laurate	0.03—0.10 *M*	0.36	0.11 *M*	0.12—0.6 *M*	0.42	19
Na-myristate	0.01—0.05 *M*	0.28	0.06 *M*	0.07—0.16 *M*	0.34	24
				0.2 *M*	0.30	
K-myristate	0.01—0.05 *M*	0.36				

micelles formed at the soap concentration in question when the turbidity appears. The composition of the mixed micelles is different in different soap concentration ranges, as shown in Fig. 5 and Table 1. The decanol content of the mixed micelles is seen to decrease with the number of carbon atoms in the hydrocarbon chain of the soap both in the range between the C.M.C. and the break point A and in the range above the latter point. The relative increase in the decanol content of the mixed micelles varies in a similar manner in both ranges (Table 1, last column). From Fig. 5 it is also seen that the compositions of the decanol-caprate and decanol-laurate mixed micelles remain constant above the break point over the range studied, whereas the decanol content of the decanol-myristate micelles remains constant at first, but decreases at the higher myristate concentrations. In the case of sodium oleate and sodium myristyl sulphate [2], there is practically no concentration range above the break point where the composition of the mixed micelles remains constant; the decrease in the decanol content of the mixed micelles begins after a very short linear range of fairly high solubility values.

That the decanol content of the mixed micelles at the turbidity point is not dependent solely upon the length of the hydrocarbon chain of the soap is shown by the collected experimental data and has also been emphasized earlier [2]. The nature of the ionic group of the colloid and the presence of a double bond influence the mixed micelle composition. For instance, the decanol content of the mixed decanol-myristyl sulphate micelles in moles per mole of colloid is about 47 % higher than that of the decanol-myristate mixed micelles in both ranges above and below the break point. If the decanol content decreases in the same proportion with increasing chain length as in the series caprate, laurate and myristate, the decanol-stearate mixed micelles should contain 0.12 and 0.18 mole of decanol per mole of soap in the ranges below and above the break point, respectively. For oleate with 18 carbon atoms, considerably higher values, 0.23 and 0.30 mole of decanol per mole of oleate, are obtained [2]; this is evidently to be ascribed to the presence of the double bond in the oleate molecule. Also the gegenion appears to exert some influence since the decanol content on the mixed micelles is higher in potassium myristate solutions than in sodium myristate solutions.

It can be further seen from Fig. 5 that the break point A in the solubility curve shifts to lower soap concentrations as the number of carbon atoms in the soap increases in the homologous series. Also other factors seem to operate here, since the break points lie higher in the curves for oleate and myristyl sulphate than in the myristate curve.

The "Second Critical Concentration". As mentioned in the introduction, we have previously observed that the break point in the solubility curve for decanol lies in oleate and myristyl sulphate solutions in the same narrow concentration range in which also other properties of these solutions undergo marked alterations. We have therefore considered it appropriate (for the lack of a better name) to call this narrow concentration range the "second critical concentration" (*2nd* C.M.C.). Since a similar variation has now been observed in the alcohol solubility in solutions of the saturated fatty acid soaps, it is of interest to examine on the basis of previously reported experimental data whether also other properties of the solutions of these soaps undergo a change

in the concentration range where the break point occurs. It should be noted in this connection that the break points in the decanol solubility curves occur at soap concentrations that are a little lower than those in which changes can be expected to occur in pure soap solutions. This was found to be the case for the oleate and the myristyl sulphate solutions; similarly as decanol lowers the C.M.C. slightly, the "second critical concentration" is evidently also shifted to a lower concentration in the presence of decanol.

One of us has previously shown that the amount of *p*-xylene solubilized at 40°C by sodium myristate solutions increases linearly with the colloid concentration (*i.e.*, the saturation capacity of the micellar substance remains constant) in the concentration range between 0.03 *M* and 0.06 *M*, but increases more rapidly (the saturation capacity has a greater value) above the latter concentration [7]. It has also been found that the equivalent conductance of sodium myristate passes through a shallow minimum at the approximately 0.14 *M* soap concentration (35—80°C) (the change in equivalent conductance is very slight above the 0.08 *M* concentration) [14]. An inspection of the $\partial\varkappa/\partial c$-concentration curve shows that after a rapid fall above the C.M.C. the curve continues horizontally up to the approximately 0.1 *M* concentration and then bends upwards. The break point in the decanol solubility curve is situated in the range from 0.055 *M* to 0.065 *M*.

McBain, Laing and Titley [15] found that a conductance minimum occurs in potassium laurate solutions at the approximately 0.13—0.15 *M* concentration; the horizontal part of the $\partial\varkappa/\partial c$-curve terminates already when the soap concentration is about 0.10 *M*. The break point in the decanol solubility curve occurs approximately in the 0.10—0.12 *M* range.

It is thus seen that also other changes typical of the *2nd* C.M.C. occur in the properties of solutions of at least two of the three soaps in the concentration range where the break point A in the decanol solubility curve is located.

According to Mysels and Dulin [16], the minimum in the equivalent conductance curve (Λ *vs.* $\sqrt{c}$) cannot be taken as an indication that the nature of the solution changes in this region. They emphasize that the specific conductance-concentration curves for soap solutions above the C.M.C. show a continuous upward curvature and that this curvature is almost constant but increases slightly and regularly. We have inspected from this viewpoint numerous conductance measurements of different association colloids by different investigators [4,5,11,14,15,17-22] and found that in nearly all cases the $\varkappa$-*c*-curve is linear and the $\partial\varkappa/\partial c$-curve consequently horizontal over a fairly wide concentration range above the C.M.C. The $\varkappa$-*c*-curve bends upwards at a concentration only slightly below that at which the minimum occurs in the Λ-$\sqrt{c}$-curve; consequently also the $\partial\varkappa/\partial c$-curve deviates from the horizontal at this point. (This applies also to sodium myristate, potassium laurate, sodium oleate and sodium myristyl sulphate.) The conclusion of Mysels and Dulin thus appears to be based on an erroneous interpretation of the experimental data. For the present it seems to us that the course of the conductance curve in the neighbourhood of the minimum of the equivalent conductance (Λ) must be considered a sign that a new factor begins to operate and effects a change in the process of micellization. This is supported by the changes observed in the decanol solubility. New conductance measurements are required before any further conclusions can be drawn.

As the number of micelles increases, a point is sooner or later reached where the electrical double layers of the micelles approach each other so closely that their charged surface layers begin to interfere with each other. This type of interaction may be considered the primary cause of the changes observed in the

properties of colloid solutions at the *2nd* C.M.C. Even if this explanation is sufficient for some of the changes, it can hardly apply to others, *e.g.*, to the variation of the solubilizing power. It is difficult to understand how the interaction between the charged micelle surfaces can alone effect a greater solubilization of hydrocarbons or an increase of the alcohol content of the mixed micelles without the occurrence of a parallel change in the micellar structure. On the basis of various observations many investigators have concluded that only one type of micelle exists, namely, that which is produced in the concentration range immediately above the C.M.C.[23-25] The available experimental evidence relating to this hypothesis is still somewhat uncertain. It seems that the changes in the properties of the micellar substances which have become clearly evident in solubilization studies have not received adequate attention. It must therefore be permissible, until further evidence for the electrical interference theory has been collected, to assume that the changes in the properties of the solutions at the *2nd* C.M.C. are primarily due to changes in the structures and/or sizes of the micelles. Starting from the assumption that the interaction between the micelles leads to further aggregation and rearrangement of the ions and molecules of the micelles (whereupon energetically more stable micelles are formed), one may offer a plausible explanation for the changes noted in the solubilizing power. If the charge density in the outermost palisade layer of the large micelles against the surrounding solution remains sufficiently high when decanol is incorporated in the inner parts of the micelle, the stability of the large micelle in the solution will remain practically unaltered. In this way larger amounts of alcohol per mole of soap can be brought into the solution by the large micelles than by the small micelles. Similarly the micelle aggregation would be expected to increase the solubilization of hydrocarbons.

Irrespective of whether it will be established that either micelle aggregation (or some other change in the micelle) occurs, or if only one type of micelle exists and the changes in the properties of the solutions are due to other yet unknown factors, it is necessary to conclude that a concentration limit is reached in the highly concentrated solutions above which the properties of the association colloid differ from the properties below this limit.

Factors determining the formation of the mesomorphic phase. In all the cases we have studied, the alcohol-soap-water phase separates from solutions that contain higher or lower concentrations of soluble aggregates consisting of soap ions and alcohol molecules; between the L.A.C. and the C.M.C. the aggregates are very small, but above the C.M.C. we have to do with the much larger mixed micelles. There must thus be some relationship connecting the occurrence of the soluble aggregates and the formation of the mesomorphic phase. The question arises whether the association of soap ions and alcohol molecules to soluble aggregates, on one hand, and the association of the components to form the mesomorphic phase, on the other, are two parallel phenomena in which similar factors play a part or whether the presence of soluble soap ion-alcohol aggregates of some kind is a necessary condition for the formation of the phase mentioned. In the latter case it seems probable that the aggregates directly take part in the formation of the new phase and that the shift in the hydrophilic-lipophilic balance of the aggregates caused by the incorporation of alcohol is of importance.

It has previously been established that there is evidently some relationship connecting the balance between the hydrophilic and lipophilic properties of the molecules and ions taking part in mixed micelle formation and the maximum amount of alcohol that the micelles can incorporate before the system becomes turbid due to the separation of the mesomorphic phase [2]. The balance shifts in favour of the hydrophilic properties as the chain length decreases in a homologous series. A similar shift occurs when a double bond is introduced into the hydrocarbon chain of the soap or when the carboxyl group in a fatty acid soap is replaced by a sulphate group. In such cases we have established that the decanol content of the mixed micelles at the turbidity point increases; this result is in agreement with observations of other investigators [26,27]. A similar shift occurs also when the solubilizate is changed: the alcohol content of the micelles at the turbidity point decreases with the chain length of the alcohol (for the heptanol-caprate system the content of heptanol is 1.0 mole of heptanol per mole of soap [28] and for decanol-caprate, 0.43 mole of decanol per mole of soap).

As the hydro-lipophilic balance of the mixed micelle is shifted sufficiently in the direction of the hydrophilic properties, we finally come to a system in which the solubilization of the polar compound is not limited by the separation of a mesomorphic phase but increases to its highest possible value, after which the excess of the polar compound separates in pure form. This has been found to occur, for example, when caproic acid is solubilized in sodium caproate solutions [28], when caprylic acid is solubilized in sodium caprylate solutions [28], when decanediol-1,10 is solubilized in solutions of various soaps [7,28,29], and when decanol-1 is solubilized in solutions of the potassium salts of the α,ω-alkanedioic acids (in some cases a mesomorphic phase appears at higher colloid concentrations; the concentration at which this occurs decreases as the temperature is lowered)[30]. When pure polar substance separates, the solubility values obtained are comparable with those for hydrocarbons, contrary to the solubility values obtained when the phase composed of polar substance, soap and water separates.

We have previously pointed out that the penetration of alcohol molecules between the soap ions in the palisade layers of the micelle leads to changes in the surface of the micelle [2,5]. Weakly hydrophilic groups become located between the strongly hydrophilic ionized carboxylic or sulphate groups. This leads to a decreased charge density on the micelle surface. The decrease should at first be compensated to some degree by a decrease in the number of gegenions bound to the micelle. As more alcohol is solubilized, the hydrophilic properties of the micelle surface will weaken while the number of lipophilic groups in the inner region of the micelle (per unit surface area) will remain practically unaltered (depending on the relative chain lengths of the alcohol and soap). The balance between the lipophilic and hydrophilic properties of the micelle will thus be shifted in favour of the lipophilic properties. As the hydrophilic properties of the micelle surface weaken in this manner, the stability of the micellar solution will decrease and the tendency of the micelles to adhere to each other will increase although the micelles are still charged (this must be true both below and above the *2nd* C.M.C.). The decrease in the hydrophilic properties of the micelle surface must therefore sooner or later lead to the sepa-

ration of a new phase. The process is the same for the small soap ion-alcohol aggregates at concentrations below the C.M.C. when the alcohol-soap ratio increases. As we have pointed out previously (Part VIII), the limits in which this ratio can vary are very narrow, and the hydrophobic properties increase rapidly as the ratio increases.

With the purpose of elucidating the formation of the mesomorphic phase, we have applied the law of mass action to the system containing alcohol, soap and water, irrespective of the fact that considerable errors must be introduced through the neglect of the activity coefficients. As was pointed out above, the formation of the mesomorphic phase can be assumed to occur by either of two ways: A) soap ions and alcohol molecules associate to soluble aggregates which form the mesomorphic phase by aggregation when their alcohol content attains a certain value, or B) soap ions and alcohol and water molecules form the mesomorphic phase directly when the decanol content of the mixed micelles attains a certain value. The calculations must, of course, lead to the same result irrespective of the mechanism chosen.

A. The formation of mixed micelles may be considered a process in which alcohol molecules are incorporated in the ordinary soap micelles or one in which new alcohol-containing micelles are produced. Under certain conditions (concentration, temperature and salt concentration) the molar ratio of alcohol and soap ions in the mixed micelles does not exceed a certain value (y/x). When this value is reached, further addition of alcohol leads to the formation of the mesomorphic phase. At the turbidity point where the soap solution is in equilibrium with the mesomorphic phase, the formation of the mixed micelles in the aqueous phase may be expressed by an equation of the following general type:

$$x\,R'COO^- + yR''OH + z\,Me^+ \rightleftharpoons ((Me^+)_z(R'COO^-)_x(R''OH)_y)^{-(x-z)} \quad (1)$$

$$\frac{[((Me^+)_z(R'COO^-)_x(R''OH)_y)^{-(x-z)}]}{[R'COO^-]^x\,[R''OH]^y\,[Me^+]^z} = K \quad (2)$$

$R'COO^-$ denotes a soap anion, $R''OH$ an alcohol molecule and Me^+ a metal ion. The values of x, y and z need not be the same as for the pure soap micelles. (The formation of the small soap ion—alcohol aggregates occurring in the concentration range between L.A.C. and C.M.C. can be treated in the same way in principle.)

Eqn. (2) may be rewritten as follows:

$$[R'COO^-][R''OH]^{y/x} = \frac{[((Me^+)_z(R'COO^-)_x(R''OH)_y)^{-(x-z)}]^{1/x}}{K'\,[Me^+]^{z/x}} \quad (3)$$

The soap anion concentration may be taken to be approximately equal to the soap concentration at the C.M.C. of the alcohol-containing solution. The alcohol concentration is less than its solubility in water. The decanol content y/x of the mixed micelles at the turbidity point has been determined experimentally and found to be constant below the break point A. When the ratio y/x exceeds a certain value, the mesomorphic phase appears.

If we assume that about 50 % of the gegenions are bound by the micelles, *i.e.* $z/x = 0.50$, it will be seen that the right member of eqn. (3) decreases with increasing soap concentration. Consequently also the concentration of free alcohol, [R″OH], at which the mixed micelles characterized by the ratio y/x are formed, will decrease with increasing soap concentration, at least in the concentration range below the break point A. This may be the explanation for the observation that the alcohol content of the mesomorphic phase decreases with increasing soap concentration below the break point A (see Part II [4]).

B. The conditions resulting in the formation of the mesomorphic phase can also be defined by means of an equation of the solubility product type:

$$[R'COO^-][R''OH]^{y/x}[Me^+]^{z/x} = P \qquad (4)$$

where y/x and z/x denote the molar ratios of alcohol to soap and of gegenions to soap in the mesomorphic phase. The ratios do not have the same values as in eqns. (1)—(3). It has been found that the ratio y/x has a smaller value for the mixed micelles in solution than for the separated phase. Furthermore, the ratio y/x does not remain constant in the separated phase but decreases with increasing soap concentration, at least up to the break point A. According to eqn. (4), the concentration of free alcohol should also decrease with increasing soap concentration.

The ratio z/x has been assumed to have values different from unity and it may hence seem at first sight that the particles of the mesomorphic phase should therefore have an enormously high electrical charge. This is of course not true. The gegenions in the water layers in the mesomorphic phase must be assumed to be partly bound to the soap ions, partly free (analogously as in the micellar solution) so that their activity is the same as in the micellar solution. In the expression for the law of mass action there remains only the activity of the bound gegenion, the activities of the free ions in solution and in the mesomorphic phase cancelling each other. Considerable errors are involved through the neglect of the activity coefficients, which must differ much from unity, especially in the mesomorphic phase.

It should finally be emphasized that the conditions for both equilibria mentioned above, *i.e.* the equilibrium between soap ions, alcohol and mixed micelles and the equilibrium between soap ions, alcohol and mesomorphic phase, must be fulfilled simultaneously.

In the qualitative respect the equations written above seem to be in accord with the observed phenomena. The available experimental data are yet so limited that a quantitative confirmation of the theory is not possible. It seems probable, however, that the soluble small soap ion-alcohol aggregates occurring between the L.A.C. and the C.M.C. and the mixed micelles occurring at concentrations above the C.M.C. partake in the formation of the separating alcohol-soap-water phase and that the increase in hydrophobic properties of these soluble aggregates caused by the incorporation of alcohol is an important factor in this process.

Studies on the Interaction of Paraffin Chain Alcohols and Association Colloids

X. The Solubility of Decanol-1 in Sodium Oleate Solutions Containing Sodium Chloride

KAAPO PASSINEN and PER EKWALL

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

The maximum amounts of decanol solubilized until sodium oleate solutions containing sodium chloride become turbid have been determined. The solubility of decanol decreases rapidly with increasing sodium chloride concentration. The general shape of the solubility curve is not altered by the addition of 0.05 *M* NaCl. The break point in the solubility curve occurs at a lower oleate concentration in salt-containing than in salt-free solutions. The break point is known to occur at the so-called "*2nd* critical concentration"; this limit is hence not only a function of the concentration of the micelle-forming hydrocarbon-chain ions in the solution, but also a function of the concentration of the gegenions. This indicates that the changes in the micellar structure that take place here do not depend solely on the fact that the micelles come so near each other that disturbances occur in their electrical double layers. The factors responsible for the decrease in the solubility of decanol are discussed.

Investigations of the effects of inorganic salts on the solubilization of simple nonpolar and polar-nonpolar substances have shown that the addition of salt increases the solubilization of nonpolar compounds [1–3], but decreases the solubility of polar-nonpolar substances, *e.g.*, long-chain alcohols [2–5]. This difference has been explained by assuming that nonpolar and polar-nonpolar molecules are incorporated in different regions of the micelles.

In studies of the effect of inorganic salts on the solubilization of very complicated organic molecules, such as dyes, it has been established that in most cases the added salt causes an increase in the solubilizing power of the colloid [6].

In Part I [7] of this series, data were given on the solubility of decanol in oleate solutions at the turbidity point where the separation of a mesomorphic phase begins. It was found that the solubility curve increases linearly up to a colloid concentration of about 0.12 *M*, then curves upwards and finally

downwards as the oleate concentration is increased further. The purpose of the present investigation was to study the effect of sodium chloride on the solubility of decanol in oleate solutions and to determine whether the shape of the solubility curve remains the same as for oleate solutions containing no added salt. It was also of interest to determine whether the breakpoint in the solubility curve at the so-called "2*nd* critical concentration" is displaced when salt is added.

MATERIALS AND METHODS

The same substances and methods have been used as in Part I [7] of this series. The sodium chloride employed was a product from E. Merck.

The experimental error of the solubility values has been estimated to be about ± 0.2 ml of decanol per litre.

The concentrations of sodium oleate and sodium chloride are given in moles per 1 000 g of oleate solution (salt-free) and are denoted by M.

EXPERIMENTAL RESULTS

The solubility of decanol at the turbidity point in 0.100 M sodium oleate solutions containing different amounts of sodium chloride is shown in Fig. 1. The solubility decreases very rapidly with increasing sodium chloride concentration. The solubility of decanol could not be measured when the sodium chloride concentration exceeded about 0.15 M, because the solutions became very viscous, nearly gel-like. The curve has the same form as Klevens has found for the system octanol-potassium myristate-potassium chloride [3].

The solubility of decanol in sodium oleate solutions containing 0.05 mole of sodium chloride per litre is shown by curve *a* in Fig. 2. Curve *b* gives the solubility of decanol at the turbidity point in salt-free oleate solutions (Part I [7]). The form of the solubility curve is similar for salt-containing as for salt-free oleate solutions. At lower oleate concentrations, the solubility increases linearly with the oleate concentration, then begins to increase a little faster, but finally the curve becomes concave against the concentration axis. In the presence of sodium chloride, the departure from linearity occurs at a lower concentration (at about 0.08 M oleate) than in salt-free solutions (at about 0.12 M oleate);

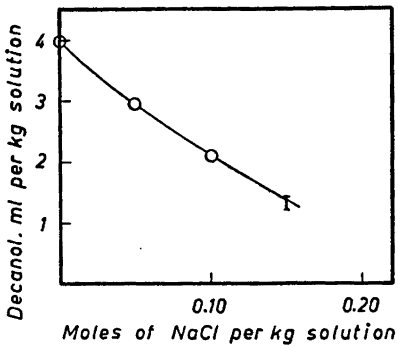

Fig. 1. The effect of sodium chloride on the solubility of decanol in a 0.100 M *sodium oleate solution. 40°C.*

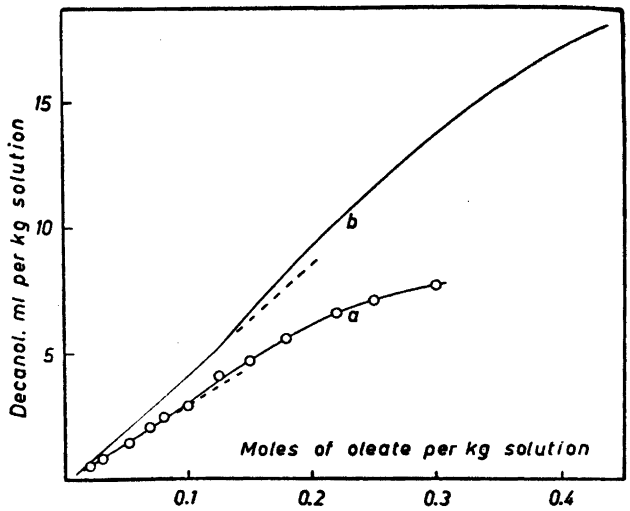

Fig. 2. The solubility of decanol at the turbidity point. 40°C. a) Sodium oleate solutions 0.05 M *in sodium chloride. b) Salt-free oleate solutions.*

the departure is less marked than in salt-free oleate solutions, but exceeds the experimental variation in the solubility determinations. The effect of the salt varies in different concentration ranges; in the linear range below 0.08 *M* oleate, the solubility is decreased by about 26 %, at higher oleate concentrations, the decrease is larger and amounts to about 33 % in the 0.2 *M* and about 44 % in the 0.3 *M* oleate solution.

DISCUSSION

As pointed out earlier [7,8], the solubility curve gives the maximum amount of decanol dissolved by the micelles before the system becomes heterogeneous. The slope of the solubility curve at each point gives the proportion of decanol and soap in the mixed micelles formed at the soap concentration in question. The curve *a* in Fig. 3 and the values in Table 1 show how the decanol content of the mixed micelles (in moles of decanol per mole of oleate) varies with the

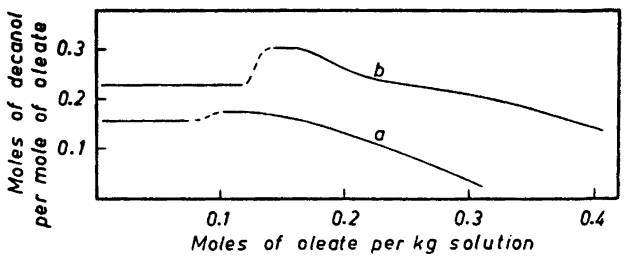

Fig. 3. The decanol content per mole of association colloid in the mixed micelles. 40°C. a) Sodium oleate solutions 0.05 M *in NaCl. b) Salt-free oleate solutions.*

Table 1. Composition of the mixed micelles at the turbidity point in sodium oleate solutions containing sodium chloride.

Concentration of sodium oleate	Maximum proportion of decanol in moles of decanol per mole of oleate		
	Concentration of sodium chloride		
	0.05 *M*	0.10 *M*	0.15 *M*
0.005–0.08 *M*	0.16	(0.11)	(0.07)
0.12 *M*	0.18		
0.20 *M*	0.13		
0.30 *M*	0.04		

oleate concentration in solutions 0.05 *M* in sodium chloride. (The values given in parentheses in Table 1 have been calculated on the basis of only one experimental solubility value and are therefore only approximate.) Curve *b* in Fig. 3 shows the corresponding curve for salt-free oleate solutions. It is seen that in the former case the decanol content of the mixed micelles remains constant at approximately 0.16 mole of decanol per mole of oleate up to an oleate concentration of about 0.08 *M*. The relative decanol content then increases to a low maximum which is about 0.18 mole of decanol per mole of oleate, and finally decreases to a very low value. The addition of sodium chloride seems to smooth out the course of the solubility curve.

We wish to stress the following factors which we hold responsible for the fact that the system becomes heterogeneous at a lower decanol content when salt is present than when the solutions are salt-free. As we pointed out in Part IX [8] of this series, the process that precedes the formation of the new phase can be represented by an equation of the type:

$$x\ \mathrm{R'COO^-} + y\mathrm{R''OH} + z\ \mathrm{Na^+} \rightleftharpoons ((\mathrm{Na^+})_z(\mathrm{R'COO^-})_x(\mathrm{R''OH})_y)^{-(x-z)} \quad (1)$$

$$\frac{[((\mathrm{Na^+})_z(\mathrm{R'COO^-})_x(\mathrm{R''OH})_y)^{-(x-z)}]}{[\mathrm{R'COO^-}]^x\,[\mathrm{R''OH}]^y\,[\mathrm{Na^+}]^z} = K \quad (2)$$

When the ratio of alcohol to soap, y/x, exceeds a certain value, a new phase is formed. This ratio is, as we have shown above, lower in the salt-containing than in salt-free solutions. We have previously assumed that a smaller number of sodium ions are bound per fatty acid ion in the mixed micelles containing alcohol than in the pure soap micelles, *i.e.* the ratio of gegenions to fatty acid anions, z/x, is assumed to be lower in the former case than in the latter. The presence of sodium chloride must lead to an increase in the number of bound gegenions, *i.e.* to a higher z/x-value. The conditions for the formation of the new phase are fulfilled in the salt-containing solutions when mixed micelles with a higher gegenion content (z/x) but smaller alcohol content (y/x) than those present in salt-free oleate solutions are formed. The observed decrease in the solubility of decanol on addition of salt can be explained fairly well on the basis of the law of mass action, eqn. (2), when certain simplifying assumptions are made. Plausible results are also obtained with an equation of the "solubility

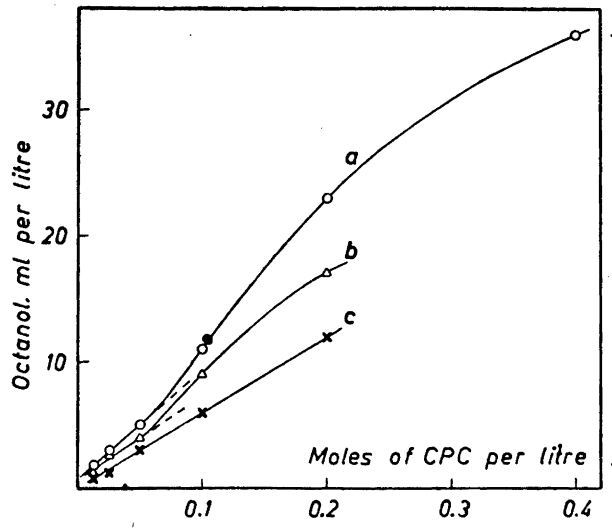

Fig. 4. The solubility of octanol at the turbidity point. 40°C. a) Salt-free cetylpyridinium chloride solutions, b) Cetylpyridinium chloride solutions 0.125 M *in NaCl, c) Cetylpyridinium chloride solutions 0.500* M *in NaCl (Richards and McBain [2])*

product" type (see eqn. (4) in Part IX [8]). It should be noted that in salt-containing soap solutions the C.M.C. is lower and hence the activities of simple ions ($R'COO^-$) are lower than in salt-free solutions.

Also other changes in the structure of the micelles than the above-mentioned, such as changes in their shapes and sizes, may occur when salt is added; this is indicated by light-scattering [9–11] and viscosity [12] measurements.

In Parts I—IV [7,13–15], it was shown that when the oleate concentration of 0.1—0.2 *M* is exceeded, so many important changes occur in the properties of oleate solutions that one has to assume that a change also takes place in the micellar substance and that therefore it is justified to speak of a concentration limit, called the "2*nd* critical concentration". In Part IX [8] it was shown that similar phenomena occur also in solutions of sodium caprate, laurate and myristate and that the concentration limit mentioned is displaced toward lower soap concentrations when the number of carbon atoms in the hydrocarbon chain increases. Our investigations have shown that the solubility of decanol is one of the properties that undergo a characteristic change at this limit. Our present measurements show that the limit is displaced to lower oleate concentrations when sodium chloride is added. The position of this limit is hence not only a function of the amount of the micelle-forming hydrocarbon-chain ions and molecules in the solution, but also a function of the concentration of gegenions (as is the case for the critical concentration). This indicates that the changes in the micellar structure that take place in this concentration range do not depend, solely at least, on the fact that the micelles come so near each other that disturbances occur in their electrical double layers.

We have examined the data on the solubility of alcohols in association colloid solutions published by other workers and have found that in all cases when the measurements have been carried out with sufficient accuracy and when a sufficient number of measurements has been made, the solubility curves (solubility in ml/l, g/l or moles/l plotted against the concentration of association colloid in moles per litre) are linear over a relatively wide concentration range above the C.M.C., then show a breakpoint, slope upwards and finally, in some cases, become concave against the concentration axis [1,2,16]. This is shown especially clearly by the solubility curve for octanol in cetylpyridinium chloride solutions according to measurements of Richards and McBain [2] (Fig. 4, curve a*). Our opinion is therefore that the type of solubility curve that we have found for the solubility of decanol in solutions of fatty acid soaps and of alkyl sulphates is characteristic for at least all the long-chain primary alcohols and all association colloids of the paraffin-chain type.

Richards and McBain reported also some data on the effect of salt on the solubility of alcohol [2]. The effect of 0.125 M sodium chloride on the solubility of octanol in cetylpyridinium chloride solutions (Fig. 4, curve b) is completely analogous to that found by us for sodium oleate solutions 0.05 M in sodium chloride. Our conclusion that a larger addition of salt smooths out the solubility curve is also verified (Fig. 4, curve c). The picture given by Figs. 2 and 4 of the effect of salt on the solubility of long-chain alcohols in solutions of association colloids may therefore be regarded as typical.

ACTA CHEMICA SCANDINAVICA 10 (1956) 1234—1242

Synthesis and Metabolism of 2,2-Dimethylnonadecanoic Acid *

N. TRYDING and G. WESTÖÖ

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The intestinal absorption and metabolism in the rat of 2,2-dimethylnonadecanoic acid has been studied. The main metabolic end-products were 2,2-dimethylglutaric acid and 2,2-dimethylpimelic acid, which were recovered in the urine. Thus the β-oxidation from the carboxyl end of the 2,2-dimethylnonadecanoic acid had been completely hindered and the last step of the degradation from the ω end — from 2,2-dimethylpimelic to 2,2-dimethylglutaric acid — had been retarded by the steric hindrance of the two methyl groups.

The intestinal absorption and metabolism of 2,2-dimethylstearic acid in the rat has been studied in an earlier investigation by Bergström, Borgström, Tryding and Westöö [1]. The acid was well absorbed. The β-oxidation from the carboxyl end of the 2,2-dimethylstearic acid molecule was completely hindered and the main metabolic end product was shown to be 2,2-dimethyladipic acid which was excreted in the urine.

Continuing the study on the influence of steric hindrance at the carboxyl group, we have now investigated the absorption and metabolism of a 2,2-dimethyl fatty acid with an odd number of carbon atoms in the chain. For this reason we have prepared 2,2-dimethyl[1-^{14}C]nonadecanoic acid by a Kolbe electrolysis of heptadecanoic acid and 3-methoxy[^{14}C]carbonyl-3-methylbutyric acid, purification of the methyl ester obtained by chromatography on acid alumina and hydrolysis of the ester.

When administered in olive oil solution *per os* to rats, the acid was well absorbed. The absorbed activity ** was recovered in the urine to 78% (mean for 6 rats), indicating that the carbon skeleton of the ^{14}C-carboxyl end was intact. Rats with a thoracic duct fistula excreted about 21—36 % of the

* Presented in part at the meeting of the Swedish Biochemical Society in Gothenburg, June 4, 1955 and at the IInd International Conference on Biochemical Problems of Lipids, Ghent, Belgium, July 29, 1955.

** Approximately calculated as the difference between the fed activity and the activity excreted in the feces.

absorbed activity in the urine, while 39—64 % was found in the lymph lipids. Thus the acid was absorbed to a considerable extent *via* the portal vessels. 11—20 % of the lymph activity was present as free acid, 77—86 % as neutral fat, while only 2—5 % was incorporated into the phospholipids. A similar distribution in the lymph has been found for 2,2-dimethylstearic acid [2] and for 2,2,17,17-tetramethylstearic acid [3].

The active substances in the urine have been identified by reversed-phase partition chromatography and repeated recrystallizations with synthetic, unlabelled compounds. Two of the urinary metabolic products of 2,2-dimethylnonadecanoic acid were shown to be 2,2-dimethylglutaric (about 55 %) and 2,2-dimethylpimelic acid (about 25 %). Approximately 5 % of these acids were found in conjugated form. There was at least one other minor component, the composition of which has not yet been established. The metabolic products identified indicate that the two methyl groups completely block the degradation from the carboxyl end of the 2,2-dimethylnonadecanoic acid. As the degradation from 2,2-dimethylpimelic acid to 2,2-dimethylglutaric acid was not complete, the last step of the oxidation from the ω end was also influenced by the methyl groups. The steric hindrance thus extends its effect as far as the ∂ carbon atom. There was relatively more 2,2-dimethylpimelic acid in the urine on the first day after the administration than on the following days (Table 5).

Using fatty acids with a phenyl group at the β-carbon atom for blocking the β-oxidation Stevens [4] found that β-phenyldecanoic acid and β-phenyldodecanoic acid were excreted in the urine as β-phenyladipic acid. After feeding acids with an odd number of carbon atoms in the chain no homogeneous product could be isolated from the urine. However, it was clear that dibasic acids were excreted. It is to be noted that substituted acids with less than nine carbon atoms in the chain were excreted mainly unaltered in the urine. Yamakawa [5] administered 2-propyltridecanoic acid to a rabbit. As judged from the mixed melting points of bis-*p*-phenylphenacyl esters the urinary excretion products were suggested to consist of 2-propylglutaric acid (7 parts), and 2-propylpimelic acid (3 parts). Our results confirm these findings.

SYNTHESES

2,2-Dimethyl[1-^{14}C]nonadecanoic acid. A methanol solution (130 ml) of heptadecanoic acid (5.7 g), 3-methoxy[^{14}C]carbonyl-3-methylbutyric acid (0.5 g) and sodium (0.06 g) was electrolysed between Pt-electrodes with a current density of 0.3 A/cm^2 until the pH was 7 (*cf.* Ställberg-Stenhagen [6]). The solution was cooled to room temperature, and the *n*-dotriacontane formed was filtered off. It was extracted twice with boiling methanol and each time filtered off after cooling to room temperature. The combined methanol solutions were evaporated to dryness. The residue was extracted with ether repeatedly. The mixture obtained from the ether extract after evaporation of the solvent was chromatographed on acid alumina (activated at 180° overnight). The hydrocarbons formed were eluted with light petroleum, the methyl 2,2-dimethyl[1-^{14}C]nonadecanoate with benzene, whereas the acids, which had not reacted, and the alcohols formed as byproducts were left on the column.

The colourless crystals of methyl 2,2-dimethyl[1-^{14}C]nonadecanoate (0.5 g) were hydrolysed with a solution of potassium hydroxide (3 g) in water (2 ml) and ethanol (23 ml) for 5 hours in an autoclave at 120°. Water was added to the hydrolysate, which was acidified and extracted twice with ether. The ether solution was washed with water and dried with sodium sulphate, and the ether was evaporated. After recrystallization

from methanol and light petroleum the 2,2-dimethyl[1-^{14}C]nonadecanoic acid melted at 67.2–67.7°. The yield was 0.35 g. (Found: C 77.3; H 13.0; equiv. wt. 326. Calc. for $C_{21}H_{42}O_2$: C 77.2; H 13.0; equiv. wt. 326.5).

2,2-Dimethylglutaric acid. The synthesis of 2,2-dimethylglutaric acid has previously been reported by several investigators. One of the better methods was that described by Franke and Bueren [7], who obtained the acid in a 75 % yield from 4-cyano-2,2-dimethyl-1-butyraldehyde (starting material: 2-methylpropionaldehyde and vinylcyanide).

In the present investigation it was synthesized by a Kolbe electrolysis from methyl hydrogen malonate (4.8 g), 3-methoxycarbonyl-3-methyl-butyric acid (1.6 g) and sodium (0.1 g) in methanol solution (30 ml). The electrolysis was continued until the pH was 7. The methanol was evaporated and the ether-soluble fraction was isolated. The excess methyl hydrogen malonate was removed from the ether solution by the ion exchanger Amberlite IRA-400. The esters (2.7 g of crude product) were partially hydrolysed with potassium hydroxide (3 g), water (2 ml) and ethanol (30 ml) at room temperature, when the hindered ester groups were almost unattacked. After the addition of water (50 ml) the solution was extracted twice with ether to remove methyl tetramethyladipate. The water-ethanol layer was acidified and extracted three times with ether. The ether solution was dried with sodium sulphate, and the solvents were evaporated. Extraction of the residue with ether left most of the succinic acid undissolved. After removal of the ether, the esters were hydrolysed with potassium hydroxide (3 g), water (2 ml) and ethanol (23 ml) in an autoclave at 120° for 5 hours. Water (18 ml) was added to the solution, which was then acidified, saturated with ammonium sulphate and extracted with ether 5 times. The ether solution was dried with sodium sulphate and evaporated to dryness. The mixture of acids obtained was chromatographed twice on hydrophobic Hyflo supercel with 2-ethylhexanol-chloroform (6:5, v/v) as the stationary phase and methanol-water (2:3, v/v) as the moving phase. They were eluted in the order: succinic, dimethylglutaric, tetramethyladipic acid.

The 2,2-dimethylglutaric acid (0.5 g) was recrystallized from concentrated hydrochloric acid and from benzene-light petroleum; m. p. 82°.

2,2-Dimethylpimelic acid. Methyl hydrogen glutarate (7.3 g), 3-methoxycarbonyl-3-methylbutyric acid (1.7 g) and sodium (0.1 g) were electrolysed in methanol (75 ml) as described above. A great excess of glutarate was used in order to suppress the formation of 2,2,5,5-tetramethyladipic acid.

The solution was hydrolysed with potassium hydroxide (8 g) and water (5 ml) in an autoclave at 120° for 3 hours. After acidification the hydrolysate was extracted with ether. From the dry substance of the ether extract, chloroform dissolved the dimethylpimelic and tetramethyladipic acids but left a considerable amount of the glutaric and suberic acid undissolved. The chloroform extract was evaporated to dryness and the solid residue was chromatographed twice on hydrophobic Hyflo supercel with 2-ethylhexanol-chloroform (1:1, v/v) as the stationary phase and methanol-water (2:3, v/v) as the moving phase. The acids appeared in the following order: glutaric, suberic, dimethylpimelic and tetramethyladipic acid.

The 2,2-dimethylpimelic acid (0.66 g) was recrystallized from water and from benzene-light petroleum. M. p. 75.4°. (Found: C 57.6; H 8.4. Calc. for $C_9H_{16}O_4$: C 57.4; H 8.6.)

METABOLIC EXPERIMENTS

A stock solution of 2,2-dimethyl[1-^{14}C]nonadecanoic acid (241.2 mg) with a specific activity of 125 000 counts/min/mg in olive oil (12.3 g) was prepared, and 0.75 — 1 ml of this was given orally in a single dose to adult male rats weighing about 250 g. The radioactivity was determined with a windowless GM-tube (with a background effect of 40 c.p.m.) after direct plating on aluminium planchets. For further experimental details see Bergström, Borgström, Tryding and Westöö [1].

Isotope recovery in excreta after the administration of 2,2-dimethyl[1-^{14}C]nonadecanoic acid

A rat was fed 0.75 ml of the above-mentioned stock solution (1 600 000 counts/min). Feces from the first 24 hours after the administration were shown to contain 17 % of the fed activity. From Table 1 it is seen that the total activity recovered in the feces in one week was 22 % of the amount administered. The total activity found in the urine during one week after the administration, 70 %, corresponds to a recovery of 90 % of the absorbed activity.

The feces from five other rats were collected for 4 days after the administration of the active acid. They contained 9—34 % of the fed activity. In the same experiment 70—91 % of the absorbed activity could be recovered from the urine during the same time.

When part of an ether extract from hydrolysed feces containing 34 % of the fed activity was chromatographed according to Howard and Martin [8] (75 % aqueous acetone as the moving phase and paraffin oil as the stationary phase supported on hydrophobic kieselguhr), 92 % of the activity was found as unaltered 2,2-dimethylnonadecanoic acid. Another part of the same extract was chromatographed on hydrophobic kieselguhr (40 % methanol as the moving phase and 2-ethylhexanol-chloroform (1:1) as the stationary phase) [1]. In this way 3 % of the active substances could be identified as 2,2-dimethylpimelic acid and 2.5 % as 2,2-dimethylglutaric acid. 2.5 %, which was eluted with the front in this system, has not yet been identified. These dicarboxylic acids are real fecal metabolites. They cannot originate from the urine, which for this special animal has been collected separately *via* a plastic funnel, sewn on to the cutis around the penis of the rat. The reason for the presence of dicarboxylic acids in the feces is being investigated.

Table 1. Activity recovered in rat urine and feces after oral administration of 2,2-dimethyl-[1-^{14}C]nonadecanoic acid.

Day No.	Per cent of administered activity found in	
	feces	urine
1	17.4	60.3

Administration of 2,2-dimethyl[1-^{14}C]nonadecanoic acid to rat with a lymph fistula

Rats with a thoracic duct cannula (Bergström, Blomstrand and Borgström [9]) were fed the stock solution. The lymph was collected at 0° (Table 2, rats 1—3) or in ethanol (Table 2, rats 4—6). During the first 12 hours 52 %

Table 2. Recovery of isotope in lymph and urine after feeding 2,2-dimethylnonadecanoic acid.

Rat No.	Per cent of fed activity absorbed	Per cent of absorbed activity recovered in lymph lipids	Per cent of lymph activity recovered as			Per cent of absorbed activity recovered in urine
			glycerides	free acids	phospholipids	
1	88.2	63.6	86.3	11.1	2.6	29.0
2	66.8	54.0	78.1	19.8	2.1	35.1
3	80.2	55.3	77.2	17.8	5.0	28.7

5	74.1	39.5				36.3
6	76.5	52.3				20.6

of the fed activity was recovered in the lymph from rat No. 1 (Table 2). Another 4 % was found during the next 24 hours. Accordingly 24-hour-specimens were collected from the other fistula rats (Table 2). The total fat from the lymph samples was separated into a neutral fat-fatty acid fraction and a phospholipid fraction on a column of silicic acid (Borgström [10]). The phospholipids contained 2—5 % of the activity of the lymph lipids. The neutral fat was separated from free acids on the ion exchanger Amberlite IRA-400 (Borgström [11]). The free fatty acid fraction was shown to contain 11—20 % of the lymph activity.

In addition the excreta from these rats were collected. In four days 8—33 % of the administered activity was found in the feces. During the same period 21—36 % of the absorbed activity was recovered from the urine, while 39—64 % of the absorbed isotope was in the lymph.

Identification of isotopic compounds in the urine after the administration of 2,2-dimethyl[1-^{14}C]nonadecanoic acid

The urine from a noncannulated rat was acidified with hydrochloric acid. When the urine from the first day was extracted three times with two volumes of ether, 77 % of the activity was found in the ether phase. In the same way 60 % of the activity in the urine from the second day and 40 % of the activity from the third day could be extracted with ether. Portions of the urine fractions with a weight of substance less than 50 mg were examined by reversed-phase partition chromatography. The phases and procedures were the same as described earlier [1]. The chromatogram of the ether extract from the first-day urine showed three distinct active bands (*cf.* Fig. 1).

Approximately 15 % (30 mg) of the residue of the ether extract was mixed with inactive 2,2-dimethylglutaric acid (8.4 mg) and subjected to partition chromatography. It is shown in Fig. 1 that this acid corresponds to the second active band. (The front titration peak represents ordinary urine excretion products.) The third active band was rechromatographed together with 7.6 mg

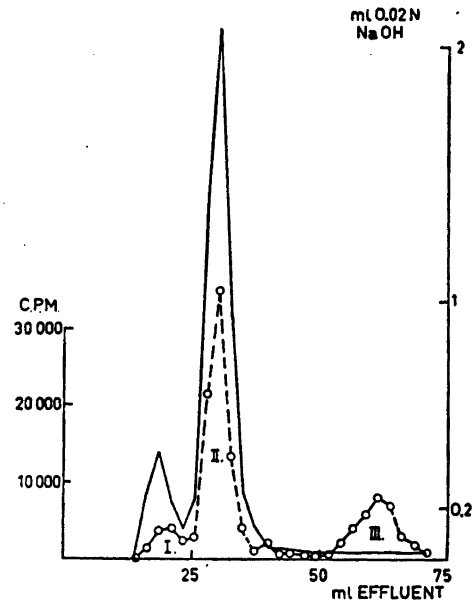

Fig. 1. Partition chromatography of 15 % of the ether extract from the first-day urine together with unlabelled 2,2-dimethylglutaric acid (8.4 mg). Stationary phase: 4 ml of i-octanol (2-ethylhexanol)-chloroform (1:1, v/v) supported on 4.5 g of hydrophobic Supercel. Moving phase: 40 % (v/v) aqueous methanol.

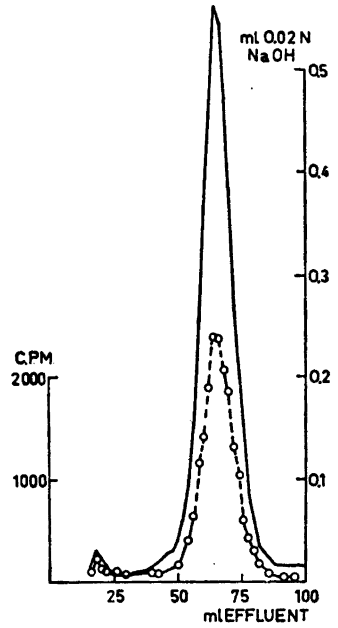

Fig. 2. Chromatography of the third active band from Fig. 1 with unlabelled 2,2-dimethylpimelic acid (7.6 mg). Phases: see Fig. 1.

Table 3. Specific activity of the most active fraction (1.2 mg) from the active band (II) of a chromatogram of urinary extract after recrystallization with inactive 2,2-dimethylglutaric acid (49.7 mg).

Recrystallization from	Crystal weight, mg	Counts / min / mg
benzene-light petroleum	41.5	2 225
water	26.0	2 313
water	14.3	2 280
benzene-light petroleum	9.9	2 307

Table 4. Specific activity of the two most active fractions (1.9 mg) from the active band III of a chromatogram of urinary extract after recrystallization with inactive 2,2-dimethylpimelic acid (79.0 mg).

Recrystallization from	Crystal weight, mg	Counts / min / mg
benzene-light petroleum	59.0	446
water	42.5	470
water	30.1	478
benzene-light petroleum	20.0	485
water	12.8	482

of 2,2-dimethylpimelic acid and the activity and titration peaks were found at the same position (Fig. 2).

The ether extract of the urine from a rat with a lymph fistula was subjected to reversed-phase partition chromatography. The isotope content of each fraction (2 ml) was determined after plating of 0.1 ml samples. The active bands appeared as in Fig. 1.

Table 5. The ratio between the three active bands in chromatograms of urine extracts.

1				>90	13	58	29
1	80				9	61	30
1		80			8	61	31
2	60				34	55	11
3	40				40	51	9

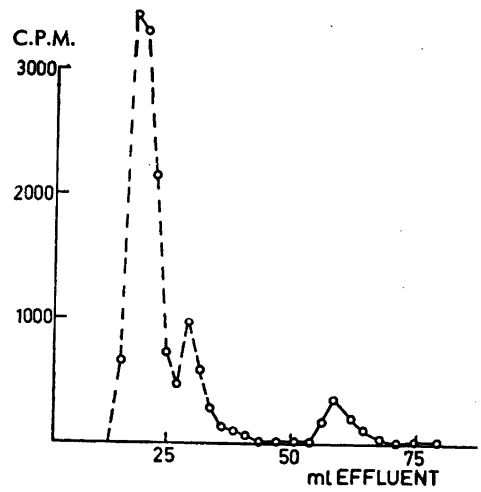

Fig. 3. Chromatogram of metabolites excreted in the urine, extracted with ethyl acetate after extraction with ether and saturation with ammonium sulphate. Phases: see Fig. 1.

The most active fraction from the second band with a weight of substance of 1.2 mg was mixed with 49.7 mg of inactive 2,2-dimethylglutaric acid and crystallized from benzene-light petroleum (b. p. 40—60°) and from water. As shown in Table 3 the activity remained constant indicating that 2,2-dimethylglutaric acid was excreted in the urine. In the same way recrystallization was performed with the two most active fractions from the third active band (with a dry weight of 1.9 mg) and inactive 2,2-dimethylpimelic acid

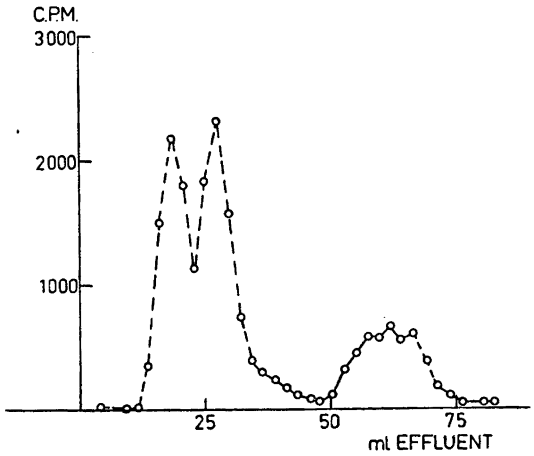

Fig. 4. Chromatogram of metabolites, after hydrolysis extracted as in Fig. 3. Phases: see Fig. 1.

(79.0 mg). From Table 4 it is seen that the activity remained constant. Consequently, 2,2-dimethylpimelic acid was another urinary metabolic product of 2,2-dimethylnonadecanoic acid.

As shown in Table 5 most of the activity of the ether extract was found in the second band (2,2-dimethylglutaric acid). In the chromatograms of the ether extracts of the urine from the second and the third day there was relatively more activity in the first band (unidentified product). The reverse was true for the third band (2,2-dimethylpimelic acid) which was distinctly lowered by the time. The ratio between the three active bands was almost unaltered after hydrolysis of the ether phase from the first-day urine. This indicates that no conjugates were present in the ether extract.

After the extraction with ether, half the water phase was saturated with ammonium sulphate and extracted three times with two volumes of ethyl acetate. In this way 47 % of the remaining activity could be extracted. When subjected to partition chromatography the main part of the activity was in the front band (Fig. 3). The other half of the water phase was hydrolysed for 6 hours at 120° with potassium hydroxide (4 g), water (2 ml) and ethanol (25 ml). After evaporation to dryness, the substance was dissolved in water, acidified, saturated with ammonium sulphate and extracted with ethyl acetate as described above. The activity could be extracted to 70 %.

A comparison between the chromatograms of ethyl acetate extracts of unhydrolysed and hydrolysed water phase of the ether-extracted urine from the first day (Figs. 3 and 4) shows that the front active band contains conjugates with the components in the second and third band. However, all the active substances in the first band could not be hydrolysed, which indicates the existence of a third metabolic product. This product is still being investigated.

We are indebted to Miss K. Sjöström for valuable technical assistance. This investigation has been supported by *Statens naturvetenskapliga forskningsråd*, by *Knut and Alice Wallenbergs Stiftelse*, and by the *Medical Faculty of the University of Lund*, which is gratefully acknowledged.

Increase of Cholinesterase Content in Mouse Liver Homogenates after Incubation

KARL HÅKON SKRAMSTAD

The Norwegian Defence Research Establishment, Toxicological group, Kjeller, Norway

The rate of hydrolysis of acetyl choline by mouse liver homogenates increases by about 100 % when the homogenates are left either overnight at room temperature or two to three hours at 37° C. Of the organs investigated, only the liver homogenates presented a real "autoactivation". This "activation" takes place in liver homogenates from mice of different ages and both sexes, but is more progressive in the female. The "activation" does not disappear with dialysis and seems to be localized to the particle-fraction of the liver cell upon centrifuging. The "activation" is independent of the isotonic milieu. Kinetic experiments with a selective cholinesterase inhibitor (Nu 683) suggest that one and the same enzyme, *viz.* a pseudo-cholinesterase is responsible for the major part of the activity with acetylcholine as substrate, both prior to and after the "activation" process.

The "activation" takes place with acetylcholine and buturylcholine as substrates, while inactivation results when tributyrine, benzoylcholine and acetyl-β-methylcholine are employed.

This indicates that we are dealing with a butyro-cholinesterase. Besides, it appears as if a benzoyl-cholinesterase is present in mouse liver, an esterase differing from the butyro-cholinesterase.

Wright and Mendel [1] have described an increasing activity towards acetylcholine in rat heart muscle after incubation at 37° C for 4—5 hours. A similar phenomenon in mouse liver homogenates was observed in our laboratory. The present work was an effort to elucidate this matter further.

METHODS

Enzymes. Activity was determined by the standard manometric technique; the temperature was 37° C and pH 7.3. Krebs Ringer's isotonic bicarbonate buffer solution was used as medium (102 parts 0.154 M NaCl, 4 parts 0.154 M KCl, 3 parts 0.11 M $CaCl_2$ and 21 parts 0.154 M $NaHCO_3$).

Readings were taken every fifth minute for half an hour, activity plotted against time and expressed finally as V_{30} values, *i. e.* microlitres carbon dioxide evolved per 30 minutes, as calculated from the linear part of the curve extrapolated to 30 minutes.

Substrates. The substrates were 0.007 M acetylcholine (ACh, La Roche), 0.01 M tributyrin (TB, British Drug Houses), 0.05 M acetyl-β-methylcholine (MeCh, Merck), 0.02 M benzoylcholine (BzCh, Hopkin and Williams) and 0.01 M butyrylcholine (BuCh, synthesized by the author).

The inhibitor was Nu 683 (Ro 2—0683, La Roche) which is dimethyl carbamate of (2-hydroxy-5-phenylbenzyl)-trimethyl ammonium bromide.

Source of enzyme. Ten per cent homogenates of liver, kidney and brain from mice were prepared at 0—5° C in Ringer's buffer solution. Heparinized blood was centrifuged, plasma used without further treatment and the erythrocytes were washed twice with three times their volume of saline. The final concentration of liver homogenates in the Warburg vessels to be analysed was 1 %. The time from the removal of the liver to the first readings of the manometers was usually 30 minutes ("un-activated" liver).

Dialysis. Ten ml 10 % liver homogenate was dialyzed in a refrigerator at 0—1° C against 10 l water, which was renewed twice over a period of two days.

RESULTS

Preliminary experiments

A typical "activation" curve is present in Fig. 2, where activity is plotted against incubation time at 37° C before manometric analysis.

A fresh liver homogenate was centrifuged at high speed (20 000 g) and the precipitate washed and recentrifuged. Activity was estimated in the supernatant and the precipitate, both immediately and after incubation at 20° C for 24 hours. In the "particle fraction" 100 % activation" was found, while the" activity in the supernatant decreased by about 5 %. The "activation" process seems therefore to be associated with the solid particles in the liver cells.

It might be suspected that a concentration gradient between the medium and the particles (nuclei and mitochondria) would cause the membranes to burst with subsequent release of enzymes that were not available for the non-lipoid soluble ACh at the beginning. This would cause a false "enzymatic" activation. However, experiments in strict isotonic milieu, even during the manometric analysis, made clear that the same degree of activation occurred as in the samples under nonphysiological conditions.

As calcium is known to be an activator of cholin-esterase (ChE) [2-5] this ion had to be omitted from the Ringer's solution in order to find out whether "activation" still occurred. Experiments showed that the activity was the same whether calcium was present during incubation or not.

Even when the liver had been homogenized in distilled water and standing overnight at room temperature, its power of splitting ACh increased.

Occurrence of the "activation"

The activities with ACh as substrate, previous to and after two hour's incubation at 37° C are presented in Table 1. Plasma, erythrocytes and brain do not present any "activation". Possibly kidney and certainly liver are "activated".

Fig. 1 shows the "activation" of enzyme with ACh as a substrate after 24 hours at 20° C. The "activation" takes place in liver homogenates from mice of different ages and both sexes, although there are large fluctuations. There

Table 1. Hydrolysis of ACh by some organs of mouse prior to and after incubation at 37° C.

	V_{30}				
	kidney-homogenate	brain-homogenate	liver-homogenate	plasma	erythro-cytes
Prior to incubation	9.5	169	115	196	100
After incubation	14	172	260	200	99.5

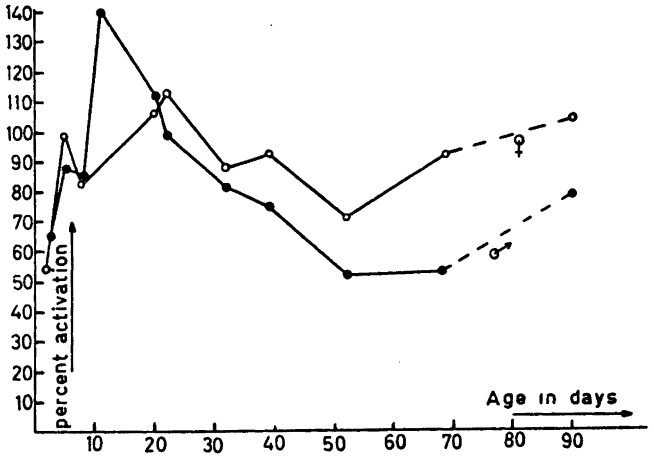

Fig. 1. Increase of cholinesterase content in mouse liver homogenates from animals of different ages and both sexes. "Activation" period lasted for 24 hours at room temperature (20° C).

seems to be a greater "activation" in livers from infantile mice than mature ones. The difference in ChE content in relation to sex is obvious [6].

After one month in the refrigerator the homogenates had lost from 5 to 10 % of their ChE activity, calculated from the 24-hours values.

Dialysis

Table 2 presents the ACh-hydrolysing values after dialysis, as compared to the same preparation not exposed to dialysis. As seen, the degree of "activation" is the same in both cases. Although the "activation" proceeds quite slowly, it might be supposed that the "activation" process is independent of any factor of low molecular weight.

Table 2. "Activation" in liver homogenates after dialysis.

Material	V_{30}
Not dialysed, measured at once	110
Not dialysed, one day at 20° C	150
Dialysed two days, measured immediately after dialysis	150
Dialysed two days, one day at 20° C	140

Different substrates

Acetylcholine. It is seen from Fig. 2 that activity increases within two to three hours at 37° C, whereupon the curve is levelling off. Hydrolysis then decreases slowly, probabely due to thermo-inactivation of the enzyme in question.

"Activation" seems to be more progressive in mature females than in males.

About the same degree of activation takes place in liver homogenates, when left overnight at room temperature (20° C).

Benzoylcholine. With this substrate the course of hydrolysis is the reverse of that with ACh. As seen from Fig. 2, the hydrolysis follows a normal course, with decreasing activity after incubation of the homogenates at 37° C.

Tributyrine. TB presents a course similar to that with BzCh. The curves for BzCh and TB differ to some extent, probably depending on factors such as concentration, pH optima and thermo-stability of the enzymes present. However, thermo-inactivation seems to increase with time of incubation in both cases.

Acetyl-β-methylcholine. True ChE, which is present in very small quantities in the liver [7], was essayed with a concentration of 2 % liver homogenate. The slight tendency of the activity to increase with time, as seen from Fig. 2, is too small to be of any experimental significance. If the "activation" had been caused by true ChE, at least a two-fold increase of the initial activity would be expected.

Buturylcholine. As seen from Fig. 2, the curve apparently is similar to that obtained with ACh as substrate. BuCh is hydrolyzed by pseudo-ChE from human plasma [8,9] and the term butyro-cholinesterase is commonly used for this type of ChE.

In accordance with these experiments one should expect that a butyro-cholinesterase is responsible for the "activation".

Nu 683 as inhibitor

This compound is considered to be a selective inhibitor of plasma-ChE [10]. It was decided to find out whether the I_{50} values prior to and after the "activation" process differed.

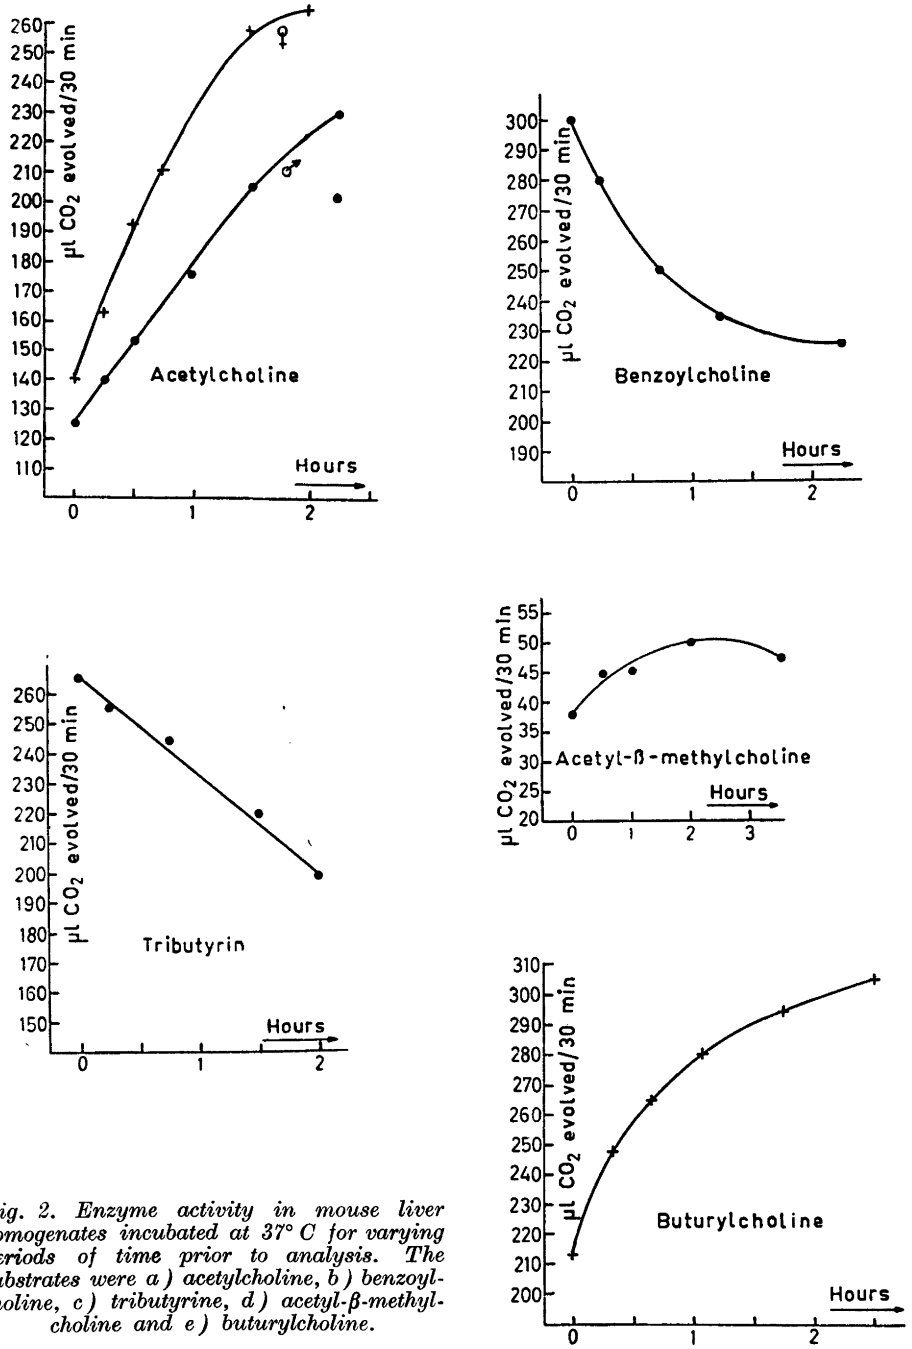

Fig. 2. Enzyme activity in mouse liver homogenates incubated at 37° C for varying periods of time prior to analysis. The substrates were a) acetylcholine, b) benzoylcholine, c) tributyrine, d) acetyl-β-methylcholine and e) buturylcholine.

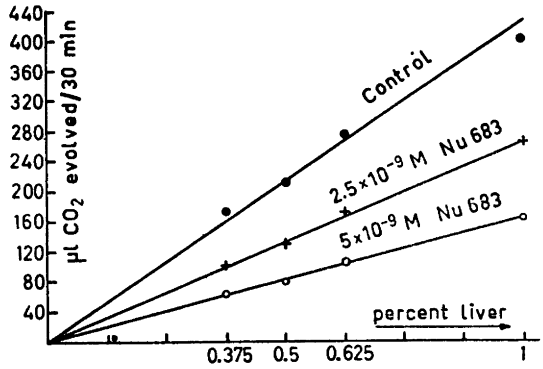

Fig. 3. Acetylcholine hydrolysis in "activated" mouse liver homogenates in presence of inhibitor (Nu 683). Activity is plotted against homogenate concentration.

In preliminary experiments the substrate and enzyme concentrations were held constant, while the inhibitor concentration was varied. A 50 % inhibition was obtained with a concentration between 2.5×10^{-9} M and 5×10^{-9} M. The inhibition was deduced by plotting V/V_i against I, to give a straight line in accordance with the equation for competitive inhibition [11]:

$$\frac{V}{V_i} = 1 + \frac{K_s}{K_i} \cdot \frac{I}{K_s + S}$$

(V and V_i are the velocities of the reaction with or without inhibitor, respectively, S is substrate concentration, I is inhibitor concentration, K_s and K_i are the dissociation constants of the enzyme-substrate and enzyme-inhibitor complexes, respectively.)

The ACh hydrolysis was measured in liver homogenates before incubation. Three samples were used: A) control, B) with 2.5×10^{-9} M Nu 683 and C) with 5×10^{-9} M Nu 683.

Table 3. ACh hydrolysis by "non-activated" and "activated" liver homogenates in the presence of Nu 683.

	control	2.5×10^{-9} M Nu 683		5×10^{-9} M Nu 683		I_{50}
	V_{30}	V_{30}	V/V_i	V_{30}	V/V_i	
"Non-activated" liver	104	73.5	1.42	46	2.26	$4.1.10^{-9}$
"Activated" liver *			1.61		2.62	$3.6.10^{-9}$

* The V/V_i values are deduced from Fig. 3.

After two hour's "activation" at 37° C the three samples were analysed in the presence of four different enzyme concentrations. Fig. 7 shows the result; activity is plotted as a function of the enzyme concentration, giving three straight lines. The ratio between the slopes of the control and the two other curves may be deduced, and from this the two V/V_i values may be found. Hence the I_{50} value, which was found to be 3.6×10^{-9} M for the "activated" liver homogenate. The I_{50} value prior to "activation" is 4.1×10^{-9} M (Table 3).

DISCUSSION

Among the organs investigated (Table 1) "autoactivation" of ACh-hydrolysis prior to incubation exists particularly in liver homogenates. This might be an indication of an increased biosynthesis of plasma-ChE in the liver, as this organ is considered to be the site of production of this esterase [12–14]. Perhaps there is an autocatalytic release of the active enzyme from some precursor, as for instance in the case of pepsinogen-pepsin. The process may be induced after the animal is dead. The transfer of "precursor" to an active enzyme seems to be independent of any dialysable factor and to take place in the solid particles of the liver cells.

It seems rather plain to decide which type of esterase is responsible for the "activation". Among the substrates investigated, only ACh and BuCh present the same "activation" features, and this suggest that a butyro-cholinesterase is the cause of the increase in activity. BzCh, often used as a specific substrate for pseudo-ChE[15], is not hydrolysed at an increased rate after incubation. On the contrary the hydrolysis of this substrate decreases with time. Thus there might perhaps be two pseudo-ChE'es in the mouse liver: one butyro-cholinesterase and one benzoyl-cholinesterase. As known, benzoyl-cholinesterases are occasionally found in the plasma of rabbits [16–18] and in the liver of guinea pigs [7,16,19].

If the "activated" hydrolysis is due to an enzyme which is not inhibited by Nu 683, the I_{50} value might be expected to increase considerably after the "activation". However, the opposite is true. The I_{50} value decreases from 4.1×10^{-9} M to 3.6×10^{-9} M after "activation". If this slight fall should be an experimental error, it might be expected that one and the same enzyme, *viz.* a pseudo-ChE, is responsible for the "autoactivation". If, on the other hand, this fall is experimentally significant, an explanation is simple when it is borne in mind that various enzymes hydrolyse ACh in the mouse liver. In addition to pseudo-ChE, the aliesterase(s) and to a lesser degree, true ChE are present. As true ChE very likely is not inhibited by Nu 683 (at the concentrations here employed) [10], the rate of hydrolysis with inhibitor present prior to "activation", is partly due to enzymes slightly or not inhibitable by Nu 683. Hence the I_{50} value becomes high. After "activation" the relative part of these enzymes (aliesterase, true ChE, benzoylChE) has decreased and thereby caused a reduced I_{50} value. This means that one and the same enzyme, a pseudo-ChE, causes the hydrolysis both prior to and after the "activation". And this pseudo-ChE, in accordance with the aforementioned circumstances, is a butyro-cholinesterase.

Acknowledgement. The author wishes to thank Dr. J. A. B. Barstad for his advice and interest in this work and Mrs. Aa. Lund-Riise for technical aid.

ACTA CHEMICA SCANDINAVICA 10 (1956) 1251—1257

Action of Neutral Sulphite Solution on Carbohydrates at High Temperatures. Part I. A Sulphocarboxylic Acid Derived from Xylose

SVEN YLLNER

Department of Wood Chemistry, Swedish Forest Products Research Laboratory, Stockholm, Sweden

When heated in neutral sulphite solution at 135°C xylose is rapidly degraded. From the reaction products an acid was isolated, which was shown to have the structure of α,δ-dihydroxy-γ-sulphovaleric acid. It was degraded to the lactone of β-sulpho-γ-hydroxybutyric acid, which was synthesised by the addition of sulphite to the lactone of γ-hydroxy*iso*crotonic acid.

In account of its technical importance, considerable interest has been devoted to the decomposition of carbohydrates in sulphite solutions at high temperatures. Thus Hägglund and Johnson [1] found that aldoses in acid sulphite solutions are oxidised to the corresponding aldonic acids, and in similar experiments on holocellulose Heiwinkel [2] and Adler [3] showed that a considerable part of the decomposition of carbohydrates must be attributed to the formation of sulphonic acids, which, on account of their stability to alkali, can be distinguished from the well-known aldehyde-bisulphite addition compounds. In continuing the early work of Marusawa *et al.*[4] concerning the action of bisulphite on glucose, Matsui [5] obtained a sulphonic acid, which he suggested was "levoglucosan-6-sulphonic acid".

A sulphonic acid of quite different type was isolated by Hägglund, Johnson and Urban [6] after heating glucose in sodium sulphite-bisulphite solution of pH 6. This acid contained one carboxyl, one carbonyl and one sulphonic acid group. From the reaction product Adler [3] isolated another sulphocarboxylic acid, which lacked the carbonyl function. Moreover, both acids, with the compositions $C_6H_9O_5(SO_3H)$ and $C_6H_{11}O_5(SO_3H)$, respectively, were proved to contain a terminal glycol grouping. The complete structure of these two acids remained unknown.

Recently, the production of wood pulp using the neutral sulphite process has steadily increased. Thus the decomposition of carbohydrates in neutral

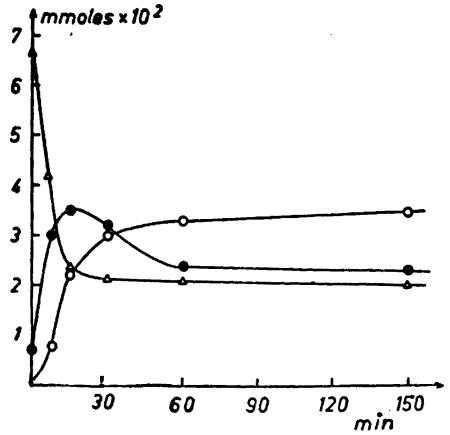

Fig. 1. The reaction of xylose in neutral sulphite solution at 135° C (using for titration 4 ml of the diluted reaction solution).

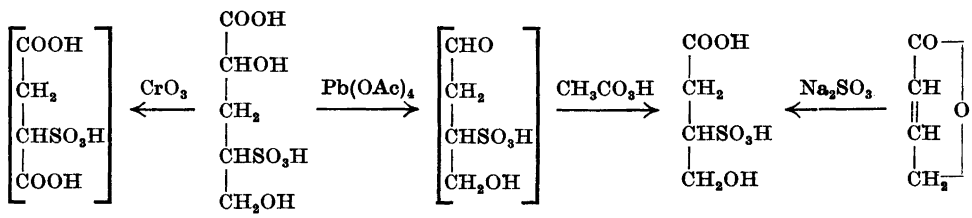
○ *"Total SO_2" consumed.*
● *"Loosely bound SO_2".*
△ *Reduction capacity calc. for xylose.*

sulphite solution is of current interest, and some additional facts pertaining to this subject have now been uncovered. As even glucose gives rise to rather complicated products, the problem has been somewhat simplified by using xylose as starting material. The present communication deals with the isolation and structural elucidation of α,δ-dihydroxy-γ-sulphovaleric acid, which is formed by heating xylose in neutral sulphite solution. Further work is in progress with the purpose of elucidating the mechanism of the formation of this acid.



The course of the reaction at 135° C of xylose, dissolved in a solution of sodium sulphite and bisulphite in equimolecular amounts, was followed titrimetrically. The titrimetric method was essentially the same as used by Hägglund, Johnson and Urban [6] in the case of glucose, and the results are shown in Fig. 1.

The reduction capacity, calculated for xylose, decreased rapidly to an almost constant value corresponding to the decomposition of about 70 % of the initial quantity of xylose. Simultaneously "total SO_2" was consumed equivalent to the formation of sulphonic acid in a maximum yield of about 50 % calculated on xylose. The percentage of "loosely bound SO_2" was low at the start of the reaction, but rapidly increased to a maximum after 15 minutes. After one hour further heating produced only insignificant changes in the reduction capacity, "total SO_2" and "loosely bound SO_2". As was also reported by Hägglund, Johnson and Urban [6] in the case of glucose, no appreciable formation of sulphate (in the present investigation determined according to Samuelson and Ögren [7]) was found. The specific rotation calculated on the xylose content in the starting solution was +7.4°, but after 15 minutes at 135° C the reaction mixture no longer showed any optical activity. The pH (determined at room temperature) remained almost constant (6.5) during the cook.

From the reaction solution, after one hour at 135°, were isolated crude, optically inactive barium salts of organic acids containing sulphur and with a Ba to S ratio of 0.93—0.97. For a pure sulphocarboxylic acid this ratio is 1.

Calculated as such the yield of crude barium salt was almost 50 %. Coloured impurities were removed by passing an aqueous solution of the crude product through a carbon column. Although the barium salts thus purified, were almost homogeneous chromatographically (and gave the same analysis as the barium salt described below) they showed no tendency to crystallise. They were therefore converted into the brucine salts, which by crystallisation gave two compounds, one of which was obtained in about 50 % yield. This brucine salt, which could also be obtained directly from the crude barium salts in about 25 % yield, calculated on xylose, was converted back into the barium salt, which now crystallised readily. The pure barium salt was optically inactive.

According to the Ba to S ratio the molecule obviously contained one carboxyl and one sulphonic acid group. The free acid showed no tendency to lactonise in aqueous solution and the titration curve showed that the carboxyl group is strongly acidic. On the assumption of a C_5 unit, and since the substance showed no reducing properties, the remainder of the oxygen could probably be assigned to two hydroxyl groups. The substance thus seemed to be a dihydroxysulphovaleric acid, and closely related to the non-reducing "glucosesulphonic acid" isolated by Adler [3]. Unlike the latter acid it was not oxidised by periodic acid, and thus contains no glycol grouping. On the other hand it consumed one mole of lead tetraacetate with the libration of one mole of carbon dioxide indicating an α-hydroxycarboxylic acid grouping. Strong evidence for the second hydroxyl group being situated in terminal position

Scheme 1.

was obtained by oxidising the acid with dichromate. The consumption of dichromate was practically equal to that calculated (2.67 moles of CrO_3 per mole of sulphonic acid) for the formation of a sulphosuccinic acid (Scheme 1, Table 1).

The formulation of the acid as α,δ-dihydroxy-γ-sulphovaleric acid was supported by the following evidence: The product from the oxidation with lead tetraacetate (a sulphoaldehyde, not isolated) was oxidised with peracetic

Table 1. Oxidation of the sulphocarboxylic acid with dichromate.

Minutes	15	60	120	180	330	1 320

acid to β-sulpho-γ-hydroxybutyric acid, which was isolated as the pyridinium salt of the corresponding lactone, the identity of which was shown by analysis and mixed melting point with an authentic sample of β-sulpho-γ-butyrolactone.

This was synthesised by the addition of sulphite to the lactone of γ-hydroxy*iso*crotonic acid, since, according to Schenck and Danishefsky [8], the addition of bisulphite to α,β-unsaturated carboxylic acids directs the sulphonic acid group to the β-position. The free β-sulpho-γ-hydroxybutyric acid lactonised spontaneously and the pyridinium salt of the lactone melted without decomposition and was suitable for the identification mentioned above. The sodium salt melted (with decomposition) about 30° lower than reported for the sodium salt of α-sulpho-γ-butyrolactone [9].

α,δ-Dihydroxy-γ-sulphovaleric acid contains two asymmetric carbon atoms. It therefore seems probable, that the crystalline brucine salt examined (rods), since it gave rise to an optically inactive barium salt, represents one of the two possible DL-forms of the acid. Further work will be done to elucidate the structure of the second brucine salt (needles), which may be derived from the other DL-form of this acid.

EXPERIMENTAL

Course of the reaction of xylose in sodium sulphite-bisulphite solution. Xylose (2.50 g), sodium pyrosulphite (3.7 g) and sodium sulphite hepta hydrate (9.8 g) were dissolved in water, and the solution made up to 100 ml. Samples (10 ml) of this solution were heated in sealed glass tubes in an oil bath at 135° C. When cooled each sample was diluted to 100 ml.

"Free SO_2" was determined by iodine titration of an acidified (pH 2) sample of this solution, and "total SO_2" by iodine titration of a sample buffered with calcium carbonate. "Loosely bound SO_2" was calculated as the difference between "total SO_2" and "free SO_2". The reduction capacity was determined according to Bertrand. The results are shown in Fig. 1.

Fractionation of the reaction products as barium salts. Xylose (5 g), sodium pyrosulphite (7.4 g), and sodium sulphite hepta hydrate (19.6 g) were dissolved in water (100 ml total volume) and the solution was heated in sealed glass tubes for one hour. The faintly yellow reaction mixture was passed through a column of Amberlite IR-120 (300 ml) in the H^+-state. Nitrogen was bubbled through the sodium free solution to remove most of the sulphur dioxide. Saturated barium hydroxide solution was then added until pH 7.5 was reached. Barium sulphate and sulphite were removed by filtration, and the solution, which had turned red, was evaporated *in vacuo* to 30 ml.

To the vigorously stirred solution ethanol (10 ml) was added dropwise, a syrupy precipitate being formed (fraction 1). The clear solution was decanted, another portion of ethanol (4 ml) was added giving a further, somewhat larger syrupy precipitate (fraction 2). Additional ethanol (20 ml) gave rise to only a small precipitate (fraction 3). The solution, containing more than 50 % ethanol, was evaporated *in vacuo* to 10 ml and further precipitation was effected by addition of this solution to ethanol (60 ml). The precipitate was washed with abs. ethanol and ether and dried (fraction 4). The syrupy fractions 1—3 were each dissolved in water (10 ml), precipitated in ethanol (60 ml), washed with ethanol-ether and dried. Amounts and compositions of the fractions 1—4 are shown in Table 2.

Chromatographic examination of the fractions. Samples (200 mg) of the fractions 1—4 were dissolved in water, and the solutions passed through columns of IR-120 in the NH_4^+-state. The ammonium salts were chromatographed on Whatman No. 1 filter paper with a solvent system of ethanol:water (4:1) using the descending technique. The chromatograms were sprayed, according to van Duuren [10], with 4 % formaldehyde and dried at 60° C in order to convert the ammonia to urotropine. The free acids were then detected by spraying with a solution containing starch, potassium iodide and iodate [10]. Fractions 1—3 were found to be very similar giving a few weak spots and one strong spot ($R_F = 0.20$),

Table 2. The crude barium salt fractions.

Fraction. No	g	% Ba	% S	Ba/S molar ratio
1	1.80	37.7	9.09	0.97
2	2.80	36.6	9.04	0.95
3	0.88	36.8	9.23	0.93
4	2.86	32.3	9.52	0.79

which obviously contained the main part of the acids. Fraction 4 on the other hand gave four almost equally strong spots with R_F-values of 0.20, 0.26, 0.30, and 0.36, and a somewhat weaker spot with R_F = 0.40. The identity of the latter four of these, which also appeared as very weak spots in the fractions 1—3 has yet not been established.

By using silver nitrate and sodium hydroxide as spray reagent according to Trevelyan *et al.*[11] no spots were obtained with R_F = 0.20, and only some of the substances in fraction 4 showed reducing properties.

Purification of the crude barium salt. Fractions 1—3 were strongly discoloured, but the impurities could be removed by filtering a water solution of the crude product through a carbon column (Carbo animalis:Celite, 1:1). The barium salt solution thus purified, was evaporated to a small volume and precipitated by pouring into ethanol. (Found: Ba 38.5; S 9.23; C 17.3; H 2.45. Calc. for $C_5H_8O_7SBa$: Ba 39.3; S 9.17; C 17.2; H 2.31.).

The purified amorphous barium salts (490 mg) were dissolved in water and the solution passed through a column (5 ml) of Amberlite IR-120 in the H^+-state. The acids were neutralised by brucine and the solution then evaporated to a small volume. By addition of acetone a rapid crystallisation was achieved. The crystals were quite uniform in the shape of rods, more or less collected in bundles. Yield 0.46 g.

The mother liquor gave a new fraction containing chiefly crystals of the same shape but also a few bundles of long needles. Yield 0.35 g. The two fractions were combined and recrystallised from water-acetone, the product being rods only. (Found: S 3.33; OCH_3 12.1. Calc. for $(C_{23}H_{26}O_4N_2)_2C_5H_{10}O_7S$: S 3.20; OCH_3 12.4).

Additional brucine salt (0.34 g), mainly the needle-like modification, was obtained from the mother liquor.

The brucine salt with rod-like crystals was converted into the barium salt which crystallised readily from a concentrated water solution in the form of short rods and was recrystallised from water-ethanol. (Found: Ba 37.2; S 8.58; C 16.4; H 2.33; H_2O 5.15. Calc. for $C_5H_8O_7SBa$, H_2O: Ba 37.4; S 8.73; C 16.4; H 2.74; H_2O 4.91.)

Oxidation of the sulphonic acid with dichromate. Crystalline barium salt (310 mg) was dissolved in water (25 ml) and a solution (50 ml) of sulphuric acid (5 ml) and potassium dichromate (0.88 g) was added. The reaction mixture was made up to 100 ml, and two samples (5 ml) were immediately taken at room temperature, when the oxidation was slow, and added to a mixture of potassium iodide and sulphuric acid. The liberated iodine was titrated with 0.05 N thiosulphate. After the starting concentration had been determined, the sealed reaction flask was placed in a boiling water bath. The reaction mixture was cooled to room temperature each time samples were taken, and these were titrated as mentioned. Results in Table 1.

Oxidation of the sulphonic acid with lead tetraacetate. a) *Course of the reaction.* The following solutions were made:

A. Crystalline barium salt (70.8 mg) was dissolved in water and the solution made up to 50 ml.

B. A saturated solution (15 ml) of lead tetraacetate in acetic acid was diluted with acetic acid to 100 ml.

C. Potassium iodide (10 g) and sodium acetate (50 g) were dissolved in water. and the solution made up to 100 ml.

Five ml of A were rapidly mixed with 5 ml of B. At the end of the reaction time 5 ml of C were added and the liberated iodine titrated with 0.01 N thiosulphate. In the blank, 5 ml of water were used instead of A. When the reaction time exceeded 20 minutes lead dioxide was precipitated, and correct titration figures could then not be obtained. Results in Fig. 2.

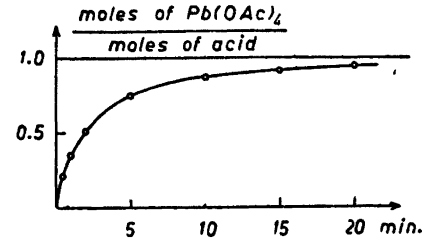

Fig. 2. Oxidation of the sulphocarboxylic acid with lead tetraacetate.

b) *Formation of carbon dioxide.* A test-tube (50 ml) fitted with a side tube and containing a saturated solution of lead tetraacetate in acetic acid (20 ml) was sealed with a rubber stopper fitted with a small separatory funnel and a capillary inlet tube reaching almost to the bottom of the test-tube. For 30 minutes a gentle stream of CO_2-free nitrogen was bubbled through the solution and was afterwards passed firstly through a tube containing $Mg(ClO_4)_2$ and kept at $-20°$ C and secondly through an absorption tube containing NaOH-asbestos. During this time the weight of the absorption tube was constant. The stream of nitrogen was cut off, a solution of the barium salt (209.6 mg) in water (5 ml) was added through the separatory funnel, which was washed out with a few millilitres of water and immediately closed. The stream of nitrogen was again passed through the apparatus, and the reaction tube warmed to 50° C. The absorption tube reached constant weight after about one hour. (Found: 25.0 mg of CO_2. Calc. for $C_5H_8O_7SBa$, H_2O: 25.1 mg of CO_2.)

c) *Degradation to β-sulpho-γ-hydroxybutyric acid.* The barium salt of the sulphonic acid (0.55 g) was dissolved in water and passed through a column (8 ml) of Amberlite IR-120 in the H^+-state. The solution of the free acid was diluted to 50 ml, and added to a saturated solution of lead tetraacetate in glacial acetic acid (50 ml). After 1 hour the reaction mixture was diluted with water (100 ml) in order to destroy excess lead tetraacetate. After filtration, a solution (2.0 ml) of peracetic acid [12] (equal volumes of H_2O_2 (30 %) and acetic anhydride, three days at room temperature) was added, and the reaction mixture kept at 75° C for 90 minutes. After cooling, excess H_2O_2 and CH_3CO_3H was destroyed by shaking the reaction mixture together with 1 g of Pd-asbestos (25 % Pd) overnight. The mixture was filtered, treated with H_2S and filtered again. The solution was evaporated *in vacuo* to 2.5 ml, kept at room temperature for three days for completion of lactonisation, neutralised with pyridine and evaporated to a syrup. This was dissolved in ethanol, some insoluble material was filtered off, and the solution again concentrated to a syrup. This was repeated once. The residual syrup was dissolved in 3 ml of ethanol, and a few drops of ether were added. A rapid crystallisation of the pyridinium salt of β-sulpho-γ-butyrolactone occurred. Recrystallisation from ethanol-ether yielded 0.21 g of optically inactive material. M. p. 160—161 °C. (Found: N 5.49; S 12.8; Calc. for $C_9H_{11}O_5NS$: N 5.72; S 13.1). No m. p. depression with an authentic sample of the pyridinium salt of β-sulpho-γ-butyrolactone was observed.

Synthesis of β-sulpho-γ-butyrolactone. γ-Hydroxy*iso*crotonic acid lactone (0.5 g), prepared according to Glattfeld *et al.*[13], was dissolved in a solution of sodium sulphite hepta hydrate (1.5 g) in water (3 ml). Sulphite was rapidly consumed, and the temperature rose to about 50° C. Next day the solution was passed through a column of Amberlite IR-120 in the H^+-state. The eluate was evaporated to 2 ml and kept at room temperature for three days. The acid was neutralised with pyridine (0.5 ml) and the solution evaporated to a syrup. When this was diluted with ethanol a rapid crystallisation of the pyridinium salt of β-sulpho-γ-butyrolactone occurred. Recrystallisation from ethanol-ether yielded prismatic plates, 1.05 g. M. p. 160—161 °C. (Found: N 5.55; S 13.2. Calc. for $C_9H_{11}O_5NS$: N 5.72; S 13.1.)

The sodium salt melted at 210-215° C (decomp.).

When chromatographed on Whatman No. 1 filter paper using the solvent system ethanol:conc. NH_3:water (20:1:4) and developing according to van Duuren [10] the acid gave two spots with R_F-values 0.28 and 0.41, respectively, the latter probably corresponding to the lactone and the former to the free sulphocarboxylic acid.

Kinetics of the Hydrolysis of Methyl-valerate Catalyzed by Horse Liver ali-Esterase

J. A. CHRISTIANSEN and JOHN GRAAE

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

The hydrolysis of methyl-valerate catalyzed by horse liver ali-esterase was investigated by continuous automatic titration of the liberated acid. The reaction was studied with different initial concentrations of enzyme and substrate and followed to a degree of reaction of 99 %. The following chronometric integral can describe the reaction

$$t = A \cdot \frac{a}{E} \cdot a + B \cdot \sqrt{\frac{a}{E}} \left[\ln \frac{1 + \sqrt{a}}{1 - \sqrt{a}} - 2\sqrt{a} \right]$$

where t is time, a initial substrate concentration, E enzyme concentration, a degree of reaction and A and B are constants. It is pointed out that the appearance of square roots in the chronometric integral indicates a reaction between two enzyme-containing molecules. A mechanism of this type is suggested.

Several attempts have been made to elucidate the kinetics of the ali-esterases. It is very often described as a zero order reaction [1–3]. Schønheyder [6] has described it in a particular case as a combination of a zero and a first order reaction, while others [4–5] have described similar cases by a Michaelis-expression, which actually amounts to the same. Many of the investigators have only studied the beginning of the reaction (*i. e.* less than 50 % degree of reaction) and it should be well known that this often leads to misinterpretations of the experimental data. It is the purpose of this investigation to study the kinetics of the enzymic ester hydrolysis including also high degrees of reaction. The substrate was methyl-valerate. This ester was chosen because of its rapid reaction in the presence of esterases [7–10].

The enzyme was obtained from horse liver which has a high content of esterase [11] and is easy to obtain in large quantities.

EXPERIMENTAL

Enzyme. Fresh horse liver was obtained directly from the slaughter house. It was disintegrated in a Waring blendor and washed four times with acetone in order to remove water and fat. After each washing the powder was drained on a Büchner funnel with moderate suction and after the last one it was dried overnight at room temperature. The dry powder was stored in the refrigerator until use. Solutions for the experiments were made by stirring the powder with ten times its weight distilled water for a few hours at room temperature. After centrifugation the clear dark red-brown supernatant was used for the experiments.

Substrate. Methyl-valerate was prepared from butanol (1) which was converted into valeronitril as described by Adams and Marvel [12]. From this nitrile the ester was prepared by interaction with methanol and sulfuric acid. The product was distilled in a Stedman column [13,14], b. p. 127.8/128.3 (uncorr.) at 767.4/768.6 mm Hg.

Apparatus. The hydrolysis of the ester was followed by continuous automatic titration in a pH-stat [14a]. All experiments were made at pH = 8.0, which is the optimum pH [2] and 20.0° C. The reaction chamber was a 100 ml beaker. The experiments were performed in 50 ml 0.1 M KCl, carefully adjusted to pH = 8 with KOH. A suitable amount of ester was added and the experiment was started by adding the desired amount of enzyme solution. Corresponding values of time and amount of KOH added from a syringe necessary to keep pH constant were read. The concentration of ester was found as the titration value when the reaction had finished.

The stability of the enzyme was checked in the following way: An enzyme solution was kept in a thermostat at 20° C. A sample of 3 ml was removed and an experiment performed in the manner described above and continued for about 10 min. This was repeated at suitable intervals for the next 20 hours. As will be seen from Fig. 1 there was no measurable alteration of enzyme activity during this time. The last enzyme sample was heated to about 95° C for 30 min. As also shown by Fig. 1 there was no measurable activity left after this treatment.

The positive interception on the ordinate axis is due to the fact that the enzyme solution has a pH lower than the experimental pH and the final adjustment of this pH is made by the pH-stat. It is seen from the figure that the amount of KOH necessary to make this adjustment is well-defined and it is of course subtracted from all measurements used for the kinetical determinations.

RESULTS

Experiments were performed at four different substrate concentrations, with the same enzyme concentration. It was found that under these circumstances the reaction could be described by the expression:

$$t = A \cdot a\alpha + B \cdot \sqrt{a}\left[\ln \frac{1+\sqrt{\alpha}}{1-\sqrt{\alpha}} - 2\sqrt{\alpha}\right]$$

where t is time, α degree of reaction, a initial substrate concentration and A and B are constants. The results of these experiments are given in Tables 1—4.

Tables 5—8. The tables indicate the measured values of time (t_{exp}) and degree of reaction (α), together with time calculated (t_{calc}) from the suggested chronometric integral. With the arbitrary values for enzyme concentration used here the constants A and B are 5 699 and 17.39 minutes respectively.

Four experiments with different enzyme concentrations, but with almost the same substrate concentration were performed. Tables 5—8 show the measured and the calculated times. The following expression was used for the calculations:

$$t = \mathrm{A} \cdot \frac{a}{E} a + \mathrm{B} \cdot \sqrt{\frac{a}{E}} \left[\ln \frac{1 + \sqrt{a}}{1 - \sqrt{a}} - 2 \sqrt{a} \right]$$

The constants A and B used for the calculations were found in the following manner: The chronometric integral was written as:

$$t = \mathrm{A}' \cdot a + \mathrm{B}' \cdot \left[\ln \frac{1 + \sqrt{a}}{1 - \sqrt{a}} - 2\sqrt{a} \right]$$

and the constants A′ and B′ were determined for every experiment. It turned out that empirically A′ could be represented by Aa/E and B′ by $B\sqrt{a/E}$ where A and B are common to all experiments in which the relative values of E are known. The deviation between measured and calculated times seen in some of the experiments are supposed to be due to difficulties in obtaining exactly the

desired enzyme concentration. It may be, however, that the deviations are due to the approximation introduced between formula (12) and (12 a) in the following discussion of the reaction mechanism.

REACTION MECHANISM

To explain the occurrence of the square root of the initial substrate concentration we have assumed that two molecules of enzyme in the same or in different forms combine with one molecule of one of the reactants. As the situation is similar to the state of affairs at certain photochemical reactions, *cf. e. g.* the classical work of Bodenstein *et al.*[15] and Jost [16], some such assumption seems very natural or even necessary.

As it is known that enzymic ester hydrolyses are often inhibited by the acid and not by the alcohol [6] we assume that in our case it is the valerate ion which combines with the enzyme, and suggest the following reaction scheme:

$$X_1 \rightleftharpoons X_2 \qquad (\pm 1)$$
$$X_2 + OH^- \rightleftharpoons X_3 \qquad (\pm 2)$$
$$X_3 + MV \rightarrow X_1 + MOH + V^- \qquad (+3)$$

with the additional equilibrium:

$$2X_3 + V^- \rightleftharpoons X_4 \qquad (\pm 3a)$$

where X_{1-4} are different enzyme forms, MV methyl-valerate, MOH methyl alcohol and V^- valerate ion. From this scheme we can theoretically deduce a chronometric integral identical with the empirical one: Using the steady state method as described by Christiansen [17,18] and with the symbols used by Christiansen we have:

$$s = x_1 w_1 - x_2 w_{-1} \qquad (4)$$
$$s = x_2 w_2 - x_3 w_{-2} \qquad (5)$$
$$s = x_3 w_3 \qquad (6)$$

where s is the steady state rate and the w_i's are reaction probabilities for the steps indicated. The other small letters indicate the concentration of the substance symbolized by the same capital letter.

Solutions of the equations yield:

$$x_1 = s\ (1 + w_{-1}/w_2 + w_{-1}w_{-2}/w_2 w_3)/w_1 \qquad (7)$$
$$x_2 = s\ (1 + w_{-2}/w_3)/w_2 \qquad (8)$$
$$x_3 = s/w_3 \qquad (9)$$

As it is known that the reaction has an energy of activation [19] we assume that X_2 must be on a higher energy level than X_1.

Fig. 2 will account for the energy levels of the enzyme during the reaction. From this it is seen that $w_{-2}/w_3 \ll 1$ and eqns. 7, 8 and 9 can be rewritten as follows:

$$x_1 = s\ (1 + w_{-1}/w_2)/w_1 = q_1 s \qquad (7a)$$
$$x_2 = s/w_2 = q_2 s \qquad (8a)$$
$$x_3 = s/w_3 = q_3 s \qquad (9a)$$

From (3a) we get

$$x_4/x_3^2 v = K \qquad (10)$$

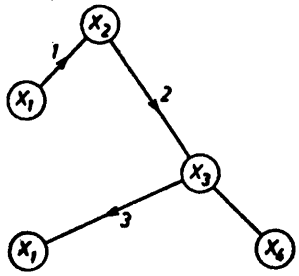

Fig. 2.

where K is an equilibrium constant and v means the concentration of valerate ions. For the total enzyme concentration we have

$$E = x_1 + x_2 + x_3 + x_4$$

Regarding the energy levels it is obvious that x_2 can be neglected and we then have

$$x_4 = E - (x_1 + x_3) \tag{11}$$

Introducing (7a), (9a) and (11) in (10) and solving the equation we find

$$\frac{2}{s} = \frac{q_1 + q_3}{E} + \sqrt{\left(\frac{q_1 + q_3}{E}\right)^2 + \frac{4K \cdot v}{E} \cdot q_3^2} \tag{12}$$

If we require this expression to conform with that derived from the chronometric integral by differentiation we must assume that:

$$\left(\frac{q_1 + q_3}{E}\right)^2 \ll \frac{4K \cdot v}{E} \cdot q_3^2$$

Regarding the energy levels we get:

$$q_3 \ll q_1$$

and eqn. 12 is then reduced to

$$2/s = q_1/E + 2q_3\sqrt{K \cdot v/E} \tag{12a}$$

From the reaction scheme it is seen that

$$\begin{aligned} w_1 &= k_1 \\ w_{-1} &= k_{-1} \\ w_2 &= k_2' \cdot c_{OH^-} \quad \text{or, at constant pH,} \\ w_2 &= k_2 \\ w_3 &= k_3\ (a - v) \end{aligned}$$

where the k's are constants and a is the initial substrate concentration. Introducing this in (12a) we find

$$2/s = 2\mathrm{d}t/\mathrm{d}v = 1/E\ (1/k_1 + k_{-1}/k_1k_2) + 2\sqrt{1/E} \cdot \sqrt{K} \cdot \sqrt{v}/k_3\ (a - v)$$

or

$$\mathrm{d}t/\mathrm{d}v = \mathrm{A}/E + \mathrm{B} \cdot \sqrt{1/E} \cdot \sqrt{v}\,/(a - v) \tag{12b}$$

where A and B are new constants. Integrating this equation and introducing the degree of reaction $\alpha = v/a$ we get

$$t = \mathrm{A} \cdot \frac{a}{E} \cdot \alpha + \mathrm{B} \cdot \sqrt{\frac{a}{E}} \cdot \left[\ln \frac{1+\sqrt{\alpha}}{1-\sqrt{\alpha}} - 2\sqrt{\alpha} \right]$$

which is identical with the empirically found chronometric integral.

It should be noted that (12b) only differs from an ordinary combination of a zero and a first order expression by the factor $\sqrt{E \cdot v}$ in the last term.

DISCUSSION

The reaction scheme suggested here is different from any one earlier found in the literature. It should be noticed that we have followed the reaction nearly to completion, while many of the earlier investigators only studied the first 50 % or less of the range. An exception is Schønheyder [6] who has published an experiment in which he follows the hydrolysis of 1-caprylyl-glycerol by rabbit liver esterase until 98.5 % degree of reaction. However, even his experiments are often followed only to 45—90 % degree of reaction.

It should be mentioned that investigations carried out in order to study the ali-esterase have been performed with enzymes isolated from many different sources and with the most different substrates. We have no reason to be sure that different enzymes will act on different substrates in the same way.

It should be mentioned too, that the chronometric integral found empirically by us could possibly be explained by other reaction schemes. The scheme mentioned must be considered as a suggestion which explains our experimental results, but we cannot postulate that it is the only possible explanation, observe, however, the remark p. 1263 and in the synopsis.

Kinetics of the Base-catalysed Reaction between Acetamide and Formaldehyde and the Ionization Constants of Formaldehyde and Hydroxymethylacetamide

J. KOSKIKALLIO

Institute of Chemistry, University of Helsinki, Helsinki, Finland

The rate of formation of hydroxymethylacetamide from acetamide and formaldehyde has been measured in aqueous solution at different sodium hydroxide concentrations. The second-order rate constant approaches a limiting value as the concentration of sodium hydroxide is increased. At a constant alkali concentration, the second-order rate constant decreases as the formaldehyde concentration is increased, but a change in the acetamide concentration does not alter the rate constant. The same applies to the reverse reaction. From these results it has been deduced that only the hydroxymethylacetamide and formaldehyde hydrate anions formed in the alkaline solution react. The ionization constants of hydroxymethylacetamide ($K_a = 6.0 \times 10^{-14}$) formaldehyde ($K_a = 8.5 \times 10^{-14}$), both at 20°, have been calculated from the kinetic data. The second-order rate constant of the reaction between acetamide and formaldehyde anion, $k_2 = 0.085$ l mole^{-1}sec^{-1}, and the first-order rate constant of the opposing reaction of hydroxymethylacetamide anion, $k_1 = 3.72 \times 10^{-3}$ sec^{-1} were obtained by an extrapolation method. From measurements made at different temperatures, the heat of the reaction

$$CH_3CONHCH_2OH + HO^- \rightarrow CH_3CONHCH_2O^- + H_2O$$

has been found to be about 1.1 kcal. The parameters of the Arrhenius equation for the formation of acetamide and formaldehyde from the hydroxymethylacetamide anion are $E = 21.8$ kcal. and $\log A = 13.8$.

Two different hydroxymethylamides are formed in the reaction between formaldehyde and an acid amide:

$$R—CO—NH_2 + CH_2O \rightleftharpoons R—CO—NH—CH_2OH \quad (1)$$

$$R—CO—NH—CH_2OH + CH_2O \rightleftharpoons R—CO—N(CH_2OH)_2 \quad (2)$$

Both reactions proceed until an equilibrium state is reached and are catalysed by various acids and bases [1-3]. The reaction between acetamide and formaldehyde was studied kinetically by Grove and Lynch [4]. From polarographic

studies they deduced that formaldehyde, which in neutral and dilute aqueous solution is known to be almost completely in the form of a hydrate (99.99 %) [5], is dehydrated in the presence of alkali, and concluded that formaldehyde reacts with acetamide only in the dehydrated form. Their value for the heat of dehydration (4 kcal.) differs considerably from the value (14.6 kcal.) obtained by Bieber [5].

The similar reaction between urea and formaldehyde has been studied by several authors. de Jong and de Jonge [3] found that the reaction rate is proportional to the hydroxyl and hydrogen ion concentrations of the medium. They believed that in alkaline solution urea forms an anion $NH_2—CO—NH^-$ which reacts with formaldehyde to form the hydroxymethylurea anion. A similar mechanism has been proposed by Okano and Ogata [6] who studied the reaction between melamine and formaldehyde, whereas Grove and Lynch [4] concluded that the amide anion is unable to react with formaldehyde. Iliceto [2] determined the equilibrium constants of the reactions 1 and 2 for various acid amides. At 20° the values for acetamide were found to be 28.2 and 0.117, respectively, and the equilibrium constant remained unchanged over a wide range of pH (7—13.5) and concentration (0.05—6 M). In dilute solutions of formaldehyde and acetamide, the formation of bishydroxymethylacetamide can be neglected. In order to study the role of alkali as catalyst in the reaction between acetamide and formaldehyde, the present author has carried out further kinetic measurements of the reaction.

EXPERIMENTAL

Materials. Acetamide (Merck, purum grade) was purified by crystallization from hot ethanol. Aqueous solutions of formaldehyde were prepared by dissolving paraformaldehyde (Merck, purum grade) in boiling water and filtering after cooling the solution. Hydroxymethylacetamide was prepared according to Einhorn [1] from acetamide and formaldehyde. The product (m. p. 51°) contained 0.98 mole of methylol and 0.01 mole of free formaldehyde per 89 g (the molecular weight) of hydroxymethylacetamide when analysed by the hypoiodite and sulphite methods. The sodium hydroxide solutions were prepared by dilution from a carbonate-free 1:1 mixture with water.

Analytical. Free formaldehyde was determined using the sulphite method [3] and the amount of free and bound (as methylol) formaldehyde with the hypoiodite method [3].

A volume of aqueous sodium sulphite solution which contained about twice the amount of sulphite corresponding to the amount of formaldehyde in the sample was added to the latter. The solution of sulphite also contained the calculated amount of sulphuric acid required to reduce the pH of the final mixture to about 6. After standing for about 30 minutes, the solution was acidified to pH 4 by introducing 3 ml of 1 M acetic acid, and the excess of sulphite titrated with 0.1 N iodine solution. Ten ml of 1 M sodium carbonate were then added and the liberated sulphite was titrated with the same iodine solution using starch as indicator. This latter titration gives the amount of free formaldehyde present in the sample. The method was checked with the aid of hydroxymethylacetamide which was not found to decompose to any appreciable extent in the sulphite solution during periods varying from 30 to 120 minutes. Determinations made on formaldehyde solutions in the concentration range involved in the experiments showed that a standing period of about 30 minutes is sufficient for the formaldehyde-sulphite reaction to go to completion.

In the hypoiodite method 4 ml of 2.5 N sodium hydroxide and 15 ml of 0.1 N iodine solution were added to a sample of 10 ml. After a period of about 15 minutes, the mixture was acidified by adding 10 ml of 1.1 N sulphuric acid, and the excess of iodine was titrated with 0.025 N thiosulphate. The consumption of iodine corresponds to the free

formaldehyde and the methylol groups present. From the data obtained with both methods, the concentration of hydroxymethylacetamide can be calculated. When the hypoiodite method was checked with hydroxymethylacetamide, uniform results were obtained with different standing periods varying from 10 to 60 minutes. Methylenebisacetamide underwent no detectable decomposition in the hypoiodite solution during periods up to 30 minutes, and only some 0.5 % formaldehyde was formed after 60 minutes. Thus if condensation of methylol and acetamide to methylenebisacetamide occurs, it would be detected as a decrease in the hypoiodite titration value. No such decrease was observed when samples were titrated after a reaction period about 20—40 times the half-life.

When a solution of formaldehyde was analysed using both methods, the hypoiodite method gave somewhat higher results (about 1.5 %) than the sulphite method. As no reason could be found for the different results, the same solution was also analysed using the cyanide method of Pfeil and Schroth [7]. The results obtained were similar to those obtained by the sulphite method (about 0.5 % lower), which is therefore believed to give the best values. The effect of the error in the analytical method is negligible when calculating rate constants but the values obtained for equilibrium constants are probably some 5 % too high.

As the hypoiodite titration value is not altered during the experiment, the slow Cannizzaro reaction of formaldehyde in alkaline solution can be neglected [8]. Other reactions such as the hydrolysis of acetamide and hydroxymethylacetamide probably occur to some extent during the experiment. The amount of ammonia and acetic acid liberated in a reaction mixture containing initially 0.01 mole of hydroxymethylacetamide and 0.01 mole of sodium hydroxide per litre was about 4 % during 1 000 minutes (20 times the half-life of the reaction studied) at 20° as determined by potentiometric titration. During the main part of the reaction, the hydrolysis could thus be neglected, but in the determination of the equilibrium constant, a small error results.

Calculations. The kinetic experiments were performed in reaction vessels described by Tommila and Lindholm [9]. The temperatures of the thermostats were electrically controlled to about 0.02°. The reaction was arrested by introducing rapidly a calculated amount of sulphuric acid in order to reduce the pH to about 6 and sulphite to react with the formaldehyde in the mixture. As the reaction did not go to completion in any of the experiments, the equilibrium mixture was analysed after a reaction time of about 20 times the half-life.

$$\mathrm{M} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{F} + \mathrm{A} \tag{3}$$

$$-\frac{\mathrm{dM}}{\mathrm{d}t} = k_1\mathrm{M} - k_2\mathrm{FA} \tag{4}$$

$$k_1 = \frac{2.303}{t} \cdot \frac{\mathrm{M_0} - \mathrm{M_{eq}}}{\mathrm{M_0} + \mathrm{M_{eq}}} \log \frac{\mathrm{M_0^2} - \mathrm{MM_{eq}}}{(\mathrm{M} - \mathrm{M_{eq}})\mathrm{M_0}} \tag{5}$$

Starting from hydroxymethylacetamide (M), the first-order rate constant k_1 can be calculated [10] using eqn. 5. $\mathrm{M_0}$ denotes the initial methylol (hydroxymethylacetamide) concentration, $\mathrm{M_{eq}}$ the methylol concentration at equilibrium and M its concentration at time t; F and A denote formaldehyde and acetamide, respectively.

The second-order rate constant k_2 for the reaction between acetamide and formaldehyde can be calculated using eqn. 6

$$k_2 = \frac{2.303}{t} \cdot \frac{\mathrm{M_{eq}}}{\mathrm{F_0A_0} - \mathrm{M_{eq}^2}} \log \frac{\mathrm{F_0A_0M_{eq}} - \mathrm{M_0M_{eq}^2}}{\mathrm{F_0A_0M_{eq}} - \mathrm{F_0A_0M}} \tag{6}$$

At equilibrium

$$K = \frac{k_2}{k_1} = \frac{M_{eq}}{F_{eq}A_{eq}} \qquad (7)$$

and thus k_1 or k_2 can be calculated easily from the latter equation if one of them is known. Tables 1 and 2 contain two examples of the measurements. Usually a good constancy of the specific rate was obtained over a wide range of the reaction (10—90 %). The rate and equilibrium constants obtained are collected in Tables 3—5.

DISCUSSION

From Tables 3 and 4 it will be seen that the first- and second-order rate constants increase with increasing sodium hydroxide concentration, but no direct proportionality is observed. At high alkali concentrations, the constants

seem to approach a limiting value. At constant alkali concentration, an increase in the methylol or formaldehyde concentration decreases the rate constant k_1 or k_2, respectively, but when the acetamide concentration is changed, the second-order rate constant remains unaffected. In order to explain these results, the following equilibria may be considered:

$$CH_2O + H_2O \rightleftharpoons HOCH_2OH \tag{8}$$

$$HOCH_2OH + HO^- \rightleftharpoons HOCH_2O^- + H_2O \tag{9}$$

$$CH_3CONHCH_2OH + HO^- \rightleftharpoons CH_3CONHCH_2O^- + H_2O \tag{10}$$

$$HOCH_2O^- + CH_3CONH_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} CH_3CONHCH_2O^- + H_2O \tag{11}$$

As already mentioned, in dilute aqueous solutions formaldehyde is almost completely in the hydrated form [5]. In strongly alkaline solutions a considerable proportion of the formaldehyde is present in the anion form [11]. If only the anion form of formaldehyde or methylol reacts, a limiting rate constant should be obtained in concentrated alkali solutions. At different alkali concentrations, the rate should be proportional to the concentration of the anion in the solution.

$$K_1 = \frac{[CH_3CONHCH_2OH] \cdot [HO^-]}{[CH_3CONHCH_2O^-]} = \frac{(M - x)(B - x)}{x} \tag{12}$$

If $B \ll x$, then $B - x \simeq B$ and $x = \frac{M \cdot B}{K_1 + B}$ (13)

$$-\frac{dM}{dt} = k_1 x = k_1 \cdot \frac{B}{K_1 + B} \cdot M = k_{exp} \cdot M \tag{14}$$

$$\frac{1}{k_{exp}} = \frac{K_1}{k_1 B} + \frac{1}{k_1} \tag{15}$$

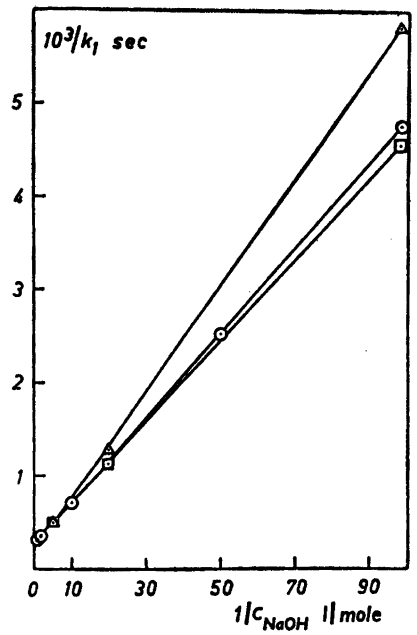

Fig. 1. Plot of the reciprocal of the first-order rate constant k_{exp} *for the reaction: hydroxymethylacetamide → acetamide + formaldehyde at 20° versus the reciprocal of the sodium hydroxide concentration (Equation 15).* △ $c_{methylol} = 0.05$ *mole/l,* ○ $c_{methylol} = 0.01$ *mole/l, and* □ *rate constant values* (k_{exp}) *relating to zero methylol concentration.*

where B and M denote the total concentrations of base and methylol and x the concentration of methylol anion, k_{exp} is the experimentally measured first-order rate constant and k_1 the first-order rate constant for the reaction 11. As the sodium hydroxide was used in excess, B > M and K_1 is large, and hence the assumption made in calculating the amount of unionized methylol (eqn. 13) is justified. In Fig. 1, $1/k_{exp}$ is plotted against 1/B. It will be seen that the curve approaches a straight line at high sodium hydroxide concentrations (Fig. 1, ○△). If the rate constants obtained at constant alkali concentrations are extrapolated to zero methylol concentration, all the points obtained lie on a straight line (Fig. 1, □). This is what is expected because the assumption $B - x \simeq B$ is valid for the extrapolated values.

The first-order rate constant of the methylol anion k_1 and the equilibrium constant K_1 (of reaction 10) can be computed from the intercept and the slope of the line (Table 6). The ionization constant is easily obtained since $K_a = K_1 / K_w$. With aid of the value obtained for the equilibrium constant

Table 6. The equilibrium constants K_1 *and* K_2 *of reactions 9 and 10 and the rate constants* k_1 *and* k_2 *of the reaction 11 calculated using eqn. 15.*

10^4 k_1 sec.$^{-1}$			E	log A	k_2 l mole^{-1} sec.$^{-1}$	K_1 l/mole			ΔH	K_2
0°	20°	40°	kcal		20°	0°	20°	40°	kcal	l/mole 20°
2.64	37.2	441	21.8	13.8	0.085	0.142	0.165	0.194	1.3	0.117

K_1, the amount of methylol anion in any mixture of methylol and sodium hydroxide can be calculated. The corresponding rate constant is $k_1 x/\mathrm{M} = k_{exp}$ (eqn. 14). These calculated rate constants are given in Tables 3 and 4 and are found to be fairly close to the experimental values over more than a 200-fold range of sodium hydroxide concentration. A similar treatment of the second-order rate constant of the reverse reaction gives a limiting rate k_2 and equilibrium constant $K_2 = 0.117$ at 20° (Table 6). From a graph given by Martin [11] which contains values of K_2 obtained by different authors, a mean value $K_2 = 0.111$ is obtained which is fairly close to the above value.

No value was found in the literature for the acid ionization constant of acetamide. When the alkali concentration is held constant, the second-order rate constant remains unaffected when the concentration of acetamide is changed. Thus it is improbable that any detectable amounts of acetamide anion are formed in the reaction mixtures used and that this ion is involved in the reaction mechanism as stated by some authors [3,6].

$$K = \frac{[\mathrm{CH_3CONHCH_2OH} + \mathrm{CH_3CONHCH_2O^-}]}{[\mathrm{CH_3CONH_2}]\,[\mathrm{HOCH_2OH} + \mathrm{HOCH_2O^-}]} \tag{16}$$

$$K' = \frac{[\mathrm{CH_3CONHCH_2O^-}]}{[\mathrm{CH_3CONH_2}] \cdot [\mathrm{HOCH_2O^-}]} \tag{17}$$

The equilibrium constant K calculated using the total methylol and formaldehyde concentrations without taking into account the ionization of these compounds decreases as the alkali concentration is increased (Tables 3—5).

Considering the two equilibria (eqns. 9 and 10)

$$K_1 = \frac{[\mathrm{CH_3CONHCH_2OH}]\,[\mathrm{HO^-}]}{[\mathrm{CH_3CONHCH_2O^-}]} = \frac{(\mathrm{M}-x)(\mathrm{B}-x-y)}{x} \tag{18}$$

$$K_2 = \frac{[\mathrm{HOCH_2OH}][\mathrm{HO^-}]}{[\mathrm{HOCHO^-}]} = \frac{(\mathrm{F}-y)(\mathrm{B}-x-y)}{y} \tag{19}$$

it can again be assumed that $\mathrm{B}-x-y \simeq \mathrm{B}$. Then

$$x = \frac{\mathrm{MB}}{K_1 + \mathrm{B}} \quad \text{and} \quad y = \frac{\mathrm{FB}}{K_2 + \mathrm{B}} \tag{20}$$

$$K' = \frac{x}{\mathrm{A}y} = \frac{\mathrm{M}}{\mathrm{F} \cdot \mathrm{A}} \cdot \frac{K_2 + \mathrm{B}}{K_1 + \mathrm{B}} = K\,\frac{K_2 + \mathrm{B}}{K_1 + \mathrm{B}} \tag{21}$$

where M, F, A and B denote the total concentrations of methylol, formaldehyde, acetamide and sodium hydroxide. According to eqn. 21, K' can be calculated for different sodium hydroxide concentrations from the experimental values of K obtained using total formaldehyde and methylol concentrations by substituting for K_1 and K_2 the values 0.165 and 0.117 obtained from the kinetic measurements at 20° (Table 6). These calculated K' values which are given in Table 5 are fairly constant (mean value $K' = 21.4$) although the K values change considerably when the alkali concentration is altered. The value $K = 22.8$ is obtained from the extrapolated rate constants: $k_2/k_1 =$

$8.5 \times 10^{-2}/3.72 \times 10^{-3}$ (Table 6). This is a further proof that the values of the ionization constants obtained for formaldehyde and methylenebisacetamide from kinetic experiments are of correct order of magnitude. At low alkali concentrations (below 0.05 mole/l) K would be expected to remain fairly constant, as has been found to be the case by several authors *e. g.* Ref.[2]

From the values for different temperatures it will be seen that the unionized form of hydroxymethylacetamide is favoured at higher temperatures, a value of about 1.3 kcal being obtained for the heat of the ionization reaction. Because of this pre-equilibrium (eqn. 10), the activation energy calculated for the reaction 11 does not remain constant when the concentration of alkali is changed (Table 3). The difference between the apparent activation energy obtained for the reaction at low alkali concentrations and the value obtained using the k_1 values for the reaction of the methylol ion (about 1.3 kcal) should be close to the heat of reaction 10 (1.3 kcal).

The energy of activation for the reaction, calculated using the k_1 values given in Table 6, is 21.80 kcal and the frequency factor $A = 7 \times 10^{13}$ which is close to the predicted value for unimolecular reactions [10]. In order to estimate the value of activation energy for the reverse reaction of methylol formation from acetamide and formaldehyde, the heats of the reactions should be of the same order of magnitude. From the value $K_2 = 0.134$ at 40° given by Martin [11] and the above value $K_2 = 0.117$ at 20°, the value $\Delta H_2 = 1.2$ kcal is obtained which is close to value $\Delta H_1 = 1.3$ kcal (Table 6). Thus using the mean value obtained for the heat of reaction 11, $\Delta H = 4.14$ (Table 5), it is found that $E_2 = E_1 - \Delta H = 17.7$ kcal and $A = 1.6 \times 10^{12}$.

All the results obtained show clearly that the reaction between formaldehyde and acetamide occurs in alkaline solution between the anion of formaldehyde hydrate and acetamide (eqn. 11). Similarly, in the reverse reaction, it is the methylol anion that undergoes change. In order to determine whether any reaction occurs between the uncharged molecules, an aqueous solution of hydroxymethylacetamide was kept for several weeks at 20°, but no formaldehyde was found to be liberated. The reaction of the methylol anion is thus at least 10^6 times faster than the reaction of unionized methylol.

Syntheses of *p*-Dimethylaminobenzyl Alcohol and Esters of its Methiodide

LARS-ERIK TAMMELIN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

p-Dimethylaminobenzyl alcohol has been synthesized by catalytic hydrogenation of the corresponding aldehyde. Methiodides of the *p*-dimethylaminobenzyl alcohol and esters from acetic-, malonic-, succinic-, glutaric- and adipic acids have been prepared. The conditions for methylation of *p*-dimethylaminobenzyl alcohol are discussed. The esters of *p*-trimethylammoniumbenzyl alcohol have been shown to have neuromuscular blocking effects.

p-Dimethylaminobenzyl alcohol has been synthesized by Smith and Welch [1] who also review earlier literature in this field. The same authors [2] point out that *p*-dimethylaminobenzyl alcohol easily reacts, through loss of water, with phenols and aromatic amines. Reactions of this type occurring as side reactions presumably explains the difficulties of earlier authors to obtain good yields of a pure product. Smith and Welch used the action of formaldehyde on dimethylaniline. Reduction of *p*-dimethylaminobenzaldehyde has also been accomplished by electrolysis [3], sodium amalgame [3], litium aluminium hydride [4] and sodium borofluoride [5]. The latter method provides the best yield (96 %). Since no report has been found on direct catalytic hydrogenation of *p*-dimethylaminobenzaldehyde it seemed reasonable to test that method of synthesis. *p*-Trimethylammoniumbenzyl alcohol and corresponding esters can be expected to have interesting pharmacological actions because of a structural resemblance to choline and the choline esters.

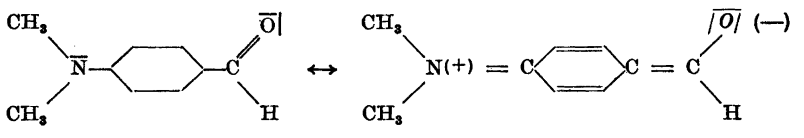
SYNTHESES

p-*Dimethylaminobenzyl alcohol.* One mole of *p*-dimethylaminobenzaldehyde was dissolved in 160 ml of hot abs. ethanol. 1 g of PtO_2 and 2 ml of 0.1 M $FeCl_3$ solution were added to the alcoholic solution and the mixture treated with hydrogen at 10 kg/cm^2 and 50° C. The hydrogenation was considered to be complete when 1.2 moles of hydrogen were consumed. The reaction mixture was filtered and the *p*-dimethylaminobenzyl alcohol purified by fractional distillation *in vacuo*, b. p. 115—120°/1 mm Hg, n_D^{25} 1.5780. Yield 50 %. For analyses see the methiodide.

p-*Trimethylammoniumbenzyl alcohol.* One mole of *p*-dimethylaminobenzyl alcohol and 1.1 moles of methyl iodide were mixed in 8 volume parts of ether in a glass stoppered round

bottomed flask and kept at 25° C. The precipitate formed was filtered off after 4 days and recrystallized twice from methanol, m. p. 261° and yield 60 %. (Found: C 41.3; H 5.4; I 43.4. Calc. for $C_{10}H_{16}ONI$ (293.2): C 41.1; H 5.5; I 43.4).

p-*Trimethylammoniumbenzyl ester of acetic acid.* One mole of acetylchloride and 1 mole of *p*-dimethylaminobenzyl alcohol were boiled in ether for one hour. The reaction mixture was washed with 5 % aqueous sodium bicarbonate solution and dried with sodium sulfate. 1.5 moles of methyl iodide were added to the water free ether solution. After two weeks at 25° C the precipitate formed was filtered off and purified by dissolution in alcohol and reprecipitation with ether. The purified product had a m.p. 186° (decomp.) and was obtained in 33 % yield. (Found: C 43.8; H 5.5; I 38.1. Calc. on $C_{12}H_{18}O_2NI$ (335.2): C 43.0; H 5.4; I 37.8).



p-*Trimethylammoniumbenzyl esters of aliphatic dicarboxylic acids.* One mole of acid dichloride (malonyl-adipyl) and 2 moles of *p*-dimethylaminobenzyl alcohol were boiled in ether for one hour. The reaction mixture was washed by 5 % aqueous sodium bicarbonate solution and dried with water free sodium sulfate. 2.5 moles of methyl iodide were added and the precipitate formed was filtered off after two weeks at 25° C, and purified by solution in alcohol and reprecipitation with ether. Yield about 30 %. For data see Table 1.

Table 1.

Ester	Formula	Molecular weight	m. p.	C		H		I	
				calc.	found	calc.	found	calc.	found
malonic	$C_{23}H_{32}O_4N_2I_2$	654.3	182	42.3	42.7	4.9	5.1	38.8	38.6
succinic	$C_{24}H_{34}O_4N_2I_2$	668.4	128	43.2	43.4	5.1	5.3	37.9	37.7
glutaric	$C_{25}H_{36}O_4N_2I_2$	682.4	144	44.0	42.9	5.3	5.5	37.2	36.8
adipic	$C_{26}H_{38}O_4N_2I_2$	696.4	147	44.9	44.3	5.5	5.5	36.4	36.1

Good yields from the catalytic hydrogenation of the *p*-dimethylaminobenzaldehyde are obtained only if the aldehyde is completely consumed. The aldehyde seems to provoke side reactions during the distillation, with diminished yield of the alcohol as a consequence. Another complication which has happened a few times is that the catalyst is poisoned during the process of hydrogenation. It is therefore recommended that the completeness of the hydrogenation is tested by the addition of new catalyst, if hydrogen consumption ceases before the calculated amount is consumed. If these possible troubles are overcome the product obtained is well in accordance with the *p*-dimethylaminobenzyl alcohol from the condensation of formaldehyde and dimethylaniline according to Smith and Welch [1] with respect to refractive index and boiling point.

The relative rapidity of the methylation of *p*-dimethylaminobenzyl alcohol gave the impulse to determine whether the *p*-trimethylammoniumbenzaldehyde could be synthesized in a similar way. However, in this case methyl iodide did not react at 25° C in ether. The phenomenon might be described in formulae as follows.

This and other resonance possibilities engage the electron pair at the nitrogen atom. In the case of the alcohol and its esters the corresponding electron pair seems to be more free and thus enables the methylation to proceed.

The present author has not isolated the *p*-dimethylaminobenzyl esters either by crystallization or by distillation *in vacuo*. The quaternary derivatives are easier to isolate but even in this case purification has its obstacles. Dissolution in alcohol and precipitation with ether, which is recommended, is not an ideal method. It does not always lead to the correct composition of the compound especially when the impurities are quaternary products. However, following the given prescriptions for the syntheses, impurities of the type mentioned above seem to have been avoided as follows from the analytical data of the final products.

The iodides of the bis-(*p*-trimethylammoniumbenzyl) esters are water soluble, crystalline, pale yellow substances. Preliminary experiments have shown that they are potent neuromuscular blocking agents and choline esterase inhibitors (although not very potent), effects which could be expected from the structural similarity to the choline esters. The pharmacological data will be published elsewhere [6].

My sincere thanks are due to the Director of this Institute, Professor G. Ljunggren, for his kind interest in this work.

On the "Entropy Effect" in Chelating Processes

SVEND ERIK RASMUSSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The available data on entropies of chelate compounds indicate that an important factor in the so-called "chelate effect" is the difference in number between monodentate and chelate molecules in a chelating reaction. The entropy differences between complex ammonia metal ions and chelate metal ions are found to be relatively small.

Let a reaction between a metal ion and a monodentate ligand be represented by the equation

$$Me(H_2O)_n + nA = MeA_n + nH_2O \quad (1)$$

and that of a metal ion and a chelating agent by

$$Me(H_2O)_n + mCh = MeCh_m + nH_2O \quad (2)$$

where n is the characteristic coordination number.

The equilibrium constant of (2) is generally much higher than that of (1) and there has been much discussion in the literature on the nature of this "chelate effect".

Let us consider a reaction:

$$MeA_n + mCh = MeCh_m + nA \quad (3)$$

which is formally independent of the solvent.

The entropy change is given by

$$\Delta S = n\ S^{\ominus}(A) - m\ S^{\ominus}(Ch) + S^{\ominus}(MeCh_m) - S^{\ominus}(MeA_n)$$

The $S^{\ominus}$s are the partial molar entropies of the species in an arbitrarily chosen standard state at the temperature in question.

In most experiments in complex chemistry the standard state is the hypothetical one molar solution in a neutral salt medium. It is sometimes stated (*e. g.* Young [1]) that equilibrium data obtained in a constant salt medium do not

give "*true thermodynamic*" values. Of course the laws of thermodynamics are applicable also to reactions occurring in a constant salt medium and the thermodynamic data obtained are true enough although more or less different from those determined at extreme dilution.

The partial molar entropies of each of the reactants may in principle be measured using the third law of thermodynamics.

Unfortunately no data exist which permit a complete calculation of the entropies of complex reactions. Not even the entropies of most of the ligands are known. An exception is ammonia. According to *Selected Values of Chemical Thermodynamic Properties* [2] the partial molal entropy of ammonia in water at 25° C is 26.3 cal/degree mole. The atmospheric molar entropy of ammonia gas is 46.01 cal/degree mole at 25° C. Using the vapour pressure measurements of J. Bjerrum [3] and the heat of solution determined by Becker and Roth [4] the partial molar entropy of ammonia in a 2 M NH_4NO_3 solution is calculated to be 25.9 cal/degree mole.

In principle the entropy of a gaseous species may be calculated from statistical mechanics provided that the appropriate spectroscopic data are known. For most of the ligands of complex chemistry no such data are available. Empirical equations have been found, however, which permit a calculation of entropies of many gaseous substances with fair accuracy. Powell and Latimer [5] have proposed an equation which bases the aqueous entropy of neutral species upon the molar volume of the pure liquid state of the solute.

Cobble [6] has combined the different empirical equations and has obtained the following expression for the partial molal entropy in aqueous solution

$$S^{\bullet} = 10 + \frac{3}{2}R\log M + 9.2N - S^{\circ}_{(s)} - 0.22V_m.$$

M is the molecular weight, N represents the number of "skeletal" bonded atoms in the compound (number of bonded atoms — number of hydrogens), $S^{\circ}_{(s)}$ is the entropy loss caused by double bonds, rings and branched chains, and V_m is the molar volume of the pure liquid compound.

For details and for references the reader is referred to the original paper.

For lack of experimental data we shall use this equation for the calculation of the partial molar entropies of ethylenediamine (en) and 1,3-diaminopropane (tn). We get the following values

$$S^{\bullet}(\text{en}) = 45 \text{ cal/degree mole at 1 M and } 25^{\circ}\text{ C}$$

$$S^{\bullet}(\text{tn}) = 50 \text{ cal/degree mole at 1 M and } 25^{\circ}\text{ C}$$

The equation yields for ammonia: $S^{\bullet}(NH_3) = 24$ cal/degree mole while the experimental value is 26. The entropy of gaseous en must be almost equal to that of *n*-butane, which is according to Pitzer [7] 74.17 cal/degree mole (25° C, 1 atm.). In Ref.[2] the entropy of vapourization of en is given as 23.8 cal/degree mole at 117° C and 760 mm Hg. Therefore the entropy of liquid en at 25° C must be about 50 cal/degree mole. It has been found by Copp and Everett [8] and others [9] that the excess entropy of mixing of amines and water is negative. Hence the value calculated for $S^{\bullet}$(en) seems reasonable.

We are now able to obtain approximate values of $nS^{\ominus}(NH_3)$—$mS^{\ominus}(en)$ and $nS^{\ominus}(NH_3)$—$mS^{\ominus}(tn)$ in chelating processes of the type (3).

If the ΔS of the reaction is known we can make rough estimates of the differences $S^{\ominus}(MeCh_m)$—$S^{\ominus}(Me(NH_3)_n)$. Surprisingly few accurate determinations of entropies of reactions of complex compounds exist.

From the recent paper by Poulsen and Bjerrum [10] and from measurements by Bjerrum [11], Fyfe [12] and Davies, Singer and Staveley [13] one obtains the following entropy changes (Standard state 1 M, 25° C)

$Ni(NH_3)_6^{++} + 3\ en = Nien_3^{++} + 6\ NH_3$	$\Delta S = 21$	cal/degree	mole
$Ni(NH_3)_6^{++} + 3\ tn = Nitn_3^{++} + 6\ NH_3$	$\Delta S = 14$	»	»
$Cu(NH_3)_4^{++} + 2\ en = Cuen_2^{++} + 4\ NH_3$	$\Delta S = 15$	»	»
$Cu(NH_3)_4^{++} + 2\ tn = Cutn_2^{++} + 4\ NH_3$	$\Delta S = 11$	»	»
$Zn(NH_3)_4^{++} + 2\ en = Znen_2^{++} + 4\ NH_3$	$\Delta S = 21$	»	»
$Cd(NH_3)_4^{++} + 2\ en = Cden_2^{++} + 4\ NH_3$	$\Delta S = 14$	»	»

From the partial molar entropies of the three ligands we calculate the following differences:

$6\ S^{\ominus}(NH_3)$—$3\ S^{\ominus}(en)$	$= 21$	cal/degree	mole
$6\ S^{\ominus}(NH_3)$—$3\ S^{\ominus}(tn)$	$= 6$	»	»
$4\ S^{\ominus}(NH_3)$—$2\ S^{\ominus}(en)$	$= 14$	»	»
$4\ S^{\ominus}(NH_3)$—$2\ S^{\ominus}(tn)$	$= 4$	»	»

These data yield the following entropy differences:

$S^{\ominus}(Nien_3^{++}) - S^{\ominus}(Ni(NH_3)_6^{++})$	$= 0$	cal/degree	mole
$S^{\ominus}(Nitn_3^{++}) - S^{\ominus}(Ni(NH_3)_6^{++})$	$= 8$	»	»
$S^{\ominus}(Cuen_2^{++}) - S^{\ominus}(Cu(NH_3)_4^{++})$	$= 1$	»	»
$S^{\ominus}(Cutn_2^{++}) - S^{\ominus}(Cu(NH_3)_4^{++})$	$= 7$	»	»
$S^{\ominus}(Znen_2^{++}) - S^{\ominus}(Zn(NH_3)_4^{++})$	$= 7$	»	»
$S^{\ominus}(Cden_2^{++}) - S^{\ominus}(Cd(NH_3)_4^{++})$	$= 0$	»	»

The experimental ΔS values are probably uncertain at about $\pm$ (10—15) %. The estimated entropy values are probably uncertain at about 3—4 cal/degree mole.

An optimistic estimation of the uncertainties involved would yield an indeterminacy of about $\pm$ 10 cal/degree mole for the values of the entropy differences between chelate and non chelate complex ions. This means that their partial molar entropies are almost equal within the experimental uncertainty. An interpretation of the figures obtained seems rather futile.

In the chelating reactions considered the entropy change is largely due to the entropy difference between the monodentate ligands and the chelating ligands. As suggested by Calvin and Bailes [14] this entropy difference is partly caused by the different numbers of monodentate and chelate molecules taking part in the reaction. The numerical value is dependent upon the arbitrary choice of standard state. The entropy differences between the complex ions are of course independent of the standard state.

Synthesis and Paper Electrophoresis of the Galactose Monomethyl Ethers

HANS BOUVENG and BENGT LINDBERG

Organisk-kemiska Institutionen and Träkemiska Institutionen, Kungliga Tekniska Högskolan, Stockholm, Sweden

The mono-*O*-methyl ethers of D-galactose have been synthesised by partial methylation of suitable galactose derivatives and the separation of the mixtures of methyl ethers obtained has been performed on carbon columns. — The M_G-values of the monomethyl ethers and of some other galactose derivatives have been determined.

In his studies on paper electrophoresis of glucose derivatives, Foster [1] found that the M_G-values were chiefly dependent on the position of a substituent and only to a lesser extent upon the nature of this substituent. In connection with an investigation of the arabogalactosan in larch wood [2], it was therefore of interest to study the migration of the monomethyl ethers of galactose in electrophoresis and to compare them with those of some oligosaccharides, obtained by partial hydrolysis of the polysaccharide.

Each of the four monomethyl ethers of D-galactose, which can exist in pyranosidic form, is known and has been synthesised by unambiguous methods [3]. The 6-*O*-methyl ether is easily available but the routes leading to the others are more tedious. We therefore prepared them by partial methylation of 4,6-benzylidene-β-methylgalactoside [4] and 6-trityl-β-methylgalactoside, respectively, and separated the mixtures of galactose methyl ethers obtained on carbon columns, using the technique described by Lindberg and Wickberg [5]. The 3- and 4-*O*-methyl ethers, however, could not be separated by this method, but were easily separated when borate was added to the eluting solvent as described by Barker, Bourne and Theander [6].

The partial methylations were performed with the modified Purdie methylation method using N,N-dimethylformamide as solvent, as devised by Kuhn *et al.* [7] for the complete one step methylation of non-reducing sugars. The yield of methoxyl groups, calculated from the added amount of methyl iodide, was 50 % in one experiment and 90 % in another. There is of course a competition for the methyl iodide between the hydroxyl groups of the sugar and the water, present as an impurity in the starting materials and formed during the reaction, and this might explain the difference between these figures.

The monomethyl ethers thus obtained were electrophoretically and chromatographically pure and the melting points and rotations were in good agreement with previously published data. The method of partial methylation and separation on carbon columns of the mixture obtained seems to be of general value for the preparation of less available ethers.

The paper electrophoresis apparatus was similar to that used by Foster [8]. The M_G-values did not differ more than ± 0.02 units from the mean value and no significant influence from differences in the applied voltages or from the use of different papers could be detected. The measurements were performed in a borate buffer of pH 10.

