Preparation of the Laevorotatory Enantiomer of Methylallylacetic Acid

GUNNEL STÄLLBERG

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

The dextrorotatory form of methylallylacetic acid ((+)-2L-methyl-$\Delta^{4:5}$-pentenoic acid) was first obtained by Ställberg-Stenhagen [1] by resolution of the racemic acid *via* the quinine salt. The configuration was determined by Ställberg-Stenhagen and Stenhagen [2], who oxidized the (+)-acid to (−)-methylsuccinic acid. The laevorotatory enantiomer has so far not been reported in the literature. In connection with work on the synthesis of phthiocerol in this laboratory, both enantiomers were needed for the synthesis of the different stereoisomeric forms of the 3-methoxy-4-methyl-grouping of the phthiocerol molecule [3]. It has now been found that the laevorotatory enantiomer of methylallylacetic acid ((−)-2D-methyl-$\Delta^{4:5}$-pentenoic acid) can be obtained *via* the (+)-1-phenylethylamine salt. The optical rotation found was numerically equal to that reported for the dextrorotatory enantiomer [4,5].

Experimental. (−)-2D-*Methyl-*$\Delta^{4:5}$*-pentenoic acid.* Partially resolved laevorotatory acid (43 g, a_D^{25} −5.3° (undiluted, *l* 1)), obtained from the mother liquor of the first crystallization of the quinine salt of the dextrorotatory enantiomer, was dissolved in ether (700 ml) and a solution of (+)-phenylethylamine (44.5 g) in ether (800 ml) was added cautiously (heat is evolved during the formation of the salt). Crystallization was allowed to take place overnight at a temperature of −15°. The salt crystallized in the form of long thin needles. Acid isolated from the mother liquor of this crystallization had an optical rotation of a_D^{25} −2.2° (undiluted, *l* 1). The salt was recrystallized from successively smaller volumes of ether and the course of the resolution followed by measuring the rotation of acid isolated from the mother liquors. Nine crystallizations were needed before the rotation attained the constant value a_D^{25} −7.80° (undiluted, *l* 1). Decomposition of the salt gave 6.6 g of (−)-methylallylacetic acid of b.p. 87−88° at 12 mm; n_D^{25} 1.4275, n_D^{18} 1.4305; d_4^{25} 0.946; R_D calcd. 31.02, found 31.01.

Optical rotation: a_D^{25} −7.80° (undiluted, *l* 1); $[\alpha]_D^{25}$ −8.25°; $[M]_D^{25}$ −9.41°.

The specimen of the dextrorotatory enantiomer, prepared in the course of the present work had $[\alpha]_D^{25}$ +8.25°. Ställberg-Stenhagen [4] gives a_D^{20} +7.88° (undiluted, *l* 1), which corresponds to $[\alpha]_D^{20}$ +8.28°. Fray and Polgar [5] give $[\alpha]_D^{19}$ +8.24°.

I am indebted to Prof. A. Fredga for placing the (+)-phenylethylamine used at my disposal. The expenses involved in this work were defrayed by a grant from *Statens Medicinska Forskningsråd* to Prof. E. Stenhagen.

α-Keto Acids in Cultures of Lactic and Propionic Acid Bacteria and in some Cheese Varieties

MATTI KREULA and ARTTURI I. VIRTANEN

Laboratory of Valio, Biochemical Institute, Helsinki, Finland

Using the same method (hydrogenolysis of 2,4-dinitrophenylhydrazones with tin in hydrochloric acid solution to the corresponding amino acids and establishing these by paper chromatography) as Alfthan and Virtanen used for the estimation of many new keto acids in plants, the present authors established the α-keto acids shown in Table 1 in cultures of lactic and propionic acid bacteria as well as in some cheese varieties. When determining keto acids in the nutrient and culture solutions, proteins were first removed by adding 10 % solution of sodium tungstate and 2/3 N sulphuric acid in the proportion test solution: tungstate solution:sulphuric acid 2:1:2 (v/v). 200 ml of test solution was generally used. The filtrate was further treated according to Alfthan and Virtanen [1] (*cf.* also Kreula and Virtanen [2]). When investigating cheese, "tear fluid", and yeast, 100 ml of 10 % sodium tungstate and 14 ml of 5 N sulphuric acid were added to 50 g of the substance to be investigated. The mixture was diluted with water to 500 ml, homogenized, and filtered. The filtrate was treated as mentioned in connection with bacterial cultures.

Table 1. The corresponding amino acids of α-keto acids found in bacterial cultures, yeast, and some cheese varieties.

Material	Corresponding amino acids of α-keto acids *
Lactic acid bacteria	
Milk	1, 2, 8, 17
Milk + *Streptococcus thermophilus* (45°C, 1 day)	1, 2, 8, 17
Milk + *Lactobacillus helveticus* (42°C, 1 day)	1, 2, (3), (5), 8, (9), 16, 17
Propionic acid bacteria	
Nutrient solution (whey fermented with *L. helveticus*, addition of chalk, + yeast extract + peptone; pH 6.5)	1, 2, 16, 17
Nutrient solution + *Propionibacterium* V (30°C, 3 days)	2, 3, 7, 16, *17*
Nutrient solution + *Propionibacterium* V (30°C, 3 days)	1, *2*, 7, 16, 17
Nutrient solution + *Propionibacterium* V (30°C, 16 days)	1, 2, 8, 16, 17
Nutrient solution + *Propionibacterium* 101 (30°C, 16 days)	1, 2, 8, 16, 17
Nutrient solution + *Propionibacterium* V (30°C, 29 days)	2, 17
Baker's yeast	1, 2, 8, 17
Cheeses	
Emmental cheese, 3 months old	1, *2*, 8, 16, 17
Emmental cheese, 6 months old	1, 2, 8, 16, 17
Emmental cheese, over 12 months old	1, 2, 3, 5, 8, 16, 17
"Tear fluid" of Emmental cheese	2, 3, 17
Mouldy cheese (Roquefort)	1, 2, 3, 4, 5, 16, 17

* The keto acids are: 1 = glyoxylic acid, 2 = pyruvic acid, 3 = α-keto*iso*valeric acid, 4 = α-keto*iso*capronic acid, 5 = α-ketocapronic acid, 7 = *para*-OH-phenylpyruvic acid, 8 = OH-pyruvic acid, 9 = β-OH-butyric acid, 16 = oxalacetic acid, 17 = α-ketoglutaric acid; italics = +++, parenthesis = +.

As can be seen from Table 1 new keto acids, in addition to 1, 2, 8, and 17, originally found in milk, were not found in the milk culture of *Str. thermophilus*, whereas in the culture of *L. helveticus* small amounts of 3, 5, and 9, and a larger amount of 16 were found. In the culture solution of propionic acid bacteria keto acid 7 was found after 3 days in addition to 1, 2, 16, and 17 which were present in the nutrient solution from the beginning, after 16 days keto acid 8, whereas after 19 days only keto acids 2 and 17 remained.

3- to 6-month-old Emmental cheese contains keto acids 1, 2, 8, 16, and 17; 12-month-old Emmental cheese keto acids 3 and 5 in addition. In the fluid secreted in the eyes of older cheese only keto acids 2, 3, and 17 were found.

In mouldy cheese (Roquefort) keto acids 1, 2, 3, 4, 5, 16, and 17 were found.

Über einen antifungalen Faktor aus den grünen Teilen der Heidelbeerpflanze *(Vaccinium myrtillus)*

K. RAIBLE* und ARTTURI I. VIRTANEN

Laboratorium der Stiftung für chemische Forschung, Biochemisches Institut, Helsinki, Finnland

In früheren Arbeiten aus diesem Laboratorium konnte gezeigt werden, dass alle bisher untersuchten Kulturpflanzen Stoffe enthalten, die das Wachstum des pflanzenpathogenen Pilzes *Fusarium nivale* und vieler anderer Pilze zu hemmen vermögen, und dass mit der Anwesenheit solcher Stoffe die Resistenz bezw. die Anfälligkeit der betreffenden Pflanze gegenüber dem genannten Mikroorganismus erklärt werden kann [1]. Aktive Substanzen sind bisher in reinem Zustand aus jungen Roggen[2]-, Weizen- und Maispflanzen [3] sowie auch aus Rotklee [4] isoliert und chemisch charakterisiert worden. Wir haben in lezter Zeit auch einige wilde Pflanzen auf das Vorkommen antifungaler Substanzen untersucht. In den grünen Teilen der Heidelbeerpflanze *(Vaccinium myrtillus)* haben wir eine ungewöhnlich hohe Aktivität gegen *Fusarium nivale* gefunden. Die Aktivität ist im frischen Laub während der Frühjahrsmonate ebenso nachzuweisen wie in altem Laub und auch in den Stengeln während des Winters, wobei auch stets die Menge an dem aktiven Stoff etwa die gleiche ist. Die antifungale Wirksamkeit 70 % alkoholischer Extrakte (Pressäfte können wegen des geringen Wassergehaltes der Pflanzen meist nur in unzureichendem Mass gewonnen werden) beträgt etwa 15 Einheiten, d.h. aus 1 g Pflanzenmaterial gewonnener Extrakt reicht aus um das Wachstum von *Fusarium nivale* auf 15 ml Hafermehlagarmedium völlig zu hemmen. Zusammensetzung des Mediums: 50 g Hafermehl, 5 ml Glycerin, 1,5 ml Milchsäure, 7 g $KHPO_4$, 35 ml 0,2 M Na_2HPO_4-Lösung, 1 000 ml Wasser. pH des Mediums 4,7—4,8.

Untersuchungen über die Art des antifungalen Faktors ergaben, dass es sich hierbei offenbar um eine gerbstoffartige Substanz oder um ein Gemisch von solchen Stoffen handelt. Der antifungale Faktor ist gut löslich in Wasser, Äthanol, Methanol und Aceton, unlöslich hingegen in wasserfreiem Äther, Petroläther und Benzol. Die Substanz reagiert neutral und passiert daher sowohl den saueren Amberlite-Jonenaustauscher IR 120 als auch die stark basischen Harze IRA 410 und IRA 400.

Aktive Extrakte mit 10—15 Einheiten pro 1 g Pflanzenmaterial konnten erhalten werden beim Variieren der Extraktionsmethoden und -temperaturen wie folgt:

1) 100 g Pflanzenmaterial + 500 ml 60 % Äthanol, 3 Std digeriert, abgepresst, Presskuchen nochmals ebenso behandelt.
2) Wie 1, jedoch 12—14 Std digeriert bei Zimmertemperatur oder bei —5°C.
3) 100 g Pflanzenmaterial + 1 l Methanol 12 und 48 Std digeriert, dann weiter wie bei 1.
4) Wie 3, jedoch Zusatz von 5 und auch 10 g K-metabisulfit (Extrakt vor dem Test selbstverständlich durch sauren und basischen Jonenaustauscher geleitet).

Über einen antifungalen Faktor aus den grünen Teilen der Heidelbeerpflanze *(Vaccinium myrtillus)*

K. RAIBLE* und ARTTURI I. VIRTANEN

Laboratorium der Stiftung für chemische Forschung, Biochemisches Institut, Helsinki, Finnland

In früheren Arbeiten aus diesem Laboratorium konnte gezeigt werden, dass alle bisher untersuchten Kulturpflanzen Stoffe enthalten, die das Wachstum des pflanzenpathogenen Pilzes *Fusarium nivale* und vieler anderer Pilze zu hemmen vermögen, und dass mit der Anwesenheit solcher Stoffe die Resistenz bezw. die Anfälligkeit der betreffenden Pflanze gegenüber dem genannten Mikroorganismus erklärt werden kann [1]. Aktive Substanzen sind bisher in reinem Zustand aus jungen Roggen[2]-, Weizen- und Maispflanzen [3] sowie auch aus Rotklee [4] isoliert und chemisch charakterisiert worden. Wir haben in lezter Zeit auch einige wilde Pflanzen auf das Vorkommen antifungaler Substanzen untersucht. In den grünen Teilen der Heidelbeerpflanze *(Vaccinium myrtillus)* haben wir eine ungewöhnlich hohe Aktivität gegen *Fusarium nivale* gefunden. Die Aktivität ist im frischen Laub während der Frühjahrsmonate ebenso nachzuweisen wie in altem Laub und auch in den Stengeln während des Winters, wobei auch stets die Menge an dem aktiven Stoff etwa die gleiche ist. Die antifungale Wirksamkeit 70 % alkoholischer Extrakte (Pressäfte können wegen des geringen Wassergehaltes der Pflanzen meist nur in unzureichendem Mass gewonnen werden) beträgt etwa 15 Einheiten, d.h. aus 1 g Pflanzenmaterial gewonnener Extrakt reicht aus um das Wachstum von *Fusarium nivale* auf 15 ml Hafermehlagarmedium völlig zu hemmen. Zusammensetzung des Mediums: 50 g Hafermehl, 5 ml Glycerin, 1,5 ml Milchsäure, 7 g $KHPO_4$, 35 ml 0,2 M Na_2HPO_4-Lösung, 1 000 ml Wasser. pH des Mediums 4,7—4,8.

Untersuchungen über die Art des antifungalen Faktors ergaben, dass es sich hierbei offenbar um eine gerbstoffartige Substanz oder um ein Gemisch von solchen Stoffen handelt. Der antifungale Faktor ist gut löslich in Wasser, Äthanol, Methanol und Aceton, unlöslich hingegen in wasserfreiem Äther, Petroläther und Benzol. Die Substanz reagiert neutral und passiert daher sowohl den saueren Amberlite-Jonenaustauscher IR 120 als auch die stark basischen Harze IRA 410 und IRA 400.

Aktive Extrakte mit 10—15 Einheiten pro 1 g Pflanzenmaterial konnten erhalten werden beim Variieren der Extraktionsmethoden und -temperaturen wie folgt:

1) 100 g Pflanzenmaterial + 500 ml 60 % Äthanol, 3 Std digeriert, abgepresst, Presskuchen nochmals ebenso behandelt.
2) Wie 1, jedoch 12—14 Std digeriert bei Zimmertemperatur oder bei —5°C.
3) 100 g Pflanzenmaterial + 1 l Methanol 12 und 48 Std digeriert, dann weiter wie bei 1.
4) Wie 3, jedoch Zusatz von 5 und auch 10 g K-metabisulfit (Extrakt vor dem Test selbstverständlich durch sauren und basischen Jonenaustauscher geleitet).

* Die jetzige Adresse: Deutsche Forschungsanstalt für Lebensmittelchemie, München 23, Leopoldstrasse 175, Deutschland.

5) Wie 3, jedoch Zusatz von 5 g Ascorbinsäure.

6) Wie weiter unten angeführt wird.

Als der einfachste Weg zur Gewinnung weitgehend vorgereinigter Rohkonzentrate erwies sich folgende Arbeitsweise: 1 kg grüne Pflanzenteile werden in 4 l *n*-Butanol mit Hilfe eines Mix-Gerätes zerkleinert und über Nacht bei Zimmertemperatur digeriert. Dann wird abgepresst. Der Presssaft wird verworfen, der Presskuchen einige Stunden in 5 l 70 % Äthanol digeriert. Man presst wiederum ab und erhält eine gelb gefärbte Lösung, die den aktiven Faktor enthält. Sie wird sodann im Vakuum auf etwa 1 l wässerige Lösung konzentriert. Man schickt sie dann durch die Jonenaustauscher IR 120 und IRA 410 oder IRA 400. Sodann wird wiederum im Vakuum konzentriert und schliesslich durch Lyophilisation völlig getrocknet. Man erhält etwa 20 g gelb-braunes, stark hygroskopisches Pulver, das die gesamte Aktivität enthält.

Mit diesem Lyophilisat angestellte Versuche zeigten, dass aus wässerigen Lösungen durch Zugabe von NaCl bis zur Sättigung der grösste Teil der gelösten Stoffe als voluminöser brauner Niederschlag gefällt wird, wobei der aktive Faktor in der Fällung enthalten ist. Pb-Acetat fällt aus 60 % äthanolischer Lösung ebenfalls den grössten Teil der Trockensubstanz und auch den aktiven Faktor. Bei Zusatz von Essigsäure geht die gesamte Fällung wieder in Lösung. Ebenso ist aus alkoholischer Lösung der Hauptteil der Trockensubstanz und des antifungalen Faktors mit K-Acetat fällbar. Aluminium-Oxyd wirkt in wässerigen, alkoholischen und auch essigsäurehaltigen Lösungen stark absorbierend sowohl auf die gesamten gelösten Stoffe als auch auf den antifungalen Faktor.

Bei längerer Aufbewahrung nimmt die antimikrobielle Wirksamkeit des Lyophilisates allmählich ab, wobei auch seine Farbe dunkler wird. Dies ist auch in wässerigen und alkoholischen Lösungen zu beobachten. Alkalische Reaktion fördert diesen Prozess stark. Es ist noch nicht eindeutig geklärt, ob diese Veränderungen allein durch Polymerisations- oder Kondensationsvorgänge bedingt sind, oder ob dabei auch Oxydationsprozesse mitspielen.

Bei chromatographischer Analyse des Lyophilisates auf Whatman-1-Papier ergab lediglich die Anwendung des folgenden Fliessmittels eine Auftrennung: Äthyl-acetat (2 Teile), Eisessig (1 Teil), Wasser (2 Teile), Äthanol (0,35 Teile). Hierbei liess sich bei R_F 0,9 eine abgegrenzte, im UV-Licht hellblau fluorescierende Zone erkennen, gefolgt von einem schwach absorbierenden Schwanz bis R_F etwa 0,2. Beräuchern mit Ammoniak verstärkt die Fluorescenz. Die fluorescierende Zone gibt auf dem Papier folgende Reaktionen: Mit $FeCl_3$ dunkelgrüne Färbung, mit Benzidin-Reagenz erst hell-orange-rote Färbung, die aber rasch etwas dunkler wird, mit ammoniakalischer Silbernitrat-Lösung schwarzbraune Färbung. Im Gegensatz dazu ergibt der Schwanz auf dem Papier mit Eisenchlorid eine blaue Färbung und mit Benzidin eine orange Farbe, wie sie sich bei der fluorescierenden Zone im nachgedunkelten Zustand erst einstellt.

Bei präparativer Chromatographie an der Zellulosesäule mit dem oben angegebenen Fliessmittel konnten wir auch bei sehr schön gleichmässig laufenden Säulen nur eine gewisse Anreicherung der fluorescierenden Substanz erzielen, nicht jedoch deren Isolierung. Es zeigte sich nämlich bei papierchromatographischer Untersuchung, dass alle Fraktionen um R_F 0,9, die allein aus der fluorescierenden Substanz hätten bestehen müssen, auch die nicht fluorescierende, schwanzbildende Substanz mitenthielten. Diese Substanz entsteht wahrscheinlich aus dem fluorescierenden Stoff. Die Ergebnisse des mikrobiologischen Tests lassen darauf schliessen, dass der antifungale Faktor wahrscheinlich nicht die fluorescierende Substanz selbst ist, sondern eines oder mehrere ihrer Umwandlungsprodukte, welche aber auch schon in der Pflanze vorhanden sind.

Alle diese Beobachtungen, sowie eine Reihe weiterer Feststellungen führten zu der bereits ausgesprochenen Annahme, dass der antimikrobiell wirkende Faktor von *Vaccinium myrtillus* ein gerbstoffartiger Stoff ist und vermutlich der Gruppe der nicht hydrolysierbaren oder kondensierten Gerbstoffe angehört (vgl. hierzu Schmidt [5]). Hierfür spricht des weiteren die Feststellung, dass sich bei Hydrolyse des Lyophilisates durch 1 stündiges Kochen in 1 N HCl-Lösung — offenbar durch Polymerisation — lediglich schwarzbraune, wasserunlösliche, amorphe Produkte ohne antimikrobielle Wirksamkeit bilden, in denen sich auch in einer grossen Anzahl verschiedener Fliessmittel auf papierchromatographischem Weg keine irgendwie definierbaren phenolischen oder zuckerartigen Stoffe nachweisen lassen.

Structure of Elastin

1. Analysis of Some Acid Peptides

A. KÄRKELÄ and E. KULONEN

Department of Medical Chemistry, University of Turku, Finland

This preliminary communication is meant to contribute to the discussion on the relations between collagen and elastin. Burton and co-workers [1] claimed, mainly on electronmicroscopic evidence, that collagen is transformed to elastin without being degraded to amino acids. If this theory were correct, the peptides from elastin should present similarities with those known from collagen [2-3].

Elastin was prepared from bovine nuchal ligament. Other non-collagenous proteins were extracted from the finely ground tissue exhaustively with 0.2 M disodium phosphate solution, and collagen subsequently with boiling water for five days.

Partial hydrolysates were made with hydrochloric acid [2] (5 % protein in 4 N acid was kept for a week at +37° C). The acid was removed by repeated evaporations and a sirupy dark-brown mass obtained. It dissolved completely in 10 % trichloroacetic acid. This material was fractionated using the method by Moore and Stein [4] with slight modifications. The resulting curve is presented as Fig. 1.

It is quite obvious that this procedure does not provide a very suitable method for structural analysis of elastin. The separations are not clear and the number of peptides produced seems small.

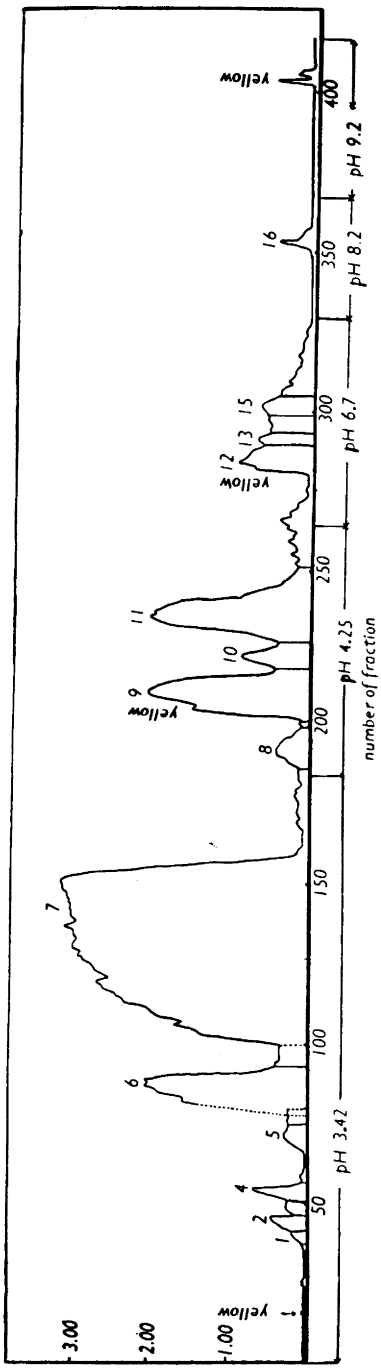

Fig. 1. Fractionation of partial hydrolysate of elastin (360 mg, for preparation see the text) in Dowex-50 column [4]. The last peak was obtained with 0.2 N NaOH. Two-ml fractions were collected (from pH 9.2 onwards 4 ml). The colour was developed from 0.2 ml samples taken from the fractions and the ordinate indicates the extinction in 1 cm cell. The numbers outside the curve refer to the text.

Structure of Elastin

1. Analysis of Some Acid Peptides

A. KÄRKELÄ and E. KULONEN

Department of Medical Chemistry, University of Turku, Finland

This preliminary communication is meant to contribute to the discussion on the relations between collagen and elastin. Burton and co-workers [1] claimed, mainly on electronmicroscopic evidence, that collagen is transformed to elastin without being degraded to amino acids. If this theory were correct, the peptides from elastin should present similarities with those known from collagen [2-3].

Elastin was prepared from bovine nuchal ligament. Other non-collagenous proteins were extracted from the finely ground tissue exhaustively with 0.2 M disodium phosphate solution, and collagen subsequently with boiling water for five days.

Partial hydrolysates were made with hydrochloric acid [2] (5 % protein in 4 N acid was kept for a week at +37° C). The acid was removed by repeated evaporations and a sirupy dark-brown mass obtained. It dissolved completely in 10 % trichloroacetic acid. This material was fractionated using the method by Moore and Stein [4] with slight modifications. The resulting curve is presented as Fig. 1.

It is quite obvious that this procedure does not provide a very suitable method for structural analysis of elastin. The separations are not clear and the number of peptides produced seems small.

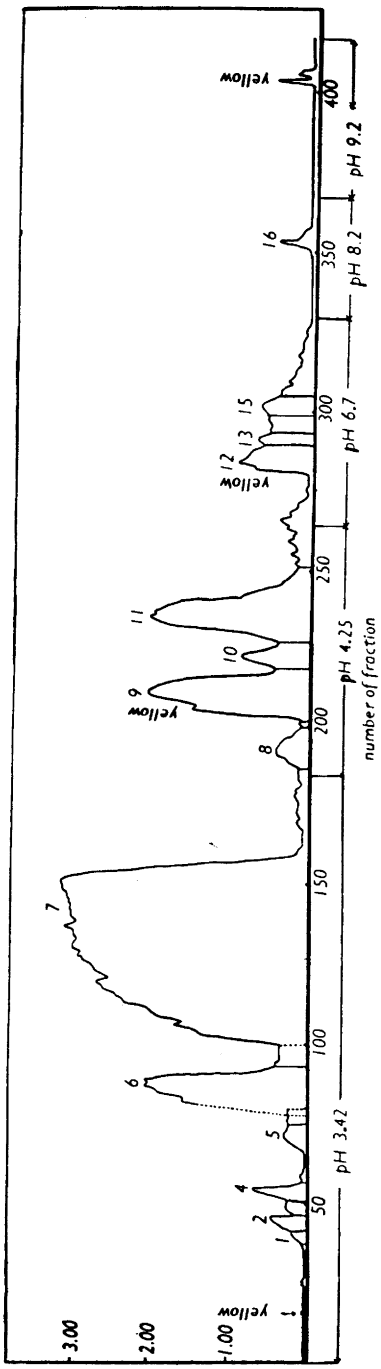

Fig. 1. Fractionation of partial hydrolysate of elastin (360 mg, for preparation see the text) in Dowex-50 column [4]. The last peak was obtained with 0.2 N NaOH. Two-ml fractions were collected (from pH 9.2 onwards 4 ml). The colour was developed from 0.2 ml samples taken from the fractions and the ordinate indicates the extinction in 1 cm cell. The numbers outside the curve refer to the text.

Fractions 6 and 7 were analysed by the dinitrofluorobenzene method following mainly Schroeder's instructions. The chromatography of DNP-compounds was, however, made according to Blackburn and Lowther [5]. The non-terminal amino acids were also converted to DNP-compounds and chromatographed. DNP-proline was identified additionally by the spectrum. All the DNP-amino acids were chromatographed with mixed crystallised references.

The following results could be obtained for peptides eluted at pH 3.42. (The asterisk indicates comparatively small amount.)

Fraction 6, peptide 1*: Glu-(Asp, Gly, Val*, Leu *)
peptide 2: Pro-(Asp, Glu, Gly, Val *, Leu*);

this peptide may be contaminated with another with valine as N-terminal amino acid.

Fraction 7, peptide 1: Gly-(Asp, Glu, Val*, Leu*, Gly?)
peptide 2: Ala-(Asp, Glu, Gly, Val*, Ala?)
peptide 3*: Val-(Asp, Glu, Gly, Ala, Pro)

The remarkable point is the abundance of aspartic and glutamic acids, which are present in small amounts in elastin, and the peptide breaks easily at aspartic acid. Common constituents are in these peptides Asp, Glu, Gly and in traces Val. Further investigation will show whether they form a characteristic sequence. In gelatin this region (pH 3.42) contains only two peptides Ala-Asp and Gly-Asp in quite small amounts, while proline and glycine peptides form the main part of the hydrolysate[2].

The form of the fractionation curve or the composition of the peptides which emerge at pH 3.42 do not support the concept of conversion of collagen to elastin at peptide level.

This work forms a part of a program which is generously supported by the *Finnish Medical Society Duodecim.*

Diamagnetism of LiNO, NaNO and KNO

Studies in Magnetochemistry 19 *

R. W. ASMUSSEN

Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

The direct reaction between sodium metal and nitric oxide results in a reduction of nitric oxide. If, however, the process is carried out in liquid ammonia the result of the reaction is the formation of sodium nitrosyl (NaNO). Joannis [1], who first studied this reaction, prepared the sodium and potassium compounds and considered these substances as hyponitrites. Zintl and Harder [2] reprepared the sodium nitrosyl. Frazer and Long [3] measured the magnetic susceptibility of sodium nitrosyl and state that the compound is diamagnetic but give no numerical value.

The alkali metal nitrosyls are colourless or nearly colourless crystalpowders. The X-ray powder photo of the sodium compound is different from that of anhydrous sodium hyponitrite. The lines are very diffuse, an indexing could not be carried out (cf. also Zintl and Harder [2]). The aqueous solution is not stable; also at 0°C the solution is decomposed under evolution of nitrous oxide. Under corresponding conditions a sodium hyponitrite solution is stable or decomposes very slowly. These facts indicate that the compounds are not $hypo_n$ nitrites but may be considered as $(NaNO)_n$ and $(KNO)_n$. We may propose the ionic structures

$$\overset{+}{Na}(N\overline{O}) \text{ and } \overset{+}{K}(N\overline{O}).$$

* No. 18 of this series: *Acta Chem. Scand.* **11** (1957) 1331.

Fractions 6 and 7 were analysed by the dinitrofluorobenzene method following mainly Schroeder's instructions. The chromatography of DNP-compounds was, however, made according to Blackburn and Lowther [5]. The non-terminal amino acids were also converted to DNP-compounds and chromatographed. DNP-proline was identified additionally by the spectrum. All the DNP-amino acids were chromatographed with mixed crystallised references.

The following results could be obtained for peptides eluted at pH 3.42. (The asterisk indicates comparatively small amount.)

Fraction 6, peptide 1*: Glu-(Asp, Gly, Val*, Leu *)
peptide 2: Pro-(Asp, Glu, Gly, Val *, Leu*);

this peptide may be contaminated with another with valine as N-terminal amino acid.

Fraction 7, peptide 1: Gly-(Asp, Glu, Val*, Leu*, Gly?)
peptide 2: Ala-(Asp, Glu, Gly, Val*, Ala?)
peptide 3*: Val-(Asp, Glu, Gly, Ala, Pro)

The remarkable point is the abundance of aspartic and glutamic acids, which are present in small amounts in elastin, and the peptide breaks easily at aspartic acid. Common constituents are in these peptides Asp, Glu, Gly and in traces Val. Further investigation will show whether they form a characteristic sequence. In gelatin this region (pH 3.42) contains only two peptides Ala-Asp and Gly-Asp in quite small amounts, while proline and glycine peptides form the main part of the hydrolysate[2].

The form of the fractionation curve or the composition of the peptides which emerge at pH 3.42 do not support the concept of conversion of collagen to elastin at peptide level.

Diamagnetism of LiNO, NaNO and KNO

Studies in Magnetochemistry 19 *

R. W. ASMUSSEN

Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

The direct reaction between sodium metal and nitric oxide results in a reduction of nitric oxide. If, however, the process is carried out in liquid ammonia the result of the reaction is the formation of sodium nitrosyl (NaNO). Joannis [1], who first studied this reaction, prepared the sodium and potassium compounds and considered these substances as hyponitrites. Zintl and Harder [2] reprepared the sodium nitrosyl. Frazer and Long [3] measured the magnetic susceptibility of sodium nitrosyl and state that the compound is diamagnetic but give no numerical value.

The alkali metal nitrosyls are colourless or nearly colourless crystalpowders. The X-ray powder photo of the sodium compound is different from that of anhydrous sodium hyponitrite. The lines are very diffuse, an indexing could not be carried out (cf. also Zintl and Harder [2]). The aqueous solution is not stable; also at 0°C the solution is decomposed under evolution of nitrous oxide. Under corresponding conditions a sodium hyponitrite solution is stable or decomposes very slowly. These facts indicate that the compounds are not $hypo_n$ nitrites but may be considered as $(NaNO)_n$ and $(KNO)_n$. We may propose the ionic structures

$$\overset{+}{Na}(N\overline{O}) \text{ and } \overset{+}{K}(N\overline{O}).$$

* No. 18 of this series: *Acta Chem. Scand.* **11** (1957) 1331.

Since $N\bar{O}$ and O_2 are isosteres it is possible that the ground state of the $N\bar{O}$-ion is a triplet state. This state gives a magnetic moment $\mu = 2.83\ \mu_B$. In order to settle this question the metal nitrosyls LiNO, NaNO and KNO were prepared and measured magnetically; LiNO was prepared for the first time. The results of the chemical analyses and the magnetic measurements are given in Table 1. The results prove that $N\bar{O}$ is in a singlet state — if present in these compounds.

Table 1. Analyses and diamagnetic susceptibilities of alkali metal nitrosyls.

Substance	% Metal calc.	% Metal found	$\chi_g \times 10^6$	$\chi_M \times 10^6$	$\chi_{N\bar{O}} \times 10^6$
LiNO	18.78	18.50	-0.56_2	−20.8	−20.1
NaNO	43.37	42.98	-0.40_0	−21.2	−17.2
KNO	56.57	56.42	-0.46_4	−32.1	−18.1

The metals were determined as sulphates. The metal nitrosyls were measured magnetically in evacuated glass tubes (Gouy method) at 20—22°C.

The gram ionic susceptibilities for NO^- were calculated from the χ_M values by means of the gram ionic susceptibilities -0.7×10^{-6}, -4×10^{-6} and -14×10^{-6} for the ions Li^+, Na^+ and K^+, respectively. *A reasonable mean value for the gram ionic susceptibility of* NO^- *is* -18×10^{-6}. This number is calculated from the 3 values in Table 1 giving the values for NaNO and KNO double weight because the analytical data for these substances are in better accordance with the theoretical values than is the case for LiNO.

On the Existence of Oscillating Enzymatic Reactions and on a Possible Interpretation of Spontaneous Spike Potentials in Nerves

J. A. CHRISTIANSEN

Københavns Universitets Fysisk-Kemiske Institut, Copenhagen, Denmark

An overall reaction

$$A_1 + A_2 + A_3 \rightleftharpoons B_2 + B_3 + B_1 \qquad (B)$$

is supposed to be catalyzed by an enzyme according to the mechanism (A)

$$\begin{aligned} A_1 + X_1 &\rightleftharpoons X_2 + B_2 \quad (\pm 1) \\ A_2 + X_2 &\rightleftharpoons X_3 + B_3 \quad (\pm 2) \\ A_3 + X_3 &\rightleftharpoons X_1 + B_1 \quad (\pm 3) \end{aligned} \qquad (A)$$

where X_1, X_2, X_3 are three different forms of the enzyme or complexes thereof with the substrates (A_i, B_i). The sum of the concentrations of the three forms is the total constant enzyme concentration E, which is supposed to be stoichiometrically small as compared to the concentrations of the substrates. Let x_1, x_2 and x_3 be the fractions of the enzyme present in the three states, and let s_1, s_2 and s_3 be the resulting rates of the three partial reactions, divided by E.

We then have the four equations

$$\begin{aligned} x_1 w_1 - x_2 w_{-2} &= s_1 \\ x_2 w_2 - x_3 w_{-3} &= s_1 \\ x_3 w_3 - x_1 w_{-1} &= s_2 \end{aligned} \qquad (1)$$

$$x_1 + x_2 + x_3 = 1 \qquad (2)$$

where w_1 is the probability in unit time for X_1 to react according to $(+1)$ in (A), w_{-1} the probability for X_2 to react with B_2 according to (-1) in (A), *etc.*

The steady state solution of the system (1) in connection with the condition (2) is well known [12]. It is characteristic for this, that if the probabilities w are exactly known the result of the calculation is of unlimited accuracy.

There exists, however, another solution of (1) and (2) for which this is not true in so far as in this case the (weighted) sums of the squared deviations from mean values have well defined constant values, different from zero.

This solution seems therefore to be inherently more probable than the usual one.

Since $N\bar{O}$ and O_2 are isosteres it is possible that the ground state of the $N\bar{O}$-ion is a triplet state. This state gives a magnetic moment $\mu = 2.83\ \mu_B$. In order to settle this question the metal nitrosyls LiNO, NaNO and KNO were prepared and measured magnetically; LiNO was prepared for the first time. The results of the chemical analyses and the magnetic measurements are given in Table 1. The results prove that $N\bar{O}$ is in a singlet state — if present in these compounds.

On the Existence of Oscillating Enzymatic Reactions and on a Possible Interpretation of Spontaneous Spike Potentials in Nerves

J. A. CHRISTIANSEN

Københavns Universitets Fysisk-Kemiske Institut, Copenhagen, Denmark

An overall reaction

$$A_1 + A_2 + A_3 \rightleftharpoons B_2 + B_3 + B_1 \qquad (B)$$

is supposed to be catalyzed by an enzyme according to the mechanism (A)

$$\begin{aligned} A_1 + X_1 &\rightleftharpoons X_2 + B_2 \quad (\pm 1) \\ A_2 + X_2 &\rightleftharpoons X_3 + B_3 \quad (\pm 2) \\ A_3 + X_3 &\rightleftharpoons X_1 + B_1 \quad (\pm 3) \end{aligned} \qquad (A)$$

where X_1, X_2, X_3 are three different forms of the enzyme or complexes thereof with the substrates (A_i, B_i). The sum of the concentrations of the three forms is the total constant enzyme concentration E, which is supposed to be stoichiometrically small as compared to the concentrations of the substrates. Let x_1, x_2 and x_3 be the fractions of the enzyme present in the three states, and let s_1, s_2 and s_3 be the resulting rates of the three partial reactions, divided by E.

We then have the four equations

$$\begin{aligned} x_1 w_1 - x_2 w_{-2} &= s_1 \\ x_2 w_2 - x_3 w_{-3} &= s_1 \\ x_3 w_3 - x_1 w_{-1} &= s_2 \end{aligned} \qquad (1)$$

$$x_1 + x_2 + x_3 = 1 \qquad (2)$$

where w_1 is the probability in unit time for X_1 to react according to $(+1)$ in (A), w_{-1} the probability for X_2 to react with B_2 according to (-1) in (A), *etc.*

The steady state solution of the system (1) in connection with the condition (2) is well known [12]. It is characteristic for this, that if the probabilities w are exactly known the result of the calculation is of unlimited accuracy.

There exists, however, another solution of (1) and (2) for which this is not true in so far as in this case the (weighted) sums of the squared deviations from mean values have well defined constant values, different from zero.

This solution seems therefore to be inherently more probable than the usual one.

The essential points in the derivation are: 1) the introduction of a system of "weights" m_1, m_2 and m_3; 2) the description of the deviations as vectors.

The weights are defined in terms of the w's by the "auxiliary equations" (3).

$$\begin{aligned} m_1w_1 - m_3w_{-3} &= 1 \\ m_2w_2 - m_1w_{-1} &= 1 \\ m_3w_3 - m_2w_{-2} &= 1 \end{aligned} \tag{3}$$

whose solutions may be written in the form (4)

$$\begin{aligned} (1-\beta)m_1w_1 &= 1 + \beta_2\beta_3 + \beta_3 \\ (1-\beta)m_2w_2 &= \beta_1 + 1 + \beta_3\beta_1 \\ (1-\beta)m_3w_3 &= \beta_1\beta_2 + \beta_2 + 1 \end{aligned} \tag{4}$$

where $\beta_i = w_{-i}/w_i$ and $\beta = \beta_1\beta_2\beta_3$

If β is small as compared to 1 the overall reaction (B) is irreversible, which we shall assume.

We define further a set g_1, g_2 and g_3 of pure numbers by

$$g_1 = m_iw_i - 1/2 \tag{5}$$

The calculations which will be published later, then lead to the following description of the deviations of x_1, x_2 and x_3 from their mean values λ_1, λ_2 and λ_3.

1) Draw a triangle with the sides λ_1, λ_2 and λ_3 where

$$\begin{aligned} \lambda_1 &= A\sqrt{g_2 + g_3} \\ \lambda_2 &= A\sqrt{g_3 + g_1} \\ \lambda_3 &= A\sqrt{g_1 + g_2} \end{aligned} \tag{6}$$

A is determined by the condition that the perimeter of the triangle $\lambda_1 + \lambda_2 + \lambda_3$ shall equal 1.

2) Project the sides of the triangle on a pointer which rotates in the direction 123 with the constant angular velocity $2\pi\nu$.

These projections then represent the (real) deviations from the fixed values λ_1, λ_2 and λ_3, respectively. The (real) sum of the deviations is evidently zero, but separately at most one of them can be zero at a certain time.

To calculate ν we use the relations

$$\begin{aligned} dq_1/dt &= \sigma_3 - \sigma_1 \\ dq_2/dt &= \sigma_1 - \sigma_2 \\ dq_3/dt &= \sigma_2 - \sigma_3 \end{aligned} \tag{7}$$

and their complex conjugates. q_1 is the (complex) deviation of x_i from λ_i and σ_i the (complex) deviation of s_i from s. Eqns. (7) follow directly from the law of conservation of matter.

(By use of (3) and the condition (2) it can be shown that

$$m_1s_1 + m_2s_2 + m_3s_3 = s(m_1 + m_2 + m_3) = 1 \tag{8}$$

The first equation (8) shows that s is the weighted mean of the different possible values of s_i and the second that this mean is exactly the steady state value. It should be noted that our mean values λ are different from the usual steady state values, the reason being that the system is never in its steady state.

The real frequency ν can then be calculated from

$$8\pi g\nu = (g_1+g_2)/m_1 + (g_2+g_3)/m_3 + (g_3+g_1)/m_3 \tag{9}$$

where

$$g^2 = g_1g_2 + g_2g_3 + g_3g_1 \tag{10}$$

By use of (5) eqn. (9) may be simplified into

$$8\pi g\nu = (w_1+w_{-1}+w_2+w_{-2}+w_3+w_{-3}) \tag{11}$$

Finally to arrive at the actual values of x_1, x_2 and x_3 we simply add to the sides of the fixed triangle λ_1, λ_2, λ_3 the respective varying deviations from our geometrical construction. The sum of the resulting lengths will then be constant, but they will vary periodically with time. The lengths separately will represent the distribution on the different forms of the enzymes at different times. Considering x_1 it will be seen that it performs harmonic oscillations between zero and $2\lambda_1$, and similarly for the others, but the oscillations are never in the same phase.

Now these oscillations may be registered by an oscillograph as spike potentials [3-5] if the enzymatic system is electrochemically active.

The source of the periodically occurring potentials is usually believed to be located in some "end-organ" from which they are transmitted through the nerve.

Such spike-potentials may perhaps not be expected to be generally observable in vessels of macroscopic dimension as the whole spectrum then may be diffuse. This is because of the vague definition of time "zero" in such cases. But in nerves whose diameters are of the order of magnitude 1 μ no such difficulty arises. It may therefore be, that we should assume the presence of an enzyme which catalyses some irreversible process, perhaps in the membrane of the end-organ or / and of the nerve.

On Hydroxylamine Compounds in *Azotobacter* Cultures. I. Formation of Hydroxylamine Compounds

NILS-ERIK SARIS and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Blom [1] was the first to demonstrate small amounts of hydroxylamine in nitrogen-fixing *Azotobacter* cultures, and later on bound hydroxylamine was found by Endres [2]. Hydroxylamine was formed only from nitrate or molecular nitrogen but not from ammonium nitrogen. On the other hand Virtanen and Hakala [3] observed that about the same amount of bound hydroxylamine was found in the nutrient solutions of *Azotobacter vinelandii* both when nitrate nitrogen, ammonium nitrogen, and molecular nitrogen were the sources of nitrogen. Virtanen and Järvinen [4] investigated the formation of bound hydroxylamine in the cell suspension of *Azotobacter vinelandii* and found that it was formed both from N_2-, NO_3-, and NH_4-N, although more rapidly from molecular nitrogen and nitrate nitrogen than from ammonium nitrogen. These authors determined bound hydroxylamine in the cell mass separated by centrifugation.

The present authors have now further studied the formation of hydroxylamine compounds found in the nutrient solution of *Azotobacter*. Under the experimental conditions used the enrichment of hydroxylamine compounds in cells was too scant to make a closer investigation of these compounds possible. On the other hand bound hydroxylamine was enriched in the nutrient solution in such amounts that a closer investigation of them could be attempted.

Nutrient solution. 1.5 g Burk's salt, 10 mg $Fe_2(SO_4)_3$, 15 mg $FeSO_4$, $7H_2O$, 0.25 mg Na_2MoO_4 per litre, pH 7.2. In the experiments proper glycerol was the source of carbon (*cf.* below); the source of nitrogen is mentioned in connection with the experimental results.

Determination of bound hydroxylamine. Csáky's method was used, with the modification that the hydrolysis time was shortened to one hour. To destroy nitrite a pinch of urea was added. Determinations were made both from 2 and 10 ml.

Azotobacter strain. In preliminary experiments the largest amount of bound hydroxylamine was found in cultures of *Azotobacter chroococcum* K 1. In cultures of other investigated strains (*A. vinelandii* Kluyver, *vinogradsky* Kluyver, *beijerinckii*, and a not closer characterized strain isolated from soil) a much smaller amount of bound hydroxylamine, if any, was enriched.

Effect of the carbon source. Because Endres obtained the largest amount of bound hydroxylamine when lactate was the source of carbon, growth experiments were performed with different carbon compounds (glycerol, Ca-lactate, saccharose, ethanol, acetone, sorbitol). In the concentrations investigated glycerol was as good a carbon source as lactate, and it was used in the experiments proper. The large amounts of hydroxylamine found by Endres in lactate nutrient solutions were not, however, even approximately obtained. He found maximum 2×10^{-4} mole NH_2OH per 10 ml, the present authors about 10^{-5} only. This circumstance made the isolation of hydroxylamine compounds and their characterization difficult.

Cultivation methods. Method 1. Azotobacter was allowed to grow without shaking in 1 litre flat flasks containing 200 ml of nutrient solution each. 200 ml of nutrient solution without combined nitrogen was inoculated with 2.5 ml of a 4-day-old *Azotobacter* culture. The experiment was terminated after 3 days, the maximum amount of bound hydroxylamine being then found in the solution. The influence of the age of the cultures on the content of bound hydroxylamine in the nutrient solution can be seen from the following results with *Azotobacter chroococcum* K 1:

1. Christiansen, J. A. *Acta Chem. Scand.* **3** (1949) 493.
2. Christiansen, J. A. *Advances in Catalysis* **5** (1953) 311.
3. Loewenstein, O. and Sand, A. *J. Exptl. Biol.* **13** (1936) 416.
4. Sand, A. *Proc. Roy. Soc. London* **B 125** (1938) 524.

On Hydroxylamine Compounds in *Azotobacter* Cultures. I. Formation of Hydroxylamine Compounds

NILS-ERIK SARIS and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Blom [1] was the first to demonstrate small amounts of hydroxylamine in nitrogen-fixing *Azotobacter* cultures, and later on bound hydroxylamine was found by Endres [2]. Hydroxylamine was formed only from nitrate or molecular nitrogen but not from ammonium nitrogen. On the other hand Virtanen and Hakala [3] observed that about the same amount of bound hydroxylamine was found in the nutrient solutions of *Azotobacter vinelandii* both when nitrate nitrogen, ammonium nitrogen, and molecular nitrogen were the sources of nitrogen. Virtanen and Järvinen [4] investigated the formation of bound hydroxylamine in the cell suspension of *Azotobacter vinelandii* and found that it was formed both from N_2-, NO_3-, and NH_4-N, although more rapidly from molecular nitrogen and nitrate nitrogen than from ammonium nitrogen. These authors determined bound hydroxylamine in the cell mass separated by centrifugation.

The present authors have now further studied the formation of hydroxylamine compounds found in the nutrient solution of *Azotobacter*. Under the experimental conditions used the enrichment of hydroxylamine compounds in cells was too scant to make a closer investigation of these compounds possible. On the other hand bound hydroxylamine was enriched in the nutrient solution in such amounts that a closer investigation of them could be attempted.

Nutrient solution. 1.5 g Burk's salt, 10 mg $Fe_2(SO_4)_3$, 15 mg $FeSO_4$, $7H_2O$, 0.25 mg Na_2MoO_4 per litre, pH 7.2. In the experiments proper glycerol was the source of carbon (*cf.* below); the source of nitrogen is mentioned in connection with the experimental results.

Determination of bound hydroxylamine. Csáky's method was used, with the modification that the hydrolysis time was shortened to one hour. To destroy nitrite a pinch of urea was added. Determinations were made both from 2 and 10 ml.

Azotobacter strain. In preliminary experiments the largest amount of bound hydroxylamine was found in cultures of *Azotobacter chroococcum* K 1. In cultures of other investigated strains (*A. vinelandii* Kluyver, *vinogradsky* Kluyver, *beijerinckii*, and a not closer characterized strain isolated from soil) a much smaller amount of bound hydroxylamine, if any, was enriched.

Effect of the carbon source. Because Endres obtained the largest amount of bound hydroxylamine when lactate was the source of carbon, growth experiments were performed with different carbon compounds (glycerol, Ca-lactate, saccharose, ethanol, acetone, sorbitol). In the concentrations investigated glycerol was as good a carbon source as lactate, and it was used in the experiments proper. The large amounts of hydroxylamine found by Endres in lactate nutrient solutions were not, however, even approximately obtained. He found maximum 2×10^{-4} mole NH_2OH per 10 ml, the present authors about 10^{-5} only. This circumstance made the isolation of hydroxylamine compounds and their characterization difficult.

Cultivation methods. Method 1. Azotobacter was allowed to grow without shaking in 1 litre flat flasks containing 200 ml of nutrient solution each. 200 ml of nutrient solution without combined nitrogen was inoculated with 2.5 ml of a 4-day-old *Azotobacter* culture. The experiment was terminated after 3 days, the maximum amount of bound hydroxylamine being then found in the solution. The influence of the age of the cultures on the content of bound hydroxylamine in the nutrient solution can be seen from the following results with *Azotobacter chroococcum* K 1:

Time after inoculation, days	1	2	3	4	5	6
Cells formed, mg/10 ml	0	30	120	165	190	205
NH_2OH after hydrolysis, μg N/10 ml	0	0.54	1.40	0.95	0.30	0

The effect of the nitrogen source on the enrichment of hydroxylamine compounds in the nutrient solution was determined after 3 days of growth in glycerol nutrient solutions in which KNO_3, $(NH_4)_2CO_3$, urea, or N_2 (without combined nitrogen) were the sources of nitrogen. The amount of each nitrogen compound used was 60 mg N per 200 ml nutrient solution. The results can be seen in Table 1.

Table 1. Effect of the nitrogen source on the enrichment of bound hydroxylamine in the nutrient solution of *A. chroococcum.*

Nitrogen nutrition	NH_2OH-N μg/10 ml	Cells mg/10 ml	Assimilated N mg/10 ml	Excret. total N mg/10 ml
N_2	1.46	160	2.15	0.08
KNO_3	1.04	85	1.23	—
$(NH_4)_2CO_3$	1.80	40	0.52	—
$CO(NH_2)_2$	1.62	140	2.05	—

Method 2. 1 Litre Kluyver flasks contained 200 ml of the above-mentioned nutrient solution. A vigorous current of air was passed through the solution after addition of bacterial mass. Under these conditions hydroxylamine was accumulated in the solution only when a large amount of bacteria was suspended in the nutrient solution.

The bacterial mass used was separated by centrifugation from two-days-old liquid cultures and suspended into the nutrient solution using a Waring-Blendor homogenisator. 250 mg of *Azotobacter* mass were added to each nutrient solution. KNO_3 (60 mg N/200 ml), urea (60 mg N/200 ml), and N_2 (no combined nitrogen in the nutrient solution) were the sources of nitrogen. The results can be seen in Fig. 1.

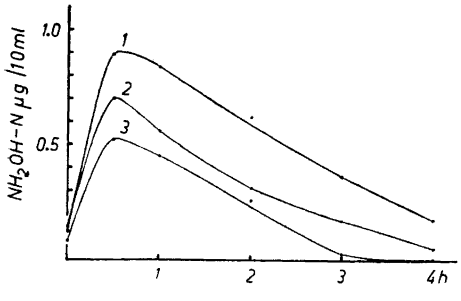

Fig. 1. Bound hydroxylamine in a vigorously aerated suspension of *A. chroococcum* in nutrient solutions with potassium nitrate (1), molecular nitrogen (2), and urea (3) as nitrogen source.

The results recorded above show that bound hydroxylamine, accumulated in the nutrient solution, disappears from flask cultures after the 4th day and from aerated suspensions of bacteria within a few hours. This disappearance may depend on assimilation or decomposition of the substance in the nutrient solution. It was also found that the yield of hydroxylamine decreases when the pH falls below 7.3. Hydroxylamine compounds were not demonstrable in cultures with a pH below 6.8.

In order to find out to what extent bound hydroxylamine, accumulated in the nutrient solution, disappears in a vigorously aerated suspension at different pH values, a fraction containing bound hydroxylamine, separated with Amberlite IR-120, was added to two suspensions of *A. chroococcum* K 1 in the nutrient solution. The pH of the one solution was regulated to 7.3 and that of the other to 6.5. An equally strong current of air was

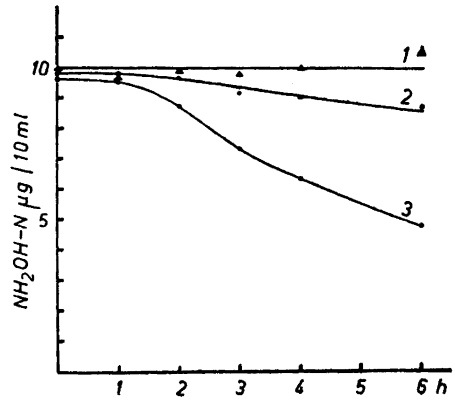

Fig. 2. Disappearance of added hydroxylamine fraction without *Azotobacter* (1), with *Azotobacter* suspension, pH 6.5 (2), and with *Azotobacter* suspension, pH 7.3 (3).

passed through both suspensions in a Kluyver flask. In the control the nutrient solution containing the hydroxylamine fraction but no bacteria was aerated. The results can be seen in Fig. 2.

These results indicate that the hydroxylamine fraction is stable without *Azotobacter* during the experimental period, *i. e.* for 6 h, and that in experiments with *Azotobacter* bound hydroxylamine disappears much faster at pH 7.3 than at pH 6.5. The results suggest accordingly that the absence of bound hydroxylamine in *Azotobacter* cultures at pH 6.5 is due to a reduced formation of hydroxylamine compounds.

Since hydroxylamine compounds are formed in our *Azotobacter* cultures from NH_4—N as rapidly as from N_2, and identical compounds seem to be in question (*cf.* paper II), there is no evidence any longer of an oxidative step in aerobic N_2 fixation. On the basis of their results with *Clostridium* Virtanen and Hakala [5] years ago suggested that N_2 fixation by anaerobic organisms is a pure reduction, di-imide being the first intermediate, and the same mechanism can now be suggested also for aerobic N_2 fixation.

On Hydroxylamine Compounds in *Azotobacter* Cultures. II. On the Chemical Nature of the Bound Hydroxylamine Fraction in *Azotobacter* Cultures

NILS-ERIK SARIS and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In the previous communication [1] it was reported that bound hydroxylamine was accumulated in the nutrient solution of *Azotobacter*. Attempts to isolate and characterize these hydroxylamine compounds are reported in this paper.

Behaviour on ion exchange columns. Bound hydroxylamine from the nutrient solution passed through a slightly basic resin (Amberlite IR-4B), but was absorbed by a strongly basic one (IR-400). It was eluted quantitatively with diluted acetic or formic acid from the latter. On the other hand it was also absorbed almost quantitatively by acid resins from more concentrated solutions. Only some per cent of the total bound hydroxylamine passed through the Amberlite IR-120 column. From this column the amino acids and part of the hydroxylamine compounds could be eluted by 1 N ammonia, the latter compounds quantitatively only with 10 % ammonia. Paper chromatographic characteristics showed that the bound hydroxylamine eluted together with amino acids by dilute ammonia was similar to that eluted by more concentrated ammonia.

Separation of the bound hydroxylamine absorbed by the Amberlite IR-120 column. The fraction obtained from the glycerol cultures (N_2 as source of nitrogen) of *Azotobacter* was investigated by paper chromatography. The fraction was obtained by evaporating the culture solution to a small volume *in vacuo*, precipitating mucous substances with ethanol, evaporating ethanol *in vacuo* from the clear solution, passing the solution through the Amberlite IR-120 column, eluting the column

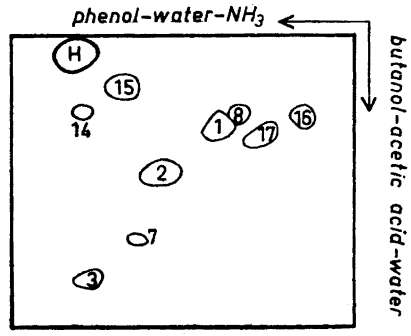

Fig. 1. Two-dimensional run of amino acids and bound hydroxylamine (formed in the culture solution of *A. chroococcum* K 1 grown in glycerol-flask-cultures for 3 days) after absorption in Amberlite IR-120 resin and elution with 1 N ammonia. On Hydroxylamine Compounds in *Azotobacter* Cultures. II. On the Chemical Nature of the Bound Hydroxylamine Fraction in *Azotobacter* Cultures

NILS-ERIK SARIS and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In the previous communication [1] it was reported that bound hydroxylamine was accumulated in the nutrient solution of *Azotobacter*. Attempts to isolate and characterize these hydroxylamine compounds are reported in this paper.

Behaviour on ion exchange columns. Bound hydroxylamine from the nutrient solution passed through a slightly basic resin (Amberlite IR-4B), but was absorbed by a strongly basic one (IR-400). It was eluted quantitatively with diluted acetic or formic acid from the latter. On the other hand it was also absorbed almost quantitatively by acid resins from more concentrated solutions. Only some per cent of the total bound hydroxylamine passed through the Amberlite IR-120 column. From this column the amino acids and part of the hydroxylamine compounds could be eluted by 1 N ammonia, the latter compounds quantitatively only with 10 % ammonia. Paper chromatographic characteristics showed that the bound hydroxylamine eluted together with amino acids by dilute ammonia was similar to that eluted by more concentrated ammonia.

Separation of the bound hydroxylamine absorbed by the Amberlite IR-120 column. The fraction obtained from the glycerol cultures (N_2 as source of nitrogen) of *Azotobacter* was investigated by paper chromatography. The fraction was obtained by evaporating the culture solution to a small volume *in vacuo*, precipitating mucous substances with ethanol, evaporating ethanol *in vacuo* from the clear solution, passing the solution through the Amberlite IR-120 column, eluting the column

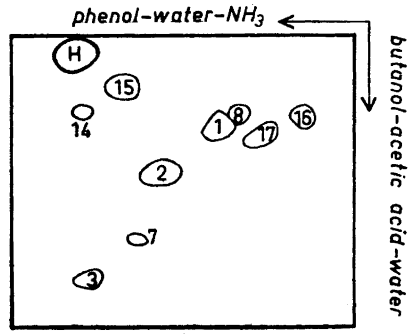

Fig. 1. Two-dimensional run of amino acids and bound hydroxylamine (formed in the culture solution of *A. chroococcum* K 1 grown in glycerol-flask-cultures for 3 days) after absorption in Amberlite IR-120 resin and elution with 1 N ammonia. H = bound hydroxylamine (a weak greyish spot with ninhydrin), 1 = gly, 2 = ala, 3 = val, 7 = tyr, 8 = ser, 14 = arg, 15 = lys, 16 = asp, 17 = glu.

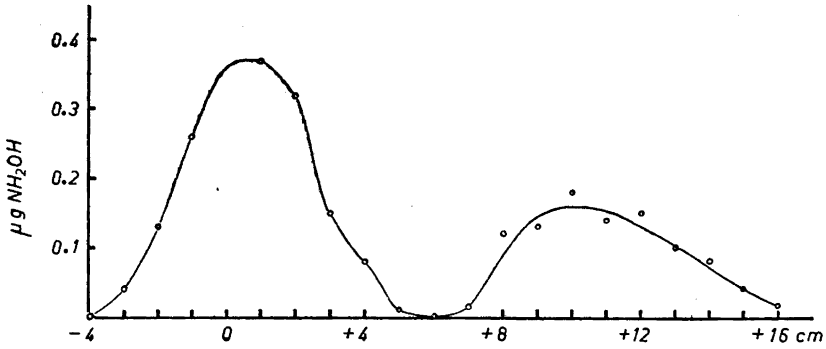

Fig. 2. Paper electrophoresis of bound hydroxylamine, pH 6.5, pyridine-acetic acid buffer, 1 000 V, 10 mA, 4 h.

with 10 % ammonia, upon which both amino acids and bound hydroxylamine went into solution quantitatively, and evaporating ammonia *in vacuo*. Phenol-water-ammonia and butanol-acetic acid-water were used as solvents. In a one-dimensional run the paper sheets were cut crosswise into narrow strips and hydroxylamine was determined from the water extracts after hydrolysis. The following R_F-values for bound hydroxylamine were found: 0.8 with phenol-water-ammonia, ~0.02 with butanol-acetic acid-water as solvents. (In parallel runs made for comparison the R_F-values for β-aspartylhydroxamic and γ-glutamylhydroxamic acids with butanol-acetic acid as solvents were 0.09 and 0.15.) Fig. 1 shows the position of bound hydroxylamine on a two-dimensional paper chromatogram. Independently of the nitrogen source (N_2-, NH_4-, NO_3—N) the same bound hydroxylamine spot was found on paper chromatograms. The spot was slightly ninhydrin positive and could thus be seen on the same chromatogram as the amino acids. No red colour was formed with ferric chloride, which indicates that simple aminohydroxamic acids were not in question. It was generally found that in the position for bound hydroxylamine a faint yellow colour was to be seen before ninhydrin spraying.

The bound hydroxylamine found in the culture solutions of *Azotobacter* cells grown with different nitrogen nutrition (N_2, NO_3^-, NH_4^+) behaved in much the same way on ion exchangers. On reduction with sodium amalgam amino acids were not formed from the bound hydroxylamine which had passed through the Amberlite IR-120 column, and hence the oximes of keto acids were not found in this fraction. This fraction, the quantity of which varied in different experiments generally constituting only a few per cent of the total bound hydroxylamine, was not closer investigated.

It is remarkable that from a one-dimensional paper chromatogram a thorough extraction brought only about 20 % of the bound hydroxylamine originally placed on the paper into water solution and about 30 % into water containing ammonia.

Bound hydroxylamine was freed from amino acids in the cellulose powder column using butanol-acetic acid as solvent. Bound hydroxylamine travelled slowest (*cf.* above), and the yellow colour made it easy to follow its run. It cannot be said for certain if the colour belongs to the hydroxylamine fraction or if it is only an impurity in this fraction. Generally it was found, however, that there was some parallelism between the yellow colour and the content of bound hydroxylamine in *Azotobacter* cultures.

On hydrolysis with 6 N HCl two unknown amino acids were formed from the bound hydroxylamine fraction and in addition glutamic acid and smaller amounts of glycine, serine, alanine, valine, and *iso*leucine. On a two-dimensional paper chromatogram the unknown amino acids travelled slowly both in phenol and butanol-acetic acid and formed one spot, provided that the run with butanol-acetic acid was not continued for 4 to 5 days. In the latter case the spot divided into two. The faster travelling spot was chromatographically identical with synthetic hydroxyaspartic acid (R_F 0.05 in both solvents). When this spot was cut off from the paper and the water extract reduced with HI and red phosphorus, mainly aspartic acid, but also small amounts of glycine, serine and alanine were formed, *i. e.* the same products as from syn-

thetic hydroxyaspartic acid. On the basis both of chromatographic behaviour and reduction products it can be regarded as proved that the amino acid studied is hydroxyaspartic acid.

The spot which travelled slower in butanol-acetic acid (R_F ~0.04) gave on reduction with HI and phosphorus glutamic acid and in addition glycine, serine, and alanine. It may be dihydroxyglutamic acid, but this cannot be regarded as proved.

Because there was no proof of the homogeneity of the isolated bound hydroxylamine fraction, it was subjected to paper electrophoresis (pyridine-acetic acid buffer, 1 000 V, 10 mA, pH 6.5, 4 h). Upon this bound hydroxylamine divided into two fractions, one of which behaved neutral and the other slightly basic (Fig. 2). On hydrolysis the neutral fraction gave hydroxyaspartic acid, glutamic acid, and alanine (in addition traces of valine and leucine), the basic fraction again the other unknown amino acids and besides the same amino acids as the neutral one. From the results it can be concluded that there are two hydroxylamine compounds, one giving hydroxyaspartic acid on hydrolysis, the other a still slower in butanol-acetic acid moving acidic amino acid (*cf.* above). If the components separated by electrophoresis are homogeneous they may be polypeptides, in which hydroxylamine is perhaps bound to one amino acid. The small amount of hydroxylamine formed on hydrolysis of these compounds — only about 1.5 % of the total N — arouses, however, the suspicion that the electrophoretically separated fractions may contain peptides as foreign substances. If this is the case nothing can be said about the chemical nature of the hydroxylamine compounds. Attention should, however, be called to the fact that hydroxyaspartic acid and another not fully characterized acid amino acid apparently belong to bound hydroxylamine in some way, since in *Azotobacter* cultures in which bound hydroxylamine was not formed, these amino acids were not found either.

A further elucidation of the problem demands more material and, accordingly, cultivation of *Azotobacter* on a larger scale. In any case it was proved that structurally complicated hydroxylamine compounds are accumulated in the culture solution of *Azotobacter;* that these compounds can be separated from amino acids by chromatography, and from each other by electrophoresis; that hydroxyaspartic acid is formed from one of these compounds on total hydrolysis and another not fully characterized amino acid from the other. In addition to these glutamic acid and alanine were formed from both.

X-Ray Crystallographic Data on Miscellaneous Sulphur Compounds

OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

The unit cells and space groups of the following derivatives of divalent sulphur, selenium and tellurium were determined some years ago in the course of crystal structure work on analogous compounds, and have not been published before. The data were derived from oscillation and Weissenberg photographs on single-crystal specimens, using iron radiation, $\lambda(\mathrm{Fe}K\alpha) = 1.934$ Å, and in one case (tellurium dibenzenethiosulphonate) copper radiation, $\lambda(\mathrm{Cu}K\alpha) = 1.542$ Å.

Tellurium dimethylxanthate [1], $\mathrm{Te(S_2C\text{-}OCH_3)_2}$. Monoclinic prismatic, $a = 4.24$ Å, $b = 14.18$ Å, $c = 17.28$ Å, $\beta = 93°$. There are four molecules per unit cell; density, calc. 2.19, found 2.18 g/cm³. The space group, from systematic absences, is $C_{2h}^5 - P2_1/c$.

The crystals occur as brownish red prisms, extended along [100] and with {001} dominant. The repeat distance along the a axis, 4.24 Å, is shorter than twice the value, 2.2 Å, listed by Pauling [2] for the van der Waals radius of tellurium, but is not in discord with Briegleb's value [3], 1.9 Å, or with the non-bonded Te-Te approaches of 4.18 Å and 4.28 Å, respectively, found in *p,p'*-dichlorodiphenyl ditelluride [4] and monoclinic barium telluropentathionate dihydrate [5].

The crystals liberate tellurium more rapidly than do those of the ethyl compound described below, perhaps because of the close Te-Te contact.

Tellurium diethylxanthate [1], $\mathrm{Te(S_2C\text{-}OC_2H_5)_2}$. Monoclinic prismatic, $a = 9.35$ Å, $b = 6.17$ Å, $c = 21.21$ Å, $\beta = 91°$. Four

thetic hydroxyaspartic acid. On the basis both of chromatographic behaviour and reduction products it can be regarded as proved that the amino acid studied is hydroxyaspartic acid.

The spot which travelled slower in butanol-acetic acid (R_F ~0.04) gave on reduction with HI and phosphorus glutamic acid and in addition glycine, serine, and alanine. It may be dihydroxyglutamic acid, but this cannot be regarded as proved.

X-Ray Crystallographic Data on Miscellaneous Sulphur Compounds

OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

The unit cells and space groups of the following derivatives of divalent sulphur, selenium and tellurium were determined some years ago in the course of crystal structure work on analogous compounds, and have not been published before. The data were derived from oscillation and Weissenberg photographs on single-crystal specimens, using iron radiation, $\lambda(\mathrm{Fe}K\alpha) = 1.934$ Å, and in one case (tellurium dibenzenethiosulphonate) copper radiation, $\lambda(\mathrm{Cu}K\alpha) = 1.542$ Å.

Tellurium dimethylxanthate [1], $\mathrm{Te(S_2C\text{-}OCH_3)_2}$. Monoclinic prismatic, $a = 4.24$ Å, $b = 14.18$ Å, $c = 17.28$ Å, $\beta = 93°$. There are four molecules per unit cell; density, calc. 2.19, found 2.18 g/cm³. The space group, from systematic absences, is $C_{2h}^5 - P2_1/c$.

The crystals occur as brownish red prisms, extended along [100] and with {001} dominant. The repeat distance along the a axis, 4.24 Å, is shorter than twice the value, 2.2 Å, listed by Pauling [2] for the van der Waals radius of tellurium, but is not in discord with Briegleb's value [3], 1.9 Å, or with the non-bonded Te-Te approaches of 4.18 Å and 4.28 Å, respectively, found in *p,p'*-dichlorodiphenyl ditelluride [4] and monoclinic barium telluropentathionate dihydrate [5].

The crystals liberate tellurium more rapidly than do those of the ethyl compound described below, perhaps because of the close Te-Te contact.

Tellurium diethylxanthate [1], $\mathrm{Te(S_2C\text{-}OC_2H_5)_2}$. Monoclinic prismatic, $a = 9.35$ Å, $b = 6.17$ Å, $c = 21.21$ Å, $\beta = 91°$. Four

molecules per unit cell; density, calc. 2.01, found 2.03 g/cm³. Space group, from systematic absences, $C_{2h}^5-P2_1/c$.

The crystals were obtained as long, red prisms, bounded by {001} and {100}, with the latter occasionally dominant.

Tellurium dibenzenethiosulphonate, $Te(S_2O_2C_6H_5)_2$, *monoclinic dimorph.* $a = 13.93$ Å, $b = 7.71$ Å, $c = 15.72$ Å, $\beta = 96°$. Density, calculated for four molecules per unit cell, 1.88 g/cm³, as compared with 1.86 g/cm³ for the orthorhombic dimorph [6]. The space group, from systematic absences, is $C_{2h}^5-P2_1/c$.

The orthorhombic dimorph (I) of this compound, the crystal structure of which was described recently [7], was obtained on crystallization from chloroform [6]. The monoclinic dimorph (II) usually occurred when benzene was used as a crystallization medium instead of chloroform, and also when the compound was crystallized from dilute chloroform solutions on addition of ether. Occasionally, mixtures were obtained, small amounts of I separating along with II from benzene, and II together with I from chloroform. Chemical analysis of the X-ray sample of II gave 26.6 % Te, calc. 26.9 %. The dimorphs appear to be about equally stable, no transition between them being observed at room temperature or on heating to about 150°C.

Tetragonal crystals, containing 75 mole % of tellurium dibenzenethiosulphonate and 25 mole % of sulphur dibenzenethiosulphonate, have been observed. The latter compound, and also the selenium analogue, crystallize in a tetragonal space group [6,8].

Disulphur dibenzenethiosulphonate [9], $S_2(S_2O_2C_6H_5)_2$. Orthorhombic bipyramidal, $a = 11.36$ Å, $b = 12.90$ Å, $c = 22.47$ Å. Density, calculated for eight molecules per unit cell, 1.66 g/cm³. This figure may be compared with the X-ray densities, 1.58, 1.57 and 1.62 g/cm³, respectively, of the analogues containing one, two and three sulphur atoms less [8,10]. The space group, from systematic absences, is $D_{2h}^{15}-Pbca$.

This hexathionic compound crystallized as plates {001} with plate edges parallel to the *ab* diagonals.

Strontium selenopentathionate dihydrate, $SrSe(S_2O_3)_2 \cdot 2H_2O$. Orthorhombic bipyramidal, $a = 4.94$ Å, $b = 10.19$ Å, $c = 21.83$ Å. Density, calculated for four formula units per unit cell, 2.58 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. These data indicate that the salt is isomorphous with orthorhombic barium pentathionate [11] and selenopentathionate [12] dihydrates, the space group of which is $D_{2h}^{16}-Pnma$. The crystals have the same morphology as the barium salts, and show the same perfect cleavage along the *c* plane.

The crystals were obtained by recrystallization from aqueous methanol of a crude sample prepared from the sodium salt [13] by metathesis with strontium perchlorate. No chemical analysis was made, but the X-ray data in connection with the known composition of the barium salts appear sufficient to establish the formula given above.

No further crystallographic work on the compounds is contemplated.

The Nature of the Sulphur-Sulphur Bond in Thiosulphate and Thiosulphonate Ions

OLAV FOSS and ASBJØRN HORDVIK

Chemical Institute, University of Bergen, Bergen, Norway

Thiosulphate and thiosulphonate ions, $[S-SO_3]^{--}$ and $[S-SO_2R]^-$, are apparently (beside the polysulphide ions) the only relatively stable species with sulphur-sulphur bonds where one of the sulphur

molecules per unit cell; density, calc. 2.01, found 2.03 g/cm³. Space group, from systematic absences, $C_{2h}^5-P2_1/c$.

The crystals were obtained as long, red prisms, bounded by {001} and {100}, with the latter occasionally dominant.

Tellurium dibenzenethiosulphonate, $Te(S_2O_2C_6H_5)_2$, *monoclinic dimorph.* $a = 13.93$ Å, $b = 7.71$ Å, $c = 15.72$ Å, $\beta = 96°$. Density, calculated for four molecules per unit cell, 1.88 g/cm³, as compared with 1.86 g/cm³ for the orthorhombic dimorph [6]. The space group, from systematic absences, is $C_{2h}^5-P2_1/c$.

The orthorhombic dimorph (I) of this compound, the crystal structure of which was described recently [7], was obtained on crystallization from chloroform [6]. The monoclinic dimorph (II) usually occurred when benzene was used as a crystallization medium instead of chloroform, and also when the compound was crystallized from dilute chloroform solutions on addition of ether. Occasionally, mixtures were obtained, small amounts of I separating along with II from benzene, and II together with I from chloroform. Chemical analysis of the X-ray sample of II gave 26.6 % Te, calc. 26.9 %. The dimorphs appear to be about equally stable, no transition between them being observed at room temperature or on heating to about 150°C.

Tetragonal crystals, containing 75 mole % of tellurium dibenzenethiosulphonate and 25 mole % of sulphur dibenzenethiosulphonate, have been observed. The latter compound, and also the selenium analogue, crystallize in a tetragonal space group [6,8].

Disulphur dibenzenethiosulphonate [9], $S_2(S_2O_2C_6H_5)_2$. Orthorhombic bipyramidal, $a = 11.36$ Å, $b = 12.90$ Å, $c = 22.47$ Å. Density, calculated for eight molecules per unit cell, 1.66 g/cm³. This figure may be compared with the X-ray densities, 1.58, 1.57 and 1.62 g/cm³, respectively, of the analogues containing one, two and three sulphur atoms less [8,10]. The space group, from systematic absences, is $D_{2h}^{15}-Pbca$.

This hexathionic compound crystallized as plates {001} with plate edges parallel to the *ab* diagonals.

Strontium selenopentathionate dihydrate, $SrSe(S_2O_3)_2 \cdot 2H_2O$. Orthorhombic bipyramidal, $a = 4.94$ Å, $b = 10.19$ Å, $c = 21.83$ Å. Density, calculated for four formula units per unit cell, 2.58 g/cm³. Systematic absences, $0kl$ when $k + l$ is odd, $hk0$ when h is odd. These data indicate that the salt is isomorphous with orthorhombic barium pentathionate [11] and selenopentathionate [12] dihydrates, the space group of which is $D_{2h}^{16}-Pnma$. The crystals have the same morphology as the barium salts, and show the same perfect cleavage along the *c* plane.

The crystals were obtained by recrystallization from aqueous methanol of a crude sample prepared from the sodium salt [13] by metathesis with strontium perchlorate. No chemical analysis was made, but the X-ray data in connection with the known composition of the barium salts appear sufficient to establish the formula given above.

No further crystallographic work on the compounds is contemplated.

The Nature of the Sulphur-Sulphur Bond in Thiosulphate and Thiosulphonate Ions

OLAV FOSS and ASBJØRN HORDVIK

Chemical Institute, University of Bergen, Bergen, Norway

Thiosulphate and thiosulphonate ions, $[S-SO_3]^{--}$ and $[S-SO_2R]^-$, are apparently (beside the polysulphide ions) the only relatively stable species with sulphur-sulphur bonds where one of the sulphur

atoms forms one bond only. Bonds of this type may be coordinate bonds, or double bonds. It was predicted by one of us [1] in 1950, on the basis of a discussion of the non-existence of branched sulphur chains, that the sulphur-sulphur bonds of thiosulphate and thiosulphonate ions possess a considerable degree of double-bond character. The argument was [1] that, since a sulphur atom, as acceptor, can be expected to add to another sulphur atom, as donor, only if the donor is *less* electronegative than the acceptor, and since the sulphur atom of sulphite and sulphinate ions is, presumably, *more* electronegative than electroneutral sulphur, the bonds cannot be pure coordinate bonds.

In the same year, Gerding and Eriks [2], on the basis of force constants from Raman spectra of aqueous sodium thiosulphate solutions, concluded that in the thiosulphate ion "the sulphur-sulphur bond undoubtedly possesses a strong double bond character".

Taylor and Beevers [3], in 1952, determined the crystal structure of sodium thiosulphate pentahydrate and found the sulphur-sulphur bond to be 1.97 Å, with a maximum error given as 0.06 Å. The present authors have now [4] made a crystal structure determination of sodium methanethiosulphonate monohydrate, $CH_3SO_2SNa \cdot H_2O$. The crystals [5] are orthorhombic bipyramidal, space group D_{2h}^{16}—*Pnma* with four formula units per unit cell, and the methanethiosulphonate ion possesses mirror plane symmetry in the crystals. The sulphur-sulphur bond was found to be 1.98 Å and the sulphur-oxygen bonds 1.45 Å, with standard deviations of probably less than 0.01 Å and 0.02 Å, respectively.

There is some uncertainty as to the length of a S—S single bond. Abrahams [6] has recently proposed 2.08 Å, and the true value may be a little larger. The double-bond length is probably [6] as in the S_2 molecule in the ground state, 1.89 Å. The S—S bonds in the thiosulphate and thiosulphonate ions, of lengths 1.97—1.98 Å, are next to that in the S_2 molecule the shortest S—S bonds measured, and correspond, according to Abrahams' tentative bond order-bond length curves [6-8], to between 50 % and 60 % double-bond character.

There may, of course, be various causes for the shortening of the sulphur-sulphur bonds of the thiosulphate and thiosulphonate ions. One picture is that, as predicted, double bonds (π bonds) exist to a considerable degree, arising from overlap of the $p\pi$ electron pairs of the outer sulphur atom with available 3*d* orbitals of the central sulphur atom. In view of the smaller tendency of the $p\pi$ electron pairs of a larger atom to participate in π-bond formation (*cf.* Ref.[9]), the amount of π-bond character of the sulphur-sulphur bonds should be smaller than in the sulphur-oxygen bonds of the same ions. The S—O distance in the methanethiosulphonate ion, 1.45 Å, corresponds [6,10] to about 90 % π-bond character. The estimate arrived at above for the S—S bond does thus not appear unreasonable.

It is interesting to note that when the thiosulphate and methanethiosulphonate ions undergo oxidation to the corresponding tetrathionic compounds, the double-bond character of the outer S—S bonds is lost, the length changing from 1.97—1.98 Å to 2.10—2.12 Å. The latter figures are from crystal structure determinations of barium tetrathionate dihydrate [11] and dimethanesulphonyl disulphide [12]. On the other hand, the new S—S bond formed on oxidation, *i. e.*, the middle S—S bond of the tetrathionic compounds, is about 2.04 Å and thus shorter than the outer bonds, probably due to *pd* π-bond formation now occurring between the divalent sulphur atoms.

Studies on the Hydrolysis of Metal Ions

19. The Hydrolysis of Bismuth(III) in Perchlorate Medium

ÅKE OLIN

Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of the Bi(III) ion has been studied at 25 °C in 3 M sodium perchlorate medium by means of the cells:

$$-\text{Bi}-\text{Hg} \mid \text{S} \mid \text{ref}+$$
$$-\quad \text{glass} \mid \text{S} \mid \text{ref}+$$

where S had the general composition,

$$B \text{ mM Bi(III)}, H \text{ mM } H^+, 3\,000 - 3B - H \text{ mM } Na^+, 3\,000 \text{ mM } ClO_4^-.$$

It has been possible to vary B between 50 and 0.1 mM.

The data can be explained assuming the equilibria:

$$Bi^{3+} + H_2O \rightleftharpoons BiOH^{2+} + H^+ \qquad \log \beta_1 = -1.58 \pm 0.02$$

$$6\,Bi^{3+} + 12\,H_2O \rightleftharpoons Bi_6(OH)_{12}^{6+} + 12\,H^+ \qquad \log \beta_{12,6} = 0.330 \pm 0.005$$

For a summary of the work on the hydrolysis of bismuth up to 1947, the reader is referred to a paper by Granér and Sillén [1]. Since the appearance of their paper, in which a continuous polymerization was proposed, a photometric study has been published by Souchay and Peschanski [2], who found evidence for the formation of a complex that might be written as $Bi_4O_4^{4+}$. They state, however, that the complexes $Bi_5O_5^{5+}$ and $Bi_6O_6^{6+}$ are just as likely. In more basic solutions than correspond to $BiOClO_4$, Faucherre [3] has proposed the complex $Bi_8O_{10}^{4+}$. In none of these three investigations has any evidence been found for the simple complexes $BiOH^{2+}$ and $Bi(OH)_2^+$. Holmberg, Kraus, and Johnson [4] have ultracentrifuged bismuth(III) solutions and found only one complex, but it was not possible to state if the complex contained 5 or 6 bismuth atoms. The present work is an electrometric investigation of bismuth(III) perchlorate solutions similar to that of Granér and Sillén but carried out over a much broader range of concentrations.

THE METHOD OF INVESTIGATION

The experimental approach to this problem is essentially the same as similar investigations carried out in this laboratory [1,5]. In short a titrating solution rich in H^+ was added to a solution low in H^+, the total Bi(III) being kept constant. This is the only possible way in this case, since starting from the acid side would require too strong a base to be convenient. The solutions had the general composition:

$[Bi(III)] : B\text{mM}, [H^+]_{tot} : H\text{mM}, [Na^+] : 3\,000—3B—H\text{mM}, [ClO_4^-] : 3\,000\text{mM},$

where B denotes the total Bi(III) concentration and $[H^+]_{tot}$ is the "analytical" hydrogen ion concentration assuming no hydrolysis. The following cells were used to measure $[H^+] = h$ and Bi^{3+}

$$-\text{glass} \mid h \mid \text{ref} + \qquad E = E^\circ_g - 59.16 \log h - E_j \qquad (1)$$

$$-\text{Bi}-\text{Hg} \mid Bi^{3+} \mid \text{ref} + \qquad E = E^\circ_{am} - 19.72 \log [Bi^{3+}] - E_j \qquad (2)$$

The reference half-cell was in both cases

Ag, AgCl | 10 mM Ag^+, 2 990 mM Na^+, 3 000 mM ClO_4^- | 3 000 mM $NaClO_4$

The salt bridge was of the "Wilhelm" type designed by Forsling, Hietanen, and Sillén [6].

MATERIALS AND ANALYSIS

Sodium perchlorate was prepared by neutralizing Na_2CO_3 (Merck p.a.) with $HClO_4$ (Kebo p.a.) following the directions given by Biedermann [7]. The filtered solution gave no reaction for heavy metals, NO_3^- or SO_4^{2-}. It contained, however, minute quantities of chloride. The solution was therefore evaporated and allowed to crystallize. By working with not-too-concentrated solutions and stirring vigorously during the crystallization, it is possible to obtain readily-filterable crystals. A yield of *ca.* 70 % is obtained under proper conditions. The crystals were redissolved in water and the stock solution analysed by evaporating a known weight of solution and weighing the residue as $NaClO_4$.

Perchloric acid solutions were prepared from $HClO_4$ p.a. (70—72 %) and standardized against $KHCO_3$ and standard NaOH. The sodium hydroxide was standardized both against $N_2H_4 \cdot H_2SO_4$ and $KH(IO_3)_2$.

Bismuth (III) perchlorate was prepared by dissolving known amounts of Bi_2O_3 in standardized $HClO_4$. The Bi_2O_3 was prepared as follows: $Bi(NO_3)_3$ aq (p.a.) was recrystallized from nitric acid and ignited in an electric resistance furnace at *ca.* 700 °C to constant weight. In this way a lemon-yellow powder was obtained which dissolved completely in *ca.* 3 M $HClO_4$ to give a colorless solution. No foreign anions could be detected in it. The bismuth perchlorate stock solution was analysed for bismuth by precipitating it as the phosphate according to Blasdale and Parle [8] or as the oxide chloride as described by Winkler [9]. Both methods gave the same result within 0.2 %. The ClO_4^- concentration was determined by passing the solution through an ion exchanger and titrating the liberated acid with NaOH. The analytical hydrogen ion concentration was obtained as the difference $[ClO_4^-] - 3[Bi^{3+}]$. The agreement between the calculated and found concentrations of ClO_4^- and Bi^{3+} was within 0.2 %.

Bismuth amalgam was prepared electrolytically using mercury (redist.) as the cathode and a platinum spiral as the anode. An attempt was made to prepare the amalgam by dissolving metallic bismuth in mercury in a CO_2 atmosphere. This failed, however, since the metal contained traces of oxide which could not be completely removed. The amalgam was kept under the acid electrolyte in an inert atmosphere. A small portion of the stock amalgam was taken out for each titration by an arrangement similar to a wash bottle. Preliminary tests showed that no electrolyte came along with the amalgam. The concentration of bismuth in the amalgam was about 0.25 % (weight).

EXPERIMENTAL DETAILS OF THE EMF MEASUREMENTS

Almost all concentrations were measured in two series with stock solutions completely independent of each other, and in each series duplicate titrations were made. The glass electrode (Blomgren) was calibrated up to 750 mM of acid, giving the sum of the liquid junction potential and the deviation of the glass electrode from ideality as a function of h. The calibration curve was the same from one time to another for acid concentrations below *ca.* 450 mM. In more acid solutions fluctuations were observed amounting to 0.5 mV.

The liquid junction potential was determined by means of the cell,

$$\text{Ag, AgCl} \;\Big|\; \text{10 mM } Ag^+,\ \text{2 990 mM } \begin{Bmatrix} H^+ \\ Na^+ \end{Bmatrix},\ \text{3 000 mM } ClO_4^- \;\Big|\; \text{ref}$$

and found to agree with the values given by Biedermann and Sillén [10] to within 0.1 mV. For higher acidities (600 mM) the potentials were uncertain to 0.3 mV.

The amalgam electrode, which consisted of a pool on the bottom of the titration vessel, gave very constant and reproducible potentials. For identical points in each series, the difference between the emf values very seldom exceeded 0.05 mV. Under the same conditions the glass electrode showed a reproducibility of 0.2 mV. The overall reproducibility between the two series can be estimated by interpolation to be, for the amalgam electrode 0.1—0.2 mV, and for the glass electrode 0.3—0.4 mV. These limits, of course, contain analytical and other errors as well. Exceptions to the behavior stated above were given by the 0.1 mM titrations. Here the amalgam potential took at least half an hour to attain a constant value, and the reproducibility was only ± 0.2 mV.