Table 1. M_G*-values of some galactose and glucose derivatives.*

Substance	Complexes formed	M_G	Substance	Complexes formed	M_G
Galactose	X Y β'	0.93	Glucose	X β' C	1.00
β-Methylgalactoside	Y	0.38	β-Methylglucoside		0.19
2-*O*-Methylgalactose	Y β'	0.43	2-*O*-Methylglucose	β'	0.23
3-*O*-Methylgalactose	X β'	0.63	3-*O*-Methylglucose	X β' C	0.82
4-*O*-Methylgalactose	X	0.30	4-*O*-Methylglucose	X	0.24
6-*O*-Methylgalactose	X Y	0.86	6-*O*-Methylglucose	X β' C	0.82
Disaccharide I	—	0.69			
Disaccharide II	—	0.83			

In Table 1 the M_G-values of the galactose monomethyl ethers and some other galactose derivatives are given and compared with the values of the corresponding glucose derivatives, these being taken from Foster's investigation [1]. Foster found that the rate of migration of the glucose derivatives in electrophoresis could be explained by the assumption that essentially three types of borate complexes are formed. The first, X, is due to complex formation between the borate and the hydroxyls at $C_{(1)} : C_{(2)}$ in the α-pyranosidic or α-furanosidic form of the derivative. The two other types are due to complex formation between the borate and two hydroxyls in the β-position in the aldehyde form of the derivative. These hydroxyl groups should be in *cis*-relationship in the Fisher projection formulae (β'C) or one of them should be a primary hydroxyl group (β'). These two possibilities are realised by the hydroxyl groups at $C_{(2)} : C_{(4)}$ and $C_{(4)} : C_{(6)}$, respectively, in the glucose molecule, and Foster found that when both alternatives are possible, β'C takes preference over β'. In galactose, there is no possibility of forming a β'C complex, but there is a contribution from a complex between borate and the two hydroxyls at $C_{(3)} : C_{(4)}$ in the ring forms, here denoted as Y. It is evident from Table 1 that the M_G-values of the galactose derivatives can also be correlated with the structure by application of Foster's theory. The contribution from the Y complexes seems to be of the same order of magnitude as those of X and β'C, and the relatively small contribution from the β' complex is also indicated.

The unexpectedly low migration of 4-*O*-methylgalactose and 4-*O*-methylglucose may be explained by the fact that these substances cannot assume a

furanosidic but only a pyranosidic structure, hence the contribution from X complexes might be reduced.

Two disaccharides (I and II) obtained from the arabogalactosan by partial hydrolysis, and which on further hydrolysis yielded galactose only, were also investigated. From previous investigations of this polysaccharide [9], the disaccharides could be supposed to be 3- and 6-β-galactopyranosyl galactopyranose, respectively, and the observed M_G-values are in good agreement with this assumption.

EXPERIMENTAL

Chromatography. Paper: Whatman No. 1.
Solvent: Butanol:ethanol:water 10:3:5.
Developer: Anisidine hydrochloride.

Electrophoresis. Papers: Whatman No. 1 and Whatman 3 MM.
Borate buffer: 7.45 g boric acid and 4.0 g sodium hydroxide in 1 000 ml of aqueous solution (pH = 10.0).
Developer: Silver nitrate/sodium ethoxide and, in the case of β-methylgalactoside, periodate/benzidine [10], the paper at first being neutralised with acetic acid.
Voltages: 600–800 volts.

All melting points corrected. All evaporations were performed under reduced pressure.

Fractions obtained in the separations were investigated by paper chromatography, paper electrophoresis and determination of the optical rotation.

Partial methylation of 4,6-benzylidene-β-methylgalactoside. To a rapidly stirred solution of 4,6-benzylidene-β-methylgalactoside (6.2 g, 1 mole) and methyl iodide (2.6 ml, 1.95 mole) in 25 ml of dimethylformamide, silver oxide (10 g, 4 mole) was added in portions during 1 hour, the apparatus and the chemicals being previously carefully dried. The temperature was kept below 20° by external cooling and the stirring was continued for another 11 hours. The reaction mixture was worked up according to Kuhn *et al.* [3]. The product obtained was then boiled for 4½ hours in 150 ml of acetone and 75 ml of 0.5 N HCl. The benzaldehyde formed was removed by steam distillation under reduced pressure. The acid was removed by filtering through a column of IR 4B and the solution concentrated to a sirup, which was treated for 14 hours in 28 ml of 0.5 N HCl at 100°, in order to remove the glycosidic group. Neutralisation (IR 4B) and concentration yielded a lightcoloured sirup (4.8 g).

Separation of products from partial methylation of 4,6-benzylidene-β-methylgalactoside. Column: 4.5 × 33 cm. Eluent: 8 l 0–10 % ethanol. Fractions: 26 ml. Amount added: 4.8 g.

Fract. 47– 49. Galactose (traces).
» 81– 98. 0.57 g of 3-methylgalactose (crystallised when seeded).
» 99–131. 1.51 g of a mixture of 2- and 3-methylgalactose of which 0.79 g of 2-methylgalactose crystallised after seeding; the rest gave after some time fairly pure 3-methylgalactose.
» 132–153. 0.30 g cryst. 2-methylgalactose.
» 218–290. 0.87 g 2,3-dimethylgalactose.

Approximate yields: 35 % 2-methyl-, 40 % 3-methyl- and 25 % 2,3-dimethylgalactose.

Partial methylation of 6-trityl-β-methylgalactoside. 6-Trityl-β-methylgalactoside (28.7 g, 1 mole) was treated in the same manner as described above with methyl iodide (6.2 ml, 1.5 mole) and silver oxide (22 g, 3.7 mole) in dimethylformamide (50 ml). The product obtained was detritylated in 100 ml 0.5 N alcoholic hydrochloric acid for 2 hours at room temperature, concentrated and diluted with water and then filtered and neutralised (IR 4B). The solution was concentrated to a sirup and treated for 12 hours in 50 ml of 0.5 N HCl at 100°. Neutralisation (IR 4B) was followed by decolorisation with carbon in 50 % alcohol. Concentration yielded 14.1 g of a light coloured sirup.

Preliminary separation of products from partial methylation of 6-trityl-β-methylgalactoside.

Column: 6.5 × 46 cm. Eluent: 8 l 0–15 % ethanol. Fractions 150–100 ml. Amount added: 14.1 g.

Fract. 22—27. 1.05 g of galactose.
» 28—31. 1.06 g of 3-methyl- and 4-methylgalactose.
» 32—33. 1.06 g of 2-methyl-, 3-methyl- and 4-methylgalactose.
» 34—41. 1.01 g of 2-methylgalactose (cryst.) and 0.71 g of 2-methyl- and 3-methylgalactose (sirup).
» 42—64. 3.71 g of dimethylgalactoses.

50 % ethanol-eluate. 2.77 g of 2,3,4-trimethylgalactose with small amounts of dimethylgalactoses.

Approximate yields: 10 % galactose, 34 % monomethyl ethers, 32 % dimethyl ethers and 24 % of the trimethyl ether.

Separation of 3-O-methyl- and 4-O-methylgalactose (fract. 28—31 above).

Column: 4.5 × 33 cm. Eluent: 1.5 l water + 4 l 0—4 % ethanol, containing 7.45 g boric acid and 4.0 g sodium hydroxide in 1000 ml. Fractions: 26 ml. Added amount: 1.06 g.

Fract. 124—151. 0.69 g of 3-methylgalactose (cryst.)
» 177—188. 0.07 g of 4-methylgalactose (cryst.)

The fractions were neutralized by adding 2 ml of strong cation exchanger (IR 120) to the fractionating tubes. After filtration and concentration the boric acid was evaporated with methanol.

Fractions 32—33 were resolved in exactly the same manner, yielding in the following order: 0.33 g 3-methyl-, 0.37 g 2-methyl- and 0.36 g 4-methylgalactose (cryst.). The separation of 3-methyl- and 2-methylgalactose was not quite complete, but both fractions crystallised on seeding.

The sirupy part of fractions 34—41 (0.71 g) was separated in the usual manner yielding 0.35 g 3-methyl- and 0.33 g 2-methylgalactose.

The approximate ratio of the monomethyl ethers thus obtained is 2-*O*-methyl-: 3-*O*-methyl-: 4-*O*-methylgalactose = 5:4:1.

The 6-*O*-methylgalactose, prepared according to Freudenberg and Hixon [11], failed to crystallise, even when purified by means of carbon column chromatography. It was therefore characterised as its osazone, prepared in the presence of bisulphite, according to Hamilton [12].

Table 2. Properties of Galactose Derivatives.

Compound	M.p.	$[\alpha]_D^{20}(H_2O)$	$R_{Galactose}$	Colour with anisidine-HCl
2-*O*-methylgalactose	149—151°	+ 50 → + 84°(c = 2)	1.50	orange-red
3-*O*-methylgalactose	145—146.5°	+147 → +106°(c = 2)	1.37	light yellow
4-*O*-methylgalactose	206—208°	+ 54 → + 81°(c = 1)	1.37	yellow
6-*O*-methylgalactose			1.39	brown
—, phenylosazone	200—201°			
Disaccharide I				light yellow
Disaccharide II				brownish yellow

The Crystal Structure of Indium Oxide Chloride and Indium Oxide Bromide

HANS-ERIK FORSBERG

Department of Inorganic and Physical Chemistry, University, and Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm, Sweden

InOCl, and InOBr, have been investigated by X-ray methods. They have an orthorhombic unit cell. Their unit cell dimensions are

InOCl		*InOBr*	
a	= (4.065 ± 0.005) Å	a	= (4.049 ± 0.005) Å
b	= (3.523 ± 0.005) Å	b	= (3.611 ± 0.005) Å
c	= (8.080 ± 0.005) Å	c	= (8.649 ± 0.005) Å
Z	= 2	Z	= 2

A structure is proposed with atomic positions for the indium, halogen, and oxygen atoms in space group No. 59, *Pmmn*. The parameters of the atoms were determined mainly from Patterson and Fourier projections.

The structures are built up of infinite In-O sheets separated by double halogen sheets. They may be described as being of a deformed BiOCl type and are isomorphous with the iron(III)oxide chloride, FeOCl.

Previously, in the Department of Inorganic Chemistry of the Royal Institute of Technology, Stockholm, the hydrolysis of In^{3+} has been studied and polynuclear complexes like In_2O^{3+} have been proved to occur.[1] In connection with this solution work, it was of interest to investigate the coordination between indium and oxygen in solid indium oxide salts. This paper presents a structure determination of indium oxide chloride and indium oxide bromide.

PREPARATION OF THE CRYSTALS

White microcrystalline powders were obtained using the methods described in Gmelin-Kraut's Handbuch (1936)[2] for preparing InOCl and InOBr. By hydrothermal hydrolysis of solutions of indium(III)chloride, only indium hydroxide could be prepared. However, by heating a mixture of indium(III)halide, indium hydroxide and some water at 300°C, crystals of indium oxide chloride and indium oxide bromide were obtained.

Indium(III)chloride and *indium(III)bromide* were prepared by dissolving indium metal (99.96 % pure from the *Consolidated Mining and Smelting Company of Canada*)

in hot conc. hydrochloric or hydrobromic acid, as described by Enslin and Dreyer [3,4]. To oxidize lower oxidation states of indium to In^{3+}, some hydrogen peroxide was added towards the end of the reaction and the solution was then evaporated to dryness, giving $InCl_3(H_2O)_4$ or $InBr_3$.

Indium(III)hydroxide was prepared by precipitation from a solution of indium(III)-nitrate using aqueous ammonia. The precipitate was filtered off, washed with water several times and dried in air at room-temperature. It contained 64.3 % In, corresponding to a hydrated $In(OH)_3$.

Indium oxide chloride was then prepared as follows. A mixture of 280 mg $In(OH)_3$, 2 g $InCl_3(H_2O)_4$ and 0.1 ml H_2O was sealed in a thick-walled glass tube and kept at 300°C in an oven. After 24 h, the tube was cooled and the melt leached with ethanol, thus dissolving the excess of $InCl_3$. The residue was then filtered off and washed with ether. It consisted of clear crystals (plane needles) of InOCl and some indium hydroxide.

Indium oxide bromide was prepared in an analogous manner. The initial mixture consisted of 280 mg $In(OH)_3$, 2.4 g $InBr_3$ and 0.2 ml H_2O. The crystals were of the same shape as those of InOCl.

The crystals of InOCl and InOBr are very slightly soluble in water but dissolve completely in dilute acids.

Analysis

A sample, dried in air, was decomposed by fusion with sodium carbonate. After cooling, the melt was leached with water and the residue filtered off. In the filtrate, the amount of *halide* was determined gravimetrically as silver halide[5].

For the determination of *indium* a sample was dissolved in nitric acid, evaporated, and then ignited and weighed as In_2O_3.

The *density* of the crystals was determined from the loss of weight in benzene.

InOCl	Found		Calculated for InOCl
% Cl	19.8	20.0	21.33
% In	68.1	67.8	69.04
Density	4.6_4	4.6_4	4.77

InOBr	Found		Calculated for InOBr
% Br	35.0	35.0	37.93
% In	55.2	55.2	54.47
Density	5.3_3	5.4_0	5.53

The differences between the experimentally determined percentages of indium and halogen and those calculated from the formula InOX are probably due to slight contaminations of the samples, *e. g.* indium hydroxide.

UNIT CELL AND SPACE GROUP

A crystal was set with (010), the needle axis, as rotation axis and rotation and Weissenberg photographs (*h0l* and *h1l*) were taken with Cu*K* radiation. From these photographs it was concluded that the crystals are orthorhombic with the following cell dimensions.

InOCl	$a \approx 4.1$ Å		*InOBr*	$a \approx 4.2$ Å	
	$b \approx 3.5$ Å			$b \approx 3.6$ Å	
	$c \approx 8.1$ Å			$c \approx 8.6$ Å	

Table 1. Powder photograph of InOCl. Cu Ka_1 *radiation. Photographs were taken with and without KCl as an internal standard.* $a = 6.2930$ Å

Reflections systematically absent according to space group No. 59, *Pmmn* have been omitted.

The intensities were calculated from the expression $0.1 \cdot \frac{p}{8} \cdot F^2$, where p is the number of equivalent reflections.

More accurate values were calculated from powder photographs in focusing cameras of Guinier type. (Tables 1 and 2) (Cu*K* radiation, internal standard KCl. $a = 6.2930$ Å [6]).

InOCl
$a = (4.065 \pm 0.005)$ Å
$b = (3.523 \pm 0.005)$ Å
$c = (8.080 \pm 0.005)$ Å
$V = 115.7$ Å^3

InOBr
$a = (4.049 \pm 0.005)$ Å
$b = (3.611 \pm 0.005)$ Å
$c = (8.649 \pm 0.005)$ Å
$V = 126.5$ Å^3

Table 2. Powder photographs of InOBr. CuKa$_1$ radiation. Photographs were taken with and without KCl as an internal standard. a = 6.2920 Å

Reflections systematically absent according to space group No. 59 *Pmmn* have been omitted.

The intensities were calculated from the expression $0{,}1 \cdot \frac{p}{8} \cdot F^2$, where p is the number of equivalent reflections.

From the observed densities given above, one could calculate that there must be $1.9_5 \approx 2$ formula units InOX in the unit cell.

The same reflections are systematically absent in both compounds and they are thus isomorphous: *hk*0 absent with $h+k$ odd, which is characteristic of the space group No. 59, *Pmmn* [7].

PATTERSON SYNTHESES

In order to find out the indium and halogen positions in the unit cell the Patterson projections, *P*(*upw*), were calculated for both compounds (Fig. 1). Relative intensities of the reflections were estimated visually and the F^2-

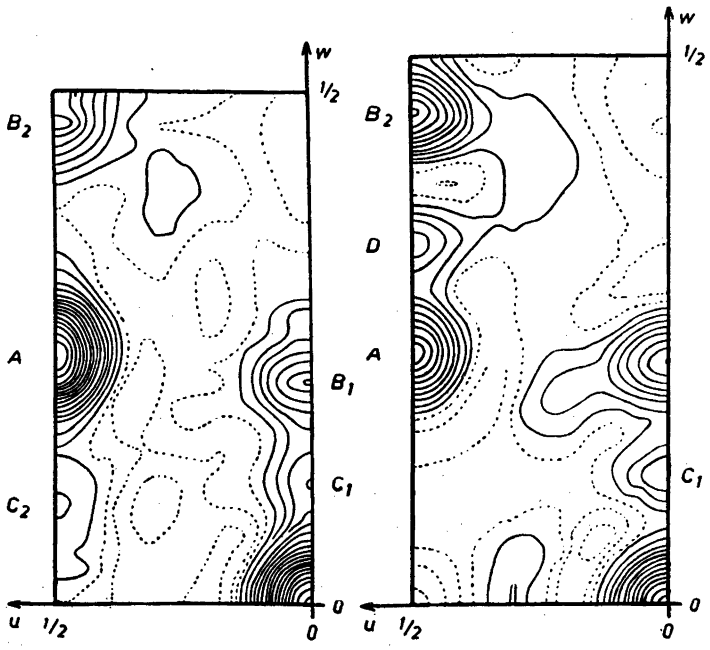

Fig. 1. The Patterson projection P(upw) *for InOCl (left) and InOBr (right). In the peak at the origin only every second contour has been shown. Dashed lines indicate negative values.*

values calculated using the curves given by Lu [8]. In all syntheses the value of $F^2(000)$ has been omitted. Corrections for absorption have not been applied. The maxima have been located by an interpolation table given by Booth [9].

Considering the space group, the indium atoms can only be situated in 2(*a*): 1/4, 1/4, *z*; 3/4, 3/4, $\bar{z}$; or 2 (*b*): 1/4, 3/4, *z*; 3/4, 1/4, $\bar{z}$. The In-In vectors would then be $\pm(\frac{1}{2}, 2z)$ in the *upw* projection.

This must correspond to the pronounced maxima A in the projections at $u = \frac{1}{2}$ and $w = 0.244$ (for InOCl) and $w = 0.229$ (for InOBr). If we assume the indium atoms to be situated in the point position 2(*a*), we thus get the following parameters for the indium atoms (we need only consider the range $0 \leq z_{In} \leq 1/4$)

$$InOCl: z \approx 0.122 \qquad InOBr: z \approx 0.115$$

In addition to the In-In peaks, the Patterson projections show other distinct maxima and we can see that two of them (B_1 and B_2) increase in relative height from the InOCl to the InOBr projection, so they should correspond to distances between indium and halogen atoms. The halogen atoms should then be situated in 2(*a*) or 2(*b*) and the In-X vectors in the *uw* plane would be:

$$\text{I} \pm (0, z_{In} - z_{Br})$$
$$\text{II} \pm (\tfrac{1}{2}, z_{In} + z_{Br})$$

If we now identify I and II with the peaks B_1 and B_2 in Fig. 1, we get the following values for the parameters of the X atoms (we need only consider the range, $0 \leq x \leq 1/4$, $0 \leq z \leq \frac{1}{2}$, if the range for the corresponding y parameter is $0 \leq y \leq 1$):

InOCl

2 Cl in 2(*a*) or 2(*b*) with $z_{Cl} \approx 0.344$

InOBr

2 Br in 2(*a*) or 2(*b*) with $z_{Br} \approx 0.335$

With this value for the Br parameter we could explain the D maximum as a Br-Br vector. The corresponding maximum for Cl-Cl is concealed by the In-In peak in the InOCl projection.

THE ELECTRON DENSITY FUNCTION

The electron density function was studied in order to locate the oxygen atoms and to get more accurate values for the parameters of the heavy atoms.

Since all the atoms of the structure must occupy twofold point positions (2(*a*) or 2(*b*)), the z parameter values may be determined from the line $x = 1/4$ of the projection $\varrho(xpz)$ of the electron density function. This function was thus calculated using the signs of F_{obs} given by the indium and halogen contributions. Fig. 2 shows (1/4, p,z) of InOBr. (The InOCl projection is of the

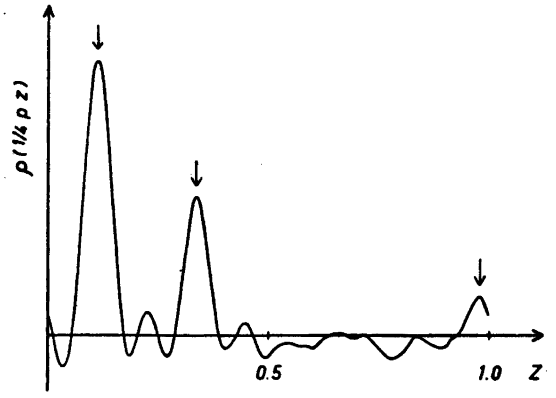

Fig. 2. Electron density of InOBr projected on the xz *plane with* x = 1/4.

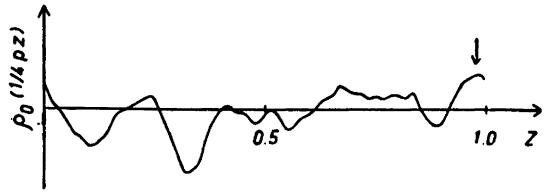

Fig. 3. Electron density of InOBr projected on the xz *plane and with* x = 1/4 *and the indium and bromine atoms substracted.*

same appearance.) It has two very pronounced maxima giving the positions of the indium atom (the highest maximum) and of the bromine atom (the lower maximum). The small peak at $z \approx 0.98$ might give the position of the oxygen atom. However, the peak may be a little displaced from the correct oxygen position by diffraction effects caused by the heavy atoms. To verify the oxygen position, a new electron density projection was calculated with the heavy atoms subtracted (Fig. 3).

Thus, from the electron density projections, the following parameters could be obtained:

InOCl	2 In	in	No. 59,	*Pmmn*	2(*a*)	with	z	=	0.121
	2 Cl	»	»	»	2(*a*) or 2(*b*)	»	z	=	0.345
	2 O	»	»	»	2(*a*) or 2(*b*)	»	z	=	0.97
InOBr	2 In	in	No. 59,	*Pmmn*	2(*a*)	with	z	=	0.113
	2 Br	»	»	»	2(*a*) or 2(*b*)	»	z	=	0.336
	2 O	»	»	»	2(*a*) or 2(*b*)	»	z	=	0.98

With these values for the oxygen parameters, we could explain the small maxima C_1 and C_2 in the Patterson projections in Fig. 1 as In-O distances.

GEOMETRICAL CONSIDERATIONS

From the electron density projections, we have only got values for the x and z coordinates. Now there are two possible values of the y coordinates for the halogen and oxygen atoms, *viz.* $y = 1/4$ or $3/4$, corresponding to the point position 2(*a*) or 2(*b*), and the correct ones can be found by considerations of space.

As 2(*a*) was arbitrarily chosen as the position of the indium atoms, the only possible sites for the halogen atoms will be in 2(*b*), since in 2(*a*) the distances In-X would be too short. (1.8 Å InOCl and 1.9 Å InOBr. In $(NH_4)_2InCl_5\,H_2O$, the In-Cl distance is 2.52 Å. Klug, Kummer and Leroy [10]).

The distance In-O is 2.16 Å in In_2O_3 (Pauling and Shappel [11]) and we should expect about the same in InOX. If the oxygen atoms were situated in 2(*a*) we get too short distances (1.1 Å in InOCl and 1.2 Å in InOBr) and the oxygen atoms must thus be situated in 2(*b*).

FINAL PARAMETERS

The following structure is proposed for InOCl and InOBr. Space group No. 59, *Pmmn*. Two formula units per unit cell.

InOCl	2 In	in	2(*a*)	with	z	=	0.121+0.002
	2 Cl	in	2(*b*)	»	z	=	0.345+0.004
	2 O	in	2(*b*)	»	z	=	0.97 +0.01
InOBr	2 In	in	2(*a*)	»	z	=	0.113+0.002
	2 Br	in	2(*b*)	»	z	=	0.336+0.004
	2 O	in	2(*b*)	»	z	=	0.98 +0.01

4	—	−2	−39	−21	+6	−4	+20				
		9	35	23	3	—	19				

In Tables 3—6 the calculated structure factors are compared with the observed ones in the Weissenberg photographs *h*0*l* and *h*1*l* of InOCl and InOBr. In all photographs, there is an absorption effect (*cf.* Wells [12]) due to the shape of the crystals (plane needles) which is very pronounced for rays passing along the plane of the crystals. The line with this high absorption has been marked and the structure factors on either side of this line must not be compared with each other. Taking this absorption into account the agreement between calculated and observed structure factors is rather good, the reliability index $R = \frac{||F_{obs}| - |F_{calc}||}{|F_{obs}|}$ being for InOCl *h*0*l* and *h*1*l*, 0.17 and 0.18 and for InOBr 0.21 and 0.19 [8]. (With absent reflections included, InOCl 0.20 and 0.21, InOBr 0.23 and 0.22.) However, for crystals like these containing both heavy and light atoms, the reliability index should not be taken as a definite proof that the structure as a whole is true, but only that the arrangement proposed for the heavy atoms is essentially correct.

DESCRIPTION OF THE STRUCTURE

Fig. 4 shows the structure of InOX. The indium and the oxygen ions form In-O-In layers which are separated by double halogen sheets. The arrangement of the metal and oxygen ions in the In-O sheets has been drawn separately in Fig. 5. The figure shows that the indium and oxygen ions form rectangular sheets and that each oxygen ion is tetrahedrically surrounded by four indium ions.

The indium oxide halides are evidently isomorphous with the iron(III)-oxide chloride, FeOCl (Goldsztaub [13]).

The arrangement of the metal and oxygen ions in the InOX crystals is approximately the same as that found in the corresponding bismuth compounds (Sillén [14]). In BiOX, the bismuth and oxygen ions form square sheets, but in InOX the indium and oxygen ions form rectangular networks.

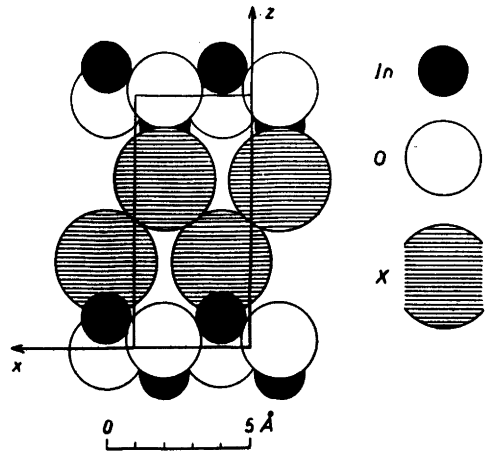

Fig. 4. The structure of InOX, viewed along (010).

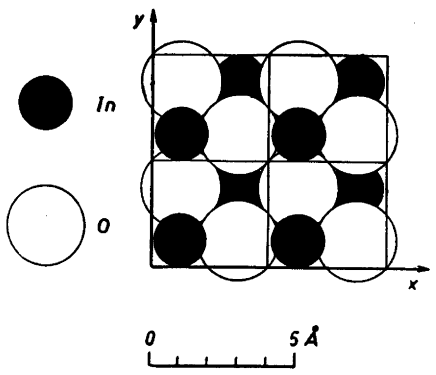

Fig. 5. The In-O sheet. The figure shows the arrangement of the In^{3+} and O^{2-} ions, viewed along (001).

The interatomic distances for the structure proposed will be (in Å):

InOCl	In — In	= 3.35	*InOBr*	In — In	= 3.35
	In — O_1	= 2.1_7		In — O_1	= 2.1_8
	In — O_2	= 2.1_6		In — O_2	= 2.1_5
	In — Cl	= 2.5_1		In — Br	= 2.6_4
	Cl_1 — Cl_1	= 3.52 and 4.07		Br_1 — Br_1	= 3.61 and 4.05
	Cl_1 — Cl_2	= 3.6_9		Br_1 — Br_2	= 3.9_4
	Cl_1 — O_1	= 3.6_8		Br_1 — O_1	= 3.8_4
	Cl_1 — O_2	= 3.0_5		Br_1 — O_2	= 3.0_8
	O_1 — O_2	= 2.7_4		O_1 — O_2	= 2.7_4

The error in the distances is assumed to be = ± 0.1 Å, the only exception being the X_1—O_2 distances with an accuracy of about ± 0.15 Å. The distances from one indium atom to its four indium neighbours are in good agreement with those of 3.38 Å reported for In_2O_3 (Pauling and Shappel [11]). The angles In-O_I-In and In-O_{II}-In are 139° and 109° in InOCl and 136° and 114° in InOBr. The shortest distance between halogen and oxygen is somewhat shorter than that which is expected from the sums of the ionic radii (Cl^- 1.81 Å, Br^- 1.96 Å and O^{2-} 1.40 Å [9]) and which is usually to be found in structures of this type.

Acknowledgements. The author is indebted to Professor Lars-Gunnar Sillén for his helpful criticism and provision of laboratory facilities and, in addition, to Professor Ölander for his kind interest. The author also wishes to thank Dr. Arne Magnéli and Dr. Georg Lundgren for many valuable discussions and Mr. D.G. Gillam for revising the English text.

Thanks are due to the *Consolidated Mining and Smelting Company of Canada, Ltd.* for generously supplying a large amount of indium metal of high purity.

The Separate Determination of Peroxide-containing Phospholipids and Other Lipoperoxides

J. GLAVIND and S. HARTMANN

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

Methods for the separate determination of peroxide-containing triglycerides (TGPO) and phospholipids (PLPO) have been studied. Tentative methods based on the following principles are described: 1) Precipitation with acetone, 2) determination of TGPO in the filtrate from adsorption on alumina; calculation of PLPO as the difference between total lipoperoxide and TGPO, 3a) determination of TGPO in the filtrate from adsorption on alumina; determination of PLPO by carrying out the colorimetric thiocyanate reaction while the phospholipids are adsorbed on the column, 3b) as in 3a) but with the *indophenol* method. The separate determination of TGPO and PLPO is possible by any of the methods, but the best results are generally obtained by method 2).

In a previous paper[1] we described methods for the determination of peroxide groups in phospholipids and phospholipid-containing fats. In nature, phospholipids are generally found together with triglycerides and other lipids, and the processes whereby peroxide groups are formed most often take place in mixtures of different kinds of lipids. At the same time the phospholipids often have a fatty acid composition different from that of the triglycerides from the same source. The phospholipids are, as a rule, more unsaturated und must be assumed to have a larger tendency towards the formation of peroxide groups. Under such circumstances the problem arises of methods for the determination of how large a fraction of the peroxide groups is situated on the individual kinds of lipids, *e.g.*, methods for the separation of phospholipid peroxides (PLPO) from other lipoperoxides, mainly triglyceride peroxides (TGPO).

In order to carry out such a fractionation it was attempted to use methods similar to those used for the separation of non-peroxidized phospholipids from other lipids, *i.e.*, especially precipitation with acetone, and adsorption. As a result of our studies tentative methods based on different principles of separation were elaborated. They are described in the following together with the results of a comparison of the methods.

METHODS

Method 1. Precipitation with acetone

The presence of peroxide groups does not greatly alter the solubility properties of the lipids, *i.e.*, when acetone is added to a solution of lipids in petro-

leum ether, PLPO are precipitated together with other phospholipids while TGPO and other triglycerides etc. remain in solution.

The lipid is dissolved in 5 ml petroleum ether, and 20 ml acetone is added. After separation by centrifuging and evaporation of the solvents, the two fractions are dissolved in a small amount of chloroform. The peroxide contents are determined in each fraction, with the exclusion of atmospheric oxygen, by the thiocyanate or the indophenol method as described in our first paper.

Method 2. Adsorption on alumina. Determination of TGPO in the filtrate, and of PLPO by substraction from total lipoperoxide

The presence of peroxide groups increases the adsorption affinity of the lipids, but, in general, phosphoric acid groups make the lipids still more strongly adsorbed. By means of a suitable adsorbent, *e.g.* alumina, TGPO and PLPO can be separated. With petroleum ether as a solvent TGPO (and other peroxides) are adsorbed on the column while non-oxidized triglycerides and other substances like carotene are washed through. Petroleum ether is, however, a less suitable solvent for the separation of TGPO and PLPO. Better results are obtained with chloroform as a solvent.

When, accordingly, a solution of lipoperoxides in chloroform is sent through a column of alumina, a fractioning is obtained in such a way that TGPO can be determined in the filtrate by one of the known methods. The PLPO are very strongly adsorbed and difficult to elute. However, when the total amount of peroxide is also determined, the PLPO can be calculated by substracting the TGPO.

The chromatographic adsorption device consists of a 100 × 13 mm glass tube provided with a constriction below which the tube is drawn out. A cotton plug is placed above the constriction, and 5 g alumina (a good commercial preparation for chromatographic use or, preferably, the purified product used in method 3) is put into the tube and packed by gently tapping the tube on the bench. The tube is placed on a suction flask by means of a rubber stopper. The flask is connected to the pump, and by means of an interposed T-tube the pressure can be regulated. The suction flask is filled to about half its volume with glass beads for the convenient placement of a centrifuge tube to collect the filtrate.

Twenty ml chloroform is sucked through the column, and the filtrate is discarded. The lipid dissolved in 5 ml chloroform is filtered through the column and washed with 25 ml chloroform (the pharmacopoea grade which contains a small amount of ethanol). The filtrate is collected in centrifuge tubes, an incidentally occurring precipitate removed by centrifuging, and the solvent evaporated to a small volume. The peroxide content is determined by the thiocyanate or the indophenol method; the result corresponds to the content of TGPO. An identical sample of lipid dissolved in 5 ml chloroform is used for the determination of total lipoperoxide. The content of PLPO is calculated as the difference between the two peroxide determinations.

Method 3. Adsorption on alumina. Determination of TGPO in filtrate, and of PLPO by color development on column

It is possible after chromatographic separation of TGPO and PLPO to carry out the determination of PLPO *in situ*, *i.e.*, by passing a color reagent through the column and measuring the color in the filtrate. Alumina is still a suitable adsorbent, but since commercial preparations are highly impure and would produce very strong colors with the color reagents, it is necessary to carefully purify the alumina in order to remove, as far as possible, all iron and other disturbing substances.

Preparation of purified alumina. Commercial alumina (*e.g.*, Aluminiumoxyd, reinst, Merck; Aluminiumoxyd, standardisiert nach Brockmann, Merck; or Aluminium Oxide for Chromatography, May & Baker) is repeatedly boiled with 5 % hydrochloric acid. The acid is removed by decantation and washing with redistilled water followed by ethanol, and the product is dried at 100 C *in vacuo*.

Method 3a. Thiocyanate procedure

Preparation of the thiocyanate reagent. In a graduated cylinder 50 ml 6 % ammonium thiocyanate in absolute ethanol (or methanol) is mixed with 50 ml chloroform. Oxygen-free nitrogen is bubbled through. After 15 minutes 1 ml ferrous chloride reagent prepared by the method of Loftus Hills and Thiel [2] is added. The reagent is protected from atmospheric oxygen by continuing the passing of nitrogen.

By means of the purified alumina a chromatographic column is prepared as described in method 2. Five ml thiocyanate reagent is filtered slowly through the column followed by absolute ethanol until a volume of about 10 ml is collected in the centrifuge tube. An incidentally occurring precipitate is removed by centrifuging, the volume adjusted to 10 ml, and light absorption at 500 mμ is measured. If the latter is high compared with the absorption of 5 ml thiocyanate reagent +5 ml ethanol, this indicates that the column does still contain traces of iron or other substances that will interfere with the PLPO determination. If that is the case, more portions of thiocyanate reagent followed by ethanol are filtered through until a constant low value is obtained.

With a well-purified alumina a low extinction is obtained in the first filtrate. In that case, the treatment of the column with thiocyanate reagent can be dispensed with, and reagent + ethanol can be used as a blank.

In the case the column has been treated with thiocyanate reagent, thiocyanate is removed by washing with about 20 ml ethanol, and the ethanol washed out with chloroform (about 20 ml). The lipoperoxide mixture containing both TGPO and PLPO dissolved in chloroform is filtered slowly through the column and eluted with about 25 ml chloroform. The filtrates, after incidental precipitates are removed by centrifuging, are evaporated, dissolved in ethanol-chloroform, and the amount of peroxide determined as usual, the result indicating the amount of TGPO present.

Suction is continued until no more chloroform drops from the tube. Then a new centrifuge tube is placed beneath the column and 5 ml thiocyanate reagent is filtered slowly through. When no more reagent is present on the

top of the adsorbent, ethanol is added, and filtration is continued until a total volume of little less than 10 ml is collected. After centrifuging and adjustment of the volume to 10 ml the intensity of the red color is measured, a reagent blank is substracted, and the peroxide content, corresponding to the PLPO content, is calculated.

Method 3b. Indophenol procedure

The method is carried out exactly as in 3a, but TGPO is determined by the indophenol method, and instead of the thiocyanate reagent the following reagent is used for preparation of the column and determination of PLPO.

Preparation of the indophenol reagent. In a graduated cylinder 50 ml 20 % $MgCl_2$,6 H_2O in absolute ethanol is mixed with 50 ml chloroform and oxygen-free nitrogen bubbled through. After 15 minutes 1 ml 2 % leuco-dichlorophenolindophenol and 1 ml 0.1 % ferric chloride, both in absolute ethanol, are added with continued bubbling.

RESULTS AND DISCUSSION

Table 1 illustrates results obtained by the methods described above. Mixtures of a triglyceride (lard) and a phospholipid (egg phosphatides repeatedly precipitated with acetone), both having a peroxide content of about 3 mequiv. per kg, were prepared and the recovery of TGPO and PLPO was determined by the different methods.

The results show that the separate determination of TGPO and PLPO may be carried out by using any of the principles mentioned in the introduction of this paper.

Precipitation with acetone has given the least satisfactory separation. Especially, too little PLPO is found in the precipitate when only a small amount of phospholipid is present. This is in accordance with the well-known fact that acetone does not give a complete precipitation of phospholipids; phospholipids, and probably also PLPO, are somewhat soluble in acetone. In other circumstances, by the examination of phospholipids of other origin than eggs, precipitation with acetone may be more advantageous in comparison with adsorption.

From the TGPO-values found by the different adsorption methods it is seen that the phospholipid preparation used has probably contained a small amount of TGPO. Taking this into consideration, it is seen that the recovery of TGPO has been almost quantitative in methods 1, 2, and 3 a. Pre-treatment of the column with indophenol reagent has resulted in loss of TGPO (method 3b).

PLPO values calculated as the difference between total lipoperoxide and TGPO are in quite good agreement with the "calculated values". In the two adsorption methods where PLPO is determined by carrying out the colorimetric reactions on the columns although oxygen could not be completely excluded, too low PLPO values are regularly found. Generally, a recovery of about 60 % PLPO is found. In most cases, therefore, a determination of PLPO as the difference between total lipoperoxide and TGPO will be the best method. In certain circumstances, the determination of PLPO by the colori-

The Acid-soluble Nucleotides of Wheat Plants

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

A method is presented for the analysis and isolation of the acid-soluble nucleotides from plant tissue.

The application of this method to wheat plants resulted in the identification of the 5'-triphosphates of adenosine, guanosine, uridine and cytidine beside mono- and diphosphates. The identifications are based on ultraviolet absorption spectra and chromatographic evidence before and after hydrolysis, together with chemical and enzymic analysis.

The demonstration in recent years of the fundamental role of nucleoside polyphosphates in mechanisms of energy transfer and biosynthesis made it desirable to develop methods for their analysis and isolation from plant materials.

The first direct demonstration of the presence of nucleoside polyphosphates in plants originates from Albaum and Umbreit [1], who isolated from germinated oat seedlings an adenine-pentose-pyrophosphate in low yield and of low purity. This compound appeared to be related to, but not identical with 5'-ADP *.

Later, an ATP-like compound was isolated from mung bean sprouts [2], a material chosen because of its low content of polysaccharides, phytic acid and non-specific ultraviolet absorbing substances, which interfered with the isolation from other plant sources. The product obtained originally appeared to be similar to ATP from animal tissue but not identical with it, and was considered [3] to represent a polymerized form of ATP, which with appropriate treatment could be depolymerized to give a compound identical with the ATP found in other tissues.

Among the radioactive compounds observed when algae or green leaves are allowed to photosynthesize in $^{14}CO_2$ Buchanan [4] *et al.* detected a nucleotide fraction, and presented paper chromatographic evidence for the presence of 5'-AMP, 5'-UMP, UDPG, UDPgalactose, an adenosine-containing nucleotide other than ATP, ADP or AMP, and a mannose-containing compound chromatographically similar to a nucleotide.

* Abbreviations used: A, adenosine; G, guanosine; U, uridine; C, cytidine; MP, monophosphate; DP, diphosphate; TP, triphosphate; UDPG, uridine diphosphate glucose; DPN, diphosphopyridine nucleotide; TPN, triphosphopyridine nucleotide.

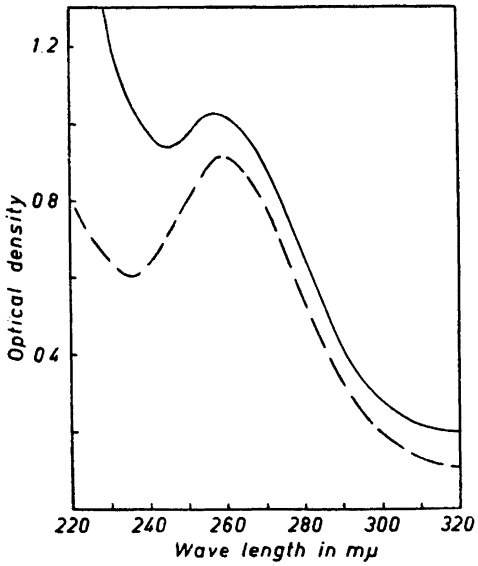

Fig. 1. Norite eluate before ———— *and after* — — — — *ether extraction.*

An ATP-like compound in chlorophyll-containing plants has been detected chromatographically by Simonis and Schwinck [5], and Sebesta and Sorm [6] have determined the ATP content of *Phaseolus vulgaris*.

The determination of the total acid-soluble nucleotide content in plants and isolation of the nucleoside polyphosphates in pure form has generally met with difficulties mainly because the procedures, which were found satisfactory for animal tissue, yielded unsatisfactory results when applied to plant materials [1-3].

The experience of previous authors in this direction was confirmed in the present investigation. Extracts prepared by homogenizing plant material from various sources in cold trichloroacetic or perchloric acids exhibited very complex ultraviolet absorption spectra, and no separation of the nucleotide fraction from other phosphorus-containing or ultraviolet-absorbing substances could be achieved by precipitation of the barium or mercury salts or by any other procedures of purification. Chromatography at this stage proved also impracticable. A crude separation of the nucleotide fraction from non-nucleotide phosphorus compounds could, however, be attained by adsorption on norite, a current method in the nucleotide field. The nucleoside derivatives from the acid extracts were quantitatively retained by norite, and could be recovered by repeated elution with 25 % aqueous ethanol containing 0.5 % ammonia.

Spectrophotometric analysis of the combined eluates showed that the nucleotides were mixed with a large quantity of non-nucleotide material. Precipitation with zinc or barium salts at this point yielded products containing less than 10 % nucleotides. Ion exchange chromatography was also unsuccessful, because of the multitude of ultraviolet absorbing, non-nucleotide fractions. Hence, further purification prior to chromatography was necessary. By the

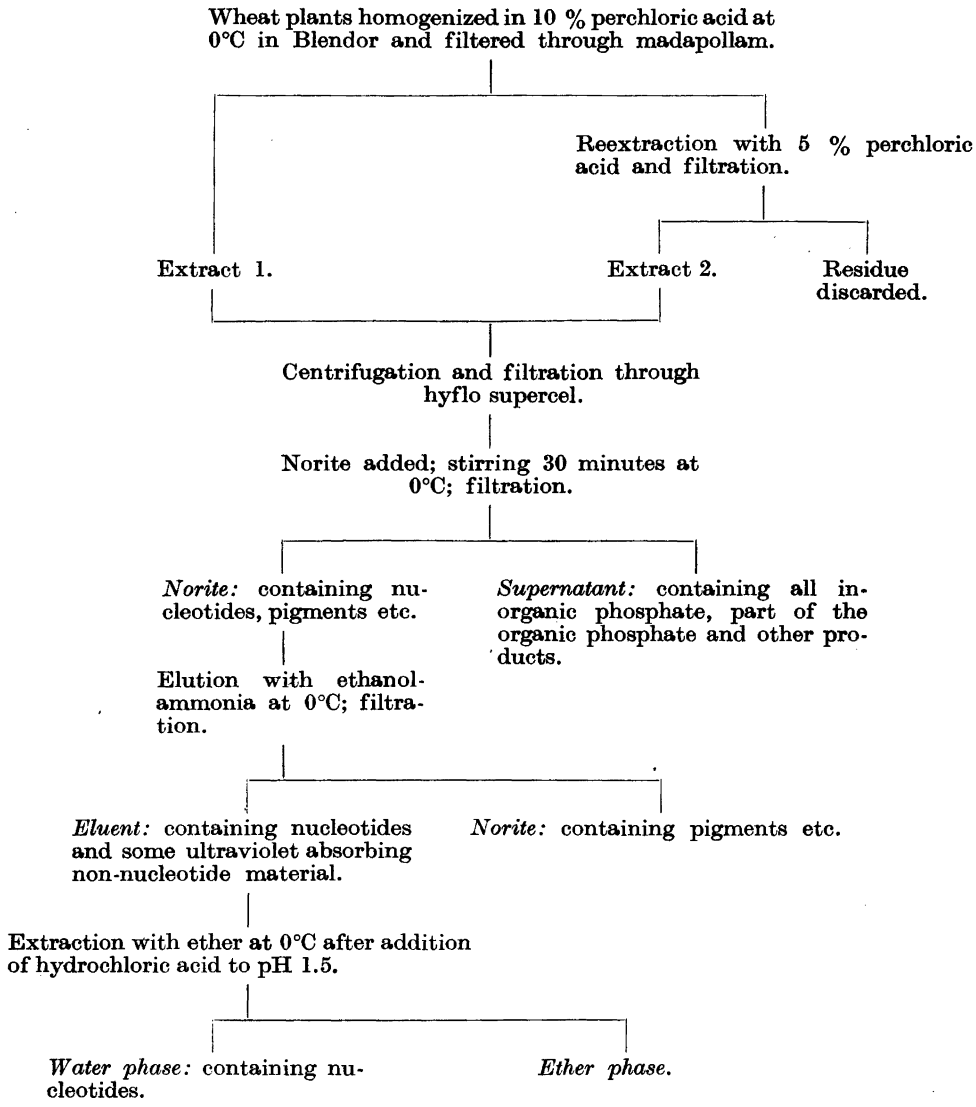

Fig. 2. Isolation of the acid-soluble nucleotide fraction from wheat plants.

addition of hydrochloric acid to pH 1.5 and extraction with ether for several hours the disturbing substances were removed from the norite-eluates. The absorption curves before and after extraction, shown in Fig. 1, indicate the effectiveness of this step in removing ultraviolet absorbing, non-nucleotide material.

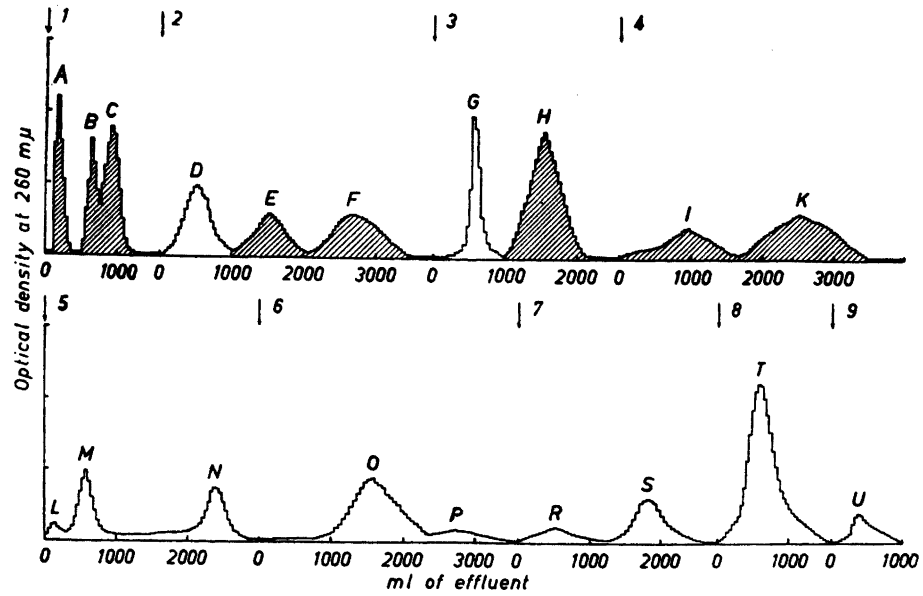

Fig. 3. Ion exchange chromatogram of acid-soluble nucleotides from 500 g of wheat plants. The crossed fractions varied in amounts in different preparations. Exchanger: Dowex 1, X-10, 200 to 400 mesh, 1.6 × 40 cm., formate form; flow rate 1.5 ml/min.

By this method, the acid-soluble nucleotide fraction from various plant tissues could be prepared in sufficient purity for further fractionation by chromatography. In the present paper the application of this procedure to wheat plants is reported.

From wheat plants, which had grown out of doors under normal conditions and begun to form grains, only the aerial part was investigated. The acid-soluble nucleotide fraction was isolated as outlined in Fig. 2.

The individual nucleotide compounds were separated by ion exchange chromatography, and the method reported by Bergkvist and Deutsch [7] was used with slight modifications. Because of employing a longer column some changes in the eluting system were necessary.

Fig. 3 shows an ion exchange chromatogram of the acid-soluble nucleotides of wheat plants, as obtained from a formate column.

The elution positions and the absorbance ratios E_{250}/E_{260} and E_{270}/E_{260} gave a preliminary identification of the individual fractions.

Peak *A* contained a mixture of purine and pyrimidine bases, which were separated by cation exchange in an acid system according to Cohn [8]. The

Table 2. Analysis of effluent fractions.

Data on absorption spectra, phosphate and ribose content, and base. The chemical data are expressed in terms of moles per mole of base, as determined spectrophotometrically. The absorption spectra were determined in acid and alkaline solutions. The ribose content of the cytosine nucleotides could not be determined by the method of Albaum and Umbreit [15]. The bases were identified by paper chromatography.

U	Guanosine	3.09	2.06	0.94	Guanine

bases adenine, guanine, uracil and cytosine were unequivocally identified by paper chromatography in different solvent systems.

The fractions corresponding to the following peaks were adsorbed on norite with subsequent elution by ethanol-ammonia. The concentrated solutions thus obtained were subjected to paper chromatography in comparison with the authentic products. The results are summarized in Table 1.

Beside elution position, absorbance ratios and paper chromatography, the ultraviolet absorption spectra at different pH values established further the identity of the different fractions.

Total and acid-labile phosphate as well as the pentose content were determined. After hydrolysis and paper chromatography in the *n*-butanol-acetic acid-water (4:1:5) system, the presence of ribose was revealed on development with aniline hydrogen phthalate.

In order to confirm the identity of the bases of the different purine and pyrimidine nucleotide fractions, the free bases were prepared by hydrolysis for one hour at 100°C, in 1 N hydrochloric acid and 70 % perchloric acid, respectively. R_F values identical with those of the corresponding authentic

products were obtained by paper chromatography in three different solvent systems. The ultraviolet absorption curves of the products of hydrolysis were likewise found to be identical with those of the corresponding bases. The results are summarized in Table 2.

Beside uridine and two phosphate groups peak *M* was found to contain glucose. Boiling in 0.01 N acid for 5 minutes liberated practically all the glucose and only a very small portion of the phosphate. After such a treatment uridine diphosphate and glucose could be identified as the breakdown products by paper chromatography and ionophoresis.

Uridine diphosphate glucose was closely associated with another UDP derivative (peak *L*), which on mild acid hydrolysis liberated UDP. This fraction was too small for more complete analysis.

The di- and triphosphates of adenosine were degraded to the monophosphate on heating the free acids for two hours to 100 °C. The uridine polyphosphates were hydrolysed for one hour at 100°C in 1 N hydrochloric acid, which resulted in the formation of the corresponding monophosphate together with orthophosphate, in agreement with the expected behavior of a pyrimidine nucleoside-5'-polyphosphate. Paper chromatography of the products of hydrolysis gave ultraviolet absorbing spots with the same R_F values as 5'-AMP and 5'-UMP, respectively, as seen from Table 3.

The location of the phosphate groups in the different nucleotides was established both by oxidation with periodate [9] and by the action of rattlesnake venom (*Crotalus adamanteus*). Treatment with the venom splits the pyrophosphate linkage between the phosphate group attached to ribose and the next phosphate [10]. The specific 5'-nucleotidase of the venom then splits off the phosphate from any 5'-monophosphate formed, yielding the nucleoside

Table 3. R_F values of the monophosphates obtained by hydrolysis of the different polyphosphates, in comparison with authentic samples.

Solvent systems: (I) ethanol-1 M ammonium acetate, pH 7.5 (75:30); (II) etanol-1 M ammonium acetate buffer, pH 3.8 (75:30); (III) *iso*propanol-saturated ammonium sulphate solution-water (2:79:19). Descending chromatography was used in all systems. Temperature 20 to 22°C.

Table 4. Periodate oxidation and action of snake venom on effluent fractions.

Periodate oxidation. 0.50 μmole of potassium metaperiodate was added to approx. 0.30 μmole of the sodium salt of the nucleotide in a total volume of 3.0 ml. The amount of periodate consumed was measured at 227 mμ against a blank containing periodate of the same concentration. Reaction time was 60 minutes at 20°C.

Incubation with snake venom. 1 μmole of nucleotide in 1.0 ml of glycine buffer (pH 8.5) and 0.05 ml of 1 M magnesium chloride were treated with 2 mg of lyophilized *Crotalus adamanteus* venom in 0.2 ml of 0.2 % sodium chloride. The mixture was incubated for 60 min. at 38°C. Phosphate was estimated after addition of 0.1 ml of 70 % perchloric acid and centrifugation. The reaction product was isolated from the remaining solution by adsorption on norite and elution with ethanol-ammonia. The products were identified by paper chromatography.

Compound	μmoles of periodate consumed per μmole of nucleotide	μmoles of orthophosphate formed per μmole of nucleotide	Reaction product

and orthophosphate. The 2'- and 3'-monophosphates are resistent towards the enzyme and should be unaffected. The reaction products were examined by phosphate analysis and paper chromatography. The results appear in Table 4.

5'-ADP, 5'-ATP, 5-'UTP and 5'-GTP have been isolated as the barium salts; the analyses are shown in Table 5. The results correspond to preparations of about 90 % purity with the exception of GTP, the amount of which was too small for further purification.

As already briefly mentioned, some doubts have arisen in the literature concerning the structural identity of adenosine triphosphate encountered in plants with that from animal tissue. The evidence outlined above leaves little or no doubt about their identity, but as a further test, the reaction with glucose in the presence of hexokinase was studied. ATP from fraction *T* transferred

Table 5. Analysis of the isolated barium salts of nucleotides.

The barium salts were washed with ethanol and ether and dried *in vacuo* over phosphorus pentoxide to constant weight. The base concentrations were calculated from optical densities and ribose concentrations from the values of periodate oxidation. Theoretical values were calculated for barium salts of triphosphates and diphosphate containing 2 and 1.5 barium atoms per mole of nucleotide, respectively, and 4 moles of water per mole of nucleotide.

half of its labile-bound phosphate to glucose, exactly as animal ATP. Furthermore, the effect on the viscosity of actomyosin solutions [11] was identical for ATP from fraction *T* and ATP isolated from muscle.

The qualitative and quantitative analysis of the fractions corresponding to each peak of the chromatogram are summarized in Table 6.

The present work establishes the occurrence in wheat plants of all the four ribonucleosides in the form of acid-soluble 5'-mononucleotides at different levels of phosphorylation, in addition to their occurrence in nucleic acids and in analogy to previous findings on animal tissue.

Nearly 90 % of the acid-soluble nucleotide material in wheat plants consists of adenosine and uridine derivatives, present in practically equimolar amounts. The predominance of uridine, beside adenosine derivatives is of considerable interest and in contrast to the dominating role of adenosine derivatives in animal tissue. But whereas about half of the acid-soluble adenosine and guanosine nucleotides were isolated as the triphosphates, only little over 20 % of the uridine derivatives were found in the form of triphosphate. In the case of cytidine, the triphosphate was the only derivative obtained; neither 5'-CMP and CDP nor 5'-GMP could be detected in any of the experiments. It is probable, that during further isolation work additional nucleotides will be found to occur in small amounts.

Table 6. Amounts and identity of effluent fractions obtained on ion exchange chromatography of the acid-soluble nucleotides from wheat plants. The second column give sthe maximum amounts of 2'- and 3'-phosphates.

Compound	Identity	μmoles/1000 g of wheat plants	μmoles/1000 g of wheat plants

In addition to nucleoside-5'-polyphosphates, varying amounts of the 2'- and 3'-monophosphates were obtained in some experiments. The fact, that nucleoside 2'- and 3'-derivatives were only encountered in some and not detectable in other experiments, together with the absence of 2'- and 3'-di- and triphosphates in all experiments, makes it possible that the 2'- and 3'-nucleotides originated from the degradation of ribonucleic acid during preparation.

The absence of diphosphopyridine and triphosphopyridine nucleotides in the nucleotide fraction, prepared from wheat plants by the present method, is due to the fact that these compounds, although present in the original acid extract and adsorbed on norite, are not eluted appreciably with ethanol-ammonia. For the isolation of DPN and TPN elution of the norite with pyridine-water is more effective, although this eluent proved unsatisfactory for the isolation of the main bulk of the acid-soluble nucleotides. DPN and TPN have been previously isolated from wheat germ [12] and from other plant materials [13].

EXPERIMENTAL

Isolation of the nucleotide fraction

1 000 g of fresh wheat plants were homogenized in 3 000 ml of ice cold 10 % perchloric acid in a Waring Blendor. The precipitated proteins and fiber masses were separated from the extract by squeezing through madapollam. The residue was re-extracted in the Waring Blendor with 1 000 ml of 5 % perchloric acid and again pressed through madapollam. The combined extracts were further freed from suspended particles by centrifugation and then filtered through hyflo supercel on a Büchner funnel.

The clear, slightly yellow solution was treated with 30 g of norite. The suspension was shaken or stirred vigorously for 30 minutes and then filtered with suction. Experiments with various amounts of norite demonstrated, that under these circumstances all nucleotides were adsorbed on the norite. The norite was washed with water and then dried by suction.

The elution of the nucleotides from the norite was investigated with a number of solvent systems. An aqueous solution containing 25 % ethanol and 0.5 % concentrated ammonia proved to be the most satisfactory for the quantitative elution of the nucleotides with a minimum of disturbing substances. Therefore the norite was suspended in 150 ml of this mixture. The suspension was stirred vigorously in the cold for 30 min. Then the norite was filtered off and the elution repeated. Each fraction was collected in the cold and immediately adjusted to pH 7 with hydrochloric acid. After 5 to 6 extractions no more ultraviolet-absorbing material could be eluted.

The combined fractions were acidified with hydrochloric acid to pH 1.5, and the remaining disturbing substances were removed by continuous liquid-liquid extraction with ether for five hours. The extraction apparatus of Kutscher and Steudel was used, and the solution was cooled with ice during extraction. Thereafter the aqueous phase was freed from the last traces of ether by aeration. Phosphorus analysis before and after extraction showed that no decomposition had occurred. The aqueous phase could now be subjected to ion exchange chromatography.

Ion exchange chromatography

The strong base anion exchange resin Dowex 1, X-10, 200 to 400 mesh, was used. After freeing from fine and coarse particles by sedimentation the resin was converted to the formate form with a mixture of 2 M formic acid and 2 M sodium formate.

A column of 1.6 × 40 cm was supported in a glass tube by a constriction covered with glass wool. The resin was poured as an aqueous slurry and allowed to settle. The column was washed with a large quantity of water until the pH of the effluent was about 7. The column was fed with eluting agent through glass tubing from a container about 1.5 meters above the column.

The nucleotide fraction was put on the column from dilute ammoniacal solution at about pH 10 at the rate of 1.5 ml per min. After washing with water the eluting agents shown in Fig. 3 were used. Fractions of 35 ml were taken with an automatic fraction collector adjustable to different time intervals. Appropriate fractions were pooled and adsorbed on norite (10 mg of norite / μmole of nucleotide), and after washing with water the norite was eluted with small amounts of 50 % aqueous ethanol containing 0.5 % ammonia.

The column could be used several times except for a small layer at the top, which darkened during the run and was replaced each time by fresh resin.

Analytical methods

Ultraviolet absorption. Optical densities were measured in a 1.00 cm quartz cuvette in a Beckman Universal Spectrophotometer, Model DU, with photomultiplier. The course of the elution was followed by measurement of the optical densities of the fractions of chromatogram at 250, 260 and 270 mμ with the suitable eluting agents as the blank. The densities at 250 and 270 mμ assisted in interpretation of the chromatogram since the ratios of the readings E_{250}/E_{260} and E_{270}/E_{260} are characteristic of the various nucleotides.

Table 7. Molar absorbancy and absorbance ratios at pH 1 of the different nucleotides. The values for the polyphosphates followed those obtained for the corresponding monophosphates very closely.

Compound	$a_M \times 10^{-3}$	Absorbance ratios	
		250/260	270/260
Adenosine phosphates	14.5	0.84	0.71
Guanosine phosphates	10.8	0.93	0.73
Cytidine phosphates	6.3	0.47	1.71
Uridine phosphates	10.0	0.76	0.87

The optical densities at 260 mμ of the effluent fractions were plotted against effluent volume to obtain the chromatograph shown in Fig. 3.

The molar absorbancy a_M at 260 mμ and the absorbance ratios in acid solution are shown in Table 7. Each peak was also identified by determining its optical density over the range 220 to 320 mμ in both acid and alkaline solution, compared with authentic samples.

Phosphate. Inorganic phosphate was determined by the method of Allen[14] adapted to a total volume of 5.0 ml (4.0 ml of aqueous sample, 0.40 ml of 70 % perchloric acid, 0.40 ml of amidol-reducer and 0.20 ml of 8.5 % ammonium molybdate). The color was read 15 minutes after mixing, in a Klett-Summerson photoelectric colorimeter with a red filter.

The acid-labile phosphate was determined from the increase in inorganic phosphate after 10 minutes in 1 N hydrochloric acid at 100°C.

For total phosphate, the sample was digested with 0.40 ml of 70 % perchloric acid at 250°C and after cooling the inorganic phosphate was determined without further addition of acid.

Pentose. All fractions were analyzed for pentose with the orcinol reagent according to Albaum and Umbreit[15]. To the sample in 3.0 ml of water, 3.0 ml of 0.1 % ferric-chloride in concentrated hydrochloric acid and 0.3 ml of a reagent, containing 0.4 % orcinol in 95 % ethanol, were added. The reaction tubes were heated for 45 min. in a boiling water bath, cooled, diluted to a total volume of 10.0 ml and read in a colorimeter with a red filter. The results obtained were calculated by use of authentic samples as standards. The values for the uridine nucleotides were very small and therefore uncertain, and the cytidine nucleotides did not give any color.

Paper chromatography

The filter paper used was Whatman No. 1. The papers were in equilibrium with the solvent mixture before the runs were started. The temperature was 20 to 22°C. Standard substances were run in every chromatogram.

The nucleoside derivatives were located by making a contact print in monochromatic ultraviolet light of 254 mμ. For quantitative estimations, spots were cut out and eluted with 0.1 N hydrochloric acid. Standing for a few hours with occasional shaking effected quantitative elution. To allow for ultraviolet absorbing substances in the paper, blanks were cut, equal in area and at equal distances from the starting line, and were eluted and read at the same wave-lengths as the corresponding spots. Aniline hydrogen phthalate was used to demonstrate the position of the sugar spots on the paper chromatograms.

The nucleotides were hydrolysed to the free bases by heating at 100°C for one hour in 1 N hydrochloric acid for the purines, and in 70 % perchloric acid for the pyrimidines. Paper chromatography of the bases was carried out with the following systems: a) *iso*-propanol-hydrochloric acid (*d* 1.180)-water (65:17:18); b) *n*-butanol-acetic acid-water (4:1:5); c) *iso*propanol-saturated ammonium sulphate solution-water (2:79:19).

For paper chromatography of the sugars, the butanol-acetic acid-water system, already described, was used, in addition to ethyl acetate-pyridine-water (2:2:1).

Paper ionophoresis

Ionophoresis on paper was performed with a technique described by Markham and Smith [16] where the paper is kept cold by immersion in carbon tetrachloride. The substances were applied near one end of a long strip of Whatman No. 1 paper (6×50 cm). It was found convenient to wash the paper with 1 N hydrochloric acid and water before use. The carbon electrodes were connected to a d.c. power supply of 900 V thus giving a voltage gradient of about 20 V/cm. Under these conditions a run of 3 h gave good separations with the different buffers used. In ionophoretic as well as in chromatographic experiments, the position on the paper was compared with the position of the authentic substances.

The 5'-phosphate esters of any ribose nucleoside possess one characteristic by means of which they may be separated from the 2'- and 3'-esters of the same nucleoside: the presence of two adjacent hydroxyl groups in the ribose moiety, which can give complexes with boric acid. In 0.1 M sodium tetraborate buffer at pH 9.2 the mobility of the 5'-nucleotide is faster than that of the corresponding 2'- and 3'-nucleotides. The sugars could also be separated with the same buffer.

Separation of mono-, di- and triphosphates was obtained using an acetate buffer of ionic strength 0.1 at pH 5.

Action of snake venom

The estimation was performed as shown in Table 4. Phosphate was determined as described above, but the blue color was read in the colorimeter first after extraction with amyl alcohol, because of interference by magnesium otherwise.

The reaction products were adsorbed on norite and then eluted with small volumes of ethanol-ammonia. The concentrated solutions thus obtained were analyzed by paper chromatography. The solvent systems used were: *iso*propanol-saturated ammonium sulphate solution-water (2:79:19) and 95 % ethanol-1 M ammonium acetate buffer; pH 3.8 (75:30).

Periodate oxidation

Oxidation with periodate was performed according to Dixon and Lipkin [9].

Hexokinase reaction

This reaction was performed according to Colowick and Kalckar [17], and the reaction was followed by the disappearance of the acid-labile phosphate.

0.1 ml of the ATP-solution (10 μmole/ml), 0.1 ml of 0.5 M magnesium sulphate solution, 0.5 ml of 0.04 M sodium bicarbonate solution (pH 7.5), and 0.1 ml of 0.3 M glucose were combined and warmed to 30°C. 0.1 ml of dilute enzyme (10 mg/ml) was added and the mixture was incubated at 30°C for 30 minutes.

The reaction was stopped by the addition of 0.4 ml of 70 % perchloric acid. After centrifugation the acid-labile and total phosphates were determined. The values were compared with similar analyses of a mixture at zero time. Identical results were obtained with ATP from wheat plants and animal tissue.

Effect on actomyosin

The reaction was followed by viscosity measurement in Ostwald viscosimeters at 21°C (time of flow for water, about 40 sec.). The viscosimeters contained 3.5 ml of actomyosin solution in 0.5 M potassium chloride with a protein concentration of approximately 3 mg/ml. 0.4, 0.8 and 1.6 μmoles of triphosphate were added in volumes of 25, 50 and 100 μl.

Materials

The mono-, di- and triphosphates used as standard substances were isolated from muscle as previously described [18,19]. GTP and hexokinase were obtained by courtesy of Sigma Chemical Company.

Acknowledgement. The author wishes to express his gratitude to Dr. A. Deutsch for his encouragement and continued interest in this work, and to *Sigma Chemical Company* for supplies of GTP and hexokinase. Fast-writing Precision Apparatus for Continuous Recording of Electrolytic Resistance

CARL-OVE ANDERSSON and EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Sweden

OLOF MELLANDER

Department of Medical Biochemistry, University of Gothenburg, Sweden

A high precision apparatus is described for the continuous recording of resistance. Full-scale response in less than 5 seconds is obtained for resistance-changes within a range variable at will from 2 to 1 900 ohms. The noise-level of the apparatus in its present form is equivalent to resistance-changes of about $1:10^6$ at a cell-resistance of 500 ohms. In practice, sensitivities up to $1:10^5$ may be employed without noise or zero drift in the recordings, provided that resistance-changes due to temperature-drift are eliminated.

During the course of a chemical reaction involving ions and taking place in aqueous solution, some of the ions originally present disappear and new ones are formed, causing change in the electrolytic conductivity of the solution. Analytical procedures involving conductrometric titrations are based upon the fact that the slope of the curve conductivity- added reagent shows an abrupt change in direction at the equivalence point. Similar changes are noted when the state of aggregation of the solute is changed. Measurements of conductivity are therefore useful in following micelle formation in solutions of paraffin-chain salts and bile salts.

Reactions in biological systems such as enzymatic hydrolysis may also be traced by measurement of the conductivity of the solutions. With the methods ordinarily used for following enzymatic hydrolysis it is impossible to cover the initial part of the reaction. In most methods samples are taken after different time-intervals, and the information obtained is thus limited to a series of

* A preliminary report of this work was made at the meeting of the Swedish Biochemical Society at Gothenburg, June 3—4, 1955 [1].

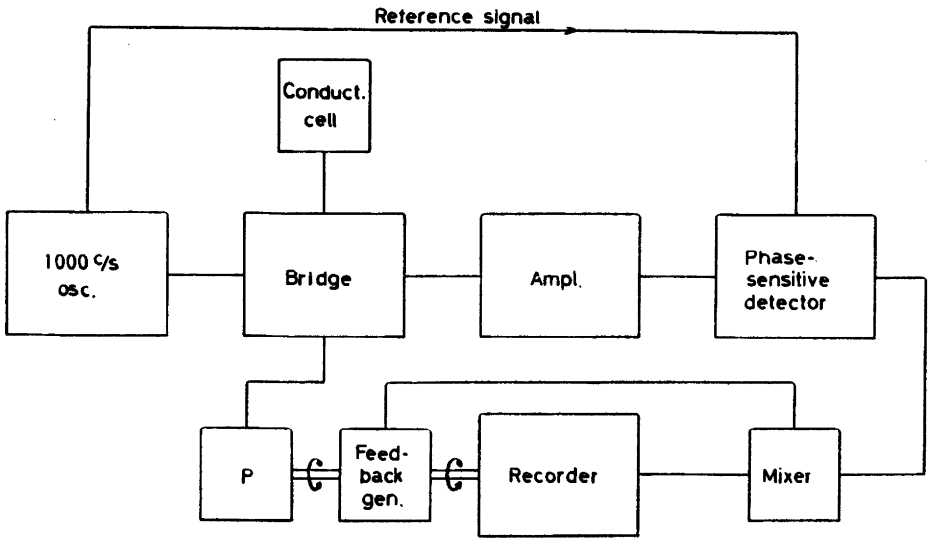

Fig. 1. Block diagram of resistance-recorder

discrete points on the reaction-time curve. The means of stopping the enzymatic reaction in the samples after they have been removed from the system are frequently such that they might influence the analytical results through secondary reactions. In contrast to this, measurement of the conductivity often enables reactions to be followed without interference but, as the ionic strength of the system is usually high and the often rapid reaction produces only small changes in the conductivity of the solution, a fast, sensitive recording system is necessary.

In recent years a number of devices have been described for recording the electrolytic conductivity of the effluent from chromatographic columns [1–6]. In this particular connexion a high recording-speed is not necessary, and none of the devices described appears to possess the combination of speed, accuracy, and stability needed for following chemical reactions of various types.

The conversion of a Shedlovsky precision bridge [7] into a fast-writing resistance recorder is described below. A block diagram of the apparatus is shown in Fig. 1.

The bridge is fed from a 1 000 c/s oscillator. The detector signal is amplified by a three-stage amplifier with automatic gain control, which prevents overloading of the recording system in case of considerable unbalance. The amplified signal and a reference signal from the oscillator are applied to a phase-sensitive detector. After filtering, the output of the phase-sensitive detector is fed *via* a cathode-follower stage to the input of the amplifier of a Speedomax-G recorder. To the potentiometer shaft of this recorder a linear high-precision potentiometer is mechanically coupled (P in Fig. 1), which forms parts of two arms of the bridge (*cf.* Fig. 2), the moving contact being connected to one side of the input of the detector amplifier. A signal from the bridge

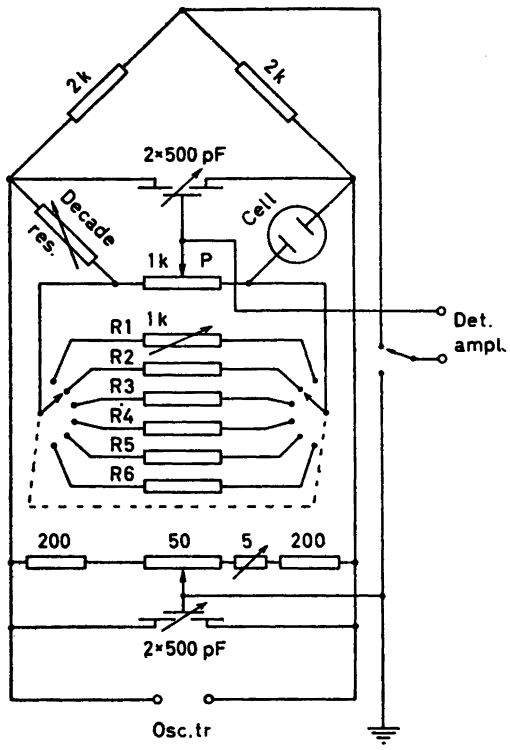

Fig. 2. Bridge circuit (shielding not shown). For details see text.

makes the recorder pen move until balance has been restored through the potentiometer attached to the recorder shaft. In order to prevent hunting of the servo system an adjustable amount of velocity feed-back to the recorder amplifier is introduced *via* a mixer from a tachometer generator geared to the balance motor of the recorder.

The use of a detector amplifier with automatic gain control ('compression amplifier'), variable phase-control in the phase-sensitive detector, velocity feed-back in the servo system, and an electro-mechanical filter in the form of a motor-generator between the A.C. mains and the power supply units of the apparatus, has resulted in very satisfactory sensitivity, stability, and speed of response.

The theory of the alternating-current Wheatstone bridge is found in standard texts [8]. The theoretical aspects of bridges for measuring electrolytic conductivity, and the sources of error involved in such measurements, have been discussed by Jones and Josephs [9] and by Shedlovsky [7]. A precision conductivity-bridge assembly has also been described by Luder [10]. A new type of alternating-current bridge suitable for measuring electrolytic resistance has recently been described by Easton and Lamson [11].

DESCRIPTION OF APPARATUS

Wheatstone bridge. The Shedlovsky type bridge [7] is similar to that used by Mellander and Stenhagen [12]. A shunted 1 000-ohm precision potentiometer P (Fernsteuergeräte PW 70 *), mechanically coupled to the potentiometer shaft of the recorder, is electrically connected between the decade and the conductometric cell as shown in Fig. 2. The movable contact is connected to one side of the primary of the detector input transformer. By means of the variable shunt, R1, the resistance range covered by full-scale travel of the recorder pen can be continuously adjusted from about 2 ohms to 1 900 ohms. Alternatively, a series of fixed shunts is provided for selecting standard resistance ranges of 20, 50, 100, 200, 500, and 1 000 ohms.

In order to determine the initial resistance of the cell, the shunt R1 is shorted, and a pair of headphones connected through a jack to the output side of the detector amplifier. The headphones are also necessary during the initial adjustment of the phase-sensitive detector.

The potentiometer, P, (Fig. 2) has 1 200 turns for 1 000 ohms. The resultant limit of precision is thus, for a recorder scale- range of 1 000 ohms, of the order of 1 ohm (0.1 %), *i.e.* the same as the pen-setting precision of the recorder. On lower scale-ranges the limitation of the precision due to the limited number of turns of the potentiometer is therefore negligible. Early in the development of the apparatus a 100-ohm potentiometer was used, when the recorder could be made to count the number of turns of the winding. The figure obtained in this way agreed with that given by the manufacturer.

All fixed resistors are of manganin wire ** (Ayrton-Perry winding or, for resistances above 200 ohms, single layer on mica card). The values of the fixed resistors R2—R6 must be determined experimentally. The bridge is fed from an oscillator *via* a shielded transformer (Svenska Radiobolaget XLT 504), the voltage across the secondary of which is usually adjusted to one volt. The requirements for low content of harmonics in the output of the oscillator do not seem critical. Both a simple, home-made RC oscillator and a commercial instrument (Philips GM 2307) have been used.

Detector amplifier. The circuit diagram of the detector amplifier is shown in Fig. 3a. Three resistance-capacity coupled stages using two 6SK7 and one 6V6 tubes give a maximum voltage amplification of 70 000 for an input voltage of 10 microvolts. The noise-level of the amplifier at the maximum gain was found to be equivalent to 10 microvolts at the primary of the input transformer. As the input voltage increases in amplitude the gain is reduced by the automatic volume control through the 6H6 diode. At 0.1 mV input at 1 000 cycles/sec the gain is 50 000; at 100 mV input it has been reduced to 600 times. The time constant of the automatic gain-control is about 2 seconds, and the amplifier can handle input signals of up to 0.3 volts without appreciable distorsion. The low gain at low frequencies reduces noise due to 50-cycle pick-up. The shielded input transformer Tr has a turns-ratio of 1:6 (Svenska Radio-

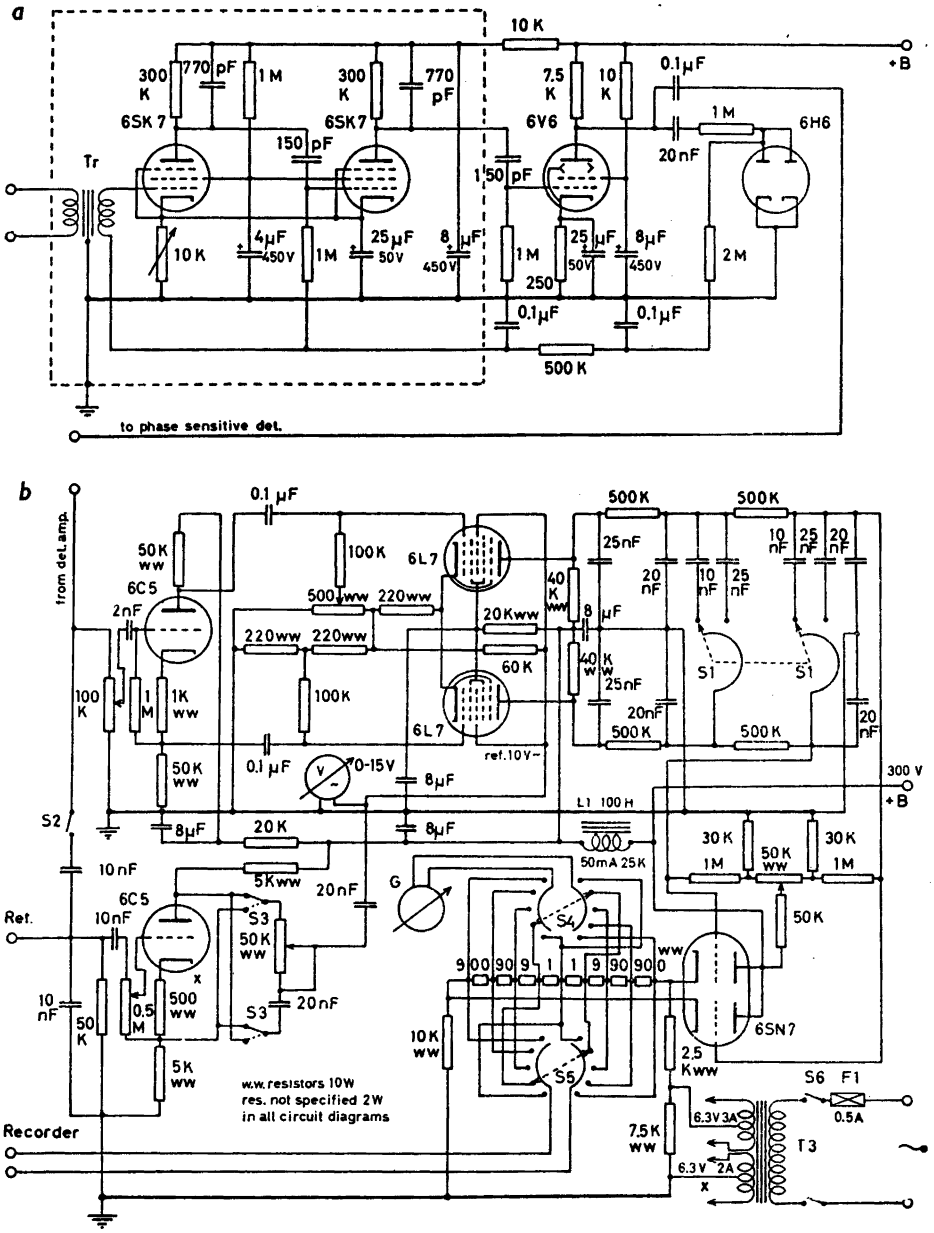

Fig. 3. a) Detector amplifier and b) phase-sensitive detector circuits.

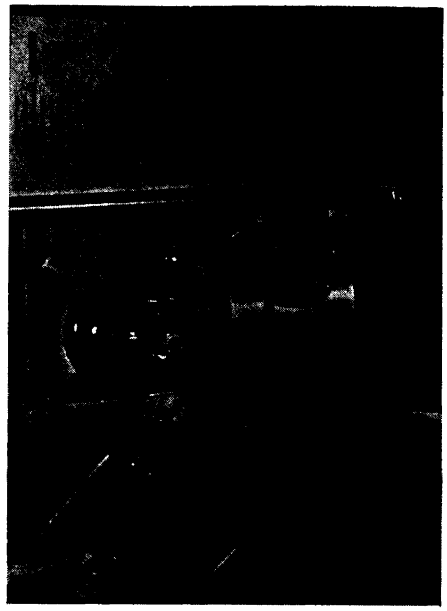

Fig. 4. Mechanical arrangement of feed-back generator in recorder.

bolaget type XLT 505). The position and orientation of this transformer have not proved critical.

Phase-sensitive detector. The circuit (Fig. 3) is almost identical with that used by Kinell [13], who also discusses the theory. (For a general discussion of phase-sensitive detectors see Ahrendt [14]). A small galvanometer with a sensitivity of 2 micro-amperes per scale division (Siemens, 450 ohms internal resistance) indicates the sign and magnitude of the direct-current output of the cathode follower which is fed to the input terminals of the recorder amplifier.

RECORDER AND ARRANGEMENT OF VELOCITY FEED BACK

A Leeds and Northrup Speedomax-G recorder with a pentravel time of 4.5 seconds across the chart is used. As shown in Fig. 4, a small direct-current generator (Pullin 5V/4798 *) is geared directly to the pen-driving motor of the recorder *via* a pair of 1:1 helical gears for crossed axles (Kremp und Söhne, Wetzlar, Germany). There must be no backlash in these gears. To prevent hunting of the servo system, part of the output of the generator is fed back to the input of the recorder amplifier *via* a mixer (Fig. 1) consisting of a 200-ohm potentiometer connected in series with one of the recorder-amplifier input leads. One of the generator terminals is connected to the movable contact,

* Obtained through Ingeniörsfirma Hugo Tillquist, Stockholm.

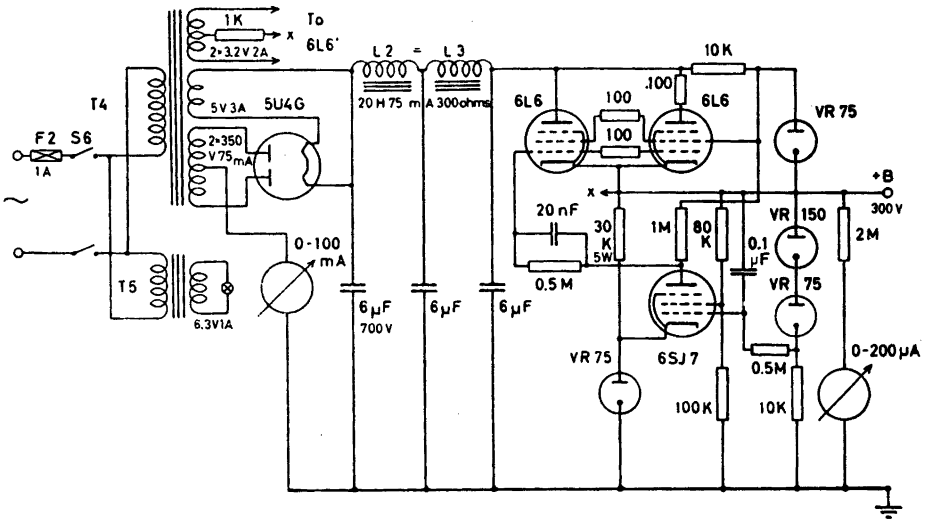

Fig. 5. Anode-voltage power supply.

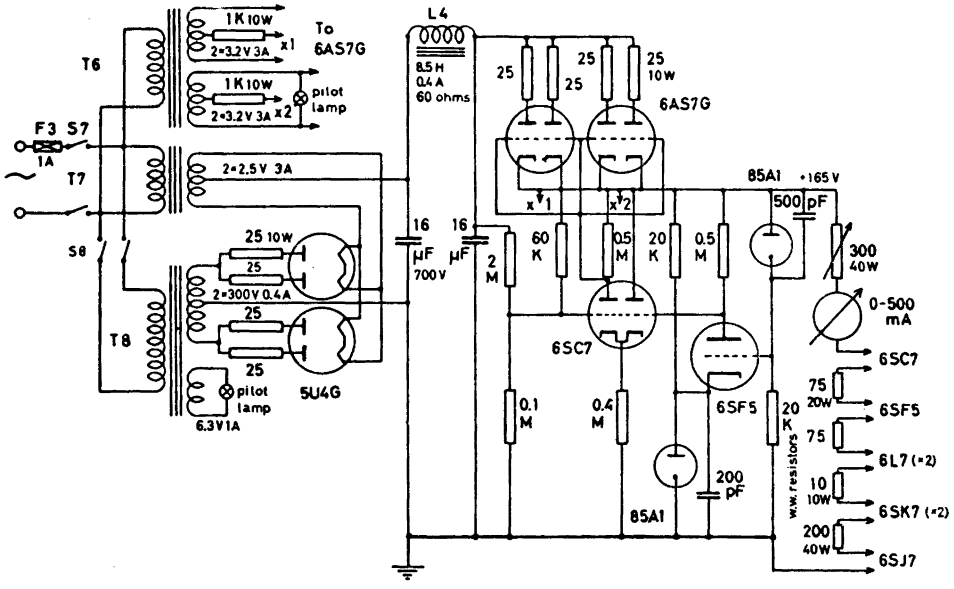

Fig. 6. Filament power supply.

and the other to one end of the potentiometer-winding. By adjusting the potentiometer the desired amount of feed-back can be introduced.

Power-supply. The stabilized anode current supply and the stabilized direct-current filament supply used are identical with those described by Kinell [13]. For convenience the circuit diagrams are reproduced in Figs. 5 and 6.

When first testing the completed apparatus in the laboratory the recordings were very disturbed by irregular 'spikes'. These were evidently caused by disturbances and transients in the 220-volt A.C. mains, as they disappeared completely when the apparatus was connected to a separate 220-volts alternating-current generator driven by a motor connected to the A.C. mains.

PERFORMANCE OF THE APPARATUS

Fig. 7 shows the response of the recorder for step-wise resistance-changes of 10 ohms each on the 100 ohm recorder range for cell-resistance of the order of 1 000 ohms. The pen-positions are reproduced within one pen-line width, *i.e.* the pen-setting precision of the recorder. The feed-back was adjusted to give a slight overshoot for the step-wise resistance change. Between the steps the paper chart was moved forwards by hand. There is complete freedom from noise.

Fig. 8 shows the response to step-wise resistance changes of 100 ohms with the paper travelling at a speed of 14" per hour (5.9 mm per minute).

The performance of the apparatus at high sensitivity is illustrated in Fig. 9, which shows the response of the recorder to resistance changes in steps of 1, 0.1, and 0.05 ohms, respectively, at a total resistance (decade box) of 5 000 ohms and a recorder-range of 6 ohms. The steps of 0.05 ohms correspond to a sensitivity of 1 part per 100 000. Taking into account variable contact resistance in the decade switches it appears that the reproducibility of the apparatus is of the order of 1:200 000, or 0.0005 per cent.

At these high sensitivities the galvanometer across the output of the phase-sensitive detector showed rapid fluctuations equivalent to resistance-changes of 0.005 ohms ($1{:}10^6$), which may be taken as representing the noise-level of the system. Superimposed upon these small rapid fluctuations were slower

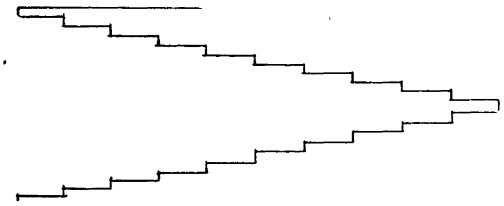

Fig. 7. Recording of step-wise resistance changes of 10 ohms at a recorder range of 100 ohms. Paper moved forward by hand between steps.

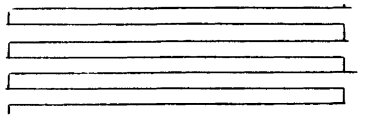

Fig. 8. Recording of step-wise resistance changes of 100 ohms at a recorder range of 200 ohms. Paper speed 5.9 mm per minute.

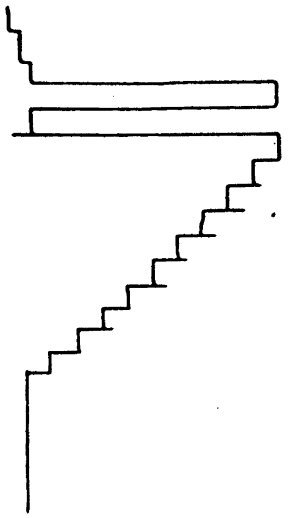

Fig. 9. Recordings of small changes in resistance at a total 'cell' resistance of 5 000 ohms and a recorder-range of 6 ohms. From above downwards: 2 steps of 0.05 ohm; 3 steps of 1 ohm; and 10 steps of 0.1 ohm. Paper speed 5.9 mm per minute.

oscillations equivalent to resistance-changes of about 0.01 ohms. These were found to be caused by small variations in the voltage of the motor generator. It seems likely that a fly-wheel on the shaft of the motor generator or the use of a larger machine * would eliminate this type of noise.

Effect of capacitative unbalance. For a cell-resistance of 500 ohms a capacitative unbalance of 400 pF introduced a zero drift of less than 0.25 ohm, or 0.05 %. The effect on the accuracy and speed of response was negligible. For a cell-resistance of 5 000 ohms the zero drift was more pronounced, and the effect on the accuracy and speed of response became marked at unbalances of about 100 pF. Under the conditions of measurement the zero drift was more marked when the capacitance was decreased, the drift for —350 pF amounting to 21.5 ohms, or about 0.4 %.

It is obvious that the ideal instrument for recording changes in electrolytic resistance should also be capable of continuously correcting errors in the capacitative balance of the bridge, as a change in resistance is usually accompanied by a change in capacitance. Drake [5] has performed some measurements on a conductivity cell using the same voltage across the cell at different conductivities of the solution (electrolyte not specified). He found that the change in capacitance was a linear function of 1/R. From this he inferred that the capacitance of the electrolytic cell is proportional to the current density. If this were true, capacitative unbalance could be corrected by altering the voltage across the bridge. It is found experimentally, however, that an increase in the current density due to an increase in the voltage across the cell has practically no effect on the effective capacitance of the cell. Both the capacitance of the cell and the current density at constant voltage are approximately proportional to the concentration of the electrolyte, but there is no direct connexion between the two.

* The machine used had a capacity of 1.8 kW.

During a run any capacitative unbalance developing may be traced on an oscilloscope connected across the output of the bridge amplifier. If the error becomes too large it may be corrected by manual adjustment. The simplest way to perform this correction automatically seems to be to arrange a separate servo system or recorder to make the adjustment at predetermined intervals as a standardizing operation. By reversal of these functions the instrument can of course be made to record capacitance changes in conducting systems. Such an instrument is being constructed.

Acknowledgements. The phase-sensitive detector and its associated equipment were built by Seve Radio, Mölnlycke, and we are indebted to Mr. S. Severinsson for his cooperation. We wish to thank Mr. P. Olsson (Uppsala) and Mr. G. Rundberg (Gothenburg) for the construction of various mechanical parts. This work has been aided in part by a grant from *The Swedish Medical Research Council.*

Studies on the Hydrolysis of Metal Ions

18. The Scandium Ion, Sc^{3+}

GEORGE BIEDERMANN, MARTIN KILPATRICK, LEWIS POKRAS and LARS GUNNAR SILLÉN

Department of Chemistry, Illinois Institute of Technology, Chicago, Ill; Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The data of Kilpatrick and Pokras concerning the hydrolysis of Sc^{3+} have been recalculated by using general methods for polynuclear complexes [3-5]. At all temperatures and ionic media studied, the data could be explained assuming the formation of "core + links" complexes of the general formula $Sc((OH)_2Sc)_n^{(3+n)+}$.

From a "direct analysis" of the data it was found that at least the complexes with $n = 1$ and $n = 2$, $Sc_2(OH)_2^{4+}$ and $Sc_3(OH)_4^{5+}$ must exist; there were also indications of the formation of higher complexes. By comparison with the calculated curves from AB II[4], a good approximation was obtained with "hypothesis IIIa". The equilibrium constants obtained with this hypothesis are listed in Table 2. Here k_0k is the equilibrium constant of the reaction $Sc^{3+} + 2\ H_2O + Sc^{3+} \rightleftharpoons Sc(OH)_2Sc^{4+} + 2\ H^+$; k is the equilibrium constant for all following steps $Sc((OH)_2Sc)_n^{(3+n)+} + 2\ H_2O + Sc^{3+} \rightleftharpoons Sc((OH)_2Sc)_{n+1}^{(4+n)+} + 2\ H^+$.

At the lowest total scandium concentration used, a small correction was necessary for the formation of the mononuclear complexes $ScOH^{2+}$ and $Sc(OH)_2^+$. For 25°C and $I = 1.0$ M, the following values of the equilibrium constants were calculated: for $Sc^{3+} + H_2O \rightleftharpoons ScOH^{2+} + H^+$ $\log \beta_1 = -5.1 \pm 0.2$, and for $Sc^{3+} + 2\ H_2O \rightleftharpoons Sc(OH)_2^+ + 2\ H^+$ $\log \beta_2 = -10.2 \pm 0.5$.

Some time ago, Kilpatrick and Pokras published the results of a very careful investigation on the hydrolysis of the Sc^{3+} ion. The most extensive measurements [1] were made at 25°C with an ionic strength 1.0 M (with $NaClO_4$). In a following paper [2], data were also given at other ionic strengths (0.01 M, 0.1 M, and 0.5 M at 25°C) and for 10°C and 40°C at ionic strength 1.0 M.

The hydrogen ion concentration at equilibrium was determined with a quinhydrone electrode since spectrophotometric studies had indicated no complex formation between Sc^{3+} and quinhydrone. The equilibria were found to be established rapidly.

Kilpatrick and Pokras concluded from their data that the chief products of the hydrolysis are $ScOH^{2+}$ and $Sc_2(OH)_2^{4+}$, and that higher polynuclear complexes are probably formed.

In the meantime, general methods for treating polynuclear complex equilibria have been given (AB I[3], AB II[4], AB IV[5]), and applied to the hydrolysis of a number of ions (parts VIII—XIV of this series [7–11]). In the present paper, the same methods have been applied to Kilpatrick and Pokras' data for scandium [1,2], the treatment on the whole confirming the conclusions of these authors and providing, in addition, some information on the higher complexes.

Notation

We shall use the following notation: h is the equilibrium concentration of H^+, b the concentration of free Sc^{3+}, B the total scandium concentration (denoted by C in [1,2]) and Z the average number of hydrogen ions set free per Sc. The ionic strength (as defined in [1,2]) is denoted by I. Instead of Z, the original papers [1,2] give the "hydroxyl number" n. The connection between Z and n is easily shown. Since the solutions are always acidic, the total number of bound OH groups per litre, $BZ = nB + h$, or $Z = n + hB^{-1}$. All concentrations are in M (mole/l) if not otherwise stated.

THE DATA FOR 25°C and I = 1.0 M

Formula of the complexes

The mathematical analysis of the data will be based chiefly on the data for 25°C and $I = 1.0$ since they are much more extensive than those for other temperatures and ionic strengths.

First of all, the original data n $(\log h)_B$ were recalculated and plotted in the form $Z(\log h)_B$. In the resulting diagram, Fig. 1, the points for each of the values of B used (1.25, 2.5, 5, 10, and 20 mM) are given with different symbols. Since the curves for different values of B do not coincide, the process cannot be explained assuming only mononuclear complexes; polynuclear species must also be formed. Moreover, the points are seen to lie on practically parallel curves. From the spacing of the curves, the derivative

$$\left(\frac{\partial \log B}{\partial \log h}\right)_Z \tag{1}$$

is found to be roughly 2.2. The value 2.0 was tested by plotting $y = \frac{1}{2} Z$ as a function of

$$x = \log B - 2 \log h \tag{2}$$

(*cf.* part VIII[7], 14—15 a). The ordinate was taken as

$$y = \frac{Z}{2} \tag{3}$$

to facilitate a comparison with the calculated curves from AB II[4].

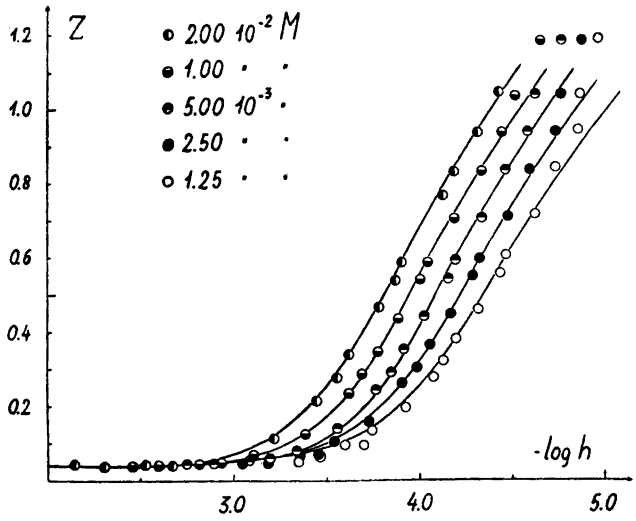

Fig. 1. Hydrolysis of Sc^{3+}. Z *(average number of OH bound per Sc) as a function of log* h, *for five different total concentrations* B. *Experimental data*[1]*: symbols, see figure. Curves calculated assuming a polynuclear unlimited mechanism (14) (IIIa, with* $k_0 = 5$, *log* $k = -6.8$), *together with a mononuclear reaction with log* $\beta_1 = -4.9$; *a correction of +0.04 has been added to the calculated* Z *values.*

From the diagram $y(x)$, Fig. 2, it is seen that the points fall on practically the same curve; only for the very lowest B value (1.25 mM) is a slight positive deviation noted while, for $x > 7$, all the data are seen to diverge.

Disregarding for a moment these small deviations, we would find that Z is a function of log B — 2 log h which, according to AB I[3] and VIII[7], implies

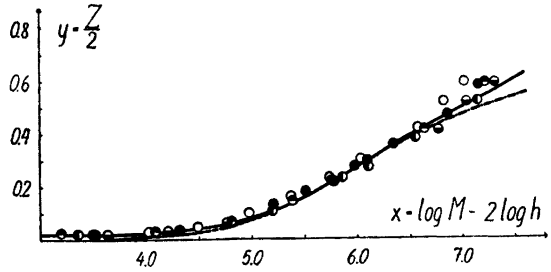

Fig. 2. Hydrolysis of Sc^{3+}. $y = \frac{1}{2}Z$ *as a function of* $x = \log B - 2 \log h$. *Points: experimental data*[1], *symbols as in Fig. 1. Full drawn curve calculated with mechanism IIIa,* $k_0 = 5$, *log* $k = -6.8$, *adding +0.02 to the calculated* y *values. Dotted curve: only two complexes, log* $k_1 = -6.1$, *log* $k_2 = -12.9$; y *corrected; for* $x < 6.4$ *it practically coincides with the full-drawn curve. Broken curve: IIIa,* $k_0 = 5$, *log* $k = -6.7$, *no correction to* y. *For* $x > 5.2$, *it practically coincides with the full-drawn curve.*

that all the predominating complex species can be written in the general "core + links" form

$$Sc((OH)_2Sc)_n^{(3+n)+} \tag{4}$$

The deviations at the lowest B values can be ascribed to the formation of mononuclear complexes, especially $ScOH^{2+}$ (see below), whereas the irregular behavior around $x = 7.0$ may be caused by some slow process, *e.g.* irreversible precipitation.

To the left in Fig. 2 it is seen that, with decreasing x, y approaches a value of 0.02 rather than 0. Similarly Z in Fig. 1 approaches 0.04 instead of 0. This behavior indicates a small systematic error, perhaps in the analysis of the perchlorate concentration in the scandium stock solution.

We shall first treat the main reaction, which leads to the formation of polynuclear complexes $Sc((OH)_2Sc)_n^{(3+n)+}$, and then consider the correction for the mononuclear reaction.

Direct analysis of $y(x)$

We could now draw a smooth curve through the data $y(x)$ and apply equations (AB II, 14 and 15) which yield the function $g(u)$ where

$$u = bh^{-2} = [Sc^{3+}]h^{-2} \tag{5}$$

$$g = \sum k_n u^n = k_1 u + k_2 u^2 + \ldots \tag{6}$$

and k_n is the equilibrium constant of the reaction:

$$(n+1)Sc^{3+} + 2\,n\,H_2O \rightleftharpoons Sc((OH)_2Sc)_n^{(3+n)+} + 2\,n\,H^+;$$
$$k_n = c_n h^{2n} b^{-(n+1)} = c_n b^{-1} u^{-n} \tag{7}$$

(c_n = concentration of n:th complex).

This procedure involves no additional assumptions besides the one, corroborated by the fitting of the data with a single $y(x)$ curve, that all complexes present in appreciable amounts can be written in the "core + links" form (4).

Fig. 3 gives the results, recalculated to

$$gu^{-1} = k_1 + k_2 u + k_3 u^2 + \ldots \tag{8}$$

as a function of u. The points marked ◐ were calculated from a smooth curve, rather similar to the dashed curve in Fig. 2; corrections applied to the integration constant could not eliminate the irregular behavior for low x.

For the dots ○, the experimental y values were corrected by subtracting 0.02 (assuming a systematic error). Disregarding deviations at the lowest values of u, which are very sensitive to small errors in y, the points are seen to lie approximately on a straight line, from the intercept and slope of which we estimate

$$k_1 = 10^{-6.1 \pm 0.1}\ M; \qquad k_2 = 10^{-12.9 \pm 0.4}\ M^2 \tag{9}$$

At the highest u values the points are seen to deviate upwards, indicating the formation of higher complexes; it did not seem possible to estimate k_3 accurately.

The $y(x)$ curve, calculated for the values (9) of k_1 and k_2, is given as a dotted line in Fig. 2.

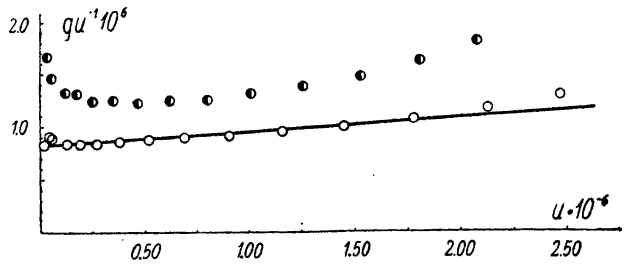

Fig. 3. gu^{-1} *as a function of* u *calculated by "direct analysis" of* y(x). *Circles* ◐ *calculated without correction to* y, *circles* O *by correcting the experimental* y *with* -0.02. *Line:* $gu^{-1} = 0.8 \cdot 10^{-6} + 1.25 \cdot 10^{-13}\,u = 10^{-6.1} + u \cdot 10^{-12.9}$.

From the $g(u)$ data we can calculate also the average number of links per complex

$$\bar{n} = \frac{\mathrm{d} \log g}{\mathrm{d} \log u} \tag{10}$$

To compute $\bar{n}$ it is convenient to apply the equation

$$\bar{n} = y(1 - y - F^{-1})^{-1} \tag{11}$$

where

$$\log F = y \log e + \int_{-\infty}^{x} y\, dx \tag{12}$$

Eqn. (11) can be obtained by combining (10) with eqns. (14) and (15) of AB II[4].

In Fig. 4 $\bar{n}$ is plotted as a function of log u. $\bar{n}$ is seen to start at about 0.90 instead of unity; this is explained by the inaccuracy of the numerical integration for low u values. As u increases, $\bar{n}$ rises monotonically, attaining the maximum value 1.84. Thus the conclusion can be drawn, in agreement with the preceding calculation, that complexes with $n = 1$ and 2 predominate in the u range studied.

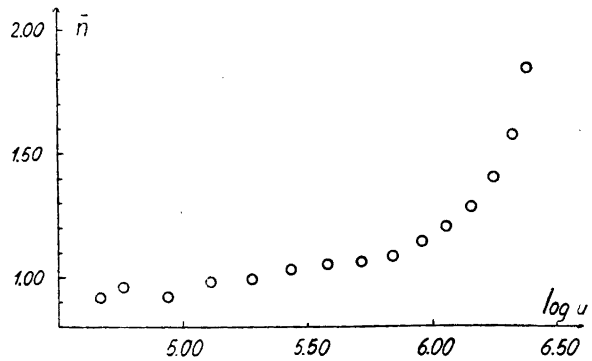

Fig. 4. $\bar{n}$ (*equation 10*) *as a function of log* u. *A correction of* -0.02 *has been added to the experimental* y *values.*

Comparison with $y(x)$ curves for simple mechanisms

Another way of treating the data is to compare the experimental $y(x)$ data with the $y(X)$ curves calculated for various simple mechanisms in AB II[4]. With mechanism I (precipitate formed, in this case *e.g.* $Sc(OH)_2ClO_4$), no good fit could be found. With hypothesis II (only one complex $Sc((OH)_2Sc)_N^{3+N}$ formed), an approximate agreement was found with $N = 1$ for low values of x. With increasing x, y became systematically higher than the calculated curve, showing that complexes higher than $Sc_2(OH)_2^{4+}$ are also formed.

Good agreement could, however, be obtained with the hypotheses IIIa—c assuming a repeated reaction, with the formation of complexes with all n values $n = 1, 2 \ldots$ Since the accuracy did not permit a distinction between IIIa, IIIb, and IIIc, only the simplest hypothesis IIIa was considered in detail:

$$\text{IIIa: } k_n = k_0 k^n \tag{13}$$

This hypothesis has been found satisfactory with Th^{4+}, UO_2^{2+}, and In^{3+} (parts IX[8], X[9], XIV[11]). Except for the lowest y, a good agreement was obtained with hypothesis IIIa, assuming $k_0 = 5$ and $\log k = -6.7 \pm 0.1$; this is the broken curve in Fig. 2.

A still better agreement in the whole range was obtained after correcting the calculated y with $+0.02$, assuming $k_0 = 5$ and $\log k = -6.8 \pm 0.1$ (full-drawn curve in Fig. 2). In the range $x > 5.2$ the curves practically coincide.

We would thus have the reactions and equilibrium constants

$$2\ Sc^{3+} + 2\ H_2O \rightleftharpoons Sc(OH)_2Sc^{4+} + 2\ H^+;\ k_1 = k_0 k = 10^{-6.1 \pm 0.1} \tag{14a}$$

and for all consecutive steps

$$Sc((OH)_2Sc)_n^{(3+n)+} + 2\ H_2O + Sc^{3+} \rightleftharpoons Sc((OH)_2Sc)_{n+1}^{(4+n)+} + 2\ H^+;\quad k_{n+1}/k_n = k = 10^{-6.8 \pm 0.1} \tag{14b}$$

This result, as far as the first two constants are concerned ($k_1 = 10^{-6.1}$, $k_2 = 10^{-12.9}$) is identical with that obtained by the direct analysis (9), and the first one agrees well with the value $k_1 = 10^{-6.0}$ given by Kilpatrick and Pokras [2] (Table IV, where the present k_1 is denoted by "K_0").

In fact, Kilpatrick and Pokras' mechanism, the one (9) obtained by direct analysis, and IIIa (13, 14) may be regarded as three successive approximations to the real mechanism. Kilpatrick and Pokras considered only the first complex, $Sc_2(OH)_2^{4+}$, whereas the data force us to assume also a second complex $Sc_3(OH)_4^{5+}$. Moreover the data indicate that higher complexes are formed, as implied by IIIa. Assuming IIIa and the constants (14) one may calculate the fraction of all Sc present in the form of the various complexes

$$\alpha_0 = [Sc^{3+}]/B;\ \alpha_1 = 2\ c_1/B;\ \ldots\ \alpha_n = (n+1)\ c_n/B \tag{15}$$

where c_n is the concentration of the n:th complex. One finds

$$\text{for } u = 1.5 \cdot 10^6 (Z = 0.9),\ \alpha_0 = 0.20,\ \alpha_1 = 0.51,\ \alpha_2 = 0.19,\ \alpha_3 = 0.06 \tag{16a}$$

$$\text{for } u = 2.4 \cdot 10^6 (Z = 1.2),\ \alpha_0 = 0.11,\ \alpha_1 = 0.41,\ \alpha_2 = 0.24,\ \alpha_3 = 0.13 \tag{16b}$$

Thus the complexes with n higher than 2 would be appreciable only in the region where the data begin to diverge.

Mononuclear complexes

In order to explain the deviations of the experimental data for the lowest B, 1.25 mM, in the $y(x)$ diagram (Fig. 2), it will be assumed that, besides the main hydrolysis products, $Sc((OH)_2Sc)_n$, *mononuclear* species are also present in appreciable concentrations.

It may be inferred from the $y(x)$ diagram that, even for the lowest B, the concentration of the mononuclear ions may amount only to a few percent of the total concentration of the hydrolysis products. Therefore it would not be practical to compute the formation constants of the mononuclear species by using some type of deviation function; this would be inevitably too strongly influenced by the uncertainty in k.

To find simultaneously the equilibrium constants of the polynuclear and mononuclear mechanisms, we shall use an approach [5] which has been worked out especially for such an unfavorable case.

This method is based on the consideration of the function $\log B(x)_Z$, where $x = \log B - t \log h$, as in (2). When only polynuclear complexes of the "core + links" type are formed, the family of functions $\log B(x)_Z$ is represented by lines parallel with the $\log B$ axis, since $x = \text{const.}$ for $Z = \text{const.}$ When mononuclear ions are present exclusively, $\log B(x)_Z$ consists of lines with a slope of unity, since $h = \text{const.}$ for $Z = \text{const.}$ In the intermediate range where both mononuclear and polynuclear species exist in comparable amounts, $\log B(x)_Z$ forms curves with continuously increasing slope.

Thus if the plot $\log B(x)_Z$ is made from the experimental data, a deviation of the points from a vertical line at low B values indicates that mononuclear ions begin to be formed in appreciable amounts. Such a deviation is more conspicuous than deviations of the data for low B from the $y(x)$ curve valid for high B.

The $\log B(x)_Z$ diagram calculated from Kilpatrick and Pokras' data is shown in Fig. 5; points for low B clearly indicate the presence of mononuclear ions.

In order to calculate the formation constants of the mononuclear complexes and a more accurate value for $\log k$, the $\log B(x)_Z$ data will be compared with the calculated curves

$$\log B(X)_Z$$

where $X = x + \log k$, $\log \boldsymbol{B} = \log B + \log k - t \log \beta_1$ (*cf.* eqns. (13) and (14) of [5]). β_1 is the equilibrium constant of the reaction

$$Sc^{3+} + H_2O \rightleftharpoons ScOH^{2+} + H^+ \qquad \beta_1 = [ScOH^{2+}]h[Sc^{3+}]^{-1}$$

If the data are superimposed on the calculated curves $\log B(X)_Z$, the differences $X - x$ and $\log \boldsymbol{B} - \log B$ give in the position of best agreement the most probable values of $\log k$ and $\log \beta_1$.

In the first instance, $\log B(X)_Z$ was calculated by assuming that only one mononuclear species is formed, namely $ScOH^{2+}$. The fit obtained is shown in Fig. 5a. Up to $Z = 0.6$, the agreement is satisfactory but, for higher values of Z, the deviations increase gradually.

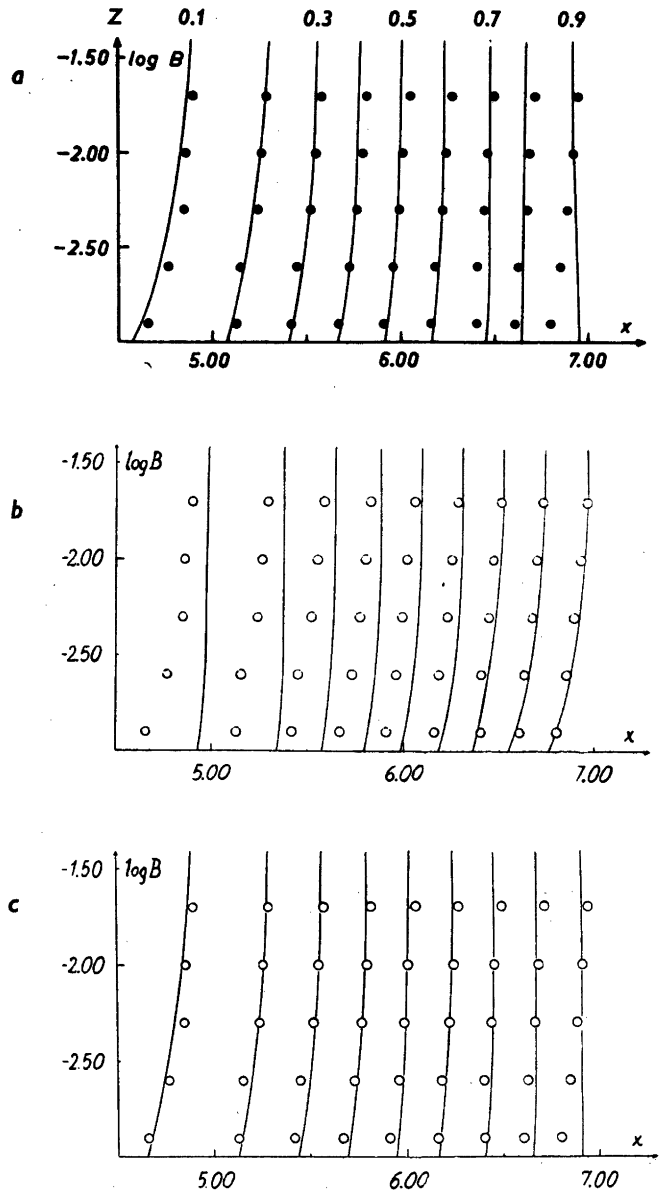

Fig. 5 a, b, c. log B *as a function of* x *for* Z *values of 0.1—0.9. Circles: experimental points. The curves have been calculated assuming the equilibrium constants given in Table 1.*

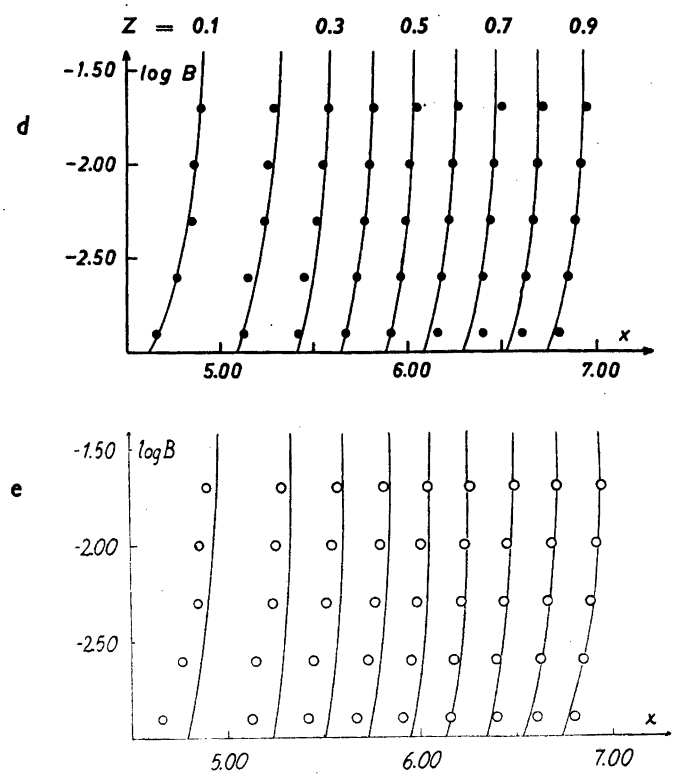

Fig. 5 d, e. log B *as a function of* x *for* Z *values of 0.1—0.9. Circles: experimental points. The curves have been calculated assuming the equilibrium constants given in Table 1.*

Next, log $B(X)_Z$ was computed assuming the equilibrium

$$Sc^{3+} + 2\ H_2O \rightleftharpoons Sc(OH)_2^+ + 2\ H^+ \qquad \beta_2 = [Sc(OH)_2^+]h^2[Sc^{3+}]^{-1}$$

In this case we have *

$$\log B = \log B + \log k - \frac{t}{2} \log \beta_2$$

$$X = x + \log k$$

As Fig. 5b shows, the agreement is acceptable for $Z > 0.6$ but, as Z is decreased, the deviations rapidly increase.

To obtain an agreement for the whole range of Z investigated, we must thus assume that $ScOH^{2+}$ and $Sc(OH)_2^+$ are both present in appreciable amounts.

* Introducing the auxiliary normalized variable $\alpha = \beta_2 h^{-2}$ we get by eqn. (8) of [5] $\log B = \log v - \log k - \frac{t}{2}$ (log α—log β_2) + log(1 + α + g + vg') where $v = k\ u$ and $g = \sum k_n u^n$. Thus for a constant value of Z $\log B = \log B + \log k - \frac{t}{2} \log \beta_2$ is a function of v only.

In this case where three constants, β_1, β_2 and k, should be determined, some assumption must be made on the ratio

$$\beta_2\beta_1^{-2} = l$$

in order to calculate $\log B(X)_Z$. With $l = 1$, the agreement is very satisfactory (Fig. 5d). With $l = 0.1$ (Fig. 5c), the deviations at the highest Z values indicate that l was chosen somewhat too low, on the other hand, with $l = 10$ (Fig. 5e) a reasonable fit is obtained only for $Z > 0.6$, indicating that a too high value of l was taken.

The constants obtained using different assumptions are summarized in Table 1.

Table 1.

l	0	0.1	1	10	infinite
$\log k$	−6.85	−6.84	−6.87	−6.88	−6.90
$\log \beta_1$	−5.0	−5.1	−5.1	(−5.6)	−
$\log \beta_2$	−	(−11.2)	−10.2	−10.2	−10.2
	Fig. 5a	Fig. 5c	Fig. 5d	Fig. 5e	Fig. 5b

We can estimate as the most probable values

$$\log k = -6.87 \pm 0.10$$
$$\log \beta_1 = -5.1 \pm 0.2$$
$$\log \beta_2 = -10.2 \pm 0.5$$

This $\log \beta_1$ value is in good agreement with that given by Kilpatrick and Pokras [1]: -4.9 ± 0.1.

We have found previously, assuming a pure polynuclear mechanism, that $\log k = -6.8 \pm 0.1$; thus no serious error was introduced by neglecting the mononuclear mechanism at $B \geq 2.5$ mM.

DATA AT OTHER TEMPERATURES AND IONIC STRENGTHS

For the other temperatures and ionic strengths, the data for only two values of $\log B$ were generally available. The data were plotted as before, giving $y = Z/2$ as a function of $x = \log B - 2 \log h$ (Fig. 6a, b; Fig. 7a, b). The points for $B = 1.25$ mM were in general found to be somewhat higher (especially for 40° C) than those for the higher concentration (usually 10 mM). Since the effect is rather small, no attempt was made to use these data for calculating accurately the variation of β_1 or β_2 with ionic strength and temperature.

The shape of the curves could be well explained with mechanism IIIa in all cases, assuming $k_0 = 5$ (10 for the lower values of I). The correction +0.02 was made to the calculated y, to account for a possible small analytical error (see above). The results are summarized in Table 2.

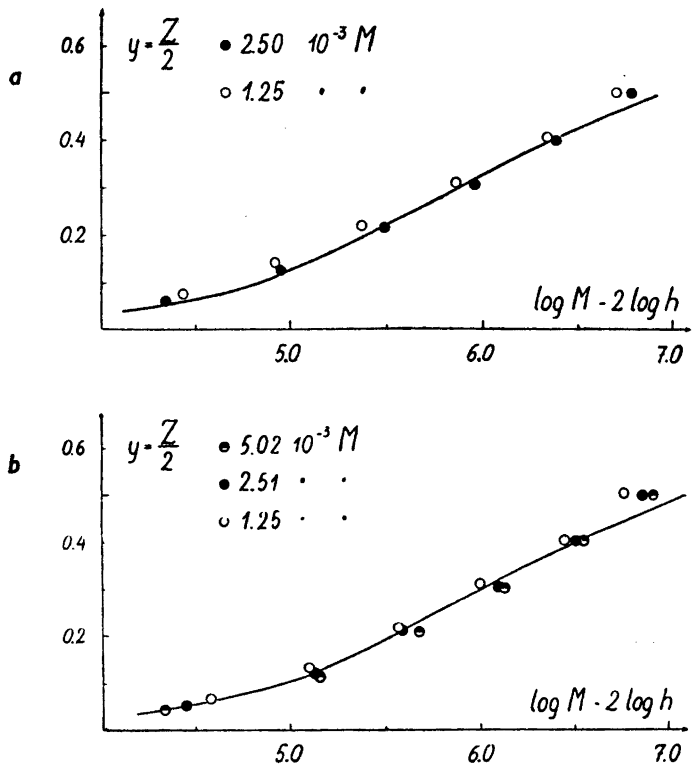

Fig. 6. Hydrolysis of Sc^{3+}. Data[2] for 25°C and ionic strengths 0.5 and 0.1 M plotted in the form y(x), *assuming* t = 2. *Fig. 6a:* I = *0.1 M; curve: IIIa,* $k_0 = 10$, *log* k = −6.8. *Fig. 6b:* I = *0.5 M; curve:IIIa,* $k_0 = 10$, *log* k = −6.9.

Table 2

Temperature °C	*I* M	k_0	log *k*	log k_0k = log k_1	log k_1[2]
25	1.00	5	−6.87 ± 0.1	−6.17 ± 0.1	−6.00
25	0.50	10	−6.9 ± 0.2	−5.9 ± 0.2	−5.90
25	0.10	10	−6.8 ± 0.2	−5.8 ± 0.2	−5.67
10	1.00	5	−7.3 ± 0.2	−6.6 ± 0.2	−6.66
40	1.00	5	−6.2 ± 0.2	−5.5 ± 0.2	−5.50

The last column gives the log k_1 ("log K_0") values given by Kilpatrick and Pokras [2] who, however, considered only the first polynuclear complex. The agreement is very satisfactory.

The formation of the polynuclear complexes is favored by increasing the temperature. From the temperature variation of the constants we may calculate, both for the first step (14a) and for the following (14b), values for ΔH of about 15 kcal, and values for ΔS of about 20 cal degree^{-1}, in good agreement with Kilpatrick and Pokras [2].

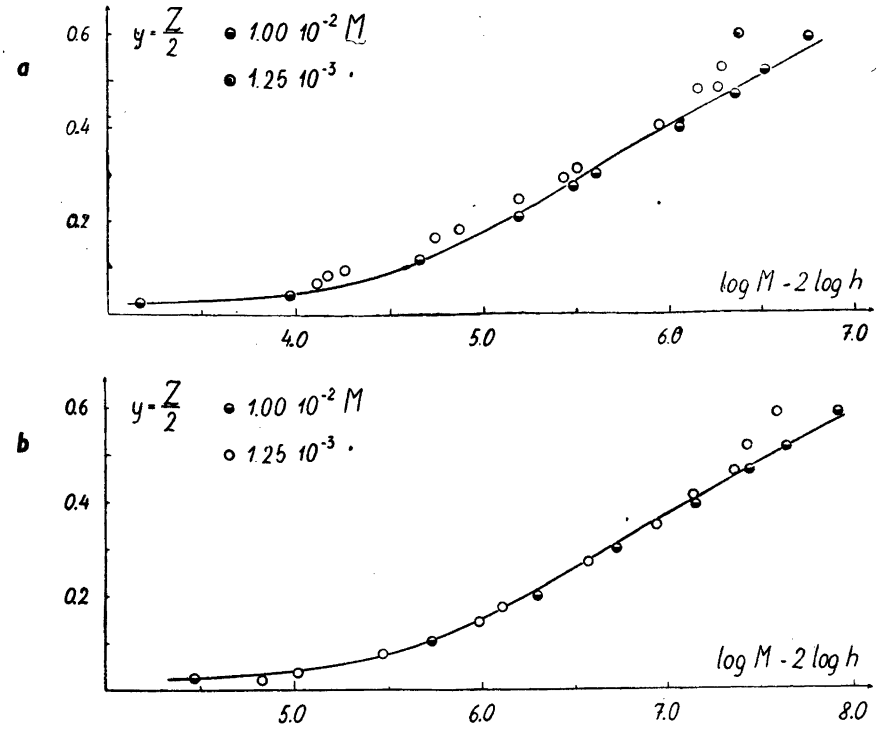

Fig. 7. Hydrolysis of Sc^{3+}. Data[3] for 10°C and 40°C plotted in the form y(x), *assuming* t = 2. *Fig. 7a: 40°C,* I = *1.00 M; curve: IIIa,* k_0 = *5, log* k = −*6.2. Fig .7b: 10°C,* I = *1.00 M; curve: IIIa,* k_0 = *5, log* k = −*7.3.*

From Table 2 it seems that log k is not much affected by changes in I. The increase in log k_0k would imply an increasing predominance of the first complex, $Sc_2(OH)_2^{4+}$, with decreasing I.

DISCUSSION

We may thus conclude that, for all temperatures and ionic media studied by Kilpatrick and Pokras, the data can be explained by the same mechanism, namely the formation of a series of "core+links" complexes, $Sc((OH)_2Sc)_n^{(3+n)+}$, with a small correction for the mononuclear complexes $ScOH^{2+}$ and $Sc(OH)_2^+$.

Complexes of the same general formula have been found for Fe^{3+} (part VII[6]), UO_2^{2+} (part X[9]), and In^{3+} (part XIV[11]). Scandium is seen to take an intermediate place in the range in the following respect. For Fe^{3+}, the data could be explained assuming only one polynuclear complex, with $n = 1$. For Sc^{3+}, we have found that at least two complexes, with $n = 1$ and 2, must be considered. For UO_2^{2+} and In^{3+} at least $n = 3$ must also be considered. However, it seems that the differences are only gradual. One may imagine

that in all cases an unlimited series of complexes may be formed but that the higher complexes do not reach appreciable concentrations within the experimental range which is limited by the precipitation of the hydroxide or some other solid phase at a sufficiently high value of Z.

Another type of reaction seems to be found for Al^{3+}, where the rather scarce data are best explained assuming only one complex, of some complicated composition like $Al_6(OH)_{15}^{3+}$ (part XI[10]). Recent crystal structure data suggest the existence of complexes $Al_{13}(OH)_{32}^{7+}$ [12].

The Basicity Constant of *p*-Benzoquinone

Comparison of the Quinhydrone Half-cell with the Hydrogen Half-cell in $HClO_4$-$NaClO_4$ Ionic Medium

GEORGE BIEDERMANN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Deviations between the quinhydrone and hydrogen half-cells at high acidities in the ionic medium $HClO_4$-$NaClO_4$ at 25°C can be interpreted by assuming the equilibrium

$$OC_6H_4OH^+ \rightleftharpoons OC_6H_4O + H^+, \text{ with } \log K_a = 1.0 \pm 0.2.$$

Investigations on cells containing quinhydrone and hydrogen electrodes [1] have established that in acid solutions of low ionic strength the quinhydrone half-cell can be considered to be equivalent to the hydrogen half-cell. This implies that under the conditions stated the electrode process

$$\text{quinone} + 2\ H^+ + 2\ e^- \rightleftharpoons \text{hydroquinone}$$

is reversible and the ratio of the activities of quinone and hydroquinone, $a_Q a_{QH_2}^{-1}$, is constant. As the ionic strength is increased, $\log (a_Q a_{QH_2}^{-1})$ is found to vary approximately linearly [1] with the concentration of the dissolved electrolytes. The dependence of the activity ratio on the composition of the solution is usually referred to as the "salt error" of the quinhydrone electrode and is explained by assuming that the dissolved substances influence differently the activity factors of quinone and hydroquinone.

Though the salt error introduces a complication, the quinhydrone electrode offers a number of advantages. It comes rapidly to equilibrium and dissolved air is without effect; in addition, the standard potential of $H^+/QH_2Q(s),Pt$ is +699.3 mV at 25°C [1] which makes it applicable to a number of systems which would react with H_2. On account of these features the quinhydrone half-cell has been extensively used to investigate protolytic reactions. So it was often employed to study the hydrolysis equilibria of metal ions [2–7]. These studies on hydrolysis were all carried out in a constant ionic medium [8]. The solutions were made to contain 1 M or 3 M ClO_4^- by the addition of $NaClO_4$, the concentration of the metal ion to be studied was kept low and the hydrogen ion concentration was varied by adding $HClO_4$ or $NaHCO_3$.

In connection with these hydrolysis studies, it was therefore of interest to compare the quinhydrone half-cell with the hydrogen half-cell and thus to ascertain whether $a_Q a_{QH_2}^{-1}$ varies as Na^+ is replaced by H^+ in the ionic media $[ClO_4^-] = 3$ M and 1 M.

EXPERIMENTAL RESULTS

For experimental details reference is made to previous work [8]. The emfs of the following cells were studied at 25°C

— CE/solution S, quinhydrone(s)/Pt + (A)

— Pt, H_2/solution S/CE+ (B)

Here CE denotes the half-cell

Hg, Hg_2Cl_2/4 M NaCl/3 M $NaClO_4$/,

and solution S had the general composition

h M H^+, (3.000 — h) M Na^+, 3.000 M ClO_4^-.

h ranged from 0.0100 to 0.600 M.

The emf of cell (A) can be written at 25°C

$$E_A = E_{0A} + 59.16 \log h + 29.58 \log \left(\frac{a_Q}{a_{QH_2}}\right) + E_j \quad (1)$$

that of cell (B) at $p_{H_2} = 1$ atm

$$E_B = E_{0B} - 59.16 \log h - E_j \quad (2)$$

where E_{0A} and E_{0B} are constants and E_j denotes the liquid junction potential between solution S and 3 M $NaClO_4$. The standard state is defined so that the activity factors of the solutes approximate to unity if the solutes are present in negligible concentrations in the solvent 3 M $NaClO_4$. In previous work [8], evidence was given that f_{H^+} remains practically constant as Na^+ is replaced by H^+ up to $h = 0.6$ M; therefore the concentration of hydrogen ions can be used in (1) and (2) instead of the activity.

If $a_Q a_{QH_2}^{-1}$ remained unchanged as h is varied, $E_A(h) + E_B(h)$ would be a constant. From the plots $E_A(h)$ and $E_B(h)$, it became apparent however that $E_A(h) + E_B(h)$, and thus $a_Q a_{QH_2}^{-1}$, decreases monotonically with h.

In order to analyze these data in more detail the function

$$\delta = \delta(h) = 29.58 \log \left(\frac{a_{QH_2}}{a_Q}\right) \quad (3)$$

is needed. To obtain δ the values of E_{0A} and E_{0B} are required. These can be found by extrapolation. When h approaches zero, E_j and δ become negligible, consequently $E_A - 59.16 \log h = E'_A$ and $E_B + 59.16 \log h = E'_B$ approach E_{0A} and E_{0B}. On plotting E'_A and E'_B against h, both functions proved to be linear up to $h = 0.250$ M. Therefore the error involved in the extrapolations did not exceed ± 0.05 mV, which is the average uncertainty of the emf measurements.

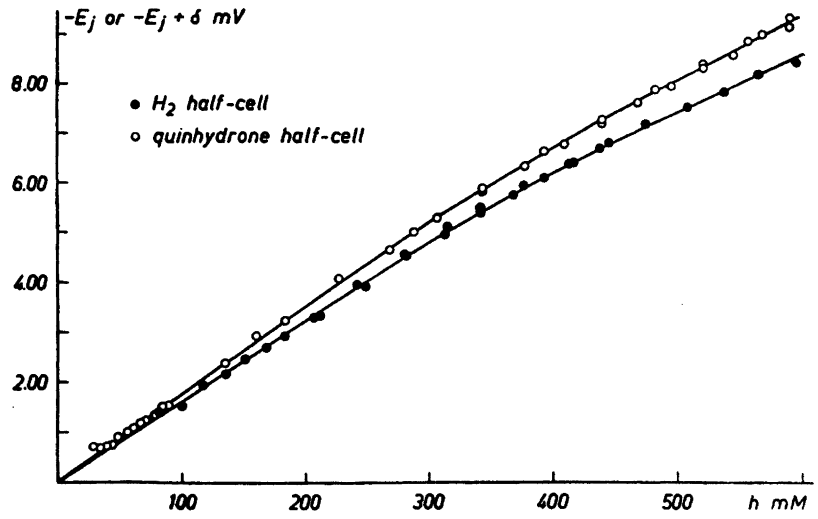

Fig. 1. $E_j - \delta$ *(equation 4) and* E_j *(equation 5) as functions of* h. *The upper curve represents the equation* $E_j - \delta = -59.16 \log\left(1 + \frac{2.00}{3.000}\,h\right) - 29.58 \log(1 + 0.1\,h)$ *mV. The lower curve:* $E_j = -59.16 \log\left(1 + \frac{2.00}{3.000}\,h\right)$ *mV.*

Using these extrapolated E_{0A} and E_{0B} values

$$E_A - E_{0A} - 59.16 \log h = 29.58 \log \left(\frac{a_Q}{a_{QH_2}}\right) + E_j = E_j - \delta \qquad (4)$$

and

$$E_{0B} - E_B - 59.16 \log h = E_j \qquad (5)$$

have been computed as functions of h, these data being plotted in Fig. 1. A smooth curve has been drawn through each set of experimental points. It was found that the curve describing the measurements with the hydrogen electrode coincides within 0.10 mV with the equation

$$E_j = -59.16 \log \left(1 + \frac{2.00\,h}{3.000}\right) \text{mV} \qquad (6)$$

which was found previously [8] to give a good fit in the whole range of h studied.

With the help of these curves, δ, which is equal to (5)—(4), was read off at a number of h values. These δ values are plotted *versus* log h in Fig. 2, where the length of the vertical lines indicates the probable error.

Solutions of $[ClO_4^-] = 1$ M have also been studied. Measurements with silver and hydrogen half-cells have indicated that, in this ionic medium, the activity factors remain constant up to $h \sim 0.100$ M. Therefore the measurements were not extended over $h = 0.200$ M. A comparison of the quinhydrone half-cell with the hydrogen half-cell has shown in this case too that δ increases gradually with h; at $h = 0.200$ M, δ attains a value of 0.20 mV.

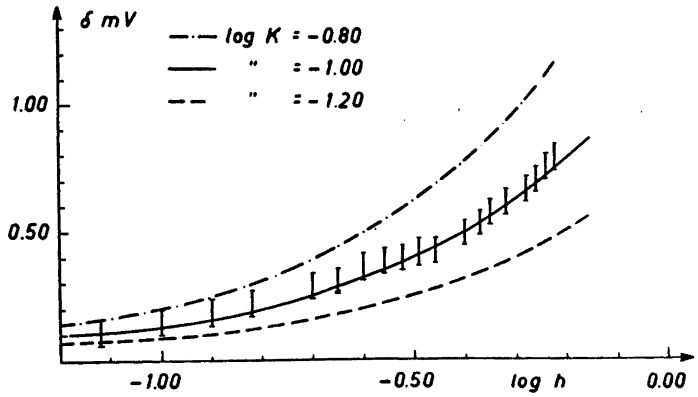

Fig. 2. δ (equation 3) as a function of log h. *Curves calculated with log* K = *−0.80, −1.00 and −1.20.*

DISCUSSION

Previous measurements on the variation of $a_Q a_{QH_2}^{-1}$ have been made [1] in solutions of varying ionic strength and the results have been explained by assuming that the ratio of the activity factors of Q and QH_2 changes with the composition of the solution. This assumption does not seem to be probable in the present case, where only solutions of constant ionic strength were investigated.

It has been shown [8] that, in the ionic medium $[ClO_4^-] = 3$ M, the activity factors of a number of positive ions of different charge, present in concentrations which are small compared with the $[ClO_4^-]$, remain practically constant as Na^+ is replaced by H^+ up to $h = 0.600$ M. It seems reasonable to expect that the ratio of the activity factors of the two *uncharged* species, quinone and hydroquinone, which are present in small concentrations, will not change in the h range where the activity factors of positive ions remain constant.

Assuming the constancy of $f_{QH_2} f_Q^{-1}$, the experimental $\delta(h)$ data are to be explained by the variation of the *concentration* ratio $[QH_2][Q]^{-1}$. Since this ratio increases with h (see Fig. 2), the simplest assumption seems to be that quinone, as a base, reacts with H^+ forming the corresponding acid $OC_6H_4OH^+$. Thus the equilibrium is established:

$$OC_6H_4O + H^+ \rightleftharpoons OC_6H_4OH^+ \qquad K = \frac{[QH^+]}{[Q]h} = K_a^{-1} \tag{7}$$

The acidity constant of hydroquinone is so small, $pK_a \sim 10$ ([9, 10]), that its ionization is negligible in the h range studied.

In order to compute the equilibrium constant K, the solubility and dissociation equilibria of quinhydrone must first be considered:

$$QH_2Q(s) \rightleftharpoons QH_2Q(\text{dissolved}) \rightleftharpoons Q + QH_2 \tag{8}$$

According to (7) and (8)

$$[QH_2] = [Q] + [QH^+] = [Q](1 + Kh) \tag{9}$$

Thus δ, the difference between (5) and (4), will be

$$\delta = 29.58 \log (1 + Kh) \tag{10}$$

K may be conveniently calculated by comparing the experimental $\delta = \delta(\log h)$ values with the function $\delta = 29.58 \log (1 + X)$. Superimposing the experimental data on the curve $\delta(\log X)$, the difference $\log X - \log h$ gives in the position of best agreement the most probable value of $\log K$. The advantages of this graphical method for finding constants from experimental data have been outlined by Sillén [11]. In this way it was calculated that

$$\log K = -1.0 \pm 0.2$$

As Fig. 2 shows, the agreement between the experimental data and the curve calculated with this constant may be considered satisfactory.