Equilibrium seems to be attained immediately, and the potential remained constant within 0.05 mV for at least 3 h. It was observed that if a large amount of acid was added at one time, exactly the same potential was obtained (as fast as it could be measured), as if the same amount of acid was added during the course of about 5 h.

RESULTS AND CALCULATIONS

Since the amount of data obtained in this investigation is very large (600 equilibrium compositions were measured), it is not possible to give them all in detail. One representative titration is given in full in Table 1 and the others from the second series in compact form in Table 2. Fig. 2 shows the data from the second series. Those from the first series agree so closely that no difference would be seen in the figure. η denotes $\log \frac{[\text{Bi(III)}]_{\text{total}}}{[\text{Bi}^{3+}]_{\text{free}}}$ and h the hydrogen ion concentration at equilibrium. All concentrations in tables and figures, and E°_{am}, are on the mM scale, whereas E°_{g} and the final equilibrium constants are on the M scale.

Determination of E°_{am} *and* E°_{g}. In order to evaluate h and $[\text{Bi}^{3+}]$ from eqns (1) and (2), it is necessary to know the E°. By assuming that at sufficiently high acidities the hydrolysis is completely repressed, one can calculate the E° values by inserting the analytical concentrations. In this way it was possible to get the E° for the glass electrode, since the effect of the hydrolysis on the hydrogen ion concentration is small in the most acid solutions. The E°_{g} so obtained agreed with the E° from separate acid-base titrations substantiating the assumption made. For the amalgam electrode, a slight but definite trend in E°_{am} was always observed. Thus only a rough value was obtained, which was used for the preliminary calculations.

Table 1. Measurements with amalgam and glass electrodes. S_1 : Bi(III) : 10 mM, H^+ : 0.00 mM, Na^+ : 2970 mM, ClO_4^- : 3000 mM, S_2 : Bi(III) : 10 mM, H^+ : 1198 mM, Na^+ : 1772 mM, ClO_4^- : 3000 mM, $E°_{am}$ = 418.1 mV.

				$E°_g$ = 297.2 mV			

In the following the same notations as those of Hietanen and Sillén [11] will be used. The calculations will chiefly be based on the η function, since this is much more accurate than the Z function.

A plot of η against log h revealed two characteristic features. For higher values of η, a different curve for each Bi_{tot} was found, thus indicating polynuclearity. For low η values the curves coincided showing that only mononuclear complexes appear besides Bi^{3+}. To evaluate a more accurate $E°_{am}$ the following method was adopted:

Table 2. Corresponding values of η and log h at equilibrium calculated with $E°_{am}$ = 418.10 mV.

these equations give

$$\left(\frac{B}{b} - 1\right)h = \beta_1 + \beta_2 \cdot h^{-1} + \beta_3 \cdot h^{-2} + \ldots\ldots$$

The problem is then to find an E° value which gives a curve of the right shape when $\left(\frac{B}{b} - 1\right) h$ is plotted against h^{-1}. In Fig 1 three such curves are shown for different E° values, namely 418.30, 418.10 and 417.90 mV . The figure shows that the curves deviate appreciably for too high or too low E° values, leaving a range in which the correct value may be found. The "best

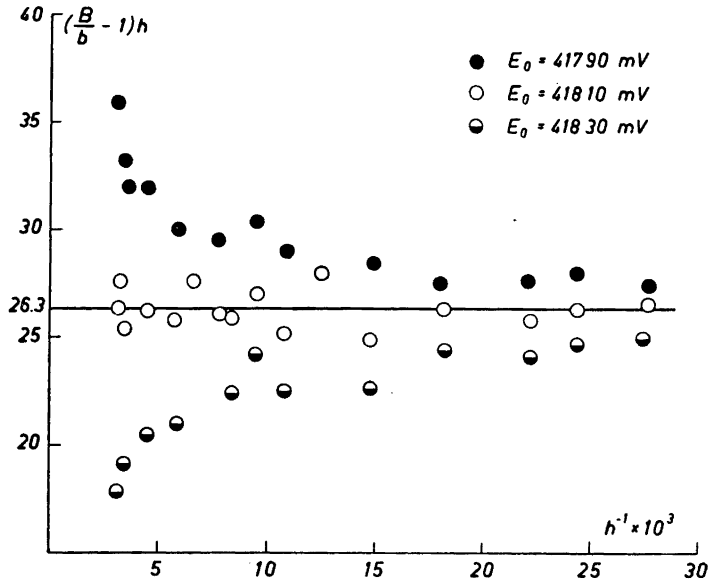

Fig 1. Determination of $E°_{am}$, β_1 and β_2. The middle curve represents $E°_{am}$ = 418.10 mV and $\left(\frac{B}{b} - 1\right)h$ = 26.3 mM.

$E°''$ = 418.10 mV was found to give an almost horizontal line with an intercept (equal to β_1) on the $\left(\frac{B}{b} - 1\right)h$ axis = 26.3 mM. Since the scatter is necessarily great a constant correct to more than 5 % cannot be expected; furthermore, it is hard to decide if the line is horizontal or has a small slope. The second mononuclear constant seems to be very small, and has not been considered in the further calculations. An analysis of the mononuclearity thus gives for the first hydrolysis stage an equilibrium constant 26.3 ± 2 mM with the second stage almost absent.

Determination of the main hydrolysis products. The recalculated η *vs.* log h curves (Fig 2) with $E°_{am}$ = 418.10 mV revealed the following features for larger η values. The curves were almost parallel with a spacing $\left(\frac{\Delta \log B}{\Delta \log h}\right)_\eta = 2.4$ and had a slope of -2. It may be pointed out that these properties are independent of any chosen $E°_{am}$, since changing this parameter only means that the curves are shifted along the ordinate axis.

Let it be assumed that the general composition of the complexes may be written Me_qH_{-p};

$$B = b + \Sigma q\beta_{pq}b^q h^{-p} \simeq \Sigma q\beta_{pq}b^q h^{-p} \quad (3)$$

$$10\eta = \frac{B}{b} = 1 + \Sigma q\beta_{pq}b^{q-1}h^{-p} \simeq \Sigma q\beta_{pq}b^{q-1}h^{-p} \quad (4)$$

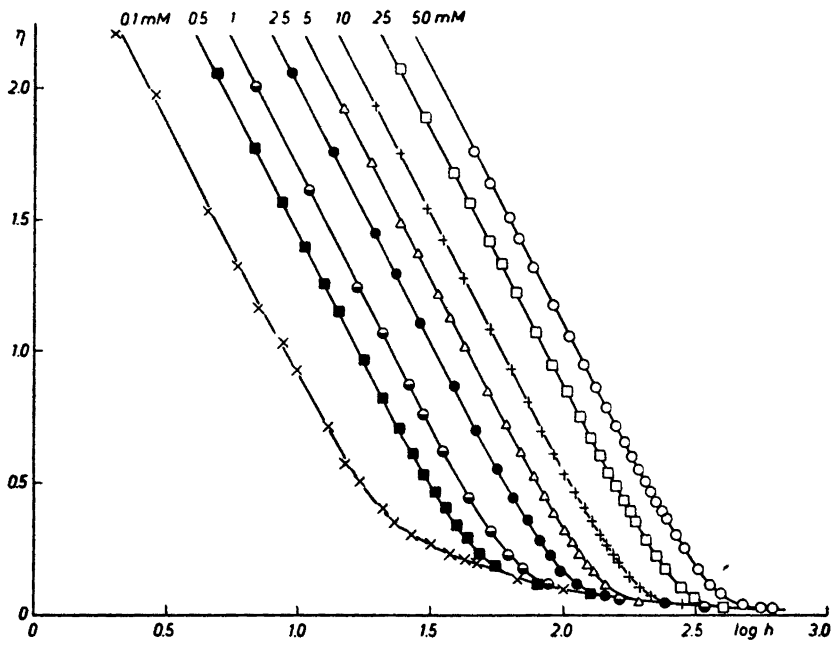

Fig 2. $\eta = \log \frac{[\mathrm{Bi(III)}]_{tot}}{[\mathrm{Bi^{3+}}]}$ as a function of log h. Curves are calculated with $\beta_1 = 26.3$ mM and $\beta_{12.6} = 2.14$ M^7. For clarity not all of the experimental points are shown for low η values.

The curves give

$$B \text{ constant} ; \eta = \mathrm{f}(B) - 2 \log h \tag{5}$$

$$\frac{B}{b} \text{ constant} ; \log B - 2.4 \log h = \text{const. or } 10\eta = \mathrm{f}(b^{-1}h^{2.4}) \tag{6}$$

Eqns (6) and (4) give

$$\Sigma q\beta_{pq} b^{q-1} h^{-p} = \mathrm{f}(b^{-1}h^{2.4})$$

which can be fulfilled only if

$$p = 2.4(q - 1) \tag{7}$$

If (5) is rewritten as $\log B - \log b = \mathrm{f}(B) - 2 \log h$, it is seen that $bh^{-2} = \mathrm{f}'(B)$. This gives with (3)

$$bh^{-2} = \mathrm{f}'(\Sigma q\beta_{pq} b^q h^{-p}) \text{ or } q = \frac{p}{2} \tag{8}$$

Eqns (7) and (8) give $q = 6$ and $p = 12$. The main complex may therefore be written $Bi_6(OH)_{12}^{6+}$ or more generally $Bi_6O_n(OH)_{12-2n}^{6+}$. The lines of argument in this discussion follow closely those of Sillén in AB I and II [12,13], and indeed the same result appears with his methods.

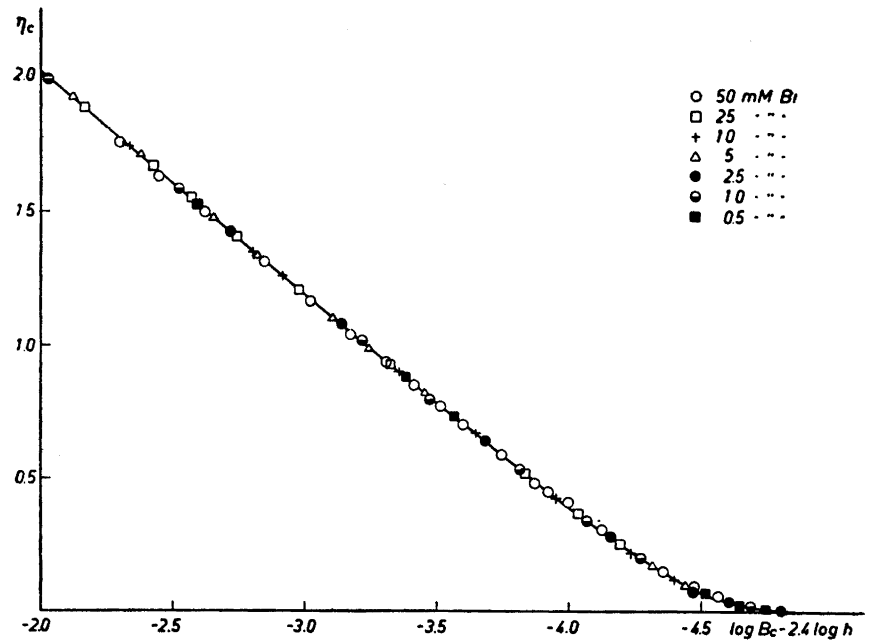

Fig 3. η_c as a function of log B_c — 2.4 log h (see text). The curve is calculated with log $\beta_{12,6} = 0.330$.

To evaluate the equilibrium constants for the hexamer the following method may be adopted. We define the functions B_c and η_c so that they have their usual meaning, except that the mononuclear part has been subtracted. From the relations,

$$B = b + \beta_1 b h^{-1} + 6\beta_{12,6} b^6 h^{-12}$$

$$B_c = B - \beta_1 b h^{-1} = b + 6\beta_{12,6} b^6 h^{-12}$$

$$\frac{B_c}{b} = 10^{\eta_c} = 1 + 6\beta_{12,6} b^5 h^{-12} = 1 + \frac{6\beta_{12,6}}{10^{5\eta_c}} [B_c h^{-2.4}]^5$$

it follows that η_c is a function of the single variable log B_c — 2.4 log h. In Fig 3, η_c is shown as a function of log B_c — 2.4 log h. Since all the experimental points fall on a single curve, we might conclude that the concentrations of complexes other than $BiOH^{2+}$ and $Bi_6(OH)_{12}^{6+}$ must be small. By comparing this curve with a "normalized" one the equilibrium constant of the hexamer is obtained as log $\beta_{12,6} = 0.330 \pm 0.005$, M scale. The uncertainty in this value lies in the E°_{am} determination.

It might at this point be asked with what certainty one can say that there are 6 Bi in the complex and not for instance 5 or 7. These complexes correspond to the spacings 2.50 and 2.33, thus lying very near to 2.4. It

was therefore decided to make calculations using these assumptions too. These calculations showed, however, that a good fit could not be obtained over the whole B range but when only a narrow concentration range in B is considered, it is not easy to draw any definite conclusions. This shows the desirability of covering as wide a concentration range as possible.

The graphic methods developed by Biedermann and Sillén [14] using "normalized" curves should be applicable to this case. On account of the preceding discussion the assumption is made that the only species present, apart from Bi^{3+}, are $BiOH^{2+}$ and $Bi_6(OH)_{12}^{6+}$. This leads to a three-parameter problem since $E°_{am}$ is unknown in addition to the equilibrium constants. The method is based on cuts for constant η. The family of experimental curves for constant η values

$$x = \log B - 2.4 \log h$$
$$y = \log h$$

are plotted and compared with a graph of the theoretical, normalized curves

$$X = \log B - 2.4 \log h + \log k = \eta + \log v$$
$$Y = -\log \alpha = \log h - \log \beta_1 = -\log(10^{\eta} - 1 - v^5)$$

where $k^5 = 6\ \beta_{12.6}$; $v = kbh^{-2.4}$.

By eliminating the parameter v, we obtain

$$Y = -\log(10^{\eta} - 1 - 10^{5(X-\eta)})$$

From this equation we can calculate the family of curves $Y(X)_\eta$. The two graphs are laid on top of each other to coincide as closely as possible and the differences on the x and y axes in this position give the equilibrium constants.

The correct $E°_{am}$ is obtained by considering the smallest η values; since in this range η is dependent on log h only, Y must be independent of v which happens only when v equals zero. Corresponding values between η and log α are obtained by putting $v = 0$. A curve $\eta(\log \alpha)$ may thus be found. From experimental data based on different $E°_{am}$, a family of curves $\eta(\log h)_{E°_{am}}$ is obtained. It is now possible to plot log $\alpha(\log h)_{E°_{am}}$ for each of the chosen $E°_{am}$. The curve for the right $E°_{am}$ should give a straight line of slope -1. In this way the same $E°_{am} = 418.1$ mV was obtained as by the earlier method. In Fig 4 the normalized curves are shown together with the experimental points in the position of "best fit". The equilibrium constants found are log $\beta_1 = -1.585$ ($\beta_1 = 0.026$ M) and log $\beta_{12.6} = 0.325$ (M scale), comparing favorably with the earlier results. It may be pointed out that in this method the constants may be varied simultaneously and independently of each other.

Since the Z values $\left(\frac{h-H}{B}\right)$ must necessarily be quite uncertain in such acid solutions as have been used in this investigation, they were thought not to be worth a separate treatment. This gap, it is hoped, will be filled by conductimetric measurements; however, there was no doubt that the limiting value of Z is 2. In addition, the quantity $\frac{h-H}{B-b}$ (the number of hydrogen

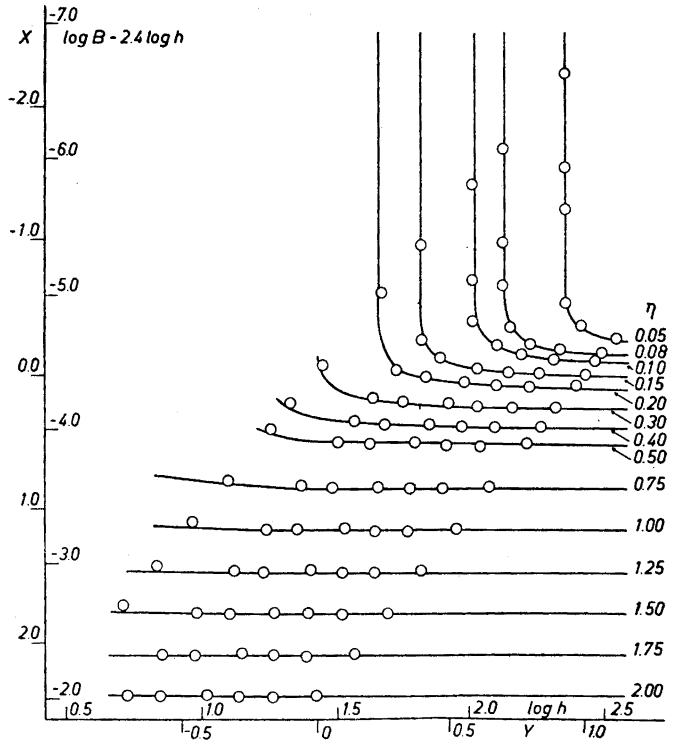

Fig 4. X, Y curves and experimental points *x, y* (see text) in position of »best fit». O experimental points.

ions set free by the complexed bismuth) was found to vary between 1.95 and 2.05 in the region where polynuclear species predominate. This strongly indicates that in the most hydrolysed solutions the ratio Bi:OH in the complex (es) formed is 1:2.

DISCUSSION

The present investigation of the hydrolysis of Bi^{3+} leads to a different mechanism from that proposed by Granér and Sillén [1], who used the same type of investigation. As has already been pointed out, it is difficult to decide what mechanism is the most likely, when only a rather small concentration range has been measured: a small error may completely change the picture. In the case of Granér and Sillén, who only studied the concentration range 10—50 mM of Bi(III), one probable error can be pointed out. They calculated with liquid junction potentials obtained from quinhydrone measurements. As was found later by Biedermann and Sillén [10] the quinone acts as a base [15] and the liquid junction potentials are not applicable to a quinhydrone-free system. This leads to an error of 0.1 units in η in the most unfavorable cases.

The most recent works on bismuth perchlorate all seem to indicate the presence of only one complex. Its composition was, however, not definitely established. There seems to be no doubt that the ratio Bi:O is 1:1, but the number of bismuth atoms in the complex has not hitherto been ascertained. The work of Faucherre [3] is not comparable since it was carried out in solutions of so low acidity, that they cannot be obtained when working in a strong ionic medium because of precipitation. In the present investigation the most hydrolysed solutions gave η values around 3. These points lie on the extensions of the curves in Fig. 3 and give no indication of a new reaction. The solutions were not quite stable but gave a small precipitate after standing for about a week. We hope, however, to be able to carry out titrations at lower ionic strength to find out what happens at higher pH values.

If only one complex is formed, it is hard to imagine it as a chain or a layer, since a complex with a certain, relatively high number of atoms in it would not be expected to dominate; however, for a complex containing six metal atoms one can visualise models of high symmetry. This symmetry could then account for the extreme stability and presence of only one predominating complex. These models must, however, be accepted with scepticism and need confirmation from structural data both in solution and in the solid state. Work in this direction is planned. The absence of $Bi(OH)_2^+$ is remarkable. The reason for this may be that the "hexamer" is so stable compared to $Bi(OH)_2^+$ that the equilibrium concentration of this complex is too low to be detected.

Acknowledgements. The author wishes to express his gratitude to Professor Lars Gunnar Sillén for suggesting this work and for his guidance in carrying it out. He also wishes to thank Dr. George Biedermann and Dr. Gösta Lagerström for the many discussions held with them on various aspects of this problem. Dr. Helen S. Dunsmore and Dr. R. Stuart Tobias are thanked for having corrected the English. Mr. Frans Ericson has been a valuable aid in constructing the apparatus.

This work has been made possible by a fellowship from *Statens Tekniska Forskningsråd (Swedish Technical Research Council)*.

The Acid-soluble Nucleotides of Barley and Oat Plants

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

The acid-soluble nucleotides of barley and oat plants are isolated and fractionated by ion exchange chromatography; they are shown to include the 5′-triphosphates of adenosine, guanosine, cytidine and uridine besides mono- and diphosphates. The identifications are based on ultraviolet absorption measurements and chromatographic and ionophoretic evidence before and after hydrolysis together with chemical and enzymic analysis.

Besides as a constituent of nucleic acids, adenosine-5′-phosphate has been known for a long time to occur in combined forms in smaller molecules which act as coenzymes in many metabolic processes. None of the other three nucleotides from ribonucleic acid had been found to occur in biological material either free or forming part of small molecules. Seven years ago Leloir and coworkers [1] studying the galactose metabolism in yeast, and Park and Johnson [2] studying the effects of penicillin on bacteria, observed independently the occurrence of acid-soluble uridine-containing compounds in living tissues. Following these important contributions to the progress of nucleotide biochemistry, derivatives of uridine-5′-phosphate, guanosine-5′-phosphate and cytidine-5′-phosphate have been isolated from different sources with the result that the number of derivatives of these nucleotides known to occur in living tissues is about the same as that in the adenosine-5′-phosphate series, so that the latter compounds have now lost the unique position, as building blocks of coenzymes, which they were believed to have.

The main difficulties encountered in the demonstration of these compounds in plants have centered around the problem of their isolation free from interfering substances and their separation. Methods developed primarily for the isolation of the nucleotides from animal tissues have proven unsatisfactory for the isolation of these compounds from plants. From mung beans, which have a low content of disturbing substances, an ATP *-like compound [3] and

quite recently a mixture of uridine diphosphate sugar compounds [4] have been isolated. Paper chromatographic evidence for the presence of adenosine and uridine containing compounds in plants has been presented by several authors [5–7].

An improved method for the isolation and quantitative estimation of the acid-soluble nucleotides from plant tissues has been described in a previous paper [8]. The application of this method to wheat plants established the occurrence of all the four ribonucleosides in the form of acid-soluble 5′-mononucleotides at different levels of phosphorylation [8]. Of interest is the predominance of uridine, besides adenosine derivatives in wheat plants, in contrast to the dominating role of the latter compounds in animal tissue.

The present paper deals with the isolation and identification of the acid-soluble nucleotides of two other kinds of grain, namely oats and barley. Because of very marked similarities in nucleotide content the two plants are described together. From oats, the isolation in low yield of a nucleotide of low purity which appeared to be related to, but not identical with 5′-ADP, had been reported by Albaum and Umbreit [9].

The acid-soluble nucleotides were isolated by homogenizing the plant material in cold perchloric acid and freed from other phosphorus-containing or ultraviolet-absorbing substances according to the method previously elaborated. After adsorption on a column of 200 to 400 mesh strong base anion exchanger in the formate form, the individual nucleotides were eluted with

formic acid solutions containing increasing concentrations of sodium formate. Elution of the nucleotides was followed by the changes in optical densities of the eluate at 250, 260 and 270 mμ. The optical densities at 260 mμ of the effluent fractions were plotted against effluent volume to obtain the chromatographs shown in Figs. 1 and 2.

The elution position and the absorbance ratios gave a preliminary identification of the individual fractions. Since the nucleotides from the column were distributed in large volumes of formate buffer, it was desirable to concentrate them and remove the excess salt by readsorption on norite and elution with ammoniacal ethanol.

The solutions thus obtained were used to identify the nucleotides and establish the purity of the peaks by comparison of their chromatographic and ionophoretic behaviour with that of the corresponding authentic nucleotides. Further characterization of the nucleotide fractions was obtained by the following criteria: (a) ultraviolet absorption spectra at different pH values; (b) determination of total phosphorus content and of phosphorus content and phosphorus liberated after hydrolysis for 10 min with 1 N hydrochloric acid; (c) determination of the sugar content; (d) paper chromatographic identification of the sugars; (e) paper chromatographic behaviour of the bases after hydrolysis with acids; and (f) ultraviolet absorption curves of the products of hydrolysis.

The position of the phosphate groups was confirmed by oxidation with periodate and by the action of rattle snake venom. All these analyses have already been described in detail [8]. In addition, special analyses of certain nucleotides were undertaken, which are described later.

The quantities of the nucleotides were calculated by using molecular extinction coefficients at 260 mμ of 14 500 for the adenine nucleotides, 10 800 for the guanine nucleotides, 6 300 for the cytosine nucleotides, and 10 000 for the uracil nucleotides. The amounts of the different components are summarized in Table 1.

An amount of ultraviolet-absorbing material, representing about 2—4 % of the total absorbancy of the sample was not adsorbed on the column but was recovered in the wash water. This fraction contained nucleosides and free bases and as main components non-nucleotide material.

Peaks A, C and D appeared to contain the 2′- and 3′-phosphates of cytidine and adenosine, respectively, together with larger amounts of ultraviolet absorbing non-nucleotide material. These nucleotides could, however, easily be separated from interfering substances and estimated by paper chromatography or ionophoresis.

The main component of the sixth peak (F) comprising 60—80 % of the total nucleotide material of that peak was found to be TPN. The minor components behaved ionophoretically and chromatographically like CDP, 2′- and 3′-UMP and 2′- and 3′- GMP.

Analysis of the nucleotides of peaks G and H gave spectra similar to that of uridine; they contained 1 μmole of acid-stable and 1 μmole of acid-labile phosphorus per μmole of base. Treatment with acid at pH 2 during 5 min at 100°C led to the formation of UDP and acetylglucosamine and glucose, respectively. With stronger acid one phosphate group was split off leaving

5′-UMP. The sugars were identified by chromatography in three solvent systems and by ionophoresis in borate buffer at pH 9.2. The sugar moiety of the substance in peak G gave the same spectrum as that from authentic UDPAG after treatment with dilute alkali and *p*-dimethylaminobenzaldehyde.

The unhydrolyzed samples from the two peaks behaved also ionophoretically and chromatographically like UDPAG and UDPG, respectively.

The acid-soluble nucleotides of barley included a small amout of an adenosine diphosphate derivative obtained as peak I, which followed closely UDPG. Both plant extracts contained another adenosine derivative, which could either be eluted between GDP and UTP or overlapped partly these fractions. The three substances could, however, be separated by ionophoresis at pH 4.15. The adenosine derivative contained 3 μmoles of phosphorus per μmole of base. A typical adenosine spectrum was obtained from both adenosine derivatives and no spectral change was observed after addition of cyanide. Paper chromatography of the base gave in both cases R_F values identical with that of adenine. Amounts sufficient for detailed structural studies have not been available yet of either substance.

The results of the present investigation establish further the occurrence in plant tissues of 5′-ribonucleotide derivatives of all the four bases present in ribonucleic acids. A preponderance of uracil derivatives besides those of adenine confirms previous findings on wheat plants. These nucleotides — without which metabolic processes would come to a standstill — are apparently involved in metabolism as coenzymes, as precursors of coenzymes and as building blocks for nucleic acids, and as such they may participate in the energy-requiring process of protein synthesis. Ever since Caputto *et al.* have shown that UDPG participates in the interconversion of D-glucose and D-galactose in yeast, it has become more and more apparent that the sugar nucleotides and specially 5′-UDP derivatives play a fundamental role in carbohydrate metabolism, and it is therefore according to expectations that these nucleotides are present or even dominate in plant tissues.

Only very small and varying amounts of the 2′- and 3′-monophosphates were detected in some experiments; they originate presumably from the degradation of ribonucleic acids. No quantitative estimation of DPN and TPN was attained with the present method; for the determination of these nucleotides other methods are available.

EXPERIMENTAL

Isolation and separation of acid-soluble nucleotides

Only the aerial portion of mature plants grown out of doors under normal field conditions, which had begun to fruit when harvested, were investigated. 1 000 g of fresh plants were homogenized in 3 000 ml of ice cold 10 % perchloric acid in a Waring Blendor and after re-extraction with 1 000 ml of 5 % perchloric acid the nucleotides were isolated and freed from disturbing substances according to the method[8] previously elaborated.

Fractionation of the isolated nucleotide mixture was carried out by ion exchange chromatography using Dowex 1, X-10, 200 to 400 mesh in the formate form. The individual nucleotides were eluted with increasing concentrations of formic acid or a mixture of formic acid and sodium formate. The eluting agents and the column size are seen from Figs. 1 and 2. The nucleotides were recovered from the pooled fractions by norite adsorption and elution with small volumes of 50 % aqueous ethanol containing 0.5 % ammonia.

Analytical methods

Ultraviolet absorption. The chromatographic fractions were analyzed by measurement of their light absorption at 250, 260 and 270 mμ in a Beckman spectrophotometer, Model DU, with photomultiplier. Each peak was also identified by determining its optical density over the range 220 to 320 mμ in acid and alkaline solution. The molar absorbancy and the absorbance ratios E_{250}/E_{260} and E_{270}/E_{260} were given in an earlier report [8].

Phosphate. Phosphorus was determined by the method of Allen [10] adapted to a total volume of 5.0 ml, and acid-labile phosphorus was determined after 10 min hydrolysis in 1 N hydrochloric acid at 100°C.

Pentose. Pentose estimations were carried out with the orcinol reagent according to Albaum and Umbreit [11]. The results were calculated by use of authentic samples as standards.

Acetylglucosamine. Mild acid hydrolysis of UDPAG liberated the hexosamine, which gave a positive Morgan-Elson reaction according to the modified test by Reissig *et al.*[12]

Periodate oxidation. Oxidation with periodate was performed according to Dixon and Lipkin [13].

Action of snake venom. The action of rattle snake venom was studied as previously described [8].

Paper chromatography

Whatman No. 1 filter paper was used, and the papers were in equilibrium with the solvent mixture before the runs were started. Standard substances were run in every chromatogram. The temperature was 20 to 22°C.

The nucleotides were located in ultraviolet light of 254 mμ photographically, eluted, and estimated spectrophotometrically. For paper chromatography of the nucleotides the following solvent systems were used: (I) *n*-propanol-ammonia-water (60:30:10); (II) ethanol-1 M ammonium acetate, pH 7.5 (75:30); (III) ethanol- 1 M ammonium acetate buffer, pH 3.8 (75:30); (IV) *iso*propanol-saturated ammonium sulphate solution-water (2:79:19); and (V) *iso*butyric acid-ammonia-water (66:1:33).

The bases obtained after hydrolysis by heating at 100°C for one hour in 1 N hydrochloric acid for the purines, and in 70 % perchloric acid for the pyrimidines, were identified with the following systems: (VI) *iso*propanol-hydrochloric acid (*d* 1.180) — water (65:17:18); (VII) *n*-butanol-acetic acid-water (4:1:5); and No. IV.

The sugar released on mild acid hydrolysis was identified by chromatography in the following solvents: (VIII) ethyl acetate-pyridine-water (2:2:1); (IX) phenol-water saturated at room temperature; and system No. VII. The positions of the sugar spots were demonstrated by spraying with aniline hydrogen phthalate or benzidine.

Paper ionophoresis

Ionophoresis on paper was performed with the technique described in the following paper [14]. Separation of the nucleotides was obtained using the acetate buffer of ionic strength 0.1 and pH 4.15. The sugars were studied in 0.1 M sodium tetraborate buffer at pH 9.2.

Materials

The nucleotides used as standard substances were obtained from Sigma Chemical Company.

This work has been supported by a grant from the *Swedish Natural Research Council*, and financial support for purchase of the reference substances has been obtained from *Sigma Chemical Company*.

The Separation and Estimation of Nucleotides

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

A method is presented for the separation and estimation of the 5′-mono-, di- and triphosphates of adenosine, guanosine, cytidine and uridine together with uridine diphosphate glucose, uridine diphosphate acetylglucosamine, diphospho- and triphosphopyridine nucleotides. The nucleotides are separated by a combination of paper chromatography and ionophoresis, and an apparatus is described which allows the ionophoretic separation of substances with very small differences in mobility.

In the course of studies of the nucleotide content of different plant materials a method has been developed for the isolation of the acid-soluble nucleotides without interfering substances [1]. A quantitative separation of the mono-, di- and triphosphates of adenosine, guanosine, cytidine and uridine has been effected by means of a column of the strong base anion exchange resin Dowex-1. The resin was used in the formate form, and separation of the nucleotides was achieved by stepwise elution with formic acid solutions containing progressively increasing amounts of formate.

The use of ion exchange resins for chromatography is particularly well suited to the study of nucleoside derivatives because of the number and variety of charged groups which these compounds possess. Ion exchange chromatography has several great advantages. It is capable of handling both large and small quantities of material. The method is suitable for preparative work, great resolving power is attained and contaminants are of smaller importance than in paper chromatography and ionophoresis. As an analytical method this procedure suffers of slowness and of the disadvantage that considerable volumes of liquid may have to be handled. In order to get a more rapid and sufficiently accurate method for preliminary analysis, a procedure has been developed in this laboratory for the fractionation of nucleotides based upon chromatography together with ionophoresis on filter paper.

In spite of numerous trials with different solvent systems including those already reported in the literature together with a great number of other solvents, no method has so far been found to be entirely satisfactory for the separation of all the purine and pyrimidine nucleotides to be found in plant

materials. Two-dimensional paper chromatography has been used for the resolution of mixtures containing the 5′- mono-, di- and triphosphates of adenosine, guanosine, inosine and uridine giving adequate resolution of all the twelve components [2]. In the first direction, the chromatogram was developed with *n*-propanol-ammonia-water (60:30:10) and in the second direction with a solvent system consisting of saturated ammonium sulphate solution-water-*iso*propanol (79:19:2). The cytosine and uracil nucleotides are not separated from each other by means of these or any other solvent mixtures described in the literature. For the present purpose the use of the strongly alkaline first solvent system had the disadvantage of hydrolysing labile nucleotides like UDPG, UDPAG, DPN and TPN *. The ammonium sulphate mixture, originally introduced for the separation of the nucleotides obtained

* Abbreviations used: A, adenosine; G, guanosine; U, uridine; C, cytidine; MP, monophosphate; DP, diphosphate; TP, triphosphate; UDPG, uridine diphosphate glucose; UDPAG, uridine diphosphate acetylglucosamine; DPN, diphosphopyridine nucleotide; TPN, triphosphopyridine nucleotide.

by hydrolysis of nucleic acids [3] and for the separation of adenosine and inosine polyphosphates [4] has, however, been retained from the previous method for obtaining a separation of the very complex nucleotide mixture into smaller groups.

The grade of filter paper most frequently used was Whatman No. 1, and when larger quantities were to be separated the thick Whatman No. 3 paper was used. For successful separation of the different groups it was necessary to use large sheets of paper (50 × 110 cm). Descending chromatography was used and the development was continued until the distance travelled by the solvent front was about 100 cm. The mixture to be analysed was applied to the paper in a series of small spots along a line across the paper, and in this way milligram amounts could be separated, which were even sufficient for the analysis of the weaker components. Emphasis must be laid on the necessity of always providing appropriate controls in chromatography with large papers thereby greatly decreasing the chances of erroneous deductions arising from unforseen variables, such as temperature changes etc.

Fig. 1 shows the fractionation of the actual nucleotides possible with this solvent system which, it will be noted, has a tendency to separate the compounds into four clear-cut bands. The components in the different bands are seen from the figure and are summarized in Table 1.

For quantitative estimations, each ultraviolet-absorbing band with the appropriate blank was cut out and eluted with 0.1 N hydrochloric acid. The optical densities of the extracts were read at the appropriate wavelengths and the total amount of nucleotides in the different bands could then be calculated. In order to concentrate the extracts sufficiently for further analysis, the substances were adsorbed on norite and eluted with small volumes of ethanol-ammonia.

The application of the method of paper ionophoresis to the separation of nucleotides has been extensively studied by various workers [5-8] but only a few papers are concerned with the separation of more than a few nucleotides. None of the techniques hitherto described has been found to give a satisfactory separation of all the nucleotides. With the following method a complete separation of all the nucleotides in the different groups was obtained, except for the uridine diphosphate sugar compounds.

Ionophoresis was carried out in sodium acetate buffer of pH 4.15 and of ionic strength 0.1. Higher and lower pH values resulted in overlapping of

Table 1. The nucleotides in the different groups obtained by paper chromatography as shown in Fig. 1.

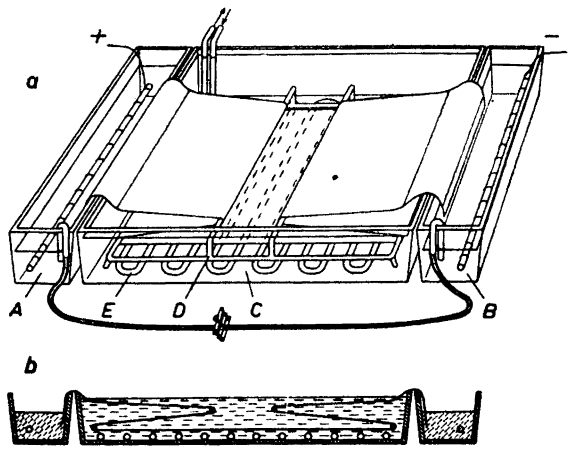

Fig. 2. Apparatus for paper ionophoresis, a) total view and b) cross section. A large sheet of filter paper, kept cool by immersion in the carbon tetrachloride vessel C (50 × 40 × 8 cm), is held in position by a glass frame D as shown in the cross section. The two ends of the paper dip into the electrode vessels A and B (50 × 10 × 8 cm). The liquid in the vessel C is cooled by running tap water in the coil E.

two or more of the cytosine and uracil nucleotides. Because of only small differences in mobility of several of the compounds it was necessary to use long travelling distances for getting sharp separations and therefore the apparatus shown in Fig. 2 has been used.

The equipment is a modification of the apparatus described by Markham and Smith [6], where the paper is kept cold by immersion in carbon tetrachloride. The apparatus consists of two vessels containing the buffer solutions and a third one containing carbon tetrachloride. Either carbon or platinum electrodes were used. Ionophoresis was carried out on large sheets of Whatman No.1 paper (40 × 110 cm) washed three times with N hydrochloric acid and finally with water for removing trace impurities. The samples to be analysed were applied to the paper at a line 15 cm from one end at right angles to the long axis of the paper. For getting compact spots the samples were applied as narrow bands instead of spots about 15 mm in length and about 3 cm from each other. The buffer was carefully brought up on either side of the samples through dipping in the desired electrolyte solution and the surplus moisture was removed by pressure between sheets of thick blotting paper. Then the paper, held in position by a frame made of glass, was immersed in the carbon tetrachloride vessel so that the two ends dipped into the electrode vessels, as shown in Fig. 2 b. The electrodes were connected to a d. c. power supply adjusted to 1 000 V giving a voltage gradient of about 10 V/cm. Under these conditions a run for 12 h gave a resolution of fractions A, B, C and D as shown in Fig. 3 in comparison with authentic nucleotides.

During the passage of the current through the long paper for several hours the carbon tetrachloride warmed up and to prevent this and to hold the

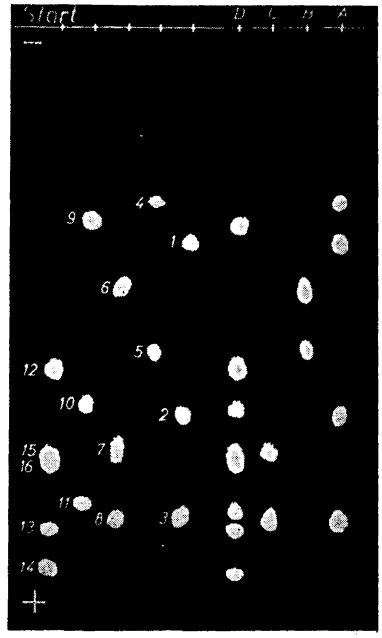

Fig. 3. Fractionation of the groups obtained in Fig. 1 by paper ionophoresis. Sodium acetate buffer of pH 4.15 and of ionic strength 0.1; 10 V/cm; 12 h. The mobility of the substances is compared with that of the authentic nucleotides and the numbers refer to the same substances as in Fig. 1.

temperature constant the liquid was cooled with tap water. The whole apparatus was placed under a cover which prevented the evaporation of the carbon tetrachloride.

When it is desirable to make a separation of a certain fraction on a large scale, it is advisable to apply the mixture as a line and if the substances to be separated have greatly differing mobilities a shorter paper can be used

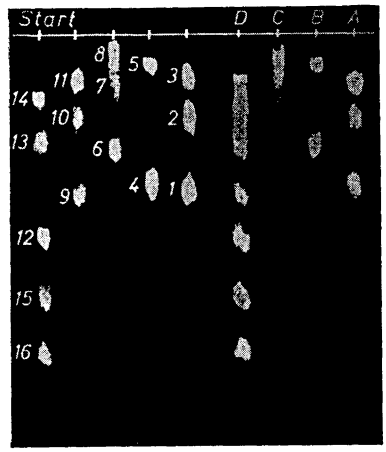

Fig. 4. One-dimensional chromatogram of the groups from Fig. 1 in 95 % ethanol-1 M ammonium acetate, pH 7.5 (75:30), 75 h. The reference substances have the same numbers as in Fig. 1.

to effect the fractionation. The length of the paper can be shortened by the use of other frames. The apparatus is suitable for two-dimensional ionophoresis and for a combination of ionophoresis and chromatography too, but these methods were not used in the present work.

When ionophoresis was completed, the paper was hung up to dry and then printed in ultraviolet light in the usual way. Then the spots containing the substances were located, cut out and eluted with 1 ml of 0.1 N hydrochloric acid. To allow for ultraviolet absorbing substances in the paper, densities were measured against the appropriate blanks. In this way the amounts of all the nucleotides could be calculated with the exception of UDPG and UDPAG, which were not separated from each other. The latter substances could be separated by chromatography in a solvent composed of 7.5 volumes of 95 % ethanol and 3 volumes of 1 M ammonium acetate solution of pH 7.5 [9]. Since the R_F values are rather low, it is advantageous to use the descending method and to cut notches in the papers at the bottom, from which the solvent is allowed to drip. Development for 75 h gave the separation shown in Fig. 4 in relation to authentic substances. Besides UDPG and UDPAG some other nucleotides were separated and another value of their concentration could be calculated. Several nucleotides, such as UDP, UTP, CDP and CTP or DPN and AMP, overlap in this solvent system. The guanosine polyphosphates form tails and are also badly separated.

Several mixtures of authentic nucleotides were analysed by the present procedure; the results of one of these analyses are summarized in Table 2.

Recoveries of 90—100 % were obtained regularly, the losses being mainly manipulational and no decomposition of any nucleotide could be detected. The method has been applied with success to the analysis of the acid-soluble nucleotide fraction from different plant materials.

EXPERIMENTAL

Paper chromatography

The group separation of the nucleotide mixture was performed in a large rectangular chromatographic chamber, 60 cm long, 30 cm wide and 115 cm high, which is large enough to handle up to 4 paper sheets, 50 × 110 cm. The atmosphere of the chamber must be saturated with the solvent mixture and therefore the walls of the chamber were lined with filter paper extending to the whole height of the chamber. Approximately 150 ml of the solvent mixture were poured into the tank, care being taken to wet the lining paper thoroughly. Before a run was started the papers were equilibrated with the solvent mixture for 8 h. When the solvent has run a convenient distance (in about 35 h) the paper was removed and dried at room temperature.

The nucleotides were located by making a contact print in monochromatic ultraviolet light of 254 mμ and then the bands were eluted and the quantitative evaluation of the amounts of material in each group performed as previously described. The nucleotides from each group were adsorbed on norite and eluted by repeated shaking with small volumes of an aqueous solution containing 50 % ethanol and 1 % ammonia. The elution was repeated in the cold until no more ultraviolet absorbing material was eluted, and the eluates were immediately adjusted to pH 7 with hydrochloric acid. In this way the concentrated solutions were also freed from salts which interfere with the ionophoretic separation.

Table 2. Analysis of a mixture of authentic nucleotides. The concentrations expressed in μmoles were calculated using the molecular extinction coefficients previously reported [1].

Compound	μmoles of nucleotide		Recovery %
	Calculated	Found	
AMP	2.39	2.28	95
ADP	3.02	3.05	101
ATP	3.24	3.08	95
DPN	2.89	2.72	94
TPN	2.16	2.10	97
GMP	2.77	2.74	99
GDP	2.74	2.74	100
GTP	2.95	2.77	94,
CMP	3.26	3.13	96
CDP	2.94	2.82	96
CTP	3.04	2.95	97
UMP	2.60	2.65	102
UDP	3.02	2.96	98
UTP	3.11	2.99	96
UDPG	2.68	2.55	95
UDPAG	2.40	2.33	97

The paper chromatographic separation in ethanol — 1 M ammonium acetate of pH 7.5 (75:30) was carried out with the standard size of paper (46 × 57 cm) and a conventional type of box was used. For quantitative estimations, the spots were cut out and eluted with 1.0 ml of 0.1 N hydrochloric acid. The optical densities of the extracts were measured in a 1.00 cm quartz cuvette in a Beckman Universal Spectrophotometer, Model DU, adapted for measuring small volumes.

Paper ionophoresis

Ionophoresis was carried out on Whatman No. 1 papers (40 × 110 cm) purified by washing three times with N hydrochloric acid and finally with water until the pH of the paper was about 7. The removal of interfering substances is particularly important in paper ionophoresis where the movement of nucleoside polyphosphates is otherwise severely retarded.

The material was applied to the dry paper at a cross line 15 cm from one edge; placing the substances in lines rather than circular spots gave much sharper separations. Sodium acetate buffer of pH 4.15 and of ionic strength 0.1 was used. Phosphate buffers were avoided because of the desirability of making phosphorus analyses on material eluted from the spots.

The paper was impregnated with buffer by dipping one edge of the paper into the buffer solution; when the buffer front has almost reached the samples, further movement

was arrested by dipping the other edge of the paper into the buffer and allowing this second front to meet the first. The excess moisture was removed and then the paper was placed on a glass frame and immersed into the vessel containing the carbon tetrachloride. After a run for 10 to 12 hours the paper was dried and then the nucleotides were revealed by taking an ultraviolet contact print. The quantitative estimations were performed as described above.

Materials

The nucleotides used were obtained from the Sigma Chemical Company. Stock solutions were first prepared of all the compounds and the composition of these solutions was carefully analysed by paper chromatography and ionophoresis. The mixture to be analysed was obtained by mixing carefully measured volumes of these stock solutions.

The author wishes to express his gratitude to *Sigma Chemical Company* for gifts of many of the nucleotides.

This work has been supported by grants from the *Swedish Natural Science Research Council.*

L'Action du Tétra-acétate de Plomb sur l'α-D-Galactopyranosyl-2-D-glucose, Préparé à Partir de l'Umbelliférose

ALF WICKSTRØM

Universitetets farmasøytiske institutt, Blindern-Oslo, Norvège

The reaction between lead tetra-acetate and 2-α-D-galactopyranosyl-D-glucose has been studied. The disaccharide was prepared from umbelliferose and the presence of a (1→2)-linkage in this trisaccharide was confirmed. The cyclic hemiacetal form of the reducing disaccharide examined is not so easily opened during the oxidation with lead tetra-acetate as in the case of 2-O-methyl-D-glucose, reported in the literature.

Par hydrolyse partielle de l'umbelliférose (α-D-galactopyranosyl-2′-α-D-glucopyranosyl-β-D-fructofuranoside) nous obtenons un disaccharide réducteur, l'α-D-galactopyranosyl-2-D-glucose. Ce disaccharide, possédant la liaison (1 → 2) assez rare, a été soumis à l'oxydation au moyen du tétra-acétate de plomb (T.A.Pb.).

Selon Perlin et coll.[2,3] le T.A.Pb. est un réactif généralement utile dans l'étude de la structure des disaccharides réducteurs. Dans des conditions bien définies le résultat de l'action du T.A.Pb. sur les disaccharides réducteurs dépend de la position du pont osidique.

Le comportement des disaccharides (1 → 2) vis-à-vis de cet oxydant a été établi par analogie avec l'oxydation des O-méthyl-2-aldoses [2,3] et ensuite confirmé par l'étude de l'α-D-mannopyranosyl-2-D-mannose [4]. En présence de catalyseur (acétate de potassium) le T.A.Pb. paraît oxyder les sucres, O-substitués sur C_2, sous leur forme linéaire en libérant une molécule de formaldéhyde. En absence de catalyseur et à la température du laboratoire ces sucres sont pratiquement résistants vis-à-vis du T.A.Pb. pendant les premiéres 30 minutes de contact. Cette rèsistance, ainsi que la libération d'une molécule de formaldéhyde pendant la réaction catalysée, distingueraient les disaccharides (1 → 2) de tous les autres disaccharides réducteurs [2,3].

Les résultats de l'oxydation non catalysée de l'α-D-galactopyranosyl-2-D-glucose se trouvent dans le Tableau 1. Ils sont conformes à ceux de Perlin et coll.

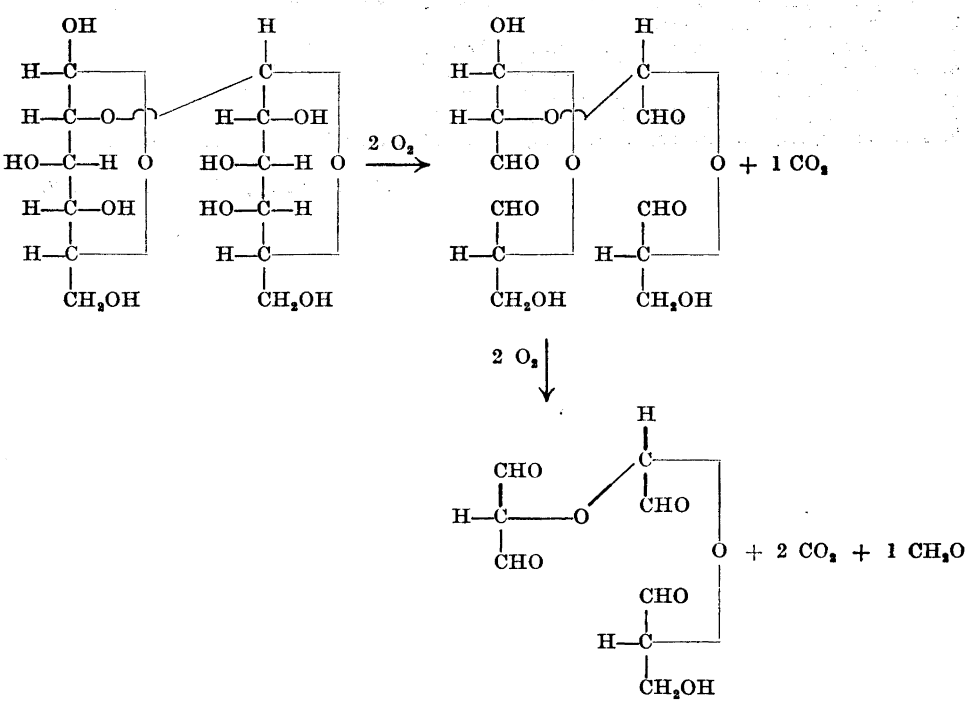
Tableau 1. Oxydations au moyen du tétra-acétate de plomb (T.A.Pb.) en absence de catalyseur.

Durée de contact à 18° (minutes)		15	30	45
Molécules [a] de T.A.Pb. réduites	I [b]	0.20	0,24	0,49
	II [c]	0,80	1,23	1,55

a) par molécule de substance mise en oeuvre.
b) α-D-galactopyranosyl-2-D-glucose
c) β-D-galactopyranosyl-4-D-glucose (lactose)

Dans le Tableau 2 sont exposé les résultats de l'oxydation catalysée de la même substance. Ils ne sont pas tout à fait conformes aux faits rapportés par Perlin et coll., notre substance ne libérant que 0,55 molécules de formaldéhyde et après 5 heures seulement. Les quantités de T.A.Pb. réduite et d'anhydride carbonique dégagée correspondent bien à la quantité de formaldéhyde retrouvée après l'oxydation. Tout se passe donc comme si la partie réductrice du disaccharide étudié est stabilisée sous forme cyclique et comme si la réaction-se passe par deux étapes (v. schéma I), la première étant la plus rapide.

La comparaison du Tableau 2 avec le schéma I fait ressortir l'influence des réactions secondaires, déjà signalées par Perlin et coll. Ces réactions sont probablement dues à l'hydrogène du carbone 2 activé par la formation d'une fonction carbonyle sur le carbone 3. Ils impliquent une consommation supplémentaire de l'oxydant. A une température légèrement plus haute (32° au lieu de 27°) les réactions secondaires sont plus importantes, la quantité de formaldéhyde libérée ne changeant guère.



Le mémoire présent donne un exemple d'un disaccharide (1 → 2) qui, soumis à l'oxydation au moyen du T.A.Pb., se comporte d'une façon légèrement différente du seul disaccharide (1 → 2) étudié jusqu'ici. La libération

Erythritol	1,90					
Mannitol	1,93					
Lactose	0					0,05

a) pour une molécule de substance mise en oeuvre.

Schéma I. Oxydation de l'α-D-galactopyranosyl-2-D-glucose au moyen du tétra-acétate de plomb (T.A.Pb.)

partiellement empechée du formaldéhyde ne semble pas nuir à l'utilité du T.A.Pb. dans l'étude de la structure des disaccharides réducteurs. L'ensemble de nos résultats confirme donc la présence d'une liaison (1 → 2) dans l'umbelliférose.

PARTIE EXPERIMENTALE

1. *Préparation de l'α-D-galactopyranosyl-2-D-glucose.* L'umbelliférose (0,8 g) dissous dans l'acide sulfurique 0,01 N (70 ml) fut chauffé à reflux (100°) jusqu'à libération complète du fructose terminal (2 à 3 h, controlée par chromatographie sur papier). L'hydrolysat fut neutralisé ($BaCO_3$) et le disaccharide réducteur fut isolé et purifié à l'aide des colonnes de charbon-celite [5]. Rendement: 0,30 g d'un poudre blanc, chromatographiquement homogène, qui cristallise après quelque temps sous vide. Analyses: (substance séchée au poids constant dans le vide sur le P_2O_5 à 60°) F: 118°—120°, $[\alpha]_D^{20}$ + 145° (c = 2, eau, équilibre), pouvoir réducteur vis-à-vis de l'hypoiodite de sodium [6]: calc. pour $C_{12}H_{22}O_{11}$: 52,64 % de celui du D-glucose, tr: 52,75 %. Traité par la phénylhydrazine il ne donne pas d'osazone.

2. *Oxydations au moyen du T.A.Pb.* Nous avons suivi les modes opératoires décrits par Perlin et coll. [3-4]. Le formaldéhyde fut dosé par photométrie selon Alexander et coll.[7]. Dans quelques expériences où la prise d'essai fut rélativement importante (12—14 mg) le formaldéhyde libéré après 5 h d'oxydation à 30° a été isolé à l'aide de dimédon. Rendement: 55—60 % de la théorie. Point de fusion de la combinaison dimédon-formaldéhyde: 190°.

Studies on the Chemistry of Lichens

II *. Chemical Components of *Haematomma ventosum* (L.) Mass. var. *lapponicum* (Räs.)

YNGVE JOHANNES SOLBERG

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Thamnolic acid and a new lichen substance, called *ventosic* acid, $C_{22}H_{44}O_6$, have been isolated from *Haematomma ventosum* (L.) Mass. var. *lapponicum* (Räs.). The new substance is an aliphatic compound. It contains four hydroxyl and one carboxyl group. Reaction with hydriodic acid and reduction with zinc and glacial acetic acid affords n-*docosanoic* acid (behenic acid). This result is in harmony with the new substance being tetrahydroxy behenic acid.

Haemotomma ventosum is a crustose lichen and is rather common on boulders and rocks on mountain-wilds. Sometimes it covers large areas. Our material was collected in Trabelia, the middle part of Gudbrandsdal, Norway, and the greatest possible care was taken to avoid contamination by other species.

The lichen *Haematomma ventosum* (L.) Mass. is known in two varieties. The one is *lapponicum* giving a bright red colour with *p*-phenylenediamine, the other does not give any colour with this reagent.

Knop, Hesse and Zopf [1–5] were the first to examine samples of this lichen, but they did not indicate which of the varieties they dealt with. The obsolete methods employed could not yield complete information regarding the composition of the lichen.

A thorough examination of *Haematomma ventosum* (L.) Mass. var. *lapponicum* (Räs.) has now been made using a series of solvents in succession for extraction. During the years 1955 and 1956 in all about four kilogrammes were extracted. As a result of this investigation it has been found that the important components of this lichen are usnic, divaricatic and thamnolic acid and a new lichen substance, for which the name *ventosic* acid was adopted. Previous investigators did not obtain thamnolic acid from this lichen. The structure of thamnolic acid has been established by Asahina and coworkers, both by degradation and by synthesis [6–10].

* Part I. *Acta Chem. Scand.* 9 (1955) 1234.

The crude thamnolic acid obtained from ether and acetone extracts was collected and thoroughly washed with chloroform and ethanol. Recrystallisation was effected several times conveniently from dioxan giving thamnolic acid with one molecule dioxan as light yellow prisms [11], m.p. 210—211° (decomp.). After drying *in vacuo* thamnolic acid gave analytical values agreeing with the formula $C_{19}H_{16}O_{11} \cdot C_4H_8O_2$. The crystalline product gave the same colour reactions and has the same properties as mentioned for thamnolic acid in the literature [12,13]. Thamnolic acid is very sparingly soluble in most organic solvents but may be crystallised from acetone or dioxan.

With barium hydroxide the substance gave the same characteristic yellow crystals as reported by Zopf for hirtellic acid [12] (identical with thamnolic acid).

A proof of the identity was possible by mixed melting point determination and X-ray diffraction patterns. The comparison of X-ray diffraction patterns of authentic thamnolic acid and the substance isolated here, both crystallised from dioxan, gave the spacing values in Å, recorded in Table 1.

Table 1. Spacing values in Å. (w = weak, m = medium, s = strong, vs = very strong).

By working up the mother liquors from the acetone extractions another aldehydic substance was obtained which was found to be identical with decarboxythamnolic acid. This substance has so far not been detected in lichens and it is most likely produced during the extraction with acetone. Asahina [8] made the same observation.

Zopf [3] and Hesse [5] isolated small quantities of an aldehydic substance from *Haematomma ventosum*, for which the name *ventosaric* acid was adopted by Zopf. Zopf gave the melting point at 205—207°, Hesse at 190° which is not far from that of thamnolic acid. Ventosaric acid further resembles thamnolic acid in having a low solubility in ethanol and acetone and in its colour reactions with ferric chloride, sodium hydroxide and concentrated sulphuric acid. These facts would suggest that ventosaric acid is identical with thamnolic acid.

When the extraction was carried out with acetone and ethanol a white amorphous, sparingly soluble precipitate was formed in the extraction flask. This precipitate gave after purification, as described in the experimental part, ventosic acid as a white amorphous powder, m.p. 183—185°. The substance was soluble in hot ethanol, glacial acetic acid, dioxan, aniline and pyridine. In other organic solvents it had a very low solubility. After drying the acid gave analytical values agreeing with the formula $C_{22}H_{44}O_6$. Several attempts were made by means of the method of Pirsch to obtain a molecular weight, but without result. Ventosic acid did not contain methoxyl groups and exhibited no carbonyl function. It was recovered unchanged after boiling with sodium hydroxide solution as well as on diluting its solution in cold concentrated sulphuric acid.

Ventosic acid on treatment with acetic anhydride and a trace of concentrated sulphuric acid gave a colourless glassy compound, m.p. about 54°, the composition of which corresponded to a tetra-acetate. The acetate has so far not crystallised. On boiling with ethanolic potassium hydroxide it was deacetylated to the orginal substance.

With *p*-phenylazobenzoyl chloride [14] the substance yielded an orange-red tetrabenzoate, $C_{37}H_{38}O_5N_4$, m.p. 153—157°.

Treated with hydriodic acid ($d = 1.7$) ventosic acid yielded a dark brown oil which could not be purified or crystallised. As the crude oily product contained iodine it was reduced with zinc dust in glacial acetic acid. The resulting product crystallised in colourless needles, m.p. 75°. Repeated recrystallisations from different solvents did not raise the melting point discernibly and no evidence was obtained for the presence of more than one component. It contained no hydroxyl groups and was identified as behenic acid, $C_{22}H_{44}O_2$, by preparation of the methyl ester, m.p. 52—53°, and by X-ray analysis. All these values correspond well with those given in the literature. (Similar reduction has been made with 13,14-dihydroxy-behenic acid by Urwanzopp [15]. The behenic acid obtained in this manner had the m.p. 74—76°)

The higher fatty acids exhibit at least three polymorphic forms and X-ray measurements show that these crystal modification possess different spacings. The most important of these modifications are designated as α- and β-, the former showing a C crystal spacing and the latter a somewhat longer B spacing, (Ref.[16]). The X-ray investigations of Müller and Shearer [17–19] showed that the fatty acids exhibit three characteristic lines d_1, d_2 and d_3. The last two

Table 2.

d_1 C spacing	49.6 »	49.0 »	48.5 »
d_2	4.14 »	—	4.1 »
d_3	3.73 »	—	3.7 »

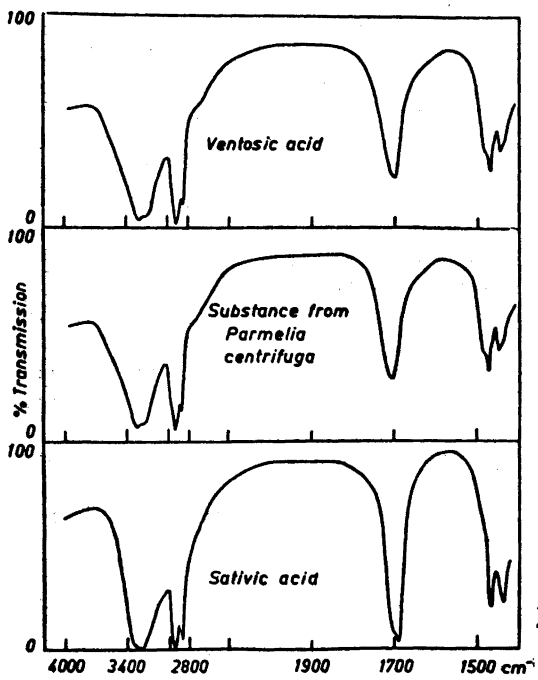

Fig. 1. Infrared absorption spectra from 4 000 — 1 450 cm^{-1}. All substances as pressed KBr — disks.

lines are essentially constant for a specific series and are the diffractions from planes parallel to the long axes of the molecules. The long spacing d_1 is a function of the number of carbon atoms in the chain.

The results of X-ray examinations of the behenic acid obtained by reduction of ventosic acid and of authentic sample of behenic acid are shown in Table 2. The acids gave extremely good reflections.

Infrared analysis of ventosic acid ascertained the presence of an aliphatic carbonyl-hydroxy-compound. The infrared absorption spectrum in the region 4 000 cm^{-1} — 700 cm^{-1} showed strong bands at 3 280 cm^{-1} and at 1 710 cm^{-1}. The observed values indicate the presence of hydroxyl and carbonyl groups, respectively. The frequency at 1 710 cm^{-1} would suggest the presence of a dimer aliphatic acid [20,21]. Further bands at 2 920 cm^{-1} and at 1 470 cm^{-1} — 1 445 cm^{-1} corresponded to C-H and C-H_2 stretching frequencies in saturated aliphatic compounds. The 1 382 cm^{-1} band shows that a C-CH_3 group is present. There were only few bands below 1 450 cm^{-1}.

An infrared spectrum of sativic acid (tetrahydroxystearic acid), m.p. 168—171°, was very similar to that of ventosic acid in the region 4 000 cm^{-1} — 1 450 cm^{-1}. The same characteristic bands were observed (Fig. 1). This adds strength to the conclusion that ventosic acid must be an aliphatic hydroxy acid.

X-Ray diffraction patterns of sativic acid showed a certain similarity with that of ventosic acid. Characteristic are the two strong peaks in the region 4.0—4.9 Å, (Fig. 2).

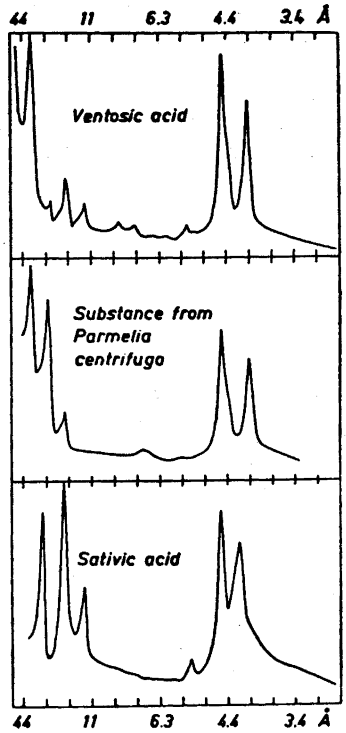

Fig. 2. X-Ray powder diagrams taken with Cu-$K\alpha_1$ radiation.

It was quite impossible to obtain an ester of ventosic acid. This is remarkable because the isolated substance most probably is an aliphatic tetrahydroxy carboxylic acid. On the other hand sativic acid was easily converted into the methyl ester by reaction with methanol and concentrated sulphuric acid.

Both ventosic and sativic acid were practically insoluble in sodium hydroxide solution.

Metabolic products of *Parmelia physodes* (L.) Ach. and *Parmelia furfuraceae* (L.) Ach. have been studied in detail by Zellner [22,23]. He obtained two white, amorphous substances which he called *hypogymnole*. The physical and chemical properties of these substances are in agreement with those of ventosic acid from *Heamatomma ventosum*. An allied substance has been isolated by Klima [24] from *Alectoria ochroleuca* (Ehrh.) Nyl. Zellner and Klima did not, however, establish the chemical composition of these substances.

A preliminary examination of these three lichens showed that the substances detected by Zellner and Klima most likely are identical with ventosic acid from *Haematomma ventosum*. Also the lichens *Parmelia centrifuga* (L.) Ach., *Cetraria nivalis* (L.) Ach. and *Cladonia alpestris* (L.) Rabh. were investigated. Hereby substances either identical or closely related to ventosic acid have been isolated. X-Ray and infrared analysis have been used.

As an example X-ray diffraction pattern and infrared absorption spectrum of the substance isolated from *Parmelia centrifuga* are shown in Figs. 1 and 2.

Lack of material has so far not permitted degradative experiments on ventosic acid on a larger scale. However, it is of interest to note that ventosic rapidly acid is oxidised by periodic acid. It is hoped to establish the structure of ventosic acid by investigation of the oxidation products.

EXPERIMENTAL

(Melting points are uncorrected.)

Extraction and isolation of the lichen substances

Usnic acid. The fresh lichen obtained was air-dried and ground into coarse powder (1 000 g), and exhaustively extracted with ether in a Soxhlet apparatus. During the extraction usnic acid separated as large yellow crystals in the flask. After 20 h when the extraction was found to be completed the crystals were removed by filtration and washed with ethanol. Usnic acid was recrystallised from chloroform-ethanol (1:3). Yield 24.5 g; m.p. 199–200°; $[\alpha]^{21}_D$ +500° (chloroform, c = 2.355).

Divaricatic acid. The ether extract was evaporated. The residue which consisted of crystals and an oily substance was treated with small quantities of ether. The ether-soluble portion was evaporated and the residue recrystallised from 60 % ethanol. The substance was identified as divaricatic acid. Repeated recrystallisations from ethanol and glacial acetic acid yielded 3.7 g; m.p. 135–137°. The acid dissolved readily in ether and ethanol at room temperature, and also in hot chloroform, benzene and glacial acetic acid. An alcoholic solution of the substance turned violet on the addition of a drop of ferric chloride solution.

The ether insoluble portion was washed with alcohol. Pale yellow crystalline product (Fraction A).

The residual lichen was subsequently extracted with acetone for 20 h. During the extraction the new compound (ventosic acid) separated as a colourless amorphous powder. It was removed by filtration and washed with acetone, ethanol and ether. Finally dried at 70° for 30 min (Fraction B). The dark red extract was concentrated by distilling off the solvent. More yellow crystalline product separated (Fraction D). The solid was filtered off and the mother liquid evaporated. The residue, a reddish brown resinous mass was shaken with 800 ml ethanol for one hour. The alcohol-soluble part was not further investigated. The insoluble part could be divided into two portions by treatment with hot chloroform. The chloroform-insoluble portion was collected by filtration and washed with alcohol (Fraction D).

Decarboxythamnolic acid. The chloroform extract yielded a pale yellow crystalline product on standing in a refrigerator. This was filtered off and washed with small quantities of ether, (1.6 g). Repeated recrystallisations from ethyl acetate yielded decarboxythamnolic acid in a pure state. Yield 23 mg; m.p. 213–215° (decomp). (Found: C 57.18; H 4.12; Calc. for $C_{18}H_{16}O_9$: C 57.46; H 4.29). As described by Asahina the decarboxythamnolic acid was soluble in hot acetone, ethanol, ethyl acetate and chloroform. On heating with potassium hydroxide and chloroform the substance gave a deep red solution. With barium hydroxide no characteristic crystals were obtained.

Thamnolic acid. Fraction A from the ether extraction and the fractions C and D from the acetone extraction of the lichen were found to be the same substance. The fractions were collected (17.7 g), and recrystallised repeatedly from dioxan. Pale yellow needles, m.p. 210–212° (decomp.). Mixed melting point with authentic sample of thamnolic acid showed no depression. (Found: C 54.43; H 4.70; Calc. for $C_{19}H_{16}O_{11} \cdot C_4H_8O_2$: C 54.33; H 4.76).

Ventosic acid. The residual lichen powder was finally extracted with 96 % ethanol for 48 h. On standing the extract gave some ventosic acid. Together with the fraction B from the acetone extract, the yield of crude ventosic acid was about 0.8 %. The sub-

stance was purified by recrystallisation from dioxan, ethanol and glacial acetic acid. White, amorphous powder, m.p. 183°. (Found: C 65.29; H 10.88; Calc. for $C_{22}H_{44}O_6$: C 65.30; H 10.96). It gave none of the colour reactions characteristic for lichen substances. The compound was without taste.

Derivatives of ventosic acid

Acetylation. Ventosic acid (1.0 g) was heated on a steam bath for 45 min with 30 ml of the following mixture: 30 g acetic anhydride +220 ml pyridine. During the reaction the solution became brown. The reaction mixture was then poured into ice-water with good stirring. The brown oily product which separated was extracted with ether and the ether solution evaporated. The dark oily residue was dissolved in ethanol and treated with active carbon, filtered and the colourless solution evaporated to dryness. The acetyl compound was thus obtained as a colourless glassy product, m.p. 54°. It could not be crystallised. (Found: for material dried *in vacuo* over KOH: C 62.67; H 9.21; Calc. for $C_{30}H_{52}O_{10}$: C 62.92; H 9.15).

Deacetylation. The acetyl compound (0.31 g) was boiled with alcoholic potassium hydroxide (25 ml 0.5 N) for 30 min. After a short time a white amorphous powder precipitated. After cooling the powder was removed by filtration and washed with water and alcohol. To remove ash-components the product was recrystallised from glacial acetic acid and washed with alcohol and ether; m.p. 182°. It was found to be identical with the original substance, ventosic acid, the mixed melting point being undepressed. X-Ray diffraction patterns were also identical. (Found: C 65.19; H 10.68; Calc. for $C_{22}H_{44}O_6$: C 65.30; H 10.96).

p-*Phenylazobenzoate.* A mixture of ventosic acid (1.0 g), *p*-phenylazobenzoylchloride (2.4 g) and dried pyridine (6 ml) was refluxed for one hour. The reaction mixture was filtered, cooled and poured into a solution of 10 % sodium hydrogen carbonate and ice. The orange-red precipitate obtained was filtered off and thoroughly washed with water. Recrystallisation from a benzene-ethanol mixture gave orange-red powder. Yield 0.68 g; m.p. 153—157°. (Found: C 71.59; H 6.63; N 8.15; Calc. for $C_{74}H_{76}O_{10}N_8$: C 71.89; H 6.19; N 9.06). The benzoate was easily soluble in benzene and ether with a dark red colour.

Reduction to behenic acid. Ventosic acid (4.35 g) was refluxed with 100 ml hydriodic acid (b.p. 126°) for 10 min. The solid rapidly turned to a dark brown oily product. The reaction mixture was diluted with water and extracted with ether. The ether extract was shaken with an aqueous solution of sodium thiosulphate and at last washed with water. The ether solution, dried and concentrated, yielded a light yellow viscous liquid, (3.1 g). As the liquid contained halogen it was boiled with zinc powder in glacial acetic acid (25 ml) for one hour. The reduction product was obtained in a crystalline state when the filtered solution was evaporated *in vacuo*. The residue was washed with much water and recrystallised several times from diluted acetic acid and petroleum ether (30—50°); m.p. 74—75°, undepressed on admixture with authentic behenic acid (m.p. 78—79°). Yield about 1 g. The substance was readily soluble in ether, acetone, ethanol and benzene. (Found: C 77.54; H 12.82; mol.wt. (Landsberger) 313, 314; Calc. for $C_{22}H_{44}O_2$: C 77.55; H 13.02; mol.wt. 341).

Behenic acid methyl ester. The methyl ester was prepared from behenic acid (110 mg) with diazomethane. The ester recrystallised from methanol (10 ml) gave a quite colourless and crystalline product; m.p. 52—53°. No depression of the melting point when mixed with an authentic sample of behenic acid methyl ester. (Found: C 78.10; H 13.01; CH_3O 9.89; $C_{23}H_{46}O_2$ requires C77.89; H 13.07; CH_3O 8.75).

Tetrahydroxystearic acid (Sativic acid). The hydroxy acid was prepared from linolic acid tetrabromide (m.p. 115—116°) in the same manner as described by Rollett [25] and Hazura [26]. The crude product of sativic acid was recrystallised from dilute hydrochloric acid, washed with water and dried. Then shaken with hot benzene and at last recrystallised from alcohol. Colourless, crystalline product; m.p. 168—171°. (Found: C 62.18; H 10.51; $C_{18}H_{36}O_6$ requires C 62.10; H 10.41).

Sativic acid methyl ester. Sativic acid (300 mg) was suspended in a solution of methanol (30 ml) and concentrated sulphuric acid (3.3 ml) and refluxed for 2 h. After cooling the solution was diluted with water. A white precipitate was formed. This was filtered off and recrystallised from methanol-water (1:1). The colourless, crystalline product was

removed by filtration and washed with methanol and ether. Yield 170 mg; m.p. 146–156°. Once more purified by recrystallisation from white spirit (160–180°) (50 ml). M.p. 147–151°. (Found: C 63.14; H 10.33. $C_{19}H_{38}O_6$ requires C 62.95; H 10.57).

By the X-ray diffraction analysis, a small amount of the substance was melted on a glass plate and spread out so as to form a very thin film. The instrument used was a Philips X-ray Geiger Counter Spectrometer with Cu-$K\alpha_1$ radiation.

The author wishes to express his indebtness to Dr. Carl Axel Wachtmeister, Stockholm, for a sample of thamnolic acid, and to Professor Dr. Endre Berner and Cand. real. Eilif Dahl for their advice and interest in this work.

Behenic acid was kindly provided by Jahres Kjemiske Fabrikker, Sandefjord, Norway.

Fungus Pigments

V*. Degradations of Cinnabarin

JARL GRIPENBERG, ERKKI HONKANEN and ORA PATOHARJU

Department of Chemistry, Finland Institute of Technology, Helsinki, Finland

Fungus material from Central-Africa, labelled as *Polystictus sanguineus*, gave, in addition to the desired cinnabarin, a second pigment, $C_{14}H_8O_4N_2$, termed cinnabarinic acid. Oxidation of cinnabarin with potassium permanganate gives benzoxazolone-4-carboxylic acid and with hydrogen peroxide oxalic or oxamic acid. No pure substances were isolated after zinc dust distillation but the spectra of some fractions indicated the occurrence of carbazole and phenoxazin-3-one derivatives. A partial formula based on the phenoxazin-3-one ring system is proposed for cinnabarin.

Shortly after publication of our first paper on cinnabarin [1], the pigment of *Trametes cinnabarina* Jacq., there appeared two papers by Australian authors [2,3] describing a pigment, polystictin, isolated from *Coriolus sanguineus* (Fr.) (*Polystictus cinnabarinus* Jacq.). However, these names are regarded as synonymous with *T. cinnabarina* [3]. Although there are some minor differences between the properties reported for cinnabarin and polystictin, both Lemberg [2] and Cavill and coworkers [3] regarded polystictin as identical with cinnabarin. This has now been confirmed by a comparison of the IR-spectrum of cinnabarin with that of polystictin published by Cavill *et al.*[3].

Although Lemberg, who had priority in the isolation of the pigment, used the name polystictin, he has proposed that the name cinnabarin should be adopted [2]. We have therefore continued to use this name.

Further work on the structure of cinnabarin was for a long time hampered by lack of material, but through kind help of Professor H. Erdtman, Stockholm, it was finally possible to secure a substantial amount of fungus material, labelled as *Polystictus sanguineus*, from tropical Africa. This material came from three different sources, namely from the Belgian Congo, Nigeria and the Gold Coast sent by Mr. J. Frasell, Dr. T. S. Robertson and Dr. M. F. Madelin, respectively.

* Part IV *Acta Chem. Scand.* **10** (1956) 1111. A preliminary account of the present work has been published in *Chemistry & Industry* **1956** 1505.

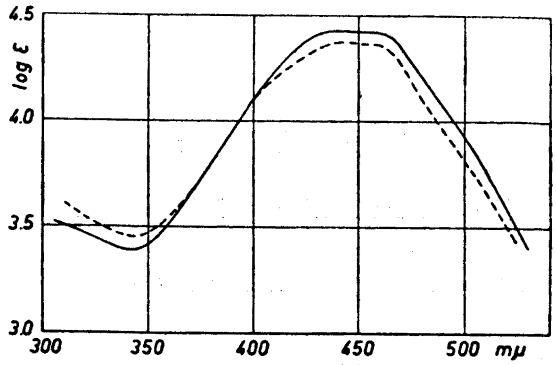

Fig. 1. Absorption curves of cinnabarin (————) and cinnabarinic acid (— — —) in pyridine.

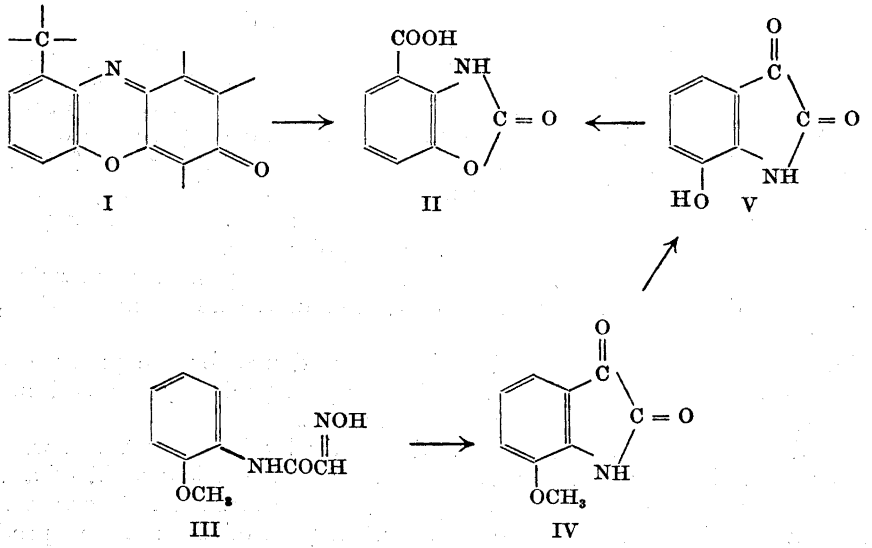
The crude pigment obtained by extraction of this fungus material as previously described [1] was found to be a mixture of cinnabarin and another pigment, for which we propose the name cinnabarinic acid. Cinnabarinic acid differs clearly from cinnabarin in its greater acidity, being readily soluble in sodium hydrogen carbonate. The separation of the two pigments can be achieved either by using this property or by fractional extraction with hot pyridine, in which cinnabarinic acid is much more soluble.

Lemberg [2] has described a pigment, polystictinin, accompanying his polystictin. A comparison of the properties of polystictinin with those of cinnabarinic acid shows, however, that these two cannot be identical.

The analytical figures for cinnabarinic acid agree well with those required for $C_{14}H_8O_6N_2$, but it should be kept in mind that this result is from analysis of a single preparation, the purity of which is difficult to assess, owing to lack of a melting point. As cinnabarin has the composition $C_{14}H_{10}O_5N_2$ cinnabarinic acid thus differs in having one oxygen atom more and two hydrogen atoms less. A close relationship between cinnabarin and cinnabarinic acid is also indicated by the almost identical absorption curves (Fig. 1). Work is in progress aimed at relating cinnabarinic acid with cinnabarin.

Earlier work had given very little information about the structure of cinnabarin. Each group had observed that cinnabarin on alkaline hydrolysis gives one molecule of ammonia [1-3]. Cavill *et al.*[3] inferred from the IR-spectrum that cinnabarin contains a carboxamide group and also concluded that cinnabarin contains an acidic hydroxyl group and an ether oxygen, as well as a quinonoid system. Nothing was known about the basic ring system.

In the hope of obtaining some products containing a smaller or larger part of the basic skeleton, we have treated cinnabarin with different oxidants under varying conditions and submitted it to zinc dust distillation.



Oxidation with potassium permanganate proved to be most informative. It gave a substance, m.p. 279—281°, of the composition $C_8H_5O_4N$. With diazomethane this gave a dimethyl derivative, $C_{10}H_9O_4N$, with however, only one methoxyl. At this stage of the investigation the electronic spectrum of

cinnabarin which shows a close similarity to that of actinomycin, suggested that cinnabarin might be structurally related to the group responsible for the spectrum of the actinomycin molecule. According to Brockmann and Muxfeldt [4] this is derived from phenoxazin-3-one, and Johnson and coworkers [5,6] showed that oxidation with alkaline hydrogen peroxide followed by acid hydrolysis to remove the amino acids, gives 7-methylbenzoxazolone-4-carboxylic acid. Our oxidation product could therefore be benzoxazolone-4-carboxylic acid (II) a view further supported by the similarity of the UV-spectrum of our product with that found by Bullock and Johnson [6] for 7-methylbenzoxazolone-4-carboxylic acid.

Benzoxazolone-4-carboxylic acid was synthesised and was found to be identical with our oxidation product. The identity was established by mixed melting points of both the free acid and its dimethyl derivative with the corresponding synthetic substances. The dimethyl derivative must be methyl N-methyl-benzoxazolone-4-carboxylate; Zinner and Herbig [7] have shown that methylation of the benzoxazolone system with diazomethane leads to the N-methyl derivative.

It was therefore concluded that cinnabarin is a derivative of phenoxazin-3-one. Cavill and Tetaz [8] have also arrived at this conclusion. The recently reported observations that on oxidation phenoxazin-3-one gives benzoxazolone [6] and 2-amino-1,9-diacetylphenoxazin-3-one gives 4-acetylbenzoxazolone [9] gives further support to this view.

The benzoxazolone-4-carboxylic acid was synthesised by an analogous method to the synthesis of 7-methylbenzoxazolone-4-carboxylic acid [6]. The starting material was 7-methoxyisatin (IV). This was prepared by a modification of the Sandmeyer reaction from *o*-anisidine. Although Sandmeyer [10] explicitly states that the ring closure to an isatin derivative cannot be affected with *iso*nitroso-acet-*o*-anisidide (III) we found that use of polyphosphoric

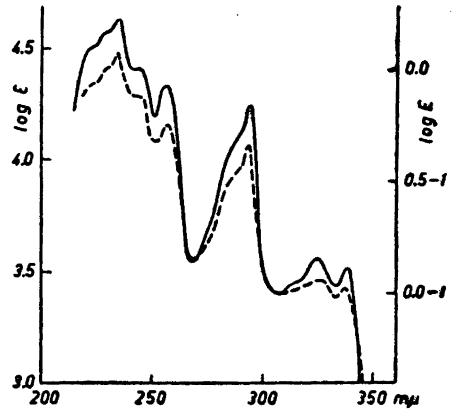


Fig. 2. Absorption curves of carbazole (————) and fraction e from zinc dust distillation (— — —) in hexane. The extinction values for the former are on the left hand side and for the latter on the right hand side.

acid instead of sulphuric acid brings about the desired ring closure, giving 7-methoxyisatin (IV). This was identified by mixed m.p. determination with an authentic sample kindly supplied by Professor A. W. Johnson, Nottingham, and originally sent to him by Professor A. Mangini, Bologna. Demethylation of 7-methoxyisatin was accomplished with pyridine hydrochloride [6] and the 7-hydroxyisatin (V) was oxidised with hydrogen peroxide in the presence of sodium hydrogen carbonate giving benzoxazolone-4-carboxylic acid (II).

The formation of benzoxazolone-4-carboxylic acid (II) places a carbon atom in position 9 in the phenoxazin-3-one nucleus leading to the partial structure I. If this carbon atom were a carboxyl group or a derivative, which would give a carboxyl group on alkaline hydrolysis, it would have been expected that benzoxazolone-4-carboxylic acid would also have been formed on oxidation with hydrogen peroxide in alkaline solution, as in the oxidation of actinomycin [5,6]. The only identifiable product from hydrogen peroxide oxidation was either oxalic acid or oxamic acid according to the alkalinity of the solution. In addition a product was formed which is very difficultly soluble in organic solvents, and is non-volatile under vacuum. It has not been possible to purify this product, which appears to be polymeric.

It is therefore concluded that the carboxyl group in benzoxazolone-4-carboxylic acid has been formed by oxidation of a side chain by the permanganate.

The formation of oxamic acid is further evidence for the presence of a carboxamide group in cinnabarin. This group is probably situated in the quinonoid ring of the phenoxazin-3-one nucleus.

Zinc dust distillation had been tried already by Lemberg [2], but without much success. Even in our hands the reaction gave a low yield of a very complex mixture. No crystalline compounds were obtained but certain fractions from the chromatography of the neutral part of the reaction product

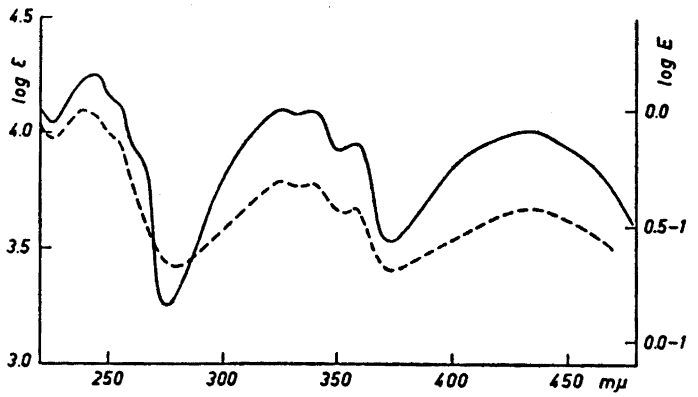

Fig. 3. Absorption curves of phenoxazin-3-one (————) and fraction 8 from zinc dust distillation (— — —) in hexane. The extinction values for the former are on the left hand side and for the latter on the right hand side.

had UV-spectra from which it has been possible to draw some conclusions about the substances present. The spectrum of one fraction was practically identical with that of carbazole (Fig. 2). This means that carbazole or a homologue (or a mixture of homologues) had been formed. Because the UV-spectra of carbazole and C-alkylated carbazoles are almost identical [11,12] it is not possible to distinguish between these alternatives.

This result was somewhat surprising. Firstly because Lemberg [2] had found no reactions typical of carbazole in his reaction product. Secondly, if cinnabarin is a derivative of phenoxazin-3-one, this means that the ring is opened at the oxygen atom which is lost, followed by ring closure again. Such an opening of the oxygen bridge during zinc dust distillation is not usually met with in simple systems such as dibenzofuran [13] and dibenzopyran [14] but there seems to be no information available about the behaviour of phenoxazines upon zinc dust distillation.

In view of the very low yield obtained, the possibility cannot be completely ruled out, that this substance was formed from some impurity in the starting material. The fact that fractions with identical UV-spectra have been obtained from two samples of cinnabarin of completely different origin can, however, be taken as evidence against such a possibility.

A further fraction had a spectrum closely similar to that of phenoxazin-3-one (Fig. 3) and this fraction evidently corresponds to the product (H) reported by Cavill and Tetaz [8].

EXPERIMENTAL

(The analyses have been performed by Dr. A. Bernhardt, Mülheim)

Separation of cinnabarin from cinnabarinic acid. a) The mixture of pigments obtained by acetone extraction of the fungus material was treated on a filter with sodium hydrogen carbonate and washed with water. This was repeated until the filtrate was no longer red.

The filtrate was run directly into dilute acid to give cinnabarinic acid as a red amorphous precipitate. This was recrystallised from pyridine giving dark brown glistening crystals, which decompose above 300° without melting. (Found: C 55.98; H 2.80; N 9.18; O 31.74. $C_{14}H_8O_6N_2$ requires C 56.01; H 2.69; N 9.33; O 31.98).

The cinnabarin remaining on the filter was purified by recrystallisation from pyridine.

b) The mixture was boiled with a small amount of pyridine, filtered hot, and allowed to crystallise. The crystals which were a mixture enriched in cinnabarinic acid, were filtered off. The mother liquor was used again for re-extraction of the undissolved material. This was repeated until the crystallisate contained pure cinnabarin, as judged by the absence of colouration upon treating a sample with sodium hydrogen carbonate. The cinnabarin was then recrystallised from fresh pyridine. Although this method readily gives cinnabarin, free from cinnabarinic acid, it is more difficult to obtain pure cinnabarinic acid and for this purpose it is better to combine it with method a).

Oxidation of cinnabarin with potassium permanganate. Cinnabarin (3.0 g) was suspended in 5 % sodium carbonate solution (120 ml) and finely powdered potassium permanganate was added with stirring until the permanganate colour persisted. The mixture was acidified with sulphuric acid and the precipitate of manganese dioxide was dissolved by adding sodium hydrogen sulphite. The solution was extracted with ten portions of ether (50 ml each). The residue from the ether extract was washed with a little water and then with benzene and sublimed (200—210°/2 mm). The sublimate was recrystallised from methanol giving benzoxazolone-4-carboxylic acid (240 mg) as slightly yellow crystals; m.p. 279—281°. (Found: C 53.17; H 2.84; N 7.74; O 34.28. $C_8H_5O_4N$ requires C 53.64; H 2.81; N 7.82; O 35.73) λ_{max} (ethanol) 239 mμ (log ε 4.05), 302 mμ (log ε 3.20); λ_{min} 224 mμ (log ε 3.80), 262 mμ (log ε 2.60); λ_{max} (0.05 N NaOH) 226 mμ (log ε 4.17), 250 mμ (log ε 4.08), 310 mμ (log ε 3.92); λ_{min} 238 mμ (log ε 3.90), 270 mμ (log ε 2.97).

Benzoxazolone-4-carboxylic acid (45 mg) was dissolved in methanol and an ether solution of diazomethane was added until the yellow colour persisted. The solution was evaporated and the residue sublimed (140—150°/2 mm) giving methyl N-methylbenzoxazolone-4-carboxylate (43 mg), m.p. 141—142° (Found: C 58.00; H 4.62; N 6.98; O 30.88; OCH_3 14.84. $C_9H_6O_3N(OCH_3)$ requires C 57.97: H 4.38; N 6.76; O 30.89; OCH_3 14.98) λ_{max}(ethanol) 240 mμ (log ε 3.90), 304 mμ (log ε 3.76); λ_{min} 226 mμ (log ε 3.74), 264 mμ (log ε 2.76).

Oxidation of cinnabarin with hydrogen peroxide. a) Cinnabarin (200 mg) was suspended in sodium hydrogen carbonate (4 %, 5 ml) and hydrogen peroxide (30 %; 5 ml) was added. More hydrogen peroxide was added from time to time until a clear almost colourless solution resulted. This took about 2 days. The solution was acidified with conc. hydrochloric acid and evaporated at room temperature in a vacuum desiccator over sodium hydroxide. The residue was extracted with several portions of hot dioxan. The dioxan solution was evaporated almost to dryness in vacuum and the crystals which formed were filtered off (*ca.* 35 mg) and recrystallised from dioxan, m.p. 210—211°. (Found N 15.40. $C_2H_3O_3N$ requires N 15.73). It gave no depression of m.p. when mixed with oxamic acid [15].

b) Cinnabarin (200 mg) was dissolved in 2 N sodium hydroxide (2 ml) and allowed to stand overnight. Hydrogen peroxide (30 %) was then added dropwise and the solution allowed to stand until it was light yellow. It was then acidified with conc. hydrochloric acid and evaporated in a vacuum desiccator over sodium hydroxide. The residue was extracted with ether and the ether evaporated giving oxalic acid.

c) Hydrogen peroxide (30 %; 2 ml) was added to cinnabarin (200 mg) followed by dropwise addition of 2 N sodium hydroxide. When the solution tended to acquire a darker colour more hydrogen peroxide was added. This was continued until a clear light yellow solution was obtained. Oxamic acid and oxalic acid were isolated from this as described in a) and b).

Zinc dust distillation of cinnabarin. A mixture of cinnabarin (252 mg) and Zn-dust (2.54 g), divided into 5 portions, was distilled in a stream of hydrogen. The volatile products were collected in a trap cooled to −70°. The distillation residue was extracted with ether which was combined with an ether solution of the volatile part. Altogether 30 mg of ether soluble material was obtained. This was divided into basic, acidic and neutral parts by extraction of the ether solution with hydrogen chloride and sodium hydroxide. Each fraction was then chromatographed on alumina using hexane, ether and methanol in that order for elution. The chromatograms on inspection by U. V., showed

several fluorescent zones. The different zones were collected in different fractions and the ultra violet spectrum of each fraction was recorded. Only the neutral part gave fractions that showed any selective absorption in the ultra-violet. Fractions Nos. 5—7 (eluted by hexane) showed two distinct maxima at 232 and 291 mμ. Further chromatography of these fractions gave finally a noncrystalline fraction with maxima at 234, 257, 293, 327 and 337 mμ, and minima at 251, 269, 307 and 332 mμ (Fig. 2).

Fraction 8 had maxima at 240, 326, 340, 358, and 528—533 mμ and minima at 225, 279, 334, 352 and 370 mμ (Fig. 3).

Fractions 9—10 had maxima at 240 and 302 mμ and minima at 227 and 280—285 mμ.

7-Methoxyisatin. (IV). *Iso*nitroso-acet-*o*-anisidide [10] (III) (0.5 g) was added to polyphosphoric acid [16] (5 ml) kept on a boiling water bath. Heating was continued until all the material had dissolved giving a dark violet-brown solution. This was cooled and a large volume of water was added. The precipitate was filtered off and treated with chloroform. The chloroform solution was chromatographed on alumina. The dark red eluate was evaporated to a small volume. 7-Methoxyisatin (0.1 g) crystallised, m.p. 242—243°, undepressed on admixture with an authentic sample.

7-Hydroxyisatin. (V). 7-Methoxyisatin (150 mg) was added to pyridine hydrochloride (1.5 g) and the mixture was heated for 20 minutes to 200° in an oil bath. Water was added to the mixture after cooling and the product was taken up in ethyl acetate. A considerable amount of dark coloured material was removed by filtering the ethyl acetate solution through a short column of silicic acid. Evaporation of the solvent gave 7-hydroxyisatin (80 mg) as brown-red crystals, which decompose around 270° without melting. (Found: C 59.01; H 3.75. $C_8H_5O_3N$ requires C 58.90, H 3.09).

Benzoxazolone-4-carboxylic acid. (II). 7-Hydroxyisatin (80 mg) was suspended in sodium hydrogen carbonate (5 %; 15 ml) and hydrogen peroxide (30 %; 2 ml) was added. After about one hour the originally dark red solution had become almost colourless. Acidification produced a crystalline precipitate of benzoxazolone-4-carboxylic acid, m.p. 279—281°. By treatment with diazomethane this was converted into methyl N-methylbenzoxazolone-4-carboxylate m.p. 140—141°. In neither case was there any depression of melting point when mixed with the corresponding substances obtained by oxidation of cinnabarin.

The authors wish to thank Mr. J. Fraselle, Yangambi, Belgian Congo, Dr. T. S. Robertson, West African Institute for Oil Research, Benin City, Nigeria, and Dr. M. F. Madelin, Botany Department, University College of the Gold Coast, Achimoto, Gold Coast, for their great kindness in collecting the fungus material used in this investigation. Our thanks are also due to Professor H. Erdtman, Stockholm, for arranging these contacts.

We wish also to thank Professor A. W. Johnson, Nottingham, for a sample of 7-methoxyisatin and for much information on the oxidation of actinomycin prior to publication.

This investigation has been financially supported by a grant from the *State Commission for Natural Sciences* (*Valtion Luonnontieteellinen Toimikunta*), which is gratefully acknowledged.

Side-chain Reactions with Furans

NIELS ELMING*

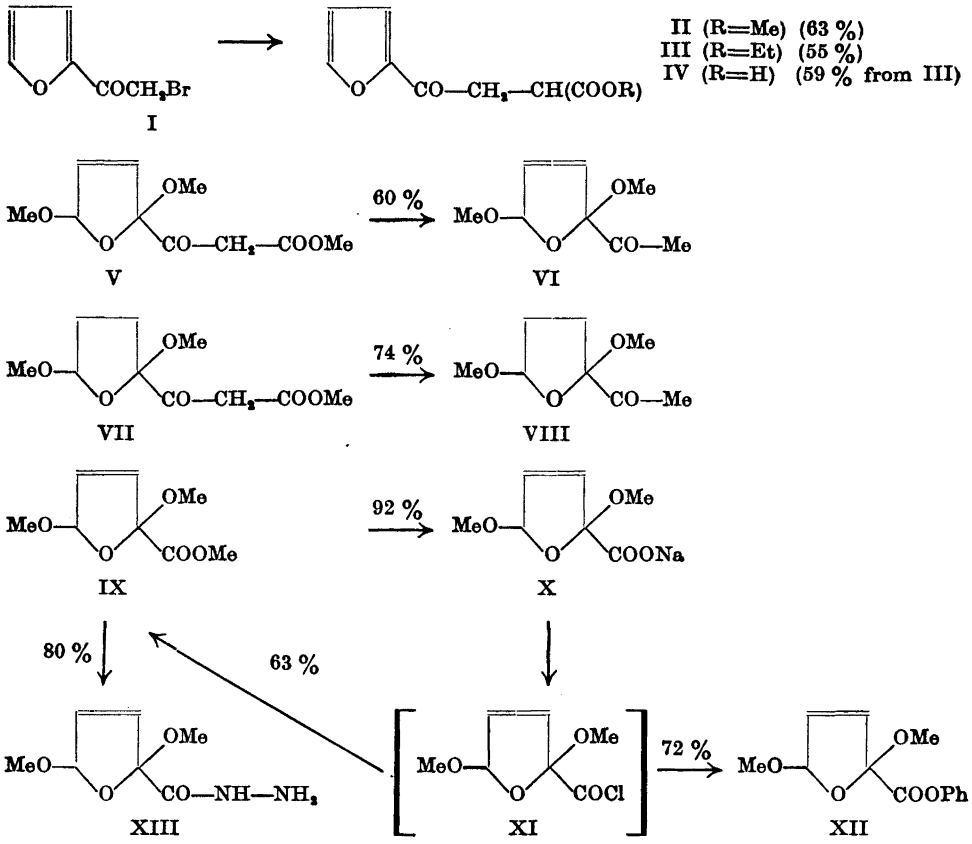
Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

As part of attempts to transform furans into other aromatic systems 9 new α-substituted furans have been prepared.

In the course of attempts to transform furans into other aromatic systems [1-8] a number of new α-substituted furans (II—IV, VI, VIII, X—XIII) have been prepared by the reactions shown below. Further syntheses employing these compounds failed, but it was found worth while to publish directions for their preparation since all the compounds at any time may become of use for synthetic work in this field.

The acid chloride of 2,5-dimethoxy-2,5-dihydrofuroic acid (XI) was not isolated pure but identified by transformation to the corresponding methyl ester (IX).

EXPERIMENTAL



Microanalyses by E. Boss and K. Glens

2-(α-Oxo-β-bromoethyl)-furan (I) was prepared after Brown [9]. The yield was 51 % [b.p.$_{0.1}$ 66—67°; n_D^{25} 1.5718; m.p. 32—34° (Hershberg apparatus, corr.)]. Brown obtained 85 % of a product with b.p.$_{20}$ 121—123°; n_D^{25} 1.5783 and m.p. 36—37° (after two crystallizations from petroleum ether). (Found: C 38.4; H 2.9; Br 41.8. Calc. for $C_6H_5BrO_2$ (189.0): C 38.1; H 2.7; Br 42.3).

2-(α-Oxo-γ,γ-(dicarbomethoxy)-propyl)-furan (II). I (25.0 g, 0.13 mole) was dissolved in anhydrous ether (20 ml) and the solution added during 15 min with stirring to a suspension of sodium dimethyl malonate [from powdered sodium (3.22 g, 0.14 mole) and dimethyl malonate (19.4 g, 0.15 mole)] in anhydrous ether (140 ml) (gentle reflux). The reaction mixture was heated under reflux with stirring for 2 h and cooled. Cold water was added, the etheral layer separated, washed twice with cold water and dried. The ether was evaporated in a vacuum and the crystalline residue removed by filtration, washed with ether and dried. The yield was 16.7 g of II (white crystals, m.p. 67—69°). (Found: C 54.8; H 5.2; OCH_3 25.0. Calc. for $C_9H_6O_4(OCH_3)_2$ (240.2): C 55.0; H 5.0; OCH_3 25.8). After crystallization from ether the m.p. was 69—71°.

The filtrate from the above 16.7 g of II was distilled and the distillate (4.0 g, b.p.$_{0.1}$ 132—135°) crystallized from ether. Hereby another 3.2 g of II was obtained (white crystals, m.p. 68—70°). (Found: C 54.9; H 5.4; OCH_3 26.8). The total yield of II thus was 19.9 g (63 %).

* Present address: Aktieselskabet Pharmacia, Copenhagen, Denmark.

2-(α-Oxo-γ,γ-(dicarbethoxy)-propyl)-furan (III) was prepared from I (19.0 g), dissolved in 20 ml of anhydrous ether, and sodium diethyl malonate [from powdered sodium (2.30 g) and diethyl malonate (16.0 g) suspended in anhydrous ether (95 ml)] as described above for the preparation of II. The reaction product was isolated by distillation. The yield was 14.7 g (55 %) of III (colorless liquid; b.p.$_{0.1}$ 141—143°; n_D^{25} 1.4853). (Found: C 58.5; H 6.2; OC_2H_5 33.5. Calc. for $C_9H_8O_4(OC_2H_5)_2$ (268.3): C 58.2; H 6.0; OC_2H_5 33.6).

2-(α-Oxo-γ,γ-(dicarboxy)-propyl)-furan (IV). III (2.20 g) and a solution of potassium hydroxide (1.02 g) in methanol (20 ml) were heated under reflux (1 h). Water (5 ml) was added, the methanol distilled in a vacuum and the mixture adjusted to pH 3 with conc. hydrochloric acid. The precipitate formed was removed by filtration, washed twice with water and dried. The yield of crude IV was 1.49 g (86 %) [light-brown crystals; m.p. 158—161° (decomp.)]. Treatment with active carbon in methanol followed by crystallization from methanol-ether gave 1.02 g (59 %) of pure IV [white crystals, m.. 159—162° (decomp.)]. (Found: C 50.7; H 3.8; neut.equiv. (phenolphthalein indicator) 105.6. Calc. for $C_9H_8O_6$ (212.2): C 51.0; H 3.8).

2,5-Dimethoxy-2-(α-oxoethyl)-2,5-dihydrofuran (VI). V[5] (17.3 g) and a solution of potassium hydroxide (5 %, 200 ml) were mixed and heated under reflux (6 h). After cooling, the mixture was extracted continuously with ether and the etheral extract dried and distilled. The yield was 7.74 g (60 %) of VI (colorless liquid; b.p.$_{11}$ 91—94°;

n_D^{25} 1.4431). (Found: C 55.6; H 7.2; OCH_3 35.3. Calc. for $C_6H_6O_3(OCH_3)_2$ (172.2): C 55.8; H 7.0; OCH_3 36.0).

2,5-Dimethoxy-2-(α-oxoethyl)-tetrahydrofuran (VIII). VIII was prepared from VII[8] (4.64 g) as described for the preparation of VI. The yield was 2.57 g (74 %) of VIII (colorless liquid; b.p.$_{12}$ 92—93°; n_D^{25} 1.4347). (Found: C 55.3; H 8.1; OCH_3 34.8. Calc. for $C_6H_8O_2(OCH_3)_2$ (174.2): C 55.2; H 8.1; OCH_3 35.6).

Sodium 2,5-dimethoxy-2,5-dihydrofuroate (X). Methyl 2,5-dimethoxy-2,5-dihydrofuroate[10] (7.52 g, 0.040 mole) and sodium hydroxide (1.05 N, 40.0 ml, 0.042 mole) were mixed and heated under reflux (19 h). After cooling, the mixture was washed with ether, filtered and evaporated in a vacuum, at last for 4 h under 0.1 mm at 60—70°. The residue was pulverized in a mortar and dried further for 2 h. The yield was 7.24 g (92 %) of X (white powder with a yellow tinge). (Found: OCH_3 30.7. Calc. for $C_6H_7O_5Na(OCH_3)_2$ (196.1): OCH_3 31.6).

2,5-Dimethoxy-2,5-dihydrofuroyl chloride (XI). X (1.96 g, 0.010 mole), anhydrous benzene (10 ml) and a drop of pyridine were mixed and the mixture cooled to 0°. Oxalyl chloride (1.55 g, 0.012 mole) was added at 0° and the mixture shaken (20 min) at 0—10° and evaporated three times under 35 mm from a water bath of 20° with anhydrous benzene. A precipitate of sodium chloride was removed by filtration and washed with a little anhydrous ether. The slightly yellow filtrate consists of about equal parts of XI and solvent (benzene and ether) and is used directly for further syntheses without isolation of the acid chloride.

In order to identify XI the solution was added to a solution of sodium acetate (1.20 g) in anhydrous methanol (20 ml) during 10 min at 0°. After standing for 15 min without cooling anhydrous ether was added, the mixture filtered and the filtrate distilled. Hereby 1.18 g (63 %) of methyl 2,5-dimethoxy-2,5-dihydrofuroate (b.p.$_{14}$ 120—122°; n_D^{25} 1.4472; previously found[10] b.p.$_{13-14}$ 119—121°; n_D^{25} 1.4476) was obtained. (Found: C 51.5; H 6.7; OCH_3 48.1. Calc. for $C_6H_7O_3(OCH_3)_3$ (188.2): C 51.1; H 6.4; OCH_3 49.4).

Phenyl 2,5-dimethoxy-2,5-dihydrofuroate (XII). A solution of XI prepared as above was added to a solution of phenol (1.04 g, 0.011 mole) in pyridine (10 ml) during 10 min at −5°. After shaking for 2 h without cooling the mixture was evaporated partly in a vacuum and ether was added. A precipitate of pyridinium hydrochloride was removed by filtration and the filtrate washed with water, dried and distilled. The yield was 1.80 g (72 %) of XII (colorless liquid; b.p.$_{0.1}$ 129—132°; n_D^{25} 1.5076). (Found: C 62.3; H 5.8; OCH_3 24.3. Calc. for $C_{11}H_8O_3(OCH_3)_2$ (250.2): C 62.4; H 5.6; OCH_3 24.8).

2,5-Dimethoxy-2,5-dihydrofuroic acid hydrazide (XIII). Methyl 2,5-dimethoxy-2,5-dihydrofuroate[10] (3.76 g) and hydrazine hydrate (90 %, 7 ml) were mixed, the mixture left standing overnight and distilled. The yield was 3.01 g (80 %) of XIII (colorless liquid; b.p.$_{0.5}$ 140—145°; n_D^{25} 1.5008). (Found: C 44.7; H 6.5; N 15.0; OCH_3 32.4. Calc. for $C_6H_6N_2O_2(OCH_3)_2$ (188.2): C 44.7; H 6.4; N 14.9; OCH_3 33.0).

After standing for some days the sample crystallized completely (m.p. 60—75°). Crystallization from methanol-ether gave a product melting at 86—91°. (Found: C 44.6; H 6.7; N 14.8; OCH_3 32.4).

Three further crystallizations from methanol-ether gave products with the following m.p.'s: 86—90°, 100—102° and 105—106°. Probably all the products are mixtures of the *cis* and the *trans* isomer (*cf.*[10]).

3-Hydroxypicolinaldehyde

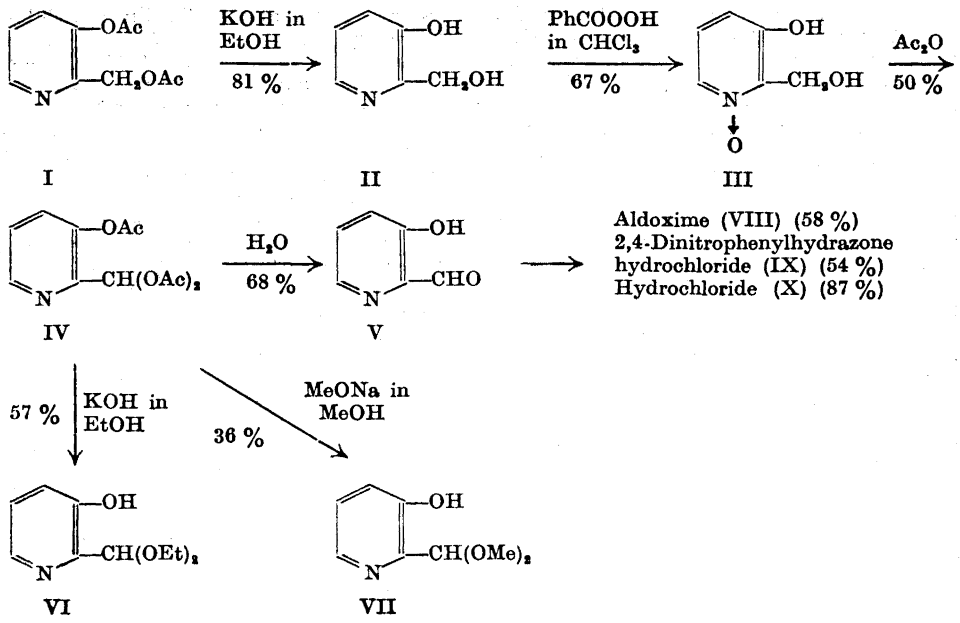
NIELS ELMING*

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

3-Hydroxypicolinaldehyde triacetate was obtained by rearrangement of 2-hydroxymethyl-3-pyridinol-1-oxide. Hydrolysis of this compound gave pure 3-hydroxypicolinaldehyde.

The following derivatives of 3-hydroxypicolinaldehyde were prepared: the diethyl acetal, the dimethyl acetal, the aldoxime, the 2,4-dinitrophenylhydrazone hydrochloride and the hydrochloride.

As part of an investigation of oximes of the pyridine series Ginsburg and Wilson [1] prepared 3-hydroxypicolinaldehyde and certain of its derivatives. Starting from 2-acetoxymethyl-3-acetoxypyridine (obtained from 3-pyridinol after Stempel and Buzzi [2]) they prepared the 1-oxide which was transformed into 3-hydroxypicolinaldehyde triacetate (method of Boekelheide and Linn [3]). The triacetate was then hydrolyzed to 3-hydroxypicolinaldehyde. The intermediate products were not isolated. The aldehyde was obtained in a 12 % yield as an oil which was not analyzed.



In connection with other experiments in the 3-pyridinol field 3-hydroxypicolinaldehyde has been prepared by a modification of the route used by Ginsburg and Wilson. Better yields were obtained and all intermediate products and derivatives were isolated pure. The reactions carried out are summarized below.

EXPERIMENTAL

Microanalyses by K. Glens and P. Hansen

2-Hydroxymethyl-3-pyridinol (II). 2-Acetoxymethyl-3-acetoxypyridine (I) (prepared from 3-pyridinol after Stempel and Buzzi [2]) (2.09 g, 0.010 mole) and 1 N potassium hydroxide in ethanol (40 ml, 0.040 mole) were mixed and heated under reflux for 2 h. Water (15 ml) was added and the ethanol evaporated in a vacuum. The solution was neutralized by adding conc. hydrochloric acid, solid potassium carbonate was added and the mixture then continuously extracted with ether overnight. The ether was evaporated and the residue washed twice with ether and dried. The yield was 1.02 g (81 %) of II [yellowish-white crystals; m.p. 136—139° (Hershberg apparatus, corr.), previously found [4] 132°]. (Found: N 11.0. Calc. for $C_6H_7NO_2$ (125.1): N 11.2).

* Present address: Aktieselskabet Pharmacia, Copenhagen, Denmark.

Sublimation (110—125°/0.05 mm) gave white crystals, m.p. 137—139°.

In another experiment I (2.09 g, 0.010 mole) and conc. hydrochloric acid (20 ml) were mixed and refluxed for 12 h. The solution was evaporated to dryness in a vacuum, dissolved in water and solid potassium carbonate added. Continuous extraction with ether overnight gave 0.91 g (73 %) of II (yellowish-white crystals, m.p. 136—139°).

2-Hydroxymethyl-3-pyridinol hydrochloride. II (125 mg, 0.0010 mole) was dissolved in N hydrochloric acid (5 ml) and the solution evaporated to dryness in a vacuum. Dissolution of the residue in 99 % ethanol and precipitation with ether gave 148 mg (92 %) of 2-hydroxymethyl-3-pyridinol hydrochloride (white crystals; the m.p. was not sharp, but the compound darkened at 209—211°; previously found [4] m.p. 206°). (Found: N 8.8; Cl 22.9. Calc. for $C_6H_8ClNO_2$ (161.6): N 8.7; Cl 21.8).

2-Hydroxymethyl-3-pyridinol-1-oxide (III). II (8.00 g, 0.064 mole) was dissolved in methanol (32 ml) and chloroform (60 ml) was added. A solution of perbenzoic acid (13.8 g, 0.10 mole) in chloroform (180 ml) was added and the mixture left standing at room temperature overnight. The solution was concentrated to about 100 ml in a vacuum, the precipitate removed by filtration, washed with chloroform and dried. Crystallization from methanol gave 6.00 g (67 %) of III [white crystals; m.p. 175—177°). (Found: C 50.9; H 5.2; N 9.8. Calc. for $C_6H_7NO_3$ (141.1): C 51.1; H 5.0; N 9.9).

III gave a red color with aqueous ferric chloride.

3-Hydroxypicolinaldehyde triacetate (IV). III (6.30 g) was dissolved in acetic anhydride (63 ml) and the solution heated under reflux for 30 min. Distillation gave 8.0 g of a pale yellow liquid ($b.p._{0.1}$ 140—145°), which crystallized completely on standing. Crystallization from ether gave 5.9 g (50 %) of III [white crystals; m.p. 79—81° (Hershberg apparatus, corr.)]. (Found: C 53.7; H 5.0; N 5.2; $COCH_3$ 49.1. Calc. for $C_6H_4NO_3(COCH_3)_3$ (267.2): C 53.9 ;H 4.9; N 5.2; $COCH_3$ 48.3). IV gave no color reaction with aqueous ferric chloride.

3-Hydroxypicolinaldehyde (V). IV (1.34 g) and water (25 ml) were heated under reflux overnight. The crystalline reaction product sitting in the reflux condenser was dissolved in ether (the remaining solution in the flask was made alkaline with potassium carbonate and continuously extracted with ether for 5 h, whereby only 40 mg of an oil was obtained), washed with a little 2 M potassium hydrogen carbonate and dried with magne-

sium sulfate. Evaporation gave 0.53 g of a yellow crystalline residue. Sublimation (40—50°/0.05 mm) gave 0.42 g (68 %) of V (yellowish-white crystals, m.p. 81—82°). Crystallization from ether followed by sublimation did not change the m.p. (Found: C 58.1; H 4.4; N 11.1. Calc. for $C_6H_5NO_2$ ((123.1): C 58.5; H 4.1; N 11.4). V gave a red color with aqueous ferric chloride. When V is placed on the skin a persistent green color develops.*

3-Hydroxypicolinaldehyde diethyl acetal (VI). IV (0.67 g, 0.0025 mole) and 0.5 N potassium hydroxide in 96 % ethanol (30 ml, 0.015 mole) were mixed, heated under reflux for 1.5 h and then evaporated in a vacuum to about 10 ml. A little water was added, the solution neutralized under cooling with acetic acid and then made alkaline by adding potassium carbonate. The solution was extracted twice with ether, the ether extract washed with a little water and dried with magnesium sulfate. Evaporation gave 0.34 g of a white crystalline residue. Sublimation (75°/0.05 mm) gave 0.28 g (57 %) of VI (white crystals; m.p. 82—83°). Crystallization from ether followed by sublimation did not change the m.p. (Found: C 61.0; H 7.7; N 7.1; OC_2H_5 44.4. Calc. for $C_6H_5NO(OC_2H_5)_2$ (197.2): C 60.9; H 7.7; N 7.1; OC_2H_5 45.7). VI gave a red color with aqueous ferric chloride.

3-Hydroxypicolinaldehyde dimethyl acetal (VII). IV (1.34 g, 0.0050 mole) was dissolved in methanol (10 ml) and sodium methoxide in methanol [prepared from 0.24 g of sodium (0.011 mole) and methanol (5 ml)] was added. After 30 min at room temperature the reaction mixture was worked up essentially as described above for the preparation of VI. The yield after sublimation (90°/0.1 mm) was 0.30 g (36 %) of VII (white crystals; m.p. 104—105°). Crystallization from ether followed by sublimation did not change the m.p. (Found: C 56.4; H 6.3; N 8.5; OCH_3 36.4. Calc. for $C_6H_5NO(OCH_3)_2$ (169.2): C 56.8; H 6.6; N. 8.3; OCH_3 36.7). VII gave a red color with aqueous ferric chloride.

3-Hydroxypicolinaldehyde aldoxime (VIII). V (0.37 g, 0.0030 mole) was dissolved in a mixture of pyridine (6 ml) and 99 % ethanol (6 ml). Hydroxylamine hydrochloride (0.33 g, 0.0048 mole) was added, the mixture heated under reflux for 1 h and then evaporated. Ether (50 ml) was added to the residue and the mixture heated under reflux for 10 min. The ether extract was washed with water, dried with magnesium sulfate and evaporated. The crystalline residue was sublimed (120°/0.05 mm). The yield was 0.24 g (58 %) of VIII (white crystals; m.p. 173—174°; previously found [5] 170°). Crystallization from ether followed by sublimation did not change the m.p. (Found: C 52.2; H 4.4; N 20.0. Calc. for $C_6H_6N_2O_2$ (138.1): C 52.2; H 4.4; N 20.3).

3-Hydroxypicolinaldehyde 2,4-dinitrophenylhydrazone hydrochloride (IX). V (10 mg) was dissolved in water (2 ml) and 15 ml of a 0.2 % solution of 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid was added. A yellow precipitate was formed at once. After 1 h the precipitate was removed by filtration, washed with water and dried. The yield was 15 mg (54 %) of IX [orange-red crystals; m.p. 305—310° (decomp.); previously found [6] 219—221° (decomp.)] (Found: C 42.5; H 3.1; N 19.7. Calc. for $C_{12}H_{10}ClN_5O_5$ (339.7): C 42.4; H 3.0; N 20.6).

IX was also obtained from IV after hydrolysis (1 h) as described above for the preparation of V. Crystallization from 96 % ethanol gave 50 % of IX, m.p. 305—310° (decomp.).

3-Hydroxypicolinaldehyde hydrochloride (X). V (40 mg) was dissolved in anhydrous ether (10 ml), gaseous hydrogen chloride was passed into the solution, the white precipitate was removed by filtration, washed with ether and dried. The yield was 45 mg (87 %) of X (white crystals, m.p. 218—221°). (Found: N 8.6; Cl 21.9. Calc. for $C_6H_6ClNO_2$ (159.6): N 8.8; Cl 22.2).

Calculation of Standard Deviations for Interatomic Distances in Benzene Based upon Spectroscopic Data

S. J. CYVIN

Institutt for teoretisk kjemi, N.T.H., Trondheim, Norway

A set of force constants in a harmonic potential function for in-plane vibrations of benzene has been computed and used for a normal coordinate determination. The ten types of interatomic distances are studied by group theory methods and the normal coordinate analysis is performed. Finally the standard deviation for all interatomic distances in benzene is given at the temperatures 0, 273, 298 and 323°K.

The subject of this paper is the calculation of standard deviations for interatomic distances in the benzene molecule by making use of a normal coordinate analysis for in-plane vibrations. The vibrations are treated as harmonic oscillations. As for the theory, the treatment given by Wilson, Decius and Cross [1] is followed. The treatment is extended to deal with all types of interatomic distances. Crawford and Miller [2] have previously evaluated a set of force constants for benzene. In this paper another set is used, as obtained by recalculation with a newer set of experimental frequencies [3].

SYMMETRY COORDINATES

The applied symmetry coordinates are of the VFSC type (linear combinations of valence force coordinates) and are specified in Table 1. The notation for valence force coordinates is: σ for C—H stretching (s in Wilson's notation [1]), τ for C—C stretching (t in Wilson's notation), α for C—C—C bending and β for C—H bending (identical with the notations by Wilson). According to Table 1, for instance, $s_{12} = 6^{-\frac{1}{2}} (\alpha_1 - \alpha_2 + \alpha_3 - \alpha_4 + \alpha_5 - \alpha_6)$. The symmetry coordinates, as well as the normal coordinates, are numbered in the same way as Wilson's [1] and Langseth's [3] numbering of fundamental frequencies.

Table 1. Symmetry coordinates for in-plane vibrations of benzene.

Species	VFSC	N	1	2	3	4	5	6	
A_{1g}	S_2	$6^{-1/2}$	1	1	1	1	1	1	σ
	S_1	$6^{-1/2}$	1	1	1	1	1	1	τ
	S_r	$6^{-1/2}$	1	1	1	1	1	1	a
A_{2g}	S_3	$6^{-1/2}$	1	1	1	1	1	1	β
B_{1u}	S_{13}	$6^{-1/2}$	1	−1	1	−1	1	−1	σ
	S_{12}	$6^{-1/2}$	1	−1	1	−1	1	−1	a
B_{2u}	S_{14}	$6^{-1/2}$	−1	1	−1	1	−1	1	τ
	S_{15}	$6^{-1/2}$	1	−1	1	−1	1	−1	β
E_{2g}	S_{7a}	$12^{-1/2}$	2	−1	−1	2	−1	−1	σ
	S_{8a}	$12^{-1/2}$	1	−2	1	1	−2	1	τ
	S_{6a}	$12^{-1/2}$	2	−1	−1	2	−1	−1	a
	S_{9a}	$1/2$	0	1	−1	0	1	−1	β
	S_{7b}	$1/2$	0	1	−1	0	1	−1	σ
	S_{8b}	$1/2$	1	0	−1	1	0	−1	τ
	S_{6b}	$1/2$	0	1	−1	0	1	−1	a
	S_{9b}	$12^{-1/2}$	−2	1	1	−2	1	1	β
E_{1u}	S_{20a}	$12^{-1/2}$	2	1	−1	−2	−1	1	σ
	S_{19a}	$1/2$	1	0	−1	−1	0	1	τ
	$S_{r;a}$	$12^{-1/2}$	2	1	−1	−2	−1	1	a
	S_{18a}	$1/2$	0	1	1	0	−1	−1	β
	S_{20b}	$1/2$	0	−1	−1	0	1	1	σ
	S_{19b}	$12^{-1/2}$	−1	−2	−1	1	2	1	τ
	$S_{r,b}$	$1/2$	0	−1	−1	0	1	1	a
	S_{18b}	$12^{-1/2}$	2	1	−1	−2	−1	1	β

Three redundants (see Table 1) are occurring among the symmetry coordinates. These have been removed by the conditions:

$$S_r = 0 \tag{1}$$

$$S_{r;a} = -S_{19a}/l_2 \tag{2}$$

$$S_{r;b} = -S_{19b}/l_2 \tag{3}$$

l_2 is the C—C equilibrium distance.

FORCE CONSTANTS

The adopted force constants of the potential function in terms of symmetry coordinates are given in Table 2. The calculation has been based on fundamental frequencies for benzene and benzene-d_6 from spectroscopic data by Brodersen and Langseth [3].

l_1 and l_2 denote the C—H and C—C equilibrium distances, respectively.

s_{18}							$0.825\ l_1^2$

NORMAL COORDINATE ANALYSIS FOR SYMMETRY COORDINATES

A symmetry coordinate is approximated to a linear combination of normal coordinates from the respective symmetry species,

$$s_i = \sum_j B_{ij} Q_j \qquad (4)$$

The transformation coefficients have been determined by Wilson's method [1], and their squares are given in Table 3. M denotes the mass of the carbon atom.

GROUP THEORY TREATMENT OF THE INTERATOMIC DISTANCES

In benzene there are ten types of interatomic distances, each type forming a symmetric equivalent set. The notation used for deviations from the equilibrium distances is as follows.

σ for the distances of type C_1—H_1, σ^* for C_2—H_1, σ^{**} for C_3—H_1 and σ^{***} for C_4—H_1;

τ for the type C_1—C_2 (*ortho*), τ^* for C_1—C_3 (*meta*) and τ^{**} for C_1—C_4 (*para*);

ϱ for the type H_1—H_2, ϱ^* for H_1—H_3 and ϱ^{**} for H_1—H_4.

Each of the equivalent sets is taken as basis for a reducible representation of the group D_{6h}. The characters of these representations are given in Table 4. Then it is a simple matter to determine the symmetric structure of the represen-

s_{20}					12.8798	0.03574	0.001341
s_{19}					0.09085	1.0503	0.3588
s_{18}					$0.03141/l_1^2$	$0.2034/l_1^2$	$14.5233/l_1^2$

tations by usual methods from group theory. The results can be expressed in the following way:

$$\Gamma(\tau\,\varrho) = A_{1g} + B_{2u} + E_{2g} + E_{1u} \tag{5}$$

$$\Gamma(\sigma,\sigma^{***},\tau^*,\varrho^*) = A_{1g} + B_{1u} + E_{2g} + E_{1u} \tag{6}$$

$$\Gamma(\sigma^*,\sigma^{**}) = A_{1g} + A_{2g} + B_{1u} + B_{2u} + 2E_{2g} + 2E_{1u} \tag{7}$$

$$\Gamma(\tau^{**},\varrho^{**}) = A_{1g} + E_{2g} \tag{8}$$

The above results show which of the normal coordinates build up a given interatomic distance coordinate. Thus for instance only normal coordinates from species A_{1g} and E_{2g} will enter into the expression of τ^{**} and ϱ^{**} as linear combinations of normal coordinates.

NORMAL COORDINATE ANALYSIS FOR INTERATOMIC DISTANCE COORDINATES

A representative set of ten interatomic distance deviations has been expressed by the set of symmetry coordinates,

$$r = Vs \tag{9}$$

V being the transformation matrix. The connection between symmetry coordinates and normal coordinates, eqn. (4), is given in matrix notation by

$$s = BQ \tag{10}$$

Then the transformation matrix in

$$r = CQ \tag{11}$$

can easily be found, since

$$C = VB \tag{12}$$

The squares of the matrix elements rather than the elements themselves have been calculated. The values $l_1 = 1.084$ Å and $l_2 = 1.397$ Å for C—H and C—C equilibrium distances have been adopted. The results are listed in Table 5.

STANDARD DEVIATIONS OF INTERATOMIC DISTANCES

At this point the standard deviations of interatomic distances,

$$u = \overline{(r^2)}^{1/2} \tag{13}$$

can be calculated by means of the formula

$$u^2 = \overline{r_k^2} = \sum_i C_{ki}^2 \frac{h}{8\pi^2 \nu_i} \coth \frac{h\nu_i}{2kT} \tag{14}$$

Table 6. Standard deviations for interaromic distances in benzene

Distance	Calculated standard deviations in Å units $T = 0$	273.16	298.16	323.16

(see, *e.g.*, Morino *et al.*[4]) C_{ki} denotes the coefficients of eqn. (11), the squares of which have been enumerated in the previous section. ν_i is a fundamental frequency, h Planck's constant, k Boltzmann's constant and T is the absolute temperature.

Table 6 shows the calculated values for u at the temperatures $T = 0$, 273.16, 298.16 and 323.16°K. The values have been compared with results from electron diffraction data as obtained by Karle [5] and later by Bastiansen *et al.*[6] A report about this has been submitted for publication elsewhere [7].

It is planned to work out the same calculations also for benzene-d_6.

The Crystal Structure of Phosphorous Acid

SVEN FURBERG and PER LANDMARK

Chemical Institute, University of Bergen, Bergen, Norway

The crystal structure of phosphorous acid, H_3PO_3, has been determined by X-ray methods. The space group is $Pna2_1$ and there are eight molecules per unit cell. Two of the P—O bonds in the molecule, presumably the P—OH bonds, are found to be about 1.54 Å, whereas the bond to the third oxygen atom is significantly shorter, 1.47 Å. There are two hydrogen bonds for each molecule. These observations are in agreement with the accepted structural formula $H_2(HPO_3)$.

As phosphorous acid, H_3PO_3, is dibasic, it is generally assumed that one of the hydrogen atoms is linked directly to the phosphorus atom. In connection with our work on phosphoric acid [2] we thought it of value to study the structure of this interesting molecule by X-ray crystallographic methods, especially as no such investigation of phosphites was reported in the literature. Only very recently the first crystal structure determination of a phosphite, $MgHPO_3.6H_2O$, was published [1], showing HPO_3^{--} ions with trigonal symmetry.

EXPERIMENTAL

Phosphorous acid was prepared by hydrolysis of phosphorus trichloride and recrystallized from water and alcohol. The best crystals were obtained from the latter solvent. Mp. 73°C (uncorr.). The crystals are hygroscopic and were kept in thinwalled glass capillaries during the exposures. Weissenberg and oscillation diagrams were taken about the *a*- and *c*-axes using Cu$K\alpha$ radiation (λ = 1.542 Å). The intensities were estimated visually, and corrected for Lorentz and polarization effects. Very small crystals with even cross-sections were used and no correction for absorption was made.

CRYSTAL DATA

The crystals are orthorhombic, generally elongated along *a*, with unit cell dimensions a = 7.27 Å, b = 12.06 Å and c = 6.85 Å. These values are probably accurate to within 0.5 %. By flotation in mixtures of carbon tetrachloride and ethylene dibromide a density of 1.806 g/cm^3 was found, corresponding to eight (calc. 7.96) molecules H_3PO_3 in the unit cell.

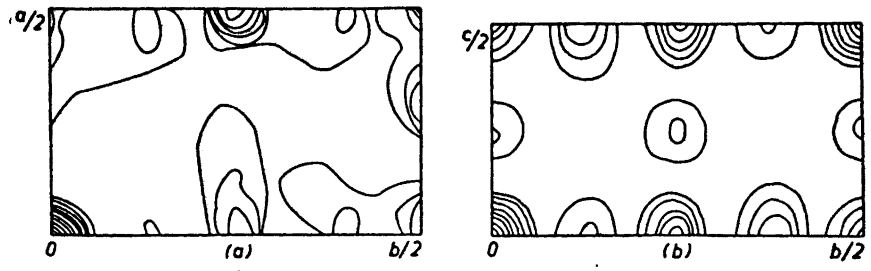

Fig. 1. Patterson projections on the (001) plane (a) and the (100) plane (b).

Systematic absences occur in the $0kl$-reflections for $k+l$ odd and in the $h0l$-reflections for h odd. The space groups $Pna2_1$ and $Pnam$ are both compatible with these observations. The crystals were tested for piezoelectric effects with a sensitive apparatus built by one of us (P.L.), but no effect was found. The space group $Pna2_1$ was nevertheless tentatively assumed on the basis of space considerations, and the subsequent structure analysis showed the choice to be correct. As this space group has four general positions, the asymmetric unit consists of two molecules H_3PO_3. Reflections $0k0$ are extremely weak when k is not 4n, and the crystals have in fact pseudotetragonal symmetry.

THE STRUCTURE DETERMINATION

Projections of the structure along the c and a axes were determined by Patterson, F and $(F_o—F_c)$ syntheses. The c projection was tackled first as it is the only one with apparent centres of symmetry.

The c-projection. The Patterson synthesis reproduced in Fig. 1a indicates that one phosphorus atom lies at $y = 1/8$ and the other at $y = 3/8$, and that approximately $x = 0$ for one or both of them. Coordinates (0, 1/8) and (0, 3/8) were chosen for the first Fourier synthesis, from which some information on the positions of the oxygen atoms was obtained. Because of the pseudotetragonal symmetry a difference of $b/4$ in the y coordinates of corresponding atoms in the two crystallographically independent molecules was assumed. Some agreement between F_o and F_c was obtained by Fourier refinement. However, the value of F_c remained very small for some strong reflections. The likely signs of these were then derived by the "multiplication rule" (Sayre [3]). The corresponding Fourier map indicated clearly radical shifts in the x coordinates of some of the oxygen atoms, and by further refinement the final electron density map given in Fig. 2a was obtained. Four further refinements of the atomic coordinates were carried out by $(F_o—F_c)$ synthesis. The same temperature factor $\exp(-2.2 \sin^2\Theta/\lambda^2)$ was used for all the atoms, although the final difference map shows this to be only approximately correct. The atomic scattering factors employed are those given by Viervoll and Øgrim [4]. No attempt was made to derive the positions of the hydrogen atoms from the difference maps, and their contribution to the structure factors was calculated from assumed positions. The final value of the reliability index $R = (\Sigma|F_o—F_c|)/\Sigma|F_o|$ is

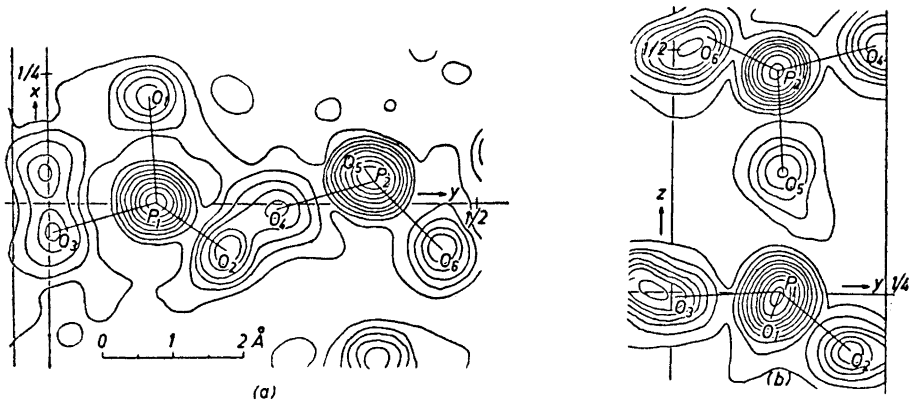

Fig. 2. Electron density projections on the (001) plane (a) and the (100) plane (b). Contours at 2, 4, 6, . . . e . Å^{-2}, every second contour being omitted above 12 e . Å^{-2}. Calculated at 1/60 of b and 1/30 of a and c.

0.10. The strongest reflection, 200, which evidently suffers from extinction (as well as 002 in the a projection), is not included in the calculation of R. Reflections not observed are only taken into account when F_c exceeds the observable limit.

The a-projection. The Patterson synthesis (Fig. 1b) shows that the difference in z-coordinates of the two phosphorus atoms probably is near $c/2$. Approximate z-coordinates for the oxygen atoms were derived from the known coordinates and the P—O distances found in phosphoric acid [2]. Two different mutual orientations of the molecules were possible, which both gave $R = 0.33$. The one chosen changed in the course of the refinement to the other possibility. Three Fourier refinements brought R down to 0.20, followed by five difference syntheses which made R drop to 0.10. As this projection is non-centrosymmetric, the atoms were in each refinement moved approximately twice the amount indicated by the Fourier- and difference-maps. The process would have been speedier if the atoms had been moved even more than this in each refinement. The final electron density map is shown in Fig. 2b, and the atomic coordinates are given in Table 1. The temperature factor is the same as in the c-projection. In Table 3 observed and calculated structure factors are given.

Table 1. Atomic coordinates as fractions of the corresponding cell edge.

Atom	x	y	z
P_1	0.002	0.1265	0.003
P_2	0.046	0.378	0.461

O_6	0.909	0.459	0.518

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

From the atomic coordinates in Table 1 the bond lengths and bond angles given in Table 2 were calculated.

Table 2. Bond lengths (in Å units) and bond angles.

Molecule I		Molecule II	
P_1-O_1	1.544	P_2-O_5	1.526
P_1-O_2	1.485	P_2-O_6	1.451
P_1-O_3	1.552	P_2-O_4	1.535
$O_1-P_1-O_2$	111°	$O_5-P_2-O_6$	114°
$O_1-P_1-O_3$	101°	$O_5-P_2-O_4$	103°
$O_2-P_1-O_3$	117°	$O_6-P_2-O_4$	114°

The standard deviation of the atomic coordinates were estimated by applying the formula given by Cruickshank [5]. The following values were found: $\sigma(x) = 0.004$ Å, $\sigma(y) = 0.003$ Å, $\sigma(z) = 0.005$ Å for the phosphorus atoms; $\sigma(x) = 0.016$ Å, $\sigma(y) = 0.012$ Å, $\sigma(z) = 0.024$ Å for the oxygen atoms. In the case of $\sigma(z)$ the lack of a centre of symmetry is taken into account by multiplication by 2. The standard deviation in the bond lengths vary between 0.013 Å for the bond $P_1—O_3$ and 0.024 Å for $P_2—O_5$. Unfortunately, an oxygen atom is very close to a phosphorus atom in each projection (O_5 and O_1, respectively), and the error in the position of these atoms may be considerably greater than should be expected from the calculated standard deviations. This does not influence the bond lengths appreciably, but makes the values derived for the bond angles rather uncertain. The maximum error is estimated to about 5° for the angles $O_1—P_1—O_2$ and $O_5—P_2—O_6$ and to about 3° for the other angles.

It will be seen that the two crystallographically independent molecules are found to be identical within the limits of error. The differences observed in the bond angles may also partly be due to deformation by van der Waals forces [6]. In each of the molecules there is one shorter and two longer P—O bonds, and one of the bond angles is considerably smaller than the others. The mean dimensions of the two molecules are given in Fig. 3. The short P—O bond, which presumably corresponds to the "lone" oxygen, has the length of 1.47 Å, and is significantly shorter than the two bonds to the "hydroxyl" oxygens, for which values close to 1.54 Å are found. The angle between the two P—OH bonds is as small as 102°, whereas all the angles involving the short P—O bond are greater than the tetrahedral angle, their mean value being 114°. The O—O distance across the small angle is only 2.39 Å in both molecules. Approximate positions for the hydrogen atoms of the hydroxyl groups may be derived from the directions of the hydrogen bonds. All O—H bonds lie roughly in the plane of the two P—OH bonds, and the whole molecule has thus approximately a plane of symmetry. These molecular dimensions are, as might be expected, somewhat different from those reported for the phosphite ion, which is found to have threefold symmetry about the P—H bond direction with P—O bonds of length 1.51 Å and O—P—O bond angles of 110°.

Table 3. Observed and calculated structure factors. The values given are one quarter of the absolute values.

It would seem to be of interest to compare the molecule of phosphorous acid with that of phosphoric acid [2]. In phosphoric acid the short P—O bond is found to be 1.52 Å and the P—OH bonds to be 1.57 Å. Values of 106° and 112° were found for the two types of bond angles. Phosphorous acid may be derived from phosphoric acid by substituting a hydroxyl group by a hydrogen atom. It is seen that this change appears to make all the bond angles deviate more from the tetrahedral angle and all the P—O bonds shorter, especially the short P—O bond. Correspondingly, the angles involving this bond are greater in H_3PO_3 than in H_3PO_4, and the angles between P—OH bonds smaller. Although these differences are small, they are probably significant in view of the agreement in the dimensions of the two independent molecules of H_3PO_3.

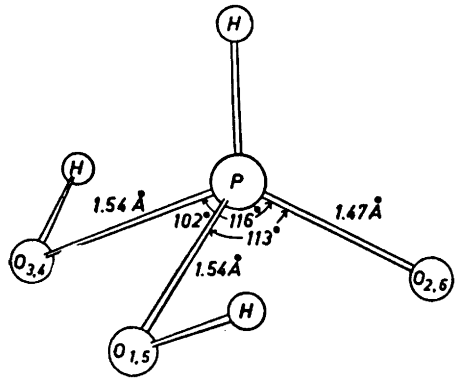

Fig. 3. Bond lengths and bond angles in H_3PO_3.

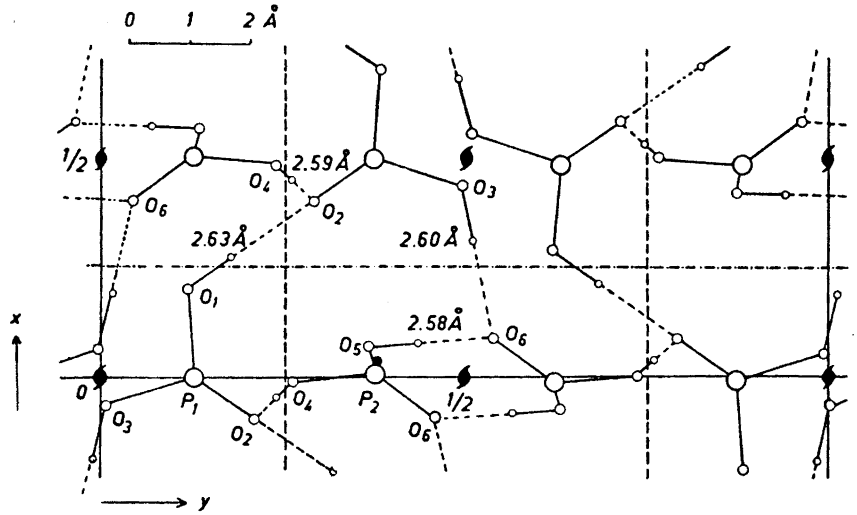

Fig. 4. The c projection of the structure. Broken lines indicate hydrogen bonds.

The molecules are linked together by hydrogen bonds, as shown in Fig. 4. There are two such bonds for each molecule, as to be expected from the formula $HPO(OH)_2$, but not from $P(OH)_3$. The four bonds are of nearly equal length, the values 2.59 Å, 2.63 Å, 2.58 Å and 2.60 Å being found. All other intermolecular O—O distances are greater than 3.0 Å. The two "lone" oxygen atoms O_2 and O_6 each take part in two hydrogen bonds, whereas each of the other oxygen atoms is involved in only one such bond. As generally found in crystal structures, the angles between the hydrogen bonds and the P—O bonds are least distorted at the oxygen atoms to which the hydrogen atoms are bonded. The two hydrogen bonds to the "lone" oxygen atom in H_3PO_4 are 2.53 Å of length, somewhat shorter than in the present case.

The structure has pseudo-tetragonal symmetry, with an approximate 4_1 axis roughly at (0, y, 1/4). This holds not only for the atomic coordinates and the molecular dimensions, but also for the hydrogen bonding scheme.

One of us (S.F.) wishes to thank *Nansenfondet og de dermed forbundne fond* for a grant.

Nucleation in Barium Sulfate Precipitation *

ARNE E. NIELSEN

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

In precipitation experiments with barium sulfate the number of crystals per unit volume was reduced to one-tenth or less by first cleaning the glass mixing vessel with condensing steam. During the precipitation higher order Tyndall spectra were observed.

It is concluded that under normal conditions the greater part of the nuclei does not originate from a homogeneous process but from the walls of the glass.

In theories of the precipitation of sparingly soluble salts such as barium sulfate different authors assume that the nuclei (i) exist before the mixing of the stable solutions, or (ii) are formed spontaneously at the moment of mixing, or (iii) originate from a homogeneous chemical process during a certain period of time in the beginning of the experiment.

As shown in a previous paper [1], the kinetics of the precipitation process measured for instance as the electric conductance in dependence of time can be made to agree with all three assumptions. It is therefore of interest to obtain a different kind of quantitative information such as the number of crystals formed per unit volume or, what is equivalent, their final size. Fischer and Rhinehammer [2] showed that the particle size and O'Rourke and Johnson [3] that the number of crystals depend on the age of the solutions used. It seems impossible to account for this phenomenon by means of any sort of theory with a nucleation process starting at the moment of mixing, that is (ii) or (iii) above.

In the experiments reported below it was found that the number of crystals formed also depends on the method of cleaning the glass vessel. The introduction of a new cleaning technique (proposed by J. A. Christiansen) reduced this number to one tenth or even less.

* This is a part of the paper that was read before the 9. Nordiske Kemikermøde in Århus, August 1956.

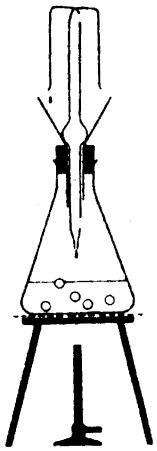

Fig. 1. The steam condenses at the inside of the beaker and through the funnel the water returns to the flask.

EXPERIMENTAL

50 ml 0.002 M $BaCl_2$ and 50 ml 0.002 M K_2SO_4 were taken up in pipettes, which were then emptied in less than 3 s in such a way that the two liquids met before reaching the bottom of the 250 ml Pyrex beaker. The solution was allowed to rest for 5 min, the precipitate became visible in 10 to 15 s and settled in a few minutes. 5 min after the moment of mixing the mixture was stirred with a glass rod and a drop of the slurry transferred to a blood cell counting chamber. It was found important to place the cover glass in less than 2 s since the precipitate sediments very quickly. At least either some 100 crystals — or all crystals inside the 9 mm^2 (0.9 mm^3) counting field were counted.

The results were controlled through sedimentation experiments. The level of the uppermost crystals was easily measured during the first two or three minutes. From a plot the sedimentation velocity was found. If v = velocity in cm/s, r = radius of a sphere with the same volume as the crystal, g = acceleration of gravity, d = density of crystal, d_0 = density of medium, f = a form factor determined from the experiments ($f = 1$ for spheres of radius r), η = viscosity, n = number of crystals per liter, $c = 0.001$ = molarity of $BaSO_4$ just after mixing, M = molecular weight, m = weight of a crystal, — then

$$v = (4/3)\pi r^3 g(d-d_0)f/6\pi\eta r$$
$$n = cM/m;\ m = (4/3)\pi r^3 d$$
$$\therefore \log f = \log v + (2/3)\log n - 3.60$$

The f-values found lie between 0.38 and 0.65 which is very reasonable.

The 250 ml Pyrex beaker used as a mixing chamber was cleaned before every experiment except the first one in a series by first rubbing it with a brush and rinsing in hot water. Then it was placed, bottom up, over boiling water, see Fig. 1, so that the steam condensed on the inside of the glass. After 10 min it was placed on a few layers of filter paper and allowed to cool.

RESULTS

In the beginning of a series of experiments usually about 2 000 or more crystals were found per mm^3. After one or two cleanings of the beaker the number decreased to about a hundred of crystals per mm^3, or 10^8 per liter, and the counts might seem to obey a Poisson distribution. But occasionally, without change in technique, the counts were as low as 25 mm^{-3} several times. See Figs. 2 and 3.

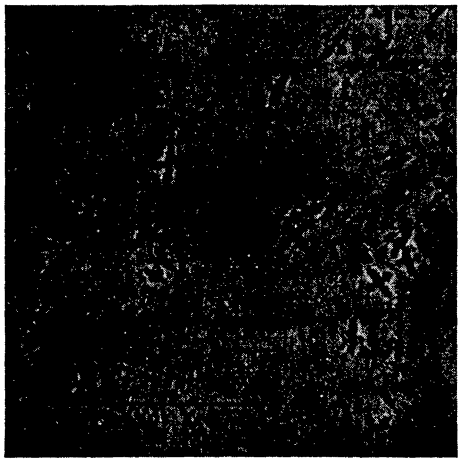

Fig. 2. The barium sulfate precipitate from an experiment where the glass had only been ordinarily cleaned. 2 050 crystals were found per mm^2. In order to get more than one crystal on the photo (at a reasonable magnification) the precipitate was concentrated by sedimentation.

These results may be compared with those of O'Rourke and Johnson [3] who in the same sort of experiments (except for the cleaning technique) found 1.1×10^9 particles per liter. That is about ten to fifty times as many as found in the present work.

Very often it was observed that *after* the sample had been withdrawn for counting, the solution became milky, and during the second sedimentation two distinct bands separated. Under the microscope another sample now displayed that new, much smaller crystals had appeared. These must be attributed to the stirring: either are new nuclei brought into the system with the stirring rod, or, what is more likely, the crystals already formed are crushed yielding nuclei. The easy breaking of the crystals upon handling was also observed by Fischer and Rhinehammer [2].

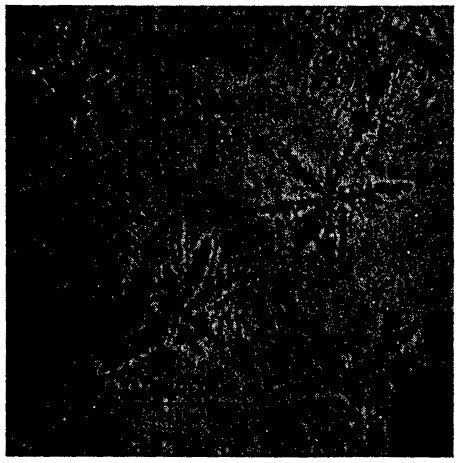

Fig. 3. The precipitate from an experiment where the glass had been cleaned as shown in Fig. 1; everything else was performed as in the experiment of Fig. 2. Only 30 crystals appeared per mm^2. The magnification is the same in Figs. 2 and 3.

When the precipitation was observed in parallel light higher order Tyndall spectra [3-5] were observed. In these experiments the glass was not treated with steam.

When looking in a direction 135° to that of the original light beam, a red and a green light were observed during 5 to 15 s after the moment of mixing. When the concentrations were 0.0025 M before mixing both first and second order red and green were observed, together with violet in between.

After about 25 s all colours had disappeared, and only white light was observed.

These colours were obtained with Merck's K_2SO_4 but not with Analar's Na_2SO_4. The cause of this difference was not sought.

The appearance of the colours imply that the crystals are equally large since otherwise the lights would mix to yield white in all directions.

CONCLUSION

It seems impossible to explain that improving of the cleaning technique of the glass can reduce the number of crystals without assuming that those extra crystals formed when the glass is not cleaned so well originate from the walls of the glass. Since this number amounts to between 90 and 98 % of all the crystals formed under ordinary conditions we may conclude that by far the greater part of these, and perhaps all of them, do not originate from spontaneous nucleation but from impurities on the glass.

The appearance of higher order Tyndall spectra indicates that the precipitate at this time is very monodisperse and from this fact, too, we may conclude that the nuclei are not formed in a homogeneous process, since they must have all started growing at very nearly the same time.

The author is much indebted to professor J. A. Christiansen who suggested the experiments reported.

Über die Reaktionen des Lignins bei der Sulfatkochung

Der Einbau des Schwefels in das Lignin

JOSEF GIERER und BO ALFREDSSON

Schwedisches Holzforschungsinstitut, Holzchemische Abteilung, Stockholm, Schweden

The sulphidizing reaction of lignin has been studied using model compounds of the *p*-hydroxybenzyl alcohol, -benzylalkyl ether and -dibenzy lether type as well as isolated lignin preparations and finely ground wood powders.

It was shown that model substances of the above-named types react readily with sodium sulfhydrate solutions at 100°C to yield the corresponding sulfides, unless this reaction is sterically hindered by the presence of a substituent in the β-position of the side-chain.

p-Hydroxybenzyl alcohols and *p*-hydroxybenzylalkyl ethers were found to react with ethylmercaptan to yield *p*-hydroxybenzylethyl-sulfides. This is in harmony with previous views regarding the course of lignin sulfidation.

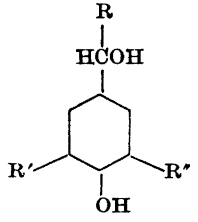
After using an "acid mixture" (hydroiodic acid, hydrochloric acid and hypophosphorous acid) the major part of the sulphur from the various thiolignins was determined to be present in an "acid-labile" fraction. On the basis of model experiments described in a previous communication [1] this fraction is considered to have benzyl-sulphidic structures as principal building units.

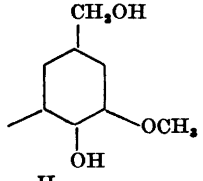
Im Jahre 1911 wiesen Klason und Segerfelt [2] nach, dass das nach einer Sulfatkochung aus der Schwarzlauge isolierbare Thiolignin organisch gebundenen Schwefel enthält. In der Folgezeit wurde aufgrund von Vergleichen zwischen Alkali- und Sulfatkochungen dem Schwefel die wichtige Rolle zugeschrieben, durch Umsetzung mit reaktionsfähigen Gruppen des Lignins Kondensationsreaktionen zu verhindern und dadurch den Delignifizierungsprozess zu erleichtern [3]. Damit erhob sich die Frage nach der chemischen Natur der reaktionsfähigen Gruppen im Lignin, welche für den Einbau des Schwefels verantwortlich sind.

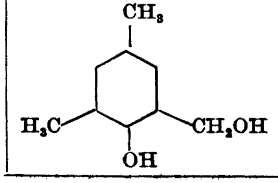
Holmberg fand, dass sich die Sulfitierung des Lignins [4], die Reaktion mit Thioglykolsäure [5] sowie die Alkylierung mit alkoholischer Salzsäure [6] durch die Annahme von Benzylalkohol- und Benzylätherstrukturen im Lignin erklären lassen. Diese Vorstellung wurde in den letzten 20 Jahren durch zahlreiche Modellversuche und vor kurzem durch den direkten Nachweis von *p*-Hydroxybenzylalkoholgruppen in Nativlignin [7] stark gestützt.

Es lag nahe, auch die Ursache der Sulfidierungsreaktion in erster Linie bei derartigen Gruppen zu suchen. Enkvist und Moilanen [8] konnten in Modellversuchen zeigen, dass Vanillylalkohol durch Behandlung mit gepufferten Schwefelwasserstofflösungen (pH 7) bei 100°C zum Teil in Divanillyldisulfid übergeführt wird. Mikawa [9] fand, dass bei dieser Umsetzung Divanillylmonosulfid als Hauptprodukt entsteht und wies darauf hin, dass die Bildung des Disulfids durch Dehydrierung des intermediär auftretenden Vanillylthiols nur als Nebenreaktion aufzufassen ist. Er beschrieb kürzlich [10] eine analoge Sulfidierungsreaktion für die homologe Modellsubstanz II (Äthyl-(3-methoxy-4-hydroxy-phenyl)-carbinol). Unter Einhaltung ähnlicher Reaktionsbedingungen hatte Zentner [11] früher aus letztgenannter Substanz nur *Iso*eugenol erhalten.

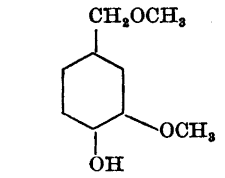
MODELLVERSUCHE

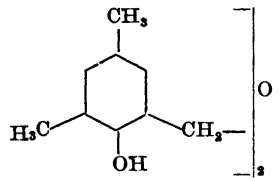


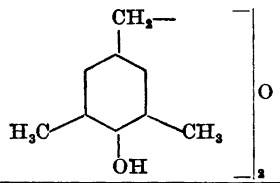




Bei der Untersuchung des Verhaltens einer Reihe einfacher Modellsubstanzen des *p*-Hydroxybenzylalkohol- und des *p*-Hydroxybenzylalkyläthertypus unter den Bedingungen einer milden Sulfidierung (8-stündiges Erhitzen auf 100°C in einer Natriumsulfhydratlösung vom pH 9) fanden wir, dass sämtliche in Tabelle 1 angeführten Verbindungen zu einem grossen Teil in die entsprechenden Sulfide übergeführt werden. Diese wurden entweder als solche isoliert oder als entsprechende Acetate bzw. acetylierte Sulfoxyde charakterisiert. Wie aus den Versuchen mit Vanillylalkoholmethyläther (VIII) und mit den beiden Dibenzyläthern IX und X hervorgeht, wird die Sulfidierungsreaktion der *p*-Hydroxybenzylalkohole unter den oben angegebenen Bedingungen durch Verätherung der benzylalkoholischen Hydroxylgruppe nicht gehemmt. Bei Verätherung der phenolischen Hydroxylgruppe hingegen tritt — wie ein Versuch mit Veratrylalkohol zeigte (vgl. Ref. 8 und 9) — vollkommene Blockierung der Sulfidierungsreaktion ein.

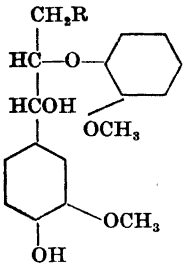






In Übereinstimmung mit früheren Versuchen [8] erwiesen sich auch Vanillin und Acetovanillon sowie *Iso*eugenol als nicht sulfidierbar.

Damit ist gezeigt, dass unter den gewählten Bedingungen die Sulfidierungsreaktion allen *p*-Hydroxybenzylalkoholen und -benzylalkyläthern mit einfacher Seitenkette (R = H, Alkyl oder $HOCH_2$-CHOH—) gemeinsam ist. Um die Abhängigkeit dieser Reaktion von der Struktur des Substituenten R weiter zu untersuchen wurden die vier dimeren Substanzen XI—XIV den gleichen Sulfidierungsbedingungen unterworfen. Ihr Verhalten war von besonderem Interesse, da das Vorkommen ähnlicher Strukturelemente im Lignin sowohl aufgrund von Modellstudien über die Alkoholyse mit alkoholischer Salzsäure [12] bzw. Acidolyse mit Chlorwasserstoff in Dioxan-Wasser [13] und über die Sulfitierung [12,14] als auch aufgrund von Untersuchungen über die Biosynthese des Lignins [15] in Erwägung gezogen wurde.



Es zeigte sich, dass die 3 Substanzen XII, XIII und XIV unter den oben angegebenen Sulfidierungsbedingungen nahezu vollkommen stabil sind und zum grössten Teil (91—96 %) unverändert zurückgewonnen werden können. Im Fall der Substanz XI konnte papierchromatographisch lediglich eine teilweise Wasserabspaltung unter Ausbildung einer zum aromatischen Kern kon-

* Das Sulfidierungsprodukt erwies sich bei papierchromatographischer Kontrolle (Lösungsmittelgemisch: Benzol-gesättigtes Wasser; Entwicklungsmittel: diazotiertes Benzidin) als uneinheitlich und dürfte sowohl mit unverändertem Ausgangsmaterial als auch mit verschiedenen Kondensationsprodukten verunreinigt sein. Auf eine weitere Reinigung musste wegen Substanzmangels verzichtet werden.

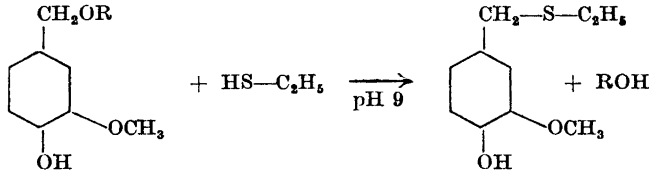
jugierten Doppelbindung nachgewiesen werden (siehe exp. Teil). Da die Substanzen XI und XII je eine *p*-Hydroxybenzylalkoholgruppe und die Substanz XIII (Pinoresinol) zwei *p*-Hydroxybenzylalkyläthergruppen enthalten, muss der negative Ausfall der Sulfidierungsreaktion bei diesen Verbindungen wohl auf eine sterische Hinderung durch den β-ständigen Substituenten (in XI bis XIII) bzw. auf eine besondere Stabilität der beiden Hydrofuranringe (in XIII) zurückzuführen sein. Eine ähnliche Erklärung dürfte auch im Falle der Substanz XIV (Dihydro-dehydro-di*iso*eugenol) gelten. Ein Vergleich des Verhaltens der letztgenannten Substanz mit dem einfacher (nicht cyklischer) *p*-Hydroxybenzylaryläther ist jedoch nicht möglich, da derartige Verbindungen bisher noch nicht synthetisiert worden sind. Das Vorkommen nicht cyklischer Benzylarylätherstrukturen im Lignin konnte jedoch durch Modellversuche über die Alkylierung mit methanolischer Salzsäure [16] ausgeschlossen werden.



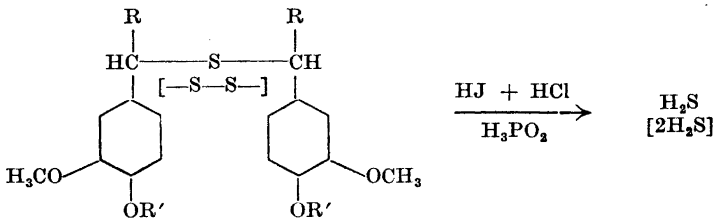
Die Sulfidierungsreaktion in α- (= Benzyl) Stellung wird demnach unter den angegebenen Bedingungen durch geeignete β-ständige Substituenten (z.B. Aroxyl) fast vollkommen gehemmt. Die Alkylierung der Carbinolgruppe mit methanolischer Salzsäure bei 20°C verläuft bei XI und XII in normaler Weise — wenngleich erheblich langsamer als bei Carbinolen ohne Aroxylsubstituent in β-Stellung [13] — während XIII nur schlecht und XIV überhaupt nicht alkyliert werden [16]. Die Sulfitierung gelingt mit XI [17], XII [17], XIII [14] und XIV [18] in neutraler Lösung.

Die Einwirkung von Natriumsulfhydratlösungen auf einfache, sterisch nicht gehinderte *p*-Hydroxybenzylalkohole, -benzylalkyläther und -dibenzyläther führt demnach überwiegend zur Bildung der entsprechenden Dibenzylsulfide. Hägglund und Enkvist [3] schlugen für diese Sulfidbildung einen Verlauf vor, der sich durch folgendes Schema formulieren lässt:

$$1)\ ROH + SH^- \rightarrow SR^- + H_2O$$

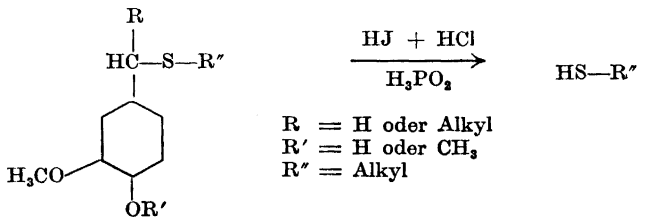
$$2)\ R'OH + SR^- \rightarrow RSR' + OH^-$$

Die erste Stufe dieser Reaktionsfolge ist wegen der grossen Reaktionsfähigkeit der *p*-Hydroxy- (und *p*-Alkoxy-) benzylthiole mit Hilfe von Modellsubstanzen bisher nicht gezeigt worden *. Hingegen konnte die zweite Stufe durch Umsetzung von Äthylmerkaptan mit Vanillylalkohol (I) sowie mit dessen Methyläther (VIII) in alkalischem Medium und Isolierung des gebildeten Sulfids anschaulich gemacht werden [1]:



R = H oder CH_3

VERSUCHE MIT THIOLIGNINEN



Die eben erwähnten Modellversuche stützen die Annahme, dass zumindest ein Teil des Schwefels in α-Stellung zu den aromatischen Kernen (= Benzylstellung) des Lignins eingebaut wird. Um dies direkt an Thioligninen zeigen zu können, wurde versucht, eine Methode zur Bestimmung des in Benzylstellung gebundenen Schwefels auszuarbeiten, worüber wir bereits an anderer Stelle [1] ausführlich berichteten.

Die Methode beruht auf der besonders leichten Spaltbarkeit der Benzylkohlenstoff-Schwefelbindung in *p*-Hydroxy- und *p*-Alkoxybenzylsulfiden und -disulfiden bei Behandlung mit einer Säuremischung,bestehend aus Jodwasserstoffsäure, Salzsäure und unterphosphoriger Säure. Hierbei bildet sich aus Bis-(*p*-hydroxybenzyl)- oder Bis-(*p*-alkoxybenzyl)-sulfiden oder -disulfiden die stöchiometrisch erforderliche Menge Schwefel-

wasserstoff (Vorgang A) und aus *p*-Hydroxy- oder *p*-Alkoxybenzylalkylsulfiden das entsprechende Alkylmerkaptan (Vorgang B). Der Schwefelmwasserstoff bzw. das Alkylmerkaptan wird mit Stickstoff übergetrieben und in der Vorlage jodometrisch bestimmt.

Ein getrennter Nachweis von Schwefelwasserstoff und Alkylmerkaptan ist nach der Methode von Bergström und Trobeck [19] möglich, wobei das Gas zunächst eine 10 %ige Lösung von Cadmiumchlorid in 1 %iger Salzsäure und hierauf eine 5 %ige Quecksilber(II)-cyanidlösung passiert. Eventuell vorhandener Schwefelwasserstoff wird in der ersten Lösung als Cadmiumsulfid aufgefangen, während Alkylmerkaptane infolge der Säureunbeständigkeit der Cadmiummerkaptide die erste Lösung passieren und sich in der zweiten Lösung zu den entsprechenden schwer löslichen Quecksilbermerkaptiden umsetzen.

Dieses Verfahren erlaubt eine Differenzierung des im Sulfatlignin enthaltenen organisch gebundenen Schwefels in eine "säurelabile" und eine "säurestabile" Fraktion, von denen die erstgenannte zum Grossteil aus benzylsulfidischen und — eventuell — -disulfidischen Einheiten bestehen dürfte. Eine Unterscheidung zwischen sulfidischen und disulfidischen Bindungen ist auf diesem Weg nicht möglich.

Ausser *p*-Hydroxy- und *p*-Alkoxybenzylsulfiden und -disulfiden werden auch entsprechend substituierte Phenacyl- und Cinnamylsulfide von der Säuremischung glatt gespalten. Die Spaltbarkeit der *p*-Hydroxy- und *p*-Alkoxyphenacylsulfide kann jedoch durch $NaBH_4$-Reduktion der Carbonylgruppe bedeutend herabgesetzt werden [1].

Die Methode wurde zunächst auf zwei Thiolignine angewandt, die durch Sulfidierung (8-stündiges Erhitzen in einer Natriumsulfhydratlösung von pH 9 bei 100°C) von Björkman-Lignin und von Brauns "native lignin" gewonnen wurden.

Das nach Björkman [20] dargestellte Nativlignin aus Fichte * nahm hierbei rund 3 % Schwefel auf, wovon ca. 70 % durch die Säuremischung als Schwefelwasserstoff abgespalten werden konnten (siehe Tabelle 2). Brauns' "native lignin" aus Fichtenholzmehl [21] ,das einen höheren Gehalt an freien phenolischen Hydroxylgruppen als Björkman-Lignin aufweist [22], enthält erwartungsgemäss auch eine grössere Anzahl sulfidierbarer Gruppen. Insgesamt wurden 6.28 % Schwefel eingebaut, wovon ebenfalls ca. 70 % bei Behandlung mit der Säuremischung als Schwefelwasserstoff abgespalten wurden (siehe Tabelle 2). Der Gehalt an Totalschwefel und v.a. an "säurelabilem" Schwefel ändert sich nur wenig, wenn die Reaktionszeit von acht auf vierundzwanzig Stunden verlängert wird (siehe Tabelle 2).

Die Abspaltung des Hauptteiles des Schwefels bei der Säurebehandlung der beiden Thioligninpräparate stützt demnach die Auffassung, dass dieser zum Grossteil in Benzylstellung eingebaut war und die oben beschriebenen Modellversuche lassen in Übereinstimmung mit früheren Untersuchungen [8-10] als wahrscheinlich erscheinen, dass *p*-Hydroxybenzylalkohol- und *p*-Hydroxybenzylalkyläthergruppen im nativen Lignin für diesen Einbau verantwortlich sind.

Die Menge des durch Behandlung mit der Säuremischung abspaltbaren Schwefels ist bei beiden Thioligninpräparaten auffallend hoch. Bei Überführung aller Phenylpropaneinheiten (mittleres Molekülgewicht ca. 210) in Dibenzylsulfideinheiten würde der Gehalt an "Benzylschwefel" rund 7.6 % betragen. Der tatsächliche Gehalt macht also beim Thiolignin aus Björkman-Lignin rund 28 % und beim Thiolignin aus Brauns' "native lignin" rund 59 % dieses Maximalwertes aus, d.h. fast 30 % (bei Björkman-Lignin) bzw. etwas

* Hrn. Dr. A. Björkman danken wir für die freundliche Überlassung eines Präparates.

mehr als die Hälfte (bei Brauns' "native lignin") aller Phenylpropaneinheiten nehmen an der Sulfidierungsreaktion teil. Diese Anteile entsprechen ungefähr dem Gehalt der beiden Ligninpräparate an Einheiten mit freier phenolischer Hydroxylgruppe, die — wie die Modellversuche ergaben — eine Voraussetzung für das Eintreten der Sulfidierungsreaktion in α-Stellung darstellen.

Die Sulfidierungsreaktion — zusammen mit der Säurespaltungsmethode — scheint somit eine neue Möglichkeit zu eröffnen, die Frage der Menge der Gruppen X_1 und X_2 in Ligninpräparaten zu beleuchten.

Die Gruppen X_1 sind durch die Indophenolreaktion [7] bestimmbar. Der Rest der phenolischen Einheiten ($X—X_1 = X_2$), der offenbar auch sulfidierbar ist, dürfte — nach den obigen Modellversuchen zu urteilen — aus reaktionsfähigen Benzylalkyläthergruppen (X_2) bestehen. Eine einwandfreie Bestimmung der letztgenannten Gruppen auf diesem Weg wird jedoch erst möglich, wenn es gelingt, die strenge Reproduzierbarkeit der Sulfidierungsreaktion zu zeigen und die unten erwähnten denkbaren Komplikationen (teilweise Disulfidbildung, Sulfidierung in anderen Stellungen als in der Benzylstellung) experimentell auszuschliessen.

Da Sulfidierbarkeit in α-Stellung ausser freien p-ständigen phenolischen Hydroxylgruppen auch noch die Abwesenheit von sterisch hindernden Substituenten in β-Stellung erfordert und somit die Strukturtypen XI bzw. XII, XIII und XIV ausschliesst (vgl. Modellversuche S. 1517) ist der gefundene, relativ hohe Gehalt der beiden Thioligninpräparate an "säurelabilem" Schwefel nicht ohne weiteres mit den gegenwärtigen Vorstellungen über die Struktur der Ligninbausteine und deren gegenseitige Verknüpfung vereinbar. Diese Vorstellungen rechnen ja z.B. mit β-aroxylsubstituierten Einheiten als wesentlichem Bauprinzip des Lignins [23, 13, 24], wobei wenigstens ein Teil dieser Einheiten freies phenolisches Hydroxyl enthalten sollte.

Eine Möglichkeit zur teilweisen Beseitigung dieser Diskrepanz liegt in der Annahme, dass ausser sulfidischen auch disulfidische Bindungen vorliegen könnten, zwischen welchen — wie bereits erwähnt — die Säurespaltungsmethode nicht zu unterscheiden vermag. Die Umsetzung von Björkman-Lignin mit Äthylmerkaptan (siehe unten), bei welcher eine Ausbildung von Disulfidstrukturen nicht möglich ist, lieferte jedoch ein Präparat, dessen "säurelabile" Schwefelfraktion der des entsprechenden Thiolignins (hergestellt durch Umsetzung mit Natriumsulfhydrat) nahezu äquivalent ist (siehe Tabelle 2.). Aus diesem Grund scheidet die Annahme von Disulfidgruppen in den beiden oben erwähnten Thioligninpräparaten als Erklärung für deren hohen Gehalt an "säurelabilem" Schwefel aus. Eine weitere Möglichkeit zur Deutung des erwähnten Sachverhaltes könnte sich dadurch ergeben, dass eventuell auch andere als Benzylsulfidbindungen von der Säuremischung gespalten werden könnten. Ein solches Verhalten wäre nach vorläufigen Modellversuchen [17] vor allem von γ-sulfidischen Einheiten mit bereits vorliegender oder während der Säurebehandlung entstehender, zum Kern konjugierter Doppelbindung (Coniferylsulfidtypus) zu erwarten, da sie zu den benzylsulfidischen Einheiten vinylog sind. Genauere Untersuchungen über die eventuelle Ausbildung γ-sulfidischer Strukturen während der Sulfidierung stehen noch aus. Doch zeigt z.B. das Verhalten des Ketols XVI, das unter den obigen Sulfidierungsbedingungen z.T. in das entsprechende γ-Sulfid übergeführt wird (siehe exp. Teil), dass mit einer solchen Möglichkeit gerechnet werden muss.

Das Vorkommen von Strukturelementen des p-Hydroxy- bzw. p-Alkoxyphenacylcarbinoltypus, deren Thioderivate ebenfalls die Spaltungsreaktion geben [1], konnte ausgeschlossen werden. Die Menge des aus dem Thiolignin abgespaltenen Schwefelwasserstoffs ist nämlich nach Behandlung mit $NaBH_4$ genau so gross wie nach einfacher Alkalibehandlung (siehe Tabelle 2) während Modellsubstanzen dieses Typus — wie oben erwähnt — durch Reduktion der Carbonyl- zu den entsprechenden Carbinolgruppen einen Grossteil ihrer Spaltbarkeit einbüssen.

Der zweite Schritt der Benzylsulfidbildung, welcher — wie oben erwähnt — modellmässig durch Umsetzung von Vanillylalkohol (I) und von dessen Methyläther (VIII) mit Äthylmerkaptan illustriert werden konnte, liess sich auch direkt am Lignin zeigen. Bei Behandlung von Björkman-Lignin mit Äthylmerkaptan nimmt das Präparat 3.67 % Schwefel auf, der zum grössten Teil (84 %) bei Einwirkung der Säuremischung wieder als Äthylmerkaptan abgespalten wird. Die Menge des mit der Säuremischung abspaltbaren Schwefels (3.08 %) entsprach hier — wie beim Produkt der Umsetzung von Björkman-Lignin mit Natriumsulfhydrat (vgl. entsprechende Werte in Tabelle 2) — ca. einem Viertel des theoretisch möglichen Maximalwertes (1 S/Phenylpropaneinheit, mittleres Molekülgewicht 263, entsprechend 12.16 %). Aufgrund der obigen Modellversuche (siehe S. 1521) lassen sich diese Befunde wohl am besten durch die Annahme erklären, dass auch bei der Reaktion des Lignins mit Äthylmerkaptan *p*-Hydroxybenzylalkohol- bzw. -benzylalkyläthergruppen eine massgebende Rolle spielen und in die entsprechenden "säurelabilen" Benzyläthylsulfidgruppen übergeführt werden.

Sulfatlignin aus technischer Schwarzlauge enthält bedeutend weniger Schwefel als die aus den isolierten Ligninen dargestellten Thiolignine (siehe Tabelle 2). Dies kann mit der Annahme erklärt werden, dass während des unter radikaleren Bedingungen verlaufenden technischen Prozesses entweder ein Teil der sulfidierbaren Einheiten durch Kondensationsreaktionen blockiert oder dass aus zunächst sulfidierten Einheiten durch Alkali wieder Schwefel abgespalten wird. Die letztgenannte Alternative konnte durch Modellversuche mit Divanillyldisulfid [8] und mit Divanillylmonosulfid [9,10] gestützt werden.