A great number of organic compounds containing oxygen have been found to be bases of appreciable strength, see *e.g.* Hammett [12], but of the quinones only anthraquinone has hitherto been investigated. Flexser, Hammett and Dingwall [13] estimated, by spectrophotometric measurements, pK_a of anthraquinone to be -8.2 ± 0.2 in concentrated sulfuric acid solutions. This substance is therefore a much weaker base than *p*-benzoquinone.

This work was financially supported by *Statens Naturvetenskapliga Forskningsråd* (*Swedish Natural Science Research Council*). I am greatly indebted to Professor Lars Gunnar Sillén for valuable criticism. I also want to thank my wife Dr. Clara Bereckí-Biedermann for helpful discussions.

Electrode Impedance Measurements on the Cerium(IV)-Cerium(III) Couple in Perchloric Acid Solutions

STURE FRONÆUS

Department of Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

A small platinum electrode, immersed in a solution of cerium(III) and cerium(IV) perchlorates in 3 M perchloric acid, is polarized by a sinusoidal alternating voltage of small amplitude, and the impedance of the metal-solution interface is determined. Owing to the high redox potential of the cerium couple the total impedance includes two parallel faradaic impedances, one of them due to the oxygen-water couple. From the measurements the rate of the electron transfer step of the cerium couple is calculated, and the result is shown to be in accord with a previous isotopic exchange investigation.

The rate of the charge transfer of the oxygen evolution on platinum is also obtained from the impedance measurements combined with separate determinations of the over-all rate of reaction. It is found that the rate-determining step is not the charge transfer but a subsequent reaction.

Furthermore, it is demonstrated that the steady-state potential of the platinum electrode is very nearly equal to the redox potential of the cerium couple.

The heterogeneous exchange reaction between cerium(III) and cerium(IV) at platinum surfaces was investigated in a previous work (Fronæus and Östman [1]) by means of a radioactive cerium isotope. At 0°C and in approximately 3 M perchloric acid as an ionic medium the following relationship was obtained for the rate r of the over-all exchange reaction

$$\frac{1}{r} = \frac{1.25 \times 10^{10}}{c^{1.5} q^{0.5}} + \frac{2.0 \times 10^{9}}{c} \qquad (1)$$

when r is expressed in mole $\cdot$ cm^{-2} $\cdot$ sec^{-1} and the concentrations c and q of cerium(IV) and cerium(III) are expressed in mM. The relationship was established for small values (< 10 mM) of c and q.

By comparing this expression with the one theoretically derived [1], it is found that the first term on the right-hand side of (1) is equal to the reciprocal of the rate r_0 of the electron transfer, and the second term is equal to the reci-

procal of the rate r_d of the diffusion of cerium(IV) to and from the electrode. Thus it was concluded that these two steps are the rate-determining ones. Furthermore, the exponent 1.5 of c in the expression for r_0 indicates [1] that the oxidizing species predominating in the electron transfer step is a dinuclear hydrolysis product of cerium(IV).

The purpose of the present investigation was to check these results and, for this reason, electrode impedance measurements were chosen, since by this method [2] it is generally possible to determine the rate of the electron transfer, even if this step is rather rapid in comparison with the diffusion processes. However, the present case is complicated by the fact that water is slowly oxidized at the electrode owing to the high redox potential of the cerium(IV)—cerium(III) couple, and the oxygen-water couple will interfere with the measurements. This complication is common to the electrical methods available.

THEORETICAL

At the platinum electrode we have simultaneously the following two overall electrode reactions

$$\mathrm{Ce(III)} \rightleftharpoons \mathrm{Ce(IV)} + \mathrm{e^-} \tag{2}$$

$$2\mathrm{H_2O} \rightleftharpoons \mathrm{O_2} + 4\mathrm{H^+} + 4\mathrm{e^-} \tag{3}$$

The electron transfer steps of these reactions are denoted

$$\mathrm{A}_n \rightleftharpoons \mathrm{B}_n + \mathrm{e^-} \tag{4}$$

where $n = 1$ refers to the cerium couple and $n = 2$ to the oxygen-water couple. For the current densities $\vec{i}_n$ and $\overleftarrow{i}_n$ of the forward and reverse reactions of (4) we have the expressions [1]

$$\vec{i}_n = k_n' \, [\mathrm{A}_n] \exp\left\{\frac{\alpha_n e F}{RT}\right\} \tag{5}$$

$$\overleftarrow{i}_n = k_n'' \, [\mathrm{B}_n] \exp\left\{-\frac{(1-\alpha_n) e F}{RT}\right\} \tag{6}$$

Here k_n', k_n'', and α_n should be constants, the transfer coefficients α_n fulfilling the condition $0 < \alpha_n < 1$. If the electrode potential e is adjusted at the redox potential e_n of the couple B_n—A_n we get $\vec{i}_n = \overleftarrow{i}_n = i_{0,n}$, where $i_{0,n}$ is the exchange current density of the couple. Then the concentrations of A_n and B_n close to the electrode become equal to the equilibrium values $[\mathrm{A}_n]_0$ and $[\mathrm{B}_n]_0$, and thus for an arbitrary value of e we get

$$\vec{i}_n = i_{0,n} \frac{[\mathrm{A}_n]}{[\mathrm{A}_n]_0} \exp\left\{\frac{\alpha_n (e-e_n) F}{RT}\right\} \tag{7}$$

$$\overleftarrow{i}_n = i_{0,n} \frac{[\mathrm{B}_n]}{[\mathrm{B}_n]_0} \exp\left\{-\frac{(1-\alpha_n)(e-e_n) F}{RT}\right\} \tag{8}$$

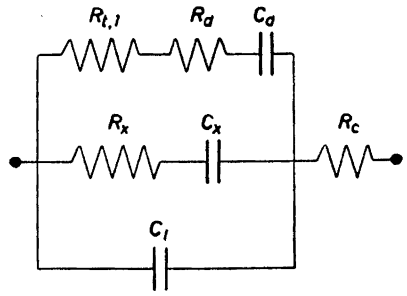

Fig. 1. Equivalent circuit of the electrochemical cell. $R_{t,1}$, R_d, *and* C_d = *transfer resistance, diffusion resistance, and diffusion capacity of the cerium couple;* R_x *and* C_x = *equivalent series resistance and capacity of the oxygen-water couple;* C_l = *double layer capacity;* R_c = *cell resistance.*

Furthermore, for the contribution i_n of the couple B_n—A_n to the total anodic current density we have the relationship

$$i_n = \vec{i}_n - \overleftarrow{i}_n \tag{9}$$

If the measurement cell consists of two platinum electrodes immersed in the solution and a sinusoidal alternating voltage is applied to the cell, the equivalent circuit can be represented as in Fig. 1. There are two so-called faradaic impedances, corresponding to the electrode reactions (2) and (3), and further the ordinary double layer capacity C_l. These parallel impedances are in series with the resistance R_c of the cell solution.

For small amplitudes (< 10 mV) of the applied alternating voltage the faradaic impedance connected with the cerium couple can be divided into the resistance $R_{t,1}$, due to the electron transfer step, and a diffusion impedance, composed of the resistance R_d and the capacity C_d. Under the condition stated $R_{t,1}$ is evidently equal to $(\partial e/\partial i_1)_{[A_1],[B_1]}$ for $e = e_0$, where e_0 is the steady-state potential of the electrode. Now, from an investigation by Sherill, King and Spooner [3] it is found that at a constant concentration (0.5 M) of perchloric acid and at cerium(IV) concentrations <10 mM the dependence of e_0 upon c and q is approximately in accordance with Nernst's formula. Thus it is very probable that e_0 is very nearly equal to the redox potential e_1 of the cerium couple. Then, remembering that $[A_1] = [A_1]_0$ and $[B_1] = [B_1]_0$ for $e = e_1$, we obtain from eqns. (7)—(9)

$$R_{t,1} = \frac{RT}{F} \cdot \frac{1}{i_{0,1}} \tag{10}$$

For diffusion impedances it has been shown before, *e.g.*, by Randles [2], Ershler [4], and Gerischer [5], that $\omega C_d R_d = 1$ and, furthermore, that R_d is proportional to $\omega^{-\frac{1}{2}}$, where $\omega = 2\pi\nu$ and ν is the frequency of the alternating current. Thus, if other experimental conditions are fixed we can put

$$R_d = \frac{K}{\sqrt{\omega}}; \qquad C_d = \frac{1}{K\sqrt{\omega}} \tag{11}$$

where K is a constant.

The expressions for R_x *and* C_x. On the basis of investigations of the oxygen evolution at electrodes (*cf.* Hickling [6] and Bockris [7]) we may presume for the oxygen-water couple that A_2 is equal to OH^- or in acid solutions H_2O, and that B_2 is the radical OH adsorbed on the platinum surface. In this case there is no diffusion impedance, but if the reaction between the adsorbed radicals is a slow process another impedance will result, and we will establish the dependence of the resistance R_x and the capacity C_x (see Fig. 1) upon ω.

For the variation in the electrode potential e with time t the differential equation

$$\frac{de}{dt} = R_x \frac{di}{dt} + \frac{i}{C_x} \tag{12}$$

is valid if i is the alternating current through this impedance. We can put $i = I \sin \omega t$, where I is the amplitude. Hence, we get

$$\frac{de}{dt} = \omega I R_x \cos \omega t + \frac{I}{C_x} \sin \omega t \tag{13}$$

Combining eqns. (7)—(9) we obtain i_2 expressed as a function of e and $[B_2]$, since $[A_2] = [A_2]_0$ according to the presumption above. A differentiation of this function gives

$$\frac{de}{dt} = R_{t,2} \frac{di_2}{dt} + R_{t,2} \frac{\overleftarrow{i_2}}{[B_2]} \frac{d[B_2]}{dt} \tag{14}$$

where $R_{t,2}$ is the electron transfer resistance of the oxygen-water couple at the electrode potential e_0 and is given by the expression

$$\frac{1}{R_{t,2}} = \frac{F}{RT} \left\{ \overrightarrow{i_2} \alpha_2 + \overleftarrow{i_2} (1 - \alpha_2) \right\} \tag{15}$$

For i_2 we have $i_2 = (i_2)_{e=e_0} + I \sin \omega t$ and hence $di_2/dt = \omega I \cos \omega t$.

Now we represent by $f([B_2])$ the rate of the reaction between the radicals adsorbed on the electrode surface. Then, if $[B_2]$ is expressed in moles per unit area, $i_2 F^{-1}$ will be the net rate at which the radicals are supplied by the electron transfer step. Hence, we obtain the differential equation

$$\frac{d[B_2]}{dt} + f([B_2]) = \frac{(i_2)_{e=e_0}}{F} + \frac{I}{F} \sin \omega t \tag{16}$$

where the first term in the right member is a constant.

For *very small amplitudes* the solution of eqn. (16) is of the form

$$[B_2] = a + \frac{I(b \sin \omega t - \omega \cos \omega t)}{(b^2 + \omega^2)F} + \varphi(t) \tag{17}$$

where the constants a and b fulfil the conditions

$$f(a) = \frac{(i_2)_{e=e_0}}{F}; \qquad b = \left(\frac{df}{d[B_2]} \right)_{[B_2]=a} \tag{18}$$

In (17) the non-sinusoidal term $\varphi(t)$ is negligible for t-values which are not very small. Then, differentiating this equation with respect to t and combining the expression obtained with (14) we get

$$\frac{de}{dt} = \omega I R_{t,2} \left\{ \cos\ \omega t + \frac{\overleftarrow{i_2}(b \cos \omega t + \omega \sin \omega t)}{[B_2](b^2 + \omega^2)F} \right\} \tag{19}$$

An equating of the coefficients of cos ωt and sin ωt in (13) and (19) gives the final expressions for R_x and C_x

$$R_x = R_{t,2} \left\{ 1 + \frac{\overleftarrow{i_2}\ b}{[B_2](b^2 + \omega^2)F} \right\} \tag{20}$$

$$\frac{1}{C_x} = \frac{\overleftarrow{i_2}\ R_{t,2}\ \omega^2}{[B_2](b^2 + \omega^2)F} \tag{21}$$

From (21) it is seen that the capacity C_x increases with the concentration of the adsorbed radicals, and if the reaction rate $f([B_2])$ is very low, which means a small value of b, the capacity is but slightly dependent on the frequency. It is also evident from (15) and (21) that if $\overrightarrow{i_2} >> \overleftarrow{i_2}$ for $e = e_0$, then the oxygen-water couple will give rise to the transfer resistance $R_{t,2}$ only.

The determination of the exchange current density $i_{0,1}$. The three parallel impedances in Fig. 1 can be replaced by an equivalent circuit, consisting of a resistance R_p and a capacity C_p connected in parallel. Then, by means of well-known transformation formulas for impedances we get

$$\frac{1}{R_p} = \frac{\omega^2 C_d^2 (R_{t,1} + R_d)}{1 + \omega^2 C_d^2 (R_{t,1} + R_d)^2} + \frac{\omega^2 C_x^2 R_x}{1 + \omega^2 C_x^2 R_x^2} \tag{22}$$

$$C_p = C_l + \frac{C_d}{1 + \omega^2 C_d^2 (R_{t,1} + R_d)^2} + \frac{C_x}{1 + \omega^2 C_x^2 R_x^2} \tag{23}$$

If the expressions for R_d, C_d, R_x, and C_x in eqns. (11), (20), and (21) are taken into consideration the following relationships are approximately valid at high frequencies

$$\frac{1}{R_p} = \frac{1}{R_{t,1}} + \frac{1}{R_{t,2}} - \frac{K'}{\sqrt{\omega}} \tag{24}$$

$$C_p = C_l + \frac{K'}{\omega\sqrt{\omega}} \tag{25}$$

where the coefficient K' is >0 and independent of the frequency.

Accordingly, R_p^{-1} and C_p experimentally determined should be plotted against $\nu^{-\frac{1}{2}}$ and $\nu^{-\frac{3}{2}}$, respectively, and extrapolated to $\nu = \infty$ giving $R_{t,1}^{-1} + R_{t,2}^{-1}$ and C_l. Then, denoting the intercept on the R_p^{-1}-axis by R_t^{-1} and observing that $i_{0,1} = r_0 F$, where the rate of the electron transfer of the cerium couple is expressed in moles per unit area and unit time, we obtain from (10) and (15)

$$\frac{RT}{F^2 R_t} = r_0 + \frac{\overrightarrow{i_2}\alpha_2 + \overleftarrow{i_2}(1-\alpha_2)}{F} \tag{26}$$

If we choose $c = q$ and keep $[H^+]$ at a fixed value the overvoltage $e_0 - e_2$ ($\approx e_1 - e_2$) of the oxygen-water couple will be constant and consequently also the current densities $\vec{i}_2$ and $\overleftarrow{i}_2$. On the other hand, for $c = q$ it is found from (1) that r_0 is proportional to c^2, if the results obtained in the isotopic exchange investigation are reliable. Then, by determining R_t for various values of c we can arrive at the corresponding rates r_0.

A test on the existence of an impedance due to the oxygen-water couple. The two faradaic impedances in Fig. 1 can be replaced by a single impedance, consisting of a resistance R_s and a capacity C_s in series. The expressions for R_s and C_s are rather complicated, but at high frequencies we get the following approximate formulas

$$R_s = \beta\left(R_{t,1} + \frac{K}{\sqrt{\omega}}\right) \tag{27}$$

$$\frac{1}{\omega C_s} = \frac{\beta^2 K}{\sqrt{\omega}} + \frac{(1-\beta)^2}{\omega C_x} \tag{28}$$

where $\beta = R_x(R_{t,1} + R_x + R_d)^{-1}$. Thus, if $R_x = \infty$ we have $\beta = 1$, whereas $\beta < 1$ for finite values of R_x. In the first-mentioned case two parallel straight lines should be obtained, when R_s and $(\omega C_s)^{-1}$ are plotted against $\nu^{-\frac{1}{2}}$. On the other hand, if $\beta < 1$ the quantity $(\omega C_s)^{-1}$ may increase more rapidly than R_s for increasing values of $\nu^{-\frac{1}{2}}$, since according to (21) C_x should be fairly independent of the frequency.

It can be mentioned that ordinarily [8-10] an extrapolation of R_s is used for the determination of R_t. However, in those cases where $C_p - C_l \ll C_p$ but $\omega R_p(C_p - C_l)$ is not $\ll 1$ the resistance R_s cannot be calculated with sufficient accuracy for such a determination.

MEASUREMENTS AND CALCULATIONS

Experimental details. The cell used in the impedance measurements was similar to that of Vetter [8]. The small, polarizable electrode was a platinum wire with a diameter of 0.32 mm and a length of 30 mm. It was placed as the axis of a cylindrical platinum electrode with a diameter of 10 mm and a length of 30 mm. The solution contained cerium(III) and cerium(IV) perchlorates in equal concentrations, and as supporting electrolyte 3.00 M perchloric acid was used [1].

The impedance of the cell was measured with an a.c. Wheatstone bridge circuit, properly shielded. Two of the arms consisted of two equal standard resistors, and in the fourth arm, adjacent to the cell, there were a decade resistor and a decade condenser, connected in parallel for technical reasons. The bridge was fed with an oscillator whose output was adjusted so that the amplitude of the voltage applied to the cell was about 7 mV. A cathode-ray oscillograph combined with a preamplifier served as a balance indicator of high sensitivity.

Calculations. From the readings on the decade resistor and the condenser, when the bridge was balanced, the corresponding values for an equivalent series arrangement of the resistance and the capacity were computed. Since the apparatus did not permit measurements at very high frequencies the eletrolyte resistance R_e could not be determined directly but was calculated from

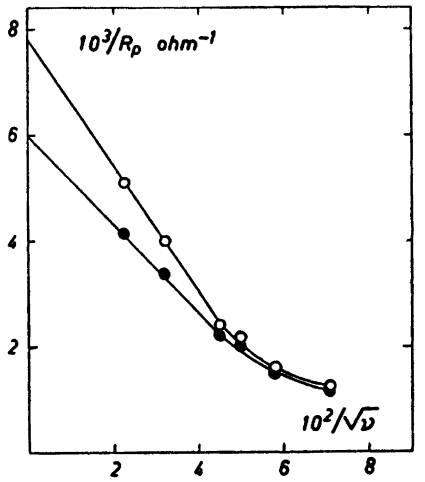

Fig. 2. The conductance R_p^{-1} *as a function of* $\nu^{-\frac{1}{2}}$ *(*ν *= frequency) at the cerium concentrations* c = q = 3.00 *mM* (●) *and* c = q = 6.00 *mM* (○).

the specific conductivity of 3 M perchloric acid and the electrode dimensions (R_c = 0.30 ohm at 20°C). After subtraction of R_c from the series resistance a re-calculation of the equivalent parallel arrangement was performed, giving the values of R_p and C_p.

For the cerium concentrations $c = q$ = 3.00 mM and 6.00 mM, which are within the ranges used in the isotopic exchange investigation [1], the measurements were at first carried out at 20°C. In Fig. 2 R_p^{-1} has been plotted against $\nu^{-\frac{1}{2}}$. Owing to the rather great values of both C_p and R_p the resistance could not be determined with sufficient accuracy at high frequencies, and accordingly R_p has been given only for $\nu \leqq 2\,000$ cycles · sec^{-1}. As predicted by the theory the curves are approximately straight-lined at the lower values of $\nu^{-\frac{1}{2}}$ and can be used for extrapolations to $\nu = \infty$. In Fig. 3 the capacity C_p has been plotted against $\nu^{-\frac{3}{2}}$. Since the variation in C_p is small we should get fairly accurate determinations of the double layer capacity C_l by the extrapolations to $\nu = \infty$.

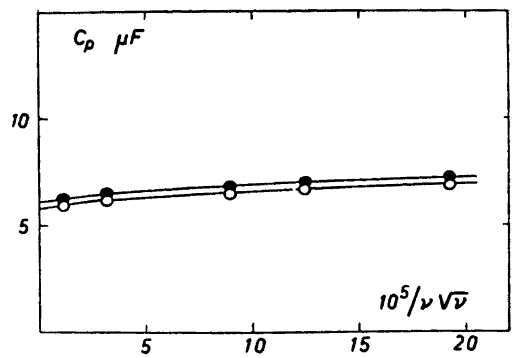

Fig. 3. The capacity C_p *as a function of* $\nu^{-\frac{3}{2}}$ *at the cerium concentrations* c = q = 3.00 *mM* (●) *and* c = q = 6.00 *mM* (○).

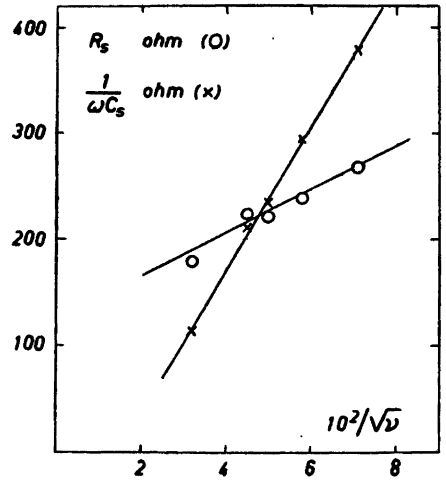

Fig. 4. The quantities R_s (O) *and* $1/\omega C_s$ (×) *as functions of* $\nu^{-\frac{1}{2}}$ *at the cerium concentrations* c = q = 6.00 *mM.*

From R_p and the difference $C_p - C_l$ the equivalent circuit consisting of the resistance R_s and the capacity C_s in series was calculated. In Fig. 4 R_s and $(\omega C_s)^{-1}$ have been plotted against $\nu^{-\frac{1}{2}}$. It is seen that $(\omega C_s)^{-1}$ increases more rapidly than R_s with $\nu^{-\frac{1}{2}}$, and according to the theory above this means that the faradaic impedance due to the oxygen-water couple influences the measurements.

The values of R_t^{-1} and C_l arrived at refer to the two electrodes of the cell. Thus we have to divide by the factor $s_1 s_2 (s_1 + s_2)^{-1} = 0.30$ cm^2, where s_1 and s_2 are the surface areas of the electrodes, in order to obtain the corresponding quantities per unit area of the interface. Since in the present case $s_1 = 0.03\ s_2$ the impedance of the great electrode is only a correction term. For C_l a value of about 20 μF · cm^{-2} is obtained at the cerium concentrations used.

In Table 1 the values of $RTF^{-2}R_t^{-1}$ are given. The corresponding rates r_0 in the next column have been calculated from eqn. (26) as described in the theoretical section. Some impedance measurements were also performed at 0°C, since the isotopic exchange measurements were carried out at this temperature. However, at 0°C it was possible to determine R_p with sufficient accuracy only at low frequencies. Then it was found that the R_p-values were about half as

Table 1. The rate of the electron transfer step of the cerium (IV)-cerium (III) couple on platinum in the presence of 3 M perchloric acid. The quantities in the columns 2—7 are expressed in mole · cm^{-2} · sec^{-1}.

c = q mM	$\frac{RT}{F^2 R_t} \times 10^9$		$r_0 \times 10^9$		$r_0 \times 10^9$	$r_d \times 10^9$
	20°C	0°C	20°C	0°C	Tracer method;0°C	
3.00	5.2	2.5	0.5	0.25	0.72	1.5
6.00	6.8	3.5	2.0	1.0	2.9	3.0

great as the corresponding values obtained at 20°C. Accordingly we may conclude that the same thing is valid for the rate r_0, as is indicated in Table 1.

From the measurements at 20°C the calculations give $\vec{i}_2\alpha_2 + \overleftarrow{i}_2(1 - \alpha_2) = 0.45$ mA · cm^{-2}. Now according to Hickling and Hill [11] the transfer coefficient α_2 is about 0.5 for platinum in acid solution, and using this value we get $\vec{i}_2 + \overleftarrow{i}_2 = 0.90$ mA · cm^{-2}. The current density $i_2 = \vec{i}_2 - \overleftarrow{i}_2$ of the oxygen evolution at the steady-state potential e_0 is equal to the current density of the simultaneous heterogeneous reduction of cerium(IV) and can be measured separately. To this end 15 ml of a solution with $c = q = 20.0$ mM and the perchloric acid concentration 3 M was shaken at 20°C for 45 hours with a platinum foil, the surface area of which was 8 cm^2. Then it was found that as a mean value 5.3×10^{-2} mmoles of cerium(IV) had been reduced. During the same time about 10^{-3} mmoles had been reduced in the homogeneous reaction. Hence we get $i_2 = 4 \times 10^{-3}$ mA · cm^{-2} at the potential[3] $e_0 = 1.67$ V. For the oxygen-water couple we compute $e_2 = 1.25$ V at $[H^+] = 3$ M, giving us the overvoltage $e_0 - e_2 = 0.43$ V. The current density obtained is consistent with the measurements by Hickling and Hill [11]. Combining the values of $\vec{i}_2 + \overleftarrow{i}_2$ and $\vec{i}_2 - \overleftarrow{i}_2$ we obtain $\vec{i}_2 = 0.45$ mA · cm^{-2}. Thus the resultant rate of the oxygen evolution at platinum is much less than the rate of discharge of OH^- or H_2O.

Furthermore, since $i_1 + i_2 = 0$ at the steady-state potential e_0, we get from eqns. (7)—(9) the approximate relationship

$$e_1 - e_0 = \frac{RT\, i_2}{F^2\, r_0} \tag{29}$$

if the value of $e_1 - e_0$ is so small that we can put $[A_1] \approx [A_1]_0$ and $[B_1] \approx [B_1]_0$ and apply the approximation $\exp(y) \approx 1 + y$ to the exponential functions containing $e_1 - e_0$. Combining the i_2-value with the rate r_0 at 20°C we find $e_1 - e_0 = 2$ mV for $c = q = 3.00$ mM, which confirms the validity of the approximation. Consequently, the steady-state mixed potential is very nearly equal to the redox potential of the cerium(IV)-cerium(III) couple.

DISCUSSION

In the last two columns of Table 1 the rate r_0 and the rate r_d of the diffusion of cerium(IV) have been calculated from the two terms in the right member of eqn. (1). It is seen that the impedance measurements and the radioactive tracer method give the same order of magnitude for r_0. The agreement is satisfactory if we take into consideration that possibly the surface states of the electrodes used in the two investigations were not the same, though the platinum wires were treated in the same way [1] prior to use. Thus a very good support is obtained for the result arrived at in the previous investigation [1] that $r_0 \leqq r_d$ for the concentrations used, so that r_0 has a considerable influence upon the over-all rate of the heterogeneous exchange reaction.

From a comparison between the values of $i_2F^{-1} = 4 \times 10^{-11}$ mole · cm^{-2} · sec^{-1} and r_d it is found that the rate of reduction of cerium(IV) at the steady-state potential is only 1 to 2 % of the rate of diffusion of cerium(IV) to and from the electrode. Consequently we have also confirmed the assumption in the previous investigation that the cerium concentrations at the interface are not affected appreciably by this reduction.

On the other hand, at the low cerium(IV) concentrations used, necessitated by the intricate hydrolysis of the cerium(IV) ion in perchloric acid solutions, the term r_0 in the right member of (26) is rather small in comparison with the constant term. Thus, even if several concentrations within the narrow range given are used it is impossible to carry out impedance measurements with such an accuracy that we can get an independent check on the relation $r_0 =$ constant · c^2 (for $c = q$), presupposed in the calculations above. It is evident that in the present case the radioactive tracer method is superior to the impedance measurements.

Interesting information about the heterogeneous oxygen evolution has been obtained in this investigation. From the calculations we arrive at the conclusion that under the conditions given the oxygen evolution is controlled not by the discharge step but by the subsequent reaction between the radicals OH, adsorbed on the platinum. This result is in agreement with recent investigations. Thus according to Bockris [7] the rate-determining step of the oxygen evolution is the following one: 2 OH → H_2O_2, where OH and H_2O_2 are adsorbed on the platinum electrode.

This investigation has been supported by a grant from the *Swedish Natural Science Research Council* which is gratefully acknowledged.

The author wishes to thank Fil.mag. C. O. Östman and Miss K. Anderson for valuable assistance in the measurements.

Short Communications

Acid Hydrolysis of Some α,β-Unsaturated Aliphatic Esters

EERO A. HALONEN

Institute of Chemistry, University of Helsinki, Finland

The ethyl esters of propiolic, tetrolic and *tert.* butylpropiolic acid and the diethyl ester of acetylenedicarboxylic acid were prepared previously [1]. In the present study, the hydrolyses were carried out in ampoules of Pyrex glass and of about 10.5 ml capacity. The sample volume was 10 ml and the concentrations of sulphuric acid and ester were both 0.02 N in the initial mixture. The reaction was arrested in ice and the acid was titrated with barium hydroxide using phenolphthalein as indicator.

Addition of water to the triple bond of the esters was not observed. If it occurred, ethyl propiolate would have given, *via* acetoacetic acid, acetaldehyde, and, correspondingly, ethyl tetrolate and ethyl *tert.*butylpropiolate would have given ketones. The acid hydrolysis of diethyl acetylenedicarboxylate cannot be studied by using the above mentioned method as the acidic ester resulting from the hydrolysis is decarboxylated at a faster rate than the diethyl ester is hydrolyzed. Also the propiolic acid formed in the hydrolysis of ethyl propiolate is decarboxylated under these conditions [2] and, as a result, a decrease in the rate constant of hydrolysis occurs when the reaction proceeds. Especially at high temperatures, this becomes evident, as the activation energy of decarboxylation is 13 600 cal greater than the activation energy of hydrolysis. Mathematically, the decrease has been shown to agree, quantitatively, with the decarboxylation. The rate constants and the calculated activation energies and frequency factors are given in Table 1.

The ratios of the rates of hydrolysis correspond approximately to those previously obtained in alkaline hydrolysis of these esters [1].

The difference in the rates for ethyl propiolate and ethyl tetrolate is greater than the difference in the rates for ethyl tetrolate and ethyl *tert.*butylpropiolate. When compounds with triple bonds are compared to the corresponding saturated ones [3] and to those with double bonds [4], it will be noted, that the acetylenic compounds will hydrolyze about 40 times slower than the saturated ones but only slightly slower than the ethylenic compounds. The activation energies of the acetylenic and saturated compounds are of the same magnitude and approximately 3 000 cal smaller than the activation energies of the ethylenic compounds. This indicates that the conjugation between the unsaturated bond and the carboxyl carbonyl group has more effect

Table 1. Acid hydrolysis of esters in water and in acetone-water mixtures.

Ester	Solvent composition wt % H_2O	10^5k l mole^{-1} sec.$^{-1}$			E cal	log A
		40.0°	60.0°	80.0°		
$HC{\equiv}C{\cdot}CO_2Et$	100	1.16	5.60	22.4	16 221	4.39
—»—	50	0.437	2.03	7.74	15 680	3.59
$H_3C{\cdot}C{\equiv}C{\cdot}CO_2Et$	100	0.713	3.83	16.4	17 220	4.88
—»—	50	0.300	1.31	5.62	16 113	3.73
$(CH_3)_3C{\cdot}C{\equiv}C{\cdot}CO_2Et$	50	0.276	1.14	4.53	15 860	3.46

on the rate of the hydrolysis than has the inductive effect and, on the basis of the reaction mechanism, this can also be expected. As compared with the ethylenic esters the decrease in the rate is due to the inductive effect of the triple bond. As a result of this either the pre-equilibrium moves from the side of the ionic conjugate acid of ester to the side of the ester or the alkoxyl linkage, after the addition of water, is less readily breakable.

The rates of hydrolysis in 60 % aqueous ethanol at 60° C for the ethyl ester of acetic, monochloroacetic, dichloroacetic and trichloroacetic acids are 1, 0.91, 0.40 and 0.11, respectively, if the rate for ethyl acetate is taken as a unity [5]. The fact that the rates of hydrolysis for the ethyl ester of propiolic and acrylic acids differ only slightly from each other gives support to the assumption that, in the case of chloroacetic acids, steric factors are of importance.

Paper Chromatographic Separation of Thiamine Phosphates

KARL-HEINZ KIESSLING

Institute of Zoophysiology, Uppsala, Sweden

Several papers have been published about paper chromatographic separation of thiamine phosphates [1-5]. In all solvents described thiamine triphosphate hardly moves at all, and its R_F value coincides in most cases with that of nucleotide di- and triphosphates.

In this paper a paper chromatographic solvent is described in which thiamine triphosphate moves easily, and in which it separates well from other thiamine compounds and from nucleotide phosphates. Also thiamine phosphates with more than three phosphate groups are separated. From a mixture of thiamine phosphates prepared according to Viscontini, Bonetti, and Karrer [6], nine thiamine compounds can be isolated.

The solvent consists of 100 ml *iso*butyric acid, 60 ml N ammonia, and 1.6 ml 0.1 M ethylene diamine tetraacetic acid. It has been used by Krebs and Hems for separating nucleotides [7] and is a modification of a solvent described by Zetterström and Ljunggren [8]. Filter papers Whatman No. 1 are used after washing in aqueous ethylene diamine tetraacetic acid according to the method described by Eggleston and Hems [9].

The di- and triphosphates of inosine, guanosine, uridine, and cytidine all have lower R_F values than adenosine diphosphate [10]. In this investigation thiamine triphosphate was shown to move faster than adenosine diphosphate. It can thus be easily separated from the nucleotides mentioned.

Fig. 1 and 2 show the separation of different amounts of thiamine phosphates prepared according to Viscontini *et al.*[6] One mg of the mixture dissolved in water is linearly spread on the filter paper in Fig. 1. The separation is very distinct. Ten lines can be seen with the naked eye, but only nine are registered on the photographic plate. When the amount of the thiamine phosphate mixture is increased to 3 mg (Fig. 2) the separation is still distinct except between thiamine mono- and diphosphate (lines 3 and 4). Nine lines can be detected.

The lines are cut out, the compounds run off with water, then added as spots on a new filter paper, and developed in the same solvent. The compounds appear as distinct spots with about the same R_F values as the lines on the original paper chromatogram (Fig. 3).

Total and hydrolyzable phosphorus per molecule of thiamine for the compounds 1–7 are seen in Table 1. Thus compound 1 and 2 were identified as different forms of thiamine *. The ratio between total and hydrolyzable phosphorus and thiamine suggests that the compounds 3–7 are thiamine mono-, di-, tri-, tetra- and pentaphosphate, respectively. Compounds

* These two forms have been separated earlier by Gaudiano, Spadoni and Tecce [11].

Paper Chromatographic Separation of Thiamine Phosphates

KARL-HEINZ KIESSLING

Institute of Zoophysiology, Uppsala, Sweden

Several papers have been published about paper chromatographic separation of thiamine phosphates [1-5]. In all solvents described thiamine triphosphate hardly moves at all, and its R_F value coincides in most cases with that of nucleotide di- and triphosphates.

In this paper a paper chromatographic solvent is described in which thiamine triphosphate moves easily, and in which it separates well from other thiamine compounds and from nucleotide phosphates. Also thiamine phosphates with more than three phosphate groups are separated. From a mixture of thiamine phosphates prepared according to Viscontini, Bonetti, and Karrer [6], nine thiamine compounds can be isolated.

The solvent consists of 100 ml *iso*butyric acid, 60 ml N ammonia, and 1.6 ml 0.1 M ethylene diamine tetraacetic acid. It has been used by Krebs and Hems for separating nucleotides [7] and is a modification of a solvent described by Zetterström and Ljunggren [8]. Filter papers Whatman No. 1 are used after washing in aqueous ethylene diamine tetraacetic acid according to the method described by Eggleston and Hems [9].

The di- and triphosphates of inosine, guanosine, uridine, and cytidine all have lower R_F values than adenosine diphosphate [10]. In this investigation thiamine triphosphate was shown to move faster than adenosine diphosphate. It can thus be easily separated from the nucleotides mentioned.

Fig. 1 and 2 show the separation of different amounts of thiamine phosphates prepared according to Viscontini *et al.*[6] One mg of the mixture dissolved in water is linearly spread on the filter paper in Fig. 1. The separation is very distinct. Ten lines can be seen with the naked eye, but only nine are registered on the photographic plate. When the amount of the thiamine phosphate mixture is increased to 3 mg (Fig. 2) the separation is still distinct except between thiamine mono- and diphosphate (lines 3 and 4). Nine lines can be detected.

The lines are cut out, the compounds run off with water, then added as spots on a new filter paper, and developed in the same solvent. The compounds appear as distinct spots with about the same R_F values as the lines on the original paper chromatogram (Fig. 3).

Total and hydrolyzable phosphorus per molecule of thiamine for the compounds 1–7 are seen in Table 1. Thus compound 1 and 2 were identified as different forms of thiamine *. The ratio between total and hydrolyzable phosphorus and thiamine suggests that the compounds 3–7 are thiamine mono-, di-, tri-, tetra- and pentaphosphate, respectively. Compounds

* These two forms have been separated earlier by Gaudiano, Spadoni and Tecce [11].

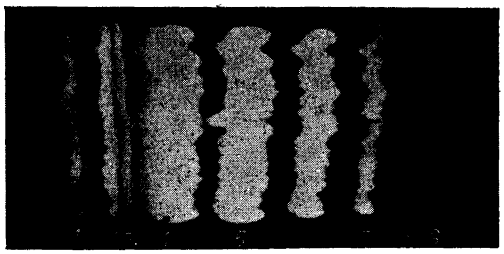

Fig. 1. Paper chromatographic separation of a mixture of thiamine phosphates.

1 mg of the mixture prepared according toViscontini *et al.* and dissolved in water is spread as a line on the filter paper. For solvent see text. Time 19 h. The thiamine compounds on the chromatogram are made visible by spraying the paper with an alkaline ferricyanide solution. In UV of 340 mμ they are seen as blue lines.

Fig. 2. Paper chromatographic separation of a mixture of thiamine phosphates.

3 mg of the mixture is dissolved in water, and placed on the filter paper. Other conditions as in Fig. 1.

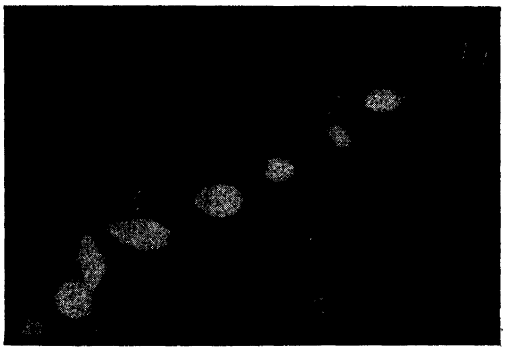

Fig. 3. Subsequent test chromatography of the compounds separated in Fig. 1.

The lines from the chromatogram in Fig. 1 are added as separate spots on a new filter paper, and run with the same solvent. The figures correspond to those in Fig. 1 and in Table 1.

Table 1. Total and hydrolyzable phosphorus of the thiamine compounds separated as in Fig. 1.

Hydrolyzable phosphorus is determined after heating the compounds in 2 N HCl at 100° for 10 min., after which all thiamine polyphosphates appear as thiamine monophosphate. Total phosphorus is determined after wet ashing. Thiamine is oxidized with alkaline ferricyanide to thiochrome, and the fluorescence estimated in a Beckman spectrophotometer with fluorescence attachment.

Compound	hydrolyzable P / total P	P / thiamine	R_F value
1	—	—	0.87
2	—	—	0.79
3	—	1	0.77
4	1/2	2	0.68
5	2/3	3	0.55
6	3/4	4	0.46
7	4/5	5	0.36
8—10		>5	0.24, 0.21 0.16

8—10 have more than five phosphate groups per molecule of thiamine.

The described method has been used for isolating biological thiamine triphosphate from yeast [12], and was found satisfactory for this purpose. The R_F value, however, is somewhat lower than for the synthetic compound depending on the contamination with impurities from the yeast.

*iso*Thiocyanates XXIII*. L (—)-9-Methylsulphinylnonyl *iso*Thiocyanate, a New Mustard Oil Present as a Glucoside (Glucoarabin) in *Arabis* Species

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark

In the course of a systematic investigation of glucosidically bound *iso*thiocyanates in seeds of various species of the cruciferous genus *Arabis*, it was observed that a glucoside, obviously different from all compounds heretofore recognized in Nature, was present in, *e. g.*, *Arabis alpina* L., a popular flower-garden subject. Paper chromatograms of seed extracts [1] indicated the presence of two glucosides both possessing R_F-values well above that of glucotropaeolin (*cf.* Ref.[2]).

When a purified, methanolic extract of a larger seed sample was subjected to enzymic hydrolysis in a buffered solution (pH 6.5), an ether-soluble *iso*thiocyanate fraction was formed. Homogeneous, optically active, crystalline thioureas were obtained upon reaction of the *iso*thiocyanate solution with various amines. The analytical data clearly indicated the composition $C_{11}H_{21}ONS_2$ for the parent mustard oil. The *thiourea*, recrystallized from ethyl acetate, had the m. p. 103.5—104.5° (uncorr.) (Found: C 50.00; H 9.13; N 10.45; S 24.40. Calc. for $C_{11}H_{24}ON_2S_2$: C 49.96; H 9.15; N 10.60; S 24.25), $[\alpha]_D^{24.5}$ −66° (96 % EtOH, c = 2.1). The infra-red spectrum in a KBr-wafer showed a characteristic strong band at 9.78 μ, attributable to a sulphoxide-grouping. The *phenylthiourea* separated from ethyl acetate in colourless prisms, m. p. 121—122° (uncorr.) (Found:

* Part XXII of this series: *Acta Chem. Scand.* **10** (1956) 1193.

Table 1. Total and hydrolyzable phosphorus of the thiamine compounds separated as in Fig. 1.

Hydrolyzable phosphorus is determined after heating the compounds in 2 N HCl at 100° for 10 min., after which all thiamine polyphosphates appear as thiamine monophosphate. Total phosphorus is determined after wet ashing. Thiamine is oxidized with alkaline ferricyanide to thiochrome, and the fluorescence estimated in a Beckman spectrophotometer with fluorescence attachment.

Compound	hydrolyzable P / total P	P / thiamine	R_F value
1	—	—	0.87
2	—	—	0.79
3	—	1	0.77
4	1/2	2	0.68
5	2/3	3	0.55
6	3/4	4	0.46
7	4/5	5	0.36
8—10		>5	0.24, 0.21 0.16

8—10 have more than five phosphate groups per molecule of thiamine.

The described method has been used for isolating biological thiamine triphosphate from yeast [12], and was found satisfactory for this purpose. The R_F value, however, is somewhat lower than for the synthetic compound depending on the contamination with impurities from the yeast.

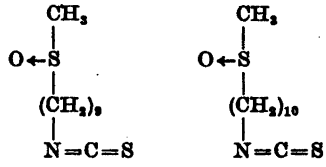
*iso*Thiocyanates XXIII*. L (—)-9-Methylsulphinylnonyl *iso*Thiocyanate, a New Mustard Oil Present as a Glucoside (Glucoarabin) in *Arabis* Species

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark

In the course of a systematic investigation of glucosidically bound *iso*thiocyanates in seeds of various species of the cruciferous genus *Arabis*, it was observed that a glucoside, obviously different from all compounds heretofore recognized in Nature, was present in, *e. g.*, *Arabis alpina* L., a popular flower-garden subject. Paper chromatograms of seed extracts [1] indicated the presence of two glucosides both possessing R_F-values well above that of glucotropaeolin (*cf.* Ref.[2]).



When a purified, methanolic extract of a larger seed sample was subjected to enzymic hydrolysis in a buffered solution (pH 6.5), an ether-soluble *iso*thiocyanate fraction was formed. Homogeneous, optically active, crystalline thioureas were obtained upon reaction of the *iso*thiocyanate solution with various amines. The analytical data clearly indicated the composition $C_{11}H_{21}ONS_2$ for the parent mustard oil. The *thiourea*, recrystallized from ethyl acetate, had the m. p. 103.5—104.5° (uncorr.) (Found: C 50.00; H 9.13; N 10.45; S 24.40. Calc. for $C_{11}H_{24}ON_2S_2$: C 49.96; H 9.15; N 10.60; S 24.25), $[\alpha]_D^{24.5}$ −66° (96 % EtOH, c = 2.1). The infra-red spectrum in a KBr-wafer showed a characteristic strong band at 9.78 μ, attributable to a sulphoxide-grouping. The *phenylthiourea* separated from ethyl acetate in colourless prisms, m. p. 121—122° (uncorr.) (Found:

* Part XXII of this series: *Acta Chem. Scand.* **10** (1956) 1193.

C 60.00; H 8.24; N 8.21. Calc. for $C_{17}H_{33}ON_2S_2$: C 59.97; H 8.29; N 8.23), $[\alpha]_D^{24}$ −54° (96 % EtOH, c = 0.84), whereas the *benzylthiourea* crystallized from acetone as thin, colourless needles, m. p. 119° (uncorr.) (Found: C 60.90; H 8.61; N 7.60; S 18.00. Calc. for $C_{18}H_{30}ON_2S_2$: C 60.97; H 8.53; N 7.90; S 18.09), $[\alpha]_D^{25}$ −64° (MeOH, c = 0.44). Treatment of the latter derivative with silver nitrate furnished in high yield (79 %) the corresponding urea-derivative, separating from ethyl acetate in colourless needles, m. p. 120.5° (uncorr.) (Found: C 63.75; H 8.96; N 8.32; S 9.37. Calc. for $C_{18}H_{30}O_2N_2S$: C 63.87; H 8.93; N 8.28; S 9.47), $[\alpha]_D^{24}$ −56° (96 % EtOH, c = 0.95). Reduction of the latter with zinc dust in HCl-containing ethanol proceeded in quantitative yield, and was accompanied by disappearance of the optical rotation and the characteristic sulphoxide-band in the infra-red spectrum. The reduced benzyl-urea separated from ethyl acetate as tiny, colourless needles, m. p. 99.5° (uncorr.) (Found: C 66.85; H 9.31; N 8.58. Calc. for $C_{18}H_{30}ON_2S$: C 67.01; H 9.38; N 8.69). Hydrogenolysis of this compound with W4-Raney nickel afforded a sulphur-free urea-derivative, which was proved to be identical with an authentic specimen of the previously unknown 1-benzyl-3-nonylurea, m. p. 99.0−99.5° (uncorr.) (Found: C 73.75; H 10.23; N 10.05. Calc. for $C_{17}H_{28}ON_2$: C 73.88; H 10.21; N 10.14), synthesized by oxygen-sulphur exchange with silver nitrate from 1-benzyl-3-nonylthiourea, m. p. 75.5° (uncorr.). (Found: C 69.90; H 9.65; N 9.71. Calc. for $C_{17}H_{28}N_2S$: C 69.81; H 9.65; N 9.58), which was, in turn, produced from benzyl *iso*thiocyanate and *n*-nonylamine.

The above sequence of reactions establishes the structure of the new *Arabis* mustard oil as a methylsulphinylnonyl *iso*thiocyanate, the optical activity of which resides solely in the sulphoxide grouping. This fact, in conjunction with the close analogy to previously recorded natural representatives of the ω-methylthioalkyl *iso*thiocyanates [3-5], strongly suggest that the *Arabis* mustard oil has its methylsulphinyl-grouping located at the terminal carbon-atom *. The physical data, notably the rotation values, are closely comparable to those of the homologous L(−)-10-methylsulphinyldecyl *iso*thiocyanate (II) which we recently established [5] as a naturally occurring species.

Therefore, we conclude that seeds of *Arabis alpina* L. contain L(−)-9-methylsulphinylnonyl *iso*thiocyanate (I) in the traditional glucosidic combination, for which we wish to introduce the name *glucoarabin*. On paper chromatography in various solvent systems, the presence of glucose and sulphate in glucoarabin has been established. A detailed account of this work, supplemented by confirmatory synthetic evidence for the structure (I), will form the subject of a forthcoming communication in this journal.

A Method of Preparing Half-esters of Alkylsuccinic Acids with Free Primary Carboxyl Group. Synthesis and Optical Configuration of Optically Active Methyl 2-Methyl-3-carboxypropanoate

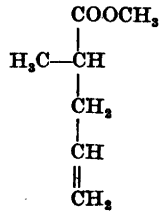
GUNNEL STÄLLBERG

Chemical Institute, and Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

The preparation of the half-ester (I) of methylsuccinic acid has proved difficult because the methods usually employed for the synthesis of monoesters of dibasic acids give mixtures of

$$HOOC—CH_2—CH(CH_3)—COOCH_3$$

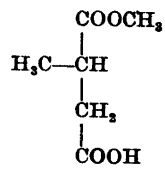
I



$$HOOC—CH(CH_3)—CH_2—COOCH_3$$

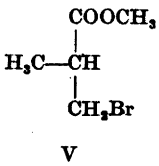
II

the two isomeric half-esters (I) and (II) [1,2]. Hancock and Linstead [2] obtained (I) in crystalline form in very poor yield by fractional crystallization of the ester mixture. The half-ester (I) has recently been prepared from citraconic anhydride by Veibel and Pedersen [3]. None of the methods appears suitable for preparation of (I) in quantity.



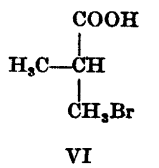
Armstrong and Hilditch [4] obtained methyl hydrogen azelate in very good yield by oxidation of methyl oleate in acetone solution with potassium permanganate. It thus appeared possible to prepare half-esters of the type (I) by oxidation of the corresponding esters of alkylallylacetic acids. It was found that simple distillation of the oxidation products of methyl methylallylacetate gives crude (I) in yields of 60—68 % of the theoretical. The half-ester may be purified by crystallization from low boiling light petroleum. The melting point of pure (I) was found to be 42.2—42.8° C. (Hancock and Linstead give 42.5—43.5° C and Veibel and Pedersen 42—44° C). The melting point was unchanged after distillation at 0.1 mm pressure.

Methyl ester of optically active methylallylacetic acid can be oxidized without racemization to give the enantiomorphs of (I). (+)-Methyl 2L-methyl-$\Delta^{4:5}$-pentenoate (III),



III

$[\alpha]_D^{23}$ +17.0° (homogeneous)



IV

$[\alpha]_D^{25}$ −9.3° (chloroform c = 17.5)

V

$[\alpha]_D^{24}$ +13.6 (homogeneous)

VI

$[\alpha]_D^{27}$ +10.1° (chloroform c = 14.4)

from acid of $[\alpha]_D^{23}$ + 8.2° [5,6,7] on oxidation gave (−)-methyl 2L-methyl-3-carboxypropanoate (IV). The active half-ester isolated by means of simple distillation had $[\alpha]_D^{25}$ −9.3° (chloroform, c = 17.5). A part of the specimen was converted into (−)-methyl methylsuccinate of α_D^{20} −3.45°, l = 0.5. For the antipode Berner and Leonardsen [8] give α_D^{20} + 6.91°, l = 1. This result shows that the oxidation of (III) by means of potassium permanganate proceeds without partial racemization in contrast to the oxidation of optically active methylallylacetic acid with chromic acid [9]. Levorotatory half-ester (IV) can also readily be obtained by resolution of the inactive ester (I) *via* the quinine salt. A specimen of (IV) obtained in this manner had after distillation $[\alpha]_D^{25}$ −9.3° (chloroform, c = 17.4).

The enantiomorphs of methyl 2-methyl-3-carboxypropanoic acid (I) are key compounds for the synthesis of a number of optically active compounds having a methyl group in α-position to a carboxyl group. Work is in progress on the prepara-

tion of the dextrorotatory antipode of (IV) and on the use of the enantiomorphs as intermediates in the synthesis of optically active compounds. For example, (IV) has *via* Hunsdieckers' procedure [10] been converted into (+)-methyl 2L-methyl-3-bromo-propanoate (V), $[\alpha]_D^{24}$ + 13.8° (homogeneous). (Found: Br 44.3. Calc. Br 44.14). Hydrolysis of the ester (V) with hydrogen bromide in glacial acetic acid gave (+)-2L-methyl-3-bromopropanoic acid ((+)-β-bromo*iso*butyric acid), $[\alpha]_D^{27}$ +10.1° (chloroform, c = 14.4). (Found Br 48.2. Calc. Br 47.85).

Experimental. For the oxidation of methyl methylallylacetate the following procedure appears to give the best results. Methyl methylallylacetate, b.p. 134.5—135.0°, 760 mm, $n_D^{22.6}$ 1.4158, (52 g) was dissolved in 450 ml of dry acetone (distilled from potassium permanganate) in a 2 l three-necked round-bottomed flask equipped with a reflux condenser and a Hershberg stirrer. Powdered potassium permanganate (400 g) was added in portions as fast as the vigorous reaction allowed. The addition of permanganate lasted 2 h after which time refluxing and stirring was continued for 4 h. The reaction mixture was filtered on a sintered glass funnel. The filtrate contained practically nothing of the desired oxidation product and was discarded. The mass on the filter was washed with about 1 l of a solution of sulfurous acid. The filtrate was acidified with hydrochloric acid and the mixture was extracted several times with ether (it is preferable to use an apparatus for continuous extraction). The ether solution was washed with a small quantity of water and dried with sodium sulphate. The solvent was distilled off and the residue distilled *in vacuo*. The main fraction (37.8 g, 64 % of the theoretical) distilled at 101—103°, 0.1 mm. On cooling to room temperature most of the material solidified to a mass of large crystals, only a very small part remaining liquid. After treatment with charcoal the half-ester was crystallized from light petroleum at —15°. M. p. 42.2—42.8°.

Preparation of the optically active half-ester (IV). a) by oxidation. The oxidation was performed as described above starting from optically active methylallylacetic acid. Once-distilled half-ester (IV) (n_D^{26} 1.4309; $[\alpha]_D^{25}$ —9.3° (chloroform, c = 17.5)) crystallized on seeding. Crystallization from light petroleum (b. p. 20—40°) after treatment with charcoal gave (IV) with m. p. 31.4—32.3° and $[\alpha]_D^{24}$ —9.3° (chloroform, c = 17.8).

b) by resolution of inactive half-ester (I). Inactive half-ester (I) (16.7 g) was dissolved in a mixture of acetone and water (1:1 by volume, 450 ml) and quinine (43.4 g) was dissolved in the warm solution. The solution was filtered and crystallization allowed to take place at room temperature. After standing overnight the crystals were collected and recrystallized thrice from progressively smaller amounts of the same solvent. The quinine salt was decomposed by means of hydrochloric acid and the half-ester extracted with ether in an apparatus for continuous extraction. After distillation the optically active half-ester (IV) (n_D^{26} 1.4309, super-cooled liquid) showed an optical rotation of $\alpha_D^{24.5}$ —0.81° (chloroform, c = 17.4, l = 0.5) $[\alpha]_D^{24.5}$ —9.3°.

The writer is indebted to Professors A. Fredga and E. Stenhagen for advice and interest.

A Correction of the Crystal Structure of $MoO_3 \cdot 2H_2O$

INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In order to refine the crystal structure of $MoO_3 \cdot 2H_2O$ [1] a reinvestigation was started in this Institute. Prolonged exposures then showed that the crystal has a considerable superstructure. The new axes a, b, c are related to the earlier a', b', c' in the following way: $a = 4a'$, $b = 2b'$, $c = 2c'$. The cell dimensions are thus $a = 15.08$ Å, $b = 13.82$ Å, $c = 14.68$ Å and $\beta = 90° 40'$. The loss of orthorhombic symmetry which could not be detected in the intensities earlier is now obvious for the superstructure reflexions. It has been checked that the main principles of the suggested structure cannot be influenced by the superstructure but there are of course, small changes in the oxygen positions. The calculated bond distances (except for Mo-Mo) are thus of little value and therefore the basis is removed for the suggestion about the existence of an ion H_4O^{2+}.

Because of change of axes during the work an obvious error has been made in the description of the structure in Ref.[1]: x and z parameters and h and l indices should be interchanged all through the paper to fit the choice of axes.

A complete reinvestigation will be very time-consuming and is not planned at present.

A Nuclear Magnetic Resonance Study of the Dihydrate of Molybdenum Trioxide

S. MARIČIĆ and J. A. S. SMITH

Department of Inorganic and Structural Chemistry, The University of Leeds, England

A combined proton magnetic resonance and infra-red investigation of the dihydrate of molybdenum trioxide has shown that the formula $(H_4O^{++})MoO_4^{--}$ is very improbable [1].

The second moment of the proton absorption line at 77° K is 27.6 gauss [2]. If a symmetrical H_4O^{++} ion existed in the crystal, this value would predict [2] an O—H distance of 1.16 Å in H_4O^{++}, compared with 0.96 Å in water vapour, and this seems an improbably large increase. In addition, the infra-red spectrum shows frequencies at 3 100 and 1 592 cm^{-1}; if these are interpreted as stretching and bending frequencies associated with O—H groups, they suggest an expansion of the order of 0.04 Å only. It would be difficult to reconcile both of these results with the existence of an H_4O^{++} ion.

We hope to publish these results in detail elsewhere.

Metalation of Pyrene

ARNE BERG

Chemical Institute, University of Aarhus, Aarhus, Denmark

Only few strictly aromatic hydrocarbons have been metalated by organolithium compounds [1] and the yields of carboxylic acids obtained upon carbonation have been poor.

Pyrene, in view of its readiness to partake in substitution reactions, and especially of the general rule of substitution in 3-position [2] governing these reactions, seemed an interesting object for metalation.

It has now been found that pyrene, by the action at room temperature of a rather large excess of *n*-butyllithium in diethyl ether not only is metalated as evidenced by the isolation of pyrene carboxylic acids upon carbonation of the reaction mixture, but also is attacked by the organometallic reagent in positions 1 and 4 in addition to the usual 3-position, that is in all isomeric positions in the pyrene molecule. This was shown by the isolation from the acid mixture of three acids two of which were

identical with the known pyrene-3- and pyrene-4-carboxylic acids. The third acid, also being, as shown by analysis, a pyrene-monocarboxylic acid, consequently must be the hitherto unknown pyrene-1-carboxylic acid [5]. Its constitution has been further established by converting it to the known 1-methyl-pyrene *via* 1-pyrenyl carbinol by reduction with lithium aluminium hydride. Also the carbinol is new. The 3-acid itself appeared difficult to isolate in a pure state, but it could be identified as the methyl ester.

The isomer ratio, as roughly estimated from the yields of the three acids in an experiment as described below, was 2:1:0.2, the positions taken in the order 1, 3 and 4. In a typical experiment a conversion of 85 % of pyrene was found, the remainder being recovered. Of converted pyrene 70 % were isolated as acidic products, 70 % of which consisted of the three pyrene-monocarboxylic acids.

More details will appear in a following paper and the present work is continued in different directions.

Experimental. Pyrene (20 g; 0.1 mole) in absolute ether (300 ml) was treated with a filtered solution of *n*-butyllithium, prepared, according to Gilman *et al.* [3], from lithium (8.5 g; 1.22 g. atoms) and *n*-butyl bromide (68.5 g; 0.5 mole) in abs. ether (200 ml). The colour of the solution rapidly turned deep red. After 14 days the solution was pressed into a mixture of dry ice and ether and worked up. From the ether layer pyrene (3.1 g) was recovered. The acidic products were separated by fractionated salting out of the sodium salts. In this way and by recrystallization from acetic acid and chlorobenzene more or less pure fractions of the three pyrene-monocarboxylic acids resulted, amounting to 10.2 g. By repeated recrystallizations pure fractions of the 1- and 4-acids were obtained. The last named acid (m.p. 327—328°) as well as the methyl ester (m.p. 139°; esterification was accomplished with methanolic hydrogen chloride) did not show any depression in mixed m.p. with authentic samples. Not quite pure 3-acid (m.p. about 260°; the pure acid has m.p. 273°) was esterified with methanol and hydrogen chloride and the crude methyl ester chromatographed (in benzene-hexane, 1:1) on alumina. The bulk of the ester was obtained with m.p. 82° and did not show any depression in mixed m.p. with authentic 3-ester (m.p. 83—84°).

Pyrene-1-carboxylic acid. Light yellow fractions with sharp m.p. 275—276° were obtained from chlorobenzene (Found: Equiv. wt. by titration 246.6; C 83.16; H 4.27. Calc. for $C_{17}H_{10}O_2$: Equiv.wt. 246.3; C 82.90; H 4.09). The 1-acid dissolves in conc. sulphuric acid with a yellow colour but without fluorescence (the 3-acid shows a strong yellow-green fluorescence). Esterification in methanolic hydrogen chloride yielded the methyl ester of the 1-acid, m.p. 107—108° (from methanol) (Found: C 83.14; H 4.79. Calc. for $C_{18}H_{12}O_2$ (260.3): C 83.05; H 4.65). Ultraviolet absorption maxima of the ester (in ethanol) were found at: 218.5, 240.4, 253, 280, 310.5, 341.5 and 380.5 mμ.

1-Pyrenyl carbinol. Pyrene-1-carboxylic acid (0.93 g) was extracted down into a stirred suspension of lithium aluminium hydride (0.5 g) in ether in the course of 4 h and the mixture refluxed for an additional hour before it was hydrolyzed and worked up. The organic layer by evaporation of the ether left the carbinol as thin, white needles. Recrystallization from benzene yielded 0.82 g with m.p. 155—155.5° (Found: C 87.50; H 5.18. Calc. for $C_{17}H_{12}O$ (232.3): C 87.88; H 5.21). Ultraviolet absorption maxima were found at 233, 242, 253.5, 264, 274.5, 307.5, 321, 336.7, 351, 363.5 and 373.5 mμ (in ethanol).

The 1-carbinol (0.5 g) was converted to the corresponding chloride as described by Bachmann and Carmack [4] for the 3-carbinol and the chloride then reduced with lithium aluminium hydride in boiling ether. After hydrolysis only a minor part could be identified as definite compounds. The crude product was fractionated from ethanol, and fractions showing a green fluorescence with conc. sulphuric acid (the carbinol does not show this) were chromatographed on alumina (from benzene-hexane, 1:1), when small amounts of 1-pyrenyl carbinol (25 mg) and of not quite pure 1-methyl-pyrene (50 mg) could be isolated. After recrystallization from ethanol the 1-methyl-pyrene fraction (30 mg) showed m.p. 144.5—145°. Repetition of the whole purification procedure brought the m.p. to 147.5—148°. There was no m.p. depression with an authentic specimen of 1-methyl-pyrene whereas a specimen of 4-methyl-pyrene (m.p. 145—146°) depressed the m.p. drastically. The two authentic methyl pyrenes were very kindly supplied by Dr. H. Dannenberg, Max-Planck Institute in Munich and by Dr. O. Kruber, the Gesellschaft für Teerverwertung, Duisberg-Meiderich, to whom I am very much indebted. Also the m.p. of the picrate (228—229°, from

benzene) as well as the ultraviolet absorption spectrum of the hydrocarbon itself agreed with 1-methylpyrene.

A Correction of the Crystal Structure of $MoO_3 \cdot 2H_2O$

INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In order to refine the crystal structure of $MoO_3 \cdot 2H_2O$ [1] a reinvestigation was started in this Institute. Prolonged exposures then showed that the crystal has a considerable superstructure. The new axes a, b, c are related to the earlier a', b', c' in the following way: $a = 4a'$, $b = 2b'$, $c = 2c'$. The cell dimensions are thus $a = 15.08$ Å, $b = 13.82$ Å, $c = 14.68$ Å and $\beta = 90° 40'$. The loss of orthorhombic symmetry which could not be detected in the intensities earlier is now obvious for the superstructure reflexions. It has been checked that the main principles of the suggested structure cannot be influenced by the superstructure but there are of course, small changes in the oxygen positions. The calculated bond distances (except for Mo-Mo) are thus of little value and therefore the basis is removed for the suggestion about the existence of an ion H_4O^{2+}.

Because of change of axes during the work an obvious error has been made in the description of the structure in Ref.[1]: x and z parameters and h and l indices should be interchanged all through the paper to fit the choice of axes.

A complete reinvestigation will be very time-consuming and is not planned at present.

A Nuclear Magnetic Resonance Study of the Dihydrate of Molybdenum Trioxide

S. MARIČIĆ and J. A. S. SMITH

Department of Inorganic and Structural Chemistry, The University of Leeds, England

A combined proton magnetic resonance and infra-red investigation of the dihydrate of molybdenum trioxide has shown that the formula $(H_4O^{++})MoO_4^{--}$ is very improbable [1].

The second moment of the proton absorption line at 77° K is 27.6 gauss [2]. If a symmetrical H_4O^{++} ion existed in the crystal, this value would predict [2] an O—H distance of 1.16 Å in H_4O^{++}, compared with 0.96 Å in water vapour, and this seems an improbably large increase. In addition, the infra-red spectrum shows frequencies at 3 100 and 1 592 cm^{-1}; if these are interpreted as stretching and bending frequencies associated with O—H groups, they suggest an expansion of the order of 0.04 Å only. It would be difficult to reconcile both of these results with the existence of an H_4O^{++} ion.

We hope to publish these results in detail elsewhere.

Metalation of Pyrene

ARNE BERG

Chemical Institute, University of Aarhus, Aarhus, Denmark

Only few strictly aromatic hydrocarbons have been metalated by organolithium compounds [1] and the yields of carboxylic acids obtained upon carbonation have been poor.

Pyrene, in view of its readiness to partake in substitution reactions, and especially of the general rule of substitution in 3-position [2] governing these reactions, seemed an interesting object for metalation.

It has now been found that pyrene, by the action at room temperature of a rather large excess of *n*-butyllithium in diethyl ether not only is metalated as evidenced by the isolation of pyrene carboxylic acids upon carbonation of the reaction mixture, but also is attacked by the organometallic reagent in positions 1 and 4 in addition to the usual 3-position, that is in all isomeric positions in the pyrene molecule. This was shown by the isolation from the acid mixture of three acids two of which were

*iso*Thiocyanates XX *. 4-Pentenyl *iso*Thiocyanate, a New Mustard Oil Occurring as a Glucoside (Glucobrassicanapin) in Nature

ANDERS KJÆR and ROALD BOE JENSEN

Chemical Laboratory of the University of Copenhagen, Denmark

A new volatile mustard oil has been isolated from seed cake of rape (*Brassica napus* L.) and identified as 4-pentenyl *iso*thiocyanate (III), the higher homologue of 3-butenyl mustard oil, (II), previously recognized in the same material. The structure proof of (III) rests on infra-red data for the corresponding thiourea, and degradation of its derivative with 1-naphthylamine, (V), to compounds of established structure.

A synthesis of pure 4-pentenyl *iso*thiocyanate has been accomplished, and synthetic 1-(1-naphthyl)-3-(4-pentenyl)-thiourea (V) shown to be identical with the product derivable from the natural mustard oil.

The latter occurs in the seed as a glucoside for which the name *glucobrassicanapin* is proposed. The identification of the new *iso*thiocyanate makes possible the establishment of a complete picture of the mustard oils of rape seed. Six individual glucosides are genuinely present, three of which in very small amounts only. They are: glucoiberin (or a closely allied compound, traces only), progoitrin (glucorapiferin), sinalbin (traces), gluconapin, glucobrassicanapin and gluconasturtiin (traces), yielding (−)-3-methylsulphinylpropyl mustard oil (or a related species), (−)-5-vinyl-2-oxazolidinethione, *p*-hydroxybenzyl, 3-butenyl, 4-pentenyl and 2-phenylethyl *iso*thiocyanate, respectively, on enzymic hydrolysis.

In a previous paper of this series [1] it was demonstrated that seed of rape (*Brassica napus* L.) on enzymic hydrolysis furnished three volatile *iso*thiocyanates. Of these, the chief constituent was proved to be 3-butenyl mustard oil (II), a conclusion independently attained at also by Ettlinger and Hodgkins [2]. One of the minor components has now been identified as the homologous and heretofore unknown 4-pentenyl *iso*thiocyanate (III).

$CH_2=CHCH_2NCS$ I $CH_2=CHCH_2CH_2NCS$ II $CH_2=CHCH_2CH_2CH_2NCS$ III

* Part XIX of this series: *Acta Chem. Scand.* 10 (1956) 1100.

The occurrence of more than one species in the volatile mustard oil fraction of rape seed has been suspected for many years. In 1899 Jørgensen [3] considered the possible existence of an "angelyl mustard oil" in admixture with the preponderant C_5-species ("crotyl mustard oil"), mainly on basis of nitrogen analyses of the corresponding crude thiourea-mixtures. Schmalfuss [4] subjected the volatile mustard oil mixture from a total of 50 kg of rape seed to fractional distillation and obtained, in addition to 4-pentenonitrile and what is known today as 3-butenyl *iso*thiocyanate, a higher boiling *iso*thiocyanate furnishing a thiourea with an unsharp m. p. of *ca.* 50°. No analytical data or suggestions as to composition and structure were presented. More recently, André and Delaveau [5] succeeded in obtaining an *iso*thiocyanate with comparable physical properties, again by fractionation of the volatile rape seed (colza) mustard oils. The product was devoid of optical activity, and analytical data of the corresponding crystalline thiourea indicated the composition C_5H_9NCS of the mustard oil. The French authors realized the theoretical existence of 13 isomerides satisfying these conditions but did not attempt any determination of the actual structure. They did present, however, good evidence for the second minor component, which is present in trifling amounts only, being 2-phenylethyl *iso*thiocyanate, a species occasionally encountered also in other crucifer seeds.

The starting material in the present experiments was commercially produced rape seed cake which was subjected to enzymic hydrolysis by the addition of white mustard seed, functioning as a source of myrosinase. It was formerly shown [6] that the latter seed gives rise to traces only of volatile mustard oils, insignificant for the present purpose. Steam distillation furnished a yield of less than 0.1 % of volatile *iso*thiocyanates which were fractionated *in vacuo*. Subsequent to the bulk of 3-butenyl mustard oil, the new *iso*thiocyanate distilled as a colourless product, containing traces only of the 3-butenyl species as estimated by paper chromatography of the corresponding thiourea. For the purpose of structure determination and characterization, the *iso*thiocyanate was transformed into crystalline thiourea-derivatives upon reaction with ammonia and 1-naphthylamine. Analyses of both derivatives indicated the composition C_5H_9NCS of the parent *iso*thiocyanate. The infra-red spectrum of the simple thiourea (IV) suggested the presence of a vinyl-grouping. The unbranched character of the five-carbon chain was demonstrated in the following way. The naphthylthiourea (V) was transformed into the corresponding naphthylurea (VI) which, on catalytic hydrogenation, afforded 1-(1-naphthyl)-3-pentylurea (VII), identified by comparison with an authentic specimen produced from *n*-pentylamine and naphthyl *iso*cyanate.

VII

As further corroboration the new natural *iso*thiocyanate (III) has been synthesized along conventional lines as shown in the following scheme.

4-Penten-1-ol (VIII), prepared from tetrahydrofurfuryl alcohol [7], was transformed into 5-bromo-1-pentene (IX) as described by La Forge *et al.*[8] N-(4-Pentenyl)-phthalimide (X), obtained according to the described direction [9] as a solid, m. p. 34°, with correct analysis (Ref.[9] m. p. 40°), afforded the requisite 4-pentenylamine (XI), b. p. 98°, on hydrazinolysis. The amine was characterized as an acid oxalate hemihydrate, m. p. 139°. These data deviate somewhat from those previously recorded. v. Braun [10] prepared the amine, b. p. 91—94°, by thermal decomposition of 5-aminopentyltrimethylammonium hydroxide, whereas Paul and Cottin [11] reported the b. p. 105—106° for the anhydrous amine which was also characterized as an acid oxalate, m. p. 129—130°. They apparently ignored the water of crystallization in this salt. Pure 4-pentenyl *iso*thiocyanate (III) was prepared from (XI) by a modification [12] of Dyson's thiophosgene method [13] and converted into 1-(1-naphthyl)-3-(4-pentenyl)-thiourea (V) in the usual way. Analyses, mixed melting point determination and infra-red spectra served to establish the identity of the naphthylthioureas derived from the natural and the synthetic mustard oil.

Three homologous, straight-chain *iso*thiocyanates possessing a terminal double bond, (I), (II) and (III), have thus been recognized in Nature, the first as the aglucone of the classical and widely distributed glucoside sinigrin. It is interesting that the analogous ω-methylthio compounds, *viz.* 3-methylthiopropyl [14], 4-methylthiobutyl [15] and 5-methylthiopentyl [16] *iso*thiocyanate as well as various higher oxidation states of these, have been encountered also as naturally occurring aglucones. This fact suggests a common biogenetic origin, a possibility which is being further considered in this laboratory. As pointed out in a previous paper [21], 4-pentenyl *iso*thiocyanate seems to occur also in various species of the genus *Alyssum*.

Paper chromatography of the *iso*thiocyanate glucosides in rape seed extracts, essentially following the directions given by Schultz and Gmelin [17], indicates the presence of six individual components, three of which appear in very small amounts only (Fig. 1) *. The same pattern has been obtained for several seed samples of different provenance and is therefore regarded as

* In paperchromatographic survey work Gmelin [18] noticed the occurrence of five glucoside spots in a seed extract of *B. napus*. More recent data from the same laboratory [19], however, indicate the presence of only two glucosides in the same material. According to the paperchromatographic values, these may be interpreted as the chief constituents, *viz.* progoitrin [22] (glukorapiferin [23]) and gluconapin [1, 2, 26], respectively.

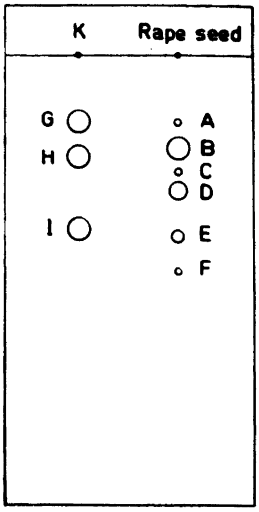

Fig. 1. Schematic, descending paper chromatogram of rape seed iso*thiocyanate glucosides in* n*-butanol : ethanol : water (4 : 1 : 4) (upper phase). A—F: see text. K: reference solution, containing G : glucoiberin [20], H : sinigrin and I : glucotropaeolin (from seeds of* Tropaeolum majus).

characteristic for the species *Brassica napus* L., including several varieties. The component of lowest R_F-value, (A), appears in traces only and may be identical with, or closely related to, glucoiberin, the glucoside previously isolated from *Iberis amara* L.[20] and containing (—)-3-methylsulphinylpropyl *iso*thiocyanate as the aglucone (*cf.* also Ref.[21]). Then follows a spot, (B), attributable to the 2-hydroxy-3-butenyl *iso*thiocyanate glucoside, recently isolated by Greer [22] in crystalline form under the name progoitrin, and almost certainly identical with the glukorapiferin of Schultz and Wagner [23], isolated from seed of a *B. napus* variety and characterized by analysis and melting point of a crystalline pentaacetate.* Enzymic hydrolysis of this glucoside is responsible [22,24,30] for the production of the goitrogenic (—)-5-vinyl-2-oxazolidinethione [25], previously isolated from seeds or fresh parts of various *Brassica* species including rape. A very weak glucoside-spot, (C), can safely be attributed to sinalbin, a long known glucoside containing *p*-hydroxybenzyl *iso*thiocyanate, on account of the correct R_F-value in conjunction with a positive reaction on spraying with diazotized sulphanilic acid [18]. This glucoside has been observed in all *B. napus* species investigated but is consistently present in traces only. Then follow the glucosides giving rise to the volatile mustard oils. First, the progenitor, (D), of the predominant 3-butenyl *iso*thiocyanate [1, 2] for which we have adopted the name gluconapin, introduced in 1905 by Ter Meulen [26] for the glucosidic precursor of the supposedly homogeneous though unidentified volatile mustard oil of rape. With a considerably higher R_F-value follows the 4-pentenyl *iso*thiocyanate glucoside (E) for which we propose the name *glucobrassicanapin*. Lastly, a very faint spot, (F), is consistently apparent, attributable to gluconasturtiin, the 2-phenylethyl *iso*thiocyanate glucoside, an assumption supported by the results of André and Delaveau [5].

* *Added in proof*: Recently, the same authors [30] have indeed presented chemical evidence for the identity of the anions of glukorapiferin and progoitrin.

This picture is regarded as an essentially complete and correct account of the *iso*thiocyanates in rape seeds, a subject of much discussion in the literature through more than five decades. Other species of the genus *Brassica* have been similarly studied in this laboratory. The results will be presented in a forthcoming communication, together with some attempts to correlate the cytological and chemical classification within this important genus.

EXPERIMENTAL

All melting points are uncorrected and determined in capillary tubes in a slowly heated bath.

Isolation. Finely divided rape seed cake (30 kg) was suspended in water (60 l), buffered to pH 6.6 with KH_2PO_4(850 g) and Na_2HPO_4, $2H_2O$ (320 g). Milled seed of white mustard *(Sinapis alba* L.) (5 kg) was added, the suspension was kept at room temperature for 18 hours and steam distilled until about 50 l were collected. The distillate was saturated with salt and extracted three times with a total of 6 l of ether. The extract was dried and the solvent removed over a Vigreux column. The residue was subjected to fractional distillation at 12 mm, using an all-glass column packed with glass-helices and equipped with a total reflux variable take-off head. A forerun, *ca.* 1 g, b. p. 43—60°, was followed by a mustard oil fraction, b. p. 61—70°, redistilled to give 14 g of pure 3-butenyl *iso*thiocyanate (b.p. 64° at 12 mm). Then came a small interfraction (0.6 g), b. p. 71—75°, followed by essentially pure 4-pentenyl *iso*thiocyanate (1.07 g), b. p. 75°. All samples were checked by transformation into thioureas followed by paper chromatography of these in water-saturated chloroform according to our usual method [27]. The last fraction showed a very faint spot only of the 3-butenylthiourea in addition to that of 4-pentenylthiourea and was used directly for preparing the following derivatives.

1-(4-Pentenyl)-thiourea (IV). Treatment of a small sample of the preceding mustard oil with ethanolic ammonia at room temperature furnished a brownish oil which was taken up in benzene. Pentane was added to turbidity, and after one week in the ice-box colourless plates separated, embedded in oily material which was removed by pressing between filter paper. Pure N-(4-pentenyl)-thiourea crystallized from water in thin, nacreous plates, m. p. 43.5—44.0° (Ref.[5] 42.5—43.5°). (Found: C 49.75; H 8.31; N 19.46. Calc. for $C_6H_{12}N_2S$: C 49.97; H 8.39; N 19.43). On descending paper chromatography in water-saturated chloroform an R_{Ph}-value [27] of 0.96 was determined.

The infra-red spectrum, determined in a potassium bromide disc, showed prominent bands at 2.90 (v.s.), 3.27 (m.), 6.08 (v.s.), 6.35 (v.s.), 6.79 (s.), 6.98 (s.), 7.29 (v.s.), 7.60 (m.), 8.27 (m.), 8.54 (m.), 8.79 (w.), 10.01 (s.), 10.92 (v.s.), 11.78 (w.), 13.46 (w.) and 14.06 μ (m.). The bands at 10.01 and 10.92 μ are particularly important in this connexion because they strongly indicate the presence of a vinyl grouping [29]. The ultra-violet absorption spectrum in ethanol was of the usual type, λ_{max} 242 mμ (ε_{max} 14 150), λ_{min} 225 mμ (ε_{min} 5 100).

1-(1-Naphthyl)-3-(4-pentenyl)-thiourea (V). A solution of the natural mustard oil (50 mg) and freshly recrystallized 1-naphthylamine (65 mg) in ethanol (3 ml) was heated to reflux for 2 hours. Removal of the solvent left an oil which crystallized on being rubbed with a few drops of ethanol. Two recrystallizations from aqueous ethanol afforded the pure thiourea (73 mg) as needles, m. p. 102°. (Found: C 70.95; H 6.60; N 10.25. Calc. for $C_{16}H_{18}N_2S$: C 71.06; H 6.71; N 10.36). A week later, the m. p. was found to be 126°, obviously a case of dimorphism. A sample prepared from synthetic 4-pentenyl *iso*thiocyanate and 1-naphthylamine (see below) still appeared as the low-melting form after two recrystallizations from aqueous ethanol, but changed to the high-melting modification on a third recrystallization from the same solvent. Once the high-melting form had appeared, it was no longer possible to realize the low-melting modification. Polymorphism has frequently been observed within the class of thioureas, the present case closely resembling that of *e. g.* 1-(*m*-methoxybenzyl)-3-phenyl-thiourea, recently discussed by Ettlinger and Lundeen [28].

Synthesis of 4-pentenyl isothiocyanate (III). The reaction of 4-penten-1-ol [7] (VIII) and phosphorus tribromide in pyridine, following described directions [8], furnished in somewhat lower yield (70 %) 5-bromo-1-pentene (IX), b. p. 58° at 70 mm. The latter was converted into N-(4-pentenyl)-phthalimide (X) in 75 % yield according to Kharasch and Fuchs [9], b. p. 163° at 2 mm (lit.[9] 155—157° at 2 mm). A sample of the phthalimide, recrystallized twice from aqueous ethanol, melted at 34° (lit.[9] 40°). (Found: C 72.45; H 6.15; N 6.49. Calc. for $C_{13}H_{13}NO_2$: C 72.56; H 6.09; N 6.51).

Hydrazinolysis was performed by refluxing the phthalimide (26 g) and hydrazine hydrate (6.7 ml) in ethanol (150 ml) for one hour. The suspension was digested for another hour at 100° with 500 ml of 6 N HCl, whereupon the ethanol was removed by distillation. The phthalylhydrazide was filtered off, the filtrate concentrated to about 200 ml and made strongly alkaline. Salt was added to saturation, the amine extracted with ether, the extract dried over KOH pellets, and the ether removed over a column. The crude 4-pentenylamine (8.5 g) was further dried over fresh KOH for two days and distilled in a system protected from the atmosphere, b. p. 98°. Analysis indicated that water was still present in the product, though less than corresponding to a monohydrate. (Found: N 15.0. Calc. for $C_5H_{11}N$: N 16.5; for $C_5H_{13}NO$: N 13.6). The amine acid oxalate hemihydrate formed colourless needles from ethanol, m. p. 139.0—139.5° (lit.[11] 129—130°). (Found: C 45.70; H 7.47; N 7.61. Calc. for $C_5H_{11}N$, $C_2H_2O_4$, 0.5 H_2O: C 45.63; H 7.66; N 7.61). Drying of the salt at 100° over P_2O_5 resulted in weight loss, but the extremely hygroscopic nature of the anhydrous product made a quantitative determination of the water of crystallization impossible.

To a solution of thiophosgene (2.08 g) in chloroform (25 ml) was added another solution of 4-pentenylamine (1.7 g) in water (7 ml). 1 N NaOH (39.5 ml) was slowly added to the stirred solution, and the yellow colour gradually disappeared. The chloroform layer was dried, the solvent removed and the residue distilled *in vacuo*. Pure 4-pentenyl *iso*thiocyanate III) (0.9 g) was obtained as a colourless oil possessing a characteristic mustard oil smell, though less penetrant than that of 3-butenyl *iso*thiocyanate, b. p. 75° at 12 mm, n_D^{25} 1.5118 (lit. 73.7°/11.5 mm[4], 76—77°/10 mm[5]; n_D^{18} 1.5187 [4], n_D^{20} 1.5172 [5]). (Found: C 56.30; H 7.28; N 10.97. Calc. for C_6H_9NS: C 56.65; H 7.13; N 11.01).

The synthetic *iso*thiocyanate was transformed into its thiourea derivative with 1-naphthylamine as described above for the natural mustard oil. The stable modification was obtained as colourless needles, m. p. 125°, alone or in admixture with the natural derivative. (Found: C 71.15; H 6.67; N 10.40. Calc. for $C_{16}H_{18}N_2S$: C 71.06; H 6.71; N 10.36). The infra-red spectra were determined for both specimens and found to be identical.

1-(1-Naphthyl)-3-(4-pentenyl)-urea (VI). The thiourea (714 mg), dissolved in ethanol (40 ml), was treated with a solution of silver nitrate (896 mg) in 75 % ethanol (15 ml), resulting in instantaneous separation of silver sulphide. Sodium hydroxide (1 N) was added dropwise to neutral reaction, and the mixture was heated to reflux for two hours. The suspension was filtered through Celite, the precipitate thoroughly washed with ethanol, and the joint filtrate and washing liquor diluted with half the volume of water, resulting in precipitation of the crystalline urea. The product was recrystallized twice from 90 % ethanol and pure 1-(1-naphthyl)-3-(4-pentenyl)-urea (VI) separated as tiny, colourless needles (470 mg), m. p. 152°. (Found: C 75.30; H 7.13; N 11.10. Calc. for $C_{16}H_{18}N_2O$: C 75.58; H 7.13; N 11.02).

1-(1-Naphthyl)-3-pentyl-urea (VII). On mixing equimolecular amounts of naphthyl *iso*cyanate and *n*-pentylamine in ether solution, 1-(1-naphthyl)-3-pentylurea crystallized spontaneously. It separated from aqueous ethanol in colourless needles, m. p. 146.5—147.0°. (Found: C 74.45; H 7.96; N 11.15. Calc. for $C_{16}H_{20}N_2O$: C 74.74; H 7.87; N 10.93).

No depression of the m. p. was observed when this product was mixed with a specimen prepared by catalytic hydrogenation of the corresponding unsaturated urea described above. The reduction was performed in ethanolic solution at ordinary pressure with Adam's platinum catalyst. The infra-red spectra of the two specimens were determined and found to be identical.

Paper chromatography. In the present work, all paper chromatograms were run by the descending technique on Whatman paper No. I in a constant temperature room. Methanolic extracts of the various seed samples were employed without further puri-

fication in the paperchromatographic analyses of the glucoside contents, the spraying and development being performed essentially as described elsewhere[17]. The identity of (B) (Fig. 1) as progoitrin (glukorapiferin) was proved in the following way. A rape seed extract was applied to an 18 cm broad paper strip as a band and chromatographed in the usual way. A small strip, cut from each edge, was developed in order to locate the component (B). The corresponding section of the main strip was cut out, eluted with water and the eluate subjected to enzymic hydrolysis by adding a droplet of a myrosinase solution. After 4 hours, the solution was extracted with ether, the solvent removed and the ultra-violet absorption spectrum determined for an ethanolic solution of the residue. An absorption pattern was obtained, identical with that previously reported for 5-vinyl-2-oxazolidinethione [25]. The other glucoside spots on the paper chromatogram were found devoid of characteristic absorption when tested in a similar way.

Microanalyses were performed in this laboratory by Mr. P. Hansen. Valuable assistance of Mr. I. Larsen in the preliminary experiments is acknowledged. We wish to thank *Dansk Sojakagefabrik* Inc. for the gift of rape seed cake, and *Pharmacia Inc.* for placing at our disposal the necessary technical equipment.

The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*.

Die Capillaritätscorrection von Routine-Viscosimetern

CARL DRUCKER

Physikalisch-chemisches Institut der Universität, Uppsala, Schweden

Durch Beobachtung im rein cylindrischen Teile eines Normalviscosimeters mit gleich weiten Gefässen können die für Capillareffecte corrigierten relativen Auslaufzeiten auf vorläufig 0,05 % genau bestimmt werden. Aus solchen Messungen ergeben sich die Factoren, mittels deren die bei beliebig geformten Routineinstrumenten gefundenen relativen Totalauslaufzeiten zu corrigieren sind. Diese Correctionen können recht wohl 0,5 bis 1 % betragen und dürfen deshalb nicht vernachlässigt werden. Da sie bei beiderseits cylindrischen, gleichweiten Gefässen — mit kurzen conischen Endteilen — wesentlich geringer sind als bei allen anderen Formen, so sollen ungleich weite cylindrische sowie kugelähnliche und doppeltconische Gefässe auch bei gewöhnlichen Routineinstrumenten nach Möglichkeit vermieden werden.

Wenn die Auslaufzeit t einer Flüssigkeit in einem Ostwaldschen Capillarviscosimeter mit der einer Standardsubstanz verglichen wird, so ist die relative Auslaufzeit ($t/t_0 = z$) mit einem Fehler behaftet, der von den Gefässdimensionen und den beiden Capillaritätsconstanten a^2 und a_0^2 abhängt. Um diesen sowohl klein zu halten wie experimentell bestimmen zu können, verfährt man am besten so, dass man beiden Gefässen des Instrumentes cylindrische Form mit gleich grossen Radien gibt.

NORMALVISCOSIMETER

Die Radien der beiden cylindrischen Rohre, deren conische Übergangsteile möglichst niedrig gehalten sind (s. Fig. 1) seien $r_0 = r_u$; ausser den üblichen Marken a und b seien auf dem oberen Gefässe noch zwei feine Ringmarken A und B so angebracht, dass der Meniscus bei A resp. bei B sich völlig im cylindrischen Teile befindet.

Beträgt die mittlere Meniscushöhe einer Standardflüssigkeit — bei den folgenden Versuchen stets Wasser — m_0, so gilt für den Auslauf von A bis B eine mittlere Druckhöhe

$$H_0=\frac{1}{2}\Big\{[(A+m_0)-(A'+m_0)]+[(B+m_0)-(B'+m_0)]\Big\}=\frac{1}{2}[(A-A')+(B-B')]$$

also derselbe Wert, wie wenn gar kein Meniscus vorhanden wäre. Bei Füllung des Instrumentes mit genau demselben Volumen einer anderen Flüssigkeit gilt eine Meniscushöhe m, und stellt man auch hier den oberen Meniscus auf A ein, so steht der untere bei A' + $2(m_0 - m)$ und H_0 geht über in

$$H = \frac{1}{2}\left\{(A + m) - [(A' + m) + 2(m_0 + m)] + (B + m) - [(B' + m) + 2(m_0 - m)]\right\}$$

$$= H_0[1 - \frac{2(m_0 - m)}{H_0} = H_0\,(1 - \lambda_2).$$

Ist $m_0 - m$, so zeigt diese Flüssigkeit eine Auslaufzeit T, welche im Vergleich zu der der Standardsubstanz, T_0, zu gross ist, und ihre wahre relative Auslaufzeit beträgt nicht $Z_m = T/T_0$ sondern $Z'_m = Z_m\,(1 - \lambda_2)$. (Dieser Effect wurde früher [3] als Verdrängungscorrection bezeichnet.) Bestimmt man auch die relative Zeit Z_t des Totalauslaufes zwischen a und b, so ist diese mit dem Factor $F' = Z'_m/Z_t$ zu corrigieren.

Diese vom Einflusse der Capillaritätseffecte befreiten wahren relativen Auslaufzeiten Z'_m müssen mit jedem Normalinstrumente gleich gross gefunden werden, falls die Versuchsbedingungen dieselben sind. Ungleiche Verticalorientierung der Instrumente oder ungenaue Füllung kann Abweichungen verursachen.

Versuche. In einem so gebauten Rohr (Nr 18) mit den Radien $r_0 = r_u = 4{,}20$ mm und der Druckhöhe $H_0 = 158$ mm wurde, mit Wasser als Bezugssubstanz, Folgendes gefunden (Tabelle 1).

Tabelle 1.

	a_2	m	T	t	λ_2	Z_m	Z'_m	Z_t	F'
Wasser	14,68	0,91	1670,8	2171,0	—	—	—	—	—
Dichloressigsäure .. 6,7 %	11,72	0,86	1870,2	2466,7	0,0006	1,1193	1,1186	1,1179	1,0006
o-Xylol	6,80	0,71	1622,9	2101,4	0,0025	0,9713	0,9689	0,9678	1,0013
Aethylenbromid ..	3,61	0,53	1396,5	1801,7	0,0048	0,8358	0,8318	0,8299	1,0023

Die Meniscushöhen m sind in bekannter Weise berechnet [1,2]; aus ihnen ergaben sich die jeweiligen Werte von λ_2.

Ein anderes Normalinstrument (Nr X) von etwas abweichenden Dimensionen ($r_0 = r_u = 5{,}06$ mm, $H_0 = 168$ mm) ergab für F' die Zahlen 1,0002, 1,0012, 1,0020, also fast identisch mit Nr. 18. Die Unsicherheit dieses Factors dürfte 0,0005 nicht erreichen.

F' weicht hier nur wenig von 1 ab, steigt jedoch bei beiden Rohren ein wenig an, antibat zur Capillaritätsconstanten. Dieser Gang braucht nicht in allen Fällen vorzuliegen, da er von Form und Grösse der beiden conischen Endteile mitbestimmt wird. Dies ging bereits aus den früher mitgeteilten

Untersuchungen hervor und kann auch aus der Tabelle 2 entnommen werden. Diese gilt, bei denselben Flüssigkeiten wie oben, für den Totalauslauf in einem Rohr (Nr VI) mit ebenfalls beiderseits gleichen Radien $r_0 = r_u = 7{,}50$ mm.

Tabelle 2.

	t	Z_t	$F = Z'_m / Z_t$
Wasser	1015,4	—	—
Dichloressigsäure 6,7 % ..	1132,8	1,1167	1,0026
o-Xylol	981,6	0,9668	1,0024
Aethylenbromid	843,8	0,8311	1,0010

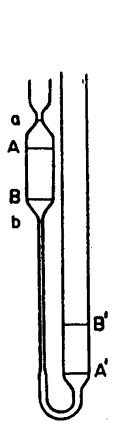
Die wahren relativen Zeiten Z'_m sind aus Tabelle 1 entnommen, und die in diesem Falle merklich verschiedene Grösse der beiden conischen Teile macht sich in dem umgekehrten Gange von F bemerklich.

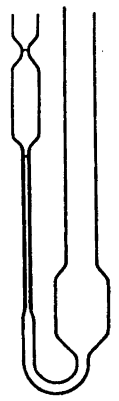
Trotzdem kann auch dieses Instrument als »secundäres» Normalinstrument verwendet werden, nachdem seine eigenen Correctionsfactoren ermittelt sind. Es bietet den Vorteil, dass seine Totalauslaufzeit viel kürzer ist als die des primären Instrumentes Nr 18.

ROUTINEVISCOSIMETER

Bei laufenden Messungen verwendet man fast immer anders gebaute Instrumente. Ihre Gefässe sind ungleich weit (Fig. 2, 3) und, wenigstens die oberen, kugelähnlich (Fig. 3) oder doppeltconisch. Infolge dessen ist die Differenz der Meniscushöhen, $m_0 - m$, nicht constant, sondern ändert sich während des Auslaufes beständig und zwar in unberechenbarer Weise.

Die Correctionsfactoren müssen also in diesen Fällen mit Hilfe der in den Normalinstrumenten gewonnenen Resultate ermittelt werden. Über die Grösse, welche sie annehmen können, mögen einige Beispiele Auskunft geben.





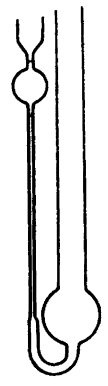


Fig. 1

Fig. 2

Fig. 3

Ein Viscosimeter (Nr XIV) mit beiderseits cylindrischen Rohren, aber verschieden grossen Radien $r_0 = 4{,}01$ und $r_u = 11{,}4$ mm (vgl. Fig. 2), zeigte folgende Totalauslaufzeiten z_t resp. z (s. Tab. 3), aus welchen sich mittels der am Normalinstrumente Nr 18 gewonnenen Zahlen (vgl. Tab. 1) die Correctionsfactoren $F = Z'_m/z_t$ ergeben. Wie man sieht, sind diese weit grösser als F' bei Nr 18.

Tabelle 3.

	t	z_t	Z'_m	$F' = Z'_m/z_t$
Wasser	1061,0	—	—	—
Dichloressigsäure 6,7 %	1180,9	1,1130	1,1186	1,0051
o-Xylol	1020,0	0,9613	0,9689	1,0079
Aethylenbromid	874,7	0,8244	0,8318	1,0091

Ein anderes Instrument (Nr II) mit nahezu kugelförmigen Gefässen, deren unteres etwa doppelt so viel Flüssigkeit fasste wie das obere (vgl. Fig. 3), wurde mit zwei verschiedenen Füllungen v_1 und $v_2 = 2\ v_1$ untersucht. Aus Tab. 4 geht hervor, dass das Verhältnis t_1/t_2 deutlich von der Füllhöhe abhängt, weil die Druckhöhen sich mit den Gefässradien ändern, und zwar, wegen der Verschiedenheit der Capillaritätsconstanten, in ungleicher Weise. Die ebenfalls auf Nr 18 bezogenen Correctionsfactoren F_1 und F_2 weichen wiederum stark von 1 ab und sind sogar unter einander verschieden.

Tabelle 4.

	t_1	t_2	t_2/t_1	Z'_m	z_1	z_2	$F_1 = \frac{Z'_m}{z_1}$	$F_2 = \frac{Z'_m}{z_2}$
Wasser	672,2	708,7	1,0536	—	—	—	—	—
Dichloressigsäure 6,7 %	747,9	789,7	1,0558	1,1186	1,1125	1,1142	1,0055	1,0040
o-Xylol	648,7	685,3	1,0563	0,9689	0,9650	0,9670	1,0050	1,0020
Aethylenbromid	556,0	587,8	1,0571	0,8318	0,8270	0,8293	1,0059	1,0031

In dieser Weise lassen sich also die durch die Capillaritätseffecte bedingten Correctionsfactoren des Totalauslaufes von Routineviscosimetern ermitteln. Sollten etwa bei solchen Aichungen andere Vergleichsflüssigkeiten als hier verwendet werden, so braucht man nur die erforderlichen Werte von F' durch Interpolation nach Massgabe der Capillaritätsconstanten zu bestimmen *.

Da übrigens diese Factoren nur wenig temperaturempfindlich sind, wird man die etwa wie hier bei 25° gefundenen Werte auch bei 20° oder 30° anwenden dürfen.

* Wäre etwa bei Tabelle 1 eine Substanz mit $a^2 = 9{,}00$ mit Wasser verglichen worden, so hätte sich für diese $F' = 1{,}0010$ ergeben.

Routineviscosimeter mit ungleich weiten, nicht cylindrischen Rohren können also Correctionen der relativen Auslaufzeiten um ½ % oder mehr verlangen. Diese dürfen vielleicht bisweilen vernachlässigt werden, doch nicht immer, z.B. nicht, wenn es sich um die Eigenviscosität einer stark capillaractiven Substanz in verdünnter Lösung handelt. Ein solcher Fall sei hier angeführt.

Es wurde in den Viscosimetern (II) und (18) die stark capillaractive Hendekafluorhexylsäure, $C_5F_{11}COOH$, in verdünnter wässriger Lösung gemessen (0,266 %, $a^2 = 11{,}7$.) In Nr II betrug die Auslaufzeit für Wasser 672,0 sec., für die Lösung 673,3 sec., somit $z_t = 1{,}0019$. Im cylindrischen Teile von Nr 18 wurde gefunden 1670,0 resp. 1683,4, also $Z_m = 1{,}0074$. Da λ_2 sich hier zu 0,0006 berechnet, wird $Z'_m = 1{,}0068$. Die Eigenviscosität, wie sie aus Z'_m folgt, ist demnach im Verhältnis 0,0068/0,0019 = 3,5 grösser als nach dem uncorrigierten Werte z_t, dessen Fehlerhaftigkeit hier besonders deutlich zu Tage tritt.

Je näher also die relative Viscosität η/η_0 einer Lösung an 1 liegt, d.h. je verdünnter diese ist, um so falscher ergibt sich die Eigenviscosität, wenn man sie aus dem uncorrigierten Resultate des Routineinstrumentes berechnet, statt dem richtigen Werte des Normalviscosimeters.

Synthesis of Compounds Related to Muscarufin

II. 3,6-Dihydroxy-2,5-bis-(2-carboxyphenyl)-benzoquinone

MARTIN NILSSON

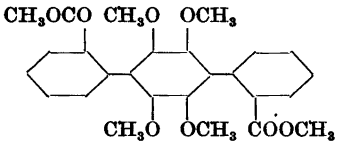
Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

3,6-Di-iodo-2,5-dimethoxybenzoquinone has been converted into 3,6-di-iodo-1,2,4,5-tetramethoxybenzene, which on Ullmann coupling with methyl 2-bromobenzoate afforded 2,3,5,6-tetramethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (I). This was transformed further into 3,6-dimethoxy-2,5-bis-(2-carbomethoxyphenyl)-benzoquinone (II) and 3,6-dihydroxy-2,5-bis-(2-carboxyphenyl)-benzoquinone (III). The last mentioned compound is related to the fungal pigments muscarufin and polyporic acid.

In the previous communication [1] the synthesis of 2,5-bis-(2-carbomethoxyphenyl)-benzoquinone was reported. The present paper deals with the synthesis of 3,6-dihydroxy-2,5-bis-(2-carboxyphenyl)-benzoquinone (III), which is interesting as an analogue of both muscarufin and polyporic acid although it has not been found in Nature.

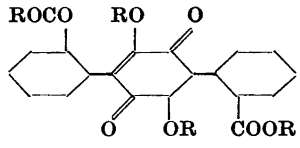
Earlier it had been found difficult to introduce further substituents on the central nuclei of 2,5-dimethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene and 2,5-bis-(2-carbomethoxyphenyl)-benzoquinone. The most suitable approach to the synthesis of the dihydroxyquinone III was therefore considered to be an Ullmann coupling of methyl 2-bromobenzoate with a *p*-di-iodo compound already possessing the essential features of the central nucleus.

Preliminary experiments aiming at the direct iodination of 1,2,4,5-tetramethoxybenzene to 3,6-di-iodo-1,2,4,5-tetramethoxybenzene were unsuccessful and interest was therefore turned to the use of 3,6-di-iodo-2,5-dimethoxybenzoquinone as a starting material. This compound was prepared in poor yield from iodo-anil *via* di-iodo-dimethoxybenzoquinone di-methyl hemiacetal according to Jackson and Bolton [2]. Reduction with phenyl hydrazine and methylation of the hydroquinone thus obtained gave 3,6-di-iodo-1,2,4,5-tetramethoxybenzene.



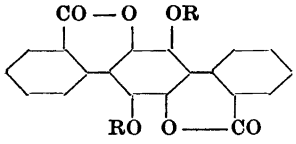
Ullman coupling with methyl 2-bromobenzoate then afforded 2,3,5,6-tetramethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (I) in good yield. The product, however, was found to be a mixture of two different types of

crystals, which could not be completely separated. They were readily interconvertible and it may be presumed that they are the *cis*- and *trans*-isomers arising from hindered rotation, the energy barrier between them being low enough to permit rapid equilibration. Similar although stable isomers have been described for 3,6-dibromo-2,5-dihydroxy-1,4-bis-(2,4-dimethylphenyl)-benzene and its derivatives [3].



2,3,5,6-Tetramethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene on cautious treatment with nitric acid yielded 3,6-dimethoxy-2,5-bis-(2-carbomethoxyphenyl)-benzoquinone (II), which on alkaline hydrolysis gave the desired 3,6-dihydroxy-2,5-bis-(2-carboxyphenyl)-benzoquinone (III). This compound is a high melting solid, which can be recrystallised from dioxan giving crystals containing five moles of solvent of crystallisation. It is somewhat soluble in hot water giving a bluish solution and it dissolves readily in aqueous alkali to give an intense violet colour.

The dihydroxyquinone III on reductive acetylation afforded a dilactone diacetate (IV). This behaviour is analogous to that of 2,5-bis-(2-carbomethoxyphenyl)-benzoquinone but is in contrast to that of muscarufin, which on similiar treatment is reported to give a triacetate (*cf.* Ref. [1]).



The controlled action of hydrobromic acid on 2,3,5,6-tetramethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene afforded a dimethoxy dilactone (V) and even when the dihydroxyquinone III itself was heated lactonisation occurred to give a quinonoid dilactone (VI), which was however far less resistant to hydrolysis than the above mentioned dilactones; it dissolved fairly rapidly in cold, dilute aqueous alkali.

III R = H-

IV R = CH_3CO-
V R = CH_3-

VI

EXPERIMENTAL

All melting points are uncorrected.

3,6-Di-iodo-2,5-dimethoxy-1,4-dihydroxybenzene. Bromo-anil was treated with an excess of sodium or potassium iodide (in successive portions) in boiling acetone or ethanol [4,5]. A crude iodo-anil was obtained, which was extracted with hot acetic acid to remove part of the bromo-iodoquinones present, and then recrystallised from large

volumes of ethyl acetate or benzene. The yield of purified iodo-anil was 20—40 %, large scale preparations giving the smaller yields. Treatment with sodium methoxide in methanol [5] (equivalent amount or a moderate excess) afforded the amorphous di-iodo-dimethoxybenzoquinone dimethyl hemiacetal, which on heating with acetic anhydride [2] gave 3,6-di-iodo-2,5-dimethoxybenzoquinone (overall yield from iodo-anil 10—35 %). It was found to be most important to use a thoroughly purified iodo-anil; with less pure material large amounts of ill-defined by-products were obtained and the yield of di-iodo-dimethoxyquinone was considerably diminished.

3,6-Di-iodo-2,5-dimethoxybenzoquinone (7.2 g) was suspended in hot (90°) acetic acid and phenyl hydrazine (2.5 ml) added dropwise with shaking until the nitrogen evolution ceased. After cooling to room temperature the product (5.2 g) was collected and recrystallised from acetic acid to give needles, which slowly darkened in the air, m.p. 240° (decomp.). (Found: C 22.9; H 1.9; I 60.1. Calc. for $C_8H_8O_4I_2$: C 22.8; H 1.9; I. 60.2.)

3,6-Di-iodo-1,2,4,5-tetramethoxybenzene. 3,6-Di-iodo-2,5-dimethoxy-1,4-dihydroxybenzene was dissolved in a mixture of ethanol and excess dimethyl sulphate. The solution was stirred under an atmosphere of coal gas and a 50 % solution of sodium hydroxide in water added. On addition of water the methylated product separated in almost quantitative yield. Recrystallisation from methanol (charcoal) gave long needles, m.p. 136—137°. (Found: C 27.2; H 2.8; I 55.6. Calc. for $C_{10}H_{12}O_4I_2$: C. 26.7; H 2.7; I 54.4.)

2,3,5,6-Tetramethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene, (I). 3,6-Di-iodo-1,2,4,5-tetramethoxybenzene (11 g), methyl 2-bromobenzoate (21 g) and copper bronze (60 g) were mixed intimately and heated to 200°; a reaction then brought the temperature up to *ca.* 270°. The reaction mixture was allowed to cool and was then exhaustively extracted with chloroform in a Soxhlet apparatus. The solvent was removed and the residue distilled *in vacuo* yielding besides dimethyl diphenate and a small amount of methyl benzoate a fraction b.p. 200—300°, 1 mm (6.6 g), which solidified to a mixture of needles and prisms on trituration with methanol. On recrystallisation from the same solvent it became evident that the two forms were crystalline modifications of the same compound. The prisms (m.p. around 130°) were apparently more stable above 30°, but below this temperature needles (m.p. about 120°) dominated in the mixture. It was not, however, possible to obtain a perfectly homegeneous sample; even after seeding and rapid separation of the various crops contaminated crystals were obtained. The interconvertibility of the forms is shown by the fact that a sample mainly consisting of one form could give a product in which the other form predominated. The product obtained after six recrystallisations from various solvents was sublimed *in vacuo* and analysed (m.p. 122—129°). (Found: C 66.5; H 5.7. Calc. for $C_{26}H_{26}O_8$; C 66.9; H 5.6.)

3,6-Dimethoxy-2,5-bis-(2-carbomethoxyphenyl)-benzoquinone, (II). Nitric acid (15 ml, *d* 1.42) was slowly added to a suspension of finely powdered 2,3,5,6-tetramethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (0.50 g) in water (5 ml) and methanol (5 ml). The colour of the mixture turned yellowish red and the crystals dissolved. After some minutes water (50 ml) was added and after 1 h the crystalline precipitate was collected (0.43 g), and recrystallised from *n*-butyl ether and from methanol to give coarse yellow needles m.p. 178—180°. (Found: C 65.9; H 4.9. Calc. for $C_{24}H_{20}O_8$: C 66.0; H 4.6.)

3,6-Dihydroxy-2,5-bis-(2-carboxyphenyl)-benzoquinone, (III). 3,6-Dimethoxy-2,5-bis-(2-carbomethoxyphenyl)-benzoquinone (0.24 g) was added to a solution of sodium hydroxide (2 g) in water (5 ml) and ethanol (15 ml). It slowly dissolved giving a violet solution which was heated on the water bath (20 min.), cooled and acidified. The reddish precipitate was collected (0.17 g) and recrystallised from dioxan giving orange prisms, which slowly crumbled in the air giving off dioxan. They were found to contain *ca.* five moles of dioxan of crystallisation. (Found: 47.4 % loss of weight on drying *in vacuo* at 130°. Calc. for 5 moles of dioxan: 48.7 %.) When heated the dried material sublimed slowly above 280°, began to decompose at *ca.* 350° and melted with decomposition at about 370—375°. The dried material was analysed. (Found: C 63.4; H 3.3. Calc. for $C_{20}H_{12}O_8$: C 63.2; H 3.2.)

3,6-Dihydroxy-2,5-bis-(2-carboxyphenyl)-benzoquinone dilactone, (VI). On sublimation or prolonged heating *in vacuo* at 200° 3,6-dihydroxy-2,5-bis-(2-carboxyphenyl)-benzoquinone turned yellow; apparently water was given off and a dilactone formed. This compound decomposed above 350° and dissolved, although not as rapidly as the parent dihydroxyquinone, in aqueous alkali giving a violet solution. The sublimed product was analysed. (Found: C 69.6; H 2.6. Calc. for $C_{20}H_8O_6$: C 69.8; 2.3.)

3,6-Diacetoxy-2,5-dihydroxy-1,4-bis-(2-carboxyphenyl)-benzene dilactone, (V), (or possibly the isomeric 5,6-diacetoxy-2,3-dihydroxy compound). A small amount of the dihydroxyquinone III was heated under reflux for 0.5 h with acetic anhydride, fused sodium acetate and zinc dust. The white precipitate was collected and recrystallised from large volumes of acetic anhydride giving small needles, m.p. *ca.* 340° (decomp.) (Found: C 66.3; H 3.3. Calc. for $C_{24}H_{14}O_8$: C 67.0; H 3.3.)

3,6-Dimethoxy-2,5-dihydroxy-1,4-bis-(2-carboxyphenyl)-benzene dilactone, (V), (or the isomer, as pointed out for the previous substance). 2,3,5,6-Tetramethoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene (0.25 g) was heated to boiling with hydrobromic acid (2 ml, *d* 1.48) and acetic acid (7 ml). The crystals dissolved immediately but after a few minutes a white precipitate appeared. Heating was continued for a total of 7 min. and the mixture allowed to cool. The precipitate (0.20 g) was recrystallised from acetic acid giving small needles, m.p. *ca.* 316°. (Found: C 70.4; H 4.2. Calc. for $C_{22}H_{14}O_6$: C 70.6; H 3.8.)

If the demethylation procedure was extended over several hours complete demethylation apparently occurred. The product obtained was rather sensitive to air and was partially oxidised on attempts to recrystallise it from acetic acid; it was not further investigated.

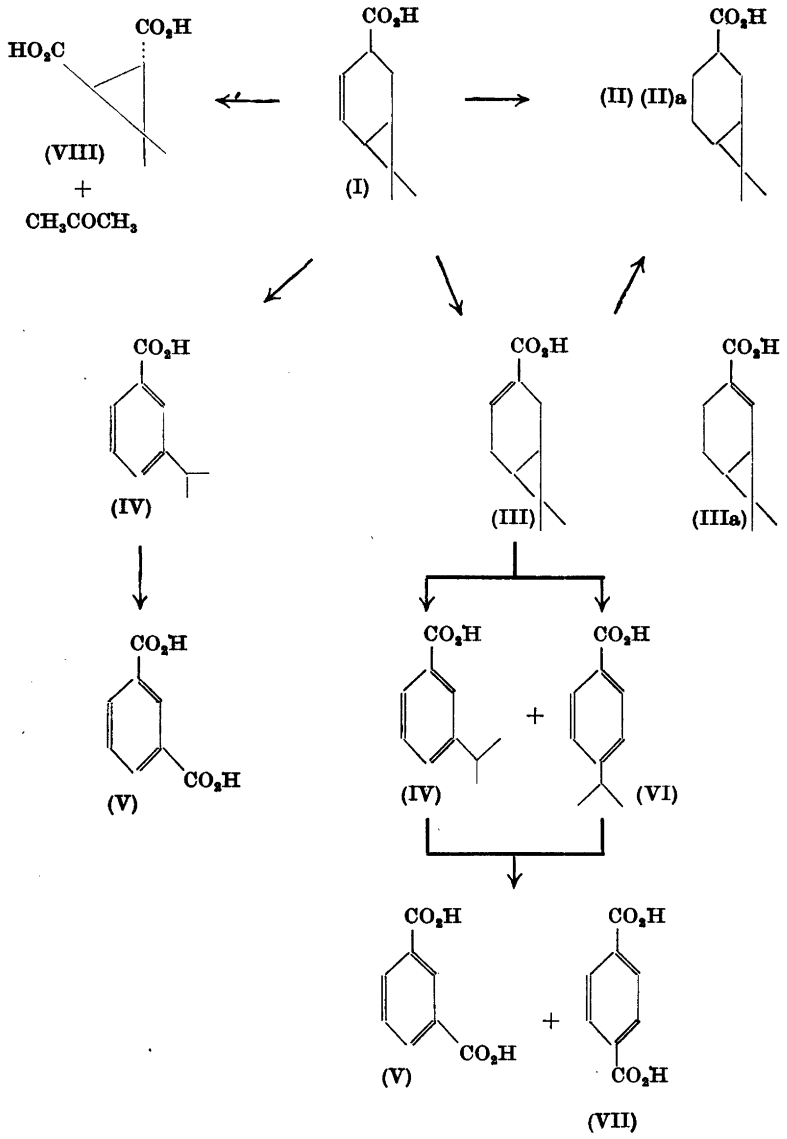
The Chemistry of the Natural Order Cupressales

XVI.* Heartwood Constituents of *Chamaecyparis nootkatensis* (Lamb.) Spach. The Structure of Chamic and Chaminic Acids

H. ERDTMAN, W. E. HARVEY and J. G. TOPLISS

Organisk-Kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Chamic acid, $C_{10}H_{14}O_2$, has been shown to be a monoterpene acid of structure (I). The presence of the dimethyl*cyclo*propyl grouping (IX) was demonstrated by the formation of *trans*-caronic acid (VIII) on permanganate oxidation and the relative positions of the carboxyl group and the *cyclo*propane ring were deduced from the transformation of chamic acid into *m*- and *p-iso*propylbenzoic acids (IV, VI) and further into *iso*- and *tere*phthalic acids (V, VII). The position of the double bond followed from a study of the ultra-violet and infra-red absorption spectra of chamic acid and its alkali isomerisation product, *iso*chamic acid (III).



Another acid, chaminic acid, has also been isolated in very small quantities from the heartwood and has been shown to be the optical antipode of *iso*chamic acid.

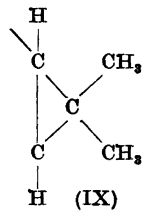
The isolation of chamic acid from the heartwood of *Chamaecyparis nootkatensis* and its characterisation as the *p*-bromophenacyl ester and the *cyclo*hexylamine and *S*-benzylthiuronium salts has been described in a previous communication [1]. The present communication describes the degradative experiments which have led to the elucidation of the structure of chamic acid and the probable structure of chaminic acid.

Permanganate oxidation of chamic acid under alkaline conditions resulted in extensive decomposition but from the mixture of oxidation products a small quantity of *dl-trans*-caronic acid (VIII) and acetone (as the 2,4-dinitrophenylhydrazone) were isolated and evidence for the presence of dimethylmalonic acid was also obtained. This establishes the presence of the grouping (IX) in chamic acid **. Moreover these results are reminiscent of the results obtained

* Part XV *Acta Chem. Scand.* **9** (1955) 1728.

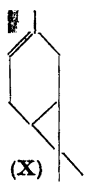
** The weak infra-red bands at 1 007 cm^{-1}, 998 cm^{-1} and 1 011 cm^{-1} for chamic, *iso*chamic and dihydrochamic acids, respectively, provide additional evidence for the presence of the *cyclo*-propane ring system in these compounds.

on oxidation of Δ^3-carene under similar conditions [2] and suggest that chamic acid may possess a close structural resemblance to the carenes.

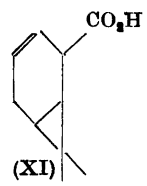


The catalytic reduction of chamic acid in alcoholic solution in the presence of Adams' catalyst resulted in the rapid uptake of one mole of hydrogen affording dihydrochamic acid (II), obtained as an oil but readily characterised by its *p*-bromophenacyl ester m. p. 79—80°. Hence chamic acid has one double bond and therefore could possess a fused *cyclo*propane-*cyclo*hexene ring system.

On hydrogenation of dihydrochamic acid in acetic acid solution with Adams' catalyst one mole of hydrogen was very slowly absorbed and this clearly corresponds to fission of the *cyclo*propane ring.

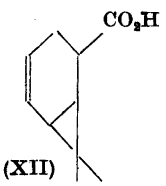


The ultra-violet absorption spectrum of chamic acid contains no strong bands thus indicating that the double bond is not conjugated with the carboxyl group. This deduction is supported by infra-red measurements, the medium intensity band at 1 644 cm^{-1} present in the spectrum of chamic acid but absent in the case of the dihydro-compound corresponding to the isolated double bond in the former substance.



When chamic acid is treated with hot aqueous alkali, crystalline *iso*chamic acid is obtained. The ultra-violet absorption spectrum of *iso*chamic acid has a maximum at *ca.* 218 mμ (ε 7 250), and the infra-red spectrum shows strong bands at 1 684 cm^{-1} and 1 647 cm^{-1} clearly demonstrating that the double bond has moved into conjugation with the carboxyl group.

*Iso*chamic acid when reduced catalytically gave a dihydro-compound (IIa) as an oil which afforded a single *p*-bromophenacyl ester not identical with that prepared from dihydrochamic acid (II) obtained by catalytic reduction of chamic acid. The two dihydro-compounds (II) and (IIa) are presumably diastereoisomers differing according to the *cis* or *trans* relationship of the carboxyl group to the *cyclo*propane ring.



(IX)

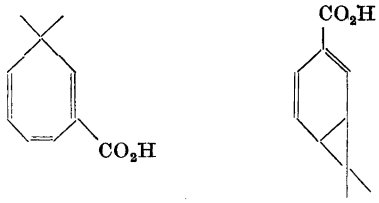
(X)

(XI)

(XII)

At this stage structures (I), (XI) and (XII) were probable for chamic acid and clearly the next step was to determine the relative positions of the carboxyl group and the *cyclo*propane ring in the molecule.

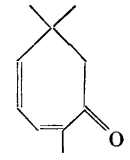
Treatment of chamic acid in chloroform solution with an equimolar quantity of bromine in the same solvent resulted in a rapid reaction with no significant formation of hydrogen bromide. Further bromine could be absorbed but at a greatly reduced rate. The crude dibromo-compound was dehydrobrominated directly by heating with dimethylaniline to give a liquid acid mixture in which the presence of a considerable quantity of aromatic material was indicated by ultra-violet and infra-red spectra measurements. In fact the ultra-violet absorption spectrum of the mixture resembled rather closely that of *m-iso*propylbenzoic acid which was therefore probably the main component of the mixture, a deduction subsequently verified. Separation of the acids by partition chromatography or by fractional crystallisation of the *p*-bromophenacyl esters was not successful, but after catalytic hydrogenation of the mixture (palladium, room temperature and pressure) and conversion of the product to the amide *via* the acid chloride, pure *m-iso*propylbenzamide could be isolated by careful chromatography of the amide mixture on alumina. In



addition, oxidation of the crude acid mixture with dilute nitric acid afforded *iso*phthalic acid, identified as its dimethyl ester.

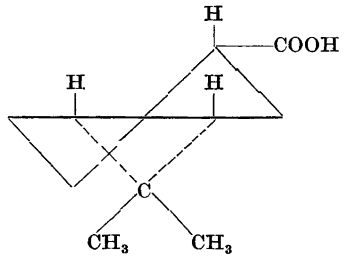
The addition of a unimolecular quantity of bromine to *iso*chamic acid proceeded at a much slower rate than in the case of chamic acid owing to the conjugation of the double bond with the carboxyl group. Dehydrobromination of the resulting dibromo-compound was accomplished by heating with pyridine to yield a liquid acid mixture which, from its ultra-violet absorption spectrum appeared to consist largely of non-aromatic material. Hydrogenation of the acid mixture, conversion to the amides and chromatography of the latter on alumina gave a small quantity of *m-iso*propylbenzamide as the only recognisable product. The addition of *cyclo*hexylamine to a petroleum ether solution of the acid mixture gave a considerable quantity of insoluble *cyclo*hexylamine salts which after crystallisation from acetone furnished what had every appearance of being a pure salt, not identical with, but according to analysis isomeric with, *iso*chamic acid *cyclo*hexylamine salt. Decomposition of the salt afforded the free acid as a crystalline solid of rather indefinite melting point. The acid (A), which was not optically active, had an ultra-violet absorption spectrum with a maximum at 260 mμ (ε 8 750), and it thus appeared that the acid possessed a conjugated system of two double bonds and a carboxyl group and had arisen by ring opening of the *cyclo*propane ring of *iso*chamic acid probably as a result of the presence of hydrogen bromide in the bromine. However, if the unpurified mixture of *cyclo*hexylamine salts obtained from the acid degradation products was refluxed with an acetic acid-hydrochloric acid mixture, distillation of the acid products gave a small quantity of material boiling at the same temperature as the original acid degradation product and a main fraction which boiled considerably higher. The lower boiling product, which partially crystallised, had an ultra-violet absorption spectrum distinctly resembling that of *p-iso*propylbenzoic acid. The higher boiling main fraction also deposited a crystalline solid, insoluble in petroleum ether, of m. p. 156—160°. The ultra-violet absorption spectrum of this compound showed a maximum at 280 mμ (ε *ca.* 30 000), and it seems very likely that it is a dicarboxylic acid formed by dimerisation of the acid (A) isolated by purification of the *cyclo*hexylamine salt as previously described, or a similar compound. The lower boiling distillate was converted to the amide and by fractional evaporative distillation followed by crystallisation a very small quantity of pure *p-iso*propylbenzamide was isolated. Also oxidation with dilute nitric acid of the acid mixture as obtained directly from the dehydrobromination gave a mixture of *iso-* and *tere*phthalic acids which were separated by fractional crystallisation of their dimethyl esters. Thus these degradations establish conclusively the relative positions of the carboxyl group and the *cyclo*propane ring in chamic acid which must therefore possess structure (I). *Iso*chamic acid consequently must be formulated as (III) or (IIIa), (III) being the most probable since the addition of bromine to, followed by the dehydrobromination of (IIIa), would be expected to give a considerable quantity of *p-iso*propylbenzoic acid (by analogy with the similar degradation of chamic acid in which a bromine atom is situated in an adjacent position to the *cyclo*propane ring) whereas in actual fact, as already described, a complex mixture of acids is formed containing very little aromatic material. However, a con-

clusive distinction between the possible structures (III) and (IIIa) for *iso*-chamic acid cannot be made on the present evidence. Further investigations on this point have been hampered by lack of material.

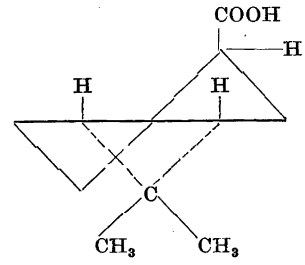


In an earlier paper [1] describing the isolation of chamic acid the presence of small quantities of other acids in the mother liquors from the precipitation of the *cyclo*hexylamine salt of chamic acid was reported. One of these acids, chaminic acid, m. p. 104—105°, $[\alpha]_D$ 6 (± 1)° has now been obtained in the pure state. The infra-red spectrum of chaminic acid is identical with that of *iso*chamic acid, m. p. 105—106°, $[\alpha]_D$ —6 (± 1)°, and chaminic acid is therefore the optical antipode of *iso*chamic acid. The fact that chaminic acid is the *d*-form whereas *iso*-chamic acid formed by isomerisation of chamic acid is the *l*-form eliminates the possibility that chaminic acid is an artefact formed from chamic acid during the isolation process which necessarily involves alkaline treatments.

Although it is clear that *m-iso*propylbenzoic acid is formed directly by the addition of bromine to, followed by dehydrobromination of, *iso*chamic acid, this cannot be stated with certainty in the case of *p-iso*propylbenzoic owing to its method of isolation. *p-Iso*propylbenzoic acid *cyclo*hexylamine salt is insoluble in petroleum ether whereas the *cyclo*hexylamine salt of *m-iso*propylbenzoic acid is soluble. Hence if *p-iso*propylbenzoic acid is a direct product of the degradation then it is possible that its separation from *m-iso*propylbenzoic acid occurred at this stage and that the treatment with acetic acid-hydrochloric acid served only to dimerise acid (A) and thus make possible a separation of *p-iso*propylbenzoic acid on account of its widely different volatility from the dimer of (A). On the other hand if either thujic acid (XIII) or "dehydrochamic acid" (XIV) are the direct products of the degradation then these, after separation as their petroleum ether insoluble salts, would be rearranged by the acetic acid-hydrochloric acid reagent to *p-iso*propylbenzoic acid [3].



(XIII)



(XIV)

(XV)

(XVI)

(XVII)

The relationship between chamic acid (I), chaminic acid (III), dehydrochamic acid (XIV) and thujic acid (XIII) is of interest particularly in view of their possible common biogenetic origin from carene-like precursors [4]. In this connection it would be desirable to effect the interconversion of chamic acid or chaminic acid and dehydrochamic acid or thujic acid. At this juncture it should be pointed out that dehydrochamic acid and thujic acid may be regarded as valence tautomers and in fact Gripenberg [5] considered the possibility that thujic acid might possess structure (XIV). Similar problems arose in the study of the structures of certain compounds prepared from eucarvone [6] (XV) and were resolved with certainty by the use of nuclear magnetic resonance measurements [7]. This method has been used very recently to distinguish between structures (XIII) and (XIV) for thujic acid [8], the results clearly pointing to structure (XIII). Moreover although one can consider an equilibrium between the *cyclo*heptatriene and *bicyclo*heptadiene structures for these compounds it seems that in all cases so far known one form is so much more stable that it is formed to the exclusion of the other form. Hence the possibility that dehydrochamic acid (XIV) exists as such is remote. The possible formation of thujic acid (in small quantity) as an intermediate product in the degradation of *iso*chamic acid to *p-iso*propylbenzoic acid has already been discussed but no direct evidence for its presence could be obtained. An alternative degradation of *iso*chamic acid involving bromination using N-bromosuccinimide followed by dehydrobromination by heating with base was briefly examined but also gave a complex mixture of acids, none of which predominated.

The formation of *dl-trans*-caronic acid rather than the *cis*-isomer on permanganate oxidation of chamic acid is presumably the result of a *cis-trans* rearrangement and racemisation at some stage in the oxidation as a *trans* ring junction in (I) is unlikely. *l-* and *dl-trans* and *cis*-Caronic acids have all been obtained from the oxidation of Δ^3-carene under different conditions [2,9,10].

The fact that stereoisomeric dihydrochamic acids (II) (IIa) are obtained depending on whether chamic acid or *iso*chamic acid is reduced enables certain deductions to be made concerning the probable stereochemistry of chamic acid. The catalytic reduction of *iso*chamic acid would be expected to give the dihydrochamic acid with an equatorially placed carboxyl group and a *cis* relationship between the carboxyl group and the *cyclo*propane ring (XVI) (*cis*-dihydrochamic acid) (*cf.* Ref.[11]). Thus the dihydrochamic acid obtained from chamic acid should have an axial carboxyl group (XVII; *trans*-dihydrochamic acid) and hence in chamic acid itself the carboxyl group and the *cyclo*propane ring can be assigned a *trans* relationship.

Since oxidation of the methyl group in Δ^3-carene would lead to *iso*chamic acid the selenium dioxide oxidation of Δ^3-carene was investigated with a view to effecting this change *via* the corresponding aldehyde. A similar oxidation of α-pinene is known to give myrtenal [12] but in the case of Δ^3-carene the oxidation apparently took place at the methylene groups adjacent to the double bond and not at the methyl group.

It is hoped to confirm the structure of chamic acid and establish with certainty the structure of chaminic acid by synthetic studies.

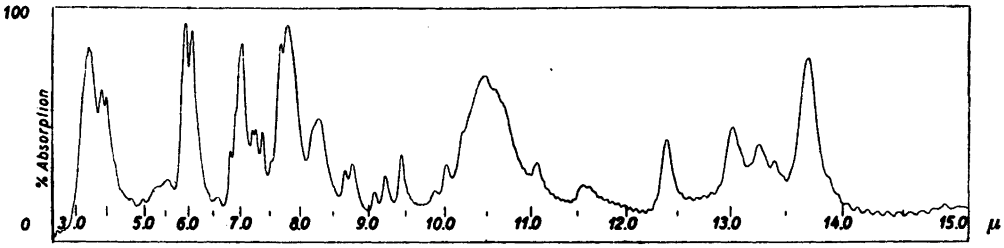

Fig. 2. Infra-red absorption spectrum of isochamic acid.

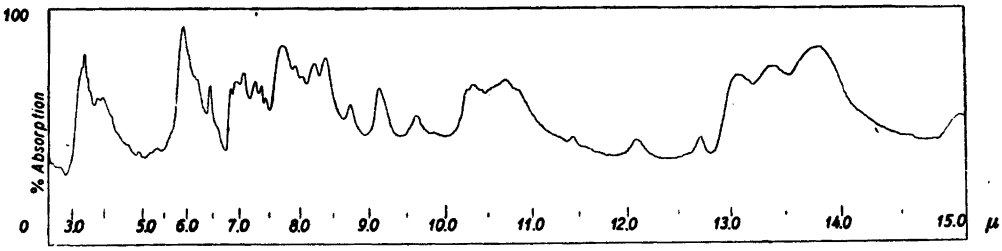

Fig. 3. Infra-red absorption spectrum of thujic acid.

EXPERIMENTAL

Isolation of chamic acid. Wood samples employed included some from large trees grown near Vancouver, Canada, which constituted the major source and some from a small Scandinavian grown tree. The latter sample gave much greater yields of chamic acid. The acetone extraction procedure described previously [1] (with omission of the preliminary ether extraction) was found to be the most convenient method for the extraction of chamic acid. The yields of crude steam volatile acid varied between 3 g and 6 g per 10 kg batch of heartwood. The crude acid normally afforded 60—80 % yields of the crude acetone insoluble *cyclo*hexylamine salt of chamic acid which after recrystallisation gave 40—50 % yields (based on the crude salt) of pure chamic acid *cyclo*hexylamine salt. Hence 0.75—2.0 g of pure chamic acid could usually be obtained from 10 kg of heartwood. In some extractions, however, the yield was much below these average values.

The ultra-violet absorption spectrum of chamic acid showed no strong bands. Infra-red spectrum: (Fig. 1.) Medium intensity band at 1 644 cm^{-1} (isolated double bond), weak band at 1 007 cm^{-1} (*cyclo*propane ring).

Isolation of chaminic acid. The mother liquors from which the *cyclo*hexylamine salt of chamic acid had been precipitated were concentrated to small volume, filtered, and the remaining solvent evaporated under reduced pressure. The free acids were recovered by acidification and ether extraction and were obtained as a faintly coloured viscous oil which slowly deposited a crystalline solid on storage in the refrigerator. The solid material was collected by filtration and recrystallised from petroleum ether yielding pure *chaminic acid*, m. p. 104—105°, $[\alpha]_D$ 6 (± 1)° (*c* 3.9 in methanol). (Found: C 72.6; H 8.56. $C_{10}H_{14}O_2$ requires C 72.3; H 8.49). The infra-red spectrum was identical with that of *iso*chamic acid, m. p. 105—106°, $[\alpha]_D$ −6 (± 1)°. A mixture of approximately equal parts of the *d*- and *l*-isomers melted at the same temperature as either of them, but if the two were mixed in non-equivalent amounts depressions in the melting point of up to 10—12° were obtained. The p-*bromophenacyl ester* was prepared in the usual manner and after recrystallisation from aqueous ethanol formed flat plates, m. p. 72.5—73,° $[\alpha]_D$ −2.6° (methanol).

Oxidation of chamic acid. Chamic acid (1.09 g) was dissolved in a solution of sodium carbonate (0.5 g anhydrous) in water (100 ml) and finely powdered potassium permanganate was added with cooling and shaking until no further reaction occurred. Further potassium permanganate (1 g) was added and the solution was warmed on the water bath, decolourisation rapidly taking place. This process was repeated until no further reaction took place at 100° by which time a total of 10 g of permanganate had been added. The solution was finally heated on the boiling water bath for 1 ½ hours. The resulting solution was cooled to room temperature, acidified with dilute sulphuric acid, treated with sulphur dioxide and steam distilled. The distillate was made alkaline by the addition of sodium hydroxide and steam distilled once more. The second distillate was treated with an aqueous solution of 2:4-dinitrophenylhydrazine hydrochloride and the yellow precipitate which formed in the cold was collected and recrystallised from ethanol giving yellow needles of acetone 2:4-dinitrophenylhydrazone, m. p. 123—124°, undepressed on admixture with an authentic specimen. The residual liquid from the first distillation was diluted with water to dissolve the salts which had separated and extracted with ether (4 × ½ volume). The ether extracts were combined, washed with a little water, dried (Na_2SO_4) and evaporated giving a semi-solid residue. This material gave a strong fluorescein reaction and paper chromatography showed that at least four substances were present although two of these apparently occurred only in small amount. The mixture was triturated with a little chloroform and the insoluble matter was collected and washed with a few drops of chloroform. It melted over a very wide range, gave a strong fluorescein reaction and on paper chromatography gave two well defined spots. The faster moving substance moved at about the same speed as pimelic acid and is in fact caronic acid whilst the slower moving substance travelled at about the same speed as succinic acid or a little faster and is probably dimethylmalonic acid. The mixture of acids was recrystallised repeatedly from water finally yielding a small amount of *dl-trans*-caronic acid, m. p. 212—213°, undepressed on admixture with an authentic specimen of *dl-trans*-caronic acid and behaving identically on paper chromatography.

Hydrogenation of chamic acid. Chamic acid, in ethanol, was shaken in an atmosphere of hydrogen at room temperature and pressure, in the presence of Adams' catalyst until one mole of hydrogen had been absorbed, at which stage the rate of uptake of hydrogen decreased sharply. The catalyst was removed by filtration and the ethanol evaporated under reduced pressure giving an almost colourless oil which was distilled in high vacuum affording *dihydrochamic acid* as a colourless viscous oil, d_{20}^{20} 1.0445, n_D^{20} 1.4835, $[\alpha]_D$ −47° (methanol). (Found: C 71.6; H 9.66. $C_{10}H_{16}O_2$ requires C 71.4; H 9.59.) Infra-red spectrum: No band corresponding to the band at 1 644 cm^{-1} (isolated double bond) found in the spectrum of chamic acid. Weak band at 1 011 cm^{-1} (*cyclo*propane ring). The same product was obtained if the hydrogenation was carried out in ethanol solution using a palladised charcoal catalyst.

Dihydrochamic acid p-*bromophenacyl ester* was prepared in the usual manner and crystallised from aqueous ethanol as long thin plates, m. p. 79—80°. (Found: C 59.45; H 5.74. $C_{18}H_{21}O_3Br$ requires C 59.2; H 5.80.)

In the presence of Adams' catalyst either in alcoholic or, preferably in acetic acid solution, a second mole of hydrogen was very slowly absorbed. The product obtained on removing the catalyst and evaporating the solvent partially solidified but has not been investigated in detail.

Iso*chamic acid*. Chamic acid (1.30 g), in aqueous sodium hydroxide (25 ml 25 %), was heated gently under reflux for 2 h. The solution was cooled and acidified with hydrochloric acid and the precipitate which formed collected by filtration and dried affording almost pure *iso*chamic acid in practically quantitative yield. Recrystallisation was effected from petroleum ether giving *iso*chamic acid as colourless prisms, m. p. 105—106°, $[\alpha]_D$ −6 (± 1)°. (Found: C 72.7; H 8.59. $C_{10}H_{14}O_2$ requires C 72.3; H 8.49). Ultra-violet absorption spectrum: max. *ca.* 218 mμ (ε 7 250). Infra-red spectrum: (Fig. 2.) Strong bands at 1 684 cm^{-1} (conjugated C=O) and 1 647 cm^{-1} (conjugated double bond). Weak band at 998 cm^{-1} (*cyclo*propane ring).

Iso*chamic acid* cyclo*hexylamine salt* was prepared by the addition of *cyclo*hexylamine to an acetone solution of *iso*chamic acid and recrystallised from acetone-ethanol forming fine needles, m. p. 166—167°, subliming readily *in vacuo* below 100°. (Found: C 72.5; H 10.28. $C_{16}H_{27}O_2N$ requires C 72.4; H 10.25).

Iso*chamic acid* p-*bromophenacyl ester* was prepared from the acid and *p*-bromophenacyl bromide by the standard procedure and recrystallised from aqueous ethanol giving colourless plates, m. p. 73.5—74°, $[\alpha]_D$ + 2.3° (methanol). (Found: C 59.6; H 5.36. $C_{18}H_{19}O_3Br$ requires C 59.5; H 5.27).

Hydrogenation of iso*chamic acid*. *Iso*chamic acid, in ethanol, was hydrogenated in the presence of Adams' catalyst until one mole of hydrogen had been absorbed, at which stage the rate of uptake of hydrogen ceased or became very slow. The catalyst was removed by filtration and the solvent evaporated under reduced pressure yielding an oil which was converted directly into the p-*bromophenacyl ester*. The crude ester melted at 53—54° and repeated recrystallisation raised the melting point only to 55.5—56.5° and no evidence was obtained for the presence of more than one component. (Found: C 59.0; H 5.70. $C_{18}H_{21}O_3Br$ requires C 59.2; H 5.80).