Um zu untersuchen, ob bei einer derartigen Schwefelabspaltung sulfidierbare Einheiten regeneriert werden, wurde das technische Präparat einer Sulfidierung unter gleichen Bedingungen wie die beiden Nativlignine unterworfen. Hierbei stieg zwar der Gehalt an Totalschwefel auf das Doppelte und der an "säurelabilem" Schwefel auf das fast Dreifache an (siehe Tabelle 2), jedoch erreichten beide Werte nur ca. 2/3 der beim Thiolignin aus Björkman-Lignin beobachteten Schwefelgehalte. Ein grosser Teil (64 %) des bei dieser milden Sulfidierung in das technische Sulfatlignin eingebauten Schwefels kann durch Einwirkung der Säuremischung wieder als Schwefelwasserstoff abgespaltet werden. Bei 8-stündiger Behandlung dieses mild sulfidierten technischen Thiolignins mit 1 N Natronlauge (170°C) sinken der Gehalt an Total- und an "säurelabilem" Schwefel wieder fast auf die Ausgangswerte (= Werte für das technische Thiolignin) ab und es zeigt sich, dass die Gesamtmenge des mit Alkali wieder abspaltbaren Schwefels (0.8 %) der "säurelabilen" Fraktion (0.86 %) angehört. Vielleicht kommt man daher den tatsächlichen Verhältnissen mit der Annahme am nächsten, dass unter technischen Bedingungen sowohl eine irreversible Zerstörung sulfidierbarer Strukturen als auch eine sekundäre Schwefelabspaltung aus primär sulfidierten Strukturelementen eintritt.

VERSUCHE MIT HOLZMEHLPRÄPARATEN

Um einen eventuellen Einfluss der Kohlenhydratbestandteile des Holzes auf die Sulfidierungsreaktion des Lignins festzustellen, wurde abschliessend auch ein nach Björkman [20] durch Ultrafeinmahlung (Schwingkugelmühle) ge-

wonnenes Fichtenholzmehlpräparat direkt Kochungen mit Natriumsulfhydrat und mit Äthylmerkaptan unterworfen und die entstandenen Thiolignine isoliert und analysiert. Durch die weitgetriebene Feinmahlung ist es möglich, begrenzende Faktoren der Sulfidierung und Delignifizierung, welche auf Penetrierungsschwierigkeiten beruhen, weitgehend auszuschalten. Die so gewonnenen Ergebnisse sind ausserdem direkt mit den beim Björkman-Lignin erzielten vergleichbar.

Sowohl bei Kochung mit Natriumsulfhydrat als auch bei Kochung mit Äthylmerkaptan werden Thiolignine erhalten, die im Gehalt an Totalschwefel und an "säurelabilem" Schwefel mit den entsprechenden Präparaten aus isoliertem Björkman-Lignin weitgehend übereinstimmen (siehe Tabelle 2).

Somit scheinen die Kohlenhydratbestandteile des Holzes unter den angegebenen Bedingungen den Einbau des Schwefels in das Lignin chemisch nicht nennenswert zu beeinflussen.

EXPERIMENTELLER TEIL

Darstellung der Modellsubstanzen

Die für die Untersuchung der Sulfidierungsreaktion verwendeten Modellsubstanzen wurden wie in der Literatur beschrieben dargestellt.

Kochung der Modellsubstanzen mit Natriumsulfhydratlösung

Die Kochung der in Tabelle 1 angeführten Modellsubstanzen wurde unter einheitlichen Bedingungen durchgeführt und soll daher nur an einem Beispiel (Syringaalkohol, V) näher beschrieben werden:

285 mg Syringaalkohol (V) wurden in einer Druckflasche mit 10 ml "Sulfidierungslösung" (3 g $Na_2S \cdot 9\ H_2O$ in 100 ml Schwefelwasserstoffwasser) versetzt und auf 100°C erwärmt. Hierbei ging die gesamte Substanz in Lösung, aus der sich im Laufe der 8-stündigen Reaktionszeit allmählich ein Öl abschied. Nach Abkühlen wurde durch Einleiten von Kohlendioxyd neutralisiert, wobei eine weitere Menge Öl ausfiel. Durch 5-malige Ätherextraktion des Reaktionsansatzes konnten 254 mg (entsprechend 90 % d.Th.) farbloses Öl isoliert werden, das beim Anreiben mit etwas Toluol zum grössten Teil kristallisierte. Dieses Rohprodukt wurde mit Essigsäureanhydrid-Pyridin (1 : 1) in üblicher Weise acetyliert und 2 mal aus Äthanol umkristallisiert. Nadeln vom Schmp. 137—138°. (Die analytischen Daten, Schmelzpunkte und Ausbeuten der einzelnen Sulfidierungsprodukte bzw. ihrer Derivate sind in Tabelle 1 zusammengestellt.)

Die Stabilität der fünf dimeren Substanzen XI—XV unter den angegebenen Sulfidierungsbedingungen und ihre Wiedergewinnung soll am Beispiel des *p*-Hydroxybenzylalkohols XII genauer beschrieben werden:

295 mg XII (Schmp. 94—96°) wurden in einer Druckflasche in 30 ml Äthanol gelöst, mit 30 ml "Sulfidierungslösung" versetzt und 8 Stunden auf 100°C erwärmt. Die gesamte Substanz war nach der Kochung in Lösung. Nach Neutralisieren durch Einleiten von Kohlendioxyd und Abdestillieren des Alkohols wurde die Lösung einigemale mit Äther ausgeschüttelt. Die vereinigten Ätherextrakte enthielten ein Öl (279 mg, entsprechend 95 % der Einwage), das sich papierchromatographisch (Lösungsmittelgemisch : Benzol-gesättigtes Wasser; Entwicklungsflüssigkeit : diazotiertes Benzidin) als einheitlich erwies und den gleichen R_F-Wert (0.64) wie das Ausgangsmaterial (XII) besass. Nach Reinigung durch Adsorption an Al_2O_3 und Umkristallisieren aus sehr wenig Methyläthylketon wurden Kristalle vom Schmp. 94—96° erhalten, die mit dem Ausgangsmaterial (XII) keine Schmp.-Depression ergaben.

Pinoresinol (XIII) und Dihydro-dehydro-di*iso*eugenol (XIV) konnten nach der gleichen Behandlung in 91 %iger bzw. 96 %iger Ausbeute zurückgewonnen werden.

Das Diol XI gab bei gleicher Behandlung und Aufarbeitung ein viskoses schwefelfreies Öl, das papierchromatographisch (Lösungsmittelgemisch: Benzol-gesättigtes Wasser) näher untersucht wurde. Es zeigte sich, dass es ausser unverändertem Ausgangsmaterial (R_F = 0.67) eine weitere phenolische Komponente (R_F = 0.52) enthielt. Diese gab beim Entwickeln mit einer alkoholischen Lösung von Chinonmonochlorimid und mit verdünnter Natronlauge eine vorübergehende Violettfärbung und beim Besprühen mit Phloroglucin-Salzsäure eine stabile Rotfärbung. Die Bildung eines instabilen Indophenolfarbstoffes beim Entwickeln mit Chinonmonochlorimid deutet auf das Vorliegen eines durch Wasserabspaltung aus dem Ausgangsmaterial entstandenen Coniferylalkoholderivates hin [7]. Die positive Phloroglucin-Reaktion zeigt, dass dieses teilweise zum entsprechend substituierten Coniferylaldehyd oxydiert worden sein dürfte [25].

Die der Guajacylverbindung XI entsprechende Veratrylverbindung XV konnte bei Einhaltung der oben erwähnten Bedingungen ebenfalls nicht sulfidiert werden. Das resultierende farblose Öl enthielt keinen Schwefel, erwies sich papierchromatographisch (Lösungsmittelgemisch: Benzol-gesättigtes Wasser; Entwicklung durch Joddämpfe) als einheitlich und besass sowohl den gleichen R_F-Wert (0.82) als auch den gleichen Methoxylgehalt (28.2 %) wie das Ausgangsmaterial.

Dagegen gab das dem Diol XV entsprechende Ketol XVI unter den gleichen Bedingungen ein kristallisiertes Sulfidierungsprodukt. Ausbeute: 21 % d. Th. Schmp. 134—136°. (Gef.: S 5.29. Ber. für $C_{36}H_{38}O_{10}S$: S 4.85.) Das Sulfid wurde von der "Säuremischung" langsam gespalten.

Kochung der Modellsubstanzen mit Äthylmerkaptan

Die Kochung erfolgte wie bereits für den Vanillylalkohol (I) beschrieben [1]. Vanillylalkoholmethyläther (VIII, Schmp. 35—36°) lieferte hierbei in 86 %iger Ausbeute Vanillyläthylsulfid.

Darstellung der Thiolignine

1) *aus Björkman-Lignin* [20]

a) *Kochung mit Natriumsulfhydratlösung.* 224 mg Björkman-Lignin wurden in einer Druckflasche mit 20 ml Äthanol und 20 ml "Sulfidierungslösung" versetzt und 8 Stunden auf 100°C erwärmt. Nach Abdestillieren des Äthanols im Vakuum wurde etwas Wasser hinzugefügt und mit 2N Salzsäure schwach angesäuert. Das hierbei ausfallende Thiolignin konnte durch kurzes Erwärmen auf 60° in eine leicht filtrierbare Form übergeführt werden. Nach Trocknung über P_2O_5, Extraktion mit Toluol und Petroläther sowie erneuter Trocknung über Paraffin gab das Produkt die in Tabelle 2 angeführten analytischen Werte. Das Ultraviolett-Spektrum war dem des Ausgangsmaterials überaus ähnlich, das Absorptionsmaximum bei 280 mμ war gleich ausgeprägt. Die Reaktion mit Phloroglucin-Salzsäure war — wie bei den anderen hier beschriebenen Thioligninpräparaten aus Nativligninen — positiv. Da jedoch — wie der Modellversuch mit der Substanz XI zeigte — während der Sulfidierungsreaktion eventuell mit der Neubildung Coniferylaldehyd-artiger Gruppierungen zu rechnen ist, darf dies nicht als Beweis für das Überleben der ursprünglich vorhandenen Coniferylaldehydgruppen betrachtet werden. Ausbeute 121 mg.

b) *Kochung mit Äthylmerkaptan.* 404 mg Björkman-Lignin wurden mit 40 ml 1/15 M Phosphatpufferlösung vom pH 6.9, 55 ml Äthanol und 5 ml Äthylmerkaptan versetzt und nach Sättigung mit Stickstoff in einem rotierenden Stahlautoklaven 24 Stunden auf 100° erwärmt. Nach Abdestillieren des Alkohols im Vakuum wurden 150 ml dest. Wasser zugesetzt und nochmals im Vakuum eingeengt. Hierbei fiel das "Äthylmerkaptan-Lignin" teilweise aus. Durch schwaches Ansäuern mit verdünnter Salzsäure wurde ein weiterer Teil ausgefällt, die gesamte Fällung sofort abzentrifugiert und einigemale mit dest. Wasser gewaschen. Nach Trocknung an der Luft wurden 364 mg hellgelbes Pulver erhalten. Zur Reinigung wurde dieses dreimal mit Hexan ausgezogen und hierauf im Vakuum über Paraffin und P_2O_5 getrocknet. (Analysenwerte siehe Tabelle 2.)

2) *aus Brauns "native lignin"* [21]

Kochung mit Natriumsulfhydratlösung. Die Darstellung erfolgte wie oben für das Thiolignin aus Björkman-Lignin beschrieben. Aus 220 mg wurden 164 mg säurefällbares Thiolignin erhalten. (Analysenwerte siehe Tabelle 2.)

Isolierung und Natriumsulfhydrat-Kochung des technischen Thiolignins

Die Schwarzlauge einer technischen Sulfatkochung von Fichtenholz wurde durch Einleiten von Kohlendioxyd neutralisiert. Das hierbei ausgefällte Thiolignin flockte bei kurzem Erwärmen auf 60° aus. Es wurde abzentrifugiert, mit Kohlendioxyd-gesättigtem Wasser gewaschen und im Vakuum über P_2O_5 getrocknet. Schliesslich wurde das Präparat mit Schwefelkohlenstoff und mit Petroläther gründlich extrahiert.

880 mg dieses Thiolignins wurden mit 180 ml "Sulfidierungslösung" versetzt und in einer Druckflasche 8 Stunden auf 100° erwärmt. Nach Einengen auf kleines Volumen wurde mit Essigsäure angesäuert und das Reaktionsprodukt auf gleiche Weise wie das Ausgangsmaterial isoliert und gereinigt. Bei Behandlung dieses Präparates mit der Säuremischung konnte nur Schwefelwasserstoff als flüchtiges Spaltprodukt nachgewiesen werden.

378 mg dieses sulfidierten technischen Thiolignins wurden in 10 ml 1 N NaOH gelöst und in einem rotierenden Stahlautoklaven 8 Stunden auf 170° erhitzt. Die Wiederisolierung und Reinigung erfolgte wie oben beschrieben. (Analysenwerte siehe Tabelle 2.)

Kochung von feinstgemahlenem Holzmehl

a) *mit Natriumsulfhydratlösung.* 3.80 g feinstgemahlenes Fichtenholzmehl [20] wurden in einer Lösung von 1.0 g Natriumsulfhydrat in 60 ml Äthanol und 40 ml dest. Wasser suspendiert und 24 Stunden in einem rotierenden Stahlautoklaven auf 100° erwärmt. Der nach dieser Kochung ungelöste Rest betrug 2.46 g (= 65 % der Einwage) und enthielt 2.59 % OCH_3. Aus dem Filtrat dieses Rückstandes wurde — auf gleiche Weise wie bei der Kochung von Björkman-Lignin beschrieben — ein Thiolignin in Form eines gelbbraunen Pulvers isoliert. Ausbeute 0.45 g (= 12 % der Einwage), Das Präparat ergab bei Totalhydrolyse 7 % reduzierende Monosaccharide, deren prozentuelle Zusammensetzung ebenso wie die der im Kochungsrückstand enthaltenen Zucker durch quantitative Papierchromatographie ermittelt und in Tabelle 3 zusammengestellt wurde.

Eine kleine Probe (60 mg) des Präparates wurde in 10 ml 0.1 N NaOH gelöst und 12 Stunden bei Zimmertemperatur aufbewahrt. Hierauf wurde das Thiolignin wie üblich isoliert und gereinigt. Ausbeute 51 mg. Eine weitere Probe (60 mg) wurde in 10 ml 80 %igem Äthanol suspendiert und mit 50 mg $NaBH_4$ versetzt. Nach 12 Stunden Schütteln bei Zimmertemperatur wurde der Versuchsansatz wie üblich aufgearbeitet. Ausbeute an reduziertem Thiolignin 53 mg. (Analysenwerte siehe Tabelle 2.)

b) *mit Äthylmerkaptan.* 3.80 g feinstgemahlenes Holzmehl wurden in einer Mischung bestehend aus 100 ml Äthänol, 80 ml 1/15 M. Phosphatpufferlösung vom pH 6.9 und 10 ml Äthylmerkaptan suspendiert, die Suspension wurde mit Stickstoff gesättigt und in einem rotierenden Stahlautoklaven 24 Stunden auf 100° erwärmt. Der nach dieser Kochung erhaltene Rückstand (1.60 g = 42 % der Einwage) enthielt 2.73 % OCH_3. Aus dem Filtrat dieses Kochungsrückstandes wurde auf übliche Weise ein "Äthylmerkaptan-Lignin" in Form eines hellbraunen Pulvers isoliert. Ausbeute 0.39 g . (Analysenwerte siehe Tabelle 2.) Bei Behandlung dieses Präparates mit der Säuremischung in der auf Seite 1521 angegebenen Weise konnte als flüchtiges Spaltprodukt nur Äthylmerkaptan nachgewiesen und nach Überführung in das Quecksilbersalz durch Schmp. identifiziert werden [72—73.5°).

Herrn Prof. E. Hägglund, Schwedisches Holzforschungsinstitut, Stockholm, danken wir für die Anregung zu dieser Arbeit, Herrn Prof. E. Adler, Chalmers Technische Hochschule, Göteborg, für sein reges Interesse, sowie für die Überlassung der Modellsubstanzen IV, XI und XII. Für wertvolle experimentelle Hilfe sei Herrn S. Söderberg bestens gedankt.

Polarographic Reduction of Hydroxamic Acids

MILDA PRYTZ and TH. ØSTERUD

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Acethydroxamic acid and propionhydroxamic acid were polarographically reduced in aqueous alcoholic solutions of tetraethyl ammonium iodide.

Over a pH range from 4.7 to 9.5 two distinct waves occur. For the acethydroxamic acid the more positive one levels off in the prescribed manner, giving a very well defined wave. The half wave potential of the more negative one has so great negative value that erratic dripping or streaming of the mercury occurs and deranges the polarographic curve, which shows a maximum. The first wave was therefore found most suitable for practical analytical purposes and accordingly studied thoroughly. For the propionhydroxamic acid the first waves also show some tendency to form rounded maxima but are still sufficiently well defined for analytical purposes.

The values of the half wave potentials seem to be practically independent of the pH of the solutions until the pH has increased to about 10. For acethydroxamic acid the values with respect to the saturated calomel electrode lie about 1.7 V, for propionhydroxamic acid about 1.85 V.

The form of the curves seems to indicate that the reaction at the cathode is irreversible and we have therefore not found it expedient to calculate $I/(I_{dc}-I)$.

Our reason for studying hydroxamic acids is their general utility in organic analysis. They owe their analytical application to the fact that they may be identified by their formation of soluble, red to violet coloured ferric salts [1]. Since esters are readily hydroxylaminolyzed in the presence of alkali, this reaction can also be employed as a test for esters. Being interested in instrumental analysis and especially in polarographic methods we wanted to use hydroxamic acids for polarographic determination of esters. The saturated aliphatic esters are not capable of producing polarographic reduction waves [2–4], and can therefore not be polarographically determined as such. The hydroxamic acids, however, which may be looked upon as oximes of the original acids, ought to be polarographically reducible, inasmuch as the corresponding oximes lend themselves to polarographic methods [4]. The authors made many negative attempts at obtaining reduction waves for hydroxamic acids, in different buffer solutions, but were nevertheless convinced that the problem could be solved

if only a suitable supporting electrolyte could be found. It must give no hydrogen wave, and only contain components with greatly negative reduction potentials. We have found that hydroxamic acids are not electro-reducible within the potential range given by buffers containing alkali salts in aqueous solution, the only resulting waves obviously being hydrogen waves. Consequently we had to make use of tetraalkylammonium salts. We noticed that Bobrowa and Matwejewa [5] by polarographic reduction of unsaturated esters had used tetramethylammonium iodide in alcoholic solution, and their curves show that the usable potential range reaches to about —2.5 V. For our experiments we used a supporting electrolyte consisting of 0.1 M $N(C_2H_5)_4I$ in 50 % C_2H_5OH with 0.005 % tylose. The pH was raised by addition of $N(C_2H_5)_4OH$. Trying to lower pH was inexpedient inasmuch as it only resulted in the reduction of hydrogen ions. Most measurements were carried out with a mercury pool anode. In order to get significant values of the half-wave potentials, however, some polarograms were recorded with a saturated calomel electrode as external anode. The hydroxamic acids studied were acethydroxamic acid and propionhydroxamic acid.

EXPERIMENTAL PROCEDURE

In these experiments a recording polarograph from Radiometer, Copenhagen, was used. Instead of the usual lead batteries an arrangement with Nife batteries in series with a rectifyer was employed. It gave high stability to the potential across the bridge. The usual precautions against oxygen interference were taken, a mixture of pure nitrogen and hydrogen being bubbled through the supporting electrolyte in the electrolysis vessel until it showed no trace of any oxygen wave. The solutions to be measured were kept under the inert gas, the flow of which was only stopped during the recording of the polarograms.

The acethydroxamic acid was prepared by Farmaceutisk Industri A/S and the propionhydroxamic acid by Dr. Else Kloster Jensen at *Sentralinstitutt for industriell forskning*. Both acids were recrystallized several times to make sure that they were chemically pure. Their molar concentration in the electrolysis vessel during the analysis was of the order 10^{-3}. The pH of the solutions was measured at the start and at the completion of the experiments.

EXPERIMENTAL RESULTS

The polarographic waves were very distinct even without the use of counter current, which was found to be superfluous in this case.

For the acethydroxamic acid as well as for the propionhydroxamic acid the polarograms consist of two waves. Of these the first wave is the best defined reduction wave, while the second wave is apt to show a somewhat irregular behaviour that need not be ascribed to the hydroxamic acids, because the occurrence of variable and erratic drops is always apt to be troublesome in aqueous alcoholic solutions near the decomposition potential of tetraalkyl ammonium halides. The irregular form of the more negative wave therefore made us limit our efforts to the more positive one, as this wave lends itself readily to analytical purposes. Both waves were registered, but we find it adequate to render only the first one. For acethydroxamic acid the curves are given in Fig. 1. The curves all start at V = 1.05, and for each of them the curve for the corresponding supporting electrolyte was always taken.

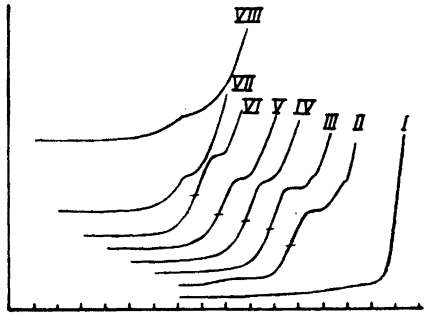

Fig. 1. Electro-reduction of the acethydroxamic acid at the pH values 4.7, 5.5, 6.5, 7.5, 8.5, 9.5 and 10.5, the pH increasing from curve II to curve VIII. Curve I represents the supporting electrolyte. Mercury pool anode.

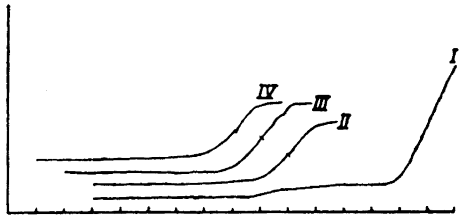

Fig. 2. Electro-reduction of acethydroxamic acid at the pH values 4.7, 7.0 and 9.0, the pH increasing from curve II to curve IV. Curve I represents the supporting electrolyte. Saturated calomel electrode as anode.

In order to express the half wave potentials with reference to the S.C.E., according to general practice, some records were made with a saturated calomel electrode as the second electrode. For the acethydroxamic acid the results are given in Fig. 2.

The value of the half wave potentials seemed to be independent of the pH except for the highest value, and referred to the mercury pool anode it was 1.7 V. Referred to the saturated calomel electrode it was 2.1 V in slightly acid solution and rose to 2.14 V only in distinctly basic solution.

The propionhydroxamic acid is also reduced in two steps. The first wave is apt to show a small rounded maximum. The second wave, on the other hand, is somewhat more regular than we were able to obtain it with the acethydroxamic acid. The value of the half wave potential as referred to the mercury pool was 1.8 V, *versus* the saturated calomel electrode 2.13 V.

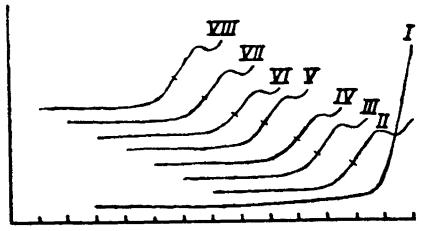

Fig. 3. Electro-reduction of propionhydroxamic acid at the pH values 4.7, 5.5 ,6.0, 6.5, 7.0, 9.0 and 10.0, the pH increasing from curve II to curve VIII. Curve I represents the supporting electrolyte. Mercury pool anode.

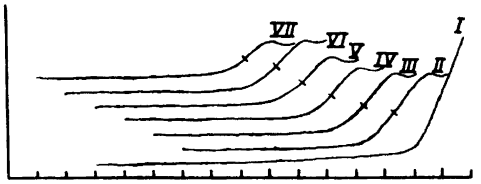

Fig. 4. Electro-reduction of propionhydroxamic acid at the pH values 4.7, 6.0, 7.0, 8.0, 9.5 and 10.5, the pH increasing from curve II to curve VII. Curve I represents the supporting electrolyte. Saturated calomel electrode as anode.

The results are given in Figs. 3 and 4. As a potential of 3 V had been laid across the bridge each interval on the abscissa represents 1.5 V. These curves were also started at 1.05 V.

DISCUSSION

If we compare the structure of the oxime tautomeric forms of the hydroxamic acids with the corresponding oximes, to wit: acethydroxamic acid $CH_3—C\begin{smallmatrix}OH\\NOH\end{smallmatrix}$ with ethanal oxime $CH_3—C\begin{smallmatrix}H\\NOH\end{smallmatrix}$, or propionhydroxamic acid $CH_3CH_2—C\begin{smallmatrix}OH\\NOH\end{smallmatrix}$ with propanal oxime $CH_3CH_2—C\begin{smallmatrix}H\\NOH\end{smallmatrix}$, we must be justified in assuming that a polarographic reduction will affect the double bond of the group $>C = NOH$ between the carbon and the nitrogen atom. Whereas the oximes have both weakly acid and weakly basic properties, the hydroxamic acids, on the other hand, are classed as acids in aqueous solution. This tends to make their reduction somewhat more sluggish and require a higher reduction potential. Even though they may be forced to accept electrons, this takes place polarographically only at relatively high negative potentials. As was to be expected, both the forms of the curves and the independence of the half wave potentials of the pH suggest irreversibility in the process.

The object of this investigation was to find an instrumental method for indication of the analytically very serviceable hydroxamic acids. This problem found its solution in a polarographic reduction of the acids in a supporting electrolyte consisting of a solution of tetraethyl ammonium iodide in an ethanol-water mixture. The curves were very well defined and always gave the same half-wave potential. This was practically independent of the pH of the solution, so that an addition of tetraethyl ammonium hydroxide seems superfluous.

The authors are indebted to Cand.mag. Per Kolsaker for the recording of the polarograms.

Evidence for the Diamagnetism of $Co(NO)_2Hal.$ and $Fe(NO)_2Hal.$

Studies in Magnetochemistry 20 *

H. SOLING and R. W. ASMUSSEN

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

The magnetic susceptibilities of $Co(NO)_2X$, X = I, Br, Cl, and $Fe(NO)_2Y$, Y = I, Br, have been measured at temperatures ranging from 85 to 295°K. The compounds are found to be diamagnetic or nearly so. This result is compatible with the generally accepted binuclear structures, if in the particular case of the iron compounds an intermetallic bond be supposed. The preparation and the purification of the compounds are described in detail.

In the years 1939 and 40 Hieber and coworkers [1, 2] prepared a series of metal-NO-halides of the composition $Co(NO)_2X$ and $Fe(NO)_2Y$, where X = I, Br, Cl and Y = I, Br. All the compounds are very instable, black solids with low melting points. They can be prepared by the action of NO-gas on the appropriate anhydrous metal-di-halide eventually under addition of metal powder, *e.g.*

$$FeI_2 + Fe + 4NO \rightarrow 2Fe(NO)_2I$$

In the present paper a magnetochemical investigation of the above mentioned compounds is reported.

The results of the measurements of the magnetic susceptibility of several samples of $Co(NO)_2I$, $Co(NO)_2Br$, $Co(NO)_2Cl$ and $Fe(NO)_2I$ are given in Table 1 together with the results of the chemical analyses of the compounds. The independent samples Nos. I to V of $Co(NO)_2I$ have been prepared by consecutive sublimations of the crude product. Considering the measurements at room temperature it is seen that the gram susceptibility decreases from No. I to No. IV; the difference between Nos. IV and V is considered of no significance. (*Cf.* the remarks below concerning the accuracy of the measurements). The low-temperature measurements of the samples No. I to No. IV display the

same features. On the other hand, when considering each preparation separately χ_g increases when the temperature is decreased. The absolute increase is the largest for preparate No. I, which has a positive susceptibility. Remembering that $Co(NO)_2$ I is undergoing some decomposition when exposed to the air even for a short time and that the products of decomposition must be strongly paramagnetic or even ferromagnetic, it seems safe to conclude that chemically pure $Co(NO)_2$ I is diamagnetic. The good accordance between the analysed and the calculated composition of the substances rather strengthens than weakens this conclusion since the amount of an ordinary paramagnetic cobaltous-compound necessary to mask completely even a strong diamagnetism is beyond the limits of what can be found by a chemical analysis.

In the cases of $Co(NO)_2Br$ and $Co(NO)_2Cl$ magnetic measurements have been performed at room temperature only. A faint diamagnetism was ultimately found for the bromide while an equally small paramagnetism was the best result we could reach with the chloride. These two compounds are even more liable to undergo decomposition than the iodide. It is furthermore highly improbable that the magnetic properties of the bromide and the chloride should be essentially different from that of the iodide. We consequently conclude that also $Co(NO)_2Br$ and $Co(NO)_2Cl$ are diamagnetic when chemically pure.

$Fe(NO)_2I$ is the only substance for which we found a reproducible, although very small, diamagnetism independent of the temperature. The apparently increased diamagnetism at lower temperatures is not considered significant. Usually we claim a much higher accuracy, but remembering that the magnetic susceptibility is found from the difference between the force exerted by the magnetic field upon the Gouy-tube + substance and that exerted upon the

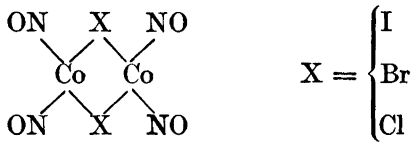

Table 2. Magnetic gram susceptibilities of $Fe(NO)_2I$ at different temperatures and different field strengths.

empty tube, it is obvious that the experimental error must be rather large when so small susceptibilities are measured as the case is here. Furthermore, during the measurements at low temperatures a continuous condensation of ice upon the tube occurs, which considerably augments the experimental errors. As an illustration of these effects a series of measurements on $Fe(NO)_2I$ is shown in Table 2.

Besides the compounds listed in Table 1 we also prepared $Fe(NO)_2Br$ and attempted to measure it magnetically. In spite of several efforts shortly reported in the experimental section we did not succeed in obtaining even a qualitative impression of its susceptibility. We suppose, by extrapolation from the above results, that this compound is so instable that an experimental demonstration of its — presumed — diamagnetism is impossible.

Hieber and coworkers [1,2] have proposed a binuclear formula for the cobalt-compounds:

The NO-metal bond contributes, according to the detailed discussion given by Seel [3], three electrons to the electron system of the acceptor metal. The four-coordinated Co-atom thus obtains an EAN = 36 which accounts for the diamagnetism. However, it must be pointed out, that since the monomer also contains an even number of electrons the above formula is no necessary consequence of the observed diamagnetism.

The four ligands around each Co-atom may utilize either the tetrahedral sp^3-hybrid or the planar dsp^2-hybrid. The latter necessitates the promotion of two electrons from the 3d orbitals to the 4p orbital not participating in the hybridization, and is therefore considered energetically less favourable.

$Fe(NO)_2Y$ contains an uneven number of electrons in the monomer form. A binuclear structure analogous to that shown above for the cobalt-compounds leaves one unpaired electron on each iron atom. The assumption of a high-

polymer structure is not in accordance with the low melting points and the fact that the compounds are easily sublimed. We consider a binuclear structure with an intermetallic bond the most acceptable explanation of the diamagnetism.

EXPERIMENTAL

Preparation and analysis of the compounds

The preparation of the compounds was carried out according to the method given by Hieber *et al.*[1,2] We have modified the technique in order to prepare the compounds in the highest possible degree of magnetic purity, and for the reason of easy handling the samples used for the magnetic measurements.

$Co(NO)_2I$. 4 g of powdered anhydrous CoI_2 were introduced in the apparatus shown in Fig. 1 and dried at 110—120°C in a current of dry nitrogen. After cooling to room temperature the nitrogen was displaced by pure, dry NO and the temperature slowly raised. At 60—80°C the powder began to react with the NO-gas under liberation of iodine which was collected on the "cold finger". When the reaction began to slow down, the temperature was cautiously raised to 105°C. The reaction vessel was maintained at this temperature until the evolution of iodine ceased. The apparatus was then cooled to room temperature. While a current of dry nitrogen was passed through, the "cold finger" was withdrawn, cleaned, dried and inserted again. The pressure was then reduced to about 1 mm Hg and the sublimation of $Co(NO)_2I$ was started by heating the apparatus to 80°C as quickly as possible. In the course of 5 to 6 h a brush of black crystals was collected on the "cold finger". This crude sublimate must be stored in an evacuated vessel. The purification of the product was accomplished by several resublimations.

$Co(NO)_2Br$ was prepared analogously from an intimate mixture of powdered, anhydrous $CoBr_2$ and freshly reduced cobalt powder (from cobaltous-oxalate). The reaction started at 100°C. $Co(NO)_2Br$ forms black crystals.

$Co(NO)_2Cl$ was obtained from anhydrous $CoCl_2$ and cobalt powder just as the corresponding bromide. Black crystals.

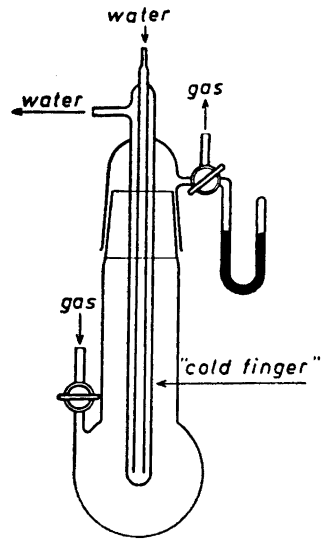

Fig. 1. Reaction- and sublimation-apparatus.

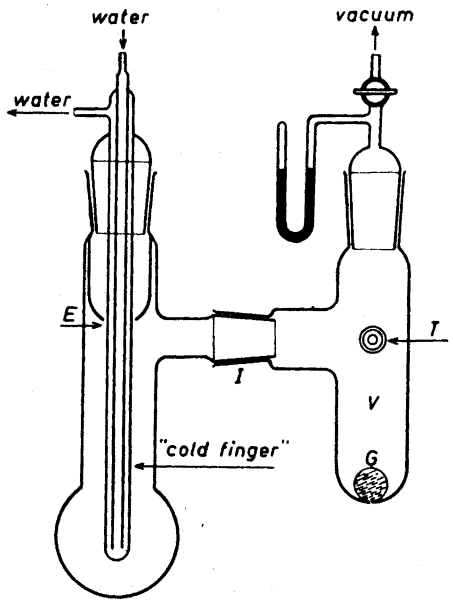

Fig. 2. Sublimation apparatus with vessel (*V*), where the sublimate is powdered by means of the glass-sphere (*G*), and filled into the Gouy-tube (*T*). The edge (*E*) scratches the sublimate off the "cold finger".

While $Co(NO)_2I$ could be sublimed nearly without decomposition, the bromide and the chloride underwent a slight decomposition during the sublimation. All three substances are very sensitive to oxygen.

The *anhydrous cobaltous-halides* used were prepared from Ni-free $CoCO_3$ which was dissolved in the appropriate halogen acid. The solution was then evaporated to dryness under dropwise addition of acid to prevent hydrolysis. $CoCl_2$ was finally dried in a current of dry HCl at 120°C, while $CoBr_2$ and CoI_2 were dried at 130—140°C *in vacuo*. The substances were all completely soluble in water.

$Fe(NO)_2I$. 4 g of powdered anhydrous FeI_2 thoroughly mixed with 1 g of freshly reduced iron powder were treated with NO-gas as described above. The reaction started at room temperature under evolution of a considerable amount of heat, and was allowed to continue without further heating. From time to time slight cooling was necessary in order to keep the reaction under control. When the temperature exceeded 80°C the reaction mixture began to melt. No free iodine was observed during the reaction. The crude nitrosate was sublimed at 80—90°C under reduced pressure. In order to obtain a sublimate of a crystal size suitable for the further manipulations, the sublimation had to be carried out in three stages: *i*, 80°C, 10 mm Hg; the substance melted and gave off NO rather vigorously. *ii*, When the evolution of NO ceased, the temperature was raised to 85°C and the pressure was reduced to 5 mm Hg. The majority of the substance was volatilized at this stage. *iii*, Finally the temperature was raised to 90°C and the pressure was lowered to about 1 mm Hg. The sublimation was now continued until only a small remanence of iron powder and decomposed substance was left. The resublimations were carried out in the same way. No liberation of NO was then observed and the yield was nearly quantitative. $Fe(NO)_2I$ forms black crystals, sensitive to oxygen.

$Fe(NO)_2Br$ was prepared in the same way as the iodide. This substance, which also forms black crystals, is the most delicate of the compounds described here. Like the

iodide' it sublimes easily, but far from quantitatively. $Fe(NO)_2I$, on the other hand, is the most stable of the five substances in question. A specimen of this substance stored in an evacuated glass-tube for three years did not show any sign of decomposition, while the other substances were more or less decomposed.

The *anhydrous ferrous-halides* used were prepared from iron powder and elementary halogens, according to standard procedures, and finally sublimed in high vacuum.

Analysis. Cobalt-compounds: Cobalt was determined as $CoSO_4$ by weighing. The compounds were converted into the sulphate, which was heated at 500°C until constant weight. Owing to the small amounts of substance available at that stage of development of the preparation technique the usual method of determination of iodine as AgI by weighing could not be used. The iodine was therefore oxidized to IO_3^- and determined iodometrically. Bromine and chlorine were weighed as the silver-halides.

$Fe(NO)_2I$: Iron was determined as Fe_2O_3 and the iodine as AgI. The results of the analyses are given in Table 1 together with the results of the magnetic measurements.

Magnetic measurements

The magnetic susceptibilities were measured by means of the Gouy method as described in earlier papers [4]. The susceptibility quoted for each sample and temperature in Table 1 is the mean value of several measurements at at least two field strengths ranging from 3 346 to 7 636 Ørsted (*cf.* Table 2). No sign of field strength dependence of the susceptibilities was found within the limits of experimental errors. In view of the obvious risk of ferromagnetic impurities in the preparates, measurements of the susceptibilities over a broader range of field strengths would have been desirable, but owing to the very feeble magnetism observed, the measurements could only be carried out with a reasonable accuracy (a few per cent) in the above mentioned interval of field strengths, 7 636 Ørsted being the maximum field strength obtainable with our magnet. On the other hand, a slight ferromagnetism would not invalidate our conclusion that the pure compounds are diamagnetic.

The delicacy of the compounds to oxygen complicated the packing of the substance into the tubes used for the magnetic measurements. The following procedure, which is the final result of several attempts, fulfils the demands for simplicity and efficiency to a reasonable degree. The resublimations were carried out in the apparatus shown in Fig. 2 as described above. After cooling to room temperature, the apparatus was tilted and while a current of dry nitrogen was passed through, the "cold finger" was slowly drawn out with a screwing movement. When reaching the edge E the crystals were scratched off and fell down into the vessel V, which then was disconnected at J and closed with a ground stopper. The vessel was evacuated, the crystals were powdered by aid of the glass-sphere G and could now be packed into the tube T by aid of a little glass rod (not shown in Fig. 2) containing an iron core, so that it could be manipulated from outside by means of a magnet. However, great difficulties were experienced at this point due to adhesion of the fine powder to the glass walls. We were therefore forced to abandon the fine-powdering and instead adapted the following way of packing. The crystals were only crushed coarsely with the glass-sphere and next filled into the tube in small portions. Each time the tube was tapped gently at the bottom until the packing appeared uniform by inspection with a magnifying glass. From our general experience concerning the packing of Gouy-tubes this procedure is judged to be sufficiently reproducible for the purpose, provided the size of the particles is nearly uniform and not too large. The apparatus was again connected to the vacuum-pump and the tube T was sealed off, while the pump was working. During the sealing-off process the upper surface of the packing melts slightly and locks the packing when it again solidifies, thus securing a defined length of the substance column. Since the upper surface of the packing is situated well outside the magnetic field during the measurements an eventual slight decomposition due to the melting cannot commit the measurements.

Several samples of $Fe(NO)_2Br$ were prepared as described above and measured magnetically. Rather large positive and completely irreproducible susceptibilities were found. Assuming that the crushing of the crystals might cause some decomposition, we finally filled the sublimate into the Gouy-tube without any crushing at all. Of course the packing became highly imperfect in this way, but still we might obtain some qualitative inform-

ation about the susceptibility. The glass-tube with the crystals was, however, still attracted by the magnetic field, and the attraction slightly increased with time. This clearly shows, that the substance is steadily decomposed even in the sealed-off tube. We therefore gave up further investigations of the magnetic properties of $Fe(NO)_2Br$.

Fractionation of Polymers by Liquid-Liquid Distribution

I. Theory

KARL ERIK ALMIN

Swedish Forest Products Research Laboratory, Paper Technology Department, Stockholm, Sweden

Equations for the calculation of molecular frequency functions of polymers from counter current experiments are deduced provided that ideal conditions prevail.

The method of fractionating polymers by distribution between two immiscible solvents was first applied by Schulz and Nordt [1]. By shaking a water solution of polyglycol with mixtures of chloroform and benzene of different composition they obtained a number of fractions of different molecular weights. The volume ratio of the two phases was kept very high.

The theory of the process was first treated by Brønsted [2]. On the basis of the assumption that in chemically similar materials the potential energy of the molecule is proportional to its magnitude he deduces the formula

$$k = \exp \frac{P \cdot \varepsilon}{RT} \tag{1}$$

where k = partition coefficient, P = degree of polymerisation and ε is a constant dependent of the composition of the solvent system. By experiments Schulz [3] found that a simple relation exists between the constant ε and the composition of the solvent system. By applying these laws Schulz and Nordt [1] could conclude that the efficiency of separation is improved by increasing the volume ratio of the two phases. The conclusion which was drawn from these investigations is that fractional precipitation can be considered more efficient, as in the latter case the volume ratio of the two phases is much higher than can be attained in practice at distribution between two solvents.

By the use of statistical thermodynamics several equations have been derived to account for the activity of polymer solutions. (For a review see *e.g.*, Ref.[4]). These equations confirm at least qualitatively the results of Schulz and Nordt [1].

As was pointed out by Almin and Steenberg [5] the liquid-liquid distribution method as carried out by Schulz and Nordt suffers from the same weakness as the solution and precipitation methods, as to the calculation of the molecular frequency function from the experimental data. By keeping the composition of the solvent system constant at all steps of the fractionation and compensating for the decreased fractionation effect by a method of multiplication, data can be obtained, making it possible to carry out the calculations in a theoretically correct way.

The scope of this work is to make use of this by distributing polymers between two immiscible solvents according to the Craig counter current method.

FREQUENCY CURVES WITH RESPECT TO PARTTION COEFFICIENT

When a pure substance is distributed between two solvents in a Craig distribution apparatus according to the fundamental procedure [6], the amount of substance present in the pth tube is

$$w(p) = m_0 \cdot \binom{n}{p} \cdot \frac{k^p}{(k+1)^n} \quad (= 0,1,2, \ldots\ldots n) \tag{2}$$

where m_0 is the total amount of substance added to the apparatus and k is the partition coefficient for the substance between the phase to be transferred and the stationary phase, n being the number of transfers. Equal volumes of the two phases are presupposed. If the substance contains molecules of different partition coefficients and the weight frequency function with respect to partition coefficients is $f(k)$, the amount of those molecules which have a partition coefficient in the range between k and $k + \mathrm{d}k$ in the pth tube is

$$\delta w(p) = m_0 \cdot \binom{n}{p} \cdot \frac{k^p}{(k+1)^n} \cdot f(k) \cdot \mathrm{d}k$$

or

$$W_n(p) = \frac{m_0}{w(p)} = \int_0^\infty \binom{n}{p} \cdot \frac{k^p}{(k+1)^n} \cdot f(k) \cdot \mathrm{d}k \tag{3}$$

$W_n(p)$ is the weight fraction of the original substance present in the pth tube.*

The condition precedent for the validity of this formula is that no interaction of molecules of different size occurs and that the partition coefficient is independent of concentration. Of course it is a prerequisite that the presence of the polymer does not cause a change in the composition of the solvents, and that real equilibrium conditions are fulfilled.

As $W(p)$ is known from experiments the integral eqn. (3) can be solved with respect to $f(k)$ according to some approximation method. The author has adopted the following method for the solution of the equation.**

* When confusion is out of question the index n of $W_n(p)$ will be omitted.

** By access of an electronic computor somewhat different treatment of the problem is conceivable.

It is considered that the frequency function $f(k)$ can be expressed as a sum of several functions $\psi_i(k)$:

$$f(k) = \sum_i \psi_i\ (k)$$

The functions ψ_i are chosen so that 1) they are bell shaped and $= 0$ for $k = 0$ and ∞, 2) the integral

$$\int_0^\infty \binom{n}{p} \cdot \frac{k^p}{(k+1)^n} \cdot \psi_i\ (k) \cdot \mathrm{d}k$$

can be expressed by elementary functions. These conditions are fulfilled if, *e.g.*,

$$\psi_i\ (k) = A_i \cdot k^{r_i} \cdot (k+1)^n \cdot \exp(-a_i \cdot k^{s_i}) \tag{4}$$

where r_i, s_i, A_i and a_i are properly chosen numbers. For the sake of simplicity r_i, s_i and a_i ought to be integers and if possible s_i shall be put equal to 1. For the special case $s_i = 1$ one obtains

$$W(p) = \binom{n}{p} \cdot \sum_i A_i \cdot \frac{(p+r_i)!}{a_i^{p+r_i+1}} \tag{5}$$

By trial and error it is posssible to find values of A_i, a_i and r_i to have the calculated and the experimentally determined $W(p)$ values agree. This can be done in a systematic way.

The method will be explained by a fictive experiment. A polymer is assumed to be defined by the frequency function

$$f(k) = 5.784 \times 10^5 \cdot k^4\ (k+1)^{19} \cdot \exp\ (-27 \cdot k^{\frac{1}{2}}) \tag{6}$$

The corresponding curve is drawn in Fig. 1. If this preparation is distributed in a 20-tube countercurrent distribution apparatus ($n = 19$) one obtains in accordance with eqn. (3)

$$W(p) = 1.157 \times 10^6 \cdot \frac{(2p+9)!}{27^{2p+10}} \tag{7}$$

The $W(p)$ values calculated from this formula are listed in Table 1.

Starting from these values $f(k)$ shall be calculated considering that it can be expressed by a sum of functions of the type

$$A \cdot k(k+1)^{19} \cdot \exp(-ak)$$

From the table can be seen that $W(p)$ has its highest value for $p = 11$. A preparation with a frequency function of the type mentioned has its highest $W(p)$ value for $p = 11$ when $a = 9$. The difference

$$\Delta W(p)' = W(p) - A'_1 \cdot \binom{19}{p} \cdot \frac{(p+1)!}{9^{p+2}} \tag{8}$$

Table 1.

p	$W(p)$ (Eqn. 7)	$\Delta W(p)$ (Eqn. 8)	$\Delta W(p)$ (Eqn. 9)
0	0.0020	19×10^{-4}	-1×10^{-4}
1	0.0058	54	3
2	0.0113	100	5
3	0.0184	153	4
4	0.0274	205	0
5	0.0386	247	−3
6	0.0519	267	−4
7	0.0669	253	−1
8	0.0826	202	2
9	0.0972	124	3
10	0.1083	47	2
11	0.1130	0	0
12	0.1091	3	−1
13	0.0959	48	0
14	0.0751	100	0
15	0.0509	123	−2
16	0.0286	104	−4
17	0.0125	61	−4
18	0.0038	23	−1
19	0.0006	4	0
	$\Sigma = 0.9999$		$\Sigma = -2 \times 10^{-4}$

is calculated assuming such a value of A_1 that the difference = 0 for $p = 11$ (*i.e.* where $W(p)$ is maximum). As can be seen from the table this difference has its highest values for p = 6 and $p = 15$. The new difference

$$\Delta W(p)'' = W(p) - \binom{19}{p} \cdot (p+1)! \cdot \left[\frac{A_1''}{9^{p+2}} + \frac{A_2''}{16^{p+2}} + \frac{A_3''}{5^{p+2}} \right]$$

is calculated assuming such values of the A''-s that $\Delta W(p)'' = 0$ for $p = 6$, 11 and 15. (It shall be borne in mind that the two last terms within the parenthesis have their highest values for $p = 6$ and 15, resp.) When the difference

$$\Delta W(p)''' = W(p) - A_1'' \cdot \binom{19}{p} \cdot \frac{(p+1)!}{9^{p+2}}$$

is now calculated, it is found that its highest values occur when $p = 7$ and 14. This means that the choice of the two last functions was not appropriate. Thus a new attempt is made with functions which give their highest $W(p)$ values for $p = 7$, 11 and 14. This procedure is now repeated until agreement is attained at least in the tubes containing the chief part of the preparation. In this case it is found that this new approach gives good agreement exept for $p = 1$, 2 and 3, but by further subtraction with an expression of the type

$$A_4 \cdot \binom{19}{p} \cdot \frac{(p+1)!}{25^{p+2}}$$

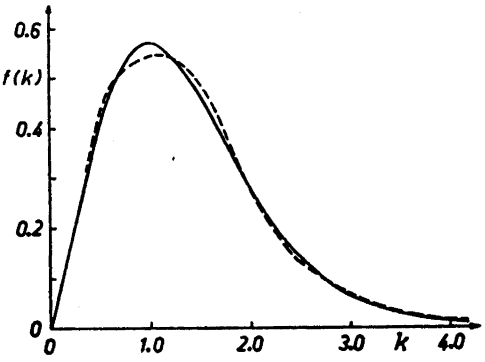

Fig. 1. Comparison between theoretical and calculated frequency curves.
———— Frequency curve according to eqn. 6.
— — — — — Frequency curve according to eqn. 10.

(this expression has its highest value for $p = 2$) good agreement is obtained. In column No. 4 of Table 1 the difference

$$\Delta W(p)'''' = W(p) - \binom{19}{p} \cdot (p+1)! \cdot \left[\frac{4.441 \times 10^{-6}}{6^{p+2}} + \frac{5.934 \times 10^{-3}}{9^{p+2}} + \frac{3.550 \times 10^{-1}}{14^{p+2}} + \frac{1.4 \times 10^{-2}}{25^{p+2}} \right] \quad (9)$$

is calculated. As can be seen, the differences can be regarded as small in comparison to experimental errors in a real experiment. If the amount of original substance had been 1 g, no error exceeds 0.5 mg. These calculations thus lead to the conclusion that the frequency curve can be expressed by

$$f_1(k) = k \cdot (k+1)^{19} \cdot [4.441 \times 10^{-6} \cdot \exp(-6k) + 5.934 + 10^{-3} \cdot \exp(-9k) + 3.550 \times 10^{-1} \cdot \exp(-14k) + 1.4 \times 10^{-2} \cdot \exp(-25k)] \quad (10)$$

The corresponding curve is drawn in Fig. 1. The agreement with the theoretical curve must be regarded as good.

In this connection it seems justified to mention that the moments of the frequency functions can easily be obtained from the data of experiments of this type. According to definition the νth moment about the origin is

$$\mu_\nu = \int_0^\infty k^\nu \cdot f(k) \cdot \mathrm{d}k = \int_0^\infty \frac{k^\nu \cdot (k+1)^n}{(k+1)^n} \cdot f(k) \cdot \mathrm{d}k = \sum_{p=0}^{n} \binom{n}{p} \cdot \int_0^\infty \frac{k^{p+\nu}}{(k+1)^n} \cdot f(k) \cdot \mathrm{d}k =$$

$$= \sum_{p=0}^{n} \frac{\binom{n}{p}}{\binom{n}{p+\nu}} \cdot W(p+\nu) = \mu_\nu' + \Delta\mu_\nu \quad (11)$$

where $$\mu_\nu' = \sum_{p=0}^{n-\nu} \frac{\binom{n}{p}}{\binom{n}{p+\nu}} \cdot W(p+\nu) \quad (12\,a)$$

$$\text{and} \quad \Delta\mu_\nu = \sum_{p=n-\nu+1}^{n} \frac{\binom{n}{p}}{\binom{n}{p+\nu}} \cdot W(p+\nu) \qquad (12\,b)$$

Although μ'_ν can be calculated from the experimental $W(p)$ values, $\Delta\mu_\nu$ cannot because all terms in this expression are of the indefinite form 0/0. Thus the calculation of the moments cannot be done completely and it can only be regarded as justified if $\Delta\mu_\nu$ is a small number in comparison to μ'_ν. In any case calculation of moments of high order cannot be done with any accuracy. In Table 2 the first three moments are calculated for the curve given in eqn. (6) and compared to those calculated from the $W(p)$ values given in Table 1. As can be seen from the table the accuracy diminishes as the order of the moment increases.

Table 2.

Order of moment	Theoretical moment	Moment calc. from eqn. 12 a
1	1.366	1.364
2	2.450	2.40_9
3	5.369	4.90_5

The fitting of the frequency curve by the method of moments as for instance developed by Pearsom (see, *e.g.*, Ref.[7]) can of course be done, but this method presupposes a frequency function of only one mode. If the frequency curve contains more than one peak this method will fail. With the first one given, however, more details can be detected.

As far as the author knows no mathematical analytical method exists to determine (calculate) the accuracy of the frequency curve. It is quite evident that a very sharp peak in the curve cannot be detected only by mathematical means. This can only be done by changing the experimental conditions so that the resolving power of the distribution apparatus is increased, *e.g.* by increasing the number of fractions or choosing another solvent system.

The result is no doubt dependent on the mathematical method chosen for the calculations. In the method adopted by the author it is considered that the frequency function can be represented by a sum of a limited number of functions of a special type. It is of course not certain that this approach is correct, but as long as it is not unreasonable it must be considered justified. The only possibility to check the results is to vary the experimental conditions and to test whether the same result is obtained when the resulting frequency curve in respect to distribution coefficient is converted into a molecular frequency curve. Negative $\Delta W(p)$ values should of course be avoided at early stages of the calculations.

RELATION BETWEEN MOLECULAR WEIGHT AND PARTITION COEFFICIENT

When the frequency function with respect to the partition coefficient in a certain solvent system is known, it remains to determine the relation between the partition coefficient and the molecular weight before the molecular frequency function can be determined. The fractionation method suggested in this paper is not selective and thus the procedure will depend upon the way and method of measuring molecular weights. As was pointed out by Almin and Steenberg [5] the average molecular weight $\overline{M(p)}$ in fraction No. p can be written

$$\overline{M(p)}^{\alpha} = \frac{1}{W(p)} \cdot \binom{n}{p} \cdot \int_0^{\infty} \frac{k^p}{(k+1)^n} \cdot f(k) \cdot M^{\alpha} \cdot \mathrm{d}k \tag{13}$$

where M is the molecular weight of molecules with the partition coefficient k, and α is a parameter fixed by the conditions of the method of molecular weight determination. This formula is valid in cases when number averages ($\alpha = -1$), weight averages ($\alpha = 1$) or viscosity averages ($0.5 < \alpha < 1$) of the molecular weight are measured.

Eqn. (13) can be solved with respect to $f(k) \cdot M^{\alpha}$ according to a method quite analogous to the one suggested for eqn. (3). By dividing the solution of eqn. (13) with the solution of eqn. (3) one obtains M^{α} as a function of k. By applying such a method serious errors can be expected because errors from the two approximate solutions are introduced. For this reason other methods to calculate M^{α} as a function of k ought to be tried. By introducing a model for the relation between M^{α} and k as below a solution is obtained which is independent of the solution of eqn. (3):

$$M^{\alpha} = B \cdot \ln\, k + \sum_i C_i \cdot k^i \tag{14}$$

where it is considered that i can only adopt small negative or positive values (including 0).

From eqns. (13) and (14) one obtains

$$S(p) \cdot \overline{M(p)}^{\alpha} = B \cdot \int_0^{\infty} \frac{k^p}{(k+1)^n} \cdot f(k) \cdot \ln k \cdot \mathrm{d}k + \sum_i C_i \int_0^{\infty} \frac{k^{p+i}}{(k+1)^n} \cdot f(k) \cdot \mathrm{d}k$$

$$= B \cdot \frac{\mathrm{d}S(p)}{\mathrm{d}p} + \sum_i C_i \cdot S(p+i) \tag{15}$$

where

$$S(p) = \frac{W_p}{\binom{n}{p}} \tag{16}$$

By dividing with $S(p)$ one obtains

$$\overline{M(p)}^{\alpha} = B \cdot \frac{\mathrm{d}\ln S(p)}{\mathrm{d}p} + \sum_i C_i \cdot \frac{S(p+\mathrm{i})}{S(p)} \tag{17}$$

As $\overline{M(p)}$ and $S(p)$ are known from the experiments and $\frac{\mathrm{d}\ln S(p)}{\mathrm{d}p}$ can be obtain-

ed graphically it is possible to calculate B and C_i for instance by the method of least squares. If a good correlation between observed and calculated values is not obtained when only a few terms of the sigma of eqn. (17) are made use of, this method is not to be recommended. Then another model must be tried or the first mentioned method must be used. The expression in eqn. (14) is, however, not chosen only because it gives a rather simple solution (eqn. 17), but also for theoretical reasons. According to the Brønsted formula (eqn. 1) ln k is proportional to the degree of polymerisation. The real relation between these quantities is certainly more complex and therefore the author has chosen a modified approach. The formula can be considered especially convenient in cases when $\alpha = 1$ or close to one, as for instance in viscometric measurements.

The range of validity of the relation obtained between the molecular weight and the partition coefficient is difficult to estimate from one experiment only. Especially at high and low molecular weights appreciable errors can be expected. By investigating several samples of different mean molecular weights of the same polymer at the same experimental conditions it would be possible to obtain a curve which covers an appreciable molecular weight range.

MOLECULAR FREQUENCY CURVES

The final problem is to convert the frequency functions of partition coefficient to molecular weight frequency functions. This can be achieved by applying the formula

$$g(M) = f(k) \cdot \frac{\mathrm{d}k}{\mathrm{d}M} \tag{18}$$

where $g(M)$ is the molecular weight frequency function. The derivative $\frac{\mathrm{d}k}{\mathrm{d}M}$ is obtained from the relation between partition coefficient and the molecular weight by graphical or other means.

DISCUSSION

The mathematical methods for treating the experimental data from counter current fractionations are based on the assumptions that the quantities involved can be represented by models. These models are chosen so that a rather simple numerical treatment is possible.

The basic assumptions which are made are discussed by Almin and Steenberg [5]. It is, however, very probable that the laws which are used to deduce eqns. (3) and (13) do not hold in practice. The relation between the molecular weight and the partition coefficient affords a special problem. The experimental conditions ought to be chosen so that this relation is a monotonous one. These problems will be discussed in the experimental parts of this series.

Some $\Delta\varepsilon$-Curves for Dissociations of Tropolones and Salts of Organic Bases

GUNHILD AULIN-ERDTMAN and LAILA HEGBOM

Cellulosaindustriens Centrallaboratorium and Organisk-Kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

In order to explore the applicability of the $\Delta\varepsilon$-method to ionisable compounds other than phenols, the $\Delta\varepsilon$-curves have been determined for a series of simple tropolones, arylamines and heterocyclic bases. It is shown that the $\Delta\varepsilon$-method should be useful for the characterisation and estimation of these types of compounds.

The analytical value of the changes in light absorption which take place when chromophores undergo certain reactions, such as substitutions, hydrogenation, ionisation and complex formation, has been pointed out earlier[1]. The changes on ionisation have been used in the so-called "$\Delta\varepsilon$-method" worked out in these laboratories primarily for the study of the nature and frequency of the phenolic groups in lignin. With phenols this reaction causes a characteristic, not too small absorption change in the easily accessible ultra-violet region. To our knowledge, ionisation $\Delta\varepsilon$-studies have so far been carried out mainly with phenolic materials (lignin, tanning agents *etc.*), and a reasonable number of model $\Delta\varepsilon$-curves relating to the ionisation of phenols is now available in the literature (*cf.* Refs.[2,3] and references given therein). However, some further types of ionisation have also been studied. The work by Goldschmid referred to in Ref.[3] includes $\Delta\varepsilon$-studies of the addition of a proton to CO-groups[4]. Investigations of a similar type have also been reported for some heterocyclic bases[5].

An examination of other types of ionisable compounds was of interest as part of an investigation into the applicability of the $\Delta\varepsilon$-method to other classes of natural and technical products. The present study includes some tropolones and a series of simple aromatic and heterocyclic bases.

MATERIALS, SOLVENTS AND MEASUREMENTS

The compounds investigated are listed in Table 1 together with brief data on their purification and properties.

Table 1.

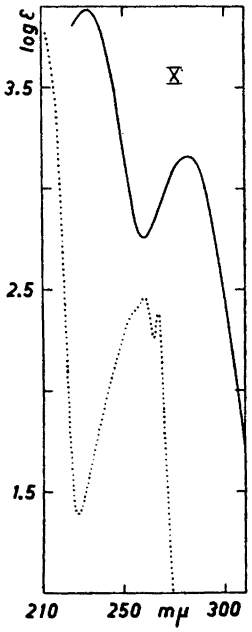

Fig. 2. Absorption curves for *m*-toluidine in 0.1 N H_2SO_4 (·····) and in pH 10 carbonate buffer solution (————).

The ultra-violet absorption curves were determined for solutions of these substances in the acidic and alkaline solvents listed in the same table. The solvents were chosen so as to give a complete set of curves for the tropolones and the tropolonate ions in ethanol and for the bases and their ions in water.

A Beckman Model DU spectrophotometer with 1 cm calibrated silica cells was used for the measurements. The concentrations of the solutes were varied so as to keep $\log(I_0/I)$ within the limits of 0.1 and 1.5. In critical regions readings were made at 1—2 mμ intervals, otherwise at every 5 mμ.

The difference curves were calculated by subtracting the ε-values for the acidic solutions from the corresponding ε-values for the alkaline solutions.

RESULTS AND DISCUSSION

The absorption maxima found are listed in Table 1. The ultra-violet absorption curves for these compounds have already been studied in various solvents and reported in the literature. It is true that earlier data in many cases show great discrepancies, but for all compounds it was possible to find curves or figures in the literature (references in Table 1) which agree well with the results reported here.

The absorption curves are not reproduced except for the toluidines (Figs. 1—3) for which the literature does not give complete information.

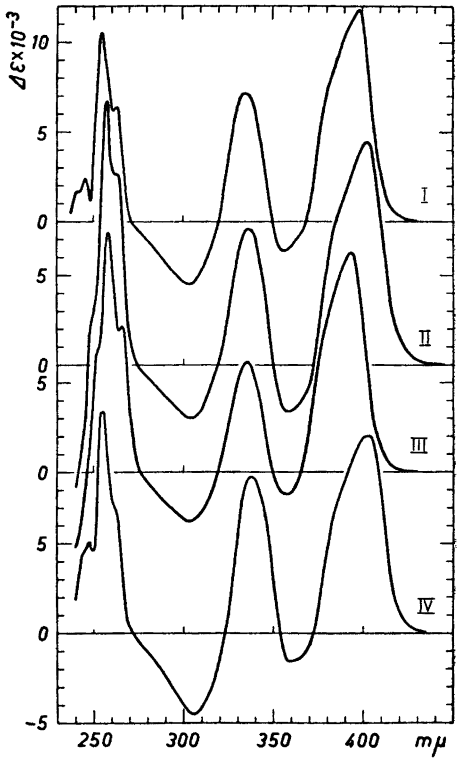

Fig. 4. $\Delta\varepsilon$-curves for ionisation of tropolone (I), *α*-thujaplicine (II), *β*-thujaplicine (III) and *γ*-thujaplicine (IV) in ethanol.

The ionisation difference curves for tropolone and its C-*iso*propyl derivatives are given in Fig. 4. Because of their similar electronic structures these compounds give closely related $\Delta\varepsilon$-curves. The curves are quite characteristic and distinct from those of any phenols so far investigated. This type of $\Delta\varepsilon$-curve is, of course, by no means characteristic of all tropolones. Changes such as the introduction of additional hydroxyl groups in the ring or ring-conjugated double bonds give rise to marked changes in the electronic structure and, hence, in the $\Delta\varepsilon$-curve.

Fig. 5 gives the $\Delta\varepsilon$-curves for the conversion of the pyridinium, quinolinium and *iso*quinolinium ions into the corresponding bases. Like most carboxylic acids these heterocyclic ammonium ions show a hypsochromic shift, hence a long-wave $\Delta\varepsilon$-minimum on loss of a proton (*cf.* Ref.[3]).

Due to the spectrochemically similar electronic structures of the arylamines and the phenolate ions and of the arylammonium ions and the phenols, the conversion of anilinium ion and the toluidinium ions into the bases gives $\Delta\varepsilon$-curves (Fig. 6) which are similar to the ionisation $\Delta\varepsilon$-curves for the corre-

sponding phenols [3]. The similarity in $\Delta\varepsilon$-curves between the naphthylammonium ions (Fig. 7) and the corresponding naphthols [3] is, however, less pronounced.

The maxima and minima of the difference curves just discussed are given in Tables 2 and 3. The accuracies of these $\Delta\varepsilon$-values were estimated approximately, assuming [2] $e_\varepsilon/\varepsilon = 0.02$. The $\Delta\varepsilon$-values were rounded off accordingly, so that errors will generally occur only in the last figure.

It follows from the results presented that all the simple tropolones and bases investigated give characteristic $\Delta\varepsilon$-curves. There is considerable similarity within groups of closely related compounds. The differences between different types of compounds are also marked. All of the substances, except perhaps pyridine, give reasonably high, sometimes very high, $\Delta\varepsilon$-values above 230 mμ. It should, therefore, be possible to characterise and estimate the above compounds by means of the $\Delta\varepsilon$-method.

	334–5	1 680						

The $\Delta\varepsilon$-method is particularly useful for the analysis of difficultly separable mixtures and for the structural elucidation of complex molecules containing two or more separate chromophores. It might for example be used to locate hydroxyl groups in the heterocyclic or in the phenyl moiety in alkaloids of the benzyl-*iso*quinoline and angostura types. There are also obvious applications in the fields of purines, pterines, nucleic acids[5] and proteins. In addition to the $\Delta\varepsilon$-curve the pH region at which the absorption change occurs is also indicative of the ionisable chromophore. One of the chief advantages of the method is that only small amounts of material are needed.

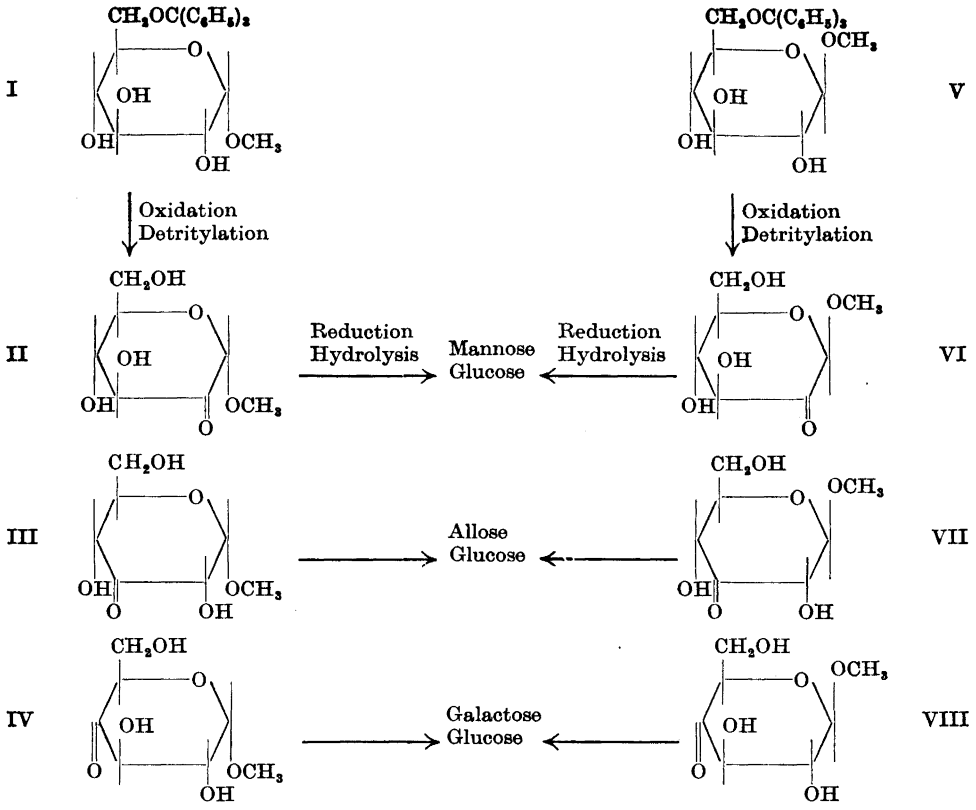
The Oxidation of Glycosides

V. Oxidation of Methyl 6-*O*-Trityl-α-D-glucopyranoside and Methyl 6-*O*-Trityl-β-D-glucopyranoside with Chromium Trioxide *

OLOF THEANDER



Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm and Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

Methyl 6-*O*-trityl-α-D-glucopyranoside and methyl 6-*O*-trityl-β-D-glucopyranoside have been oxidised with chromium trioxide in acetone. After detritylation of the resulting mixture, the 2-oxo-, 3-oxo and 4-oxo-methylglucosides in both the α- and the β-series were isolated. The position of the oxo-groups were shown by characterising the sugars formed after hydrolysis of the reduced oxoglucosides.

In part IV [1] the isolation of methyl β-D-3-oxoglucopyranoside and methyl β-D-6-oxoglucopyranoside from the reaction mixture after oxidation of methyl β-D-glucopyranoside with dichromate in the presence of oxalic acid was described. These two oxocompounds were isolated only in low yield with the aldehyde predominating. In order to improve the yields of the 3-oxo-glucoside and the other potential oxidation products, the primary hydroxyl at $C_{(6)}$ was now protected by tritylation prior to oxidation (V). The oxidation of methyl 6-*O*-trityl-α-D-glucopyranoside (I) was also investigated.

Chromium trioxide-pyridine [2] was tried as oxidant, but chromium trioxide in acetone was found to give better yields of oxoglucosides. After oxidation (see Experimental) the brown precipitate of chromium oxides was filtered off and the trityl groups were removed by mild hydrolysis. The chromium in the solution was reduced by ethanol at the same time. The water soluble, neutral part of the oxidation mixture, obtained after separation of triphenylcarbinol and other water insoluble products followed by deionizing, was investigated by paper chromatography and was found to contain at least a dozen different components. The mixture was separated by chromatography on a carbon column and by chromatography and electrophoresis on thick filter paper. The yields are given in Table 1 of the methyl β-3-oxoglucoside (VII) and the

* Part. IV. *Acta Chem. Scand.* 8 (1954) 1870.

unoxidised methyl β-glucoside, obtained after carbon column chromatography of the reaction product from the oxidation of V with varying amounts of chromium trioxide.

The yield of VII has a flat maximum of about 4.5 % at 1—2 moles oxidant per mole of sugar; at the same time there is still much unchanged methyl glucoside left. The amount of oxoglucosides is obviously limited by further oxidation of these compounds and perhaps also by side reactions, *e.g.* oxidation of glucose at $C_{(1)}$. In addition to VII which was crystalline and identical to the substance m.p. 129.5-131°, $[\alpha]_D$-62° in water, previously isolated, there were also isolated two other ketoglucosides in the β-series (VI and VIII), and the corresponding compounds in the α-series (II, III and IV). VI was crystalline, m.p. 120-121°, and $[\alpha]_D$-47° in water. VIII and the last three were amorphous, but chromatographically and electrophoretically pure. The specific rotation of III was $[\alpha]_D$ +84° in water. The structure of the oxoglucosides was proved by characterising the sugars obtained after reduction with Raney nickel[3] and hydrolysis of the glucoside formed (compare the scheme above). Each sugar gave glucose and one of the sugars mannose, allose or galactose. Constants and details of the separation are given in Table 2.

Table 1. Oxidation of methyl 6-*O*-trityl-β-D-glucopyranoside with chromium trioxide in acetone (The yields are given as a percentage of amount of starting material calculated as methyl β-glucoside

Moles chromium trioxide per mole of trityl sugar	Water soluble, neutral products	Methyl glucoside	Methyl 3-oxo-glucoside
1.0	64	46	4.0
1.5	53	31	4.4
1.5	57	33	4.9
4.0	18	9	3.2

The amounts of 3-oxoglucosides formed were much higher than those of the 2- and 4-oxoglucosides. This is obvious also from the direct paper chromatogram of the hydrolysed oxidation mixture, before the separation procedure. On the other hand it was found in preliminary experiments that the 2-oxo and 4-oxoglucosides are more labile than the corresponding 3-oxo-compound at a pH near the neutral point and give epimerisation and decomposition products. As they emerge from the carbon column together with unchanged methyl glucoside their separation is more complicated than that of 3-oxoglucoside, which is obtained directly from the carbon column almost pure, crystallises readily (in the β-series) and is less labile.

The differences in the R_F values and the relative rates of the electrophoretic migration in hydrogen sulphite buffer between the various oxoglucosides is remarkable and much more marked than for, *e.g.*, hexoses. All oxoglucosides gave strong reducing reactions with the silver nitrate-sodium ethoxide reagent and a particularly sensitive and characteristic colour reaction was given by the resorcinol-hydrochloric acid reagent. In addition to unchanged methyl glucoside and mono-ketoglucosides there were many other compounds present in small amounts, amongst which were: (in the order of emergence from the carbon column) salts, traces of arabinose, glucose (about 0.1 %), methyl 6-oxoglucoside (isolated in the β-series only), a group of substances probably condensation products, with low R_F values and finally products with high R_F values, which might be dioxo compounds, emerging from the column at about 10 % ethanol. One or more of the latter group gave a strong red-violet colour reaction with the resorcinol-hydrochloric acid reagent and one gave a strong yellow colour with anisidine hydrogen chloride. A small amount (0.3 %) of the last mentioned compound was isolated both in the α-series and β-series and after reduction and subsequent hydrolysis gave spots corresponding to glucose, galactose and also arabinose in smaller amount on paper chromatograms. They gave positive Schiff reactions, consumed hypoiodite [5] (corresponding to a purity of about 70 %), and the electrophoretic migration in hydrogen sulphite had the magnitude expected for a dioxo compound. On the paper chromatograms they gave one dominating spot with a high R_F value and a minor one with low R_F value with trailing between, probably explained by a slow equilibrium between different forms (behaving similarly to methyl-β-6-

Table 2. Oxo-glucosides; preparation and characteristics.
Oxidant per mole = 1.5. The yields are calculated as percentage of the amount of glucoside before oxidation. Data of the carbon column chromatography and the solvents and buffers used by the paper chromatography and electrophoresis are given in Experimental. f. = fluorescence; a. = absorption.

Resorcinol-hydrochloric acid	brick red (red-brown a.)	orange (orange f.)	brick red (red-brown a.)	

oxoglucoside [1]). These facts might indicate the presence of methyl-4.6-dioxoglucosides in the α- and β-series, respectively.

Only 0.5 % of the material was soluble in water directly after the oxidation and this gave approximately the same chromatographic picture as the main mixture obtained after hydrolysis, (*i.e.* methyl glucoside and methyl 3-oxoglucoside predominated) showing that the protecting trityl group is hydrolysed to a very small extent during the oxidation. In spite of that the 6-oxoglucoside and a possible dioxo compound containing an aldehyde-group were formed (about 0.7 % isolated altogether), which might indicate tritylation on secondary hydroxyls to some extent leaving the primary hydroxyl group free.

An interesting observation was made on the rate of detritylation in a case where the strength of the acid for the hydrolysis following the oxidation of V was unintentionally lower than usual. Methyl β-glucoside and VII were isolated by carbon column chromatography from this "weak" hydrolysate and from the hydrolysate obtained after further hydrolysis of the water insoluble material with the usual strength of acid. The total amount of methyl

Table 2. (continued)

	Methyl β-D-oxoglucopyranosides				Methyl β-D-glucopyranoside
	2-oxo	3-oxo	4-oxo	6-oxo	
Yield (%)	0.5	4.7	0.4	0.4	32
Percentage of ethanol in the eluant, when the substance emerged from the carbon column	3.0	6.6	4.6	5.3	3.4

Colour reactions on paper chromatograms (the data in brackets refer to the colour in UV-light):					
Anisidine hydrogen chloride	yellow (brownish yellow a.)	yellow (brownish) yellow a.)	yellow (brownish yellow a.)	reddish brown (grey yellow a.)	
Resorcinol-hydrochloric acid	brick red (red brown a.)	orange (orange f.)	brick red (red. brown a.)	weak pink (reddish a.)	

β-glucoside was distributed 65 to 35 % between the "weak" and "normal" hydrolysates, respectively, but the corresponding values for the oxoglucoside were 10 to 90 %, indicating that removal of the trityl group from the latter is more difficult.

EXPERIMENTAL

Melting points corrected. All evaporations were made under reduced pressure and at a bath temperature under 40°, unless freeze-drying was used. Whatman 1 filter papers were used for paper chromatography and electrophoresis except for the preparative separations, which were made on Whatman 3 MM filter papers, previously washed thoroughly with water.

Solvents and buffers used:

A. Ethyl acetate-acetic acid-water, 3 : 1 : 3 (the upper phase).
B. Butanol-ethanol-water, 10 : 3 : 5.
C. Butanol-pyridine-water, 3 : 1 : 1.5.
D. Hydrogen sulphite buffer [4] pH 4.7, 0.1 M. (The electrophoresis was run at 50° if not otherwise stated.)
E. Borate buffer [6] pH 10.0, 0.1 M.

Oxidation of methyl 6-*O*-trityl-β-D-glucopyranoside and fractionation of the product

Methyl 6-*O*-trityl-β-D-glucopyranoside (V)[7], dried in a vacuum over P_2O_5 at 70° (65.0 g) was dissolved in acetone (800 ml), which had been purified by refluxing in the presence of potassium permanganate, drying over potassium carbonate and distilling. A solution of chromium trioxide (22.5 g), corresponding to 1.5 moles of oxidant per mole of sugar, in purified acetone (800 ml), at about 5°, was poured in a slow stream with agitation into the sugar solution which was kept in an ice water bath. This procedure took about 20 min and the temperature was kept below 15°. As has been previously observed[8], it is important to add the chromium trioxide to the solvent in small portions with agitation; it then dissolves readily to give a reddish brown solution. If the two chemicals are mixed in the reverse order, *i.e.* acetone to chromium trioxide it usually inflames!

The oxidation was carried out by refluxing the mixture for 30 min (leaving the mixture at room temperature for a day gave almost the same result). During the oxidation a dark brown precipitate formed. The solution was cooled and filtered and the precipitate was washed with acetone, refluxed with fresh acetone (400 ml) for 10 min and again filtered and washed. This procedure was repeated three times. After the last treatment the amount of extractable material was negligible. The brown chromium oxides, probably hydrated, were heated to about 300—400°, giving green Cr_2O_3 (77 % of the theoretical amount). The combined filtrates and washings were evaporated to a dark brown clear solution (adjusted to 540 ml with acetone), which was mixed with 6 N ethanolic hydrogen chloride (60 ml). The acid treatment was performed at 25° for 30 min. The colour turned to green and there was a typical odour of acetaldehyde, indicating a reduction of chromium in the solution. Silver carbonate was added with agitation and cooling (the temperature kept below +10°) until a drop of the solution showed pH 5 when put on a moist pH paper. The silver precipitate was filtered off and washed first with acetone and then with water. The aqueous acetone solution was evaporated to a small volume and the crops of triphenyl carbinol separating during this process were removed (82 % of the theoretical amount, m.p. 159—161°). The concentrated aqueous solution was extracted with chloroform several times and then passed through columns of the ion exchange resins Amberlite IR-120 (H^+) and IR-4B (free base). The solution, which had a pH about 4.5 was evaporated to a thick, light green-yellow syrup (15.9 g). To make sure that the detritylation was complete, the concentrated chloroform extract (3.3 g), was given a further treatment with hydrogen chloride as described above using hydrogen chloride at twice the concentration but yielded negligible amounts of water soluble material (0.1 g), which gave the same paper chromatographic picture as the main water extract. The possibility of detritylation during the oxidation procedure was checked by taking an aliquot of the acetone solution directly after oxidation, shaking it with water and chloroform several times and evaporating the water phase, which had a pH of about 5. The water soluble material (0.15 g) gave approximately the same paper chromatographic picture as the main water extract.

The water soluble, deionised material (15.9 g) was fractionated on a charcoal-Celite column (48 × 6 cm) using linear gradient elution (16 l 0—20 % aqueous ethanol) in the usual way. The substances present emerged in the following order: salts, arabinose (traces only), glucose, unknown substances (small amounts), methyl-β-glucoside together with 2-, 4- and 6-oxoglucoside, 3-oxoglucoside and unknown substances, probably condensation or decomposition products of oxocompounds, and also dioxo compounds. Methyl β-glucoside crystallised directly on evaporation of the fractions containing this substance (m.p. 110—111° after recrystallisation from ethanol). Further amounts of methyl β-glucoside and the 2-, 4- and 6-oxoglucosides were isolated from the mother liquors by repeated separations on Whatman 3 MM papers run in solvent A. The final separation of the 4-oxoglucoside was carried out by electrophoresis in buffer D at room temperature and subsequent ion exchange of eluants from the paper strips. The 3-oxoglucoside was obtained quite pure from the column, in a fraction with only small amounts of methyl β-glucoside and other substances. It crystallised directly on evaporation, and was recrystallised from *n*-propanol. The yield was increased by working up the mother liquors and higher fractions from the column by separations on thick papers. The amounts isolated and the characteristics of the oxoglucosides and methyl β-glucoside are given in Table 2.

The figures are averages of two similar batches. Glucose (0.03 g) and the 6-oxoglucoside (0.12 g) were isolated only in one case. By fractionation on thick papers a compound which might be a dioxoglucoside was isolated (0.09 g) from the late fractions from the carbon column.

As the oxo compounds were quite labile, particularly the 2- and 4-oxoglucosides, which were epimerised to 3-oxoglucoside and further transformed to other products even at pH 4—7, the eluants from the final thick paper separations were evaporated by freeze-drying in silicone treated flasks.

Oxidations were also carried out with 1.0 and 4.0 moles of oxidant, respectively, per mole of sugar and the product formed worked up as described above. but only methyl β-glucoside and the 3-oxoglucoside were isolated (Table 1).

In one case, with 1.5 moles oxidant per mole of sugar, the strength of the acid used for the hydrolysis was unintentionally lower than usual. The water soluble material obtained from this "weak" hydrolysis and from a further hydrolysis of the chloroform extract using the normal conditions were both worked up separately on a carbon column in the usual way. The total amount of methyl β-glucoside was distributed as 64 and35% in the "weak" and "normal" hydrolysate, respectively, and the corresponding figures for methyl β-3-oxoglucoside were 10 and 90 %.

Characterisation of methyl β-oxoglucosides

Methyl-β-D-3-oxoglucopyranoside (VII) was identical with that previously isolated [1], but the physical data, m.p. 129.5—131°, $[\alpha]_D^{22}$ −62° (c = 2, water), recorded now are more accurate since more substance was available. After reduction of VII (1.00 g) with Raney nickel [3], hydrolysis with 0.5 N sulphuric acid for 16 h at 100° and neutralisation with the ion exchange resin Amberlite IR-4B, the sugars formed were separated on thick papers using solvent A (2 × 16 hours). After elution, evaporation and recrystallisation from ethanol, D-allose (0.32 g, m.p. and mixed m.p. 127°) was isolated.

A small amount of *methyl β-D-2-oxoglucopyranoside* (VI) was obtained in crystalline form from ethanol but the values given here, m.p. 120—121° and $[\alpha]_D^{22}$ −47° (c = 2, water) (Found: C 44.1; 6.43; OCH_3 16.9. Calc. for $C_7H_{12}O_6$ (192.2): C 43.7; H 6.26; OCH_3 16.1) were obtained when more substance became available from a procedure which will be described in a later publication.

Small amounts (about 40 mg) of VI and *methyl β-D-4-oxoglucopyranoside* (VIII), respectively, were reduced, hydrolysed and deionised as above and the sugars formed fractionated on thick filter paper in solvent C for two days. It was shown by paper chromatography and electrophoresis in solvents A—C and buffers D and E, that the only sugars formed were glucose and mannose (from VI) and glucose and galactose (from VIII). Glucose was characterised as the phenylosazone, m.p. 206—208° from VI and VIII, undepressed on admixture with authentic material, mannose as the phenylhydrazone, m.p. and mixed 195—196°, and galactose as the methylphenylhydrazone, m.p. and mixed m.p. 188—189°, in the usual way.

The Methyl β-D-6-oxoglucopyranoside was shown to be identical with that previously isolated [1] by paper chromatography and electrophoresis; it gave a positive reaction with Schiff's reagent and gave only glucose on reduction and subsequent hydrolysis as above.

The possible *methyl β-D-4,6-dioxoglucopyranoside* had the $R_{Glucose}$ values 2.92, 0.65 (B) and M_V value 2.25 (D, at 50°), gave a strong lemon yellow reaction with anisidine hydrogen chloride, a positive Schiff's reaction and consumed hypoiodite [5] (corresponding to a purity of 70 %). After reduction and subsequent hydrolysis, glucose, galactose and smaller amounts of arabinose were shown by paper chromatography.

Oxidation of methyl 6-*O*-trityl-α-D-glucopyranoside

Methyl 6-*O*-trityl-α-D-glucopyranoside (I) [7] was oxidised and the product worked up using the same amounts and conditions as described above for the corresponding β-compound. Data for the isolation and characteristics of the mono-oxoglucosides isolated are given in Table 2. The methyl α-glucoside recovered had m.p. 165—165.5° after recrystallisation from ethanol. A possible 4,6-dioxoglucoside corresponding to that in the β-series was also isolated (0.07 g).

Characterisation of methyl α-oxoglucosides

The same technique of reduction, hydrolysis, neutralisation and preparative isolation and characterisation of the sugars formed was used as in the β-series.

Methyl α-D-*2-oxoglucopyranoside* (II) gave glucose phenylosazone, m.p. and mixed m.p. 207—208°, and mannose phenylhydrazone, m.p. and mixed m.p. 196—198°.

Methyl α-D-*3-oxoglucopyranoside* (III) gave very little glucose, sufficient only for characterisation by paper chromatography and electrophoresis. The predominant D-allose was isolated, m.p. and mixed m.p. 126—127°. Amorphous III showed $[\alpha]_D^{22}$ +84° (c = 2, water).

Methyl α-D-*4-oxoglucopyranoside* (IV) gave glucose phenylosazone, m.p. and mixed m.p. 206—208°, and galactose methylphenylhydrazone, m.p. and mixed m.p. 186—187°.

The possible *methyl* α-D-*4,6-dioxoglucopyranoside* had the $R_{Glucose}$ values 2.64, 0.62 (B) and M_V values 2.06 (D, at 50°), gave a strong lemon yellow reaction with anisidine hydrogen chloride, a positive Schiff's reaction, consumed hypoiodite [5] (corresponding to a purity of 69%) and gave glucose, galactose and small amounts of arabinose on reduction and subsequent hydrolysis.

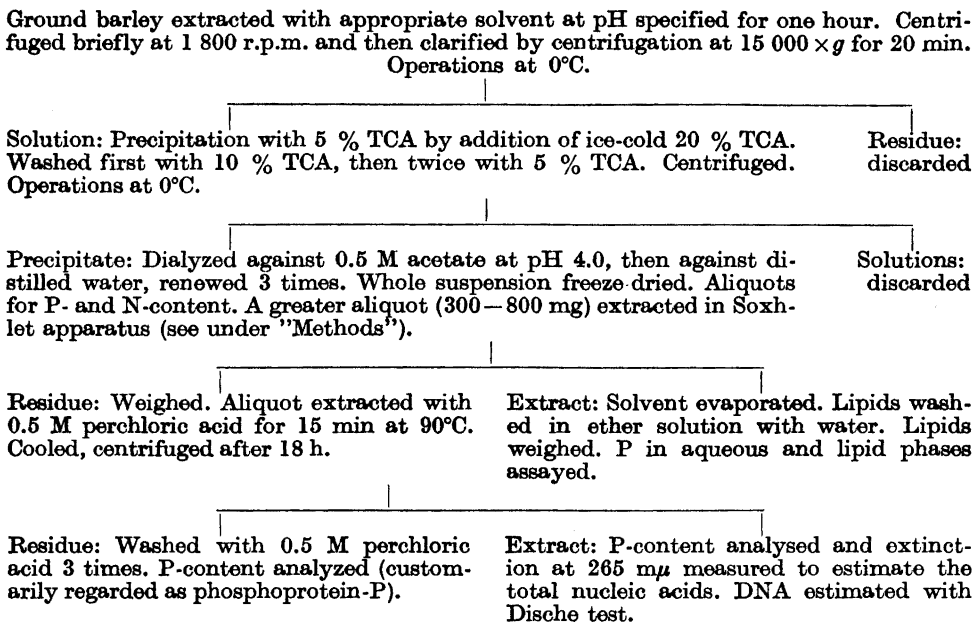
On the Presence of Nucleoproteins and Lipoproteins in the Salt-soluble Protein Fraction of Barley

TEUVO ÄYRÄPÄÄ

Forskningslaboratoriet LKB, Åppelviken, Sweden

Considerable amounts of nucleic acids and protein-bound lipids are found in extracts obtained from ground barley grain with 1 M sodium chloride. About 5 % of the nitrogenous material precipitated from such extracts with cold trichloroacetic acid (TCA) consists of nucleic acids (both RNA and DNA), representing about a third of the total nucleic acids of barley. The lipids bound to salt-soluble proteins, represent only 2.5—5 % of the total barley lipids. Distilled water dissolves no nucleoprotein below pH 7 and only moderate amounts (only RNA) above this value. The solubility of the lipoproteins is also lower when extracted with distilled water. Calcium ion at a concentration of 0.01 moles/l completely inhibits the extraction of TCA-stable phosphorus-containing protein complexes at low ionic strengths.



The methods used for nucleic acid and lipid assays, and for the determination of phosphorus distribution, and the origin and character of the nucleoproteins and lipoproteins are discussed.

Our knowledge of the nucleoproteins and lipoproteins of barley is very limited. Pool and Shooter [1] showed that small amounts of nucleic acid were present in a protein fraction. Similar observations have been made by Äyräpää [2], who also found lipids in the same fraction. A phosphorus-containing protein fraction supposed to be nucleoprotein has been found in brewery wort by Hopkins, Amphlett and Berridge [3]. The presence in brewery products of purine and pyrimidine derivatives, supposed to be degradation products of nucleic acids, has been demonstrated by several workers [4–6].

The corresponding protein complexes of wheat, which could be supposed to have their analogues in barley, are somewhat better worked out, but the investigations are almost exclusively limited to the nucleic acid complexes of wheat germ [7,8] (first recognized by Osborne [9]) and gluten-lipid complexes (*cf. e. g.* Olcott and Mecham [10]). A peculiar wheat lipoprotein has been isolated and described by Balls, Hale and Harris [11].

This paper gives no complete picture of the nucleoproteins and lipoproteins of barley grain. The aim of this investigation is to elucidate the extent to which such complexes occur in the much investigated so-called salt-soluble

Fig. 1. Outlines of the analytical procedure.

protein fraction of barley. Hence the extraction has been limited to the "natural" pH range (pH 5—8) mostly used in such investigations.

Trichloroacetic acid (TCA) at 0—+2°C has been chosen as the protein-precipitating agent, because cold TCA separates loosely bound phosphates [12–14], especially inositol phosphates [15], from the more stable posphorus-containing complexes (nucleoproteins, lipoproteins and phosphoproteins). It was also used to wash the tissues before lipid extraction [16]. TCA is generally regarded as the most selective protein-precipitating agent [17].

The TCA-precipitates from different extracts were freeze-dried and then subjected to an analytical procedure which may be regarded as a combination and modification of the methods of Schneider [12] and of Ogur and Rosen [18]. The outlines of the procedure are given in Fig. 1; the details are described under "Materials and Methods".

RESULTS

I. *Orientation experiments; comparison between barley and malt.* The amounts of phosphorus and nitrogen precipitated with 5 % TCA from different barley and malt extracts are shown in Figs. 2 and 3. (The experimental procedure was similar to the first two steps described in Fig. 1, with the exception that the extraction was performed at +25°C for 2 h.) The solubility properties of the phosphorus-containing protein complexes in barley and malt

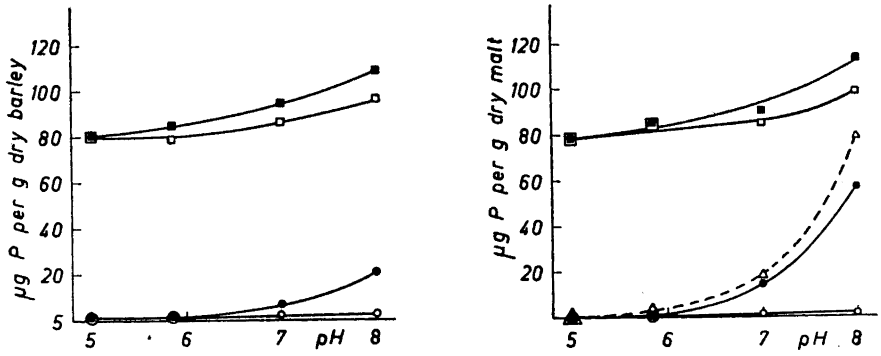


Fig. 2. The amounts of TCA-precipitated phosphorus in barley and malt extracts. Ordinate: μg precipitated P corresponding to 1 gram of dry barley or malt. Asbcissa: pH at extraction. Extraction solutions: -●—●- distilled water, -○—○- 0.01 M $CaCl_2$, -■—■- 1 M NaCl, -□—□- 1 M NaCl+0.01 M $CaCl_2$ and -△--△- 0.01 M EDTA.

are evidently very similar. Distilled water, however, in the alkaline range dissolves more protein-bound phosphorus, probably nucleic acid, from malt.

The nitrogen curves presented in Fig. 3, indicating the amounts of TCA-precipitable nitrogen extracted, suggest that a relatively phosphorus-rich fraction would be extracted with 1 M sodium chloride at pH 8 if the bulk of protein were first removed at pH 7 with distilled water. The activity of nucleases necessitates a rapid extraction and centrifugation procedure. A nucleic-acid rich protein fraction has been prepared in this way, but has not yet been further investigated.

The other conclusions drawn from these figures will be presented together with the results of phosphorus distribution analyses.

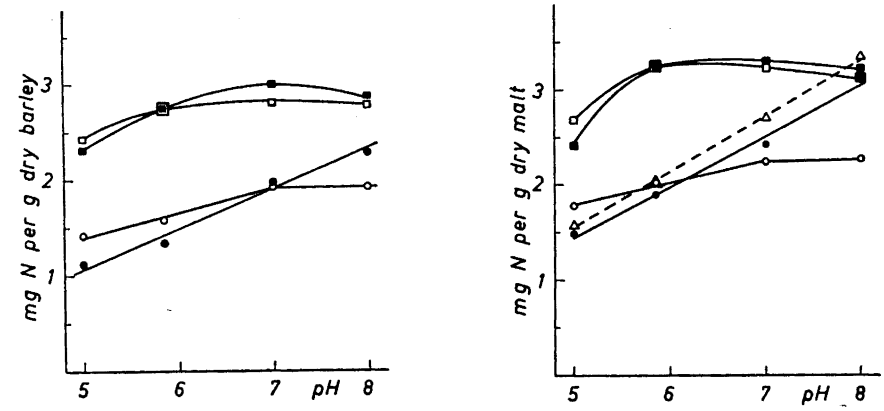

Fig. 3. The amounts of TCA-precipitated nitrogen in barley and malt extracts. Ordinate: mg precipitated N corresponding to 1 gram of dry barley or malt. Otherwise as in Fig. 2.

Table 1. The amounts of TCA-precipitates obtained from barley extracts and their nitrogen and phosphorus content.

Solvent and pH at extraction	Yield mg dry matter per g dry barley	% N in dry matter	% P in dry matter
Distilled water, pH 5.85	8.04	14.4	0.025
» » pH 7.0	9.48	14.5	0.040
» » pH 8.0	13.1	14.0	0.175
1 M NaCl, pH 5.85	22.1	13.7	0.440
» » pH 7.0	21.0	14.4	0.445
» » pH 8.0	20.4	14.3	0.545

II. *The distribution of phosphorus.* The amounts of freeze-dried TCA-precipitates obtained from barley extracts and their nitrogen and phosphorus contents are shown in Table 1. The distribution of phosphorus in these precipitates is shown in Table 2. The results presented in Table 2 and in Figs. 2 and 3 may be condensed to the following conclusions:

1) The nucleic acids are extracted by 1 M sodium chloride in considerable amounts at all the pH values investigated. The amounts extracted at pH 8 are only slightly higher than those obtained at pH 5.85. Distilled water dissolves moderate amounts of nucleic acids at pH values above 7 but not at lower values.

2) The lipoprotein phosphorus is found in considerable amounts only in sodium chloride extracts at pH 8, but small amounts are present in all the extracts, somewhat more in sodium chloride extracts than in distilled water extracts.

3) The other phosphorus-containing fractions are small. The phosphorus left in the residue after extraction with perchloric acid, customarily designated as phosphoprotein phosphorus, and another unknown phosphorus fraction, extracted with neutral alcohol-ether mixture but found in the aqueous phase after the washing of the lipids, are both present in greater amounts in sodium

Table 2. The distribution of phosphorus in TCA-precipitates from barley extracts.

Solvent at extraction	Lipid-P µg/g barley	Nucleic acid-P µg/g barley	Unknown P		Control	
			P in rest substance "Phosphoprotein-P"	P extracted with alcohol-ether but water-soluble	P by direct assay	P by addition
Dist. water pH 5.85	0.7	0.6	0.3	0.2	2.0	1.8
» » pH 7.0	1.1	1.9	0.3	0.8	3.8	4.1
» » pH 8.0	2.6	16.1	0.5	1.0	22.9	20.2
1 M NaCl pH 5.85	3.7	86.4	2.8	2.9	97.0	95.8
» pH 7.0	3.3	83.6	1.5	2.2	93.0	90.6
» pH 8.0	19.3	97.0	1.8	2.4	111.5	120.5

chloride extracts. Their amounts are not much influenced by the pH value at extraction.

4) The influence of calcium ion is marked in distilled water extracts: at a concentration of 0.01 M it inhibits the extraction of practically all the protein-bound phosphorus. In 1 M sodium chloride extracts, the presence of similar amounts of calcium has only a slight inhibiting effect above pH 7 (as seen in Figs. 1 and 2).

III. *Nucleic acids.* The amounts of nucleic acids calculated on the basis of phosphorus analyses compared with the amounts calculated from the ultraviolet absorption data are shown in Table 3. The agreement (except when only traces of phosphorus are present) is generally good. Only in the sodium chloride extract obtained at pH 5.85 is there appreciably more phosphorus. This excess of phosphorus seemed to be acid-stable (it was not hydrolysed to inorganic phosphate by 1 M hydrochloric acid at 100°C in 10 min). Since, in the course of attempts to prepare nucleic acid from whole barley, phytic acid was found in some combination with nucleic acid, the presence of phytic acid was especially tested for, but with negative results.

Table 3. The amounts of nucleic acids in TCA-precipitates from barley extracts. (Phosphorus and U.V. extinction values compared).

Solvent at extraction	Nucleic acid by P-det. µg/g barley	Nucleic acid by extinction µg/g barley	DNA by Dische reaction µg/g barley	% nucleic acid N of the total N of TCA-ppt. (by extinction)
Dist. water pH 5.85	6(?)	0	0	—
» » pH 7.0	20(?)	11	0	0.15
» » pH 8.0	169	165	0	1.9
1 M NaCl, pH 5.85	890	748	274	4.0
» » pH 7.0	870	835	300	4.4
» » pH 8.0	1000	978	344	5.4

The nucleic acids are calculated to constitute 4.0—5.5 % of the TCA-precipitable nitrogen in the sodium chloride extracts.

In order to estimate how much of the total nucleic acid of barley is extracted by 1 M sodium chloride solution, an attempt to estimate the nucleic acid content of barley is made by the cupric precipitation method, as described by Vendrely [19] (but on a larger scale, see under "Methods"). By assuming that the nucleic acids contain 10.7 % purine nitrogen and by neglecting the presence of free nucleotides, the nucleic acid content is calculated to be 0.27 % of the barley dry matter. Thus 1 M sodium chloride dissolves about 35—40 % of barley nucleic acid under the conditions described above.

The differentiation of RNA and DNA by hydrolytic methods [13,18] has not been found successful (*cf.* the experiences of Martin and Morton [20]). Thus the presence of DNA in the perchloric acid extracts containing total nucleic acid

was tested by the method of Dische [21], which is often considered to give too high values (*cf.* Markham [22]). The color given by perchloric acid-extracted nucleic acids, derived from sodium chloride extracts was the same as that of standard DNA (maximum at 595 mμ), whereas the nucleic acids derived from distilled water extracts gave no color. Moreover, in preliminary experiments starting from sodium chloride extracts we have obtained appreciable amounts of fibrous DNA, which is not digested by ribonuclease and shows an intense Feulgen reaction. Although the amounts given in Table 3 may be approximate, the presence of considerable amounts of DNA in sodium chloride extracts thus seems well established.

IV. *Lipids.* The amounts of lipids obtained from the TCA-precipitates and the phosphorus contents of these lipids are shown in Table 4.

Table 4. The lipids in TCA-precipitates from barley extracts and their phosphorus content.

Solvent at barley extraction	Lipid extracted with alcohol-ether		Lipid extracted with acidified alcohol-ether		Lipid as % of total barley lipid	Lipid as % of TCA-precipitated dry matter
	μg per g barley	% P in lipid	μg per g barley	% P in lipid *		
Dist. water pH 5.85	110	0.09	30	1.9	0.4	1.8
» » pH 7.0	330	0.16	30	1.9	1.1	3.6
» » pH 8.0	820	0.21	30	3.0	2.6	6.5
1 M NaCl pH 5.85	920	0.15	110	1.2	3.1	4.7
» » pH 7.0	820	0.12	100	2.4	2.8	4.4
» » pH 8.0	1460	1.25	50	2.8	4.6	7.4

* See under »Methods» how these values are estimated.

The amounts of lipids extracted with the HCl-containing alcohol-ether mixture is in most cases of the same order of magnitude as the error in the lipid analysis. But since the phosphorus content of this fraction is relatively important and since the removal of this fraction is necessary for the subsequent estimation of nucleic acids (*cf.* Ogur and Rosen [18]), this step cannot be omitted.

The nature of these lipids has not yet been investigated. Since their phosphorus content is generally low, the majority probably consist of various neutral components. (Abundance of neutral fat seems to be characteristic of plant lipoproteins [20,23]).

It has hitherto been possible to demonstrate the presence of steroids only in the lipids from the sodium chloride extract at pH 8 (by the method of Pijoan and Walter [24]; they amount to about 5 % of the protein-bound lipids).

DISCUSSION

1) *Accuracy of results.* The values presented above must be regarded as tentative only. In the first place, the extraction cannot be made exhaustively, as the enzymic degradation of nucleic acids, which is found to be appreciable

even in ice-cold solutions, necessitates a rapid extraction and clarification procedure. The long washing in TCA-solutions may also remove some of the nucleic acids.

As the clarification of the extract is another critical point, the barley cannot be ground too finely. Pool and Shooter [1] have shown that extracts from fine meal are difficult to clarify by centrifugation. Vendrely, Palmade and Vendrely [25], have found that the grinding of microorganisms in a ball mill renders the extraction of DNA more difficult. Filtration through filter pads (*e. g.* Seitz K 10) removes an appreciable fraction of the soluble high molecular nitrogen components, as was also pointed out by Pool and Shooter [1]. Hence we have chosen a grinding giving 70 % fine meal (as recommended by E.B.C.-Analytica [26]), extraction at 0°C for one hour and the clarification of extracts by centrifugation at 15 000 × *g*, as described under "Methods". Under other conditions, different values may be found.

As seen in Table 2, the accuracy of the values obtained in the phosphorus distribution analyses is scarcely greater than ±10 %. The lipid extraction and washing procedures may be somewhat incomplete. Further, the evaluation of nucleic acids is approximate owing to the use of standards obtained from different organisms. It must be emphasized that the method described in this paper is limited to TCA-precipitates from barley extracts. It is not applicable to whole barley, which contains both UV-absorbing and phosphorus-containing disturbing components.

2) *The origin of complexes.* The solubility properties of the nucleoproteins and lipoproteins of barley are similar to those of such complexes in general. For instance, from animal mitochondria the nucleoproteins may be extracted with 1 M sodium chloride at neutrality and the lipoproteins then with a more alkaline solution (for complete extraction a pH value of about 11 is needed) [27]. To what extent the nucleoprotein and lipoprotein complexes of saline barley extracts are derived from cytoplasmic particles remains to be shown. Some observations suggest that a part of the RNA may be derived from particles centrifuged down at 15 000 × *g* (probably plastids and mitochondria present in all the parts of the grain [28]). As the extraction of the nucleoproteins and lipoproteins is enhanced by the same factors, the lipoproteins may partially originate from similar particles. The submicroscopic particles (microsomes), if present, are probably left in solution after centrifugation at 15 000 × *g*, and may thus contribute to the nucleic acid and lipid content of the TCA-precipitates. (A centrifugation experiment at 150 000 × *g* has yielded slightly opaque pellets from sodium chloride extracts, previously clarified at 15 000 × *g*).

The DNA found in sodium chloride extracts may also partly originate from cytoplasmic particles, for Martin and Morton [23] have found appreciable quantities of DNA in cytoplasmic particles from wheat rootlets. On the other hand, when we tried to prepare nucleic acid from saline extracts of wheat flour (= endosperm fraction), a preparation consisting mainly of DNA was obtained. As RNA always preponderates in cytoplasmic particles, the presence of nuclear constituents in the saline extracts cannot be excluded.

3) *On the general character of nucleoproteins and lipoproteins.* The fractionation methods hitherto used in the study of barley proteins cannot be expected to give much information about native nucleoprotein and lipoprotein com-

plexes. During the slow fractionation procedures, an appreciable degradation by different enzymes is probable, since plant ribonucleases [29] and some lipases [30] are stable and active in a wide variety of conditions. Such procedures as salt fractionation may result in a dissociation of nucleoproteins, and in the subsequent dialysis the nucleic acid may then combine with new protein components [7,31,32].

In some preliminary fractionation experiments, we have certainly found lipids and nucleic acids in the globulin fraction and in the insoluble dialysis precipitate but never in the albumins. But just as phytic acid, on combining with proteins, may change their solubility properties [33,34], so nucleic acids and lipids may behave in a similar manner. For the reasons mentioned above, these experiments warrant no definite conclusions.

The presence of artificial lipoprotein complexes in barley extracts is possible, as evidenced with respect to wheat gluten by Olcott and Mecham [10]. But as all organisms contain lipoproteins, at least a part of those found in barley extracts may be expected to be natural.

The observations made in the course of this work suggest that greater attention paid to the structure of the grain, along the lines introduced by Säverborn, Danielsson and Svedberg [35], Danielsson [36] and Hess [37], might be fruitful in continued investigations on cereal proteins in general. In examination of lipoproteins and nucleoproteins, the separation of different cell fractions by differential centrifugation would be especially useful.

MATERIALS AND METHODS

Barley, Variety Herta, grown in 1955 in South Sweden, was used. It was milled immediately before the experiments with an Electrolux mill, adjusted to give about 70—75 % "fine meal" (passing through a Pfungstadt No. 3 sieve). N 1.69 %, P 0.37 % and total lipid 3.27 % (dry basis). Moisture 10.1 %.

Malt, Herta, grown in 1953 in South Sweden, was used. Milled as barley, about 90 % fine meal was obtained. N 1.57 % and P 0.42 % (dry basis). Moisture 6.8 %.

Nucleic acid standards. As RNA-standard, yeast nucleic acid from the Nutritional Biochemical Co. was used. It was deproteinized according to the method of Sevag, Lackmann and Smolens [38], dialyzed for one day and reprecipitated with 2 vols. ethanol. P 8.0 %, N 14.0 %, after heating with 0.5 M perchloric acid for 15 min at 90°C the extinction measured in 0.1 M HCl at 260 mμ was 10 800 per mole phosphorus.

The DNA standard was prepared from calf thymus according to the procedure of Mirsky and Pollister [39]. It was digested with crystalline pancreatic ribonuclease (Sigma Chemical Co.) and then deproteinized (as RNA above); dialyzed and reprecipitated with 1 vol. ethanol. P 8.53 %, N 14.1 %; the extinction measured as above was at 268 mμ (maximum) 10 100 per mole phosphorus.

The calculations of nucleic acid amounts are based on the assumption that the purine: pyrimidine ratio is unity, that RNA contains 9.6 % P and DNA 9.9 % P. Thus the DNA-RNA mixture present in sodium chloride extracts is considered to have a molar extinction of 10 600 at 265 mμ and a phosphorus content of 9.7 %.

Extraction of barley. The extraction was made on an ice bath or at room temperature. The flour was added as a fine stream to the stirred solution, in order to avoid the formation of artificial lipid complexes on moistening the flour by doughing (*cf.* Olcott and Mecham[10]). The pH value was repeatedly checked and adjusted by addition of 2 M sodium hydroxide or hydrochloric acid through a capillary to the vortex of the stirred solution.

Centrifugation. The extracts were first centrifuged at 1 800 r.p.m. and the turbid solution then clarified by centrifugation at high speed for 20 min at 15 000 × *g*. The clear or slightly opalescent middle layer was collected by pipette, contamination with the lipid-

containing top layer being avoided. Extraction and clarification of a sufficient quantity of extract generally required 3 h.

Precipitation with TCA and dialysis. This was performed as described in Fig. 1. The precipitate was washed ready for dialysis 10—12 h after the beginning of the extraction. Practically no nitrogen and little phosphorus (less than 10 %) was lost during the dialysis, which required 42 h.

Extraction of lipids. Generally 300—800 mg of the freeze-dried TCA-precipitate was extracted in a semimicro Soxhlet apparatus, first with 80 ml of ethanol-ether (3:1) for 48 h, then with 60 ml of absolute ethanol to which had been added 0.8 ml of concentrated hydrochloric acid per 100 ml (about 0.1 M). After 24 h 20 ml of ether was added to the solvent and extraction continued for a further 24 h. The two extracts were dealt with separately. They were evaporated on a water bath, the last 10 ml *in vacuo* without heating. The residues were moistened with 0.6 ml of absolute ethanol, after which 20 ml of ether and 20 ml of distilled water were added and the mixtures shaken in separatory funnels. The separated ether phases were washed twice with water and the original aqueous phases (probably containing proteinaceous material, carbohydrates and polyphenols) shaken again twice with 15 ml of ether, which was likewise washed with water. The ether phases were transferred to 50 ml volumetric flasks with 2 g of anhydrous sodium sulphate. The flasks were filled to the volume. After drying overnight aliquots of 40—45 ml were removed and evaporated and the residues transferred with ether to small weighed capsules through a little funnel with a minute filter paper disk in the stem. The ether was finally evaporated in a desiccator by cautious suction, with ether in the vacuum trap. The capsules with their contained lipid droplets were finally weighed after 24 h drying *in vacuo*.

It may be mentioned that we have tried many different lipid extraction methods, including enzymatic proteolysis and acid pressure hydrolysis, extraction with chloroform and *n*-butanol (Morton [40]). The hydrolytic methods seem not to offer any advantage: they are tedious and much evidently non-lipid material which is soluble in alcohol-ether is obtained. The chloroform extracts gave a dark and solid residue. Extraction with *n*-butanol seemed in some cases suitable, but in other cases gave definitely less lipids; it is evidently useful but has not yet been systematically investigated.

The method described above is not ideal. Phospholipids are hydrolyzed during the acid extraction, which is proved by treating known amounts of soybean lecithin in the same manner. The lipids obtained contain some other material (they often give a positive Molisch reaction). Actually, it cannot be said if this material is an integral part of the lipid or not (*cf.* Lovern [41], p. 42).

From experiments with soybean lecithin it appears that the lipid phosphorus extracted with acid alcohol and ether is to be found in the aqueous phase after the washing of lipids. The phosphorus content of the "firmly bound" lipids listed in Table 4 is only a rough approximation. Owing to the various possible sources of error, the phosphorus percentage is calculated without regard to the lost unknown lipid fragments.

Extraction of nucleic acids. As already mentioned, we did not obtain any reproducible results with the differential hydrolytic extraction method of Ogur and Rosen [18]. The amounts of RNA extracted with cold perchloric acid were generally low. Thus the total nucleic acids were extracted with hot perchloric acid. Heating at +70°C for 20 min produced extracts which were difficult to clarify and which showed an appreciable extinction at 300—330 mμ. When the heating temperature was raised to +90°C and the extracts cooled overnight at 4°C, the turbidity was easy to centrifuge off and the absorption curve between 220 and 330 mμ was close to those of the nucleic acids, as shown in Fig. 4. The heating time seemed not to be critical; 10 and 30 min gave practically identical results.

Purine nitrogen determination. The method of Vendrely [19] was adopted, but on a larger scale. Barley samples of 2 g were hydrolyzed in 20 ml of 1 M hydrochloric acid by gently boiling for 6 h with reflux. After centrifugation, the brown solutions were neutralized (with bromocresol purple as indicator), acidified with acetic acid to about pH 5, heated to 100°C and centrifuged again. A sample of the solution corresponding to a known amount of original extract was then taken for the copper precipitation, performed according to the original method but with sixfold amounts of reagents (3 drops was taken to be 0.1 ml). The nitrogen was determined in the second precipitate by the usual Kjeldahl method (modification of Blom and Schwartz [42], see below).

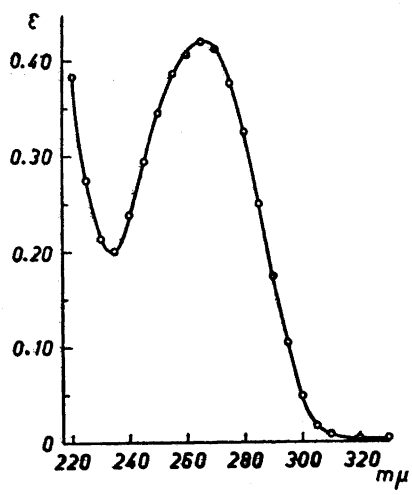

Fig. 4. The ultraviolet absorption spectrum of hot perchloric acid extract containing nucleic acids. (Delipidated TCA-precipitate from sodium chloride extract, obtained at pH 8).

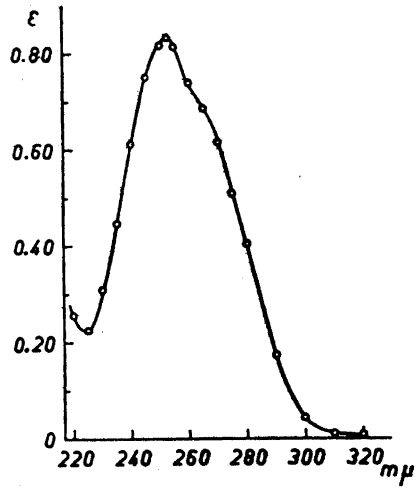

Fig. 5. The ultraviolet absorption spectrum of the decomposed copper-purine complex from barley hydrolysate, measured in 0.1 M hydrochloric acid.

Since the values given by the cupric precipitation method may be too high, they were checked for some samples by measuring the ultraviolet absorption of the decomposed cupric precipitate as follows: The second cupric precipitate was decomposed by 1 % sodium sulphide (exactly as the first precipitate according to the original method). The cleared supernatant was diluted with 0.1 M hydrochloric acid and the ultraviolet absorption measured. Fig. 5 shows the absorption curve of such a solution, corresponding well to the curve of an adenine-guanine mixture. If the molar extinction coefficient of an equimolar adenine-guanine mixture is considered to be 12 000 (at 253 mμ) [22], virtually equal values were found by nitrogen determination and by extinction measurement.

Assay of nitrogen. The semimicro modification of the Kjeldahl method suggested by Blom and Schwartz [42] was used. Distillation was performed in Markham's apparatus.

Assay of phosphorus. The Fiske-SubbaRow method as modified by King [43] was used. Especially when the presence of phytic acid was suspected, a droplet of 0.4 % ammonium molybdate was added to the digestion tube to ensure rapid hydrolysis of phytic acid [44].

Phytic acid analysis. The method of Leva and Rappoport [45] was adopted, since preliminary experiments showed that relatively large amounts of mucleic acid do not interfere.

The author is indebted to the head of the laboratory, Dr. S. Brohult, to Dr. E. Sandegren and to Mr. H. Nihlén for valuable advices and discussions. For the revision of the English text I wish express my cordial thanks to Mrs. Jean-Margaret Perttunen, B. Sc.

The Effect of Ions on the Catalytic Activity of Enzymes: Yeast Glucose-6-phosphate Dehydrogenase

WILLIAM J. RUTTER*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm 60, Sweden

1. The catalytic activity of yeast glucose-6-phosphate dehydrogenase preparations is markedly altered in the presence of various ions. At low ion concentrations there is a strong augmentation of catalytic activity, while at high concentrations there is an inhibition.

2. Anions are important in the activation process. The relative effectiveness of various anions for augmentation of catalytic rate is $F^- > PO_4^{\equiv} > Cl^- > Br^- > SO_4^{\equiv} > I^- > SCN^-$.

The concentration for maximum activation varies with each anion.

3. Cations also play a role in augmentation of finite catalytic rate. Calcium and magnesium ions are more effective than sodium or potassium ions.

4. The inhibition of *Zwischenferment* activity at high ion concentrations is apparently due to a competition with substrates glucose- 6-phosphate and TPN, for site on the enzyme surface.

5. Possible mechanisms for the augmentation of a finite catalytic rate by both anions and cations are discussed.

The marked influence of the ionic environment on physiological activity is usually explained in terms of ionic effects on enzymes in the biological system. Many purified enzyme preparations absolutely require a particular ion or closely related group of ions for catalytic activity; while the catalytic activity of many other enzyme preparations is influenced by ionic environment to a greater or lesser degree.

In cases where an absolute ionic requirement for enzyme activity has been demonstrated, specific monovalent and/or divalent metal ions have usually been implicated as the actual cofactor. The anionic species may usually be varied without observable effect. From this it has been inferred that the accompanying anionic species is relatively unimportant in the cases where a specific cationic requirement exists; and that the metal ions are intimately associated in the catalytic apparatus and are obligatorily involved in the catalytic process.

* U. S. Public Health Service Fellow, 1954—55. Present address, Division of Biochemistry, University of Illinois, Urbana, Illinois, USA.

There are in addition some observations which are more easily explained in terms of an augmentation of a finite catalytic rate. These effects may be the reflection of a general influence of ionic strength of the medium, or may be more specifically related to a particular cationic or anionic species. Of particular interest for the present discussion, for example, is the stimulation of the activity of the pancreatic and salivary α-amylases by chloride ions [1]; the augmentation of the catalytic activity of fumarase by polyvalent anions [2], the affects of both cationic and ionic species on the activity of β-galactosidase [3,4], and the influence of the ionic strength on the catalytic activity of urease [5].

The earlier observations from this laboratory concerning large effects of anions on certain flavoprotein systems [6,7] as well as with the reaction catalyzed by liver alcohol dehydrogenase [8] has prompted additional studies of ionic effects on other enzyme systems in order to ascertain, 1) the generality and magnitude of such effects, 2) the mechanism of stimulation, and, 3) the physiological significance of such phenomena.

The present paper presents the data which have been obtained in the *Zwischenferment* system *. It has been found that a variety of ions, including phosphate and the substrate glucose-6-phosphate stimulate enzymatic activity markedly. At high concentrations inhibition is observed. Possible mechanisms of ionic effects on the catalytic activity of this and other enzymes are discussed.

MATERIALS AND METHODS

Glucose-6-phosphate dehydrogenase (*Zwischenferment*) was prepared according to the procedures of Warburg and Christian [9], and of Kornberg [10]. The reaction was followed spectrophotometrically. The specific activity of these preparations is expressed as μmoles TPNH formed/min/mg protein under optimum assay conditions. The results obtained were independent of the preparation used. Crystalline barium glucose-6-phosphate (G-6-P) was converted to the sodium or potassium salt which in turn was used as the substrate.

The rates reported here are the initial rates when the reaction rate was zero order with respect to concentration of substrates. The experiments were performed at 23°C.

RESULTS

The initial experiments to be reported here concern the effects of certain ions on *Zwischenferment* activity. The addition of monovalent ions to the assay system is typified by the data presented in Fig. 1. In the presence of sodium chloride or sodium fluoride there was observed an increase in activity, especially on the acid side of the pH activity curve, and a change in the pH of optimum activity. It is noteworthy that fluoride and chloride did not elicit identical effects on catalytic activity. The strong role of the anion is indicated in the experiments summarized in Fig. 2 in which enzyme activity was measured as a function of anion concentration. A stimulation of activity was

* Abbreviations used in this manuscript are as follows: *Zwischenferment*, yeast glucose-6-phosphate dehydrogenase; G-6-P, glucose-6-phosphate; TPN, triphosphopyridine nucleotide; DPN, diphosphopyridine nucleotide; 6PGL, 6-phosphogluconolactone.

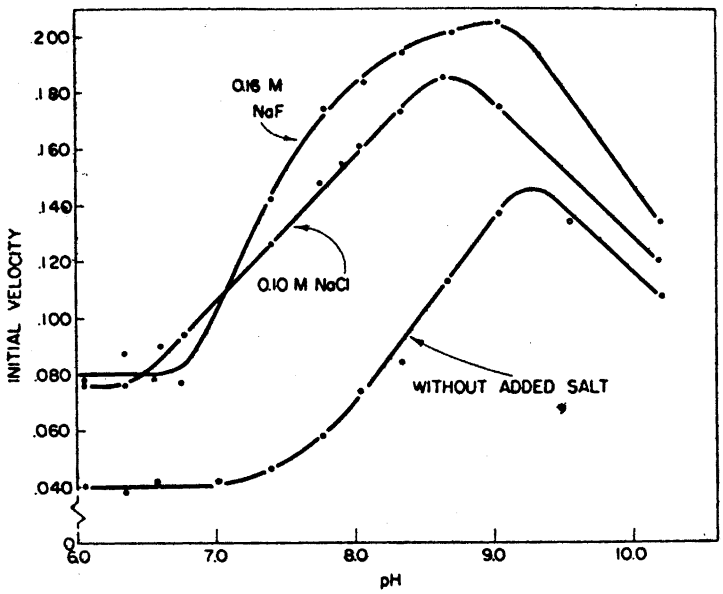

Fig. 1. Influence of ions on the *Zwischenferment* reaction as a function of pH. The reaction mixtures contained 6 μM G-6-P, 0.3 μM TPN, 100 μg *Zwischenferment* preparation, 100 μM buffer. (Histidine pH 0.6—7.0; glycyl-glycine pH 7.0—9.0, glycine pH 9.0—10.2) salt added when indicated, final volume 3.0 ml, temperature 23°C. Initial velocity is expressed in terms of change in optical density change at 340 mμ/min. The pH of each reaction was tested imediately after assay of enzymatic activity.

observed at low concentration and an inhibition at higher concentrations; the degree of stimulation and concentration required for stimulation and inhibition varied with the anionic species. The "effectiveness" of various anions in augmentation of *Zwischenferment* activity may be stated qualitatively $F^- > PO_4^{\equiv} > Cl^- > Br^- > SO_4^{\equiv} > I^- > SCN^-$; and for inhibition of catalytic rate $SCN^- > I^- > SO_4^{\equiv} > PO_4^{\equiv} > Br^- > Cl^- > F^-$. The position of $PO_4^{\equiv}$ in these series is noteworthy. The wide variation in effects elicited by anions precludes ionic strength as the sole cause of activation and inhibition phenomena. It is true, however, that certain of the data, for example the stimulation by low concentrations of phosphate, chloride, and fluoride may be so related. The finite activity observed without the further addition of ions does not represent activity of a salt free system, but that in the presence of 3×10^{-2} M glycylglycine buffer and 2×10^{-3} M glucose-6-phosphate. The ionic strength of the solution, therefore, was high enough to allow the possibility of an absolute requirement for added ions for enzyme activity. Suitable experiments with dialyzed preparations, however, showed that glycylglycine as well as versene and citrate give practically no activation or inhibition of this system. These observations make it unlikely that the activation by ions is due to the solvation of a contaminating inhibitory metal ion, and also emphasize the role of the anionic species in the activation process.

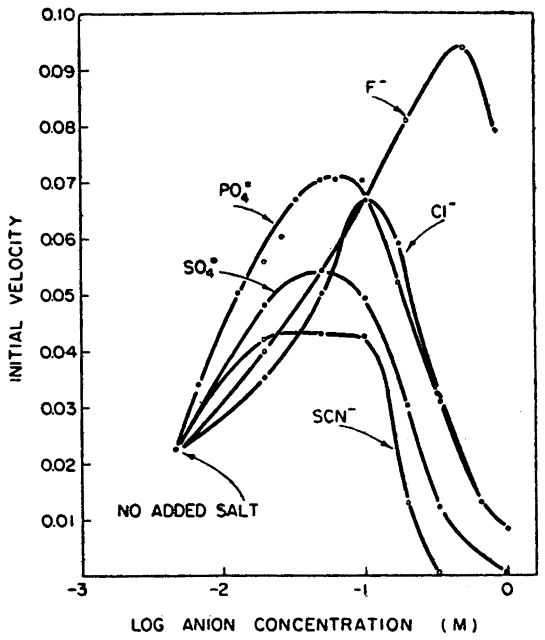

Fig. 2. Effect of anions on the rate of the *Zwischenferment* reaction.
The reaction mixtures contained 6 μM G-6-P, 0.3 μM TPN, 100 μg *Zwischenferment*, 100 μM glycyl-glycine pH 7.4, anions as indicated, water to 3.0 ml, temperature 23°C. All of the anions were added as the sodium salts.
The rate expressed as optical density change at 350 mμ/min.

Fig. 3 shows the effect of substrate concentration in the presence and absence of added ions. Glucose-6-phosphate does, itself, stimulate enzyme activity at concentrations higher than those needed to saturate the enzyme, but it is less effective than the simple inorganic anions. The presence of other anions markedly influences the apparent affinity of the enzyme for its substrate (*i. e.*, the K_m of the substrate). At a concentration of 0.5 M NaCl, for example, at least ten times more glucose-6-phosphate is required to obtain maximum activity than at 0.1 M NaCl. The early reports [11,12] concerning the phosphate inhibition of *Zwischenferment* activity, could, on the basis of the present investigation, be related to the concentrations of glucose-6-phosphate and/or TPN present in the assay system used.

Fluoride ions are more effective than chloride or other ions in augmenting the catalytic rate, especially at low substrate concentrations. The small size of the fluoride ion could conceivably allow more effective collisions of enzyme and substrate.

In Fig. 4 are presented Lineweaver-Burk plots of representative data on the interrelationship of ions and G—6—P in the *Zwischenferment* reaction at a constant TPN concentration. There is an apparent competitive relationship between ions and the substrate. The strong activation by high concentrations

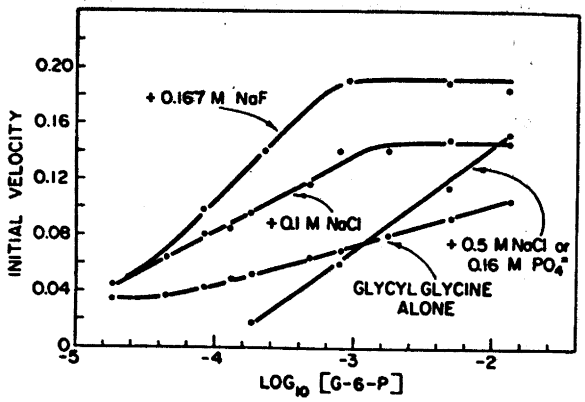

Fig. 3. Ion-glucose-6-phosphate interrelationships in the *Zwischenferment* reaction. The general reaction conditions are as indicated in Fig. 2. The molar G-6-P- concentration was varied as indicated. The sodium salts of anions were employed.

of the substrate is evidenced by the rather marked inflection in the curve. It is not possible to say definitely whether G—6—P itself is the activating ion, or whether contaminating ions (traces of sodium sulfate, *e. g.*, any sodium) are responsible for this effect.

Similar data concerned with the influence of ions on the reaction of *Zwischenferment* with TPN at constant glucose-6-phosphate concentration are

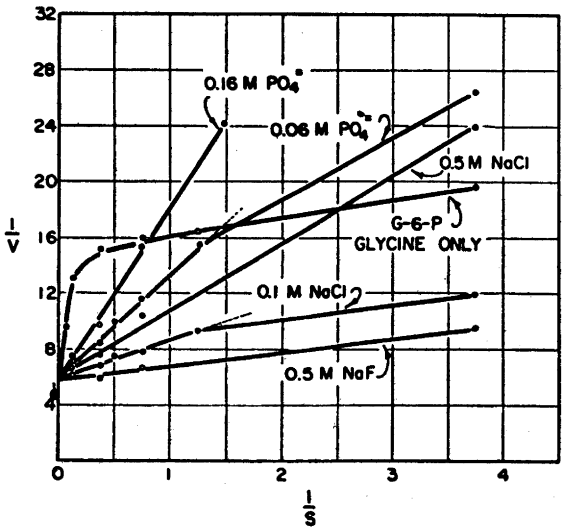

Fig. 4. Ion-glucose-6-phosphate relationships in the *Zwischenferment* reaction. The general reaction conditions are as indicated in Fig. 3. In these Lineweaver-Burk plots the units of reaction velocity are optical ensity change at 340 mμ/min and the units of substrate concentration are μM/ml reaction medium.

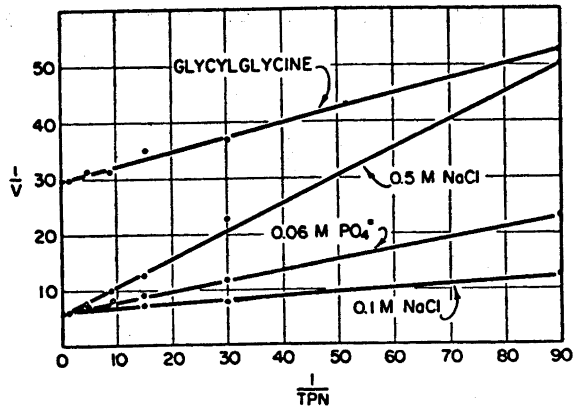

Fig. 5. Ion-TPN relationship in the *Zwischenferment* reactions.
General reaction conditions are as described in the legend of Fig. 2, 6 μM G-6-P present, and TPN concentration varied as indicated. In these Lineweaver-Burk plots, the units of reaction velocity are — O.D. 340 mμ/min, and units of TPN concentration μM/ml reaction medium.

presented in Fig. 5. Again there is a competitive relationship between TPN and the ions tested, presumably for a site on the enzyme surface. TPN in the concentrations used is not effective as an ion activator, and may be contrasted to glucose-6-phosphate in this respect.

The difference between the maximum velocities in the presence and absence of added ions is considered a point of some significance. At concentrations of G—6—P below those at which activation occurs (10^{-3} M) and in the absence of added activating ions, either a large fraction of total enzyme molecules are catalytically inactive, or, perhaps more likely, catalysis proceeds at all active sites of the enzyme population, but at a much slower rate. Some of the inflec-

Table 1. Effect of substrate and TPN in overcoming anion inhibition of glucose-6-phosphate dehydrogenase

In 0.5 molar NaCl Additions	Initial rate
1. 0.4 μmoles G-6-P 0.18 μmoles TPN	0.020
2. 10 μmoles G-P-6 0.18 μmoles TPN	0.030
3. 0.4 μmoles G-6-P 1.5 μmoles TPN	0.042
4. 10 μmoles G-6-P 1.5 μmoles TPN	0.042

Each reaction mixture contained 1.5 μmoles NaCl, 100 μg *Zwischenferment*, 100 μM glycyl glycine buffer, pH 7.4, and the concentration of G-6-P and TPN indicated above. The final volume was 3.0 ml., temperature 23°C.
The initial rate is expressed in terms of change in optical density.

Table 2. Effect of cations on *Zwischenferment* activity.

Ion	μ	% Stimulation
NaCl	0.02	87
	0.04	175
	0.10	312
	0.15	250
KCl	0.04	175

$MnCl_2$	0.02	312
	0.05	350
	0.10	300

Each reaction mixture contained 1 μmole G-6-P, 0.3 μmoles TPN, 100 μmole glycyl glycine, pH 7.4. 100 μg *Zwischenferment* (lyophilized preparation, original specific activity approximately 1.0). Ions added when indicated, final volume 3.0 ml, temperature 23°C. The figures represent stimulations of the rate observed in the absence of added ions (Δ O.D./min = 0.032).

tions in the Lineweaver-Burk curves in Fig. 4 (which have been consistently observed) may be the result of transitions between the two types of catalysis. The possibility that anions influence the dissociation of the enzyme-product complex will be considered in the discussion section.

Since the reaction of both G—6—P and TPN with the enzyme is inhibited in a competitive manner by a variety of ions, the question arises whether the binding of one substrate to the enzyme influences the binding of the other; that is whether the competitive inhibition by anions of the reaction of G—6—P with *Zwischenferment* is independent of TPN and vice versa. The experiment reported in Table 1 was performed to test this possibility. At high salt concentrations, increasing the concentration of either substrate (G—6—P or TPN) increases the reaction rate. This observation is most easily explained in terms of an increased affinity for the second substrate, when the enzyme is combined with the first substrate.

The fact that anions elicit more or less specific effects on the catalytic activity of *Zwischenferment* does not, of course, rule out a role of the cationic species. An experiment, therefore, was designed to test the effects of various chloride salts on enzyme activity. As shown in Table 2, the divalent metals ions, Ca^{++}, Mg^{++}, and Mn^{++} are more effective than sodium and potassium, especially at low ionic strengths *. Moreover, inhibition of the reaction by

* Dr. Hans Klenow, Universitetets Institut for Cytofysiologi, Copenhagen, Denmark, has independently observed a stimulation of *Zwischenferment* by certain ions (private communication).

chloride salts occurs according to the concentration of chloride ions, and is not, apparently, simply related to the overall ionic strength; thus at 0.1 M NaCl there is already a significant decrease in activity, while at this concentration of $MgCl_2$ and $CaCl_2$ maximum activity is still observed. The report of Kornberg [10] that magnesium ions stimulate *Zwischenferment* activity is thus confirmed, but it is emphasized that there is no apparent specific requirement for magnesium or other divalent metal ions in the system [13]. This is not to deny the possible existence of a non-dissociable metal ion in the enzyme itself. The possible role of divalent metal ions as non-specific activators will be considered in the discussion.

DISCUSSION

The ionic effects observed here are more easily interpreted in terms of an augmentation of catalytic rate, rather than an absolute requirement for added ion. It would not be wise, however, to suggest that there is not an absolute requirement for ions, since the H_3O^+ and OH^- ions of the solvent are doubtless contributory in the system. As a matter of fact, one explanation for the comparative lack of ionic effect in the basic portion of the pH activity curve, may be the increasing number OH^- ions in solution. The marked influence of ions on the catalytic rate cannot be a simple function of the ionic strength, since widely varying effects were observed with different ionic species at the same ionic strength. Any interpretation of the data must consider the role of both cationic and anionic species in the catalytic process.

Michaelis and Pechstein[14] have advanced a theory to explain ionic stimulation of enzymatic activity. According to their argument, enzymatic activity is related to both acidic and basic dissociable groups; the optimum catalytic activity being at that pH where maximum dissociation of both acidic and basic groups occurs. The presence of salts then may affect catalytic activity by altering the dissociation of these groups involved in the catalytic process. This theory extended by Alberty [15] has satisfactorily explained much of the data concerned with the effect of ions on enzymatic activity. The extensive studies on the influence of ions on fumarase activity by Massey [2], and Massey and Alberty [16], for example, suggest effects of anions on the dissociation of groups at, or near, the active center.

This type of explanation may at least in part have validity here. It is true that the apparent affinity (K_m) of the enzyme for G—6—P and TPN is markedly affected by the ionic environment. The strong stimulation of catalytic activity on the acidic side of the pH-activity curve would presumably be related to the influence of anions present, and the smaller but significant increase on the basic side of the curve, to the influence of cations.

There is, however, another interpretation of effects observed in this and in certain other cases. As is the case with any enzymatically catalyzed reaction which is presumed to proceed through the formation of an enzyme substrate complex, the catalytic process associated with *Zwischenferment* may be considered to be composed of several partial reactions: (a) the association of the enzyme with its substrates, (b) the catalytic process *per se*, and (c) the dissociation of the enzyme from the products of the reaction. For the *Zwischenfer-*

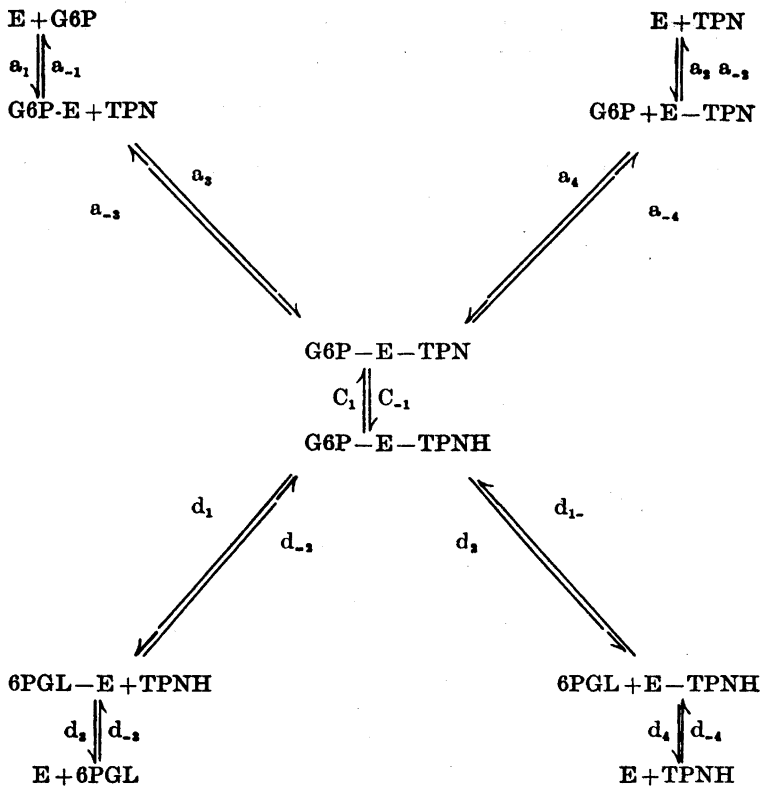

Fig. 6. Hypothetical kinetic mechanism for the *Zwischenferment* reaction.

ment system, the partial reactions formulated in Fig. 6 have been arbitrarily selected as an expression of the overall process. The actual catalytic reaction is represented by C, which is a composite constant of the partial reactions involved in this process. Clearly the observed overall rate of the reaction will be a function of the rate constants for the partial reactions, and in particular instances could, therefore, be a reflection of association of enzyme and substrates, the catalytic reaction, or of dissociation to enzyme and products, or combinations of these. If the formation of the enzyme-substrate complex can be considered according to the ion association theory, then at low dielectric constant (in the absence of salts), there would exist a greater tendency for the enzyme and substrate, to associate, and at higher dielectric constant (*i. e.*, at higher ionic strength), a greater tendency to dissociate since both charged species would then be solvated. The stimulatory effects of ions on *Zwischenferment* activity are explicable on this basis if it be assumed that the dissocia-

tion of products is rate limiting *. An increase in the anion concentration would simultaneously decrease the association reaction, and increase the dissociation reaction. The net result would be a stimulation of activity together with an increased K_m for the substrate. In the observations presented in this paper, note that at a given substrate concentration a stimulation of activity followed by an inhibition was observed as the ionic concentration increased. The degree of effectiveness of a particular anion, either as an activator or inhibitor, would then be related to its effectiveness in displacing the product from the complex, and the ease with which it in turn was displaced by the substrate. Thus, phosphate is especially effective as an activator at low concentrations, while sulfate inhibits at comparatively low concentrations presumably because it would be less readily displaced by the substrate. The increased effectiveness of the divalent metal ion can be easily visualized, since these cations would readily form an ion pair with the divalent phosphate groups on the product molecules, enhancing the rate of dissociation. The pH optimum of the enzyme in the absence of added ions then might be expected to be in the basic region where the hydroxyl ions could increase dissociation rate of enzyme product complex. The change in pH optimum with salt concentration could conceivably be a reflection of the relatively smaller effect of hydroxyl ions in the presence of salt. It would be expected that effects of added anions would be proportionally greater at lower pH values, as has been observed in these studies.

The argument presented provides a means of explaining the effect of ions on catalytic activity of glucose-6-phosphate dehydrogenase, and could be applied to other cases of ion stimulation and inhibition, especially when concomitant effects on the apparent affinity of the enzymes for the substrates are also observed.

It is not a novel idea that the rate limiting reaction of an enzymatic catalysis be the association or dissociation of enzyme-substrate complex. Theorell and Chance [19] have, for example, shown that in the reaction of ethanol with DPN catalyzed by alcohol dehydrogenase, the dissociation of Enzyme-DPNH is in all probability the limiting step.

The above treatment allows the qualitative prediction of this type of ionic effects on the rate constants in the catalytic process. For example, an increase in appropriate ion concentration should increase A_{-1}, A_{-2}, A_{-3}, A_{-4}, d_1, d_2, d_3, d_4, and decrease A_1, A_2, A_3, A_4, d_{-1}, d_{-2}, d_{-3}, d_{-4}, in the *Zwischenferment* system as written. It is conceivable that ionic affects of the type suggested, could be observed on the catalytic step C_1 and C_{-1}. In this case, however, the manner in which C_1 and C_{-1} would be affected would be considerably more difficult to predict.

* It is true in the present instance, that ionic effects observed might also be related to a conversion of the product, 6-phosphogluconolactone (6PGL) to a compound not involved in the reaction, namely, 6-phosphogluconic acid [14]. Since the observations were initial reaction rates, it is believed the large effects observed cannot be solely related to this additional reaction. The results also cannot be effects on the lactonizing enyme, since Ca++ ions stimulate the present reaction while magnesium, manganese, or cobalt ions are required for gluconolactonase; and in addition, fluoride ions are efficient activators of *Zwischenferment*, yet they inhibit gluconolactonase [15].

An effect of ions on the dissociation of groups involved in the combination of the substrate or products with the enzyme, or in the catalytic reaction itself could on the other hand alter the individual rate constants in either direction, depending on the chemical circumstances.

According to the nature of the reacting groups the present hypothesis provides an explanation for ionic effects on reactions involving groups which are completely ionized under the conditions imposed. It is an adjunct to the more often expostulated theory which concerns the effects of added ions on reactions involving groups which dissociate under the conditions imposed; together, they provide a general mechanism for the interpretation of cases in which there is a general ionic influence in catalytic activity, but no specific ion erquirement.

The author wishes to express appreciation to Prof. H. Theorell for his active interest in this work and for the gracious hospitality extended by him and other members of the Biochemical department.

Determination of Accurate Interplanar Spacings and Lattice Parameters from Guinier Powder Photographs

SVEN WESTMAN and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

X-Ray powder photographs obtained in a Guinier type focusing camera of 80 mm diameter (transmission position) often permit the calculation of interplanar spacings and unit cell dimensions with considerable accuracy provided that an internal standard is admixed with the powder specimens. The procedure is rapid and simple. The high accuracy obtained in the low-angle region is particularly valuable when applying analytical methods for indexing powder patterns.

Accuracy in powder data is of great importance in many instances of X-ray diffraction studies, *e. g.* when indexing complicated patterns by analytical methods [1,2]. Access to accurate interplanar spacings and unit cell dimensions has been essential also in connection with studies carried out by members of the present research team on some series of closely related, discrete phases giving very similar X-ray patterns (homologous series of oxides of transition elements) [3,4]. The information thus needed has to a large extent been obtained from powder photographs.

The determination of interplanar spacings and unit cell dimensions with the highest degree of accuracy is a complicated task [1,2]. Quite often, however, a more modest degree of accuracy in the interplanar spacings values is required and for such cases the employment of a Guinier focusing camera[5] has been found to give, by a simple and rapid procedure, results satisfactory for most needs.

The two Guinier camera sets used in the present investigation were built according to a design by Professor G. Hägg, Uppsala, at the workshop of the Chemistry Department, Research Institute of National Defence (FOA 1) through the kind permission of the head of the Department, Professor G. Ljunggren. The delicate adjustment of the camera sets, which were designed for taking transmission photographs with Cu$K\alpha$ radiation, was carried out by Dr. J. Österlöf of this Institute. One of the cameras, intended for precision measurements, utilizes strictly monochromatized Cu$K\alpha_1$ radiation, while the

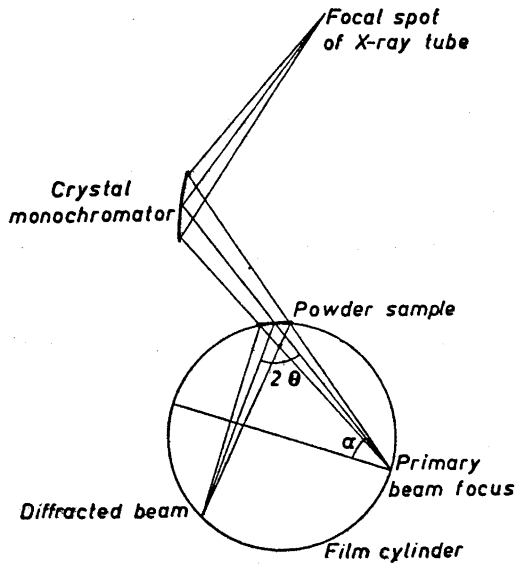

Fig. 1. Guinier focusing camera (transmission position).

other, used for ordinary work and with somewhat higher intensity, employs the Cu$K(\alpha_1 + \alpha_2)$ doublet. The diameter of the film cylinder is 80 mm. The exposure times are generally rather short, being about 30 min for substances of high symmetry and simple structure.

A condition for the camera to give sharp interference lines on the film is that the powder sample is situated on the cylinder defined by the film (*cf.* Fig. 1). In the actual procedure, the sample is stuck to a piece of thin Scotch tape which is attached to a flat metal ring rotated in a plane tangent to the focusing cylinder. A minor deviation of the sample from the correct site causes a slight broadening of the interference lines and considerable displacements of their positions on the film. Thus, if the sample is moved outwards Δa at right angles to the tangent plane, the position (s) of the interference line on the film will shift towards increasing s by an amount $\Delta s = F(\Theta,\alpha) \cdot \Delta a$, where Θ is the Bragg angle and α the angle between the incident beam and the normal to the powder specimen. Fig. 2 gives a representation of the quotient $\Delta s/\Delta a$ as a function of Θ when α is given the value, 35°, of the actual camera sets. It is obvious that, with this method of mounting the specimen, accurate Θ values for the reflexions cannot be obtained by straight-forward measurements of the distances s_{obs} between the positions on the film of the primary beam and the reflexions.

Admixture of an internal standard with accurately known lattice dimensions makes it possible to correlate for each individual exposure the readings on the film s_{obs} with the Θ values of the standard. This is advantageously done by determining for every reflexion of the standard substance the difference

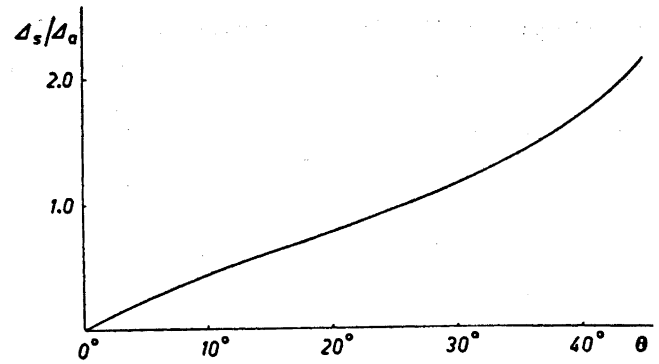

Fig. 2. Relation between line displacement (Δs) and sample displacement (Δa) as a function of diffraction angle (Θ).

$\Delta s = s^\circ - s_{obs}$, where s° represents the value calculated for a nominal value r° chosen for the camera radius. By plotting Δs against s_{obs}, a correction curve is obtained which is of a form analogous to that given in Fig. 2 if the camera is truly cylindrical and correctly adjusted. Within the limits given by the accuracy of the readings, this function corresponds to a line $\Delta s = \text{const} \times s_{obs}$.

The use of admixed standard substances in X-ray powder work has been discussed by Bacon [6], Andrews [7] and Parrish [8]. For the present investigation, use was generally made of a potassium chloride standard (Analar, British Drug Houses) the lattice parameter and linear expansion coefficient of which have been determined by Hambling [9], $a = 6.2930$ Å (25°C) and $\beta = 3.37 \times 10^{-5}$/°C. After grinding and recrystallization at 600°C for one hour, this substance gave powder interferences of good quality. Seven reflexions of suitable intensity and distribution appear within the diffraction range of the Guinier cameras used.

Other standard substances may be preferable for special purposes. Thus, when studying phases displaying solid solubility, addition of a pure component as a standard may make possible very accurate measurements of the changes of the lattice parameters accompanying the solution phenomenon, provided that the changes are large enough to give good resolution of corresponding lines. For very accurate determinations of absolute cell dimensions, it may sometimes be advisable to use a standard giving more reflexions than those obtained from potassium chloride in order to be able to fix the correction line $\Delta s = \text{const} \times s_{obs}$ more accurately.

When evaluating the films an automatic correction for film shrinkage was obtained according to Hägg [10] by printing a scale (graduated to 0.1 mm) on the film prior to development. The films were measured in a projection comparator obtained by slightly modifying an ordinary 35 mm "Prado" projector. The high quality of the Guinier photographs allowed a linear magnification as high as 7 or 8 times to be used.

Following a procedure introduced by Österlöf [11], the measurement of the reflexions was made not, as has usually been the case, on the maximum den-

sity but on the very sharp high-angle edge of the lines. Provided that the lines are of good quality and that their intensities are not very high or too low, this method has been found to give very good results. It is essential that the reflexions of the test substance and of the standard are similar in their sharpness.

The usefulness of the camera for accurate work was tested by studying the photographs of several substances. All the exposures were made at about 20°C. For several of the test substances, accurate lattice parameters at this temperature have been reported in the literature or could be calculated from data obtained at other temperatures and the values for the thermal coefficient.

The cylindrical form and the adjustment of the camera were checked by means of the diagram obtained from mercuric tellurate, Hg_3TeO_6. According to Hägg and Holmberg [12], this substance is cubic with the cube edge equal to 13.4 Å. A sample prepared according to Hutchins [13] was kindly lent by Professor Hägg. The powder photograph (Table 1) indicated that the form and adjustment of the camera were perfect. The 29 observed reflexions give the relative value of the lattice parameter to ± 0.004 % (confidence limits for 95 % probability). The absolute value for the parameter, given in Table 1, lacks significance due to the inadequate knowledge of the purity of the sample. The differences between the s values corresponding to $\sin^2\Theta_{obs}$ and $\sin^2\Theta_{calc}$, given in the column $s^o - s_{calc}$ of Table 1, show that the error in the readings is of the magnitude of 0.01 mm. The use of a vernier for the film measurements thus seems warranted. However, it ought to be emphasized that the maximum error of the scale printed on the film is also of this magnitude [10].

Table 2 gives lattice parameters obtained for samples of aluminium (99.99% pure), thallous bromide (British Drug Houses), sodium chloride (Merck, Analytical reagent) and lead nitrate (Riedel — E. de Haën p.a.). The influence of refraction has been considered when warranted. The confidence limits are given for 95 % probability. The agreement with precision data reported in the literature is satisfactory. It is evident that the accuracy obtained is high enough to require that the temperature is maintained constant to within about $\pm$ 1°C during the exposure.

Lattice parameters may also be obtained with a considerable degree of accuracy for substances of symmetry lower than cubic. This is illustrated in Tables 3 and 4 which give the powder patterns of orthorhombic molybdenum trioxide (C. P., Baker's Analyzed) and triclinic pentatitanium enneaoxide (prepared from titanium metal and titanium dioxide, both of high purity) [4]. The very satisfactory agreement between observed and calculated values of $\sin^2\Theta$ clearly suggests the suitability of Guinier camera data for the analytical methods of indexing powder patterns.

The camera with $CuK(\alpha_1+\alpha_2)$ radiation has also been found to give data of rather high accuracy although it does not completely match the $CuK\alpha_1$ camera in this respect. The superposition or close vicinity of the α_1 and α_2 reflexions and the shift of their relative position ($\Theta_{\alpha_2}-\Theta_{\alpha_1}$ negative for $\Theta < 14.3°$ and positive for higher values of Θ) makes it somewhat difficult to apply the Österlöf measuring technique within extensive parts of the diffraction range. However, measurements of the sharp α_1 reflexion edge for Θ values below 14.3°, of the α_2 reflexion edge for unresolved doublets at higher values of Θ and of the edges of both components for well resolved doublets have been found to give results which compare favourably with those obtained from measurements on the maximum density of the lines.

Acknowledgements. The authors wish to express their sincere gratitude to Professor G. Hägg, Uppsala, and to Dr. J. Österlöf of this Institute for valuable information and discussions. Several members of the research staff have contributed to the results reported in this article by their observations and discussions of previous experiences. Thanks are especially due to Mr. Sten Andersson, Mr. Ulf Kuylenstierna, Mrs. Stina Nord and Docent Herbert Pestmalis.

The Crystal and Molecular Structure of β-Arabinose

SVEN FURBERG and ASBJØRN HORDVIK

Chemical Institute, University of Bergen, Bergen, Norway

The crystal and molecular structure of β-arabinose has been determined, mainly by means of the "multiplication rule". There is a *cis*-glycol grouping on C_1 and C_2, and the molecule has the structure 1*a*2*e*3*e*4*a*.

As the pyranose ring has the staggered "chair" form, there are according to Hassel [1] two possibilities for the molecular structure of each pyranose sugar, the one being formed from the other by conversion of the ring. For some sugars it is fairly evident which structure is the more stable one and to be expected in the crystalline state. In other cases, such as the present one, it would appear difficult to settle this question without determining the crystal structure. So far detailed structure analysis of two pyranose sugars, α-glucose and α-rhamnose monohydrate, have been reported in the literature (Beevers *et al.*[2,3]).

EXPERIMENTAL CRYSTAL DATA

A commercial sample of β-D-(−)-arabinose from Eastman Kodak Co. was used for the investigation. Good crystals were obtained by recrystallization from alcohol. They are needle-shaped and elongated along the *c*-axis. Weissenberg- and oscillation diagrams were taken about two axes, using filtered copper radiation. The crystals are ortorhombic, with unit cell dimensions $a = 6.50$ Å, $b = 19.41$ Å, and $c = 4.83$ Å (±0.5 %). The values agree well with those given by Cox [4]. The density is 1.627 g/cm³ and there are four molecules $C_5H_{10}O_5$ in the unit cell. The only systematic absences occur in the odd-order reflections $h00$, $0k0$ and $00l$, and the space group is therefore $P2_12_12_1$, as was also found by Cox [4].

The relative intensities were estimated visually from a series of Weissenberg photographs of the $hk0$ and $0kl$ zones. 93 of the 146 $hk0$ reflections and 100 of the 127 $0kl$ reflections accessible with Cu$K\alpha$ radiation were recorded with measurable intensity. The intensities were corrected for Lorentz and polarisation effects, but not for absorption, as small crystals of dimensions less than 0.2 mm were used. For the $0kl$ reflections a correction was also made for the "spot-shape" effect [5].

DETERMINATION OF THE STRUCTURE

Projections of the structure along the *c* and *a* axes were determined by Patterson projections, trial and error methods, the "multiplication rule", and

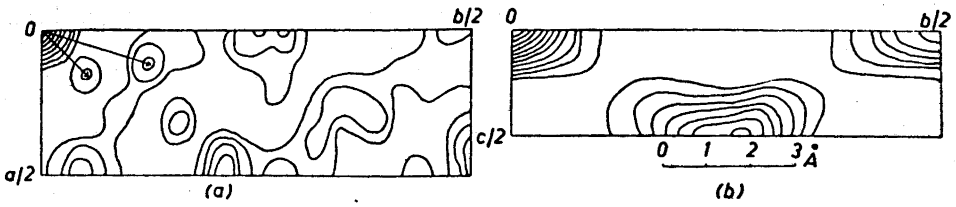

Fig. 1. Patterson projections on the (001) plane (a) and the (100) plane (b).

F_0 and $(F_0—F_c)$ refinement. As the *c* axis is the shortest one, this projection was first determined.

The c-projection. The Patterson synthesis is reproduced in Fig. 1a. The orientation of the six-membered ring could be derived from the two intramolecular vectors shown in the figure. Following the procedure described by Beevers [2], two possible positions of the centre of the ring were found, but attempts at further interpretation were not successful. A number of reasonable structures were then postulated by studying selected reflections by Bragg-Lipson charts. However, all attempts at Fourier refinement of these structures failed. It was then tried to deduce the signs of the strongest reflections by inequalities and the "multiplication rule" [6,7]. The intensities were put on an approximately absolute scale by Wilson's method [8]. The reflection 1,17,0 was found to have a unitary structure factor (U) as high as 0.68, and 26 reflections had unitary structure factors greater than 0.30. Negative signs were chosen for 1,17,0 and 4,11,0 ($U = 0.52$) and the signs of the reflections 240 ($U = 0.38$), 0,18,0 ($U = 0.55$), 2,17,0 ($U = 0.44$) and 3,12,0 ($U = 0.45$) were denoted by a, b, c and d, respectively. Only two additional signs could be deduced from simple inequality relations, but the "multiplication rule" led to the determination of the probable signs of 18 more structure factors in terms of the letter symbols. Furthermore, the relations d = b and bc = —a were strongly indicated. Twenty of the reflections could be divided in four groups whose signs were expressed by —1, a, c and ac, respectively. Six other strong reflections for which the signs were given in terms of b and ab, were not con-

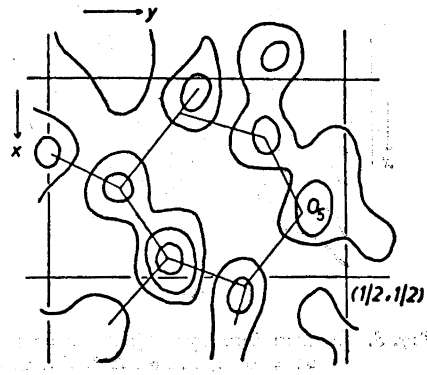

Fig. 2. The best electron density map obtained by permutation of the signs of groups of reflections. The postulated structure is shown.

sidered in order to limit the number of permutations. The Fourier synthesis of the reflections within each group was then calculated, and the electron density maps corresponding to the four possible combinations of the signs of the groups were derived. In one of the maps (Fig. 2) a six-membered ring was indicated, although not very clearly. Fourier refinement of a structure postulated on this basis led eventually to the correct structure. Three (F_0—F_c) refinements were also carried out. The final structure factors showed that two of the reflections used to calculate the map in Fig. 2 had the wrong sign, and that the values used for the unitary structure factors were about 35 % too high. The reliability factor $R = (\Sigma|F_0—F_c|)/\Sigma|F_0|$ is 0.18, and the corresponding electron density map is shown in Fig. 3a. The contributions from the hydrogen atoms were not included in the structure factors. The atomic scattering factors employed are those given by Berghuis *et al.*[9] A temperature factor exp. ($-3.5\sin^2\Theta/\lambda^2$) was used.

The a-projection. The Patterson synthesis (Fig. 1b) gave little information,

but confirmed that the "plane" of the molecule is nearly perpendicular to the *c*-axis. Approximate relative *z* coordinates were derived from the *c*-projection and known interatomic distances. The position of the molecule was deduced mainly by considering the possibilities for favourable hydrogen bond formation between neighbouring molecules. By Fourier and difference refinement satisfactory agreement between F_0 and F_c was finally obtained ($R = 0.16$). The electron density map is shown in Fig. 3b. In Table 1 the coordinates of the atoms are given.

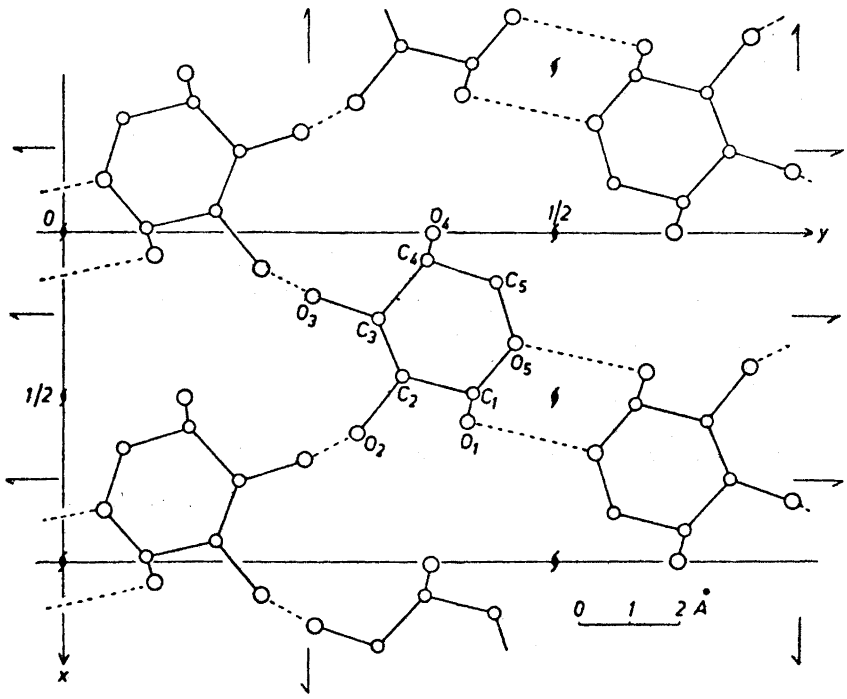

Fig. 5. The *c*-projection of the structure. Broken lines indicate hydrogen bonds.

DISCUSSION OF THE STRUCTURE

The electron density maps in Fig. 3 show that the molecule of β-arabinose has the structure given in Fig. 4. The ring has the staggered "chair" form, and the structure of the molecule is 1*a*2*e*3*e*4*a* (*a* = axial, *e* = equatorial). Thus β-arabinose has the "*cis*" configuration at atoms C_1 and C_2, as a study of its interaction with boric acid also indicates [10]. Its anomer α-arabinose consequently has the conformation 1*e*2*e*3*e*4*a* or 1*a*2*a*3*a*4*e*, probably the former.

The aim of the present investigation was to determine the molecular structure. Hydrogen atoms were neglected and the same temperature factor was used for all the atoms, although the $(F_0—F_c)$ synthesis indicates considerable differences. No great accuracy can therefore be claimed in the bond lengths and bond angles derived from the coordinates in Table 1. Values between 1.48 Å and 1.59 Å were found for the C—C bonds whereas the C—O bonds vary in length between 1.38 Å and 1.46 Å, in agreement with the expected values of 1.54 Å and 1.42 Å, respectively. As was found also for α-glucose and α-rhamnose [2,3], $C_1—O_1$ appears to be somewhat shorter than the other C—O bonds. Possibly this bond has some double bond character, a point which may be of considerable interest for the understanding of the reactions of pyranose sugars. The molecules are linked together by a system of hydrogen bonds, as shown in Fig. 5. The atoms O_1, O_2, O_3 and O_5 take part in hydrogen bonds of lengths between 2.65 Å and 2.75 Å. Surprisingly, the distance from O_4 to the nearest oxygen atom in a neighbouring molecule is as great as 3.0 Å. In order to decide whether or not this corresponds to a weak hydrogen bond, it would appear necessary to determine the position of the corresponding hydrogen atom.

A further refinement of the structure will be carried out by one of us.

The Composition of Ribonucleic Acids Isolated from Chloroplasts of *Lamium album* and *Symphytum officinale*

H. LEYON

Institute of Biochemistry, University of Uppsala, Sweden *

The purpose of this investigation was to analyze the nucleic acids of chloroplasts of some plant species to find, eventually, any indication of a species-specificity and of a difference between the RNA of the chloroplasts and that of the corresponding cytoplasm (microsomes).

Chloroplasts of *Lamium album* and *Symphytum officinale* were isolated and fragmented and these preparations were freed from protein by boiling at pH 8. The RNA of the solutions thus obtained was precipitated by means of acid ethanol and was purified by repeated redissolutions and precipitations in combination with centrifugations. After acid hydrolysis the preparations were analyzed quantitatively with respect to guanine, adenine, cytidylic and uridylic acids by means of paper chromatography and spectrophotometry in U.V.

Similar analyses were performed on preparations of sap of fragmented leaves freed from chloroplasts and nuclei.

The analytical data show a characteristic difference between *Lamium album* and *Symphytum officinale* with respect to the molar ratios of the components of the RNA of their chloroplasts. The data obtained for the chloroplasts also differed from those of the cytoplasm of the same species.

From data available by analytical techniques ribonucleic acid has been estimated to be present in chloroplasts and to form up to 2 % of their dry weight [2,3,5,6,10]. Histochemical techniques suggest that both DNA and RNA are to be found in chloroplasts [1,2,7]. There is some ambiguity, however, concerning the presence of DNA since highly polymerized RNA may be responsible for the colouring of the plastids by methyl green [4].

In purified preparations of chloroplasts no trace of DNA was detected but enough RNA could be obtained for analysis regarding its purine and pyrimidine bases.

* Present address: Klarinettgatan 15, *Järnbrott*, Sweden.

MATERIAL AND METHODS

In the autumn (September 1953) nucleoproteins were isolated from purified preparations of chloroplasts from several plant species. After treatment with acid ethanol most of this material was stored at —15°C for further investigations during the winter season. However, when this frozen material was investigated with respect to the composition of its RNA it was found that the material had obviously hydrolyzed and no reproducible data could be obtained. Thus the results reported here are from preliminary experiments made on fresh material immediately after the isolation of the chloroplasts.

Chloroplasts from different plants were found to vary considerably in their stability during the purification procedures. Species with the most stable chloroplasts were selected for further work. All preparative work was carried out in the cold room at about +4°C. Detached leaves were fragmented in a domestic mincing machine and the mass was pressed through cloth. The sap, about 700 ml from each preparation, was diluted immediately with 1/3 volume of 2 M sucrose solution. The suspension was freed from coarse material by filtration through a thin layer of glass wool and by a few minutes centrifugation at low speed. The sap was then centrifuged for 30 min at about 2 000 r. p. m. (radius approximately 10 cm). The green upper layers of the pellets were resuspended in about 50 volumes of cold 0.5 M sucrose solution and centrifuged until the supernatant liquid was clean. This washing was repeated once. During the purification samples were withdrawn occasionally for inspection under the microscope. In this way the chloroplast fragmentation process was observed carefully. Great care was taken to free the suspension from whole and fragmented nuclei. These were detected by the carmine-acetic acid method of Belling and Heitz [9]. It was found that nuclei could be removed by repeated washings and centrifugations as stated by Weier and Stocking [12] or by centrifugation of a chloroplast suspension superimposed on a 2 M sucrose solution in which case nuclei sedimented also through this concentrated solution of sucrose but most of the chloroplasts formed an intermediary layer above the layer of 2 M sucrose. Treatment with the ion exchange resin Amberlite IR 120 (Rohm & Haas, Philadelphia), also removed nuclei effectively.

To obtain an effective extraction of nucleoprotein from the chloroplasts it was found necessary to disintegrate the chloroplasts thoroughly. This was achieved by resuspending the pellet of purified chloroplasts in distilled water (about 30 ml per preparation) to which a few drops of xylene had been added and shaking with glass beads over night in the cold room. By ordinary microscopy and electron microscopy it was found that the fragmentation was very effective. Only small parts of chloroplasts could be seen in the electron micrographs.

The pH of the suspension was raised to 8 by adding some sodium hydroxide solution, traces of sodium chloride was also added after which the solution was kept in boiling water for 10 min. During this procedure there was a fall of pH of 0.4—0.8 units. The precipitate was removed by 45 min centrifugation. The clear supernatant fluid was diluted with an equal volume of ethanol and this mixture was acidified with HCl. The precipitated nucleic acid was sedimented in the centrifuge and then dissolved in distilled water to which a few drops of

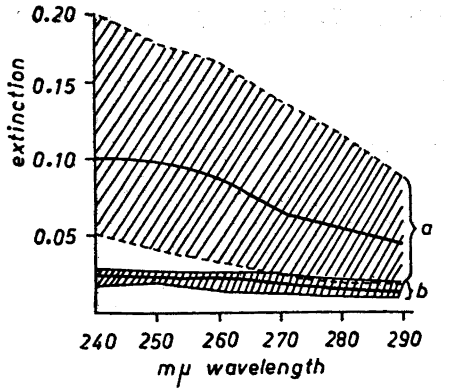

Fig. 1. Absorption in U.V. light of extracts from filter paper Whatman No. 1 before and after washing the paper with 0.1 N HCl. Circular pieces of the paper 2.5 cm in diameter were cut out and extracted each with 5 ml 0.1 N HCl. Heavy lines show average values of 10 measurements at each wave-length. The lined areas include all measurements; a) nontreated papers; b) papers washed in HCl and distilled water.

NaOH had been added. The solution was cleared by centrifugation for 1 h at 3 500 r. p. m. Such precipitation and redissolution of the nucleic acid was twice repeated. The preparation was then only slightly tinged with dark-coloured material.

The alcohol was evaporated from the precipitated nucleic acid in an evacuated vessel. 0.6 ml of 1 N HCl was added to 3 mg of the dry preparation and hydrolysis was performed at 100°C for 1 h. As shown by Smith and Markham [11] this hydrolysis gives guanine, adenine, and the nucleotides cytidylic acid and uridylic acid. The hydrolysis products were analyzed quantitatively by means of paper chromatography as recommended by Smith and Markham [11].

The paper was, however, first investigated with respect to its content of substances absorbing in ultraviolet light and extractable with 0.1 N HCl. For this purpose a series of 10 spots 2.5 cm in diameter were cut out from papers which had not been treated with any solvent. These paper samples were extracted with 5 ml 0.1 N HCl each for about 10 h and the absorption of the extracts in the ultraviolet region was measured. As shown in Fig. 1 the filter paper was rather heterogeneous with respect to its content of U.V.-absorbing material and could be freed from this material by washing with hydrochloric acid. Therefore papers to be used for chromatography were first treated with 0.1 N HCl over night and were then washed with water and dried.

Since a very acid solvent was used in the chromatographical analysis there would be an inherent tendency for the solvent front to remove most of the disturbing material from those areas of the paper where spots were located at the end of the run. However, the best results were obtained on papers which had been washed previously with hydrochloric acid and water.

A mixture which was 0.8 N with respect to HCl and contained 70 % by volume of *tert.* butanol, the remainder being water, was used as solvent during chromatography. Ascending fronts were run on paper Whatman No. 1 in glass vessels. Each spot contained 0.2 ml of the hydrolysate mentioned above. A length of flow of 20—25 cm was obtained after about 30 h at 18—20°C. The papers were dried at room temperature over a ventilating fan. By examining the fluorescence in ultraviolet light the spots could be located easily. The occupied parts of the paper were cut out and the hydrolysis products were extracted from these paper pieces by means of 0.1 N HCl over night in the cold

* Absorbancy coefficients according to Smith and Markham[11] and Ploeser and Loring[8] were used: guanine 10.6×10^3 at 250 mμ
adenine 13.0×10^3 „ 260 „
cytidylic acid 12.72×10^3 at 280 mμ
uridylic acid 9.89×10^3 „ 260 „.

room. The absorption in ultraviolet light of the four samples was measured in a Beckman spectrophotometer model DU against similar extracts of paper pieces cut out near the respective spots.

The R_F-values obtained for the four products were in good agreement with those reported by Smith and Markham and so were the wave-lengths of maximum absorption of the four curves.

In two separate runs the hydrolysate was investigated for amino acids by spraying with ninhydrin. No trace of amino acids was found.

Table 2. Composition of acid hydrolysates of ribonucleic acid from chloroplasts and the corresponding cytoplasms of *Lamium album* ans *Symphytum officinale.* Ratio of molar concentrations, adenine = 1.

Source of RNA	Guanine	Adenine	Cytidylic acid	Uridylic acid
L. album, chloropl.	1.30	1.00	1.00	0.67
L. album, cytopl.	1.17	1.00	0.75	0.35
S. officinale, chloropl.	1.26	1.00	0.76	0.65
S. officinale, cytopl.	1.43	1.00	0.85	0.55

RESULTS

In Table 1 values are collected from chromatograms of 3 preparations of nucleic acid isolated from chloroplasts of *Lamium album* and in Table 2 the molar ratios of guanine, adenine, cytidylic acid and uridylic acid in hydrolysates from nucleic acid preparations from chloroplasts and cytoplasm of *Lamium album* and *Symphytum officinale* are recorded.

There is a clear difference between the two kinds of chloroplasts with respect to cytidylic acid. There is also, within each species, a difference between the RNA from the chloroplasts and that from the cytoplasm. The values for the cytoplasmic RNA were obtained from only one analysis each, those for the chloroplasts represent average data each from three experiments (*cf.* Table 1).

Short Communications

Protein-bound Sialic Acids in Human, Hog and Horse Kidneys

ERIK MÅRTENSSON, AINO RAAL and LARS SVENNERHOLM

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

As part of an investigation of the protein-bound carbohydrates in mammalian kidneys, carried out by one of us (E.M.), the sialic acids were isolated from human, hog and horse kidneys. Blix *et al.*[1] have by the X-ray diagram pattern differentiated between four sialic acids, *viz.* ovine (N-acetylsialic acid), porcine (N-glycolylsialic acid), bovine and equine (N, O-diacetylsialic acid) sialic acids. All these acids were isolated from the submaxillary mucin of the animals. The procedure applied by Blix *et al.* is unsuitable for the isolation of sialic acids from organs with a low sialic acid content[2]. In such cases chromatography on anion exchange resins is to be preferred, but by this technique only N-acetylsialic acid and N-glycolylsialic acid can be isolated quantitatively as the labile O-acetyl group is partly split off in the course of the preparation. However, our main problem was to ascertain the possible occurrence of N-glycolylsialic acid, as at quantitative estimation it gives about 20 % higher molar absorbancy than N-acetylsialic acid and N,O-diacetylsialic acid[3,4]. The three species investigated were chosen because their submaxillary mucins contain different sialic acids.

Experimental. Materials. Human kidneys, from three young healthy persons killed by accidents, were removed as soon as possible after death (12—24 h) with intact blood vessels. The hog and horse kidneys were also dissected with intact vessels.

Isolation procedure. The kidneys were perfused with physiological saline through their renal artery until the perfusion solution was free from visible amounts of blood cells or pigments. Then the kidneys were homogenized in a Turmix blendor and extracted twice with four volumes of acetone at +4°C for 24 h. The remaining lipids were extracted with methanol-chloroform (2:1 v/v) in a Soxhlet apparatus for 24 h. The isolation of the sialic acids from the defatted kidney tissues was performed with the ion-exchange procedure earlier described[2]. The lyophilized sialic acids were rather impure and rechromatography on the resins was done as a routine. The yields of recrystallized sialic acids were 50—75 % (the lowest yield was obtained from horse kidney).

Identification. The specific optical rotation had the same value for the three specimens, $[\alpha]_D$ —31° ± 1. In paper partition chromatography[2] an elongated spot was given by hog and horse sialic acids, while the spot of the human acid was more round and distinct. The X-ray diffraction patterns (Fig. 1) of the sialic acids were all of the same type as the pattern of ovine sialic acid[1] (N-acetylsialic acid). No lines of the porcine sialic acid pattern were indicated. The determination of glycolic acid, performed according to Klenk and Uhlenbruck[5], showed that the human sialic acid contained no glycolic acid, while the other two contained about 3 % of glycolic acid (Table 1).