Dehydrobromination of dibromochamic acid. To a solution of chamic acid (1.35 g), in chloroform (25 ml) was added dropwise, with shaking, a solution of bromine (1.30 g, 1 mole) in chloroform (10 ml). Immediate decolourisation of the bromine solution took place and no evolution of hydrogen bromide was detected. The chloroform was evaporated and the residue refluxed with freshly distilled dimethylaniline for 1 h. Most of the dimethylaniline was removed by heating on a water bath under reduced pressure. The residue was shaken with ether and dilute hydrochloric acid and the ether layer removed. The acid layer was extracted with fresh ether and the combined ethereal solutions washed with dilute hydrochloric acid followed by water and dried (Na_2SO_4). The ether was removed and the residue distilled *in vacuo* to give 0.66 g of nearly colourless product (A), b. p. *ca* 120—170° (bath temperature) / 0.15 mm. Ultra-violet absorption: max. 230 mμ (ε 7 500); 277 mμ (ε 1 000); *m-iso*propylbenzoic acid: max. 230 mμ (ε 7 500); 277 mμ (ε 1 050). The infra-red spectrum showed bands at 1 652, 1 606 and 1 582 cm^{-1}, indicative of an aromatic carboxylic acid. On paper chromatography using propanol-ammonia-water (80 : 4 : 16) or *t*-butanol-ammonia-water (80 : 4 : 16) as solvents a single spot was obtained. No *cyclo*hexylamine salt was precipitated in acetone or petroleum ether solution. Conversion to the *p*-bromophenacyl esters gave a product m. p. 83—87° (corr.), clearly a mixture, which could not be purified by fractional crystallisation or by chromatography on alumina. The distilled product (A) (0.65 g), in ethanol (15 ml), was hydrogenated in the presence of 10 % palladium charcoal (0.1 g) as catalyst at room temperature and atmospheric pressure. The uptake of hydrogen after 2 h was 45 ml when the hydrogenation had practically ceased. The catalyst was removed by filtration, the alcohol evaporated and the residual acid refluxed for 15—20 min with freshly distilled thionyl chloride. The excess of thionyl chloride was removed by distillation and the residual acid chloride dissolved in dry ether (25 ml). Ammonia gas was passed into the ether solution for 15—20 min. and water was then added. The ether layer was separated and the aqueous layer extracted with fresh ether. The combined ether solutions were washed with a little 2 N sodium hydroxide solution followed by water, dried (Na_2SO_4) and the ether removed to give 0.40 g of brown semi-solid amide. Sublimation of a small portion of this material followed by crystallisation of the solid part of the sublimate from petroleum ether gave needles, m. p. 81—82.5°. This material was undoubtedly impure *m-iso*propylbenzamide (m. p. of the pure compound 93—94° (corr.) since its melting point was not depressed on admixture with the authentic compound and the ultra-violet absorption spectra of the two samples were amost identical. However, the impure sample could not be purified by repeated recrystallisations. The remainder of the semi-

solid amide preparation (0.380 g) was chromatographed on alumina (40 g), (column 22.5 cm × 1.7 cm), in benzene solution and eluted successively with ether-benzene mixtures and finally ether. The ether-benzene eluates yielded small quantities of oily material (total 0.035 g). A total of 18 fractions were obtained from the elution with ether and of these, 12 (total 0.250 g) consisted of substantially pure *m-iso*propylbenzamide judged by mixed melting point and ultra-violet absorption spectra determinations. Recrystallisation of the combined fractions from petroleum ether gave pure *m-iso*propylbenzamide as fine needles, m. p. 93—94° (corr.), (Found: C 73.2; H 8.0; N 8.5. $C_{10}H_{13}ON$ requires C 73.6; H 8.0; N 8.6) undepressed on admixture with authentic *m-iso*propylbenzamide. When this work was carried out *m-iso*propylbenzamide had not been reported in the literature. *m-Iso*propylbenzoic acid[13] was converted into its acid chloride by the action of thionyl chloride and an ethereal solution of the acid chloride treated with ammonia gas. The resulting amide crystallised from petroleum ether in fine needles, m. p. 93—94° (corr.), (Found: C 73.5; H 7.8; N 8.5. $C_{10}H_{13}ON$ requires C 73.6; H 8.0; N 8.6).

Distilled product (A) (0.150 g) from the dehydrobromination was heated overnight at 170—180° in a sealed tube with a mixture of concentrated nitric acid (4 ml) and water (8 ml). The crystalline precipitate which formed was collected and washed with water. It melted above 300°, gave no fluorescein reaction and was readily and completely soluble in barium hydroxide solution (distinction from *tere*phthalic acid). The methyl ester, prepared in ethereal solution with diazomethane, was recrystallised from aqueous methanol giving dimethyl *iso*phthalate as fine needles, m. p. 63—64°, undepressed on admixture with an authentic specimen.

*The dehydrobromination of dibromo*isochamic acid. To *iso*chamic acid (3.45 g, 1 mole) in chloroform (75 ml) was added portionwise over 2 ½ hours, a solution of bromine (3.33 g, 1 mole) in chloroform (50 ml). The reaction was complete 1—2 h after the addition of the last portion of bromine. No detectable amount of hydrogen bromide was evolved. The chloroform was removed and the gummy, pale yellow residue was refluxed in pyridine for 30 min. The reaction mixture was poured into 15 % hydrochloric acid (300 ml), the product extracted with ether (2 × 100 ml) and the ether solution washed with 15 % hydrochloric acid followed by water and then extracted with 2 N sodium hydroxide solution (2 × 50 ml). The alkaline extracts were acidified (hydrochloric acid), the liberated acids, isolated with ether, amounting to 1.70 g. Distillation of the product *in vacuo* gave a practically colourless distillate (B) (1.16 g), b. p. 120—140° / 0.02 mm (bath temp.). The ultra-violet absorption spectrum of this material showed no maxima above 220 mμ. A small higher boiling fraction was also obtained from the distillation. On keeping it partially solidified and was crystallised from aqueous acetic acid (small prisms) m. p. 95—100° (corr.). Recrystallisation from the same solvent increased the melting point to 115—116° (corr.), which was strongly depressed on admixture with *p-iso*propylbenzoic acid, m. p. 117—118° (corr.). The ultra-violet absorption spectrum showed no maxima above 220 mμ and the substance was not further investigated.

Distillate (B) (0.36 g) was hydrogenated in ethanol solution (20 ml) with a 10 % palladium charcoal catalyst (0.50 g), 35 ml of hydrogen (N.T.P.) being absorbed. The hydrogenation product was converted to the acid chloride by refluxing with thionyl chloride (3 ml) for 30 min. and after removal of excess of thionyl chloride ammonia gas was bubbled through a solution of the acid chloride in dry ether (25 ml) for 15 min. The ether solution was washed with water, dilute sodium hydroxide solution and water again, dried (Na_2SO_4) and the ether removed yielding the crude amide as a brown gum (0.235 g). The amide, in benzene solution, was placed on a column of alumina (40 g) and eluted with ether, 30 fractions being taken. The ultra-violet absorption spectra of fractions 11—13 indicated the presence of *m-iso*propylbenzamide. These fractions were combined and recrystallised from petroleum ether affording a small quantity of pure *m-iso*propylbenzamide, m. p. and mixed m. p. 93—94°. Examination of the other fractions yielded only small quantities of impure crystalline material which did not give any characteristic absorption in the ultra-violet and was not further investigated.

To distillate (B) (0.58 g), in petroleum ether (5 ml) was added a solution of *cyclo*hexylamine (0.39 g), in petroleum ether (5 ml). There was a considerable heat of reaction and the *cyclo*hexylamine salt began to separate almost immediately. After 30 min. in the refrigerator the *cyclo*hexylamine salt (C) was filtered off (0.54 g, m. p. 135—140°). The crude salt (0.250 g) was refluxed for 5 h with concentrated hydrochloric acid (5 ml) containing enough glacial acetic acid to produce a homogeneous solution at the boiling

point. The reaction mixture was diluted with water and extracted with ether (2 × 75 ml). The ethereal solution was washed with water, dried (Na_2SO_4) and the ether evaporated. The residue was evaporatively distilled and separated into two fractions. The more volatile fraction (0.035 g) was refluxed with thionyl chloride (2 ml) for 30 min. and the excess of thionyl chloride then removed by distillation. The resulting acid chloride was dissolved in dry ether (25 ml) and ammonia gas bubbled through the solution for 30 min. The ether solution was washed with 2 N sodium hydroxide solution followed by water, dried (Na_2SO_4) and the ether evaporated. Evaporative distillation of the residue gave a small crystalline fraction which, after two recrystallisations from petroleum ether (fine needles), had m. p. 148.5—149.5° (corr.), undepressed on admixture with an authentic specimen of *p-iso*propylbenzamide.

Crude *cyclo*hexylamine salt (C) (0.360 g), repeatedly recrystallised from acetone gave what was apparently a single, pure *cyclo*hexylamine salt (0.07 g), m. p. 170—171° (depresses the melting point of the *cyclo*hexylamine salt of *iso*chamic acid). (Found: C 72.3; H 10.1. $C_{16}H_{27}O_2N$ requires C 72.4; H 10.25). Treatment of this salt with dilute hydrochloric acid followed by ether extraction afforded the free acid which crystallised from aqueous methanol as thin plates of rather indefinite melting point (115—130°). The melting point behaviour was unchanged after further recrystallisation. $[\alpha]_D$ 0° (chloroform). Ultra-violet absorption: max. 260 mμ (ε 8 750).

Distillate (B) (0.200 g) was oxidised with nitric acid (4 ml) and water (8 ml) in a sealed tube at 170—180° overnight and the crystalline product formed was collected and washed with water. This material was not completely soluble in barium hydroxide solution. It was converted to the methyl ester by treatment with phosphorus pentachloride followed by methanol and the crystalline product obtained was recrystallised from methanol forming long flat needles of dimethyl *tere*phthalate, m. p. 139—140°, undepressed on admixture with an authentic specimen. The methanol mother liquors were diluted with water and the crystalline material which precipitated was recrystallised from aqueous methanol yielding fine needles of dimethyl *iso*phthalate, m. p. 63.5—64°, undepressed on admixture with an authentic specimen.

The oxidation of Δ^3-Carene with selenium dioxide. To a stirred refluxing solution of Δ^3-carene (20 g, 1 mole), in ethanol (40 ml), was added over 30 min. a solution of selenium dioxide (18 g, 1. 1 mole) in ethanol (40 ml). The formation of red selenium metal was soon noticed. The reaction mixture was refluxed for 5 h, filtered to remove selenium, and the filtrate concentrated and steam distilled. The steam volatile product was extracted with ether and the ether extract washed with 2 N sodium hydroxide solution. Acidification of the alkali washings revealed the absence of steam volatile acidic material. The ether solution was washed with water, dried (Na_2SO_4) and the ether removed giving 6.67 g of crude product. Distillation *in vacuo* afforded the following fractions as pale yellow oils: (1) b. p. 65—73°/7 mm, 1.07 g (2) b. p. 80—97° (mainly 92—97°)/10 mm, 3.1 g (3) b. p. 115—120°/10 mm, 1.0 g. Ultra-violet absorption: fraction (1) max. 245 mμ; fraction (2) max. 242 mμ.

Fraction (2) (1.0 g), in ethanol (100 ml), containing a trace of sodium hydroxide, was refluxed with freshly precipitated silver oxide (2.32 g, 1.5 mole) for 4 h. The silver and unchanged silver oxide were removed by filtration and most of the solvent was evaporated from the filtrate (A). The inorganic material was treated with dilute nitric acid and the ether washings were added to the concentrated filtrate (A). The ether solution was washed with water and dried (Na_2SO_4). Removal of the ether yielded only a trace of acidic material. A similar treatment of fraction (1) gave the same result.

Countercurrent Fractionation of Cellulose Derivatives with Porous Charcoal II

HAROLD A. SWENSON* and AGNETA ROSENBERG

Paper Technology Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

The effect on the resulting cumulative integral and differential DP weight distribution curves, of altering the uptake to the charcoal stages is investigated. This is accomplished through variation of the concentration of the polymer charge and the number of charcoal stages.

In an earlier paper by Swenson [1] it was shown that secondary cellulose acetates could be fractionated with a countercurrent procedure of the Craig type [2] in which porous charcoal was used as the stationary phase.

The separations were shown to occur by the preferential diffusion and adsorption of the lower, in preference to the higher weight molecules, by the charcoal stages, the unadsorbed polymer of higher DP advancing to later stages. The fractionation method and the fifty stage countercurrent apparatus designed for the experiment were also described.

In the present paper, the effect on the resulting integral and differential DP weight distribution curves, of altering the uptake to the charcoal stages is investigated. This is accomplished through variation of the concentration of the polymer charge and the number of charcoal stages.

The fractionation of a high DP secondary cellulose acetate and a cellulose nitrate are also reported and the osmotically determined molecular weights of the original samples and of a limited number of the fractions are given.

The low concentration, fifty stage fractionation of cellulose acetate 1.62

Two grams of the sample — the samples are identified in the text by their intrinsic viscosity values — in 30 ml acetone, were introduced to the first of the 50 stages, each containing 8 g of charcoal saturated with solvent. 5 min. shaking periods were used.

The concentration of the polymer charge was chosen so that the removal of a high percentage of the sample to the charcoal would be obtained while also

* Present address: The Institute of Paper Chemistry, Appleton, Wisc., USA.

taking advantage of all the charcoal stages. It was known that 49 additions of following solvent to the first stage would have resulted in the fractionation effect of no more than 42 of the stages, because of the detaining, countercurrent effect of the charcoal on the polymer [1]. Consequently, 59 additions of 25 ml acetone were made, between the successive shaking and transfer operations which served to spread the polymer to further stages. The 10 extra additions of the solvent, free of polymer, were decanted from the last charcoal stage of the apparatus.

At the conclusion of the run, after the routine removal of the solvent from the transfer reservoirs and the charcoal tubes with a syringe, elution was done by shaking the charcoal stages twice with 25 ml dioxan. The run was then duplicated and the respective fractions combined to afford more material for analyses. The accuracy of the duplication was checked by separate determinations of the amounts and intrinsic viscosities of the unadsorbed polymer found at the later stages in the two runs.

Of the sample 74 % was recovered, 9 % was not taken up by the charcoal. The average intrinsic viscosity of the recovered fractions was 1.47. Correction for irreversible precipitation effects (see Experimental) increased this figure to 1.53.

This run is compared to an earlier fractionation of the same sample [1] in which the amount of polymer charge appreciably exceeded the uptake capacity of the charcoal stages. 5 g of sample 1.62 was introduced in this run in 70 ml acetone to the first two stages followed by 50 additions of 25 ml acetone to the first stage. To elute the adsorbed polymer, two shakings with 25 ml dioxan were used. Of the sample 25 % was in the decanted acetone which, when added to the eluted material accounted for a total recovery of 60 %. The average intrinsic viscosity of the recovered fractions, uncorrected, was 1.53.

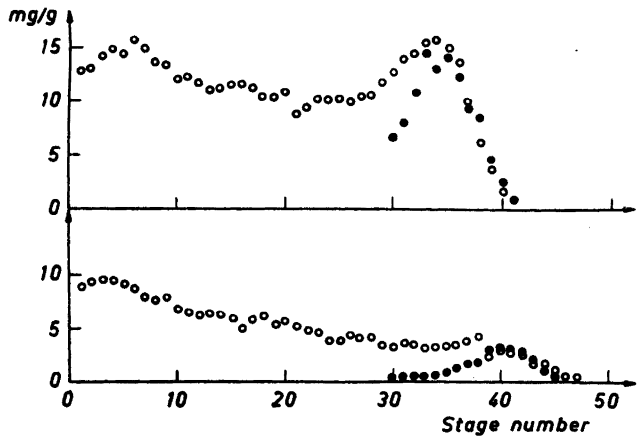

Fig. 1. Eluted and free material expressed as mg/g charcoal found at each stage in fifty stage fractionations of cellulose acetate sample 1.62. Upper figure: Five grams of sample followed by 50 solvent additions. Lower figure: Two grams of sample followed by 60 solvent additions. Open symbols: the eluted fractions. Solid symbols: the material not taken up by the charcoal.

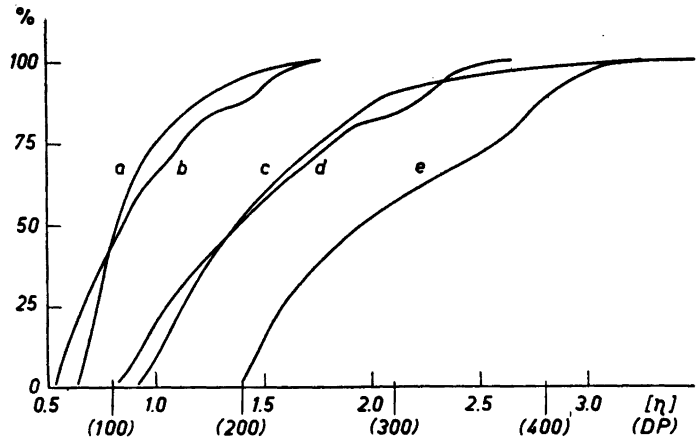

Fig. 2. The cumulative integral fractionation curves from the cellulose acetate fractionations. a. 0.5 g of sample 0.95; 20 stages and 19 additions of solvent. b. 5 g of sample 0.95; 50 stages and 50 solvent additions. c. 2 g of sample 1.62; 50 stages and 60 solvent additions. d. 5 g of sample 1.62; 50 stages and 50 solvent additions. e. 3.6 g of sample 2.24; 50 stages and 60 solvent additions.

In this and subsequent fractionations reported, the amounts eluted from the charcoal are corrected to 100 % recovery assuming, following an earlier finding [1], in which the amounts and intrinsic viscosities from successive elutions were determined, that representative elution of like proportions of the polymer regardless of DP were recovered.

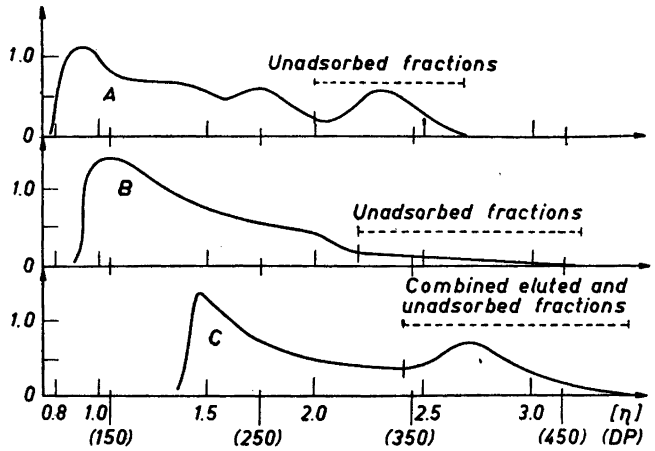

Fig. 3. The differential weight distribution curves of cellulose acetate samples 1.62 and 2.24. A. 5 g, 50 stage fractionation of sample 1.62. B. 2 g, 50 stage fractionation of sample 1.62. C. 3.6 g, 50 stage fractionation of sample 2.24.

The quantities of adsorbed and unadsorbed polymer found at each apparatus stage in the two fractionations are shown in Fig. 1. It can be seen in the lower part of the figure how the polymer has been spread to further charcoal stages in the lower concentration run as a result of the extra additions of solvent.

The integral fractionation curves from the two runs are shown in Fig. 2, curves *c* and *d*. The DP weight distribution curves, obtained by graphical differentiation of the integral curves, are given in Fig. 3, the latter closely reflecting the amounts found at each apparatus stage as shown in Fig. 1.

In the DP weight distribution curve resulting from the high concentration fractionation, Fig. 3 A, the first peak from the right derives from the decanted, unadsorbed material of highest DP and the peak next to the left, the material eluted from the corresponding underlying charcoal stages.

In the lower concentration run, Fig. 3 B, the material in these peaks of less fractionated higher DP polymer have largely been taken up by the charcoal stages resulting in a single maximum distribution curve, an extension of the DP range of the fractions and higher apparent homogeneity of the fractions.

Twenty stage fractionation of cellulose acetate 0.95

To determine how the fractionation is influenced by using fewer stages in combination with high uptake of sample to the charcoal, the low DP sample was run at low concentration. 0.5 g of the sample in 25 ml acetone was introduced to the first of 20 stages, each containing 9 g of charcoal, the effective charcoal capacity of the apparatus.

Nineteen 25 ml additions of acetone were made between successive 5 min. shaking periods. Elution was done by shaking twice for two or more hours with dioxan. Total recovery was 59 %. Less than 4 % of the sample was not taken up by the charcoal. The average intrinsic viscosity of the recovered fractions, which required no correction for irreversible precipitation effects, was 0.94.

This run is compared to an earlier[1] 50 stage fractionation of the same sample in which the amount of sample again exceeded the uptake capacity of the charcoal. 5 g was introduced in 70 ml acetone, in two 35 ml portions to the first two stages of the apparatus followed by fifty additions of acetone. 9 g of charcoal per stage and 5 min. shaking periods were used. Recovery after three elutions with 25 ml dioxan was 92 %, 15 % of the sample was unadsorbed. The average intrinsic viscosity of the recovered fractions, uncorrected, was 0.95.

The experimental integral curves which resulted from the two runs are shown in Fig. 2, curves a and b, and the differential weight distribution curves in Fig. 4. In the latter figure, curve A, from the high concentration 50 stage fractionation, the two peaks from right to left, the unadsorbed material and the material later eluted from the corresponding underlying charcoal stages, respectively, have again resulted from exceeding the uptake capacity of the 50 charcoal stages. More stages or more charcoal per stage were needed to adsorb and further fractionate the free material.

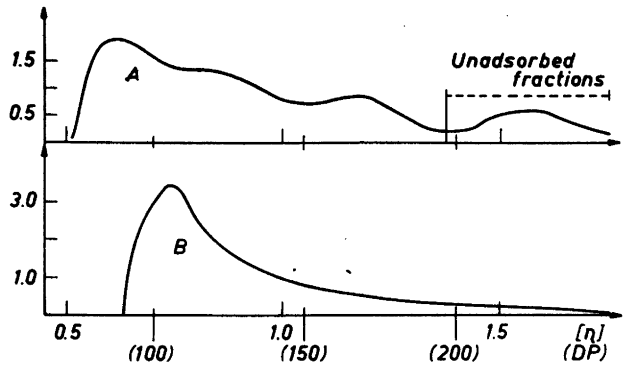

Fig. 4. The differential weight distribution curves of cellulose acetate 0.95. Upper figure: 5 g, 50 stage fractionation. Lower figure: 0.5 g, twenty stage fractionation.

Little polymer material was found in the transfer reservoirs following the 20 stage run and no polymer was found in the first 25 reservoirs after the 50 stage run. This shows, since little or no transfer of polymer was occurring between stages, that the lower DP peaks in the two distribution curves have largely been stabilized by irreversible adsorption. As a result, extending the runs to further stages could not be expected to effect appreciable further fractionation of this lower DP material.

Fractionation of cellulose acetate 2.24

The fractionation of a high DP secondary cellulose acetate was of particular interest since it appeared from earlier fractionations of the lower DP acetate 1.62 that a limit was being approached in the DP of the polymer sample which could be effectively fractionated. In the fractionation run, 3.6 g of acetate 2.24 was introduced in 60 ml acetone in two 30 ml portions to the first stage followed by sixty 25 ml additions of acetone between the successive shaking and transfer operations. 9 g of charcoal were used in each of the 50 apparatus stages and 5 min. shaking periods.

Total recovery, after two 25 ml dioxan elutions was 73 %, 21 % of the sample remaining free of the charcoal. The average intrinsic viscosity of the fractions was 2.00, before correction, and 2.20, after correction for the irreversible precipitation effect.

The experimental integral fractionation curve is given in Fig. 2, curve e, and its graphical differentiation in Fig. 3, curve c. The peak to the right is again the apparent result of too high sample concentration for the uptake capacity of the charcoal stages. The peak contains, however, in contrast to earlier runs with lower DP acetates, both unadsorbed decanted polymer and a smaller amount of adsorbed polymer which was eluted with dioxan. The latter adsorbed material was found in the charcoal stages over the entire DP range of the fractions to DP *ca.* 450 in comparison to the runs with acetate sample 1.62 (*cf.* Fig. 3, A, B), in which the highest DP fractions removed from the charcoal had a DP of *ca.* 300.

A further indication that the experiment shows no apparent limit in the DP of the polymer which can be fractionated, is indicated by the percentage of the sample not taken up by the charcoal, 21 % from 3.6 g of sample 2.24 compared to 25 % not taken up by the charcoal in a similar 50 stage fractionation of 5 g of sample 1.62.

Osmotic pressure determinations

Measurements were made on the original cellulose acetate samples and on the lower DP fractions, Nos. 4, 6 and 8, from the 2 g, 50 stage fractionation of sample 1.62, Fig. 3 B. The small amounts in the fractions were insufficient to allow determinations on more of the fractions from the run.

The measurements were made in Schulz type osmometers at 25° C ± 0.02. The osmotic pressure molecular weight of the original acetate 2.24 and of additional samples not included in the paper were determined at the Institute of Physical Chemistry, Uppsala University, Uppsala, Sweden. Zimm-Myerson osmometers [3] were used in the latter measurements. "Ultracellafilter, allerfeinst" membranes from Membran-Gesellschaft, Göttingen, were used in the determinations with both types of osmometers.

The osmotically determined M_n values and K_m values calculated from the intrinsic viscosities by means of the Staudinger relation $[\eta] = K_m \cdot (DP)$, are listed in Table 1. $K_m = 7 \times 10^{-3}$ was chosen in the present paper to convert the intrinsic viscosity values to DP.

Table 1.

Sample	(η) exp	M_n	$K_m \times 10^3$	M_w (K_m 7.0 × 10^{-3})	DP
0.95	0.95	30 000	8.3	35 300	136
1.63	1.62	62 000	6.8	60 000	230
2.24	2.24	78 000	7.3	83 000	320
Fractions					
4	1.04	38 000	7.1	38 700	149
6	1.09	43 800	6.5	40 500	156
8	1.14	48 000	6.2	42 300	163

It is seen from the table that the M_n of the three fractions rises with the corresponding increase in intrinsic viscosity and fraction number. Because so few analyses on limited amounts from a narrow band of the total distribution could be made, the drop in the K_m value from fraction 4 to fraction 8 cannot safely be interpreted to be due to a corresponding decrease in polydispersity.

The substitution degree of secondary cellulose acetate fractions

Duplicate acetyl analyses were obtained on the eluted fractions 1, 3, 5, 7 and 9 and on combined contiguous eluted fractions Nos. 10 to 44 from the 1.62 fractionation (*cf.* Fig. 3 B) and single analyses on both combined contiguous,

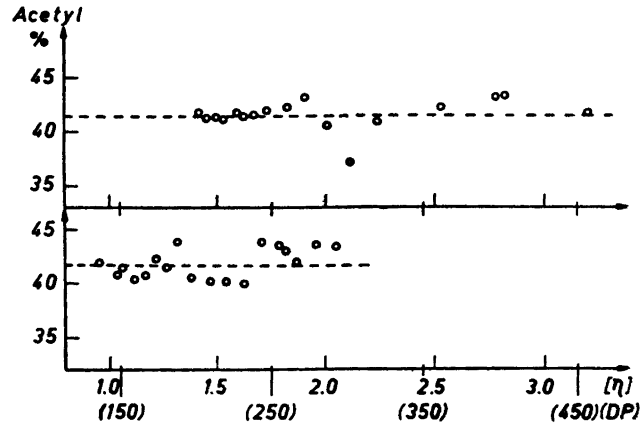

Fig. 5. The acetyl substitution of the fractions versus *their DP. Upper: Fractions from 3.6 g fifty stage fractionation of sample 2.24. Lower: fractions from 2 g fifty stage fractionation of sample 1.62.*

eluted and unadsorbed fractions from the fractionation of sample 2.24 (*cf.* Fig. 3 C).

A plot of the percent acetyl of the fractions *versus* their respective DP values is given in Fig. 5. The original samples 1.62 and 2.24 had 39.1 and 40.1 % acetyl while the average of the analyses on the fractions were 41.0 % and 41.5 %, respectively. The higher average acetyl content of the fractions appears to have been due either to the presence of non-acetyl contaminants or to analytical reasons since the fractions analyzed were largely representative of the entire sample.

No significant variation of acetyl content with DP is apparent from Fig. 5. The variation in acetyl content between fractions, however, is roughly ten times as great as that reported by Staudinger and Eicher [4] following the fractional precipitation of a commercial secondary cellulose acetate of similar DP and substitution degree from acetone with water. The higher apparent non-uniformity shows that the countercurrent fractionation is relatively free of substitution effects. This would be expected since the counter-current separations depend primarily on variations in diffusion rates. Rosenthal and White [5] found variations in substitution of a similar order to those in Fig. 5 by the fractional cross precipitation of secondary cellulose acetates from acetone with water. The variations they reported were also apparently independent of DP.

The five stage fractionation of cellulose nitrate

1.5 g of a cellulose nitrate with intrinsic viscosity 1.95 (see Experimental) was introduced in 25 ml acetone to the first of 5 charcoal stages followed by four 25 ml additions of acetone between 5 min. shaking periods. 9 g of charcoal were used per tube. To elute, the charcoal was shaken twice with 25 ml dioxan.

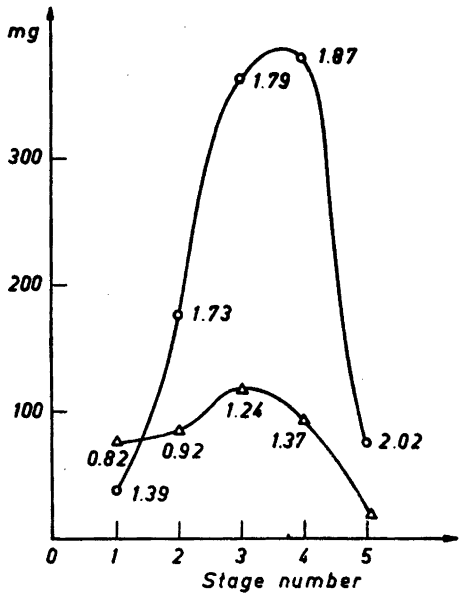

Fig. 6. The amounts of eluted and free material in the fractions from the five stage fractionation of cellulose nitrate 1.95. Circles: the eluted fractions. Triangles: the unadsorbed fractions. The intrinsic viscosities are inscribed for each fraction.

The fractions, in both acetone and dioxan, were precipitated in water, evaporated and further dried under vacuum at room temperature before redispersing in acetone for the viscosity measurements. The total recovery was 95 %, 69 % of which was unadsorbed, decanted, material.

The average intrinsic viscosity of the recovered fractions was 1.62. This low value evidently resulted from degradation of the fractions since the high recovery apparently precluded unrepresentative elution as the cause for the low average intrinsic viscosity of the recovered fractions.

Fig. 6 shows the amounts taken up by each charcoal stage, the amounts decanted at each stage and the intrinsic viscosity of the fractions. The figure, which shows how rapidly and effectively the fractionation begins, also illustrates how the peak of free material appears at an early stage when the uptake capacity of the five charcoal stages is far exceeded. If the run were extended to more charcoal stages the peak of free material would gradually lessen as more material is removed to the charcoal stages. The higher polydispersity of the large fractions in the peak of free material is indicated by their viscosity values which, although the degradation effect must be taken into consideration, are close to that of the original sample.

The result of a 50 stage fractionation of the cellulose nitrate sample is not reported due to the degradation of the fractions which apparently occurred primarily during the precipitation and drying of the fractions. Erratic drops in viscosity were found when some of the fractions in acetone, which had not

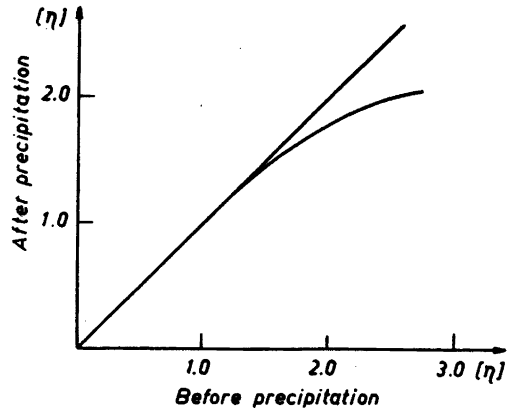

Fig. 7. The intrinsic viscosity of the original cellulose acetate samples after precipitation from dioxan versus *the intrinsic viscosity of the samples dispersed directly in acetone. The figure was used to correct the intrinsic viscosity of some of the eluted fractions.*

altered in viscosity after standing for a week, were reprecipitated in water, dried below 55° C and redispersed in acetone. The viscosity efflux time of the original cellulose nitrate sample in acetone dropped only very slightly after six weeks at room temperature. In dioxan the sample did not change in efflux time after six weeks following an initial drop due to the formation of a slight haze of precipitate which formed after a few days.

EXPERIMENTAL

Materials. The cellulose acetates are Hercules Powder Company products. The samples with intrinsic viscosities of 0.95, 1.62 and 2.24 are substituted to the extent of 2.45, 2.39 and 2.48 respectively. The cellulose nitrate sample from Nitroglycerin AB, Gyttorp, Sweden, had a nitrogen content of 12.02 %, an intrinsic vicosity of 1.95.

The acetone had analytical purity and the dioxan, of *ca.* 99 % purity was used without further treatment. The charcoal, a Norit Company product, is a rather soft, extruded carbon with particle diameter 0.7 mm and with *ca.* 10 % ash content, half of which could be removed with concentrated hydrochloric acid. The untreated charcoal, except for drying, was used in the experiments.

The characteristics sought for in choosing the charcoal were maximum uptake capacity, adequate adsorptive capacity and a particle size from which the polymer solution could be readily decanted. Hard charcoals would be desirable to minimize the charcoal fines that develop from abrasion of soft charcoals during the shaking. Since the uptake capacity was found to increase with increasing softness and porosity, however, the rather soft charcoal was chosen for the experiments. Prior screening and washing of the charcoal was done to minimize the fines. Centrifuging the fraction solutions was necessary [1].

Irreversible precipitation. Evidently due to variations in the purity of the dioxan, it was found that when the cellulose acetates in dioxan were precipitated in water on a steam bath and dried in vacuum at 105° C, theoretical recoveries, on which the concentration values were based were difficult to obtain. Further, the very dry precipitates would not disperse completely in acetone and low viscosity values resulted.

The dioxan fractions were, thereafter, precipitated in water, dried and evaporated at room temperature. The precipitates, containing some moisture, were then dispersed in acetone. The concentration of the latter solutions, used for the viscosity measurements,

was determined on a part of this solution by precipitating in water on the steam bath and drying at 105° C, under vacuum. Theoretical recoveries were obtained in this way but the viscosity values were still low.

To determine the degree of the insolubility effect on the viscosity, varying concentrations of the 0.95, 1.62 and 2.24 cellulose acetates in dioxan were precipitated without heat and the viscosity of the precipitates, redispersed in acetone, determined. The insolubility was found to be independent of the concentration of the solutions precipitated.

In Fig. 7 is shown a plot of the viscosity values on the redispersed precipitates *versus* the viscosity of the original samples dispersed directly in acetone. The graph which was used to correct the viscosity values illustrates that the insolubility increases with increasing DP.

Viscosity measurements. A single measurement method described in the earlier paper [1] was used for the cellulose acetates. The intrinsic viscosity of the cellulose nitrate samples were made by extrapolation of plots of the reduced viscosity *versus* concentration at three or more concentrations below 0.5 g/dl. Ostwald pipettes requiring 2 ml of solution recommended [6] for a range between 0.3 and 5.0 centipoises were used at 25° C ± 0.02.

DISCUSSION

When complete uptake to the charcoal stages was approached in the fractionations of secondary cellulose acetate, single maximum positively skewed, DP weight distribution curves were obtained of the theoretical type to be expected from the random degradation of an original high DP polymer.

While a peak of lower DP material may be expected on theoretical grounds, it is also in the first stages of the apparatus that the highest concentration gradient as well as diffusion rate can be expected to combine in greatest uptake to the charcoal, both effects diminishing as the polymer solution advances to later stages.

Since the fractions in the charcoal stages are held by irreversible adsorption as the runs proceed, the adsorbed material is not further fractionated and the percentage of the sample held by the charcoal stages will determine in part their relative polydispersity. It is important, in consequence, to choose the amount of sample to be fractionated in relation to the uptake capacity, as well as the number, of charcoal stages.

In the countercurrent fractionations, too small a sample in relation to the adsorptive capacity resulted in detention of a higher proportion of lower DP material (*cf.* Fig. 4 B). Too large a sample, on the other hand (*cf.* Fig. 3 A) resulted in the apparent finer fractionation of the lower DP material in the distributions, while higher DP material of consequently higher polydispersity was left unadsorbed since more stages were needed to fractionate the latter material.

The uptake to the charcoal which has been varied in the present experiments by altering the polymer concentration and number of stages while keeping the charcoal capacity and shaking times constant, could also be varied by altering the shaking times, by using a diffusion medium of different porosity and adsorptive capacity or by altering the polarity of the solvent.

Comparison of the first fractions in the two runs in which 0.5 and 5.0 g of acetate 0.95 were introduced to the stages with 9 g charcoal, illustrates the effect of variation in the percentage of sample in the fraction on the selectivity of the separation. The percentages recovered, for example, in the first fraction stage, in the two fractionations, were 10.3 % and 2.6 %, respectively. The

higher apparent polydispersity to be expected of the higher percentage fraction is shown by the intrinsic viscosity, 0.63, compared to that of the low percentage fraction 0.53. The larger percentage fractions from the low concentration 20 stage run also appear to be less sharp when comparison is made of the intrinsic viscosity 0.63 of the single fraction containing 10.3 % of the sample, with the average intrinsic viscosity 0.57 of the first four fraction stages from the high concentration 50 stage run which contained 11.4 % of the sample.

It should be stressed that the solid phase counter-current fractionations are rigorously reproducible, this has been confirmed repeatedly in the course of the experiments. The method, in consequence, is useful for comparative determinations of polymolecularity pending the time when the comparative accuracy of the DP weight distribution curves can be established by determination of the M_w/M_n ratios of the fractions or by other means.

The upper and lower limits in DP which can be fractionated with the method also remain to be established since with the samples investigated, no apparent limit was found. Fractions varying in DP from *ca.* 70 to 500 were obtained in the experiments.

Acknowledgements. The authors wish to express their appreciation to Docent Bengt Rånby, Institute of Physical Chemistry, Uppsala University, Uppsala, Sweden, for the osmotic pressure analyses and also thank Dr. Bertil Enoksson of Nitroglycerin AB, Gyttorp, Sweden, for kindly providing cellulose nitrate samples with accompanying analyses.

The authors are also indebted to Dr. Per Olof Betghe and Miss Rose Marie Persson of the analytical department of this laboratory for the acetyl analyses and to Miss Maj-Britt Eriksson for her assistance in the experiments.

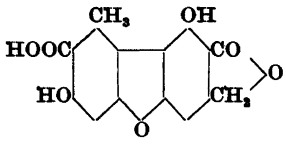
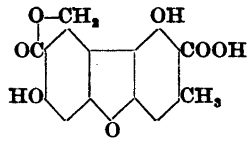
Porphyrilic acid from *Haematomma coccineum* (Dicks.) has been ascribed the structure (III) consistent with the results of oxidative degradations described earlier [1,2] and in harmony with the negative Gibbs' reaction of methyl porphyrilate as well as the negative ferric reaction of O-monomethylporphyrilic acid (IV). The position of the nuclear methyl group has been confirmed by oxidation of O,O-dimethylporphyrilic acid to a tricarboxylic acid (XIII), further degraded to 1,7-dihydroxy-3-methyldibenzofuran (X), obtained synthetically. The acidity of the phenolic groups of porphyrilic acid and its derivatives before and after hydrolysis is discussed.

As described in part VII of this series [2], porphyrilic acid, a lichen acid of the composition $C_{16}H_{10}O_7$ from *Haematomma coccineum* (Dicks.), has been subjected to oxidative degradation, the result of which established the acid as a derivative of 1,7-dihydroxydibenzofuran. A consideration of the properties and colour reactions of the acid together with derivatives and degradation products led to three alternative formulae, (I)—(III), as the most probable structures for the acid itself. Of these, alternative (III) with the carboxyl group in the *para*-position to a phenolic hydroxyl group was rejected since chromatography of porphyrilic acid on buffered paper gave evidence for the formation of a borate complex, characteristic for aromatic *ortho*-hydroxy carboxylic acids [3]. However, porphyrilin [2], the decarboxylation product of porphyrilic acid, has now been found to be retarded on a borate paper as compared with a phosphate paper, provided the pH-values of the buffer solutions are chosen above 9, and hence the borate method is of little value in the present case. Furthermore, methyl porphyrilate, prepared by methanolysis of methyl O,O-diacetylporphyrilate, gave no colour with 2,6-dichloroquinone monochloroimide (Gibbs' reagent) [4] whereas the acid itself gave a clear blue colour with this reagent, as characteristic for phenolic compounds devoid



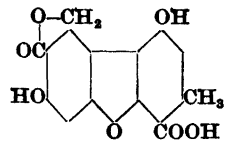
* Part IX: *Acta Chem. Scand.* **9** (1955) 1395.
** Preliminary note: *Chemistry and Industry* **1956** 960.

of ordinary carbonyl functions and containing a free position or an easily removable grouping, *e. g.* a carboxyl group, in the *para*-position to a free hydroxyl group [5,6]. It was therefore necessary to reconsider structure (III), the only formula which accounts for a negative Gibbs' reaction after esterification of the carboxyl group.



Further evidence in favour of structure (III) has now been obtained by partial methylation of porphyrilic acid. As stated in the experimental part of part VII [2], the acid titrates in the cold approximately as a dibasic acid with thymolphthalein as indicator. The titration is conveniently carried out in aqueous acetone with thymol blue as indicator. Hence, one of the two phenolic hydroxyl groups should be fairly acidic and the acid when treated for a short time with an excess of diazomethane in aqueous acetone at —10° gave a good yield of a methyl O-monomethylporphyrilate, hydrolysed by alkali to O-monomethylporphyrilic acid. These derivatives were only very sparingly soluble in the common solvents, the methyl ether being conveniently purified *via* its acetate, crystallising as a mixed anhydride from acetic anhydride. The methyl ether as well as its methyl ester gave no or at most a faintly yellowish colour with ferric chloride in ethanol, whereas an ethanolic solution of porphyrilic acid of a similar, very low concentration (0.01 %) gave a quite distinct, reddish-blue colour. Since, of the six possible monomethyl ethers derivable from the structures (I)—(III), only the methyl ether (IV) should give a negative ferric reaction, these results point definitely to this structure for the methyl ether and structure (V) for the corresponding methyl ester. The methyl ether (IV), in contrast to its ester (V), gave a clear blue colour with Gibbs' reagent, which constitutes a further confirmation of the proposed structures.

Porphyrilin, according to the above results formulated as (VI), also possesses a phenolic hydroxyl group of a high acidity, as revealed in aqueous acetone or aqueous pyridine when the lactone titrates in the cold approximately as a monobasic acid with thymol blue as indicator. Furthermore, treatment of porphyrilin in aqueous acetone containing a trace of methanol with an excess of ethereal diazomethane for 5—10 minutes at —10° afforded a quantitative yield of a monomethyl ether which gave no ferric reaction but a strong blue colour with Gibbs' reagent and hence must be ascribed the structure (VII). It melted with decomposition at 315—320° which is higher than the melting point of porphyrilin and was conveniently characterized by paper chromatography and by its acetate (VIII), m.p. 254—257°. The same monomethyl ether (VII) of porphyrilin was obtained from O-monomethylporphyrilic acid (III) by sublimation *in vacuo* or more conveniently by prolonged boiling with formic acid.



A derivative of porphyrilin containing a free acidic hydroxyl group could be prepared by treatment of its diacetate [2] with aniline at room temperature. The resulting monoacetate, which crystallised directly from the reaction mixture, gave an intense blue ferric reaction but no blue colour with Gibbs' reagent and hence must be ascribed the structure (IX). It titrated in the cold as a monobasic acid with thymol blue as indicator and on methylation with diazomethane yielded the O-monomethylporphyrilin monoacetate (VIII), m. p. 254—257°, mentioned above.

The colour reactions given by these monosubstituted derivatives of porphyrilin provide strong evidence for formulating this compound as (VI) and hence establish porphyrilic acid as derived from 1,7-dihydroxy-3-methyldibenzofuran (alternatives (II) or (III)), and not from 1,7-dihydroxy-9-methyldibenzofuran (alternative (I)).

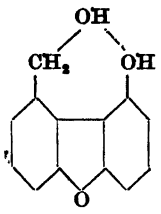
The position of the nuclear methyl group has been confirmed by partial oxidation of O,O-dimethylporphyrilic acid [2], carried out in a dilute alkaline solution at 80—90° with an excess of permanganate. The desired tricarboxylic acid (A) could be isolated in a pure state as the monomethyl ester of its anhydride (B) which on prolonged boiling with hydrobromic acid lost two molecules of carbon dioxide with simultaneous demethylation to a dihydroxy-monocarboxylic acid (C), characterised by paper chromatography and by its methyl ester. The methyl ester, like the free acid, gave no distinct ferric reaction.

On decarboxylation with quinoline and a copper chromite catalyst, the acid (C) yielded a phenol $C_{13}H_{10}O_3$, (D), m. p. 165—166°, shown to be identical with 1,7-dihydroxy-3-methyldibenzofuran (X), synthesised by a method analogous to that used for 1,7-dihydroxydibenzofuran [2].

The mixed Ullmann-coupling, carried out with 4-iodo-3,5-dimethoxytoluene and an excess of 4-iodoresorcinol dimethyl ether, yielded a mixture of diphenyls which could not be easily separated into its components. The crude mixture on treatment with boiling hydrobromic acid furnished a mixture of dihydroxydibenzofurans partly freed from 3,7-dihydroxydibenzofuran [7] by crystallisation from benzene. The desired phenol (X) was isolated from the mother liquor by chromatography on thick filter paper or on aluminium oxide. Its identity with the phenol (D), indicated by paper chromatography, was definitely established by mixed melting points of the phenols as well as of their acetates.

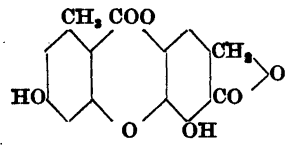
Hence the acid (C) must have structure (XII), the carboxyl group of which is not in the *ortho*- or *para*-position to any hydroxyl group. The structure of the tricarboxylic acid (A) and the corresponding ester-anhydride (B) however can be established as (XIII) and (XIV), respectively, only with due regard to the results obtained concerning the position of the carboxyl group of porphyrilic acid. Taking into account these results, the tetracarboxylic acid $C_{18}H_{12}O_{11}$ (tetramethyl ester, m. p. 221.5—223°) obtained earlier [2] must be ascribed the structure (XV), previously considered improbable.

The proposed structure (III) for porphyrilic acid can be substantiated by a more detailed examination of the acidic functions of the acid and its derivatives. It is a well known fact that intramolecular hydrogen bonds in aromatic *ortho*-hydroxy carboxylic acids strikingly affect the dissociation constants of the acidic groups in these acids as compared with their *meta*- or *para*-isomers. Thus salicylic acid and *p*-hydroxybenzoic acid show $pK_1 = 3.0$ and 4.5, respectively [8,9]. The former acid can be titrated with some accuracy even with an indicator such as bromocresol green (pH-range 3.8—5.4) whereas the latter requires at least bromothymol blue (pH-range 6.0—7.6). Porphyrilic acid, when titrated in aqueous acetone, behaves like *p*-hydroxybenzoic acid.



Similarly, the phenolic hydroxyl group in salicylic acid or its esters is of extremely low acidity [9,10], also revealed by the slow reaction of methyl salicylate with diazomethane (compare, *e. g.*, Schönberg and Mustafa [11]). On the other hand, the hydroxyl group of *p*-hydroxybenzoic acid ($pK_2 = 9.3$) [9] is acidic enough to interfere in the titration of this acid using thymol blue and its acidity is still further enhanced in methyl *p*-hydroxybenzoate [10], which can be titrated in aqueous acetone or pyridine with thymolphthalein as indicator. It is therefore in harmony with structure (III) that methyl porphyrilate in cold aqueous pyridine can be titrated fairly sharply as a dibasic acid using the indicator mentioned. Furthermore, porphyrilic acid contains no hydroxyl group showing great resistance towards methylation with diazomethane.

The high acidity of that phenolic hydroxyl group which accounts for the blue ferric reaction of porphyrilic acid and porphyrilin, also found in, *e. g.*, mycophenolic acid [12] or in 7-hydroxy-3-methylphthalide ($pK = 8.5$) [13], is evidently characteristic for *ortho*-hydroxyphthalides containing the hydroxy-group in the *ortho*-position to the lactonised carboxyl group and points to a



reduced chelation in these compounds as compared with, *e. g.*, methyl salicylate. The rapid methylation with diazomethane in aqueous acetone of the hydroxyl group in question is then explained as is also the very low solubility of porphyrilin even in boiling chloroform. It is of interest that recent infra-red measurements by Duncanson, Grove and Zealley [14] on simple compounds of the types discussed show strongly reduced though still distinct chelation in the 7-hydroxyphthalides.

While the above considerations account for the results obtained by titration in the cold of porphyrilic acid and its derivatives, the hydrolytic titrations require further discussion. Unexpectedly, O-monomethylporphyrilin (VII) titrated fairly sharply as a dibasic acid after hydrolysis with excess of alkali in aqueous ethanol and back titration with thymolphthalein as indicator. The titration could not be performed in an aqueous solution since the lactone, being of the phthalide type, precipitated at high pH-values. Porphyrilin (VI) was still more easily precipitated even from alkaline solutions containing ethanol, but on hydrolytic titration in aqueous pyridine this compound also titrated approximately as a dibasic acid. The result previously reported of the hydrolytic titration of porphyrilin in an aqueous solution with thymol blue as indicator could not be reproduced. Furthermore, porphyrilic acid (III) as well as its monomethyl ether (IV) proved approximately tribasic on hydrolytic titrations using the indicator mentioned.

A possible explanation of the observed low equivalent weights involves the assumption of an intramolecular hydrogen bond between the methylol group and the phenolic hydroxyl group of the partial structure (XVI), resulting in an increased acidity of the phenolic hydroxyl group. It seems quite possible that the postulated hydrogen bond, perhaps weak in an unionized phenol of the type (XVI), becomes fairly strong only after ionization of the phenolic group, but this question clearly requires further investigations on simple model compounds. A somewhat analogous case is given by 1,8-dihydroxynaphthalene [15]. Also 1,9-dihydroxydibenzofuran which titrates sharply as a monobasic acid with thymol blue as indicator offers an interesting example of a similar intramolecular hydrogen bond, which in this case seems to be of a considerable strength in the unionized phenol also [16]. The hydroxyl group in the *ortho*-position to the lactonised carboxyl group is not titrated after hydrolysis of the lactone ring, when the hydroxyphthalide structure changes to a salicylic acid structure (*cf.* [12]).

XVI

XVII

The indigo-blue colour reaction with ferric chloride given by porphyrilic acid and some of its derivatives seems to be of diagnostic value as it is reported also for 7-hydroxyphthalide [14] itself as well as for related compounds such as strepsilin [17] or mycophenolic acid [12]. Salicylic acid and related compounds generally give a violet ferric reaction.

The possibilities for formation of borate complexes of porphyrilic acid and its derivatives seem to be greater than previously supposed. As not only porphyrilin and methyl porphyrilate but also O-monomethylporphyrilic acid is slowed down on a borate paper, no conclusions concerning their structures can be drawn from these results without further studies on model compounds.

The unsymmetrical dihydroxydibenzofuran structure of porphyrilic acid (III) is unique among the lichen acids although there is paper chromatographic evidence for the occurrence of another closely related acid in very small amounts in *H. coccineum*. The crustose lichen *Ochrolechia parella* (L.) Mass. contains an isomeric compound of the depsidone type, variolaric acid, ascribed the structure (XVII) by Murphy, Keane and Nolan [18]. Both porphyrilic acid and variolaric acid are composed of orsellic acid units and contain the hydroxyphthalide structure and they may both be considered as having been formed from the same two phenolic acids by different mechanisms of dehydrogenative coupling. It is possible that in *O. parella* a preformed depside is dehydrogenated with formation of the depsidone, whereas in *H. coccineum* the dehydrogenase system attacks the simple phenolic compounds resulting in the formation of a diphenyl derivative further stabilised by ring closure to the dibenzofuran derivative, porphyrilic acid. The positions involved in the presumed dehydrogenative couplings to variolaric acid and porphyrilic acid are unusual, being *ortho* to both hydroxyl groups of the orcinol skeleton of one of the components, whilst as a rule in the lichen series the coupling involves the *o*-, *p*-positions. The chemical relations discussed may be of special interest in view of the presumed close relations between the genera *Haematomma* and *Ochrolechia*. Thus, in both lichens identical dehydrogenase systems may operate, *H. coccineum*, however, largely lacking the enzymatic requirements for the formation of depsides of the orcinol type.

EXPERIMENTAL *

Unless otherwise stated the paper chromatography was carried out at 25° using the solvent system *n*-butanol-water. Whatman No. 1 paper was used after impregnation with buffer solutions as previously described [2,3,19].

Methyl porphyrilate. Methyl O,O-diacetyl porphyrilate [2] (1 g) was boiled for 30 min. with 1.5 N methanolic hydrogen chloride (50 ml), yielding methyl porphyrilate (0.8 g) which crystallised from the boiling solution. The analytical sample crystallised as needles from a mixture of pyridine and glacial acetic acid (1:1) and was dried *in vacuo* at 150° C. It showed no melting point but decomposed gradually above 320°. The ester gave no colour with Gibbs' reagent [4] when tested in a borate buffer of pH 9 but a light brown colour with *bis*-diazotised benzidine [20] (on buffered filter paper) and a distinct blue colour with ferric chloride in ethanol. R_F-values on phosphate-impregnated papers: 0.65 (0.1 M Na_2HPO_4, pH 8.9); 0.10 (0.1 M Na_3PO_4, pH 12.1) and on borate-impregnated paper: 0.35 (0.1 M borate buffer of pH 9.1).

The equivalent weight was determined by titration of the ester in a cold pyridine solution with 0.05 N aqueous sodium hydroxide using thymolphthalein as indicator. (Found: C 61.9; H 3.60; OCH_3 9.6; equiv. weight, 165. $C_{17}H_{12}O_7$ requires C 62.2; H 3.68; OCH_3 9.5; equiv.weight (as a dibasic acid) 164.1.)

Methyl O-monomethylporphyrilate (V). To a solution of porphyrilic acid (1 g, *ca.* 3 mmole) in acetone (800 ml) and water (75 ml), cooled to −10 – −15°, diazomethane

* All melting points uncorrected.

(20 mmole) in ether (60 ml) was added in a few portions with stirring during 5 min. After another 5 min., the excess of diazomethane was destroyed by the addition of acetic acid. The reaction product, which rapidly crystallised from the cold solution, was collected after a few hours and proved to be fairly pure methyl O-monomethylporphyrilate (0.65 g). It gave no colour with Gibbs' reagent and no or only a faintly yellowish colour with ferric chloride in ethanol. On buffered paper (0.1 M Na_3PO_4) a spot, $R_F = 0.45$, of greenish-white colour in ultra-violet light was obtained, which gave a faint yellowish-brown colour with *bis*-diazotised benzidine. In addition a faint spot of methyl porphyrilate ($R_F = 0.10$) was observed on the chromatogram. The mother liquor on evaporation yielded a second fraction (0.35 g), only partly soluble in cold alkali and evidently containing methyl O,O-dimethylporphyrilate [2]. This compound was obtained as the main reaction product when the methylation was performed at higher temperature or when too large an excess of diazomethane was used.

The analytical sample was crystallised from pyridine and from pyridine-ethanol. Needles, dried *in vacuo* at 150°. M. p. 340–345° (decomp.) after darkening from 300°. (Found: C 63.6; H 4.51; OCH_3 17.7. $C_{18}H_{14}O_7$ requires C 63.2; H 4.12; OCH_3 18.1.)

O-Monomethylporphyrilic acid (IV). Crude methyl O-monomethylporphyrilate (V) (0.3 g) in 0.2 N sodium hydroxide solution (200 ml) was warmed to 50° overnight and the solution then diluted with acetone (200 ml) and acidified with hydrochloric acid, whereupon the monomethyl-derivative (IV) crystallised as microscopic needles containing solvent of crystallisation. It was almost insoluble in dry acetone but could be crystallised from 80 % aqueous acetone (150 ml to 100 mg of the acid). The analytical sample was obtained by hydrolysis of the mixed anhydride of its monoacetate (see below) with equal volumes of 0.1 N sodium hydroxide solution and acetone. It was dried *in vacuo* at 150°. M. p. 305–310° (decomp.). The equivalent weight was determined before hydrolysis by back titration of a solution of the acid in an excess of 0.05 N sodium hydroxide using phenol red as well as after hydrolysis by treatment of the acid with excess alkali for 1 h at 90° and back titration with thymolphthalein as indicator. (Found: C 62.0; H 3.51; OCH_3 8.8; equiv. weight 335 (before hydrolysis) and 114 (after hydrolysis). $C_{17}H_{12}O_7$ requires C 62.2; H 3.68; OCH_3 9.5; equiv. weight 328.3 (as a monobasic acid) and 109.4 (as a tribasic acid).)

O-Monomethylporphyrilic acid (0.01 % in ethanol) gave only a faintly yellowish colour with ferric chloride but a strong blue colour with Gibbs' reagent and a dark wine-red colour when treated with the benzidine reagent on buffered paper. The R_F-values of the acid on buffered paper were 0.20 (Na_2HPO_4), 0.05 (Na_3PO_4) and 0.10 (borate buffer, pH 9.1), respectively. The spots showed a greenish-white fluorescence in ultra-violet light.

Acetylation of O-monomethylporphyrilic acid. Crude monomethyl ether (IV) (0.5 g) was warmed with acetic anhydride (15 ml) and a few drops of pyridine until complete solution had been effected. The acetate crystallised on cooling and was obtained chromatographically pure as needles, m. p. 212–215°, from acetic anhydride. For chromatography, the acetate was dissolved in pyridine and the chromatogram run on buffered paper (Na_3PO_4) when a single spot of the monomethyl ether (IV) was obtained due to hydrolysis of the acetoxyl groups. The acetate which in the crystalline state exhibited an extraordinarily intense white fluorescence in ultra-violet light proved insoluble in cold aqueous sodium hydroxide and was established as a mixed anhydride by the hydroxamate test as well as by analysis. (Found: OCH_3 7.5; CH_3CO 20.7. $C_{21}H_{16}O_9$ requires OCH_3 7.5; CH_3CO 20.9.)

When warmed with glacial acetic acid the above acetate dissolved but acetolysis of the mixed anhydride occurred and the sparingly soluble monoacetate of O-monomethylporphyrilic acid soon crystallised from the hot solution.

The same monoacetate was obtained by acetylation of the monomethyl ether (50 mg) with acetic anhydride (0.5 ml) and pyridine (1 ml). Needles, m. p. 260–270° (decomp.), dried *in vacuo* at 150°. The equivalent weight was determined by hydrolytic titration (thymolphthalein). (Found: CH_3CO 11.0; equiv. weight 95. $C_{19}H_{14}O_8$ requires CH_3CO 11.6; equiv. weight 93.3 (after complete hydrolysis).)

O-Monomethylporphyrilin (VII). a) *Partial methylation of porphyrilin* (VI). Porphyrilin (360 mg, 1.2 mmole) in acetone containing a trace of methanol (200 ml) and water (20 ml) was methylated at −10° with diazomethane (5 mmole) in ether (25 ml), added in portions during 10 min. Acetic acid was then added and evaporation of the solution yielded a crystallisate practically free from porphyrilin as found by paper chromato-

graphy. The substance gave no ferric reaction but an immediate blue colour with Gibbs' reagent. R_F-value on buffered paper (Na_3PO_4): 0.85. It crystallised as colourless needles from acetone and was finally sublimed *in vacuo*, m. p. 315—320° (decomp., darkening from 300°). The equivalent weight was determined by hydrolysis of 50 mg with 0.1 N aqueous sodium hydroxide (6 ml) and ethanol (10 ml) for 1 hour at 90°, followed by back titration of the cooled solution with 0.1 N hydrochloric acid, using thymolphthalein as indicator. (Found: C 67.5; H 4.54; OCH_3 10.8; equiv. weight 140. $C_{16}H_{12}O_5$ requires C 67.6; H 4.25; OCH_3 10.9; equiv. weight (as a dibasic acid) 142.1.)

Acetylation with acetic anhydride and a trace of pyridine yielded O-monomethylporphyrilin monoacetate (VIII), needles from acetone, m. p. 254—257° after sintering from 245°. (Found: CH_3CO 13.1. $C_{18}H_{14}O_6$ requires CH_3CO 13.2.)

b) *Decarboxylation of O-monomethylporphyrilic acid (IV).* The methyl ether (IV) (50 mg) in formic acid (5 ml; $d = 1.22$) was boiled for two days and the solution was then filtered hot and evaporated to dryness. The product obtained, m.p. 305—310° after sublimation *in vacuo*, proved to be identical with the monomethyl ether (VII), obtained from porphyrilin, by its colour reactions, by paper chromatography and finally by conversion to its acetate, m.p. 250—255° (after sintering), undepressed on admixture with the acetate (VIII) described above. The decarboxylation could also be effected by sublimation of the acid (IV) *in vacuo*, although some decomposition then occurred.

Partial deacetylation of porphyrilin diacetate [2]. The diacetate (350 mg) in aniline (10 ml) was kept at room temperature with occasional stirring. The acetate soon dissolved and the crude monoacetate (IX) (120 mg) which gradually crystallised from the reaction mixture was filtered off after 24 h. It crystallised from acetone as needles, m.p. 227—229°, dried *in vacuo* at 150°. The monoacetate gave an intense blue reaction with ferric chloride in ethanol but no blue colour when tested with Gibbs' reagent in a borate buffer of pH 9. The equivalent weight was determined by titration in cold acetone with thymol blue as indicator. (Found: equiv. weight 310. $C_{17}H_{12}O_6$ requires equiv. weight 312.3.)

A small sample of the monoacetate was methylated with ethereal diazomethane yielding a product of m.p. 255—258° which by mixed melting point determination proved identical with the derivative (VIII) described above.

Partial oxidation of O,O-dimethylporphyrilic acid [2]. The dimethyl ether (1.5 g, 4.5 mmole) in 0.2 N potassium hydroxide solution (100 ml) was boiled for 10 min. to hydrolyse the lactone ring. After dilution with water (700 ml) the solution was warmed on the boiling water bath and 0.06 M potassium permanganate solution (130 ml, a 30 % excess of the amount calculated for oxidation of the carbinol group) added dropwise with rapid stirring during 10 h. After filtration, the solution was acidified with conc. hydrochloric acid (10 ml) and heated to boiling, when a yellow crystalline material separated. It was filtered off (1.0 g) and dried *in vacuo* at 180° to complete the formation of the anhydride. The desired anhydride of the tricarboxylic acid (A) proved difficult to isolate in a pure state but after short treatment of the reaction product in acetone suspension with an excess of ethereal diazomethane, the monomethyl ester of the anhydride (B) could be isolated from the reaction product by extraction with hot methyl ethyl ketone. It was obtained in a pure state as yellow needles, (0.3 g), m. p. 286—292°, by recrystallisation from the same solvent. The equivalent weight was determined by titration in aqueous pyridine with thymol blue as indicator. (Found: C 61.3; H 3.80; OCH_3 24.5 equiv. weight 187. $C_{19}H_{14}O_8$ requires C 61.6; H 3.81; OCH_3 25.1; equiv. weight (as a dibasic acid) 185.1.)

Demethylation and decarboxylation of acid (A). The methyl ester monoanhydride (B) of acid (A) (0.24 g) was boiled in a nitrogen atmosphere with hydrobromic acid (25 ml, $d = 1.5$) for two days. After cooling, the crude monocarboxylic acid (C) (0.16 g) was collected by filtration and purified by precipitation with hydrochloric acid from a bicarbonate solution. The acid did not crystallise well but was obtained as a microcrystalline brownish powder, reasonably pure as shown by chromatography on buffered paper (Na_3PO_4; $R_F = 0.45$). The spot which showed a greenish white fluorescence in ultraviolet light gave a red colour with *bis*-diazotised benzidine and an intense blue colour with Gibbs' reagent. A small sample of the acid was purified *via* the methyl ester (see below) and obtained as yellowish needles, m. p. 265—270°, by sublimation *in vacuo* (1 mm, bath-temperature 250—260°). It gave no distinct colour with ferric chloride. (Found: equiv. weight 263. $C_{14}H_{10}O_5$ requires equiv. weight 258.2.)

The methyl ester, obtained by short treatment of the crude acid in ice-cold acetone solution with ethereal diazomethane, crystallised as yellowish prisms from ethanol and

was finally sublimed *in vacuo*. It gave no colour with ferric chloride and showed m. p. 232–235°. (Found: OCH_3 12.1. $C_{15}H_{12}O_5$ requires OCH_3 11.4.)

Decarboxylation of the acid (C). The crude acid (C) (0.13 g) in quinoline (2.5 ml) was boiled for 2 h with a copper chromite catalyst (25 mg). The reaction mixture was diluted with ether, filtered and the insoluble material washed with ether. The combined ether solutions were washed with 4 N sulphuric acid, bicarbonate solution and water, dried with sodium sulphate and evaporated to dryness, yielding the crude phenol (D) as an oil (0.11 g) which crystallised after distillation *in vacuo*. It was crystallised from methanol-water and finally from benzene, yielding prisms, m. p. 165–166°, undepressed on admixture with synthetic 1,7-dihydroxy-3-methyldibenzofuran (X), described below. The two phenols also showed the same R_F-values (0.20; solvent system benzene-water) and gave identical colour reactions: *bis*-diazotised benzidine, red, Gibbs' reagent, blue, and ferric chloride, no colour. (Found: C 72.3; H 4.45. $C_{13}H_{10}O_3$ requires C 72.9; H 4.70.)

The phenol was further characterised by its diacetate which crystallised from methanol in needles, m. p. 129–130°, undepressed on admixture with synthetic 1,7-diacetoxy-3-methyldibenzofuran (XI), m. p. 129–130°. (Found: C 68.6; H 4.70. $C_{17}H_{14}O_5$ requires C 68.5; H 4.73.)

1,7-Dihydroxy-3-methyldibenzofuran. 4-Iodo-3,5-dimethoxytoluene [21] was prepared *via* 4-nitro-orcinol obtained in 5–6 % yield by nitration of orcinol in ether solution and subsequent steam distillation as described by Henrich and Meyer [22]. Methylation of the crude nitro-orcinol with dimethyl sulphate and alkali yielded 4-nitro-3,5-dimethoxytoluene, m. p. 147–148° after crystallisation from ethanol (Posternak *et al.*[21] report m. p. 147–147.5°). It was hydrogenated in ethanol with Adams platinum oxide catalyst to 4-amino-3,5-dimethoxytoluene and the crude product (m. p. 60–62°; Posternak *et al.*[21] give m. p. 64–65°) was diazotised and transformed into 4-iodo-3,5-dimethoxytoluene as described by Posternak *et al.*[21]. After crystallisation from ethanol it showed m. p. 96–97°, in agreement with the value given by Posternak *et al.*[21].

4-Iodo-3,5-dimethoxytoluene (1 g), 4-iodoresorcinol dimethyl ether [23] (9 g) and copper bronze (30 g) were thoroughly mixed and the reaction carried out in an analogous manner to that described in an earlier paper [2]. It proved convenient to extract the reaction product in a Soxhlet apparatus with light petroleum (b. p. 40–60°) for 12 h. In contrast to acetone, this solvent did not extract much resinous by-product, nor the symmetrical 4,4′-dimethyl-2,6,2′,6′-tetramethoxydiphenyl[21] (m. p. 145–146°) which should be formed in minute amounts. The petroleum extract deposited an oil which soon crystallised (3.4 g; m. p. 80–105°). All attempts to isolate the desired unsymmetrical diphenyl derivative in the pure state were unsuccessful.

The mixture of diphenyls (3.0 g) was boiled for 7 h under reflux with hydrobromic acid (60 ml; $d = 1.5$) in a carbon dioxide atmosphere. After cooling overnight in the refrigerator, the deposited crystalline material was collected, washed with water and dried *in vacuo* (yield, 1.9 g). Paper chromatography of the crude product (solvent system: benzene-water) showed one spot (grey colour with Gibbs' reagent) of 3,7-dihydroxydibenzofuran [7], $R_F = 0.07$, and a second spot, $R_F = 0.20$, which gave a blue colour with Gibbs' reagent, as expected for 1,7-dihydroxy-3-methyldibenzofuran. This second spot was in all respects identical with the spot from the phenol (D) described above. On extraction of the crude product with benzene in a Soxhlet apparatus a considerable enrichment of 3,7-dihydroxydibenzofuran in the crystallisate obtained was achieved. The unsymmetrical compound could be isolated from the mother liquor by chromatography on thick filter paper or more conveniently on alumina. The column was constructed in benzene using aluminium oxide (10 g) deactivated with nitric acid [24]. The phenol mixture (200 mg) in benzene (150 ml) was adsorbed on the column and eluted with benzene (750 ml). The fractions (25 ml) were tested with Gibbs' reagent and if necessary analysed by paper chromatography. Ca. 50 mg of chromatographically pure 1,7-dihydroxy-3-methyldibenzofuran (X) was obtained from the fractions Nos. 10–25. It was crystallised from methanol-water, and finally obtained from benzene as prisms, m. p. 166–167°. (Found: C 73.0; H 4.74. $C_{13}H_{10}O_3$ requires C 72.9; H 4.70.)

1,7-Diacetoxy-3-methyldibenzofuran (XI) was obtained from the above phenol by the action of acetic anhydride and pyridine and crystallised from methanol in needles, m. p. 129–130°. (Found: C 68.5; H 4.67. $C_{17}H_{14}O_5$ requires C 68.5; H 4.78.)

Paper chromatography of porphyrilin. The R_F-values of porphyrilin obtained on buffered papers were as follows: With 0.1 M phosphate buffer, pH 8.9: 0.78; pH 10.0: 0.70; pH 10.6: 0.60, and with 0.1 M borate buffer, pH 9.1: 0.55; pH 9.8: 0.40.

Titration of porphyrilin (VI). a) *Before hydrolysis:* The lactone, dissolved in 90 % aqueous acetone or in 90 % aqueous pyridine, was titrated in the cold with 0.05 N aqueous sodium hydroxide, using thymol blue as indicator. (Found: equiv. weight 275 ± 10. $C_{15}H_{10}O_5$ requires equiv. weight 270.2.)

b) *After hydrolysis:* Porphyrilin (40 mg) in 0.1 N sodium hydroxide solution (6 ml) and pyridine (10 ml) was hydrolysed on the boiling water bath for 1 h and back titrated with 0.1 N hydrochloric acid (thymolphthalein). The sample of porphyrilin used gave a yellow solution with alkali (*cf.* [2]) and the end point was somewhat indefinite. (Found: equiv. weight 150 ± 20. $C_{15}H_{10}O_5$ requires equiv. weight 135.1 (as a dibasic acid).)

Titration of porphyrilic acid (III) after hydrolysis. The acid was hydrolysed for 1 h at 90° with an excess of 0.05 N sodium hydroxide solution and back titrated with 0.02 N acid (thymolphthalein). (Found: equiv. weight 109. $C_{16}H_{10}O_7$ requires equiv. weight 104.7 (as a tribasic acid).)

A grant from *Hierta-Retzius' fond för vetenskaplig forskning* is gratefully acknowledged.

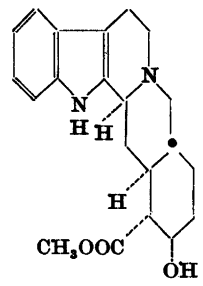
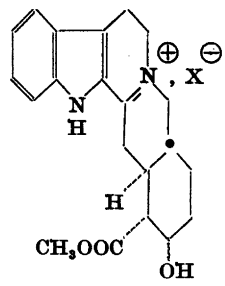
Dehydrogenation of Alkaloids of the Yohimbine Type with *tert.*-Butyl Hypochlorite. Conversion of Yohimbine to Pseudoyohimbine



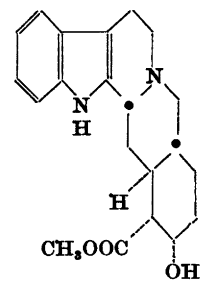
W. O. GODTFREDSEN and S. VANGEDAL

Leo Pharmaceutical Products, Copenhagen, Denmark



The dehydrogenation of alkaloids of the yohimbine type with *tert.*-butyl hypochlorite is described and the structure of the dehydrogenation products discussed.

It is shown that catalytical hydrogenation of dehydroyohimbine under alkaline conditions leads to the formation of a mixture of yohimbine and pseudoyohimbine.

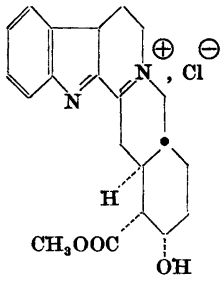


In a recent communication Weisenborn and Diassi [1] describe the oxidation of yohimbine (I) with mercuric acetate to salts of Δ^3-dehydroyohimbine (II).

I

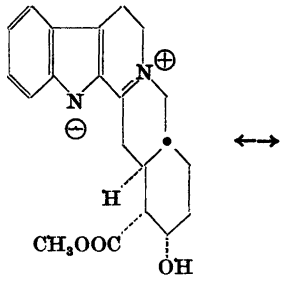
II

III



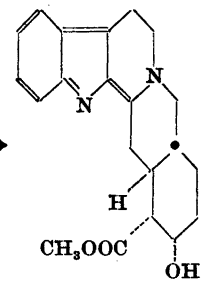
Other alkaloids of the yohimbine type containing an axial hydrogen at C_3 were oxidized in the same manner, while compounds containing an equatorially oriented hydrogen failed to react.

Catalytical reduction of II with platinum in methanol gave only yohimbine, while reduction with zinc and hydrochloric acid yielded a mixture of yohimbine (I) and pseudoyohimbine (III).



In this paper, it is shown that the same dehydrogenation can be accomplished in good yield with *tert.*-butyl hypochlorite in methylene chloride. By this method, the following compounds have been oxidized: Yohimbine, pseudoyohimbine, corynanthine, α-yohimbine, apoyohimbine, and deserpidine.

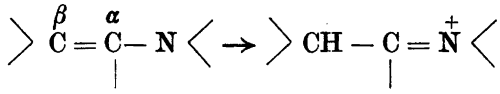
It will be seen that compounds containing an axial hydrogen at C_3 (yohimbine, corynanthine, α-yohimbine, and apoyohimbine) as well as compounds with an equatorially oriented hydrogen atom (pseudoyohimbine and deserpidine) can be dehydrogenated in this way.



The fact that in the infrared spectrum of Δ^3-dehydroyohimbine chloride no band appears in the NH-region while, on the other hand, all N-unsubstituted indole derivatives are characterized by an intense sharp band at 2.9 μ, suggests that the structure of this compound is better represented by formula IV than by formula II.

IV

V



Va

The dehydroyohimbine base is proposed to be a resonance hybrid of the limiting structures V and Va.

The difference between the chromophoric systems in IV and V ⟷ Va is clearly demonstrated by the ultraviolet spectra (curves 1 and 2, Fig. 1).

In this connection it is worth mentioning Leonards [2] observation, that the transformation

takes place when an α,β-unsaturated amine is converted to its salt.

The formulae IV and V ⟷ Va involve a difference between the ultraviolet spectra of the methiodide and the salts of dehydroyohimbine. It is seen from Fig. 1 (curves 1 and 3) that, actually, such a difference is present.

The choice between the structures VI and VII for dehydroyohimbine methiodide was made by catalytical reduction of this compound. The result that the hydrogenation product turned out to be a mixture of yohimbine methiodide and pseudoyohimbine methiodide indicates that VII is the correct structure.

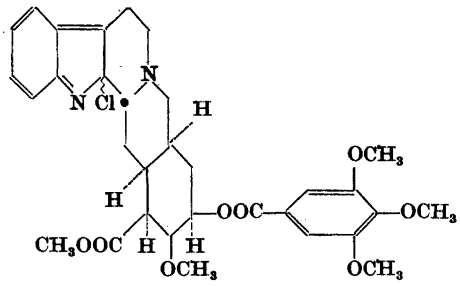
VI



VII

By dehydrogenation of deserpidine a chlorodeserpidine was isolated as an intermediate. This compound was smoothly transformed to dehydrodeserpidine chloride by short treatment with methanolic hydrogen chloride.

The intermediary formation of chloro compounds by dehydrogenation with *tert.*-butyl hypochlorite may be explained by assuming the following reaction sequence:

The assignment of formula VIII to chlorodeserpidine is supported by the experimental findings mentioned below.

VIII

1) The infrared spectrum contains no band in the NH-region (2.9 μ).
2) The substance does not show the oxidizing properties which would be expected for N-chlorodeserpidine.
3) Catalytical reduction with platinum in ethylene glycol monomethyl ether yields only deserpidine.
4) Hydrogen chloride is readily eliminated with the formation of dehydrodeserpidine chloride.

Catalytical reduction of Δ^3-dehydrodeserpidine chloride with platinum in methanol afforded the hitherto unknown compound 3-isodeserpidine, isolated as the nitrate.

We are able to confirm Weisenborn and Diassi's [1] observation that reduction of salts of dehydroyohimbine with hydrogen and platinum in methanol gives only yohimbine. The same result is obtained with sodium borohydride in methanol.

If, however, the catalytical reduction is carried out in basic solution a mixture of yohimbine and pseudoyohimbine is obtained. With Raney nickel in ethylene glycol monomethyl ether the yield of pseudoyohimbine was approximately 50 %.

The influence of the solvent and the catalyst appears from Table 1. It will be seen that the formation of pseudoyohimbine is favoured by a low dielectric constant of the solvent.

EXPERIMENTAL

All melting points are corrected.

Dehydroyohimbine

A stirred solution of 17.7 g (0.05 mole) of yohimbine and 7 ml of triethylamine in 350 ml of dry methylene chloride was cooled to $-10°$ C and, during 45 min, a solution of 7 ml of *tert.*-butyl hypochlorite in 50 ml of dry carbon tetrachloride was added. The cooling bath was removed and, after standing for about 15 min, the resulting solution was washed with two 50 ml portions of water, and dried. The solvent was evaporated *in vacuo* and the oily residue dissolved in 75 ml of absolute ethanol. After acidification with ethanolic hydrogen chloride, the dehydroyohimbine chloride was crystallized by addition of ether.

Yield of crude product: 17.4 g. Recrystallization from methanol-ether gave 17.0 g of yellow needles, m. p. 268–270° C (decomp.). $[\alpha]_D^{20}$ + 213° (1 % in water). Ultraviolet absorption spectrum: λ_{max}^{EtOH} 246 mμ, log ε 4.03; 355 mμ, log ε 4.35. (Found: C 64.68; H 6.40; Cl 9.27; N 7.40. Calc. for $C_{21}H_{25}Cl\,N_2O_3$: C 64.86; H 6.48; Cl 9.12; N 7.21).

The iodide was obtained by addition of aqueous potassium iodide to a methanolic solution of the chloride. Recrystallization from methanol gave yellow needles; m. p. 276–277° C (decomp.). (Found: C 52.36; H 5.22; I 26.17; N 5.83. Calc. for $C_{21}H_{25}I\,N_2O_3$: C 52.50; H 5.25; I 26.42; N 5.83).

The dehydroyohimbine base was precipitated from a solution of 5.0 g of dehydroyohimbine chloride in 50 ml of methanol by addition of concentrated aqueous sodium hydroxide followed by water. Yield of crude product: 3.7 g, m. p. 174–176° C (decomp.). Recrystallization from methanol-water yielded pale yellow crystals, m. p. 176–178° C (decomp.). (Found: C 71.46; H 7.06; N 7.74. Calc. for $C_{21}H_{24}N_2O_3$: C 71.57; H 6.86; N 7.95).

The following alkaloids were dehydrogenated in the same way as yohimbine:

Pseudoyohimbine [3]. Yield of dehydroyohimbine chloride: 65 %. The I. R.-spectrum was identical with the I.R.-spectrum of dehydroyohimbine chloride prepared from yohimbine.

Apoyohimbine [4]. Yield of dehydroapoyohimbine chloride: 73 %. Recrystallization from alcohol-ether gave yellow needles, m. p. 284–285° C (decomp.). (Found: C 67.81; H 6.44; Cl 9.74; N 7.76. Calc. for $C_{21}H_{23}Cl\,N_2O_3$: C 68.01; H 6.25; Cl 9.56; N 7.55). Ultraviolet absorption spectrum: λ_{max}^{EtOH} 246 mμ, log ε 3.95; 355 mμ, log ε 4.31.

Corynanthine *. Yield of dehydrocorynanthine chloride after recrystallization from methanol-ether: 66 %. M. p. 227–229° C (decomp.). Ultraviolet absorption spectrum: λ_{max}^{EtOH} 247 mμ, log ε 4.03; 353 mμ, log ε 4.35. (Found: C 63.62; H 6.63; Cl 8.98; N 7.25. Calc. for $C_{21}H_{25}Cl\,N_2O_3$, ½ CH_3OH: C 63.78; H 6.72; Cl 8.76; N 6.92).

α-Yohimbine *. Dehydro-α-yohimbine chloride was isolated in 77 % yield as a yellow amorphous powder. A crystalline perchlorate was obtained by addition of aqueous sodium perchlorate to a methanolic solution of the chloride. Recrystallization from water gave m. p. 206–208° C. (Weisenborn and Diassi [1] report m. p. 211–212° C). Ultraviolet absorption spectrum: λ_{max}^{EtOH} 246 mμ, log ε 4.01; 355 mμ, log ε 4.33.

Chlorodeserpidine (VIII)

To a stirred solution of 1 734 mg (0.003 mole) of deserpidine ** and 0.45 ml of triethylamine in 30 ml of dry methylene chloride a solution of 0.45 ml of *tert.*-butyl hypochlorite in 5 ml of carbon tetrachloride was added at −10° C during a period of 15 min. After standing for another 15 min. at 0° C, the resulting solution was washed with two 10 ml portions of water, and dried. The solvent was removed *in vacuo* and the solid residue recrystallized from ethanol to give 1 400 mg (76 %) of white crystalline material. M. p. 189–193° C (decomp.). Recrystallization from *iso*propanol raised the melting point to 191–196° C (decomp.). $[\alpha]_D^{20}$ −184.5° in chloroform (c = 1). Ultraviolet absorption spectrum: λ_{max}^{EtOH} 266 mμ, log ε 4.14. (Found: C 62.69; H 6.27; Cl 5.67; N 4.65. Calc. for $C_{33}H_{37}ClN_2O_8$: C 62.69; H 6.08; Cl 5.78; N 4.57).

Dehydrodeserpidine chloride

A suspension of 400 mg of chlorodeserpidine in 6 ml of methanol was acidified with strong methanolic hydrogen chloride and the resulting clear solution was refluxed for five minutes. After cooling dehydrodeserpidine chloride was precipitated as an amorphous powder. Yield: 380 mg. Crystallization from water afforded yellow crystals, m. p. 185–187° C (decomp.).

---

* Kindly supplied by E. Merck AG., Darmstadt.

** Supplied by S. B. Penick & Co., New York.

Ultraviolet absorption spectrum: λ_{max}^{MeOH} 252 mμ, log ε 4.19; 260—265 mμ (shoulder), log ε 4.07; 355 mμ, log ε 4.36. (Found: C 60.13; H 6.60; Cl 5.68; N 4.61. Calc. for $C_{32}H_{37}ClN_2O_3$, 1½ H_2O: C 60.05; H 6.30; Cl 5.54; N 4.38).

Dehydroyohimbine methiodide (VII)

2.5 g of dehydroyohimbine base were dissolved in a mixture of 20 ml of absolute ethanol and 10 ml of methyl iodide. After standing overnight in the dark, 1.87 g of a crystalline methiodide were obtained, which were recrystallized from ethanol. M. p. 213—215° C (decomp.). Ultraviolet absorption spectrum: λ_{max}^{MeOH} 305 mμ, log ε 4.35. (Found: C 52.66; H 5.81; I 24.80; N 5.82. Calc. for $C_{22}H_{27}I N_2O_3$, ½ H_2O: C 52.48; H 5.61; I 25.21; N 5.57).

Hydrogenation of dehydroyohimbine methiodide

A solution of 988 mg of dehydroyohimbine methiodide in 30 ml of ethylene glycol monomethyl ether was hydrogenated at *ca.* 60° C under one atm. of hydrogen in the presence of 200 mg of a platinum oxide catalyst.

When the theoretical amount of hydrogen had been absorbed, the catalyst was removed by filtration and the filtrate evaporated to dryness. The light yellow sirupy residue crystallized on scratching in the presence of a few ml of acetone. The solid was filtered and washed with acetone to give 890 mg of a mixture of yohimbine methiodide and pseudoyohimbine methiodide, which was dissolved in 20 ml of boiling methanol. After cooling yohimbine methiodide crystallized upon seeding while pseudoyohimbine methiodide remained in solution. Filtration and washing with methanol yielded 150 mg of pure yohimbine methiodide which softened at 240—242° C and thereafter was gradually decomposed. The infrared spectrum was indistinguishable from the spectrum of authentic yohimbine methiodide.

Addition of ether to the filtrate afforded 580 mg of pseudoyohimbine methiodide, m. p. 271—272° C (decomp.). The melting point of a mixture with an authentic sample was undepressed and their infrared spectra were identical.

Hydrogenation of chlorodeserpidine (VIII) to deserpidine

A solution of 307 mg (0.0005 mole) of chlorodeserpidine (VIII) in 10 ml of dioxan was shaken at room temperature in the presence of 30 mg of platinum oxide under one atm. of hydrogen. When the theoretical amount of hydrogen had been absorbed (30 min.), the catalyst was removed by filtration and the solution evaporated to dryness under reduced pressure. The residue was dissolved in 10 ml of methanol and the resulting solution basified with aqueous ammonia. Addition of water yielded 220 mg of white crystalline material. M. p. 224—226° C (decomp.). After recrystallization from methanol the melting point was 225—227° C (decomp.) alone and by admixture with deserpidine. $[\alpha]_D^{20}$ —135° in chloroform (c = 1). Schlittler *et al.*[5] report for deserpidine: $[\alpha]_D^{24,5}$ —137° ± 1 in chloroform.

3-Isodeserpidine

235 mg of dehydrodeserpidine chloride were dissolved in 10 ml of methanol and hydrogenated at room temperature under one atmosphere of hydrogen in the presence of 20 mg of a platinum oxide catalyst.

When the theoretical amount of hydrogen had been absorbed (15 min.), the catalyst was removed by filtration. The solution was basified with aqueous ammonia and the hydrogenation product precipitated as a white amorphous powder by addition of water.

The amorphous base was converted to a crystalline nitrate by careful acidification of an ethanolic solution with nitric acid. Filtration and washing with ethanol and ether yielded 170 mg which melted at 189—194° C (decomp.). Recrystallization from ethanol raised the melting point to 194—198° C (decomp.). Ultraviolet absorption spectrum: λ_{max}^{EtOH} 271 mμ, log ε 4.26. (Found: C 58.34; H 6.55; N 6.47. Calc. for $C_{32}H_{39}N_3O_{11}$, H_2O: C 58.25; H 6.28; N 6.37).

The substance was readily distinguishable from deserpidine nitrate [6] by its low melting point, its optical rotation ($[\alpha]_D^{20}$ −153° in pyridine (c = 1)), and its high R_F value in the paper chromatographic system described below.

For deserpidine nitrate Mac Phillamy *et al.*[6] report m. p. 254—260° C (decomp.). The optical rotation was found to be $[\alpha]_D^{20}$ −138° in pyridine (c = 1).

Reduction of dehydroyohimbine

a) With sodium borohydride. To a stirred solution of 777 mg of dehydroyohimbine chloride in 20 ml of methanol was added drop by drop 1 ml of a 10 % methanolic solution of sodium borohydride. From the resulting colourless solution the reduction product was precipitated by addition of 50 ml of water. The precipitate was filtered off, washed with water and dried. Yield: 525 mg of white crystals, m. p. 234—235.5° identified as yohimbine by mixed melting point and by optical rotation $[\alpha]_D^{20}$ +102° in pyridine (c = 1).

b) Catalytically. A series of catalytical hydrogenations were carried out with the aim to study the influence of the solvent, the catalyst, and the addition of base on the content of pseudoyohimbine in the hydrogenation product. The general procedure is described below and the results are summarized in Table 1.

Table 1. Catalytical hydrogenation of dehydroyohimbine chloride.

Solvent	Dielectric constant of the solvent	Catalyst	Mole equivalent triethylamine added	Yield of pseudoyohimbine %
Methanol	32.6	PtO_2 (100 mg)	0	0
—	—	—	1	26
—	—	—	2	27
Ethylene glycol monomethyl ether	16.0	—	2	34
Dioxan *	2.2	—	2	47
Methanol	32.6	5 % Pd on $CaCO_3$ (1.0 g)	2	20
—	—	Raney nickel (*ca.* 0.5 g)	2	30
Ethylene glycol monomethyl ether	16.0	Raney nickel (*ca.* 0.5 g)	2	48

*) In this experiment dehydroyohimbine acetate was dehydrogenated since the chloride was insoluble in dioxan.

General procedure. 1.554 g (0.004 mole) of dehydroyohimbine chloride were dissolved in 40 ml of the appropriate solvent. The catalyst and the base were added and the resulting mixture was shaken at room temperature under one atmosphere of hydrogen. When the theoretical amount of hydrogen had been absorbed (5—60 min.) the catalyst was removed by filtration and the filtrate concentrated *in vacuo* to a volume of 10 ml. The solution was made alkaline with aqueous ammonia and the hydrogenation product precipitated by addition of water. The crystalline precipitate was filtered, washed with water and, after drying, treated with 10 ml of boiling methanol. By this treatment, the yohimbine went into solution, while the highly insoluble pseudoyohimbine, after cooling, was collected on a filter and washed with methanol. From the filtrate the yohimbine was precipitated by addition of water.

The pseudoyohimbine was identified by its melting point (266—268° C (decomp.). and its optical rotation $[\alpha]_D^{20}$ +28° in pyridine (c = 1).

Paper chromatography

It was found that two of the paper chromatographic systems described by Bush [7] for the separation of steroids were well suited for the separation and identification of alkaloids of the yohimbine type.

The relatively polar alkaloids such as yohimbine, corynanthine, and α-yohimbine were best separated in the B5 system, while the B3 system was more convenient for the relatively non-polar alkaloids such as reserpine, deserpidine, and isodeserpidine.

Whatman No. 1 paper was used and the chromatograms were run at 32° C for three hours after equilibration overnight.

The alkaloids were located on the dried papers by their ultraviolet fluorescence after irradiation with ultraviolet light for about ten min. Quantities ranging from 0.5 to about 5 μg could be detected by this method.

It was necessary to use known alkaloids as controls, since the R_F values varied with the amount of material applied.

Acknowledgment. The authors wish to express their gratitude to Dr. E. Frederiksen and Dr. E. Juhl Nielsen for their kind encouragement and advice. We are also indebted to Dr. P. Mørch for the ultraviolet and infrared spectra and to Mr. G. Cornali for the microanalyses.

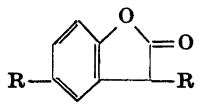
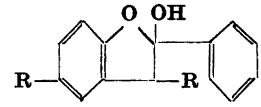
Studies on Lignin



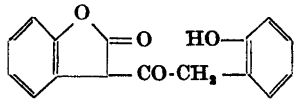
XVII.* Properties of Some 2'-Hydroxydesoxybenzoins

ÅKE SPETZ



Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

As potential lignin models compounds of *semi*-acetal 2-phenylcoumaranol-(2) type (II) were desired. The reaction between coumaranone-(2) (Ia) and phenylmagnesium bromide yielded 3-(*o*-hydroxyphenylacetyl)-coumaranone-(2) (IV) — also obtained from coumaranone-(2) on treatment with potassium — and a small amount of 2'-hydroxydesoxybenzoin (IIIa) also obtained in good yield by reduction of *o*-hydroxybenzil. 3,5-Dimethylcoumaranone-(2) (Ib) and phenylmagnesium bromide gave exclusively *α*,5'-dimethyl-2'-hydroxydesoxybenzoin (IIIb). The 2'-hydroxydesoxybenzoins were readily dehydrated to the corresponding coumarones when treated with strong acids or subjected to a sulphite cook. Because of their instability it is unlikely that 2-phenylcoumaranol-(2) systems occur in lignin.



In connection with certain lignin chemical problems we were interested in the stability of compounds of the 2-phenylcoumaranol-(2) type (II)[1]. A convenient method for the preparation of such compounds appeared to be the condensation of coumaranones with suitable phenylmagnesium halides.

* Part XVI. *Svensk Papperstidn.* **55** (1952) 816.

When an ethereal solution of phenylmagnesium bromide was added to coumaranone, $C_8H_6O_2$ (Ia), reaction took place but from the reaction product only a small amount of a substance, $C_{14}H_{12}O_2$ (A), could be isolated. The main product was a pale yellow compound, $C_{16}H_{12}O_4$.

It was suspected that the latter compound might be 3-(*o*-hydroxyphenylacetyl)-coumaranone-(2) (IV) formed by an acetoacetic ester type of condensation from two molecules of coumaranone, the Grignard reagent simply functioning as the base catalyst. The correctness of this assumption was shown by the formation of the same compound when a solution of coumaranone in dry ether was treated with potassium.

Compound A could be more conveniently obtained by reduction of *o*-hydroxybenzil with zinc in the presence of ammonium chloride (compare Pearl [2] for the similar reduction of vanillil to desoxyvanilloin).

3,5-Dimethylcoumaranone-(2) (Ib) was prepared by transforming 2-methoxy-5-methylacetophenone into its cyanohydrin which was hydrolysed to 2-methoxy-5-methylhydratropic acid. The acid was demethylated with pyridinium chloride and distilled to give the desired product. This compound when treated with phenylmagnesium bromide furnished a compound, $C_{16}H_{16}O_2$ (B), in moderate yield. No condensation products of the acetoacetic ester type could be isolated in this case.

Compound A is not the semiacetal 2-phenylcoumaranol-(2) (IIa) but the corresponding 2′-hydroxydesoxybenzoin (IIIa) and compound B is α,5′-dimethyl-2′-hydroxydesoxybenzoin (IIIb). This follows from the close similarity of the U.V. absorptions of compound A, its methyl ether, compound B and desoxybenzoin [3].

Maxima:	mμ	log ε	mμ	log ε
Desoxybenzoin	240	4.10	278*	2.90
2′-Methoxydesoxybenzoin	243	4.03	275*	3.42
2′-Hydroxydesoxybenzoin (comp. A)	242	4.13	275*	3.54
α,5′-Dimethyl-2′-hydroxydesoxybenzoin (comp. B)	245	4.11	283	3.50

* inflexion

In 0.25 N sodium hydroxide solution the phenol-phenolate shift was observed with compound A (max.: 240 mμ, log ε 4.29; infl.: 288 mμ, log ε 3.70). However, above 350 mμ a new maximum was gradually developed (log ε increasing from 2.7 to 3.3 at 400 mμ in 90 minutes). This indicates that some secondary changes take place. Moreover the original absorption was not immediately restored on acidification.

When compound A was treated with acids, water was easily eliminated and 2-phenylcoumarone was formed and similarly when heated with bisulphite cooking acid 2-phenylcoumarone was obtained but no sulphonic acid.

Compound B behaved in exactly the same manner yielding 3,5-dimethyl-2-phenylcoumarone in good yield.

These results indicate that it is unlikely that 2-hydroxy-2-phenylcoumarone systems occur in lignin.

EXPERIMENTAL *

2'-Hydroxydesoxybenzoin (IIIa). Method a. Phenylmagnesium bromide (from 7.8 g bromobenzene) in dry ether (100 ml) was slowly added with mechanical stirring to coumaranone-(2) (10 g) in dry ether (50 ml). The reaction product was decomposed with ammonium chloride in ice-water and the aqueous phase carefully acidified with dilute hydrochloric acid (to pH 2—3) and extracted with ether. The combined ether solutions were washed with cold dilute hydrochloric acid and then extracted with dilute sodium hydroxide. Carbon dioxide was bubbled into the alkaline solution and at pH 9 a pale yellow precipitate formed which was dissolved in ether. The ether solution was dried over magnesium sulphate and evaporated to dryness. The residue (compound A, 1.5 g) was crystallised from ethanol-water. Pale yellow crystals starting to sinter at 110° and, melting at about 120°. The unsharp melting point is probably due to loss of water and partial formation of 2-phenylcoumarone. (Found: C 80.5; H 5.6. Calc. for $C_{14}H_{12}O_2$: C 79.2; H 5.7).

Method b. *o*-Hydroxybenzil (1.6 g) in ethanol (100 ml) and zinc dust (5 g) were heated to boiling and a warm solution of ammonium chloride (5 g) in water (20 ml) added and the mixture boiled under reflux for one hour. The zinc was removed and acetic acid (10 ml) carefully added to the cooled solution which was then concentrated at reduced pressure to a small volume whereupon water (100 ml) was added. The remaining ethanol was now removed by further distillation. On cooling a pale yellow precipitate was obtained. The product (0.9 g) was dissolved in dilute aqueous alkali, filtered and precipitated with carbon dioxide. Crystallisation from ethanol-water gave crystals m.p. 110—120° (decomp.).

2'-Methoxydesoxybenzoin, which is a stable compound with a sharp melting point, was prepared in order to identify the reaction products from *methods a* and *b* by dissolving 2'-hydroxydesoxybenzoin (0.5 g), prepared according to either of the methods, in 2 N aqueous sodium hydroxide (5 ml) and shaking with dimethyl sulphate (0.5 ml). The crystalline reaction product was dissolved in ether and the solution filtered through a short column of aluminium oxide. On evaporation almost pure methyl ether m.p. 59—60° was obtained. Recrystallisation from a small volume of methanol raised the m.p. to 61.5—62°. The products obtained from both preparations were identical (mixed m.p.). (Found: C 79.7; H 6.4; OCH_3 13.6. Calc. for $C_{15}H_{14}O_2$: C 79.6; H 6.2; OCH_3 13.7).

3-(o-Hydroxyphenylacetyl)-coumaranone-(2) (IV). Method 1. On further acidification of the alkaline phase from the preparation of 2'-hydroxydesoxybenzoin according to *method a* (to pH 6—7) a precipitate (3.5 g) was obtained. Crystallisation from ethanol-water yielded pale yellow needles m.p. 150—155° (decomp.) (Found: C 71.5; H 4.7. Calc. for $C_{16}H_{12}O_4$: C 71.6; H 4.5).

Method 2. In a flask fitted with a condenser, potassium (1.2 g) was powdered under dry toluene (100 ml) which was then replaced by dry ether (25 ml). Coumaranone-(2) (4.6 g) in dry ether (50 ml) was added through the condenser with shaking at room temperature. The mixture was then boiled for six hours and left overnight. Acetic acid (2.5 ml) in water (25 ml) was added with vigorous shaking. The ethereal layer was separated, washed with water, dried over magnesium sulphate and evaporated to dryness. Crystallisation of the residue (2 g) from ethanol-water yielded a pale yellow substance m.p. 151—154° not depressed on admixture with 3-(*o*-hydroxyphenylacetyl)-coumaranone-(2) from the previous experiment (*method 1*).

2-Phenylcoumarone. 2'-Hydroxydesoxybenzoin (0.5 g) was dissolved in acetic acid (2 ml) and conc. hydrochloric acid (2 drops) added. On heating the solution to boiling it gave almost instantly a white precipitate. It was collected, dissolved in ether, shaken with dilute aqueous alkali, dried over calcium chloride and the solution evaporated to dryness. Crystallisation of the residue (0.4 g) from ethanol gave white plates exhibiting a blue fluorescence, m.p. 120.5—121°. (Found: C 86.4; H 5.2. Required for $C_{14}H_{10}O$: C 86.6; H 5.2).

2-Methoxy-5-methylhydratropic acid. Concentrated hydrochloric acid (70 ml, *d* 1.18) was added from a dropping funnel in five to ten drop portions to a mixture of 2-methoxy-5-methylacetophenone (82 g) and potassium cyanide (55 g) and ether (100 ml) cooled in

* All melting points uncorrected.

ice-water and vigorously stirred. The pale yellow colour appearing at each addition of the acid was allowed to disappear before the next addition. Towards the end of the reaction the mixture remained yellow. The ethereal layer was separated, washed several times with water, concentrated at reduced pressure and the crude 2-methoxy-5-methylacetophenone cyanohydrin (100 g) used for the next step without further purification.

Crystalline stannous chloride (100 g), acetic acid (100 ml), conc. hydrochloric acid (100 ml) and hydriodic acid (10 ml, *d* 1.7) were added to the crude 2-methoxy-5-methylacetophenone cyanohydrin (100 g). The mixture was heated on a steam bath for five hours. After cooling the mixture was filtered and the filtrate diluted with water and extracted with ether. The ethereal solution was extracted with sodium bicarbonate solution from which on acidification with hydrochloric acid a colourless crystalline product (18 g) was precipitated. The substance crystallised from ethanol-water in plates, m.p. 125—126°. (Found: C 68.5; H 7.3; Equiv. wt. 192. Calc. for $C_{11}H_{14}O_3$: C 68.0; H 7.3; Equiv. wt. 194).

The ethereal solution was then extracted with 2 N sodium hydroxide from which on acidification a crystalline, phenolic substance (about 5 g) was obtained by extraction with ether. The substance crystallised from ligroin in needles m.p. 47—48° undepressed on admixture with 2-hydroxy-5-methylacetophenone. It is evidently formed by demethylation of unchanged 2-methoxy-5-methylacetophenone.

The *amide* of 2-methoxy-5-methylhydratropic acid separated from the aqueous phase on standing and was crystallised from benzene. Plates, m.p. 144—145°. (Found: N 7.25. Calc. for $C_{11}H_{15}O_2N$: N 7.25). It was converted to 2-methoxy-5-methylhydratropic acid, m.p. 125—126° undepressed on admixture with an authentic specimen, by refluxing with 50 % ethanolic potassium hydroxide for five hours.

Concentration of the extracted solution yielded a residue (about 40 g) consisting chiefly of unchanged 2-methoxy-5-methyl-acetophenone.

3,5-Dimethylcoumaranone-(2) (Ib). A mixture of 2-methoxy-5-methylhydratropic acid (17 g) and pyridinium chloride (50 g) was heated to 180° for two hours. The reaction mixture was poured into 2 N hydrochloric acid (500 ml) and extracted with ether. The ethereal solution was washed with dilute hydrochloric acid and with water. After removal of the ether and distillation of the residual oil at reduced pressure a colourless product (12 g) was obtained which readily crystallised. Plates, m.p. 36—37°. Crystallisation from methanol-water and repeated distillation raised the melting point to 39—39.5°. (Found: C 74.3; H 6.5. Calc. for $C_{10}H_{10}O_2$: C 74.1; H 6.2).

a,5'-Dimethyl-2'-hydroxydesoxybenzoin (IIIb). Phenylmagnesium bromide (from 3.1 g bromobenzene) in dry ether (10 ml) was slowly added to a solution of 3,5-dimethylcoumaranone-(2) (4 g) in dry ether (150 ml) with mechanical stirring. The reaction product was worked up exactly in the same way as for 2'-hydroxydesoxybenzoin and yielded a crystalline substance (1.5 g) melting at 125—127°. Recrystallisation from ligroin gave needles m.p. 129.5—130°. (Found: C 80.1; H 6.8. Calc. for $C_{16}H_{16}O_2$: C 80.0; H 6.7).

Sulphite cooking of the desoxybenzoins. The cooking acid was obtained by bubbling sulphur dioxide into 10 % aqueous sodium hydroxide until the desired pH was reached. The heating was carried out in a sealed glass tube. Time 12 hours. Temperature 135°C.

2'-Hydroxydesoxybenzoin. a: pH 1.5. The compound (0.5 g) was heated with cooking acid (10 ml). The reaction mixture was extracted with ether which was then washed with dilute alkali, dried over calcium chloride and concentrated. A crystalline substance (0.5 g) m.p. 118—120° with a blue fluorescence was obtained. Recrystallisation from ethanol yielded plates, m.p. 120—121° showing no depression when mixed with 2-phenylcoumarone. *b*: pH 5.5. The experiment was carried out in a similar way and the alkali-washed ethereal solution on concentration yielded 2-phenylcoumarone (0.4 g). When carbon dioxide was bubbled through the alkaline washings unchanged 2'-hydroxydesoxybenzoin (0.1 g) was recovered.

a,5'-Dimethyl-2'-hydroxydesoxybenzoin. The experiments were carried out as above. At pH 1.4 3,5-dimethyl-2-phenylcoumarone was obtained in a quantitative yield. Crystallisation from methanol gave needles exhibiting a strong blue fluorescence m.p. 69.5—70° (Found: C 86.7; H 6.2. Calc. for $C_{16}H_{14}O$: C 86.5; H 6.3).

No sulphonic acids were found in any of these experiments.

Studies on Lignin

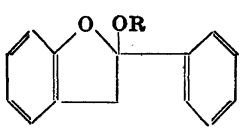
XVIII.* Sulphite Cooking of Salicil

HOLGER ERDTMAN and ÅKE SPETZ

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

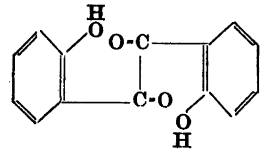
Salicil (II) when subjected to a sulphite cook in neutral or slightly alkaline medium gave phenol, salicoylformic acid and xanthene-9-sulphonic acid (VIII). Similarly 4,5-dihydro-2,3;6,7-dibenzoxepin-dione-(4,5) (IX) and salicilic acid (V), the former in excellent yield, both furnished VIII. Salicil was oxidised to disalicylide (IV) with lead *tetra*-acetate indicating that salicil can react in the cyclised form IIIa.

At one stage in our researches on the sulphonation of lignin it was suggested that "group B" which is sulphonated only at a low pH but not with neutral sulphites might possess a *cyclo*-acetal structure of the type I [1]. However, our further studies especially on the sulphonation of various benzylalcoholic model substances and their ethers soon made this hypothesis superfluous [2] and in a recent publication [3] we have shown that *cyclo-hemi*-acetals of this type (I, R = H) are unstable.



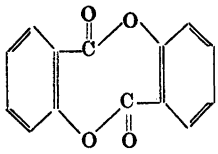
Not entirely unexpectedly salicil (II) shows a greater tendency to react in the *bis-cyclo*-acetal form (IIIa) and for example we have found that it readily forms a dimethyl acetal (IIIb) which will be described in a forthcoming publication. Further it gives disalicylide (IV) in good yield when treated with lead *tetra*-acetate in acetic acid.

Hence it was of interest to investigate whether salicil reacts, when subjected to sulphite cooking, with formation of a sulphonic acid.

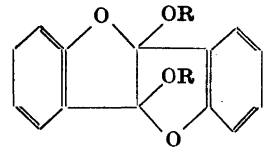


However, salicil did not react with a normal "acid sulphite cooking acid" and was recovered unchanged, but at pH 7—10 a series of interesting reactions occurred resulting in the formation of phenol, salicoylformic acid, and a sulphonic acid, (Scheme 1, VI, VII and VIII, respectively) the sparingly soluble sodium salt of which separated from the reaction mixture on cooling.

The free sulphonic acid was very unstable but the sodium salt when oxidised with permanganate furnished xanthone in good yield. This lead to the assumption that the sulphonic acid was xanthene-9-sulphonic acid and this



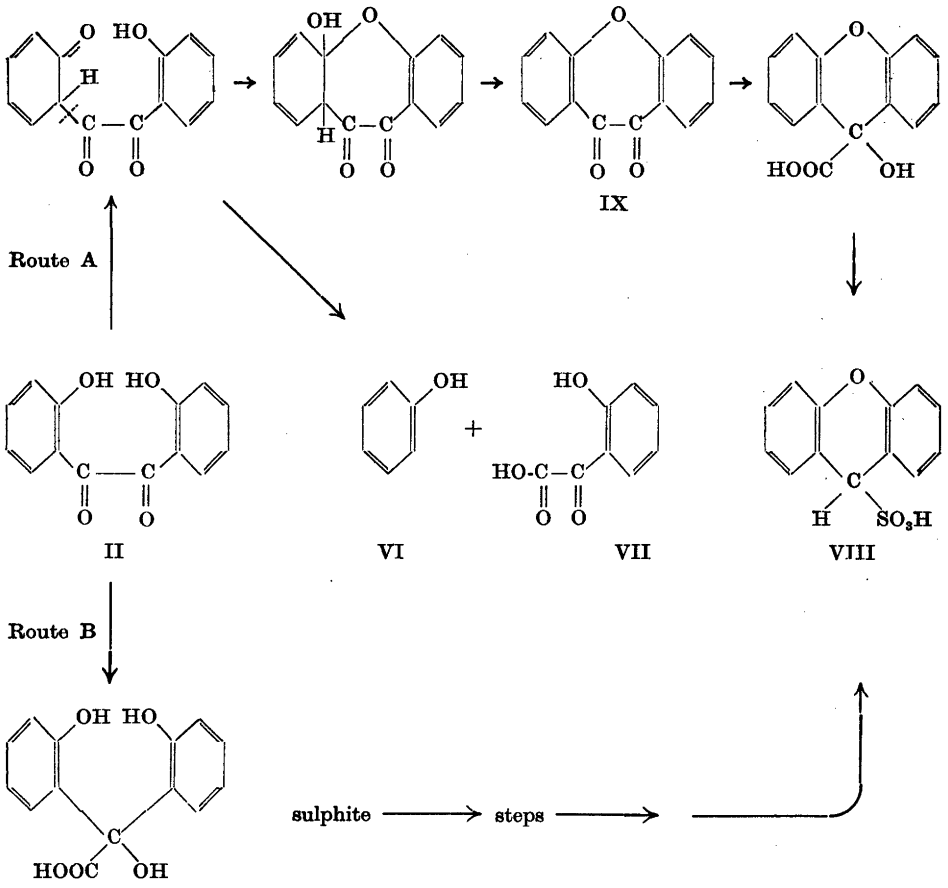
* Part XVII. *Acta Chem. Scand.* **10** (1956) 1422.



I

II

IV



III a R = H
III b R = CH_3

was confirmed by direct sulphonation of xanthydrol and identification of the sodium salts of the sulphonic acids by means of their X-ray powder photographs.

The formation of phenol and salicoylformic acid is easy to understand. It simply represents a hydrolytic fission as indicated in scheme 1 (Route A) and phenol was, moreover, obtained when salicil was heated with a saturated sodium bicarbonate solution in the same way as in the case of the sulphite cook. A similar case has recently been recorded [4].

There are several ways in which the formation of xanthene-9-sulphonic acid can be explained. One is illustrated in scheme 1 (Route B) and involves the intermediate formation of salicilic acid (V) which suffers dehydration, decarboxylation and sulphonation to xanthene-9-sulphonic acid as indicated in the scheme. Salicilic acid was obtained by a rather drastic treatment of salicil with strong alkali although it was impossible to isolate the compound in a completely pure state. It was characterised by conversion into the dimethyl ether and into the diacetate of salicilic acid lactone both of which are readily obtainable in good yield from the crude salicilic acid preparation. This crude preparation, when subjected to a sulphite cook under the conditions employed for salicil furnished xanthene-9-sulphonic acid in moderate yield. In view of this and because it seems improbable that salicil would readily undergo a benzilic acid rearrangement under the conditions employed it appears doubtful that the formation of xanthene-9-sulphonic acid from salicil proceeds *via* salicilic acid. An alternative reaction mechanism was therefore considered involving the intermediate formation of 4,5-dihydro-2,3;6,7-dibenzoxepindione-(4,5) (IX, Scheme 1: route A) which would bear some analogy with tropolones and therefore might readily rearrange to 9-hydroxyxanthene-9-carboxylic acid. A synthesis of this compound was contemplated when recently Mathys, Prelog and Woodward [5] reported its synthesis and also commented upon its facile rearrangement to 9-hydroxyxanthene-9-carboxylic acid with even weak alkali. Through the courtesy of Professor V. Prelog to whom we extend our

Scheme 1.

gratitude, we have been able to investigate the action of sulphite on this compound. It was found to give an excellent yield of xanthene-9-sulphonic acid and it therefore appears probable that the formation of xanthene-9-sulphonic acid from salicil largely follows route A in scheme 1.

EXPERIMENTAL *

Lead tetra-acetate oxidation of salicil. To salicil (0.5 g) in acetic acid (15 ml) was added a solution of lead *tetra*-acetate (1 g) in acetic acid (10 ml). The mixture was heated to 70° and then left for one hour at room temperature. On cooling disalicylide precipitated in rhombic crystals. The crude reaction product (0.4 g, yield 80 %) had a m. p. 165—195° which was raised to 225—230° by repeated crystallisation from chloroform. The compound gave an I. R. spectrum identical with that of authentic disalicylide prepared according to Baker *et al.*[6].

* All melting points uncorrected.

Sulphite cooking of salicil. Here and in the following experiments the "cooking acid" was prepared by bubbling sulphur dioxide into 10 % aqueous sodium hydroxide until the desired pH was reached. The cookings were all carried out in sealed tubes at 135° C.

pH 1.5. Salicil (1.1 g) was heated with "cooking acid" (50 ml) for 20 hours. After cooling the solid (1.07 g) was collected and recrystallised from ethanol to give yellow needles, m. p. 153—154°, undepressed on admixture with salicil.

pH 7.1. Salicil (5 g) was heated with "cooking acid" (70 ml) for 8 hours. After cooling, the sodium salt of the sulphonic acid VIII (1.5 g, yield 25 %) was collected by filtering. The filtrate (pH 6.9) was extracted with ether and the ether solution evaporated to give phenol (1 g, yield 51 %). The aqueous phase was run through a cation exchanger, immediately neutralised with barium carbonate and filtered and evaporated to give the barium salt of salicoylformic acid (3.5 g, yield 72 %).

Identification of phenol (VI). The phenol was transformed into phenoxyacetic acid and into *tri*-bromophenol, both derivatives showing no melting point depression when mixed with authentic specimens.

Identification of salicoylformic acid (VII). The barium salt (1.5 g) was dissolved in water, excess of 2 N sodium hydroxide (5 ml) was added and carbon dioxide bubbled into the solution which was then filtered and weakly acidified with dilute hydrochloric acid. Phenylhydrazine (0.5 ml) was added and the solution heated to boiling. After cooling the reaction product (1 g), m. p. *ca.* 148°, was collected and dissolved in acetic acid (20 ml). Conc. hydrochloric acid (1 drop) was added and the solution heated to boiling. A crude reaction product (about 1 g, yield 67 %) was obtained which was recrystallised from acetic acid to yield yellow prisms, m. p. 184—185°, undepressed on admixture with coumarandion-3-phenylhydrazone prepared according to Fries *et al.*[7].

Identification of the sulphonic acid (VIII). The sodium salt was recrystallised from ethanol to yield white needles. A sample of the salt (0.93 g) was dissolved in water (5 ml) and heated for one hour on a steam bath, finely powdered potassium permanganate (0.59 g) g) being added from time to time. After cooling the reaction mixture was saturated with sulphur dioxide and filtered. A crystalline product (0.4 g, yield 67 %) was obtained which was recrystallised from ethanol to give colourless needles m. p. 172—173°. The reaction product was soluble in conc. sulphuric acid with a yellow colour exhibiting a strong blueish fluorescence. Admixture with xanthone did not depress the melting point.

After drying in a high vacuum a sample of the sodium salt (43.8 mg) was dissolved in water and after cation exchange titrated with 0.0417 N sodium hydroxide (3.68 ml). (Found: Equiv. weight 285. Calc. for $C_{13}H_9O_4S$ Na: Equiv. weight 284). The *cyclohexylammonium salt* of the sulphonic acid was prepared by running an ethanolic solution of the sodium salt through a cation exchanger into an ethereal solution of *cyclo*hexylamine. The crystalline precipitate was collected and recrystallised several times from ethanol yielding white needles without distinct melting point which started to decompose with a red colour at about 230°. (Found: C 62.9; H 6.5; N 4.0; S 8.9. Calc. for $C_{19}H_{23}NO_4S$: C 63.1; H 6.4; N 3.9; S 8.9).

Sulphite cooking of xanthydrol. Xanthydrol (5 g) was heated with "cooking acid" (70 ml, pH 7) for 8 hours. The crystalline reaction product (6.5 g, yield 91 %) was recrystallised from ethanol and the product shown to have an X-ray powder photograph identical with that of the sulphonic acid sodium salt obtained by sulphite cooking of salicil.

Salicilic acid (V). With vigorous mechanical stirring salicil (5 g) in 2 N sodium hydroxide (50 ml) was heated on a steam bath and solid sodium hydroxide (100 g) was added in portions. A yellowish brown semi-solid product was precipitated which crystallised on continued stirring forming an almost colourless suspension. The reaction mixture was poured into finely crushed ice (1 l) and carefully acidified with conc. hydrochloric acid (250 ml) and extracted with ether. The ether solution was washed with water and then extracted with saturated aqueous sodium bicarbonate (2 × 25 ml). The bicarbonate solution was acidified with 2 N hydrochloric acid (40 ml) to yield the reaction product as an oil which crystallised on standing. The crude salicilic acid (5 g) was collected by filtration, washed with cold water and dried. M. p. 100—110°. Repeated attempts to recrystallise the acid from water and from benzene yielded a red-coloured product without distinct melting point.

Salicilic acid dimethyl ether. The crude salicilic acid (2.6 g) was dissolved in 2 N sodium hydroxide (20 ml) and shaken with dimethyl sulphate (3 ml). The reaction mixture was boiled for five minutes, then cooled and acidified with dilute sulphuric acid. The crystalline reaction product (2 g, yield 71 %) was recrystallised several times from ethanol to yield the pure dimethyl ether, m. p. 160.5—161°, undepressed on admixture with *o,o'*-dimethoxybenzilic acid prepared according to Ford-Moore [8].

Salicilic acid lactone diacetate. The crude salicilic acid was dissolved in pyridine and acetic anhydride added. The solution was heated for some minutes and then poured into ice. The crystalline reaction product was collected and recrystallised from ethanol (charcoal) to yield colourless plates, m. p. 167—169.5°. Distillation at 1 mm Hg raised the m. p. to 169—169.5°. (Found: C 66.2; H 4.5. Calc. for $C_{18}H_{14}O_6$: C 66.3; H 4.3).

Sulphite coking of salicilic acid. Crude salicilic acid (0.5 g) was heated with "cooking acid" (10 ml, pH 7) for 8 hours. The reaction mixture was cooled and filtered to yield xanthene-9-sulphonic acid sodium salt (0.1 g, yield 18 %).

Sulphite cooking of 4,5-dihydro-2,3:6,7-dibenzoxepindione-(4,5). The dihydrodibenzoxepindione (90 mg) was heated with "cooking acid" (1 ml, pH 7) for 8 hours. On cooling, the sodium salt of xanthene-9-sulphonic acid (100 mg, yield 87 %) precipitated.

We are indebted to Dr. G. E. H. Lundgren, Inst. för Oorg. Kemi, KTH, Stockholm, for the X-ray determinations.

A Procedure for the Determination of Proteins and Similar Compounds in Large Numbers of Fractions

BENGT v. HOFSTEN

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

Fraction collector work gives rise to large numbers of samples, and the chemical analysis of these necessitates methods which are sensitive but as simple as possible. Some of the current methods used when nitrogenous biological material is fractionated have been experimentally evaluated, and their relative merits are discussed.

A relatively simple procedure using a ninhydrin reaction is proposed. In this method a small sample from every fraction is first hydrolyzed with HCl at 120°, after which the acid is removed *in vacuo*. The ninhydrin reaction is then performed on a suitable aliquot of the residue. Useful technical arrangements and precautions are described, and the advantages and limitations of the method are discussed.

Fractionation work using chromatography, electrophoresis or counter current distribution gives rise to a great number of fractions, the analysis of which requires considerable time. The determination of biological or chemical activity in these fractions is often the main problem, but the activity is usually wanted as specific activity. In the case of fractionation of nitrogenous compounds, the specific activity is often expressed as activity per mg dry weight or nitrogen. Dry weight determinations of proteins is no easy matter and requires a comparatively large amount of material. In certain cases the simple method of Johnson [1] can be used to obtain an estimate of total organic matter. In this method, conc. H_2SO_4 and sodium dichromate of known strength reacts with the organic compounds in the sample. The sensitivity of the method is high but the accuracy is rather low, especially when interfering metals are present.

The determination of nitrogen according to Kjeldahl and conversion to protein by multiplication with a certain factor has long been the standard method for protein determinations. Besides the variable nitrogen content of different proteins, all other nitrogen containing substances interfere. Many different methods of precipitating the protein before the determination have been proposed, but it is often difficult to get a quantitative precipitate without co-precipitation [2]. Dialysis or ultrafiltration has been used extensively, but

some proteins tend to become adsorbed to the membranes, and neither precipitation nor dialysis is suitable for compounds of intermediate size such as peptides and certain enzymes.

Ordinary digestion of the sample and distillation of ammonia according to Kjeldahl is not practical with large numbers of fractions and, in addition, samples containing less than 0.1 mg N are difficult to analyse. A hypobromite titration is useful and easy to perform even on a few micrograms of nitrogen, provided small but usually constant errors can be tolerated. As modified by Harvey [3], the titration can be carried out directly in the digestion flasks or tubes without distillation, which is a definite advantage. It is thus possible to perform a large number of determinations in a comparatively short time, provided the approximate nitrogen content is known so that a suitable amount of hypobromite can be added. The method needs to be standardized on samples of known nitrogen content, and its pH-sensitivity is sometimes irritating. Boissonas and Haselbach [4] have used a sulfuric acid digestion followed by neutralization and a ninhydrin reaction to determine the nitrogen content in series of fractions. This elegant method is claimed to give good values in the 1—20 μg range, and it is certainly valuable when the total nitrogen content of fractions is wanted. For accurate determination of small quantities of nitrogen, the diffusion method of Conway [5] combined with the sealed-tube digestion of Greenbaum *et al.*[6] is certainly more exact.

When the available amount of protein is comparatively large, turbidimetric determinations may be useful. A procedure using trichloroacetic acid is very rapid and has been much used by Smith in his work on proteolytic enzymes [7] and by Stadtman *et al.*[8]. More than 20 μg protein per ml is needed for a determination and the precision of the method is rather low because of the inherent difficulties of all turbidimetric determinations.

The method of Greif [9] modified by Nayyar and Glick [10] using bromosulfalein has been developed particularly for use in histochemistry. The acid bromosulfalein reagent is used to precipitate the protein, and the residual concentration of the dye is measured at an alkaline pH. The method is useful down to very small amounts of protein and the specificity is high. In fractionation work, it should be useful in distinguishing between proteins and low molecular weight material, but as it involves a precipitation followed by a centrifugation on a micro-scale, it is of limited use in the analysis of large numbers of fractions.

The much used method of Lowry *et al.*[11], in which a combination of the biuret and Folin reactions is used, has the advantage of being rather specific for proteins. It is definitely the easiest method in many cases, and has a quite high accuracy if it is calibrated with the protein determined. The Lowry method is rather sensitive to the pH of the analyzed solution, and in many cases the only possibility of overcoming this is a preliminary precipitation. The tyrosine content of the sample influences the colour yield, but this disadvantage is balanced by the sensitivity of the method compared to a simple biuret reaction.

For a preliminary localization of protein material in fractions, the absorption of proteins at 280 mμ is often made use of routinely because of the simplicity and relative sensitivity of the method. The reviews by Dannenberg [12] and Beaven and Holiday [13] are useful when ultraviolet absorption data of proteins

are compared. Because of the abundance of ultraviolet absorbing substances in biological materials, it is often difficult to use the absorbance at 280 mμ for strictly quantitative purposes, and some buffers containing aromatic substances nessesitate other methods.

Ninhydrin reacts directly with proteins and peptides, and this has been utilized by Kunkel and Ward [14] for the quantitative determination of serological precipitates. As it is the free amino groups that are responsible for the reaction, different proteins give variable amounts of colour, and a slight contamination of ammonium salts will produce relatively large errors. Moreover, certain peptide linkages seem to be broken up by the comparatively violent reaction involved in the ninhydrin procedure. These factors make the use of a direct ninhydrin reaction of proteins uncertain and unsuitable for material of unknown behaviour.

The purpose of this study is to investigate the possibility of using the ninhydrin reaction of Moore and Stein [15] on aliquots from large numbers of fractions after hydrolysis and subsequent evaporation to dryness over sodium hydroxide. Upon acid hydrolysis, proteins and peptides are broken down chiefly into amino acids and ammonium salts. As the reaction of ninhydrin with these substances, with the exception of proline and hydroxyproline, is practically quantitative, the colour yield is an estimate of the nitrogen content of the samples. It is true that some nucleic acid components may be converted to ninhydrin-reacting compounds during the hydrolysis but ringbound nitrogen does not interfere. The main disadvantage of the method is the high sensitivity for ammonia, but this can be corrected for. The procedure of Boissonas [16] employing a solution of 1 % KOH in methanol to volatilize ammonia without decomposition of the amino acids is relatively simple, and the difference in ninhydrin colour obtained before and after such a treatment is an estimate of ammonium salts, provided the small amounts formed during hydrolysis can be neglected.

DESCRIPTION OF PROCEDURE USING HYDROLYSIS AND NINHYDRIN REACTION

The following procedure is suitable for fractions containing more than about 3 μg of nitrogen (in the form of proteins, peptides, amino acids etc.) per ml, but smaller amounts can also be determined by slight modifications, as will be outlined later.

One-tenth ml from every fraction is pipettes into small ampoules or tubes preferably with the aid of constriction pipets of the Lang-Levy type. Simple, inexpensive 2 or 3 ml ampoules of the sort * shown in Fig. 1 have been found suitable and easy to open and seal. With the aid of a semiautomatic syringe ** shown in the same figure, 0.5 ml of distilled constant-boiling hydrochloric acid is added, after which the ampoules are sealed over a narrow flame. Hydrolysis is carried out in a thermostated oven at 120°C for 10—24 h. The ampoules are then cooled below room temperature and opened with a sharp file. They are put in a desiccator with sodium hydroxide and dried *in vacuo* overnight. 2 ml

* Manufactured by Johnsen & Jorgensen Flint Glass LTD, London.
** Available through KELAB, Stockholm, Sweden.

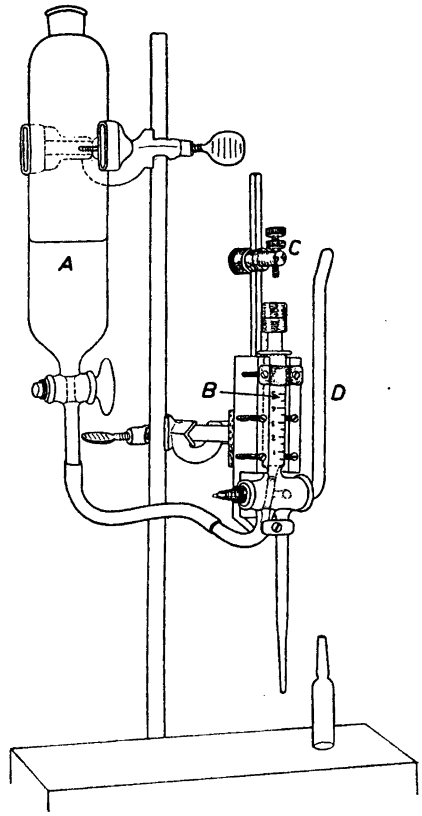

Fig. 1. Semiautomatic syringe used to deliver reagents into ampoules. The solution in A is forced into the all-glass syringe B by means of a slight air pressure. The volume to be delivered is set by the screw C and the plunger, which is filled with mercury, empties the syringe when the handle D of the stopcock is turned.

of water is added to each ampoule with a semi-automatic syringe, and 1 ml of the resulting solution is taken for ninhydrin analysis. This is performed according to Moore and Stein [15] using 1 ml ninhydrin solution prepared by dissolving 2.0 g ninhydrin and 0.3 g hydrindantin in 75 ml methyl cellusolve, adding 25 ml 4 N sodium acetate buffer pH 5.5 immediately before use. The reaction is carried out in test tubes immersed for 15 minutes in a boiling water bath, after which the tubes are immediately cooled and diluted with 3 ml 50:50 ethanol-water. When the tubes have been thoroughly shaken to oxidize any residual hydrindantin, they are read at 570 mμ against blanks from ampoules containing buffer, that have been subjected to the same procedure as the samples to be analysed. It is of special importance to use well cleaned tubes for the reaction, and the use of semi-automatic syringes for the addition of ninhydrin solution and dilution is of great convenience.

When extinction values that are too high are obtained with a final volume of 5 ml, the contents of the tubes can be further diluted with 5 or 10 ml ethanol:water without deviation from the linear relationship between the amount of nitrogen and colour. If the hydrolyzed residue in the ampoules is dissolved in 2 ml of water, of which 1 ml is taken for the ninhydrin reaction, the upper limit of such a determination is about 10 μg N taken from the fractions. However, as the hydrolysis of much larger amounts of protein is complete under the conditions described, as much as 1 mg N can be determined simply by diluting a portion of the 1 ml remaining in the ampoules. Table 1 shows that it is possible to determine very wide range of protein concentrations in this way without significant loss in precision. As test sample, a commercial protein standard, Pro-Sol,

distributed by the Standard Scientific Supply Corp., New York, has been used. This standard is a partly purified preparation of bovine serum albumin and has been used throughout this investigation.

It has been found that the concentration of hydrochloric acid during hydrolysis is not critical, as long as it is at least 3 M. When comparatively large and unequal volumes are to be hydrolyzed, samples can be reduced in volume before the addition of HCl, but this is seldom necessary.

If very small amounts of material are available, the following modifications can be made. The hydrolyzed residue in the ampoules is dissolved in only a few tenths of a ml, an aliquot of which is taken for analysis with ninhydrin with a final volume of 1 ml. In this way as little as 0.1 μg of protein N can be determined with comparatively high precision. It is possible to perform the ninhydrin reaction directly in the ampoules, but it is then more difficult to oxidize the residual hydrindantin. For approximate determinations, the ninhydrin colour can then be read in the ampoules, as these vary comparatively little in width.

No detailed investigation of the time necessary for the complete hydrolysis of different proteins has been made; however, it seems advisable to try different times before using the method on samples of unknown behaviour. Since a few hours is sufficient in most cases, and prolonged hydrolysis does not seem to change the colour yield with ninhydrin very much, 24 hours has been used routinely at this laboratory. Fig. 2 shows the influence of different times of hydrolysis of Pro-Sol. As the ninhydrin reaction gives slightly different amounts of colour depending on the reagents and the exact procedure em-

ployed at a laboratory, it is necessary to calibrate the method with proteins of known nitrogen content if accurate quantitative data are wanted. It is then possible to convert the colour to protein nitrogen, but in fractionation work it is often sufficient to compare the colour yields of the different fractions directly. Table 2 illustrates the precision of the method when the same amount of protein is hydrolyzed in a series of ampoules. When other proteins have been tested, they have given similar values, but no detailed comparison between different proteins has been made as yet.

To keep blank readings as low as possible, it is necessary to use ammonia-free reagents and to clean all glassware well. The hydrochloric acid used for hydrolysis is best distilled in Pyrex and kept in a bottle provided with an arrangement to protect it from ammonia in the atmosphere. Water is obtained

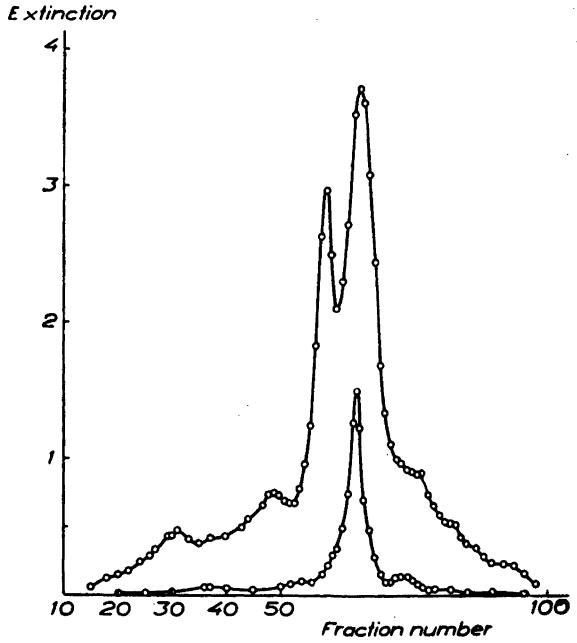

Fig. 3. Electropherogram of an extract from hog neurohypophysis. Lower curve: ninhydrin colour without hydrolysis. Upper curve: ninhydrin colour after hydrolysis with HCl at 120°. The extinction values are given for equal sample size in estimating the two curves.

Table 3. Comparison of some methods of protein determination. The approximate extinction values are given for a concentration of 1 μg of Pro-Sol protein nitrogen per ml measured in a 1 cm cell.

Ultraviolet absorption	280	0.0046
Turbidity with trichloroacetic acid at a final concentration of 3 %	420	0.0082
Direct ninhydrin reaction	570	0.092
Method according to Lowry *et al.*[11]	750	0.124
Hydrolysis and ninhydrin reaction	570	1.17

by distillation from an acid medium in a Pyrex still. The ampoules are sealed when delivered from the manufacturer and therefore do not contribute to high blanks, but the tubes used for the ninhydrin reactions must be kept free from contamination. If fractions can not be analysed soon after collection, they should be stored in a box provided with an acid adsorbent. If blank readings higher than 0.1 on the optical density scale are obtained, the reagents should be tested for impurities.

As an example of the usefulness of the method, Fig. 3 shows an electropherogram of an extract from hog neurohypophysis *. Electrophoresis was carried out in an apparatus described by Porath [17] with a buffer composed of 0.1 M pyridine adjusted to pH 5.0 with acetic acid. The fractions eluted from the column had a volume of approximately 10 ml each, of which 0.25 ml was taken for the ninhydrin reaction without hydrolysis. 0.2 ml was pipetted into ampoules and hydrolyzed for 24 hours with 0.5 ml 6.4 N HCl at 120°C. After removal of HCl, 2 ml of water was added, and 1 ml of the resulting solution taken for the ninhydrin reaction. The extract is a very complicated mixture of amino acids and peptides, and no attempt is made in this connection to discuss its different components. From the shapes of the two curves, it is possible to draw certain conclusions about the contents of the different fractions, because a high ratio between the colour yield of hydrolyzed and unhydrolyzed material indicates the presence of peptide-bound nitrogen. In this special case, it would have been impossible to use either optical density readings at 280 mμ or nitrogen determinations because of the pyridine content of the buffer. Pyridine does not react with ninhydrin and has the advantage of being volatile, so that the fractions can be lyophilized.

Table 3 has been arranged to allow a comparison of some of the colorimetric methods discussed. The values have been obtained from determinations made on the previously mentioned protein standard, Pro-Sol. In order to facilitate a comparison of the sensitivity of the methods, the extinction has been given for 1 μg of protein nitrogen per ml solution measured at the specified wave length.

The author wishes to thank Professor A. Tiselius and colleagues at the Institute for helpful discussions. The technical assistance of Mrs. B. Malmström and Mrs. I. Stark is gratefully acknowledged. This investigation was supported by grants from the *Swedish Natural Science Research Council.*

* Data from experiments by H. Kiessling.

X-Ray and Magnetic Study of Nickel Selenides in the Range NiSe to $NiSe_2$

FREDRIK GRØNVOLD and EINAR JACOBSEN

Kjemisk Institutt A, Universitetet i Oslo, Blindern, Norway

Two nickel selenide phases are identified in the range NiSe to $NiSe_2$ by means of X-rays.

1. *The NiSe phase* has a broad range of homogeneity extending from $NiSe_{1.02}$ to $NiSe_{1.30}$. Its structure is of a NiAs-like type up to the composition $NiSe_{1.20}$. At higher selenium content the structure becomes monoclinic (pseudo-hexagonal) with doubled *c*-axis. The lattice constants vary between these limits:

$NiSe_{1.00}$: $a = 3.6613$ Å, $c = 5.3562$ Å.
$NiSe_{1.30}$: $a = 6.196$ Å, $c = 2 \times 5.232$ Å,
$b = 3.634$ Å, $\beta = 90.78°$.

Weak reflections observed on single crystal photographs of $NiSe_{1.15}$ are due to an orthorhombic superstructure with

$a' = b\sqrt{3} = 6.2932$ Å, $b' = 3b = 10.901$ Å, $c' = 3c = 15.957$ Å.

Density determinations show that the solid solution of selenium in the NiSe phase takes place by subtraction of nickel atoms with increasing selenium content. The observed density decreases from 7.269 g cm^{-3} for $NiSe_{1.00}$ to 6.918 g cm^{-3} for $NiSe_{1.30}$.

2. *The $NiSe_2$ phase* has a structure of the pyrite ($C2$) type and a narrow range of homogeneity on the nickel-rich side of $NiSe_2$, with lattice constant decreasing from $a = 5.9626$ Å for $NiSe_{1.975}$ to $a = 5.9604$ Å for $NiSe_{2.00}$. The shortest selenium selenium distance is determined as 2.40 Å.

Magnetic measurements were carried out by the Gouy method. All samples are weakly paramagnetic and for those richer in selenium than $NiSe_{1.07}$ the susceptibility increases slightly with increasing temperature. The effective magnetic moment at 450° C is 1.08 Bohr magnetons for $NiSe_{1.00}$ and 1.34 Bohr magnetons for $NiSe_{2.00}$.

A nickel selenide was described for the first time by Little [1] in 1859. He obtained a silver white, crystalline, non-magnetic product with composition close to NiSe (found 43.23 % Ni, calc. 42.64 % Ni) by heating a mixture of the elements. Fabre [2] made NiSe in the same way and used the product to determine the enthalpy of formation of NiSe by solution calorimetry in bromine water. His result has been re-evaluated by Rossini *et al.*[3] who give $\Delta Hf° = -10$ kcal/mole at 25° C.

In 1900, Fonzes-Diacon [4] prepared gray, crystalline NiSe by leading selenium vapor diluted with nitrogen over red hot nickel. In another experiment, a gray black mass of $NiSe_2$ was prepared by the action of hydrogen selenide on nickel(II) chloride at about 300° C. If the chloride was kept at red heat, the compounds Ni_2Se_3 or Ni_3Se_4 were formed instead. By heating any of these compounds in hydrogen at bright red heat, Fonzes-Diacon obtained a gold-colored compound which he assumed had the composition Ni_2Se.

The existence of a fifth nickel selenide was claimed by Meyer and Bratke [5] who heated mixtures of nickel powder and selenium with potassium carbonate at 1 250° C. Analysis of the crystalline reaction products gave the result: 37.8 % Ni, 61.6 % Se and on this basis they deduced the formula Ni_5Se_6 or $3NiSe \cdot Ni_2Se_3$, which corresponds to 38.25 % Ni and 61.75 % Se.

Nickel selenides have also been prepared by precipitation. Reeb [6] obtained a black precipitate by the action of hydrogen selenide or potassium selenide on a nickel salt solution containing acetic acid and sodium acetate. His experiments were repeated by Moser and Atynski [7], who found that the products contained 1.4 to 2.8 % more selenium than NiSe. They succeeded, however, in preparing almost stoichiometric NiSe by precipitating it from alcoholic solutions (found Ni:Se = 1:1.035).

Alsén [8] studied NiSe by means of X-rays and found that it had a hexagonal structure of the NiAs ($B8$) type. This was later confirmed by Levi and Baroni [9]. As a result of electron diffraction studies these authors claimed the existence of two more NiSe phases, α-NiSe, which was amorphous, and γ-NiSe, which was found to be isomorphous with millerite (NiS).

The structure of $NiSe_2$ was established by de Jong and Willems [10] by X-ray diffraction studies on a sample prepared by heating a mixture of NiSe and selenium (in slight excess of $NiSe_2$) at 230° C for 48 hours. Although the product contained some elemental selenium, a phase with structure of the pyrite ($C2$) type was recognized. Its lattice constant and atomic parameter were determined. The lattice constant of $NiSe_2$ was later redetermined by Tengnér [11].

The only known nickel selenide mineral is penroseite from Colquechaca, Bolivia. It was first studied by Gordon [12] who proposed the formula $2PbSe_2 \cdot 3CuSe \cdot 5(Ni, Co)Se_2$ or $PbSe \cdot Cu_2Se \cdot 3(Ni, Co)Se_3$. Ten years later, Herzenberg and Ahlfeld [13] also described a nickel selenide mineral from the same locality. They concluded that it had the formula $(Ni, Cu)Se_2$ and gave the name blockite to it. The structural identity of penroseite, blockite and artificial $NiSe_2$ was established by Bannister and Hey [14] by X-ray diffraction and chemical analysis.

In view of the many nickel selenides that have been described and as a continuation of the work going on in this institute on the chalcogenides of the transition elements, a systematic study of the nickel selenium system seemed highly desirable. An X-ray study of this system was therefore started in 1950 by Olaf Holwech [15] on the suggestion of professor Haakon Haraldsen.

The work has been continued by Osvald Knop, now at Nova Scotia Technical College, and by the present authors. While Mr. Knop has mainly been concerned with the nickel-rich region of the system, we have especially studied the selenium-rich region, and an account of our work in the NiSe-$NiSe_2$ region will be given here.

EXPERIMENTAL

The *nickel* used for preparing the alloys was made from "Nickel oxide, low in cobalt and iron" from the British Drug Houses Ltd. by reduction with hydrogen at 600° C until constant weight was obtained. A spectrographic analysis showed only the presence of traces of copper and magnesium as impurities in the metal.

Highly purified *selenium* was placed at our disposal by Bolidens Gruvaktiebolag, Sweden. It contained the following impurities: copper 0.0002 %, iron 0.0007 %, tellurium 0.003 %, sulfur 0.01 %, non volatile matter 0.003 %.

The nickel selenides rich in nickel were synthesized by heating appropriate amounts of the elements in evacuated and sealed silica tubes. Samples in the composition range $NiSe_{0.90}$ to $NiSe_{1.333}$ (50.00 to 57.14 atomic % Se) were kept at 800° C for one day and furnace-cooled. The grayish, sintered products were then ground, homogenized by heating at 550° C for five days in pyrex tubes and afterwards air-cooled. One part of each sample was annealed at 300° C for six weeks and cooled down to room temperature during two weeks. X-ray photographs of these samples were not different from those of the 550° C annealing. The 300° C samples were therefore subjected to another annealing, this time at 400° C. After six weeks, they were slowly cooled. Changes were now noticed in some of the samples.

Samples with composition $NiSe_{1.95}$, $NiSe_{1.975}$, $NiSe_{2.00}$, $NiSe_{2.025}$ and $NiSe_{2.05}$ were prepared by mixing NiSe and selenium. They were heated for four weeks at 300° C but X-ray photographs proved this to be insufficient for complete reaction. After being transferred to new tubes they were heated at 400° C for another week and slowly cooled. Prepared in this way, the samples $NiSe_{1.95}$, $NiSe_{1.975}$ and $NiSe_{2.00}$ looked homogeneous, while small amounts of elemental selenium were observed in the samples $NiSe_{2.025}$ and $NiSe_{2.05}$.

X-Ray powder photographs of the samples were taken at 20 ± 2° C in 11.48 cm diameter cameras with asymmetric film mounting. In most cases filtered copper radiation was used, while iron radiation was used to obtain greater dispersion in the range from $NiSe_{1.80}$ to $NiSe_{1.40}$. The lattice constants are expressed in Å units, taking $\lambda CuK\alpha_1$ = 1.54051 Å and $\lambda FeK\alpha_1$ = 1.93597 Å. The probable error in the lattice constants is estimated as 0.01 % for the cubic structure, 0.02 % for the hexagonal structure and 0.03 % for the monoclinic structure. Lattice constants from earlier investigations have been transformed from kX to Å units by multiplication by the factor 1.00202.

Density determinations were carried out at 25° C by the vacuum pycnometric method. Approximately 2 g of substance were used in each experiment, and the displacement liquid was redistilled kerosene (200°—240° C fraction). The standard error in the density measurements is of the order 0.3 % but the values found for powdered samples of this type are usually about 1 % lower than those calculated on the basis of the unit cell dimensions.

Magnetic measurements were carried out by the Gouy method at different field strengths and temperatures. The samples were filled in thin-walled quartz tubes of about 1 mm internal diameter and to a height of about 80 mm. The field was calibrated at 20° C by means of $Mn_2P_2O_7$, which has a susceptibility of 102 × 10^{-6} per g at 20° C according to Foëx and Brunet [16] and by means of an aqueous $NiCl_2$ solution, for which Nettleton and Sugden [17] have given a formula for the susceptibility in terms of concentration and temperature.

To reduce the corrections for the empty tubes, a piece of quartz tubing was fused on to the bottom end of the specimen tube. In this way a correction for the empty tubes was avoided at room temperature and above, but a slight correction had to be taken into account below room temperature, with a maximum value of 0.043 mg.

RESULTS

A. X-Ray study and density measurements

In the range NiSe to $NiSe_2$ two phases were found, one with a broad range of homogeneity in the region $NiSe_{1.02}$ to $NiSe_{1.30}$, the other with a narrow range

of homogeneity close to $NiSe_{2.00}$. They will here be designated as the NiSe phase and the $NiSe_2$ phase, and the NiSe phase will be considered first.

The NiSe phase. Irrespective of whether samples with the composition $NiSe_{1.00}$ were heat-treated at 550°, 400° or 300° C they consisted of more than one phase. The major phase present was found to have a structure of the NiAs ($B8$) type. In addition, weak lines from phases richer in nickel were observed *.

The results of the lattice constant determinations of the NiSe phase for samples in the range $NiSe_{0.90}$ to $NiSe_{1.40}$ are listed in Table 1. Only the values found for samples heated at 550° C are given in the table, since the differences in cell dimensions due to the heat treatment are very small.

Table 1. Lattice constants of the NiSe phase.

Sample	a, ($b\sqrt{3}$) in Å	b in Å	c in Å	β
$NiSe_{0.90}$	(6.3410)	3.6610	5.3566	(90°)
$NiSe_{1.00}$	(6.3416)	3.6613	5.3562	(90°)
$NiSe_{1.04}$	(6.3330)	3.6564	5.3484	(90°)
$NiSe_{1.07}$	(6.3208)	3.6493	5.3407	(90°)
$NiSe_{1.10}$	(6.3092)	3.6426	5.3331	(90°)
$NiSe_{1.15}$	6.2932	3 × 3.6336	3 × 5.3190	(90°)
$NiSe_{1.175}$	(6.2824)	3.6279	5.3038	(90°)
$NiSe_{1.20}$	(6.2771)	3.6241	5.2951	(90°)
$NiSe_{1.225}$	6.235	3.631	2 × 5.277	90.2°
$NiSe_{1.25}$	6.224	3.635	2 × 5.260	90.52°
$NiSe_{1.275}$	6.206	3.635	2 × 5.250	90.63°
$NiSe_{1.30}$	6.196	3.634	2 × 5.232	90.78°
$NiSe_{1.40}$	6.199	3.635	2 × 5.230	90.77°

Within their limited accuracy the lattice constants found by Alsén [8] for NiSe ($a = 3.67$ Å, $c = 5.34$ Å) agree reasonably well with ours. Alsén studied only a sample with composition ratio 1 : 1 and noted, in agreement with our findings, that NiSe was not a pure product.

At the composition $NiSe_{1.04}$ the interferences belonging to the NiAs type structure are shifted slightly compared to $NiSe_{1.00}$ and the extraneous lines have disappeared. The X-ray photographs show the simple $B8$-pattern in the range from $NiSe_{1.04}$ to $NiSe_{1.20}$. Only the photographs of $NiSe_{1.04}$ and $NiSe_{1.07}$ are, however, free from weak additional lines. From the composition $NiSe_{1.10}$ on, many weak lines are observed in the low angle region, indicating that the true unit cell is larger than the $B8$-cell. In Table 2 are listed the more characteristic lines occurring in the low angle region on a powder photograph of $NiSe_{1.15}$.

After several attempts, some single crystals were obtained of $NiSe_{1.15}$ and by means of Weissenberg photographs the superstructure was found to be orthorhombic with

$$a' = b\sqrt{3} = 6.2932 \text{ Å}, \quad b' = 3b = 10.901 \text{ Å}, \quad c' = 3c = 15.957 \text{ Å}.$$

* The phase relationships in the Ni-rich region are rather complicated. The three intermediate phases that have been identified in this concentration range will be considered in another communication.

Table 2. Superstructure lines observed in the low angle region on a powder photograph of $NiSe_{1.15}$ taken with Cu radiation.

At the composition $NiSe_{1.20}$ the hexagonal structure still exists, but at $NiSe_{1.225}$ many of the reflections are split into several components, indicating a change to lower symmetry. This deformation is even more pronounced at the compositions $NiSe_{1.25}$, $NiSe_{1.275}$ and $NiSe_{1.30}$.

Small crystals were obtained of $NiSe_{1.25}$ in a preparation that had been heated in a sealed quartz tube at 750° C for six weeks and then slowly cooled. By means of Weissenberg photographs the structure * was found to be pseudo-hexagonal, monoclinic, with identity periods: $a = 6.22$ Å, $b = 3.63$ Å, $c = 10.53$ Å.

By means of powder photographs the unit cell dimensions were determined more accurately (see Table 1). The assignment of indices to the powder photograph of $NiSe_{1.25}$ is seen from Table 3. The lattice dimensions of the remaining monoclinic samples, $NiSe_{1.225}$, $NiSe_{1.275}$ and $NiSe_{1.30}$, were then easily found and the results are listed in Table 1.

The unit cell dimensions of the NiSe phase are plotted against composition in Fig. 1. The orthohexagonal cell description is used and the corresponding lattice sub-periods are given in the figure to facilitate the comparison. It is seen that the lattice constants decrease almost linearly with increasing selenium content in the hexagonal range $NiSe_{1.02}$ to $NiSe_{1.20}$. Further addition of selenium causes a slight increase in the length of the b-axes. This is compensated by an abrupt contraction of the a-axis as soon as the monoclinic deformation starts.

From Fig. 1 the selenium-rich limit for the homogeneity range of the NiSe phase appears to be $NiSe_{1.30}$. This is in accordance with the fact that faint lines from the $NiSe_2$ phase are visible on the powder photographs of $NiSe_{1.333}$.

Density determinations were carried out on the NiSe phase in order to ascertain that the solid solution of selenium in NiSe takes place by subtraction of nickel atoms from the NiSe structure. The densities calculated under that assumption are listed in Table 4 together with the observed densities. The

* The atomic arrangement in $NiSe_{1.35}$ and $NiSe_{1.15}$ will be discussed in a forthcoming paper.

good agreement between the two sets of values confirms the correctness of the above assumption. As to the question why the observed densities are consistently lower than the calculated ones, this seems primarily to be related to the large surface area of the powdered samples, and only to a smaller extent to missing metalloid atoms.

In the case of $NiSe_{1.00}$ there is a significant difference in density due to the heat treatment. This may be understood by comparison with the X-ray results, as the $NiSe_{1.00}$ sample heat-treated at 300° C contained much stronger lines from phases richer in nickel than the sample heated at 550° C. Furthermore, the density of $NiSe_{0.95}$ heated at 300° C was only 7.142 g cm^{-3}.

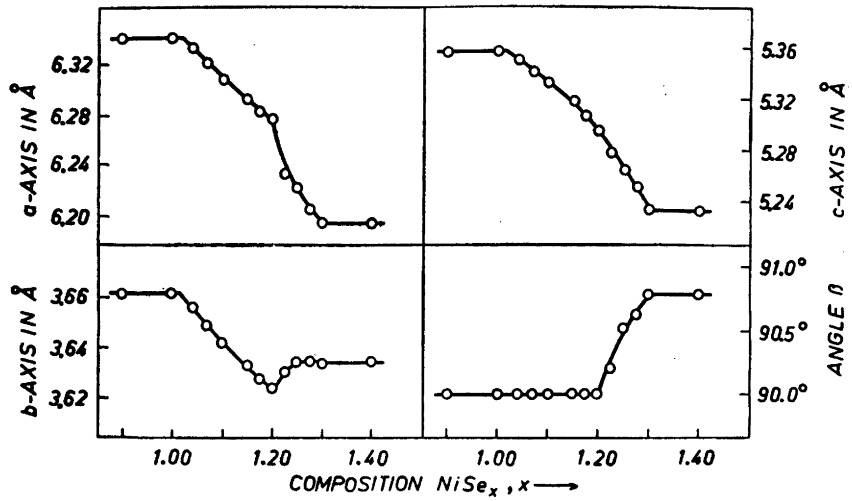

Fig. 1. Lattice constants of the NiSe phase as functions of composition.

In the NiSe structure each nickel atom is surrounded by six selenium atoms at the corners of a deformed octahedron (trigonal antiprism). The distances are 2.50 Å for $NiSe_{1.00}$, and 2.48 Å for $NiSe_{1.20}$. Each nickel atom is further surrounded by two nickel atoms at the distance $c/2 = 2.68$ Å ($NiSe_{1.00}$) and 2.65 Å ($NiSe_{1.20}$). The selenium atoms are arranged in a hexagonal close packing which is compressed in the c-direction so that the shortest distance between selenium atoms in adjacent planes is 3.41 Å against 3.66 Å for nearest neighbors in the hexagonal plane for $NiSe_{1.00}$ and 3.38 Å against 3.62 Å for $NiSe_{1.20}$.

The $NiSe_2$ phase. X-Ray photographs of samples in the $NiSe_2$ region showed the existence of a phase with pyrite ($C2$) structure. While several lines from the NiSe phase were present in $NiSe_{1.95}$, only one line was present in $NiSe_{1.975}$

Table 4. Observed and calculated densities in g cm^{-3} for the NiSe phase. The atomic weight unit is taken as 1.660 × 10^{-23} g.

that could possibly be attributed to the NiSe phase. No foreign lines were found in $NiSe_{2.00}$, $NiSe_{2.025}$ or $NiSe_{2.05}$.

The lattice constant was determined for these five samples and the results are listed in Table 5. A slight contraction of the unit cell takes place from $NiSe_{1.975}$ to $NiSe_{2.00}$, which denotes that the $NiSe_2$ phase has a narrow range of homogeneity on the nickel-rich side of $NiSe_2$. The lattice constant value found by Tengnér [11] for $NiSe_2$, $a = 5.960$ Å, is in perfect agreement with the present results, while the value $a = 6.034 \pm 0.003$ Å found by de Jong and Willems [10] is considerably higher.

Table 5. Lattice constants and densities of samples in the $NiSe_2$ region.

Composition	a in Å	D_{obs} in g cm^{-3}
$NiSe_{1.95}$	5.9628	6.730
$NiSe_{1.975}$	5.9626	6.724
$NiSe_{2.00}$	5.9604	6.720
$NiSe_{2.025}$	5.9605	6.703
$NiSe_{2.05}$	5.9603	6.693

Results of the density determinations carried out in the $NiSe_2$ region are also listed in Table 5. The observed density of $NiSe_{2.00}$ (6.720 g cm^{-3}) is as usual a little lower than the X-ray density (6.792 g cm^{-3}). The density calculated for $NiSe_{1.975}$ assuming different types of solid solution is given in Table 6. Since a decrease in density from $NiSe_{2.00}$ to $NiSe_{1.975}$ is not compatible with the observations, it is concluded that nickel atoms are taken up interstitially in this range.

Table 6. Calculated densities for $NiSe_{1.975}$. The atomic weight unit is taken as 1.660×10^{-23} g.

Type of solid solution	Formula	D_{calc} in g cm^{-3}
Interstitial	$Ni_{1.012}Se_2$	6.808
Substitutional	$Ni_{1.008}Se_{1.992}$	6.780
Subtractive	$NiSe_{1.975}$	6.723

In structures of the pyrite ($C2$) type, each metal atom is surrounded octahedrally by six metalloid atoms, and each metalloid atom is surrounded tetrahedrally by one metalloid atom and three metal atoms. The metalloid metalloid distance is equal to $a(1-2x)\sqrt{3}$, where x is a parameter to be determined. De Jong and Willems found $x = 0.375$ for $NiSe_2$, which led to a selenium selenium distance of 2.61 Å. This value is rather large, and a redetermination of the parameter was therefore undertaken.

The relative intensities of the $NiSe_2$ reflections were determined photometrically from powder photographs taken with Cu radiation. The best agreement between observed and calculated intensities was obtained with $x = 0.384$. The results are listed in Table 7. In the left column are found the $\sin^2\Theta$ values for the α_1 reflections.

According to the present results, the selenium selenium distance is 2.40 Å. The nickel selenium distance is, however, only slightly altered by the new constants, 2.49 Å now against 2.50 Å from the data by de Jong and Willems *.

B. Magnetic properties

All samples studied were found to be weakly paramagnetic and to have susceptibilities that were only slightly dependent on the temperature. In the range NiSe to $NiSe_{1.07}$, the susceptibility decreases with increasing tempera-

* The distance nickel selenium given by de Jong and Willems [10] as 2.47 Å is not consistent with their data. The correct value should be $a\sqrt{3x^2-2x+\frac{1}{2}} = 2.50$ Å.

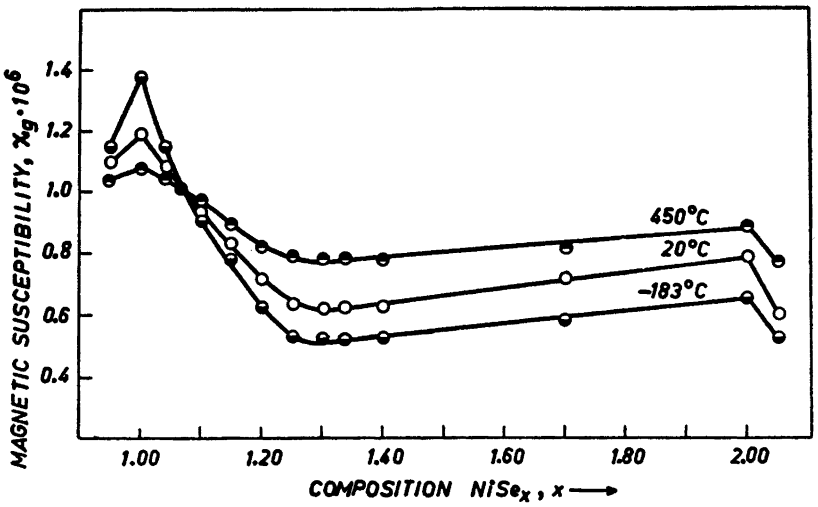

Fig. 2. Magnetic susceptibilities of the nickel selenides at −183°, 20° and 450° C.

ture while the opposite is true for all samples with higher selenium content than $NiSe_{1.07}$ in the temperature range studied. The results of the measurements are listed in Table 8. No specimen was found to have field strength dependent susceptibility and only the mean values of the results at H_{max} = 4 015, 4 700 and 5 110 Ørsteds are recorded in the table.

Table 8. Magnetic susceptibility of the nickel selenides, $\chi_g \times 10^6$.

$NiSe_{2.05}$	.53	.56	.60	.75	.76	.77

The susceptibility isotherms at —183°, 20° and 450° C are drawn in Fig. 2 and they show the phase relationships very clearly. A pronounced maximum close to $NiSe_{1.00}$ defines the nickel-rich limit of the homogeneity range of the NiSe phase. With increasing selenium content especially the —183° C isotherm has a non-linear character which is indicative of a single phase domain. At about the composition $NiSe_{1.30}$ minima occur in the isotherms and they define the selenium-rich limit of the NiSe phase. From the composition $NiSe_{1.30}$ on, the susceptibilities increase linearly and reach another maximum at $NiSe_{2.00}$. The decrease which is observed from $NiSe_{2.00}$ to $NiSe_{2.05}$ is probably due to the selenium phase.

In cases where the magnetic susceptibility of a substance is inversely proportional to the absolute temperature (*i. e.* the Curie law is fulfilled) a definite electronic state might be ascribed to the magnetic atom. This condition is far from fulfilled for the nickel selenides, and one can therefore only hope to obtain information about the magnetic state of the nickel atom at high temperatures, where the disturbing interactions are smaller. Since the magnetic susceptibility of the nickel selenides does not even obey the Curie-Weiss law, this information is best obtained by calculating the effective magnetic moment of the nickel atom.

This has been done * for NiSe and $NiSe_2$ and the results are shown in Fig. 3. The effective magnetic moment rises to 1.08 B. M. (Bohr magnetons) at 450° C

* The susceptibilities are corrected for induced diamagnetism with the value —17.7 $\times 10^{-6}$ mole^{-1} for Ni^{+2} according to Asmussen [18] and the value —47.58 $\times 10^{-6}$ mole^{-1} for Se^{-2} according to Angus [19].

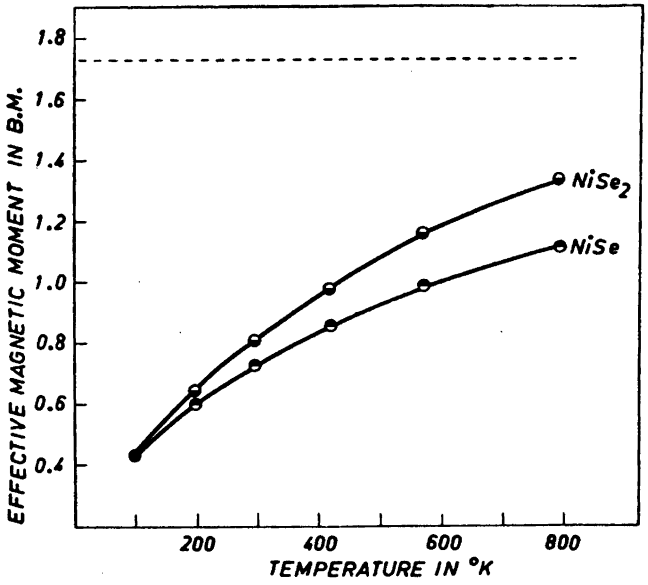

Fig. 3. Effective magnetic moments of NiSe and $NiSe_2$ as functions of temperature.

for NiSe and to 1.34 B. M. for $NiSe_2$. The slope of the curves is rather flat and the effective magnetic moments are of a much smaller magnitude than expected for Ni^{+2} ions.

According to Van Vleck [20], the magnetic moment of the free, gaseous Ni^{+2} ion is 5.56 B. M. at room temperature when the effect of the multiplet width is taken into account. When the crystalline field is so strong as to destroy the coupling of the spin angular momentum S and the orbital angular momentum L to a quantized resultant J, a "spin only" value of 2.83 B. M. is expected for Ni^{+2}. Also in case of nickel(II) forming covalent d^2sp^3 bonds the same value might be expected. The magnetism of the nickel selenides is, however, so weak that it cannot be explained satisfactorily in any of these ways.

The departure of the magnetism from Curie's law shows that strong interactions are present between the paramagnetic ion and its neighbors. It is not yet known to what extent this is due to interactions between paramagnetic ions, leading to antiferromagnetism, and to interactions with neighboring diamagnetic ions.

DISCUSSION

Of all the nickel selenides described by earlier investigators in the composition range NiSe to $NiSe_2$ only the NiSe phase and the $NiSe_2$ phase exist. The variable composition of the NiSe phase might, however, account for the conclusions by some of the earlier investigators about the existence of other intermediate phases. Thus, the compound $3NiSe \cdot Ni_2Se_3$ postulated by Meyer and Bratke [5], falls well within the homogeneity range of the NiSe phase.

The nickel selenide with approximate composition Ni_3Se_4, consisted according to Fonzes-Diacon [4] of a mixture of cubic crystals and a product containing slightly less selenium. It seems probable that the latter product, which he was not able to avoid, was the NiSe phase and that the cubic crystals were of the $NiSe_2$ phase. The polymorphism of NiSe which was found by Levi and Baroni [9] has not been observed in the present study. Their γ-NiSe is presumably identical with one of the phases we have observed on the nickel-rich side of NiSe. The same is probably also the case with the cubic NiSe crystals found by Little [1] and Fonzes-Diacon [4].

The atomic configuration in the NiSe and $NiSe_2$ phases is rather alike in that each nickel atom is surrounded octahedrally by six selenium atoms at practically the same distances, 2.50 Å in NiSe and 2.49 Å in $NiSe_2$. The values for the NiSe phase agree very well with the sum of the metallic radii given by Pauling [21]. In $NiSe_{1.00}$ the coordination number of the nickel atom is 8 and that of the selenium atom is 6 and the radius sum is 1.19 Å + 1.31 Å = 2.50 Å. For $NiSe_{1.20}$ the coordination numbers are 7.3 and 5 and the radius sum is 1.19 Å + 1.29 Å = 2.48 Å, in perfect agreement with the observed value (2.48 Å). In $NiSe_2$, nickel has coordination number 6 and selenium 4 which makes the radius sum 1.15 Å + 1.26 Å = 2.41 Å.

In structures of the pyrite ($C2$) type, the conditions are favorable for deriving characteristic radii since the metalloid atoms are bonded to each other. For $NiSe_2$ the empirical radius of the selenium atom is 1.20 Å (see

p. 1448) and the radius of the nickel atom is thus 2.49 Å — 1.20 Å = 1.29 Å. The nickel radius found here is considerably smaller than the octahedral covalent d^2sp^3 radius 1.39 Å for Ni(II) given by Pauling and Huggins [22]. This is not very surprising, however, as Lewis and Elliott [23] found that $NiSe_2$ is a conductor of electricity. The nickel atom might perhaps more aptly be designated as Ni(III), with electrons transferred to the conduction band. The transition of Ni(II) to Ni(III) causes a decrease in radius of 0.09 Å according to Pauling and Huggins.

A compilation of the interatomic distances in the diselenides of manganese, iron, cobalt and nickel is found in Table 9. $FeSe_2$ has a structure of the marcasite ($C18$) type and it is interesting to note that it has the largest selenium selenium distance among the four compounds. This case is analogous to the sulfide case where Buerger [26] showed that the sulfur sulfur bond distance for marcasite was appreciably larger than for pyrite and for MnS_2, CoS_2 and NiS_2 as well — see Haraldsen [27]. It thus seems that the conditions for the metalloid atoms to form sp^3 bonds are not so favorable in the marcasite structure as in the pyrite structure, which is in keeping with the larger deformation of the tetrahedral configuration. The sp^3 orbitals might therefore to some extent be taken up by unshared pairs, thus increasing the distance between the metalloid atoms and leaving fewer electrons for the conduction band.

Table 9. Shortest interatomic distances in Å for some diselenides.

Substance	Me-Se	Se-Se	Me-Me	Authors
$MnSe_2$	2.70	2.38	4.55	Elliott [24]
$FeSe_2$	2.37	2.50	3.58	Tengnér [11]
$CoSe_2$	2.42	2.43	4.14	Bøhm *et al.*[25]
$NiSe_2$	2.49	2.40	4.22	Present

The selenium selenium distances in $MnSe_2$, $CoSe_2$ and $NiSe_2$ are almost equal with 1.20 Å as mean value for the radius of the selenium atom. A rather abrupt decrease in the distance metal selenium and therefore also in the metal radius is observed as one goes from manganese (r = 1.50 Å) to iron (r = 1.17 Å). From then on the radius rises again to cobalt (r = 1.22 Å) and nickel (r = 1.29 Å). The anomalously large manganese radius was explained by Pauling [21] as a result of $4s4p^3$ resonating bonds for manganese compared to $3d^24s4p^3$ bonds for iron. The magnetic measurements of Haraldsen and Klemm [28] on natural MnS_2 (hauerite-)indicated the presence of five unpaired 3d electrons in manganese at high temperatures, which leaves no 3d orbitals available for bond formation. FeS_2 shows, as recently confirmed by Serres [29], almost zero magnetism so that in this compound all 3d electrons are paired. The six 3d electrons of Fe^{+2} presumably make use of three 3d orbitals, and the remaining two 3d orbitals are utilized in the d^2sp^3 bond formation.

Huggins [30] has suggested that d orbitals with principal quantum number one higher than normal might be used for bond formation in compounds of the

pyrite ($C2$) type and that intermediate bond types comprising both kinds of orbitals were possible. These outer orbitals are not so useless for bond formation as the separation of the energy levels of the free ion indicates, since they have their maximum probability density further out in space and can thus overlap appreciably with orbitals of the surrounding atoms. Actual overlap calculations carried out by Craig *et al.*[31] have confirmed Huggins' predictions and provided support for the view that 4d orbitals may be used for σ-bond formation in "ionic" complexes involving the first transition group metals.

The magnetic behavior of $NiSe_2$ seems to support this view. At low temperatures the octahedral bonds might be of a $3d4s4p^34d$ type with zero magnetism, and as the temperature is raised, the 4d character of the bonds increases. Simultaneously, unpaired electrons populate the available 3d orbitals and the effective magnetic moment of $NiSe_2$ increases. Evidently, the bonds do not relinquish much of their 3d character, since the effective magnetic moment does not even reach the "spin only" value for one unpaired electron per nickel atom at 450° C, *i.e.* 1.73 B.M.

The magnitude and temperature dependence of the effective magnetic moment for the NiSe and $NiSe_2$ phases are rather similar to what was found for the corresponding cobalt selenides by Bøhm, Grønvold, Haraldsen and Prydz [25] and the cobalt tellurides by Haraldsen, Grønvold and Hurlen [32]. Discussion of these relationships will be postponed to a later paper.

The authors wish to express their appreciation to professor Haakon Haraldsen for his encouragement and interest, and for extending to them the facilities of the laboratory. They should like to thank Bolidens Gruvaktiebolag for a generous supply of selenium and to thank siv.ing. Sigurd Rutlin, Sentralinstitutt for Industriell Forskning, for a spectrographic analysis of the nickel used.

Insulin Crystals

I. The Minimum Mole-Fraction of Metal in Insulin Crystals Prepared With Zn^{++}, Cd^{++}, Co^{++}, Ni^{++}, Cu^{++}, Mn^{++}, or Fe^{++}

J. SCHLICHTKRULL

Novo Terapeutisk Laboratorium, Copenhagen, Denmark

Recrystallized insulin is made zinc-free by a simple salting-out process.

The metal-free insulin is crystallized with Zn^{++}, Cd^{++}, Co^{++}, Ni^{++}, Cu^{++}, Mn^{++} and Fe^{++}. Of these metals, Cu^{++}, Mn^{++} and Fe^{++} have not hitherto been known to form crystals with insulin.

After recrystallization without any further addition of metal ions, the recrystallized insulin contained 2 atoms of metal per crystal unit of insulin. This amount of metal is considered a fundamental part of the crystal structure.

Abel [1] crystallized insulin as the first protein hormone in 1926. The rhombohedral crystals were precipitated in the isoelectric region at pH 5.5—5.6 from an insulin solution buffered with brucine, pyridine and ammonium acetate. The rather poor and uncertain yields were increased in 1929 by Harrington and Scott [2] who replaced brucine with saponin. The reason for this improvement was discovered in 1934 by Scott [3] who found that both the insulin crystals obtained with either method as well as the saponin contained zinc. Scott and Fisher [3-5] showed that the presence of either Zn, Cd, Co or Ni ions is an essential condition for the formation of crystals. Other metals were tried, *e. g.* Mg and Fe, but without success.

It was furthermore demonstrated by Scott and Fisher [4,5] that the metal content of the insulin crystals is directly proportional to the atomic weight of the metal (0.52 % Zn, 0.77 % Cd, 0.44 % Co and 0.41 % Ni). Cohn *et al.*[6] observed in 1941 that the zinc content of insulin crystals increases from 0.33 % to 0.65 % when the pH of crystallization is changed from 5.1 to 6.5. Two extremes were reported in the same year by Sahyun [7] (0.15 %) and Eisenbrand and Wegel [8] (0.8 %). In 1951 it was shown by the present author and his associates [9,10] that insulin crystals may combine with zinc to the extent of at least 2.3 % Zn.

Rhombohedral insulin crystals have apparently never been prepared without these metals. In 1949, however, Ellenbogen [11] obtained insulin crystals with various other compounds instead of metals, *e. g.* from a solution of insulin and sodium sulphate made slightly acid with sulphuric acid. These crystals were found to be orthorhombic and their unit weight was only one third of that of the rhombohedral crystal.

The presence of anions is also essential for the crystallization of insulin as shown by Hallas-Møller [12]. Rhombohedral insulin crystals were not formed with zinc and chloride ions alone; an addition of other anions (*e. g.* citrate, phosphate or carbonate) was found necessary.

From the experimental evidence listed above it can be concluded that the zinc content of insulin crystals is not merely defined by the molecular weight of insulin and the crystal structure; the metal content of the insulin crystals is rather dependent on the chemical composition of the suspension medium. It must nevertheless be assumed that at least a part of the metal found in the crystals is somewhat related to the structure, as the metal ions are necessary for the formation of crystals. The amount of metal which is an essential part of the crystal structure is considered identical with the metal content of crystals prepared with the minimum amount of metal necessary for the crystal formation. This minimum metal content was determined experimentally. The investigation was carried out with Zn^{++}, Cd^{++}, Co^{++}, Ni^{++}, Cu^{++}, Mn^{++} and Fe^{++}.

EXPERIMENTAL

Preparation of zinc-free insulin. Three-times-recrystallized insulin from beef pancreas was salted out 5 times (15 % NaCl, 0.5 % insulin, pH = 2—3) and isolated after precipitation at pH = 5. It contained less than 0.01 % zinc calculated on the dry weight of insulin.

First crystallization. The metal-free insulin was first crystallized from a medium containing a surplus of one of the metal ions. The composition of the mixture was as follows: 0.5 % insulin, 0.05 M sodium citrate, 15 % (v/v) acetone, and a salt of one of the metals, pH = 6.0 (glass electrode). It is preferable to use citrate buffer rather than the phosphate buffer, as the phosphate may precipitate the metal ions so that the crystals will be defiled by metal phosphate [13]. The ammonium acetate buffer which is frequently employed for the crystallization of insulin has the disadvantage that it contaminates the insulin crystals with non-protein nitrogen thus invalidating the subsequent Kjeldahl analyses. The acetone prevents the insulin from precipitating as amorphous particles from the supersaturated solution.

The zinc-free insulin was dissolved in water made slightly acid (pH = 2) with hydrochloric acid. The solution was distributed in glass beakers, acetone and metal salt solutions were added and the pH adjusted to 6.0 by adding a solution of sodium citrate. The mixture was stirred mechanically overnight with a glass propeller at room temperature. The precipitate was collected on a sintered glass filter without washing and dried to a water content of 4—7 %. The yield of a crystallization was expressed in % and calculated on the basis of Kjeldahl analysis.

Recrystallizations. The insulin crystals were recrystallized from a medium of the same composition as used for the first crystallization except that no metal salts were added. The crystals thus obtained contained less metal than the original crystals. This procedure was repeated until the crystal shape deteriorated severely (spherical shape) and amorphous particles appeared. The yield of a recrystallization was expressed in % and calculated on the basis of Kjeldahl analysis.

RESULTS

The precipitates are characterized by their microscopical appearance. Normal twinned rhombohedrons are indicated as NC (normal crystals) in Table 1. A tendency towards spherical shape is denoted by DC (defective crystals). Furthermore, if amorphous insulin particles are present in considerable amounts, an A is added.

From the paper by Sanger and co-workers [14] it is known that the smallest molecule of insulin contains 65 atoms of nitrogen. As it is assumed that one crystal unit contains 6 of the small molecular units, it contains 390 atoms of nitrogen. Thus the metal content per crystal unit is calculated as atoms of metal per 390 atoms of nitrogen.

Table 1. Crystallization of insulin with Zn++, Cd++, Co++, Ni++, Cu++, Mn++, and Fe++.

(1)	Zn++ $ZnCl_2$	Cd++ $3CdSO_4$, $8H_2O$	Co++ $CoCl_2$, $6H_2O$	Ni++ $NiCl_2$, $6H_2O$	Cu++ $CuCl_2$, $2H_2O$	Mn++ $MnCl_2$, $4H_2O$	Fe++ $FeCl_2$, $4H_2O$
(2)	94	95	94	96	95	89	93

(10)	NC	NC	DCA	DCA	NC	(DC)A	A
(11)	DC	NC	DCA	DCA	DC	—	—

(1) Metal salt employed.
(2), (3) and (4) Yields from 1st, 2nd and 3rd crystallization, respectively, expressed in per cent nitrogen recovered.
(5) Total amount of metal present during the first crystallization, expressed as atoms of metal per 390 atoms of nitrogen.
(6), (7) and (8) Metal content of crystals from 1st, 2nd and 3rd crystallization, respectively, expressed as atoms of metal per 390 atoms of nitrogen.
(9), (10) and (11) Character of precipitate from 1st, 2nd and 3rd crystallization, respectively. NC = normal appearance of crystals; DC = defective crystals, *i. e.* tendency towards spherical shape; A = amorphous insulin particles present in considerable amounts.

DISCUSSION

It has been a common practice to remove the zinc from insulin by electrodialysis. Preference was, however, given to a more easy method with no detrimental effect on the insulin. As already shown by Netter [15] in 1939, hydrogen ions may displace metal ions bound to insulin. The ordinary salting-out procedure for insulin, using an acid insulin solution and salt, is a similar process, and the zinc actually remains in the solution while the insulin is precipitated. The zinc content of insulin crystals can also be simply extracted by acid saline which does not dissolve the crystals.

It may be inferred from Scott and Fisher's [16] findings that the metal ions are chemically bound to the protein in a stoechiometric relation. The unit weight of the rhombohedral insulin crystal has been found to be 37 000 by Crowfoot [17] in 1935. Thus, the zinc content determined by Scott and Fisher (0.52 %) corresponds to 3 atoms of zinc per unit weight of insulin. The interpretation of the metal content is nevertheless complicated by the later findings of diverging zinc contents. In view of the present investigation it seems that 2 rather than 3 atoms of metal per crystal unit form the structural basis of the insulin crystal.

The metal content of crystals prepared in the presence of a surplus of metal ions (first crystallization) varies considerably, 2.1—3.4 atoms per crystal unit. This variation is explainable, as the metal content of the crystals is known to depend on the concentration of metal ions in the medium.

In the recrystallization process Mn^{++} and Fe^{++} crystals failed to reappear. The Mn^{++} and Fe^{++} ions must be present in a relatively high concentration to bring about crystallization.

The change in metal ion concentration in the medium from the first to the second crystallization did not greatly influence the Zn, Co, Ni and Cu contents of the crystals. This invariability is quite compatible with the concept of a fundamental metal insulin compound.

The minimum metal content of insulin crystals prepared with Zn^{++}, Cd^{++}, Co^{++}, Ni^{++} or Cu^{++} was found to be 2—5% less than 2 atoms per crystal unit. A closer proximity to the integer cannot be claimed when it is considered that the crystal structure becomes visibly imperfect through repeated recrystallization. The structure may already be somewhat defective after the second crystallization.

Insulin Crystals

II. Shape of Rhombohedral Zinc-Insulin Crystals in Relation to Species and Crystallization Media

J. SCHLICHTKRULL

Novo Terapeutisk Laboratorium, Copenhagen, Denmark

The shape of insulin crystals depends on the species of insulin. When crystallized by ordinary methods (citrate, phosphate, ammonium acetate buffer), recrystallized pig insulin precipitates as single, sharp and perfect rhombohedral bodies. The shape of cattle and sheep insulin crystals often shows a twinned appearance (*e.g.* star shape). The faces are curved.

Pig and cattle insulins are found to have identical biological insulin activities (units per molecule). The confidence limits for the ratio between pig and cattle insulin activity were 0.99 and 1.07 (P = 0.95).

Recrystallized insulin from all tree species yields perfectly shaped rhombohedral single crystals when urea or a halogenide are present in the mother liquid during crystallization.

The angle of a large rhombohedron is measured with an eye-piece goniometer. The estimate, 114°22′, is in agreement with the X-ray analysis, 114°16′.

In 1929 Abel [1] crystallized insulin and observed that the crystals were rhombohedral, and in 1935 this structure was proved by X-ray diffraction analysis by Crowfoot [2]. In the papers by Abel [1], Harrington and Scott [3], Scott [4], Netter [5] (Ni-insulin crystals), Romans *et al.*[6] and Sahyun [7] the rhombohedral shape is apparent from the photomicrographs. Scott [4] showed by means of a movie strip, however, that the crystals were actually twins, and he writes in this connection: "This twinned appearance of insulin crystals is the rule rather than the exception, but of course, is not observed unless the crystal is moved to expose various faces to view". When crystallizing at pH 5.2 instead of at the usual pH 6, Scott [4,8] obtained dumb-bell shaped crystals (wedge-shaped, no plane faces). Crowfoot [9] reviewed the literature dealing with insulin crystals of various shapes and studied some of these crystals by X-ray.

The primary purpose of the present paper is to define, within limits of particular interest, the dependence of the crystal shape on insulin and the conditions of crystallization. A new crystallization medium is introduced contain-

ing saline and sodium acetate. This medium causes the development of rhombohedral shape regardless of insulin species.

The second part of the present paper comprises a goniometric confirmation of the X-ray estimate of the obtuse angle of the rhombohedron, for which purpose large, perfectly shaped rhombohedral single crystals were prepared.

EXPERIMENTS WITH CRYSTAL SHAPES

In order to establish the sources of shape variation, the conditions of crystallization are initially fixed and the quality of insulin varied, with respect to species (pig, cattle and sheep). The dependence of shape on purity within the species cannot be properly studied as the impurities are not well defined.

1. Crystallization from a buffered solution

The crystallization mixture contains 0.5% insulin; 0.04% Zn^{++} (as chloride); 0.05 M sodium citrate; 15 % (v/v) acetone; and the pH = 6.0—6.3. The insulin is dissolved in water containing HCl (pH = approximately 2.5), whereupon acetone and buffer solution are added. The crystallization is carried out at room temperature without stirring.

Only a few observations were made with sodium phosphate or ammonium acetate buffers. The results were identical with those obtained with the citrate buffer.

A. Insulin from pig pancreas. Fig. 1 shows pig insulin crystals obtained by recrystallization. The crystals are beautiful single rhombohedrons. All attempts, without any exception, to obtain this shape by recrystallizing various lots of pig insulin proved successful. The pig insulin crystals (citrate buffer, recrystallized insulin) are thus defined as perfectly shaped, rhombohedral singlecrystals.

B. Insulin from cattle pancreas. Cattle insulin crystals from several times recrystallized insulin are shown in Fig. 2. They have the star-shaped appearance described by Crowfoot [9]. When agitation is avoided the crystals may grow even larger and develop the needle shape [9]. The gradual perfection of shape seen when recrystallizing pig insulin has not been observed in this laboratory in the case of cattle insulin even after as many as ten recrystallizations.

The shape of cattle insulin crystals is correlated with the size of crystals. When agitating, a great number of smaller crystals (5—10 μ) are obtained. These crystals, apparently twins, resemble those shown in the publications listed above. They have rounded edges and faces and their vertices are not well defined. The curved surface of cattle insulin crystals may be explained by the presence of impurities which are not removed by recrystallization. To test this question, cattle insulin was fractionated by salting out with NaCl at pH 3 or by extracting the crystals with neutral citrate or phosphate buffers. No perfect rhombohedral shape could be observed in crystals obtained by crystallization of these fractions.

Fig. 1. Rhombohedral zinc-insulin crystals from pig pancreas. × 250.

Fig. 2. Twinned zinc-insulin crystals from beef pancreas. × 250.

C. Insulin from sheep pancreas. Only one lot of sheep insulin crystals has been examined. After recrystallization the crystals developed a shape similar to that of cattle insulin crystals.

2. Crystallization from a buffered solution of urea or a halogenide

If it is assumed that the impurities of both pig and cattle insulin are removed by the recrystallizations from citrate buffer it follows that the peculiar shape of cattle insulin crystals is not due to impurities. In order to investigate the question of equal purity, the biological activities of recrystallized pig and cattle insulin were estimated by biological assays on rabbits. The activity is expressed in units per molecule of insulin. The ratio between the activities of insulin from the two species was estimated as:

$$\frac{\text{activity of pig insulin}}{\text{activity of cattle insulin}} = 1.03 \pm 0.04 \text{ (confidence limits: } P = 0.95).$$

The activities are found identical. This finding also supports the hypothesis of equal purity.

The crystallization of pig insulin was then compared with the crystallization of cattle insulin in order to find an explanation of the shape difference. Under apparently identical conditions (citrate, pH, acetone, *etc.*) cattle insulin crystals are formed more rapidly than pig insulin crystals, and this is more pronounced when the pH is increased above 6. The solubility of the two species of insulin crystals also presents a difference. By increasing the pH from 6 to a value below 7, the solubility of pig insulin is increased more than

that of cattle insulin. This difference in solubility and rate of crystallization may or may not have any relation to the shape of the crystals. In order to investigate this question, these differences were tentatively eliminated by using solubilizing agents for the crystallization of cattle insulin. Urea, which is known to have solubilizing properties, was added to the citrate medium for the crystallization of cattle insulin. The solubility of the cattle insulin was thereby increased and the rate of crystallization decreased. Sodium chloride which also increases the solubility of the crystals in the citrate buffer was likewise tested.

A. Addition of urea, citrate buffer, cattle insulin. Acetone was tentatively substituted by 20 % urea, which caused the insulin tc stay in solution. 10 % urea was tried with the result that perfect rhombohedrons developed which could not be distinguished from pig insulin crystals. After recrystallization without urea, the beautiful sharp rhombohedrons were transformed into the usual shape typical of cattle insulin. Thus the shape seems to be related to solubility and the rate of crystallization rather than to the presence of impurities.

B. Addition of halogenides. The solubilizing effect of sodium chloride is less pronounced, but when acetone is replaced by 7—8 % sodium chloride, rhombohedrons are obtained which are just as perfect as those obtained with 10 % urea. Sodium acetate, nitrate, sulphate, citrate or phosphate were found ineffective, whereas KCl, NH_4Cl, $CaCl_2$ and $(HOCH_2CH_2)_3NHCl$ produced the effect. Thus the effect seems to be due to the chloride ion.

Sodium fluoride was ineffective, but the following halogenides, KCl, KBr, KI, were all effective, especially KI as judged from the dependence of shape upon molar concentration of the halogenide.

In order to demonstrate that the effect of the halogenides is not contingent on the presence of citrate buffer, the following composition may be employed:

0.5—4.0 % insulin
0.8 % Zn^{++} (as chloride) calculated on the weight of insulin
0.1 M sodium acetate
7.0 % sodium chloride
HCl to pH 5.45—5.55.

The insulin is dissolved in water containing HCl and $ZnCl_2$, whereupon a solution of sodium acetate and sodium chloride is added. The crystallization is carried out at room temperature under mechanical stirring. The process is completed within one or two days. The advantages of this method are the following:

1) The shape of crystals is perfectly rhombohedral irrespective of the species of insulin and, to a certain extent, the purity.
2) Non-protein nitrogen is not introduced (as with ammonium acetate).

When the acid insulin solution is mixed with the alkaline buffer solution to produce pH 5.5, the insulin is precipitated as amorphous particles and gradually converted into crystals. When impure insulin is used, an amorphous

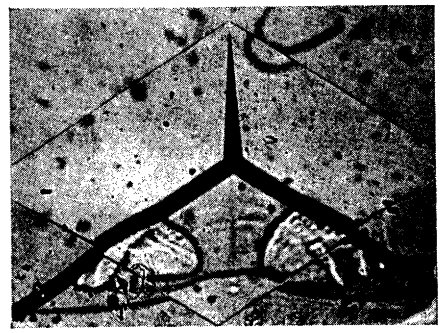

Fig. 3. 1.3 mm large insulin crystal from pig pancreas.

fraction is left which may be removed by acetone (30 % (v/v)). The acetone dissolves the amorphous fraction so that the crystals can be isolated by filtration or centrifugation. When pure, recrystallized insulin is crystallized by this method, only a small fraction, approximately 3 % of the protein, is left as amorphous particles, and the amount of insulin left in solution is of the same magnitude.

The halogenide ions do not alter the shape of pig insulin crystals.

MEASUREMENT OF THE ANGLE BETWEEN THE EDGES OF THE RHOMBOHEDRON

Several times recrystallized insulin from pig pancreas was crystallized from the acetone-citrate buffer at pH 6.2 (1 litre). Agitation was avoided. Within a few days, large (1 mm), beautiful, extremely sharp and colourless rhombohedrons could be observed on the glass walls, at the bottom of the beaker and hanging on the surface. The crystals shrink, harden and become crackled when taken up and left in the air. Therefore, for the microscopical examination, a crystal was placed in its mother liquid on a slide and covered with a cover glass, a ring of vaseline between the glasses providing space for the crystal. The crystal was lying on a face which was therefore in level (see Fig. 3). The horizontal position was checked by adjusting the microscope to the edges of the face. A 10 × objective in connection with a 8 × eye-piece goniometer was used for the measurements. Ten goniometer readings of the obtuse angle between the edges were made with the following result: $\alpha = 114° 22' \pm 4'$ (S.D.). This estimate agrees with the X-ray estimate for wet insulin crystals, *viz.*: $\alpha = 114° 16'$, as determined by Crowfoot and Riley [10].

Spectroscopic Conformational Analysis of Some Monohalogenated *Cyclo*hexanes

PETER KLÆBOE, JOHAN J. LOTHE and K. LUNDE

Universitetets Kjemiske Institutt og Sentralinstitutt for Industriell Forskning, Blindern-Oslo, Norway

The vibrational spectra of monohalogenated *cyclo*hexanes in the liquid and solid states have been investigated.

In the liquid state of monochloro- and monobromo-*cyclo*hexane both the *e*- and the *a*-conformation are present, the *e*-conformation preponderating in both compounds. The same dynamic equilibrium between the two conformations of monochloro*cyclo*hexane was observed in the rotating, cubic modification. No cubic modification was found for the monobromo-compound. In the anisotropic modification (at −150° C) only the *e*-conformation of the two compounds could be detected.

Investigation of the spectra of monofluoro*cyclo*hexane in the liquid, cubic (rotating) and anisotropic modification revealed the presence of only one conformation.

The stereochemistry of halogen substituted *cyclo*hexanes has been studied in considerable detail by Hassel and co-workers [1] using X-ray and electron diffraction methods and in some cases dipole moment measurements. As a result of the investigation of *cyclo*hexane Hassel [2] pointed out that for the majority of the substituted *cyclo*hexanes two different conformations are possible through the conversion of the carbon ring. In the vapour the relative amounts of the two conformations present at equilibrium are to a large extent determined by steric factors. In the solid state only one of the two possible conformations has been observed.

The electron diffraction method will in most cases not be sensitive enough to detect a small percentage of one conformation in an equilibrium. The method is furthermore not suited for investigation of the liquid phase.

It was hoped, however, that the infrared spectrophotometric method would be more sensitive to small amounts of a second conformation. The method might also be valuable in elucidating the structure of some of the more complicated halogen substituted *cyclo*hexanes.

A great advantage of the infrared method is that it is equally suited for the solid, liquid and even for the vapour phase of the lower boiling compounds. Since the two conformations of monohalogeno derivatives of *cyclo*-

hexane represent two different molecular species, they will have two different sets of vibrational frequencies. Some of the corresponding infrared bands, at least in the lower frequency region, should be so strongly influenced by the different directions of the halogen substituent that they should be resolved by an infrared spectrophotometer. Provided that only one conformation is present in the solid state it should be possible by noting the disappearance of a set of bands on going from the liquid to the solid state to assign some of the bands to one or another of the two conformations. The more complicated problem to decide which of the two conformations is present in the solid state may be solved either by an X-ray study or in more special cases by direct assignment of some of the bands to each of the two conformations. This assignment is greatly facilitated if polarization data from the Raman spectrum are available, or, as will be discussed in a forthcoming paper [3], if it is possible to displace the conformational equilibrium by changing the solvent.

As an introduction to the spectroscopic study of the stereochemistry of halogen substituted *cyclo*hexanes a discussion of the infrared and Raman spectra of monochloro- and monobromo-*cyclo*hexane and of the infrared spectrum of monofluoro*cyclo*hexane is presented in this paper. In a subsequent paper [3] the spectra of some 1,2-dihalogen substituted *cyclo*hexanes will be dealt with.

An electron diffraction investigation of the vapour of monochloro*cyclo*hexane published in 1943 by Hassel and Viervoll [4] has shown that the *e*-conformation must be present in a concentration considerable greater than the *a*-conformation.

More recently Larnaudie [5] in a study of the infrared spectra of the monohalogenated *cyclo*hexanes concluded from a consideration of the band envelopes of the vapour spectra that both conformations of the iodo-, bromo-, chloro-, and probably also of the fluoro-compound were present in the liquid phase. It is obvious, however, that the band envelopes are not very sensitive to the structure of these molecules of low symmetry (C_s), and the interpretation given by Larnaudie cannot be regarded as conclusive.

It has been known for several years that some simple derivatives of *cyclo*hexane exhibit molecular rotation in the crystals just below the melting point. This phenomenon has been shown both for *cyclo*hexane itself and for monochloro*cyclo*hexane [6]. Usually organic compounds which exhibit rotation below the melting point crystallize in the cubic system. This rotation can, however, not continue down to the absolute zero of temperature. The crystals must consequently undergo a transition into a non-rotating, generally anisotropic modification. This gives us the possibility of learning, by means of polarized light, whether the crystals are in a rotating or a non-rotating state.

The true nature of molecular rotation in the crystal lattice is not very well understood, but it will be shown in this paper that the rotation in the cubic modification permits the free interconversion between the two conformations.

EXPERIMENTAL

The *cyclo*hexane derivatives were synthesized using well known methods and their purity checked by the refractive indices.

The infrared spectra were recorded with a Perkin-Elmer Model 21 double beam spectrophotometer equipped with sodium chloride and caesium bromide prisms. A cell similar to the one described by Lord *et al.*[7], was used and only minor alterations introduced in order to record the spectra at low temperatures. Teflon spacers were, however, found to be more efficient than the conventional metal spacers to prevent leakage. One welding point of the thermocouple was placed as close as possible to the cell windows and a rough estimate of the temperature gradient between this spot and the sample was made. Before running the spectra the solids were inspected by placing the cell in a light beam between two opposed polaroid films.

The Raman spectra were recorded with a three-prism f : 3, Steinheil spectrograph. The source unit consisted of eight 450 watts mercury lamps surrounded by a cylindrical

metal jacket the inner surface of which was coated with magnesium oxide [8]. The same source unit, with the addition of a set of parallel baffles inside the circle of mercury lamps, was used in order to obtain polarization data by means of the two-exposure method by Crawford and Horwitz [9].

EXPERIMENTAL RESULTS

The infrared and Raman data for the monochloro- and the monobromo-*cyclo*hexane in the liquid and solid states are reproduced in Tables 1 and 2. The frequencies for the Raman spectra of these compounds are in reasonably good agreement with those reported by Kohlrausch [10]. The most significant difference is found in the Raman spectrum of the chloro compound. We have found two polarized lines of about equal intensity at 807 and 818 cm^{-1}. Kohlrausch observed only one line. The polarization data of Tables 1 and 2 represent the average of four plates and should be more reliable than the results from the rather incomplete investigation by Canals [11].

It is very interesting to note that all of the bands observed in the liquid state of monochloro*cyclo*hexane (Table 1) are also found in the cubic, semi-solid modification. A set of bands has disappeared, however, from the spectrum of the solid, anisotropic modification at —150° C.

For the monobromo-compound only *one* crystalline modification has been found [6]. Inspection in polarized light revealed that the crystals were anisotropic. A comparison of the infrared bands of the two states (Table 2) shows that a set of bands disappeared on going from the liquid to the solid state. Only by very slow cooling and crystallization of the bromo compound could these bands be eliminated.

The infrared data for the monofluoro*cyclo*hexane in the liquid state are in good agreement with a spectrum obtained by Bak [12]. The data for the liquid state and for the two crystalline modifications are given in Table 3. It will be seen that in this case all the bands observed for the liquid state are present in the semi-solid, cubic as well as in the solid, anisotropic modification. The

infrared spectrum of the anisotropic modification was repeatedly investigated with the same result.

The infrared spectra of solutions of the monochloro- and monobromo-compound in different solvents of high and low dielectric constant (nitromethane - *cyclo*hexane) did not reveal any change in the conformational equilibrium, judging from the relative absorbancy values of the bands.

DISCUSSION

The discussion will mainly be concerned with monochloro*cyclo*hexane as this compound exhibits all of the special features of substituted *cyclo*hexanes: Both conformations are present in the liquid state; two solid modifications are found, one cubic, rotating, where both conformations are observed, and one anisotropic, non-rotating, where only one of the two conformations can be present.

The monochloro*cyclo*hexane molecule possesses $3 \times 18 - 6 = 48$ normal modes of vibration which are all active both in the infrared and the Raman spectra. A more detailed consideration indicates that the molecule would be expected to have at most 6 polarized Raman lines below 700 cm^{-1}: 4 ring frequencies, 1 C—Cl stretching and 1 C—Cl bending frequency. The Raman spectrum of liquid monochloro*cyclo*hexane (Table 1) shows, however, a great number of polarized, strong Raman lines in the lower frequency region, 16 below 1 000 cm^{-1} and 9 below 700 cm^{-1}. Already this behaviour indicates strongly that both conformations must be present in appreciable concentrations in the liquid state of monochloro*cyclo*hexane. This assumption is confirmed by the observation that several bands of high intensity in the spectrum of the liquid are lacking from the spectrum of the solid at —150° C. As only one conformation can be present in the true solid state, this behaviour points unequivocally to an equilibrium between the two conformations in the liquid state. Only with molecules of high symmetry, where forbidden bands are observed in the liquid state owing to the breaking-down of the selection rules, may some of these bands disappear on going to the solid state.

The Raman spectrum of liquid monobromo*cyclo*hexane (Table 2) does not as clearly indicate the presence of two conformations as was the case with the chloro compound. Only 5 lines below 700 cm^{-1} can unambigously be identified as polarized. The intensity of the other lines is too low to permit observation of the polarization ratio. A consideration of the total number of frequencies, 15 in all, observed below 700 cm^{-1} in the Raman and infrared spectra indicates, however, that both conformations are probably present in the liquid state as about 9 frequencies only would be expected for monobromo*cyclo*hexane. A comparison of the liquid and solid state infrared spectra of monobromo*cyclo*hexane shows, furthermore, that at least 4 bands of medium intensity are lacking from the solid state spectrum. Unfortunately, the solid state spectrum has only been run in the sodium chloride region, but it is quite probable that a study of the spectrum below 650 cm^{-1} would reveal the absence of other bands. At any rate the presence of both conformations in the liquid state is clearly revealed.

For monofluoro*cyclo*hexane all of the infrared bands present in the liquid persisted in both the cubic and in the anisotropic modification. It seems thus as if only *one* conformation can be detected in the liquid state of the monofluoro compound.

ASSIGNMENTS

It would be of great help for the infrared determination of the structure of polyhalogenated *cyclo*hexanes if some bands could be assigned to definite groupings within the molecules. Attention should especially be paid to the effect of *a*- and *e*-substituents on the position and intensity of the bands.

The infrared spectra of the monohalogenated *cyclo*hexanes would be expected to have at least 3 comparatively strong bands in which the polar carbon-halogen linkage participates to a large extent in the vibration *. The stretching of the carbon-halogen bond, a totally symmetrical vibration and consequently polarized in Raman, would be expected to show up strongly in both the infrared and the Raman spectra. Of the two vibrations connected with the bending of the carbon-halogen bond, one should give a polarized, the other an unpolarized Raman line.

Kohlrausch [10] identifies the C—Cl stretching vibration of monochloro*cyclo*hexane with the very strong, polarized Raman line at 732 cm^{-1}. Kohlrausch did not, however, consider the possibility of two conformations. As the C—Cl stretching frequency is usually found around 700 cm^{-1}, it is reasonable to assign the polarized Raman line at 686 cm^{-1} to the C—Cl stretching frequency of the other conformation. This corresponds well with the observation that the 732 cm^{-1} band persists in the infrared spectrum of the solid, whereas the 686 cm^{-1} band is absent.

The polarized and very strong Raman line at 339 cm^{-1} in the spectrum of the chloro compound is obviously the C—Cl bending vibration. It is somewhat surprising that the corresponding band for the other conformation has not been identified. Probably this band is located in the region below 200 cm^{-1} which is obscured by the exciting Raman lines. It is also possible that the line is covered by the broad 339 cm^{-1} line.

The pair of lines at 807 and 818 cm^{-1}, both equally strongly polarized in the Raman spectrum of monochloro*cyclo*hexane, are probably the symmetrical ring stretching frequencies of the two conformations, corresponding to the line at 802 cm^{-1} in *cyclo*hexane [13].

The bands at 1 014 and 1 098 cm^{-1}, lacking in the spectrum of solid monochloro*cyclo*hexane may be ascribed to the methine C—H group, or possibly to a ring stretching frequency. This question will be discussed more completely in the forthcoming paper on dihalogenated *cyclo*hexanes.

The assignment of the bands in the spectra of monobromo*cyclo*hexane will be mentioned in a few words. The polarized Raman lines at 688 and 659 cm^{-1} are obviously the C—Br stretching vibrations of the two conformations. The very strong and polarized Raman line at 262 cm^{-1} is the symmetrical

* It should be pointed out that the term "polar" here has a real physical signification and should not be mistaken for the old designation used in the *cyclo*hexane stereochemistry instead of an axial -*a*-substituent.

deformation vibration of the C—Br linkage of one of the two conformations. Again it is not quite clear where the C—Br bending frequency of the other conformation is located. The symmetrical ring stretching frequency, at 802 cm^{-1} in *cyclo*hexane, is probably found at 809 cm^{-1} in monobromo*cyclo*hexane. A close inspection of the Raman spectrum reveals that the 809 cm^{-1} band is a doublet. Seemingly the symmetrical ring stretching frequency of the halogeno compounds is not very sensitive to the geometrical direction of the substituent.

The problem of deciding which of the two conformations is present in the solid state of monochloro- and monobromo-*cyclo*hexane is best solved by considering the relative positions of the carbon-halogen stretching frequencies. As will be evident from the forthcoming paper on dihalogenated *cyclo*hexanes,

there are strong indications that the carbon-halogen stretching vibration is of higher frequency in the *e*-conformation than in the *a*-conformation. Consequently, the C—Cl stretching band of monochloro*cyclo*hexane at 728 cm^{-1} should be assigned to the *e*-conformation. The observed ratio of the intensities of the 728 cm^{-1} and the 683 cm^{-1} band is as 2 to 1 in the liquid infrared and somewhat higher in the Raman spectrum; this is in accordance with the general trend of the intensity ratios of other pair of bands in the spectra. Qualitatively, the higher intensity of the *e*-band is in good agreement with the observation by Hassel and Viervoll [2] that only the *e*-conformation could be detected in the vapours by the electron diffraction method.

Correspondingly, of the two C—Br stretching frequencies of monobromo-*cyclo*hexane, the 685 cm^{-1} band should be assigned to the *e*-conformation and the 658 cm^{-1} band to the *a*-conformation.

These assignments make it possible to identify the conformation in the solid. Tables 1 and 2 show that of the carbon-halogen stretching frequencies it is the *a*-bands, 683 cm^{-1} in the monochloro- and 658 cm^{-1} in the monobromo-compound, that disappear in the solid state spectra. Consequently, the *e*-conformations are energetically preferred in the lattice of the anisotropic modifications of both the monochloro- and the monobromo-*cyclo*hexane. A conclusion regarding the conformation present in crystalline monofluoro*cyclo*-hexane cannot be reached at the present time.

ROTATIONAL, SEMISOLID STATE

The observed close similarity of the spectra of monochloro*cyclo*hexane in the liquid state and in the semi-solid, cubic modification is quite interesting but not surprising. The disappearance of a set of bands on going to the solid, anisotropic modification provides a clear evidence for the presence of two conformations both in the liquid and in the cubic modification. As the energy barrier of the conversion of the carbon ring is very low and considering the easy transition of one conformation into the other at the transition-point, a static equilibrium can be excluded. The conclusion must be that the molecular rotation permits an unhindered interconversion of the two conformations in the cubic lattice. Furthermore it must be assumed that the dynamic equilibrium ratio between the two conformations is approximately the same in the liquid and in the rotational, cubic state of monochloro*cyclo*hexane.

Monofluoro*cyclo*hexane also exhibits molecular rotation in the cubic lattice. In this case, however, all spectra of the solid states at any temperature down to —150° C were identical with that of the liquid compound, although a transition from the cubic to an anisotropic modification at a higher temperature was ascertained by inspection in polarized light. This leads to the conclusion that only *one* conformation of the monofluoro*cyclo*hexane can be identified in the solid as well as in the cubic, semi-solid and liquid states of the compound. The physical explanation of this behaviour may possibly involve a stabilizing effect by intramolecular C——H- - -F bonding due to the strong electronegativity of the fluorine atom. The finding that only one conformation prevails, even when steric interactions does not exclude the other conformation, is not unique [14].

The spectrum of the solid monobromo*cyclo*hexane is not changed through the temperature range from just below the melting point to —150° C. This is in full accordance with the lack of a cubic, rotating state for this compound.

The Alkaline Hydrolysis of Alkoxymethyl Ureas

J. UGELSTAD* and J. de JONGE

Philips Research Laboratories N. V. Philips Gloeilampenfabriken, Eindhoven, Netherlands

Alkoxy methyl ureas, surprisingly enough, were found to be quite readily hydrolysed in moderately alkaline solution at room temperature, giving urea, formaldehyde and an alcohol as end products. The decomposition of different alkoxymethyl ureas was investigated kinetically. The hydrolysis was found to be proportional to the OH^- ion concentration. Based on kinetic investigations in strongly alkaline solution a choice is made between two possible reaction paths for the reaction. It may be concluded that the reaction involves the breaking of an ether bond, *i.e.* that methylol urea and alcohol are the first decomposition products.

The reaction is specific for ethers of methylol urea, ethers of methylol compounds of carboxylic acid amides being comparatively very stable in alkaline solution.

The reaction mechanism is discussed.

Ethers of methylol urea are usually prepared in acid solution from methylol urea and alcohol.

$$NH_2CONHCH_2OH + ROH \rightleftharpoons NH_2CONHCH_2OR + H_2O$$
$$HOCH_2NHCONHCH_2OH + 2ROH \rightleftharpoons ROCH_2NHCONHCH_2OR$$

As indicated in the above equations these reactions are reversible. The ethers are readily decomposed under the catalytic influence of acids, probably giving the methylol compound and the alcohol as the first decomposition products. The details of this decomposition in acid solution are not yet known.

Contrary to some observations in the literature, it can be shown that such ethers are also hydrolysed in alkaline solutions. The experimental evidence for a hydrolysis of this type of ethers in alkaline aqueous solution is the appearance of free formaldehyde.

This result could be due to the decomposition of the urea part of the ether molecules. The breaking of a C—N bond at one of the places indicated by the dotted lines in equation (a) would result in a total break-down of the ether molecule:

$$NH_2{:}CO{:}NHCH_2OCH_3 + 2H_2O \rightarrow 2NH_3 + CO_2 + CH_2O + CH_3OH \qquad (a)$$

* Present address: Sintef, Norges Tekniske Högskole, Trondheim, Norway.

From what is known of the stability of urea in alkaline solution it is not very probable that such a reaction occurs in the present instance. The conditions under which the alkaline hydrolysis of the ethers appears to occur are so mild that the urea molecule may safely be regarded as stable.

It was possible to confirm this experimentally.

The compound $NH_2CONHCH_2OCH_3$ was hydrolysed practically completely after being dissolved in 0.3 N NaOH for 24 hours at room temperature (95 % free CH_2O). Urea could then be precipitated from the solution as its addition compound with xanthydrol with a yield of 90 % (More details of these experiments are to be found in the experimental part of this chapter).

It is therefore more probable that the ether will break initially at one of the points indicated by a dotted line in $NH_2CONH:CH_2:OR$. In both cases the final products will be urea and formaldehyde, in accord with experimental evidence. Should the C-N bond between the urea fragment and the methylene group be broken initially the decomposition would proceed as follows:

$$\left.\begin{array}{ll} 1. & NH_2CONHCH_2OR \rightarrow NH_2CONH_2 + HOCH_2OR \\ 2. & HOCH_2OR \rightarrow CH_2O + ROH \end{array}\right\} \quad (b)$$

The hemiacetal primarily formed is known to be very unstable in alkaline solution and will quickly decompose into formaldehyde and the alcohol.

If the C-O bond is broken initially the following reaction occurs:

$$\left.\begin{array}{ll} 1. & NH_2CONHCH_2OR \rightarrow NH_2CONHCH_2OH + ROH \\ 2. & NH_2CONHCH_2OH \rightarrow NH_2CONH_2 + CH_2O \end{array}\right\} \quad (c)$$

Under the catalytic influence of hydroxyl ions, the ether is decomposed into the alcohol ROH and methylol urea, this involving the rupture of an ether bridge $—CH_2:OR$. The methylol compound is broken down further in a subsequent reaction into urea and formaldehyde, a reaction which is known to occur in alkaline solution [1].

The two latter reaction paths (b) and (c) are very similar and both involve a series of two subsequent reactions with an unstable intermediate. It is very difficult to show by any chemical method which of these two reactions paths (b) or (c) does in fact predominate since the possible intermediates are both highly unstable compared to the parent compound. Later in this paper arguments will be given that monomethylol urea is the initial product in the ether decomposition (scheme (c)). The evidene for this has been derived from kinetic measurements. The kinectic investigation of the decomposition also gave an insight into the mechanism of the reaction.

KINETIC INVESTIGATIONS

A. General outline of the kinetic measurements

1. The rate of hydrolysis of various alkyl ethers of methylol urea was measured in alkaline solution at 25°C.

$$NH_2CONHCH_2OR \rightarrow NH_2CONH_2 + CH_2O + ROH$$

Formaldehyde was considered to be the component most suitable for determination. It was possible to obtain satisfactory results with "the KCN method"[2]. In alkaline solution formaldehyde reacts very rapidly and completely with KCN by the familiar equation:

$$CH_2O+CN^-+H_2O\rightarrow CH_2(OH)CN+OH^-$$

The excess KCN is titrated with $Hg(NO_3)_2$ after reducing the pH of the sample to about 5.

2. As already indicated the decomposition of the ether may be formulated as a sequence of two reactions:

$$1.\ E\rightarrow I+\ldots \quad 2.\ I\rightarrow F+\ldots,$$

in which E is the ether, I the intermediate (hemiacetal or methylol urea) and F formaldehyde.

If it is required to use rate of formation of free formaldehyde in ascertaining the rate of decomposition, it should be noted that reaction 2 does not go to completion but reaches an equilibrium. This inconvenience can be overcome by arranging for the measured amount of KCN to be present from the very start of a kinetic run. (To keep the pH constant during the run the experiments were carried out in strong phosphate-buffer. More details of the experimental procedure are found in the experimental part).

Under these conditions reaction 2 will be irreversible because in the alkaline solution any free formaldehyde will be completely removed by KCN by an instantaneous reaction. Nothing is known regarding the reversibility of reaction 1. From what is known of similar organic chemical reactions it is to be expected that a possible equilibrium will be far over to the right. In any case under the present experimental conditions, reaction 1 may be considered as going to completion because the concentration of the intermediate will always be very low compared to the concentration of the undecomposed ether.

The system is therefore considered as being a sequence of two irreversible reactions 1 and 2 (scheme b or c). Later in this chapter it will be shown experimentally that the ether decomposition is a first order reaction. The concentration of the compounds in the system can be derived from the following equations:

$$-\frac{d[E]}{dt} = k_1[E] \tag{1}$$

$$\frac{d[I]}{dt} = k_1[E]-k_2[I] \tag{2}$$

in which E is the ether, I is the initially formed intermediate, (hemiacetal or methylol urea) k_1 and k_2 are the rate constants for reaction 1 and 2. This gives:

$$[E] = [E_0]e^{-k_1t} \tag{3}$$

$$[I] = \frac{[E_0]k_1}{k_2-k_1}\left(e^{-k_1t}-e^{-k_2t}\right) \tag{4}$$

Accordingly, for the ratio α of the amount of formaldehyde liberated to the amount of ether decomposed is obtained the expression:

$$\alpha = \frac{[F]}{[E_0]-[E]} = 1 - \frac{k_1}{k_2-k_1} \frac{e^{-k_1 t}-e^{-k_2 t}}{1-e^{-k_1 t}} \quad (5)$$

The required rate constant for the ether decomposition in reaction 1 is given by:

$$k_1 = \frac{1}{t} \ln \frac{[E_0]}{[E_0]-([E_0]-[E])} \quad (6)$$

We define an "experimental rate constant" by:

$$k_1' = \frac{1}{t} \ln \frac{[E_0]}{[E_0]-[F]} \quad (7)$$

which is obtained by substituting for the amount of ether decomposed $[E_0]-[E]$ the measured concentration of formaldehyde liberated [F].

From eqn. (5) it will be seen that the ratio $\alpha = \frac{[F]}{[E_0]-[E]}$ is less than 1 and approaches 1 as the time increases which from eqns. (6) and (7) means that the "experimental rate constant" k_1' will approach the true constant k_1 as the degree of decomposition increases. From eqn. (5) it also follows that the value of α will approach 1 the more rapidly the higher the ratio k_2/k_1 is. The same applies therefore to the way in which k_1' will approach k_1 with increasing reaction time. When k_2 is much larger than k_1 the ratio α will be practically equal to 1 already at low degrees of decomposition and accordingly we shall find that the "experimental rate constant" k_1' is constant and equal to the required rate constant k_1 after a low degree of decomposition. This appeared to be the case for all experiments at moderate pH values. Table 1 shows an example of a run.

Table 1. The decomposition of methoxymethyl urea.
E_0 = 0.02 moles/l. Temp. = 25°C
pH = 11.27–11.30. k_2 = 16.5 10^{-5}
k_2/k_1 = 142.

Time (hours)	$Hg(NO_3)_2$ 0.1073 N	% F	$k_1' \times 10^7$ (sec.$^{-1}$)
0	6.60		
14	6.30	5.4	11.0
24	6.08	9.3	11.1
48	5.64	17.2	10.9
96	4.72	33.6	11.8
168	3.80	50.1	11.5
264	2.84	67.2	11.7

The second column of Table 1 gives the amount of $Hg(NO_3)_2$ required for the titration of excess KCN. The third column gives the % of formaldehyde liberated and in the fourth column are given the values of the rate constant k_1' as calculated from eqn. (7). The value of k_1' is within experimental error constant

already at low degrees of decomposition and may be taken as equal to the required rate constant k_1. With all ethers of methylol urea decomposed at pH 11—12 and 25°C the "experimental rate constant" k_1' was constant at low degrees of decomposition.

As explained above this result means that the second step in the decomposition reaction, the splitting of hemiacetal (scheme b) or the splitting of methylol urea (scheme c), is very fast compared to the ether decomposition. However, the results do not give any indication as to what scheme is the right one, because both possible intermediates decompose very fast compared to the ether decomposition under the given conditions. The hemiacetal may be expected to split practically spontaneously under the conditions cited in Table 1 [3]. The decomposition of methylol urea was measured separately under the same condition. The value for the rate constant is given in the top of Table 1 (k_2) and has indeed also a much higher value than the rate constant of the ether hydrolysis ($k_2/k_1 = 142$). Therefore both schemes b and c are in agreement with the constant value experimentally observed for the "experimental rate constant". The question is further discussed in part D of this chapter.

B. The order of the decomposition reaction

The hydrolysis of methoxymethyl urea is a first order reaction. This follows from the fact that in each separate run we find a constant value for the rate constant as calculated from the equation for a first order reaction (Table 1).

Furthermore the reaction is shown to be first order by decomposition measurements with different initial concentrations of the ether: The degree of decomposition after a certain time is independent of the initial concentration of the ether (Table 2).

Table 2. The decomposition of methoxymethyl urea is a first order reaction. Temp. = 25°C pH = 11.27—11.30.

Time (hours)	24	48	96	168	
% F liberated	9.3	18.3	32.7	49.0	$[E_0]$ = 0.01 mole/l
	9.3	17.2	33.6	50.1	$[E_0]$ = 0.02 mole/l
	9.0	18.0	32.1	49.8	$[E_0]$ = 0.03 mole/l

C. The influence of pH on the rate of decomposition

Table 3 gives the value of the rate constant k_1 for the decomposition of methoxymethyl urea at three different pH values at 25°C. It is evident that the rate is directly proportional to the concentration of hydroxyl ions.

Table 3. The first order rate constant for the decomposition of methoxymethyl urea at different pH values.

pH	11.27—11.30	11.61—11.63	11.97—12.0
$10^7 k_1$(sec^{-1})	11.6	24.8	58.6

D. Evidence that monomethylol urea is initially formed as an intermediate in the decomposition of the ethers

In the introduction it was pointed out that the appearance of free formaldehyde from, *e.g.*, methoxymethyl urea may be described by two different reaction schemes both involving a series of two subsequent reactions. The molecule $NH_2CONH\overset{x}{:}CH_2\overset{y}{:}OCH_3$ may break at x giving the hemiacetal as intermediate product (scheme b) or at y with methylol urea as intermediate (scheme c). As explained above the measurements hitherto described do not give any indication as to which of these two possibilities does in fact occur.

Let us now tentatively assume that methylol urea (UF) is the intermediate, *i.e.* that the reaction course given in scheme c is correct.

$$1. \quad E \xrightarrow{k_1} UF$$

$$2. \quad UF \xrightarrow{k_2} U+F$$

and let us try to find conditions under which the rate of decomposition of methylol urea k_2 (which can be measured separately) is much closer to the value of k_1 than it was under the conditions given in Table 1 ($k_2/k_1 = 142$).

From the discussion of the rate expressions (5) (6) and (7) it will be evident that in this case we shall (if our assumption is right) expect to find that the "experimental rate constant" increases with time and only reaches a constant value after a considerably degree of decomposition.

Ether decomposition experiments at slightly different pH values from 11—12 will not change the ratio of the rates of the two subsequent reactions, because both are proportional to $[OH^-]$. However, the authors have shown in the investigation of the kinetics of formaldehyde — amide reactions [4] that the velocity of the decomposition of monomethylol urea at very high alkalinities (0.1 N NaOH and higher) is not longer proportional to the OH^- concentration but approaches an upper limit where a further increase in $[OH^-]$ no longer affects the rate. Fortunately the hydrolysis of the ether was now found to be still proportional to $[OH^-]$ even in these strongly alkaline solutions. The result is a smaller value of the ratio k_2/k_1 as is required.

The decomposition of methoxymethyl urea was measured in 0.4 and 1 N NaOH at 0°C. The amount of formaldehyde formed was determined with the KCN-method as described. (At such high OH^- concentrations as used here, the increase in $[OH^-]$ due to the reaction of KCN with formaldehyde, is negligible compared to the $[OH^-]$ already present. Therefore no buffers are necessary under these conditions. More details are found in the experimental part.)

The results are shown in Table 4. It can be seen that the rate constant for the hydrolysis of the ether k_1 ($=k_1'$ at high conversions) is indeed still proportional to the OH^- concentration. The independently measured values for the rate constant of the decomposition of monomethylol urea (k_2) are given at the top of the tables. As will be seen the value of k_2 at such high alkalinities is no longer proportional to $[OH^-]$. The result is that the ratio k_2/k_1 is less than its

value at pH 11—12, where k_2/k_1 was about 140. This effect is most obvious at the highest alkalinity.

With this more favourable ratio of k_2/k_1 the predicted increase in the value of k_1' on increasing the reaction time is now clearly observed.

In the tables are also given the values of the ratio $\alpha = [F]/([E_0]—[E])$

Table 4. The decomposition of methoxymethyl urea in 0.4 N and 1 N NaOH at 0°C.

a) $[Na^+] = 0.40$; $k_2 = 2.45 \times 10^{-4}$; $k_2/k_1 = 44.5$

Time in min.	% F	$k_1' \times 10^6$ (sec^{-1})	$\frac{[F]}{[E_0]-[E]}$	k_1 calc. $\times 10^6$
215	4.60	3.66	0.702	5.27
360	9.40	4.57	0.819	5.66

946	53.7	13.6	0.965	
1251	64.1	13.7		
1675	74.8	13.7		
1749	76.3	13.7		

at the different time intervals, calculated from eqn. (5), using the value of $k_1' = k_1$ for high conversions and the measured value of k_2. With the aid of the values of α and eqn. (6), the rate constant k_1 can now be calculated for low conversions from the [F]-values measured. The values are given in the table as k_1 calc.

It will be seen that these calculated values for k_1 at low conversions are constant, allowance being made for the experimental error, and have practically the same value as $k_1' = k_1$ found at high conversions. This result is a very strong indication that methylol urea is indeed the initial intermediate compound in the splitting of ether since we used the directly measured value of the rate constant for the decomposition of methylol urea (k_2) to obtain this result. It is extremely unlikely that the rate constant for the hydrolysis of the hemi-acetal $HOCH_2OCH_3$ has the same value under these conditions. In fact, the hydrolysis of a hemiacetal should be expected to be spontaneous at such high alkalinities, which means that not even qualitatively an increase in k_1' could have been observed.

E. Influence of the alkyl group on the rate of decomposition

To establish the influence of the alkyl group R on the rate of hydrolysis of the ethers $NH_2CONHCH_2OR$ investigations were made on the methyl, ethyl, propyl and *iso*propyl ethers. These ethers have been prepared by a procedure described by Kadowaki [5]. The propyl and *iso*propyl ethers are new compounds. The results of the decomposition experiments are given in Table 5. As will be seen the rate constant is roughly doubled in going from the *iso*propyl ether to the propyl ether, is nearly unchanged in going from the propyl ether to the ethyl ether and is again doubled in going from the ethyl ether to the methyl ether.

Table 5. The rate of decomposition of various alkyl ethers of methylol urea. Temp. = 25°C; pH = 11.98.

	$k_1 \times 10^6$ (sec^{-1})
$NH_2CONHCH_2OCH_3$	5.87
$NH_2CONHCH_2OC_2H_5$	2.87
$NH_2CONHCH_2OCH_2CH_2CH_3$	2.96
$NH_2CONHCH_2OCH(CH_3)_2$	1.67
$(CH_3)_2NCONHCH_2OCH_3$	27

F. Hydrolysis of di-alkyl ethers of dimethylol urea

A few experiments have been performed with some of the ethers of dimethylol urea $ROCH_2NHCONHCH_2OR$. These compounds were likewise found to hydrolyse readily in alkaline solution, at a higher rate even than the monoethers. It has been observed that practically the theoretical amount of formaldehyde can be obtained from such a di-alkyl ether after a prolonged reaction time which means that both ether bonds can be hydrolysed. The overall reaction is rather complicated. The complexity of the reaction makes it difficult to derive any accurate value for the rate constant in this case.

In the kinetic investigations the hydrolysis of a di-ether was followed up to a degree of conversion, where about 5—10 % of the theoretical amount of formaldehyde had been set free. The hydrolysis of the second ether group then may probably be neglected and the rate of liberation of formaldehyde will be determined by the following two reactions.

1. $ROCH_2NHCONHCH_2OR \xrightarrow{k_1} ROCH_2NHCONHCH_2OH + ROH$

2. $ROCH_2NHCONHCH_2OH \xrightarrow{k_2} ROCH_2NHCONH_2 + CH_2O$

The rate constant k_2 is unknown and cannot be readily determined, because methylol alkoxymethyl ureas are unknown compounds and will be difficult to prepare. However, the experimental rate constant for the appearance of formaldehyde, as calculated from a first order reaction equation, appears to be nearly constant after 10 % conversion, and as explained in connexion with the mono ethers we may therefore assume that in this manner we are measuring the rate of decomposition of the first ether group in the di-ether.

The rate constants at 35°C and pH 11.9 found in this way, for three di-alkyl ethers, are collected in Table 6. As will be seen the rates of decomposition with different alkyl groups vary in the same manner as was observed for the monoethers, *viz.* $CH_3 > C_2H_5 \sim CH_2CH_2CH_3$. The ratios of the rate constants are about the same as those found for the mono ethers.

Table 6. Rate constants for the hydrolysis of some di-alkyl ethers of dimethylol urea. Temp. = = 35°C; pH = 11.90.

	$k_1 \times 10^5$(sec.$^{-1}$)
$CH_3OCH_2NHCONHCH_2OCH_3$	6.4
$CH_3CH_2OCH_2NHCONHCH_2OCH_2CH_3$	3.3
$CH_3CH_2CH_2OCH_2NHCONHCH_2OCH_2CH_2CH_3$	3.6

The fact that a di-ether like $CH_3OCH_2NHCONHCH_2OCH_3$ decomposes in alkaline solution proves that for the decomposition it is not necessary for the molecule to have a free amino group H_2N. An even better proof is provided by the observed decomposition of the methyl ether of N-dimethyl N'-methylol urea $(CH_3)_2NCONHCH_2OCH_3$. The rate constant for the decomposition of this ether is about 5 times higher than for $NH_2CONHCH_2OCH_3$. (The value has been given in Table 5).

G. Hydrolysis of ethers of methylolamides

Urea may be looked upon as a special type of amide, and it might have been expected that ethers of methylol compounds of amides of carboxylic acids would also be hydrolysed in alkaline solution at a rate of the same order of magnitude as the rate of hydrolysis of ethers of methylol urea.

This did not appear to be the case. The methyl ether of methylol benzamide did not liberate any detectable amount of formaldehyde after long intervals under conditions, which had led to a ready break-down of the ethers of methylol urea (pH 11—12, temp. 25°C).

To find any measurable hydrolysis in a reasonable time it was necessary to use a much higher alkalinity. Table 7 gives the result of the hydrolysis of the methyl ether in 1 N NaOH at 25°C.

Table 7. The rate of decomposition for the methyl ether of methylol benzamide. Temp. 25°C; $[OH^-]$ = 1.0 N.

Time (hours)	% F	$k_1 \times 10^7$
24	12.3	15.2
43.5	20.8	14.9
120	50.1	16.0
168	61.3	15.7

However, the experimental conditions in the above hydrolysis are so severe, that the formation of formaldehyde may quite well be due to another reaction, *e.g.* to an amide hydrolysis:

$$C_6H_5CO{:}NHCH_2OCH_3 \rightarrow C_6H_5COOH + NH_3 + CH_2O + CH_3OH$$

Ogato and Okano [6] give $k = 2.14 \times 10^{-4}$ sec^{-1} for the first order rate constant for the hydrolysis of benzamide in 1 N NaOH at 70°C; at 25° the value will be about 5×10^{-6} sec^{-1} at a very rough estimate. The apparent rate constant for the hydrolysis of the ether is calculated from the present measurements to be 1.5×10^{-6} sec^{-1} in 1 N NaOH at 25°C. These values are of the same order of magnitude.

Alkyl ethers of other methylol amides also are known to be fairly stable towards alkali. Haworth, Peacock and Smith [7] observed that ethers of some other methylol amides liberate formaldehyde on treatment with strong alkali. The rate constant for the decomposition, which can be calculated from their experimental data, is of about the same magnitude as the rate constant for the decomposition of N-methoxymethyl benzamide.

REACTION MECHANISM

The decomposition of alkoxymethyl ureas in alkaline solution is shown to be a first order reaction with a rate proportional to the hydroxyl ion concentration. The decomposition probably involves the rupture of an ether bridge:

$$NH_2CONHCH_2OR + H_2O \rightarrow NH_2CONHCH_2OH + HOR$$

While ordinary dialkyl ethers such as CH_3—OR are known to be very stable towards alkali, it is well known that hemiacetals like $HOCH_2$—OR are readily split in alkaline solution. The mutarotation of glucose, which also involves the splitting of an ether bridge in a hemiacetal structure, is known to be catalysed by bases [8].

It is assumed in the literature that the instability of the ether bond in these cases is due to the active hydrogen in the β position to the oxygen atom of the ether group. This is in harmony with the fact that diacetals like RO—CH_2—OR are stable towards alkali. The ethers of methylol urea $NH_2CONHCH_2$—OR also have an active hydrogen in β position, in this case at an N atom. It seems reasonable to assume that with these ethers also the instability is primarily due to this fact. In accordance with the reaction scheme proposed in the literature for the mutarotation of glucose we may assume that the hydrolysis of the ethers of methylol urea in alkaline solution will take place in a sequence of steps as indicated below.

$$a.\quad NH_2CONHCH_2OR + OH^- \rightleftharpoons NH_2C\bar{O}\bar{N}CH_2OR + H_2O$$

$$b.\quad NH_2C\bar{O}\bar{N}CH_2OR \rightleftharpoons NH_2CON{=}CH_2 + OR^-$$

$$c.\quad RO^- + H_2O \rightleftharpoons ROH + OH^-$$

$$d.\quad NH_2CON{=}CH_2 + H_2O \rightleftharpoons NH_2CONHCH_2OH$$

In step *a* a proton is removed from the N atom, and this step is followed by the elimination of the alkoxy group in step *b* with the formation of an unstable Schiff's base. In step *c* the base is formed back by neutralisation of the alkoxy group and in step *d* the Schiff's base reacts with water with formation of the methylol compound. As in the mutarotation of glucose, steps *b* and *c* may be assumed to take place simultaneously in one single step.

Step *c* or *d* cannot be rate determining in this reaction scheme because such an assumption does not lead to the right expression for the rate. Moreover from a chemical point of view these reactions may be expected to be rapid. In principle either reaction *a* or reaction *b* can be the rate-determining step to explain the first order, base-catalysed, decomposition reaction. Most probably

step *b*, the elimination of the alkoxy group, will be rate-determining. With this assumption the rate constant for the decomposition will be given by

$$k = k_b \cdot K_a[OH^-] = k_b \cdot K_N[OH^-]/K_w \qquad (8)$$

where k_b = the rate constant for step *b*.
K_a = the equilibrium constant of step *a*.
K_N = the acid dissociation constant of the ether.
K_w = the ionisation product of water.

The rate of hydrolysis will therefore be determined by two factors: the acidity of the hydrogen at the N atom in β position to the ether group (K_N) and the rate of step *b* (k_b).

It is known that an increased branching of an alkyl group increases the polarisibility of the group while an increase in chain length has hardly any effect in this respect. Thus, when an electron-attracting group *x* is bound to the alkyl group, the electron density at the group *x* will increase in the following order:

$$CH_3x < CH_3CH_2x \sim CH_3CH_2CH_2x < (CH_3)_2CHx$$

The nature of the alkyl group R will hardly influence the value of the acidity constant K_N of the urea methylol ether because the distance between the N atom and the alkyl group is too great. It may, however, be expected to influence the value of k_b appreciably. An increased branching of the alkyl group R in $NH_2CONHCH_2OR$ increases the electron density at the O atom and will counteract the introduction of a negative charge into the O atom as is involved in the transition state of step *b*:

$$NH_2CO\overset{-\delta}{N}{=}CH_2{-}{-}\overset{-\delta}{O}R$$

The value of k_b will therefore be lowered. This explains the experimental observation that the rate of splitting of the urea methylol ethers decreases in the order: methyl>ethyl>*iso*propyl ether.

It is difficult to explain this effect if reaction step *a* is taken as rate determining. Also from a chemical point of view step *a* would be expected to establish equilibrium rapidly since this step involves a proton transfer at an N atom.

On comparing the ether of methylol benzamide and the ether of methylol urea it seems probable that the benzamide compound will have a higher value of K_N which from eqn. (8) should in fact favour the reaction. The surprisingly slow rate of decomposition of the benzamide compound compared with the urea compound as found experimentally must therefore be explained by a low value of k_b. If we formulate the formation of the transition state of step *b* as follows:

$$R'CO\bar{N}CH_2OR \rightleftharpoons R'CO\overset{-\delta}{N}{=}CH_2{-}{-}\overset{-\delta}{O}R$$

it will be seen that the formation of the transition state involves an electron displacement from left to right. This displacement may be expected to be largely influenced by the nature of the group R'; thus it will be hampered by the electron attracting C_6H_5 group and facilitated by the electron releasing

NH_2 group. Therefore we may expect that k_b for the benzamide ether will indeed be lower than for te urea ether and apparently this effect more than outweighs the higher value of K_N for the benzamide ether.

The suggestion that a decreased acidity of the amide favours the rate of decomposition of the ether is further supported by the comparison of the ethers $(CH_3)_2NCONHCH_2OCH_3$ and $NH_2CONHCH_2OCH_3$. The former may be expected to be the less acidic and the rate of decomposition of this ether has been found to be about 5 times higher than that for the ether from urea (Table 5).

EXPERIMENTAL PART

Materials

Monomethylol urea methyl ether (m.p. 91°C), monomethylol urea ethyl ether (m.p 111°C), dimethylol urea dimethyl ether (m.p. 101°C), dimethylol urea diethyl ether (m.p. 124°C) and dimethylol urea di-*n*-propyl ether (m.p. 95°C) were prepared by Kadowaki's method [5] by treating the appropriate methylol compound with the appropriate alcohol in the presence of small amounts of HCl.

Other ethers were prepared for the first time: Methylol urea appeared to be only slightly soluble in propyl or *iso*propyl alcohol. It was therefore found preferable in the preparation of the *n*-propyl and *i*-propyl ether of monomethylol urea to dissolve monomethylol urea in a small amount of water before the addition of the alcohol and the catalysing acid. This appreciably reduces the reaction time and thus reduces the danger of condensation reactions (resinifying) which is otherwise appreciable. The procedure for the preparation of the two new propyl ethers is the same. The preparation of the *n*-propyl ether is given below in detail: 10 g methylol urea were dissolved in 15 ml H_2O at *ca.* 40°C. Thereupon 100 ml propyl alcohol were added, followed by 0.5 ml of 2 N HCl. The temperature was maintained at 40°C for *ca.* 5 minutes. The reaction mixture was then neutralised by shaking with Ag_2O, filtered and evaporated *in vacuo*. The residue was crystallised from propyl alcohol-diethyl ether (1:1) giving *monomethylol urea* n-*propyl ether* in colourless needles, m.p. 86.5—87.5°C.

Monomethylol urea iso*propyl ether* was crystallised from *iso*propyl alcohol-diethyl ether (1:1) giving colourless plates, m.p. 103°C.

	H	N	C
Calculated for $C_5H_{12}O_3N_2$	9.15	21.18	45.43
Found for *n*-propylether	9.08	21.12	45.52
Found for *i*-propylether	9.11	21.33	45.41

N,N-dimethyl-N'-methylol urea methyl ether (m.p. 66°C) was prepared from N,N-dimethyl-N'-methylol urea by a similar procedure as was used for monomethylol urea methylether.

N-methylol benzamide methyl ether has hitherto not been reported in the literature. It was prepared as follows: 5 g N-methylol benzamide were dissolved in 10 ml methyl alcohol at room temperature and 5 drops of conc. HCl were added. After standing for 10 min. at room temperature the solution was neutralised with an excess of Ag_2O, and after filtration the solution was cooled to 0°C. Long, prismatic, colourless crystals separated out and were recrystallised from ether. M.p. 73—74°C. (Found: C 65.47; H 6.68; N 8.57. Calc. for $C_9H_{11}O_2N$: C 65.45; H 6.67; N 8.48).

Isolation of urea after hydrolysis of the ether

208 mg of the methyl ether of monomethylol urea were dissolved in 40 ml of an alkaline KCN solution (0.24 N NaOH, 0.1 N KCN) and the solution was left to stand at room temperature for 24 hours. Then 12 ml of concentrated acetic acid and 12 ml of a 10 % solu-

tion of xanthydrol in ethyl alcohol were added. After 4 h the white finely crystalline precipitate was filtered off, washed 3 times with alcohol and dried at 60°. Yield: 762 mg. Calculated for $C_{27}H_{20}O_3N_2$: 840 mg. In a separate experiment, with the same time of hydrolysis for the ether, a titration was made with $Hg(NO_3)_2$ and 97.1 % of the theoretical amount of formaldehyde was found.

The decomposition of an ether at pH 11-12 and 25°C

The reaction medium was made up of 100 ml Na_2HPO_4 solution (1 M) 50 ml KCN (0.1 N) and a certain volume of NaOH solution (2 N). It was diluted to 200.0 ml with water (the amount of NaOH was variable depending upon the pH value of the solution required). This mixture was transferred into a well stoppered erlenmeyer flask which was placed in a thermostat at 25°C. A weighed amount of the finely powdered ether was added to the solution and dissolved by vigorous shaking. The time when the ether was added was taken as zero time for the kinetic run. A sample of this solution was taken and the pH carefully measured.

In order to follow the decomposition of the ether, samples of 30 ml were drawn out of the solution after suitable time intervals. 5 drops of diphenyl carbazone solution were added and the solution was then acidified with 2 N HNO_3 to the appearance of a faint orange-yellow colour (pH 5—4). The solution was then at once titrated with 0.1 N $Hg(NO_3)_2$ from a micro burette. The time when HNO_3 was added was taken as the time of sampling.

The decomposition of an ether in NaOH solution at 0°C

Solutions were made up consisting of 2 N NaOH, 10 ml 0.1 N KCN and diluted to 50.0 ml with water. The mixture was brought into an erlenmeyer flask which was placed in ice-water. When the temperature of the mixture had reached 0°C, 52 mg of finely powdered methoxymethyl urea were added and dissolved immediately on shaking the mixture.

After a certain time the reaction was stopped by neutralising the mixture with a solution containing as much HNO_3 as is equivalent to the NaOH in the sample and 20 ml of a phosphate buffer (0.5 M KH_2PO_4 + 0.5 M Na_2HPO_4). The excess KCN was determined with $Hg(NO_3)_2$ as described earlier.

Identification of Dialkylsulfides as Dialkyl *p*-Bromophenacyl Sulfonium Picrates

STIG VEIBEL and BENT JUHL NIELSEN

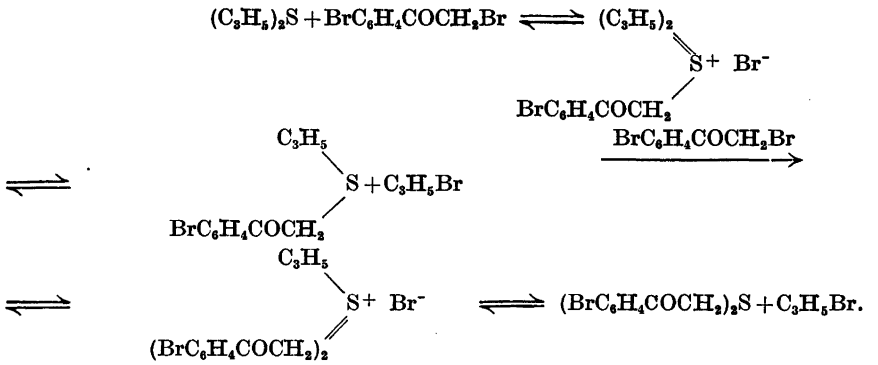
Department of organic chemistry, University of Technology, Copenhagen, Denmark

The preparation and the titratability of dialkyl *p*-bromophenacyl sulfonium picrates with perchloric acid in glacial acetic acid has been investigated.

Diarylsulfides and thioanisoles do not react with *p*-bromophenacyl bromide.

Dialkyl sulfides with mobile alkyls (allyl or benzyl), refluxed with *p*-bromophenacyl bromide, form bis-(*p*-bromophenacyl) sulfide instead of dialkyl *p*-bromophenacyl bromide.

Jureček, Večeřa and Gasparič [1], referring to previous work of Bost and Schultze [2], recommended the characterisation of dialkyl sulfides as dialkyl *p*-bromophenacyl sulfonium salts, preferring for the picrates or bromides the perchlorates, as these salts showed the widest range of melting points.



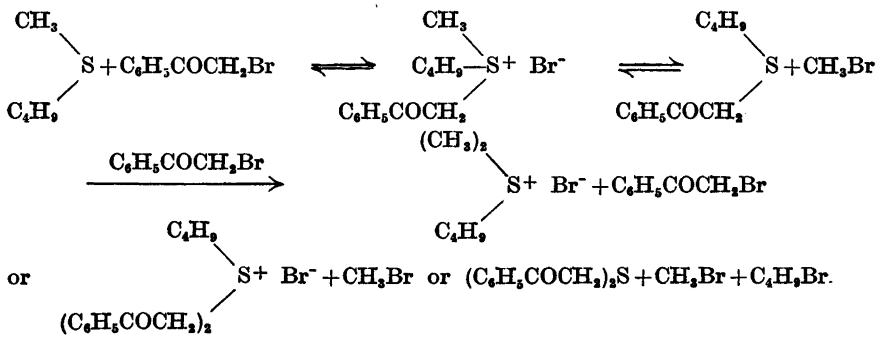
Recalling the very convenient method of estimating alkyl halides by converting them into alkyl thiuronium picrates which are then dissolved in glacial acetic acid and titrated with perchloric acid in the same solvent (Schotte and Veibel [3]), we investigated the preparation of a series of tertiary sulfonium picrates and their titratability with perchloric acid, examining at the same time the possible extension of the method to aromatic sulfides and mixed aromatic-aliphatic sulfides (thioanisoles).

We found that in the case of uncomplicated dialkyl sulfides the preparation of the dialkyl *p*-bromophenacyl sulfonium picrates presented no serious difficulties, although some of the picrates, as stated by Jureček *et al.*[1], may first separate as oils. As expected, the picrates are easily titratable with perchloric acid.

As to the aromatic sulfides, however, no formation of a tertiary sulfonium salt took place, neither from the diaryl sulfides nor from the thioanisoles.

Using aliphatic sulfides where the carbon-sulfur bond may be expected to be weakened, due to the structure of the aliphatic radical (as in diallyl sulfide or dibenzyl sulfide) we were unable to isolate the dialkyl *p*-bromophenacyl sulfonium picrate. Instead of this we isolated a substance which was in both instances bis-(*p*-bromophenacyl) sulfide, formed by exchange of the radicals originally bound to the sulfur atom for *p*-bromophenacyl radicals. Evidently, the sulfide thus formed is unable to combine with *p*-bromophenacyl bromide to form tris-(*p*-bromophenacyl) sulfonium bromide.

In order to explain the formation of bis-(*p*-bromophenacyl) sulfide the mechanism proposed by Ray and Levene [4] is adopted:



Bost and Schultze [2] indicate that when methyl *n*-butyl sulfide is allowed to react with phenacyl bromide in absolute methanol, the resulting product is dimethyl *n*-butyl sulfonium bromide and not methyl *n*-butyl phenacyl sulfonium bromide, assuming as an explanation the mechanism proposed by Ray and Levene [4]. Jureček *et al.*[1], allowing methyl *n*-butyl sulfide to react with phenacyl bromide or *p*-bromophenacyl bromide in absolute methanol, met no difficulties in obtaining the expected methyl *n*-butyl phenacyl sulfonium perchlorate or methyl *n*-butyl *p*-bromophenacyl sulfonium perchlorate, neither did other unsymmetrical sulfides present such anomalies. They found it difficult, however, to isolate the bromides as these salts separated as oils, but they were converted without difficulty into crystalline picrates or perchlorates.

We, too, repeated the preparation of methyl *n*-butyl phenacyl sulfonium salts and had no trouble in preparing the picrate, which by titration with perchloric acid gave the molecular weight 449.5 (calculated 451.5), whereas M for dimethyl *n*-butyl sulfonium picrate is only 350.4.

Also with *p*-bromophenacyl bromide we found a normal reaction (as did Jureček *et al.*[1]), $M_{Picrate}$ found by titration with perchloric acid 530.1, calculated 530.5.

A possible explanation of the discrepancy may be found in the observation of Jureček *et al.* that the yield of the sulfonium bromides usually decreases when the refluxing time is increased. Accepting the scheme of Ray and Levene [4], prolongation of the refluxing time will favour the precipitation of the slightest soluble of the compounds in an equilibrium mixture as:

just as we obtained the bis-(*p*-bromophenacyl) sulfide by reacting, *e.g.*, diallyl sulfide with *p*-bromophenacyl bromide.

EXPERIMENTAL

The sulfonium bromides were prepared according to Jureček *et al.*[1] by refluxing equivalent amounts of *p*-bromophenacyl bromide and the sulfide under investigation (0.005 mole) in methanol (5 ml) during 10 minutes. After cooling the sulfonium bromide was precipitated by addition of 200 ml of ether, isolated, if possible, by filtration, washed with ether, dissolved in water and precipitated as picrate on addition to a saturated aqueous solution of picric acid. The picrates were recrystallised from ethanol.

0.001 mole was dissolved in 50 ml glacial acetic acid and titrated with 0.1 N perchloric acid in glacial acetic acid (indicator: crystal violet, end point: green). Some results are given in Table 1.

Table 1. Titration of some dialkyl p*-bromophenacyl picrates with perchloric acid in glacial acetic acid.*

Alkyl	M.p. Lit.	M.p. Found	M calc.	M found
Di-*n*-propyl	119°[1]	120°	544.4	545.3 546.6 544.5
Di-*n*-butyl	79°[1]	80—81°	572.5	573.7 573.3 573.8
Methyl hydroxyethyl	—	140—41°	518.3	518.7 517.2 517.5
Methyl *n*-butyl	121—21.5°[1]	119—20°	530.4	530.1
Diallyl		142°		*
Dibenzyl		142°		*

* In these cases a substance (the same for both sulfides) precipitated during the refluxing. The substance was not able to form a picrate with aqueous picric acid, its m. p. (142°) and composition corresponded to that of bis-(*p*-bromophenacyl) sulfide. (Found: C 44.85; H 2.85; Br 37.52; S 7.56. Calc. for $C_{16}H_{12}O_2Br_2S$: C 44.88; H 2.83; Br 37.32; S 7.49.

Reaction between n*-butyl sulfide and phenacyl bromide.* The standard procedure yielded an oily picrate which crystallised after 24 h in the ice box. Purified by recrystallisation from ethanol it showed m.p. 99—100° and M 449.5, calculated for methyl butyl phenacyl sulfonium picrate ($C_{19}H_{21}O_8N_3S$) 451.5.

The Flavonoid Glycosides of *Dahlia variabilis*

IV. 3-Glucosido-5-arabinosidocyanidin from the Variety "Dandy"

C. G. NORDSTRÖM

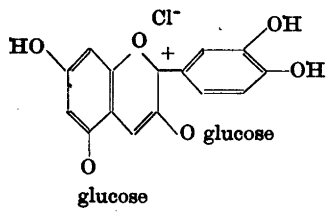
Institute of Chemistry, University of Helsingfors, Finland

A method for the identification of anthocyanins on a micro-scale has been developed and applied to an anthocyanin separated from the petal extracts of the blue dahlia "Dandy". The anthocyanin was identified as 3-glucosido-5-arabinosidocyanidin.

In Part I of this series [1] the presence of a cyanidin glycoside, yielding glucose and arabinose on hydrolysis, was reported in the petal extracts of the variety "Dandy". Further attempts to characterise this compound using methods similar to those developed for the identification of flavone glycosides were then unsuccessful due to the instability of cyanidin in solution. Investigation of the causes of this instability has resulted in the successful development of methods for the determination of the aglycone:sugar ratio and position of carbohydrate attachment in anthocyanins. Application of these methods to investigations of anthocyanins from natural sources gives more precise information regarding their structure than previously used micro-methods [2,3].

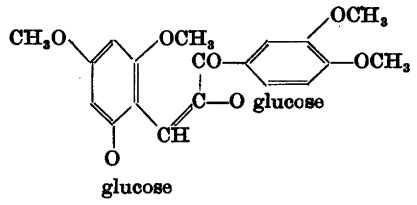
As previously described (*cf.* Part I) large scale paper chromatography of the ethanolic hydrochloric acid extracts of the petals of the blue garden dahlia "Dandy" by butanol-acetic acid-water yields, besides a number of flavone glycosides, an anthocyanin which after further purification yielded an aglycone, tentatively identified as cyanidin, arabinose and glucose on hydrolysis. This glycoside was now further tested for homogeneity by running in a number of solvents. Using acetone-0.1 N hydrochloric acid (1:3) an impurity having a weak yellow fluorescence in ultra-violet light was removed and chromatograms of the ethyl acetate extract of the hydrolysed anthocyanin indicated the absence of further impurities. The aglycone which so far had been identified only by its R_F value in one solvent was now conclusively identified as cyanidin by its absorption spectrum in visible light and its R_F values in a number of other solvents [4] (Table 1).

All previous attempts to determine the molar aglycone:sugar ratio of this and other anthocyanins using the methods developed in Part I had so far been



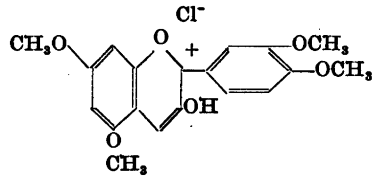
unsuccessful due to the fading of the colour of the anthocyanidins in solution, making spectrophotometric determination of their concentration impossible. Such fading in acid solution in the light has previously been reported by Spaeth and Rosenblatt [5]. It was found that in 0.1 to 2 N hydrochloric acid solutions kept in darkness at room temperature no significant decrease in cyanidin concentration could be detected, whereas when similar solutions were exposed to light the cyanidin concentration decreased fairly rapidly. In six hours the concentration of a solution exposed to diffuse light had decreased by 10 % but in sunlight the decrease of concentration of the solution amounted to about 95 % of the cyanidin initially present. These experiments were repeated in nitrogen atmosphere and although the decrease in cyanidin concentration was slightly less, it was of the same order as in the previous cases. In no case could the cyanidin be restored by increasing the acid concentration. Model experiments on the hydrolysis of cyanin with 2 or 4 N aqueous hydrochloric acid at 100° yielded calculated amounts of cyanidin provided the hydrolysis was carried out in darkness. Thus it was possible to determine spectrophotometrically the cyanidin concentration in hydrolysed extracts of the "Dandy" anthocyanin.

In this connection the effect of the solvent on the main absorption peak of cyanidin and its glycosides should be mentioned. Thus the absorption maximum of cyanidin in 0.1 N 80—100 % ethanolic hydrochloric acid is at 545 mμ moving towards shorter wave-lengths on further decrease of ethanol concentration. In a solution containing 20 % ethanol the maximum lies at 530 mμ. Variations in the acid concentration has no influence provided this concentration is high enough to prevent colour-base formation. Similar solvent effects have been reported by Sondheimer and Kertesz [6] in case of 3-glucosidopelargonidin.



The amount of arabinose in the hydrolysed extracts of the "Dandy" anthocyanin was determined after removal of the aglycone using the orcinol-ferric chloride method described by Fernell and King [7] and the glucose was quantitatively determined directly by the revised anthrone method [1] applying corrections for arabinose and cyanidin. The results of these estimations gave a cyanidin:glucose:arabinose ratio of approximately 1:1:1.

The position of carbohydrate attachment was determined by identification of the compounds obtained on acid and alkaline hydrolysis of the product of methylation of the anthocyanin with dimethyl sulphate in aqueous alkaline solution. In such strongly alkaline solutions the heterocyclic ring of the anthocyanins is broken and chalkones formed but only when the 5-hydroxyl is blocked by a sugar molecule can the anthocyanidin methyl ether be reformed on acid hydrolysis [8]. Thus on methylation of cyanin (I), the chalkone (II) is obtained which yields (III) on hydrolysis.



Methylation and subsequent acid hydrolysis of the "Dandy" anthocyanin yielded an anthocyanidin methyl ether indicating that carbohydrate is attached to the 5-hydroxyl. In order to investigate the possibility of further glycosidation in the aromatic nuclei the cyanidin methyl ether was hydrolysed with 10 % aqueous sodium hydroxide solution, a treatment known to degrade 3-hydroxyflavylium compounds and anthocyanins to a phloroglucinol component and an acid component [9], but no compound could be isolated. Experiments with a

I

II

III

3',4',5,7-tetra-*O*-methyl cyanidin showed that relatively large amounts of material had to be used in order to obtain enough degradation products to be detected even by paper chromatography. However, it was found that alkali treatment of methylated cyanin without previous acid hydrolysis gave much better yields of degradation products. When this technique was applied to the "Dandy" anthocyanin, phloroglucinol dimethyl ether and veratric acid were identified (Table 2). Since the cyanidin methyl ether obtained on acid hydrolysis of the methylated "Dandy" anthocyanin, when run alongside 3',4',5,7-tetra-*O*-methyl and 3,3',4',5,7-penta-*O*-methyl cyanidin on paper chromatograms, showed R_F identity with the former compound it must be concluded that the sugars are attached to the 3- and 5-hydroxy-groups.

Partial hydrolysis of the anthocyanin with 1 % aqueous hydrochloric acid yielded a monoside which after separation on streak chromatograms by butanol-acetic acid-water and further purification by running in acetone-0.1 N hydrochloric acid (1:3) on hydrolysis showed the presence of cyanidin and glucose together with traces of arabinose (Table 1). The behaviour of the monoside in a number of specific tests (*i.e.* stability towards ferric chloride, colour in sodium carbonate solution and regeneration on acidification of an alkaline solution) was identical with that of mecocyanin and 3-glucosidocyanidin but different from that reported for 5-glucosidocyanidin [10] and shown by cyanidin and its 3',4',5,7-tetramethyl ether. Since León and Robinson [11] claim that they obtained 5-glucosidocyanidin on partial hydrolysis of cyanin, this latter compound was partially hydrolysed and the resulting monoside purified as described above. The monoside obtained showed all the above mentioned characteristics of a 3-glucoside. Both monosides, on methylation and hydrolysis with alkali, yielded phloroglucinol trimethyl ether and so conclusively proved to be 3-glucosidocyanidin. Consequently the "Dandy" anthocyanin must be 3-glucosido-5-arabinosidocyanidin. This compound has not previously been found to occur in Nature and is a new type of anthocyanin since all previously isolated pentose containing anthocyanins are of the type 3-pentose glucoside.

EXPERIMENTAL

Separation and purification of the "Dandy" anthocyanin. Petals (122 g) of the variety "Dandy" were crushed under 0.1 N ethanolic hydrochloric acid (600 ml), kept at 0° for one week and filtered (total solids 8.2 mg/ml, cyanidin 0.08 mg/ml). The extract was then stored at 0°.

Portions (25 ml) of the extract were applied to Whatman No. 3 MM paper 22 × 22" and the chromatograms developed with butanol-acetic acid-water (6:1:2). The separated anthocyanin band was cut out without previous drying and the glycoside eluted with 0.05 N aqueous hydrochloric acid as described in Part I. The eluate was applied as a streak to No. 3 MM paper and further purified by *iso*propanol-2 N hydrochloric acid. On elution as above the anthocyanin was tested for homogeneity on Whatman No. 1 paper in other solvents. Separation from a yellow fluorescing compound took place in acetone-0.1 N hydrochloric acid (1:3) and the whole eluate was rerun in this solvent. The anthocyanin solution obtained on eluting the final chromatograms was used for further investigation. R_F values and wave -lengths of maximum absorption of the "Dandy" anthocyanin and a few reference compounds are given in Table 1.

Identification of the anthocyanin. (a) *Qualitative hydrolysis.* A portion of the glycoside solution was made 2 N by the addition of concentrated hydrochloric acid and heated in the dark at 100° for 2 h., then cooled and the aglycone extracted with butanol. The extract was washed with water and after removal of the solvent the aglycone was dissolved in 0.1 N ethanolic hydrochloric acid. The aglycone was then identified by compairing its R_F values and main absorption maximum with those of synthetic standards [4] (Table 1).

The identification of the sugar components has been described in Part I of this series [1].

(b) *Quantitative hydrolysis.* (i) Determination of aglycone concentration. A portion of the glycoside solution (1 ml) and concentrated hydrochloric acid (0.5 ml) was heated at 100° in total darkness for 30 min. On cooling, the solution was diluted with ethanol to 10 ml. The concentration of the aglycone was determined spectrophotometrically, standards being determined in the same medium. (Cyanidin: λ_{max} 545 mμ, ε 29 270).

(ii) Determination of sugar concentration. Arabinose. A portion of the glycoside solution was made 2 N by the addition of concentrated hydrochloric acid and heated at 100° for 2 h. On cooling the aglycone was extracted with butanol, the extract washed with water and the combined mother liquor and washings made up to 25 ml. The arabinose concentration of this solution was determined by the orcinol-ferric chloride method [7] using a Fisher photoelectric colourimeter. No correction for glucose was necessary.

Glucose. Portions (5 ml) of the glycoside solution were taken to dryness in 3/4" test tubes. The glucose concentration was then measured directly using the revised anthrone method [1]. Glucose and arabinose standards were measured simultaneously and a blank containing the corresponding amount of cyanidin was similarly measured. Corrections for arabinose and cyanidin were then applied. Results: Cyanidin:glucose:arabinose = = 1:0.98:0.95; 1:0.96:0.87.

(c) *Determination of the position of sugar substituents.* A portion of the glycoside solution was carefully taken to dryness under reduced pressure at room temperature, and the glycoside was dissolved in 2—3 drops of 1 N aqueous sodium hydroxide solution. With extremely vigorous stirring freshly distilled dimethyl sulphate (0.5 ml) and 30 % aqueous sodium hydroxide (2 ml) were added dropwise during 1.5—2 h. in nitrogen atmosphere and the stirring was continued for another hour. A part of the mixture was neutralised with 2 N hydrochloric acid and made about 4 N with concentrated hydrochloric acid.

On heating at 100° for 30 min. the cyanidin methyl ether was extracted with chloroform, the extract washed with water and taken to dryness. The residue was dissolved in a small amount of acid ethanol and run on paper chromatograms alongside synthetic standards. Results are given in Table 2. To the remainder of the methylation mixture one half of its volume of 30 % aqueous sodium hydroxide was added and while nitrogen was passed through the solution, it was boiled for 4 h., acidified and boiled for 30 min. longer to hydrolyse any remaining glycosides. On cooling, the products of degradation were extracted with ether. The extract was washed free of acid and separated into a phenolic and an acid fraction. Both fractions were run on paper chromatograms alongside synthetic standards, the phenolic fraction in toluene-acetic acid-water (4:1:5)[13], the spots being made visible with Millons reagent or diazotised *p*-nitroaniline, the acid fraction in butanol saturated with 2 N ammonia, the spots in this case being rendered visible by spraying with dilute aqueous silver nitrate followed by phenol saturated with aqueous sodium hydroxide [13]. Results are given in Table 2.

Identification of the monoside. A final portion of the glycoside solution was carefully taken to dryness and heated with 1 % aqueous hydrochloric acid at 100° for 30 min. The mixture was cooled, applied as a streak to No. 3 MM paper and separated with butanol-acetic acid-water. The monoside was eluted with 0.05 N 70 % ethanolic hydrochloric acid and separated from free sugars on paper chromatograms run in acetone-0.1 N hydrochloric acid. On final elution the monoside was identified in the usual way. Results of this identification are given in the tables.

Cyanin was similarly partially hydrolysed and the 3-monoside identified as described above.

Mecocyanin was partially hydrolysed and the 3-monoside separated in the same way.

The reference compounds needed for this investigation were prepared by recorded methods.

The author gratefully acknowledges a grant from the *Finnish Academy*. Thanks are also due to Dr. T. Swain for the gift of cyanin and mecocyanin specimens.

Short Communications

A Diagram for the Determination of the Surface Tension of Mineral Oil Fractions (Hydrogenated and Non-hydrogenated) from their Kinematic Viscosity and Density

J. CORNELISSEN, O. HARVA and H. I. WATERMAN

Institute of Chemical Engineering, The University, Delft, Holland

In a recent publication [1] the present authors presented a method to determine the surface tension at 20°C in dynes/cm, σ_{20}, of *saturated* mineral oil fractions from their kinematic viscosity at 20°C in centistokes, ν_{20}, and refractive index, n_D^{20}. The values obtained by this method are generally as accurate as the experimental values.

In a second publication [2] a method was described to determine σ_{20} of *non hydrogenated* (original) mineral oil fractions from ν_{20}, n_D^{20} and the density at 20°C, d_4^{20}. Use was made of 5 cross-sections for constant ν_{20}-values of the ν-n-d space model [3-5]. Again good results were obtained.

It appears that the lines of constant σ_{20} values are straight and are running parallel to the n_D^{20} axis of the n, d-cross-sections. This means that for a constant

value of ν_{20} and d_4^{20} the value of σ_{20} is independent of the refractive index. Therefore it is possible to construct a diagram with the coordinates log ν_{20} and d_4^{20}, (Fig. 1). In the diagram lines of equal values of σ_{20} have been given.

This diagram has primarily been constructed for the determination of the surface tension of non-hydrogenated mineral oil fractions.

It appears however to be possible after the necessary extension of the diagram to use it also for the determination of σ_{20} of saturated oil fractions. The diagram (Fig. 1) has been tested on several (164) mineral oil fractions, with the results shown in Table 1. In this table the graphically determined σ_{20} values have been indicated by $(\sigma_{20})_{\text{pred.}}$, and the experimental values of σ_{20} by $(\sigma_{20})_{\text{exp.}} \cdot \Delta\sigma = (\sigma_{20})_{\text{pred.}} - (\sigma_{20})_{\text{exp.}}$ The hydrogenated mineral oil fractions are indicated by H.

As can be seen from the table the results obtained in the determination of the

surface tension at 20°C by means of the new method are as good as those obtained by means of the previous methods [1,2]. The advantages of the new method are that the surface tension at 20°C can be determined for hydrogenated as well as for non-hydrogenated mineral oil fractions by means of only one graph, using two, properly chosen, physical constants.

Die Verbreitung der Umbelliferose in der Pflanzenfamilie der Umbelliferen

ANDERS BÆRHEIM SVENDSEN

Pharmazeutisches Institut der Universität Oslo, Oslo-Blindern, Norwegen

Nach der Ermittelung der Konstitution der Umbelliferose [1] (2'-α-D-galactopyranosyl-2-α-D-glucopyranosyl-β-D-fructofuranose) haben wir es von Interesse gefunden, zu untersuchen, ob das neue Trisaccharid, das wir früher in 3—4 verschiedenen Doldenpflanzen nachgewiesen haben [2], ein allgemein vorkommender Bestandteil bei den Umbelliferen sei. Um diese Untersuchung durchführen zu können, haben wir Papierchromatographie benutzt. In einem Flüssigkeitsgemisch von Amylalkohol, Pyridin und Wasser ist es möglich, Trisaccharide — u.a. Raffinose und Umbelliferose — zu trennen. Die erwähnten Zucker passieren bei einer 20—24-stündigen Durchlaufschromatographie (Whatman Filtrierpapier No. 1) etwa 8 cm, beziehungsweise 10 cm.

In einigen der unten beschriebenen Fälle wurde nur der oberirdische Teil der Pflanze, in den meisten Fällen aber wurden sowohl der unterirdische als der oberirdische Teil untersucht; in einigen Fällen wurden sogar Wurzel, Stengel, Blatt, Blumendolde und Dolde mit unreifen, grünen Früchten je für sich untersucht. In sämtlichen Fällen konnte die Umbelliferose in allen Teilen der Pflanze nachgewiesen werden. Die Menge schien von Art zu Art und von Pflanzenteil zu Pflanzenteil etwas zu variieren, ohne dass diese quantitative Frage vorläufig näher behandelt wurde. Neben der Umbelliferose haben wir in allen untersuchten Arten bedeutende Mengen von Saccharose und kleine Mengen von Monosacchariden gefunden. Bei den Untersuchungen wurde wegen der Gefahr eines enzymatischen Abbaus der Umbelliferose immer frisches Pflanzenmaterial nach Stabilisierung in kochendem Alkohol verwendet.

Nachstehend sind die untersuchten Arten tabellarisch zusammengestellt. Sämtliche enthalten Umbelliferose.

Aegopodium podagraria L.
Aethusa cynapium L.
Angelica archangelica L.

surface tension at 20°C by means of the new method are as good as those obtained by means of the previous methods [1,2]. The advantages of the new method are that the surface tension at 20°C can be determined for hydrogenated as well as for non-hydrogenated mineral oil fractions by means of only one graph, using two, properly chosen, physical constants.

Die Verbreitung der Umbelliferose in der Pflanzenfamilie der Umbelliferen

ANDERS BÆRHEIM SVENDSEN

Pharmazeutisches Institut der Universität Oslo, Oslo-Blindern, Norwegen

Nach der Ermittelung der Konstitution der Umbelliferose [1] (2'-α-D-galactopyranosyl-2-α-D-glucopyranosyl-β-D-fructofuranose) haben wir es von Interesse gefunden, zu untersuchen, ob das neue Trisaccharid, das wir früher in 3—4 verschiedenen Doldenpflanzen nachgewiesen haben [2], ein allgemein vorkommender Bestandteil bei den Umbelliferen sei. Um diese Untersuchung durchführen zu können, haben wir Papierchromatographie benutzt. In einem Flüssigkeitsgemisch von Amylalkohol, Pyridin und Wasser ist es möglich, Trisaccharide — u.a. Raffinose und Umbelliferose — zu trennen. Die erwähnten Zucker passieren bei einer 20—24-stündigen Durchlaufschromatographie (Whatman Filtrierpapier No. 1) etwa 8 cm, beziehungsweise 10 cm.

In einigen der unten beschriebenen Fälle wurde nur der oberirdische Teil der Pflanze, in den meisten Fällen aber wurden sowohl der unterirdische als der oberirdische Teil untersucht; in einigen Fällen wurden sogar Wurzel, Stengel, Blatt, Blumendolde und Dolde mit unreifen, grünen Früchten je für sich untersucht. In sämtlichen Fällen konnte die Umbelliferose in allen Teilen der Pflanze nachgewiesen werden. Die Menge schien von Art zu Art und von Pflanzenteil zu Pflanzenteil etwas zu variieren, ohne dass diese quantitative Frage vorläufig näher behandelt wurde. Neben der Umbelliferose haben wir in allen untersuchten Arten bedeutende Mengen von Saccharose und kleine Mengen von Monosacchariden gefunden. Bei den Untersuchungen wurde wegen der Gefahr eines enzymatischen Abbaus der Umbelliferose immer frisches Pflanzenmaterial nach Stabilisierung in kochendem Alkohol verwendet.

Nachstehend sind die untersuchten Arten tabellarisch zusammengestellt. Sämtliche enthalten Umbelliferose.

The Electrostatic Model for Calculation of the Ligand Field Parameter of Octahedral Complexes

OLE BOSTRUP and
CHR. KLIXBÜLL JØRGENSEN

Chemistry Departments B and A, Technical University of Denmark, Copenhagen, Denmark

Since 1951, several authors [1,2] have applied the ligand field theory to the absorption spectra of octahedral complexes with partly filled d-shells and found very good agreement with the observed energy levels, provided that reasonable values are chosen for the ligand field parameter Δ (also denoted by $(E_1 - E_2)$ or $10\,Dq$ or $\frac{10}{21}\,K$), the energy difference between the high γ_3-orbital and the low γ_5-orbital (containing at most four and six electrons, respectively). All the wavenumbers of the Laporte-forbidden bands can be expressed as multiples of Δ plus linear combinations of term distances, which seem [3] to have somewhat smaller values for complexes than the corresponding gaseous ions.

When the observed values of Δ are compared, many regularities are conspicuous, which support the value of the treatment: For a given ligand, Δ increases with the oxidation state of the central ion and with the principal quantum number 3d, 4d, and 5d. For a given central ion, Tsuchida's spectrochemical series can be expressed as increasing values of Δ, depending mainly on the atom in the first coordination sphere:

$$\mathrm{Br} < \mathrm{Cl} < \mathrm{F} < \mathrm{O} < \mathrm{N} < \mathrm{C} \quad (1)$$

Ilse and Hartmann [4] applied an electrostatic model to explain the absolute value of Δ. Six point charges q, representing the ligands, perturb a hydrogen-like 3d-wavefunction yielding an energy difference in atomic units between the two possible energy levels γ_3 and γ_5:

$$\Delta \cong \frac{8}{27} q \cdot \frac{Z_*}{3} \cdot G_4\left(\frac{Z_*}{3} \cdot R\right)$$
$$\text{where } G_4(x) \cong \frac{14\,175}{8x^5} \quad (2)$$

where Z_* is the effective charge acting on the hydrogen-like 3d-wavefunction and R the distance between the centre of the metal ion and the point charge. However, the actual 3d-radial function cannot be hydrogen-like; *e. g.* in a nickel(II) ion, the potential near the nucleus must necessarily correspond to $Z = 28$ and for large distances r to $Z = 3$, while Z_* is some average value between these two limits. Recently, Hartree [5] calculated self-consistent field functions (with exchange) for gaseous ions which support this qualitative argument: When compared to a hydrogen-like function with the same average distance r of the electron from the nucleus, Hartree's function is larger both for small values of r (giving a smaller r_{max}) and for large values of r (vanishing more slowly, corresponding to the external charge plus one), while it is smaller for intermediate r. Thus, it will be more generally valid to write eqn. 2 in the more old-fashioned way, discussed by Belford [6]:

The Electrostatic Model for Calculation of the Ligand Field Parameter of Octahedral Complexes

OLE BOSTRUP and
CHR. KLIXBÜLL JØRGENSEN

Chemistry Departments B and A, Technical University of Denmark, Copenhagen, Denmark

Since 1951, several authors [1,2] have applied the ligand field theory to the absorption spectra of octahedral complexes with partly filled d-shells and found very good agreement with the observed energy levels, provided that reasonable values are chosen for the ligand field parameter Δ (also denoted by $(E_1 - E_2)$ or $10\,Dq$ or $\frac{10}{21}\,K$), the energy difference between the high γ_3-orbital and the low γ_5-orbital (containing at most four and six electrons, respectively). All the wavenumbers of the Laporte-forbidden bands can be expressed as multiples of Δ plus linear combinations of term distances, which seem [3] to have somewhat smaller values for complexes than the corresponding gaseous ions.

When the observed values of Δ are compared, many regularities are conspicuous, which support the value of the treatment: For a given ligand, Δ increases with the oxidation state of the central ion and with the principal quantum number 3d, 4d, and 5d. For a given central ion, Tsuchida's spectrochemical series can be expressed as increasing values of Δ, depending mainly on the atom in the first coordination sphere:

$$\mathrm{Br} < \mathrm{Cl} < \mathrm{F} < \mathrm{O} < \mathrm{N} < \mathrm{C} \quad (1)$$

Ilse and Hartmann [4] applied an electrostatic model to explain the absolute value of Δ. Six point charges q, representing the ligands, perturb a hydrogen-like 3d-wavefunction yielding an energy difference in atomic units between the two possible energy levels γ_3 and γ_5:

$$\Delta \cong \frac{8}{27} q \cdot \frac{Z_*}{3} \cdot G_4\left(\frac{Z_*}{3} \cdot R\right)$$
$$\text{where } G_4(x) \cong \frac{14\,175}{8x^5} \quad (2)$$

where Z_* is the effective charge acting on the hydrogen-like 3d-wavefunction and R the distance between the centre of the metal ion and the point charge. However, the actual 3d-radial function cannot be hydrogen-like; *e. g.* in a nickel(II) ion, the potential near the nucleus must necessarily correspond to $Z = 28$ and for large distances r to $Z = 3$, while Z_* is some average value between these two limits. Recently, Hartree [5] calculated self-consistent field functions (with exchange) for gaseous ions which support this qualitative argument: When compared to a hydrogen-like function with the same average distance r of the electron from the nucleus, Hartree's function is larger both for small values of r (giving a smaller r_{max}) and for large values of r (vanishing more slowly, corresponding to the external charge plus one), while it is smaller for intermediate r. Thus, it will be more generally valid to write eqn. 2 in the more old-fashioned way, discussed by Belford [6]:

$$\Delta \cong \frac{5}{3} q \cdot \frac{\overline{r^4}}{R^5} \qquad (3)$$

As emphasized by Williams [7], it is a very peculiar feature of the series (1) that neutral ligands such as H_2O and NH_3 produce similar or larger values of Δ than OH^-, Cl^- and other anions. The effect has been explained [4,8] as a perturbation from six dipoles with the point dipole moment μ. It must be pointed out that the parameter μ has no connection at all with the dipole moment of the ligand; only the negative end of a polarized molecule will have any appreciable effect (eqn. 3) independent of the distance to the positive end. Generally, the spatial distribution of charge will have larger effects, according to eqn. 3, than identical charges concentrated on a point. Thus, Δ would be calculated as 3 000 K for $q = 1$, $Z_* = 7.2$ and $R = 2.51$ Å from eqn. 2, while the $CsNiCl_3$ studied by Asmussen and Bostrup[9] actually has $\Delta = 6\,900$ K, even though it contains octahedral environments, $NiCl_6$, of the dimensions given above. However, this can easily be explained by the assumption of spherically symmetrical charge distributions (yielding, of course, no proof for the validity of the electrostatic model), since the most important contribution to Δ is produced by the charge density just outside the nickel(II) ion with radius r_M.

If eqn. 3 is integrated for a sphere with radius r_L and charge q equally distributed in each volume element, one finds by neglecting the angular dependence of the perturbations from charge elements not on the axis containing the ligand's centre, that this expression can be derived:

$$\Delta \cong \frac{5}{12} q \cdot \frac{\overline{r^4}}{r_L^3 r_M^2} \qquad (4)$$

The double segment common to the ligand and the sphere with $r < r_0$ has the volume $\frac{1}{3}\pi h_1^2 (3r_0 - h_1) + \frac{1}{3}\pi h_2^2 (3r_L - h_2)$, which for r_0 not much larger than r_M and $r_L >> r_M$ ($\equiv h_1 >> h_2$) can be written $\pi h_1^2 r_0$, and thus, the volume element is $2\pi r(r - r_M)dr$ and the charge element is $\frac{3r(r-r_M)}{2r_L^3} dr$, which then can be integrated from r_M outwards.

The expression (3) might of course be evaluated for different charge distributions, taking also the angular dependence of the perturbations into account; but these results would not have sufficiently quantitative significance, relative to the necessary effort. The important feature of eqn. 4 is that Δ is much increased, since $r_L^{-3} r_M^{-2}$ generally is larger than $4(r_L + r_M)^{-5}$; i. e. for $r_L = 1.8$ Å and $r_M = 0.7$ Å it is increased by a factor 9. The proportionality to r_L^{-3} seems confirmed to a certain degree by the series (1), even though the low values of Δ for halide complexes (see the Table) may also be connected with π-bonding in the direction from the ligand to the central ion[3].

Ligands:	6 Br^-	6 Cl^-	6 H_2O	6 NH_3
Nickel(II)[9]	6 500	6 900	8 500	10 800
Rhodium(III)[2]	18 900	20 300	27 000	33 900

The latter trend of thought was initiated by Van Vleck [10], who demonstrated that the molecular orbital theory, assuming partly covalent bonding, implies nearly the same results as the electrostatic model. While much evidence for partly covalent bonding can be derived from the decrease of the F^k-integrals, relative to the gaseous ions [11], the most conspicuous difficulty for the electrostatic theory, assuming pure d-orbitals, is the extension of the d-electrons. There is no doubt that a considerable amount of the partly filled shell in the gaseous ion is present [5] outside the crystallographic radius of the metal ion $\sim 0.5 - 0.8$ Å, and this effect is further accentuated in the complexes [3,11]. However, the values of Δ do not seem very much changed from those predicted by the electrostatic model. It is a rather general feature of the theoretical chemistry that the covalent and ionic structures have nearly the same energy, and the intermixing of them therefore does not produce large relative energy differences between the possible excited levels. Actually, the electrostatic model can be considered as yielding the perturbations, which are the further cause of introducing overlap with certain of the ligands' orbitals, as described by the group theory, of which the results are common to both theories.

Recently, several authors have attempted the difficult task of determining the absolute value of Δ from combined electrostatic and molecular orbital theory. Kleiner [12] considered it impossible to apply the electrostatic theory to $Cr(H_2O)_6^{+++}$, since Δ turned out to be slightly negative. However, it can easily be seen that this is caused by the neglect of orthogonality of

the d-wavefunction with the neighbourhood of the oxygen nuclei, since Hartree's function still has a large value there. From a magnetochemical study of FeF_2 and CoF_2, rather small electrostatic field splittings have been obtained [13], which nearly disappear or are reversed by introduction of the overlap. The level scheme does not agree well with the optical spectra of similar compounds, while Tanabe and Sugano [14] have taken up again the chromium(III) problem. Even though Δ turns out to be of the right order of magnitude, it is a small effect as a difference between large quantities. So far, the electrostatic model seems still useful as a first order approximation, and there is much evidence that the partly covalent bonding * has not yet reached the Pauling limiting value [11], even for cobalt(III) and rhodium(III) complexes, while manganese(II) and nickel(II) complexes of the first transition group are nearer to the electrostatic case.

* Recently, Tinkham [15] investigated the binding of fluoride to Mn(II), Fe(II), Co(II), and Cr(III) by hyperfine-structure of paramagnetic resonance. It was concluded that both 2s, 2p, 3s, and 3p orbitals of fluorine are included, implying very complicated and uncertain expressions for the absolute magnitude of Δ.

Absorption Spectra of Red Uranium(III)Chloro Complexes in Strong Hydrochloric Acid

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Someya [1] reported that solutions of uranium(III) are red in concentrated hydrochloric acid, while they are greyish green in less acidic solutions. Fig. 1 gives the absorption spectra of grey uranium (III) solutions, which are identical in 2 M and 6 M HCl (and practically coincident with the spectrum, reported by Stewart [2] of the U(III) aquo ion in 1 M $HClO_4$), and of a dark red solution in 11 M HCl. Since the normal redox potential [3] of U(III):U(IV) is -0.64 V, a hydrogen activity, corresponding to 10^{21} atm would be necessary to render the U(III) solutions thermodynamically stable; however, amalgamated zinc can in most cases produce a stationary state after one day, containing $\sim$ 80 % U(III). It cannot be argued that the colour of the grey solution in 6 M HCl is caused by admixed pale green [4] U(IV), since it turns red by addition of a large excess of 12 M HCl after removal of the zinc.