Discussion. Although the X-ray diffraction patterns only showed the occurrence of N-acetylsialic acid, the acids from hog

Table 1. Determination of glycolic acid in sialic acids.

Source of sialic acid	Glycolic acid, %	Calc. amount of N-glycolylsialic acid, %
Human kidney	0.1	0
Hog kidney	3.2	14
Horse kidney	2.6	11
Human serum	0.1	0
Hog submaxillary mucin	20.9	90

Fig. 1. X-Ray diffraction patterns of sialic acids isolated from (a) human, (b) hog and (c) horse kidneys.

and horse kidneys contained appreciable amounts of glycolic acid. The diversity of the results might be explained either by some unspecificity of the glycolic acid method or by lacking sensitivity of the X-ray method for rather large admixtures of a second sialic acid.

The first alternative seems rather unlikely as no glycolic acid could be indicated in sialic acids from human sources. The sialic acid isolated from hog submaxillary mucin contained 90 % of the theoretical value for N-glycolylsialic acid. In the resorcinol method [4] the sialic acids from hog and horse kidneys had some per cent higher molar absorbancy indices than our standard sample of N-acetylsialic acid. That is also a support of the occurrence of N-glycolylsialic acid, as the latter has about 20 % greater molar absorbancy index than N-acetylsialic acid.

Regarding the second alternative it might be possible that N-glycolylsialic acid is built into the crystal lattice of N-acetylsialic acid, as the two sialic acids only differ by the substitution of a hydrogen atom in the acetic acid moiety of N-acetylsialic acid with a hydroxyl group. We have also evidence that N-acetylsialic acid can be built into the crystal lattice of N-glycolylsialic acid. In a preparation of sialic acid from beef serum N-acetylsialic acid made out 60 % and N-glycolylsialic acid 40 %. The X-ray diffraction pattern was the same as that of porcine sialic acid (N-glycolylsialic acid). This may appear puzzling as the amount of N-glycolylsialic acid is lower than that of N-acetylsialic acid, but might be explained by the lower solubility of N-glycolylsialic acid.

Conclusion. The sialic acids from human, hog and horse kidneys were isolated. X-Ray diffraction patterns showed N-acetylsialic acid only, but the estimation of glycolic acid demonstrated that hog and horse sialic acids also contained N-glycolylsialic acid. It is concluded that the X-ray diffraction pattern is unsuitable as a criterion of the uniformity of a sialic acid.

Acknowledgement. The authors are indebted to Dr. S. Abrahamson, Kemiska Institutionen, Uppsala, for performing the X-ray diagrams.

Note on the Crystal Structure of Trititanium Pentoxide

STIG ÅSBRINK and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The crystal structure of trititanium pentoxide has been determined from single-crystal X-ray data using Fourier techniques. The oxide specimen was prepared by melting an appropriate mixture of titanium metal and titanium dioxide (both better than 99.97 % pure) in an electric arc furnace under argon atmosphere and subsequent annealing of the crushed sample for two weeks at 1 150°C in a sealed, evacuated silica tube. In this way black, prismatic crystals several hundredths of a millimeter in length were obtained. The composition of the sample after the heat-treatment was found to be $TiO_{1.667}$ (calculated for Ti_3O_5: $TiO_{1.667}$). Powder photographs of samples quenched in the electric arc furnace and of those annealed at 1 150°C were identical.

The following data were obtained for the monoclinic structure:

Unit cell dimensions (from Guinier powder photographs taken with Cu$K\alpha_1$ radiation using potassium chloride (a = 6.292 Å) as an internal standard)

a = 9.757 Å, b = 3.802 Å, c = 9.452 Å, β = 93°.11

Cell content: 4 Ti_3O_5 (observed density 4.20, calculated density 4.24).

Space-group: $C2/m$ (No. 12)

Arrangement of atoms: All atoms occupy four-fold positions 4(i):
(000, $\frac{1}{2}\frac{1}{2}$0) + x0z, $\bar{x}$0$\bar{z}$

4 Ti_1 with x = 0.129, z = 0.043
4 Ti_2 with x = 0.280, z = 0.268
4 Ti_3 with x = 0.053, z = 0.366
4 O_1 with x = 0.187, z = 0.063
4 O_2 with x = 0.236, z = 0.239
4 O_3 with x = 0.095, z = 0.337
4 O_4 with x = 0.454, z = 0.161
4 O_5 with x = 0.371, z = 0.442

The quotient $\Sigma||T_o|-|T_c||/\Sigma|T_o|$ is 0.14 (calculated for all reflexions $h0l$, $h1l$ and $h2l$ registered with Cu$K\alpha$ radiation).

Interatomic distances:
Ti—O 1.78—2.21 Å
O—O 2.55—3.25 Å

The structure is illustrated in Fig. 1. The titanium atoms are indicated by

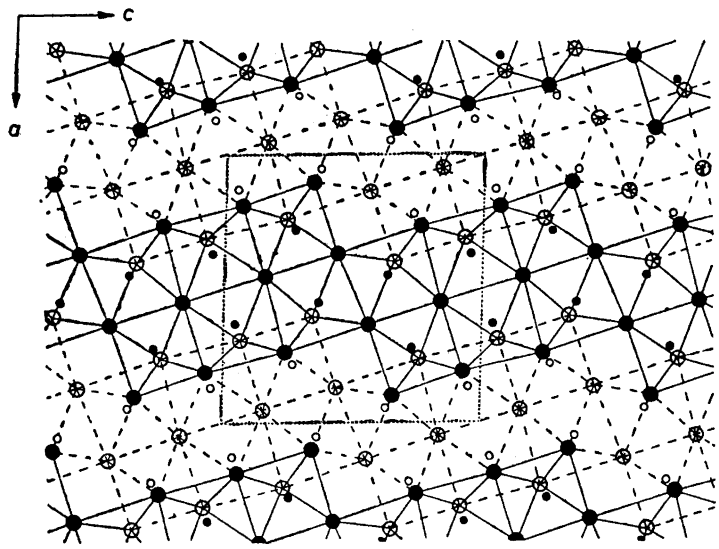

Fig. 1.

smaller rings and the oxygen atoms by larger ones. Open and filled circles represent atoms at $y = 0$ and $y = \frac{1}{2}$, respectively. The extension of the unit mesh is indicated by dotted lines. The titanium atoms are surrounded by six oxygen atoms to form TiO_6 octahedra which are joined by edges and corners. The coupling together of the octahedra is different from that found in anosovite (pseudobrookite structure) by Zhdanov and Rusakov [1]. Studies on the $(Ti_{1-x}, Fe_x)_3O_5$ system have shown the pseudobrookite-type structure to be present even at rather low contents of iron ($x < 0.05$)[2]. Further studies on the relationships between the Ti_3O_5 structure found in this investigation and the anosovite structure are in progress.

Full details on this investigation and a discussion of the structure will be given elsewhere.

This investigation forms part of a research programme on metal oxides and related compounds financially supported by the *Swedish Natural Science Research Council.*

The Selenium Analogue of 6-Thioctic Acid

GÖRAN BERGSON

Chemical Institute, University of Uppsala, Sweden

In connection with preparative and physico-chemical studies on organic disulphides and diselenides [1], particularly cyclic molecules [2], the author started a synthesis of the selenium analogue of 6-thioctic acid (α-lipoic acid) some months ago. The new acid (I), for which the name 6-selenoctic acid is proposed, has now been obtained in crystalline form, and investigations of its chemical and biochemical properties are in progress.

(I)

The primary aim of this investigation was twofold. First one could expect the 5-membered ring in 6-selenoctic acid to be more stable than the unsubstituted 1,2-diselena*cyclo*pentane, because it is known that substituents stabilize strained rings. Secondly, 6-selenoctic acid might possess interesting biological properties because of its similarity to 6-thioctic acid. When the present investigation was in progress, Schwarz and Foltz [3] reported the very remarkable discovery of a selenium-containing factor in casein and yeast. This factor ("factor 3") has been known for some years to be active against dietary necrotic liver degeneration and other diseases [3,4], but only recently Schwarz and Foltz showed that the biological action was connected with a low molecular weight organic selenium compound of unknown structure. Since pyruvic acid and lactic acid are accumulated in the blood of factor 3 deficient animals it seems possible to the present author that factor 3 is a cofactor in the oxidative decarboxylation of pyruvic acid. It is not impossible that 6-selenoctic acid might act as such a cofactor like 6-thioctic acid, and the hypothesis might be advanced that factor 3 is identical with or related to 6-selenoctic acid.

6-Selenoctic acid has been prepared in a way analogous to that used by Reed and

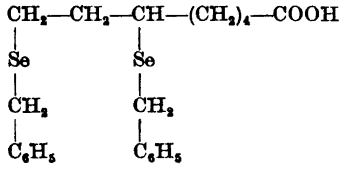
The Selenium Analogue of 6-Thioctic Acid

GÖRAN BERGSON

Chemical Institute, University of Uppsala, Sweden

In connection with preparative and physico-chemical studies on organic disulphides and diselenides [1], particularly cyclic molecules [2], the author started a synthesis of the selenium analogue of 6-thioctic acid (α-lipoic acid) some months ago. The new acid (I), for which the name 6-selenoctic acid is proposed, has now been obtained in crystalline form, and investigations of its chemical and biochemical properties are in progress.



(I)

The primary aim of this investigation was twofold. First one could expect the 5-membered ring in 6-selenoctic acid to be more stable than the unsubstituted 1,2-diselena*cyclo*pentane, because it is known that substituents stabilize strained rings. Secondly, 6-selenoctic acid might possess interesting biological properties because of its similarity to 6-thioctic acid. When the present investigation was in progress, Schwarz and Foltz [3] reported the very remarkable discovery of a selenium-containing factor in casein and yeast. This factor ("factor 3") has been known for some years to be active against dietary necrotic liver degeneration and other diseases [3,4], but only recently Schwarz and Foltz showed that the biological action was connected with a low molecular weight organic selenium compound of unknown structure. Since pyruvic acid and lactic acid are accumulated in the blood of factor 3 deficient animals it seems possible to the present author that factor 3 is a cofactor in the oxidative decarboxylation of pyruvic acid. It is not impossible that 6-selenoctic acid might act as such a cofactor like 6-thioctic acid, and the hypothesis might be advanced that factor 3 is identical with or related to 6-selenoctic acid.

6-Selenoctic acid has been prepared in a way analogous to that used by Reed and

Ching-I Niu [5] in the preparation of 6-thioctic acid. Ethyl 6,8-dichlorooctanoate was allowed to react with the sodium salt of benzylselenol in absolute alcoholic solution, after which the ester was saponified and 6,8-dibenzylselenoloctanoic acid (II) isolated. This acid was treated with sodium

(II)

in liquid ammonia, and the product oxidized with air. From the reaction mixture 6-selenoctic acid was isolated. It consists of brownish-red crystals melting at 88—90.5°. The UV-absorption of 6-selenoctic acid has a maximum at 440 mμ. This is a good proof for the existence of the 5-membered ring and it shows that the substance is monomer [2]. The IR-absorption in the region 2—15 μ has been recorded and it is in accord with formula I. The molecular weight as determined by the Rast camphor method is 326 (calc. 300).

Experimental: 6,8-Dibenzylselenoloctanoic acid (II). 1.56 g of sodium is dissolved in 50 ml of abs. ethanol and 11.59 g of benzylselenol and 8.17 g of ethyl 6,8-dichlorooctanoate [5] is added. The mixture is stirred and refluxed in nitrogen atm. for 5 h. After cooling to room temperature 3.80 g of potassium hydroxide is added, and the mixture stirred at room temperature for 20 h. The reaction mixture is poured into 175 ml of water, acidified with 6 N HCl, and the product extracted with 2 × 50 ml ether. The combined etherial extracts are dried with sodium sulphate and the ether removed in vacuum. The crude acid solidifies at room temperature. It can be purified by dissolving it in a mixture of ether and petroleum ether and allowing the ether to evaporate slowly. In this way a fine crystalline almost white powder was obtained. Melting point 54—57°. (Equiv. wt: Found 477; calc. 482. % Se: Found 33.0; calc. 32.8).

6-Selenoctic acid (I): 0.35 g of sodium was dissolved in about 50 ml of liquid ammonia and 2.41 g (0.005 mole) of II in 10 ml toluene was added dropwise. A little more sodium was added to complete the reaction, and the ammonia was allowed to evaporate slowly. The residue was extracted with 70 ml of water, and the pH of this solution was adjusted to 7—8. A trace of $FeCl_3$ was added and a rapid stream of air passed through the solution. When excess hydrochloric acid was added a dark oil separated which was taken up in 50 ml of chloroform. The extract was dried with sodium sulphate, and when the solvent was removed in vacuum the crude 6-selenoctic acid solidified. The substance was purified by recrystallization from *n*-hexane, which gave a dark brownish-red crystalline powder m.p. 87—90°. (Equiv.wt: Found 298; calc. 300. Mol. wt: Found 326; calc. 300. % Se: Found 51.9; calc. 52.6).

A small sample was recrystallized again from *n*-hexane. The product consisted of brownish-red crystal flakes, m.p. 88—90.5°. The exact yield of the syntheses described above cannot be specified at present, but it exceeds 50 %.

I wish to express my gratitude to Professor Arne Fredga for his stimulating interest and much helpful advice. I am also indebted to Dr. Lennart Schotte for many important discussions and for his kind interest in this work. Optically Active α-(2-Naphthyl)-ethylamine as Resolving Base

ARNE FREDGA, BERNDT SJÖBERG and RUNE SANDBERG

Chemical Institute, University of Uppsala, Uppsala, Sweden

The number of bases available for optical resolution of racemic acids is rather restricted. To be suitable for this purpose, a base must be optically active, chemically stable and not too expensive. In addition, its salts must have good crystallisation properties. About ten commercially available natural alkaloids fulfil these conditions. A few synthetic bases, *e. g.* α-phenylethylamine and α-phenyl*iso*propylamine [1] (benzedrine), for which both antipodes are available, have also been used with good success. In recent years, quaternary alkaloid salts [2] and *iso*thiuronium salts [3] have been recommended, especially for weak acids. The purpose of this paper is to draw attention to α-(1-naphthyl)-ethylamine and α-(2-naphthyl)-ethylamine, especially to the latter compound.

The synthesis and resolution of these bases were first described by Samuelsson in 1923 [4]. The preparation of the methyl naphthyl ketones used as starting materials was, however, very tedious in those days and to our knowledge the amines have not found practical use for stereochemical purposes. For some years the ketones have been commercially available and the optically active bases are now as easily accessible as the active phenylethylamines. The salts of the 2-naphthyl derivative especially crystallise very readily and we have found this base suitable for the resolution of several acids, *e. g.* terpenylic acid and α-(2-thianaphthenyl)-propionic acid. For the resolution of the latter acid, ten different bases were tried but only α-(2-naphthyl)-ethylamine yielded the levorotatory acid [5]. In the case of terpenylic acid, this amine had far better resolving power than any other base tried [6].

The resolution of the racemic α-(2-naphthyl)-ethylamine was carried out according to the method of Samuelsson. We have found, however, that a slight modification in the amount of solvent is advisable to ensure the best resolution. A brief description is given here; for details the original paper of Samuelsson should be consulted.

Experimental. Racemic α-(2-naphthyl)-ethylamine was prepared according to Organic Reactions [7].

Resolution. A mixture of 128.4 g (0.075 mole) of the racemic amine and 112.6 g (0.075 mole) of tartaric acid is dissolved in 5.0 l of hot water. After standing at room temperature over-night, the crystals are filtered off. This procedure gives about 120 g salt of the (+)-amine. The base is liberated with dilute sodium hydroxide and taken up in ether. The ether solution is transferred to a 5-l beaker and 95 ml (0.19 mole) of 2 M sulphuric acid is added with vigorous stirring. The salt obtained is recrystallised twice from the necessary amount of boiling water, yielding the sulphate of the pure (+)-amine with the composition $(C_{12}H_{13}N)_2 \cdot H_2SO_4 \cdot 2H_2O$ and the m. p. 261—263°.

From the mother liquor after the first crystallisation of the tartrate the partially resolved (—)-amine is liberated and treated in the same way.

The yield of each antipode is 50—60 % of the theoretical.

The amines are best stored as sulphates. The free bases have the m. p. 53° and $[\alpha]_D = \pm 19°$ (in ethanol solution).

Inhibition of *Lactobacillus leichmannii* 313 by Purine Nucleotides

ARNE E. BOLINDER

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Plate assays for vitamin B_{12}-factors, deoxyribosides, and deoxyribotides as well as bioautography of these growth factors have been carried out in this laboratory using *Lactobacillus leichmannii* 313 ATCC 7830 as the test organism [1,2]. This paper deals with the growth inhibitory activity of several purine nucleotides, notably adenine ribotides, in the *Lb. leichm.* 313 cup plate assay for vitamin B_{12}, deoxyribosides, and deoxyribotides. A report is also given on the usefullness of *Lb. leichm.* 313 for the cup plate assay and bioautography of the growth inhibitory purine nucleotides.

Large plates were used, each containing 150 ml of agar medium inoculated with *Lactobacillus leichmannii* 313 ATCC 7830. The media contained high concentrations of vitamin B_{12}, deoxyribosides, or deoxyribotides, in order to obtain heavy growth in the plates and thereby give a more pronounced appearance of growth inhibition. For the cup plate assays, 0.03 ml aliquots of the test solutions were pipetted into cups, 6 mm in diameter and the plates were incubated over night at 37° C. A detailed report of the preparation of these plates will be published later in this journal.

A series of plate experiments were first made, using *Lb. leichm.* 313 in two types of media which contained: 1) 150 mμg of vitamin B_{12} and 2) 150 μg of thymidine per plate. When tested in the cup plate assay the following purine nucleotides formed clear (or almost clear) inhibition zones: AMP-3'*, adenylic acid (mixture of AMP-2' and AMP-3'), AMP-c2'3' [b], AMP 5' [b], DAMP-5' [c], IMP-5' [d].

Table 1. The inhibitory activity of purine nucleotides in *Lb. leichmannii* 313 ATCC 7830 plates with media containing either vitamin B_{12} (150 mμg per plate) or thymidine (150 μg per plate).

Compound tested	Concentration μg/ml	Inhibition zone diameter in mm [a] *Lb. leichm.* 313 medium containing: Vit. B_{12}	Thymidine
AMP-3' [b]	10	12.0	12.0
	30	14.7	14.8
	100	18.0	18.0
	300	21.5	21.3
	500	23.2	23.0
Adenylic acid [b] (mixture of AMP-2' and AMP-3')	30	13.0	13.3
	100	16.0	16.4
	300	19.0	19.3
	1 000	23.2	23.2
AMP-c2'3' [b]	30	14.0	14.2
	100	17.0	17.2
	300	20.0	20.7
	1 000	25.0	24.8
AMP 5' [b]	10	12.3	13.2

IMP-5' [d]	30	12.7	12.5
	100	14.4	14.0
	300	15.7	15.6
	1 000	16.9	17.2

[a] Each figure for the inhibition zone diameter represents the average reading obtained from twelve cups, evenly distributed in three plates.

[b] Forms sharp edged and completely clear inhibition zones.

[c] Forms well defined and almost clear inhibition zones.

[d] Forms somewhat fainter inhibition zones than those formed by DAMP-5'.

* The following abbreviations are used in this paper: AMP-2', AMP-3' and AMP-c2'3' for the 2'-, 3'-, and the cyclic 2'3'-monophosphates of adenosine; AMP-5', DAMP-5', IMP-5', GMP-5', and DGMP-5' for the 5'-monophosphates of adenosine, deoxyadenosine, inosine, guanosine, and deoxyguanosine; ADP, IDP, ATP, and ITP for the 5'-di- and -tri-phosphates of adenosine and inosine.

and AMP-3′), AMP-c2′3′, AMP-5′, DAMP-5′, and IMP-5′. The sizes of the inhibition zones formed by these compounds are given in Table 1. Bioautography using five different solvent systems showed that the UV-absorbing spot of each of AMP-3′, AMP-c2′3′, AMP-5′, DAMP-5′, and IMP-5′ always corresponded to the growth inhibition spot. Bioautography of adenylic acid revealed that its growth inhibitory activity was due only to AMP-3′; AMP-2′ was inactive.

Very faint and diffuse inhibition zones were formed by DGMP-5′, GMP-5′, and guanylic acid (mixture of the 2- and 3′-phosphates) when these compounds were tested in high concentrations.

When high concentrations of AMP-2′ and ADP were tested in the *Lb. leichm.* 313 plates small inhibition zones were formed, but bioautography revealed that these growth inhibitory effects were due to trace contamination by AMP-3′ and AMP-5′, resp. Similarly the low inhibitory activity of high concentrations of IDP and ITP were probably due to trace contamination by IMP-5′.

No inhibition zones could be detected in the plates when the following compounds were tested separately at concentrations of 1 mg/ml: (a) the ribosides of cytosine, uracil, adenine, guanine, xanthine, and hypoxanthine, (b) uridylic acid and cytidylic acid (mixtures of the 2′- and 3′-phosphates), (c) the 2′- and the 3′-phosphates of cytidine, (d) the 5′-phosphates of uridine and cytidine, (e) the cyclic 2′3′-phosphates of uridine and cytidine, (f) ATP, and (g) yeast nucleic acid (also tested in 10 mg/ml).

As can be seen from Table 1, the two types of *Lb. leichm.* 313 plates gave almost the same size of inhibition zones for each of the strongly growth-inhibitory purine nucleotides. The straight-line relationship between the logarithm of the concentration of the test solutions in the cups and the mean zone diameter normally found in cup plate assays, was obtained for all these compounds. Already after 3—4 h of incubation at 37° C the inhibition zones produced by the purine nucleotides could be seen against the faint background growth in the *Lb. leichm.* 313 plates. These inhibition zones were almost the same size as those formed after the routine incubation time of 16—18 h, when heavy background growth was obtained in the plates. Prolonged incubation of the plates to 48 h did not have any influence on the inhibition zones already formed.

Using these *Lb. leichm.* 313 plates as little as 0.1 μg of either AMP-3′, AMP-c2′3′, or AMP-5′, or 0.5 μg of DAMP-5′ could be detected bioautographically, whereas about 2—3 μg was required for the detection of these compounds by inspection in UV-light. Only amounts larger than 1 μg of IMP-5′ could be detected bioautographically.

In another series of inhibition experiments *Lb. leichm.* 313 plates were made using media containing 150 μg per plate of one of the following nine compounds: deoxyadenosine, DAMP-5′*, deoxyguanosine, DGMP-5′, deoxyinosine, deoxycytidine, deoxycytidylic acid, deoxyuridine, and thymidylic acid. In all these nine different plates the same inhibition patterns for the purine nucleotides were observed as for the two types of plates previously used in which the media contained either vitamin B_{12} or thymidine.

Turbidimetric tube tests with *Lb. leichm.* 313 showed that only early growth of this organism was inhibited by the adenine ribotides. Merely prolonged incubation was sufficient to overcome growth inhibition, in contrast to the plate tests mentioned above.

Inhibition experiments were also made with *Lactobacillus leichmannii* 327 ATCC 7831 plates containing vitamin B_{12} 150 mμg, thymidine 150 μg, or thymidylic acid 150 μg per plate. The same inhibition pattern for the adenine nucleotides was obtained as in the *Lb. leichm.* 313 plates. However, no inhibition zones were formed by IMP-5′ in the *Lb. leichm.* 327 plates.

Some additional inhibition plate experiments were made with other test organisms. However, none of the purine nucleotides which were found to be inhibitory in the plate tests with the two *Lb. leichm.* strains had any inhibitory effect on the growth of the following organisms: *Thermobacterium acidophilus* R-26 ATCC 11506, (grown with large amounts of thymidine or thymidylic acid), *Escherichia coli* 113—3 ATCC 1105 (grown with large quantities of vitamin B_{12} or methionine),

* At the low concentration of 1 μg/ml in the plate medium, DAMP-5′ showed only growth promoting activity. When tested at concentrations of 10 μg/ml and above, DAMP-5′ formed inhibition zones in the cup plate assay.

Streptococcus faecalis ATCC 8043 (grown with large amounts of folic acid or thymidine), and *Pediococcus cerevisiae (Leuconostoc citrovorum)* ATCC 8081 (grown in a high concentration of folinic acid or thymidine).

Some earlier reports in the literature have dealt with the growth inhibitory activity of adenylic acids on certain vitamin B_{12} requiring lactobacilli. Using tube assay procedures Skeggs *et al.* have studied this effect on *Lb. acidophilus (Lb. bifidus)* ATCC 4963 [3-5] and on *Lb. leichm.* 326 ATCC 4797 [6]. The specific growth inhibitory activity of several purine nucleotides in the *Lb. leichm.* 313 plate assay for vitamin B_{12}, deoxyribosides, and deoxyribotides as observed here, needs further investigation before any conclusions can be drawn concerning the mechanism of these inhibitions.

Several of the nucleotides were kindly supplied by Dr. P. Reichard, Karolinska Institutet, Stockholm.

N-Substituted Alkyltriaminosilanes

I. On the Reaction of *n*-Propyltrichlorosilane with Primary and Secondary Amines

LEWI TANSJÖ

Department of Organic Chemistry, University of Lund, Lund, Sweden

As a part of an investigation on aminosilanes the synthesis of N-substituted *n*-propyltriaminosilanes from *n*-propyltrichlorosilane and various primary and secondary amines was studied.

Observations were made which indicate a probable influence by the steric and electric properties of the amines on the reaction between *n*-propyltrichlorosilane and amines.

The preparation of thirty compounds which have not earlier been reported in the literature is described.

During the last ten years a great number of organosilicon compounds in which silicon is bound to one or more amino-nitrogen atoms have been described in the literature. Among these, however, there are only a few [1-3] with three silicon-nitrogen bonds and one silicon-carbon bond. In this work there will be reported the synthesis of some new aminosilanes of this type, containing the trifunctional silicon group n-$C_3H_7Si{\equiv}$.

It is well known that the silicon-chlorine bond reacts readily with ammonia and primary and secondary amines. If all the chlorine atoms in *n*-propyltrichlorosilane are exchanged, the reaction in the case of a primary amine takes part according to the formula

$$n\text{-}C_3H_7SiCl_3 + 6\ RNH_2 \rightarrow n\text{-}C_3H_7Si(NHR)_3 + 3\ RNH_3Cl \qquad (A)$$

Amine hydrochlorides containing silicon were not obtained, and tertiary amines (trimethylamine, triethylamine, and pyridine) did not react with *n*-propyltrichlorosilane to give quaternary salts. Nor did they under the conditions employed give addition compounds, n-$C_3H_7SiCl_3{:}xR_3N$, of the type which was proposed by Trost [4] to be formed between silicon tetrachloride and tertiary amines.

When *n*-propyltrichlorosilane in ether or benzene solution reacted with an amine with a small R-group, the above reaction proceeded rapidly with

evolution of considerable heat, giving the calculated amount of hydrochloride which could be filtered from the reaction mixture.

However, when an ether or benzene solution of *n*-propyltrichlorosilane was added to an excess of *tert.*-butylamine or diethylamine in ether or benzene, only two chlorine atoms — and in the case of di-*iso*propylamine or di-*cyclo*hexylamine only one chlorine atom — were replaced even after several hours at the boiling point of the reaction mixture. Even on prolonged heating of the compounds in a steel-bomb at 160°C, with excess of amine, no more amine hydrochloride was formed. This illustrates the great resistance against further replacement of chlorine atoms. It is most likely due to the steric effects of the bulky groups in these amines, since the residual chlorine atoms reacted readily with ammonia and after refluxing even with *iso*propylamine.

Aniline gave after refluxing for some hours in benzene or ether solution complete reaction with the chlorine in *n*-propyltrichlorosilane, but it did not react so readily as *cyclo*hexylamine, thus indicating that not only the size but also the electric properties of the amine influences reaction (A). The fact that N-methylaniline in ether or benzene reacted even with the second chlorine atom only to a small extent then may be explained as a result of both the steric properties and the low base strength of N-methylaniline as compared to aliphatic amines. The influence of the electric properties of the amine on reaction (A) is also supported by the fact that diphenylamine did not react at all with *n*-propyltrichlorosilane at room temperature, while di-*iso*propylamine and di-*cyclo*hexylamine under the same conditions readily reacted with one of the chlorine atoms. This is in agreement with observations made on the reaction of silicon tetrachloride with diphenylamine and di-*iso*propylamine [5].

It is interesting to note that while diethylamine reacted with only two chlorine atoms in *n*-propyltrichlorosilane even after prolonged heating in benzene solution, piperidine after refluxing for about 5 h in the same solvent gave total replacement. This difference in behaviour between these two amines can hardly be explained by the small difference in base strength (for piperidine $K_b = 16 \times 10^{-4}$ at 25°C, and for diethylamine $K_b = 12.6 \times 10^{-4}$ at 25°C). It may, however, be caused by the difference in free rotation around the carbon-nitrogen bonds: in diethylamine the free rotation is not hindered, but in the case of piperidine it is prevented because of the ring structure of this amine. This difference must obviously diminish the steric requirement of piperidino groups as compared to that of diethylamino groups. The observed difference between the reactivity of diethylamine and piperidine is in full analogy with the fact that diethylamine in benzene solution reacted with only three chlorine atoms in silicon tetrachloride, while piperidine gave total replacement [6].

*Cyclo*hexylamine reacted more readily than *sec.*-butylamine with *n*-propyltrichlorosilane. This difference may be explained as a result of the difference in free rotation around the carbon-carbon bonds in these amines, but, of course, the difference in this case was much less.

The following compounds have been prepared (the Arabic figures refer to the numbering in the experimental part):

I	(1)	n-$C_3H_7Si(NHCH_3)_3$
II	(2)	n-$C_3H_7Si[N(CH_3)_2]_3$
III	(3)	n-$C_3H_7Si(NHC_2H_5)_3$
IV	(4)	n-$C_3H_7Si(NHC_3H_7\text{-}n)_3$
V	(5)	n-$C_3H_7Si(NHC_3H_7\text{-}i)_3$
VI	(6)	n-$C_3H_7Si(NHC_4H_9\text{-}n)_3$
VII	(7)	n-$C_3H_7Si(NHC_4H_9\text{-}i)_3$
VIII	(8)	n-$C_3H_7Si(NHC_4H_9\text{-}s)_3$
IX	(9)	n-$C_3H_7Si(NHC_6H_{11})_3$
X	(10)	n-$C_3H_7Si(NHC_6H_5)_3$
XI	(11)	n-$C_3H_7Si[N(CH_2)_5]_3$
XII	(13)	n $C_3H_7Si(NHC_4H_9\text{-}t)_2NH_2$
XIII	(14)	n-$C_3H_7Si(NHC_4H_9\text{-}t)_2(NHC_2H_5)$
XIV	(15)	n-$C_3H_7Si(NHC_4H_9\text{-}t)_2(NHC_3H_7\text{-}i)$
XV	(19)	n-$C_3H_7Si[N(C_2H_5)_2]_2NH_2$
XVI	(20)	n-$C_3H_7Si[N(C_2H_5)_2]_2(NHC_3H_7\text{-}i)$
XVII	(31)	n-$C_3H_7Si[N(CH_3)(C_6H_5)]_2(NHC_3H_7\text{-}i)$
XVIII	(17)	n-$C_3H_7Si(NHC_4H_9\text{-}t)(NHC_3H_7\text{-}i)_2$
XIX	(22)	n-$C_3H_7Si[N(C_2H_5)_2](NHC_3H_7\text{-}i)_2$
XX	(24)	n-$C_3H_7Si[N(C_3H_7\text{-}i)_2](NHC_3H_7\text{-}i)_2$
XXI	(26)	n-$C_3H_7Si[N(C_6H_{11})_2](NHC_3H_7\text{-}i)_2$
XXII	(29)	n-$C_3H_7Si[N(CH_3)(C_6H_5)](NHC_3H_7\text{-}i)_2$
XXIII	(12)	n-$C_3H_7Si(NHC_4H_9\text{-}t)_2Cl$
XXIV	(18)	n-$C_3H_7Si[N(C_2H_5)_2]_2Cl$
XXV	(30)	n-$C_3H_7Si[N(CH_3)(C_6H_5)]_2Cl$
XXVI	(16)	n-$C_3H_7Si(NHC_4H_9\text{-}t)Cl_2$
XXVII	(21)	n-$C_3H_7Si[N(C_2H_5)_2]Cl_2$
XXVIII	(23)	n-$C_3H_7Si[N(C_3H_7\text{-}i)_2]Cl_2$
XXIX	(25)	n-$C_3H_7Si[N(C_6H_{11})_2]Cl_2$
XXX	(28)	n-$C_3H_7Si[N(CH_3)(C_6H_5)]Cl_2$

The assigned structural formulas for these compounds have been based on the way of the syntheses (amount of amine hydrochloride formed), and the silicon content and neutralization equivalents have been determined to confirm the composition of the expected compounds.

The prepared compounds are all colourless, water-insoluble liquids, soluble in organic solvents. Some of their reactions will be described in a later part of this work. Physical constants and analyses are given in Tables 1 and 2.

The author wishes to thank Professor E. Larsson for his kind interest in this work.

EXPERIMENTAL

The n-propyltrichlorosilane used for the syntheses was a sample of technical grade from Hopkins and Williams Ltd., England, which was fractionated before use (B.p. 123°C).

All experiments were performed with carefully dried reagents and solvents and precautions were taken to exclude moisture from the reaction vessels.

The aminosilanes were distilled at reduced pressure in a glass-helix packed column of a length of 15 cm.

Analyses

Silicon analyses were performed according to Smith [7].

The equivalent weights of the compounds containing three aliphatic or alicyclic amino groups could be determined by direct titration with standard hydrochloric acid using methyl red as the indicator, if a weighed sample was dissolved in a water-alcohol mixture

Table 1. Physical constants and analyses of compounds with three silicon-nitrogen bonds.

a) *In non-aqueous medium*

containing sufficient alcohol to give a homogeneous system throughout the titration (about 25 ml 96 % alcohol were used for 10 ml 0.1 N hydrochloric acid). With considerably less alcohol the solution became turbid during the titration and too high an equivalent weight resulted. In such a case an excess of hydrochloric acid had to be added and after digesting for several hours back-titration with standard base gave the expected equivalent weight, *i.e.*, $M/3$ (M = molecular weight).

In an analogous way compounds of the types n-$C_3H_7Si(NHR)_2Cl$ and n-$C_3H_7Si(NHR)Cl_2$ gave equivalent weights = M, the first type with standard hydrochloric acid and the second type with standard base.

For the trianilino compound (X) a titration in a non-aqueous solvent had to be used. A weighed sample was dissolved in glacial acetic acid and titrated with standard perchloric acid in glacial acetic acid using methyl violet (violet to blue green) as the indicator giving an equivalent weight = $M/3$.

Compounds with aromatic amino groups and unexchanged chlorine atoms (XXV and XXX) were titrated in water. After agitating a weighed sample of the compounds in an excess of base and digesting for some hours back-titration with standard hydrochloric acid gave the expected equivalent weights.

For compounds with both aliphatic and aromatic amino groups (XVII and XXII) titration in water-alcohol mixture with standard hydrochloric acid and methyl red indicator gave equivalent weights corresponding to the aliphatic amino groups = M or $M/2$, and a non-aqueous titration as above gave equivalent weights = $M/3$, corresponding to the sum of amino groups.

Beside the analyses the following data are given in the tables: Boiling points, refractive indices (determined with an Abbe refractometer), densities (determined with an Ostwald-Sprengler pycnometer of a volume of 1.5 ml) and molecular refractivities (calculated from Lorenz-Lorentz formula).

Table 2. Physical constants of compounds containing silicon-chlorine bonds.

Syntheses

All the reactions were performed in a three-necked flask equipped with a mechanical stirrer, a dropping funnel and a reflux condenser. The amine hydrochloride formed was filtered from the mixture on a fine-porous glass-filter in an atmosphere of dry air and was carefully washed with the solvent and dried before the weighing. The complete separation of amine hydrochloride sometimes caused considerable difficulty. If it was not completely removed, it contaminated the aminosilanes, subliming with them during the distillation. After the filtration the filtrate and wash-liquid were combined, and the solvent was removed at atmospheric pressure before distillation of the aminosilane at reduced pressure.

1. n-*Propyltri-(methylamino)-silane (I)*. To an ice-cooled, vigorously stirred solution of about 30 g (1.0 mole) of methylamine in 150 ml of ether a solution of 17.8 g (0.1 mole) of *n*-propyltrichlorosilane in 50 ml of ether was added dropwise. After all had been added the stirring was continued, and the temperature was slowly raised by the removal of the ice-bath. Finally the stirred mixture was heated to reflux temperature for 2 h to remove the excess of methylamine. Filtration of the cooled mixture left 20.2 g (calc. 20.3 g) of methylamine hydrochloride on the filter. Distillation of the filtrate gave 14.2 g (88 %) of I.

2. n-*Propyltri-(dimethylamino)-silane (II)*. Under exactly the same conditions as above 45 g (1.0 mole) of dimethylamine and 17.8 g (0.1 mole) of *n*-propyltrichlorosilane gave only 23.6 g (calc. 24.5 g) of dimethylamine hydrochloride, and 18 g of a product with an equivalent weight of 74 (calc. for II 67.8) was obtained. When this was again heated for 2 h in benzene containing dimethylamine, more amine hydrochloride was obtained; distillation gave 15.0 g (74 %) of II with the data given in Table 1. The observed difference in reactivity between dimethylamine and methylamine must be ascribed to the greater steric requirement of the former one.

3. n-*Propyltri (ethylamino) silane (III)*. As described for the methylamine compound 44.4 g (0.25 mole) of *n*-propyltrichlorosilane in 50 ml of ether and about 90 g (2.0 moles) of ethylamine in 250 ml of the same solvent gave 61.2 g (calc. 61.2 g) of ethylamine hydrochloride and 47.2 g (93 %) of III.

4. n-*Propyltri*-(n-*propylamino*)-*silane (IV)*. 17.8 g (0.1 mole) of *n*-propyltrichlorosilane in 50 ml of benzene were added to 53 g (0.9 mole) of *n*-propylamine in 100 ml of benzene. The mixture was refluxed for 2 h. Thereafter the excess of *n*-propylamine was distilled off. Filtration left 28.7 g (calc. 28.7 g) of *n*-propylamine hydrochloride on the filter, and fractionation of the filtrate gave 22.1 g (90 %) of IV.

5. n-*Propyltri-(iso propylamino)-silane (V)*. In the same way 8.9 g (0.05 mole) of *n*-propyltrichlorosilane in 50 ml of ether and 30 g (0.5 mole) of *iso*propylamine in 75 ml of the same solvent gave 14.4 g (calc. 14.4 g) of *iso*propylamine hydrochloride and 10.5 g (86 %) of V.

6. n-*Propyltri*-(n-*butylamino*)-*silane (VI)*. 8.9 g (0.05 mole) of *n*-propyltrichlorosilane in 75 ml of benzene were added to 37 g (0.5 mole) of *n*-butylamine in 100 ml of the same solvent. After refluxing for 2 h and cooling, filtration left 16.0 g (calc. 16.4 g) of *n*-butylamine hydrochloride on the filter; fractionation of the filtrate gave 11.1 g (77 %) of VI.

7. n-*Propyltri-(isobutylamino)-silane (VII).* In the same way 8.9 g (0.05 mole) of *n*-propyltrichlorosilane in 75 ml of benzene and 37 g (0.5 mole) of *iso*butylamine in 100 ml of the same solvent gave 16.4 g (calc. 16.4 g) of *iso*butylamine hydrochloride and 11.7 g (81 %) of VII.

8. n-*Propyltri-(sec.-butylamino)-silane (VIII).* 7.1 g (0.04 mole) of *n*-propyltrichlorosilane in 50 ml of ether were added to 21.9 g (0.3 mole) of *sec.*-butylamine in 50 ml of the same solvent. After refluxing for 1.5 h and cooling, filtration left 11.1 g (calc. 13.2 g) of *sec.*-butylamine hydrochloride on the filter. A little more *sec.*-butylamine was added to the filtrate, and the mixture was refluxed for 6 h. On cooling, filtration left 2.0 g of amine hydrochloride; distillation gave 7.8 g (68 %) of VIII.

9. n-*Propyltri-(cyclohexylamino)-silane (IX).* In exactly the same way 29.8 g (0.3 mole) of *cyclo*hexylamine gave already after refluxing for 1 h the calculated amount of *cyclo*hexylamine hydrochloride (16.3 g). From the filtrate 11.3 g (77 %) of IX were obtained.

10. n-*Propyltrianilinosilane (X).* 17.8 g (0.1 mole) of *n*-propyltrichlorosilane in 50 ml of ether were added dropwise to 70 g (0.75 mole) of aniline in 125 ml of the same solvent. The mixture was refluxed for 2 h. After cooling, filtration left 34.2 g (calc. 38.9 g) of aniline hydrochloride on the filter. After removal of the ether from the filtrate by distillation, the residual mixture was heated at about 100°C for 2 h. On cooling and addition of 150 ml of ether, filtration left another 4.6 g of amine hydrochloride on the filter. Fractionation gave 29.5 g (85 %) of X as a colourless, very viscous syrup, which soon achieved the yellow tint, which aniline usually has.

In another experiment the reactivity of aniline and *cyclo*hexylamine was studied as follows. A mixture of 1.78 g (0.01 mole) of *n*-propyltrichlorosilane and 5.59 g (0.06 mole) of aniline in 25 ml of benzene was agitated for 15.0 min at room temperature and filtered. 1.95 g of aniline hydrochloride were left on the filter, which makes 50.1 % of the calculated amount according to formula (A). After standing for 12 h, 1.05 g more aniline hydrochloride were obtained, yielding a total of 77.1 %.

5.95 g (0.06 mole) of *cyclo*hexylamine under exactly the same conditions gave 3.38 g (82.3 %) of *cyclo*hexylamine hydrochloride and after 12 h 0.59 g. This makes a total of 97.5 % of the calculated amount. Therefore it must be concluded that *cyclo*hexylamine reacts more readily than aniline with *n*-propyltrichlorosilane.

11. n-*Propyltripiperidinosilane (XI).* 17.8 g (0.1 mole) of *n*-propyltrichlorosilane in 50 ml of benzene were added to 60 g (0.7 mole) of piperidine in 100 ml of the same solvent, and the mixture was refluxed for 5 h. Filtration of the cooled mixture left 34.0 g (calc. 36.5 g) of piperidine hydrochloride. The filtrate was again refluxed for 5 h, and filtration then gave 2.3 g more amine hydrochloride. From the filtrate 22.0 g (68 %) of XI were obtained.

12. n-*Propyldi-(tert.-butylamino)-chlorosilane (XXIII).* In the same way 17.8 g (0.1 mole) of *n*-propyltrichlorosilane and 55 g (0.75 mole) of *tert.*-butylamine after refluxing for 2 h gave 22.5 g of *tert.*-butylamine hydrochloride. This is in agreement with the calculated amount for the replacement of only two of the chlorine atoms in *n*-propyltrichlorosilane (21.9 g). The filtrate did not give more amine hydrochloride even when refluxed for 10 h. On fractionation of the mixture 20.5 g (81 %) of XXIII were obtained.

12.5 g (0.05 mole) of XXIII were heated with 11 g (0.15 mole) of *tert.*-butylamine and 50 ml of benzene in a steel-bomb at about 160°C for 8 h. Only traces of amine hydrochloride were formed, and XXIII could be recovered by distillation. Thus it must be concluded that *n*-propyltri-(*tert.*-butylamino)-silane cannot be obtained in this way.

13. n-*Propyldi-(tert.-butylamino)-aminosilane (XII).* 10.0 g (0.04 mole) of XXIII in 50 ml of ether were added dropwise to about 50 ml of liquid ammonia, cooled in a dry ice and acetone bath. The temperature was slowly raised to room temperature, and the mixture was at last refluxed for 1 h to remove the excess of ammonia. Filtration left 2.1 g (calc. 2.1 g) of ammonium chloride on the filter, and distillation of the filtrate gave 6.5 g (70 %) of XII.

14. n-*Propyldi-(tert.-butylamino)-(ethylamino)-silane (XIII).* 5.0 g (0.02 mole) of XXIII dissolved in 15 ml of ether were added to an ether solution containing excess of ethylamine. After stirring at room temperature for about half an hour, the excess of ethylamine was removed. Filtration left 1.6 g (calc. 1.6 g)of ethylamine hydrochloride on the filter, and on fractionation of the filtrate 4.6 g (89 %) of XIII were obtained.

15. n-*Propyldi-(*tert.-*butylamino)-(iso*propylamino*)-silane (XIV).* 10.0 g (0.04 mole) of XXIII in 25 ml of benzene were added to 7 g (0.12 mole) of *iso*propylamine in 40 ml of the same solvent. No amine hydrochloride precipitated until the mixture had been heated for a while. After refluxing for 1.5 h and removal of the excess of *iso*propylamine, filtration left only 1.8 g (calc. 3.8 g) of *iso*propylamine hydrochloride on the filter. 7 g of *iso*propylamine were added to the filtrate, and the mixture was refluxed for 15 h. The excess of *iso*propylamine was again distilled off. Filtration now left another 1.9 g, and from the filtrate 8.0 g (73 %) of XIV were obtained.

n-Propylamine and *n*-butylamine gave immediately a heavy precipitate of amine hydrochloride when XXIII, dissolved in benzene, was added to their benzene solutions. The low reactivity of *iso*propylamine may be attributed to its steric properties.

16. n-*Propyl-(*tert.-*butylamino)-dichlorosilane (XXVI).* This compound was obtained by the addition dropwise of 36.5 g (0.5 mole) of *tert.*-butylamine in 75 ml of ether to 44.4 g (0.25 mole) of *n*-propyltrichlorosilane in 75 ml of the same solvent and refluxing for 1.5 h. Filtration left 27.3 g (calc. 27.4 g) of *tert.*-butylamine hydrochloride, and distillation of the filtrate gave 36.0 g (67 %) of XXVI.

17. n-*Propyl-(*tert.-*butylamino)-di-(iso*propylamino*)-silane (XVIII).* 10.7 g (0.05 mole) of XXVI in 50 ml of benzene were added to 15 g (0.25 mole) of *iso*propylamine in 50 ml of the same solvent. After refluxing for 1.5 h and removal of the excess of *iso*propylamine, filtration left 9.6 g (calc. 9.6 g) of *iso*propylamine hydrochloride. Thus it is seen that the chlorine is more easily replaced by *iso*propylamine in XXVI than in XXIII. From the filtrate 9.9 g (76 %) of XVIII were obtained.

18. n-*Propyldi-(diethylamino)-chlorosilane (XXIV).* 17.8 g (0.1 mole) of *n*-propyltrichlorosilane in 50 ml cf benzene were added to 59 g (0.8 mole) of diethylamine in 75 ml of the same solvent. Thereafter the mixture was refluxed for 4.5 h. After the excess of diethylamine had been removed by distillation, filtration left 22.4 g of diethylamine hydrochloride on the filter. This corresponds with the calculated amount for the replacement of only two chlorine atoms in *n*-propyltrichlorosilane (21.9 g), and no more amine hydrochloride precipitated on further refluxing with diethylamine in benzene. Fractionation gave 18.5 g (73 %) of XXIV. The resistance of this compound against further reaction with diethylamine was illustrated in the same way as for XXIII.

19. n-*Propyldi-(diethylamino)-aminosilane (XV).* This substance was prepared as described for XII from 5.0 g (0.02 mole) of XXIV giving 1.1 g (calc. 1.1 g) of ammonium chloride and 3.2 g (69 %) of XV.

20. n-*Propyldi-(diethylamino)-*iso*propylaminosilane (XVI).* 8.3 g (0.033 mole) of XXIV were refluxed with 12 g (0.2 mole) of *iso*propylamine in 50 ml of benzene for 20 h, and then the excess of *iso*propylamine was removed. Filtration left 3.1 g (calc. 3.2 g) of *iso*propylamine hydrochloride on the filter, and from the filtrate 5.8 g (64 %) of XVI were obtained.

21. n-*Propyl-(diethylamino)-dichlorosilane (XXVII).* This substance was prepared as described for XXVI from 35.5 g (0.2 mole) of *n*-propyltrichlorosilane in 90 ml of benzene and 30 g (0.41 mole) of diethylamine in 100 ml of the same solvent. Filtration left 21.4 g (calc. 21.9 g) of diethylamine hydrochloride and 31.0 g (72 %) of XXVII were obtained.

22. n-*Propyl-(diethylamino)-di-(iso*propylamino*)-silane (XIX).* As described for the preparation of XVIII, 10.7 g (0.05 mole) of XXVII and 15 g (0.25 mole) of *iso*propylamine gave 9.5 g (calc. 9.6 g) of *iso*propylamine hydrochloride and 10.7 g (82 %) of XIX.

23. n-*Propyl-(di-*iso*propylamino)-dichlorosilane (XXVIII).* 60.7 g (0.6 mole) of di-*iso*propylamine in 75 ml of benzene were added dropwise to 53.3 g (0.3 mole) of *n*-propyltrichlorosilane in 100 ml of the same solvent. The mixture was then refluxed for 1 h. Filtration left di-*iso*propylamine hydrochloride on the filter, which even after ordinary washing contained some grams of a material containing silicon (total weight 45.2 g; calc. for the replacement of one of the chlorine atoms in *n*-propyltrichlorosilane 41.3 g). From the filtrate 38.3 g (53 %) of XXVIII were obtained. When this substance was refluxed for several hours with di-*iso*propylamine in benzene, only a very small amount of amine hydrochloride was formed.

In another experiment 18.2 g (0.075 mole) of XXVIII and 20 g (0.2 mole) of di-*iso*propylamine in 50 ml of benzene were heated to about 170°C for 15 h in a steel-bomb. Only 0.4 g of amine hydrochloride was formed. — Therefore it must be concluded that *n*-propyldi-(di-*iso*propylamino)-chlorosilane cannot be obtained in reasonable yield in this way.

24. n-*Propyl-(di-*iso*propylamino)-di-(*iso*propylamino)-silane (XX).* 9.7 g (0.04 mole) of XXVIII and 18 g (0.3 mole) of *iso*propylamine in 50 ml of ether were refluxed for 1 h. Filtration of the cooled mixture left 6.0 g (calc. for total replacement 7.7 g) of *iso*propylamine hydrochloride. The ether was distilled off from the filtrate, and 50 ml of benzene containing about 10 g of *iso*propylamine were added to the rest. After refluxing for about 5 h and removal of the excess of *iso*propylamine, a new filtration left the expected amount of *iso*propylamine hydrochloride (1.6 g). From the filtrate 6.5 g (57 %) of XX were obtained.

25. n-*Propyl-(di-*cyclo*hexylamino)-dichlorosilane (XXIX).* 35.5 g (0.2 mole) of *n*-propyltrichlorosilane in 75 ml of benzene were added dropwise to 81.6 g (0.45 mole) of di-*cyclo*hexylamine in 100 ml of benzene. Amine hydrochloride was immediately formed. After refluxing for 5 h, filtration left 44.0 g (calc. 43.6 g) of di-*cyclo*hexylamine hydrochloride on the filter. On fractionation of the filtrate 44.1 g (68 %) of XXIX were obtained. 16.1 g (0.05 mole) of this substance were refluxed with 22 g (0.12 mole) of di-*cyclo*hexylamine in 100 ml of benzene for 8 h, but no more amine hydrochloride was formed. Thereafter the benzene was distilled off and the rest was heated at 180°C for 12 h, but even now only traces of amine hydrochloride were formed. Thus it is seen that *n*-propyldi-(di-*cyclo*hexylamino)-chlorosilane cannot be obtained in reasonable yield in this way.

26. n-*Propyl-(di-*cyclo*hexylamino)-di-(*iso*propylamino)-silane (XXI).* A mixture of 16.1 g (0.05 mole) of XXIX and 24 g (0.4 mole) of *iso*propylamine in 100 ml of benzene were refluxed for 15 h, and then the excess of *iso*propylamine was removed. Filtration of the cooled mixture left 9.3 g (calc. 9.6 g) of *iso*propylamine hydrochloride, and from the filtrate 14.0 g (77 %) of XXI were obtained.

27. n-*Propyltrichlorosilane and diphenylamine.* 8.9 g (0.05 mole) of *n*-propyltrichlorosilane in 25 ml of benzene were added to 34 g (0.2 mole) of diphenylamine in 100 ml of the same solvent. No reaction could be observed at room temperature, so it is evident that the reactivity of diphenylamine is much less than that of di-*iso*propylamine and di-*cyclo*hexylamine. Since the steric properties of these amines are of about the same order, the difference may be attributed to the difference in their base strength. Even after refluxing for 8 h and cooling no solid precipitated, and on fractionation more than 8 g of the *n*-propyltrichlorosilane could be recovered.

28. n-*Propyl-(N-methylanilino)-dichlorosilane (XXX).* 8.9 g (0.05 mole) of *n*-propyltrichlorosilane in 25 ml of benzene were added to 27 g (0.25 mole) of N-methylaniline in 50 ml of benzene. The precipitate of N-methylaniline hydrochloride, which was first formed, dissolved on heating of the mixture to reflux. After refluxing for 4.5 h and cooling of the mixture, filtration left 6.4 g (calc. for the replacement of one of the chlorine atoms in *n*-propyltrichlorosilane 7.2 g). The filtrate was again refluxed for 20 h, and filtration now left 1.2 g of amine hydrochloride. Reflux of the filtrate for another 22 h caused the formation of only about 0.5 g of amine hydrochloride, so it is evident that the second chlorine atom in *n*-propyltrichlorosilane is difficultly replaced by N-methylaniline. If the benzene is distilled off and the residue is heated to reflux of the N-methylaniline for several hours, more amine hydrochloride is formed and *n*-propyldi-(N-methylanilino)-chlorosilane (XXV) can be obtained in reasonable yield from the reaction mixture.

In another experiment 43 g (0.4 mole) of N-methylaniline in 50 ml of ether were added dropwise to 35.5 g (0.2 mole) of *n*-propyltrichlorosilane in 100 ml of ether. After refluxing for 2.5 h, filtration of the cooled mixture left 22.9 g (calc. 28.7 g) of N-methylaniline hydrochloride on the filter. The ether was distilled off from the filtrate, and the residue was heated to about 100°C for 2 h. After cooling the ether was again added, and filtration now left 2.0 g of amine hydrochloride. The ether was again distilled off, and refluxing for about 5 h now left 3.1 g of amine hydrochloride on the filter (totally 28.0 g). Distillation of the filtrate gave 32.1 g (65 %) of XXX.

29. n-*Propyl-(N-methylanilino)-di-(*iso*propylamino)-silane (XXII).* 12.4 g (0.05 mole) of XXX in 50 ml of benzene were added to 24 g (0.4 mole) of *iso*propylamine in 50 ml of benzene. After refluxing for 8 h and removal of the excess of *iso*propylamine, filtration left 9.5 g (calc. 9.6 g) of *iso*propylamine hydrochloride on the filter. From the filtrate 12.0 g (82 %) of XXII were obtained.

30. n-*Propyldi-(N-methylanilino)-chlorosilane (XXV).* 21 g (0.2 mole) of N-methylaniline were added to 20.0 g (0.089 mole) of XXX in 100 ml of ether. After refluxing for 3 h, only traces of N-methylaniline hydrochloride had precipitated. Therefore the ether

was distilled off, and the residual mixture was heated to about 100°C for 8 h. When the ether was again added to the cooled mixture, 3.5 g of amine hydrochloride were obtained on filtration. After repeating the same procedure, 2.5 g of amine hydrochloride were left on the filter. On fractionation of the filtrate about 4 g of XXX and 5.1 g (20 %) of XXV were obtained.

31. n-*Propyldi-(N-methylanilino)-(iso*propylamino*)-silane (XVII).* 4.2 g (0.013 mole) of XXV and 9 g (0.15 mole) of *iso*propylamine in 50 ml of benzene were refluxed for 10 h, and the excess of *iso*propylamine was removed. Filtration left 1.2 g (calc. 1.3 g) of *iso*propylamine hydrochloride, and from the filtrate 3.5 g (78 %) of XVII were obtained.

32. n-*Propyltrichlorosilane and tertiary amines.* When *n*-propyltrichlorosilane was added to absolutely dry trimethylamine, triethylamine or pyridine in ether or benzene solution, no reaction was observed in any case and the *n*-propyltrichlorosilane could be recovered by distillation.

Studien über Metallcyanate

ERIK SÖDERBÄCK

Chemisches Institut der Universität Uppsala, Schweden

Es wurden vorher unbekannte Cyanate von Cadmium und von ein- und zweiwertigem Kupfer synthetisiert und von beiden letzteren Doppelcyanate mit Alkalimetallen.

Ein katalytischer Effekt der Cuprocyanate bei der Einführung der *Iso*cyanatgruppe in einen Benzolkern nach Sandmeyer wurde entdeckt und als Beispiel die Synthese von *o*-Tolylisocyanat durchgeführt.

Neue Methoden für die Darstellung von Mercuricyanat sind ausgearbeitet worden; diese Substanz wurde näher studiert und Ähnlichkeiten mit dem Mercurichlorid nachgewiesen. Eine neue bequeme Methode für die Darstellung von Bariumcyanat ist angegeben und die Löslichkeit des Salzes in Wasser bestimmt worden.

Die Leitfähigkeitbestimmungen und einige der Analysen sind im hiesigen Centralanalytischen Laboratorium, Vorstand Dr. F. Nydahl, ausgeführt worden. Für diese sowie für Debye-Scherrer-Aufnahmen durch Herrn Privatdozent Dr. I. Lindqvist bin ich sehr zu Dank verpflichtet.

Die Metallcyanate sind im Verhältnis zu den Metallrhodaniden recht wenig untersucht worden, und viele einfache Cyanate von gewöhnlichen Metallen sind noch unbekannt. Der Grund dafür ist hauptsächlich die relative Schwäche und Unbeständigkeit der Cyansäure in wässriger und alkoholischer Lösung. Die Säure wird in wässriger Lösung rasch zu Ammoniak und Kohlensäure hydrolysiert, in alkoholischer sind Urethane und Allophansäureester die Reaktionsprodukte.

Das Cyanation wird häufig als ein Analogon der Hypohalogenitionen, z.B. des Hypochloritions betrachtet, weil es durch Hydrolyse des Dicyans in alkalischer Lösung nebst Cyanidion gebildet wird. Diese Übereinstimmung ist aber ausschliesslich formal, da keine Übereinstimmung in Eigenschaften besteht; die Cyanate haben z.B. keine oxydierende Wirkungen. Das Cyanation zeigt vielmehr gewisse Ähnlichkeiten mit den Halogenidionen, namentlich mit dem Chloridion, und diese sind besonders bei gewissen Schwermetallcyanaten hervorstechend. So ist z.B. schon längst ein Kaliumchloroplatinatcyanat $K_2Pt(OCN)Cl_5H_2O$ bekannt [1].

Das Cyanation besitzt indessen eine mehr ausgeprägte Neigung zur Bildung von schwerlöslichen Doppelcyanaten als das Chloridion zu Bildung von Doppel-

chloriden, was bei der Darstellung einfacher Metallcyanate manchmal Schwierigkeiten macht *. Es ist mir gelungen die einfachen Cyanate von Cadmium und Kupfer darzustellen und Doppelsalze von ein- und zweiwertigem Kupfer mit Alkalicyanaten. Ferner sind neue Methoden zur Darstellung von Mercuricyanat aufgefunden worden, ein Salz das grosse Ähnlichkeiten mit dem Chlorid aufweist.

Cadmiumcyanat

Versetzt man eine nicht zu verdünnte Wasserlösung von einem normal ionisierten Cadmiumsalz mit Kaliumcyanat, kristallisiert das Salz $KCd(OCN)_3$ rasch aus [3]. Die Bereitung des einfachen Cyanats als Hydrat bietet indessen keine grössere Schwierigkeiten; es kann, wie ich gefunden habe, entweder durch Umsatz von Cadmiumsulfat mit Bariumcyanat in verdünnter wässriger Lösung und Konzentrieren der Lösung durch Vakuumdestillation bis zur eintreten der Kristallisation oder durch Reaktion von Cadmiumjodid in Acetonlösung mit der genau äquivalenten Menge Silbercyanat und Auslagen des Gemenges von AgJ und $Cd(OCN)_2$ mit Wasser gewonnen werden. Das aus Wasser kristallisierte Cyanat ist immer etwas von basischem Salz verunreinigt und löst sich deshalb nicht klar in Wasser, es kann aber leicht durch Waschen mit verdünnter Essigsäure ** gereinigt werden und ist dann analysenrein. Die Zusammensetzung entspricht der Formel $2Cd(OCN)_2 \cdot 5H_2O$, der Wassergehalt ist also derselbe als für Cadmiumchlorid ***. Das Salz ist in Methanol und Äthanol ziemlich löslich.

Die Löslichkeiten in Wasser von Cadmiumsalzen der zusammengesetzten Halogene $(OCN)_2$, $(SCN)_2$ und $(SeCN)_2$ sind nicht besonders gross. Nach von mir ausgeführten Messungen sind sie bei 20° für $2Cd(OCN)_2 \cdot 5H_2O$ $9{,}1 \times 10^{-2}$, für $Cd(SCN)_2$ $4{,}8 \times 10^{-2}$ und für $Cd(SeCN)_2$ $2{,}3 \times 10^{-2}$ M. Die beiden letzten Salze kristallisieren anhydrisch und können aus konzentrierten $Cd(NO_3)_2$-Lösungen durch KSCN bezw. KSeCN gefällt werden. Der Grund für die relative Schwerlöslichkeit dieser Salze in Vergleich mit $CdCl_2$, $CdBr_2$ und CdJ_2 dürfte in Autokomplexbildung zu suchen sein.

Mercuricyanat

Von Birckenbach und Kolb [6] sind eine Reihe von Doppelcyanaten von Quecksilber(II) hergestellt und studiert worden, von welchen durch Ramananalyse einige als O-Cyanate andere als N-Cyanate zu formulieren seien. Die Verhältnisse sind indessen sehr verwickelt, und die Strukturen können kaum als endgültig geklärt betrachtet werden. Von denselben Autoren ist auch das einfache Mercuricyanat $Hg(OCN)_2$ dargestellt worden durch Umsetzung von $HgCl_2$ mit AgOCN in Methanol und Verdampfen des Lösungsmittels. Die Struktur soll nach Ramanaufnahmen der Ket-Imidformel entsprechen, was

* Bei den mit den Cyanaten isomeren Fulminaten ist diese Tendenz noch stärker ausgeprägt.

** Über die relative Stärke von Essigsäure und Cyansäure, siehe weiter unten.

*** Das bei Zimmertemperatur aus wässriger Lösung kristallisierte Cadmiumchlorid ist nach Untersuchungen von Cohen [4] und Dietz [5] das Hydrat $2CdCl_2.5H_2O$. Diese Tatsache ist seit Ende des vorigen Jahrhunderts bekannt. Nichts destoweniger wird das käufliche Chlorid von chemischen Fabriken als Dihydrat formuliert.

an und für sich nicht unwahrscheinlich ist. Methanol dürfte indessen kein geeignetes Solvenz für Mercuricyanat sein wegen mangelnder Stabilität des Salzes in diesem Lösungsmittel. Um es rein zu erhalten muss es sehr schnell aus der Lösung isoliert werden. Wie ich gefunden habe, ist es viel besser Äther als Solvenz zu verwenden, in welchem die Reaktion glatt verläuft. Es wird zwar von Birckenbach und Kolb behauptet, dass $Hg(OCN)_2$ in Äther wenig löslich sei; nach meinen eigenen Messungen ist die Löslichkeit bei 20° 1,3 g per 100 ml, eine Löslichkeit die ausreicht um das Salz mit Äther gut extrahieren zu können. Bei Abdestillieren des Äthers kristallisiert $Hg(OCN)_2$ in analysenreiner Form aus. Es dürfte dies die beste Darstellungsmethode sein.

Mercuricyanat kann ferner, wie ich gefunden habe, durch Neutralisation von gelbem HgO mit Cyansäure in Äther gewonnen werden. Die Reaktion muss aber einen möglichst rapiden Verlauf haben, weil sonst durch eine sekundäre Reaktion zwischen HgO und $Hg(OCN)_2$ letzteres in eine weisse schwerlösliche Substanz verwandelt wird, die nicht durch HOCN in normales Cyanat umgewandelt wird. Das HgO muss deshalb höchstreaktiv, in der Kälte dargestellt sein. Die Cyansäure lässt sich sehr bequem durch Umsatz von AgOCN mit HCl in trocknem Äther darstellen *. Die Isolierung des $Hg(OCN)_2$ geschieht wie oben beschrieben, und die Ausbeuten sind befriedigend. Keine Unterschiede zwischen dem aus HgO und dem aus $HgCl_2$ in Methanol synthetisierten $Hg(OCN)_2$ konnten bei Debye-Scherreraufnahmen im hiesigen Institut durch Lindqvist beobachtet werden.

Das Mercuricyanat lässt sich auch nach einer dritten Methode gewinnen und zwar durch Erhitzen von Mercurocyanat $Hg_2(OCN)_2$ mit Wasser, wobei jenes in Quecksilber und $Hg(OCN)_2$ zerfällt. Es stellen sich Gleichgewichte ein, die sich mit der Temperatur stark verschieben; bei Zimmertemperatur wird die Reaktion quantitativ rückgängig. Durch Erneuerung der Wasserphase kann die Dissoziation von $Hg_2(OCN)_2$ leicht vollständig gemacht werden. Durch möglichst rasches Einengen der abgekühlten Wasserextrakte mittelst Vakuumdestillation wird das Cyanat fraktioniert auskristallisiert und durch Umlösen in Äther gereinigt. Es konnten in dieser Weise Ausbeuten von etwa 80 % erreicht werden.

Das Mercuricyanat kristallisiert aus Äther in prismatischen Kristallen, die sich in Licht etwas gräulich färben und deshalb im Dunkeln aufzubewahren sind. Die Löslichkeit in Äther nimmt mit dem Wassergehalt des Äthers zu, was auch für Quecksilberchlorid gilt. Während in trocknem Äther die Löslichkeit bei 20° 1,3 g/100 ml beträgt, steigt sie für einen Äther, dessen Wassergehalt 0,1 M ist zu 1,8 g und für 0,25 M zu 2,7 g. Diese Löslichkeiten wurden durch Wägen des Verdampfungsrückstandes eines abgemessenen Volumens gesättigter Lösung bestimmt. $Hg(OCN)_2$ ist wie $HgCl_2$ leicht löslich in einer Menge von organischen Solvenzien, in Methanol und Äthanol, in aliphatischen Nitrilen wie Acetonitril, in den verschiedensten aliphatischen Ketonen, wie Aceton, Methyläthylketon und *Cyclo*hexanon. Es ist ferner beträchtlich löslich in Wasser. 100 ml lösen bei 20° 7,5 g $Hg(OCN)_2$ ** und 5,7 g $HgCl_2$. Bei 0°

* Ganz analog lässt sich eine ätherische Rhodanwasserstofflösung durch Umsatz von AgSCN mit HCl bereiten.

** Die Löslichkeit von $Hg(ONC)_2$ in Wasser ist bei 18° 0,74 g in 100 ml.

sinkt die Löslichkeit für das Cyanat zu 3,7 g und für das Chlorid zu 3,6 g. Eben wie $HgCl_2$ ist $Hg(OCN)_2$ in Wasser anomal wenig ionisiert. Alkalicarbonate erzeugen keinen Niederschlag von HgO, wohl aber Alkalihydroxyde. $AgNO_3$ fällt nicht; aus Lösungen von $HgCl_2$ wird bekanntlich AgCl partiell gefällt. Es ist dazu zu bemerken, dass das Löslichkeitsprodukt von AgCl, 2×10^{-10} nicht unwesentlich kleiner ist als dasjenige von AgOCN, $\sim 10^{-7}$. Dass $Hg(OCN)_2$ anomal wenig ionisiert ist, geht aus der Tabelle 1 hervor, wo die molekularen Leitfähigkeiten Λ bei 25° in reciprok. Ohm für 4 verschiedene Verdünnungen angeführt sind. Die letzte Kolumne enthält die Leitfähigkeiten für $HgCl_2$ bei denselben Verdünnungen nach Ley [7]. Die Zeiten Z sind von dem Augenblick, wo das Salz mit dem Lösungsmittel in Berührung kam, gerechnet.

Es geht aus der Tabelle hervor, dass die Leitfähigkeit von $Hg(OCN)_2$ von derselben Grössenordnung wie diejenige von $HgCl_2$ ist *. Sie steigt mit der Zeit, offenbar durch eine Reaktion des Salzes mit Wasser. Die wässrigen Lösungen von $Hg(OCN)_2$ sind nämlich nicht stabil, sondern setzen allmählich gelblich gefärbte Niederschläge ab unter gleichzeitiger Entwicklung von CO_2. Über die Art dieser Reaktion kann gegenwärtig nichts bestimmtes gesagt werden. Auch in wasserhaltigem Äther wird $Hg(OCN)_2$ allmählich zersetzt.

Die Mercurisalze der elementaren Halogene sowie diejenige der zusammengesetzten $(SCN)_2$ und $(SeCN)_2$ werden bei Zimmertemperatur in Wasser oder organischen Solvenzien leicht und quantitativ durch Quecksilber zu den entsprechenden Mercurosalzen reduziert und derselben Reaktion unterliegt auch das Mercuricyanat. Es wurden Versuche in Wasser und Äther angestellt. Das Abschliessen der Reaktion konnte leicht durch Ausbleiben der Ausfällung von HgO bei Zusatz von Alkalihydroxyd, im Falle Äther auch durch das Verschwinden von Eindampfungsrückstand festgestellt werden, da Mercurocyanat in Äther sehr schwerlöslich ist. Die Identität des Reaktionsproduktes mit $Hg_2(OCN)_2$ konnte dadurch gezeigt werden, dass beim Aufkochen mit Wasser $Hg(OCN)_2$ ausgelöst wurde und wie oben beschrieben, isoliert werden konnte.

Das Mercuricyanat gibt genau wie $HgCl_2$ die Edersche Reaktion d.h. es wird in wässriger Lösung bei Gegenwart von $(NH_4)_2C_2O_4$ durch Belichtung zu $Hg_2(OCN)_2$ reduziert unter gleichzeitiger Bildung von CO_2

$$2Hg(OCN)_2 + (NH_4)_2C_2O_4 + h\nu \longrightarrow Hg_2(OCN)_2 + 2NH_4OCN + 2\,CO_2$$

Bei einem derartigen Versuch wurden 16,6 g $Hg(OCN)_2$ in einer Lösung von 17 g $(NH_4)C_2O_4$ in 400 ml Wasser aufgelöst mit einer Quarzquecksilberlampe mehrere Tage belichtet. Es wurden dabei 12,7 g $Hg_2(OCN)_2$ ausgefällt = 89 %. Das Präparat war durch kleine Mengen von ausreduziertem Hg etwas gräulich gefärbt.

Von Interesse ist, dass die Doppelverbindungen Hlg · HgOCN (Hlg = Cl, Br oder J) eben wie die entsprechenden Rhodanide und Selenocyanide Phototropie zeigen. Die Empfindlichkeit steigt von Cl zu J an [8].

Wie schon erwähnt, ist Mercuricyanat in Methanol, Äthanol und aliphatischen Ketonen leichtlöslich. Wenn eine Lösung von anhydrischem Cupri-

* Das mit Mercuricyanate isomere Fulminat hat eine Leitfähigkeit die nicht merkbar grösser als diejenige von Wasser ist.

bromid in Methanol oder Äthanol mit einer äquivalenten Menge von $Hg(OCN)_2$ in demselben Solvenz versetzt wird, so schlägt die braune Farbe der $CuBr_2$-Lösung sofort in grün um. Der Farbenwechsel ist durch eine Umsetzung von $CuBr_2$ in $Cu(OCN)_2$, welch letzteres in alkoholischer Lösung grün ist, bedingt. Gleichzeitig wird $HgBr_2$ gebildet. Wenn bei der Reaktion Aceton oder Methyläthylketon als Lösungsmittel gebraucht werden, so fällt das gebildete $Cu(OCN)_2$ zum grössten Teil aus und kann nach Waschen mit den Ketonen und schliesslich mit Äther als lichtgrünes mikrokristallines Pulver isoliert werden. Das reinste Produkt wurde aus Aceton erhalten. In dieser Weise ist das aus wässriger oder alkoholischer Lösung wegen solvolytischer Zersetzung nicht gewinnbare Cyanat leicht darstellbar. Wie von Naumann [9] beobachtet worden ist, setzt sich $HgCl_2$ mit $CuBr_2$ in Aceton um, wobei zunächst $CuCl_2$ gebildet, aber allmählich zu CuCl reduziert wird. Wie ich selbst konstatiert habe, tritt in Methanol und Äthanol derselbe momentane Farbenumschlag ein wie mit $Hg(OCN)_2$.

Das Mercurichlorid wirkt bekanntlich auf viele organische Verbindungen merkurierend, wobei Quecksilber an Kohlenstoff fixiert wird. Die Ähnlichkeit zwischen Chlorid und Cyanat lässt vermuten, dass wenigstens in gewissen Fällen das Chlorid bei solchen Reaktionen durch das Cyanat vertreten werden kann. So wird, wie ich festgestellt habe, *Pyrrol* in Wasser glatt durch $Hg(OCN)_2$ zu einer Verbindung $C_4H_2NH(HgOCN)_2$ merkuriert unter gleichzeitiger Entwicklung von Cyansäure. *Thiophen* wird von einer acetatgepufferten Wasserlösung von $Hg(OCN)_2$ eben wie von $HgCl_2$ langsam angegriffen. Isoliert wurden durch Extraktion mit Aceton ein Monomerkurierungsprodukt und ein dimerkuriertes, deren Untersuchung jedoch noch nicht abgeschlossen ist. Ersteres, welches durch seine Ätherlöslichkeit leicht von letzterem separiert werden kann, kristallisiert aus Äther in Prismen von Schmelzp. 105°.

Mercurocyanat

Mercurocyanat scheint erstmalig von Wöhler [10] dargestellt zu sein, er gewann es durch Umsetzen von $Hg_2(NO)_2$ mit $Ba(OCN)_2$. Das Salz ist sehr wenig untersucht worden. Von Knoll & Co.[11] ist es für Darstellung von α-Brom*iso*-

valerylharnstoff gebraucht worden und von Rao und Watson [8] für die Synthese von Br · Hg(OCN) und J · Hg(OCN). Wie ich festgestellt habe, kann das Salz durch Fällen einer halbmolaren mit HNO_3 angesäuerten Wasserlösung von $Hg_2(NO_3)_2$ mit NaOCN in einigem Überschuss in 95 %-iger Ausbeute und von grosser Reinheit erhalten werden. Es ist in heissem Wasser etwas löslich und daraus bei Abkühlen als kleine Nadeln erhältlich. Seine Dissoziation in Wasser in der Wärme sowie die umgekehrte Reaktion bei Zimmertemperatur sind schon erwähnt worden, ebenso seine Bildung nach der Ederschen Reaktion. Wässriges NH_3 bewirkt sofortige Schwärzung durch Bildung von met. Hg.

Kupfercyanate

Normale Cyanate von Kupfer waren meines Wissens bis jetzt unbekannt *, woran die leichte Hydrolysierbarkeit hauptsächlich die Schuld trug. Wie *Cupricyanat* aus Acetonlösung darzustellen ist, wurde oben mitgeteilt. Ein Doppelsalz mit Kaliumcyanat kann aber in Wasser dargestellt werden; es fällt bei Vermischen einer konzentrierten $Cu(NO_3)_2$-Lösung mit KOCN in Überschuss als ein voluminöser Kristallniederschlag aus. Das Salz, welches die Formel $KCu(OCN)_3$ hat, löst sich in Wasser mit blauer Farbe, die Löslichkeit beträgt bei 20° 5,2 g pro 100 ml (durch Cu-Analyse einer abgewogenen Menge gesättigter Lösung bestimmt). In absolutem Alkohol ist die Löslichkeit so gering, dass der Alkohol farblos bleibt. Aceton löst kleine Mengen mit hellgrüner Farbe. Die Verbindung kann nur kurze Zeit in Wasserlösung aufbewahrt werden, da sie rasch unter Bildung von basischem Cyanat zersetzt wird. Versuche ein entsprechendes Natriumsalz zu bereiten scheiterten, wahrscheinlich wegen einer zu grossen Löslichkeit des Salzes in Wasser.

Die Fähigkeit Doppelcyanate zu bilden ist auch für das *Cuprocyanat* CuOCN eigentümlich. Wenn eine Wasserlösung von Kupfersulfat oder Nitrat mit überschüssigem Kaliumcyanat und dann mit Kaliumbisulfit versetzt wird, tritt bald Ausfällung von glänzenden farblosen Kristallblättern ein, und gleichzeitig beginnt eine ziemlich lebhafte Entwicklung von CO_2. Die Zusammensetzung der Kristalle ist $KCu_3(OCN)_4$. Bei später ausgeführten Synthesen wurde immer als Cu^{2+}-Salz das Nitrat verwendet und das Bisulfit gegen eine frisch bereitete Lösung von SO_2 in Wasser ausgetauscht. Die Lösung muss dann um die Auskristallisation zu beschleunigen gepuffert werden. Die Pufferung ist auch dadurch geboten, dass die Zersetzung der bei der Reduktion gebildeten Cyansäure in CO_2 und NH_4-Salz unbedingt verhindert werden muss um Komplikationen durch Doppelsalzbildung von NH_4OCN mit CuOCN zu vermeiden. Als Puffer wurde Kaliumacetat benutzt, wodurch die CO_2-Bildung praktisch vollständig zurückgedrängt werden konnte. Nach neuesten Messungen von Amell [12] ist die thermodynamische Dissoziationskonstante der Cyansäure bei 20° $2{,}0 \times 10^{-4}$, diejenige von Essigsäure ist bekanntlich ungefähr ein Zehntel von diesem Wert.

* In Williams, H. E. *Cyanogen Compounds*, 2. Aufl. s. 73, wird Cupricyanat als eine grüne in Wasser unlösliche Verbindung beschrieben. Wie ich festgestellt habe, handelt es sich hier um ein basisches Cyanat von der Formel $Cu(OH)_2 \cdot Cu(OCN)_2$.

Dieselbe Zusammensetzung wie das Kaliumsalz hat das in analoger Weise dargestellte Rubidiumsalz, also $RbCu_3(OCN)_4$, während diejenige der Natriumverbindung der Formel $NaCu_4(OCN)_5$ gehorcht. Auch dieses Salz kristallisiert in Tafeln *. Selbstverständlich ist bei Synthesen der Na- und Rb-Verbindungen Na- bezw. Rb-Acetat als Puffer zu verwenden.

Die Komplexizität dieser in Wasser schwerlöslichen Doppelcyanate ist schwach; sie werden z.B. von Wasser unter Bildung von gelbem Cu_2O hydrolytisch zersetzt.

Die abweichende Formel des Na-Salzes gab mir den Anlass, auch die Darstellung eines Lithiumsalzes zu versuchen. Bei Zusatz von Lithiumcyanat zu einer Mischung von $Cu(NO_3)_2$, LiOAc und SO_2 trat in einigen Fällen keine, in anderen eine geringfügige Kristallisation ein, bei Einleiten von SO_2 jedoch eine reichliche. Die Analyse der gewaschenen und getrockneten prismatischen Kristalle zeigte, dass sie alkalifrei waren und die Formel CuOCN hatten. LiOCN ist also zur Bildung von schwerlöslichem Doppelcyanat unfähig, und damit war also eine Methode zur Darstellung von CuOCN gefunden.

Das Cuprocyanat ist in seinem chemischen Verhalten Cuprochlorid sehr ähnlich. Es wird wie dieses leicht von Wasser under Gelbfärbung hydrolysiert und in feuchtem Zustand leicht durch den Luftsauerstoff unter Grünfärbung oxydiert. Dieses ist auch bei seinen Doppelverbindungen der Fall, weshalb das Abfiltrieren und Auswaschen in einer Stickstoffatmosphäre auszuführen ist. Brom in Wasser bewirkt sofortige Auflösung zu $CuBr_2$, und $Cu(OCN)_2$, $(SCN)_2$ in einem organischen Solvenz schwärzt unter Bildung von $Cu(SCN)_2$. Konzentrierte Wasserlösungen von KOCN lösen CuOCN zu einer leicht oxydablen Lösung. Längeres Aufbewahren geschieht am besten in Vakuum unter Ausschluss von Tageslicht. CuOCN wirkt ferner als Katalysator nach Sandmeyer bei Einführung von einer *Iso*cyanatgruppe in den Benzolkern, wovon weiter unten die Rede sein wird.

Die für die Synthesen von $RbCu_3(OCN)_4$ und CuOCN erforderlichen Rb- bezw. Li-Cyanate sind aus den entsprechenden Sulfaten durch Umsatz mit Bariumcyanat und Konzentrieren der filtrierten Lösung durch Vakuumdestillation erhältlich. Die Methoden der Literatur zur Herstellung von $Ba(OCN)_2$ sind wenig befriedigend; das Salz kann aber, wie ich gefunden habe, sehr bequem durch Fällen einer gesättigten wässrigen Lösung von Natriumcyanat mit einer äquivalenten Menge von Bariumrhodanid- oder Perchlorat in Methanol gewonnen werden **. Das Cyanat kristallisiert anhydrisch in kleinen Prismen von neutraler Reaktion, seine Löslichkeit in Wasser bei 20° wurde durch Ba-Analyse der gesättigten Lösung zu 10,6 g pro 100 ml = 0,45 M bestimmt.

Wie schon oben erwähnt, zeigt sich die Halogenähnlichkeit der Cyanatgruppe auch darin, dass CuOCN als Sandmeyerkatalysator bei der Einführung von einer *Iso*cyanatgruppe in den Benzolkern wirken kann. Für eine solche Reaktion via ein Diazoniumsalz war man früher auf Katalyse nach Gattermann [14] also mit metallischem Cu hingewiesen.

---

* Von Wöhler und Berthmann [13] sind Natriumcuprofulminate der Formeln $NaCu(ONC)_2$ und $Na_2Cu(ONC)_3 3H_2O$ dargesteilt worden.

** Versuche analog das Strontiumcyanat aus dem Rhodanid und NaOCN zu gewinnen scheiterten, wahrscheinlich wegen einer zu grossen Löslichkeit des Salzes in Methanol-Wasserlösung.

Wird zu einer diazotierten Lösung von Anilinhydrosulfat KOCN gesetzt und dann sofort $KCu_3(OCN)_4$ oder $NaCu_4(OCN)_5$, tritt unmittelbar eine lebhafte Stickstoffentwicklung ein, und es scheidet sich C_6H_5NCO als Öltropfen ab, die mit einem passenden Solvenz wie Benzol, Chloroform oder Tetrachlorkohlenstoff aufgenommen werden können. Die Reaktion ist wegen der Wasserempfindlichkeit des Isocyanats etappenweise auszuführen; der Katalysator ist in Portionen zuzusetzten und das Reaktionsprodukt jedesmal zu extrahieren. Die Ausbeuten sind aus dem genannten Grunde nicht besonders gut, auch nicht bei möglichst rapidem Arbeiten. Etwas bessere Ausbeuten, bis auf 30 %, sind mit *o*-Toluidin erhalten worden, was wohl hauptsächlich der geringeren Wasserempfindlichkeit des *o*-Tolyl*iso*cyanats zuzuschreiben ist.

Das durch Fraktionieren isolierte Reaktionsprodukt wurde durch kurzes Erwärmen mit *o*-Kresol identifiziert, wobei in fast quantitativer Ausbeute der *o*-Tolylester der *o*-Tolyl-Carbaminsäure entstand.

EXPERIMENTELLER TEIL

Das für die folgenden Versuche benutzte Kaliumcyanat war Bakers' Analyzed ebenso das Cuprinitrat; das Natriumcyanat war von Hopkin und Williams geliefert.

Cadmiumcyanat aus Sulfat und Bariumcyanat

12,82 g $3CdSO_4 \cdot 8H_2O$ wurden in 100 ml H_2O gelöst und zu dieser Lösung eine solche von 11,09 g $Ba(OCN)_2$ in 150 ml H_2O gesetzt. Um alles $Cd(OCN)_2$ in Lösung zu bringen, wurde auf ein Volumen von 550 ml verdünnt. Das Reaktionsgemisch blieb über Nacht bei Zimmertemperatur stehen, wonach der Niederschlag von $BaSO_4$ auf einem grossen Jenaer Glasfilter G4 abfiltriert wurde. Durch Vakuumdestillation wurde dann die Lösung sofort auf ein Volumen von 55 ml konzentriert, wobei Kristallisatiou in seideglänzenden Blättern eintrat. Nach etwa zweistündigem Kühlen in Eisbad wurde die Mutterlauge abgesogen, die Kristalle zunächst mit Aceton und dann mit Äther gewaschen und kurz an der Luft getrocknet. Gewicht 10,0 g statt theor. 12,0. Das so präparierte Salz war mit etwas basischem Salz gemengt und löste sich nicht klar in Wasser. Zwecks Reinigung wurden 2,2 g in 100 ml H_2O gelöst und soviel einer 0,25 M Essigsäurelösung zugesetzt, dass die Trübung verschwand. Es wurde nun sofort durch Vakuumdestillation mit einer Badtemperatur, die nicht 50° überstieg, auf ein Volumen von 25 ml eingeengt und dann nach Zugabe von 3 ml 0,25 M HOAc in Eisbad der Kristallisation überlassen. Nach etwa 3 Stunden Abfiltrieren, Waschen und Trocknen, wie oben angegeben. Ausbeute 1,6 g = 73 %.

Das Cd wurde als Oxid bestimmt, C und H nach Liebig (Gef. Cd 46,64; C 9,96; H 2,08. Ber. für $2Cd(OCN)_25H_2O$ [482,92]: Cd 46,55; C 9,94; H 2,08; für $Cd(OCN)_22H_2O$ (232,45): Cd 48,35; C 10,32; H 1,73). Bei Aufbewahren in Vakuum über konz. H_2SO_4 gibt das Salz langsam sein Kristallwasser ab.

Cadmiumcyanat aus Jodid und Silbercyanat

21,976 g CdJ_2 wurden in 100 ml reinem Aceton suspendiert und zu der Lösung 17,988 g AgOCN in Portionen gesetzt. Beide Präparate waren von hochgradiger Reinheit. Reaktion unter Wärmeentwicklung. Das Gemisch blieb während 2 Tagen bei Zimmertemperatur unter zeitweiligem Umschütteln stehen. Dann wurde der Niederschlag abfiltriert, in Vakuum getrocknet, pulverisiert und dann wieder in die Acetonlösung hineingebracht. Nach weiteren 2 Tagen war die Lösung jodidfrei, der Niederschlag wurde abfiltriert, mit Äther gewaschen und in Vakuum getrocknet. Gewicht 41,7 statt 39,9 g. Zwecks Gewinnung des Cyanats wurden 6,66 g des Gemenges von AgJ und anhydrischem $Cd(OCN)_2$ mit 115 ml Wasser digeriert, die Wasserlösung abgesogen, und der Niederschlag mit

2 × 10 ml Wasser gewaschen. Gewicht nach Trocknen 4,73 statt 4,70 g. Durch Konzentrierung der Lösung wie oben angegeben auf ein Volumen von 25 ml und nachfolgender Kühlung konnten 1,43 g Ag-freies Cyanat isoliert werden.