The present author [5] identifies the narrow bands of grey U(III) in the visible as Laporte-forbidden transitions from the groundstate 5 $f^3\ {}^4I_{9/2}$ to the other $5f^3$-levels, while the high and broad bands in the ultraviolet have $5f^26d$-levels as excited levels, to which the transitions are allowed by Laporte's rule. Similar $f^n \rightarrow f^{n-1}d$ transitions have been observed [5] of Ce(III), Sm(II), Eu(II), Pa(IV), Np(III), and Pu (III). The individual $5f^26d$-levels are not easily identified; in U(III) both the ligand

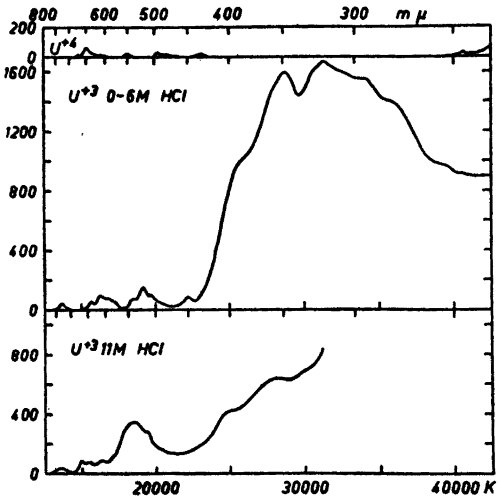

Fig. 1. The absorption spectra of uranium (IV) aquo ions [4] in $HClO_4$ and of 0.001 M to 0.008 M uranium(III) in 2 M—6 M HCl (several solutions of the grey form) and in 11 M HCl (the dark red chloro complexes). Measured on a Cary spectrophotometer at 25°C. The content of U(IV) is corrected [2] for from the absorption ~ 650 mμ. The half-life time for spontaneous evolution of hydrogen is ~ 10 minutes in 11 M HCl and longer in more dilute acids.

field parameters and the intermediate coupling (*i. e.* ζ_{5f} and ζ_{6d}) are not small compared to the energy differences between the multiplet terms with given values of L and S, while usually only one of these conditions prevails (in the d^n-complexes and in the lanthanides, respectively). Thus most of the $\frac{14 \cdot 13}{2} \cdot \frac{10}{2} = 455$ possible $5f^2 6d$-levels may have different energy. In addition to the two principal peaks [2] at 350 and 319 mμ, the shoulders at 390, 327, 294, 280, and ~ 250 mμ are probably caused by such levels or by superposed f^n-transitions. It is remarkable that the broad bands seem only to occur [2] in a range between 400 and 250 mμ.

The narrow f^2-peak at 521 mμ is shifted to a comparatively broad and high band at 540 mμ, having an area and thus an oscillator strength ~ 5 times larger for the red solution in 11 M HCl than for the grey aquo ion. (The reflection spectrum [6,7] of anhydrous UCl_3 exhibits a similar shift to ~ 545 mμ, compared to [7] ~ 510 mμ for UF_3). In the ultraviolet, the $5f^2 6d$-bands are lower and shifted towards higher wavelengths; only the shoulders at 401, 361, and 330 mμ can be observed, because U(IV) in 12 M HCl (as UCl_6^{--}?) has an electron transfer band at 286.5 mμ (ε = 2 300, δ (−) = 1 400 K), which is shifted towards shorter wavelengths by dilution and has disappeared in 4 M HCl. The U(IV) aquo ion is remarkably non-absorbing in the ultraviolet [4] (see the Figure). U(III) in 9 M HBr has a spectrum similar to that of the grey solutions in < 6 M HCl.

It cannot be completely excluded that the red colour in 11 M HCl is caused by a mixed oxidation state U(III, IV) analogous to Ti(III, IV)[8]. However, it is much more probable that a chloro comples of U(III) is formed. Actually, the actinides exhibit other exchange ion properties in strong HCl than do the lanthanides [9], and recently, Ward and Welch [10] reported equilibria between chloride ions and Pu (III), Am(III), and Cm(III): The decreased affinities to cation exchange resins imply formation constants of the monochloro complexes of all three metals equal to 15, when extrapolated to infinite dilution, and 1 to 2.5 in the actual solutions. Further, Pu(III)is strongly bound to anion exchangers in 12.6 M HCl (implying the partial presence of $PuCl_4^-$ or higher complexes). This is not the case for Am(III) or Cm (III) in 12.6 M HCl, nor for Pu(III) in 10 M HCl. Kraus, Moore and Nelson [11] have made a comparative study of quadrivalent metals in HCl and found strong adsorption on anion exchangers of U(IV) above 5.5 M and of Zr(IV) above 7 M HCl, while Th(IV) was not extracted at all.

It is surprising that the trivalent actinides (and also Ce(III)[10]) should occur mainly as monochloro complexes in 1 M HCl, since no change of absorption spectrum can be observed below 6 M HCl. Thus, Hindman [3] investigated Pu(III), and the spectrum of Nd(III)[12] changes only above 6 M HCl. Of course, the f^n-transitions might be less perturbed than the $f^n \rightarrow f^{n-1}d$ transitions. However, the three high bands of Ce(III) at 253, 240, and 222 mμ are identical within the experimental uncertainty of 0.002 M $CeCl_3$ in H_2O, 1 M, 3 M, and 5 M HCl. Only in stronger HCl, a new spectrum appears [12]. The evidence for U(III) in this note is analogous.

It may be questioned whether the chloro complex formation, implied by physicochemical methods, apply to association in the second co-ordination sphere (analogous to $Co(NH_3)_6^{+++}$, I^-) or to substitions of water in the first co-ordination sphere. The old statement that changes of the absorption spectra occur only in the latter case [13] has been highly justified for d^n-transitions in the recent years. The present author believes that the first co-ordination sphere of the aquo ions of trivalent lanthanides and actinides is not changed to a large extent in solutions, containing less than 4 M HCl, while in concentrated HCl actual complexes are formed with one or more chloride ions bound directly to the central ion. J. Bjerrum [14] investigated the case of Cu(II) and the strongly increasing chloride activity of strong HCl. The mass-action law on concentration units is very far from being valid; this is probably caused by the strong tendency towards dehydration of the aquo ions in strong HCl of low H_2O-activity [15]. It is interesting that Katzin effect [16], *i. e.* that complexes with anions are much more readily formed in anhydrous alcohols than in aqueous solutions or in alcohols with 10 % water content, can be described a similar dehydration effect: the spectral changes of Ce(III) in above 10 M aqueous HCl are reproduced by 0.002 M $CeCl_3$ alone in absolute ethanol[12], but not of $Ce(ClO_4)_3$. Thus, water (and amines) have an extraordinarily large tendency to occupy the whole of the first co-ordination sphere (rather independently of the dielectric constant of the solvent), thus displacing anions to form second-sphere associates or leading to complete ionic dissociation.

The Hump of Ionization Potentials at Half-Filled Shells and the Influence of Spin-Pairing Energy on Standard Oxidation Potentials

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Recently, many properties of chemical complexes have been related to atomic spectroscopy [1]. Especially, the ligand field stabilization of partly filled d-shells has been evaluated [2] in terms of the parameter Δ (also called $(E_1\text{-}E_2)$ or 10 Dq), determined from the absorption spectra.

The standard oxidation potentials [3] (with the opposite sign of that used by Latimer) express the ionization potentials in aqueous solutions when corrected for the energy necessary for the reaction $\frac{1}{2}H_2 \rightarrow H_{aq}^+ + e^-$. Since the latter energy probably is between 4.5 and 5 eV, the ionization potentials in solution are much lower, 4—7 eV, than for the gaseous ions known from atomic spectroscopy [4]. The divalent and trivalent hexaaquo ions of the first transition group represent the only case where the redox potentials are known for systems having several different numbers of d-electrons. In Table 1, these potentials [3] are corrected for the influence of ligand field stabilization [2] (1 eV = 8 067

It may be questioned whether the chloro complex formation, implied by physicochemical methods, apply to association in the second co-ordination sphere (analogous to $Co(NH_3)_6^{+++}$, I^-) or to substitions of water in the first co-ordination sphere. The Hump of Ionization Potentials at Half-Filled Shells and the Influence of Spin-Pairing Energy on Standard Oxidation Potentials

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Recently, many properties of chemical complexes have been related to atomic spectroscopy [1]. Especially, the ligand field stabilization of partly filled d-shells has been evaluated [2] in terms of the parameter Δ (also called $(E_1\text{-}E_2)$ or 10 Dq), determined from the absorption spectra.

The standard oxidation potentials [3] (with the opposite sign of that used by Latimer) express the ionization potentials in aqueous solutions when corrected for the energy necessary for the reaction $\frac{1}{2}H_2 \rightarrow H_{aq}^+ + e^-$. Since the latter energy probably is between 4.5 and 5 eV, the ionization potentials in solution are much lower, 4—7 eV, than for the gaseous ions known from atomic spectroscopy [4]. The divalent and trivalent hexaaquo ions of the first transition group represent the only case where the redox potentials are known for systems having several different numbers of d-electrons. In Table 1, these potentials [3] are corrected for the influence of ligand field stabilization [2] (1 eV = 8 067

Table 1.

Ionization Process	V(II)→(III)	Cr(II)→(III)	Mn(II)→(III)	Fe(II)→(III)	Co(II)→(III)
Standard oxidation potential	—0.25 V	—0.41 V	+1.5 V	+0.77 V	+1.84 V
$\triangle$ of divalent ion	12 600 K	13 900 K	7 800 K	10 400 K	9 700 K
Stabilization of divalent ion	15 100 K	8 300 K	0 K	4 200 K	7 800 K
$\triangle$ of trivalent ion	18 600 K	17 400 K	21 000 K	13 700 K	18 600 K
Stabilization of trivalent ion	14 900 K	20 900 K	12 600 K	0 K	44 600 K —37 000 K
Ligand field correction	—200 K	+12 600 K	+12600 K	—4 200 K	—200 K
Corrected potential	—0.27 V	+1.10 V	+3.0 V	+0.25 V	+1.82 V

K (= cm^{-1})). In the case of tetragonally distorted d^4-systems [2], *viz.* Cr(II) and Mn (III), the stabilization is assumed to be expressed by the increased value of $\triangle$. In the case of the diamagnetic d^6-system Co(III), it is necessary to correct for the large energy $5\ B + 8\ C$ in atomic term differences [5], necessary to obtain the large stabilization $-\ 2.4\ \triangle$ of the magnetically anomalous groundstate.

The last row in the table demonstrates that the oxidation potentials, when corrected for the ligand field stabilization, regularly increase 1.5 V per unit of atomic number, Z, except between manganese and iron, where a hump $\sim$ 4 V occurs. This hump can be ascribed to the special stability of half-filled shells with the maximum value of the total spin S. Actually, the ionization potentials of neutral Al, Si, P, S, Cl, A demonstrates a similar hump $\sim$ 3.4 eV at p^3 besides the regular increase $\sim$ 2.6 eV per unit of Z (*cf.* Koefoed [6]). Orgel [7] and Griffith [8] have recently discussed the spin-pairing energy necessary for formation of magnetically anomalous complexes (*cf.* Co(III) in the table). For a given d^n-electron configuration, the energy necessary in average [9] (of all the terms with the same S) to decrease S by one unit is $S\left(\frac{35}{6}B + \frac{7}{3}C\right) \sim S \times 14\,000$ K. The theoretical comparison of spin-pairing energies in different electron configurations is not as easy; the hump seen from the Table suggests that the ionization process necessitates 32 000 K less energy, when it increases S by a half unit rather than to decrease it. Actually, this value is comparable to the 37 000 K spin-pairing energy of Co(III) from $S = 2$ to $S = 0$.

The ionization potentials [4] of the gaseous divalent d^n-ions are in eV for Sc 24.75, Ti 28.14, V 29.7, Cr 30.95, Mn 33.69, Fe 30.64, Co 33.49, Ni 36.16, Cu 36.83 and for Zn 39.70, corresponding to an increase of 2.2 eV for each unit of Z, and a d^5- hump = 4.8 eV. The small irregularities can be explained, if it is assumed that ions with F-groundstates are stabilized $\frac{3}{10} \cdot 15\ B \sim 4\,000$ K, relative to ions with D- or S-groundstates. Thus, the corrected Cr(II): Cr(III) oxidation potential is also somewhat too low, because the transition is from ^5D to ^4F. Since the similar increase is 1.5 eV per unit of Z for the hexaaquo ions, it can be concluded that the aquation stabilization increases 0.7 eV more for the trivalent than for the divalent ions per unit of Z, corresponding to smaller ionic radii and larger electric potentials near the trivalent ions.

By extrapolation from the table it can be shown that the standard redox potentials would be:

Sc(II) → Sc(III)	— 2.7 V
Ti(II) → Ti(III)	— 1.6
Ni(II) → Ni(III)	+ 3.1
Cu(II) → Cu(III)	+ 2.6
Zn(II) → Zn(III)	+ 4.8

assuming $\triangle$ = 12 000 K for the divalent and 20 000 K for the trivalent ions, and no formation of magnetically anomalous complexes. Thus, Ti(II) is probably a stronger reducing agent than reported [3] (— 0.37 V), and Sc(II) should disproportionate to the metal and Sc(III) in aqueous solution.

Since the d^5-hump has no direct influence on the relative stability of different complexes of the same central ion (as has the competition between $\triangle$ and the spin-pairing energy in Co(III) complexes), it is not surprising that the ^6S-states of d^5 (or ^8S of f^7) exhibit smaller complex formation constants than their neighbours, due to the absence of ligand field stabilization. However, if the integrals of electrostatic interaction between the d-electrons,

forming a part of the d^5-hump energy differences, actually decrease in anion complexes, compared to complexes of neutral ligands [10], it cannot be excluded that this effect will produce a slight decrease of ligand field stabilization in the complexes with stronger partial covalent bonding.

Identification and Semiquantitative Determination of Phenyl Thiohydantoins

PEHR EDMAN and JOHN SJÖQUIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

In an earlier paper [1], one of us described a paper chromatographic procedure for identification of the phenyl thiohydantoin (PTH) derivatives of natural amino acids. The procedure has now been improved in a way, that permits a semiquantitative determination based on the strong ultraviolet absorption of the PTH. This called for a method of locating the PTH's on the paper without destroying them and also for a low background absorption. For the first purpose a low pressure mercury lamp and a fluorescent screen with excitation in the appropriate ultraviolet region and emission in the visible were used *. In order to cut out the visible light from the mercury lamp a dye emitting in the visible red was used and observations were made through red glasses. The PTH's then appear on the paper as black spots on a red background. The lower limit of sensitivity is approx. 1 μg of PTH in a spot**. For a semiquantitative determination at least 5 μg in each spot is required. After location of the spot the area is cut out, the material extracted from the paper and its absorption measured. The yield varies between 75 and 105 %, the lower figure usually being obtained for the PTH's with highest R_F-values.

The solvents were chosen so that after drying the paper they did not leave material absorbing in the critical UV region around 270 mμ.

* Related procedures have been described for the location of steroids [2] and nucleic acid material [3] on paper chromatograms.

** For identification purposes the iodine-azide reaction [1] should afterwards be applied.

forming a part of the d^5-hump energy differences, actually decrease in anion complexes, compared to complexes of neutral ligands [10], it cannot be excluded that this effect will produce a slight decrease of ligand field stabilization in the complexes with stronger partial covalent bonding.

Identification and Semiquantitative Determination of Phenyl Thiohydantoins

PEHR EDMAN and JOHN SJÖQUIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

In an earlier paper [1], one of us described a paper chromatographic procedure for identification of the phenyl thiohydantoin (PTH) derivatives of natural amino acids. The procedure has now been improved in a way, that permits a semiquantitative determination based on the strong ultraviolet absorption of the PTH. This called for a method of locating the PTH's on the paper without destroying them and also for a low background absorption. For the first purpose a low pressure mercury lamp and a fluorescent screen with excitation in the appropriate ultraviolet region and emission in the visible were used *. In order to cut out the visible light from the mercury lamp a dye emitting in the visible red was used and observations were made through red glasses. The PTH's then appear on the paper as black spots on a red background. The lower limit of sensitivity is approx. 1 μg of PTH in a spot**. For a semiquantitative determination at least 5 μg in each spot is required. After location of the spot the area is cut out, the material extracted from the paper and its absorption measured. The yield varies between 75 and 105 %, the lower figure usually being obtained for the PTH's with highest R_F-values.

The solvents were chosen so that after drying the paper they did not leave material absorbing in the critical UV region around 270 mμ.

* Related procedures have been described for the location of steroids [2] and nucleic acid material [3] on paper chromatograms.

** For identification purposes the iodine-azide reaction [1] should afterwards be applied.

Another possible use of this procedure, in addition to the determination of the N-terminal amino acids, may be briefly referred to here. In conjuction with a micro procedure for the synthesis of PTH's from amino acids at present being developed in our laboratory [4] it can be used for amino acid analysis. It offers the advantages of rapidity, small material requirements (0.1 —0.2 mg of protein hydrolyzate) and noninterference of salts.

Experimental. *o*-Xylene is shaken three times with 1/10 vol. of conc. H_2SO_4 for 1/2 h with cooling to below 30° C. The organic phase is then washed with water, dried over KOH pellets overnight and distilled.

n-*Butyl acetate* is distilled and the fraction boiling at 126—127° C used.

Propionic acid is refluxed for 4 h with chromic acid (10 g/750 ml), distilled on a Widmer column and the fraction boiling at 140—141° C collected.

n-*Heptane* is shaken three times with 1/10 vol. of conc. H_2SO_4 and then washed successively with water, 10 % aqueous NaOH and water. It is finally dried over Na_2SO_4 and distilled.

Ethylene chloride, puriss (Fluka).

Formic acid, analytical reagent (Merck).

Formamide, analytical reagent (Fluka).

Filter paper. Whatman No. 1. Impregnation with starch prior to use [1] does not interfere with the quantitative determinations.

Fluorescent screen. A fine suspension of fluorescent cadmium borate * in acetone-amyl acetate (2:1) is sprayed evenly on to a 500 × 500 × 2 mm celluloid sheet, dried, and the operation repeated a number of times. When a good and even coverage has been obtained a hot solution of polyethylene in heptane is sprayed on to form a protective coating. The screen is more convenient to use if put in a frame in a slightly curved position.

Mercury lamp. Original Hanau NK 20/40 with main UV emission at 254 mμ.

PTH-references. The synthesis of the PTH-amino acids has been described earlier [5-7]. A molar extinction coefficient in ethanol at 269 mμ of 14 000—16 000 applies to most PTH-amino acids with the exception of PTH-ε-phenyl thiocarbamyl lysine (ε_{269} = 29 000) and PTH-tryptophane (ε_{269} = 19 700). The reference solutions are made up in ethylene chloride (0.5—1.5 mg/ml) except PTH-arginine and PTH-histidine which owing to their low solubility in ethylene chloride are dissolved in hexanol. In solution the PTH-amino acids decompose slowly and should therefore be stored in the cold.

Solvent systems:

D. *o-Xylene/formamide.* The paper is dipped into a solution of formamide in acetone (2:7) and immediately placed horizontally on a filter paper to remove excess solution. The strip is then suspended for a few minutes in the air for the acetone to evaporate. Reference compounds and unknowns in appropriate solvents (*cf.* above) are applied to the paper, and descending elution of the chromatogram immediately started using *o*-xylene.

E. n-*Butyl acetate/propionic acid/formamide.* The paper strip is impregnated with formamide as described for solvent system *D*. The butyl acetate is saturated with water, 3 % (v/v) propionic acid added and this mixture subsequently saturated with formamide. The filter paper lining of the chromatography tank is moistened with the solvent mixture. The paper strip is allowed to equilibrate in the chamber for 1/2 h before starting development.

F. n-*Heptane/ethylene chloride/formic acid.* The upper phase obtained after mixing 1 vol. of *n*-heptane, 2 vols. of 75 % aqueous formic acid and 2 vols. of ethylene chloride is used for developing the chromatogram and the lower phase is poured on the filter paper lining of the chromatography tank. An equilibration time of 1/2 h is required.

For the semiquantitative determination a sample of the unknown (5—20 μg) is applied together with varying, known amounts of the corresponding PTH-reference compound. An empty lane serves as a blank. After development the paper is dried at 90° C for 10 min, the spots marked out on the paper with the aid of the fluorescent screen, and cut out with a margin of *ca.* 3 mm. An area corresponding in size and level is cut out from the blank lane. The spots are eluted with 1.5 ml of ethanol for 2 h at room temperature and the extinctions of the ethanolic extracts read at 269 mμ in a Beckman spectrophotometer model DU provided with micro cuvettes. The accuracy of a single determination is ± 10 % although the yield in absolute terms may be reduced to 75 % for the faster moving spots.

This work has been aided by a grant from Eli Lilly and Company to one of us (P. E.) which is gratefully acknowledged.

Isotope Effect in the Hydrolysis of Grignard Compounds. II *

LARS OLOF ASSARSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

Measurements of the hydrogen isotope effect in the hydrolysis of methylmagnesium iodide and phenylmagnesium iodide in a solution of anisole and pyridine were reported in a previous preliminary paper [1]. Pyridine, with its fairly basic character, and its ability to form addition products, may influence the reaction mechanism. The reactions have now been carried out in a more inert solvent, *i.e.* a mixture of anisole and tetrahydrofuran. The hydrolytic agent was in some of these experiments tritiated water and in others a tritiated mixture of water and hydrochloric acid.

The water was present in at least tenfold excess in all experiments and in the acid experiments the hydrogen chloride was present in twice the amount stoichiometrically needed. (The acid concentration in the acid-water mixture was about 18 % HCl by weight.) The technique was analogous to the one used earlier, *i.e.* the Grignard compound, dissolved in anisole-tetrahydrofuran, was added by means of an injection syringe or a dropping funnel to the water or the dilute hydrochloric acid, both dissolved in tetrahydrofuran. The anisole had been dried according to current methods, while the drying of the tetrahydrofuran was carried out by shaking it with anhydrous $CaCl_2$, thereafter with metallic sodium and finally by distilling it from methylmagnesium iodide. After the preparation of the phenylmagnesium halide, a fraction of the solvent was distilled off at reduced pressure in order to eliminate benzene formed by moisture or other side reactions. The mixture of anisole and tetrahydrofuran in the proportion used

dissolved the water or the hydrochloric acid, as well as the magnesium salts formed. The hydrocarbons produced were burnt over cupric oxide, and the radioactivity of the water formed, as well as that of the initial water used for the hydrolysis, was determined by means of a Geiger-Müller counter.

It should be noted that the yields of benzene from phenylmagnesium iodide were not very high. An experiment, done to find the approximate yield in the neutral hydrolysis, gave the result of about 20 %, determined by the method of isotope dilution. However, phenylmagnesium bromide seems to give better yields. In four of the five decompositions reported here the bromide was used.

The results, all obtained at 20°C, are given in Table 1. The reported values have not been corrected for the small change in the activity of the water or the dilute hydrochloric acid occurring during the reaction.

Experiments were also done with *tert.*-butylmagnesium bromide. However, in this case, it was found to be impossible to use tetrahydrofuran as solvent, because it reacts instantly with the Grignard compound with evolution of heat and formation of a white precipitate, after which it will give no gas on admixture with water. Probably other branched chain alkylmagnesium halides will react in the same manner. It has been known for a long time that Grignard compounds react with ethylene oxide [2] and trimethylene oxide [3].

Constituents of the Wood of *Juniperus communis* L.

JOHAN B-SON BREDENBERG and JARL GRIPENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

The neutral part of the extract of the wood of *Juniperus communis* L. contains, in addition to the previously reported sugiol, a substance which most probably is a mixture of ferruginol and some closely related compound, and also a yellow compound termed xanthoperol. Xanthoperol appears to be an artefact and a partial structure is suggested.

We have previously [1] reported the presence of sugiol in the wood of the common juniper (*Juniperus communis* L.). Although this work dealt primarily with the phenolic part of the extract, it could be demonstrated that sugiol occurred also in the neutral part.

A more thorough investigation of this neutral part has now been made. It was divided by steam distillation into a volatile and non-volatile fraction, and it is the investigation of the latter, which forms the subject of the present paper.

This fraction, which amounted to 1.8 % of the air-dried wood, was hydrolysed with alcoholic potassium hydroxide after preliminary experiments had shown that direct chromatography gave no useful results. The acids obtained in the hydrolysis were mainly fatty acids and no separation of them was attempted. The high equivalent weight of a crude preparation indicated, however, the presence of considerable amounts of acids higher than stearic acid.

The unsaponifiable part was chromatographed giving as a first fraction a thick oil, this being followed by two colourless crystalline compounds and finally a yellow compound.

The oil showed absorption at 280 mμ, indicating the presence of a phenol. Further attempted purification by chromatography followed by acetylation failed to give any crystalline material. However, vacuum distillation of the oil gave fractions from which a crystalline acetate could be obtained. This analysed for $C_{22}H_{32}O_2$, corresponding to the composition $C_{20}H_{30}O$ for the parent phenol. Hydrolysis of the acetate gave the phenol as an only partially crystalline material, which indicates that it is a mixture. As there is no reason to believe that the hydrolysis has caused any change in the phenol it can be assumed that even the acetate is a mixture, in spite of the fact that it behaves as a pure compound. The properties of both the acetate and the free phenol

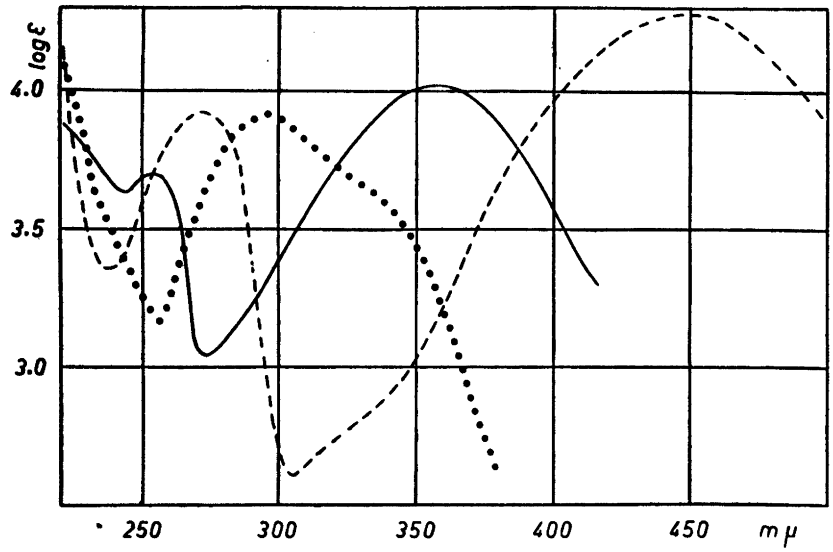

Fig. 1. Ultraviolet absorption curves of (————) *xanthoperol in ethanol,* (— — — —) *xanthoperol in 0.05 N sodium carbonate and* (. . . . . .) *xanthoperol acetate.*

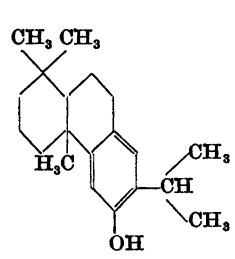
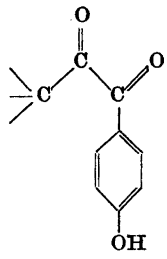
are rather close to those of ferruginol (I), previously isolated from the wood of some conifers [2], suggesting that the present material is a mixture of ferruginol with some other closely related compound, most probably the corresponding dehydroderivative.



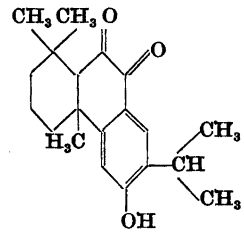
The two colourless compounds that are eluted from the chromatogram in the following fractions have been identified as sugiol and β-sitosterol.

The compound, which was most strongly absorbed on the column was obtained as yellow needles and melts between 255 and 270° with decomposition. It is optically active, with $[\alpha]_D^{20}$ +132,5° (ethanol) and has the composition $C_{20}H_{28}O_3$. The name xanthoperol is proposed for this apparently new compound. The nature of the three oxygen atoms can be deduced from the infra-red spectrum. This shows peaks at 3 436, 1 717 and 1 658 cm^{-1}, which can be attributed to a hydroxyl not involved in a chelate ring formation, an unconjugated ketone in an open chain or a six membered ring and a conjugated ketone, respectively. Further bands at 1 595, 1 567 and 1 502 cm^{-1} are attributed to an aromatic ring. A band at 883 cm^{-1} indicates the presence of isolated hydrogen atoms in the aromatic ring.

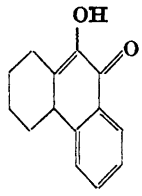


The presence of a hydroxyl group is further demonstrated by the formation of an acetate. That the hydroxyl is phenolic is shown by the large hypsochromic effect of acetylation and bathochromic effect of alkalinisation on its U.V.spectrum (see Fig. 1). This last mentioned shift (~ 90 mμ), taken together with the infra-red evidence presented above, points to the presence of a carbonyl group in the *p*-position to the phenolic hydroxyl, although the shift is even larger than those usually given by this grouping [3,4]. The p*K*-value, which is lower than 8.5 is also in agreement with the presence of such a grouping. The

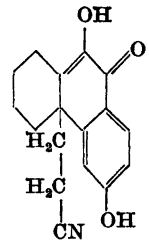
yellow colour indicates either a 1,2-diketone or a quinone. The latter is, however, incompatible with the infra-red absorption in the carbonyl region.



The facts mentioned above lead to the proposal of the partial structure (II), where the aromatic ring must carry at least two substituents in such positions that there are no adjacent hydrogen atoms.



I



II

III

IV

V

The obvious extension of this to the complete formula (III) must be regarded with some doubt, because such a structure ought to exist mainly in the enolic form. Parham *et al.*[5] have synthesised the compound IV and Gates [6] the compound V. In neither case is there any evidence for the presence of the diketo form.

That xanthoperol does not exist as such in the wood can be seen from the fact that no yellow zone corresponding to that of xanthoperol is observed when chromatographing the material before hydrolysis. This has also been confirmed by a spectrophotometric investigation of fractions obtained in this way. There was in no fraction any selective absorption at 350 mμ in neutral or at 450 mμ in alkaline medium, characteristic of xanthoperol. After hydrolysis certain fractions showed these maxima, indicating that xanthoperol had been formed.

Experiments are in progress aimed at establishing the structure of xanthoperol and its precursor, as well as the nature of the ferruginol-like mixture.

EXPERIMENTAL

(All m.p.s are determined on a Kofler microscope. The microanalyses have been performed by Dr. A. Bernhardt, Mülheim.)

Separation of the compounds. The non-steam volatile portion of the neutral extract [1] was dissolved in ethanol and heated on a water bath with 2 N potassium hydroxide for 2 h. The ethanol was evaporated in a stream of carbon dioxide and water and ether were added. A gelatinous precipitate was thereby formed. The aqueous phase gave, after acidification and recrystallisation from methanol, a mixture of acids, m.p. 61 – 64°, equiv. wt. 308.

The precipitate and the ether soluble part were chromatographed separately but found to yield essentially the same results. Chromatography was carried out on standardised alumina using light petroleum as solvent and light petroleum-ether mixtures followed by ether as eluent, the appropriate fractions being combined.

Light petroleum eluted a comparatively large amount of a non-crystalline material. Ether-containing light petroleum eluted first sugiol, followed by a sterol, and finally the yellow xanthoperol. The last mentioned came out just before changing to ether as eluent. Further elution with ethanol-containing ether or pure ethanol failed to give any recognisable substances.

The non-crystalline light petroleum eluate (36.2 g) was distilled under vacuum. After a forerun boiling at 94—185°/0.2 mm, two main fractions b.p. 175—185°/0.15 mm (7.6 g) and b.p. 185—205°/0.1 mm (7.4 g) were obtained. The residue (18.3 g) was a dark brown resin. The first fraction was acetylated and the acetate subjected to chromatography. Elution with light petroleum gave a crude crystalline acetate, m.p. 50—60° (5.2 g). Acetylation of the second fraction and seeding with crystals from the first one gave a further amount (2.8 g) of the acetate. Recrystallisation from methanol furnished the acetate as colourless rods, m.p. 92—93°, $[\alpha]_D^{20}$ −9±1° (c = 1.5; ethanol). (Found: C 80.6; H 9.7; O 9.9; mol.wt. (Rast) 329. $C_{22}H_{32}O_2$ requires C 80.4; H 9.8; O 9.7; mol.wt. 328.5). λ_{max} (in ethanol) 268 mμ (log ε 3.71).

Hydrolysis with N potassium hydroxide and chromatography in light petroleum-ether mixture gave the free phenol as a semisolid mass, $[\alpha]_D^{15}$ +43 ± 1° (c = 1.5; ethanol), λ_{max} (in ethanol) 282 mμ (log ε 3.70). From this a small amount of crystals with m.p. 56—57° could be obtained.

The benzoate was obtained from the acetate (100 mg) by hydrolysis followed by benzoylation with benzoyl chloride in pyridine. After chromatography, crystallisation from methanol and sublimation it had m.p. 154.5—156° (yield 20 mg).

β-Sitosterol. Recrystallisation of the sterol from alcohol gave leaflets of m.p. 139—139.5,° $[\alpha]_D^{20}$ −35.5±1° (c = 1.0; chloroform). The acetate had m.p. 126—127°, $[\alpha]_D^{20}$ −41.3±1° (c = 1.0; chloroform), the benzoate m.p. 148—149°, $[\alpha]_D^{20}$ −13.0±1° (c = 1.0; chloroform) and the 3,5-dinitrobenzoate m.p. 203.5—205°, $[\alpha]_D^{20}$ −12.5±0.5° (c = 1.0; chloroform). All these values correspond well with those given for β-sitosterol [7].

Xanthoperol. Recrystallisation from benzene gave xanthoperol as yellow needles. It decomposes between 255 and 270°, $[\alpha]_D^{20}$ +132.5±2.5° (c = 1.2; ethanol). (Found: C 76.1; H 8.4; O 15.5; mol.wt. (Rast) 303. $C_{20}H_{26}O_3$ requires C 76.4; H 8.3; O 15.3; mol.wt. 314). IR-maxima: (KBr) 3 380 (s), 2 960 (m), 2 910 (m), 2 870 (m), 1 717 (m), 1 658 (s), 1 595 (s), 1 567 (s), 1 508 (m), 1 470 (m), 1 365 (w), 1 327 (s), 1 290 (s), 1 261 (s), 1 180 (m), 1 163 (m), 1 149 (m) 1 108 (w), 1 047 (w), 917 (w), 883 (w) cm^{-1}.

Xanthoperol is soluble in alkali and conc. sulphuric acid with a strong yellow colour. It gives no colouration either with ferric chloride, or with diazotised benzidine.

Xanthoperol acetate. Xanthoperol (20 mg) mixed with acetic anhydride (1 ml), and pyridine (3 drops) was allowed to stand for 3 days at room temperature. The mixture was poured into water and the precipitate recrystallised from dilute ethanol giving yellow rods (13.5 mg), m.p. 157.5—158.5°. (Found: C 74.0; H 7.95. $C_{22}H_{28}O_4$ requires C 74.1; H 7.9).

This work has been financially supported by a grant from *Statens Naturvetenskapliga Kommission*, which is gratefully acknowledged.

Studies on Arabogalactans

I. Products from the Mild Hydrolysis of the Arabogalactan from *Larix occidentalis*

HANS BOUVENG and BENGT LINDBERG

Organisk-kemiska Institutionen och Träkemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The arabogalactan from *Larix occidentalis* yielded a mixture of arabinose, galactose, two disaccharides and a small trisaccharide fraction when hydrolysed under conditions mild enough to cleave furanosidic linkages almost exclusively. One of the disaccharides was shown to be 3-β-L-arabopyranosyl-L-arabinose which had previously been obtained from a similar polysaccharide by Jones [1]. The other disaccharide was demonstrated to be 6-β-D-galactopyranosyl-D-galactose. The trisaccharide mixture was not further fractionated but on partial hydrolysis the arabopyranosyl-arabinose referred to above was obtained, together with arabinose and galactose.

The water-soluble polysaccharides from species of the *Larix* genus have been subject of several investigations. The literature up to 1952 has been summarised by Whistler and Smart [2]. The polysaccharide is branched and built up from 1,3′- and 1,6′-β-linked D-galactopyranosidic units and terminal L-arabofuranosidic units. Jones [1] isolated a disaccharide, 3-β-L-arabopyranosyl-L-arabinose, after mild hydrolysis of the arabogalactan from *L. decidua*. Considering the mild conditions during the hydrolysis, Jones assumed, that this disaccharide, as well as the free arabinose formed at the same time, is linked through a furanosidic linkage to the rest of the polysaccharide. He indicated the possibility that the free galactose, which is formed in small amounts under these mild conditions, should possess a furanosidic linkage also.

Sedimentation analyses showed that the polysaccharide from *L. occidentalis* consisted of two fractions with molecular weights of 16 000 and 100 000, respectively. Lystad Borgin [3] however, demonstrated that the heartwood contained only the fraction of the highest molecular weight, while both fractions were present in the sapwood.

Polysaccharides of this type are probably present in all Conifers, as indicated by their high percentage of galactose, and an arabogalactan has recently been isolated from *Pinus Jeffreyi* by Wadman, Anderson and Hassid [4].

The present paper is the first in a series with the aim of studying the arabogalactans in coniferous woods. The water-soluble polysaccharide from *L. occidentalis* was subjected to mild hydrolyses, first with 0.01 N hydrochloric acid at 100°C for two hours and then, after separation of the sugars and oligosaccharides, with 0.02 N hydrochloric acid at 100°C for two hours. Even after the last treatment the polysaccharide contained small amounts of arabinose. Chromatograms of the hydrolysates showed the presence of arabinose and galactose in dominating quantities, two disaccharides and traces of substances in the trisaccharide region. As the products from the two hydrolyses gave essentially the same chromatographic picture, they were combined and separated on a carbon column. L-Arabinose (5.9 %), D-galactose (2.2 %), two disaccharides, I (2.0 %) and II (0.8 %), and a mixture of trisaccharides (0.8 %) were isolated. The yield of higher oligosaccharides, eluted from the column with 50 % ethanol, was 2.5 %. The nature of these oligosaccharides is now under investigation.

Considering the high proportions of low-molecular weight saccharides formed under conditions when the velocity constants for hydrolysis of glycosidic linkages (expressed in minutes and Briggs logarithms) are about 10^{-4} for pyranosides and 10^{-1} — 10^{-2} for furanosides [5], it is strongly indicated, that these saccharides are linked to the rest of the molecule through furanosidic linkages, and that only a minute amount of pyranosidic linkages are cleaved during these mild conditions.

On hydrolysis, disaccharide I yielded arabinose only and disaccharide II galactose only. After methylation and hydrolysis, disaccharide I yielded a mixture of two substances, which were separated on a carbon column. One of these was identified as 2,3,4-tri-*O*-methyl-L-arabinose by transferring it into the amide of the corresponding arabonic acid, identical with an authentic specimen. The other substance was identified as 2,4-di-*O*-methyl-L-arabinose. This substance has not yet been synthesised, but its identity has been unambiguously proved [1,6], and it was now characterised as the N-phenylamine derivative and as the amide of the corresponding arabonic acid. The disaccharide therefore is a 3-L-arabopyranosyl-L-arabinose, and from its specific rotation +200°, the β-configuration of the pyranosidic linkage is highly probable. Thus it is identical with the disaccharide isolated by Jones [1] from the arabogalactan obtained from *L. decidua*.

On methylation and hydrolysis of the other disaccharide (II), a mixture of 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,4-tri-*O*-methyl-D-galactose was obtained. They were separated by chromatography on thick filter paper and characterised as their N-phenylamine derivatives, identical with authentic specimens. The disaccharide therefore is a 6-D-galactopyranosyl-D-galactose The specific rotation, +30°, indicates a β-pyranosidic structure.

The trisaccharide fraction on total hydrolysis yielded a mixture of arabinose and galactose. On partial hydrolysis with 0.01 N hydrochloric acid for one hour at 100° a substance, chromatographically indistinguishable from disaccharide I above, was also obtained. This indicates that, in at least one of the trisaccharide components, the 3-L-arabopyranosyl-L-arabinose is a structural unit with a furanosidic linkage to either arabinose or galactose.

The rather simple picture of the arabogalactan given by previous investigators was complicated by Jones [1], who demonstrated the presence of

arabopyranosidic units in the molecule. The results of the present investigation introduce further complications. It is not yet settled, whether the polysaccharide is homogeneous or consists of a mixture of a galactan and an arabogalactan; the results of previous sedimentation studies [3] indicate, however, that the material here investigated should be homogeneous. In the highly branched framework of 1,3′- and 1,6′-linked β-galactopyranosidic units, the arrangement of which is not known, arabinose, galactose and di- and higher saccharides of these sugars are linked to the rest of the molecule through furanosidic linkages. In these saccharides some of the linkages between the monomers are pyranosidic, 1,3′-bonds for arabinose to arabinose and 1,6′-bonds for galactose to galactose being demonstrated. Other bonds, however, must be furanosidic, as indicated by the results from the partial hydrolysis of the trisaccharide fraction. The amount of easily hydrolysed parts of the molecule may be estimated at about 25 % of the polysaccharide.

EXPERIMENTAL

All melting points corrected. All evaporations performed under reduced pressure.

Chromatography. Papers: Whatman No. 1 and 3MM. Solvent: Butanol, ethanol, water, 10:3:5. Developers: Silver nitrate/sodium ethoxide and anisidine hydrochloride.

Preparation of arabogalactan. Ground heartwood of *Larix occidentalis* (580 g) was continuously extracted with ether (30 h) and subsequently with methanol (90 h). The wood (540 g) was then extracted with cold water (4 + 2 + 2 l) for 12 – 18 h with continuous stirring. The extracts were separated from the wood by filtering through a cotton cloth and then through paper, using a filter aid (Celite). The extracts were concentrated until they became viscous and then precipitated in anhydrous ethanol. The sticky precipitate was washed with anhydrous ethanol and ether and dried in a desiccator, yielding a light-coloured powder (46.5 g, 8.6 %). $[\alpha]_D^{20}$ + 7.5° (*c*, 2.0 in water).

Partial hydrolysis of arabogalactan. The polysaccharide (25 g) was treated with 0.010 N hydrochloric acid (650 ml) at 100°C for 2 h. After being cooled, the solution was neutralised by filtering through a column of IR 4B and then concentrated to a viscous liquid, which was poured into ethanol to a concentration of 90 % ethanol. The precipitate formed was filtered off and the filtrate treated with active carbon in 50 % ethanol to free it from dextrins and then filtered and concentrated to a colourless syrup (1.42 g).

The precipitate mentioned above was treated with 0.020 N hydrochloric acid (600 ml) at 100°C for 2 h. After neutralisation (IR 4B) and concentration the product was precipitated in ethanol at 90 % concentration and filtered. The precipitate was dissolved in water and the procedure repeated. The filtrates (2.15 and 0.89 g, resp. when concentrated) were combined and yielded, after being treated with carbon in the same manner as described above, a colourless syrup (3.08 g) upon concentration. The amount of high molecular weight material, recovered after the last hydrolysis, was 20.0 g.

Separation of the products from the partial hydrolyses of arabogalactan. Column: 4.5 × × 33 cm. Eluent: 8 l 0 – 20 % ethanol. Fractions: *ca.* 150 – 100 ml. Added amount: 4.50 g.

Fract. 10 – 15. Arabinose (1.47 g). M.p. 157 – 158°. $[\alpha]_D^{20}$ +104° (*c*, 2.0 in water)

» 16 – 21. Galactose (0.54 g). M.p. 164 – 165° $[\alpha]_D^{20}$ + 82° (*c*, 2.0 in water)

» 32 – 37. 0.51 g of an amorphous disaccharide (I), giving a carmine colour with anisidine hydrochloride and on total hydrolysis arabinose only. $[\alpha]_D^{20}$ + 212° (*c*, 2.0 in water).

» 38 – 46. 0.20 g of an amorphous disaccharide (II) (traces of (I) in fract. 38), giving a brown-yellow colour with anisidine hydrochloride and on total hydrolysis galactose only. $[\alpha]_D^{20}$ + 30° (*c*, 2.0 in water).

» 54 – 70. 0.19 g of at least two trisaccharides.

Elution with 50 % ethanol yielded on concentration 0.63 g of higher saccharides. The recovery of 3.48 g of an in all added 4.50 g shows that the added material was not dry.

Methylation of (I) and hydrolysis of the methylated products. 0.51 g of (I) was dissolved in water (5 ml) and methyl sulphate (1 ml) added, the solution being vigorously stirred and the temperature kept at 0°C. During 7 h 30 % sodium hydroxide (2 ml) was added dropwise, and stirring continued for 4 h more, when all methyl sulphate had dissolved. The reaction mixture was then deionised (IR 120 followed by IR 4B).

The product was concentrated and water removed by repeated distillation, first with anhydrous chloroform and then with dimethyl formamide. Complete methylation was performed by adding methyl iodide (2.5 ml) and silver oxide (2.5 g) to a rapidly stirred solution of the premethylated disaccharide in dimethyl formamide (10 ml), the apparatus and reagents being previously carefully dried and the reaction mixture kept below 20°C by external cooling. The silver oxide was added during one hour and the stirring continued for another 11 h. The reaction product was worked up according to Kuhn *et al.*[7]. Yield: 0.56 g (87 %).

The methylated disaccharide was hydrolysed in 0.5 N hydrochloric acid at 100° for 12 h. After neutralisation (IR 4B) the solution was concentrated, yielding a light brown syrup (0.50 g).

Separation on a carbon column of the products from the methylated and hydrolysed disaccharide (I). Column: 3 × 20 cm. Eluent: 4 l. 10 — 40 % ethanol. Fractions: 26 ml. Added amount: 0.50 g.

Fract. 8 — 14. 0.18 g of a substance with a rather high R_F-value (Ia).
» 17 — 32. 0.21 g of a substance with a somewhat higher R_F-value (Ib).

*Identification of (Ia) as 2,4-di-*O*-methyl-*L*-arabinose.* 0.06 g of (Ia) in water (0.7 ml) was oxidised with bromine (0.11 ml) for two days at room temperature. The reaction mixture was neutralised with silver carbonate and the acid liberated with hydrogen sulphide. After filtering and concentration, the product was distilled *in vacuo* in order to obtain the lactone, and then treated with methanolic ammonia over night at 0°C. On concentration the amide crystallised and was recrystallised from ethanol. M.p. 160—161°.

0.06 g of (Ia) was boiled with aniline (0.1 ml) in anhydrous ethanol (3 ml) for 4 h. The reaction mixture was concentrated and dried in a desiccator over phosphorus pentoxide. The 2,4-di-*O*-methyl-N-phenylarabinosylamine was recrystallised from butanol, m.p. 142—144°.

These melting points are in good agreement with those of 2,4-di-*O*-methyl-L-arabonamide and 2,4-di-*O*-methyl-N-phenyl-L-arabinosylamine reported by Smith [6] and Jones [1].

*Identification of (Ib) as 2,3,4-tri-*O*-methyl-*L*-arabinose.* 0.11 g of (Ib) was oxidised with bromine and worked up in the same manner as described above. The amide was crystallised from benzene-acetone-ethanol. M.p. 104—105°, undepressed on admixture with an authentic specimen of 2,3,4-tri-*O*-methyl-L-arabonamide.

Methylation of (II) and hydrolysis of the methylated product. The fraction containing (II) was purified on thick filter paper, yielding 0.11 g of a chromatographically pure (II). This was dissolved in water (5 ml) and methylated with methyl sulphate (1 ml) and 30 % sodium hydroxide (2 ml) in the same manner as described above.

The premethylated disaccharide was carefully dried and methylated with silver oxide (2 g) and methyl iodide (2 ml) in dimethyl formamide and worked up as above. The product formed a soft crystalline mass but no attempt of recrystallisation was made.

Hydrolysis of the completely methylated disaccharide was performed in 0.5 N hydrochloric acid (4 ml) at 100°C for 14 h. Neutralisation (IR 4B) and concentration yielded a light coloured syrup (0.11 g).

The methyl ethers from the hydrolysed disaccharide were separated on thick filter paper yielding 0.05 g of a compound with a relatively high R_F-value (IIa) and 0.04 g of a somewhat slower one (IIb).

*Identification of (IIa) as 2,3,4,6-tetra-*O*-methyl-*D*-galactose.* (IIa) was boiled with aniline (0.1 ml) in anhydrous ethanol (3 ml) for 4 h. After concentration and drying over phosphorus pentoxide, the N-phenylgalactosylamine was recrystallised from ethanol. M.p. 199—200°, undepressed on admixture with authentic 2,3,4,6-tetra-*O*-methyl-N-phenyl-D-galactosylamine.

*Identification of (IIb) as 2,3,4-tri-*O*-methyl-*D*-galactose.* The N-phenylgalactosylamine of (IIb) was prepared in the same manner as above. M.p. 167—169°, undepressed on admixture with authentic 2,3,4-tri-*O*-methyl-N-phenyl-D-galactosylamine.

The authors are indebted to Dr. W. M. Hearon, Crown Zellerbach Corp., Camas, Wash., USA for a generous gift of Western larch wood and to *Fonden för Skoglig Forskning* for financial support.

Bond Energies in Transition Metal Complexes

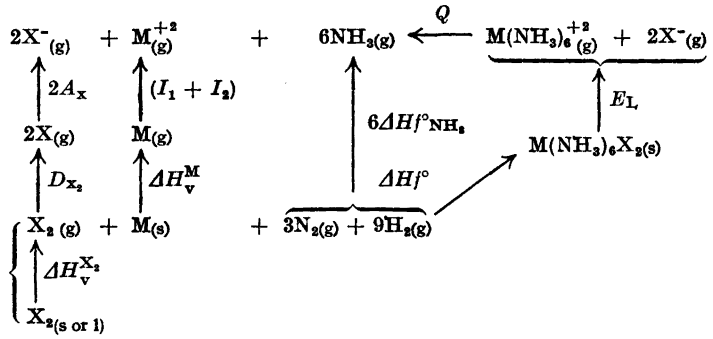
F. ALBERT COTTON

Department of Chemistry, Massachusetts Institute of Technology, Cambridge 39, Mass, U.S.A.

The feasibility of calculating the heat of formation of a gaseous complex ion, $MX_{p(g)}^{+m-px}$, from $M_{(g)}^{+m}$ and $pX_{(g)}^{-x}$ and hence the total bond energy by a procedure similar to the Born-Haber cycle is examined critically. It is concluded that at least in some cases the procedure has merit and application is made to some hexammines of divalent first transition series ions. Some implications of the results with regard to theories of the bonding in such complex ions are noted.

There have been three general theoretical approaches to the problem of bonding in transition metal complexes, *viz.*, the valence bond theory, the crystal field (ligand field) theory, and the molecular orbital theory. The valence bond approach as formulated by Pauling [1] makes the approximation that the energy of the process

$$M^{+m} + pX^{-x} = MX_p^{+m-px} \qquad (1)$$



as well as other properties of the resulting complex can be accounted for by the formation of x directed bonds, more or less covalent. While this theory has had considerable qualitative success in accounting for stereochemistry and bulk magnetic properties it is not completely satisfactory even in these respects and fails seriously in dealing with detailed magnetic properties and spectra. The ligand field theory (a term proposed [2] to replace the term "crystal field theory" when the concepts of the latter are applied to complex ions) while saying nothing explicitly about the overall process (and energy) of complex ion formation focuses attention on the effects of an electrostatic field of given symmetry upon the partially filled *d*-shell of the metal ion. It is thus able to account for the spectral and magnetic properties in some cases quantitatively, in general semiquantitatively. It is also successful in explaining the stereochemistry of the complexes, sometimes more reliably than valence bond theory. These successes of ligand field theory for a time led to the suggestion that perhaps, where transition metal complexes were concerned, the valence bond theory was wholly inappropriate, or at least that the formation of directed covalent bonds was a negligible part of the problem. However, there are a

number of points on which a *purely electrostatic* ligand field model is not satisfactory, and it now seems that a molecular orbital theory in which both directed covalent bonding and ligand field effects upon the metal *d*-shell may be simultaneously recognized and their interrelations formulated is the best conceptual approach to the problem *.

With these considerations in mind the various energy terms involved in the overall process (1) are of considerable interest and we may enquire whether the total energy or any of the contributing energies may be calculated from experimental data. It is well known [2] that the energy contribution resulting from ligand field stabilization of the partially filled *d*-shell of the metal ion can be computed from spectroscopic data. It is the purpose of this note to suggest and utilize a simple method for estimating the total energy of the process.

METHOD OF CALCULATION

In principle the total energy, Q, of process (1) for the hexammine of a divalent metal ion may be calculated from the following thermodynamic cycle analogous to the Born-Haber cycle for simple ionic crystals.

(2a)

$$Q = -\Delta Hf^\circ + 6\Delta Hf^\circ_{NH_3} + D_{X_2} + 2A_X + \Delta H_v^{X_2} + (I_1 + I_2) + \Delta H_v^M - E_L \qquad (2b)$$

The symbols have their customary meanings **. It is clear that the energies of all of the steps in this cycle can be evaluated with considerable accuracy from known experimental data with the exception of E_L. The validity of the computed value of Q will thus depend upon the reliability of the method used to evaluate the pseudo-lattice energy, E_L. We have adopted the approximation that the hexammine ion, $M(NH_3)_6^{++}$, can be regarded as a large, spherical, monatomic cation whose interactions with other ions in the lattice is essentially coulombic as is that of Na^+ in the NaCl lattice for example.

If this assumption were strictly correct then we might anticipate calculating E_L with the usual accuracy of the Born approximation, ± 3 %. The two effects which will most appreciably detract from the validity of this approximation

* A good general discussion of these points will be found in Ref. [2], parts b and c.

** For information concerning this general type of calculation see Ref. [4].

are the high polarizability of the large complex ion and the possible existence of other non-central coulombic interactions, especially hydrogen bonding to the halide ions. That these two effects are probably not large in the compounds to be treated below may be inferred from the following facts. (a) Each ion is centrosymmetrically coordinated by a large number of other ions thus tending to balance out polarization effects by symmetry; (b) the lattice does not provide geometry especially suitable for the formation of N—H $\cdots$ X bonds *; and (c) it has been observed that in crystals similar to those treated here various types of free or nearly free rotation occur at room temperature which requires that hindering energies are so small as to be negligible compared to the total lattice energy. Murray and Waugh [3] have found rotation ($\sim$ 5 000 cps) of the ammonia ligands about the metal-ligand axis in several salts of $Co(NH_3)_6^{+3}$ and also rotation *even of the* BF_4^- *ion* in $Co(NH_3)_6(BF_4)_3$. Finally it may be noted that application of the Born equation to lattices containing polyatomic ions has been made before. Sherman [4] used this method to compute the lattice energies of the ammonium halides from which he derived the energy of protonation of ammonia. It is interesting to note that Stephenson [5] has recently concluded that rotation of the NH_4^+ ion may occur in crystalline NH_4I thus lending further confidence to Sherman's calculation. The possible sources of uncertainty in calculating E_L which have been discussed are such as to make the estimate too low, and hence, in view of eqn. (2b), to make the estimated value of Q too high.

One further point requires consideration, namely, the form to be assumed for the repulsive potential. The Born-Mayer equation using an exponential repulsive potential, while fundamentally the most correct, will not be used because of the difficulty of evaluating the constant ϱ [4] in the present case. Instead we shall use the original Born equation

$$E_L = \frac{Az^2e^2}{R}\left(1-\frac{1}{n}\right) \tag{3}$$

in which the repulsive potential is of the form $1/R^n$. Rather than merely assuming n to be equal to 9, an attempt has been made to adjust it to the nature of the ions concerned in this case, and using the usual empirical relation of n to ion size [6] the following values were chosen:

$M(NH_3)_6Cl_2$	8.70
$M(NH_3)_6Br_2$	8.73
$M(NH_3)_6I_2$	8.80

While the number of hexammino, hexaquo (or even hexahalo) salts for which the calculation might be made is large, there are actually very few indeed for which all necessary data are available. It is necessary to know, *inter alia*, the appropriate ionization potential of the metal ion, the heat of formation of the solid salt, the crystal structure of the solid and the Madelung constant for that structure. (Approximations might be made for some of these but it seems undesirable to add unnecessary approximations to an already

* It may also be remarked that hydrogen bonds to Cl are generally only very weak, while hydrogen bonding to Br and I is considered to be negligible.

Table 1.

Values of Q calculated for $M(NH_3)_6^{++}$ ions

Compound M	X	Lattice Constant [a] a_0 in Å	E_L kcal	$-\Delta Hf$ [b] kcal	ΔH_V^M [c] kcal	I_1+I_2 [d] kcal	Q kcal	Average Q for metal M

(a) The lattices are of the fluorite type for which the Madelung constant to be used in conjunction with a_0, the length of the unit cube edge, is 11.637. The a_0 values are from Bödtker-Naess, G. and Hassel, O. *Z. physik. Chem.* **B22** (1933) 471.

(b) All taken from Bichowsky, F. R. and Rossini, F. D. *The Thermochemistry of the Chemical Substances*, Reinhold Publishing Corp., New York 1936. The value they list for $Mn(NH_3)_6I_2$ (201.8) is in error and the above value was recalculated from the supplementary data also listed.

(c) All taken from *Handbook of Chemistry and Physics*, 32nd Ed., Chemical Rubber Publishing Co., Cleveland, Ohio 1954.

(d) All taken from Moore, C. E. *Atomic Energy Levels*, Natl. Bur. Standards, Circular 467, Vols. I, II, 1952.

The quantities $D_{x_2} + 2A_x + 6\,\Delta Hf_{NH_3} + \Delta H_V^{X_2}$ computed from data in *Handbook of Chemistry and Physics*, 32nd Ed., Chemical Rubber Publishing Co., Cleveland, Ohio 1954 and using "best values" of A_x given by Pritchard, H. O. *Chem. Rev.* **52** (1953) 554 for X = Cl, Br, I, respectively, are −184.0, −182.0 and −178.8 kcal.

long list of unavoidable ones.) For the series of salts $M(NH_3)_6X_2$ where M = Ca, Mn, Fe, Co,Ni and Zn and X = Cl, Br and I sufficient data are at hand. The various parameters used and the results of the calculation for this group of compounds are summarized in Table 1.

DISCUSSION

The calculated values of the Q's, the total heats of dissociation of the complex ions, require comment in three respects. It is first to be clearly realized that these are and ought to be lower than the heats of solution of the gaseous

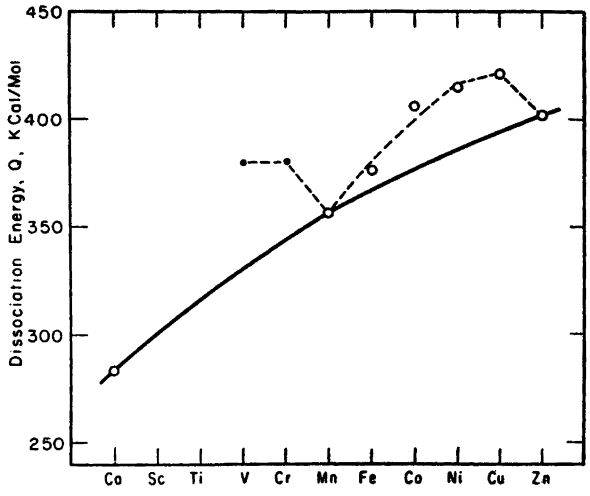

Fig. 1. Energy in kcal/mole of the gas phase dissociation of $M(NH_3)_6^{++}$ ions. Calculated points, O; - - - values predicted by adding ligand field stabilization energies to points on solid curve.

divalent metal ions of the first transition series as quoted by Orgel [7]. The latter values are the sum of an association energy analogous to that calculated here with water instead of ammonia as ligand (and probably not too different in magnitude) plus the heat of solution of the resulting complex ion. The $-Q$'s are about 100 kcal. less than the total heats of solution which is a reasonable magnitude for the heat of solution on an ion of the size and charge of these hexammine cations. Secondly, the mean deviation of the Q values averaged for the several halides of a given hexammine run from 1 to 8 kcal., or 1 to 3 %. While in terms of kilocalories these deviations are rather large, the percentages are less than the expected absolute errors of perhaps 3 to 5 %. It will be observed that the calculated Q's for a given metal ammine vary randomly with the halide ion. This indicates the absence of any important special energy contributions such as hydrogen bonding in the case of the chlorides. Finally, it has been noted by Orgel [7] that when the hydration energies of the divalent cations from Ca^{++} to Zn^{++} are plotted *versus* atomic number and a smooth curve drawn through the points for Ca^{++}, Mn^{++} and Zn^{++}, the ions for which no ligand field stabilization occurs, then the (positive) deviations of the other ions follow very closely the ligand field stabilization energies calculated from spectroscopic data. If the calculated Q's are at least not erratic (which of course indicates little about their *absolute* accuracy) they should show similar behavior. In Fig. 1 the Q's are plotted *versus* atomic number. The dotted line represents the calculated curve through Ca^{++}, Mn^{++} and Zn^{++}. The agreement is seen to be satisfactory. The ligand field stabilization energies were computed from the data summarized by Klixbüll-Jørgensen [2a].

It may also be noted that although the ligand field stabilization energies play a critical role in determining the detailed chemistry of the transition metal

ions, they actually constitute a rather small fraction of the total bond energy. Also the mean ligand-metal bond energies are 60 to 70 kcal. This might be taken to mean that the reactions of the more labile complex ions which have activation energies of 20 to 30 kcal. do not proceed by a simple S_N-1 mechanism in which the activation energy is simply that required to break one metal-ligand bond without some other compensatory action.

ADDENDUM ADDED IN PROOF

F. A. Cotton and Marilyn C. Verdier

It was felt that the results of a calculation of the type described above applied to $Co(NH_3)_6^{+3}$ might be of interest. This was not done previously because there were no salts of this ion with crystal structures for which the Madelung constant was known. It was found however that $[Co(NH_3)_6]\,I_3$ and the isomorphous $[Co(NH_3)_5H_2O]\,I_3$ crystallize in a cubic structure[1] in which the units to be considered ($[Co(NH_3)_6]^{+3}$, $[Co(NH_3)_5H_2O]^{+3}$, I^-) occur at lattice positions having coordinates which are integral multiples of 1/12 of the unit cell edge. (This structure is the *anti* form of that found by Pauling[2] for $(NH_4)_3AlF_6$ and $(NH_4)_3FeF_6$). The Madelung constant for such a structure may be computed relatively simply from the table compiled by Emersleben[3]. For this structure we have calculated A_{a_0} (*i.e.*, Madelung constant to be used with lattice parameter a_0, the length of the unit cell edge) to be 22.12196. The third ionization potential of Co was taken from C. E. Moore's table. The heats of formation of the above salts were taken as -201.6 and -240.9 kcal/mole respectively[4]. Using these and other data from sources cited above we have obtained for $[Co(NH_3)_6]I_3$, $E_L = 593.8$ kcal/mole and $Q = 854.7$ kcal/mole and for $[Co(NH_3)_5H_2O]I_3$, $E_L = 597.6$ kcal/mole and $Q = 843.3$ kcal/mole. Thus the mean ligand metal bond energies in these complexes of Co^{+3} are about 140 kcal. The ~10 kcal difference accords with the expectation that water would be less strongly bound than ammonia, but is of no quantitative significance in view of the possible errors (perhaps as much as 5—10 kcal/mole).

It has also been found that although no data on $Cu(NH_3)_6X_2$ compounds are given in the general reference for lattice parameters consulted previously, such data are available for $Cu(NH_3)_6Br_2$[5]. The compound has the fluorite structure with $a_0 = 10.30$ Å and the heat of formation (Bichowsky and Rossini) is -193.2 kcal/mole. From these data $E_L =$ $= 327.3$ kcal/mole and $Q = 420.6$ kcal/mole were computed. The use of this crystallographic data requires comment since they were previously criticized on the logical ground that while the structure is given as cubic, the crystals are also said to be *slightly* dichroic. This is not necessarily inconsistent because Jahn-Teller distortion, which would of course occur in $Cu(NH_3)_6^{+2}$, could conceivably give rise to a noticeable spectral effect without causing sufficient steric distortion to be observed in X-ray studies of moderate accuracy.

Thanks are due to Professor R. G. Pearson who read the manuscript and caught a potentially disasterous numerical error.

Synthesis of the Racemic and Optically Active Forms of 10-Methylnonadecanoic Acid

ROBERTO CAVANNA

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

The synthesis of the racemic and optically active forms of 10-methylnonadecanoic acid is described and several physical constants for the acids, methyl esters and amides are given.

The synthesis of the racemic and the optically active forms of 11-methylnonadecanoic acid was described in a previous communication [1]. It was pointed out that none of the acids synthesized could be identical with phytomonic acid from *Agrobacterium tumefaciens* and that data already at hand also showed the non-identity of the racemic or one of the optically active forms of 10-methylnonadecanoic acid with phytomonic acid. The suggestion was made that phytomonic acid was a *cyclo*propane derivative similar to the lactobacillic acid isolated by Hofmann and Lucas [2] from *Lactobacillus arabinosus*. A large-scale growth of *Agrobacterium tumefaciens* was then undertaken at the Istituto Superiore di Sanitá in Rome, with the object of preparing phytomonic acid and investigating its structure. For reasons outside our control the analytical work had to be postponed, and in the meantime Hofmann and collaborators [3] showed that phytomonic acid is indeed a *cyclo*propane derivative as suggested by Ställberg-Stenhagen and the writer [1]. According to Hofmann *et al.* the acid is identical with lactobacillic acid with the proposed structure of *cis*-11,12-methyleneoctadecanoic acid [4,5].

The details of the preparation of the 10-methylsubstituted acids are now given. The synthetic routes used were the same as those for the 11-methyl-substituted isomers. 10DL-Methylnonadecanoic acid of m.p. 26.8—27.2° was prepared by Clemmensen reduction of 8-oxo-10DL-methylnonadecanoic acid. The oxo-acid of m.p. 47.0—47.2° was prepared by the β-oxo-ester synthesis [6] from methyl 3-oxo-5DL-methyltetradecanoate and methyl 6-iodohexanoate. 10DL-Methylnonadecanoic acid prepared from the enantiomorphs melted at 26.8—27.1°.

The optically active forms were synthesized by the Kolbe reaction (*cf.* Ref. 1) from the enantiomorphs of 3-methyldodecanoic acid and methyl hydro-

gen azelate. The active 3-methyldodecanoic acids were also prepared by the Kolbe reaction using the enantiomorphs of methyl hydrogen β-methylglutarate[7] and *n*-nonanoic acid as initial material.

After solidification from the melt optically active 10-methyl-nonadecanoic acids remelt at 12.5°. After crystallization from solvents slightly higher melting points have been recorded. Similar behaviour was encountered by Hallgren [8] in the case of (+)-9D-methyloctadecanoic acid, when it was possible to obtain a higher-melting form by slow crystallization from methanol at a low temperature. It seems likely that the behaviour of the 10-methylnonadecanoic acids also indicates the existence of a higher-melting modification although the conditions for obtaining the acids in this form alone have not been established.

The D-acid, the derived amide, and the methyl ester are all dextrorotatory, although the specific rotations are very small. 9D-Methyloctadecanoic acid and 11D-methylnonadecanoic acid [1] are both dextrorotatory [8], whereas 10D-methyloctadecanoic acid (tuberculostearic acid) is laevorotatory [9,10].

EXPERIMENTAL [1]

3DL-Methyl-5-oxododecanoic acid. Methyl 3DL-methyl-5-ketopimelate (40 g) was alkylated with *n*-hexyl iodide (45 g of b.p. 46°, 4 mm) using dry potassium carbonate (60 g) and methyl-*n*-propyl ketone (300 ml). For details of alkylations of this type see Ref.[6]. After refluxing for 24 h, hydrolysis and ketonic cleavage were performed in the standard manner, using potassium hydroxide (85 g) in water (80 ml) and methanol (1000 ml). The reaction mixture was kept overnight at a temperature of 50°. The product was isolated from the reaction mixture in the usual way. Distillation gave 3DL-methyl-5-oxododecanoic acid as a colourless oil of b.p. 140°, 1 mm. Yield 26 g or 49 % of the theoretical. (Found: C 68.68; H 10.42. Calc. for $C_{13}H_{24}O_3$ (228.3): C 68.50; H 10.51.)

Ethyl 3DL-methyldodecanoate was obtained by Clemmensen reduction of the oxo-acid (15 g) with 250 g of amalgamated zinc in 250 ml of absolute ethanol. A moderate stream of dry hydrogen chloride was led into the reaction mixture for 15 min. every 7th hour. After 70 h the reduced ester was isolated and distilled through a 1 m Podbielniak column. Yield 8 g of b.p. 104°, 0.3 mm (50 % of the theoretical). (Found: C 74.04; H 12.46. Calc. for $C_{15}H_{30}O_2$ (242.4): C 74.32; H 12.48).

3DL-Methyldodecanoic acid was obtained in 75 % yield after hydrolysis of the ester and distillation of the acid. B.p. 137°, 0.5 mm. (Found: C 73.20; H 12.20. Calc. for $C_{13}H_{26}O_2$ (214.3): C 72.84; H 12.23).

Methyl 3-oxo-5DL-methyltetradecanoate was prepared by the general procedure of Ställberg-Stenhagen [11]. 3-DL-Methyldodecanoyl chloride (prepared from 8 g of the acid by means of 5 ml of oxalyl chloride in 25 ml of dry benzene) was condensed with ethyl sodioacetoacetate (from 15 ml of the ethyl acetoacetate and 1.5 g of sodium). Hydrolysis and ketonic cleavage was performed with 1.5 g of sodium in 45 ml of methanol. The oxo-ester distilled at 134°, 0.5 mm. Yield, 6 g (59 % of the theoretical). (Found: C 71.00; H 11.04. Calc. for $C_{16}H_{30}O_3$ (270.4): C 71.06; H 11.18).

3-Oxo-10DL-methylnonadecanoic acid was synthesized from the above oxo-ester (6 g) and methyl 6-iodohexanoate (5.7 g prepared from the silver salt of methyl hydrogen pimelate by bromine degradation according to Hunsdiecker and Hunsdiecker [13]). After hydrolysis and ketonic cleavage in the usual way (*cf.* Ref. [1]) using 15 g of potassium hydroxide in 15 ml of water and 200 ml of methanol, the oxo-acid was crystallized from light petroleum (b.p. below 40°) at a temperature of −18°. Two recrystallizations from the same solvent gave the oxo-acid in the form of fine needles melting at 47.0−47.2°. The X-ray diffraction pattern of the oxo-acid did not show any characteristic series of 00*l* reflexions. (Found: C 73.68; H 11.75. Calc. for $C_{20}H_{38}O_3$ (326.5): C 73.57; H 11.73).

Amide of 10DL-methylnonadecanoic acid. 0.6 g of the oxo-acid was reduced by Clemmensen's method in the manner described for the C_{13} oxo-acid. After saponification, the crude acid was converted into the amide *via* the acid chloride prepared by means of

oxalyl chloride in benzene solution. The amide was crystallized from methanol-water (85:15 by volume). Yield 0.32 g (56 % of the theoretical), m.p. 78.8—79.2°. Long X-ray spacing 41.0 Å. No polymorphism has been observed. (Found: N 4.61. Calc. for $C_{20}H_{41}ON$ (311.5): N 4.50).

*10*DL-*Methylnonadecanoic acid* was obtained by saponification of the amide. Crystallization from light petroleum (b.p. below 40°) gave acid in the form of white crystals melting at 26.8—27.2°. The X-ray diffraction pattern was similar to that of 9DL-methyloctadecanoic acid in that it showed no distinct series of 00*l* reflexions. (Found: C 77.15; H 12.92. Calc. for $C_{20}H_{40}O_2$ (312.5): C 76.86; H 12.90).

*10*DL-*Methylnonadecanoic acid* from the enantiomorphs. Equal amounts of the enantiomorphs described below were mixed, a little ether being added for mixing, and the solvent evaporated at room temperature. After removing the last traces of solvent *in vacuo* the liquid solidified to a mass of fine, hard crystals. The DL-acid prepared in this manner melted without recrystallization at 26.8—27.1°.

(+)-*3*D-*Methyldodecanoic acid* was prepared in a similar way to that described for the next lower homologue in Part I. The initial materials were (+)-methyl hydrogen β-methylglutarate (20.8 g, 0.13 mole) and *n*-nonanoic acid (27 g, 0.171 mole, 25 % excess; the acid had been purified *via* the methyl ester). The anodic synthesis was performed as described in the previous paper [1]. Saponification of the methyl ester and distillation gave 10.2 g of (+)-3D-methyldodecanoic acid, b.p. 121°, 0.2 mm. The optical rotation was $[\alpha]_D^{22}$ +4.16° (homogeneous, *l*,1). n_D^{25} 1.4408.) Found: C 72.71, H 12.20. Calc. for $C_{13}H_{26}O_2$ (214.3): C 72.84; H 12.23). Hallgren [8] gives $[\alpha]_D^{24.5}$ +4.23° (homogeneous), $d_4^{24.5}$ 0.8848 and n_D^{25} 1.4405.

(−)-*3*L-*Methyldodecanoic acid* was obtained in the same way, starting from (−)-methyl hydrogen β-methylglutarate (27 g) and *n*-nonanoic acid (34 g). Yield, 13.5 g of acid distilling at 107°, 0.1 mm. n_D^{25} 1.4408. Optical rotation $[\alpha]_D^{24}$ −2.06° (homogeneous; *l*, 0.5). (Found: C 72.84; H 12.16. Calc. for $C_{13}H_{26}O_2$ (214.3): C 72.84; H 12.23).

Methyl hydrogen azelate was prepared by partial esterification of azelaic acid. The mono-ester used distilled at 137°, 0.5 mm.

(+)-*10*D-*Methylnonadecanoic acid.* 10.2 g (0.05 mole) of methyl hydrogen azelate was electrolyzed together with 8.6 g (0.04 mole) of (+)-3D-methyldodecanoic acid in 250 ml of methanol containing 0.28 g of sodium. The reaction was started with half the above amounts of reagents, the second half being added when the pH of the electrolysis mixture had risen to 7. A current of 5 A were passed through the cell for a total time of 1 h. Near the end of the reaction more methyl hydrogen azelate (2 g) was added in order to use up as much of the optically active acid as possible. The reaction mixture was extracted and saponified in the usual way (*cf.* Ref. [1]). Distillation gave 3.0 g (24 % of the theoretical) of (+)-10D-methylnonadecanoic acid as a thick colourless oil, b.p. 173—174°, 0.1 mm. The properties of the optically active hydrocarbon ((−)-10L,13D-dimethyldocosane) found in the unsaponifiable material have been described by Hallgren [8].

The amount of D-acid of m.p. 12.5° purified *via* the amide was too small to allow the determination of the optical rotation in the 0.5 dm polarimeter tube available. n_D^{25} 1.4521. d_4^{24} 0.880. (Found: C 76.8; H 13.1. Calc for $C_{20}H_{40}O_2$ (312.5): C 76.86; H 12.90). The D-amide melted after crystallization from acetone at 75.0—75.5°. Long X-ray spacing at room temperature 40.0 Å. Optical rotation α_D^{25} +0.05° (chloroform; *l*,1; *c*, 21.5). (Found: N 4.6. Calc. for $C_{20}H_{41}ON$ (311.5): N 4.50).

*Methyl 10*D-*methylnonadecanoate* was prepared by means of diazomethane from a specimen of acid that had been chromatographed on de-activated aluminium oxide. The ester distilled at 142°, 0.2 mm, and had an optical rotation α_D^{25} +0.03° (homogeneous, *l*, 0.5). d_4^{24} 0.861 (Found C 77.0; H 12.6. Calc. for $C_{21}H_{42}O_2$ (326.5): C 77.72; H 12.42).

(−)-*10*L-*Methylnonadecanoic* acid was prepared in an analogous manner starting from (−)-3L-methyldodecanoic acid. The acid distilled at 176—177°, 0.15 mm. The distilled material (5 g) had m.p. 12.5°. After two crystallizations from acetone at −25° the m.p. was 13.0—13.3°. Yield 4.17 g. n_D^{25} 1.4524; d_4^{24} 0.879. Optical rotation α_D^{25} −0.03° ± 0.01° (homogeneous, *l*,1); α_{4358}^{25} −0.07° (homogeneous, *l*,1). Hydrolysis of 0.5 g of the amide described below was carried out with a solution of 5 g of potassium hydroxide in

water (5 ml) and ethanol (30 ml). The solution was refluxed for two days. After acidification the acid was extracted in the usual way and distilled, giving 0.12 g of distilled material of m.p. 12.0—12.6°. Solidification took place at 9.5—9.0°. (Found: C 76.7; H 12.8. Calc. for $C_{30}H_{40}O_2$ (312.5): C 76.86; H 12.90).

(—)-*10*L-*Methylnonadecanamide* was prepared in the same way as the DL-amide, and crystallized from acetone. M.p. 75.0—75.5°. The melting point was the same after the amide had been chromatographed on aluminium oxide. Long X-ray spacing 40.0 Å. Optical rotation α_D^{25} —0.08° (chloroform; *l*,1; *c*,21.25). (Found: N 4.6. Calc. for $C_{30}H_{41}ON$ (311.5): N 4.50).

The writer is indebted to Professor D. Marotta, Director of the Istituto Superiore di Sanità, Rome, for financial support. This work was aided by a grant to S. and E. Stenhagen from the *Swedish National Association for Cancer Research*. The analyses were performed in the microanalytical laboratory of this institute.

Studies on the Hydrolysis of Metal Ions

17. The Hydrolysis of the Uranium(IV) ion, U^{4+}

SIRKKA HIETANEN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of U^{4+} has been studied in a 3 M (sodium) perchlorate medium at 25°C by two series of electrometric titrations; in one, $[H^+] = h$ was measured with glass or hydrogen electrodes, in the other, $b = [U^{4+}]$ was measured with a Pt—Pd redox electrode, after the addition of UO_2^{2+}.

The data could be explained, assuming the mononuclear reaction $U^{4+} + H_2O \rightleftharpoons UOH^{3+} + H^+$, equilibrium constant β_1, and a polynuclear "core+links" reaction, according to hypothesis IIIa: $(n+1)U^{4+} + 3\ n\ H_2O \rightleftharpoons U((OH)_3U)_n^{4+n} + 3\ n\ H^+$, equilibrium constant $k_n = k_0 k^n$. The best agreement was found with $\log \beta_1 = -2.00 \pm 0.1$, $\log k_0 = -1.2 \pm 0.3$, $\log k = -3.4 \pm 0.1$.

By analogy with Th^{4+} and considering the crystal structure of $U(OH)_2SO_4$ it seems plausible that the complexes are chain-like, of formula $U(^{O}_{OH}U)_n^{4+n}$.

Lawrence [1] found that the magnetic susceptibility of uranium(IV) solutions decreases with decreasing $[H^+]$ and ascribed this effect to the hydrolysis of U^{4+} to form UO^{2+}. From his magnetic data he estimated the equilibrium constant $K = [UO^{2+}][H^+]^2[U^{4+}]^{-1} = 5 \times 10^{-3} \sim 10^{-2.3}$ M² in perchlorate solutions. The effect of ionic strength on the activity factors was not considered. (From Lawrence's data one may calculate values of K varying from $10^{-3.41}$ to $10^{-1.41}$. In the range studied by Lawrence, U^{4+} forms predominantly mononuclear complexes according to the present investigation.)

Kraus and Nelson [2] have studied the hydrolytic behavior of U^{4+} by spectrophotometric measurements on chloride and perchlorate solutions. They described the first stages of hydrolysis in terms of the formation of the mononuclear complex UOH^{3+} and calculated the acidity constant $K_a = [H^+][UOH^{3+}][U^{4+}]^{-1}$ for various ionic strengths. For instance, for 2.004 M perchlorate they found $K_a = 2.36 \times 10^{-2}$ M. By extrapolation to zero ionic strength they estimated the true (activity) constant $K_a^\circ = 0.21 \pm 0.02$. According to Kraus, Nelson and Johnson [3], further hydrolysis occurs above pH = 2, to give a polymer of approximate composition $U(OH)_4$; no intermediate product be-

tween UOH^{3+} and the polymer was found. The same authors have found that plutonium(IV) gives a similar polymer, approximately $Pu(OH)_4$ at 0.2 mM Pu(IV) and a pH as low as 1.5.

Kraus and Nelson [4] found the acidity constant 0.0125 at 10°C and 0.100 at 43°C with U(IV) perchlorate solutions on further spectrophotometric investigations for 0.5 ionic strength.

The aim of the present work was to investigate the hydrolysis of uranium(IV) by the methods developed in this laboratory [7,9,12,13]. Among other things, it seemed interesting to compare its behavior with the mechanism previously found for thorium.

METHOD

The hydrolysis of uranium(IV) was studied by two series of potentiometric titrations at 25°C, referred to below as Z and η titrations. We shall denote the concentrations of free H^+ and U^{4+} by

$$[H^+] = h; \; [U^{4+}] = b \tag{1}$$

B is the total concentration of uranium(IV), whether hydrolyzed or not, and H is the analytical excess concentration of H^+, assuming all uranium(IV) to be present as U^{4+}; thus H may be negative. The quantities B and H for each solution are known from the analytical data.

In each Z titration, B was kept constant, and h was measured for varying H. Then one could calculate Z, the average number of OH bound per U(IV) (= the number of H^+ split off per U(IV)):

$$Z = (h—H)/B \tag{2}$$

Curves $Z(\log h)_B$ could thus be calculated from this type of titration.

In the η titrations, both b and h were measured, the former using redox emf:s in the presence of a comparable amount of UO_2^{2+}. From these titrations, each of which was also carried out at constant B, one obtained

$$\eta = \log\frac{B}{b} \tag{3}$$

as a function of h, thus $\eta(\log h)_B$.

By addition of $NaClO_4$, all solutions were made to contain 3 M ClO_4^-, and no other anions. Since h and B were always small compared with $[Na^+]$ and $[ClO_4^-]$, the activity factors of all species were assumed to be constant so that true stoichiometric equilibrium constants could be obtained.

The acidity of the solutions was increased by adding $H^+ClO_4^-$, and decreased by adding $Na^+HCO_3^-$. NaOH was avoided, since local high pH might cause a precipitate which would be hard to redissolve.

Types of cells

In all cells used, the reference electrode was

$$SE\| = Ag|\ 0.01\ M\ AgClO_4,\ 2.99\ M\ NaClO_4|\ 3\ M\ NaClO_4| \tag{4}$$

The three types of cell used, and expressions for their emf:s, were

—Pd, $H_2(g)|H^+||SE+$; $E_h = E_{0h} + jh - 59.16 \log h$ (5)

— glass electrode$|H^+||SE+$; $E_g = E_{0g} + jh - 59.16 \log h$ (6)

— $Pd|U^{4+}, UO_2^{2+}||SE+$; $E_r = E_{0r} + jh - 29.58 \log [UO_2^{2+}] + 29.58 \log b -$
$-118.32 \log h$ (7)

In eqns. (5) to (7), E is the measured emf, E_{0g}, E_{0h} and E_{0r} are constants in each titration (although E_{0r} was found to vary between different titrations). In the liquid junction potential $E_j = jh$, the constant j was 15 mV M^{-1} for E_h, 22 mV M^{-1} for E_g.

In the pH and concentration range studied, the hydrolysis of UO_2^{2+} is negligible according to the data of Ahrland [5].

For the Z titrations, E_g or sometimes E_h was measured; the η titrations required measurements of E_r and E_g, usually in a range of higher acidity. If j is known, the E_0 can be calculated from data at higher acidities (negligible hydrolysis); then one may readily obtain h from E_h or E_g, and b from E_r.

Reagents

The starting material for the *uranyl perchlorate* and *uranium(IV) perchlorate* solutions was an ammonium uranyl hydroxide, which had been precipitated from uranyl nitrate, purified by ether extraction. The hydroxide was heated to form U_3O_8, which was dissolved in HNO_3, and the uranyl nitrate so obtained was repeatedly evaporated with 70—72 % $HClO_4$ under an infrared lamp until no trace of HNO_3 could be detected. This product was used for preparing uranyl perchlorate solutions.

Uranyl perchlorate solution was adjusted to contain about 0.5 M UO_2^{2+} and 2.5 M $HClO_4$; it was then reduced to uranium(IV) by electrolysis, using a mercury cathode and a platinum anode, separated by a diaphragm of sintered glass [6]. Air was kept away with a stream of CO_2. The potential difference between the electrodes was 4—5 V, and the current 0.15—0.25 A. With 6 V and about 1.0 A, chloride ions could be detected after 10 min. The acidity of the $UO_2(ClO_4)_2$ solution to be reduced is important. If it is too low, a black solid (probably UO_2) will precipitate during the electrolysis; if it is too high, H will be unnecessarily high in the uranium(IV) solution, and it is then hard to determine Z accurately.

The uranium(IV) perchlorate solution finally obtained was stored under purified CO_2 in an automatic buret.

Perchloric acid solutions were prepared from 70—72 % $HClO_4$ (Kebo p.a.) and analyzed using HgO + KI, or recrystallized hydrazine sulfate.

Sodium hydrogen carbonate solutions were prepared from $NaHCO_3$ (Riedel-de-Haen p.a.) and titrated with $HClO_4$.

Silver perchlorate solutions were prepared as described in previous papers from this laboratory [7].

Sodium perchlorate solutions were prepared by mixing $HClO_4$ and Na_2CO_3. No Cl^- could be detected. The stock solutions were analyzed as described before [7].

Carbon dioxide, nitrogen, and *hydrogen* were purified as described previously [7].

Analysis

The *total uranium* in the uranium(IV) or uranyl stock solutions was determined by precipitating with oxine, igniting, and weighing as U_3O_8. The concentration of *uranium(IV)* had to be checked repeatedly, since it may easily decrease by oxidation. After each titration, the following convenient method was used: Equal volumes of uranium(IV) solution and conc. HCl were mixed in a measuring cylinder fitted with a glass stopper; then ICl solution and 10 % $FeCl_3$ solution were added, and the free I_2 titrated with KIO_3,

using $CHCl_3$ as indicator. — Another method was to add excess of $FeCl_3$ solution, which oxidizes U^{4+} to UO_2^{2+}, and to determine the Fe^{2+} formed by potentiometric titration with $K_2Cr_2O_7$ solution.

The *perchlorate* ion concentration was determined by ion exchange. First U^{4+} was oxidized to UO_2^{2+} with a stream of air or oxygen, and then the solution was passed through a column of the H^+ form of Amberlite IR 120. The total amount of ClO_4^- was found by titrating the eluate ($H^+ClO_4^-$) with NaOH solution. — When uranium(IV) solution was passed through the same type of ion exchange column without previous oxidation, nevertheless the same total amount of ClO_4^- was found. This shows that uranium(IV) on the ion exchange resin is not associated with any ClO_4^-.

Apparatus

The cell was of the type described by Forsling, Hietanen and Sillén [9]. It was kept in a paraffin oil thermostat at 25.0±0.1°C, and the titrations were carried out in a room thermostated at approximately 25°C.

The hydrogen electrodes were lightly palladinised Pt foils [8]. Two glass electrodes were used, a commercial Radiometer electrode, and one prepared by Mr Erik Blomgren in Uppsala. The redox electrodes were palladinised Pt foils. In measurements of E_T and E_g, air was kept out of the titration vessel by bubbling purified N_2 through the solution.

The emfs of the cells were measured with a Vernier compensator (Cambridge Instrument Co.) and a Multiflex galvanometer type MG 2, or with a valve potentiometer (Radiometer PHM 3i).

PROCEDURE AND DATA

Z Titrations

The data from Z titrations with a glass electrode are given in Fig. 1, those with a hydrogen electrode in Fig. 3, both in the form of plots of $Z(\log h)_B$. As an example, the primary data for a titration with a hydrogen electrode for $B = 10.00$ mM are given in Table 1.

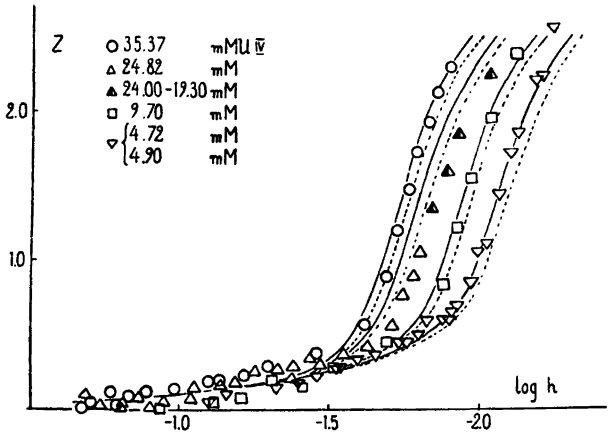

Fig. 1. Data for glass electrode measurements. Vertical axis: Z = *average number of* OH^- *bound per U(IV) atom. Horizontal axis: log* h (*M scale*). *Full drawn curve: calculated for the various values of* B *with "hypothesis IIIa"* $k_0 = 0.06$, *log* $k = -3.37$, *assuming one mononuclear step with* $\log \beta_1 = -1.98$. *Broken curve: calculated for* $k_0 = 0.06$, *log* $k = -3.45$, $\log \beta_1 = -1.95$.

The correction for uranyl is made by reducing E_0' with 0.50 mV.

The titration procedure was practically the same as that used for thorium [7]. Usually, as in Table 1, $E_0' = E_0 + jh$ was obtained from an immediately preceding acid-base titration with no uranium present; sometimes E_0' was calculated from E values measured in the most acidic solutions containing U, where the hydrolysis of U^{4+} could be neglected.

The accuracy of the Z values is lower than for many other ions studied in this series, especially at the highest acidities. At 100 mM H^+, where Z is already about 0.1, an error of 0.2 or 0.3 mV in E will make an error of 0.8 to 1.2 mM in h, which makes the Z value for the lowest values of B (2 or 5 mM) very uncertain. For higher B, and lower h, the accuracy increases.

Influence of uranyl ions. It was practically unavoidable that the uranium(IV) solutions contained 1—2 % of the total uranium in the form of uranyl ions UO_2^{2+}. Fig. 2 shows measurements with glass and hydrogen electrodes on a solution, where the analytical H^+ and uranium(IV) concentrations, H and B, were kept constant, while the concentration of UO_2^{2+} was increased by adding from a buret a uranyl solution, of the same H and B as the original solution. The presence of uranyl ions does not seem to affect the glass electrode,

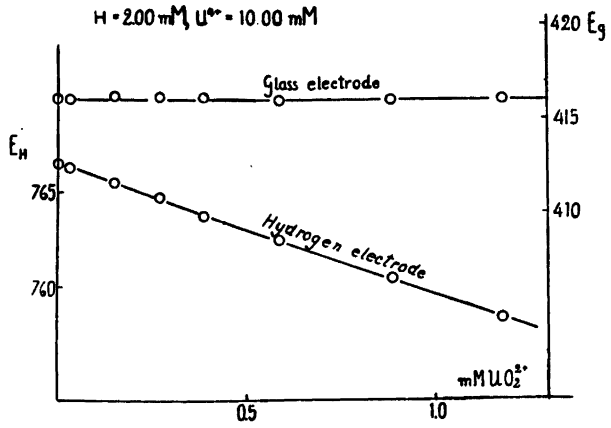

Fig. 2. Influence of uranyl ion on glass and hydrogen electrodes.

whereas E_h (and thus E_{0h}) are seen to decrease. The difference amounted to about 7 mV for 1 mM UO_2^{2+}; in experiments with other values for B and H, approximately the same slope was obtained.

The glass electrode data would thus seem more reliable. To evaluate the hydrogen electrode data, E_{0h} was taken from points of high acidity ($Z = 0$) and assumed to be constant.

η Titrations

In preliminary experiments, various redox electrodes were tried: Pt, Pt—Ir, platinised Pt, palladinised Pt, gilded Pt, Au, and Hg. The emf obtained using Hg electrodes was usually about 6—7 mV lower than with the others. Equilibrium was reached most quickly with the palladinised and platinised Pt electrodes. If a few drops of indigo tetrasulfonate solution was added [11], the gilded Pt electrodes also came to equilibrium rather rapidly.

Palladinised Pt electrodes were used, since they were most easily prepared. New electrodes were palladinised for each titration.

The data, calculated in the form $\eta(\log h)_B$ are given in Fig. 4. Full data for two titrations are given in Table 2, one in which h was increased and one in which h was decreased.

The procedure for η titrations was similar to that of the Z titrations. The hydrogen ion concentration was sometimes measured directly with the glass electrode; in such cases, an acid-base titration preceded the uranium titrations. In other cases, h was calculated as $h = H + BZ$. The correction term BZ for the H^+ split off from U^{4+} was assumed to be a function of h and B and was interpolated from previous Z titrations.

Variation of E_{0r}. When the values of E_{0r} for different titrations were compared, they were found to differ, usually by about 1 mV although sometimes deviations up to 6—8 mV were observed. However, in each titration E_{0r} seemed to be constant, since the difference in E_r values found in parallel

titrations was always constant. Since in (7) only the difference E_{0r}—E_r is important, and not the absolute value of E_{0r}, η could still be calculated. It is hard to understand the reason for this deviation. The equilibria between U(IV), U(V), and U(VI) should be reached within the times used. There may be differences in the surface of the electrode, but when two electrodes were immersed in the same solution, they gave the same emf within ± 0.2 mV at low values of Z (or η) and within 0.5 mV close to the point of precipitation.

The equilibrium E_r or E_h was obtained within 20-30 min. and E_g much more quickly; it was sometimes checked that E did not change after two hours.

A number of back-titrations were made, adding H^+: Z titrations for $B =$ $= 9.81$ mM (from $Z = 0.50$) and 9.74 mM (from $Z = 0.40$) with the hydrogen electrode, and for $B = 4.90$ (from $Z = 0.85$) with the glass electrode; and η titrations for $B = 10.00$ (from $\eta = 0.11$) $B = 9.32$ mM (from $\eta = 0.260$), $B = 5.00$ (from $\eta = 0.163$ and for $B = 4.78$ (from $\eta = 0.167$). They seem to agree well with titrations in the other direction.

Influence of carbonate. To make sure that no error was caused by carbonate complexes formed on the addition of $NaHCO_3$, the following experiment was carried out. A solution was prepared with $H = 22$ mM, $B = 35$ mM and $[UO_2^{2+}] = 7$ mM. In this solution, $Z \approx 0.35$, and $\eta \approx 0.17$. The redox emf E_r was measured in the cell (7), and then a stream of CO_2 was bubbled through the solution. E_r increased by 1 mV, which may indicate a weak complex formation with uranium(IV). However, when N_2 was again bubbled through the solution, after 10 min. E_r had attained the same value as before the treatment with CO_2. The experiment was repeated and found to be fully reproducible. Thus there is no indication of strong or irreversible complex formation with carbonate.

Precipitation. In order to study the tendency to slow precipitation, four series of solutions were prepared; in each series, the total concentrations of uranium(IV) and uranyl ions were kept constant, whereas the excess of H^+, H, was varied. The solutions which were initially clear were stored in flasks under paraffin oil to avoid oxidation, and the E_r with each solution was measured daily. The flasks were also scrutinized for a possible precipitate.

The maximum change in E was 2 mV, and the variations were usually less than 1 mV. In the most acidic solutions, E often varied by 1 mV during the first day.

The results may be summarized as follows:

B, mM	$[UO_2^{2+}]$, mM	Precipitate at H, mM	no ppt at H, mM
5.05	4.61	0, 2, 5	10, 30, 50...200
10.00	8.65	−10, 0, 5	10, 30...200
25.00	25.00	−10, 0, 5	10, 30...200
50.00	50.00	−20, −15	− 10...

In the most concentrated solution, the black precipitate appeared after three days and in the other solutions after one day. In these experiments, the uranium(IV) perchlorate contained some Cl^-, which had formed on electrolytic reduction of UO_2^{2+}.

In other experiments it was noticed that the presence of UO_2^{2+} ions favored precipitation, which was observed at higher acidities than in the absence of UO_2^{2+}.

The polynuclear mechanism: first approximation

From the plots of $Z(\log h)_B$ in Figs. 1 and 3 or of $\eta(\log h)_B$ in Fig. 4 it is seen that for different values of B the steep part of the curves do not coincide but are parallel. This shows that polynuclear complexes are formed and indicates, as a first approximation, that they can be written in a "core + links" form [12]. The spacing between the curves indicates $t = 3$, whence the formula of the complexes would be $U((OH)_3U)_n^{4+n}$. As a test, the data of the Z and η titrations were recalculated and plotted as functions of the variable

$$x = \log B - 3 \log h \tag{8}$$

For convenience, Z was replaced by the variable

$$y = Z/t = Z/3 \tag{9}$$

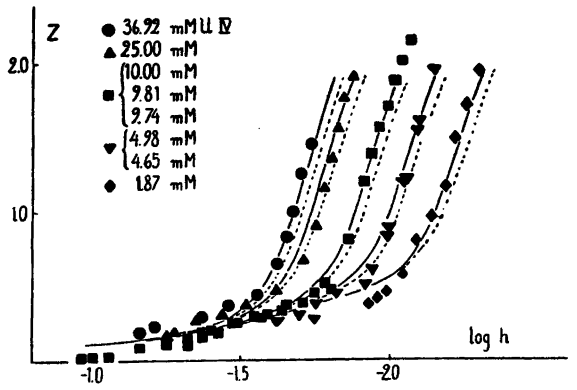

Fig. 3. Data for hydrogen electrode measurements. Vertical axis: Z = *average number of* OH^- *bound per U(IV) atom. Horizontal axis: log* h (*M scale*). *Full-drawn curve: calculated for the various values of* B *with "hypothesis III a"* $k_0 = 0.06$, log k = −3.37, *assuming one mononuclear step with log* $\beta_1 = -1.98$.

The data $y(x)$ are seen to fall on single curves, independent of B, at least in the steep parts of the curves. In the flat part, for higher h(lower x), the agreement is less good; on the other hand, the experimental inaccuracy is also much greater.

It would thus seem that a "core + links" mechanism would give a good approximation.

For two of the titrations in Fig. 5, the values of E'_0 taken differed from those used for calculating Z for Figs. 1 and 3. In one of them, with $B = 4.72$ mM, $E'_{0g} = 202.7$ mV (giving $Z = 0.11$ at $H = 45.88$ mM) was used in Fig. 1, and $E'_{0g} = 202.8$ mV (giving $Z =$ = 0,15) in Fig. 5. In the other, with $B = 36.92$ mM, we used $E'_{0h} = 834.62$ (giving $Z =$ = 0.195 at $H = 62.26$) in Fig. 3, and $E'_{0h} = 832.25$ (giving $Z = 0.030$) in Fig. 5. These

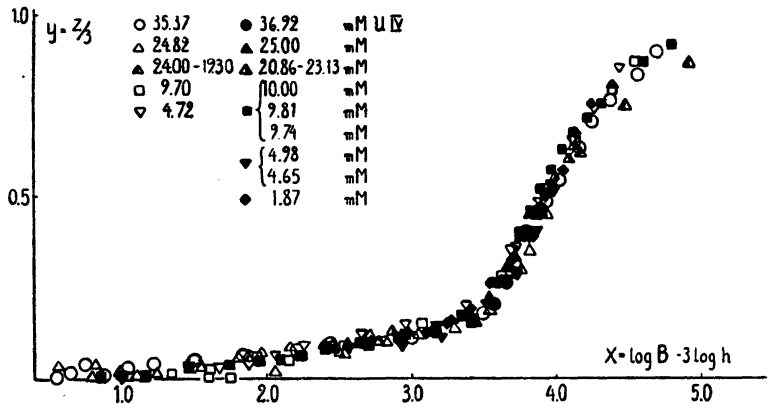

Fig. 5. Data for glass electrode measurements (circles) and hydrogen electrode measurements (dots) recalculated to the form y(x) *assuming* t = 3, x = *log* B − 3 *log* h (*M scale*), y = Z/3.

adjustments were attempted to make the $Z(x)$ curves coincide more closely; large as they may seem, they will influence the Z very little in the steep part of the curve: by about 0.01 in the former case and 0.04 in the latter.

Comparison with simple mechanisms. The $y(x)$ curve was now compared with those calculated for a number of simple mechanisms discussed in AB II[12] and in part 8[13]. The steep part gave no fit with hypothesis I (no soluble complex, precipitate formed) or II (single complex formed, with $n = N$). An acceptable fit was found with hypothesis IIIa, for values of k_0 between 0.1 and 0.01. In mechanism IIIa it is assumed that complexes with all values of n are formed, and that the equilibrium constant k_n for the formation of the n:th "core + links" complex (concentration = c_n) in this case

$$(n+1)U^{4+} + 3\,n\,H_2O \rightleftharpoons U((OH)_3U)_n^{(4+n)+} + 3\,n\,H^+;\ k_n = c_n h^{3n} b^{-(n+1)} \quad (10)$$

is given by

$$k_n = k_0 k^n \quad (11)$$

where k and k_0 are constants.

A better value of k_0 was found using the equation (AB II, 37)

$$k_0 = y[1 - 10^X(1-y)]^2(1-2\,y)^{-2} \cdot 10^{-X} \quad (12)$$

The abscissa x was measured for $y = 0.7$, $0.5(x_{\frac{1}{2}})$, 0.3, 0.2 and, for each value, $10^X = 2 \cdot 10^{(x-x_{\frac{1}{2}})}$ was calculated. This gave $k_0 = 0.042$, $\log k_0 = -1.38$ when $y = 0.7$, $k_0 = 0.06$, $\log k_0 = -1.22$ when $y = 0.3$ and $k_0 = 0.134$, $\log k_0 = -0.87$, $y = 0.2$.

To estimate the uncertainty in k_0 the difference $x(y = 0.633, Z = 1.9) - x(y = 0.267, Z = 0.8)$ was plotted against k_0. The experimental value of this difference varied between 0.45 and 0.55, which would correspond to $\log k_0 = -1.2 \pm 0.3$.

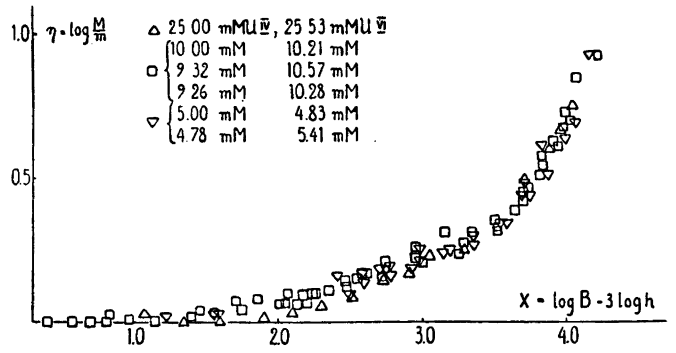

Fig. 6. Data for redox titrations recalculated to the form η (X) *assuming* $t = 3, \eta = log(B/b)$, $x = log\ B - 3\ log\ h$ (*M scale*).

From $x_{\frac{1}{2}}$ one also finds $\log k = \log 2 - x_{\frac{1}{2}} = 3.6 \pm 0.1$.

Direct analysis of the curve $y(x)$. A smooth curve $y(x)$ was drawn through the points of Fig. 5. This curve was used to calculate

$$\log F = y \log e + \int_{-\infty}^{x} y\, dx = \eta \tag{13}$$

$$g = (1-y)F-1; \quad u = 10^x F^{-1} \tag{14}$$

In this case

$$u = bh^{-t} = bh^{-3}; \quad g = \sum k_n u^n \tag{15}$$

The average number of $U(OH)_3$ links per complex is defined by

$$\bar{n} = \sum n c_n / \sum c_n \tag{16}$$

One may calculate $\bar{n}$ either by differentiating $\log g(\log u)$, or directly from y and F. (The second formula may be derived from eqns. 5, 6 and 7 in part 10[5] and eqns. 13 and 14 in this paper)

$$\bar{n} = \frac{\mathrm{d}\ \log\ g}{\mathrm{d}\ \log\ u} = \frac{y}{1-y-F^{-1}} \tag{17}$$

The squares (□) in Fig. 7 were obtained in this way. Whatever the details of the "core + links" reaction, one would expect $\bar{n}$ to start at 1.0 for low x and then to increase with increasing x. The absurd behavior of the function $\bar{n}(x)$ in Fig. 7, with a minimum less than 1, was at first ascribed to analytical errors. So, new $\bar{n}(x)$ curves were calculated, subtracting 0.04 (○) or 0.08 (×) units from each value of y. The $\bar{n}$ curves are still senseless for low x; moreover, these corrections would correspond to a very improbable error in the value of H for the original uranium(IV) solution.

So it was concluded that in the first stages of the hydrolysis, some species other than the "core + links" complexes must be formed. The values of $\bar{n}$

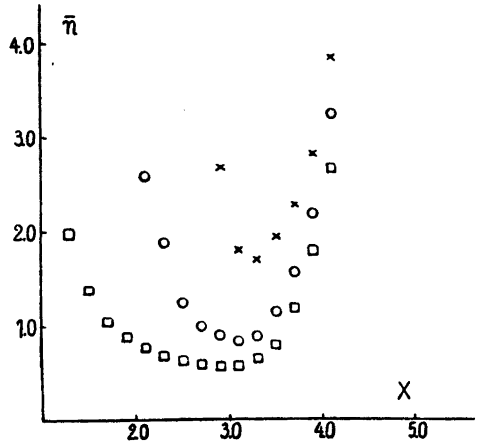

Fig. 7. Direct analysis of y(x) *curve:* $\bar{n}$ *as a function of* x. y = *0* (□) y = *0.04* (○), *y* = = *0.08* (×).

for high values of x, where the "core + links" mechanism seems to predominate, indicate that complexes with $\bar{n}$ greater than 3, *i.e.* with more than 4 U, are present.

Correction for mononuclear reaction

It was found that the Z curves could be explained on the reasonable and simple assumption that, in addition to the "core + links" complexes, the mononuclear complex UOH^{3+} is formed

$$U^{4+} + H_2O \rightleftharpoons UOH^{3+} + H^+;\ \beta_1 = [UOH^{3+}]hb^{-1} \qquad (18)$$

To determine the best values for the constants β_1 for the mononuclear reaction and k for the "core + links" mechanism, a normalized projection map was used as indicated by Biedermann and Sillén [14]. If the "core + links" complexes with $t = 3$, and in addition only the first mononuclear complex are formed, then the total concentration of uranium(IV) is

$$B = b(1+\beta_1 h^{-1}+\sum(n+1)k_n u^n) \qquad (19)$$

and the concentration of OH bound by uranium(IV) is

$$BZ = \beta_1(h^{-1}+3\sum nk_n u^n) \qquad (20)$$

We shall introduce the auxiliary normalized variables

$$\alpha = \beta_1 h^{-1};\ \mathbf{B} = k\beta_1^{-3}B;\ v = ku \qquad (21)$$

and the function $g(v) = \sum k_n u^n;\ vg'(v) = \sum nk_n u^n$ (22)

For the special case of hypothesis IIIa (with an integer value of t) we have

$$g(v) = k_0 v(1-v)^{-1};\ vg'(v) = k_0 v(1-v)^{-2} \qquad (22a)$$

Introducing (21) and (22) we find from (19) and (20)

$$B = b(1+\alpha+g+vg');\ BZ = b(\alpha+3\ vg') \qquad (19a,\ 20a)$$

$$\mathbf{B} = v\alpha^{-3}(1+\alpha+g+vg');\ \mathbf{B}Z = v\alpha^{-3}(\alpha+3\ vg') \qquad (19b,\ 20b)$$

The method consists in preparing a projection map of the experimental data in the form of curves $y(x)_Z$, with the experimental variables

$$x = \log B - 3 \log h;\ y = \log B \qquad (23)$$

This plot is moved parallel to the axes across a projection map of calculated curves $Y(X)_Z$ where the normalized variables are

$$X = \log \mathbf{B}\alpha^3 = x+\log k; \qquad Y = \log \mathbf{B} = y+\log k - 3 \log \beta_1 \qquad (24)$$

In the position which gives the best fit one can at once read the best values of $X-x = \log k$ and $Y-y = \log k - 3 \log \beta_1$

For calculating the normalized projection map one may eliminate α from (19a) and (20a), to find

$$\alpha = (Z(1+g+vg')-3\ vg')(1-Z)^{-1} \qquad (25)$$

$$X = \log v+\log\ (1+g-2\ vg')-\log(1-Z) \qquad (26)$$

$$Y = X-3 \log \alpha = \log v+2 \log(1-Z)+\log(1+g-2\ vg')-$$

$$-3 \log(Z(1+g+vg')-3\ vg') \qquad (27)$$

Thus for a constant value of Z, corresponding values of X and Y can be calculated for various values of the auxiliary variable v. On applying this method (always using $k_0 = 0.01$) and (21a) we found

$$\log k = X-x = -3.40 \pm 0.10 \qquad (28)$$

$$\log k - 3 \log \beta_1 = Y-y = 2.5 \pm 0.3$$

$$\log \beta_1 = -1.95 \pm 0.10$$

The constants k and β_1 can be determined independently from the η titrations, also using normalized projection maps [14]. In this case, an experimental plot $\log B(\log h)_\eta$ and calculated curves $\log \mathbf{B}(\log \alpha)_\eta$ were used. From (19a) and (19)

$$\eta = \log(1+\alpha+g+gv');\ \alpha = 10^\eta - (1+g+vg') \qquad (29)$$

and from (19b)

$$\log \mathbf{B} = \log v+\eta-3 \log \alpha \qquad (30)$$

From the positions of best agreement, we found

$$\log k = \log \mathbf{B} - \log B = -3.30 \pm 0.05$$

$$\log \beta_1 = \log \alpha - \log h = -2.00 \pm 0.10$$

In order to test whether some other value of k_0 could be used successfully, the family of curves $y(x)_Z$ was constructed from the experimental data, when $x = \log B - 3 \log h$ and $y = \log B$. This diagram was compared with projection maps of calculated curves when k_0 was 0.00 and 0.20. These two values could be eliminated in the region of vertical lines, their spacing in the calculated projection map was much too narrow with $k_0 = 0$, and too broad with $k_0 = 0.20$.

A diagram $\log k(\log \beta_1)$ was made in which for each value of $\log k$, the range of $\log \beta_1$ which gave the best fit with the Z and η data, was marked out. From the common area, a middle set and two extreme sets were selected:

$\log k = -3.30$,	$\log \beta_1 = -2.00$
-3.37	-1.98
-3.45	-1.95

With these three sets, theoretical curves $Z(\log h)_B$ were calculated for the different B values used in the Z titrations with hydrogen and glass electrodes. The second (full-drawn) and the third (broken) sets gave the best agreement (Figs. 1 and 3).

The same three sets of constants were also used to calculate curves $\eta(\log h)_B$ (Fig. 4) for the B values used in the titrations. Here also, the second and third set gave the best agreement. It may thus be assumed that

$$\log k = -3.4 \pm 0.1;\ \log \beta_1 = -2.0 \pm 0{,}1;\ \log k_0 = -1.2 \pm 0.3$$

The constant of the mononuclear reaction, β_1, agrees reasonably well with Kraus's constant [2] $\log \beta_1 = -1.63$ in 2 M perchlorate solution. The constant $\log \beta_1 = -1.63$ in 2 M perchlorate is somewhat higher than $\log \beta_1 = -2.0 \pm 0.1$ in 3 M perchlorate as one would expect, especially when one compares it with the constants of Kraus [2] at other ionic strengths:
$\log \beta_1 = -1.56$ for 1 M, $= -1.45$ for 0.55 M, and $= -1.23$ for 0.1 M ClO_4^-
It was tested whether the experimental data could be explained by assuming only the second mononuclear complex $U(OH)_2^{2+}$. The projection map $\log \mathbf{B}(X)_Z$ was calculated when

$$\mathbf{B} = v\alpha^{-3}(1+\alpha^2+g+vg') \quad (31)$$

$$\mathbf{B}Z = v\alpha^{-3}(2\alpha+3\ vg') \quad (32)$$

The experimental data $\log B(x)_Z$ were compared with these curves. The fit was somewhat satisfactory with the high Z values but not with the low Z values.

Then it was assumed that both the mononuclear complexes UOH^{3+} and $U(OH)_2^{2+}$ are formed. The projection map (14) $\log \mathbf{B}\ (X)_Z$ was constructed for

$$\log\ \mathbf{B} = \log v + \log (1+\alpha+l\alpha^2+g+vg') - B \log \alpha \quad (33)$$

$$X = \log v + \log (1+\alpha+l\alpha^2+g+vg') \quad (34)$$

Here $l = \beta_2\beta_1^{-2}$ (35)

where β_1 is the equilibrium constant for the reaction

$$U^{4+} + H_2O \rightleftharpoons U(OH)_2^{2+} + 2H^+ \quad (36)$$

The statistical value $l = 1/4$ was assumed, which means that both protons are split off equally easily. As before, g was taken from (22 a).

The agreement of experimental data with these theoretical curves was somewhat less satisfactory than with the curves when only the first complex UOH^{3+} was assumed. The following constants were calculated from glass electrode and hydrogen electrode measurements.

$$\log \beta_1 = -1.7 \pm 0.2$$
$$\log \beta_2 = -4.0 \pm 0.2$$

The data of the redox electrode measurements were treated in the same way. Only the second complex was at first assumed and the projection map was calculated when

$$\log \alpha = \tfrac{1}{2} \log (10^{\eta} - (1 + g + vg')) \quad (37)$$

and

$$\log \mathbf{B} = \log v + \eta - 3 \log \alpha \quad (38)$$

The experimental data did not fit in this case either and therefore the both complexes with $l = 1/4$ were assumed. The projection map was constructed with

$$\log \mathbf{B} = \log v + \log (1 + \alpha + l\alpha^2 + f + vg') - 3 \log \alpha \quad (39)$$

$$\log \alpha = \log (2\sqrt{1 - (1 + g + vg' - 10^{\eta})} - 2); \quad \eta = \log \frac{B}{b} \quad (40)$$

Also here the fit was not so good as with the assumption that only one mononuclear complex UOH^{3+} is formed. The constants obtained on testing were:

$$\log \beta_1 = -1.7 \pm 0.1$$
$$\log \beta_2 = -4.0 \pm 0.1$$

Influence of uranium (V). In the previous calculations on the η titration data, the presence of uranium(V), UO_2^+, was neglected. According to Kraus [15], $K = 9.6 \times 10^7$ for the reaction $2\,UO_2^+ + 4\,H_3O^+ \rightleftharpoons UO_2^{2+} + U^{4+} + 6\,H_2O$ in 1.96 M perchlorate medium; a specific solution contained 0.361 mM U(IV), 0.536 mM U(V), 2.41 mM U(VI), and 4.95 mM H^+. A rough calculation, using $K = 10^9$, indicates that appreciable amounts of U(V) are present in solutions which contain both U(IV) and U(VI) and $[H^+]$ approximately equal to or less than 10 mM. Then the correct $\eta(x)_B$ curves would be slightly to the left of these now used. The correction would in our experiments be at most of an order of magnitude corresponding to about 1 mV in E_r, which is still within the limits of the experimental error.

STRUCTURE OF THE COMPLEXES

The equilibrium data give no information about the shape of the complexes $U((OH)_3U)_n^{(4+n)+}$. Lundgren [16,17] has studied the crystal structures of two uranium(IV) hydroxide sulfates. In $U_6O_4(OH)_4(SO_4)_6$ he found separate groups, $.U_6O_4(OH)_4^{12+}$; on the other hand, in $U(OH)_2SO_4$ he found infinite chains $(U(OH)_2^{2+})_n$, which are analogous to the chains in the isomorphous compound $Th(OH)_2SO_4$.

It therefore seems reasonable to assume that the uranium(IV) complexes are thread-like, $U(^{O}_{OH}U)_n^{4+n}$, by analogy with the thorium structure.

Acknowledgements. The author is greatly indebted to Professor Lars Gunnar Sillén for many valuable discussions in connection with this work. The author also wishes to thank fil.lic. George Biedermann and fil.lic. Georg Lundgren for helpful suggestions. Mr Frans Ericson is thanked for his help in connection with the equipment.

Thanks are due to Dr Hazel Rossotti, Dr Francis Rossotti and Mr D. G. Gillam for helpful comments during the correction of the English text.

Incorporation of ^{59}Fe into Different Iron Compounds of Liver Tissue

ROBERT B. LOFTFIELD* and ROGER BONNICHSEN

Biochemical Department, Medical Nobel Institute and Wallenberg Laboratory of Physiological Chemistry, Stockholm, Sweden

Techniques are described for isolating and radioassaying the iron of individual iron proteins from rat liver. These compounds include two ferritins, catalase, cytochrome b and cytochrome c.

After intraperitoneal injection of ^{59}Fe, radioactivity appears most rapidly in supernatant ferritin, followed by microsome ferritin, cytochrome b and catalase. After four hours, cytochrome b is the most radioactive.

It is suggested that the injected iron reaches the liver over a period of several hours. Because only a part of the iron of ferritin is labile, the average specific activity of ferritin iron does not rise as high as that of intracellular free iron. Cytochrome b which appears to have a turnover time of only a few hours more nearly reflects the free iron specific activity. It is possible that cytochrome b is a precursor of catalase.

There have been several reports of the use of radio-iron to study iron metabolism *in vivo*[1-4]. The techniques used for isolation of individual iron compounds and the rather low specific activity of the iron employed have limited the conclusions to be drawn. By restricting our investigation to a single rather homogeneous organ, rat or guinea pig liver; by utilizing the Hogeboom-Schneider [5] cell fractionation; by using high specific activity iron; and by developing new isolation methods for the iron containing proteins, we hoped to get a closer view of iron metabolism than has heretofore been possible. Following a single injection of radio-iron, ferritin has been isolated from the microsomes and from the 105 000×g supernatant fraction, cytochrome b from the microsomes, cytochrome c from the mitochondria, and catalase from the supernatant fraction and mitochondria. The radio-iron content of these substances has been followed from one hour to fourteen hours.

EXPERIMENTAL

Iron determination. Each substance to be examined was digested with sulfuric acid and hydrogen peroxide and the total iron was determined using the sulfosalicylic acid method [6,1]. In each case additional ferric sulfate was added to bring the total amount to

* Damon Runyon fellow.

500 μg and all the iron was then precipitated as iron sulfide by saturating the solution with hydrogen sulfide. The iron sulfide was filtered on hard paper and assayed with a shielded end-window counter. Under these conditions the counting efficiency for ^{59}Fe was about 3 %.

Table 1. Iron distribution in liver tissue.

Cytochrome b (hemin iron)	0.029	0.037	0.218	0.22

Fractionation. The rats used were between four and six months old and weighed between 150 and 200 g. They had been on a high iron diet for at least three months. 20 000—100 000 counts per min. of ^{59}Fe (1—5 μg of Fe as ferric ammonium citrate) was administered intraperitoneally to each animal. After the chosen time three to five animals were sacrificed, the livers excised and homogenized in 0.25 M sucrose solution. Fractionation according to the method of Hogeboom and Schneider [5] yielded a nuclear fraction (10 min. 700 × g sediment), mitochondrial fraction (10 min. 5 000 × g sediment), microsomal fraction (40 min. 100 000 × g sediment), and a soluble fraction (100 000 × g supernatant). Table 1 shows average values for the iron content of these fractions and for several iron-proteins.

Supernatant ferritin. To the 100 000 × g supernatant was added one half its volume of saturated ammonium sulfate. The supernatant was saved for isolation of catalase. The precipitate was dissolved in water, repeatedly fractionated with ammonium sulfate (25 to 35 %), and eventually dissolved in water. The solution was heated 5 min. at 70°, and centrifuged to yield a clear solution of ferritin containing between 17 and 20 % iron. When 2 % of cadmium sulfate was added to a very concentrated solution of this ferritin, part crystallized as shown in Fig. 1.

Microsome ferritin. The microsomes were suspended by homogenization in ten volumes of water and the pH was adjusted to 5 by addition of acetic acid. After 30 min., the

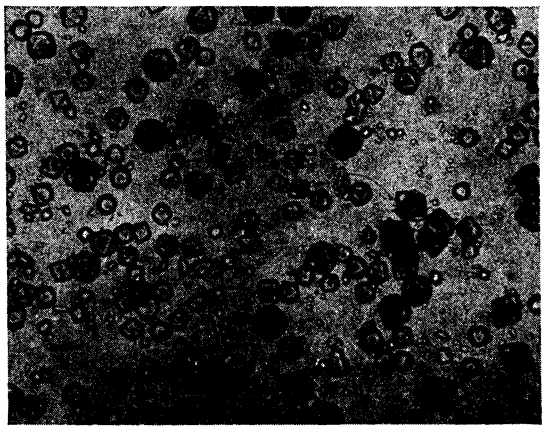

Fig. 1. Rat ferritin crystallized from cadmium sulfate (350 ×).

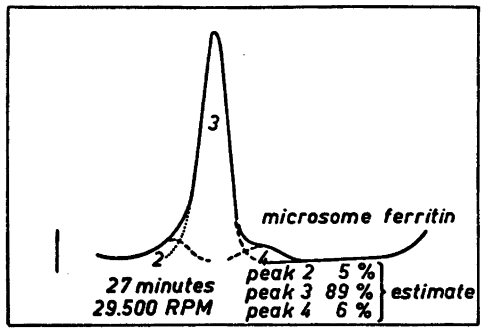

Fig. 2. Ultracentrifugation of microsome ferritin.

suspension was centrifuged and the supernatant was decanted. The sediment was extracted once more with water. The combined supernatants were treated as the supernatant above to isolate the microsome ferritin. This contained 18 to 22 % iron.

Cytochrome b. The sediment remaining after extraction of the ferritin from the microsomes could be solubilized with desoxycholic acid. In agreement with Strittmatter and Ball [7] the only photometrically detectable cytochrome was cytochrome b. Pyridine hemochromogen determinations confirmed this observation. Routinely the extracted microsomes were treated with 1:1 000 HCl-acetone which releases the hemin. The acetone solution was filtered, concentrated and partitioned between water and *peroxide-free* ether. The ether phase was evaporated and ^{59}Fe was determined.

Catalase. To the 100 000 × g supernatant from which ferritin had been isolated more ammonium sulfate was added to 60 % saturation. The precipitate was dissolved in 0.1 M phosphate buffer, pH 7.0, and dialyzed against the same buffer. Four volumes of the dialyzed solution were shaken with one volume of chloroform ethanol (1:3). This denatures all of the hemoglobin present. After centrifugation, the supernatant solution was heated to precipitate the catalase. The precipitate was treated with HCl-acetone and worked up like the cytochrome b. Catalase could also be isolated in the same fashion from the mitochondria.

Cytochrome c. A suspension of mitochondria was adjusted to pH 4.2 with 1.0 N H_2SO_4 and allowed to stand at 4° for one hour. After centrifugation the solution was adjusted to pH 7.0 with 1.0 N NH_4OH and again centrifuged. The clear solution was passed through

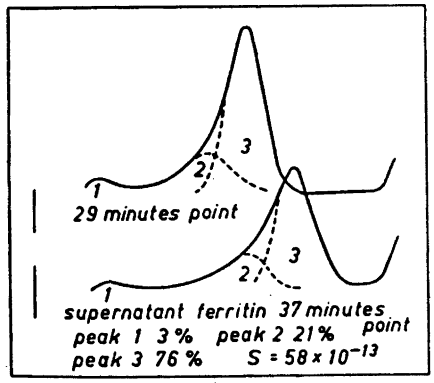

Fig. 3. Ultracentrifugation of supernatant ferritin.

a 4 × 1 cm column of Amberlite XE-69 in the ammonium form. (We are indebted to Rohm and Haas, Inc., and to their associates Chas. Lemming and Co., Ltd., for gifts of this material). All of the cytochrome c is retained by the upper part of the column while hemoglobin and other pigments pass through. After washing with about 20 ml of water, the cytochrome c is eluted with about 4 ml of 1 N sodium sulfate. After reduction with dithionite, cytochrome c was determined by its absorption at 550 mμ. Radio-iron was determined as described above.

RESULTS AND DISCUSSION

Although the isolation of ferritin from rat liver has not been described previously, it was not surprising that ferritin could be obtained. Interestingly, ferritin prepared in this manner from both the microsomes and from the supernatant fraction, gives very sharp peaks in the ultracentrifuge in contrast to previous observations on other ferritins [8] (Figs. 2 and 3). Nonetheless, both of our ferritins give sedimentation constants of 58 and 60×10^{-13} in essential agreement with other workers. Occasionally, we observe in the "supernatant ferritin" a small amount of a colorless protein with a sedimentation constant about 7.5 or 10×10^{-13}. This may be due to apoferritin. The electrophoretic mobilities of our two ferritins are within about 10 % of each other at pH 6.0 namely $-2.2\ u \times 10^{-5}$ for microsome and $-1.95\ u \times 10^{-6}$ for supernatant ferritin. (Figs. 4 and 5).

The radioactivity data is summarized in Table 2 and Fig. 6. The ratios of specific activities at each time interval are quite significant. It appears that ^{59}Fe reaches the liver rather slowly over a period of as much as ten hours. The activity reaching the liver is first incorporated into the "supernatant ferritin" more than twice as rapidly as into the microsome ferritin. This may be compared with earlier observation [9] that ^{14}C-leucine is incorporated into supernatant ferritin ten times as rapidly as into microsome ferritin in a 20 min. period and supports our belief that these two ferritins are biochemically distinct. With the passage of time, iron atoms or perhaps entire ferritin molecules move from the supernatant ferritin pool to the microsome ferritin pool and from ten hours onward the specific activities in each fraction are essentially the same.

It is extremely interesting that the specific activity of the cytochrome b is lower than either ferritin at first and then higher than either. Obviously, the

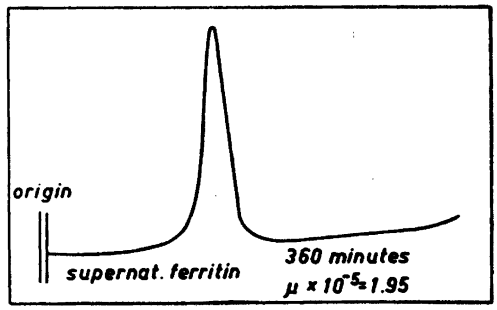

Fig. 4. Electrophoresis of supernatant ferritin.

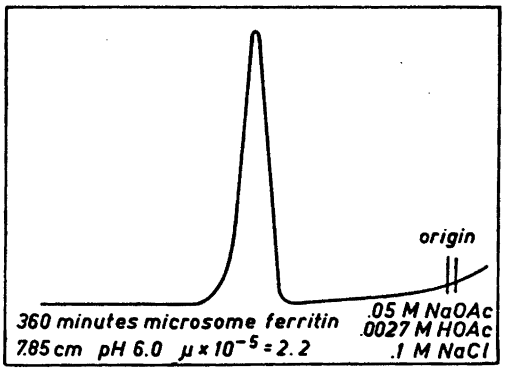

Fig. 5. Electrophoresis of microsome ferritin.

specific activities of all iron precursor substances must have been as high or higher than that of cytochrome b at its highest point. Ultimately, this requirement includes free iron. It would appear that free iron entering the liver is very rapidly picked up or equilibrated with a small amount of the ferritin iron. Accordingly, in the early phase there is a nearly linear rise in the average specific activity of the ferritins and in the total activity of the ferritins, which include about half of the iron of the liver. Because the superficial or most labile ferritin iron (which is in equilibrium with the free iron) is not rapidly equilibrated with the more deeply "buried" iron of the ferritin, the specific activity of the free iron is at all early times higher than the average activity of ferritin iron atoms. Substances synthesized more or less directly from free iron might be expected to reflect the rapid rise in free iron activity to levels much higher than the ferritin average. Cytochrome b appears to be such a substance.

The very high incorporation rate of cytochrome b is made doubly interesting because this substance is found in the microsomes where the bulk of the cell's protein synthetic activity is located. Cytochrome b has as yet no well defined cell function. Perhaps it is a precursor of one or several hemoproteins. If cytochrome b were the precursor of catalase, one might expect the peak of the catalase curve to come at the point that the two curves intersect. This is obviously not the case, but possibilities such as the presence of comparatively

radioactivity inert blood catalase [1] or inert catalase-like substances in the cell extract tend to reduce the observed specific activity of liver catalase by dilution. Hence it is still presumptuous to exclude cytochrome b as a precursor of catalase.

A final noteworthy observation concerns the rather short time required to reach maximum specific activity in each substance in comparison to previous observations [1]. This may very well be due to the much smaller doses of iron and hence the much shorter time required to bring free iron in the liver to its maximum specific activity. From our data we believe that the turnover time of cytochrome b is sufficiently short to permit its being an important precursor of hemoproteins. In turn it is possible that the turnover time of catalase may be short enough to account for the rapid disappearance of catalase on tumor implantation [10]. Liver catalase may also be released to provide part of the blood catalase. The single cytochrome c point serves only to show that liver cytochrome c must also have a rather high turnover rate.

Changes in Glycogen and Nitrogen-containing Compounds in *Escherichia coli B* during Growth in Deficient Media

II. Phosphorus and Sulphur Starvation

T. HOLME and H. PALMSTIERNA

Bacteriological Department and Chemical Department I, Karolinska Institutet, Stockholm, Sweden

The glycogen per dry weight and litre of culture did not increase during the starvation phase in phosphorus-starved cultures to the same extent as in nitrogen-starved ones. An addition of phosphate to the phosphorus-starved cultures caused an immediate increase in the rate of glycogen synthesis, followed by a decrease when the rate of synthesis of nitrogen-containing compounds increased.

Some basic mechanism involving the syntheses of both nitrogen-containing compounds and glycogen seemed to be affected during the starvation phase in sulphur-deficient cultures.

In a preceding article [1] experiments have been described which deal with the chemical composition of *Escherichia coli B* starved of the nitrogen or carbon sources. In this paper the observations have been extended to cells starved of the phosphorus or sulphur sources. As in the experiments previously described, the changes in the chemical composition of the cells after addition of the limiting factor was also investigated.

METHODS

The media used in these experiments were modified from Friedlein's salt-sodium lactate medium [2]. In the experiments with the phosphorus source as the limiting factor, the initial concentration of phosphate (KH_2PO_4) was 7.4×10^{-2} M. Instead of the phosphate buffer, 2×10^{-2} M tris(hydroxymethyl)-aminomethane was used. Growth curves of cultures in non-limited media were not affected by this concentration of "tris" buffer. The medium was made 1.3×10^{-2} M with regard to the potassium concentration by adding KCl. After sterilisation, the pH of the medium was 7.0. In the experiments in which the sulphur source was the limiting factor, the initial concentration of the sodium sulphate was 7.0×10^{-5} M. Instead of magnesium sulphate, magnesium chloride was added.

After a certain period of starvation, an amount of the limiting factor was added to the cultures in order to give them the same concentration as in the complete medium. In the event of phosphorus starvation, the phosphate buffer of the Friedlein medium was added. To the sulphur-starved culture, sodium sulphate was added.

The cultivation techniques and chemical methods were the same as those previously described [1].

RESULTS

Phosphorus starvation. (Expts. E and F, Table 1). The duration of the lag phase was about the same as in the complete medium. A starvation phase, characterized by an almost constant cell concentration, followed after an initial multiplication period. The dry weight of cells during the starvation phase was in expt. E 165 mg, and in expt. F 185 mg per litre of culture. After the addition of the limiting factor, a difference occurred in the behaviour of the two cultures. In expt. E there followed a phase of rapid cell division during the first 30 min. after the addition, whereupon a cell division lag of about one hour's duration was noted, followed by a further cell division period. The dry weight of the cells per litre of culture increased independantly.

In expt. F the cell division rate was low during the first hour after the addition of the limiting factor. Then there was a period of more rapid cell division lasting for about two hours before the culture reached the stationary phase.

The glycogen in per cent of the dry weight did not reach the same high values as in nitrogen-starved cultures [1]. These values varied between 1 and

4 % of the dry weight at the beginning of the starvation phase, and increased approximately 1.5 times during the first hour of this phase (four experiments). The addition of phosphate was followed within five minutes by a very rapid increase in the rate of glycogen synthesis. Total glycogen (glycogen per dry weight and litre of culture) reached a maximum in about 30 min. from the addition of the limiting factor. The maximum rate in the glycogen increase observed immediately after the addition coincided with a lag in the synthesis of nitrogen-containing compounds. When the synthesis of these compounds was resumed, the total glycogen decreased.

Sulphur starvation. (Expts. G and H, Table 2). During the starvation phase in the sulphur-starved cultures, the dry weight of cells per litre of culture continued to increase, but at a low rate in comparison with the rate in non-limited cultures. In expt. G the cell concentration increased from 5.7 to 7.8×10^8 cells per ml during the starvation phase, which was interrupted after about one hour by the addition of sodium sulphate. After this addition there was a small increase in glycogen in per cent of the dry weight during the first five minutes, but it is doubtful whether it is significant. In fact, the glycogen in per cent of the dry weight remained in the neighbourhood of the lowest values observed in cultures grown in lactate media. When the limiting factor was added after at least one hour's starvation, the rate of increase in the dry

weight remained at the same low level as during the starvation phase (expt. G). If, however, the addition was made at the moment when the starvation phase was expected to begin (expt. H), the increase in dry weight per litre of culture proceeded at about the same rate as during the logarithmic phase in non-limited cultures, grown in lactate medium.

No significant increase in the absorption between 220 and 310 mμ of the cell-free culture medium was observed during phosphorus or sulphur starvation.

DISCUSSION

In previous experiments it was shown [1] that glycogen accumulated rapidly in cultures of *Escherichia coli B* when the synthesis of nitrogen-containing compounds was prevented by nitrogen starvation.

During the starvation phase in phosphorus-starved cultures, there was a considerable difference in glycogen in per cent of the dry weight between different cultures, but the glycogen values never reached the high values observed in nitrogen-starved cultures. There was, however, a slow increase in total glycogen during the starvation phase. During the lag in the synthesis of nitrogen-containing compounds following the addition of phosphate, there was an immediate increase in the rate of glycogen synthesis, showing that it was a lack of phosphate that caused the comparatively low increase in glycogen during the starvation phase. As in all other cases tested, the decrease in total glycogen that followed coincided with an increased rate of synthesis of nitrogen-containing compounds.

As shown in expt. E (Table 1), a synchronous cell division occurred immediately after the addition of phosphate, *i.e.* the cell count was doubled in about 20 min. This was followed by a cell division lag of about one hour's duration, which was followed in turn by a new cell division period. This result indicates that it may be possible to obtain simultaneous cell divisions by using the phosphate starvation technique.

Sulphur starvation caused a slowing down of the synthesis of nitrogen-containing compounds as well as of the glycogen synthesis (expt. G). The fact that these syntheses proceeded at a relatively slow rate even after the limiting factor had been added, indicates that some basic mechanism was affected. It seems probable that this change in the cells occurred during the starvation phase, since the addition of sulphate at the beginning of this phase rendered possible a synthesis of these substances at the same rate as in non-limited cultures.

On the Glycogen in *Escherichia coli B*; its Synthesis and Breakdown and its Specific Labeling with ^{14}C

T. HOLME and H. PALMSTIERNA

Bacteriological Department and Chemical Department I, Karolinska Institutet, Stockholm, Sweden

A technique has been devised by which it is possible to label the glycogen in *E. coli B* cells with ^{14}C without labeling the protein to any appreciable extent.

It has been shown that those glucose residues that were the last to be incorporated during a net synthesis of glycogen in *E. coli B*, were the first to be split off by the cells when the conditions were changed in order to cause a breakdown of the glycogen.

If there is a pool of substances on the pathway from medium glucose towards glycogen, this pool will not be large enough to cause any measurable dilution of the medium glucose, when it is incorporated in the glycogen.

It appears that cells in the starvation phase in a nitrogen-starved culture do not break down glycogen simultaneously as they synthesize it.

After the injection of ^{14}C-labeled glucose into rats, Stetten and Stetten [1] found that after a short interval the rat liver glycogen was predominantly labeled in those glucose residues that were the first to be split off by enzymic degradation of the glycogen.

The methods employed by us [2,3] have made possible investigations of the synthesis and breakdown of glycogen in metabolizing bacterial cells. *Escherichia coli B* cells accumulate glycogen during nitrogen starvation. During the last part of this accumulation phase the carbon source was labeled with ^{14}C. The conditions were thereupon changed, so as to make the cells break down part of the glycogen that had accumulated. The results indicate that also in this case those glucose residues that were last incorporated in the glycogen were the first to be split off when the glycogen was degraded, in our case, by the cells.

METHODS AND RESULTS

Nitrogen-starved cultures of *E. coli B* were prepared as previously described [2]. Instead of Friedlein's sodium lactate-salt medium, the glucose-salt medium devised by Hook and coworkers was used [4]. The glucose concentration was 1 g/l instead of 4 g as in the original medium. This reduction had no influence on the length of the lag phase nor on the mean generation time in the log phase. It was possible to starve the cells of the nitrogen source by reducing the concentration of ammonium chloride to 50 mg/l of medium. As in nitrogen-starved cultures grown in lactate medium, the dry weight of cells per litre of culture remained constant during the starvation phase.

During the starvation phase, totally labeled ^{14}C-glucose was added to the culture, and the phase was allowed to proceed for another 45 min. in the labeled medium. The cultivation was then interrupted by cooling the culture rapidly to 4°C. The cell suspension was divided into two equal parts which were centrifuged separately. The wet weight of the cells obtained from these centrifugations [5] was the same for both portions. One portion was taken for analysis, and the cells of the other were incubated for a further 90 min. in a medium from which the glucose had been totally omitted. It contained the same amount of ammonium chloride as the complete medium. The sample taken at the end of this incubation period is called +90 (Table 1). Prior to inoculation the cells were washed once with the medium in which they were to be inoculated. During the nitrogen starvation an increase in ultra violet absorption of the cell-free culture medium was observed, just as in lactate-grown, nitrogen-starved cultures [3]. No such absorption was observed in the glucose-free medium. The results are summarized in Table 1 (expt. A).

Cells that had not been subjected to nitrogen starvation were also used (expt. B, Table 2). Cells from an 18 hours' praeculture in the complete medium were harvested and washed, and then inoculated into an ammonium chloride-free medium (volume: 6 l). The incubation was interrupted by cooling after 10 min. The cells were centrifuged and reincubated in a fresh medium (volume: 4 l) of the same composition, but in this case the glucose was totally labeled with ^{14}C. After an incubation period of 30 min. the culture was cooled and the cells centrifuged and washed. Then they were inoculated into a medium (volume: 2 l) containing ammonium chloride in excess (1 g/l) but no glucose, the incubation lasting in this case 60 min. The results are shown in Table 2.

Prior to inoculation into a new medium, the cells were washed once in the medium in which they were to be incubated. In both experiments the initial culture volume was 6 l. Each analysis is based on cells taken from about one third of the culture. When reinoculating cells into a new medium, the volume of this new medium was always the same as that from which they were harvested. In all particulars other than those described in the present paper, the methods employed were the same as those previously reported [2,3,5].

The results obtained from a nitrogen-starved culture with lactate as the carbon source are reproduced in Fig. 1. Isotopic lactate was added in the same way as described in expt. A. The cells treated in this way were incubated in a medium free of lactate, but containing the nitrogen source in excess. The methods and results have already been described in a preliminary paper [2] (expt. C).

Table 1. Experiment A.

Time after inoculation in min.	Glycogen-glucose per litre of culture (mg)	Counts per min. per μg	
		glycogen carbon	protein carbon
0	1.0	—	—
130	11.0	0	0
175	13.4	113	6
+90	10.2	23	24

The isotope was added at 130 min. after inoculation which in this case was the beginning of the starvation phase. At 175 min. after inoculation the cells were harvested and reincubated for 90 min. in the carbon-less, ammonium chloride-containing medium. During the starvation phase there was no increase in protein nitrogen per litre of culture (8.36 mg/l at 130 min. and 8.32 mg at 175 min.). The number of cells, however, increased during this time from 3.4 to 5.3×10^8 cells per ml. The specific activity of the glucose carbon in the medium was 593 c.p.m. per μg.

An experiment was performed in order to follow the breakdown of glycogen and the protein synthesis in a medium free of carbon but containing the nitrogen source in excess. The methods were the same as those described in expt. C, except that no isotope was added, *i.e.* the cells were praecultured for 270 min. in a nitrogen-deficient medium with lactate as the carbon source, and then incubated in a medium of the same basic composition, but containing 1 g/l of ammonium chloride and no lactate. The dry weight of cells per litre of culture and the cell concentration during the nitrogen starvation was the same as during the starvation phase in expt. C. The results are shown in Fig. 2 (expt. D).

In all cases the specific activity of the protein carbon has been estimated in the following way. Nitrogen determinations were performed on the protein (hydrolyzed for 2 h in 6 N HCl), and the specific activity was calculated per μg of protein nitrogen. These values were converted to specific activity per μg of protein carbon by using a N:C ratio of 0.23. The N:C ratio was determined in four samples and found to be 0.23 ± 0.02.

DISCUSSION

The results given in Table 1 and Fig. 1 (expts. A and C) show that if labeled carbon was added during the starvation phase in a nitrogen-starved culture, it was possible to label the glycogen in *E. coli B* without labeling the protein to any appreciable extent.

When cells labeled in this way were incubated in a medium containing ammonium chloride but no carbon source, glycogen was broken down and some protein synthesized, as shown in Fig. 2.

A lowering of the glycogen to about 75 % of the original value caused most of the label in the glycogen to disappear. This means that those glucose residues

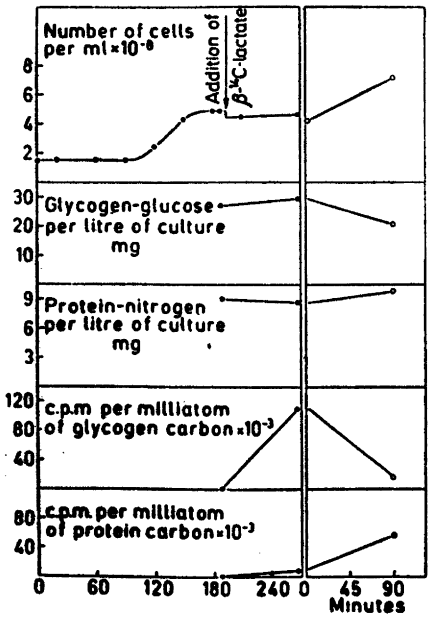

Fig. 1. Experiment C. The curves on the left-hand side of the double line show the course of events during nitrogen starvation. Part of the cells were reincubated in a medium containing the nitrogen source in excess but from which the carbon source was omitted (the curves on the right-hand side of the double line).

that were the last to be incorporated in the glycogen were the first to be split off by the cells, when incubated in a medium containing nitrogen. Under the circumstances the flow of carbon in the cell was directed away from glycogen towards the protein carbon, as shown by the increasing specific activity of the protein carbon.

The results were less marked when cells grown for 18 h in Hook's medium were allowed to accumulate a certain amount of glycogen and were thereupon incubated in a labeled medium (Table 2, expt. B). In these cells the label did not disappear from the glycogen to the same extent when incubated in the carbon-free medium with the nitrogen source in excess. The results show, however, that the specific activity of the glycogen decreased to about 40 % of the original value when the glycogen per litre of culture decreased from 8.9 to 5.1 mg. This shows that the glycogen was not evenly labeled, and that, as in the other experiments, those glucose residues that were the last to be incorpo-

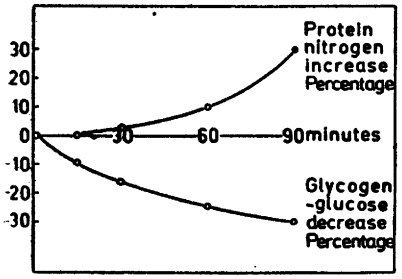

Fig. 2. Experiment D, illustrating the increase in protein nitrogen and decrease in glycogen during the second incubation period in an experiment performed in the same way as expt. C (Fig. 1, the curves on the right-hand side of the double line). The values are represented as increase or decrease in per cent of the values at the moment of inoculation.

Table 2. Experiment B.

Time after inoculation in minutes	Glycogen-glucose per litre of culture (mg)	Counts per min. per μg	
		glycogen carbon	protein carbon
0	1.1	—	—
10	5.8	0	0
40	8.9	348	117
110	5.1	140	320

Media: 0—10 min.: N-free Hook medium, glucose unlabeled.
10—40 min.: N-free Hook medium, glucose labeled.
40—110 min.: N-containing (NH_4Cl), glucose-free Hook medium.
The specific activity of the medium glucose carbon was 590 c.p.m. per μg.

From zero time to the end of the second incubation period (40 min.) the protein nitrogen per dry weight and litre of culture increased from 7.7 mg to 9.1 mg, showing that the cells contained reserves of nitrogen that were incorporated in the protein. At 110 min. the protein nitrogen per litre of culture was 11.5 mg.

rated in the glycogen were the first to be split off. In this case, too, there was an increase in the specific activity of the protein carbon during the last incubation period.

During the time the cells were cultivated in isotope medium in expt. A (130 to 175 min. after inoculation) the glycogen increased from 11.0 to 13.4 mg/l of culture. If this increase had been due solely to glucose of the same specific activity as that of the medium glucose, the specific activity of the glycogen carbon would have been 106 c.p.m. per μg at 175 min. The specific activity noted was 113 c.p.m. per μg of glycogen carbon. This means that during nitrogen starvation there was no large pool of substances on the pathway from glucose to glycogen, at any rate not during the starvation phase. Furthermore, the results may be taken as an indication that in nitrogen-starved cultures there was no appreciable breakdown of glycogen during the starvation phase.*

In expt. B the specific activity of the glycogen should have been 205 c.p.m. per μg when calculated in the same way. The specific activity observed was 348 c.p.m. This means that under the circumstances some of the non-labeled glycogen carbon present at the moment when the cells were inoculated into the labeled medium was broken down during the following incubation period. A net synthesis and a breakdown of glycogen seem to have occurred simul-

* Another possible, but rather unlikely explanation shou'd perhaps be pointed out. If some of the nonlabeled glycogen was broken down, *and* there was a pool of substances on the pathway from medium glucose towards glycogen, the non-labeled substances in this hypothetic pool may have compensated for a loss of non-labeled glycogen, present at the moment when the isotope was introduced. Since the specific activity of the hypothetic pool must have increased during the time in the labeled medium, the culture must have been harvested in this experiment exactly at the time when as much non-labeled carbon had disappeared from the glycogen as had been incorporated in the glycogen from the pool.

taneously in this experiment. This may possibly be attributed to the fact, that there was a considerable protein synthesis during this period in spite of the absence of any nitrogen source in the medium (*cf.* the text under Table 2). As shown by previously reported experiments [3,5] glycogen is utilized by the cells when protein is synthesized.

The Chemistry of the Natural Order Cupressales

XVII.* Heartwood Constituents of *Pilgerodendron uviferum* (D.Don) Florin (=*Libocedrus tetragona* Ends.)

H. ERDTMAN, Z. PELCHOWICZ** and J. G. TOPLISS

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The heartwood constituents of *Pilgerodendron uviferum* (D. Don) Florin have been investigated. From the alkali soluble fraction a very small quantity of a highly dextrorotatory crystalline phenol, probably of the flavanone type has been isolated. The large neutral fraction has been shown to contain a mixture of cadinenes and also a new crystalline cadinol for which the name *pilgerol* is proposed.

As already mentioned in a previous communication [1] the genus *Libocedrus sensu lato* does not constitute a natural group and has been subdivided into several small or monotypic genera. It appears that the still very incomplete chemical investigation of the genus is in harmony with the views of modern botanical taxonomists as regards its heterogeneity. The monotypic genus *Pilgerodendron* differs botanically very distinctly from the other species of *Libocedrus s.l.* and as Florin has remarked it seems strange that this genus was ever included in *Libocedrus*. *Pilgerodendron uviferum* grows along the extremely humid western slopes of the Andes in southern Chile (down to Tierra del Fuego) at altitudes of 600—1 000 metres. The wood is renowned as the most durable wood in the country.

Through the good offices of Jägmästare J. Lagerborg, Talca, Chile, to whom our gratitude is expressed, we have been able to subject a sample of this wood to a preliminary chemical investigation. The wood came from a mature tree about one foot in diameter.

From the alkali soluble fraction of the ether soluble part of the acetone extract of the wood, a minute amount of a highly dextrorotatory crystalline compound was isolated which, judging from its ultra-violet absorption and composition, is probably a flavanone derivative but it is doubtful whether the substance was obtained in a completely pure state.

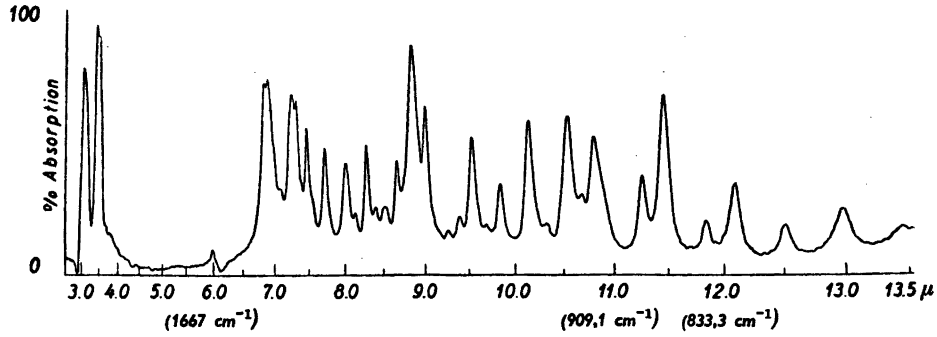

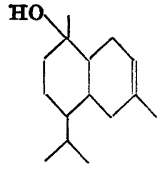

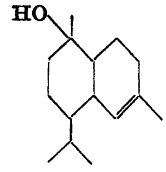

Fig. 1. Infra-red spectrum of pilgerol (KBr disc).

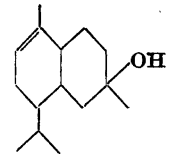

The bulk of the extract was neutral and the steam distillable portion of this was fractionally distilled *in vacuo*. The main hydrocarbon fractions yielded cadalene on dehydrogenation and cadinene dihydrochloride with hydrogen chloride and thus can be considered to be mixtures of cadinenes. From the high boiling fractions a crystalline sesquiterpene alcohol, $C_{15}H_{26}O$, was isolated for which the name *pilgerol* is suggested. It yielded cadalene on dehydrogenation and cadinene dihydrochloride on treatment with hydrogen chloride and is thus a cadinol. Attempts to prepare a crystalline phenylurethane were unsuccessful. Catalytic reduction of pilgerol in ethanol using Adams' catalyst afforded a mixture of diastereoisomeric dihydropilgerols which could be partially separated by fractional sublimation. The infra-red spectrum (Fig. 1) of pilgerol indicated the presence of a trisubstituted double bond (medium-strong band at 873 cm^{-1} and weak band at 1 668 cm^{-1}, both absent in the spectrum of the dihydrocompound). Pilgerol must therefore possess one of the structures (I), (II) or (III). It is hoped to proceed with chemical studies which will distinguish between these three alternatives when more material becomes available.

(I)

(II)

(III)

The remainder of the high boiling fraction from which pilgerol had been separated was chromatographed on alumina and yielded, as the only solid product, a further small quantity of pilgerol. The chromatographic separation was not sharp but of the liquid fractions obtained one, $[\alpha]_D$ —90° ($CHCl_3$), n_D 1.5104 and analysing for $C_{15}H_{26}O$ which corresponded to a peak on the weight per ml of eluate/volume of eluate graph of the chromatogram, was further investigated. On selenium dehydrogenation a good yield of cadalene was obtained but no crystalline hydrochloride was formed by reaction with hydro-

gen chloride. This fraction, therefore, does not appear to consist, in the main, of alcohols of the cadinol type.

Only one crystalline cadinol (m.p. 72.5°, $[\alpha]_D$ —39.4) has previously been reported (from Java-citronella oil [2] and *Chamaecyparis lawsoniana* [3]). Cadinols have been reported to occur in several other species belonging to the natural order Cupressales, *e.g. Cryptomeria*, *Taiwania* [4], *Fokenia* [5], and *Chamaecyparis pisifera* [6]. No tropolones were found in *Pilgerodendron* in contrast to *Heyderia decurrens* (β- and γ-thujaplicin) and *Austrocedrus* (β-thujaplicin) and in no other respect does *Pilgerodendron* appear to exhibit chemical similarities to the other species of *Libocedrus s.l.*

EXPERIMENTAL

All melting points are corrected.

Extraction of the heartwood. The powdered heartwood (9 kg) was extracted continuously with acetone for 32 h and the acetone removed by distillation yielding 550 g of extract. This was vigorously shaken with ether (2.5 l) when it partly passed into solution leaving some of the material (*ca.* 200 g) undissolved. The latter was of the usual "membrane substance" type and was discarded. The ether solution (A) was shaken with a saturated solution of sodium bicarbonate (1.5 l). Ether phase = A′, aqueous phase = B′. Acidification of B′ with dilute sulphuric acid and extraction with ether *etc.* yielded only 3 g of an acidic material (B^{1a}). The ether solution A′ was shaken with a 10 % solution of sodium carbonate (1.5 l). Ether phase = A^2, aqueous phase = B^2. Acidification of B^2 with dilute sulphuric acid and extraction with ether *etc.* yielded another acid fraction (B^{2a}, 14 g). The ether solution A^2 was shaken with a 5 % solution of potassium hydroxide (1.5 l). Ether phase = A^3, aqueous phase = B^3. Acidification of B^3 and extraction with ether etc. yielded still another acidic material (B^{3a}, 25 g). A^3 on evaporation of the ether yielded a neutral fraction (310 g).

Examination of the sodium carbonate extract. The material extractable with 10 % sodium bicarbonate solution (fraction B^{2a}) was dissolved in ether (35 ml) and the solution filtered through a column of aluminium oxide (1.5 × 3.5 cm) which was then washed with ether (100 ml). The solvent was evaporated, the residue treated with methanol and the crystals which separated were recrystallised from a little methanol. After several recrystallisations needles, m.p. 217—219°, were obtained (0.107 g), $[\alpha]_D$ 324° (c = 1.2, acetone). (Found: C 64.6; H 4.9. $C_{16}H_{14}O_6$ requires C 63.6; H 4.7), Ultra-violet absorption: min 248 mμ (ε 725), max 290 mμ (ε 9 000), shoulder 225 mμ (ε 1 800). The acetate was

* refractive indices from first and last portions
** refractive indices from first, middle and last portions

prepared by dissolving the compound (0.030 g) in a mixture of acetic anhydride (2 ml) and pyridine (3 drops). After 24 h at room temperature water was added and the solid collected. This was recrystallised from ethanol, m.p. 187.5—189°. (Found: C 62.5; H 4.9; OCH_3 8.8. $C_{15}H_8O_2$ $(OCOCH_3)_3OCH_3$ requires C 61.7; H 4.7; OCH_3 7.25.). Ultraviolet absorption max 220 mμ (ε 7 400), min 250 mμ (ε 980), max 278 mμ (ε 4 500).

Examination of the neutral fraction. The neutral fraction A^3 was steam distilled and the steam volatile part, (A^{3a}, 213 g) collected and subjected to fractional distillation at 6.5 mm with the results shown on p. 1565.

Dehydrogenation. Of the distillation fractions, numbers A^{3a5}—A^{3a10} were subjected to dehydrogenation with selenium (14 h, 300°) and all yielded cadalene, identified as the picrate m.p. 114.5—115°, not depressed on admixture with an authentic sample.

Hydrochloride. A sample (0.40 g) corresponding to a mixture of fractions A^{3a5}—A^{3a10} was dissolved in ether (40 ml), and the solution cooled to 0° and saturated with dry hydrogen chloride. After 15 min. the ether and excess of hydrogen chloride were removed and the remaining oil dissolved in ethanol (3 ml). After 24 h in the refrigerator 0.40 g of a crystalline hydrochloride had separated, m.p. 117—118°, $[\alpha]_D$ —36° (c = 1.4 in $CHCl_3$). The melting point was not depressed on admixture with an authentic sample of cadinene dihydrochloride (kindly supplied by Professor F. Šorm, Prague).

Pilgerol. From the highest boiling fraction A^{3a13} crystalline material (2 g) slowly separated and was collected by filtration. After several recrystallisations from ethanol--water followed by sublimation *in vacuo*, pure *pilgerol*, m.p. 138.5—139°, $[\alpha]_D$ —107° (c = 1.1 in $CHCl_3$) was obtained. (Found: C 80.63; H 11.60. $C_{16}H_{26}O$ requires C 81.00, H 11.78.) Infra-red spectrum (Fig. 1): bands at 873 cm^{-1} and 1 668 cm^{-1}, (trisubstituted double band).

Dehydrogenation. Pilgerol was dehydrogenated with selenium (24 h, 300°) giving cadalene (65 % yield), identified as the picrate.

Hydrochloride. Pilgerol (0.100 g) was dissolved in dry ether and dry hydrogen chloride passed into the solution at 0°. After removal of the ether and excess of hydrogen chloride the crystalline residue was recrystallised from ethanol (2 ml) affording cadinene dihydrochloride, m.p. 117—118°, $[\alpha]_D$ —35° ($CHCl_3$), in 80 % yield. The melting point was undepressed on admixture with an authentic sample of cadinene dihydrochloride.

Attempted preparation of the phenylurethane. Pilgerol, when heated with excess of phenyl*iso*cyanate at 90° for 1 h or treated with excess of phenyl*iso*cyanate at room temperature for several days or refluxed with phenyl*iso*cyanate (1.1 mole) in petroleum ether (60—80°) solution for 30 min. did not yield any crystalline phenylurethane.

Hydrogenation. Pilgerol (0.076 g) was hydrogenated in ethanol (15 ml) in the presence of Adams' catalyst (0.044 g), at room temperature and atmospheric pressure for 100 h. The catalyst was then removed by filtration, the alcohol evaporated and the residue sublimed *in vacuo* to give *dihydropilgerol* (*ca.* 0.06 g) as feathery needles, m.p. 79—80°, $[\alpha]_D$ +17° (c = 1.4 in $CHCl_3$), (Found: C 80.39; H 12.60. $C_{15}H_{28}O$ requires C 80.29; H 12.57). The product showed no unsaturation by the tetranitromethane test (in contrast to pilgerol itself) and the infrared spectrum exhibited no bands corresponding to ε double bond. Fractional sublimation, however, gave a small fore-fraction m.p. 74—75° and a main fraction m.p. 80—81°. Resublimation of the latter fraction gave more of the previously obtained fore-fraction m.p. 74—75° and a less volatile fraction m.p. 90—94°. The hydrogenation product thus appears to consist of a mixture of diastereoisomers. Substantially the same result was obtained when the hydrogenation was carried out in glacial acetic acid as solvent.

Chromatography of the sesquiterpene alcohol fraction The distillation fraction A^{3a13} (from which the separated pilgerol had been removed by filtration) (7.5 g) in petroleum ether (25 ml), was placed on a column of alumina (250 g) and eluted successively with petroleum ether, petroleum ether-benzene mixtures, benzene, benzene-ether mixtures, ether and finally methanol. In all 49 fractions were taken. The fractions (total weight 1.74 g) corresponding to a peak in the weight per unit volume of eluate/volume of eluate graph all completely or partially solidified. By addition of a little petroleum ether and filtration the solid material was isolated and recrystallised from petroleum ether (40—60°) (needles) giving pure pilgerol (0.150 g) m.p. 140—141°, undepressed on admixture with pilgerol previously isolated. Other fractions (total weight 1.37 g) corresponded to another main peak in the weight per volume of eluate/volume of eluate graph. A middle fraction of these, $[\alpha]_D$ —90° (c = 2.14 in $CHCl_3$), n_D^{23} 1.5104, was analysed, (Found: C

80.45; H 11.44. $C_{15}H_{26}O$ requires C 81.00; H 11.78.). Further samples were (a) dehydrogenated by heating with selenium powder to give a good yield of cadalene (identified as the picrate, m.p. and mixed m.p. 116—116.5°) and (b) treated with dry hydrogen chloride in dry ether at −10° to 0° when no crystalline hydrochloride could be obtained.

We wish to thank *Statens Naturvetenskapliga Forskningsråd* for financial support and Dr. I. Fischmeister, *Medicinsk-Kemiska Institutionen*, Uppsala Universitet, for the infrared spectra determinations.

An investigation of polynucleotide and protein turnover in regenerating rat liver has been made using ^{15}N-labeled glycine. Ten time stages, between 10 and 80 h after operation, have been studied, and particular attention has been paid to the incorporation pattern during the early period after hepatectomy.

1. The maximum of total cell PNA purine incorporation occurred at 14 h, considerably ahead of any other maximum. There was a smaller, broader peak of uptake into PNA around 26 to 56 h.

2. Incorporation into DNA purines was less than into those of PNA but of the same order of magnitude; the exact ratio between the two nucleic acids varied at different times. The peaks of incorporation into the DNA purines occurred at 26—32 and at 56 h.

3. In both PNA and DNA the two purine bases were not identical either in absolute uptake of ^{15}N or in time changes of incorporation. Guanine consistently showed a greater uptake of isotope than did adenine, but the ratio between the bases varied with time.

4. Total protein and its glycine constituent both showed two peaks of incorporation, at 20—26 and at 44 h, respectively, considerably later than the initial PNA maximum.

5. Cytological studies located the peak of mitosis frequency around 32 h; this coincided rather well with the major peak of isotope incorporation into DNA. Estimations of the relative size of the various cell parts revealed that the nucleolus showed maximum size earlier than did the nucleus and cytoplasm.

* Part of this work was presented at the Ciba Foundation conference on Isotopes in Biochemistry, London, 1951. The work was aided by grants from *Statens Medicinska Forskningsråd.*

** Research fellow of the American Association of University Women and the American Scandinavian Foundation; present address, National Institutes of Health, Bethesda, Maryland.

Previous work from this laboratory [1] undertook an investigation of polynucleotide and protein turnover in regenerating rat liver, as revealed by the incorporation of ^{15}N-glycine. Protein turnover was judged by the uptake of isotope into the glycine constituent of the total protein, and nucleic acid turnover by the incorporation of tracer into the purine bases, which have been shown to be specifically labeled by this precursor [2-7]. This work showed that the maxima of turnover of these substances, particularly the polynucleotides, occurred soon after hepatectomy, rather than in the later stages of regeneration which have been studied in certain other investigations [8-10]. Further work was therefore undertaken to examine the time curve more closely during this early period, under more carefully controlled experimental conditions but similar conditions of isotope administration.

EXPERIMENTAL

The animals used were adult albino rats weighing 180—200 g. The investigation included eleven groups of animals, each comprising five to ten rats; one group of non-hepatectomized rats represented the normal base line of no regeneration, while the other groups represented various time points of regeneration — 10, 12, 14, 17, 20, 26, 32, 44, 56 and 80 h, respectively (time from hepatectomy to death).

Partial hepatectomy was performed as described in previous work [3]. The wet weight of the extirpated portion of liver was recorded in each case and the weight of the remaining portion calculated, as in earlier work [1]. The weight of the total original liver was thus recorded.

Since the voluntary consumption of food by the hepatectomized animals is considerably below normal, especially at early stages after operation, all rats were fed a definite amount of food by means of stomach tube. The diet [11] * was made up as a water suspension containing 10 g per 24 ml, and each rat was given 4 ml of this suspension per 200 g (weight at the beginning of the experiment) every 4 h. Feedings of the hepatectomized rats were begun 4 h after operation. The non-hepatectomized animals were fed in this manner for 32 h, with the last feeding being given 4 h before death.

Labeled glycine (32.9 atom per cent excess ^{15}N) was injected subcutaneously in aqueous solution. The total dosage was 200 mg per 200 g (weight at the time of first injection) divided in half and given in two injections, 5 and 4 h, respectively, before death.

The livers from all animals were removed and weighed. From these figures and the calculated weights of the total original liver, the extent of regeneration was determined (weight of regenerated liver as per cent of weight of total original liver).

Samples of each liver were taken for determination of water content and for cytological examination. In the cytological studies the relative size of the nucleus, nucleolus, and cytoplasm areas (optical cross-section areas), were determined as described previously[1]; the mitosis frequency was also measured [1].

The livers from each group of animals were pooled in alcohol, homogenized, and dried. The material was then disintegrated by vibration with glass beads [12] and extracted with boiling alcohol-ether to remove lipids. Mixed polynucleotides were extracted by the method of Hammarsten [12], hydrolyzed in alkali, and separated into pentose nucleic acid (PNA) and desoxypentose nucleic acid (DNA) with lanthanum nitrate.

The PNA mononucleotides were purified by precipitation with mercuric nitrate and decomposition with hydrogen sulfide, and the purine bases were split off by hydrolysis in

* This synthetic amino acid diet was originally set up as a basis for further investigation on the effect of single amino acid deficiencies on liver regeneration. However, preliminary experiments indicated that a deficiency of one of the essential amino acids produced no decrease in this liver growth or in the incorporation of glycine, and in later work this diet was replaced by a less elaborate one containing 18 % casein instead of the synthetic amino acids. The authors are grateful to Dr. Arvid Wretlind for advice on the composition of the diet and for assistance with the animal experiments.

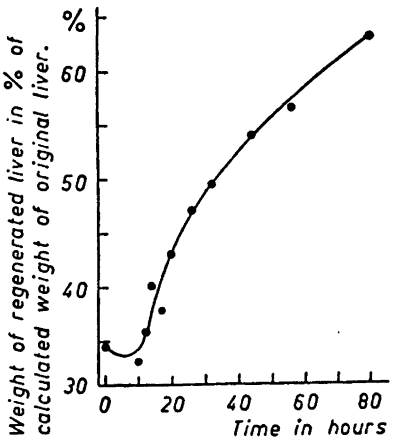
acid and precipitated with silver, according to established methods [13,14]. The silver purines were decomposed with hydrochloric acid [13], excess hydrochloric acid removed *in vacuo*, and the free bases isolated and purified by starch chromatography, using a solvent system of butanol-water [15]. The pyrimidine bases were not analyzed.

The lanthanum precipitate of DNA was decomposed with potassium carbonate and the DNA precipitated with acid alcohol and dried [16]. The DNA was then hydrolyzed with dry hydrochloric acid in methanol [17]. The purine hydrochlorides were dissolved in water, the excess hydrochloric acid removed, and the pure bases again separated on starch.

All purine bases from both PNA and DNA were analyzed for ^{15}N content in the mass spectrometer, nitrogen being determined by a semi-micro Kjeldahl procedure. Purity was checked in each case by determination of the ultraviolet light absorption and the ratio $E_{max}/\mu g$ N per ml.

The protein residue from the polynucleotide extraction was treated twice with hot 5 % trichloroacetic acid, according to Schneider [18], to remove any remaining traces of polynucleotides. It was then dried, hydrolyzed with 6 N hydrochloric acid, and separated into the constituent amino acids by starch chromatography, according to Åqvist [19]. Both the total unhydrolyzed protein and the isolated glycine constituent were analyzed for excess ^{15}N.

RESULTS



The average extents of regeneration found for these various time stages are shown in Fig. 1. It can be seen that after a slight initial drop the liver weight increased to 63 % of the original weight by 80 h. The differences in extent of regeneration at the earlier time stages are within the limits of biological variation and probably do not indicate significant deviation from the curve of steady increase.

Table 1 shows the figures for the atom per cent excess ^{15}N found in the PNA and DNA purines as well as in the total protein and its glycine constituent. The figures are calculated on the basis of 100 % ^{15}N in the administered glycine.

From these figures it can be seen that when the turnover picture is examined with time intervals so close together in the period soon after hepatectomy, the trends appear to be more complicated than could be seen from previous work with regeneration stages farther apart. The highest peak of PNA incorporation occurred as early as 14 h after operation, considerably ahead of any other maximum. In agreement with earlier work in this laboratory on glycine-^{15}N incorporation *in vivo* [1,3,20], the uptake into guanine was considerably greater than that into adenine, but the ratio between the two bases varied at different regeneration times. The time changes for the PNA purines showed that after 14 h guanine incorporation fell off rapidly to increase again around 26 h, while adenine incorporation decreased somewhat more slowly and then rose to a broader maximum between 26 and 56 h.

The incorporation into DNA was lower than that into PNA, although the figures for both nucleic acids had the same order of magnitude. The exact ratio between PNA and DNA varied with time, as did that between the two purine bases. As in the case of PNA, the DNA guanine showed a greater uptake of tracer than did adenine, but again the two purines did not show the same changes with time, both exhibiting considerable variation with both increases and decreases during the total time range. The highest incorporation was found at 26—32 and at 56 h.

From Table 1 it can also be seen that the total protein and the protein glycine both showed two peaks of isotope incorporation, also in the later stages,

at 20—26 and 44 h, respectively. This is in agreement with previous work [1]. It should be emphasized that this maximum is considerably later than the initial high peak of PNA incorporation.

The results of the cytological studies also showed considerably more variation than previously observed for regeneration stages farther apart in time [1,21]. The nucleolus was the first cell part to increase in size (optical cross-section area), reaching a maximum as early as 10—20 h. Both nucleus and cytoplasm approached maximum size around 26 h. The peak of mitotic activity came rather late in this series, based on the average of results for all livers within each group; the mitosis frequency remained at the normal low level through 20 h of regeneration and then increased to a maximum of about 10 % (per cent of cells counted which were undergoing mitosis) by 32 h. With such close time

Table 1.

* The values are calculated on the basis of 100 % ^{15}N in the administered glycine.

** The curves for the time changes of ^{15}N content in the PNA purines and in the protein have been previously published [23].

intervals it was observed that mitotic activity increased very sharply at a particular time point for each liver, but examination of the individual livers indicated considerable variation among animals in the time point at which this began. Thus, around 26 to 44 h, each liver showed either great mitotic activity or very little mitosis, and the composite figure for each time interval could only be obtained by averaging the extremes for each group.

If the cytological findings are compared with the findings on isotope incorporation, it can be seen that the maximum of mitosis frequency correlated rather well with the major peak of isotope incorporation into DNA. Such correlation has also been emphasized in earlier work [1,22]. By and large, however, the appearance of the cell parts, as expressed in the other cytological magnitudes, does not seem to have a direct relationship to the chemical events reflected in the pattern of isotope incorporation.

DISCUSSION

As pointed out in previous work [1,23], an ideal precursor for isotope experiments would be incorporated directly, or by identical pathways, into all of the materials being analyzed. This situation can almost never be realized for a variety of substances, but a direct incorporation is approached in the uptake of glycine by protein[23]. In this case, therefore, the turnover indicated by glycine incorporation might be assumed to approximate that of the protein itself, with time changes being indicative of actual changes in the protein turnover rather than simply variations in biosynthetic patterns associated with this particular precursor. Explanation of the double maximum in the protein uptake of isotope could, then, be sought in the protein itself. Such a double maximum has been observed previously in this laboratory in a study similar to this [1] as well as in an investigation of the incorporation of ^{15}N-glycine into all the constituents of protein [24]. The double peak has been discussed in this earlier work in connection with heterogeneity of the protein fraction; since the fraction is a composite of cell proteins, the figures for isotope incorporation would be affected by variations in the composition of the total fraction.

Although the incorporation of glycine into polynucleotide purines has also been shown to be specific [2,4–7], the pathway is a complex one [25-29] and the uptake of this amino acid into the purine molecule might be expected to be somewhat more complicated than that into protein; the results in the present study would support this idea. The differences between the two purine bases, not only in extent of incorporation but also in pattern of time changes, indicate non-identical patterns of incorporation in the two cases *cf.* [30-33]. Studies on differences in the pattern of nucleic acid turnover revealed by the incorporation of various precursors [34-39] have served to emphasize the complexity of this problem. Thus, it is known that parts of the pattern found in these results, such as the high guanine to adenine ratios and the comparatively low PNA to DNA ratios, are typical of glycine incorporation and are not as evident with certain other nucleic acid precursors [3,4,6,16,20,23,34,36-44]. It is also apparent that these ratios reflect incorporation by purine bases themselves and are not due only to differences in uptake by the pyrimidine or carbohydrate portions

of the nucleic acid molecule [cf. 36]. Possible factors contributing to differences between dissimilar precursors include the availability of any particular one for biosynthesis in a specific tissue, dilution by unlabeled pools of intermediates, and the metabolic effects of enzyme distribution and activity. Moreover, the incorporation pattern for any one precursor could be affected by independent turnover of specific parts of the molecule being synthesized, so that the problem is the extent to which the incorporation is representative of overall nucleic acid turnover. In the light of the known differences in turnover results, it would seem highly probable that there are different paths of biosynthesis of nucleic acid components and that these paths may coexist in one tissue. Since we know very little about how such paths may vary in importance during function, data with various precursors must be correlated before the incorporation of any particular one can be fully evaluated as an accurate reflection of total nucleic acid turnover during liver regeneration. In addition to reflecting any such effects of a particular precursor, the nucleic acid turnover pattern, like that of the protein, could be affected by any heterogeneity of the material.

All such variations could affect the time changes for both PNA and DNA. The DNA figures here showed particularly irregular changes, but since glycine incorporation into DNA is high even in non-dividing tissue [cf. 41,45], the isotope uptake here might be expected to show variations due to DNA synthesis not associated with cell division, or even to some dynamic turnover having no relation to actual synthesis. The factors mentioned above could enter into such turnover; heterogeneity of DNA has been specifically pointed out [46-48]. DNA is considered to be metabolically a rather stable cell component. However, it may also be that at least the smaller variations in DNA incorporation here represent merely biological variation during regeneration (*cf.* the results on mitosis frequency). This question of the reproducibility of the biological phenomenon being studied must be kept in mind in evaluating all of these time curves, since it is virtually impossible to know to what extent the groups representing the various time points actually correspond to each other in regeneration.

The time changes in PNA incorporation of isotope seemed considerably more distinct, and the double maximum in this incorporation, revealed by this examination of such close time intervals, was of considerable interest. It appeared to be of value to try to investigate further the significance of this curve for PNA in terms of some of the variables discussed above. One possible explanation of the double peak in incorporation was cellular heterogeneity of the PNA; the PNAs from nucleus and cytoplasm are known to show great differences in the absolute uptake of various precursors [1,3,36-38, 49-53] and might well vary also in their changes of incorporation with time. Another possibility was a difference among the various nitrogen atoms of the purines in rate of incorporation. Further work was therefore undertaken to explore these particular possibilities.

The distinction between turnover and synthesis is a difficulty always encountered in the evaluation of isotope incorporation pattern. It is evident that the pattern will be influenced by changes in the equilibrium between synthesis and degradation. In the case of both protein and nucleic acid it appeared desirable, therefore, to determine to what extent the turnover figures

here represented actual net synthesis of new molecules. Towards this end a comparable study was undertaken to determine the quantitative changes in the content of these materials in liver during regeneration.

Further Studies on the Turnover of Polynucleotides in Regenerating Rat Liver

E. P. ANDERSON* and S. AQVIST

Department of Biochemistry, Karolinska Institutet, Stockholm, Sweden

A further study has been made on polynucleotide and protein turnover in regenerating rat liver, using ^{15}N-labeled glycine. Liver tissue at 14, 18, 26, 37 and 126 h after hepatectomy was fractionated into nuclei and cytoplasm and the incorporation of glycine nitrogen into PNA and DNA purines and into total protein was determined. The purine bases from cytoplasm PNA were further degraded in order to analyze separately ^{15}N incorporation into the amino group, into N_7 of the ring, and into the pool of ring nitrogen atoms 1, 3 and 9.

The time curves of incorporation into both polynucleotides and protein were, for the most part, in agreement with those found in earlier work. Incorporation into cytoplasm PNA purines showed an early peak at 18 h after hepatectomy and a second one at 37 h. Nuclear PNA tended to reach maximum uptake around 26 h, somewhat later than the major peak for cytoplasmic PNA. The peak of incorporation into DNA was at 26—37 h. The curve for incorporation into protein showed two maxima, at 26 and 37 h, respectively.

The animals in this series showed appreciably greater liver regeneration than did those in the earlier study, in which the diet contained synthetic amino acids instead of casein. The absolute levels of incorporation were also higher than those in the previous study.

This study aimed at exploring possible explanations for the double peak found previously in the time curve of PNA incorporation. The two possibilities specifically investigated, cellular heterogeneity of the PNA and differences among the constituent nitrogen atoms of the purines, could not explain this double peak. Although the uptake into nuclear PNA was much greater than into cytoplasm PNA, both showed essentially the same time changes in incorporation. Likewise, the various nitrogen atoms of the purines followed time curves similar to those seen for the parent compounds. The high ratio of incorporation into guanine to that into adenine also carried over into all the constituent nitrogen atoms.

This study was undertaken in conjunction with another more intensive examination of the time curves of polynucleotide and protein turnover in regenerating liver, as indicated by the incorporation of ^{15}N-glycine [1]. This

previous study included time intervals very close together in the early period after hepatectomy, and the results revealed a somewhat surprising complexity in the time curves of incorporation for the purine bases of the nucleic acids. Of particular interest was a double maximum in the incorporation into the pentose nucleic acid (PNA) purines, the higher of the two peaks occurring at 14 h, and the second, lower one somewhat later. It was thought possible that this double maximum might be explained by cellular heterogeneity of the PNA, since the previous study had been made on total cell PNA, or by differences among the various nitrogen atoms of the purines, which had not been examined separately. The present study was undertaken to investigate these specific possibilities.

EXPERIMENTAL

The study was again made on groups of animals at various stages of liver regeneration. The present study included fewer time points than did the previous study, and larger groups of animals were used. Five groups of adult albino rats weighing 180—200 g were subjected to partial hepatectomy [2] and the livers allowed to regenerate for 14, 18, 26, 37 and 126 h, respectively (time from operation to death). The groups were made up of 17 to 29 animals, depending upon the amount of liver tissue which could be expected for that particular regeneration stage.

During all but the longest regeneration period the animals were fed every four hours by stomach tube to insure adequate food intake. The diet was somewhat different from that used in the earlier study [1]. The one used previously was made up from synthetic amino acids and was to serve as a basis for further studies of amino acid deficient diets. Since preliminary work indicated no effect on liver growth or isotope uptake from such deficient diets, this rather elaborate diet was abandoned and replaced in the present study by one containing 18 % casein instead. This diet was given as a water suspension containing 10 g per 24 ml, and each rat received 4 ml of this suspension per 200 g (weight at time of hepatectomy) at each feeding. The animals undergoing 126 h of liver regeneration received the same diet in dry form rather than by stomach tube; they obtained and consumed 12 g per day.

An aqueous solution of labeled glycine (32.9 atom per cent excess ^{15}N) was injected subcutaneously at a total dosage of 200 mg per 200 g (weight at time of injection). This was divided into two equal doses given 5 and 4 h, respectively, before death.

The regenerated livers from all animals were removed and weighed, and the average extent of regeneration calculated for each group, as described in previous work [1].

The livers for each group of animals were pooled, homogenized, and fractionated into nuclei and cytoplasm in citric acid, as in earlier work [2,3]. The nuclei were washed, disintegrated by vibration with glass beads in alcohol [4], and extracted with alcohol-ether to remove lipids [1]. The cytoplasm material was precipitated with alkali [3] and similarly extracted with alcohol-ether. From the dried tissue preparations mixed polynucleotides were then extracted by the method of Hammarsten [4], hydrolysed in alkali, and separated into PNA and desoxypentose nucleic acid (DNA) with lanthanum acetate [4].

The solutions of PNA nucleotides were hydrolyzed in 1 N hydrochloric acid at 100°C for 1 h, and the resulting mixture of purine bases and pyrimidine nucleotides was fractionated on Dowex 50, the pyrimidine components being eluted with 0.1 N acetic acid and the purine bases with 2 N hydrochloric acid [5]. Aliquots of each of the purines were purified by starch chromatography and the purity was checked and the ^{15}N content determined in the usual way [1]. This determination constituted the entire examination of the nuclear PNA purines. In the case of cytoplasm PNA, however, only small portions of the purines were used for this estimation of the isotope content in the total compound. The rest of each purine fraction was deaminated with sodium nitrite and hydrochloric acid, according to a modification of the methods of Strecker [6] and Kossel [7], under conditions found from preliminary experiments to give the best recovery of oxypurine in each case. Aliquots of the resulting hypoxanthine and xanthine were further purified by Dowex 50 and starch [8] chromatography in the same way as the amino purines and used for deter-

mination of ^{15}N. Other aliquots of the oxypurines were evaporated to dryness at an alkaline pH to remove contaminating ammonia and further degraded by combustion in 6 N hydrochloric acid at 175°C for 24 h [9] to break the purine ring. This splits off the N_7 atom in the form of glycine, leaving a pool of ammonia from the nitrogen atoms 1, 3, and 9 [10,11,12]. The resulting glycine and ammonia were isolated on Dowex 50 [13,14] and ^{15}N content determined on each.

The lanthanum-DNA was decomposed with potassium carbonate and the DNA precipitated with acid alcohol [1,15], dried, and hydrolyzed with dry hydrochloric acid in methanol [16]. The purines were dissolved, freed of excess hydrochloric acid, and purified on starch for determination of ^{15}N content. The quantities of DNA purines were too low to allow sufficient material for any further degradation.

The protein residues remaining after the extraction of polynucleotides were treated as described in earlier work [1] to determine the content of ^{15}N in the total protein and, when possible, in the glycine constituent as well.

RESULTS

In comparison with the previous series [1], these groups attained appreciably greater liver regeneration. The two earliest stages showed around 40—45 % (weight of regenerated liver as per cent of weight of original liver), in agreement with results found previously for these time intervals, but the regeneration increased to 66 % by 37 h (compared to around 51 % for this time interval in the previous study). This amount of regeneration is equivalent to that found in earlier series at 80 h. In the present series the regeneration then increased to 73 % by 126 h, giving a much less steep curve for the later time period.

Table 1 gives the figures for the ^{15}N content in the various purines and the constituent nitrogen atoms analyzed, as well as in the nuclear and cytoplasmic protein and the glycine constituent of the latter. In general the absolute figures for isotope incorporation were higher than in earlier series.

In the case of protein the levels of incorporation of isotope were approximately the same in both nuclei and cytoplasm. If one compares the time curve of protein or glycine uptake of tracer with that of the previous series, the peaks of incorporation can be seen to occur at about the same time in both cases. The highest figures for the time points included here are at 26 h for the nuclear protein and at 37 h for the total cytoplasmic protein as well as for its glycine constituent. The stages of 44—56 h are not represented in this series.

It is difficult to compare the absolute figures for the purines with those of the earlier series, since those for the nuclear PNA purines here are so much higher than those for the cytoplasm PNA compounds. However, in view of the complexities of nucleic acid turnover [1], such a comparison may be invalid for two series as different as these. If the present series is considered alone, it can be seen that cytoplasm PNA adenine showed two peaks of incorporation, one at 18 h, and a lower one at 37 h. This is in agreement with the earlier series, except that there the initial peak occurred at 14 rather than at 18 h. These time changes could be seen not only in the figures for the purine base itself but also in those for the hypoxanthine obtained by deamination, those for the ammonia nitrogen derived from nitrogen atoms 1, 3, and 9, and those for the N_7 atom isolated as glycine. The latter showed the highest content of ^{15}N, representing the most direct incorporation of the precursor. It can be seen, then, that the various nitrogen atoms did not materially differ except

* The values are calculated on the basis of 100 % ^{15}N in the administered glycine.

in the level of incorporation; their changes of incorporation with time were essentially the same. The time curve for nuclear PNA adenine also showed an early maximum at 18 h, with the level falling off slowly after that time. This is then not greatly different from the pattern for cytoplasmic PNA adenine.

A comparison of these figures with those for the uptake into guanine shows that, as previously observed [1,17], the incorporation of glycine-^{15}N into guanine was considerably greater than into adenine. From the figures for the degraded purines of cytoplasmic PNA, it can be seen that this difference between guanine and adenine uptake carried over into all the constituent nitrogen atoms and was not due to only one particular part of the respective molecules. The figures for the various time stages showed that, as in the previous series, the two purines did not follow identical time curves of incorporation, although the similarities between the two bases were somewhat greater in the present series. Cytoplasmic PNA guanine again showed an early peak at 18 h, with the level of incorporation falling off rather slowly after that time. Here, too, the same changes with time could be seen in the figures for the oxypurine, the $N_{1,3,9}$ ammonia, and the N_7 glycine, so that there were no real differences among the various nitrogen atoms in the time curve of incorporation. The nuclear PNA guanine also showed only one peak, which occurred, however, at 26 h rather than at 18 h.

The incorporation into the DNA purines was, as in other studies with glycine, less than into those of PNA, although of the same order of magnitude. The time curves of incorporation showed single peaks. There was a high maxi-

mum for guanine at 26 h, with the level decreasing somewhat slowly with time, while adenine showed a broad maximum between 26 and 37 h. Thus, the maximum incorporation into DNA occurred considerably later than did that for PNA; the figures here serve to emphasize the peak found for DNA at 26—32 h in the previous series.

DISCUSSION

The difference between this series and the earlier one in amount of liver regeneration shown by the animals was somewhat unexpected. This difference may have been a result of the change from the synthetic amino acid diet to the casein diet. Other results in this laboratory [18] confirm more extensive liver regeneration on the casein diet than on the other one, and a casein diet has been found by others to be conducive to liver growth [19,20].

It is hard to know what effect more rapid regeneration may have had on the turnover picture, but the higher incorporation figures, compared with the earlier series, may well have been due to this greater extent of regeneration for all time points. Certainly, in view of this difference, it would seem to be somewhat hazardous to compare any absolute turnover figures for the two series.

With regard to the time curves, the two points of maximum protein turnover (26 h for nuclear protein and 37 h for cytoplasmic protein) confirm earlier findings [1,21] within the limitations of the time points included in the present series. In contrast, the time curves of nucleic acid incorporation for this series are somewhat different from those for the previous one. One major difference is the location of the inital PNA peak at 18 instead of at 14 h. It is possible that this delay in PNA uptake could have been due to the difference in diet; the casein diet could conceivably have been more slowly metabolized, which might have affected the incorporation during early stages of regeneration. However, the turnover picture for both PNA and DNA showed essentially the same changes with time as that found previously. Thus, the initial high peak of incorporation into PNA occurred considerably ahead of any other maximum, and there was a second increase in PNA uptake somewhat later; the peak of DNA incorporation of isotope also occurred at a later time. It can be seen, then, from these results that the specific possible explanations for heterogeneity of PNA turnover investigated in these experiments could not explain the time changes. Thus, when the cytoplasmic PNA purines were degraded and individual nitrogen atoms analyzed, the changes of isotope incorporation with time were found to be very nearly the same for all the various atoms. It is apparent, therefore, that the two peaks in the PNA uptake of isotope are not due to differences among these atoms. Especially in the case of adenine, the double peak could again be seen in this series, and the figures for the degradation products showed that the same time curve carried over into all the constituent nitrogen atoms.

It has been noted in previous work that glycine-^{15}N incorporation is greater into nucleic acid guanine than into adenine *cf.*[1] and this was confirmed by the present results. The figures here for the purine degradation products showed that the incorporation into xanthine was similarly high compared with that for hypoxanthine; the high ratio found in these experiments is, therefore, not

due to a difference in the metabolic activity of the amino group, which appears to be approximately the same for both purine bases. In fact, this high ratio also carried over into all the nitrogen atoms of the oxypurines, although it varied somewhat with time in each case. From these data adenine is not an intermediate in the synthesis of guanine from glycine, a finding supported by recent results of *in vitro* experiments [22-25]. Data on adenine incorporation, indicating an adenine to guanine conversion, merely reflect the probability that in this case the biosynthesis follows different pathways.

The double peak in PNA incorporation of isotope was also considered to be, possibly, an effect of the known cellular heterogeneity of PNA [2,3,17,26-34]. However, from these data, differences between cytoplasmic and nuclear PNA would seem to be unable to account for this double peak, since both showed essentially the same time changes in incorporation. In the case of adenine, a double maximum was apparent in the figures for cytoplasmic PNA alone, and the peak for nuclear PNA coincided with the main peak for cytoplasmic PNA. In the case of guanine, the peak for nuclear PNA occurred somewhat later than that for cytoplasmic PNA, and this difference may have, to some extent, contributed to the double maximum observed for guanine in the previous series. However, this contribution must have been small because of the great difference in the amounts of the two fractions, and in view of the slow decrease in cytoplasmic PNA incorporation here, the cytoplasmic PNA would appear to have been the major contributor to the later peak as well as to the first one. These conclusions do not, of course, eliminate the possibility of PNA heterogeneity of some other kind as an explanation of the turnover curve.

The absolute figures for incorporation into nuclear material, compared with cytoplasm, were very high for the PNA purines, in contrast with those for protein, which were approximately, the same in both cases. This has been found in work with various precursors [2,3,26-31], and the possible significance of the finding for the theory of a function of PNA in protein synthesis has been discussed [27]. However, although this nuclear PNA/cytoplasmic PNA ratio remained high throughout the regeneration time curve, the maximum incorporation by nuclear PNA occurred at a later period of regeneration than that by cytoplasm PNA. As pointed out above, this was especially obvious in the guanine figures. This finding may be of relevance in elaborating the relationship between nuclear and cytoplasmic PNA.

This later maximum of nuclear PNA bears upon the cytological findings in the previous paper [1]. In that study, the maximum of nucleolar size was observed around 10—15 h, which coincided rather well with the initial peak in PNA incorporation at 14 h. A correlation of the two is attractive but, on the basis of the present data, would appear to be erroneous, since the PNA of the nuclei is apparently much less important than the cytoplasmic PNA in this first PNA peak. This makes it impossible for the part of the nuclear PNA located in the nucleolus to account for the peak, and the coincidence of the two is, therefore, probably a chance one.

The authors are glad to express their thanks to Professor Einar Hammarsten for his active interest and helpful advice throughout this investigation. The work was aided by grants from *Statens Medicinska Forskningsråd.*

The Synthesis of Polynucleotides and Protein in Regenerating Rat Liver

S. ÅQVIST and E. P. ANDERSON*

Department of Biochemistry, Karolinska Institutet, Stockholm, Sweden

A study has been made of the changes in quantitative content of PNA and DNA phosphorus and protein nitrogen in regenerating liver 8 to 80 h after hepatectomy. This study has been correlated with a comparable one made previously on incorporation of ^{15}N-labeled glycine into these same substances, in an attempt to compare the time curves of turnover and synthesis.

During the first 80 h of regeneration the protein, lipid, and DNA content of liver remained relatively constant, *i.e.* these substances increased proportionately with liver weight. In contrast, the content of PNA per mg protein nitrogen increased from the original level to a maximum at 40 h.

The relative increases in these materials, over the normal values, were plotted and compared with that of the liver itself. From these, rates of synthesis could be estimated. PNA showed the first and most rapid increase and attained maximum rate of synthesis between 20 and 25 h. Protein synthesis reached a peak at about 40 h, and the maximum for DNA occurred between these two points. The maximum for protein synthesis corresponded with the peak of PNA content.

Correlation of the time curves for synthesis and turnover showed that the peaks of incorporation and synthesis agreed for protein, and, to a large extent, for DNA. In the case of PNA, the second peak in incorporation correlated with the maximum of synthesis, but the initial high peak apparently represented some turnover process distinct from net synthesis of new molecules.

Other work in this laboratory had undertaken a study of polynucleotide and protein turnover in regenerating liver, using ^{15}N-labeled glycine [1]. From this, time curves of turnover during regeneration were determined for these substances. In an attempt to define to what extent these turnover figures could be due to actual net synthesis of new molecules during this process, another study was made of the changes in the quantitative content of these materials in liver during identical periods of regeneration. This study was made as nearly comparable as possible to the earlier one on isotope incorporation [1].

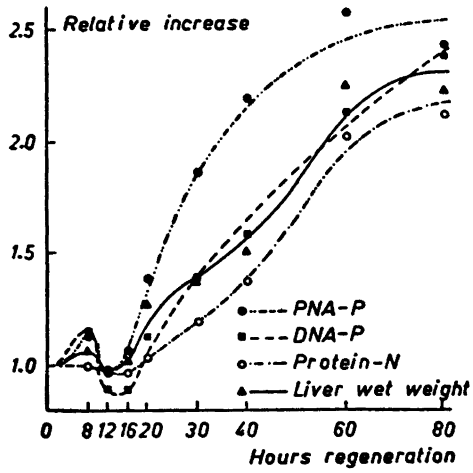
EXPERIMENTAL

The experiments employed adult albino rats weighing 180—200 g. Eight groups of eight to twelve rats were subjected to partial hepatectomy, according to a previously described method [2], and the livers allowed to regenerate for a different period of time in each case — 8, 12, 16, 20, 30, 40, 60 and 80 h, respectively, from operation to death.

The hepatectomized animals were fed by stomach tube every four hours during the period of regeneration in order to insure an equal and adequate consumption of food. The diet administered was the same as that used in the comparable isotope experiments [1], except for the two longest periods of regeneration. The animals in these two groups were fed by stomach tube for only the first 24 h after operation, being given a diet containing 18 % casein instead of synthetic amino acids [3]; after this time they were fed 10 g per day of the same diet in dry form.

The regenerated livers from all animals were removed and weighed, and the extent of regeneration calculated as in the previous work [1]. The livers for each group were pooled, homogenized in alcohol, disintegrated by vibration [4], and extracted with alcohol-ether to remove lipids, in a manner corresponding to that described for other work [1], except that recoveries of all fractions were made quantitatively. The liver removed from one of the groups at the time of hepatectomy was taken as a sample of normal, non-regenerating liver and was treated in the same way.

The lipid extracts were evaporated to dryness, and the dry weight of the extracted material determined.



The tissue samples remaining after lipid extraction were treated according to Hammarsten [4] to extract mixed polynucleotides. The method was the same as that usually employed in this laboratory, involving extraction with saturated urea and saturated salt (sodium chloride and ammonium sulfate) solution, precipitation of the extracted polynucleotides with copper, decomposition of the copper salt with potassium acetate and solution of the residue with urea, and final precipitation of the free polynucleotides with alcohol. For this work, however, the exact procedure was somewhat modified in order to insure complete extraction. The extraction was performed on four to twelve weighed aliquots (around 100 mg each) of the original dry, lipid-free tissue, each aliquot being ground by hand during extraction in a small, conical centrifuge tube with a closely fitting ground glass piston. This centrifuge tube constituted a modified McShan-Erway grinder [5]; each tube and its piston were specially ground to fit very closely. The grinder was operated by hand to insure more complete disintegration, since the tissue became rather gummy during the first extraction.

The extracted mixed polynucleotides were hydrolyzed in alkali and separated into pentose nucleic acid (PNA) and desoxypentose nucleic acid (DNA) with lanthanum acetate at pH 2 [4,6]. Both the PNA supernatant and the lanthanum precipitate of DNA were combusted directly for quantitative phosphorus determinations, which were made on aliquots of each digest by the colorimetric method of Fiske and Subbarow [7].

Comparable weighed aliquots of the original dry, lipid-free tissue were also extracted twice with hot trichloroacetic acid (TCA), according to Schneider [8], to obtain a TCA-insoluble protein residue free of salt and other extraneous material. The dry weight of this protein residue was determined for each aliquot, and its nitrogen content estimated by a semi-micro Kjeldahl method.

RESULTS

The time curve of regeneration for these animals is given in Fig. 1, shown as the relative increase in the wet weight of the liver after hepatectomy. In absolute per cent regeneration (weight of regenerated liver as per cent of weight of original liver) the first seven of these groups corresponded very closely to the comparable groups from the previous isotope series [1]. Only the groups representing the two longest time periods showed regeneration much greater in extent. These two groups were fed the casein diet, which has been found in another series [3] to be associated with more extensive liver regeneration. The

amount of regeneration shown by the last two groups in the present series was even more than that previously observed on the casein diet, the figures here being greater than that found previously for 126 h of regeneration. These last two groups seem to have attained almost a plateau of growth, the extent of regeneration being no greater at 80 h than at 60 h.

The figures for the quantitative determinations on liver from these groups are shown in Table 1. This table shows for each group the extent of growth (per cent regeneration), the protein nitrogen content (nitrogen found in the TCA-insoluble protein residue) and the lipid content (dry weight of the residue from lipid extracts) of the dry whole liver tissue, and the content of PNA and DNA phosphorus, expressed per mg protein nitrogen. Because of irregular variations found, from preliminary estimations, in the glycogen content of the liver samples (reflected in the third column of Table 1, giving the protein nitrogen content), the protein nitrogen was considered to be the most constant as well as the most significant basis on which to express the quantitative figures for polynucleotide content.

Table 1.

Hours of regeneration	Per cent regeneration	mg protein N per 100 mg dry weight *	mg lipids per 100 mg dry weight *	μg PNA P per mg protein N	μg DNA P per mg protein N
0	34.6	7.52	19.8	24.9	7.21
8	36.8	7.25	25.3	28.2	8.33
12	34.0	8.31	24.7	25.2	6.65
16	35.3	7.81	23.7	27.6	6.67
20	44.1	6.29	26.3	33.5	7.85
30	47.6	6.64	26.0	38.9	8.40
40	52.4	7.19	27.8	39.8	8.31
60	78.1	6.90	31.7	31.8	8.23
80	77.4	7.39	27.0	28.6	8.09

* Dry weight of whole liver.

From Table 1 it can be seen that the protein content of the whole liver varied irregularly around a figure of approximately 7 mg protein nitrogen per 100 mg dry weight of liver. The lipid content, which was about 25 mg per 100 mg liver, was somewhat more constant, and there was no evidence of accumulation of lipid material during regeneration [9,10]. These substances, then, increased approximately proportionately with liver weight.

From the last column it can be seen that, except for slight irregularity in the early stages of regeneration, the content of DNA as expressed here also remained rather constant throughout the various time stages, *i.e.* the level increased proportionately with protein and with liver weight [cf.11]. The actual figure for DNA content was about 8 μg DNA phosphorus per mg protein nitrogen. Column five gives the values for PNA phosphorus and indicates that this constituent showed initial irregularities during the first 16 hours of regeneration and then increased steadily, compared with the level of protein, to a rather high maximum content at 40 h. If these nucleic acid contents are calculated on the basis of dry weight of liver, the initial irregularities in the curves are less, but the shape of both curves is essentially unchanged, with the maximum in PNA content falling at the same time point.

Figure 1 gives the time curves of regeneration for PNA phosphorus, DNA phosphorus, and protein nitrogen, as well as liver wet weight. These curves represent the change with time of the total amount of each of these constituents, expressed as relative increase over the zero point value. The zero point for each curve represents the content of that constituent in a unit of liver before regeneration has begun. For each time stage the total content of each constituent has then been calculated for the amount of liver expected at that stage of regeneration from this unit of liver. The curves serve to indicate when and with what speed each constituent was produced in the liver during the regeneration process. From them it can be seen that all these constituents increased rather steadily with time. The PNA began its increase somewhat earlier than the other substances and showed a somewhat steeper rise. It must be remembered that the increase in these constituents should actually be less than that seen here for the last two time points, especially the increase between 40 and 60 h, since these two groups had a high extent of regeneration which was out of proportion to that of the earlier groups. With this in mind, if the rates of formation of these materials are estimated from the curves, the maximum rate of PNA synthesis can be seen to have occurred between 20 and 25 h. Protein synthesis reached a maximum at about 40 h, and the peak for DNA occurred between these two points. If these results are compared with the figures in Table 1, it can be seen that the period of maximum rate of protein synthesis coincided with the peak of PNA content.

DISCUSSION

If the results of these quantitative determinations are correlated with those of the corresponding study on incorporation of ^{15}N-labeled glycine [1], some indications can be obtained as to the extent to which the time curves of isotope incorporation reflect net synthesis of protein and nucleic acid molecules. It must be remembered that the time periods recorded in the isotope series

were the duration of life after hepatectomy, and that isotope was administered 5 and 4 h prior to death, so, in making the correlation, these time points should be moved ahead to include this total period.

In the case of protein the highest peak of isotope incorporation was found at 39—44 h. This correlates with the time of most rapid synthesis of protein, as determined in the present series. The earlier, smaller peak of protein uptake of isotope, at 20—26 h, could also have included some lesser contribution from the synthesis of new molecules, since this synthesis had begun by that time. A correlation of the pattern for incorporation into protein with that for net synthesis helps to explain the relatively uncomplicated picture obtained for glycine uptake by protein during regeneration, and supports the claim [1] that this incorporation picture reflects changes in the actual protein rather than simply a biosynthetic pattern associated with this particular precursor.

It is of interest to note the correlation in time between the maximum content of PNA and the maximum rate of protein synthesis. A high PNA content during rapid growth and protein synthesis has been reported by many investigators for various systems of cell growth and function, and has been much discussed in relation to a postulated function of PNA in protein synthesis[2,9,12-27]. Without reviewing the evidence as to the pros and cons of this theory, it can be said that the results in the present study are in agreement with these previous studies in regard to high PNA content during the period of most rapid protein synthesis. However, it should be stressed that data such as these indicate only a time sequence and correlation and can throw no light upon the problem of mechanism for any relationship between these substances.

For DNA the maximum in rate of formation is broader than that for protein and thus harder to place exactly in time, but the curve would indicate that net synthesis of DNA could have materially contributed to the main peak of isotope incorporation around 30 h. This period of synthesis and incorporation also correlates rather well with the maximum of mitosis frequency *cf.*[28]. Actually certain cellular studies have indicated that DNA synthesis occurs during interphase, preceding mitosis [29-31], but the significance of this for a time study of total tissue changes is not clear. Price and Laird [32], using chemical methods, have found a doubling of DNA content just before the maximum of mitosis in regenerating rat liver. Such results cannot be seen from these figures. The picture here is more one of steady increase in the DNA content of the liver, paralleling the total regeneration, and it is difficult to perceive any period of much greater synthesis *cf.* [11,33]. Since the incorporation curve, furthermore, showed variations throughout the time range studied, specific time point correlations are of somewhat doubtful value in the case of DNA.

With respect to the rate of PNA synthesis, in relation to the time curve for PNA incorporation of glycine, the data here show that synthesis attained a maximum between 20 and 25 h, which could have contributed to the second peak in PNA incorporation of isotope. However, the initial high peak of isotope uptake, at 9—14 h, occurred ahead of any material increase in PNA content. It would seem that this peak, therefore, must represent some turnover process quite distinct from net increase in number of molecules. Such turnover might be more likely to depend upon and vary with the precursor used, and its inter-

pretation is more difficult. Thus, it is apparent that the double maximum observed in PNA incorporation [1] reflects the biological complexity of the metabolic processes involved in and contributing to the turnover of this material, but at present the data are still too incomplete to allow a more exact definition of the nature of this complexity.

The authors wish to express their appreciation for the kind help and advice of Professor Einar Hammarsten. Acknowledgement for grants-in-aid is made to *Statens Medicinska Forskningsråd.*

Quantitative Bromination of Phenols

BENGT SMITH

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The quantitative bromination of 47 phenols was carried out using 0.1 N potassium bromide—bromate solution and glacial acetic acid as the solvent. The required conditions were established for the analysis of various types of phenols whose reactivity toward bromine is also discussed.

For a long time bromination has been an important part of methods for the quantitative determination of phenol. It has also been used in the analysis of a limited number of other types of phenols such as alkylphenols, halophenols and nitrophenols. It was the basis of the first method [1] used for this purpose and, in spite of the introduction of conductometric titration [1-4] and more recently titration in nonaqueous solvents [5] as tools for the analysis of phenols, it is in some respects still superior. Thus the bromination method is the only one by which it is possible to analyze mixtures of isomers, such as the *meta*-substituted phenols in the presence of the corresponding *ortho* or *para* isomers.[6] * Furthermore, unlike the two other methods, bromination reveals the number of free *ortho* and *para* positions in the ring, a fact of great value for the identification of phenols.

Hitherto the quantitative bromination method has been applied only to a limited number of phenols. It was felt that the potential value of the method had not been utilized fully, partly because of the somewhat tedious procedure generally used, and partly because of unsuitable conditions which hinder its application to the quantitative analysis of a larger number of phenols. Furthermore no systematic study has been made of the relationship between the structure of a phenol and the conditions necessary for its quantitative bromination. It was proposed therefore to investigate the possibility of altering the procedure in such a way that the bromination method may be of more general use. Some relationships between structure and reactivity would also be studied. To give the background for the present work it is necessary to discuss, in some detail, the development of the quantitative bromination method.

* Added in proof. After the completion of this work Karrman and Johansson[6a] have reported that a mixture of *o*-, *m*- and *p*-cresol can be analyzed using high frequency titration.

In 1876 Koppeschaar [1] introduced his method for the quantitative determination of phenol which with few alterations has been in use up to now (see, *e.g.* Ref. [7]). The principle of the method was to dissolve the phenol in water and add an excess of a solution containing sodium bromide and sodium bromate. On acidification with hydrochloric acid bromine was liberated, part of which reacted with the phenol to form tribromophenol. After 15 min potassium iodide was added and the iodine liberated titrated with thiosulfate. From the volume of bromide-bromate solution taken and the volume of thiosulfate used in the back-titration the amount of bromine consumed by the phenol could be calculated.

It was not until 1928 that this Koppeschaar "excess" method was tested on several other types of phenols. Thus Day and Taggart [8] were able to analyze about 10 phenols using essentially the same procedure as Koppeschaar. They also tried a so-called "direct" method developed by Callan and Henderson.[9] To the alkaline solution of the phenol a potassium bromide solution was added and then, after acidification, the necessary volume of standard potassium bromate. The end point was determined using spot tests on starch-iodide paper. This "direct" method is reported to be tedious and there is some possibility that bromine might be lost. Most analyses were made therefore using the "excess" method.

The work of Day and Taggart seems still to be the most comprehensive in its field although several papers on the same subject have appeared since. Riemschneider,[10] for example, used sodium sulphite for the reduction of the excess of bromine and determined the sum of the hydrogen bromide formed here and in the bromination reaction by a titration according to Volhard. Singh [11] recently used the Day and Taggart method for the analysis of some phenols with the modification that chloramine-B was substituted for the potassium bromate. Bielenberg *et al.*[12] stated that the Koppeschaar method gave inaccurate results, when applied to phenols other than cresolic acid. They proposed a modified procedure which, however, still utilized water as solvent (concerning water as solvent see below). Bielenberg [13] unsuccessfully tried to indicate the end point of the bromination reaction by methyl orange and other bromine-sensitive dyes.

Of special interest are two investigations by Sprung [14] and Ruderman [15], respectively, concerning the application of the Koppeschaar method to the quantitative analysis of alkylphenols. Sprung found that the method failed for most types of alkylphenols except for some with alkyl groups in the *meta* position or tertiary alkyl groups in the *ortho* or *para* position. Ruderman, varying the excess of bromine, concluded that phenols with primary and secondary alkyl groups *ortho* or *para* to the hydroxyl group tend to overbrominate in the presence of excess bromine while phenols with *ortho*, *meta*, or *para* tertiary alkyl groups brominate quantitatively regardless of the bromine excess. Furthermore hydroxymethyl groups were found to be displaced by bromine in certain instances.

Some attempts have also been made to use a potentiometric method for the indication of the end point in the quantitative bromination of phenols [16,17]. This method should be valuable in the analysis of dark coloured substances,

but the number of phenols to which it has been applied is still too small to permit an estimation of its usefulness.

Day and Taggart reached a high precision in their analyses but at the cost of frequent changes of such variables as dilution, bromination time and the time elapsed between the addition of the potassium iodide and the back titration of the iodine. In spite of this such a simple phenol as *p*-cresol could not be analyzed either by the "excess" method or by the "direct" method. Reliable values for thymol and β-naphthol could be obtained only if chloroform was used as solvent instead of alkali. A decarboxylation reaction was also observed for salicylic acid which consumed 6 equiv. of bromine per molecule instead of the expected 4 equiv. * Another irregularity is the need of allowing the reaction mixture to stand in some cases between the addition of the potassium iodide and the back titration of the iodine. Thus in the case of resorcinol the mixture was kept for 5 min, in the case of *m*-cresol for 60 min. Some of these difficulties might be caused by the choice of solvent. Most of the phenols are not soluble enough in water, but have to be dissolved in alkali. On acidification prior to the addition of bromide-bromate there is a risk that the phenol is partly precipitated and that the reaction thus takes place in an inhomogeneous medium. The long reaction time (30 min) necessary in several cases might be due partly to this circumstance. As mentioned above thymol, which has a low solubility in water, could not be analyzed by the general "excess" method.

From the discussion above it follows that a solvent suitable for general use in the bromination method should have a good dissolving power for phenols. Of course it must be reasonably inert to bromine under the conditions used. It is also desirable that it is mixable with the titrant and has some dissolving capacity for the products of bromination. The last condition arises from the fact that the products of bromination when precipitated might enclose incompletely brominated compounds (*cf.* Ref. [8]). Day and Taggart used chloroform in some of their experiments. It is fairly stable toward bromine but is reported to retain the last of the iodine tenaciously. Furthermore it is not mixable with the titrant. Ethyl alcohol was employed as solvent by Francis and Hill.[6] Its stability toward bromine is, however, reported to be poor.[18] Acetic acid has been used in isolated cases with good results [18]. As it fulfills all the conditions above it was decided to investigate its general usefulness.

It was found that a large number of phenols could be directly titrated in acetic acid solution using 0.1 N bromide-bromate (see Table 1). Instead of the tedious spot test method used by Day and Taggart a small excess of bromide-bromate was added and then immediately back-titrated with standard thiosulfate. The average accuracy of this "direct" method was 0.3 %.

Phenols which could not be quantitatively determined by the "direct" method were analyzed using an "excess" method (see Table 2). In most of the cases the reaction was complete in 3 min with 100 % excess of bromide-bromate. The average accuracy of the "excess" method was 0.4 %.

* Francis and Hill [6], using water, dilute sulphuric acid or ethyl alcohol as the solvent, also reported a decarboxylation to take place in the bromination of the hydroxybenzoic acids. Furthermore carbon monoxide was shown to be formed in the bromination of the hydroxybenzaldehydes, originating from the formyl group which was split off.

It was the objective of the present investigation to develop general procedures which were applicable to the largest possible number of phenols. This was attained so far in that 22 (84 %) of the 26 phenols determined by the "direct" method could be analyzed under identical conditions as could 15 (75 %) of the 20 compounds analyzed by the "excess" method. This unification of the bromination method was partly enabled by the fact that the same number of active centres (*ortho* and *para* positions) were present in each case which also permitted a comparison to be made between the reactivities of the various phenols (see below).

EXPERIMENTAL

Materials. Most of the phenols in Tables 1 and 2 were commercial products. Their purity was tested by melting point or boiling point determinations and they were, if necessary, recrystallized or redistilled.

Procedure for the direct method: 1.5 mequiv. * of the phenol were weighed and dissolved in the prescribed volume of glacial acetic acid (see Table 1). Five ml of conc. hydrochloric acid were added and then dropwise 16 ml of 0.1 N potassium bromide-bromate solution. A larger excess of bromide-bromate solution was never allowed to occur. After addition of 5 ml of a 10 % potassium iodide solution the iodine was immediately titrated with 0.1 N thiosulfate using starch solution as indicator.

Procedure for the excess method. The same amount of the phenol as in the previous method was weighed and dissolved in the prescribed volume of glacial acetic acid in a flask fitted with a ground joint (see Table 2). Thirty ml of 0.1 N potassium bromide-bromate solution were added and then 5 ml of conc. hydrochloric acid. The flask was immediately stoppered, shaken and left for generally 3 min (see Table 2). After that period 10 ml of a 10 % potassium iodide solution were added and the iodine at once titrated as above.

DISCUSSION

In the following the conditions necessary for the quantitative bromination of various types of phenols will be discussed in some detail.

The dominating influence in the bromination of phenols is exerted by the hydroxyl group whose well known activation of the aromatic ring towards electrophilic reagents causes bromine to replace hydrogen at the free *ortho* and *para* positions. Other substituents in the phenol molecule as a rule have only a minor influence on its reactivity.

Phenol and alkylphenols. All of the 5 monoalkylphenols tested (Nos. 2—6) could be analyzed under standard conditions (1.5 mequiv. of the phenol in 10 ml of glacial acetic acid) using the "direct" method. They were found to be more reactive than phenol (No. 1) as the bromine consumption of the latter was too low under standard conditions. This difference in reactivity is natural considering the electron releasing effect of alkyl groups toward the ring. In view of this the dialkyl- and polyalkylphenols might be expected to be even more reactive than the monoalkylphenols. However, for many of the compounds investigated the opposite was the case. Thus, while 2,4- and 2,6-xylenol (Nos. 7 and 8) could be analyzed by the "direct" method the "excess" method had to be used in most cases involving *meta*-substituted dialkyl- and polyalkylphenols (Nos. 27—33). The cause of the decrease in reactivity in those

* It is assumed that each vacant *ortho* or *para* position consumes 2 equiv. of bromine.

cases where a free *ortho* position is flanked by an alkyl group might be, at least in part, that this position is less readily substituted by bromine.*

* In fact it is often observed that substitution in an aromatic nucleus is retarded at a position flanked on both sides by substituent groups.

As seen from Tables 1 and 2 a higher dilution than 10 ml had to be used in some cases as the bromine consumption was too high under standard conditions. The reason for this might be an added substitution at vacant *meta* positions or in side chains. Another possible cause is the formation of compounds of the tribromophenol bromide type [19,20].

The phenols containing hydroxymethyl groups (Nos. 11, 12 and 34) may be discussed in connection with the alkylphenols. The difference in reactivity between the three monosubstituted isomers is here enhanced in comparison with the cresols as the *meta* isomer had to be analyzed by the "excess" method.

Chlorophenols. Four of the five chlorophenols which in addition to the hydroxyl group contained only chlorine (Nos. 36—39) had to be analyzed by the "excess" method. This result is to be expected from the standpoint of the deactivating influence of halogen on the aromatic ring. By introducing a methyl group the reactivity is increased as shown by the results of the titration of the two chlorocresols (Nos. 20 and 21).

Phenols with meta directing substituents. These compounds are conveniently discussed together. Phenols with the following *meta* directing groups have been tested: nitro, carboxyl, formyl and alkylketone (Nos. 22—25 and 40—47). Considering the electronwithdrawing influence of these groups a decreased reactivity in comparison with phenol might be expected *. However, with the exception of the nitrophenols, the *para* isomers (Nos. 23—25) and in one case also the *ortho* isomer (No. 22) are more reactive. The *meta* isomers are less readily substituted than the rest as the "excess" method invariably had to be employed. No splitting off of carboxyl or formyl groups has been observed.

Dihydroxy- and polyhydroxyphenols. Only *meta* isomers could be analyzed by the present bromination method (Nos. 16—18). The "direct" method was applicable.

Diphenylols and naphthols. Of the three diphenylols tested (Nos. 13, 14 and 35) *o*-hydroxy- and *β*-hydroxydiphenyl could be titrated directly, while *o,o'*-dihydroxydiphenyl was less reactive. This fact is obviously a result of decreased resonance due to steric hindrance and hydrogen bonding. *β*-Naphthol (No. 15) consumed only two bromine atoms per molecule although four might be expected **. *α*-Naphthol, on the other hand, consumed four equivalents of bromine. The values are not communicated, however, as the results were less accurate because of discolouration of the solution.

Phenol ethers. The bromination method was tried on several alkoxyphenols. However, it was found to be not suitable for the quantitative analysis of this type of phenols. The result of the direct titration of one aryloxyphenol showed, that only the ring containing the hydroxyl group was attacked (No. 26).

* In the discussion above it has been assumed that alkyl groups increase the nucleophility of a phenol and *meta* directing groups and chlorine decrease it. Such an assumption is not necessarily correct. It must be taken into account that when one of these groups or atoms is substituted for a hydrogen atom in a phenol, the resonance between the oxygen atom of the hydroxyl and the ring also changes. The combined nucleophilic effect may well be contrary to that expected when only the influence of the substituent on the ring is considered. This fact in connection with other effects originating from steric hindrance and hydrogen bonding might explain the apparently contradictory results obtained in some cases.

** To obtain accurate results it is necessary to use a volume of bromide-bromate solution corresponding to the substitution of one hydrogen atom.

With the establishment of the suitable conditions for the quantitative analysis of the phenols collected in Tables 1 and 2 the application of the bromination method to other phenols should be considerably facilitated.

On some Properties of the Aromatic Constituent of Male Sperm Antagglutin and its "Active Group"

P. E. LINDAHL, J.-E. KIHLSTRÖM and S. ROSS

Institute of Zoophysiology, Uppsala, Sweden

Some properties of an aromatic constituent of the male sperm antagglutin have been studied spectrophotometrically. Its absorption properties like those of its *p*-quinone and its hydroquinone are similar to those of the known tocopherols. On account of many dissimilarities between the substance and the latter its identity with any of the known tocopherols is excluded.

The aromatic compound is part of a protein free complex also containing sulphuric acid, and sugar residues. In this complex it may also occur as quinone.

From male sperm antagglutin we obtained in 1954 [1] a substance which appeared to be aromatic by nature, and which by reason of its absorption curve and its behaviour at oxidation was suggested to be related to vitamin E. It was provisionally denominated as a "tocopherol derivative". Its non-identity with α-tocopherol was, however, stressed, and will be further discussed below.

From samples of bull semen obtained during the spring of 1954 we rather frequently isolated antagglutin which on extraction with ethyl ether from water solution gave the above mentioned aromatic compound. More recently, however, this happened very sporadically only. Accordingly we now consider the occurrence of the aromatic constituent in extractable form as an artefact. So far we have not been able to establish the conditions provoking this state. As the possibilities of splitting off the aromatic residue from the rest of the molecule by means of chemical and physical agents is now being investigated in this laboratory it seems appropriate to publish some early observations on this spontaneously liberated material which has been available in such very minute quantities that it could be studied only by spectrophotometric methods.

EXPERIMENTS AND RESULTS

The semen from which the antagglutin used in these experiments was obtained came chiefly from the A.I.-station of Eskilstuna. The antagglutin was isolated according to Lindahl and Kihlström [2], the procedure including twice repeated salting out with ammo-

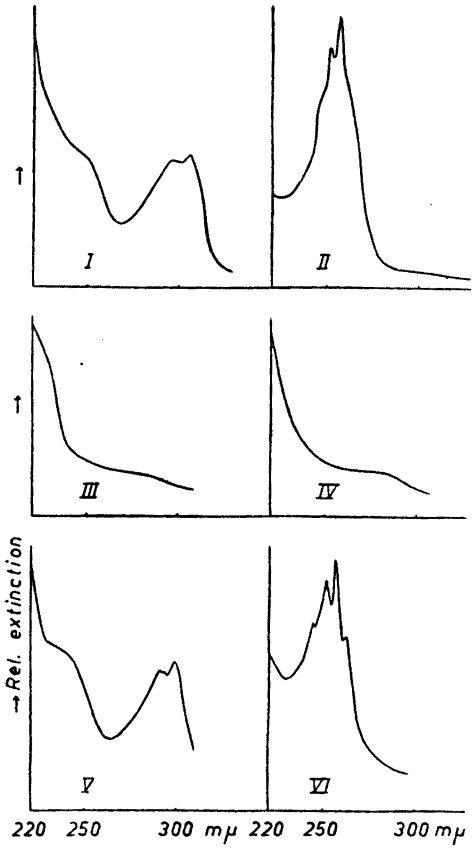

Fig. 1. Absorption curves of the aromatic constituent and the "active group" of male spermantagglutin. I the aromatic constituent in its original form, II after mild oxidation as quinone, III after prolonged oxidation. IV the "active group" split from the protein residue and chromatographed (spectrum of aromatic constituent not visible), V after extraction with ethyl ether showing aromatic constituent in original form, and VI with the aromatic constituent as quinone. I—III in ethanolic, IV—VI in aqueous solution.

nium-sulphate, and subsequent chromatography on calcium carbonate. The antagglutin was always in the reduced form when extracted with ethyl ether, the reduction being generally brought about with hydrogen, and platinum as a catalyst.

The absorption curve (I, Fig. 1) of the extracted compound was measured in absolute ethanol ("Spectroscopically pure", Vin och Spritcentralen, Ltd.) with maxima at 295 and 305 mμ, and a minimum at 268 mμ. Because of the similarity in the general trend of this curve with that of δ-tocopherol in ethanol (*cf.* [3]) a closer comparison is made. The single maximum [4] of δ-tocopherol is at 298 mμ, and its minimum at about 257 mμ. The α-, β-, and γ-tocopherols also have single absorption maxima in ethanol [3]. On the other hand the absorption curve of α-tocopherol in hexane has two maxima [5], and the same was found for δ-tocopherol (from Eastman Kodak Comp.). However, when transferred into hexane ("for spectroscopical use" B.D.H.) our substance yielded a smooth curve without maxima and minima [1] persisting also when the substance was brought back into ethanol again.

In order to provide further comparison our substance was subjected to mild oxidation by being aerated for 16 h at +5°C in ethanolic solution in the presence of $FeCl_3$ and $CuSO_4$ (10^{-4} M). The absorption curve (II, Fig. 1) in ethanol of the product formed has a narrow double peak with maxima at 251 and 256 mμ, with about twice as high extinction coefficient as the substance before oxidation. These absorption data may be compared with those obtained in ethanolic solution for the *o*-quinone of α-tocopherol and the *p*-quinones of the α- and δ-tocopherols (Table 1).

Table 1.

	λ in mμ		max. of ox.prod. / max. of tocoph.	
α-Tocopheryl *p*-quinone	261—263	267—268	6—7	(6)
α-Tocopheryl *o*-quinone	258	(270)	3	(6)
δ-Tocopheryl *p*-quinone	257		2.5	(4)
Ox. antagglutin constituent	251	256	2	

As seen from Table 1 the oxidation product of the antagglutin constituent comes nearest to δ-tocopheryl *p*-quinone which, however, has only one maximum. Further it should be stressed that neither α- nor δ-tocopherol will be oxidized to a quinone under the conditions employed for the antagglutin constituent.

When subjected to catalytic reduction with hydrogen the absorption curve of the oxidized antagglutin constituent changes rapidly. The strong absorption band disappears, and a new weak one around 310 mμ appears, the whole absorption curve now being very similar to the curve of the originally extracted substance. There is, however, a single maximum, and the minimum as well as the maximum absorption occur at longer wavelengths. The existence of a transition stage in the reduction is suggested by the fact that during the first minutes of the reduction, when the high absorption-band of the oxidation product is beginning to decrease, much higher extinction values appear around 310 mμ than those remaining when the reduction is finished.

As the oxidation product appears to be a quinone its reduction should give the corresponding hydroquinone. On account of the different positions of the absorption bands of *ortho*- and *para*-diphenols in general, it may be concluded that we are dealing with a hydroquinone. This hydroquinone is very quickly oxidized to quinone on exposure to air, being in this respect similar to α-tocopheryl hydroquinone [7]. The latter has a single extinction maximum [7] at about 290 mμ, as compared with the maxima of α-tocopherol at 292 and 298 mμ. A corresponding comparison of the extinction maxima of our hydroquinone, about 310 mμ, with those of the originally extracted compound, 292 and 305 mμ, makes probable that besides the quinone-hydroquinone transformation also other changes must have occurred.

Treatment of the tocopherol-like constituent with 4 M hydrochloric acid at 40°C for 11 h in ethanolic solution under H_2-atmosphere did not cause any change in its extinction properties. Thus none of the aromatic hydroxyls may be engaged in an easily hydrolyzed ester bond. In a similar experiment the

H_2-atmosphere was replaced by air. Also here the extinction curve was unchanged, indicating a rather high stability against oxidation by air under these conditions. However, when exposed to air at the same temperature for 48 h with 0.5 M hydrochloric acid the absorption curve was very much changed (Fig. 1, III). It appears from these two experiments that high concentrations of hydrochloric acid protect the substance from being oxidized in air. This is of special interest as acids are known to promote ring closure in α-tocopheryl hydroquinone which is by this process transformed into tocopherol.

Occasionally the *p*-quinone, produced by oxidation of the tocopherol-like substance, may instead of the latter be extracted from antagglutin solutions. In case both are present in a sample the quinone is extracted first, and seems thus to be the more hydrophobic substance of the two. — Also the absorption bands of this quinone are changed in hexane solution under the conditions in question.

The splitting-off of the active group from the protein constituent was performed as a dissociation, promoted by a high pH (9.6) and certain ions. In one type of experiment it was then separated from the protein by adsorption, in the other by ultrafiltration.

In an experiment of the first mentioned type a purified antagglutin sample, dissolved in water, was incubated at 5°C and pH 9.6 with 10^{-4} M $CuSO_4$ and $FeCl_3$ for 44 h. To minimize possibly occurring oxidation the sample was then reduced catalytically with hydrogen at pH 5.5. The solution was afterwards neutralized, brought to pH 8.5 with glycine-sodium hydroxide buffer, and filtered through a column of calcium carbonate, activated by heating for 3 h at 150°C. With CO_2containing water (pH 5.5) an eluate was obtained showing a spectrum without specific absorption (IV). This eluate was evaporated to dryness, and the residue extracted with ethyl ether. The latter was again evaporated, and the remaining substance extracted with water. Part of this residue did not dissolve, and remained as an unwettable coat on the inside of the vessel. This phenomenon was observed regularly when the "active group" had been treated with ether or any other slightly polar solvent. The aqueous extract showed an extinction curve (V) very similar to that (I) of the tocopherol-like substance described above, but with absorption maxima at 290 and 299 mμ. This material contained some impurities, probably salts, which could be further removed by adsorption of the aromatic substance on quartz powder and subsequent washing out which ethyl ether. After this the absorption curve, measured in water, showed a third maximum at 240 mμ (*cf.* Lindahl and Kihlström [1]). This substance which may be dissolved in ether only in a dry state has also appeared spontaneously on some occasions during the isolation of the antagglutin. In such cases it is found in the eluates obtained after the elution of the antagglutin was completed.

In some experiments besides Fe^{3+} and Cu^{2+}, also Mg^{2+}, Mn^{2+}, and Zn^{2+} were present during the incubation in concentrations of 10^{-4} M, and the treatment was shortened to 16 h. In these cases already the eluate showed a characteristic extinction curve (VI), yet with maxima identical with those of the quinone (II). There were, however, two further small peaks at 244 and 263 mμ. Also this substance has occurred spontaneously in some instances (*cf.* above). We are, however, not able to state whether these two small peaks

may be demonstrated also in the extinctior curve of the free quinone or not, as our measurements were not sufficiently extensive at the relevant points.

The ultrafiltration was performed in the following way. The pH of the antagglutin solution was raised to 8.6 with NaOH, and the solution immediately sucked through a washed collodion membrane (Membranfiltergesellschaft, Sartoriuswerke, Göttingen), the pores of which permit the passage of particles corresponding to a max. molecular weight of about 4 000. The filtrate did not give a positive ninhydrin reaction but contained sugar (positive benzidine reaction). The absorption curve was identical with (V). Obtained in this way, the "active group" did not exhibit any antagglutinic activity.

With this method we have also been able to localize the incorporation of radioactive sulphur with the antagglutin molecule (*cf.* [8]) to the "active group". The occurrence of sulphuric acid residues in the "active group" was assumed earlier for different reasons [2,8]. This has now been verified by hydrolyzing the isolated protein-free material obtained from rabbits injected with $Na_2{}^{35}SO_4$ (*cf.* [8]) and following precipitation with Ba^{2+}. The precipitate contained about 95 % of the radioactivity registered in the "active group".

DISCUSSION

The observations on the aromatic constituent of male sperm antagglutin recorded above suggest that we are dealing with a 6-hydroxy-chromane structure, possibly a tocopherol derivative. To decide whether this idea is right or not larger samples of the substance are necessary. The many dissimilarities between this substance and all the known tocopherols, *e.g.* the higher reactivity at oxidation and hydrogenation, the influence of hexane or impurities in the latter on the absorption spectrum, exclude, however, the identity with any known member of the latter group. It was further stated [1] that oxidation of this tocopherol-like substance with nitric acid according to Ungnade and Smith [9] yields a yellow colour instead of the red obtained for the α-, β-, and γ-tocopherols. This is of great interest as it was shown by Smith *et al.*[10] that the presence of an ethylenic bond or a carbonyl group in the side chain of the quinone formed gives rise to a yellow colour instead of a red one. On the other hand also the substituents of the benzene ring in the chromane molecule influence this reaction as δ-tocopherol gives an orange-yellow colour [4].

When the protein constituent has been removed the complex which has been called the "active group" represents the rest of the antagglutin molecule in a more or less denaturated state. Most probably this complex with a molecular weight below 4 000 in its native state has an absorption curve similar to that of the male antagglutin. A moderate change brings about the appearance of the absorption bands of the tocopherol-like constituent — although somewhat displaced towards shorter wavelengths — without impairing the antagglutinic activity. A more far-reaching change abolishes this activity without further altering the absorption spectrum. Oxidation then gives the complex an absorption curve very similar to that of the quinone described above. The occasional spontaneous appearance of the "active group" at the preparation of antagglutin must depend upon some change in the molecule of the latter,

having occurred probably already in the semen. This altered "active group" as well as the tocopherol-like substance extractable with ethyl ether from aqueous solutions must by looked upon as artefacts.

As long as the antagglutin molecule is not in some way denaturated the tocopherol-like constituent seems to be rather resistant against catalytic hydrogenation.

So far the "active group" has been shown to consist of the tocopherol-like substance, sugar, and sulphuric acid residues. The presence of the many hydrophilic groups in the two last mentioned residues causes the water solubility of the complex, and makes it dissolve in ethyl ether only when dry.

We are very much indebted to Drs. B. Ström and T. Svensson for semen material. The financial support of the *Swedish Agricultural, Natural Science* and *Medical Research Councils* is gratefully acknowledged. We thank Prof. E. Stenhagen for reading the manuscript.

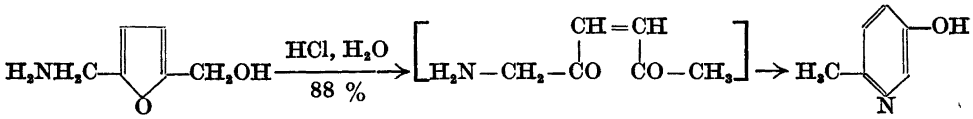
Transformation of 2-(Hydroxymethyl)-5-(aminomethyl)-furan into 6-Methyl-3-pyridinol *

NIELS ELMING

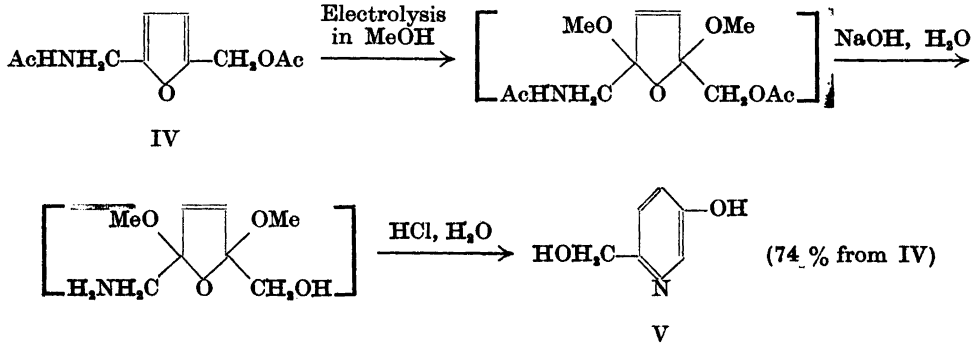


Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

NIELS CLAUSON-KAAS

Department of Chemistry, Israel Institute of Technology, Haifa, Israel

6-Methyl-3-pyridinol has been prepared from 2-(hydroxymethyl)-5-(aminomethyl)-furan by the action of hydrochloric acid. Electrolytic methoxylation of 2-(acetoxymethyl)-5-(acetamidomethyl)-furan followed by alkaline hydrolysis and treatment with hydrochloric acid gave 6-(hydroxymethyl)-3-pyridinol.



Furfuryl alcohol is transformed by the action of methanolic hydrogen chloride into a mixture of distillable products (yield 42 %) consisting of 2,3 (or 4), 5-trimethoxytetrahydrosilvan, methyl levulinate, methyl levulinate dimethyl ketal and 2 (or 3)-methoxylevulinaldehyde dimethyl acetal [1]. It has been proved [1,2] that this transformation proceeds through *cis*-3-acetylacrolein or its equivalent. We have now found that 2-(hydroxymethyl)-5-(aminomethyl)-furan (I) forms 6-methyl-3-pyridinol (III) by the action of hydrochloric acid. It is reasonable to assume that this transformation also takes place through an unsaturated 1,4-dicarbonyl compound, *viz.* 1-amino-3-hexene-2,5-dione (II) or its equivalent.

I II III

* Presented before the Division of Organic Chemistry at the 9th Scandinavian Chemical Meeting, Århus, Denmark, August 1956.

I is a new compound which was prepared by reductive amination of 5-(hydroxymethyl)-furfural (yield 72 %). It was characterized by the hydrochloride, the diacetate [2-(acetoxymethyl)-5-(acetamidomethyl)-furan (IV)] and by transformation of IV into the known 6-hydroxymethyl-3-pyridinol (V) by the sequence of reactions shown below (*cf.* [3]).

EXPERIMENTAL

Microanalyses by E. Boss and K. Glens

2-(Hydroxymethyl)-5-(aminomethyl)-furan (I). 5-(Hydroxymethyl)-furfural [4] (12.8 g), methanol (30 ml), liquid ammonia (5 ml) and Raney nickel (0.4 g) were mixed and shaken (1 h) under 100 atmospheres of hydrogen at 65—75°. After cooling, the reaction mixture was filtered and the filtrate distilled. The yield was 9.30 g (72 %) of I (pale yellow liquid, b.p. $_{0.1}$ 102—105°, n_D^{25} 1.5278). (Found: C 56.8; H 7.4; N 11.1. Calc. for $C_6H_9O_2N$ (127.1): C 56.7; H 7.1; N 11.0).

2-(Hydroxymethyl)-5-(aminomethyl)-furan hydrochloride. Gaseous hydrogen chloride was passed into a solution of I (130 mg) in ether. The precipitate was removed by filtration, washed with ether and dried. The yield was 120 mg (72 %) of 2-(hydroxymethyl)-5-(aminomethyl)-furan hydrochloride [almost white crystals, m.p. 118—121° (Hershberg apparatus, corr.)]. (Found: C 44.3; H 6.2; N 8.5; Cl 21.2. Calc. for $C_6H_{10}O_2NCl$ (163.6): C 44.1; H 6.2; N 8.6; Cl 21.7).

2-(Acetoxymethyl)-5-(acetamidomethyl)-furan (IV). I (1.27 g) was dissolved in a mixture of acetic anhydride (15 ml) and pyridine (15 ml). The reaction mixture was left standing for 2 days and then evaporated in a vacuum. The residue was crystallized from ether. The yield was 1.93 g (92 %) of IV (white crystals, m.p. 65—67°). (Found: C 56.9; H 6.2; N 6.3; $COCH_3$ 38.5. Calc. for $C_6H_7O_2N(COCH_3)_2$ (211.2): C 56.9; H 6.2; N 6.6; $COCH_3$ 40.8).

6-Methyl-3-pyridinol (III). I (1.27 g) was dissolved in a mixture of N hydrochloric acid (60 ml) and water (40 ml). The reaction mixture was heated under reflux (15 h) and then evaporated in a vacuum. The residue was dissolved in water (15 ml), solid potassium carbonate was added and the mixture continuously extracted with ether overnight. The ether extract was evaporated, the residue washed twice with ether and dried. The yield was 0.96 g (88 %) of III (light-brown crystals, m.p. 168—170°, previously found[5] 167—169°). III gave a red color with aqueous ferric chloride. (Found: C 66.0; H 6.5; N 12.7. Calc. for C_6H_7ON (109.1): C 66.0; H 6.5; N 12.8). Sublimation (150°, 0.05 mm) gave white crystals, m.p. 169—171°.

Picrate. After crystallization from ethanol the m.p. was 205—208° (decomp.), previously found[6] 203°. (Found: C 42.8; H 3.2; N 16.3. Calc. for $C_{12}H_{10}O_8N_4$ (338.2): C 42.6; H 3.0; N 16.6).

6-Methyl-3-pyridinol hydrochloride. In another experiment the reaction mixture was evaporated as described above. The residue was then sublimed (160°, 0.1 mm). The yield

was 75 % of 6-methyl-3-pyridinol hydrochloride (white crystals, m.p. 145—150°). (Found: C 49.6; H 5.7; N 9.9; Cl 24.1. Calc. for C_6H_8ONCl (145.6): C 49.5; H 5.5; N 9.6; Cl 24.4).

6-(Hydroxymethyl)-3-pyridinol (V). IV (1.70 g) and ammonium bromide (200 mg) were dissolved in methanol (15 ml) and the solution electrolyzed with the set-up described previously[7] (temperature of cooling-bath −21°).

Time h	Current Amp.	Potential across the cell during electrolysis Volt	Ampere hours (% of theoretical) amount)	
0.1	0.30	4.6	0.02	(5 %)
0.2	0.29	4.7	0.05	(12 %)
0.5	0.29	4.9	0.14	(33 %)
1.0	0.29	4.9	0.26	(60 %)
2.0	0.22	5.1	0.48	(111 %)

After electrolysis the liquid was poured into a solution of sodium methoxide (from 250 mg of sodium) in methanol (5 ml) and the methanol and the ammonia evaporated in a vacuum. Sodium hydroxide (3 N, 14 ml) was added, the mixture heated under reflux (18 h) and then continuously extracted with ether for 20 h. The ether was evaporated in a vacuum and the mixture heated under reflux (20 min) with hydrochloric acid (N, 15 ml). The mixture was evaporated to dryness in a vacuum and the residue then dissolved in water (15 ml). Solid potassium carbonate was added and the mixture continuously extracted with ether overnight. The ether extract was evaporated, the residue washed twice with ether and dried. The yield was 0.74 g (74 %) of V (light-brown crystals, m.p. 123—125°, previously found[6] 124—125°). V gave a red color with aqueous ferric chloride (Found: C 57.6; H 5.8; N 10.8. Calc. for $C_6H_7O_2N$ (125.1): C 57.6; H 5.6; N 11.2). Sublimation (125°, 0.05 mm) gave white crystals, m.p. 123—125°.

A Kinetic Study by Measurements of Steady-State Potentials of Platinum in Persulphate Solutions Containing Ammonium and Silver Salts

STURE FRONÆUS

Department of Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The oxidation of ammonium ions by silver(II), which is presupposed to be a partial process of the silver(I) catalyzed self-decomposition of ammonium persulphate in acid solution, is investigated by measurements of the steady-state potential of a platinum electrode. From the dependence of the potential upon the concentrations of different ions taking part in the reactions, the kinetic laws of the oxidations of ammonium ions and water are determined. A mechanism of the oxidation of ammonium ions is proposed and is proved to be in accord with the laws obtained.

By measurements of the impedance of the electrode-solution interface it is shown that redox couples formed in the last-mentioned oxidation take part in the electron exchange between the electrode and the solution.

The principal features of the mechanism of the silver(I) catalyzed self-decomposition of ammonium persulphate in aqueous solution were clarified in a previous investigation (Fronæus and Östman [1],) dealing with the silver(I) catalyzed reaction between cerium(III) and ammonium persulphate. A partial process of the mechanism proposed is the reaction between silver(II), formed as an intermediate, and the ammonium ions. Since this reaction is not rate-determining for the over-all reactions studied, the kinetic law for the partial process mentioned could not be obtained from the measurements performed. Actually, no experimental determination of this rate law has been reported but only assumptions (*cf.* Carman [2]), that have not been tested quantitatively.

The purpose of the present investigation is a further elucidation of this problem by determinations of the concentration ratio between silver(II) and silver(I) by emf measurements with a platinum electrode. Since the solutions to be studied contain several redox couples which are not exactly in equilibrium, the steady-state electrode potential is theoretically a so-called mixed potential (for previous literature about this conception, the reader is referred

to papers by Wagner and Traud [3], and Kolthoff and Miller [4]), and this fact should be borne in mind when treating the emf values obtained. In order to determine whether several couples are actually involved in the adjustment of the electrode potential, measurements of the impedance of the electrode-solution interface have been chosen.

THEORETICAL

According to the mechanism for the silver(I) catalyzed decomposition of ammonium persulphate in acid solution, arrived at in the previous paper [1], we have the following set of homogeneous reactions as the predominating ones

$$Ag(I)+S_2O_8^{2-} \rightarrow Ag(II)+SO_4^{-}+SO_4^{2-} \quad (1)$$

$$Ag(I)+SO_4^{-} \rightleftharpoons Ag(II)+SO_4^{2-} \quad (2)$$

$$8\ Ag(II)+NH_4^{+}+3\ H_2O \rightarrow 8\ Ag(I)+10\ H^{+}+NO_3^{-} \quad (3)$$

where (1) is the rate-determining step and reaction (3) certainly involves several steps. The set of reactions has been extended somewhat, in that we take the backward process of (2) into consideration.

Furthermore, we have the oxidation of water, that should be of importance at low ammonium ion concentrations

$$SO_4^{-}+H_2O \rightarrow HSO_4^{-}+OH \quad (4)$$

$$Ag(II)+H_2O \rightarrow Ag(I)+H^{+}+OH \quad (5)$$

$$2\ OH \rightarrow H_2O+\tfrac{1}{2}O_2 \quad (6)$$

Here (5) and (6) are not simple steps [5,6].

In preliminary measurements it was established that the presence of platinum surfaces has no effect on the rate of persulphate decomposition. Evidently the persulphate ions take no appreciable part in the electron exchange with the electrode, and the oxidizing agents formed as intermediates in the reactions above must be responsible for the high steady-state electrode potential obtained. Thus we regard the electrode reactions

$$Ag(I) \rightleftharpoons Ag(II)+e^{-} \quad (7)$$

$$SO_4^{2-} \rightleftharpoons SO_4^{-}+e^{-} \quad (8)$$

and represent by

$$A \rightleftharpoons B+e^{-} \quad (9)$$

the further reactions that may be involved in the adjustment of the potential. The anodic current densities of (7), (8), and (9) are denoted i_1, i_2, and i_3. Thus i_3 is the sum of anodic currents due to the oxygen-water couple and couples formed in the oxidation of the ammonium ion.

When a steady-state electrode potential has been attained the following relationship is valid

$$i_1+i_2+i_3=0 \quad (10)$$

Furthermore, denoting by r_1, $\vec{r}_2$, $\overleftarrow{r}_2$ and $r_3 \cdots r_6$ the rates of the reactions (1)—(6), and applying the steady-state approximation to Ag(II) and SO_4^- in the bulk of the solution by putting $d[Ag(II)]/dt = 0$ and $d[SO_4^-]/dt = 0$ (t = time), we get the equations

$$r_1 + \vec{r}_2 - \overleftarrow{r}_2 - r_3 - r_5 = 0 \tag{11}$$

$$r_1 - \vec{r}_2 + \overleftarrow{r}_2 - r_4 = 0 \tag{12}$$

If r_1 is not equal to r_4 the redox potential e_1 of the silver couple will be different from the redox potential e_2 of the SO_4^-—SO_4^{2-} couple. However, since the reaction (1) is the rate-determining step we can presume that r_1 and r_4 ($<2\,r_1$) are very small in comparison with $\vec{r}_2$ and $\overleftarrow{r}_2$, so that $\vec{r}_2 \approx \overleftarrow{r}_2$ and hence $e_1 \approx e_2$. If we further presume that the absolute value of the difference between $e_1 \approx e_2$ and the steady-state potential e_0 of the electrode is sufficiently small to permit us to put the concentrations of the last-mentioned two couples close to the interface approximately equal to the concentrations in the bulk of the solution, we have the following relationship (*cf.* Fronæus [7]) for i_1 and i_2 at the steady-state potential.

$$i_n = i_{0,n}\left(\exp\left\{\frac{\alpha_n(e_0 - e_1)F}{RT}\right\} - \exp\left\{-\frac{(1-\alpha_n)(e_0-e_1)F}{RT}\right\}\right) \tag{13}$$

($n = 1$ and 2)

Here $i_{0,n}$ is the exchange current density and $0<\alpha_n<1$. But for small absolute values of $(e_0 - e_1)$ this expression can be replaced by

$$i_n = \frac{i_{0,n}(e_0 - e_1)F}{RT} \tag{14}$$

Now $RTF^{-1}i_{0,n}^{-1}$ is equal to the electron transfer resistance [7] $R_{t,n}$ of the electrode reactions (7) and (8), and using eqn. (10) we get

$$e_1 - e_0 = \frac{i_3}{R_{t,1}^{-1} + R_{t,2}^{-1}} \tag{15}$$

In the emf measurements below we will presuppose that the difference $e_1 - e_0$ is negligible and from variations in e_0 calculate the corresponding variations in the concentration ratio between silver(II) and silver(I). It should be emphasized that a very small value of i_3 does not imply that the transfer resistance $R_{t,3}$ of (9) is very high (*cf.* Fronæus [7]).

Adding eqns. (11) and (12) we obtain $r_3 + r_4 + r_5 = 2\,r_1$. According to the results of the previous investigation [1] we have $r_1 = \text{constant} \cdot [Ag(I)][S_2O_8^{2-}]$. If the complex formation between Ag^+ and the anions present is neglected [Ag(I)] can be replaced by $[Ag^+]$. Then we try to use the expression $[Ag^{2+}]^j \cdot \varphi$ for $r_3 + r_4 + r_5$, where φ may be a function of the concentrations of different species except silver(II) and persulphate, and get the relationship

$$\frac{[Ag^{2+}]}{[Ag^+]} = \text{constant}\,\frac{[S_2O_8^{2-}]^{\frac{1}{j}}}{[Ag^+]^{\frac{j-1}{j}}\,\varphi^{\frac{1}{j}}} \tag{16}$$

Thus by determining the dependence of $[Ag^{2+}][Ag^{+}]^{-1}$ upon the different concentrations it should be possible to obtain the value of j and the expression for φ.

MEASUREMENTS AND CALCULATIONS

Chemicals used. Sodium persulphate solutions were prepared by mixing equivalent amounts of solutions containing potassium persulphate and sodium perchlorate, cooling down to about 5°C and filtering off the potassium perchlorate precipitated. The concentration of the sodium persulphate solution was determined as described previously (Fronæus and Östman [8]).

Other chemicals used were prepared as before [1] or were commercial preparations of analytical grade.

Emf measurements. The cells measured were of the following type

−Au	quinh. 10 mM $HClO_4$ 990 mM $NaClO_4$	1000 mM $NaClO_4$	solution	Pt+

The solution of the right half-cell was obtained by mixing different solutions containing ammonium or sodium persulphate, ammonium, silver, and sodium perchlorates, perchloric acid, and ammonium or sodium sulphate. The sodium perchlorate was supplied in order to keep the ionic strength equal to 1 M. The measurements were carried out at a temperature of 25.0°C.

At first when the platinum electrodes were used no steady potentials were obtained. However, when the electrodes had been kept in decomposing persulphate solutions for some days, fairly steady potentials were attained when the electrodes were immersed in new solutions. Probably this fact must be ascribed to the formation of an oxide of platinum on the surface of the electrodes (*cf.* Bowden [9], Ershler [10]). In order to get reliable results every cell solution was freshly prepared many times, and different platinum electrodes were used. Then it was found that within 1 or 2 mV, the same emf mean values were obtained with different electrodes.

For the emf E in mV we have

$$E = E_0 + 59.16 \log \frac{[Ag^{2+}]}{[Ag^{+}]} \qquad (17)$$

where E_0 should be approximately constant. Taking the value 2 000 mV for the standard potential e_1^0 of the silver couple (*cf.* Noyes *et al.* [11]) and 560 mV for the potential of the quinhydrone electrode we get $E_0 \approx 1\,400$ mV. Then we find from the E-values in Tables 1 and 2 that $[Ag^{2+}] < 3 \times 10^{-4}[Ag^{+}]$. Thus, unless the complex formation between Ag^{2+} and the anions of the solutions is very strong, and this is not probable, the concentration of silver(II) is so low that we can put the concentration of silver(I) approximately equal to the total silver concentration. The values of $[H^{+}]$ and $[SO_4^{2-}]$ in the tables were calculated from the concentrations of perchloric acid and sulphate, the secondary dissociation constant $K_s = 8.5 \times 10^{-2}$ M being used for sulphuric acid (Fronæus [12]).

The emf values obtained in the presence of ammonium ions in the cell solutions are collected in Table 1. In order to determine an empirical expression for the right member of (16) we write

$$\frac{[Ag^{2+}]}{[Ag^{+}]} = \text{constant } [Ag^{+}]^a [NH_4^{+}]^b [H^{+}]^c [SO_4^{2-}]^d [S_2O_8^{2-}]^e \qquad (18)$$

Table 1. Emf and electrode impedance measurements on persulphate solutions containing ammonium and silver salts.

$[Ag^+]$ mM	$[NH_4^+]$ mM	$[H^+]$ mM	$[SO_4^{2-}]$ mM	$[S_2O_8^{2-}]$ mM	E mV	R_i^{-1} ohm^{-1}cm^{-2}
3.00	200	380	30	100	1 192	0.40
3.00	500	380	30	100	1 183	0.37
3.00	400	380	0	100	1 188	0.43
3.00	450	145	30	100	1 156	0.40
3.00	500	115	65	100	1 147	0.35
1.50	100	380	30	20	1 134	0.28
3.00	100	380	30	20	1 160	0.32
6.00	100	380	30	20	1 177	0.40
12.00	100	380	30	20	1 192	0.47
6.00	200	380	30	100	1 207	0.67
6.00	500	380	30	100	1 199	0.67

The derivative $\partial E/\partial \log [Ag^+]$ is found to be approximately constant and gives $a = 0.8$, except for the lowest silver(I) concentration, where a higher value is obtained which must be excluded. By combining the other E-values all the exponents in (18) can be determined, and we get $b = -0.4$, $c = 1.1$, $d \approx 0$, and $e = 1.0$. An equating of the right-hand members of (16) and (18) gives $j = e^{-1} = 1.0$ and an expression for φ. Then we have

$$r_3+r_4+r_5 = \text{constant } \frac{[Ag^{2+}][NH_4^+]^{0.4}}{[Ag^+]^{0.8}[H^+]^{1.1}} \qquad (19)$$

In order to obtain an empirical expression for r_4+r_5 emf measurements were also performed in the absence of ammonium ions. The E-values are given in Table 2. Eqn. (18) is applied, and it is found that also in this case $\partial E/\partial \log [Ag^+]$ is constant except for $[Ag^+] = 1.50$ mM. The following exponents are arrived at: $a = 0.8$, $c = 1.0$, $d \approx 0$, and $e = 0.8$. Thus $j = 1.2$ and for r_4+r_5 we get

$$r_4+r_5 = \text{constant } \frac{[Ag^{2+}]^{1.2}}{[Ag^+]^{1.2}[H^+]^{1.2}} \qquad (20)$$

Table 2. Emf and electrode impedance measurements on sodium persulphate solutions containing silver salts.

$[Ag^+]$ mM	$[H^+]$ mM	$[SO_4^{2-}]$ mM	$[S_2O_8^{2-}]$ mM	E mV	R_i^{-1} ohm^{-1}cm^{-2}
3.00	380	30	100	1 215	0.18
3.00	380	0	100	1 223	0.20
3.00	145	30	100	1 190	0.20
3.00	115	65	100	1 185	0.18
1.50	380	30	20	1 162	0.13
3.00	380	30	20	1 182	0.14
6.00	380	30	20	1 197	0.16
12.00	380	30	20	1 213	0.23
6.00	380	30	100	1 230	0.23

It should be emphasized that the real dependence of $r_3+r_4+r_5$ and r_4+r_5 upon $[SO_4^{2-}]$ cannot be ascertained from the measurements without information about the complex formation.

In a previous work [8] we arrived at the conclusion that r_4 is proportional to $[SO_4^-]$. Then, if we have a redox equilibrium between the couple SO_4^-—SO_4^{2-} and the silver couple, r_4 should be proportional to $[Ag^{2+}][Ag^+]^{-1}[SO_4^{2-}]$. For r_5 Noyes *et al.*[13] have found complicated expressions, but at low concentrations of silver(II) r_5 seems to be proportional to $[Ag^{2+}]^2[Ag^+]^{-1}$ and decreases for increasing values of $[H^+]$. Since the two last-mentioned rate laws are of different form, our empirical laws (19) and (20) can be applicable only within limited ranges of concentration.

Electrode impedance measurements. For a description of the apparatus used and the theory on which the calculations are based the reader is referred to a recent work [7]. The impedance of the electrode-solution interface can be represented by an equivalent circuit, consisting of a resistance R_p and a capacity C_p connected in parallel. From the measurements R_p was calculated at different values of the frequency ν of the polarizing alternating current. Then the conductance R_p^{-1} was plotted against $\nu^{-\frac{1}{2}}$ and extrapolated to $\nu = \infty$. For the intercept R_t^{-1} on the R_p^{-1}-axis we have

$$\frac{1}{R_t} = \frac{1}{R_{t,1}} + \frac{1}{R_{t,2}} + \frac{1}{R_{t,3}} \tag{21}$$

Also in these measurements it was found that in the beginning no steady values were obtained. R_t decreased continuously when the small polarizable platinum electrode was immersed in a decomposing persulphate solution, but after a few days the electrode gave reproducible impedances with fresh solutions. It is evident that the exchange current densities increased when a surface oxide was formed on the electrode.

If the over-all electrode reactions (7) and (8) are identical with the corresponding electron transfer steps, then $i_{0,1}$ should be proportional to $[Ag^{2+}]^{\alpha_1}[Ag^+]^{1-\alpha_1}$ and $i_{0,2}$ proportional to $[SO_4^-]^{\alpha_2}[SO_4^{2-}]^{1-\alpha_2}$ (*cf.* Fronæus and Östman [14]). Furthermore, if we have a redox equilibrium between these two couples and assume that the transfer coefficients α_1 and α_2 are approximately equal to 0.5, we should have the relationship

$$\frac{1}{R_{t,1}} + \frac{1}{R_{t,2}} = 10^{0.5E/59}(K_1[Ag^+] + K_2[SO_4^{2-}]) \tag{22}$$

where K_1 and K_2 are constants.

The final values of R_t^{-1} obtained from the measurements are given in the last columns of Tables 1 and 2. It is seen that the differences between the values belonging to one and the same table are rather small, but in Table 2 the variation is on the whole in qualitative agreement with the variation in $R_{t,1}^{-1}$ that can be expected according to eqn. (22). On the other hand, the term $R_{t,2}^{-1}$ seems to be of minor importance.

From (22) it is obvious that for small values of E and $[Ag^+]$ the quantity $R_{t,1}^{-1}$ will be small, and thus the difference e_1—e_0 in eqn. (15) may be appreciable.

Possibly this is the reason of the surprisingly small E-value in Table 1 for $[Ag^+] = 1.50$ mM.

Comparing the values of R_t^{-1} in Table 1 with those in Table 2 we find that, if ammonium ions are supplied but the concentrations of the other ions given in the tables are kept constant, the values of R_t^{-1} *increase* considerably, though the values of E decrease. The only explanation of this fact is that the couples formed in the different stages in the oxidation of ammonium ions take part in the electron exchange between electrode and solution, and thus the term $R_{t,3}^{-1}$ in (21) increases.

DISCUSSION OF THE REACTION MECHANISM

If the concentrations of silver(I) and persulphate are kept constant then we have $r_3+r_4+r_5 =$ constant. From Tables 1 and 2 it is evident that by the supply of ammonium ions the E-values decrease 20—38 mV. This means that $[Ag^{2+}]$ is from 2 to 5 times smaller in the presence of the ammonium ions, and from the empirical law (20) it is seen that approximately the same decrease must be valid for r_4+r_5. Accordingly, for the ammonium ion concentrations used we have $r_4+r_5<r_3<4(r_4+r_5)$.

However, it was found experimentally that the rate of the oxygen evolution was slight in the presence of ammonium ions and not at all as great as could be expected from these calculations. In order to explain this fact it must be presumed that the OH radicals, which are probably formed intermediately in the reactions (4) and (5), are made use of to a certain extent in one (or several) of the steps of the over-all reaction (3). For this reason the following mechanism is proposed for the first steps (*cf.* Fronæus and Östman [1]).

$$Ag^{2+}+NH_4^+ \rightleftharpoons AgNH_3^{2+}+H^+ \qquad (23)$$

$$AgNH_3^{2+}+OH \rightarrow Ag^+ + H^+ + NH_2OH \qquad (24)$$

(23) is presupposed to be a rapid complex equilibrium and (24) a slow step. Then r_3 should be proportional to $[AgNH_3^{2+}][OH]$, and substituting for $[AgNH_3^{2+}]$ the mass law expression we get

$$r_3 = \text{constant}\ \frac{[Ag^{2+}][NH_4^+][OH]}{[H^+]} \qquad (25)$$

Then, since $r_3/8$ is the rate at which ammonium ions are consumed in reaction (3), the steady-state approximation applied to OH in the solution gives

$$r_4+r_5-\frac{r_3}{8}-r_6 = 0 \qquad (26)$$

The mechanism proposed evidently requires that $r_3 \leqq 8(r_4+r_5)$, and this condition is satisfied according to the calculations above. Now we substitute the empirical expression (20) for r_4+r_5 with the exponents rounded off to 1.0.

Furthermore, the rate r_6 of reaction (6) should be proportional to $[OH]^2$, and then we have

$$k_1 \frac{[Ag^{2+}]}{[Ag^+][H^+]} = k_2 \frac{[Ag^{2+}][NH_4^+][OH]}{[H^+]} + k_3[OH]^2 \qquad (27)$$

where k_1, k_2, and k_3 are constants. From (27) it is seen that if the first term in the right member predominates then [OH] is proportional to $[Ag^+]^{-1}[NH_4^+]^{-1}$. On the other hand, if the second term predominates then [OH] is proportional to $[Ag^{2+}]^{0.5}[Ag^+]^{-0.5}[H^+]^{-0.5}$. Thus, within limited ranges of concentration it should be possible to represent [OH] by an expression of the form

$$[OH] = \text{constant } [Ag^{2+}]^{\varepsilon_1}[Ag^+]^{\varepsilon_2}[NH_4^+]^{\varepsilon_3}[H^+]^{\varepsilon_4} \qquad (28)$$

with the following conditions fulfilled

$$\begin{aligned} 0 &< \varepsilon_1 < 0.5 \\ -1 &< \varepsilon_2 < -0.5 \\ -1 &< \varepsilon_3 < 0 \\ -0.5 &< \varepsilon_4 < 0 \end{aligned}$$

For ε-values close to the middles of the intervals we then obtain

$$r_3 = \text{constant } \frac{[Ag^{2+}]^{1.2}[NH_4^+]^{0.5}}{[Ag^+]^{0.7}[H^+]^{1.2}} \qquad (29)$$

Combining this expression with (20) and taking into account that $r_3 > r_4 + r_5$, we can predict that if the resulting expression for $r_3 + r_4 + r_5$ is represented approximately by a law similar to (29) the exponents of $[Ag^{2+}]$ and $[H^+]$ will be unchanged, the exponent of $[Ag^+]$ will be slightly higher and that of $[NH_4^+]$ slightly lower than in (29). This conclusion is verified by the experimentally determined law (19), and it is evident that the mechanism proposed can explain the measurement results in a very satisfactory way.

The author is grateful to Miss K. Anderson for valuable assistance in the experimental work.

*iso*Thiocyanates XXI. * (−)-10-Methylsulphinyldecyl *iso*Thiocyanate, a New Mustard Oil Present as a Glucoside (Glucocamelinin) in *Camelina* Species

ANDERS KJÆR, ROLF GMELIN and ROALD BOE JENSEN

Chemical Laboratory of the University of Copenhagen, Denmark

Seeds of the cruciferous species *Camelina sativa* (L.) Crantz, *C. microcarpa* Andrz. and *C. dentata* (Willd.) Pers. contain two *iso*-thiocyanate glucosides according to paperchromatographic analysis. The chief constituent, *glucocamelinin*, has been identified as a glucoside containing (−)-10-methylsulphinyldecyl *iso*thiocyanate (VII) as the aglucone.

The new mustard oil is characterized as crystalline thiourea derivatives, formed by reaction with ammonia, aniline and benzylamine. The derivative with the last amine, (I), is degraded through well-defined steps to the compound (III), identical with a synthetic specimen of the previously unknown 1-benzyl-3-(10-methylthiodecyl)-urea. The mustard oil constitutes an addition to the class of naturally occurring sulphoxide-*iso*thiocyanates discussed in a preceding communication of this series.

In the search for new naturally occurring *iso*thiocyanates it was discovered that seeds of the crucifer *Camelina sativa* (L.) Crantz contained two mustard oils, different from those previously recognized in Nature. Although *C. sativa*, indigenous to the Mediterranean region, has been cultivated as an oil-producing plant since ancient times, its contents of *iso*thiocyanates do not appear to have been recognized previously.

In the present work paper chromatography of a seed extract of *C. sativa*, performed essentially as described by Schultz and Gmelin [1], clearly disclosed the presence of two glucosides (Fig. 1). Schultz and Wagner [2] recently introduced the symbol R_B, *i.e.* the ratio of the movement of the glucoside in question to that of a reference sample of glucotropaeolin, for paperchromatographic characterization of mustard oil glucosides. Adopting this convention we found the R_B-values 1.17 and 1.34 for the glucosides of *C. sativa* by descending chro-

* Part XX of this series: *Acta Chem. Scand.* **10** (1956) 1365.

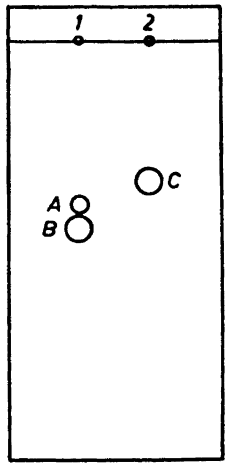

Fig. 1. Descending paper chromatogram of iso*thiocyanate glucosides on Whatman paper No. 1. Solvent system:* n*-butanol:ethanol: water (4:1:4). 1: Extract of seeds of* Camelina sativa *Crantz; 2: extract of seeds of* Tropaeolum majus *L. matography on Whatman paper No. 1 with the upper layer of the solvent system *n*-butanol:ethanol:water (4:1:4) as the mobile phase. The glucoside possessing the highest R_B-value appeared to be the predominant constituent. Seed extracts of the closely related species *C. microcarpa* Andrz. and *C. dentata* (Willd.) Pers. showed the same paperchromatographic pattern. The two glucosides were selectively eluted from the proper regions of the paper and subjected to enzymic hydrolysis, followed by spectrophotometric investigation of the individual *iso*thiocyanates. Both exhibited strong end-absorption in the short wave-length region in addition to a low-extinction shoulder at *ca.* 250—260 mμ, attributable to the *iso*thiocyanate grouping. From previous results in this laboratory [3] it appeared that the *iso*thiocyanates were not of the volatile type.

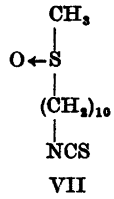
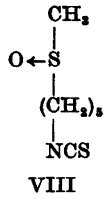
When a larger seed sample was subjected to enzymic hydrolysis in the usual way, a crude *levo*-rotatory *iso*thiocyanate fraction could be isolated by extraction with organic solvents. The product was transformed, without further purification, into crystalline, optically active thiourea derivatives by reaction with ammonia, aniline and benzylamine. After recrystallization, the derivatives were homogeneous as estimated from paper chromatography. Moreover, paperchromatographic comparison of the crude thiourea and an analytical specimen showed that the pure compounds were derivable from the *iso*thiocyanate corresponding to the main glucoside. Analytical data clearly indicated the composition $C_{12}H_{23}ONS_2$ for the parent mustard oil. Infra-red spectra left no doubt as to the presence of the side-chain sulphur atom in a sulphoxide-grouping, narrowing the above formula down to $C_{11}H_{23}(SO)NCS$. In order to elucidate the structure further, the benzylthiourea (I) was transformed into the corresponding benzylurea (II) which, in turn, was reduced to the optically inactive sulphide-urea (III). Consequently, the sulphoxide-grouping represented the sole centre of asymmetry in the parent mustard oil. Raney-nickel hydrogenolysis of (III) furnished a sharp-melting, sulphur-free product which was not homogeneous, however, according to infra-red and analytical data. All



attempts to fractionate the product failed but available data indicated that it consisted of *ca.* 25 % of 1-*cyclo*hexylmethyl-3-decyl-urea and about 75 % of 1-benzyl-3-decyl-urea (IV). An authentic specimen of the latter was prepared from decylamine and benzyl *iso*thiocyanate *via* the thiourea (V), and was found to melt 10° higher than the hydrogenolysis product.

$$\underset{\text{I}}{C_{11}H_{23}(SO)NHCSNHCH_2C_6H_5} \rightarrow \underset{\text{II}}{C_{11}H_{23}(SO)NHCONHCH_2C_6H_5}$$



$$\underset{\text{VI}}{CH_3S(CH_2)_{10}NHCSNHCH_2C_6H_5} \rightarrow \underset{\text{III}}{CH_3S(CH_2)_{10}NHCONHCH_2C_6H_5}$$

$$\underset{\text{V}}{CH_3(CH_2)_9NHCSNHCH_2C_6H_5} \rightarrow \underset{\text{IV}}{CH_3(CH_2)_9NHCONHCH_2C_6H_5}$$

In order to establish the structure of (III) in an unambiguous way, a specimen of 1-benzyl-3-(10-methylthiodecyl)-urea was synthetized from the corresponding thiourea (VI) which, in turn, was produced from benzyl *iso*thiocyanate and 10-methylthiodecylamine. Analyses, mixed melting point determination and infra-red spectra served to establish the identity of (III) as 1-benzyl-3-(10-methylthiodecyl)-urea. Consequently, the *Camelina* mustard oil, whence it derives, is 10-methylsulphinyldecyl *iso*thiocyanate (VII).

VII

VIII

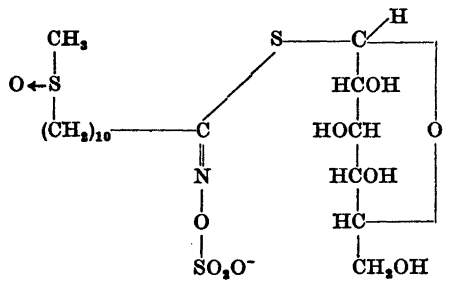
The mustard oil (VII) represents a novel addition to the class of naturally occurring, straight-chain ω-methylsulphinylalkyl *iso*thiocyanates. A previous paper of this series [4] described the identification of (—)-5-methylsulphinylpentyl *iso*thiocyanate (VIII), the aglucone of the natural glucoside glucoalyssin, and contained a discussion of various analogous substances and their configurational relationship.* The provenance and sign of rotation of (VII), as well as its thiourea derivatives, indicate that it belongs to the same configurational series as the formerly recognized species. Therefore, the new mustard oil is L(—)-10-methylsulphinyldecyl *iso*thiocyanate (VII), depicted as proposed elsewhere ** (*cf.* Ref. [4]).

* *Added in proof:* After this paper has been submitted for publication we have identified (−)-9-methylsulphinylnonyl *iso*thiocyanate as the mustard oil derivable from the natural glucoside glucoarabin [9].

** *Added in proof:* By means of X-ray structural analysis Hine and Rogers [10] have recently related the configuration at the S atom of (+)-S-methyl-L-cysteine sulphoxide with that at the α-carbon atom, which is known, thus rendering the arbitrary proposal of Schmid and Karrer[11] to use sulphoraphene as a configurational reference compound for sulphoxides superfluous.

The progenitor of this compound is a glucoside for which we wish to propose the name *glucocamelinin*, in accord with general practice in this field. No efforts were made to isolate or characterize the glucoside, but its contents of sulphate and glucose were established by means of paper chromatography *. The nature of the minor glucoside in seeds of the *Camelina* species will be discussed in a forthcoming paper.

10-Methylthiodecylamine, required in the synthetic work, was prepared by Curtius degradation of 11-methylthioundecanohydrazide as described by Walker [5]. The latter compound was obtained by hydrazinolysis of the previously unknown methyl 11-methylthioundecanoate, easily prepared by photo-induced addition of methanethiol to methyl undecenoate in the presence of benzoyl peroxide and mercuric acetate. The addition reaction appears to be a more convenient route to the sulphide-ester than the previously employed four-step reaction from the same starting material [5].



EXPERIMENTAL

All melting points are uncorrected and determined in capillary tubes in a slowly heated bath.

Extraction and purification of glucocamelinin. Finely ground seeds of *Camelina sativa* Crantz (200 g) were defatted and extracted with hot 70 % methanol. The solution was purified by lead salt as previously described for an analogous case [4]. The buffered solution was subjected to enzymic hydrolysis and the liberated *iso*thiocyanates taken up in chloroform. The extract was shaken briefly with a sodium bicarbonate solution in order to remove further impurities. The resulting crude, *levo*-rotatory mustard oil was divided into two halves and treated with ethanolic solutions of excess ammonia and aniline, respectively. Next day, the solvent was removed, and the crystalline derivatives purified by recrystallization from suitable solvents.

(−)-10-Methylsulphinyldecylthiourea. Three recrystallizations from ethyl acetate afforded the pure thiourea (115 mg) as tiny, colourless prisms, m.p. 92−92.5°. (Found: C 51.60; H 9.23; N 9.91; S 22.95. Calc. for $C_{12}H_{26}ON_2S_2$: C 51.75; H 9.41; N 10.06; S 23.03 $[\alpha]_D^{24}$ −65°±1.5° (96 % ethanol, c = 1.03). On paper chromatography in water-saturated chloroform by our usual method [7], the new thiourea possessed the R_{Ph}-value 1.15. The ultra-violet spectrum in ethanol was of the usual type, λ_{max} 242 mμ (ε 13 300) and λ_{min} 224 mμ (ε 3 240). Infra-red analysis of the solid thiourea in a potassium bromide disc

* Glucocamelinin appears to be of the usual glucoside structure type; available evidence in this laboratory, supplemented by the conclusive work by Ettlinger and Lundeen [6] on the revised Gadamer-structure for the mustard oil glucosides, favour the expression:

for the glucocamelinate ion, yet leaving the geometrical isomerism around the C=N linkage undecided.

disclosed conspicuous bands at 2.91 (s)*, 3.30 (s), 6.10 (vs), 6.32 (vs), 6.93 (s), 7.32 (s), 8.59 (w), 9.83 (vs, S→O) and 13.60 μ (m).

(—)-1-(10-Methylsulphinyldecyl)-3-phenylthiourea. The reaction product of the new mustard oil and aniline separated from acetone as flat prisms, m.p. 139°. (Found: C 60.90; H 8.51; N 7.81; S 18.10. Calc. for $C_{18}H_{30}ON_2S_2$: C 60.97; H 8.53; N 7.90; S 18.08). $[\alpha]_D^{24}$ −46°±1.5° (96 % ethanol, c = 0.43). The ultra-violet spectrum in ethanol exerted a maximum at 248 mμ (ε 14 600), a minimum at 228 mμ (ε 9 350) and a plateau at 255—265 mμ (ε 13 950). In the infra-red spectrum a very strong band at 9.99 μ was attributable to the sulphoxide grouping.

(—)-1-Benzyl-3-(10-methylsulphinyldecyl)-urea (II). The thiourea derivative, formed from the new mustard oil and benzylamine, separated from all solvents tested as a gelatinous product which was not brought to analytically pure condition. The benzylthiourea (I) (618 mg) was desulphurized with silver nitrate (573 mg) in dilute ethanol by heating on the steam bath for 10 min. during which period 1 N NaOH (3.4 ml) was gradually added in order to keep the reaction mixture near pH 7. The calculated amount of silver sulphide was filtered off, and the filtrate concentrated to dryness *in vacuo*. The residue was repeatedly triturated with hot ethyl acetate from which the urea (II) separated in tiny, colourless needles on cooling (405 mg), m.p. 113—114° (slight decomp.). (Found: C 64.60; H 9.09; N 7.92; S 9.27. Calc. for $C_{19}H_{32}O_2N_2S$: C 64.74; H 9.15; N 7.95; S 9.10). $[\alpha]_D^{24}$ −53.6°±1.5° (96 % ethanol, c = 1.17).

1-Benzyl-3-(10-methylthiodecyl)-urea (III). The sulphoxide-urea (II) (288 mg) was dissolved in ethanol and treated with acid-activated zinc dust and a few drops of conc. HCl on the steam bath. After the rotation had decreased to practically zero, the solution was filtered hot and the filtrate evaporated to dryness. On digestion with water the solid urea (264 mg) remained. It separated from aqueous ethanol in colourless platelets, m.p. 98.5—99.0°. (Found: C 67.70; H 9.42; N 8.21; Calc. for $C_{19}H_{32}ON_2S$: C 67.83; H 9.59; N 8.33).

1-Benzyl-3-decyl-thiourea (V). This compound was easily obtained from *n*-decylamine and benzyl *iso*thiocyanate as colourless, nacreous plates, m.p. 82.5°. (Found: C 70.50; H 9.87; N 9.06. Calc. for $C_{18}H_{30}N_2S$: C 70.53; H 9.87; N 9.15).

1-Benzyl-3-decyl-urea (IV). The thiourea (V) was desulphurized with silver nitrate, essentially as described above. The urea separated from 80 % ethanol in thin, colourless needles, m.p. 97°. (Found: C 74.60; H 10.47; N 9.69. Calc. for $C_{18}H_{30}ON_2$: C 74.43; H 10.41; N 9.65).

Attempted hydrogenolysis of (III) with W-4 Raney nickel led to a sharply melting mixture (m.p. 87.5°) of (IV) and the corresponding ring-hydrogenated product as estimated from analytical figures and from comparison of the infra-red spectrum of the mixture with that of pure (IV).

Methyl 11-methylthioundecanoate. A mixture of methyl undecenoate (32.6 g), benzoyl peroxide (80 mg) and mercuric acetate (150 mg) was placed together with methanol (50 ml) and methanethiol (7.91 g) in a water-cooled quartz flask, which was exposed to ultraviolet irradiation from a quartz-mercury lamp for 7 hours. Next day, a slight precipitate was filtered off, and methanol was removed from the filtrate by distillation. Pure methyl 11-methylthioundecanoate (31.7 g, 80 %) distilled as a colourless oil, b.p. 119°/0.1 mm; n_D^{25} 1.4651. (Found: C 63.50; H 10.72; S 12.80. Calc. for $C_{13}H_{26}O_2S$: C 63.37; H 10.64; S 13.02).

Hydrolysis of the ester with ethanolic KOH afforded 11-methylthioundecanoic acid, separating from aqueous ethanol in colourless, nacreous plates, m.p. 44° (Ref. [8] m.p. 43—45°).

10-Methylthiodecylamine. The above methyl ester was transformed into the corresponding hydrazide as described elsewhere [5]. The pure hydrazide, separating from aqueous ethanol as flat prisms, was found to melt at 92.0—92.5° (Ref. [5] m.p. 88—89°). (Found: C 58.70; H 10.58; N 11.38. Calc. for $C_{13}H_{26}ON_2S$: C 58.49; H 10.64; N 11.37).

The Curtius degradation of the hydrazide was performed as described by Walker [5], yet in somewhat lower yield. The amine distilled as a viscous, colourless oil at 165°/15 mm. The hydrochloride was prepared, m.p. 161—162° (Ref. [5] m.p. 160—161°).

* vs=very strong; s=strong; m=medium and w=weak.

1-Benzyl-3-(10-methylthiodecyl)-thiourea (VI). The reaction between 10-methylthiodecylamine and benzyl *iso*thiocyanate proceeded smoothly to give a quantitative yield of the thiourea (VI). This separated from 70 % ethanol in colourless, shiny platelets, m.p. 73°. (Found: C 65.10; H 9.06; N 8.00. Calc. for $C_{19}H_{32}N_2S_2$: C 64.73; H 9.15; N 7.95).

Desulphurization of (VI) to (III). When the thiourea was subjected to desulphurization with silver nitrate, essentially as described above, 1-benzyl-3-(10-methylthiodecyl)-urea (III) was obtained in 84 % yield, m.p. 100°, undepressed on admixture with the above specimen, prepared by degradation of the natural derivative. The identity of the two preparations was further substantiated by their coinciding infra-red spectra.

Microanalyses were performed in this laboratory by Mr. P. Hansen. We wish to thank the *Department of Plant Culture of the Royal Danish Veterinary and Agricultural College* for the gift of a substantial sample of *Camelina* seeds.

This work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*.

On the Sulfides, Selenides and Tellurides of Palladium

FREDRIK GRØNVOLD and ERLING RØST

Kjemisk Institutt A, Universitetet i Oslo, Blindern, Norway

The phase relationships in the systems palladium sulfur, palladium selenium and palladium tellurium have been studied by means of X-rays. Density determinations and magnetic susceptibility measurements have also been carried out.