Darstellung von Mercuricyanat aus $HgCl_2$ und AgOCN in Äther

27,25 g gepulvertes $HgCl_2$ wurden in 600 ml trocknem Äther gelöst und 33 g reines AgOCN zugesetzt (theor. 30,0). Das Reaktionsgemisch wurde während einer Stunde geschüttelt und dann während eines Tages sich selbst überlassen. Die Lösung war dann chlorfrei. Nach Filtrieren wurde der Äther abdestilliert, wobei Kristallisation von $Hg(OCN)_2$ eintrat. Der von AgCl, AgOCN und $Hg(OCN)_2$ bestehende Niederschlag wurde dann erschöpfend mit Äther extrahiert, wodurch insgesamt 27 g reines $Hg(OCN)_2$ erhalten wurden. Das Präparat ist in einer trocknen Atmosphäre, am besten in Vakuum aufzubewahren. Bei der Analyse wurde Hg als HgS bestimmt, N nach Kjeldahl und C auf nassem Wege durch Verbrennung mit einem Gemisch von H_2SO_4, CrO_3, H_3PO_4 und KJO_3. (Gef. Hg 70,66; N 9,80; C 8,36. Ber. für $Hg(OCN)_2$ (284,61): Hg 70,49; N 9,84; C 8,44). Die Dichte wurde pyknometrisch bei 20° zu 4,35±0,01 mit Brombenzol als Sperrflüssigkeit bestimmt.

Darstellung von Mercuricyanat aus Quecksilberoxyd und Cyansäure

In 75 ml eisgekühltem trocknem Äther wurden 8,9 g trocknes HCl eingeleitet und zu der Lösung in Portionen 47 g AgOCN gegeben (theor. 36,9). Reaktion unter Wärmeentwicklung. Nach Umschütteln unter Kühlung während etwa 1,5 Stunden wurde der Niederschlag auf einem Glasfilter G3 mit 65 ml Äther in Portionen ausgewaschen und zu der Lösung sofort 24,4 g gelbes, in der Kälte ausgefälltes, mit Wasser, Alkohol und Äther gewaschenes HgO in Portionen unter Umschütteln gesetzt. Reaktion unter einiger Wärmeentwicklung, weshalb anfänglich etwas mit kaltem Wasser gekühlt wurde. Beim Stehen wurde die gelbe Farbe des Bodenkörpers allmählich blasser und war nach 12 Stunden gelblich weiss. Der stechende Geruch von HOCN war nun verschwunden. Der Bodenkörper wurde abfiltriert, mit etwas Äther gewaschen und in Vakuum getrocknet. Gewicht 23,4 g. Die Mutterlauge wurde durch Abdestillieren des Äthers konzentriert, wobei Kristallisation eintrat. Die Kristalle wurden sofort von dem wasserhaltigen Äther abfiltriert und in Vakuum getrocknet. Die 23,4 g Bodensubstanz wurden mit Äther erschöpfend extrahiert und insgesamt konnten nach Konzentrieren der Lösungen 21,7 g $Hg(OCN)_2$ isoliert werden. (Gef. Hg 70,41; N 9,24 (Kjeldahl). Ber. Hg 70,49; N 9,84).

Als Kontrolle der Reinheit von $Hg(OCN)_2$ kann die restlose Auflösung in Äther oder Aceton benutzt werden. Wenn sich eine Probe nicht vollständig löst, ist eine Umlösung in Äther für die Reinigung genügend.

Darstellung von Mercurocyanat

56,1 g (0,1 Mol) $Hg_2(NO_3)_2 \cdot 2H_2O$ wurden in einer Mischung von 150 ml H_2O und 20 ml 2 M HNO_3 bei gelinder Wärme aufgelöst, die Lösung mit Eis gekühlt und sofort mit einer Lösung von 17,5 g NaOCN in 200 ml H_2O gemischt, Die Menge von NaOCN war so bemessen, dass sie ausser zur Ausfällung von $Hg_2(OCN)_2$ auch zur Pufferung der überschüssigen HNO_3 ausreichte. Es entstand sofort ein rein weisser Niederschlag, der sich ziemlich rasch absetzte. Nach einer Viertelstunde wurde der Niederschlag auf einem grösseren Jenaer Glasfilter G3 abfiltriert, durch Umrühren mit eiskaltem Wasser viermal ausgewaschen, dann zweimal mit Alkohol und Äther und zuletzt in Vakuum über H_2SO_4 getrocknet. Gewicht 46,2 statt 48,5 g = 95 %. (Gef. Hg 82,90. Ber. für $Hg_2(OCN)_2$ (485,22): Hg 82,68).

Dissoziation von Mercurocyanat durch Erhitzen mit Wasser

41,9 g $Hg_2(OCN)_2$ wurden mit 200 ml siedeheissem Wasser kurz umgeschüttelt, wobei der Niederschlag sich sofort grau färbte. Die warme Lösung wurde durch ein grosses Glasfilter G3 filtriert und sofort gekühlt, wobei eine kleine Menge einer in kleinen Nadeln anschiessenden Substanz sich absetzte, ($Hg_2(OCN)_2$). Das Digerieren wurde nun mit neuen Portionen von 200 ml heissem Wasser fortgesetzt, bis bei Ankühlen keine weitere Kristallisation von $Hg_2(OCN)_2$ eintrat. Der rückständige Niederschlag konnte nach Trocknen praktisch vollständig zu flüssigem Hg zusammengerieben werden. Gewicht 15,8 statt 16,9 g. Die vereinigten völlig klaren Wasserextrakte, deren Volumen etwa 1 Liter betrug, wurden möglichst rasch durch Vakuumdestillation konzentriert, wobei Kristallisation allmählich eintrat. Die Kristalle wurden fraktioniert aufgesammelt und in Vakuum getrocknet, und die Konzentrierung der Mutterlauge bis zu wenigen ml getrieben. Insgesamt konnten 20,2 g Substanz statt theor. 24 g isoliert werden und daraus nach Umlösen in Äther 18,4 g reines $Hg(OCN)_2$.

Reduktion von $Hg(OCN)_2$ zu $Hg_2(OCN)_2$

Lösungsmittel Wasser. 2,84 g $Hg(OCN)_2$ wurden in 50 ml H_2O gelöst und während einer Stunde mit 33 g met. Hg geschüttelt. Probe auf Hg^{2+} mit NaOH gab dann keinen Niederschlag von HgO. Nach Absaugen der Wasserlösung wurde mit Wasser, Alkohol und Äther gewaschen und luftgetrocknet. 29 g Hg wurden entfernt und der Rückstand fünfmal mit je 25 ml siedeheissem Wasser ausgelaugt, der wässrige Extrakt eisgekühlt, wobei 0,11 g $Hg_2(OCN)_2$ ausfiel. Die Mutterlauge wurde durch Vakuumdestillation eingetrocknet und dabei ein Salzrückstand von 2,33 g erhalten. Dieser löste sich bei Digerieren mit 170 ml Äther mit einem äusserst kleinen gelben Rückstand. 1,82 g $Hg(OCN)_2$ wurden aus der Ätherlösung isoliert.

Lösungsmittel Äther. 4,40 g $Hg(OCN)_2$ wurden in 100 ml Äther suspendiert und mit 125 g met. Hg geschüttelt. Die Reduktion war nach 2 Stunden beendet, da die Probe mit NaOH einen negativen Ausfall hatte. Der Niederschlag wurde abfiltriert, wie oben beschrieben gewaschen und getrocknet und mit 3×50 ml heissem Wasser ausgelaugt. Beim Einengen der filtrierten Lösung konnten 3,0 g Mercuricyanat isoliert werden. Die Ätherlösung, wo die Reduktion ausgeführt wurde, gab keinen Eindampfungsrückstand, was also zeigt dass der Reaktionsverlauf ein quantitativer war.

Cupricyanat

6,2 g $Hg(OCN)_2$ wurden in 50 ml Aceton gelöst und zu der Lösung 4,46 g anhydrisches $CuBr_2$ gesetzt. Unter gelinder Wärmeentwicklung geht das Bromid in Lösung und reagiert mit dem Cyanat unter Ausfällung eines hellgrünen Niederschlags. Die Umsetzung ist nach wenigen Minuten beendet *. Nach stundenlangem Stehen bei Zimmertemperatur wird der Niederschlag unter Ausschluss von Feuchtigkeit abfiltriert, dreimal mit kleinen Mengen des Ketons unter Umrührung und dreimal mit trocknem Äther gewaschen und dann in Vakuum über P_2O_5 bis zu Gewichtskonstanz getrocknet. Ausbeute 2,6 g statt theor. 2,95. (Gef. Cu 42,34; C 16,62. Ber. für $Cu(OCN)_2$ (147,59): Cu 43,08; C 16,27).

$Cu(OCN)_2$ ist leicht und vollständig löslich in Wasser zu einer blauen Lösung, die aber bald unlösliches basisches Salz absetzt. In Methanol und Äthanol sowie in Aceton ist es mit grüner Farbe etwas löslich. Diese Lösungen sind bei längerem Aufbewahren auch nicht stabil. Die Dichte wurde bei 20° pyknometrisch mit Xylol als Sperrflüssigkeit zu 2,45± 0,01 bestimmt.

* In rigorös getrocknetem Aceton ist die Reaktion träger

Kaliumcupricyanat

Eine Lösung von 8,2 g KOCN in 25 ml H_2O wurde durch Zusatz von 0,2 g $Ba(NO_3)_2$ und Abfiltrieren des Niederschlags von Carbonat befreit, und die eisgekühlte Lösung mit einer ebenfalls eisgekühlten Lösung von 6,0 g $Cu(NO_3)_2 \cdot 3H_2O$ in 15 ml H_2O gemischt. Es entstand sofort ein aus feinen Nadeln bestehender hellgrüner Kristallbrei. Nach etwa 30 Min wurden die Kristalle auf einem Glasfilter G3 aufgesammelt, mit 10 ml eiskaltem Wasser und dann mit Alkohol und Äther unter Umrühren gewaschen und in Vakuum über konz. H_2SO_4 getrocknet. Ausbeute 4,2 g. Bei der Analyse wurde K als Sulfat und Cu als Rhodanur bestimmt. (Gef. K 16,51; Cu 27,74. Ber. für $KCu(OCN)_3$ (228,62): K 17,09: Cu 27,86).

Kaliumcuprocyanat

12,0 g $Cu(NO_3)_2 \cdot 3H_2O$ wurden in 50 ml Wasser gelöst und dazu 50 ml einer 1,3 M Lösung von SO_2 in Wasser gesetzt. Bei Zugabe von 9,8 g KOAc in 50 ml H_2O entstand ein gelbgrüner Niederschlag der sich sofort auflöste, wenn eine Lösung von 8,1 g KOCN in 50 ml H_2O zugegeben wurde. Die grüne Farbe der Lösung wurde rasch abgeblasst, und Ausfällung von glänzenden Kristallblättern setzte sofort ein. Das Gemisch wurde 45 Min im Eisbad gekühlt und dann die Kristalle auf ein Glasfilter von mittlerer Feinheit aufgesammelt, mit 0,2 M SO_2-Lösung dreimal unter Umrührung gewaschen, dann zweimal mit Alkohol und dreimal mit Äther und dann sofort in Vakuum über H_2SO_4 getrocknet. Ausbeute 5,4 statt theor. 6,6 g. Abfiltrierung und Auswaschen sind in einer N_2-Atmosphäre auszuführen, und bevor der Zugabe von Alkohol ist das SO_2 mit N_2 zu verjagen, da alkoholisches SO_2 mit CuOCN eine braune Färbung gibt.

Bei der Analyse wurde K als Sulfat nach Entfernen des Cu mit H_2S als Cu_2S bestimmt. Für die Cu-Analyse wurde die Probe in Wasser suspendiert; soviel Brom wurde zugesetzt, dass vollständige Auflösung eintrat, und dann nach Zugabe von SO_2 wurde Cu als CuSCN ausgefällt und gewogen. (Gef. K 9,42; Cu 47,37; C 12,29; H 0,19. Ber. für $KCu_3(OCN)_4$ (397,85): K 9,83; Cu 47,94; C 12,07).

Natriumcuprocyanat

12,1 g $Cu(NO_3)_2 \cdot 3H_2O$ in 25 ml H_2O + 50 ml einer 1,4 M SO_2-Lösung + 17 g $NaOAc \cdot 3H_2O$ in 50 ml + 6,5 g NaOCN in 75 ml. Auskristallisation etwas langsamer als beim Kaliumsalz. Kristallisationszeit 1 Stunde. Auswaschen und Trocknen wie oben beschrieben mit der Ausnahme, dass statt mit Alkohol mit einer 0,1 M Lösung von HOAc in Alkohol gewaschen wurde. Ausbeute 4,5 g statt 6,1. Ziemlich grosse rein weisse Blätter. Das Na wurde als Sulfat, Cu als CuSCN bestimmt. (Gef. Na 4,68; Cu 51,80. Ber für $NaCu_4(OCN)_5$ (487,32): Na 4,72; Cu 52,12).

Rubidiumcuprocyanat

Zu einer Lösung von 6,0 g $Cu(NO_3)_2 \cdot 3H_2O$ in 15 ml H_2O wurde eine Lösung von RbOAc, aus 6,52 g Rb_2CO_3 und 3,25 ml Eisessig in 25 ml H_2O dargestellt, gesetzt und dann eine Lösung von RbOCN, die aus 6,52 g Rb_2SO_4 und 5,4 g $Ba(OCN)_2$ in 100 ml H_2O bereitet und dann durch Vakuumdestillation auf ein Volumen von 25 ml konzentriert worden war. Kleine Mengen eines hellgrünen Niederschlages entstanden, die aber bei Zusatz von 25 ml einer 1,5 M SO_2-Lösung sofort verschwanden. Rasches Ausfallen eines weissen Niederschlags von kleinen Schuppen. Nach halbstündigem Stehen in Eisbad Abfiltrieren und Waschen wie bei der Na-Verbindung und Trocknen in Vakuum. Gewicht 3,3 g, theor. 3,9 g. Die Mutterlauge setzte bei Stehen noch etwa 0,1 g Substanz als grössere Tafeln mit rhombischer Begrenzung ab. Bei der Analyse wurde Rb als Perchlorat und Cu als CuSCN bestimmt. (Gef. Rb 18,89; Cu 43,19. Ber. für $RbCu_3(OCN)_4$ (444,23): Rb 19,24; Cu 42,93).

Cuprocyanat

24,2 g $Cu(NO_3)_2 \cdot 3H_2O$ in 25 ml H_2O + 0,3 Mol LiOAc in 60 ml H_2O, wobei eine dunkelblaue Lösung entstand. Zu dieser wurde eine Lösung von 0,2 Mol LiOCN gegossen, aus 0,1 Mol $Li_2SO_4 \cdot H_2O$ + 0,1 Mol $Ba(OCN)_2$ dargestellt und durch Vakuumdestillation auf

ein Volumen von 50 ml konzentriert.* Die Farbe der Lösung wurde dabei etwas dunkler. Nun wurde 100 ml einer 1,4-M SO_2-Lösung zugesetzt, was einen Farbenumschlag in grün bewirkte. Bald setzte unter Abblassen der Farbe Kristallisation ein, und es wurde nun während 30 Min SO_2 in die Lösung eingeleitet. Die Kristalle wurden wie vorher beschreiben abfiltriert und gewaschen und in Vakuum unter Lichtausschluss getrocknet und aufbewahrt. Ausbeute 9,3 g = 88 %. Kleine Prismen von der Dichte 3,13 ± 0.01 bei 20°, pyknometrisch mit Brombenzol und Xylol als Sperrflüssigkeiten bestimmt. Bei der Analyse wurden Cu als CuSCN und N nach Kjeldahl bestimmt. (Gef. Cu 60,15; N 13,29; Ber. für CuOCN (105,58): Cu 60,23; N 13,27).

Darstellung von Bariumcyanat

Zu einer Lösung von 13,0 g NaOCN in 115 ml H_2O wurden 0,3 g $Ba(ClO_4)_2$ (Anhydrid) gesetzt und der kleine Niederschlag von $BaCO_3$ abfiltriert. Ferner wurden 33,6 g $Ba(ClO_4)_2$ in 115 ml reinem Methanol gelöst und die beiden Lösungen gemischt. Auskristallisieren setzte fast sofort ein. Nach Aufbewahren über Nacht in Kälteschrank, wurden die Kristalle abfiltriert mit Methanol und Äther gewaschen und in Vakuum getrocknet. Ausbeute 15,8 g = 71 %. (Gef. Ba 62,35. Ber. für $Ba(OCN)_2$ (221,38) Ba 62,04). Das Salz ist auch wiederholt aus Methanollösungen von $Ba(SCN)_2$ mit ungefähr derselben Ausbeute dargestellt worden.

Darstellung von *o*-Tolyl*iso*cyanat

Zu einer Lösung von 10,8 ml konz. H_2SO_4 in 100 ml H_2O wurden 10,7 ml *o*-Toluidin gesetzt und das Gemisch bis zur vollständigen Auflösung der Base gewärmt. Die eisgekühlte Lösung wurde nun mit 7,5 g $NaNO_2$ in 10 ml H_2O diazotiert. Farbe der Lösung blassgelb. Zusatz einer Lösung von 10 g KOCN in 15 ml H_2O und sofort 5 g $KCu_3(OCN)_4$. Ein braunes Addukt von Katalysator und Diazoniumsalz endstand sofort und bei dessen Zersetzung lebhafte Stickstoffentwicklung und Abscheiden einer Flüssigkeit. Sofortiges Ausschütteln mit 70 ml eisgekühltem Chloroform, das stark braun gefärbt wurde. Das ganze wurde durch ein grosses Glasfilter G2 filtriert und die Chloroformschicht schnell abseparіert. Zu der lichtgrünen Wasserlösung wurden weitere 3 g des Katalysators gesetzt, wobei nochmals Gasentwicklung eintrat, jedoch schwächer als vorher. Erneutes Ausschütteln mit $CHCl_3$, das sich diesmals schwächer braun färbte. Die Prozedur wurde ein drittes Mal mit 3 g Katalysator wiederholt, wobei kaum Gasentwicklung stattfand und das Chloroform fast farblos blieb. Die vereinigten Chloroformextrakte wurden sofort mit P_2O_5 getrocknet und das Lösungsmittel in Vakuum bei einer Badtemperatur unter 40° abdestilliert. Gewicht des flüssigen Rohprodukts von 3 solchen Synthesen 37 g. Zunächst wurde in Vakuum fraktioniert, wobei als Mittelfraktion 16 g Flüssigkeit gewonnen wurden. 30 g derart dargestelltes Präparat lieferten bei einer zweiten Fraktionierung unter gewöhnlichem Druck 21 g zwischen 183° und 187° siedendes *Iso*cyanat = 28 %.

Die Synthese des *o*-Tolyl*iso*cyanats ist auch mit Benzol als Extraktionsmittel ausgeführt worden. Die Abtrennung der Benzolschicht geht jedoch langsamer, was sich in einer verschlechterten Ausbeute kundgibt.

Wie ich gefunden habe, enthält das mit $CHCl_3$ oder CCl_4 extrahierte Tolyl*iso*cyanat immer kleine Mengen von Chlor, und dies gilt auch für das durch Katalyse nach Gattermann hergestellte. Das *o*-Tolyl*iso*cyanat ist wie Phenyl*iso*cyanat zu Tränen reizend, jedoch nicht so stark, dass Arbeiten damit eigentliche Unannehmlichkeiten mitführt.

o-Tolylcarbaminsäure-*o*-Tolylester aus *o*-Tolyl*iso*cyanat

In 6,0 g wie oben beschrieben dargestelltes $CH_3C_6H_4NCO$ wurden 4,87 g *o*-Kresol gelöst, was unter Temperaturerniedrigung geschah. Die Lösung wurde auf dem Wasserbade gewärmt, wobei der Inhalt des Kolbens bald zu einem Kristallkuchen erstarrte.

* Eine Wasserlösung von LiOCN kann ebensowenig wie die Lösungen von Li-Halogeniden durch Destillation konzentriert werden ohne durch Hydrolyse alkalisch zu werden. Diese Tatsache wirkt aber in diesem Falle kaum belästigend, da die Lösung bei Zusatz von SO_2 sauer wird.

Nach etwa 7 Stunden wurde das Reaktionsprodukt pulverisiert. Gewicht 10,70 g statt theor. 10,87. Die Substanz, die nicht mehr nach *Iso*cyanat roch, wurde zwei Stunden bei Zimmertemperatur mit 50 ml Benzin digeriert, dieses scharf abgesogen, die Kristalle mit etwas Benzin gewaschen und in Vakuum getrocknet. Gewicht 9,34 g. 2 g der Substans wurden nun aus 5 ml warmen Eisessig kristallisiert, wobei 1,34 g zurückgewonnen wurden. Schmelzp. 115—118°. Durch zwei weitere Kristallisationen aus Eisessig konnte der Schmelzpunkt auf 124—126° erhöht werden aber nicht weiter. Prismen aus Eisessig. Von Gattermann wurde als Schmelzpunkt 126° gefunden.

Metal-Metal Bonding in Some Transition Metal Dioxides

BENGT-OLOV MARINDER and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

Short metal-metal distances found in the rutile-type phases in the systems $(Ti,V)O_2$ and $(V,Mo)O_2$ indicate the presence of bonds between the metal atoms. There is a close relation between the axial ratio of these compounds and the number of free valence electrons available per bond. A comparison is made with the bonds observed in the dioxides of MoO_2-type and in orthorhombic rhenium dioxide and also in some complex ions containing transition metals of valence numbers lower than their maximum ones.

In the dioxides of MoO_2-type, *i.e.* vanadium, molybdenum, wolfram, technetium and rhenium dioxide, and in the orthorhombic modification of the latter, short metal-metal distances have been observed which indicate the presence of bonds between the metal atoms. All these oxides contain metal atoms with valence numbers lower than their maximum ones, which implies that there are valence electrons not engaged in metal-oxygen bonding. It has been pointed out in previous articles that there exists a qualitative relation between the metal-metal bond distances and the number of free electrons available per bond [1,2].

In order to throw further light on this relationship a few systems of mixed transition metal dioxides have been studied [3]. These systems have contained representatives of the structure types mentioned above and titanium dioxide (rutile type). A surprising result of this investigation was the occurrence of extended regions of rutile-type structure not only in pseudobinary systems containing titanium dioxide as a component, *e.g.* TiO_2-VO_2, but also in systems that did not contain a component of rutile structure, *e.g.* VO_2-MoO_2.

The structure types of rutile, molybdenum dioxide and orthorhombic rhenium dioxide are alike in being built up of metal-oxygen octahedra joined by corners and by edges. The short metal-metal distances are associated with the octahedra sharing edges. For the rutile type this distance is simply equal to the length of the *c* axis of the unit cell, while the calculation of the metal-metal distances for the two other structure types requires the knowledge of the actual values of the metal atom parameters.

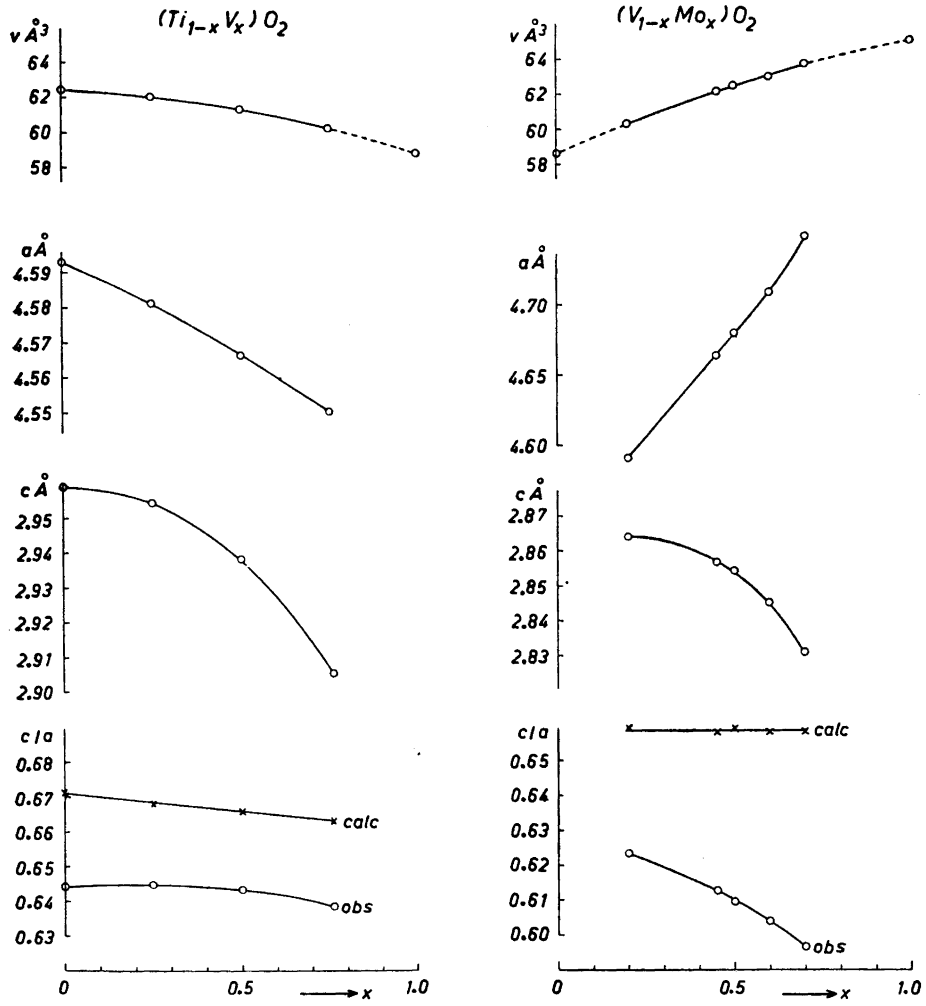

Fig. 1. Lattice parameters of the rutile-type phases in the systems (Ti,V)O_2 and (V,Mo)O_2.

The factors determining the length of the close metal-metal approach may be rather complicated in nature but for a simplified discussion the following factors will be considered:

1) The geometrical relations connected with the ratio of the metal and oxygen atom radii.
2) The repulsive forces caused by the charges of the atoms.
3) The bonding forces between the metal atoms.

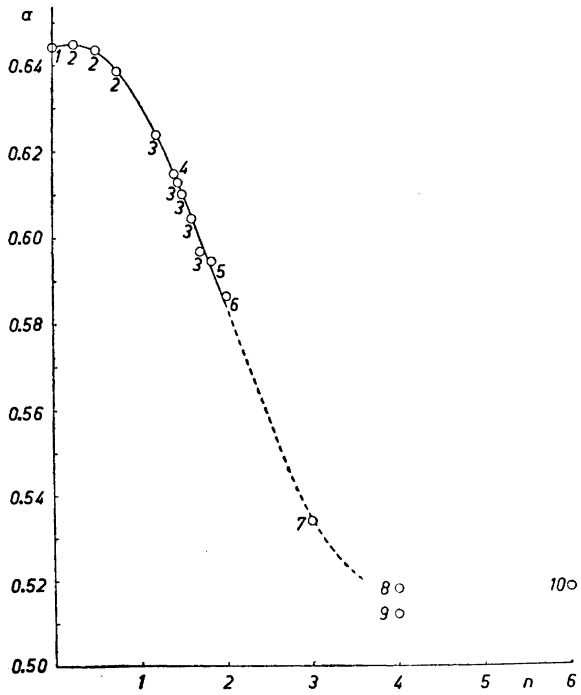

Fig. 2. Axial ratios of rutile-type phases and equivalent quantities for other types of transition metal dioxides (a) *versus* number of valence electrons available per metal-metal bond (n). The figures correspond to the following samples: 1-TiO_2, 2-$(Ti,V)O_2$, 3-$(V,Mo)O_2$, 4-$(Re,V)O_2$, 5-$(Re,Mo,V)O_2$, 6-VO_2, 7-ReO_2 (orthorhombic), 8-MoO_2, 9-WO_2, 10-TcO_2 and ReO_2 (MoO_2-type).

The lattice parameters of the rutile-type phases in the systems $(Ti_{1-x},V_x)O_2$ and $(V_{1-x},Mo_x)O_2$ are represented in Fig. 1 as functions of the composition. The decrease with increasing x of the volume per formula unit (v) of the former is in accordance with the formula volumes of the pure components. The same is true for the increase with x of the volume of the $(V_{1-x},Mo_x)O_2$ rutile phase.

For $(Ti,V)O_2$ both the a and c axes decrease with increasing x. At about $x = 0.4$ the shortening of c seems to be slightly accelerated. For $(V,Mo)O_2$ the increase of the a axis with x parallels the change of the formula volume, while the c axis shows a simultaneous shortening. The results indicate the presence in $(V,Mo)O_2$ of considerable attractive forces between neighbouring metal atoms, increasing in strength with the molybdenum content. They also suggest the possibility of slight attraction in $(Ti,V)O_2$ for high vanadium contents.

Pauling [4] has given an expression for the axial ratio of rutile-type crystals considering the influence of the ratio of the atomic radii and of the anion-anion repulsive forces. The metal-metal interaction was considered negligible.

Fig. 1 also shows the axial ratio derived by this formula, c/a (calc), and those obtained from the experimental data, c/a (obs). For $(Ti,V)O_2$ the calculated and experimental ratios differ by approximately the same amount as that found by Pauling for pure titanium dioxide. The deviating slope of the observed ratios for $(V,Mo)O_2$ indicates that a contracting force acts between the metal atoms in the c direction and that this effect increases with increasing molybdenum content.

It appears that the axial ratio may provide a suitable "normalized" measure of the metal bond length present in these phases. Fig. 2 gives the values of c/a (obs) for the various samples of $(Ti,V)O_2$ and $(V,Mo)O_2$ as a function of the number of valence electrons available per metal-metal bond, *i.e.* the number of valence electrons not engaged in metal-oxygen bonding divided by the number of short metal-metal distances. The corresponding data for two samples of rutile structure obtained in the $(V,Re)O_2$ and $(V,Mo,Re)O_2$ systems also fit the smooth curve.

Fig. 2 also contains data for the various dioxides of MoO_2-type (deformed rutile structure) and for the orthorhombic rhenium dioxide. For these substances a different normalized bond length had to be chosen instead of the axial ratio used for the rutile-type structures. Thus, for the monoclinic MoO_2-type compounds, the quotient $d/\sqrt{bc\sin\beta}$ was adopted as an appropriate equivalent of c/a (rutile). In this expression, d denotes the length of the metal-metal bonds which extend approximately parallel to the a axis of the unit cell, this direction corresponding to that of the unique axis of the ideal rutile lattice. For the orthorhombic rhenium dioxide where the bonds form zig-zag strings through the structure, the bond length was analogously divided by the square root of the unit mesh area projected parallel to the bond direction.

It must be emphasized that the bond lengths of the pure dioxides are less accurately known than those present in the rutile-type structures. This is especially so for the technetium and rhenium dioxides. The d values for these two compounds have thus been roughly estimated assuming the metal atom positions to be the same as those found for molybdenum dioxide.

The change of direction of the curve for high number of electrons is very likely associated with the considerable electrostatic repulsion between the metal atoms at the very short metal-metal distances present in these compounds which are significantly shorter than those occurring in the metals.

It seems probable that similar but not identical curves may be given by other mixed oxide systems. Thus niobium dioxide, the structure of which is a superstructure of the rutile type [5], gives an axial ratio of the subcell falling considerably below the curve given in Fig. 2. This may indicate the existence of stronger bonds in this compound than those found in the present investigation. On the other hand tantalum dioxide of rutile structure [6] shows an axial ratio rather close to that of titanium dioxide, which may be an indication of weak or no bonding between the tantalum atoms. Similar values of the axial ratio (0.642—0.673) are also shown by several rutile-type structures found by Brandt [7] among mixed oxides of antimony, niobium or tantalum with aluminium, gallium or transition elements which are likely to be present in a trivalent state (chromium, iron and rhodium). The group of trirutile structures, studied by Byström, Hök and Mason [8], and comprising mixed

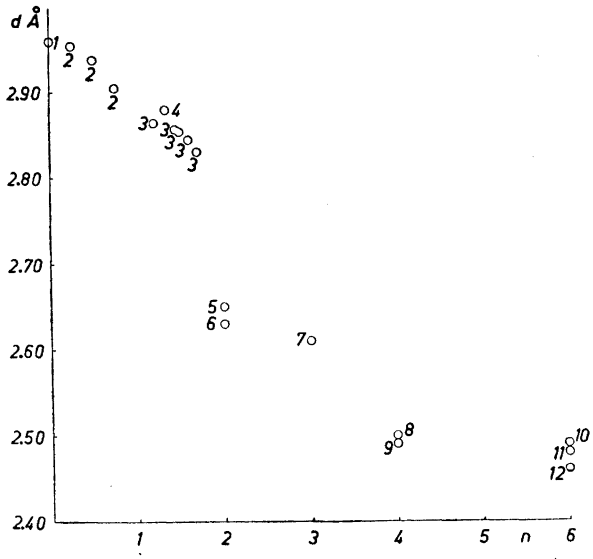

Fig. 3. Metal-metal bond lengths for various transition metal compounds (d) *versus* number of valence electrons available per bond (n). The figures denote the following substances: 1-TiO_2, 2-(Ti,V)O_2, 3-(V,Mo)O_2, 4-$(Ta_6Cl_{12})^{2+}$, $(Ta_6Br_{12})^{2+}$ and $(Nb_6Cl_{12})^{2+}$, 5-VO_2, 6-$(Mo_6Cl_8)^{4+}$, 7-ReO_2 (orthorhombic), 8-MoO_2, 9-WO_2, 10-ReO_2 (MoO_2-type), 11-TcO_2, 12-$(W_2Cl_9)^{3-}$.

oxides ASb_2O_6 and ATa_2O_6, where A is magnesium, zinc, iron, cobalt or nickel, likewise gives high values for the ratio $c/3a$ (0.645—0.665). X-Ray studies on further systems of mixed transition metal dioxides are in progress. It is also planned to start magnetic investigations of these substances in the near future.

Very short metal-metal distances have also been found in other transition metal compounds, *e.g.* the ions $W_2Cl_9^{3-}$ and $Mo_6Cl_8^{4+}$ studied by Brosset [9–11] and the ions $Nb_6Cl_{12}^{2+}$, $Ta_6Br_{12}^{2+}$ and $Ta_6Cl_{12}^{2+}$ investigated by Vaughan, Sturdivant and Pauling [12]. The geometrical conditions present in these compounds are of course quite different from those in the dioxides. It is, however, interesting to note that the rough qualitative relation found to connect the metal-metal distances with the number of valence electrons available per metal-metal bond in the dioxides also seems to be valid for these complex ions (*cf.* Fig. 3).

These studies form part of a research program on metal oxides and related compounds supported by the *Swedish Natural Science Research Council.*

Phase Analysis Studies on the Titanium-Oxygen System

STEN ANDERSSON, BENGT COLLÉN, ULF KUYLENSTIERNA and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The titanium-oxygen system has been studied by means of X-ray powder photographs of preparations quenched after annealing at various temperatures. A number of phases not previously described has been observed, *viz.*

Ti_2O, TiO (low-temperature modification), Ti_4O_7, Ti_5O_9, Ti_6O_{11}, Ti_7O_{13}, Ti_8O_{15}, Ti_9O_{17} and $Ti_{10}O_{19}$.

The extensions of the homogeneity ranges have been determined for the phases with variable composition.

The first phase analysis by means of X-ray methods on the titanium-oxygen system was carried out by Ehrlich [1,2], who reported the existence of three intermediary oxides and a high solubility of oxygen in the hexagonal titanium modification. Subsequent investigations by other authors have been numerous and comprise in addition to X-ray studies the employment of other techniques, *e.g.* microscopy and thermal measurements. These studies have contributed some modifications and added further details to the general conception of the titanium oxides established by Ehrlich but the results are not consistent throughout.

A phase diagram for the titanium-oxygen system constructed on the basis of data published up to 1954 has been given by De Vries and Roy [3]. The uncertainty in several respects was emphasized by these authors who actually characterized the diagram as a "not-impossible" phase diagram.

As there seemed to be reasons for considering the knowledge of the titanium-oxygen system as inadequate it was thought worth-while to undertake a comprehensive phase analysis. The results obtained so far will be reported in this article. X-Ray diffraction data for the various phases will be published seperately [4]. Crystal structure studies on several of the oxides are in progress.

STARTING MATERIALS

Starting materials for the syntheses were titanium metal, titanium dioxide and intermediary titanium-oxide preparations of known compositions. The metal was "Matthey Titanium Sponge" (Johnson, Matthey & Co., Ltd), the principal impurities of which were stated by the manufacturer to be 0.01 % magnesium, 0.01 % iron and 0.003 % silicon. A determination according to Kjeldahl of the nitrogen content gave the result < 0.01 %. The titanium dioxide was of "Baker Analyzed" quality, the principal impurities being zinc (0.01 %), lead (0.006 %) and iron (0.008 %). The X-ray diffraction pattern showed that the sample consisted of the anatase modification.

The samples of intermediary titanium oxides used in the syntheses were prepared by melting mixtures of titanium metal and dioxide in an electric arc furnace. The products were analyzed in the way described below.

PREPARATION METHODS

The samples used in the present investigation were obtained by heat-treating appropriate mixtures of the starting materials. The heating was carried out in three different ways, *viz.* in an electric arc furnace under argon atmosphere, in an electric resistance furnace in a stream of argon and finally with the samples sealed in evacuated silica tubes. In order to accelerate the attainment of equilibrium, samples intended for heat-treatment at lower temperatures were generally premelted in the arc furnace.

The electric arc furnaces employed were of a design by Hägg and Kiessling [5]. The arc (DC) is formed between a negative wolfram electrode and the specimen in the form of a pressed tablet or pellet (positive electrode), which rests on a strongly water-cooled copper base. In this way no reaction occurs with the base, nor is there any transport of material from the wolfram electrode to the specimen. The cooling rate of the sample after disconnecting the arc is very high. The argon pressure within the furnace was for the actual preparations kept at about 0.5 at. When needed, the tablets were remelted once or twice in order to obtain a complete reaction. Due to segregation the samples prepared in the arc furnace were often not in a complete state of equilibrium — this was indicated by the relatively diffuse powder photographs given by these specimens.

For the syntheses in an argon stream, a horizontal electric resistance furnace (maximum temperature 1 200°C) with a Pythagoras mass tube was used. The specimen tablets were kept in an alumina boat. For low contents of oxygen a superficial reaction was found to occur between the specimens and the boat. The reaction product, however, stuck to the boat and thus did not contaminate the titanium oxide samples. For high contents of oxygen no appreciable attack on the boat was observed. The argon was purified by passing it at about 770°C over finely divided uranium, obtained according to Kiessling [6] by thermal decomposition of partially hydrogenated uranium chips. The titanium oxide samples were allowed to cool in the furnace under argon, the cooling rate thus being rather slow.

Most of the annealing operations were carried out with the specimen tablets sealed in evacuated silica tubes, which were heated in vertical, electric resistance furnaces. All the samples treated in this way were quickly quenched in water. For the lowest heating temperatures applied (400° and 600°C) no reaction was found to occur between the silica and the samples. Specimens low in oxygen only slightly affected the silica when heated for long periods of time at 800°C. At 1 150°C preparations with oxygen contents below about $TiO_{1.5}$ attacked the tubes to an extent that made annealing under these conditions impracticable. Samples richer in oxygen did not react in a serious way with the silica at this temperature. In order to prevent a reaction with the silica tube at the beginning of the heating, it was found necessary to avoid as far as possible the use of titanium metal or low oxides as components in the sample.

CHEMICAL ANALYSIS

The oxygen contents of all samples prepared by arc-melting and by heating in an argon stream and of several of those heated in silica tubes were determined by the increase of weight when oxidized to titanium dioxide. Weighed samples of 0.3—0.5 g were heated in silica boats in an oxygen stream at 1 000°C for periods ranging from one hour for specimens of high oxygen content to some ten hours for those low in oxygen. Following Ehrlich [1] the latter specimens were admixed with a known amount of titanium dioxide in order to avoid spitting. Only the rutile form (preheated at high temperatures) could be used for this purpose since anatase was found to cover the specimen grains with rigid shells of rutile, thus preventing complete oxidation. The reproducibility of the analyses was found to be good. The difference between starting composition and the analytically found composition after the various heat-treatments was small in most cases.

X-RAY METHODS

The phase analysis was performed by means of X-ray powder photographs taken in a Guinier focusing camera of 80 mm diameter with strictly monochromatized Cu$K\alpha_1$ radiation. In order to depress the back-ground fogging caused by the fluorescence radiation from the titanium content of the samples, an aluminium filter foil of 35 μ thickness was placed in contact with the photographic film. The registration and evaluation of the patterns were carried out in the way described in a previous article [7]. Thus an internal standard (potassium chloride, British Drug Houses, Analar, $a = 6.2919$ Å at 20°C [8]) was added to the powder specimens. Photographs of samples without admixture were used to reveal superpositions of lines. The effect of film shrinkage was overcome according to Hägg by printing a scale on the film prior to development [9]. Following Österlöf the measurement of the reflexions was made on the sharp, high-angle edge of the lines [10]. In this way it was generally possible to determine the line positions to within $\pm$ 0.01 mm.

The single-crystal photographs were taken in a Weissenberg camera using CuK radiation.

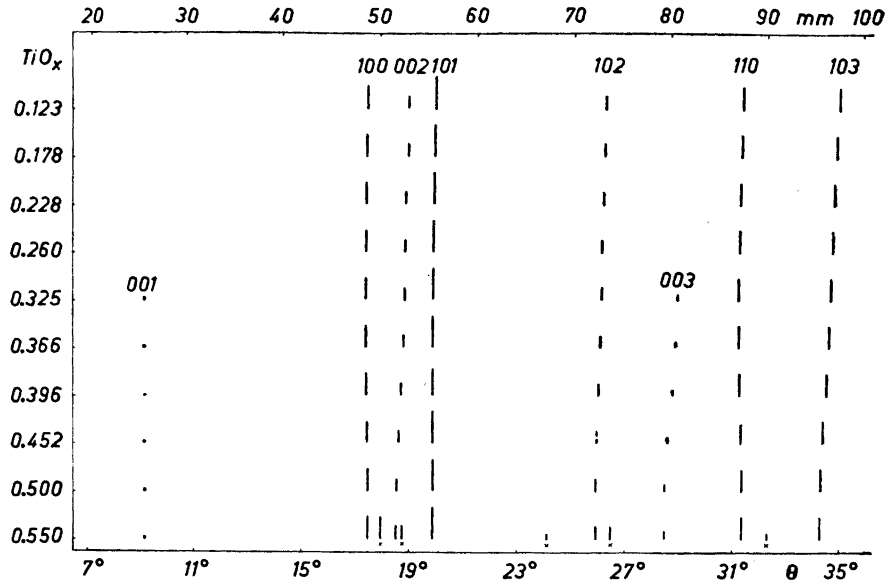

Fig. 1. Powder patterns of preparations $TiO_{0.12}$-$TiO_{0.55}$ annealed at 400°C. The lines marked with an X in $TiO_{0.55}$ belong to the δ-oxide.

RESULTS OF THE PHASE ANALYSIS

On account of the experimental difficulties mentioned above the phase analysis studies have so far been restricted to a few temperature regions. Thus samples low in oxygen have been mostly studied after quenching from annealing temperatures of 800°, 600° and 400°C. The composition range $TiO_{0.5-1.5}$ has also been investigated by means of specimens quenched from the melting temperature (about 1 800°C). For higher oxygen contents, samples heat-treated at 1 150°C have been studied.

The results obtained for the various regions of composition will be discussed in the following.

The composition range $TiO_{0-0.5}$.

Data on the solubility of oxygen in α-titanium have been given by several authors [11]. They all give values for the maximum oxygen content of this phase, corresponding to the approximate formula $TiO_{0.5}$, and the oxygen atoms are supposed to occur randomly distributed in the octahedral interstices of the hexagonally close-packed titanium lattice. The c-axis is said to increase over the whole composition range while the a axis, which is only slightly affected by the incorporation of the oxygen atoms, reaches a maximum value at about $TiO_{0.25}$ and then remains constant with increasing oxygen content.

The powder patterns of several samples within this composition range heat-treated at 400°C for 6 weeks are represented in Fig. 1. Photographs of samples annealed for several weeks at 600° and 800°C and of specimens quench-

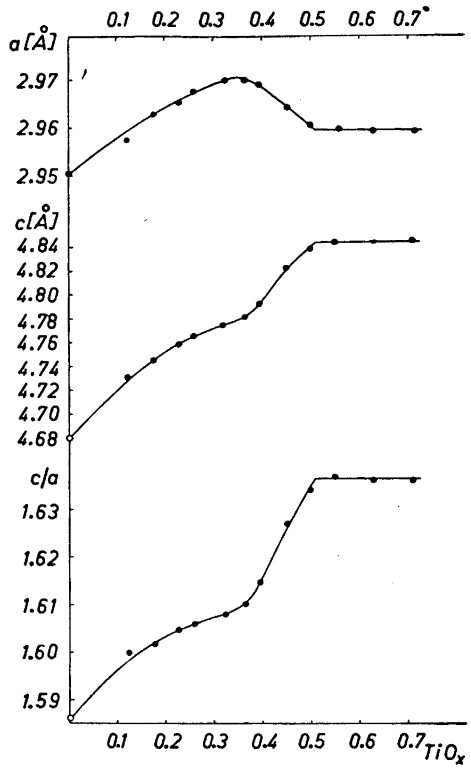

Fig. 2. Lattice parameters and axial ratios of the hexagonal specimens α-Ti-$TiO_{0.5}$.

ed in the arc furnace are all in full agreement with those shown in Fig. 1 ecxept for the fact that the reflexions 001 and 003 are not always present (*v. infra*).

Fig. 2 shows the variation of the lattice parameters with the oxygen content. The dimensions for pure titanium are those given by Szántó [12], which, however, do not differ considerably from recent values reported by other authors [11]. The maximum solubility of oxygen corresponds closely to $TiO_{0.50}$ and this value is evidently valid irrespective of the heat-treatment. The length of the a axis goes through a maximum at about $TiO_{0.35}$ and the steady increase of the c axis is suddenly accelerated at the same composition.

The lines 001 and 003, both of very low intensity, are incompatible with an hexagonal close-packed titanium structure containing randomly distributed oxygen atoms. The value of the axis ratio ($c/a = 1.637$) reached at the composition $TiO_{0.5}$ is evidently not connected with the presence of an almost perfect hexagonal close-packing of the atoms (ideal value of $c/a = 1.633$). For samples heat-treated at 400°C, the extra lines 001 and 003 occur in $TiO_{0.33}$ and specimens higher in oxygen. This is close to the composition where anomalous changes of the lattice parameters have been found to occur. For preparations annealed at 600° and 800°C and quenched in the arc furnace, however,

the minimum compositions for the appearance of these two lines are about $TiO_{0.40}$, $TiO_{0.45}$ and $TiO_{0.50}$, respectively. In the patterns of the high-temperature samples the two lines are slightly diffuse.

The two extra lines may be accounted for if the oxygen atoms are assumed to be arranged in every second layer of octahedral interstices extending normally to the hexagonal axis of the titanium host lattice. Simultaneously the oxygen atoms force the adjacent titanium atom layers somewhat apart. The transition from the random TiO_{0+x} to the ordered Ti_2O_{1-y} arrangement will be further studied. Details for the Ti_2O structure will appear elsewhere.

Ehrlich's observation [2] that samples $TiO_{\sim 0.2}$ are remarkably volatile has been confirmed by experiments in sealed, evacuated silica tubes and also in an argon stream at about 1 000°C. Further studies on this phenomenon are in progress.

The composition range $TiO_{0.5-1.4}$

According to Ehrlich [1] titanium monoxide is of the NaCl type with randomly distributed vacancies in both the titanium and oxygen lattices. The range of homogeneity extends from between $TiO_{0.58}$ and $TiO_{0.69}$ to between $TiO_{1.25}$ and $TiO_{1.33}$. All the titanium positions are occupied at the lower limit and all the oxygen sites are filled at the higher limit. At the composition $TiO_{1.00}$, 15 % of both atomic positions are vacant. Similar ranges of homogeneity have been reported by subsequent authors for samples prepared at high temperatures.[11]

Naylor [13] found, from heat capacity measurements, indications of a phase transition in TiO at 991°C. Jenkins [14] reported that the powder photograph of $TiO_{1.00}$ heat-treated at 870°C is composed of the patterns of two distinct bodycentered cubic structures. Wang and Grant [15] and also two of the present authors [16] found that TiO (NaCl type) when annealed at 925° and 800°C transforms giving a phase of the stoichiometric composition TiO and a complicated powder pattern.

The existence of a phase of a composition close to Ti_3O_2 or Ti_4O_3 formed by annealing below 925°C was reported by Bumps, Kessler and Hansen [17].

In the present investigation, arc-melted samples of compositions between $TiO_{0.64}$ and $TiO_{1.25}$ were found to give powder photographs showing exclusively the pattern of a NaCl-type phase. The lines were very sharp. No superstructure reflexions could be observed. Samples outside this composition region gave powder patterns showing an additional phase (α-Ti or Ti_2O_3). The homogeneity range of TiO (NaCl-type) derived from the observed unit cell dimensions extends from $TiO_{0.64}$ to $TiO_{1.26}$ (*cf.* Fig. 3). Table 1 lists the observed densities for the various TiO samples and the corresponding values for the occupancy of the atomic positions. The data confirm the results reported by Ehrlich[1].

Samples TiO_x ($0.5 < x < 1$) annealed at 900°C for 2 weeks gave powder photographs showing the pattern of Ti_2O and a great number of extra lines which appeared alone at the composition $TiO_{1.00}$. No reflexions of the NaCl-type oxide were present. The powder pattern of $TiO_{1.00}$ could not be accounted for by assuming the coexistence of two cubic phases as suggested by Jenkins [14]. Annealing at 800°C for two weeks was also performed for preparations with x values ranging from 0.55 to 1.40. For oxygen contents x below 1 the patterns were found to contain all those lines observed in the 900°C samples and in addition a considerable number of extra ones. The specimens annealed at

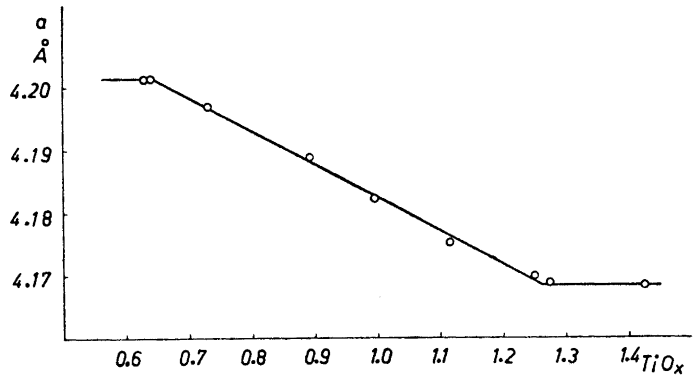

Fig. 3. Lattice parameter of TiO_x (NaCl type).

800°C were not in a state of equilibrium. The same three sets of X-ray reflexions were also found to occur in preparations heated for several weeks at 600°C.

Specimens TiO_x ($1 < x < 1.15$) annealed at 800°C gave powder patterns containing the lines found in the sample $TiO_{1.00}$ and those of TiO (NaCl-type). The latter pattern appeared alone in samples around $TiO_{1.20}$ and mixed with a corundum-type pattern (Ti_2O_3) at higher contents of oxygen. None of the systems of reflexions observed for the preparations heat-treated at 900—600°C showed any indication of line displacement with varying oxygen content.

The results may be accounted for in the following way. At 800°C there exist the phases Ti_2O, an oxide of the approximate composition $TiO_{0.65}$, not prepared in a pure state, TiO (low-temperature modification of stoichiometric composition), TiO (NaCl-type with a very narrow range of homogeneity and the approximate composition $TiO_{1.20}$) and Ti_2O_3. The $TiO_{\sim 0.65}$ phase, the powder pattern of which is similar to that given by Bumps, Kessler and

Table 1. Occupancy of the atomic positions in TiO_x (defective NaCl-type)

0.892	4.188_9	4.96	5.62	88.3	78.8
0.995	4.182_2	4.95	5.79	85.5	85.1
1.116	4.175_2	4.89	6.00	81.5	91.0
1.195	4.172_5	4.83	6.13	78.8	94.2
1.250	4.169_9	4.77	6.22	76.7	95.9
(1.275	4.168_9	4.80	6.26	76.7	97.8)

Hansen [17] for the δ-phase, forms also at 600°C but not at 900°C. The low-temperature TiO is stable also at 900°C.

It has been pointed out [15,16] that the densities of TiO (low-temperature form) and $TiO_{1.00}$ (NaCl-type) are very nearly the same, *viz.* 4.91 and 4.95, respectively, and that there seems to be a pronounced relationship between the powder patterns of these two phases. This may indicate close structural kinship and it may be that the random atomic vacancies present in TiO (NaCl-type) occur in an ordered way in the low-temperature form.

The composition range $TiO_{1.4-1.7}$

The phases reported by previous authors within this range of composition are Ti_2O_3 and Ti_3O_5. The former, which according to Zachariasen [18] has the corundum structure, was said by Ehrlich [1] to have an extended range of homogeneity, $TiO_{1.46-1.56}$. A compound said to be Ti_3O_5 has been studied by Rusakov and Zhdanov [19] who found this substance to be isomorphous with pseudobrookite.

The phase conditions within this range of composition were studied by means of samples heat-treated at 1 150°C for four days. A slight variation was found for the lattice parameters of Ti_2O_3 (corundum type), the limiting values being reached in the preparations $TiO_{1.49}$ ($a = 5.160$ Å, $c = 13.60$ Å) and $TiO_{1.51}$ ($a = 5.147$ Å, $c = 13.64$ Å). The range of homogeneity thus lies within the limits $TiO_{1.49-1.51}$.

The powder pattern of a phase appearing pure at the composition $TiO_{1.67}$ (Ti_3O_5) is independent of the oxygen content. This pattern (*cf.* Fig. 4) is incompatible with the one reported by Rusakov and Zhdanov [19] for Ti_3O_5. Single crystals have been obtained in the electric arc furnace and a structure determination using Weissenberg photographs is in progress. The single crystal data have made it possible to interpret the powder pattern and the following dimensions have been obtained for the monoclinic unit cell:

$$a = 9.757 \text{ Å}, \qquad b = 3.802 \text{ Å}, \qquad c = 9.452 \text{ Å}, \qquad \beta = 93.11°$$

The observed density of 4.20 is in good agreement with the one calculated for a cell content of four formula units of Ti_3O_5 (4.24). The results of the structure determination will be published elsewhere [20].

It is of interest to note that studies on the system $(Ti_{1-x}, Fe_x)_3O_5$ have revealed the existence of a phase of pseudobrookite type for iron contents down to $x = 0.03$ [21]. It may be that the crystal studied by Rusakov and Zhdanov, which was obtained from slag, contained impurities stabilizing the pseudobrookite structure.

The composition range $TiO_{1.7-1.9}$

Previous authors have reported the existence in this region of a phase with an extended homogeneity range, *viz.* $TiO_{1.70-1.80}$ (Ehrlich [1]) and $TiO_{1.80-1.83}$ (Filonenko, Kudryavtsev and Lavrov [22]).

The samples used in the present studies were with few exceptions annealed at 1 150°C for three days. Specimens quenched in the arc furnace showed the same phases as those obtained at 1 150°C, but were found less suitable

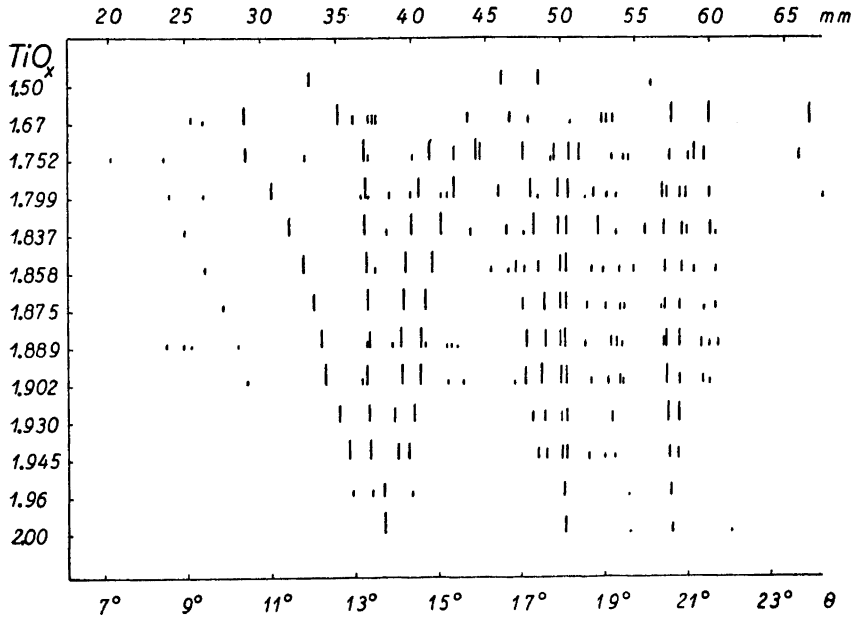

Fig. 4. Powder patterns of preparations $TiO_{1.50}$-$TiO_{2.00}$.

for X-ray studies because they gave less distinct powder lines. The reaction rate at 1 000°C was too low for equilibrium to be reached within a reasonable period of time.

Samples slightly higher in oxygen than $TiO_{1.70}$ still showed the presence of Ti_3O_5 but at about the composition $TiO_{1.75}$ the powder pattern showed only the reflexions of a new phase. With increasing oxygen content the pattern changed but was always of a similar general character (*cf.* Fig. 4). A detailed analysis, however, showed that this change was not a continuous one but that there was a periodic alternation of single-phase and two-phase regions of composition. This is demonstrated in Fig. 5 which shows the reflexions observed within a narrow range of Θ. The reflexions at low Θ angles provide the most sensitive test for the identification of these phases.

In order to find the compositions of the various phases, samples TiO_x were used with x values varied stepwise down to 0.002. Fairly large quantities were employed for the annealing in order to minimize the influence of the reaction with the silica. Chemical analyses performed on several of the samples confirmed that the compositions did not change during the heat-treatment.

The compositions of the phases thus derived are, within the limits of accuracy, in accordance with the general formula Ti_nO_{2n-1} (*cf.* Table 2). Phases were thus identified with all values of n from 4 to 10. The formula Ti_5O_9 has been verified by means of the unit cell dimensions obtained from

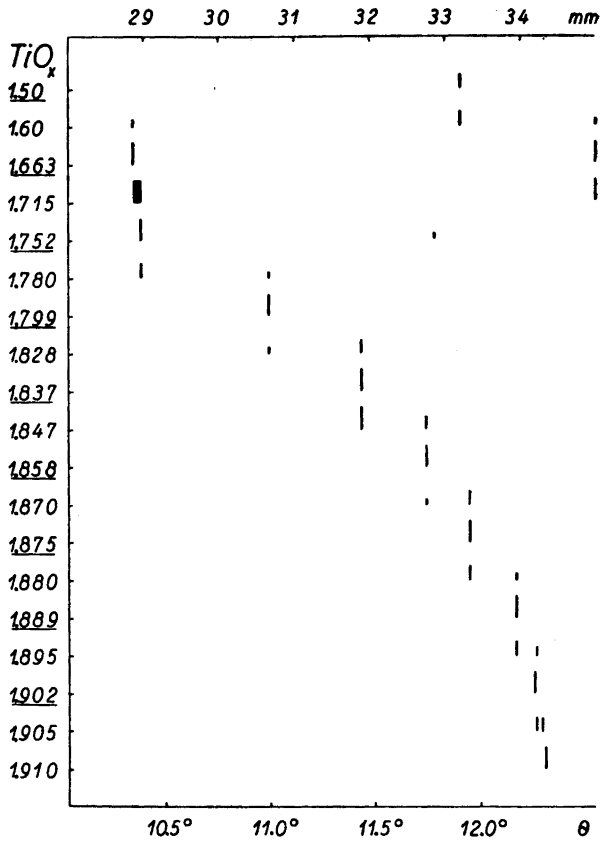

Fig. 5. Powder patterns within a narrow range of Θ of preparations $TiO_{1.50}$-$TiO_{1.91}$, demonstrating alternation of single-phase and two-phase regions of composition. Underlined x values correspond to single-phase photographs.

Table 2. Comparison between experimentally obtained compositions TiO_x and ideal compositions corresponding to a series Ti_nO_{2n-1}.

x_{obs}	n	$2n-1$	$x_{calc}=\frac{2n-1}{n}$	Ti_nO_{2n-1}

1.875	8	15	1.875	Ti_8O_{15}
1.889	9	17	1.889	Ti_9O_{17}
1.902	10	19	1.900	$Ti_{10}O_{19}$

single crystal data (triclinic symmetry) and density measurement. (The cell parameters were incorrectly given in a preliminary communication [23].)

$a = 5.569$ Å $\quad b = 7.120$ Å $\quad c = 8.865$ Å
$\alpha = 97.55°$ $\quad \beta = 112.34°$ $\quad \gamma = 108.50°$

The observed density is 4.29 in good agreement with the value 4.31 calculated for a cell content of two formula units of Ti_5O_9.

The general appearance of the X-ray patterns suggests that the oxides Ti_nO_{2n-1} form a homologous series of structurally interrelated compounds based on the rutile-type structure [23,24].

The composition range $TiO_{1.9-2}$

Several authors have reported on an extended homogeneity range of TiO_2 [11]. There are, however, no statements as to changes of the unit cell dimensions.

For higher oxygen contents than $TiO_{1.90}$ the powder patterns (samples annealed at 1 150°C) are still of the same type (*cf.* Fig. 4), which may suggest the existence of still higher members of the homologous series. It has, however, not been possible to prove the existence of two-phase regions above $TiO_{1.90}$. The difference between the powder patterns of consecutive homologues decreases with increasing n and it may be that the resolving power of the camera does not suffice to reveal the coexistence of two phases. Indications in favour of the supposition of distinct homologues above $Ti_{10}O_{19}$ are the considerable line displacements, which are not easily accounted for assuming a mechanism of solid solubility, and, especially, a periodical appearance of line broadenings with varying x. Anyhow, it is at present not possible to judge whether distinct phases Ti_nO_{2n-1} exist up to the limit of the two-phase region towards rutile or whether the series ends with a phase of variable composition. It is worth mentioning that equilibrium conditions are not easily reached in this border region.

The first trace of TiO_2 (rutile) was observed at the composition $TiO_{1.95}$. The lattice parameters of TiO_2 in the two-phase region differ slightly but significantly from those of pure rutile. The data obtained for the latter

$a = 4.593$ Å $\quad c = 2.959$ Å

are in good agreement with figures recently reported in the literature [25,26]. For the lower oxygen limit (sample quenched from 1 150°C) the corresponding values obtained were:

$a = 4.603$ Å $\quad c = 2.960$ Å

The data do not permit any accurate estimation of the width of the homogeneity range. The minimum content of oxygen is, however, higher than $TiO_{1.96}$.

When melted in the arc furnace, TiO_2 (rutile) was found to loose considerable amounts of oxygen. Thus, in one case, the composition of the sample after melting was found to be $TiO_{1.90}$. The powder photograph of this sample was diffuse. It showed no rutile lines but a pattern similar to that of the phases of the homologous series.

Acknowledgements. This investigation has been greatly facilitated by the support and assistance given by members of the research staff and representatives of other institutions. Thanks are due to Professor A. Ölander for his kind interest and for placing laboratory facilities at our disposal. Mrs. Stina Nord, Mr. G. Kruuse and Docent H. Pestmalis have given valuable assistance in the experimental and computational work.

Professor G. Hägg, Uppsala, and Docent R. Kiessling, AB Atomenergi, have given valuable information and advice in connection with the building of the electric arc furnace. In addition, Professor Hägg allowed the arc furnace of the Institute of Chemistry, University of Uppsala, to be used for the preparative work during the early stages of the investigation. This preparative work was carried out by Mr. S. Wahlgren.

Mr. H. Brynielsson, managing director, and Docent R. Kiessling of the AB Atomenergi kindly placed the uranium metal at our disposal.

These studies form part of a research program on metal oxides and related compounds financially supported by the *Swedish Natural Science Research Council.*

Identification of Titanium Oxides by X-Ray Powder Patterns

STEN ANDERSSON, BENGT COLLÉN, GEORG KRUUSE, ULF KUYLENSTIERNA, ARNE MAGNÉLI, HERBERT PESTMALIS and STIG ÅSBRINK

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

X-Ray powder data are given for fifteen phases occurring in the titanium-oxygen system.

Recent phase analysis studies carried out at this Institute on the titanium-oxygen system have revealed the existence of several previously unknown titanium oxide phases [1]. The analysis was performed by means of X-ray powder patterns, which were found to provide a powerful tool for the identification of the various oxides, both when occurring pure as well as in mixtures with each other.

The powder patterns were obtained using a Guinier focusing camera (80 mm diameter) with strictly monochromatized Cu$K\alpha_1$ radiation. Reflexions could be registered within the diffraction range $1.25° < \Theta < 43.5°$, the lower limit corresponding to a "cut-off" spacing of 35 Å. Potassium chloride (Analar, British Drug Houses, lattice parameter $a = 6.2919$ Å at 20°C [2]) was added to the powder specimens as an internal standard. The back-ground fogging caused by the fluorescence radiation from titanium was effectively depressed by means of an aluminium foil (35 μ) covering the photographic film. The techniques employed in evaluating the photographs have been described in a previous article [3].

The oxides were prepared from starting materials of high purity, *viz.* titanium metal (99.97 %) and titanium dioxide (99.98 %) by methods described previously [1]. The latter substance was found to be of the anatase form and was consequently used for registering the powder pattern of this modification of the dioxide.

All the synthesized oxides were obtained in a pure state except the so-called δ-phase ($TiO_{\sim 0.65}$) which always appeared together with Ti_2O and TiO (low-temperature form). The tables list parts of the powder patterns suitable for identification purposes, ranging from the lower "cut-off" limit

Table 1. α-Ti and Ti_2O. The hexogonally close-packed structure of α-Ti can dissolve considerable amounts of oxygen in a random distribution. At an oxygen content of about $TiO_{0.3}$, a transition occurs to an ordered arrangement of the oxygen atoms. The maximum solubility of oxygen corresponds to the composition Ti_2O, the powder pattern of which is given below. Reflexions indicating the ordered state are indicated by asterisks. The unit cell dimensions for Ti_2O are $a = 2.959_3$ Å and $c = 4.845_4$ Å.

and upwards. The phases are of stoichiometric composition if not otherwise stated in the tables.

The effectiveness of the powder patterns for the identification of the titanium oxides may be illustrated by the following example, encountered when analyzing the composition region around the phase Ti_6O_{11}. Photographs of samples TiO_x differing in composition from that of the pure phase by $\Delta x = \pm 0.002$ clearly showed weak extra reflexions which were identified as the strongest lines of the neighbouring phases ($\sin^2\Theta = 0.07011$ of Ti_5O_9 and $\sin^2\Theta = 0.06545$ of Ti_7O_{13}, respectively). The approximate amounts of the extra phases were thus about 5 % of the sample. The exposure times used for these photographs were of normal length, *viz.* one hour. Since the background of the films was quite low, considerably longer exposure times might have been applied, which would correspondingly increase the sensitivity of the method for the identification of minute amounts of extra phases.

Thanks are due to Mrs. Stina Nord for her valuable assistance in preparing the majority of the X-ray photographs.

This work forms part of a research program on metal oxides and related compounds financially supported by the *Swedish Natural Science Research Council.*

ACTA CHEMICA SCANDINAVICA 11 (1957) 1658—1662

Paper Chromatography and Colorimetric Determination of Free and Esterified Cholesterol in Very Small Amounts of Blood

PREBEN W. HANSEN and HENRIK DAM

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

A simple and rapid method for paper chromatography and colorimetric determination of cholesterol and total cholesterol esters in very small amounts of blood is described.

Cholesterol and cholesterol esters are separated within 20 min on paper with *iso*octane as mobile phase.

The quantitative determination after elution of the spots on the chromatogram is based on a modification of Zlatkis' color reaction. Equivalent amounts of cholesterol and cholesterol esters show the same optical density.

Total amounts of cholesterol and esters as low as 2.5 μg can be determined with an accuracy of 5 %.

In 1953 Zlatkis, Zak and Boyle [1] described a rapid and simple method for the determination of total cholesterol in blood. By the present modification of this method it is possible to determine cholesterol and its esters in amounts from 2.5 μg to 25 μg per 0.5 ml of reaction mixture.

The method of Zlatkis *et al.* is less specific than the methods of Liebermann-Burchard and Tschugaeff and frequently gives too high cholesterol values when used directly on plasma [2, 3].

We have, therefore, combined our modification of the method with a new and rapid paper chromatographic separation of cholesterol and its esters from other components which might interfere with the colorimetric determination.

EXPERIMENTAL

Reagents and Solvents

1. Standard cholesterol solution: 25.0 mg in 100 ml of chloroform.
2. Standard cholesterylacetate solution: 27.75 mg in 100 ml of chloroform.
3. Standard cholesterylpalmitate solution: 40.40 mg in 100 ml of chloroform.
4. Ferric chloride solution: 1.0 g in 10 ml of 99.5 % glacial acetic acid. (This solution can be kept for weeks).

5. Color reagent: 0.5 ml of the ferric chloride solution diluted to 25 ml with concentrated sulfuric acid. (The reagent has to be prepared just before the colorimetric determination is carried out).
6. Acetone-ethanol 1:1 (v/v).
7. 2,2,4-Trimethylpentane ("*iso*octane").
8. Chloroform.
9. Phosphotungstic acid solution: 10 % in ethanol.

Procedures

A. Preparation of sample for chromatography: 20 µl of plasma is pipetted by means of a constriction pipette (Carlsberg pipette [4]) into 300 µl of warm acetone-ethanol reagent in a 4.5 ml polyethylene-stoppered centrifuge tube. (In case the cholesterol is expected to be high the ratio of plasma taken to volume of extract should be reduced.) The tube is stoppered and placed for 5 min in a water bath at 80—85°C and then shaken violently for 1 min in a shaking apparatus (Microid Flask Shaker, Griffin & George Ltd., England). The tube is then centrifuged (approximately 1 min) and the supernatant liquid applied to the paper with a constriction pipette as described below. The precipitate is re-extracted twice with 100 µl acetone-ethanol reagent, every extract being applied to the paper.

B. Paper chromatography. Schleicher & Schüll 2043 b paper is cut out in sheets 15 cm long and 24.7 cm wide. Parallel to the longer edge of the paper three pencil lines are drawn at distances of 1, 2, and 12 cm from this edge. Between the 1 and 12 cm lines the paper is divided by means of a scalpel into 8 strips separated from each other by 1 mm open spaces.

The sheets are washed with *iso*octane by placing them for 5 min in the solvent in a glass bowl under slow motion. After drying the sheets are treated with chloroform in the same way.

By means of a constriction pipette the solution containing the cholesterol and cholesterol esters (from 2.5 to 25 µg) is applied as 1.5 cm streaks along the 2 cm line on each of the 6 strips in the middle. The first strip serves as a blank, whereas 100 µl from the cholesterol standard solution and 100 µl from one of the ester standard solutions are applied to the last strip. During application warm air is blown upward against the starting lines.

The paper is placed in the tank containing the mobile phase on the bottom. The tank must be completely saturated with vapor of *iso*octane before the chromatogram is started. Therefore, precaution must be taken to avoid vapor from escaping when the paper is brought into the tank. The chromatogram is started 5 min later and is run until the solvent front reaches the upper end of the strips. This requires about 20 min.

C. Elution of cholesterol and cholesterol esters. After chromatography the paper is removed from the tank and allowed to dry at room temperature for 1 min. The last strip is cut out and the spots are made visible by spraying with a solution of phosphotungstic acid (10 % in ethanol) followed by drying at 100°C for about 1 min. The zones on the other strips, including the blank, corresponding to the spots on the last strip, are cut out, placed in weighing glasses and extracted with 1.0 ml chloroform under gently shaking. The chloroform extracts are transferred to 1.5 ml test tubes with a constriction pipette, and the chloroform is evaporated by placing the tubes in a water bath at 70—80°C. The extraction procedure is repeated twice with 0.5 ml of chloroform.

While the chloroform extracts are evaporated, 20 µl of the cholesterol standard solution is pipetted into two test tubes and dried simultaneously with the eluates from the chromatogram. When dry the tubes are allowed to cool to room temperature, and subsequently 0.30 ml of glacial acetic acid is added. The tubes are stoppered and carefully shaken.

D. The colorimetric determination. From a Krogh-syringe [5] (mounted in a burette holder) 0.20 ml of the color reagent is added to the first of the tubes, and after rapid mixing with a small glass rod the tube is placed in a boiling water bath for exactly 1 min. The remaining tubes are treated similarly.

After cooling to room temperature in ice water the reaction mixtures are transferred to micro cuvettes with 1 cm light path and the optical density is measured at 530 mµ in a Beckman spectrophotometer.

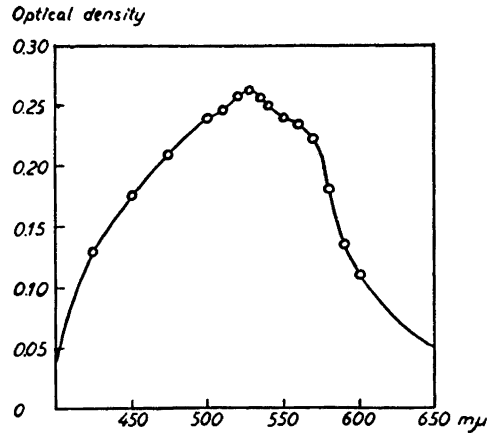

Fig. 1. Absorption curve for 5 μg cholesterol (free or esterified) per 0.5 ml reaction mixture.

DISCUSSION OF THE METHOD

The method of Zlatkis *et al.* consists in mixing a solution of cholesterol in 3 ml of glacial acetic acid with 2 ml of the color reagent, whereby a light brown color appears which changes to purple within a minute. This color shows a maximum at 560 mμ.

During our attempts to modify the method for determination of cholesterol and its esters in amounts from 2.5 μg to 25 μg per 0.5 ml (total) reaction mixture it was observed that by mixing the reagents as described by Zlatkis *et al.*, only the light brown color appeared. The temperature of the reaction mixture did not, because of the small volume, reach the level required for full development of the color (60—65°C)[6].

By placing the reaction mixture in a boiling water bath the light brown color changed to purple within a few seconds. After one minute in the boiling water bath followed by cooling in ice water the color obtained showed a maximum at 530 mμ for cholesterol as well as for cholesterol esters as shown in Fig. 1.

The color follows Beer's law in the concentration range examined, and equivalent amounts of cholesterol, cholesterylacetate and cholesterylpalmitate show the same optical density as it appears from Table 1.

The method of Zlatkis *et al.* was originally used on serum directly, but several authors [2,3] have stated that in this way the method often shows too high cholesterol values because of the interference of other compounds with the development of the color. It might be expected that combination of the method with a paper chromatographic separation of cholesterol and its esters from the interfering compounds would eliminate this error.

Several methods for paper chromatographic separation of cholesterol and its esters have been published [7-9], but most of these methods employ as mobile or stationary phase solvents which are difficult to remove from the

Table 1. Optical density at 530 mμ obtained with cholesterol and cholesterol esters per 0.5 ml reaction mixture (the total volume of the mixture).

mg/100 ml					
46.00	91.20	137.20	43.35	89.30	132.65
39.30	69.90	109.20	35.50	67.35	102.85
47.80	75.50	123.30	45.40	75.00	120.40

paper after chromatography. When the chromatogram is eluted with chloroform these solvents will pass into solution and interfere with the development of the color.

We therefore tried to find a paper chromatographic procedure by which cholesterol and its esters could be separated on untreated paper and with a mobile phase which is easy to remove from the paper after chromatography. *Iso*octane fulfills this requirement, and with this solvent we were able to obtain clear separation of cholesterol and total cholesterol esters in 20 min. On Schleicher & Schüll 2043 b paper the R_F values for cholesterol and cholesterol esters were 0.35 and 0.80, respectively.

Table 2 shows the recovery after chromatography of mixtures of cholesterol, cholesterylacetate and cholesterylpalmitate.

Table 3 shows the results obtained with hamster plasma by the present method (0.02 ml plasma) and by the method of Sperry and Webb [10] (0.2 ml plasma).

By the present method determination of free and esterified cholesterol in plasma from 6 animals can be carried out within 5 h, whereas the same determination by the Sperry-Webb method requires 2 days.

The Effect of Ions on the Catalytic Activity of Enzymes: The Old Yellow Enzyme

WILLIAM J. RUTTER* and BRITA ROLANDER

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The present communication is concerned with a study of the effect of ions on the activity of the old yellow enzyme system. In addition to a general inhibitory effect by anions, certain specific effects were observed. Fe^{3+} ions can, for example, act as the electron acceptor in the reaction, and in fact, with chelated iron compounds as the electron acceptor, the reaction rate increases markedly. The old yellow enzyme, as isolated, is apparently not a metallo flavoprotein.

The implications of the date with regard to the physiological activity of the old yellow enzyme are discussed.

The old yellow enzyme (OYE) ** facilitates the oxidation of TPNH (and to a lesser extent DPNH) according to equations (1) and (2).

$$\text{TPNH} + \text{H}^+ + \text{yellow enzyme} \rightleftharpoons \text{TPN}^+ + \text{leuco enzyme} \qquad (1)$$

$$\text{leuco enzyme} + \text{oxygen or dye} \rightarrow \text{H}_2\text{O}_2 \text{ or leuco dye} + \text{yellow enzyme} \qquad (2)$$

This enzyme was discovered by Warburg and Christian [1], and later purified extensively and studied by Theorell [2]. It has recently been crystallized by Theorell and Åkesson [3].

OYE preparations are characterized by a low turnover number in oxygen (approximately 35 moles O_2/min/mole enzyme at 30°C for the crystalline enzyme [3]), and also a very slow reaction rate with cytochrome c. Under aerobic conditions [4] reaction with oxygen takes precedence over reaction with cytochrome c. On this basis, OYE could be considered the TPN counterpart to the diaphorases.

---

* U. S. Public Health Service Fellow, 1954—55. Present address, Division of Biochemistry, University of Illinois, Urbana, Illinois, USA.

** Abbreviations used in this paper are OYE, old yellow enzyme; TPN, TPNH, oxidized and reduced triphosphopyridine nucleotide, respectively; Zwischenferment, yeast glucose-6-phosphate dehydrogenase; EDTA, ethylene diamine tetraacetic acid.

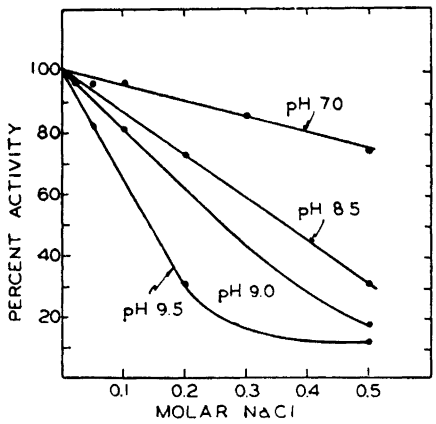

Fig. 1. Inhibition of activity of the Zwischenferment OYE system by sodium chloride. The measurements were made in conventional Warburg apparatus, each flask contained 15 μM glucose-6-phosphate; 0.5 μM TPN; 2 mg *Zwischenferment* (activity under optimal conditions, 1 μM TPNH formed/min/mg); 334 μg OYE; 29 mμM catalase; 100 μM buffer (glycine, pH 9.0, 9.5; glycylglycine, pH 8.5, 7.0); salts were added to the final concentration indicated; total volume 3.0 ml. Under these conditions 4.2 μM O_2 disappeared in 10 min, in control flasks at pH 8.5.

Theorell and Nygaard [5-7] have studied in a thorough manner the reaction of the old yellow protein, and the prosthetic group, FMN:

$$FMN + \text{old yellow enzyme apoprotein} \rightleftharpoons \text{old yellow enzyme} \qquad (3)$$

It was found that the ionic environment, especially the anionic species, influenced the reaction markedly.

METHODS

The old yellow enzyme was prepared by a modification of methods used for some time in the laboratory of Professor Theorell. A preparation having a β 280/β 465 ratio of 12.8 corresponding to 80 % purity was used in these experiments. Glucose-6-phosphate dehydrogenase (*Zwischenferment*) was prepared by the method of Warburg and Christian [8] and a modification of the procedure of Kornberg [9].

TPN, 90 % pure, was procured from Sigma Company. Oxygen consumption by the glucose-6-phosphate dehydrogenase — old yellow enzyme system was measured in the conventional Warburg apparatus. TPNH oxidation was followed spectrophotometrically or by the decrease in the intensity of fluorescence [10].

RESULTS

Effects of anions on the Zwischenferment— old yellow enzyme system. The influence of anions on the coupled Zwischenferment-old yellow enzyme system was studied using O_2 as the electron acceptor. Because of the experience already gained with Zwischenferment reaction [11], it was possible to keep this enzyme activity in considerable excess. The TPN concentration was

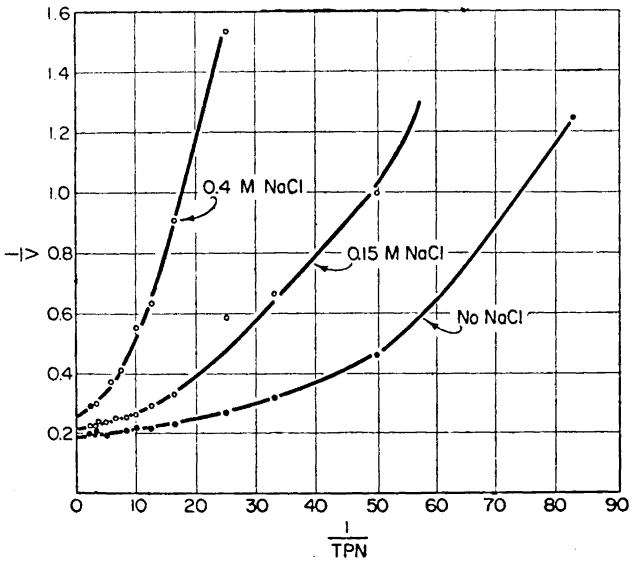

Fig. 2. Effect of TPN concentration on the inhibition of activity of the Zwischenferment OYE system by salts. Experimental conditions are essentially those described under Fig. 1; salt concentration, and TPN concentration varied as indicated.

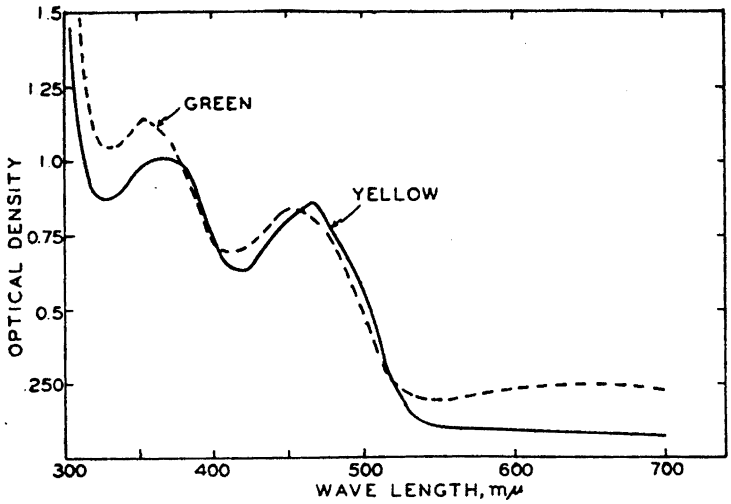

Fig. 3. Absorption spectra of OYE in acidic and basic ammonium sulfate solutions. OYE used in these experiments was approximately 80 % pure, spectra were taken in approximately 0.50 saturated $(NH_4)_2SO_4$, pH 10.2 (by addition of concentrated ammonium hydroxide, and in the same solution after bubbling with N_2.)

kept at a level of several times required to saturate the system under control conditions. Under these conditions the pH of optimal activity was 8.3 It was found that various salts inhibited oxygen uptake by the system, especially on the alkaline side of the pH activity curve. The inhibitory effect of sodium chloride, for example, as a function of pH, is presented in Fig. 1. Similar data were obtained with other salts. The degree of inhibition was in large measure a reflection of the anionic species present. Table 1 summarizes the data obtained with various salts. The inorganic salts may be placed in the order of decreasing effectiveness PO_4, CO_3, $I > SO_4$, $NO_3 > Br > Cl > F$.

The possibility that the inhibitory effects were simply related to a decreased affinity of the system for TPN was tested. The inhibition could be partly reversed by the addition of additional TPN to the system. As shown in Fig. 2, the saturation of the system with TPN was a function of the ions present in the assay system. A substantial inhibition remained, however, even after extrapolation to infinite TPN concentration. It was also confirmed that additional Zwischenferment and glucose-6-phosphate did not affect the inhibition. These observations suggested that some of the inhibitory effects might be on the catalytic process associated with the old yellow enzyme. This result was interesting in view of the effects of anions on the dissociation of the old yellow enzyme observed by Theorell and Nygaard. Addition of large amounts of FMN did not, however, increase the reaction rate in the presence of salts, and calculations from their data show that dissociation as measured by appearance of fluorescence is still much too small to account for inhibition by salts in the presence of excess TPN.

The solubility of oxygen in the medium is not significantly altered by salts at the concentrations used in these experiments, but the reaction of the old yellow enzyme with oxygen may be markedly affected.

Of particular interest was the strong inhibition observed with divalent anions and especially with EDTA.

The transformation of the old yellow enzyme into a green-colored protein. It was observed that addition of saturated ammonium sulfate solutions, adjusted to pH 10—10.5 with ammonium hydroxide, to solutions of the old yellow enzyme produced greenish solution. This did not reflect a complete dissociation of FMN from the protein, since OYE could be precipitated in this green form, redissolved in buffer (becoming yellow instantly) and reprecipitated in the green form without leaving absorption at 465 mμ. It was found that if the ammonia were removed, by bubbling a gas through the solution, for example, the yellow color would also reappear. Fig. 3 presents the absorption spectra of the green compound, and the spectra of the same solution after bubbling with oxygen. There was less than 4 % difference in the fluorescence of the solutions of the yellow and green proteins. It would not, however, be wise to conclude that the green form of OYE is nonfluorescent as is the yellow form, since the high concentrations of NH_4^+, $SO_4^=$, and NH_3 might effectively quench fluorescence, if present.

Several cycles of conversion from the green to the yellow form did not influence the catalytic activity of the enzyme.

Metal ion content of old yellow enzyme preparations. The strong inhibition of activity of old yellow enzyme preparations by EDTA (see Table 1) prompted an examination of the relationship of various metal ions to this catalysis. The effect of prolonged dialysis against chelating agents and subsequent addition of metal ions was studied, and in addition, the metal content of OYE preparations was assayed by emission spectroscopic and chemical methods.

Table 2. Effect of metal ions on oxygen consumption by Zwischenferment—OYE system. Conditions essentially the same as those described in the legend of Figure 1. Glycylglycyl buffer, pH 7.8, 200 μgm OYE (dialyzed against 0.001 M versene), metal ions were added at the concentration listed, as their chloride or sulfate salts.

* Visible precipitate formed

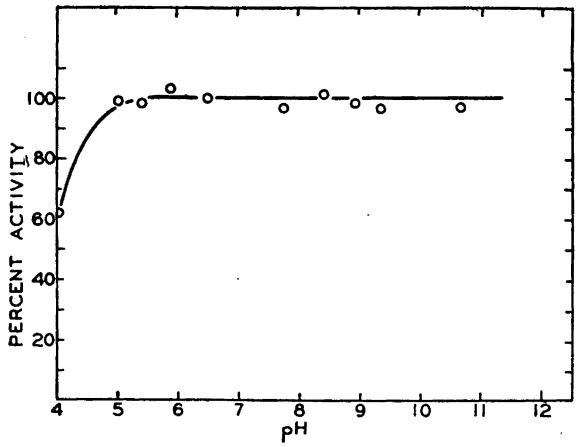

Fig. 4. Oxidation of TPNH by OYE as a function of pH. Each reaction mixture contained 50 μg OYE β 280/β 464 = 12.8 (~80 % pure), 0.15 μM TPNH, 100 μM buffer (acetate pH 4.0, 5.0; histidine, pH 5.4, 5.8; phosphate, pH 6.4, 6.7, 7.2; glycylglycine, pH 7.4, 7.8, 8.3; glycine pH 8.7, 9.1, 10.2, 10.7), total volume 3 ml. 100 % activity under these conditions represented an optical density change at 340 mμ of 0.045.