In the Pd-S system five intermediate phases were identified:

1. Pd_4S, with tetragonal structure, $a = 5.1147$ Å, $c = 5.5903$ Å. The observed density is 10.27 g cm^{-3}.
2. $Pd_{2.8}S$, which is only present in quenched preparations. Its structure is unknown.
3. $Pd_{2.8}S$, with cubic structure, $a = 8.9300$ Å and a density of 8.67 g cm^{-3}.
4. PdS, with tetragonal structure. The redetermined lattice constants are $a = 6.4287$ Å, $c = 6.6082$ Å.
5. PdS_2, with orthorhombic structure and unit cell dimensions $a = 5.460$ Å, $b = 5.541$ Å, $c = 7.531$ Å.

In the Pd-Se system four intermediate phases were identified:

1. Pd_4Se, isomorphous with Pd_4S, $a = 5.2324$ Å, $c = 5.6470$ Å. The observed density is 10.74 g cm^{-3}.
2. $Pd_{2.8}^{xx}Se$, with unknown structure.
3. $Pd_{1.1}Se$, with cubic structure and lattice constant $a = 10.604$ Å. It has a density of 8.30 g cm^{-3}.
4. $PdSe_2$, isomorphous with PdS_2 and with lattice constants $a = 5.741$ Å, $b = 5.866$ Å, $c = 7.691$ Å. The observed density is 6.77 g cm^{-3}.

In the Pd-Te system six intermediate phases were identified:

1. Pd_4Te, with cubic structure, $a = 12.674$ Å. The observed density is 11.40 g cm^{-3}. The structure might be looked at as an approximately body-centered arrangement of palladium atoms of which one fifth has been substituted by tellurium atoms.

2, 3 and 4. Three phases have been identified in the range between Pd_4Te and PdTe. Their approximate compositions are Pd_3Te, $Pd_{2.5}Te$ and Pd_2Te.

5. PdTe, with structure of the NiAs-type. The redetermined lattice constants are $a = 4.1521$ Å, $c = 5.6719$ Å.
6. $PdTe_2$, with structure of the $Cd(OH)_2$-type. The redetermined lattice constants are $a = 4.0365$ Å, $c = 5.1262$ Å. No extended mutual solubility of PdTe and $PdTe_2$ was observed.

The magnetic susceptibility of Pd_4S, $Pd_{2.8}S$, Pd_4Se, $Pd_{1.1}Se$, $PdSe_2$ and Pd_4Te has been measured between −183° and 450°C. The compounds Pd_4S, Pd_4Se and Pd_4Te are weakly ferromagnetic with Curie temperatures in the range 20° to 300°C. Above this temperature they have almost zero magnetic susceptibility like the compounds $Pd_{2.8}S$, $Pd_{1.1}Se$ and $PdSe_2$.

Palladium monosulfide was prepared by direct combination of the elements by Berzelius [1] in 1813. It has been studied by many investigators since that time, and the results have been reviewed by Gmelin [2]. Three other palladium sulfides, Pd_2S, Pd_3S_4 and PdS_2, were obtained by Schneider [3]. The existence of the compound Pd_2S has later been confirmed by Petrenko-Kritschenko [4] and Roessler [5]. Furthermore, the compound Pd_4S exists according to Maxted [6], and the compound Pd_3S according to Iwanoff [7].

The region Pd to PdS of the palladium sulfur system was studied by Weibke and Laar [8] by means of thermal, metallographic and X-ray methods. The compounds Pd_4S and PdS were found in slowly cooled samples, and in addition, a phase with composition around 73.5 atomic per cent palladium ($Pd_{2.8}S$) which disproportionated into Pd_4S and PdS at temperatures below 554°C.

A tensimetric analysis of the sulfur-rich part of the system was carried out by Biltz and Laar [9]. No intermediate compounds between PdS and PdS_2 were found.

The crystal structure of PdS was determined by Gaskell [10] by means of single crystals. The structure of the other palladium sulphides are unknown.

Palladium monoselenide was obtained by Rössler [11] as an insoluble product after heating some precipitates containing palladium and selenium and treating them with nitric acid. The existence of PdSe has later been confirmed by Roessler [5] and by Moser and Atynski [12]. Roessler [5] also found a phase with composition Pd_4Se by heating dichlorodiammine palladium with selenium.

Thomassen [13] did not succeed in preparing stoichiometric palladium diselenide from the elements. Laue photographs taken of the crystals showed only twofold symmetry. $PdSe_2$ was later prepared by Wöhler, Ewald and Krall [14] by heating palladium dichloride with excess selenium. As a result of microscopic examination they concluded that the crystals were hexagonal and of the $Cd(OH)_2$-(*C*6)-type.

Palladium monotelluride was prepared by Tibbals, Jr.[15] by precipitation, and later by Thomassen [13] by heating a mixture of the elements. In the same way Thomassen prepared palladium ditelluride. By means of X-ray powder photographs he found that PdTe had a hexagonal structure of the NiAs-(*B*8-) type, and that $PdTe_2$ had a structure of the $Cd(OH)_2$-(*C*6-) type.

EXPERIMENTAL

The *palladium* metal used in this study was kindly placed at our disposal by Falconbridge Nikkelverk A/S, Kristiansand S. To remove adsorbed hydrogen, the metal was heated at 900°C at a pressure of the order 10^{-6} cm Hg. A spectrographic analysis showed that Ag was present in the order of 0.01 % and Cu, Mg, Fe, Si and Na in less than 0.01 % each.

Sulfur from Schering-Kahlbaum A.G. (Sulfur cryst. puriss.) was purified by double distillation in a silica apparatus. Only the middle fractions were used. The highly purified *selenium* was a gift from Bolidens Gruvaktiebolag, Sweden. It carried the analysis: 0.0002 % Cu, 0.0007 % Fe, 0.003 % Te, 0.01 % S and 0.003 % non volatile matter. *Tellurium* from The British Drug Houses Ltd. was subjected to vacuum distillation in silica vessels. According to the spectrographic analysis it contained less than 0.01 % Fe and only traces of Al, Mg and Pb. This analysis and the palladium analysis were kindly carried out by siv.ing. S. Rutlin, Sentralinstitutt for Industriell Forskning, Blindern.

Alloys were prepared by heating mixtures of palladium and sulfur, selenium or tellurium, respectively, in the stoichiometric ratio 1:1 in evacuated and sealed silica tubes.

After being heated for a few days at temperatures ranging between 500° and 800°C the samples were cooled and finely ground. Alloys with other desired compositions were obtained by adding Pd, S, Se or Te in the right proportions to the mono compounds and heating the samples for some days at 600°C. Most of the samples were afterwards annealed at temperatures ranging between 250° and 650°C and cooled slowly to room temperature. In some cases the samples were quenched in ice water. During some of the heat treatments single crystals were formed.

X-Ray single crystal photographs were taken in an oscillation camera with 6.0 cm diameter and a Weissenberg camera with 5.73 cm diameter. The powdered samples were investigated by X-rays in cameras with 11.46 cm effective diameter and asymmetric film mounting. Lattice constants are expressed in Ångström units on basis of the wave lengths $\lambda CuK\alpha_1 = 1.54051$ Å, $\lambda FeK\alpha_1 = 1.93597$ Å and $\lambda CrK\alpha_1 = 2.28962$ Å. Results from earlier investigations, expressed in kX, have been transformed to Å by multiplication by the factor 1.00202.

Lattice constants of the cubic phases were found by extrapolation according to the method given by Nelson and Riley [16]. In this way the lattice constant of palladium was determined as $a = 3.8902$ Å, in perfect agreement with the high precision value $a = 3.89022$ Å given by Owen and Yates [17] for spectrographically pure palladium at 18°C.

The density of the samples was determined by the pycnometric method at 25°C with kerosene as displacement liquid. To remove gases adsorbed by the sample, the pycnometer was filled under vacuum with kerosene. Each sample weighed around 1.5 g.

The magnetic susceptibility of the samples was measured by the Gouy method at three different maximum field strengths at −183°, −78°, 20°, 150°, 300° and 450°C. The samples were filled in thin walled silica tubes of about 0.10 cm internal diameter and to a height of about 8.5 cm.

X-RAY RESULTS

A. Palladium sulfides

In the system palladium sulfur five intermediate phases were identified by means of X-rays: Pd_4S, $Pd_{2.2}S$, PdS, PdS_2 and a high temperature phase with composition around $Pd_{2.8}S$. PdS and samples richer in palladium were brittle and of gray, metallic color. The existence of a compound Pd_3S_4, claimed by Schneider [3], was not confirmed, while all the other palladium sulfides described earlier exist if one associates the compound Pd_3S by Iwanoff [7] with $Pd_{2.8}S$, and Pd_2S by Schneider[3], Petrenko-Kritschenko [4] and Roessler [5] with $Pd_{2.2}S$.

The lattice constant found for palladium in equilibrium with Pd_4S was equal to that of pure palladium within the limits of experimental error. This confirms the observations by Jedele [18] and Weibke and Laar [8] that sulfur is practically insoluble in solid palladium.

The Pd_4S phase. The Pd_4S phase could be indexed on basis of a tetragonal unit cell with dimensions:

$$a = 5.1147 \text{ Å}, \qquad c = 5.5903 \text{ Å}, \qquad c/a = 1.0930.$$

Results of the measurements are listed in Table 1. The systematic missing reflections are of the type $h\,h\,l$ with $l = 2n+1$ and $h\,0\,0$ with $h = 2n+1$. They characterize the space group $P\,\bar{4}\,2_1c$ (D^4_{2d}). The Pd_4S phase is isomorphous with the Pd_4Se phase.

The density of Pd_4S was determined to be 10.27 g cm^{-3} at 25°C, which gives a unit cell content of eight (7.90) palladium and two (1.97) sulfur atoms.

Table 1. Powder photograph data of Pd_4S annealed at 450°C, CuKa radiation. The a_2 reflections have been omitted.

The $Pd_{2.8}S$ phase. When samples with composition Pd_3S were quenched from 580° and 600°C their X-ray photographs showed the presence of a phase which was not found in the furnace cooled samples. Weak reflections from the Pd_4S phase were found in the quenched Pd_3S sample, while rather strong reflections from the $Pd_{2.2}S$ phase were found in the quenched $Pd_{2.5}S$ sample. The high temperature phase thus seems to have a composition in the vicinity of $Pd_{2.8}S$. This agrees well with the results of Weibke and Laar [8]. We have not yet been able to determine the structure of this phase and only its characteristic reflections are listed in Table 2.

The $Pd_{2.2}S$ phase. In contrast to the results by Weibke and Laar, another intermediate phase between Pd_4S and PdS was found both in slowly cooled samples and in samples quenched from 600°C. The composition of the phase is probably close to $Pd_{2.20}S$ as the powder photograph of this sample contains no lines from other phases, while that of $Pd_{2.25}S$ shows some weak Pd_4S lines and that of Pd_2S shows many lines from the PdS phase.

The powder photograph of $Pd_{2.20}S$ could be indexed as cubic with lattice constant $a = 8.9300$ Å. No significant variation in lattice constant with composition was observed, and in Table 3 is given the indexing for the $Pd_{2.25}S$ sample.

Table 2. Characteristic low angle reflections and interplanar spacings of the $Pd_{2.8}S$ phase as found from a powder photograph of Pd_4S quenched from 600°C, CuKa radiation.

* Reflections probably from the Pd_4S phase.

Reflections $h\,k\,l$ of the type $h+k+l = 2n+1$ are missing, which is characteristic of a body centered unit cell. The experimentally found density of $Pd_{2.20}S$ is 8.67 g cm^{-3} and the unit cell accordingly contains 30.7 palladium and 13.9 sulfur atoms.

The PdS phase. A redetermination of the lattice constant of the tetragonal PdS phase gave the values:

$$a = 6.4287 \text{ Å}, \qquad c = 6.6082 \text{ Å}, \qquad c/a = 1.0279.$$

* Reflections from the Pd_4S phase.

The determination by Bannister [19] gave $a = 6.44$ Å, $c = 6.60$ Å and the values reported by Gaskell [10], who determined the atomic arrangement in PdS, were $a = 6.44$ Å, $c = 6.64$ Å.

The complete indexing of a powder photograph of PdS taken with chromium radiation is given in Table 4.

The PdS_2 phase. Experiments to get the PdS_2 phase by heating the components were not entirely successful. Even after treating PdS with excess of sulfur for six months at various temperatures between 300° and 500°C, reflections from unreacted PdS could still be seen on the X-ray photographs together with those from another phase, probably PdS_2.

It was then tried to prepare PdS_2 by the method of Wöhler, Ewald and Krall [14] by heating palladium dichloride with excess of sulfur for four days at 450°C in an evacuated silica tube. The product was obtained in form of a black, crystalline powder after washing with carbon disulfide. The X-ray photographs resembled the earlier ones, but all the reflections from PdS had disappeared, and the sample was supposedly pure PdS_2.

The powder photograph could be indexed as orthorhombic with unit cell dimensions:

$$a = 5.460 \text{ Å}, \qquad b = 5.541 \text{ Å}, \qquad c = 7.531 \text{ Å},$$

$$a:b:c = 0.9854:1:1.3591.$$

In Table 5 are found the results of film measurements and indexing.

According to Biltz and Laar [9] the density of PdS_2, synthesized from $PdCl_2$ and sulfur, is 4.833 g cm^{-3}. The unit cell should then contain four (3.883) formula units of PdS_2.

The systematic missing reflections on the powder photograph seem to be the same as those for the $PdSe_2$ phase. Since the number of atoms in the unit cell and the axial ratios are about the same as found for $PdSe_2$, these phases are probably isomorphous.

B. Palladium selenides

Four intermediate phases were identified in the palladium selenium system: Pd_4Se, $Pd_{2.8}Se$, $Pd_{1.1}Se$ and $PdSe_2$. The phases were all obtained both in quenched and slowly cooled preparations. They were of gray, metallic color and also brittle, except $PdSe_2$ which formed soft, platelike crystals.

The $Pd_{2.8}Se$ phase was not found by earlier investigators and the $Pd_{1.1}Se$ phase was given the composition PdSe by Roessler [5], Rössler [11] and Moser and Atynski [12].

The Pd_4Se phase. Powder photographs of Pd_4Se showed great similarities with those of Pd_4S and could be indexed as tetragonal. The unit cell dimensions were found to be:

$$a = 5.2324 \text{ Å}, \qquad c = 5.6470 \text{ Å}, \qquad c/a = 1.0792.$$

A record of the interferences which occur on a powder photograph of Pd_4Se taken with copper radiation is found in Table 6.

After annealing a Pd_4Se sample at 450°C for forty-five days some small crystals had been formed. Weissenberg photographs with the *b*-axis as rotation axis confirmed that the systematic missing reflections were of the type *h h l* absent when $l = 2n+1$ and *h* 0 0 absent when $h = 2n+1$. The characteristic space group is thus $P\,\bar{4}\,2_1c$ (D^4_{2d}) as found for Pd_4S.

The pycnometric density of Pd_4Se is 10.74 g cm^{-3} which means that eight (7.95) palladium and two (1.99) selenium atoms are present in the unit cell. A discussion of the atomic arrangement in the two isomorphous phases Pd_4S and Pd_4Se will be given in a later paper.

The $Pd_{2.8}Se$ phase. Powder photographs of samples in the composition range between Pd_4Se and $Pd_{1.1}Se$ contain reflections from a phase with composition around $Pd_{2.8}Se$. The photographs of Pd_3Se show some additional very weak reflections that are probably from the Pd_4Se phase, and the photograph of $Pd_{2.5}Se$ shows rather strong reflections from a phase richer in selenium.

In Table 7 are listed the lines found in the low angle region on a powder photograph of the $Pd_{2.5}Se$ sample. The structure of this phase is unknown. On some photographs a few additional reflections were found that are possibly due to an unidentified phase, perhaps only stable at higher temperatures.

Table 7. Low angle reflections on a powder photograph of $Pd_{2.5}Se$ annealed at 450°C, CuKa radiation.

* Reflections probably from the $Pd_{1.1}Se$ phase.

The $Pd_{1.1}Se$ phase (Pd_9Se_8?). Powder photographs of PdSe samples contain some of the strongest reflections from the $PdSe_2$ phase in addition to the characteristic pattern of a cubic phase. These additional reflections are absent on photographs of $Pd_{1.1}Se$ and the cubic phase is therefore assumed to have a composition close to Pd_9Se_8.

A record of the reflections observed for $Pd_{1.1}Se$ is found in Table 8. The unit cell is primitive with lattice constant $a = 10.604$ Å.

A density determination on $Pd_{1.1}Se$ gave 8.30 g cm^{-3} and thus a cell content of 33.7 palladium atoms and 30.0 selenium atoms.

It is interesting to note that Juza, Hülsmann, Meisel and Biltz [20] found a phase at the composition Rh_9S_8 by tensimetric analysis of the rhodium sulfur system. According to X-ray studies by Mr. Ø. Steen in this institute the structure of Rh_9S_8 is also cubic and probably closely related to that of Pd_9Se_8.

The $PdSe_2$ phase. After annealing $PdSe_2$ for fifty days at 650°C some small, badly developed crystals were obtained. Weissenberg photographs showed that the crystals were orthorhombic and gave the approximate cell dimensions. The powder photograph of $PdSe_2$ could then be indexed as shown in Table 9 and these lattice constants were arrived at:

$$a = 5.741 \text{ Å}, \qquad b = 5.866 \text{ Å}, \qquad c = 7.691 \text{ Å},$$

$$a:b:c = 0.9787:1:1.3111.$$

Missing reflections are of the type 0 $k\,l$ absent when $k = 2n+1$, $h\,0\,l$ absent when $l = 2n+1$ and $h\,k\,0$ absent when $h = 2n+1$. The characteristic space group is thus $P\,b\,c\,a$ (D_{2h}^{15}) and on basis of the observed density 6.77 g cm^{-3} the unit cell contains four (4.00) palladium and eight (8.00) selenium atoms.

C. Palladium tellurides

In the palladium tellurium system the following intermediate phases were found: Pd_4Te, Pd_3Te, Pd_2Te, PdTe and $PdTe_2$. In addition, a sixth phase probably exists in the range between Pd_3Te and Pd_2Te. The exact composition limits of the phases have not been determined, and the formulae only indicate

the approximate composition of the phases. All phases have been found both in quenched and in slowly cooled preparations. The samples are gray in color and apart from $PdTe_2$ they are brittle.

The only palladium tellurides described earlier are the monotelluride by Tibbals, Jr.[15] and Thomassen [13] and the ditelluride by Thomassen [13].

The Pd_4Te phase. Single crystals of the Pd_4Te phase were obtained in a sample with gross composition Pd_6Te that had been heated at 550°C for fifty days. Weissenberg photographs showed primitive cubic symmetry, and by means of powder photographs the lattice constant of Pd_4Te was found to be $a = 12.674$ Å.

The single crystal photographs show strong reflections only in the equatorial and fourth layer line while those in the first, second, third, fifth and sixth layer line are weak. This suggests that the true unit cell is a superstructure cell, and as apparent from Table 10 the strong reflections are multiples of $h^2+k^2+l^2 = 32$, indicating that the "subcell" with $a' = 3.168$ Å is approximately body centered.

In agreement with this, the observed density 11.40 g cm^{-3} of Pd_4Te confirms that the number of atoms in the subcell is close to two (1.575 Pd atoms and 0.394 Te atoms). The structure can probably be looked at as a body centered arrangement of palladium atoms of which one fifth has been substituted by tellurium atoms in an ordered way. However, the atoms are slightly displaced from the ideal positions as evidenced especially by the strong $h^2+k^2+l^2 = 251$ reflection.

The phases between Pd_4Te and $PdTe$. Samples in this range give very complicated powder photographs and the phases are not easily identified. The Pd_4Te reflections are found in $Pd_{3.5}Te$ but are absent in Pd_3Te. No lines from a tellurium richer phase are presumably present in Pd_3Te since the powder photographs of Pd_3Te and $Pd_{2.75}Te$ are alike. The low angle reflections found on a powder photograph of Pd_3Te are collected in Table 11.

There also exists a phase with composition around Pd_2Te. Its characteristic low angle reflections are listed in Table 11 too. A sample with composition $Pd_{1.5}Te$ was found to contain both the Pd_2Te and the PdTe phase.

The powder photograph of $Pd_{2.5}Te$ is markedly different from that of Pd_2Te and does not resemble that of $Pd_{2.75}Te$ either, see Table 11. Probably therefore a third phase exists in this range.

The PdTe and $PdTe_2$ phase. A redetermination of the lattice constants of hexagonal PdTe with structure of the NiAs-($B8$-)type gave the result:

$$a = 4.1521 \text{ Å}, \qquad c = 5.6719 \text{ Å}, \qquad c/a = 1.3660.$$

These values are in good agreement with those determined by Thomassen [13] ($a = 4.135 \pm 0.004$ Å, $c = 5.674 \pm 0.005$ Å).

The homogeneity range of the PdTe phase is apparently rather narrow since the lattice constants of the PdTe phase are equal within the limits of experimental error both in $Pd_{1.5}Te$, PdTe and $PdTe_{1.5}$.

The structure of $PdTe_2$ is also hexagonal and for a sample that had been heated with excess tellurium at 300°C for 30 days the following lattice constants were computed:

$$a = 4.0365 \text{ Å}, \qquad c = 5.1262 \text{ Å}, \qquad c/a = 1.2700.$$

According to Thomassen [13] the structure is of the $Cd(OH)_2$-(*C*6-) type and the lattice constants given by him ($a = 4.036 \pm 0.003$ Å, $c = 5.128 \pm 0.004$ Å) are in excellent agreement with ours.

A continuous solid solution between PdTe and $PdTe_2$ is not found, and in general it seems like none of the palladium chalcogenides have extended ranges of homogeneity. Among the chalcogenides of the 3d transition elements solid solutions involving a continuous transition from the *B*8 to *C*6 structure type are quite common. As examples might be mentioned the CoTe - $CoTe_2$ and NiTe - $NiTe_2$ transitions found by Tengnér [21] and the TiTe - $TiTe_2$ transition studied by Ehrlich [22]. Recently, the phases RhTe and $RhTe_2$ have been identified by Geller [23]. RhTe was found to have a structure of the *B*8 type and the high temperature form of $RhTe_2$ a structure of the *C*6 type. No samples with intermediate compositions were studied so it is not known to what extent these phases show mutual solubility.

MAGNETIC PROPERTIES OF THE PALLADIUM CHALCOGENIDES

The magnetic susceptibility of Pd_4S, $Pd_{2.2}S$, Pd_4Se, $Pd_{1.1}Se$, $PdSe_2$ and Pd_4Te was measured at six different temperatures from —183° to 450°C and the results are listed in Tables 12 and 13.

Table 12. Magnetic susceptibility of the palladium chalcogenides, $\chi_g \times 10^6$.

Compound	Temperature °C					
	−183	−78	20	150	300	450
Pd_4S	*	*	*	0.20	0.01	0.06

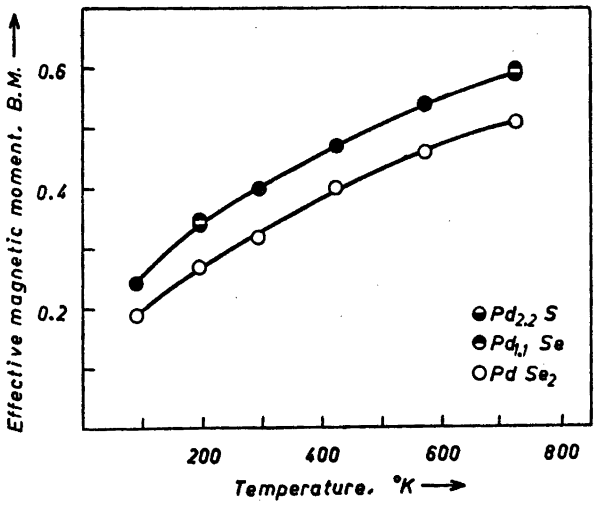

Fig. 1. Effective magnetic moments of the compounds $Pd_{2.2}S$, $Pd_{1.1}Se$ and $PdSe_2$ as functions of temperature.

Disregarding the peculiar behavior of the Pd_4X compounds at low temperatures, the magnetic susceptibilities are exceedingly low. If one subtracts the induced diamagnetism in the palladium (-21.3×10^{-6} per mole Pd^0 according to Hoare and Matthews [24]) and in the chalcogen (-32.6×10^{-6} per mole S^{-2}, -47.6×10^{-6} per mole Se^{-2} and -70.6×10^{-6} per mole Te^{-2} according to Angus [25]) one finds effective magnetic moments in the range 0.19 to 0.60 Bohr magnetons for the compounds $Pd_{2.2}S$, $Pd_{1.1}Se$ and $PdSe_2$, see Fig. 1. Considerable uncertainty is connected with the diamagnetic corrections. They are most probably too high since they refer to completed electron shells, thus resulting in too high effective magnetic moments.

Even so, the magnetic moments are rather small and show that the compounds are of an essentially metallic or covalent type. In case the bonds had been of the ionic type, a magnetic moment of 2.83 B.M. was expected for the Pd^{+2} ion and 4.90 B.M. for the Pd^{+4} ion according to the "spin only" theory. The tendency, present among the nickel chalcogenides, for the magnetism to be weaker than expected, is even more pronounced among the palladium chalcogenides. One possible explanation for this behavior is that interaction between the atoms changes the coupling of the 4d electrons of palladium so that the stable configuration does not have the maximum multiplicity required by the Hund rule.

Below certain temperatures, the magnetic susceptibilities of Pd_4S, Pd_4Se and Pd_4Te are field strength dependent and increase with decreasing temperature. The field strength dependence is observed at room temperature for Pd_4S and Pd_4Se and also at 150°C for Pd_4Te.

The authors should like to express their appreciation to professor Haakon Haraldsen for his interest in this study. They wish to thank Falconbridge Nikkelverk A/S for generously supplying palladium metal and to thank Bolidens Gruvaktiebolag for the selenium. They also wish to thank siv.ing. Sigurd Rutlin, Sentralinstitutt for Industriell Forskning, for carrying out the spectrographic analysis.

Chromatographic Separation of two Vitamin A_2 Isomers

B. BARNHOLDT and WILLY HJARDE

The National Vitamin Laboratory, Copenhagen, Denmark.

The presence of two vitamin A_2 isomers in perch and pike liver extract has been demonstrated, and the spectroscopic properties of the substances have been given.

By the action of iodine on natural vitamin A_2 a vitamin A_2 mixture is obtained which may be separated by chromatography into two substances, *a* and *b*, the ratio of *a* to *b*, expressed by $E_{351m\mu}$, being about 1 to 2. Substance *a* seems to be identical with the neovitamin A_2 occurring in the liver extract. There are some doubts as to whether substance *b* and the vitamin A_2 occurring in Nature are identical. Even though substance *b* and natural vitamin A_2 exhibit a number of similarities both spectroscopically and chromatographically, certain discrepancies as regards spectroscopic properties have made it impossible to ascertain whether *b* is a single substance or a mixture of vitamin A_2 and an irrelevant substance with light absorption in the wavelength range below 310 mμ.

When an isomerized mixture of vitamin A_1 and vitamin A_2 was chromatographed on dicalcium phosphate, the four substances present were eluted in the following order: neovitamin A_1 — substance *a* (neovitamin A_2) — all-*trans* vitamin A_1 — substance *b* (natural vitamin A_2?).

In view of the close relationship between vitamin A_1 and vitamin A_2 (= dehydrovitamin A_1) it is a reasonable assumption that vitamin A_2 may also occur in more than one of the theoretically possible stereoisomeric forms. In their determinations of the content of vitamin A_1 and vitamin A_2 in certain Nile fish Abdullah, Morcos and Salah [1] have assumed the existence of two different geometrical isomers of vitamin A_2 (neovitamin A_2 and vitamin A_2) and have determined the ratio of neovitamin A_2 to vitamin A_2, assuming that under identical experimental conditions the reactions of the two vitamin A_2 isomers with maleic acid anhydride both qualitatively and quantitatively are identical with the corresponding reactions of neovitamin A_1 and all-*trans*-vitamin A_1, respectively.

Since it has been shown to be possible to separate neovitamin A_1 and all-*trans* vitamin A_1 by chromatography (Bro-Rasmussen, Hjarde and Porotnikoff[2]), it would be reasonable to ascertain whether by applying a similar method to a supposed mixture of vitamin A_2 isomers it would be possible to obtain a

separation, or at any rate a partial separation, of the isomers, enabling a further examination of the course of their absorption curves. In the above-mentioned publication from this laboratory it has been suggested that vitamin A_2 may be present in cod liver oil in two stereoisomeric forms, which differ with regard to the readiness with which they are eluted when chromatographed on dicalcium phosphate.

However, preliminary investigations show fresh liver from various freshwater fish to contain almost exclusively one of the vitamin A_2 forms. On chromatography, the greater part of the light-absorbing substances with absorption maximum at about 350 mμ is found to be present in the form of one fraction with an absorption curve which is in good agreement with the one given in the above publication [2]. It was therefore necessary to perform an isomerization of the isolated vitamin A_2 fraction followed by chromatography to separate the isomeric substances.

In the following an account will be given of these experiments and the results obtained.

EXPERIMENTAL

The technique used is, with the exception of the isomerization process, described in the above publication. A few modifications will be referred to in connection with the individual experiments. The isomerization process will be described in section II below. All the chromatographic separations mentioned in the following have been performed at room temperature (22–23°C) and protected against daylight. The spectrophotometric measurements were made with a Beckman spectrophotometer, type D.U., slit-width about 0.15–0.08 mm within the measuring range used in the present investigation.

I,1. ISOLATION OF VITAMIN A_2 FROM PIKE LIVER

A dicalcium phosphate column, 86 cm long, 1.8 cm diam., was used for chromatography of the unsaponifiable fraction from 5.95 g of pike liver, the absorption curve of which when measured in light petroleum displayed three maxima (277 mμ, 287 mμ and 348—352 mμ, $E^{1\%}_{1cm,\ 350\ m\mu} = 0.920$ measured in relation to the liver weight) and $\frac{E_{287\ m\mu}}{E_{350\ m\mu}} = 0.513$. The eluent used was a mixture of light petroleum and diethylether (86:14 v/v). Eluate was collected in 4.7 ml fractions by means of an automatic fraction collector. The fractionation curve is illustrated in Fig. 1. The fractions collected were measured spectrophotometrically (after dilution with light petroleum, if necessary) at the wavelengths 325 mμ and 351 mμ. The value of the ratio $\frac{E_{351\ m\mu}}{E_{325\ m\mu}}$ for each individual fraction is also given in Fig. 1.

The peak fraction (No. 30) and the immediately subsequent fractions all displayed the same value of the ratio $\frac{E_{351\ m\mu}}{E_{325\ m\mu}}$. The vitamin A_2 fraction (No. 31) following the peak fraction with $E^{1cm}_{351\ m\mu} = 6.01$ was evaporated to dryness in a stream of carbon dioxide and redissolved in absolute ethanol. The resulting absorption curve (Fig. 2, curve 1) displayed three maxima (276.5 mμ, 287 mμ

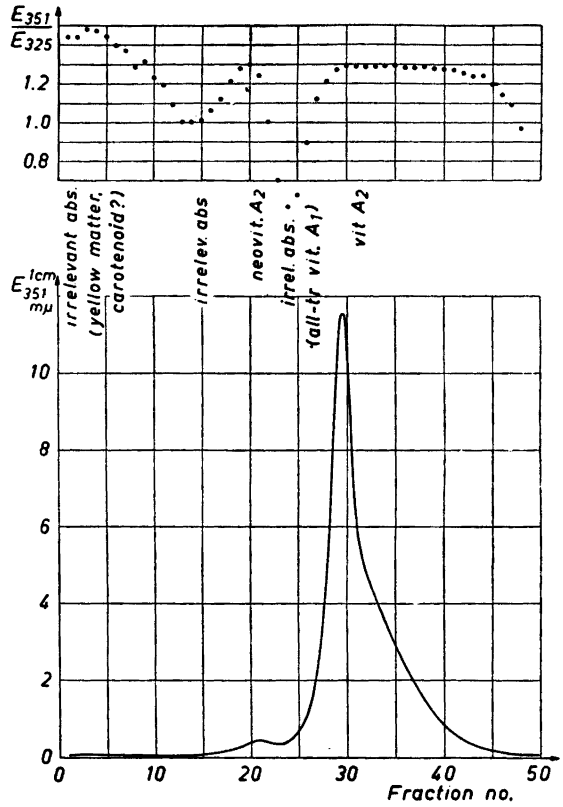

Fig. 1. Fractionation curve for the unsaponifiable fraction from pike liver with a column 86 cm long, diam. 1.8 cm. The upper part of the figure illustrates the ratio $\frac{E_{351\ m\mu}}{E_{325\ m\mu}}$ *for the individual fractions.*

and 351.5 mμ) and two minima (280 mμ and 297 mμ) and the following ratios were found:

$$\frac{E_{276.5}}{E_{351.5}} = 0.388, \quad \frac{E_{280}}{E_{351.5}} = 0.369, \quad \frac{E_{287}}{E_{351.5}} = 0.493, \quad \frac{E_{297}}{E_{351.5}} = 0.298 \quad \frac{E_{325}}{E_{351.5}} = 0.735$$

I,2. ISOLATION OF VITAMIN A_2 FROM PERCH LIVER

A dicalcium phosphate column, 70 cm long, 1.8 cm diam., was used for chromatography of the unsaponifiable fraction from 15.76 g of perch liver ($E^{1\%}_{1cm,\ 350\ m\mu} = 0.085$ measured in light petroleum and calculated in relation to the liver weight). Eluents used: light petroleum-ether mixtures, 300 ml (92:8 v/v), 300 ml (90:10 v/v). Eluate was collected in 3.2 ml fractions. The fractionation curve is illustrated in Fig. 3.

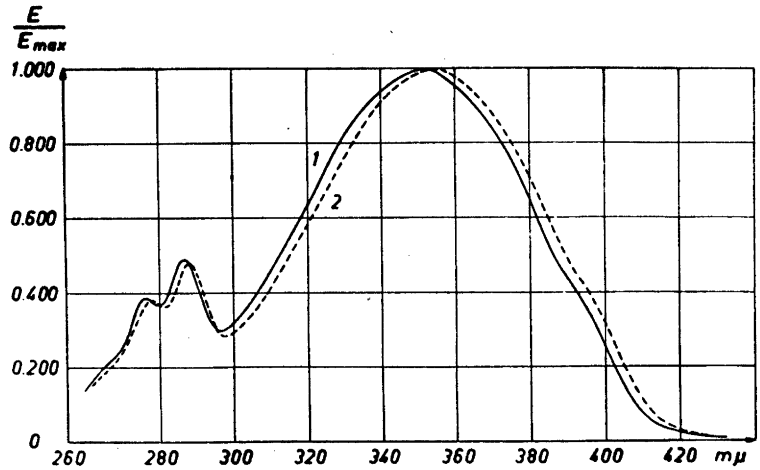

Fig. 2. Light absorption curves for natural vitamin A_2 (curve 1) and the substance a (curve 2). Solvent absolute ethanol.

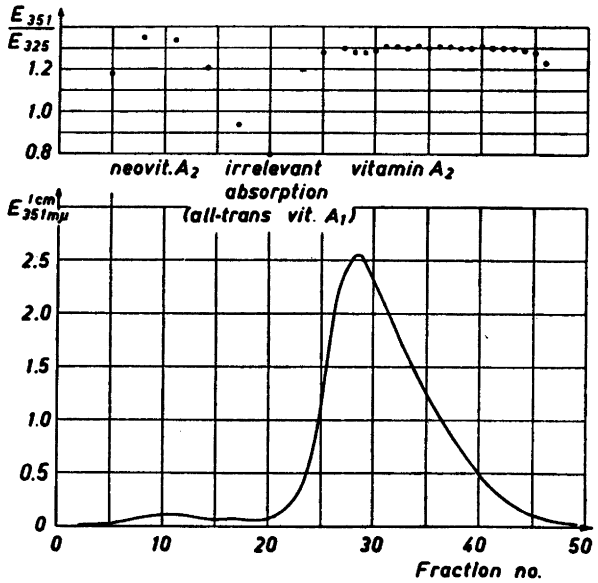

Fig. 3. Fractionation curve for the unsaponifiable fraction from perch liver with a column 70 cm long, diam. 1.8 cm. The upper part of the figure illustrates the ratio $\frac{E_{351\ m\mu}}{E_{325\ m\mu}}$ *for the individual fractions.*

The peak fraction with $E^{1\,cm}_{351.5} = 2.52$ displayed, when dissolved in ethanol, three maxima and two minima at the wavelengths mentioned under I,1. The following ratios were found:

$$\frac{E_{276.5}}{E_{351.5}} = 0.384, \quad \frac{E_{280}}{E_{351.5}} = 0.369, \quad \frac{E_{287}}{E_{351.5}} = 0.490, \quad \frac{E_{297}}{E_{351.5}} = 0.297, \quad \frac{E_{325}}{E_{351.5}} = 0.734.$$

In a subsequent chromatographic isolation on a dicalcium phosphate column, 82 cm long, 1.8 cm diam., of vitamin A_2 from 65 g perch liver (a solution of the unsaponifiable fraction in light petroleum gave $E^{1\,\%}_{1\,cm\ 351\ m\mu} = 0.236$, calculated in relation to the liver weight) all the vitamin A_2-containing fractions for which the ratio $\frac{E_{351.5}}{E_{325}}$ had the same value (1.29—1.31) were combined and again subjected to chromatography on a dicalcium phosphate column, 65 cm long, 1.8 cm diam. Previous to the chromatography, but after activation (*cf.* Brö-Rasmussen, Hjarde and Porotnikoff [2]) this dicalcium phosphate had been washed with ether * on a glass Büchner filter (1.5 l pure, peroxide free ether per 200 g $CaHPO_4$). The washed dicalcium phosphate was transferred into a 500 ml round-bottomed flask and exhausted for half an hour at room temperature. Finally the flask was filled with nitrogen, exhausted and again filled with nitrogen, the process being repeated altogether four times, following which the dicalcium phosphate powder was suspended in light petroleum. According to Schlabach [3], the light petroleum (b.p. 40—60°C) used for the chromatography had been filtered through a column of silica gel (70 cm long, 5.3 cm diam., grain size 100—200 mesh) and subsequently distilled to remove all substances which absorb light within a wavelength range from 240 mμ to 400 mμ when measured against distilled water.

The vitamin A_2 thus isolated by repeated chromatography was dissolved in ethanol and showed an absorption curve with characteristic $\frac{E}{E_{351.5}}$ values in good agreement with those previously given.

The fractionation curves illustrated in Figs. 1 and 3 both display 2 maxima of which the highest correspond to the vitamin A_2 isomer just mentioned. The peak fraction corresponding to the lower maximum of Fig. 1 displayed, when dissolved in absolute ethanol, three maxima, at 277.5 mμ, 287.5 —288 mμ and 353 mμ, and two minima, at 281 mμ and 298 mμ. The following ratios were found:

$$\frac{E_{277.5}}{E_{353}} = 0.46, \quad \frac{E_{281}}{E_{353}} = 0.44, \quad \frac{E_{288}}{E_{353}} = 0.54, \quad \frac{E_{298}}{E_{353}} = 0.36, \quad \frac{E_{325}}{E_{353}} = 0.74$$

The peak fraction corresponding to the lower maximum in the fractionation curve Fig. 3 also displayed three maxima (277 mμ, 287.5 mμ and 353.5 mμ) and two minima (283 mμ and 299.5 mμ), and the following ratios were found (in absolute ethanol):

$$\frac{E_{277}}{E_{353}} = 0.71, \quad \frac{E_{283}}{E_{353}} = 0.63, \quad \frac{E_{287.5}}{E_{353}} = 0.68, \quad \frac{E_{299.5}}{E_{353}} = 0.39, \quad \frac{E_{325}}{E_{353}} = 0.70$$

* The residue obtained by evaporation of the first 400 ml ether filtrate showed after solution in 5 ml absolute ethanol a certain light absorption within the wavelength range 275—325 mμ.

It must be assumed that the substances found in the first fractions by chromatography of pike liver and perch liver are identical, although mixed with different amounts of other light-absorbing substances. The substance which is presumably a vitamin A_2 isomer might be denoted neovitamin A_2 by analogy with neovitamin A_1 which, when chromatographed on a dicalcium phosphate column under corresponding circumstances, leaves the column immediately before all-*trans* vitamin A_1. As the content of this isomer in the liver extracts used is very small (about 1.5 % of the extinction at 351 mμ deriving from the total quantity of eluted neovitamin A_2 + vitamin A_2 is due to neovitamin A_2) and as, moreover, its location in the dicalcium phosphate column is in the transition range between the bands representing the small quantities of the neovitamin A_1 and all-*trans* vitamin A_1 deriving from the liver extract, the fractions containing this neovitamin A_2 cannot, of course, be expected to be pure.

II. ISOMERIZATION

Vitamin A_2 which has been isolated by chromatography according to the method described in section I was dissolved in light petroleum and isomerized by addition of an iodine solution (10 mg iodine per 100 ml light petroleum). To 9 ml of vitamin A_2 solution was added 1 ml iodine solution and after shaking for 30 s the mixture was poured over 0.5 g pulverized sodium thiosulphate ($Na_2S_2O_3$, $5H_2O$) in a 100 ml Erlenmeyer flask, and the flask was shaken until the violet iodine colour disappeared, the sodium thiosulphate precipitate being subsequently removed by filtration through a folded filter. The isomerization process was performed at 23°C, protected against daylight. Three experiments were made, in which the vitamin A_2 solution used had the following values of $E^{1\,cm}_{351\,m\mu}$: 0.980, 7,22 and 34,5 and consequently 0.882, 6.50, and 31.0 at the moment of admixture. After the isomerization $E_{351\,m\mu}$ had dropped by 6—10 % in all three cases. The ratio $\frac{E_{287}}{E_{351}}$ (measured in light petroleum) changed from 0.50 to 0.53—0.55. There was no measurable alteration in the location of the maxima and minima.

Finally an isomerization experiment was made in which 9 ml of a solution of vitamin A_2 in light petroleum, with $E^{1\,cm}_{351\,m\mu} = 0.895$, was mixed with 1 ml of the iodine solution previously mentioned, the iodine being removed after shaking for 100 s as already described. $E^{1\,cm}_{351\,m\mu}$, which at the moment of admixture was 0.805, had after isomerization dropped by about 15 % and $\frac{E_{287}}{E_{351}}$ had altered from 0.495 to 0.629.

III. CHROMATOGRAPHY OF ISOMERIZED VITAMIN A_2

III,1. A sample of 40 ml of a solution of vitamin A_2 in light petroleum which had been isomerized as described in section II (the iodine being allowed to act for a period of 30 s) and with $E^{1\,cm}_{351\,m\mu} = 0.882$ was used for this experiment. For the chromatography a dicalcium phosphate column, length 78 cm, dia-

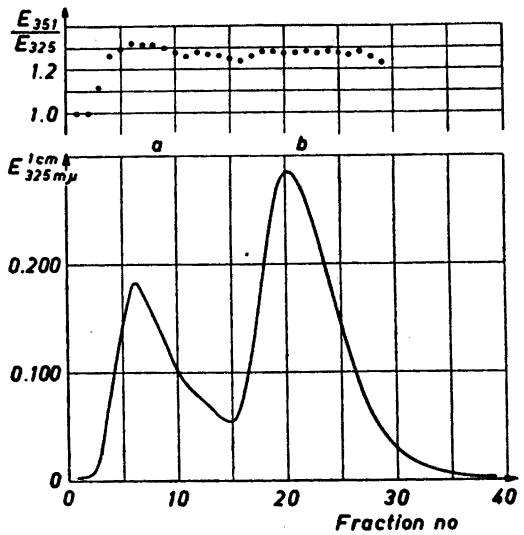

Fig. 4. Fractionation curve for isomerized vitamin A_2 chromatographed on a 78 cm column, diameter 1.8 cm.

meter 1.8 cm, was used. The eluent was a mixture of light petroleum and ether (85:15 v/v). Eluate was collected in 4.7 ml fractions.

The fractionation curve is given in Fig. 4 and shows the presence of two substances with absorption maximum at about 350 mμ. The peak fractions from each of the two curve sections *a* and *b* display the following spectrophotometric properties in absolute ethanol:

Substance a: three maxima: 277.5 mμ, 288—288.5 mμ, and 353.5 mμ
two minima: 281.5 mμ and 298 mμ

$$\frac{E_{277.5}}{E_{353.5}} = 0.432, \quad \frac{E_{281.5}}{E_{353.5}} = 0.415, \quad \frac{E_{288}}{E_{353.5}} = 0.530, \quad \frac{E_{298}}{E_{353.5}} = 0.344, \quad \frac{E_{325}}{E_{353.5}} = 0.724$$

Substance b: three maxima: 276.5 mμ, 287 mμ and 351.5 mμ
two minima: 280 mμ and 297 mμ

$$\frac{E_{276.5}}{E_{351.5}} = 0.472, \quad \frac{E_{280}}{E_{351.5}} = 0.453, \quad \frac{E_{287}}{E_{351.5}} = 0.574, \quad \frac{E_{297}}{E_{351.5}} = 0.339, \quad \frac{E_{325}}{E_{351.5}} = 0.735$$

The ratio of the two substances *a* and *b* may be calculated from the fractionation curve. Ratio *a* to *b* expressed by E_{351} measured directly in the eluate was found to be 34.5/65.5.

III,2. Larger quantities of the two substances *a* and *b* were prepared as follows: The unsaponifiable fraction from 157.6 g of perch liver was subjected to chromatography twice on alumina columns, 18 × 1.8 cm (standardized according to Brockmann). Half of the quantity of purified vitamin A_2 obtained, which in 180 ml light petroleum had an $E^{1\,cm}_{351\,m\mu} = 7.22$ and $\frac{E_{287}}{E_{351}} = 0.50$, was

isomerized as described in section II. After filtration and evaporation, chromatography on a 48×3.0 cm dicalcium phosphate column was applied. The eluents used were various mixtures of diethylether and light petroleum, in the following order:

100	ml	light	petroleum	—	ether	mixture (95: 5 v/v)
100	»	»	»		»	» (92: 8 v/v)
100	»	»	»		»	» (90: 10 v/v)
100	»	»	»		»	» (88: 12 v/v)
300	»	»	»		»	» (86: 14 v/v)
200	»	»	»		»	» (75: 25 v/v)

The eluate was collected in 4.7 ml fractions. The fractionation curve is illustrated in Fig. 5.

It should be mentioned at this point that while it is possible when chromatographing a mixture of neovitamin A_1 and all-*trans* vitamin A_1 on the dicalcium phosphate column to observe a fairly distinct difference in the fluorescence of neovitamin A_1 (yellowish green) and all-*trans* vitamin A_1(more bluish green), the two vitamin A_2 bands displayed only a slight difference in ultraviolet light. Both vitamin A_2 bands displayed a brown fluorescence, that of substance *a* having, however, a slightly reddish tinge while that of substance *b* was of a more violet-brown colour.

The ratio of the quantities in which the two substances *a* and *b* are present is 32: 68, when expressed by E_{351} measured directly on the eluate.

The three peak fractions corresponding to substance *a* which showed the same value of ratios $\frac{E_{288}}{E_{351}}$ and $\frac{E_{351}}{E_{325}}$ were combined, evaporated and rechromatographed on a dicalcium phosphate column, 28×0.8 cm (purified with ether as previously described) ,the eluent used was light petroleum (which had been purified by means of silica gel) mixed with diethylether (86: 14 v/v). Eluate was collected in 2 ml fractions. The fractionation curve showed the presence of one substance only with absorption maximum at about 351 mμ. The values of the ratios $\frac{E_{288}}{E_{351}}$ and $\frac{E_{351}}{E_{325}}$ for the peak fraction and the subsequent fractions were the same. When the peak fraction was dissolved in ethanol, the corresponding curve displayed three maxima and two minima at the wavelengths previously determined (III,1 *a*). The following ratios were found:

$$\frac{E_{277.5}}{E_{353.5}} = 0.383, \quad \frac{E_{281.5}}{E_{353.5}} = 0.364, \quad \frac{E_{288}}{E_{353.5}} = 0.480, \quad \frac{E_{298}}{E_{353.5}} = 0.286, \quad \frac{E_{325}}{E_{353.5}} = 0.674.$$

The absorption curve is illustrated in Fig. 2, (curve 2).

The peak fractions corresponding to substance *b*, for which the value of $\frac{E_{287}}{E_{351}}$ (= 0.55, measured in absolute ethanol) and of $\frac{E_{351}}{E_{325}}$ (= 1.36 = $\frac{1}{0.735}$, measured in absolute ethanol) were found to be the same, were given a corresponding treatment: rechromatography on a 28×0.8 cm column of dicalcium phosphate (purified by means of ether) and elution with a (85: 15 v/v) mixture of light petroleum (purified by means of silica gel) and diethylether.

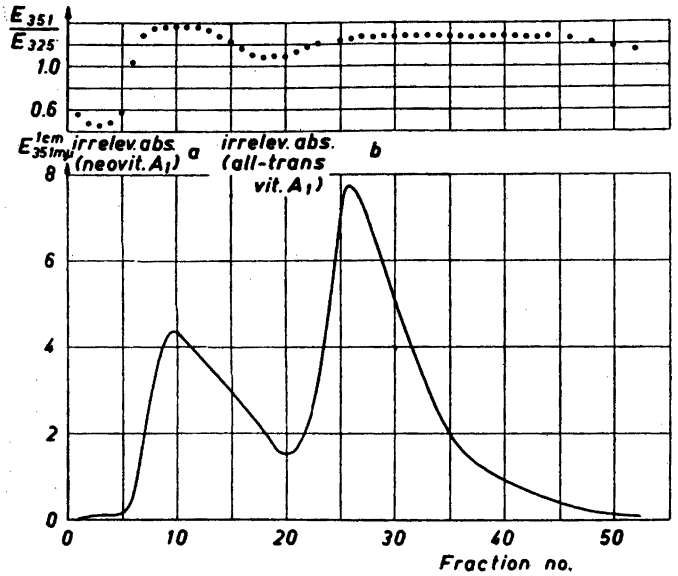

Fig. 5. Fractionation curve for isomerized vitamin A_2 with a column 48 cm long, diameter 3.0 cm.

Eluate was collected in 2 ml fractions. The fractionation curve showed the presence of one substance only with absorption maximum at 351 mμ. When dissolved in ethanol, the peak fraction gave a curve with three maxima and two minima at the wavelengths determined in section III,1 *b*, and the following ratios were found:

$$\frac{R_{276.5}}{R_{351.5}} = 0.445, \quad \frac{E_{280}}{E_{351.5}} = 0.426, \quad \frac{E_{287}}{E_{351.5}} = 0.555, \quad \frac{E_{297}}{E_{351.5}} = 0.321, \quad \frac{E_{325}}{E_{351.5}} = 0.738$$

The peak fractions from the last-mentioned chromatographic separation were combined and rechromatographed on a 58 × 1.0 cm dicalcium phosphate (ether-purified) column, elution with light petroleum (silica gel purified)-diethylether mixtures (90: 10 v/v increasing to 65: 35 v/v). Eluate was collected in 2 ml fractions. The peak fraction dissolved in absolute ethanol gave the same values of the five $\frac{E}{E_{351.5}}$ ratios as the material before it was rechromatographed.

It may be mentioned that after the isomerization experiment described in section II, in which the action of iodine on vitamin A_2 was prolonged for a period of 100 s, the subsequent chromatography resulted in a ratio of *a* to *b* equal to 33.4: 66.6 (expressed by E_{351} measured directly on the collected fractions).

IV. CHROMATOGRAPHY OF A MIXTURE OF VITAMIN A_2 AND SUBSTANCE *b*

A mixture was prepared consisting of 100 ml solution in light petroleum of natural vitamin A_2 purified by chromatography on dicalcium phosphate as described in section I, with $E^{1\,cm}_{351\,m\mu} = 0.466$ and $\frac{E_{287}}{E_{351}} = 0.495$, and 100 ml solution in light petroleum of substance *b*, with $E^{1\,cm}_{351\,m\mu} = 0.428$ an $\frac{E_{287}}{E_{351}} =$ $= 0.555$. The mixture was evaporated and chromatographed on a 78×1.0 cm column of (ether-purified) dicalcium phosphate. Elution by means of mixtures of light petroleum (silical gel purified) and diethylether in the following order:

20	ml	light	petroleum	—	ether	mixture (95: 5 v/v)
20	»	»	»		»	(92: 8 v/v)
40	»	»	»		»	(88: 12 v/v)
40	»	»	»		»	(85: 15 v/v)
20	»	»	»		»	(82: 18 v/v)
100	»	»	»		»	(79: 21 v/v)

Eluate was collected in 2 ml fractions.

The fractionation curve showed the presence of one substance only with absorption maximum at 351 mμ. Direct spectrophotometric measurements on the collected fractions gave $\frac{E_{287}}{E_{351}} = 0.52$—$0.55$. The variation of the ratio throughout the series of fractions did not, however, suggest any pronounced tendency towards separation into two substances. A subsequent, corresponding experiment gave the same result.

V. CHROMATOGRAPHY OF AN ISOMERIZED MIXTURE OF VITAMIN A_1 AND VITAMIN A_2

A mixture was prepared consisting of 15 ml solution of vitamin A_2 in light petroleum ($E^{1\,cm}_{351\,m\mu} = 2.00$) and 15 ml solution in light petroleum of (all-*trans*) vitamin A_1 ($E^{1\,cm}_{325\,m\mu} = 1.920$), and the mixture was isomerized by means of iodine in the manner described in section II. After filtration and evaporation to a volume of about 5 ml, the mixture was chromatographed on a 76×1.0 cm dicalcium phosphate column. Elution with light petroleum-ether mixtures as follows:

100	ml	light	petroleum	—	ether	mixture (90: 10 v/v)
200	»	»	»		»	(86: 14 v/v)

Eluate was collected in 4.7 ml fractions.

The fractionation curve (measurement of $E^{1\,cm}_{335\,m\mu}$ of the eluted fractions) is illustrated in Fig. 6.

Even if a complete separation of the four substances present has not been obtained, it appears clearly from the course of the $\frac{E_{351}}{E_{325}}$ curve that the four substances are eluted in the following order: neovitamin A_1, substance *a* (= neovitamin A_2), all-*trans* vitamin A_1 and finally substance *b* (= all-*trans* vitamin A_2?).

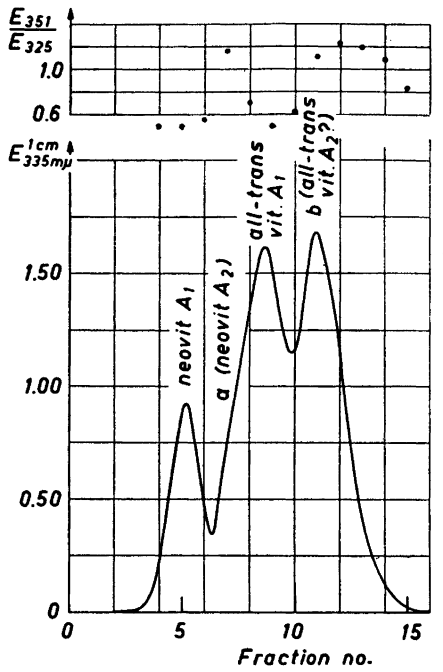

Fig. 6. Fractionation curve for an isomerized mixture of vitamin A_1 and vitamin A_2 with a column 76 cm long, diameter 1.0 cm.

DISCUSSION

Experiments III,1 and III,2 show that it is possible after treatment with iodine of vitamin A_2 prepared by chromatography to isolate from the isomerization product two different substances, *a* and *b*, the absorption curves of which show great similarity, although differing clearly with regard to the location of maxima and minima. In the case of substance *a* the wavelengths of the maxima and minima exceed by about 1—2 mμ those of substance *b* and of natural vitamin A_2, the isolation of which is described in experiments I,1 and I,2.

When bearing in mind that by chromatography on dicalcium phosphate substance *a* is eluted slightly before *b*, it will be seen that there is analogy between substances *a*, *b* and neovitamin A_1, all-*trans* vitamin A_1 — neovitamin A_1 being eluted slightly more readily from dicalcium phosphate than all-*trans* vitamin A_1. It is therefore a reasonable assumption that also as regards geometrical configuration the relationship of the two substances *a* and *b* is as that of neovitamin A_1 and all-*trans* vitamin A_1. In this connection it should also be mentioned that Robeson and Baxter [4] after isomerization for 2 h in daylight of all-*trans* vitamin A_1 anthraquinone-β-carboxylate by the action of iodine dissolved in benzene ascertained that the isomerization product contained 31 % neo-isomer. In the present isomerization experiments on free vitamin A_2 alcohol dissolved in light petroleum, with a reaction period of 30—100 s, the ratio of substances *a* to *b* — expressed by E_{351} — was about 1 to 2.

Keeping in mind the analogy *a*, *b* to neovitamin A_1, all-*trans* vitamin A_1, *a* and *b* might be expected to be identical with neovitamin A_2 and vitamin A_2, respectively, the two vitamin A_2 isomers which occur in the eluate from the liver extracts.

As the amounts of the supposed neovitamin A_2 fractions isolated from the liver extracts were insufficient to allow for further chromatographic purification, additional experiments to confirm the identity of the neovitamin A_2 occurring in the liver extracts and substance *a* have not been made. The location of the maxima and minima for substance *a* and the impure neovitamin A_2 isolated from the liver extracts show fairly good agreement, particularly with regard to the main maximum; at this wavelength (353.5 mμ) less interference from irrelevant substances may also be expected than at lower wavelengths. The difference between $\frac{E}{E_{353.5}}$ for the impure neovitamin A_2 of pike liver extract — which is obviously purer than the neovitamin A_2 isolated from perch liver — and for substance *a*, purified by chromatography, is greatest at the lower wavelengths (270—300 mμ) and small at wavelengths above 350 mμ, which seems to indicate that the difference is due solely to irrelevant light absorbing substances in the neovitamin A_2 isolated directly from liver.

When comparing the spectrophotometric properties of substance *b* and the vitamin A_2 isolated directly from liver, it would be reasonable to establish comparisons with previous investigations on the spectrophotometric properties of vitamin A_2 (Schantz [5], Cama and Morton [6], Farrar, Hamlet, Henbest and Jones [7]).

In Table 1 the experimental results are represented by a series of ratios between the extinctions at the maxima and minima. The table also lists the results of measurements made in this laboratory on chromatographically (dicalcium phosphate) purified synthetic all-*trans* vitamin A_1 and neovitamin A_1 prepared by chromatography after iodine isomerization of synthetic all-*trans* vitamin A_1.

As it will be seen from this table, there is good agreement between the location of the maxima and minima of the natural vitamin A_2 isolated in the present investigation and the synthetic and natural vitamin A_2 preparations described in the literature [5,6,7] although Schantz [5] and Farrar *et al.*[7] do not mention the existence of a maximum at 276.5 mμ, while Cama and Morton [6] mention the presence of an inflexion at 277 mμ. The ratios $\frac{E}{E_{max}}$ and $\frac{E}{E_{min}}$ calculated for the characteristic maxima and minima on the other hand show a certain deviation, since for the range 275—325 mμ the ratio $\frac{E}{E_{351.5}}$ in case of the vitamin A_2 isolated in the present investigation is about 5—20 % below and the ratio $\frac{E_{287}}{E_{297}}$ 9—15 % above the corresponding ratios given in the table for earlier vitamin A_2 preparations [5,6,7]. Maximum difference is observed in the case of the minimum at 297 mμ. The differences seem to suggest a greater purity of the vitamin A_2 prepared in the course of the present investigation.

* $\frac{E}{E_{351}}$ ** $\frac{E_{275}}{E_{351}}$ *** $\frac{E_{297.5}}{E_{352}}$ † $\frac{E_{287}}{E_{352}}$

As already mentioned, substance *b* might be expected to be identical with natural vitamin A_2. With regard to the location of the characteristic maxima and minima the two substances show fairly good agreement, while the ratios $\frac{E}{E_{351.5}}$ at wavelengths below 310 mμ are somewhat higher in the case of substance *b* than in the case of the natural vitamin A_2 isolated according to section I, although at wavelengths above 310 mμ the differences between the ratios are only of a magnitude of 0—0.010. The object of the experiments made with respect to substance *b* has therefore been to find out whether it represented a single substance — a third vitamin A_2 isomer — or a mixture of substances, of which at least one might be expected to be a vitamin A_2 isomer, presumably the vitamin A_2 occurring in nature.

The assumption that substance *b* is identical with natural vitamin A_2, although in a state of incomplete purity, is supported by the agreement existing between the location of the maxima and minima of the absorption curves of the two substances and also by the fact that is has not hitherto been possible

to separate the two substances by chromatography on dicalcium phosphate — as appears from experiment IV.

On the other hand the rechromatographic experiments described in section III suggest that *b* is a single, pure substance; if this is the case, we are thus faced with a vitamin A_2 isomer which cannot, by chromatography on dicalcium phosphate, be separated from the vitamin A_2 occurring in nature, and which has maxima and minima at the same wavelengths as the latter and which only with regard to the ratio $\frac{E}{E_{351.5}}$ at wavelengths below 310 mμ deviates spectrophotometrically from the vitamin A_2 occurring in nature.

Consequently it is not possible on the basis of the results of the present investigation to decide whether substance *b* is a mixture of the vitamin A_2 isolated from pike and perch liver and an impurity deriving from the isomerization process, or a single substance, a third vitamin A_2 isomer, which are not readily separated by chromatography on dicalcium phosphate.

When the adsorption isotherm is linear, the isochrones in elution chromatography are Gauss'ian curves moving along the column at a rate proportional to the flow rate; simultaneously the standard deviation increases proportionally to the square root of the flow rate. Consequently the isoplanes can only in some cases be approximated by Gauss'ian curves, whereas a better approximation is obtained by considering them as Gauss'ian functions of the square root of the eluted volume. As it is very difficult to decide whether or not a series of experimental values fit a certain type of non-linear curve, attention is called to the method of Bliss according to which the problem concerning the normal distribution is converted into an investigation of a linear dependency. The results are tested experimentally in ion-exchange chromatography of chloride ions.

In the theoretical treatment of elution chromatography Vermeulen and Hiester [1] have given a solution of the general case in which the adsorption isotherm is non-linear and the flow rate is too great to obtain equilibrium. Furthermore, several authors have given approximate solutions which in many cases may be satisfactory. All these solutions are, however, rather inconvenient as it is very difficult to make a series of experimental values fit a non-linear curve in such a way that the parameters of the function are determined most accurately. The following elucidation is founded on the plate theory applied by Martin and Synge [2] and Mayer and Thompkins [3].

Consider the column as divided in segments by planes perpendicular to the axis of the column. Each segment contains v ml liquid and they are numbered 0, 1, 2, ... p ... The process is started by pouring v ml solution of the substance in question on the top of the column, and when v ml are drawn off from the bottom, the substance is now in segment No. 0. It is assumed that the adsorption isotherm is linear; then the fraction α of the solute in the liquid phase and the fraction $1-\alpha$ in the solid or stationary phase are independent of the concentration. When adsorption equilibrium has been established, v ml eluant are poured on the top of the column and the whole liquid phase is displaced one segment. The v ml which are hereby drawn off from the bottom of the column are collected as the first fraction, these being numbered 1, 2 ... n ... When equilibrium has again been established the next displace-

ment of one segment takes place. Let the total quantity of solute in the p'th segment after n fractions of v ml have passed the column be $q_{n,p}$ measured in units of the originally introduced quantity. Then the condition of material balance is

$$q_{n,p} = \alpha\ q_{n-1,p-1} + (1-\alpha)\, q_{n-1,p} \tag{1}$$

When n fractions have passed, the total quantity of substance is distributed in the n+1 segments from p = 0 to p = n, while for p > n and p = —1 (pure eluant entering the column) $q_{n,p} = 0$. From these data and $q_{o,o} = 1$, $q_{n,p}$ can be calculated for all values of n and p by successive application of (1). It is however simpler to substitute

$$q_{n,p} = Q_{n,p}\, \alpha^p\, (1-\alpha)^{n-p} \tag{2}$$

by which (1) becomes

$$Q_{n,p} = Q_{n-1,p-1} + Q_{n-1,p} \tag{3}$$

Employing the conditions for $q_{n,p}$ above (2) yields

$$Q_{o,o} = 1,\ Q_{n,-1} = 0 \text{ and } Q_{n,n+1} = 0$$

and as (3) is identical with the recursion formula for the binomial coefficients (2) is converted into

$$q_{n,p} = \binom{n}{p}\, \alpha^p (1-\alpha)^{n-p} \tag{4}$$

In statistics the probability in the binomial distribution, *i.e.* the probability that an event happens p times out of n, the probability of the single event being α, is given by (4). It can be shown [4] that when n increases (4) converges against the normal frequency function

$$q_{n,p} \rightarrow \frac{1}{\sigma}\, \varphi\left(\frac{p-\mu}{\sigma}\right) \tag{5}$$

with the mean value $\mu = n\alpha$ and the standard deviation $\sigma = \sqrt{n\alpha\ (1-\alpha)}$. Here and in the following the Gauss'ian frequency function and distribution function are designated $\varphi\ (x)$ and $\Phi\ (x)$, respectively:

$$\varphi\ (x) = \frac{1}{\sqrt{2\pi}}\, e^{-\frac{x^2}{2}} \text{ and } \Phi\ (x) = \int_{-\infty}^{x} \varphi\ (t)\ dt$$

Measured in units of the initial concentration the concentration in the liquid phase is

$$c = \frac{\alpha \cdot q_{n,p}}{v}$$

Introducing $V = pv$ and $U = nv$ (5) becomes

$$c = \frac{\alpha}{\sqrt{U\alpha\ (1-\alpha)\ v}}\, \varphi\left(\frac{V-\alpha U}{\sqrt{U\alpha\,(1-\alpha)\ v}}\right) \tag{6}$$

which gives the concentration as a function of the two variables V, the distance from the top of the column to the regarded point measured in ml of interstitial volume and U, the eluted volume of liquid.

As the liquid in practice moves continually the above deduction is valid only for infinitely small quantities of substance. Actually the experiment is

started by pouring a finite quantity, say A ml solution on the top of the column. The concentration $c = \mathrm{f}\ (V, U)$ is then the result of a superposition of an infinite number of infinitely small quantities, the first and last of which have moved $V—A$ and V ml along the column, respectively. The total amount of solute that has accumulated in a differential segment with abscissa V when U ml of eluate have passed is given by

$$A \cdot c = \int_{V-A}^{V} \mathrm{f}(V, U)\ \mathrm{d}V = \int_{V-A}^{V} \frac{\alpha}{S}\ \varphi(t)\,\mathrm{d}V,$$

in which

$$S = \sqrt{U\alpha(1—\alpha)\ v} \text{ and } t = \frac{V—\alpha\, U}{S}$$

$$\text{As } \mathrm{d}t = \frac{\mathrm{d}V}{S} \text{ and } t_A = \frac{V—A—\alpha\, U}{S}$$

$$A \cdot c = \alpha \int_{t_A}^{t} \varphi\ (t)\ \mathrm{d}t = \alpha(\Phi(t)—\Phi(t_A))$$

According to the mean value theorem

$$\Phi(t)—\Phi(t_A) = \varphi\left(\frac{V—a—\alpha U}{S}\right)\left(\frac{V—\alpha U}{S} — \frac{V—A—\alpha U}{S}\right)$$

in which $0 < a < A$

Consequently $c = \frac{\alpha}{S}\ \varphi\left(\frac{V—a—\alpha U}{S}\right)$

When $A \ll V$, a may be neglected, and (6) is valid for finite quantities.

The discussion of this formula is divided in two parts: 1°. $U = U_0 = constant\ (isochrones)$. In this case the standard deviation is also a constant and c is a Gauss'ian function of V, the mean value being $\alpha\ U_0$ and the standard deviation $S_0 = \sqrt{U_0\alpha\,(1—\alpha)\,v}$. When U increases this distribution of the solute moves through the column with a rate proportional to that of the eluant, V_{max} being equal to $\alpha\ U$; simultaneously the curve is flattened out, S being proportional to $\sqrt{U}$. 2°. $V = V_0 = constant\ (isoplanes)$. This is the case encountered in practice, the eluate being collected in fractions and the concentrations of solute herein determined in some conventional way. Equation (6) is written

$$c = \mathrm{f}\ (U) = \frac{1}{\sqrt{U\frac{1—\alpha}{\alpha}\,v}}\ \varphi\left(\frac{V_0/\alpha—U}{\sqrt{U\frac{1—\alpha}{\alpha}\,v}}\right) \tag{7}$$

This is not a normal distribution, the "standard deviation" containing the variable U. If, however, U is great compared with $\sqrt{Uv(1—\alpha)/\alpha}$, U_0 may, as a first approximation, be substituted for U in this expression and (7) takes the form of a Gauss'ian equation:

$$c \approx \mathrm{f}_1\ (U) = \frac{1}{s}\ \varphi\left(\frac{U_0—U}{s}\right) \tag{8}$$

in which $U_0 = V_0/a$ and $s = \sqrt{U_0 v(1-a)/a}$
A great ratio between U_0 and s

$$\frac{U_0}{s} = \sqrt{\frac{V_0}{v}\frac{1}{1-a}}$$

means that the longer the column and the greater a the better is the approximation. It should be noticed that in the normal distribution 95 % of the area lies between the values $U_0 \pm 2s$ and 99.7 % lies between $U_0 \pm 3s$.

When necessary, a better approximation may be obtained by the following transcription of (7):

$$c = \frac{1}{\sqrt{U}} \cdot \frac{1}{\sqrt{\frac{1-a}{a} v}} \varphi \left(\frac{(\sqrt{U_0} - \sqrt{U})(\sqrt{U_0} + \sqrt{U})}{\sqrt{U}\sqrt{\frac{1-a}{a} v}} \right)$$

By substituting $\sqrt{U_0}$ for $\sqrt{U}$ in the sum in the numerator and in the denominator in φ we get

$$c \approx f_2(U) = \frac{1}{2\sqrt{U}} \cdot \frac{1}{\frac{1}{2}\sqrt{\frac{1-a}{a} v}} \varphi \left(\frac{\sqrt{U_0} - \sqrt{U}}{\frac{1}{2}\sqrt{\frac{1-a}{a} v}} \right) \qquad (9)$$

If a function $g(U)$ is normally distributed:

$$F(U) = \varphi\left(\frac{g(U) - g(U_0)}{\sigma}\right)$$

the frequency function becomes

$$f(U) = F'(U) = \frac{1}{\sigma} g'(U) \varphi \left(\frac{g(U) - g(U_0)}{\sigma}\right)$$

and as $\frac{d\sqrt{U}}{dU} = \frac{1}{2\sqrt{U}}$ (9) indicates that c is a Gauss'ian function of $\sqrt{U}$, the mean value and standard deviation of which are $\sqrt{U_0}$ and $\frac{1}{2}\sqrt{\frac{1-a}{a} v}$, respectively.

The result of an experiment consists of a table giving the concentration of the solute as a discontinued function of the eluted volume. Even if a continuous curve is drawn by a recording instrument, measuring some physical property of the flowing solution, that varies with concentration, it is necessary to determine from the curve the concentration for some discrete values of the volume. When the fractions or intervals of w ml each are numbered 1, 2 . . . m . . . the problem to solve is whether the stair-shaped curve, which is a result of a plot of c against m, approximates a Gauss'ian curve, and next to determine the mean value and standard deviation thereof. According to statistical methods [6] this is done in the following way: The expressions

$$H(m) = \frac{\sum_{a}^{m} wc}{\sum_{a}^{b} wc} = \frac{\sum_{a}^{m} c}{\sum_{a}^{b} c} \tag{10}$$

are calculated. Here the first and last eluted fraction in which the concentrations are above the analytical error are numbered a and b, respectively. Thus H (m) means the fraction of the total amount of solute contained in the eluted fractions from number a to m inclusive, and it should be valid:

$$H(m) \approx \Phi\left(\frac{m-\mu}{\sigma}\right)$$

in which μ and σ are the mean value and standard deviation, respectively. Consequently the inverse function

$$\Phi^{-1}(H(m)) = \frac{m-\mu}{\sigma}$$

and this equation represents a straight line having the slope $\frac{1}{\sigma}$ and intersecting the abscissa axis in μ. The values of $\Phi^{-1}(x)$, $0<x<1$ are called quantiles; as a rule quantiles + 5 called probits are tabulated [7] in order to avoid negative values.

If the points (m, Φ^{-1} (H(m))) sufficiently well fit a straight line, $c = H(m)$ can be regarded as a Gauss'ian function, the constants of which are determined by the line. As

$$\frac{d\,\Phi^{-1}(x)}{dx} \to \infty \text{ for } x \to 0 \text{ and } x \to 1$$

the points near the ends of the line are rather uncertain and may be neglected. According to (8)

$$w \cdot \mu = U_0 = V_0/\alpha \text{ and } w \cdot \sigma = s = \sqrt{U_0 \frac{1-\alpha}{\alpha} v}$$

and thus α and v can be calculated.

If the line is curved it is tried whether the points ($\sqrt{m}$, Φ^{-1} (H(m))) give a straight line.

In this case the constants are related to the constants of (9) by

$$\sqrt{w} \cdot \mu = \sqrt{U_0} = \sqrt{V_0/\alpha} \text{ and } \sqrt{w} \cdot \sigma = \tfrac{1}{2}\sqrt{\frac{1-\alpha}{\alpha} v} \tag{12}$$

from which α and v may be calculated.

EXPERIMENTAL

The process investigated was the elution of chloride ions through columns containing Amberlite IRA 400 loaded with some other anion, preferably nitrate, the eluant being a solution of a salt containing the same anion:

$$RCl + X^- \rightleftharpoons RX + Cl^-$$

When 1 ml of the column filling contains β ml liquid with a total concentration of l mequiv./ml, and $1-\beta$ ml resin with an exchange capacity of r mequiv. the mass action law for small amounts of chloride gives

$$K_c = \frac{[RX]\,[Cl^-]}{[RCl]\,[X^-]} \approx \frac{[Cl^-]}{[RCl]}\,\frac{r}{l(1-\beta)}$$

The ratio of the total amount of chloride in the liquid phase to that in the resin is

$$\frac{a}{1-a} = \frac{\beta\,[Cl^-]}{(1-\beta)\,[RCl]} = K_c \cdot \frac{\beta\,l}{r}$$

$$K_c = \frac{a}{1-a} \cdot \frac{r}{\beta\,l} \qquad (13)$$

The substitution of [RX] and $[X^-]$ by $r/1-\beta$ and l, respectively, is justified by the fact, that in the experiments performed in this work $[X^-]$ varied between 0.1 and 1, while the maximum chloride concentrations measured in the adsorption bands were between 10^{-3} and 10^{-2}. Three types of column systems were used.

I. The column consisted of a glass tube of 27 mm inner diameter and 100 cm length. The lower end of the tube was narrowed down to the diameter of the outlet tube (inner diameter 1—2 mm, outer 6—7 mm). The filling was Amberlite IRA 400 (NO_3) resting on a glass wool plug. The top of the tube was provided with a three hole rubber stopper, through which were inserted a tube for the eluant, a funnel tube for introducing the chloride solution and a tube for letting out air. The eluant reservoir was a Mariotte bottle, the level of which was adjustable, and a flowmeter was inserted in the line. Immediately after the outlet tube the eluate passed an enlargement of the tube containing a silver-silver chloride electrode and a Radiometer K 9001 reference electrode (saturated K_2SO_4 Hg_2SO_4 / Hg; 650 mV referred to the normal hydrogen electrode). The silver-silver chloride electrode was made by electrolysing with a silver wire 50×0.5 mm as anode a 0.1 M sodium chloride solution with about 5 mA for two minutes. The potential of this cell was measured by a Radiometer PHM 22 and recorded by a Rec. Ia, from the same firm. As it appeared difficult to keep the flow rate constant the eluate after passage of the measuring cell ran to a siphon pipet, the emptying of which operated a relay. This switched the potentiometer to measure the potential of a fixed cell, and as the drainage of the siphon pipette lasted about half a minute, the pen came to rest and put a mark on the record for each fraction eluted.

II. The second type of column was very similar to type I, but it was provided with ten silver—silver chloride electrodes arranged as seen in Fig. 1. In order to prevent the electrolyte solution from creeping along the silver wires, where they pass through the rubber tubings, the central tube was filled with silicone oil. The recording of potentials from all ten electrodes was arranged by means of a selector from an automatic telephone exchange. The selector had eleven positions, and it was operated by minute pulses from the main electric clock of the institute; in this way the ten electrodes were successively connected to one terminal of the potentiometer, while the reference electrode constantly was connected to the other one. In the eleventh position of the selector the terminals of the potentiometer were short-circuited in order to record zero potential. It was thus always easy in the rather confused diagram on the paper strip to identify the marks corresponding to any of the electrodes.

III. The third column system consisted of ten single columns 17 mm inner diameter and 150 cm long. From the outlet tube the eluate passed an electrode system similar to that described in I and next a pump that transported it to the top of the next column. The pumps were magnetically operated pipette rubber bulbs attached to a side tube between two glass valves. The lumina of the measuring cell, valve housings and connecting tubes were chosen as small as practicable in order to avoid mixing. As the time elapsed between the passage of the adsorption band by two consecutive measuring cells was considerably greater in this case, the selector was operated by five minute pulses.

The electromotive force of the measuring cell is related to the chloride concentration by

$$E = 650 - 222 + 58 \log [Cl^-]\ \text{mV},$$

the standard potential of the silver—silver chloride electrode being 222 mV at room temperature. Now it proved difficult to keep the standard potential of the cell equal to the theoretical value; it could differ somewhat for different electrodes, and for the same electrode it could alter with time. Another potential also proved to alter with the treatment and age of the electrode, *viz.* the potential in a chloride-free solution. This was as a rule about 200 mV corresponding to a chloride concentration of 10^{-4}.

Because of these facts and as equation (10) contains ratios of concentrations, the potential curves were treated as follows. The horizontal part of the curve immediately before and after the band passage a−1 and b+1, *cf.* eqn. (10) were interconnected by a straight line; as a rule this was parallel to the abscissa axis and only rarely the difference exceeded 10 mV. At appropriate intervals the ordinate differences between this line and the curve were determined, and this potential difference is related to the chloride ion concentration c and the fictive zero concentration c_0 by

$$E = 58 \log (c/c_0)$$

from which

$$c - c_0 = c_0(\text{antilog } (E/58) - 1)$$

The difference $c - c_0$ was taken as a measure of the chloride concentration in the fraction in question; and as the absolute value was irrelevant the expression antilog $(E/58) - 1$ was inserted for c in (10). This procedure was justified by the following experiment: 5 ml 1 M potassium chloride were poured on the top of column I and eluted by 0.5 M potassium nitrate. The fractions were titrated according to Volhard, and the expressions antilog$(E/58) - 1$ with E values referring to the midpoints of the fractions were calculated. The ratios of corresponding values were determined, and the mean error was found to be 3 %.

The interstitial volume of the ion-exchanger was determined by washing down a column with 0.1 M nitric acid until the eluate had the same concentration as the entering

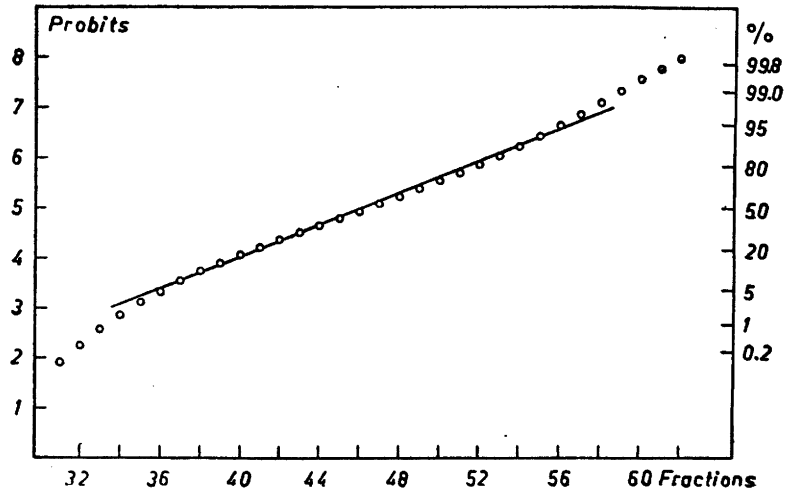

Fig. 2. Column I. 5 ml 1 M potassium chloride eluted with 0.5 M potassium nitrate at 2.3 ml/min. Probits versus *fractions of 20.5 ml each.*

solution. The acid level was adjusted to the surface of the ion-exchanger, and the acid was rinsed out with distilled water and titrated. After removal of the ion-exchanger the volume of the glass wool plug and the buret tip was determined in the same manner. The capacity of the resin was determined in the same column; the nitrate ions were displaced by chloride ions, a 2 M sodium chloride solution being washed through until the eluate gave no reaction for nitrate with sulphuric acid and brucine. After washing out with distilled water the chloride ions were removed by means of 0.5 M potassium nitrate and titrated. The capacity was referred to the nitrate resin. The mean values of duplicate determinations gave the following results: column I and II: $\beta = 0.74$ and $r = 1.55$; column III: $\beta = 0.75$ and $r = 1.45$.

RESULTS

Fig. 2 shows a characteristic diagram of an experiment. As mentioned, the first and last points of the line are rather uncertain; furthermore H(m) is not a stochastic variable, every value containing the errors of the preceding ones. In most cases the lines show a systematic curvature, probably as a result of these facts and also because eqn. (8) is an approximation to eqn. (7), and this, in addition, is derived on assumptions, the validity of which are questionable. The determination of the mean value, the abscissa for probit 5, is only slightly affected hereof, but the estimation of the standard deviation, which is the reciprocal of the slope is made somewhat uncertain. In order to obtain comparable results from the different experiments it was decided to exclude all points, the ordinates of which were less than 3 and greater than 7. This means that the constants of the distribution are determined mainly by the central 95 % of the material as indicated by the Φ values shown at the right hand of the diagram. The straight line has the constants $U_0 = 46.1$ fractions and $s =$ $= 6.29$ fractions. The standard deviation of the observed ordinates from the

corresponding ones of the line between the ordinates 3 and 7 amounts to 0.07. In some other experiments the deviations were calculated and found to be of the same order of magnitude.

A series of five experiments were performed under identical circumstances to try the reproducibility of the procedure. In column I 5 mmoles of potassium chloride were eluted by means of 0.5 M potassium nitrate at a rate of 2.24 ml/min ± 3 %. The mean errors of the 5 sets of values of U_0 and s were found to be 1.5 % and 4 %, respectively.

Tables 1 and 2 show the results of some experiments made to determine the permissible limits to flow rate and initial concentration. It is seen that if the velocity is less than 3.3 ml/min and the quantity of chloride does not exceed 5 mmoles, the constants of the distribution are independent of these two variables. The cross section of column I was 6.0 cm^2 and as the interstitial volume amounted to 74 % of the total volume, the limiting velocity corresponded to 0.8 cm/min. Furthermore the chloride being applied as a 1 M solution occupied 1.2 cm of the column height. These conditions were observed in all the following experiments.

In column II a series of experiments were performed with different concentrations of the eluant, the chloride concentration being recorded at ten places in the column. In two of the experiments some of the electrodes were in disorder, wherefore the corresponding isoplanes could not be calculated. The results are shown in Tables 3—6. In column system III two experiments were carried out to investigate the moving of the adsorption band along a very long column. The travelled distances in the experiments, the results of which

are shown in Tables 7 and 8, were 12 and 15 m, respectively. A summary of these six experiments are seen in Table 9. The value of the equilibrium constant is in good agreement with the value 3.8 which Wheaton and Bauman [8] found for the chloride-nitrate equilibrium on Dowex 1, which is also a strong base anion exchange resin.

Finally two experiments were made to try if the second approximation (9) was satisfactory when eqn. (8) could not be used, and that is the case if α is small enough. As acetate ions are much weaker adsorbed by the ion-exchanger than chloride ions, the resin in column II was converted into the acetate form and sodium acetate was used as the eluant. In the graphical representations the points (m, Φ^{-1} (H(m))) gave curved lines while the points ($\sqrt{\text{m}}$, Φ^{-1} (H(m))) rather satisfactorily gave straight lines. One example is given in Fig. 3, and the entire results of the two experiments appear in Tables 10 and 11. In this case the agreement of the equilibrium constant with the value 0.17 found by Wheaton and Bauman [8] is not so good, but it should be borne in mind, that although Dowex 1 and Amberlite IRA 400 are of the same type there may be differences in their properties.

The validity of formula (8) requires the constancy of α and s^2/V_0 shown in the two last columns of Tables 3—8. It has been mentioned that the mean error of s is somewhat greater than that of U_0, and consequently the mean error of the last ratio is expected to be considerably greater than that of α. The experimental results indicate, however, these methods of treating elution curves to be a rather good approximation and a valuable tool in designing

columns for chromatographic separations. It should be emphasized that all experimental values constituting the isoplane are used in calculating the parameters. The calculating work is rather easy, but it can be further simplified by plotting H(m) directly against m on "probability paper".

Short Communications

Crystal Modifications of Bigeranyl Tetrahydrochloride

HARALD SÖRUM, JAN BARSTAD and JOHANNES DALE

Forsvarets Forskningsinstitutt, Kjeller, Norway

Bigeranyl tetrahydrochloride, $C_{20}H_{38}Cl_4$, first described by Sörensen *et al.*[1], is a lower homologue of squalene hexahydrochloride, $C_{30}H_{56}Cl_6$, which has previously been investigated by Sörum and Dale [2], with the result that the two crystalline isomers could be identified as the two *meso*-forms out of the six possible diastereoisomers. From the point of view of a complete structure determination, bigeranyl tetrahydrochloride might be expected to be more favourable than the squalene derivatives, as its carbon chain is only two thirds of that of the latter.

For bigeranyl tetrahydrochloride two diastereoisomers should be possible; one *meso*-form, and one enantiomorphic pair. From the X-ray data given below it was concluded that the crystalline isomer is the *meso*-form. It was not possible to isolate the other isomer, either because it may not be formed at all by the addition of hydrogen chloride to bigeranyl, or, more likely, because it does not readily crystallize. However, it was found that the *meso*-form crystallized in two modifications: thin plates of approximately hexagonal form, melting at 95° C, and long needleshaped crystals, melting at 110° C. The lower melting form can be obtained by crystallization from cold acetone, the higher melting one by evaporation of a carbon disulfide solution at room temperature. The lower melting modification is labile and is spon-

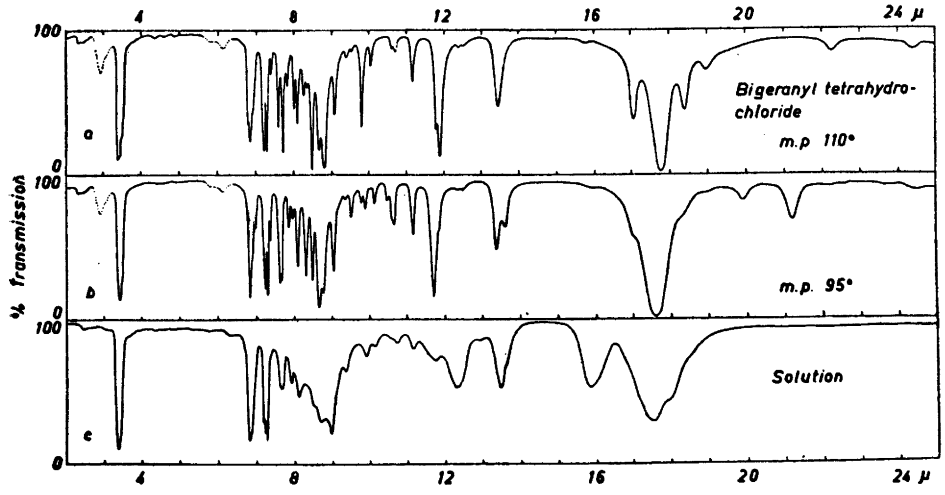

Fig. 1. Infrared absorption spectra from 2—15 μ (NaCl-prism) and from 15—25 μ (KBr-prism) of a) the higher melting and b) the lower melting crystal form of bigeranyl tetrahydrochloride as pressed KBr-disks, and of c) solutions in CCl_4 (2—8 μ, 15—25 μ) and in CS_2 (8—15 μ).

taneously converted in the solid phase to the higher melting and stable modification. This conversion may take several weeks at room temperature, but only minutes or hours at 80° C. After melting at 95° C the substance may solidify on further heating and melt again at 110° C. The degree of conversion may be established by X-ray diffraction, but more conveniently by infrared spectroscopy (Fig. 1).

Some preliminary crystal data for the two modifications of bigeranyl tetrahydrochloride have been collected for further determination of their structures, and shall be reported here. For the *lower melting form* the unit cell dimensions obtained from oscillation and Weissenberg photographs using Cu$K\alpha$ radiation, are: $a = 38.6 \pm 0.1$ Å; $b = 10.20 \pm 0.05$ Å; $c = 5.99 \pm 0.02$ Å, $\gamma = 93.0 \pm 0.3°$, $V = 2\,358$ Å^3, $Z = 4$ mol./u.c., $d_{calc} = 1.181$ g/cm^3, $d_{obs} \approx 1.18$ g/cm^3. Systematic absences are found for $00l$ when l odd; for $hk0$ when k is odd. The same systematic weaknesses of the reflections as for the isomers of squalene hexahydrochloride are also found, *i. e.*, $h00$ when h is odd; $0k0$ when k is odd; and $h0l$ when $h + l$ is odd. Space group $P2_1/b$.

A comparison of these data with those of the squalene hexahydrochloride isomers [2] will show that the a-axis length for bigeranyl tetrahydrochloride is about two thirds of that of squalene hexahydrochloride, the other data being very closely the same for both compounds. A one-dimensional projection of electron density on the a-axis has been calculated, and this synthesis also shows that the low melting modification of bigeranyl tetrahydrochloride closely resembles the squalene hexahydrochloride isomers, especially the higher melting one; hence, it must be the *meso*-form.

A single crystal of the *higher melting form* of approximate size $0.5 \times 1.0 \times 10$ mm has been prepared. This shows good cleavages parallel to (100) and (010), but inferior parallel to (001). The crystal data for this modification are: $a = 20.91 \pm 0.05$ Å; $b = 9.77 \pm 0.02$ Å; $c = 6.04 \pm 0.02$ Å; $\alpha = 87°\ 13' \pm 10'$; $\beta = 92°\ 52' \pm 10'$; $\gamma = 102°\ 55' \pm 10'$; $V = 1\,175$ Å^3; $Z = 2$ mol./u.c.; $d_{calc} = 1.186$ g/cm^3; $d_{obs} \approx 1.19$ g/cm^3.

By comparing the crystal data and the infrared spectra (Fig. 1) of the two crystalline isomers it may be seen that marked differences exist, indicating that we have to do with two different conformational isomers. The spontaneous solid phase conversion of one form into the other can therefore hardly be due to simple translations of the molecules in the crystal lattice, but must rather involve a rotation about some of the bonds in the chain. It is instructive to note the remarkable difference between the spectra of these two conformational isomers even in the C—Cl stretching frequency region, 17—18 μ, where one would expect a fairly constant "group frequency". The solution spectrum represents, of course, the equilibrium mixture of a very large number of conformational isomers and is accordingly more diffuse and less characteristic.

Transformation of 2-(β,β-Dicarbomethoxyethyl)-furan into *m*-Hydroxybenzoic Acid

NIELS ELMING

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

Furans with suitable substituents in the 2-position may be transformed into other systems with aromatic character by methoxylation to cyclic acetals of 1,4-dicarbonyl compounds, followed by intramolecular condensation in acid solution [1-6]. Further application of this principle has led to the transformation of 2-(β,β-dicarbomethoxyethyl)-furan (I) into *m*-hydroxybenzoic acid (III) as shown below.

Trans-2-furanacrylic acid was isolated as a by-product of the reaction (yield 2 %). This indicates that to a small extent an ethylenic linkage has been formed in the side-chain of I by oxidation during electrolysis.

I was prepared from furfuryl chloride as shown below *cf.* [7]. Dimethyl difurfuryl malonate (IV) was isolated as a by-product of this reaction.

taneously converted in the solid phase to the higher melting and stable modification. This conversion may take several weeks at room temperature, but only minutes or hours at 80° C. After melting at 95° C the substance may solidify on further heating and melt again at 110° C. The degree of conversion may be established by X-ray diffraction, but more conveniently by infrared spectroscopy (Fig. 1).

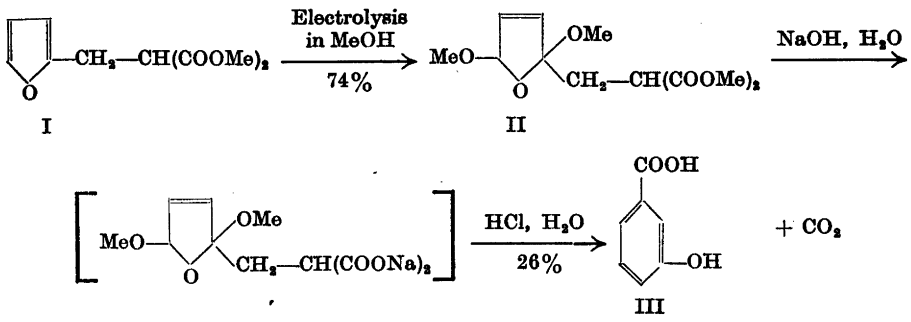
Transformation of 2-(β,β-Dicarbomethoxyethyl)-furan into *m*-Hydroxybenzoic Acid



NIELS ELMING

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

Furans with suitable substituents in the 2-position may be transformed into other systems with aromatic character by methoxylation to cyclic acetals of 1,4-dicarbonyl compounds, followed by intramolecular condensation in acid solution [1-6]. Further application of this principle has led to the transformation of 2-(β,β-dicarbomethoxyethyl)-furan (I) into *m*-hydroxybenzoic acid (III) as shown below.

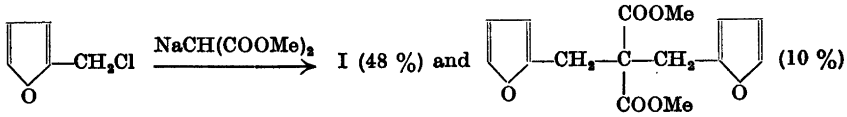
Trans-2-furanacrylic acid was isolated as a by-product of the reaction (yield 2 %). This indicates that to a small extent an ethylenic linkage has been formed in the side-chain of I by oxidation during electrolysis.

I was prepared from furfuryl chloride as shown below *cf.* [7]. Dimethyl difurfuryl malonate (IV) was isolated as a by-product of this reaction.

I II III

The dimethoxydihydrofuran (II) could, as expected, be catalytically hydrogenated to the corresponding tetrahydrofuran, 2,5-dimethoxy-2-(β,β-dicarbomethoxyethyl)-tetrahydrofuran (V).

I, II, IV and V are new compounds, but the free acid and the diethyl ester corresponding to I have been prepared previously [7].



Experimental. 2-(β,β-Dicarbomethoxyethyl)-furan (I). Dimethyl malonate (17.0 g, 0.128 mole) was added to a solution of sodium methoxide in methanol [from sodium (2.80 g, 0.122 mole) and anhydrous methanol (60 ml)]. Furfuryl chloride [8] (14.3 g, 0.123 mole) was added dropwise with stirring during 20 min at 30—40°. The mixture was stirred for a further 10 min at 30° and then heated under reflux with stirring for one hour. The methanol was evaporated in a vacuum and ether added. The mixture was washed twice with cold water and the etheral layer dried with magnesium sulfate. Distillation gave 12.5 g (48 %) of I (colorless liquid, $b.p._{0.1}$ 83—88°, n_D^{25} 1.4667). (Found: C 56.6; H 5.8; OCH_3 29.0. Calc. for $C_8H_6O_3(OCH_3)_2$ (212.2): C 56.6; H 5.7; OCH_3 29.2).

Further distillation gave 1.67 g of pale yellow liquid ($b.p._{0.1}$ 88—130°), which was discarded, and then 2.81 g of pale yellow liquid ($b.p._{0.1}$ 130—136°) which crystallized completely on standing, [m.p. 55—60° (Hershberg apparatus, corr.)]. Crystallization of 500 mg from ether gave 310 mg (10 %) of IV (white crystals, m. p. 67—69°). (Found: C 61.6; H 5.3; OCH_3 21.1. Calc. for $C_{13}H_{10}O_4(OCH_3)_2$ (292.3): C 61.6; H 5.5; OCH_3 21.2).

2-5-Dimethoxy-2-(β,β-dicarbomethoxyethyl)-2,5-dihydrofuran (II). I (4.24 g, 0.020 mole) and concentrated sulfuric acid (412 mg) were dissolved in anhydrous methanol (45 ml) and the solution electrolyzed and worked up as described for the methoxylation of 2-carbomethoxy-5-*iso*propylfuran [9]. The yield was 4.04 g (74 %, current efficiency 59 %) of II (pale yellow liquid, $b.p._{0.2}$ 129—132°, n_D^{25} 1.4560). (Found: C 52.7; H 6.6; OCH_3 44.9. Calc. for $C_8H_6O_3(OCH_3)_4$ (274.3): C 52.6; H 6.6; OCH_3 45.3).

2,5-Dimethoxy-2-(β,β-dicarbomethoxyethyl)-tetrahydrofuran (V). II (2.66 g) and anhydrous methanol (15 ml) were shaken (3 h) with Raney nickel (0.2 g) under hydrogen (100 atm). The product was isolated by distillation. The yield was 2.30 g (83 %) of V (colorless liquid, $b.p._{0.1}$ 129—131°, n_D^{25} 1.4499). (Found: C 52.3; H 7.3; OCH_3 44.8. Calc. for $C_8H_6O_3(OCH_3)_4$ (276.3): C 52.2; H 7.3; OCH_3 44.9).

m-Hydroxybenzoic acid (III) and trans-2-furanacrylic acid. II (4.12 g, 0.015 mole) and N sodium hydroxide (45 ml, 0.045 mole) were mixed and heated under reflux (1 h). After cooling the pH was adjusted to 1—1.5 by addition of concentrated hydrochloric acid. The mixture was heated under reflux for 1 h and the dark brown solution evaporated in a vacuum to about 30 ml. The precipitate formed was removed by filtration, washed once

IV

with water and dried (yield 70 mg). Sublimation (110—120°/0.05 mm) gave 47 mg (2 %) of *trans*-2-furanacrylic acid (white crystals, m. p. 140—142°, mixed m. p. with an authentic specimen of *trans*-2-furanacrylic acid 141—143°). [Found: C 60.9; H 4.6. Neut.equiv. 137.8 (phenolphthalein indicator). Calc. for $C_7H_6O_3$ (138.1): C 60.9; H 4.4].

The filtrate from the crude furanacrylic acid was continuously extracted with ether (2 h), the etheral extract dried with magnesium sulfate and the ether evaporated in a vacuum. 1.45 g of a semisolid residue remained. Crystallization from water followed by sublimation (130—140°/0.05 mm) gave 0.53 g (26 %) of III (white crystals, m. p. 197—200°, mixed m. p. with an authentic specimen of *m*-hydroxybenzoic acid 198—200°). [Found: C 61.0; H 4.5. Neut.equiv. 137.8 (phenolphthalein indicator) Calc. for $C_7H_6O_3$ (138.1); C 60.9; H 4.4].

In another experiment the acid solution was not refluxed. After standing for 6 days at room temperature a 6 % yield of *trans*-2-furanacrylic acid was obtained, but no III could be isolated.

On the Carbohydrate Components of the α_1-Acid Glycoprotein of Human Plasma

IKUO YAMASHINA

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

α_1-Acid glycoprotein of human plasma was first isolated in a pure state by Weimer, Mehl and Winzler [1] in 1950. They used ammonium sulphate fractionation under pH control. In 1953, Schmid [2] independently isolated a glycoprotein, called α_1-acid glycoprotein, from the supernatant of fraction V of Cohn's fractionation procedure. Judging from the physicochemical and analytical figures, this substance was considered to be the same one as Weimer *et al.* described.

The α_1-acid glycoprotein is one of the best characterized substances among the numerous plasma proteins. The carbohydrate content is extremely high, amounting to nearly 40 %. Neutral sugars, amino sugars and sialic acids were found by Winzler [1], Schmid [2] and Odin [3].

The present author prepared a certain amount of this glycoprotein for study. After hydrolysis, the substance was analyzed for neutral sugars, amino sugars and sialic acids by means of chromatographic methods. Galactose, mannose, fucose, glucosamine, ovine-type sialic acid and its derivative were determined quantitatively.

In order to investigate the chemical structure proteolytic degradation of the glycoprotein was attempted. At first, the glycoprotein was submitted to a mild hydrolysis in order to remove sialic acids because the intact glycoprotein, was hardly digested by trypsin or papain. The degraded sialic acid free glycoprotein, however, could be digested by trypsin. Actually, a peptide carrying carbohydrate was obtained.

Experimental: Preparation. The electrophoretically pure glycoprotein was prepared principally according to Schmid's method [4]. However, the ethanol concentration was raised to 25 % instead of 20 at the final stage of the fractionation. In this way, the pure substance was regularly obtained, although the yield was somewhat low. Thus, 1 gm of glycoprotein was usually obtained from 50

with water and dried (yield 70 mg). Sublimation (110—120°/0.05 mm) gave 47 mg (2 %) of *trans*-2-furanacrylic acid (white crystals, m. p. 140—142°, mixed m. p. with an authentic specimen of *trans*-2-furanacrylic acid 141—143°). [Found: C 60.9; H 4.6. Neut.equiv. 137.8 (phenolphthalein indicator). Calc. for $C_7H_6O_3$ (138.1): C 60.9; H 4.4].

On the Carbohydrate Components of the α_1-Acid Glycoprotein of Human Plasma

IKUO YAMASHINA

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

α_1-Acid glycoprotein of human plasma was first isolated in a pure state by Weimer, Mehl and Winzler [1] in 1950. They used ammonium sulphate fractionation under pH control. In 1953, Schmid [2] independently isolated a glycoprotein, called α_1-acid glycoprotein, from the supernatant of fraction V of Cohn's fractionation procedure. Judging from the physicochemical and analytical figures, this substance was considered to be the same one as Weimer *et al.* described.

The α_1-acid glycoprotein is one of the best characterized substances among the numerous plasma proteins. The carbohydrate content is extremely high, amounting to nearly 40 %. Neutral sugars, amino sugars and sialic acids were found by Winzler [1], Schmid [2] and Odin [3].

The present author prepared a certain amount of this glycoprotein for study. After hydrolysis, the substance was analyzed for neutral sugars, amino sugars and sialic acids by means of chromatographic methods. Galactose, mannose, fucose, glucosamine, ovine-type sialic acid and its derivative were determined quantitatively.

In order to investigate the chemical structure proteolytic degradation of the glycoprotein was attempted. At first, the glycoprotein was submitted to a mild hydrolysis in order to remove sialic acids because the intact glycoprotein, was hardly digested by trypsin or papain. The degraded sialic acid free glycoprotein, however, could be digested by trypsin. Actually, a peptide carrying carbohydrate was obtained.

Experimental: Preparation. The electrophoretically pure glycoprotein was prepared principally according to Schmid's method [4]. However, the ethanol concentration was raised to 25 % instead of 20 at the final stage of the fractionation. In this way, the pure substance was regularly obtained, although the yield was somewhat low. Thus, 1 gm of glycoprotein was usually obtained from 50

liters of pooled supernatant of fraction V of Cohn's fractionation procedure (Method 6).

Analytical methods. Total neutral sugars were determined both by the orcinol reaction according to Hewitt [5] and by the cysteine reaction according to Dische [6]. For the chromatographic analysis, Gardell's method [7] was used after hydrolysis with 2 N sulphuric acid for 12 h at 100° C. Amino sugars were determined also according to Gardell's method [8] after hydrolysis with 6 N hydrochloric acid for 8 h at 100° C. For the sialic acid determination, Bial's reagent [9] was used on the intact glycoprotein and Ehrlich's reagent [9] on the fractions of the column chromatography. Paper chromatographic analysis of sialic acid was performed with butanol-acetic acid-water (4:1:5) and butanol-pyridine-water (6:4:3) as solvents according to the directions of Blix, Lindberg, Odin and Werner [10]. The sialic acids were detected by spraying the paper with the orcinol-trichloroacetic acid reagent of Klevstrand and Nordal [11].

Digestion by proteolytic enzymes. For the tryptic digestion, the autoactivation product of trypsinogen was used which was prepared by keeping trypsinogen in borate buffer (0.1 M, pH 8.0) containing 0.1 M $CaCl_2$ for 24 h at 0° C. Trypsinogen was prepared according to Northrop and Kunitz [12] through crystallization and further purification by trichloroacetic acid.

The papain used in this experiment was the product of Worthington (Freehold, New Jersey, U.S.A.).

The digestion was followed by measuring the ninhydrin reaction [13] on the whole reaction mixture.

Results and Discussion. Analytical values on sugar components are given in Table 1 together with the figures given by the earlier workers. As shown in the table, chromatographic values are consistent with the values obtained by direct determination.

From the X-ray diffraction patterns of the isolated and crystallized sialic acid, Odin [3] concluded that the glycoprotein contains sialic acid having N-acetyl group (ovine-type sialic acid). However, two types of sialic acid were found by the present author when the glycoprotein was submitted to a mild hydrolysis (0.01 N H_2SO_4, 100° C, 1 h).

The sialic acids liberated were chromatographed on a Dowex 2 column (formate form) according to the directions of Svennerholm [14]. Thus, the hydrolysate was treated by Dowex 50 (H^+ form) in order to remove the excess amount of $Ba(OH)_2$ used for the neutralization, and the solution was freeze-dried. The residue was dissolved in 0.1 N formic acid and put on a column of Dowex 2 which had been equilibrated by 0.1 N formic acid. A stepwise elution was carried out. A chromatogram on Dowex 2 is shown in Fig. 1.

Sialic acid	—	10.6 [9]	—	10.8 [9]

* Orcinol reaction.

The sialic acid which was eluted by 0.1 N formic acid was identified as O-sialic acid by means of paper chromatography. The other sialic acid, tentatively named sialic acid II, whose structure is not elucidated yet, migrates faster than the first one on paper chromatography using the aforementioned solvents.

The amount of both types of sialic acid depends on length of hydrolysis time, the total amount being constant and about

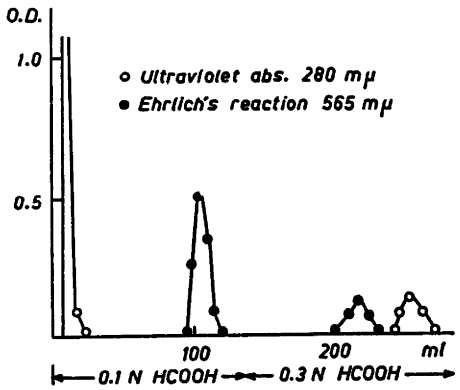

Fig. 1. Chromatogram on Dowex 2 (200—400 mesh), 0.9 × 32 cm. 67 mg of α-acid glycoprotein was hydrolyzed for 40 min. Elution rate: 1 ml per 10 min.

Table 2. Relation between the amount of sialic acids (I and II) and the time of hydrolysis.

Time (Min)	Sialic acid I	Sialic acid II (μg per mg glycoprotein)	Total
30	58	31	89
60	37	43	80
90	27	54	81
120	18	70	88

80—90 % of sialic acid present in the original glycoprotein. The relation between the amount of both sialic acids and the time of hydrolysis is shown in Table 2.

As could be expected, the isolated N-acetyl sialic acid can be converted to sialic acid II by heating in 0.01 N sulphuric acid.

While the structural studies on sialic acid II will be performed in due time, the present findings would provide a definite method for the isolation of sialic acids from glycoproteins. Actually, similar findings, the presence of two transformable sialic acids, were also observed on prothrombin which was prepared according to Seegers [15] and supposed to be a glycoprotein (Magnusson [16]).

After the removal of sialic acid by means of mild hydrolysis as mentioned above, the remaining product was dialyzed against distilled water and freeze-dried. This sialic acid free glycoprotein contained practically the whole amount of sugar present in the original glycoprotein. It behaved as a homogeneous and rather neutral substance, the isoelectric point being higher than 4. Thus, the acidic nature of the original glycoprotein is mainly due to the presence of silaic acid.

While the original glycoprotein is essentially resistant to proteolytic digestion both by trypsin and by papain, the sialic acid free glycoprotein could be digested by trypsin. Thus, to the 0.5 % solution of the sialic acid free glycoprotein in 0.1 M borate buffer (pH 8.0), trypsin was added to a final concentration of 0.25 mg per ml. The digestion was carried out at 25° C for 24 h. The digestion product was separated into two groups, one being dialyzable and the other non-dialyzable. The latter is quite resistant to the further addition of trypsin. The dialyzable part comprises 45 % of the total neutral sugars as determined by the orcinol reaction.

This work was made possible through a research grant to Professor Erik Jorpes from the *Swedish State Medical Research Council*. The author's thanks are also due to Dr. S. Gardell for the analysis of the sugars and to Dr. L. Odin for the gift of sialic acids.

The Crystal Structures of Acetyl Choline Bromide and Acetyl Choline Iodide

HARALD SÖRUM

Forsvarets Forskningsinstitutt, Kjeller, Norway

Acetyl choline is known as a very powerful biological reactant showing special effects in the cholinergic nerve system. Chemically, acetyl choline belongs to the choline subgroup of the "onium" compounds or tetrasubstituted ammonium bases. In view of the chemical interest of "onium" compounds in general and the biological importance of this type of compounds in particular it appears worth while to investigate their crystal and molecular structure in detail.

The bromide and the iodide of acetyl choline are easily obtained in crystalline form. The bromide is the more stable compound, the iodide being to some extent decomposed by light. The chloride is more difficult to crystallize, and is furthermore very hygroscopic.

Crystals of acetyl choline bromide were prepared by recrystallization from absolute alcohol. The crystals are colourless, transparent, monoclinic prisms of cell edge ~1 mm or less. The most frequent limiting faces of the crystals are parallel to (010), (110), (1$\bar{1}$0) and (001). Faces parallel to (101), (120), (1$\bar{2}$0) and {111} have been observed, but are less frequent. (100) and (10$\bar{1}$) have not been found as external crystal faces. Cleavage is fairly good parallel to (010), less good along (101).

The crystallographic data for acetyl choline bromide obtained from X-ray diffraction photographs, using Cu$K\alpha$ radiation, are: $a = 10.55 \pm 0.05$ Å, $b = 13.67 \pm 0.05$ Å, $c = 7.18 \pm 0.02$ Å, $\beta = 70.0 \pm 0.03°$, $V = 1\,043$ Å^3, $d_x = 1.43$ g/cm^3 with $Z = 4$ molecules per unit cell. $0k0$ reflexions are absent when k is odd. Possible space groups are $P2_1$ and $P2_1/m$. A Patterson projection on (001) is incompatible with the holohedric space group.

Strictly, however, the unit cell thus described is apparently a pseudo-cell only, as fairly strong superstructure reflexions, indicating very long true repeats, are found in the X-ray photographs. This superstructure seems to be of some peculiar and hitherto unknown type, the superstructure reflexions being defined by:

1. $h0l$ reflexions for h odd integer are absent, but subsidiary reflexions occur slightly displaced from these points.
2. $k = 0$. Subsidiary reflexions occur close to principal reflexions when h even and l even but not for l odd and h even.
3. $k \gtrless 0$. Subsidiary reflexions occur close to principal reflexions for all values of h and l.
4. No subsidiary reflexions accompany the $h00$, $hk0$ reflexions.
5. In terms of the reciprocal lattice the displacement of the subsidiary reflexions from the points corresponding to integral values of hkl is largest near the plane through $0kl$ and decreases towards the plane through $hk0$. In the present case the subsidiary reflexions occur only on one side of the principal reflexions, and not as the more usual pairs of reflexions placed symmetrically to the principal ones.

It cannot be definitely excluded that these extra reflexions in some way may be due to a special sort of twinning. Further investigation on this problem is going on.

The structure of acetyl choline bromide has been solved by Patterson, Fourier and least squares methods, and a detailed report on this work will appear elsewhere.

Acetyl choline iodide crystallizes from alcohol-acetone in very thin, soft, colourless and partly transparent plates. X-Ray oscillation and Weissenberg photographs show that the crystals are pseudo-orthorhombic with axial lengths: $a = 8.32 \pm 0.05$ Å, $b = 16.44 \pm 0.05$ Å, $c = 31.80 \pm 0.1$ Å, $\beta \simeq 90°$, cell volume $V = 2\,172$ Å^3, $Z = 16$ and d_x calculated 1.67 g/cm^3. Reflexions $h00$ are absent when h odd, $0k0$ when k odd and hkl when $h + k$ odd. There is apparently no close similarity between the crystal structure of this compound and that of the bromide. No further structure determination is contemplated for the iodide of acetyl choline.

The crystals used in these investigations were prepared by Mr. G. Aksnes of this Institute.

On the Crystal Structures of the Zirconium and Hafnium "Cupferrates"

GEORG NEUMANN, GEORG LUNDGREN and BENGT AURIVILLIUS

Institute of Inorganic and Physical Chemistry, University, Stockholm; Research Institute of National Defence, Dpt 1, Sundbyberg 4; Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Recently Dyrssen investigated the formation of complexes between Th^{4+} ions and the anions of N-nitroso-N-phenylhydroxylamine ($C_6H_5N(NO)OH$) [1]. The question as to how the ligands are arranged in the complexes then arose and, as a hypothesis, Dyrssen suggested a "fourblade propeller" arrangement for $Th(C_6H_5N_2O_2)_4$. The organic ligands could then be arranged either in the *syn* form with both their oxygens in contact with the metal ion or in the *anti* form with one oxygen and one nitrogen per ligand in contact with the metal ion. Dyrssen preferred the first possibility. By investigating the crystal structure of a compound of this formula, it should be possible to reveal the actual structure of the complexes. The heavy thorium atoms, which dominate the X-ray scattering too much, should then preferably be replaced by a lighter tetravalent atom, *i. e.* Zr^{4+}.

From Dr. Dyrssen we obtained crystals of $Me(C_6H_5N_2O_2)_4$, Me being Zr^{4+}, Hf^{4+} and also a mixture of these ions in the

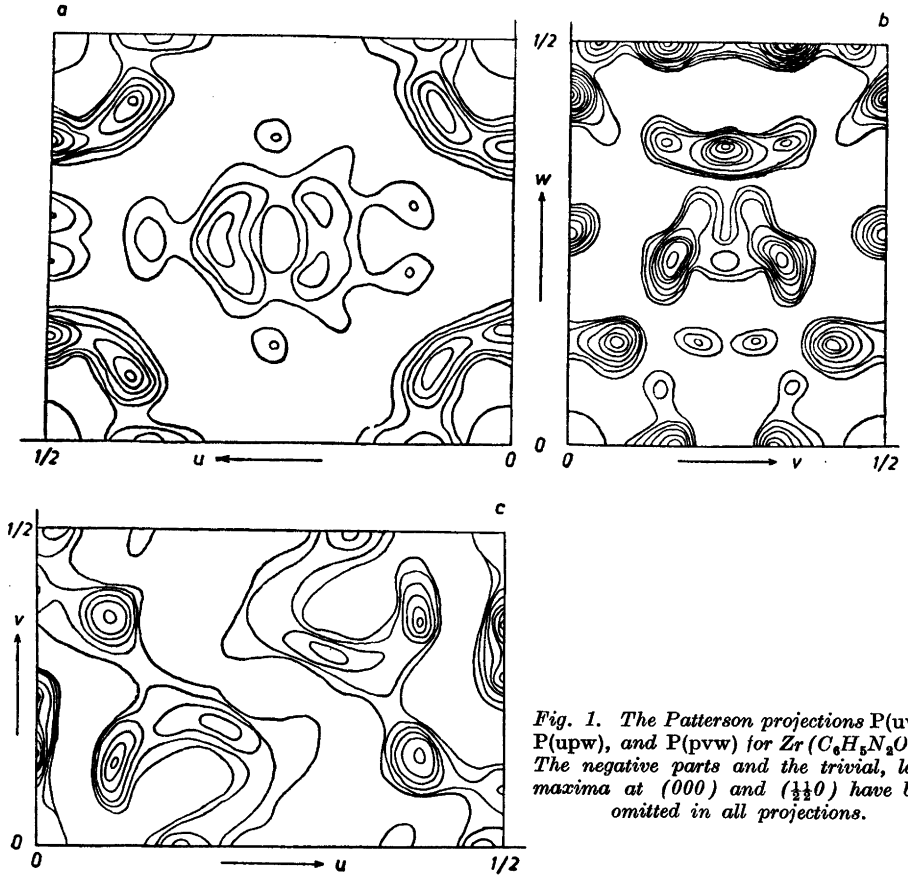

Fig. 1. The Patterson projections P(uvp), P(upw), *and* P(pvw) *for* $Zr(C_6H_5N_2O_2)_4$. *The negative parts and the trivial, large maxima at (000) and* $(\frac{1}{2}\frac{1}{2}0)$ *have been omitted in all projections.*

atomic ratio 1:1. These compounds had been prepared by precipitating water solutions of Me^{4+} perchlorates with the equivalent of "cupferron" (= $NH_4C_6H_5N_2O_2$), dissolving the compounds obtained, preferably in chloroform, and slowly evaporating the solutions. The crystals were light yellow for Me = Zr^{4+}, light yellowish brown for Me = $(Zr, Hf)^{4+}$ and light brown for Me = Hf^{4+}. They were all rather long rods with a rhombic cross-section.

From single crystal photographs of $Zr(C_6H_5N_2O_2)_4$ ($hk0$-$hk7$, $h0l$-$h5l$, $0kl$-$8kl$) taken in Weissenberg cameras with CuK radiation, it was concluded that it is orthorhombic with the following dimensions:

$$a = 16.7 \pm 0.2 \text{ Å}$$
$$b = 11.2 \pm 0.1 \text{ Å}$$
$$c = 14.4 \pm 0.2 \text{ Å}$$
$$V = 2.69 \cdot 10^3 \text{ Å}^3$$

From a few Weissenberg photographs of the (Zr, Hf) and Hf compounds, it was found that the three compounds are isomorphous and that their cell dimensions, within the experimental errors, are identical. For all three compounds, the c axis coincides with the needle axis of the crystals.

From the density of the zirconium compound, 1.573 ± 0.002 g/ml as determined by flotation methods, the cell content was found to be $3.99 \approx 4$ formula units $Me(C_6H_5N_2O_2)_4$.

The following reflections are systematically absent:

$hk0$ with $h + k$ = odd
$h0l$ with l = odd
$0kl$ with k = odd

which is characteristic for the space group No. 60 *Pbcn* [2].

The positions of the metal atoms were determined from the three Patterson projections *P (upw)*, *P (pvw)*, and *P (uvp)* of the zirconium compound (*cf.* Fig. 1). Their parameters were found to be:

4 Zr in *Pbcn* 4(*e*): $\pm(0, y, \frac{1}{4})$;
$\pm(\frac{1}{2}, \frac{1}{2} + y, \frac{1}{4})$ with $y = 0.074$

They are thus situated on the twofold axes in the unit cell and consequently have the special extinction: hkl absent for $h+k$ = odd. The fact that the metal ions are situated in this way is also consistent with a "propeller" arrangement since the organic ligands, lacking twofold symmetry, must be situated outside the twofold axes and, consequently, must be paired within the complexes.

The determination of the O, N, and C parameters has also been begun. It was possible to determine the majority of the signs of F_{hk0} and F_{0kl}, whereas, because of the special extinctions for the Me atoms, only half of the signs of F_{h0l} could be determined. In this way, reliable electron density maps $\varrho(xyp)$ and $\varrho(pyz)$ could be obtained. The work to interpret these projections and to find out the arrangement of the oxygen, nitrogen, and carbon atoms is continuing.

Chromatographic Separation of Aliphatic Monocarbonyl Compounds

HENRIK WALLGREN and ERIK NORDLUND

Department of Nutritional Chemistry, University of Helsinki, Viikin Koetila, Malmi, Finland

In work on the chromatographic separation of the 2,4-dinitrophenylhydrazones of aliphatic methylketones and aldehydes, Meigh's two-phase methanol-heptane system [1,2] gave promising results. The separation and identification of components in a mixture was, however, impossible owing to the trailing of the spots. Addition of 10 % glacial acetic acid to the moving phase resulted in well concentrated spots. Ligroin (B.D.H., b.r. 90—110° C) and even a technical petrol fraction (Shell, b.r. 80—110° C) were as effective as pure heptane.

Chromatographic method. The paper (Whatman No. 1) is soaked in methanol, the excess methanol allowed to drip off, and the paper dried for 10—15 minutes at 80° C. It should be used within two hours after this procedure. The hydrazones (0.5—30 μg may be used) are then pipetted on to the paper, which is suspended in a dry trough and left to stand overnight. The chamber should be airtight and the cover provided with holes for filling the troughs. The chamber holds two containers, the one with heptane(ligroin)-in-

atomic ratio 1:1. Chromatographic Separation of Aliphatic Monocarbonyl Compounds

HENRIK WALLGREN and ERIK NORDLUND

Department of Nutritional Chemistry, University of Helsinki, Viikin Koetila, Malmi, Finland

In work on the chromatographic separation of the 2,4-dinitrophenylhydrazones of aliphatic methylketones and aldehydes, Meigh's two-phase methanol-heptane system [1,2] gave promising results. The separation and identification of components in a mixture was, however, impossible owing to the trailing of the spots. Addition of 10 % glacial acetic acid to the moving phase resulted in well concentrated spots. Ligroin (B.D.H., b.r. 90—110° C) and even a technical petrol fraction (Shell, b.r. 80—110° C) were as effective as pure heptane.

Chromatographic method. The paper (Whatman No. 1) is soaked in methanol, the excess methanol allowed to drip off, and the paper dried for 10—15 minutes at 80° C. It should be used within two hours after this procedure. The hydrazones (0.5—30 μg may be used) are then pipetted on to the paper, which is suspended in a dry trough and left to stand overnight. The chamber should be airtight and the cover provided with holes for filling the troughs. The chamber holds two containers, the one with heptane(ligroin)-in-

methanol, the other with methanol-in-heptane(ligroin), for saturating the atmosphere. In these are dipped strips of filter paper to increase the evaporating surface. In the morning the moving phase, 10 % acetic acid in heptane(ligroin), is poured into the trough. Freshly prepared solutions should always be used. It is essential that the temperature is kept equal around the whole chamber to prevent condensation. For reasons that will appear below, the chromatogram can be run for *ca.* 1.5 h when the mixture contains hydrazones of the lower aldehydes and ketones. A chromatogram with only higher aldehydes and ketones (5—8 C-atoms) can be run for about 4 h. The spots are clearly brought out in UV-light.

With this method, the following R_F-values were obtained:

Formaldehyde	0.19—0.26	2-Pentanone	0.53—0.59
Acetaldehyde	0.29—0.37	2-Hexanone	0.65
Heptaldehyde	0.65—0.71	2-Heptanone	0.69—0.79
Acetone	0.40—0.52	2-Octanone	0.83
2-Butanone	0.48—0.55		

It is obvious that identification should be based on comparison with runs of known preparations. Complete separation of formaldehyde, acetaldehyde, acetone, 2-butanone, 2-pentanone, and 2-heptanone was achieved. The spots of the higher homologues, especially, are slightly elongated, and therefore 2-hexanone and 2-octanone are partly overlapped by the nearest members of the series. Identification is possible, but not quantitative separation. This is perhaps the chief draw-back of the system, but it can be almost completely overcome with the aid of Matthias' method [8]. Another weakness is that after *ca.* 1.5 h a second solvent front is formed and starts to run up the first one. Apparently this is due to diffusion of the methanol into the acetic acid-heptane mixture and the formation of a new equilibrium. The spots now travel close to the second front and are no longer clearly separated.

Among the methods which the authors have tested [1-9], this has been the most satisfactory for aldehydes and ketones of higher molecular weight, whereas the system of Tarbell *et al.*[3], as modified by Buyske *et al.*[9], is very useful for chromatography of compounds with 5 C-atoms or less. With Matthias' device [8], our method gives equally good separation of these compounds.

Quantitative determination of 2-heptanone and heptaldehyde in fat. The aldehyde or ketone is removed from the fat by steam distillation (20 min) [10-12]. The distillate is collected in a cooled vessel containing 2 ml of a 0.5 % solution of 2,4-dinitrophenylhydrazine in 2 N HCl. The distillate (*ca.* 100 ml) is allowed to stand at least 1 h at room temperature and then extracted with diethyl ether until the ether is colourless. The extract is then washed with 2 N HCl and distilled water, the ether evaporated *in vacuo*, and the residue dissolved in chloroform and chromatographed. The spots are cut out and the pieces of paper crushed in test tubes containing 5 ml of 30 % ethanol made 0.2 N with NaOH. Samples of this solution are sucked out with a pipette provided with a G 2 glass sinter and measured after exactly 20 min in a Beckman spectrophotometer, model DU, at 430 mμ.

The recovery of known amounts of hydrazone run on the paper were: 2-heptanone 76.1 ± 1.17 % (s = 6.5, 31 samples); heptaldehyde 76.2 ± 1.43 % (s = 7.1, 25 samples). When known amounts were mixed in 10 g of lard the recovery was only 35.5 ± 1.43 % in the range 10—200 μg, whereas from 1 000 μg it was 33.1 ± 0.29 %. Thus the variation was considerably smaller when the amounts were greater, but the recovery was not improved. The chief reason for the low percentage recovery was probably incomplete formation of the hydrazones.

The absorption of extracts from pieces of paper treated in the same manner as the chromatograms and of equal size as the spots was 0.031 ± 0.0017 (s = 0.009, 30 samples). Absorption values lower than 0.050 were therefore not concerned, and the lower limit for the determinations is then 1.25 μg of 2-heptanonehydrazone or heptaldehydehydrazone, corresponding to about 0.5 μg of pure ketone or aldehyde. Amounts of about 0.5 μg of hydrazone can, however, be detected in UV-light.

The quantitative method described here cannot be used as such for determination of ketones and aldehydes with lower R_F-values than the two used in this investiga-

tion. Washing of the ether extract with HCl does not remove all the excess dinitrophenylhydrazine, and this forms five spots, of which one travels about as far as 2-hexanone. The method of Pool and Klose[13] could most probably be used, however, for purification of the ether extract.

A Low-Resistance Vapour-Phase Chromatograph Column

IB SØRENSEN and P. SØLTOFT

Laboratoriet for almen teknisk Kemi, Danmarks tekniske Højskole, Copenhagen, Denmark

In vapour-phase chromatographic separation of high-boiling compounds, as for instance methyl esters of higher fatty acids, it is convenient to apply low pressures as this enables the use of correspondingly low column temperatures. It is not possible, however, fully to utilize such a pressure reduction in columns of the usual type, as for instance those in which Celite is used as the inert carrier of the static phase, as the pressure drop is very great, about 400 mm mercury pressure in the case of a column length of 1 m. Cropper and Heywood [1] have suggested the substitution of sodium chloride crystals for Celite, enabling a reduction of the pressure drop to 20 mm mercury per metre of column length, and column packing of this type has been used successfully in this laboratory. However, it would be convenient — for several reasons — to be able to reduce the pressure drop further, and since the technique of vapour-phase chromatography offers many points of resemblance to that of fractional distillation, it would be reasonable to assume that packing elements of the types used in lowpressure fractionating columns might also be applied in a vapour-phase chromatograph column. This assumption has been confirmed by experiments with gauze helices of stainless steel, so-called Dixon Gauze Rings, made from fine-mesh steel gauze.

A column packing was prepared with helices of the above-mentioned type, Griffin & George, Ltd., Cat. No. B24—420, dimensions 1/16″ × 1/16″, the helices being carefully mixed with a solution of Dow Corning High Vacuum Silicone Grease in ethyl acetate. After evaporation of the solvent, the grease was left as a film which covered the gauze meshes, but did not fill out the interior of the helix. The helices were packed into a 2 m column of stainless steel tubing with an inside diameter of 8 mm. At 200° C, 20 mm outlet pressure and a rate of flow of carrier gas of 8 ml N_2 per min a pressure drop from one end of the column to the other of 4.5 mm mercury was measured. For purposes of comparison it may be mentioned that the pressure drop measured across the same column when packed with sodium chloride crystals, but otherwise under identical working conditions, was found to be 52 mm.

For our experiments a mixture of methyl esters of C_8—C_{18} fatty acids was used, and it was ascertained that the degree of separation obtained by means of the column was practically the same for both types of packing (see Table 1), but that the elution peaks yielded by the steel gauze packing were of a more perfect shape and more symmetrical. The low pressure drop

tion. Washing of the ether extract with HCl does not remove all the excess dinitrophenylhydrazine, and this forms five spots, of which one travels about as far as 2-hexanone. The method of Pool and Klose[13] could most probably be used, however, for purification of the ether extract.

A Low-Resistance Vapour-Phase Chromatograph Column

IB SØRENSEN and P. SØLTOFT

Laboratoriet for almen teknisk Kemi, Danmarks tekniske Højskole, Copenhagen, Denmark

In vapour-phase chromatographic separation of high-boiling compounds, as for instance methyl esters of higher fatty acids, it is convenient to apply low pressures as this enables the use of correspondingly low column temperatures. It is not possible, however, fully to utilize such a pressure reduction in columns of the usual type, as for instance those in which Celite is used as the inert carrier of the static phase, as the pressure drop is very great, about 400 mm mercury pressure in the case of a column length of 1 m. Cropper and Heywood [1] have suggested the substitution of sodium chloride crystals for Celite, enabling a reduction of the pressure drop to 20 mm mercury per metre of column length, and column packing of this type has been used successfully in this laboratory. However, it would be convenient — for several reasons — to be able to reduce the pressure drop further, and since the technique of vapour-phase chromatography offers many points of resemblance to that of fractional distillation, it would be reasonable to assume that packing elements of the types used in lowpressure fractionating columns might also be applied in a vapour-phase chromatograph column. This assumption has been confirmed by experiments with gauze helices of stainless steel, so-called Dixon Gauze Rings, made from fine-mesh steel gauze.

A column packing was prepared with helices of the above-mentioned type, Griffin & George, Ltd., Cat. No. B24—420, dimensions 1/16″ × 1/16″, the helices being carefully mixed with a solution of Dow Corning High Vacuum Silicone Grease in ethyl acetate. After evaporation of the solvent, the grease was left as a film which covered the gauze meshes, but did not fill out the interior of the helix. The helices were packed into a 2 m column of stainless steel tubing with an inside diameter of 8 mm. At 200° C, 20 mm outlet pressure and a rate of flow of carrier gas of 8 ml N_2 per min a pressure drop from one end of the column to the other of 4.5 mm mercury was measured. For purposes of comparison it may be mentioned that the pressure drop measured across the same column when packed with sodium chloride crystals, but otherwise under identical working conditions, was found to be 52 mm.

For our experiments a mixture of methyl esters of C_8—C_{18} fatty acids was used, and it was ascertained that the degree of separation obtained by means of the column was practically the same for both types of packing (see Table 1), but that the elution peaks yielded by the steel gauze packing were of a more perfect shape and more symmetrical. The low pressure drop

further enables the use of lower column temperatures or higher outlet pressures, and in both cases the degree of separation obtained from a column is increased considerably. It is also possible to use long columns, the pressure drop in the case of a 4 m column being for instance 8 mm mercury.

It remains to be ascertained whether the type of packing described is also applicable for vapour-phase chromatography at normal pressures, but considering the great similarity between vapour-phase partition chromatography and fractional distillation there is every probability that this is the case.

Distribution of Enzymes Involved in the Breakdown of Uracil to β-Alanine in Rat Liver Cells

PER FRITZSON*

Wenner-Gren Institute of Experimental Biology, Department of Physiological Chemistry, University of Stockholm, Stockholm, Sweden, and Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

Previous studies of the catabolism of ^{14}C-labeled uracil, dihydrouracil (DHU) and β-ureidopropionic acid (BUP) in the rat [1,2] demonstrated the following reactions in rat liver slices *in vitro* and in the intact rat:

Uracil → DHU ⇌ BUP → β-alanine

The results further indicated that the liver is the main site of these reactions. The localization of the enzymes responsible for the different reactions in this process in the liver cells, has now been investigated.

White rats were decapitated, and the livers were homogenized in 0.25 M sucrose as described by Ernster and Löw [3]. Uracil-6-^{14}C *, DHU-6-^{14}C and BUP-3-^{14}C were incubated with the homogenate and with three fractions of the homogenate obtained by successive removal of nuclei, mitochondria and microsomes by fractional centrifugation at 1 600 × g for 10 min, 4 100 × g for 15 min, and 105 000 × g for 45 min, respectively. The reaction mixtures were analyzed for radioactive compounds by paper strip chromatography in *n*-butanol-acetic acid-water (4:1:5) and in collidine saturated with water, and the distribution of radioactivity along the strips was determined, as described previously [1,2]. The total radioactivity of the incubation mixtures before and after incubation was determined by plating aliquots on planchets and subsequent counting, as described by Canellakis [5]. The results showed, within the limits of experimental error, that no volatile, radioactive compounds were formed during incubation, indicating that all the radioactive products can be detected in the chromatograms. The results are recorded in Table 1. The incubations with BUP as substrate show that the yield of β-alanine is the same in the presence of the homogenate and the particle-free supernatant fluid. The removal of nuclei and mitochondria has no effect on the enzymatic activity. These facts clearly demonstrate that the enzyme catalyzing the conversion of BUP to β-alanine is present entirely in the supernatant fraction. The data from the incubations of DHU with homogenate and supernatant fluid are consistent with the finding that the enzyme catalyzing the interconversion of DHU and BUP was present entirely in the supernatant fraction of isotonic KCl homogenates of rat liver [6]. The incubation of uracil with the supernatant fluid demonstrates that β-alanine is the only radioactive product which can be clearly detected in the chromatograms.

8 μmoles DHU-6-^{14}C	Homogenate	0	72	6	22	
	Supernatant	0	73	10	17	102
1 μmole uracil-6-^{14}C	Supernatant	78	0	0	17	96

* Expressed in per cent of the total radioactivity on the paper strip after chromatography.
** Determined by plating TCA-treated aliquots of the incubation mixture.

Additional data from the work of Rutman *et al.*[7] indicate that the ureido carbon of uracil is released as carbon dioxide in the supernatant fluid from rat liver homogenates. The particulate fraction was found to inhibit the enzymatic activity. These results were confirmed by the recent work of Canellakis [5], and it was demonstrated that the enzymatic activity of rat liver slices approximated that of the supernatant fluid. On the basis of these findings it can be concluded that the enzyme catalyzing the reduction of uracil to DHU is present mainly or entirely in the part of the cytoplasm represented by the nonparticulate system.

The author wishes to express his deep appreciation to Dr. Hans Löw, Wenner-Gren Institute, for his valuable advice and assistance in connection with tissue preparations.

On the Molecular Weights of Human and Ox Pituitary Growth Hormones

A. EHRENBERG and F. HEIJKENSKJÖLD

Biochemical Department, Nobel Medical Institute, and Department of Clinical Biochemistry, Karolinska Sjukhuset, Stockholm, Sweden

A growth-hormone-like principle in human pituitaries has recently been demonstrated by Gemzell and Heijkenskjöld[1]. The human pituitary growth hormone has now been isolated in an electrophoretically pure form [2], and investigations are being carried out concerning its chemical and physical nature. Some preliminary experiments on the sedimentation behaviour and molecular weight of this hormone are re-

Table 1. Sedimentation constants of human pituitary growth hormones under various conditions.

Buffer	pH	Protein mg/ml	S^0_{20}
Borate	10.0	7	1.99
»	9.9	8	2.12
»	9.9	15	2.30
»	9.9	15	2.20
Acetate	4.1	9	1.6
Phthalate	4.0	5	1.3

ported here and comparison is made with the ox hormone.

Experimental. The sedimentation coefficients were determined in a Spinco ultracentrifuge at 59 780 r.p.m. The molecular weight determinations were carried out in the same centrifuge at lower speeds as will be described elsewhere by Ehrenberg [3].

The human growth hormone was prepared by Heijkenskjöld [2] and the ox hormone was a gift from Dr. C. H. Li [4] to Dr. C. A. Gemzell, who kindly put it at our disposal.

At pH 9.9 a 0.028 M borate buffer was used, and at pH 4 either 0.125 M acetate or 0.045 phthalate. In all cases 1 % sodium chloride was added.

Results and discussion. The sedimentation coefficients from the experiments on the human growth hormone are listed in Table 1. The hormone protein appeared to be homogeneous in the experiments at pH 9.9, whilst the presence of small amounts of both faster and slower components is likely at pH 4. A single experiment on the ox hormone at pH 9.9 gave a sedimentation coefficient of 3.51 S in agreement with previous data [5,6]. As is seen the values for the human hormone are appreciably lower at this pH. The same differences persist in more acid buffers where the ox hormone still shows values above 3 S[6]. At the rather high pH 11.5, however, the sedimentation coefficients of ox hormone [6] are comparable to those of human hormone at pH 4 and 10. These data suggest that the human hormone has a lower molecular weight than the ox hormone at pH 4 and 10.

The molecular weights were determined on both hormones at pH 9.9. Two runs were made on the human hormone (10 and 5 mg/ml), both giving a molecular weight close to 30 000 in the first part of the experiment. In these calculations use was made of the value 0.76 of the partial specific volume of the ox hormone [7]. A decrease in the calculated molecular weight was observed in the later part of the experiment. This behaviour can be explained either by an inhomogeneous sample or by a concentration dependent equilibrium between molecules of different sizes. One experiment with ox hormone, also at pH 9.9 gave in the early part a molecular weight of about 75 000 and in the later part a decrease similar to that just described. Li and Pedersen [6] observed at this H an increase of S^0_{20} with protein concentration, which was explained by the assumption that the ox hormone protein behaves like a mixture of monomeric and dimeric forms. A similar concentration dependence of S^0_{20} of human hormone is indicated by the data of Table 1. There are thus good reasons to assume that this hormone protein also behaves like a mixture of molecules of different sizes at pH around 10.

The molecular weight of the ox hormone at pH 10 calculated by Li and Pedersen [6] from separate sedimentation and diffusion experiments was about 50 000; the sedimentation coefficient was extrapolated to zero protein concentration and the diffusion coefficient was determined at the low concentration of 2.5 mg/ml. This value is likely to correspond to the monomeric ox hormone, and our value of 75 000 to a sample of more or less aggregated molecules. In the later part of the experiment the observed molecular weight decreased towards the value for the monomeric form. By analogy herewith the value of the molecular weight of the human growth hormone of about 30 000 at pH 10 would be a mean for molecules of different sizes. The smallest hormone molecules present at this pH might have molecular weights as low as 15 000 – 20 000.