Prolonged dialysis against EDTA at pH 9.4, 7.5, and 5.0 did not decrease the specific activity; in fact, when most of the EDTA was removed by dialysis against triple-distilled water, the specific activity consistently increased 10—15 %.

The metal content of OYE preparations dialyzed against dilute buffer, and against EDTA solutions was measured in cooperation with Kandidat Molt, of Sveriges Geologiska Undersökning, Geokemiska avdelningen. Emission spectroscopic assays were made for the presence of Zn, Fe, Mn, Cu, Mg and Ca. Fairly large and variable quantities of Mg and Ca and insignificant amounts of Fe, Mn, Cu, Zn were found. The zinc and iron content of OYE preparations was also assayed by chemical methods with a similar result. In addition, a preparation of OYE of approximately 80 % purity which had

Table 3. Fe^{3+} and oxidation of TPNH by OYE. The control reaction mixture contained 0.1 μM TPNH, 50 μg OYE, 100 μM glycylglycine, pH 8.2, total volume, 3.0 ml. The experimental cuvettes contained in addition $FeCl_3$ in the amount indicated, and 1 μM *a,a'*-dipyridyl when indicated. Measurements were made spectrophotometrically at 340 mμ with appropriate correction for absorption of other materials.

		TPNH Oxidized μM/min

been dialyzed against dilute ammonia buffer, was kindly assayed by Professor B. L. Vallee of Harvard University. Only traces of Zn, Fe, Cu, and Mn were found, in all cases less than 0.1 mole metal/mole protein.

It is concluded that the old yellow enzyme, as isolated at least, is not a metallo flavoprotein involving Fe, Zn, Cu, or Mn. Mg and Ca are commonly present in many enzyme preparations, and it is presumed, though not proved, that these cations are contaminants not involved in the catalytic function of OYE.

Effect of metal ions on the catalytic activity of old yellow enzyme. The effect of metal ions on the activity of the Zwischenferment-OYE system assayed by measurement of oxygen uptake was studied. As shown in Table 2, it was found that no significant stimulation of activity occurred under the conditions employed, but that concentrations of Mn^{2+} or Fe^{3+} higher than 10^{-4} M caused marked inhibition. Since a visible precipitate accompanied Mn^{2+} inhibition, but none occurred with Fe^{3+} inhibition, further studies of this inhibitory phenomena were made primarily with Fe^{3+} ions. At 10^{-3} M, Fe^{3+} did not markedly influence the activity of isolated Zwischenferment, nor did increased TPN concentration influence the inhibition of oxygen uptake of the coupled system. It was, therefore, likely that the inhibition of oxygen uptake by Fe^{3+} concerned the activity of OYE itself. Experiments on the activity of OYE were carried out by measuring the oxidation of added TPNH spectrophotometrically. Fig. 4 presents the remarkable relationship between pH and activity for this reaction; essentially full activity is measured over the range from pH 5.0 to pH 10.

The Fe^{3+} ions did not inhibit TPNH oxidation by OYE in the concentration ranges 10^{-5} to 10^{-1} M, but instead acted as an electron acceptor. The formation of Fe^{2+} during the reaction was detected by spectrophotometric measurement of its complex with α,α'-dipyridyl. Table 3 presents the results of these experiments. The apparent inhibition of the Zwischenferment system by Fe^{3+} is likely a result of its competition with oxygen for electrons. Since the solubility of oxygen is 10^{-3} M, these data suggest Fe^{3+} to be a more efficient electron acceptor than oxygen for OYE.

Table 4. Effect of various electron acceptors on TPNH oxidation by OYE. The control reaction mixture contained 0.5 μM TPNH, 50 μg OYE, 100 μM glycylglycine, pH 8.2, total volume 3.0 ml. The experimental cuvettes contained, in addition when indicated: DCPIP (2,6-dichlorophenolindophenol); ferricyanide at a final concentration of 4×10^{-4} M; H_2O_2, 0.05 ml 30 % solution; catalase, 50 μg crystalline beef liver preparation. Measurements were made spectrophotometrically at 340 mμ; corrections for absorption of other materials were made when necessary.

		TPNH oxidized μM/min
1.	Control	0.022
2.	» + DCPIP	0.032*
3.	» + H_2O_2 + catalase	0.12*
4.	» + 4×10^{-4} M Fe $(CN)^{3-}$	0.18*
5.	» + 10^{-4} M Fe^{3+} + H_2O_2 + catalase	0.13

* Corrected for endogenous TPNH oxidation which occurred at a slow rate in the absence of substrate.

Table 4 presents a typical experiment in which different electron acceptors were used. Coupling to the dye dichlorophenolindophenol did not alter the rate markedly, but the presence of a chelated iron compound $Fe(CN)_6$ stimulated the catalytic rate 8 to 10-fold over the rate observed under ordinary conditions. The addition of H_2O_2 and catalase also caused a substantial increase in rate. This might be the reflection of an increased oxygen tension, although rates could not be obtained by bubbling oxygen through the solutions. It is possible that a more specific reaction is involved.

Attempts to find in bottom yeast a system which would stimulate oxidation of TPNH by OYE preparation have thus far been unsuccessful.

DISCUSSION

Although the old yellow enzyme is present in high concentration in yeast (1 mg OYE/g dry weight) and although the enzyme has been studied extensively, its physiological role is yet unclear (like the majority of flavoprotein enzymes). Its turnover number with oxygen or cytochrome c as electron acceptor is very low. Several experimental observations are consistent with the postulate that the old yellow enzyme has been separated from its appropriate acceptor during the course of purification. Haas [12] has shown that the reduction of OYE by TPNH according to equation (1) occurs at 60 times the rate of the oxidation of the leuco enzyme by oxygen. The present experiments indicate that appropriate electron acceptors indeed allow a much faster rate. It is not surprising that Fe^{3+} acts as an electron acceptor. Kaplan *et al.*[13] have recently shown that this is perhaps a general phenomenon with flavoprotein enzymes. It is pertinent, however, that Fe^{3+} is a more efficient electron acceptor than oxygen, and that with ferricyanide very considerable increases in catalytic rates are obtained. It would be unwise to conclude from this that the biological electron acceptor system for OYE is mediated through Fe^{3+} or another suitable metal ion, but the attractiveness of this possibility is manifest. The possible role of metals in the activity of flavoprotein enzymes has been recently discussed by Mahler [14].

The authors wish to thank Prof. H. Theorell for his active interest in this work. W. J. R. wishes to express his appreciation for the gracious hospitality extended by him and other members of the Biochemical Department.

A New Volumetric Method for Determination of Tin Beside Antimony

JOHN V. VILLADSEN and KNUD G. POULSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

A volumetric method is described for the determination of tin in the presence of antimony. The antimony is at first titrated with bromate according to Györy and afterwards precipitated with thioacetamide and filtered off, while keeping tin in solution as oxalate complexes. After oxidizing the oxalate, tin is reduced to the stannous state and titrated with bromate in an inert atmosphere (CO_2). The complete time required for an analysis was 2—2½ h and the accuracy was 0.2 %.

The well-known determination of tin [7-9] based upon its reduction to the stannous state by means of some metal, *e.g.* lead, iron or aluminium, and subsequent titration with bromate in an inert atmosphere has for a long time been used in this laboratory, where the procedure, described by Kühnel Hagen *et al.*[12] has been followed. In connection with the Györy [10] titration of antimony it has been our standard method in the analysis for tin and antimony in "white metal" alloys. The method has the advantage of being a rapid one and is accurate as long as the ratio antimony/tin is low.

When, however, this ratio increases above 1 : 3, the method involves increasing difficulties for the accurate determination of the tin content due to interference from the large amount of solid antimony then suspended in the solution. The present work has been carried out in order to improve the accuracy while trying to maintain the rapidity of the previous procedure.

The suggestion by Barber and Grezekowiak [6] of using thioacetamide instead of hydrogen sulphide in quantitative analysis has been developed by Musil, Flaschka and their coworkers to valuable gravimetric methods for most of the heavy metals, including also tin and antimony [3,5]. The antimony is for example precipitated and weighed as Sb_2S_3, giving excellent results [2,5]. The quantitative precipitation of tin by means of thioacetamide is more difficult, but Flaschka [1] gives details of a procedure where the results are only slightly low, the weighing form being SnO_2. Flaschka, Musil and coworkers [1] point out, however, that no difficulties are encountered in the quantitative precipitation of tin when thioformamide is used instead of thioacetamide. Musil and co-

workers [4] describe a procedure for determination of arsenic, antimony and tin, in which arsenic and antimony are titrated with bromate and thereupon separated by precipitation with thioformamide in 6 N hydrochloric acid for arsenic and in weak acid solution for antimony. The tin is kept in solution as oxalate complexes and determined by electrolysis or gravimetrically as SnO_2. The method we propose below combines the advantages of the method of Musil and coworkers for the separation of antimony from tin (arsenic is not considered in the present paper) with that of the volumetric determination of tin.

PROCEDURE

The solution, which should contain the metals as Sn^{4+} and Sb^{3+} or Sb^{5+}, respectively, the latter being the case if the alloy is dissolved in hot sulfuric acid and subsequently titrated with bromate according to Györy to determine the antimony content. Aliquots containing approx. 0.15 g Sn are pipetted off from the titrated solution, and 7.5 g oxalic acid and 20 ml conc. hydrochloric acid added whereafter the aliquot is diluted to 100 ml with water. The solution is heated to boiling and 0.3 g of thioacetamide dissolved in 3 ml water is added for each 0.1 g antimony present. During the addition of the thioacetamide the solution is well stirred, and the stirring is continued while 100 ml hot water is added. After cooling to 50°C the crystalline red precipitate of Sb_2S_5 is filtered off on a G 4 glass-filter, which is washed beforehand with a 1 % solution of oxalic acid to avoid separation of SnS_2 in the collector flask. The precipitate is washed with warm 0.1 % oxalic acid. The filtrate is transferred to a 1 liter beaker or a 500 ml Erlenmeyer flask and sufficient ammonium persulfate (17 g) is added to oxidize all oxalic acid. The flask is warmed on a gas burner or an electric heater for 15–20 min in order to destroy all persulfate. After cooling 50 ml conc. hydrochloric acid, 10 ml conc. sulfuric acid and 200 ml of water are added. The tin can now be determined according to one of the well-known procedures. We usually add a sheet of high purity aluminium to reduce the tin to metallic state. After the aluminium (*ca.* 3 g) has been added, the flask is fitted with a stopper with 3 holes, one of which is fitted with a glass tube to the bottom and is used to pass a stream of carbon dioxide into the solution. The second is fitted with a long glass tube as a refluxer and the third is available for the burette tip but is initially closed by a glass rod. With the concentration of acid used the aluminium is slowly dissolved while the tin separates as a spongy mass. After 20 min the flask is heated without boiling and the tin and a possible rest of aluminium is dissolved. When all is dissolved the flask is cooled, while the flow of carbon dioxide is temporarily increased.

In a test tube 0.5 g KI and 5 ml of a 0.5 % starch solution are mixed with 0.5 ml diluted sulfuric acid, a little $NaHCO_3$ is added to expel dissolved oxygen. This mixture is added with a pipette to the analysis and the burette tip is introduced through the third hole. Bromate solution is added until one drop gives a pertaining blue colour.

Chemicals

Tin solutions were made by dissolving pure tin in hot sulfuric acid and diluting to known volumes. Tin was either "AnalaR" or in some cases "Banka Tin" of unknown manufacture.

Antimony solutions were made from "AnalaR" $SbCl_3$ and were analyzed by titration with potassium bromate according to Györy.

Potassium bromate solutions were made from Merck potassium bromate *p.a.* dried at 150°C. Weighed amounts were dissolved in water to known volumes. The solutions were also standardized on tin, and the usual corrections of the titer found by weighing off the potassium bromate were +0.4 % and 0.2 % compared to "AnalaR" tin and "Banka" tin, respectively. The titers used for calculation of "mg tin found" are the ones based on "AnalaR" tin.

Thioacetamide and ammonium persulfate were "Merck" products.

Table 1. Analysis of tin solution without antimony. Standard procedure, no oxalate or persulfate added.

Expt. No.	mg Sn taken	mg Sn found	Deviation mg	Deviation %
1	150.1	150.3	0.2	0.1

28	147.1	147.2	0.1	0.1
29	147.1	147.2	0.1	0.1

The aluminium sheet used for reduction was known to be 99.9 % pure.

Carbon dioxide was taken from cylinders which had been used for some time, so that the small amount of oxygen present in freshly filled cylinders had escaped.

Sulfuric and hydrochloric acids were chemically pure products.

All volumetric glasswares were calibrated before use.

The oxalic acid ($H_2Ox,2H_2O$) was a high grade "Merck".

RESULTS

The results given in Table 1 are obtained by pipetting off 20 ml samples from the stock solution of pure tin and analyzing the aliquots according to the nor-

mal procedure, *e.g.* reducing with aluminium and titration with potassium bromate. An average error of less than 0.1 % is found. When these results are compared with those in Tables 2 and 3, it is seen that the last two show a tendency to lower values. The samples in Tables 2 and 3 were both analyzed according to the procedure described above. In Table 3 no antimony was present, but the procedure was followed except that no thioacetamide was added. The somewhat higher error found when the sample was treated for antimony can evidently not be due to co-precipitation of tin when antimony sulfide is precipitated.

In order to see whether some tin escaped as $SnCl_4$ during the oxidation of oxalate with persulfate, we have carried out the experiments in Table 4. The procedure was changed such that the heating for destruction of oxalate and persulfate was carried out in the Erlenmeyer flask later to be used for the titration of tin. This flask was fitted with a stopper with a long glass tube acting as a refluxer. The results seem rather to indicate an increase than a decrease in the error.

That no tin seems to disappear during the heating to nearly 100°C for 20 min is in accordance with qualitative tests made in the following way: the tube otherwise used as a refluxer was bent downwards just above the stopper and the vapour now distilled was collected in dilute sodium hydroxide solution. After heating for 25 min, when approx. 10 % of the volume had distilled, the basic solution was neutralized and tested for tin with dithiol and mercaptoacetic acid, according to Charlot and Gauguin [11]. In four experiments no tin at all could be found with this very sensitive reaction. Experiments with prolonged heating (120 min) showed the same results.

It is important that all persulfate is destroyed during the heating, since the experiments show that persulfate remaining in the solution after the heating was not reduced completely by the aluminium and therefore invalidated the tin titration. We therefore made some experiments to find the time of heating necessary for the complete destruction of the excess of persulfate when different kinds of glassware were used: 1) a 1 liter beaker, 2) the 500 ml Erlenmeyer flask used as in Table 4. To the analysis containing 7.5 g oxalic acid and 15 g ammonium persulfate were added a few drops of a 0.1 N titanium chloride. The presence of peroxide is indicated by the formation of the yellow peroxytitanate ion when the solution is heated. With electrical heating of the solutions in the beaker the destruction temperature of the persulfate excess was measured to 80°C and somewhat higher (85—90°) in the Erlenmeyer flask owing to the higher partial pressure above the latter solution. Complete destruction, indicated by the sudden disappearance of the yellow colour, was obtained after 8 min in 1) and after 13 min in 2). The importance of a relatively long time of heating, when no catalyst is present, is emphasized by the results given in Table 5, where larger excess of persulfate has been combined with shorter time of heating with remarkable results.

That heating on a steam bath requires more time than heating by a free flame or electrical heating was realized from results obtained when 24 g (10.4 g excess) ammonium persulfate was used to oxidize 7.5 g oxalic acid and heating on a steam bath for 15 min. The average of 5 tin determinations was 4 % lower than calculated.

Table 4. As in Table 3 but using 500 ml Erlenmeyer flask and refluxer when destroying persulfate.

Expt. No.	mg Sn taken	mg Sn found	Deviation mg	Deviation %
30	150.1	148.8	−1.3	−0.9
31	150.1	148.9	−1.2	−0.8
32	150.1	148.8	−1.3	−0.9
33	150.1	148.8	−1.3	−0.9
34	150.1	148.8	−1.3	−0.9
35	150.1	148.7	−1.4	−0.9
36	150.1	148.6	−1.5	−1.0
37	150.1	148.5	−1.6	−1.1
38	150.1	148.5	−1.6	−1.1

The deviations are seen to be somewhat larger compared to the results of Table 3 when the Erlenmeyer flask is used.

Table 5. The influence of time of heating on excess of persulfate.

Expt. No.	mg Sn taken	mg Sn found	Deviation mg	gram per-sulfate used	Time of heating, min	°C
39	150.1	81.9	−68.2	24	5	
40	150.1	149.5	− 0.6	24	30	90−95
41	150.1	147.4	− 2.7	17	5	
42	150.1	144.4	− 5.6	17	5	

The experiments show that the treatment of the tin solution with persulfate will cause some lowering of the tin content found. The small — constant — deviation can easily be determined in the individual case (for other chemicals used). No tin seems to escape from the containers and excess persulfate is evidently completely removed by 20 min heating. It is likely then that the tin is to some extent transformed to a state not easily reduced. Experiments, where small glass pellets were introduced in order to increase the surface, showed no increase in error, which excludes the possible adhering of some tin to the walls of the containers. The error is, however, almost negligible when traces of antimony as in Table 2 are present, probably owing to catalytic effects.

We have finally made a few experiments using $KMnO_4$ as oxidizing agent instead of $(NH_4)_2S_2O_8$. When due care is taken to the vigorous evolution of CO_2 when adding $KMnO_4$ to the hot solution, this method has some advantages over the method described above, *i.e.* the destruction of excess oxidizing agent is avoided as the end point is easily visible and dissolving of the tin is very quickly accomplished due to catalytic effects ($Mn^{+2} \rightleftharpoons Mn^{+1}$). The theoretical amount of $KMnO_4$ for 7.5 g $H_2Ox,2H_2O$ is 3.76 g. Deviations with $KMnO_4$ as destructing agent for the oxalic acid were 0.1—0.3 %, and the complete analysis is accomplished in 2 h.

The dissolution of the spongy tin may be a rather tedious process when no traces of other metals are present (Table 1). The time for dissolution can be

reduced to less than 1 h by adding a few drops of a very diluted Pd solution. Owing to the same kind of catalytic effects as obtained by using a Pd (or Au) catalyst we have obtained considerably lower dissolution times in the experiments with both Sn and Sb where minute traces of Sb are still present at this stage. The time of dissolution should, however, not be shortened by adding more acid as the reaction will tend to be too vigorous with foaming and even splashing (thus invalidating the determination).

The method gives results with an average deviation of ± 0.2 % when the titer of the potassium bromate is increased by 0.3 %. The time required for a complete analysis was 2—2 ½ h.

Spectroscopic Conformational Analysis of Some 1,2-Dihalogeno *Cyclo*hexanes

PETER KLÆBOE, JOHAN J. LOTHE and K. LUNDE

Sentralinstitutt for Industriell Forskning og Universitetets Kjemiske Institutt. Blindern-Oslo, Norway

The infrared spectra of the *trans* 1,2-dichloro- and *trans* 1,2-dibromo-*cyclo*hexanes are highly dependent on the dielectric properties of the solvents. This suggests a method of determining the conformational equilibrium ratio. The mole fractions of the *ee*-conformations were calculated to 0.34 and 0.19 for the dichloro- and dibromo-compound, respectively, when dissolved in *cyclo*hexane and 0.71 and 0.63 when dissolved in nitromethane.

Trans 1,2-dichloro*cyclo*hexane crystallizes in the *ee*-conformation whereas *trans* 1,2-dibromo*cyclo*hexane crystallizes in the *aa*-conformation.

A discussion of some of the steric factors which may be important for the conformational equilibrium is presented.

Using some assumptions concerning the relative intensities of the infrared carbon-halogen stretching bands of the monohalogeno *cyclo*hexanes, the mole fraction of the *e*-conformation was calculated to 0.8 for the chloro compound and 0.85 for the bromo compound.

A previous paper [1] reported on a conformational investigation of some monohalogenated *cyclo*hexanes using infrared and Raman spectra. It was concluded that both the *e*- and the *a*- conformation of the monochloro- and the monobromo*cyclo*hexane were present in the liquid state, the *e*-conformation preponderating in both compounds. In the anisotropic modification of the crystalline state only the *e*-conformation of the two compounds could be detected, whereas in the semisolid cubic modification of the chloro compound both conformations were present.

The conformational equilibrium of the *trans* 1,2- dihalogeno *cyclo*hexanes has previously been given a quantitative treatment by some authors [2–5] measuring the dipole moments of the *cyclo*hexane compounds dissolved in carbon tetrachloride and benzene. Kozima and co-workers [2] were able to draw certain semiquantitative conclusions about the conformational equilibrium by considering the Raman spectra. From an investigation of the infrared spectra Larnaudie [6] concluded that both conformations were present in the liquid state.

The present paper is concerned with an examination of the conformational equilibrium of some 1,2-dihalogeno *cyclo*hexanes using the infrared and the Raman spectra. A quantitative determination of the conformational equilibrium ratio, using data from the infrared spectra of the compounds in solvents of different dielectric constant is proposed. The method, although involving several assumptions, is believed to present a good approximation, and has been applied to the *trans* 1,2-dichloro- and the *trans* 1,2-dibromo-*cyclo*hexane in 10 solvents of different polarity.

EXPERIMENTAL

Preparations. Trans 1,2-dichloro*cyclo*hexane was prepared by bubbling chlorine gas through *cyclo*hexene in the darkness as reported by Carrol *et al.*[7] The *trans* configuration of this compound has been confirmed in different ways [8,9].

Trans 1,2-dibromo*cyclo*hexane was prepared by adding a solution of bromine in carbon tetrachloride to *cyclo*hexene at −5°C [10]. It was found necessary to remove hydrochloric and hydrobromic acid from the products by shaking with an alcoholic solution of potassium hydroxide, because traces of these acids catalyze the decomposition of the halogenated *cyclo*hexanes during the Raman exposures.

Cis 1,2-dichloro*cyclo*hexane was a sample prepared by Stevens and Grummit [11].

The purity of the three 1,2-dihalogeno *cyclo*hexanes was checked by their refractive indices and melting points.

Infrared spectra. Infrared spectra of the two *trans* 1,2-dihalogeno *cyclo*hexanes and the cis 1,2-dichloro*cyclo*hexane were recorded in the pure liquid state using sealed cells of 0.05 mm thickness in the sodium chloride region, and demountable cells of approximately the same thickness in the caesium bromide region. The position of the infrared bands of the three compounds are given in Tables 1, 2 and 3, their intensities being indicated with numbers from 0 to 10.

The infrared data used for calculating the conformational equilibrium of the two *trans* 1,2-dihalogeno *cyclo*hexanes were obtained on solutions of concentrations below 5 % in 0.5 mm cells. In order to allow comparison of the extinction values of the bands, the different solution spectra were obtained using the same split program, program 3 on the Perkin-Elmer Model 21 double beam spectrophotometer, which was used for all the recordings. Apparent molar extinction values for the strong and the medium bands of the three compounds were calculated from the infrared spectra by subtracting the back-

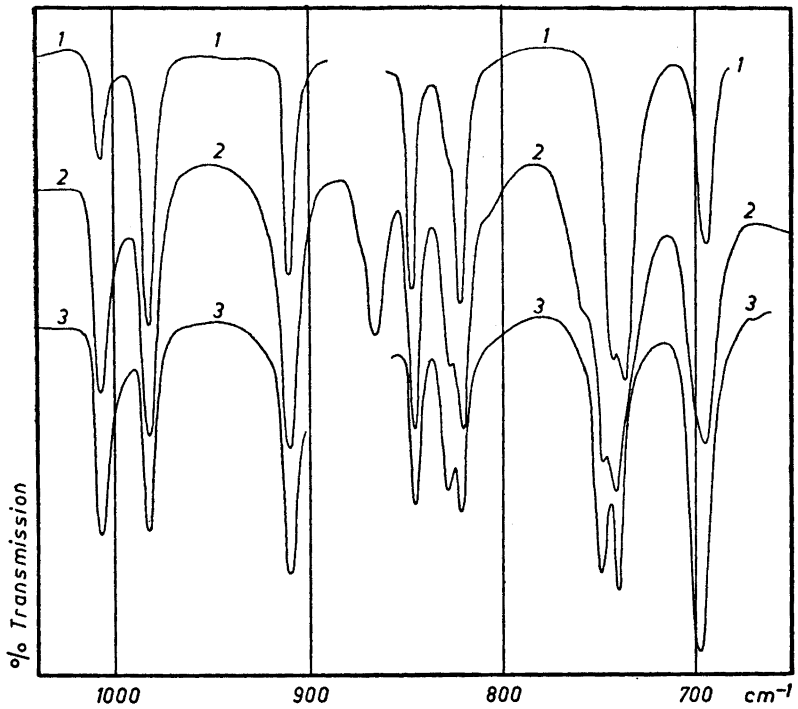

Fig. 1. Infrared spectra of *trans* 1,2-dichloro*cyclo*hexane. 1.—15% solution in nitromethane. 2. — pure liquid. 3. — 15 % solution in *cyclo*hexane. The open spaces indicate regions where the solvents have strong bands.

ground and making allowance for the concentrations and the specific gravity of the solutions. Correction for stray radiation in the region below 900 cm^{-1} was carried out using a calcium fluoride plate.

The infrared spectra of the three *cyclo*hexane compounds were also run in the solid state at —50°C. (Tables 1, 2 and 3).

Raman spectra. The Raman lines and the polarization data for the two *trans* 1,2-dihalogeno *cyclo*hexanes are reproduced in Tables 1 and 2 for the chloro and the bromo compound, respectively. The frequencies of the Raman lines are in good agreement with those reported by Kozima [2] and by Bastiansen [12]. For the *trans* 1,2-dibromo-*cyclo*hexane we have found some lines not reported by Kohlrausch [13]. The polarization data represent the average from three and four exposures of the dichloro and dibromo derivatives, respectively, and seem to be much more complete than the results from an earlier investigation by Canals [14].

The amount of *cis* 1,2-dichloro-*cyclo*hexane available was not sufficient for Raman investigations.

The Raman spectrograph was described in the previous paper [1].

THE CONFORMATIONAL EQUILIBRIUM

Effect of solvents

The most striking difference between the *cis* and the *trans* 1,2-dihalogeno *cyclo*hexanes is that while the infrared spectra of the first one is practically

unaffected by the solvent, the extinction values of some of the bands belonging to the *trans* compounds are quite sensitive to the dielectric constant of the solvent (Fig. 1). It was possible to make the following rough classification of the bands of the *trans* dihalogeno *cyclo*hexanes: Class 1 — extinction value increases with increasing polarity of the solvent; Class 2 — extinction value decreases with increasing polarity, and Class 3 — no apparent variation of the extinction value with change of polarity. The solvents were selected to give a large range of dielectric constants, with the extremes *cyclo*hexane ($D = 2.05$) and nitromethane ($D = 39.4$).

The different effect of solvents on the spectra of the *cis* and the two *trans* 1,2-dihalogeno *cyclo*hexanes can most likely be explained by the fact that the *trans* compounds [9,15] appear in two different conformations, *ee* and *aa*, interconvertible by inversion of the carbon ring, whereas only one, the *ea*-conformation, is possible for the *cis* compound.

While the *aa*-conformation of the *trans* 1,2-dihalogeno *cyclo*hexanes has a dipole moment of zero, or because of induced moments very near zero, the *ee*-conformation has, according to Tulinskie [3], a dipole moment very near the moment of the *cis* 1,2-dihalogeno *cyclo*hexanes which was found to be 3.1 *D* for both the chloro and the bromo compound [4]. Taking into account a dipole theory by Onsager [16] the conformational equilibrium of the *trans* compounds would be expected to be displaced toward the polar *ee*-conformation in solvents of high dielectric constant.

It may be concluded that the three classes of infrared bands of the *trans* 1,2-dihalogeno *cyclo*hexanes, found to increase (Class 1), decrease (Class 2), and to undergo no significant variation (Class 3) on going from unpolar to more polar solvents, should be assigned respectively to specific *ee*-bands, *aa*-bands and bands common to both conformations. This assignment seems justified as the relative intensity of the bands of the *cis* compound did not change with the solvent, and it is in accordance with the dipole theory of Onsager that the *ee*-conformation of the *trans* compound is stabilized by solvents of high dielectric constant.

Quantitative treatment of the equilibrium

Having divided the bands into classes belonging to one or both of the two conformations of the *trans* 1,2-dihalogeno *cyclo*hexanes, the infrared spectra give directly qualitative information about the relative displacement of the conformational equilibrium with change of the solvent. It is, however, also possible to gain quantitative values for the equilibrium ratio from the infrared spectra provided the following set of assumptions is accepted:

1. The bands assigned to the *ee*-conformation (Class 1) and the *aa*-conformation (Class 2) are not contaminated with bands from the other conformation.

2. The apparent molar extinction coefficients for the selected *ee*-and *aa*-bands are independent of the solvent.

3. Beer's law is valid for the concentration range investigated.

Let us assume that two bands have been selected, belonging to the *ee*- and the *aa*-conformation, respectively. Measurement of the extinction values

of these bands in two solvents, one of low the other of high dielectric constant, leads to the following set of equations:

$$E'_{ee} = \varepsilon_{ee} c'_{ee} d \quad (1)$$

$$E'_{aa} = \varepsilon_{aa} c'_{aa} d \quad (2)$$

$$E''_{ee} = \varepsilon_{ee} c''_{ee} d \quad (3)$$

$$E''_{aa} = \varepsilon_{aa} c''_{aa} d \quad (4)$$

$$C' = c'_{ee} + c'_{aa} \quad (5)$$

$$C'' = c''_{ee} + c''_{aa} \quad (6)$$

where E'_{ee}, E''_{ee}, and E'_{aa}, E''_{aa} are the measured extinction values of the *ee*- and *aa*-bands in the two solvents. ε_{ee} and ε_{aa} are the molar extinction coefficients of the *ee*- and the *aa*-bands.

C' and C'' are the total concentrations of the *trans* 1,2-dihalogeno *cyclo*hexane in the two solvents.

c'_{ee}, c''_{ee} and c'_{aa}, c''_{aa} are the concentrations of the *ee*- and *aa*-conformation in the two solvents.

d is the thickness of the cell.

Eliminating the unknown quantities ε_{ee}, ε_{aa}, c''_{ee}, and c''_{aa} from these equations, one obtains the following expression for the mole fraction, X_{ee}, of the *ee*-conformation in one solvent

$$X'_{ee} = \frac{c_{ee}}{C'} = \frac{E'_{ee}}{C'} \cdot \frac{C''E'_{aa} - C'E''_{aa}}{E''_{ee}E'_{aa} - E''_{aa}E'_{ee}} \quad (7)$$

It is thus possible to calculate the conformational equilibrium ratio in one solvent from the measured extinction values of the selected pair of bands in two solvents of different dielectric constant.

Tables 4 and 5 give the values of the mole fraction, X_{ee}, of the *ee*- conformation of the *trans* 1,2-dichloro- and the *trans* 1,2-dibromo-*cyclo*hexane in ten different solents. The data were obtained by applying eqn. 7 to the measured extinction values of several pairs of band.

The calculations are based on the validity of Beer's law. Furthermore, the contribution of solute to the dielectric properties of the solutions at higher concentrations also makes the use of low concentrations preferable. This requires consequently the use of rather thick absorption cells, about 0.5 mm. Especially the choice of polar organic solvents will for this reason be highly limited as these solvents usually display strong absorption bands in infrared. It was, however, found that both acetonitrile ($D = 38.8$) and nitromethane ($D = 39.4$) were sufficiently transparent to permit the use of 0.5 mm cells for the quantitative determination of the extinction values of several bands.

The specific *ee*- and *aa*-bands, selected for the determination of the equilibrium ratio, were mostly neighbour bands (Tables 4 and 5). This makes the construction of the background line, a necessary correction before obtaining the extinction values, less ambiguous. In some cases the *ee*- and *aa*-bands were somewhat overlapping, and it was necessary to apply a correction for

the contribution of one band to the extinction at band maximum of the other conformation. This was carried out by drawing a Gauss' curve by hand. It is obvious that this correction is somewhat ambiguous and the corresponding calculated mole fractions should be regarded with some reservation. This is especially the case with the pair of bands at 1 212 and 1 202 cm^{-1} of Table 4, and the pair 1 177 and 1 160 cm^{-1} of Table 5.

It is evident from eqn. 7 that the highest accuracy for the mole fraction is achieved when the extinction values in unpolar solvents are compared with

those in highly polar solvents. The results in Tables 4 and 5 were consequently obtained in the following way. The mole fractions in the unpolar solvents *cyclo*hexane, carbon tetrachloride, and carbon disulfide were first calculated by combining the measured extinction values in these solvents with those from the highly polar acetonitrile and nitromethane. The results were the basis for the calculation of the molar extinction coefficients of the *ee*- and *aa*-band. The mole fraction in the other solvents, including the pure liquid, was thereupon easily calculated from the extinction coefficients and the measured extinction values. It is highly gratifying to note the close agreement in Tables 4 and 5 between the mole fractions calculated from different pairs of bands. This agreement seems partially to justify the assumptions 1—3 upon which the calculations are based.

Unfortunately, it is not possible to estimate a confidence limit for the mole fractions of Tables 4 and 5. It is believed that the data represent qualitatively the actual situation, that is the displacement of the equilibrium with solvent and the relatively higher stability of the *aa* conformation of the bromo compound than that of the chloro compound. The absolute values of the mole fractions may, however, be wrong by several per cent relative. A possible source of error would be the non-constancy of the molar extinction coefficient of the bands of any one configuration in the different solvents. It has actually been observed on some systems [17] that bands are broader and lower in polar solvents than in nonpolar, and that consequently the integrated extinction values are a better measure of the concentration. Careful examination of the infrared bands of the two *trans* halogeno *cyclo*hexanes in solvents of different polarity did not indicate any increase in half-width of the bands on going towards polar solvents. Only the carbon-halogen stretching frequencies around 700 cm^{-1} showed a slight increase in half-width. The increase was too small, however, to be of any significance to the calculated mole fractions.

Another source of error would be the contamination of the bands, assumed to be pure *ee*- and *aa*-bands, with bands from the other conformation. The use of several band pairs for the calculations should minimize this source of error.

It may be added that the selected pair of bands of Tables 4 and 5 may probably be assigned to the same type of vibration in the two conformations. The fact that these pair of bands occur in the same spectral region in both compounds, but somewhat displaced to shorter wave numbers in the bromo compound, strongly suggests such an assignment. It is obvious, however, that the validity of the calculations made from eqn. 7 is quite independent of this assumption.

DISCUSSION

The data of Tables 4 and 5 show that the equilibrium values for both compounds in the pure liquid state are close to the values in chloroform. This is quite reasonable as in the liquid state there will be an appreciable interaction between neighbour molecules some of which are in the polar * *ee*-conformation. The result would be the same as if the compounds were dissolved in solvents of medium polarity like chloroform. The calculated equilibrium ratios of the *trans* 1,2-dihalogeno *cyclo*hexanes indicate the presence of 50 % of the *ee*-conformation of the chloro-derivative and 40 % of the bromo-derivative in the pure liquid state at room temperature. Transition from one conformation to the other is assumed to take place through a very low energy barrier. From Tables 4 and 5 the difference in energy between the two conformations, calculated by applying the Boltzmann distribution law, is found to be less than 0.8 kcal/mole at room temperature in the dielectric area investigated.

It seems reasonable to assume that the conformational equilibrium ratio in the unpolar solvents, like *cyclo*hexane, should approach the equilibrium ratio in the vapour phase, the *ee*-conformation being only slightly more favoured in the non-polar solvents than in the vapour phase. An infrared spectrum of *trans* 1,2-dichloro*cyclo*hexane, run in an 1 meter gas cell, seemed to verify this statement. It should be pointed out, however, that the calculated mole fraction of the *ee*-conformation of the *trans* 1,2-dichloro- and the *trans* 1,2-dibromo*cyclo*hexane dissolved in *cyclo*hexane (0.34 and 0.19, respectively) do not agree at all with the electron diffraction data (0.5 and 0.6, respectively) [9,15] obtained on the vapour phase.

The infrared bands found in the solid state of *cis* 1,2-dichloro*cyclo*hexane at −50°C are the same as those found in the liquid state. This is in agreement with the existence of only one conformation of this compound, (*ae*). In the two *trans* derivatives, however, a set of bands appearing in the liquid state spectra are absent in the solid state ones, but on the other hand, all bands in the solid state spectra are present in the liquid. The bands which disappear in the solid spectra, are just the same as those assigned to *aa* and *ee* in the chloro- and bromo-compound, respectively. The conclusion must be drawn that *trans* 1,2-dichloro*cyclo*hexane exsist in *ee* and that *trans* 1,2-dibromo-

* Polar points here to polarity and not to the old designation p — polar for an *axial* (*a*) substituent.

Table 6. The unfavourable distances between the halogen substituents (X) and other atoms in the *trans* 1,2-dihalogeno *cyclo*hexanes compared with the sum of the appropriate van der Waals radii.

Distance	*trans* 1,2-dichloro-*cyclo*hexane		*trans* 1,2-dibromo-*cyclo*hexane		Multiplicity
	calculated	van der Waals	calculated	van der Waals	
$X_1(a)-H_3(a)$	2.61	3.0	2.67	3.15	4
$X_1(a)-H_2(e)$	2.89	3.0	3.04	3.15	4
$X_1(e)-H_2(e)$	2.89	3.0	3.04	3.15	2
$X_1(e)-H_2(a)$	2.89	3.0	3.04	3.15	4
$X_1(a)-H_1(e)$	2.38	3.0	2.56	3.15	2
$X_1(e)-H_1(a)$	2.38	3.0	2.56	3.15	2
$X_1(e)-X_2(e)$	3.21	3.6	3.42	3.9	1

The calculations are based on the following distances that apply to *cyclo*hexane derivatives [30]

C—C = 1.54 Å
C—Cl = 1.78—1.79 Å
C—Br = 1.98—1.99 Å
C—H = 1.09 Å

and no distortion from tetrahedral angles.

*cyclo*hexane exist in *aa* in the solid state. Kozima *et* al.[2] suggested the same conformations on the basis of a Raman investigation. It will indeed be gratifying if these findings can be verified through an X-ray crystallographic investigation which we know is under way [18].

The interaction between the halogen substituents and the carbon and hydrogen atoms of the *cyclo*hexane ring may explain the difference in energy between the conformations [19]. If the distance between non-bonded atoms is less than the sum of the van der Waals radii a repulsion between the respective atoms will occur. A kind of stressing or deformation of the *cyclo*hexane ring with increase of the energy will probably be the result. By electron diffraction methods a certain amount of deformation of the valence angles in several substituted *cyclo*hexanes has been reported [20].

Provided that there is no such deformation, Table 6 gives the unfavourable distances within the molecule as compared to the normal van der Waals distances as well as the number of occurrences of these within the same molecule.

We assume that the most important factor for evaluating the relative stability of two possible conformations are the unfavourable atomic distances which are specific for each conformation. It will appear from Table 6 that the most unfavourable distances are $Hal_1(a) - H_3(a)$ and $Hal_1(e) - Hal_2(e)$. The first one will favour the formation of the *ee*-conformation, the latter will countercurrently favour the formation of the *aa*-conformation. The question is: Which effect is the stronger? There can be but little doubt that the $Hal_1(a) - H_3(a)$ distance represents a very strong steric hindrance. Hassel and Bastiansen have calculated the distortion of the appropriate valence angles to approximately 7°. This distance also has the high multiplicity of 4.

On the other hand it seems reasonable to assume that a still stronger steric hindrance arises from the $Hal_1(e) - Hal_2(e)$ configuration. In this case there is a marked violation of the normal van der Waals distance between the two strongly electronegative halogen atoms, whereas the repulsion between the electronegative halogen atoms and the electropositive hydrogen atom would be assumed to be of a weaker character.

It is interesting to note that in the monohalogeno derivatives of *cyclo*hexane only the $Hal_1(a) - H_3(a)$ repulsion is present, and the equilibrium is highly displaced towards the *e*-conformation [1]. In the *trans* 1,2-dihalogeno *cyclo*hexanes, however, where both effects are active, the equilibrium in the pure liquid state is found to be equally distributed between both conformations in the chloro compound, but displaced somewhat towards *aa* in the bromo compound. It seems probable that by increasing the atomic radii in going from the chloro to the bromo derivative, the $Hal_1(e) - Hal_2(e)$ repulsion will increase more than the $Hal_1(a) - H_3(a)$ repulsion and make the *aa* conformation energetically more favourable. The fact that the dichloro- and dibromo compound crystallize in the *ee* and *aa* conformation, respectively, seems to support this assumption, even if the forces involved in the crystal lattice may be important in this respect.

It must be pointed out, however, that the result of X-ray crystallographic [21,22] and electron diffraction measurements [23] of the 1,2-dichloro-4,5-dibromo*cyclo*hexane (*aa-ee* — *ee-aa*) revealed the compound to be present entirely in the *aa-ee* conformation in the solid and vapour state. The conclusions drawn for the 1,2-dichloro-4,5-dibromo*cyclo*hexane [24] seem at the present state to be quite inconsistent with the conclusions which can be drawn for the *trans* 1,2-dihalogeno *cyclo*hexanes.

By measuring the dipole moments of *trans* 1,2-dichloro- and *trans* 1,2-dibromo*cyclo*hexane dissolved in carbon tetrachloride or benzene, several authors [2–5] have calculated the conformational equilibrium. They find smaller dipole moments of the bromo than of the chloro compound, and conclude that the equilibrium is more displaced towards the unpolar conformation *aa* in the bromo compound than in the chloro compound. This is in agreement with the results in the present paper. The absolute values for the equilibrium ratio calculated from the dipole moment measurements indicate, however, a conformational equilibrium displaced more towards the *ee* conformations than the results from our investigation. The calculations made by these authors are based upon severe assumptions concerning the dipole moments of each conformation. It must be admitted, however, that the present work also is based upon several assumptions.

Carbon-halogen stretching frequencies

Among the normal vibrations of the 1,2-dihalogeno *cyclo*hexanes the vibrations dominated by stretching of the highly polar carbon-halogen bond can easily be assigned to specific bands near 700 cm^{-1} in the infrared and Raman spectra.

In the *trans* compounds one would expect two vibrations for each conformation, one symmetric and one asymmetric. A consideration of models

Table 7. Apparent molar extinction coefficients in infrared, and relative intensities in Raman of the carbon-halogen stretching frequencies.

trans 1,2-dichloro-*cyclo*hexane				*trans* 1,2-dibromo-*cyclo*hexane				Vibration type	Conformation
IR		Raman		IR		Raman			
ν cm^{-1}	ε	$\Delta\nu$ cm^{-1}	I	ν cm^{-1}	ε	$\Delta\nu$ cm^{-1}	I		
746	117	749	1.0	693	70	699	1.0	asym.	*ee*
738	117	738	2.4	684	70	686	1.9	sym.	*ee*
		703	2.8			652	12.4	sym.	*aa*
692	94			663	58			asym.	*aa*

of the *trans* 1*a*—2*a*-dihalogeno *cyclo*hexanes shows that the symmetric carbon-halogen stretching vibration should not, to the first approximation, involve a change of the dipole moment of the molecule. The corresponding infrared bands would correspondingly be weak. In the Raman spectra, however, the symmetric stretching vibration would be expected to give a rather strong and polarized line. This is indeed observed. The much higher intensity of the symmetric Raman line for the bromo- than for the chloro-compound is striking. It is probable that the normal vibration is better defined as a carbon-halogen stretching vibration with the heavier bromo atoms than with the lighter chloro atoms where possibly other parts of the molecule takes part in the normal vibration. The asymmetric stretching of the carbon-halogen bonds of the *trans* 1*a*—2*a*-dihalogeno *cyclo*hexanes should give a strong band in the infrared spectra and probably only a weak line in the Raman spectra. Again, this is found to be true (Table 7).

A similar description of the two carbon-halogen stretching vibrations of the *trans* 1*e*—2*e*-dihalogeno *cyclo*hexanes is more difficult. Models indicate that both the symmetric and the asymmetric stretching vibrations should involve a change of dipole moment. Any prediction as to the relative intensity of the bands in the infrared spectra would be somewhat dubious. Correspondingly, two carbon-halogen bands, belonging to the *ee*-conformation are observed in the 700 cm^{-1} region. The bands are of approximately equal intensity.

In the *cis* 1,2-dichloro*cyclo*hexane one chlorine atom is in the *e*- the other in the *a*-position. The carbon-chlorine bonds make an angle of about 70°. Because of repulsion between the chlorine atoms the angle may be somewhat larger. If the bonds made an angle of 90° one might assume the stretching vibrations of the two carbon-halogen bonds not to be coupled. Two frequencies should be observed, characteristic of the stretching of the *equatorial* and the *axial* bonds. In the infrared spectra of the *cis* 1,2-dichloro*cyclo*hexane the carbon-chlorine stretching bands are found at 744 and 696 cm^{-1}, values that are very near those observed for the stretching vibrations of the *e*, respectively the *a*-conformation of monochloro*cyclo*hexane [1]. This may in fact suggest only a weak coupling of the two carbon-chlorine stretching vibrations of the *cis* 1,2-dichloro*cyclo*hexane. The 744 cm^{-1} vibration should then involve mainly a stretching of the *equatorial* carbon-chlorine bond, and the 696 cm^{-1}

vibration a stretching of the *axial* bond. The two bands have very near the same intensity.

In the previous paper [1] on the monohalogenated *cyclo*hexanes it was not possible to calculate the conformational equilibrium value from the intensities of the characteristic frequencies because the molar extinction coefficients were unknown. According to the discussion above the two carbon-chlorine stretching vibrations of the *cis* 1,2-dichloro*cyclo*hexane are probably characteristic of the *equatorial* and the *axial* bond, respectively. As the intensity of the corresponding infrared bands are nearly the same, one may assume that the molar extinction coefficients of the characteristic *e* and *a* stretching bands are approximately equal. On this basis one calculates the mole fraction of the *e*-conformation to 0.78 for the monochloro*cyclo*hexane and to 0.85 for the monobromo*cyclo*hexane. It must be admitted that the assumptions upon which these calculations are based, are somewhat drastic. The results are, however, not inconsistent with those obtained from electron diffraction measurements [25].

For monosubstituted *cyclo*hexanes and steroids it has been pointed out by several authors [26-29] that the stretching motion of an *equatorial* substituent induces a higher vibrational frequency than the stretching motion of the corresponding *axial* substituent. This empirical rule is substantiated by the data of Table 7, which shows that the rule holds even for disubstituted *cyclo*hexanes.

The authors desire to express their sincerest thanks to Professor O. Hassel for helpful discussions and encouragement during the work. One of the authors (K.L.) wishes to thank *Norges Almenvitenskapelige forskningsråd* for financial support.

On the Preparation of Cholesterol Labelled with Tritium at Carbon Atoms 24 and 25 (Cholesterol-24,25-T_2)

Bile Acids and Steroids 54

S. BERGSTRÖM, S. LINDSTEDT and D. SEN*

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Cholesterol-24,25-T_2 has been prepared by electrolysis of 3β-hydroxychol-5-enic acid and *iso*valeric acid-2,3-T_2 obtained by reduction of 3,3-dimethylacrylic acid with tritium gas.

In order to study the metabolism of cholesterol we have synthesized cholesterol labelled with tritium mainly at carbon atoms 24 and 25.

Cholesterol has been obtained by anodic (Kolbe) synthesis from 3β-hydroxychol-5-enic acid and *iso*valeric acid. With a 25-fold excess of *iso*valeric acid a 17 % yield of cholesterol calculated on the amount of bile acid used has been obtained (*cf.* Ref.[1]).

Adsorption chromatography on alumina followed by reversed phase partition chromatography had to be used to obtain a pure product from the reaction mixture.

Tritium labelled *iso*valeric acid was obtained by reducing 3,3-dimethylacrylic acid with tritium gas in dioxan solution in presence of platinum catalyst. The isotope is presumably located at carbon atoms 2 and 3 of the *iso*valeric acid but according to the experience of reduction with tritium gas in other cases, some isotope might also be located in the terminal methyl groups.

EXPERIMENTAL

All melting points were taken on an electrically heated aluminum block and are corrected. The radioactivity was estimated in a Tracerlab gas flow counter in an "infinitely thin" layer.

Δ^5-3β-Hydroxycholenic acid. An impure sample of the acid was purified by chromatography of its methyl ester on alumina. We are indebted to Ciba Ltd., Basel, for a generous sample of this acid. Electrolysis was carried out in wide test tubes (i.d. 35—38 mm)

* Present adress: Department of Applied Chemistry, University College of Science and Technology, Calcutta 9, India.

in which 3 platinum electrodes (20 × 26 mm) were fixed parallel to and at distances of 2 mm from each other. The middle one served as anode and the two outer ones as cathode. The current used was 2.2 A.

262 mg (0.7 mmole) of 3β-hydroxychol-5-enic acid, 2 ml (1.80 mmole) of isomer-free *iso*valeric acid and 42 mg (1.87 mmole) of sodium was dissolved in a mixture of 26 ml methanol and 9 ml dry pyridine. (The cholenic acid did not dissolve in methanol alone.)

The vessel was cooled in an ice-salt mixture and the solution was also cooled by dipping into it a glass tube through which cold water was circulated. The temperature of the reaction mixture remained between 35° and 45° during the electrolysis that was continued until pH 7.5 was reached. The solution was then taken to dryness *in vacuo*. 20 ml of 2 N hydrochloric acid was added and extracted with four 50 ml portions of ether. The ethereal solution was washed with 2 N hydrochloric acid, water, 10 % sodium hydroxide solution and water, and then taken to dryness *in vacuo*. The residue weighed 230 mg.

Chromatography. The residue was dissolved in benzene and brought onto a column (i.d. of tube 15 mm) of 20 g aluminum oxide (alkali free [2]), prepared with benzene. The column was eluted as shown in Table 1, fractions of 40 ml being collected.

Table 1.

Fraction	Eluent	Eluate

23	»	4 mg	»	
24	»	2 mg	»	

Similar chromatograms were also obtained in the preparation of active cholesterol.

Fractions 19, 20 and 21 after one crystallization from methanol yielded 71 mg of crystals of m.p. 133—37°. 23.6 mg of this was mixed with 1 mg of cholesterol-4-^{14}C and

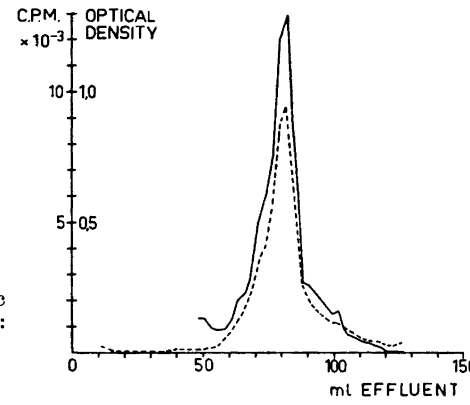

Fig. 1. Partition chromatogram of synthetic cholesterol. Full line: c.p.m. Broken line: cholesterol color reaction [4].

subjected to reversed phase partition chromatography at 23° on hydrophobic Supercel (4.5 g) with 55 % *iso*propanol in water as the mobile phase and chloroform/heptane (1:4) (4 ml) as the stationary phase as described by Danielsson [3].

Fractions of about 2 ml were collected with a fraction-collector. Aliquot parts of the fractions were taken and the radioactivity estimated by plating and counting. The total cholesterol was determined with the Tschugaeff's reaction [4]. The results are shown in Fig. 1.

The substance (17 mg) was collected from the fractions between 66 and 90 ml effluent. One crystallization from methanol gave 14.0 mg of crystals, m.p. 147–48°. A mixed melting point determination with authentic cholesterol gave no depression.

3,3-Dimethylacrylic acid was prepared by oxidation of mesityl oxide [5].

Isovaleric acid-2,3 T. The hydrogenation was carried out in a high vacuum apparatus similar to that described by Glascock [6]. The reaction vessel had a volume of 2.9 ml and was connected to the vacuum line with a balljoint. We have also found it convenient to introduce a 15 mm long gold-plated iron rod as a magnetic stirrer. By this technique the long reaction time described by Glascock can be much reduced.

2 mg of platinum oxide suspended in 0.1 ml dry dioxan was reduced with inactive hydrogen in the reaction vessel. 5 mg of dimethylacrylic acid in 0.15 ml of dioxan was then added. The apparatus was evacuated with the reaction vessel cooled in liquid air and 0.208 ml of tritium gas (0.5 C) pumped into the reaction space with the Toepler pump. After 1 h 95 % of the tritium gas had been taken up. 0.5 ml of inactive hydrogen was then pumped into the vessel. This gas was consumed in 2 h and the reduction then brought to completion with a further portion of inactive hydrogen.

Cholesterol-24,25-T. The labelled *iso*valeric acid was dissolved in 5 ml dioxan and added to the same mixture as described above and was then electrolysed and worked up as before. 230 mg of residue was obtained.

Chromatography on alumina followed by partition chromatography yielded in all 46 mg cholesterol (m.p. 147–48°), *i.e.* a 17 % yield calculated on the amount of 3β-hydroxychol-5-enic acid used.

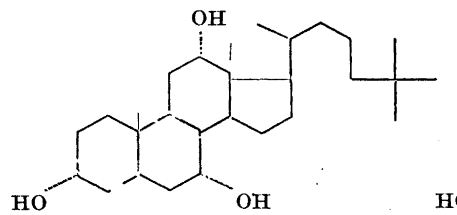
Synthesis of the Tritiated 25-Methyl Homologues of 3α,7α,12α-Trihydroxy Coprostane and Coprocholic Acid

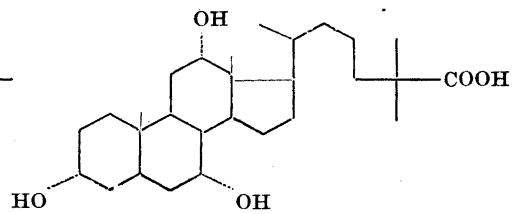
Bile Acids and Steroids 55

SUNE BERGSTRÖM, URS GLOOR and LENNART KRABISCH



Department of Physiological Chemistry, University of Lund, Lund, Sweden

The compounds have been prepared through electrolysis of tritiated cholic acid together with *tert.* butyl acetic acid, respectively the monoester of 2,2-dimethylsuccinic acid.



Previous work at this institute has shown that the hydroxylating enzyme systems involved in the transformation of cholesterol into bile acids have very exacting requirements as far as the structure of the side chain is concerned.

A 12α-hydroxyl is introduced resulting in the formation of cholic acid when labelled cholesterol (*cf.* Summary [1]), 3α,7α-dihydroxycoprostane [2] or 7α-hydroxycholesterol [3] is administered. If the side chain contains a carboxyl at the end of the C_5-cholanic or the C_8-"coprocholanic" side chain, however, the molecule is hydroxylated at other positions. Furthermore the 7α-hydroxylating enzyme system present in rat liver microsomes that transforms taurodeoxycholic acid into taurocholic acid does not work on free deoxycholic acid [1] *in vitro*.

As a step in the investigation of the influence of the side chain structure on the hydroxylating system and on the taurine conjugating system and also as a useful substrate in studying the ω- or methyloxidation we have prepared 3α,7α,12α-trihydroxy-25-methylcoprostane (I), *i.e.* a coprostane with the stable cholic acid structure in the ring system and a tertiary butyl group at the end of the side chain, thus blocking any β-oxidation after a possible ω-oxidation.

I

II

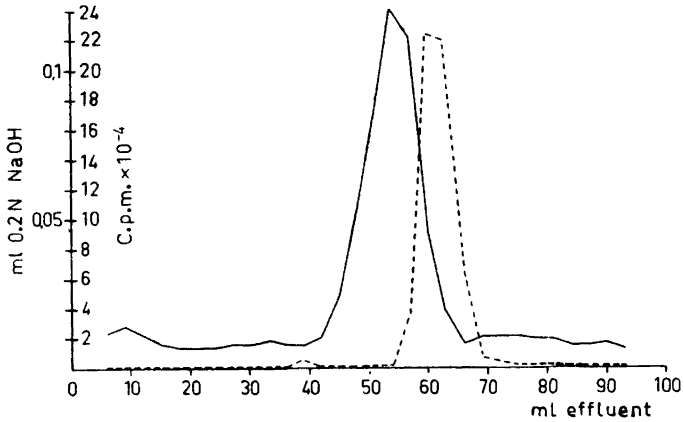


Fig. 1. Reversed phase partition chromatography of deoxycholic acid (solid line) and [T]-25-methyl-coprocholic acid (<0.1 mg) (broken line, cpm) in 55 % aqueous methanol/chloroform-heptane 9:1, *cf.* Ref.[1]

We have also prepared the corresponding possible metabolite that would be formed if one of the terminal methyl groups was oxidized to a carboxyl, *i.e.* 3α,7α,12α-trihydroxy-25-methylcoprocholanic acid (II).

The preparation of these two compounds (I and II) from tritium labelled cholic acid is described in this publication. Some data on the metabolism of these compounds are given in a separate communication.

EXPERIMENTAL

3,7,12-Trihydroxy-25-methylcoprostanic acid (25-methyl-coprocholic acid). Tritiated cholic acid (250.8 mg) was dissolved in methanol (50 ml) and 2,2-dimethyl-succinic acid mono-methyl ester (tertiary) (2.33 g) and sodium (35 mg in one ml of methanol) was added.

The solution was electrolyzed as described earlier [4] until a pH of about 7.5 had been reached. The solution was then taken to dryness *in vacuo* and the residue distributed between ether and water. The ether phase was washed neutral with carbonate and brought to dryness leaving a residue of 884 mg.

The crude product was dissolved in methylene chloride and chromatographed on a column of silicic acid (dried at 120° for 24 h) and Hyflo Supercel. The material eluted with 6 % methanol in methylene chloride. The centre of the material eluted with this solvent was saponified in 2 N potassium hydroxide for 4 h at 130°.

Of the free acid recovered (129 mg) 70 mg was subjected to reversed phase partition chromatography on hydrophobic Kieselguhr (18 g) with 60 % aqueous methanol as mobile phase and chloroform-heptane as stationary phase [5].

The well defined peak between 100 and 180 ml effluent was combined and crystallized from aqueous acetone. The product melted at 224—226°C. (Found: C 72.8; H 10.5. Calc. for $C_{28}H_{48}O_5$: C 72.4; H 10.4).

A sample of the acid was also run with deoxycholic acid in a system of 55 % aqueous methanol and chloroform-heptane 9:1.

As seen in Fig. 1 the peak of the labelled material appeared at 60—65 ml effluing slightly after the deoxycholic acid (55 ml) whereas coprocholic acid has been found to appear at 40—45 ml and cholic acid at 20—25.

The addition of three carbons to the side chain of cholic acid thus does not quite counterbalance the effect of one hydroxyl in this system, whereas the further addition of one methyl group makes the acid less polar than deoxycholic acid.

3,7,12-Trihydroxy-25-methylcoprostane. Tritiated cholic acid (50 mg) was dissolved in methanol (5 ml). Tertiary butylacetic acid (316 mg) was added together with sodium methylate (7 mg). The platinum electrodes were 5×7 mm at a distance of 2 mm from each other and the electrolysis was run as indicated above. The neutral product was chromatographed on silicic acid and the material eluted with methylene chloride containing 2 % of methanol, combined and recrystallized from aqueous acetone yielding 14 mg of a product melting at 203°. (Found: C 77.3; H 11.7. Calc. for $C_{28}H_{50}O_3$: C 77.4; H 11.6).

We are very grateful to Dr. S. Lindstedt for supplying us with cholic acid labelled with tritium through catalytic exchange essentially according to the method of Trenner *et al.*[6]

Bifunctional Amines and Ammonium Compounds

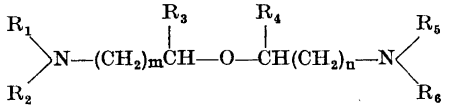
VI.* Further Homologs and Analogs of bis-Choline Ether Salts

JØRGEN FAKSTORP and JYTTE CHRISTIANSEN

Aktieselskabet Pharmacia, Copenhagen-Vanløse, Denmark

As an extension of earlier work twelve aliphatic bis-alkylammonium alkyl ethers, representing different chain-lengths, distribution and size of N-substituents, and chain branching, are reported together with twenty-four quaternary salts. Six aromatic ethers are reported along with eight bis-quaternary and three mono-quaternary salts derived therefrom. Transformation to non-halide salts is discussed. Alkylation of bis-(2-dimethyl-2'-diethyl)-aminoethyl ether with various alkyl halides gave ten different quaternary salts, which are reported.

In the current investigations on the relation of structure to pharmacological activity in an extended series of bis-ammonium salts, the need arose for salts representing further extensions on the structural theme exemplified by bis-choline ether. A number of such variations have been reported earlier from this laboratory [1-4].



The present paper reports twelve additional bis-tertiary aliphatic ethers, representing variations in chain-length, degree of asymmetry, size of N-substituents and chain-branching (Table 1). These ethers were obtained essentially as described earlier [1]. They were prepared, in most cases, from known aminoalcohols or aminoalkylhalides, respectively.

This paper further presents six bis-tertiary ethers having an aromatic ring system in the chain (Table 2). The bis-tertiary ethers have been transferred to their corresponding methiodides and ethobromides or ethiodides, respectively. The twenty-four salts corresponding to the aromatic ethers are shown in Table 4. The quaternary salts were obtained by conventional procedures.

The substituted choline phenyl ethers are formed with considerable difficulty, and in several cases only the mono-quaternary salt (retaining the tertiary amino group on the aromatic ring) was obtained. Three such mono-quaternary salts are shown in Table 5.

Among the bis-quaternary salts described in the second paper of the series [1], high ganglion blocking activity was found in the asymmetric compound N,N,N,N'-tetraethyl-N',N'-dimethyl-3-oxa-pentane-1,5-diammonium di-bromide (As-4179) [5]. Because of the toxic nature of the bromide anion, it was of importance to study other salts of the biologically active ion. A number of such salts have been prepared or their preparation attempted. Most of them were not useful in that they were either deliquescent, or contained toxic anions (Table 6). One of the few salts which seemed to be of interest, was the acid tartrate (As-4137) *. This salts has been the basis of further pharmacological and clinical work [6,7].

The tartrate and the other salts were available by addition of the appropriate acid to a solution of the free alkyl ammonium hydroxide. A number of methods for the transformation of the direct products of quaternization, bromide, iodide or alkyl sulfate, into salts of any given anion have been in-

sulfate according to Barber and Gaimster [8], by addition of propylene oxide to an aqueous solution of the quaternary bromide and the desired acid (*cf.* Sackur [9]). A special method for transformation into chloride is that of Phillips and Baltzley [10]. The use of double decomposition with salts of aromatic acids was also explored. Since the sodium salt of retene-3-sulfonic acid is soluble, while the potassium salt is not, it was hoped that an insoluble salt of the bis-quaternary ion would form with this acid. This was, however, not the case. Similarly no sparingly soluble salt is formed with 2,2'-dihydroxy-1,1-dinaphthylmethane-3,3'-dicarboxylic acid (Barner and Gaimster's [11] "embonic acid"). Sparingly soluble salts were obtained, however, with 2,2'-dihydroxy-1,1'-dinaphthyl-3,3'-dicarboxylic acid ("bis-hydroxy-naphtoic acid" [11]) and with 4,4'-diamino-stilbene-2,2'-disulfonic acid as disclosed by Slack [12]. Tartaric acid expels these weak acids from their salts in the form of the insoluble free acid.

In view of the interesting pharmacological results obtained with the simple quaternary salts of the asymmetric base, bis-(2-diethylamino-2'-dimethylamino)-ethyl ether (Asa 41), it appeared of interest to prepare some salts containing higher alkyls as N-substituents. These salts were obtained in conventional fashion and are shown in Table 7.

Attempts to prepare the "totally asymmetric" 2-trimethylammonium-ethyl-2'-triethylammoniumethyl ether by various routes were unsuccessful. In several cases N-dialkyl morpholinium ions, however, were obtained from the reaction mixtures.

EXPERIMENTAL *

Bis-tertiary *amino ethers.* With the exceptions mentioned below these substances were obtained simply by Williamson ether condensation of the appropriate tertiary amino alcohols resp. amino halides as described earlier [1].

Bis-(2-ethylmethyl-2'-dimethyl)-aminoethyl ether

a) Bis-(2-ethyl-2'-dimethyl)-aminoethyl ether. Twenty-three grams of sodium (1 mole) was dissolved by heating in a solution of 90 g of N-ethylethanolamine in 800 ml dry toluene. Condensation with N-dimethyl-aminoethyl chloride prepared *in situ* from 144 g (1 mole) of the corresponding hydrochloride. After removal of sodium chloride and toluene the residue is distilled in vacuum to give 10 g of oil, b.p. 87—95°C/20 mm Hg. (Found: N 16.41. Calc. for $C_8H_{20}N_2O$ (160.6): N 17.48). Purity (by perchloric acid titration) 98.0 %.

b) Methylation of (a) (Eschweiler-Hess procedure) (Asa 120). To 49 g (0.3 mole) of the amine in a flask is added 45 g of 85 % formic acid (0.6 mole) at such a rate that the temperature never exceeds 60°C. After cooling to room temperature 11 g of 37 % formalin is added at once. The mixture is heated to approximately 60° at which temperature an exothermic evolution of CO_2 begins. After this has subsided the mixture is refluxed for 3 h. The mixture is made just acid with 4 N HCl and air blown through for 1 h for removal of volatile products. More HCl is added and the mixture is evaporated in vacuum till the residue is semisolid. After addition of a large excess of NaOH extraction with ether, 200 ml, three times. The residue from the dried ether is distilled. Yield: 34 g (64 %). See Table 1 for analytical data.

Bis-(2-ethylmethyl-2'-diethyl)-aminoethyl ether is obtained in essentially similar fashion from the intermediate bis(2-ethyl-2'-diethyl)-amino ethyl ether (b.p. 120°C at 20 mm Hg).

* All melting and boiling points are uncorrected. The nitrogen and halogen values are semi-micro determinations by Mrs. G. Speggers and her staff. Carbon and hydrogen values are micro determinations by Messrs. W. Egger and P. Hansen, University of Copenhagen.

Bis-(2-ethyl-*n*-propyl-2'-dimethyl)-aminoethyl ether (Asa-135)

From 32 g (0.2 mole) of bis-(2'-ethyl-2'-dimethyl)-aminoethyl ether and 25 g of *n*-propylbromide in *iso*propanol. Yield 5 g (12 %). See Table 1 for analytical data.

By substituting 27.4 g of *n*-butylbromide for the propyl bromide in the procedure given immediately above one obtains the corresponding *bis-(2-ethyl-n-butyl-2'-dimethyl)-aminoethyl ether (Asa-136)*. Yield 6 g (11 %). See Table 1 for analytical data.

Acknowledgement. The authors are pleased to acknowledge a gift of retene-3-sulfonic acid from professor H. Lund, University of Århus, Denmark, and a generous sample of N-ethylaminoethanol from Carbide & Carbon Chemicals Corporation, Geneve, Switzerland.

Initial Steady State Velocities in the Evaluation of Enzyme-Coenzyme-Substrate Reaction Mechanisms

KEITH DALZIEL*

Biochemistry Department, Nobel Medical Institute, Stockholm, Sweden

The initial rate equations for a number of possible reaction sequences for enzyme-coenzyme-substrate reactions deduced by the steady state treatment are compared and contrasted.

For certain mechanisms the initial rate equations may be considered to be derived from a common equation which is most conveniently and simply expressed in terms of four kinetic coefficients. In this equation the reciprocal rate is linearly related to the reciprocal of each substrate concentration. A method for determining the kinetic coefficients from initial rate measurements, as slopes and intercepts of double plots, is described.

The distinctive Haldane relations between kinetic and equilibrium constants which exist for certain mechanisms [5] are a consequence of differences between the initial rate equations: either there are distinctive relations between the kinetic coefficients or certain of the coefficients are equal to zero. These mechanisms can sometimes be rejected on the basis of initial rate data alone, with greater certainty than by the Haldane relations.

Certain more complex mechanisms are considered which make provision for deviations from the linear reciprocal form of initial rate equation at high concentrations of one substrate. Substrate inhibition of various types may be distinguished experimentally, and a possible explanation of substrate activation is also considered.

From initial overall velocity measurements in the steady state, Theorell, Nygaard and Bonnichsen [1] were able to calculate all six rate constants in the mechanism proposed by Theorell and Chance [2] for the liver alcohol dehydrogenase reaction. There was reasonably good agreement between two of the rate constants so obtained and values determined in single reaction steps [2], and also between the equilibrium constant for the overall reaction calculated from the six rate constants and the value obtained from equilibrium measurements [3].

* Rockefeller Fellow, 1955—57; present address, Biochemistry Department, (Radcliffe Infirmary), University of Oxford.

The importance of such comparison of kinetic and equilibrium data as a test of the suitability of a postulated reaction sequence [4] was emphasized by Alberty [5], who discussed a number of possible mechanisms for enzyme-coenzyme-substrate reactions, and showed that for some the Haldane relation between the overall equilibrium constant and initial rate parameters (maximum rate and Michaelis constants) assumes a distinctive form. Theorell *et al.*[3] and Nygaard and Theorell [6] tested their data for liver and yeast alcohol dehydrogenases by means of these relations, and found the Theorell-Chance mechanism to be satisfactory for the liver enzyme but not for the yeast enzyme, and that certain other reaction sequences could be rejected in both cases.

Further kinetic studies of liver alcohol dehydrogenase [7,8] have revealed deviations from the Theorell-Chance mechanism under certain conditions. It is the purpose of the present paper to describe in general terms the theoretical basis and design of those experiments, to extend the discussion by Alberty [5] of possible mechanisms for enzyme-coenzyme-substrate reactions and of the manner in which initial rate data may be used to distinguish them, and to consider more complex reaction sequences which might account for substrate inhibition. The distinctive Haldane relations deduced by Alberty result from differences between the initial rate equations for certain mechanisms, and initial rate data alone can be used, with advantage, to distinguish these alternatives. It is of course essential that the appropriate Haldane relation also be fulfilled by the data if a particular reaction sequence is to be accepted as a satisfactory hypothesis. The relations are simplified by an alternative formulation of the initial rate equations, analogous to that of Lineweaver and Burk [9] for single-substrate reactions, but not employing Michaelis constants.

THE STEADY STATE METHOD

The steady state method [10] of deriving the relation between the initial rate, the total enzyme concentration and the initial substrate concentrations is preferable to the more restrictive equilibrium method [11] and except for one mechanism has been used throughout this paper. The assumptions involved are (i) that the enzyme concentration is small compared with the substrate concentrations (ii) that the rate of change of concentration of all enzyme-substrate complexes is zero. For initial rates the product concentrations are set equal to zero, a proceeding which has been widely adopted [4,5] if not theoretically justified [12]. To the succinct description of the steady state method given by Alberty [5] it needs only be added that in deducing the initial rate equation it is simpler to disregard all reactions involving products in setting up the rate equations for the enzyme-substrate complexes than to obtain the general rate equation and then set the product concentrations equal to zero. For single-substrate reactions, the deduction of the initial rate equation is equivalent to using the Michaelis-Menten formulation, $E + S \rightleftharpoons EX \rightarrow E + S'$, ignoring the reverse of the second step. For reactions involving a coenzyme and a substrate, however, it is not desirable to group together all steps after the formation of the ternary complex as a single step [13] as the rates of breakdown of binary enzyme-product complexes enter into the steady state expression for the initial rate, and in some cases can be evaluated from initial rate data.

THE THEORELL-CHANCE MECHANISM

Theorell and Chance [2] proposed that in the liver alcohol dehydrogenase reaction, binary compounds of enzyme and coenzyme (diphosphopyridine nucleotide) react with the substrate (alcohol or acetaldehyde) without the intervention of a rate-limiting ternary complex. If the overall reaction of coenzyme and substrate is represented in general by $S_1 + S_2 \rightleftharpoons S_1' + S_2'$, the Theorell-Chance mechanism may be written:

$$\begin{aligned} E + S_1 &\underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES_1 \\ ES_1 + S_2 &\underset{k_3'}{\overset{k_3}{\rightleftharpoons}} ES_1' + S_2' \qquad \text{II (iii)} \\ ES_1' &\underset{k_1'}{\overset{k_2'}{\rightleftharpoons}} E + S_1' \end{aligned}$$

Both the coenzyme, S_1, and the substrate, S_2, will be referred to as substrates. Steady state treatment [2] yields the following relations, for the forward and reverse reactions respectively, between the total enzyme concentration e, the initial rate v_0, and the initial substrate concentrations:

$$\frac{e}{v_0} = \frac{1}{k_2'} + \frac{1}{k_1[S_1]} + \frac{1}{k_3[S_2]} + \frac{k_2}{k_1k_3[S_1][S_2]} \qquad 1(a)$$

$$\frac{e}{v_0'} = \frac{1}{k_2} + \frac{1}{k_1'[S_1']} + \frac{1}{k_3'[S_2']} + \frac{k_2'}{k_1'k_3'[S_1'][S_2']} \qquad 1(b)$$

Because of the symmetry of the mechanism and of the numbering of the rate constants, the forward and reverse initial rate equations 1(a) and 1(b) are interchangeable by the insertion or deletion of primes on the rate constants, and this will be true throughout. The reciprocal initial rate is linearly related to the reciprocal concentration of each substrate, so that if either substrate concentration is varied whilst the other is kept constant, plots according to Lineweaver and Burk [9] should be linear. If each substrate concentration is varied in turn whilst the other is kept at a sufficiently high level, the last term and either the second or third terms of the above equations will be negligible, and therefore all 6 rate constants could be determined from the slopes and intercepts of four Lineweaver-Burk plots for the forward and reverse reactions. This was in principle the method used by Theorell *et al.*[1], but because a sufficiently great concentration of the constant partner could not be used in every case, some corrections were necessary. Moreover, elimination of the last terms of 1(a) and 1(b) neglects the important relation between the last three terms of each equation and the first term of the other.

The initial rate eqns. (1) may be written in a general form:

$$\frac{e}{v_0} = \Phi_0 + \frac{\Phi_1}{[S_1]} + \frac{\Phi_2}{[S_2]} + \frac{\Phi_{12}}{[S_1][S_2]} \qquad (2)$$

for the forward reaction; for the reverse reaction, the coefficients will be distinguished by primes. Comparison of eqns. (1) and (2) shows that there are complementary relationships between the kinetic coefficients of the forward and reverse reactions:

$$\Phi_0' = \Phi_1\Phi_2/\Phi_{12} \qquad 3(a)$$

$$\Phi_0 = \Phi_1'\Phi_2'/\Phi_{12}' \qquad 3(b)$$

These relations distinguish the Theorell-Chance mechanism from others which conform to (2). To test them, all 4 coefficients for the forward and reverse reaction must be determined; the determination of Φ_{12} and Φ_{12}' requires initial rate measurements with low concentrations of both substrates.

It can be shown that the overall equilibrium constant is equal to two functions of the kinetic coefficients (Haldane relations):

$$K_{Eq} = \Phi_{12}'/\Phi_{12} \qquad (4)$$

$$K_{Eq} = \Phi_0'\Phi_1'\Phi_2'/\Phi_0\Phi_1\Phi_2 \qquad (5)$$

Other mechanisms which conform to (2) also conform to (4), but (5) is distinctive for the Theorell-Chance mechanism (*cf.* Alberty [5], eqn. 9) and is a consequence of relations 3(a) and 3(b) between the coefficients. If experimental data conform to (4) but not to (5), either 3(a) or 3(b), or both, will not be satisfied. These latter relations are a more sensitive test than (5) because they involve fewer experimental quantities, do not involve separate equilibrium measurements, and are independent of one another, whereas (5) is a resultant of both of them.

GENERAL FORM OF THE INITIAL RATE EQUATION

It will be seen that the initial rate equations for a number of other mechanisms may also be considered as special cases of eqn. (2), and that certain of these mechanisms may be distinguished by the fact that one or more of the kinetic coefficients is equal to zero, or, as in the case of the Theorell-Chance mechanism, by a relation between the coefficients.

Initial rate equations are usually, but not always [13], formulated in terms of Michaelis constants, defined as the concentration of the substrate which gives half the maximum rate approached asymptotically with increase of substrate concentration [4]. With this definition, the steady state treatment [10,4] of single-substrate reaction mechanisms in which one or two intermediate enzyme-substrate compounds are postulated gives the same initial rate equation as the equilibrium teatment, *viz.* the Michaelis-Menten equation. For two-substrate reactions, the Michaelis constant for each substrate varies with the concentration of the other [4,2]. Alberty [5] defines the Michaelis constant in this case as the concentration which gives half the maximum rate approached with increase of *both* substrate concentrations, and obtains by steady state treatment of several possible mechansims an initial rate equation analogous to that of Michaelis and Menten [11]:

$$v_0 = \frac{V}{1 + \frac{K_1}{[S_1]} + \frac{K_2}{[S_2]} + \frac{K_{12}}{[S_1][S_2]}} \qquad (6)$$

V is the maximum rate and K_1 and K_2 are the Michaelis constants for S_1 and S_2. K_{12} is a new kinetic constant [5]. This equation is equivalent to eqn. (2).

The Michaelis constant has its original theoretical significance as the dissociation constant of a compound of the substrate with the enzyme only when the relative reaction rates are such that the compound can be assumed to be in equilibrium throughout with the free substrate and enzyme. This is true for two-substrate reactions also, the dissociation in this case being from the ternary complex [13] (Mechanism I below). With the less restrictive steady state assumption, the Michaelis constant has no obvious physical significance. For a single-substrate reaction in which one intermediate enzyme complex is postulated, it is still a simple function of rate constants relating to the substrate and its enzyme compound [10]. When more than one intermediate enzyme compound is postulated [4] and for two-substrate reaction mechanisms in general [5], the Michaelis constant of a substrate is a more or less complex function of several rate constants, some of which relate to reaction steps not involving either the free or bound substrate [2,14]. In the initial rate equation for one mechanism discussed by Alberty, and considered to be a special case of (6), V, K_1, and K_2 do not conform to the definitions given above, and this seems to have led to an erroneous formulation of the kinetic expression for the equilibrium constant (Alberty [5]: mechanism I (6), eqns. (11) and (12)).

Equation (2) is analogous to that of Lineweaver and Burk [9] for single-substrate reactions, which could be written $e/v_0 = \Phi_0 + (\Phi_1/[S_1])$. The coefficients are simpler functions of the rate constants than are Michaelis constants, and can be determined as slopes and intercepts by an extension of the Lineweaver-Burk plot (*vide infra*). Φ_0 has the dimension of a reciprocal first order rate constant, and is equal to the reciprocal of the maximum rate with unit enzyme concentration, or the reciprocal of the maximum turnover number. Φ_1 and Φ_2 are equivalent to reciprocal second-order rate constants, and are related to the Michaelis constants, as defined by Alberty [5], by $\Phi_1/\Phi_0 = K_1$ and $\Phi_2/\Phi_0 = K_2$. Φ_{12} has the dimension of a third order rate constant, and $\Phi_{12}/\Phi_0 = K_{12}$ in Alberty's equation.

EXPERIMENTAL DETERMINATION OF THE KINETIC COEFFICIENTS

Rearrangement of eqn. (2) gives:

$$\frac{e}{v_0} = \Phi_0 + \frac{\Phi_2}{[S_2]} + \left(\Phi_1 + \frac{\Phi_{12}}{[S_2]}\right)\frac{1}{[S_1]}$$

If a series of initial rate measurements is made with a constant initial concentration of S_2 (not necessarily large) and different concentrations of S_1, a plot [9] of e/v_0 against $1/[S_1]$ should give a straight line, with both slope and intercept linear functions of $1/[S_2]$. If several such series of initial rate measurements are made, each with a different constant value of $[S_2]$, the slopes and intercepts of the primary plots may be plotted against $1/[S_2]$, to give the 4 coefficients directly as slopes and intercepts, thus:

Secondary plots of intercepts: slope $= \Phi_2$, intercept $= \Phi_0$.
Secondary plots of slopes: slope $= \Phi_{12}$, intercept $= \Phi_1$.

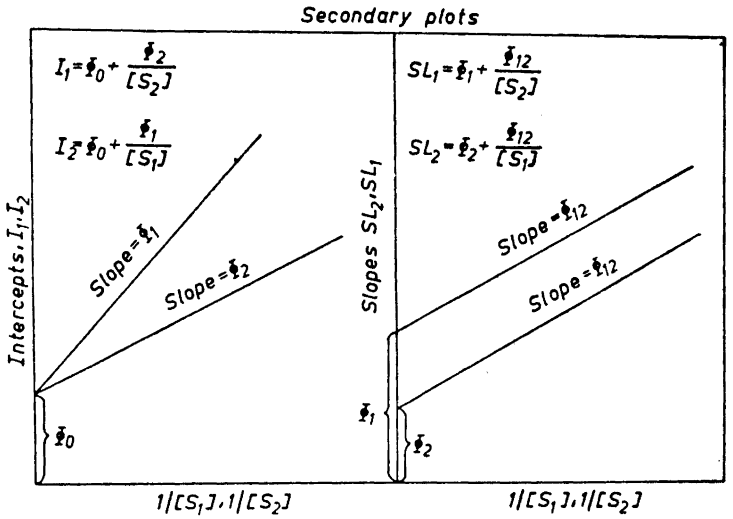

Fig. 1. Illustration of the determination of the kinetic coefficients of eqn. (2) by secondary plots of slopes and intercepts of primary Lineweaver-Burk plots.

The initial rate eqn. (2) is symmetrical in $[S_1]$ and $[S_2]$, and $[S_2]$ could equally well be chosen as the variable in the primary plots, and $[S_1]$ as the variable in the secondary plots. If say 5 different concentrations of both substrates are used, the 25 initial rate measurements may be plotted in both ways, thereby grouping them in different sets of 5 for the primary plots. Two sets of values for the 4 coefficients will be obtained from the secondary plots, as illustrated in Fig. 1.

This procedure seems to make the best use of the data, and is a generalisation of those described by Schwert and Hakala [15], Hakala, Glaid and Schwert [16] and Alberty [5]. It has the advantage of giving all the coefficients in the initial rate equation directly, but it depends upon initial rate measurements with low concentrations of both substrates. Accurate data can only be obtained under these conditions if a sensitive method of analysis is available, so that small enzyme concentrations can be used and measurements made over a small fraction of the total reaction to equilibrium.

DISCUSSION OF MECHANISMS CONFORMING TO EQUATION (2)

The most obvious general mechanism for an enzyme-catalysed reaction $S_1 + S_2 \rightleftharpoons S_1' + S_2'$ is one in which both substrates form binary compounds with the enzyme, providing two alternative pathways for the formation of a ternary complex, which undergoes intramolecular transformation (see I, below). The steady state treatment of this mechanism does not give an initial rate equation of the simple form of (2)[13]. Less complex mechanisms which do [5] may be divided into four types according to the simplifying assumptions. The coefficients in the initial rate eqn. (2) in terms of the rate constants or equilibrium constants for the cases to be discussed are given in Table 1,

Table 1. Initial rate equations (steady state) and Haldane relations for possible mechanisms for an enzyme-catalysed reaction $S_1+S_2 \rightleftharpoons S_1'+S_2'$.

General initial rate equation: $\frac{e}{v_0} = \Phi_0 + \frac{\Phi_1}{[S_1]} + \frac{\Phi_2}{[S_2]} + \frac{\Phi_{12}}{[S_1][S_2]}$

(For description of mechanisms, see text. Only the kinetic coefficients for the forward reactions are given; those for the reverse reaction, denoted by primes, are obtained by inserting or deleting primes on the rate constants.)

Mechanism	Kinetic coefficients				Relations between coefficients	Haldane relation
	Φ_0	Φ_1	Φ_2	Φ_{12}		K_{Eq}
I(a)	$\frac{1}{k}$	$\frac{K_4}{k}$	$\frac{K_3}{k}$	$\frac{K_1K_3}{k}$		$\frac{\Phi_{12}'}{\Phi_{12}}$
I(b)	$\frac{1}{k}$	$\frac{K_4}{k}$	$\frac{K_3}{k}$	$\frac{K_3K_4}{k}$	$\frac{\Phi_1\Phi_2}{\Phi_{12}} = \Phi_0$	$\frac{\Phi_{12}'}{\Phi_{12}} = \frac{\Phi_0\Phi_1'\Phi_2'}{\Phi_0'\Phi_1\Phi_2}$
II(i)	$\frac{1}{k_2'}+\frac{1}{k_4'}+\frac{1}{k}+\frac{k'}{kk_4'}$	$\frac{1}{k_1}$	$\frac{k_4k_4'+k_4k'+k_4'k}{k_3k_4'k}$	$\frac{k_2(k_4k_4'+k_4k'+k_4'k)}{k_1k_3k_4'k}$	$\frac{\Phi_1\Phi_2}{\Phi_{12}} < \Phi_0'$	$\frac{\Phi_{12}'}{\Phi_{12}}$
II(ii,a)	$\frac{1}{k_2'}+\frac{1}{k_4'}$	$\frac{1}{k_1}$	$\frac{k_4+k_4'}{k_3k_4'}$	$\frac{k_2(k_4+k_4')}{k_1k_3k_4'}$	$\frac{\Phi_1\Phi_2}{\Phi_{12}} < \Phi_0'$	$\frac{\Phi_{12}'}{\Phi_{12}}$
II(ii,b)	$\frac{1}{k_2'}$	$\frac{1}{k_1}$	$\frac{k_4+k_4'}{k_3k_4'}$	$\frac{k_2(k_4+k_4')}{k_1k_3k_4'}$	$\frac{\Phi_1\Phi_2}{\Phi_{12}} = \Phi_0'$	$\frac{\Phi_{12}'}{\Phi_{12}} = \frac{\Phi_0'\Phi_1'\Phi_2'}{\Phi_0\Phi_1\Phi_2}$
II(iii)	$\frac{1}{k_2'}$	$\frac{1}{k_1}$	$\frac{1}{k_3}$	$\frac{k_2}{k_1k_3}$	$\frac{\Phi_1\Phi_2}{\Phi_{12}} = \Phi_0'$	$\frac{\Phi_{12}'}{\Phi_{12}} = \frac{\Phi_0'\Phi_1'\Phi_2'}{\Phi_0\Phi_1\Phi_2}$
III	$\frac{1}{k_4'}$	0	0	$\frac{k_4+k_4'}{k_3k_4'}$	—	$\frac{\Phi_{12}'}{\Phi_{12}}$
IV(i)	$\frac{1}{k_2'}+\frac{1}{k_4'}$	$\frac{k_2+k_2'}{k_1k_2'}$	$\frac{k_4+k_4'}{k_3k_4'}$	0	—	$\frac{\Phi_1'\Phi_2'}{\Phi_1\Phi_2}$
IV(ii)	0	$\frac{1}{k_1}$	$\frac{1}{k_2}$	0	—	$\frac{\Phi_1'\Phi_2'}{\Phi_1\Phi_2}$

together with the Haldane relations between the kinetic coefficients and the overall equilibrium constant, and in some instances relations between the kinetic coefficients themselves. Only the forward initial rate coefficients are given; the expressions for the reverse coefficients are obtained by inserting or deleting primes on the rate constants.

Type I. Four binary and two ternary enzyme complexes are in rapid equilibrium with the free substrates, so that the intramolecular reaction of the ternary complex is the rate-limiting step:

$$\begin{array}{llll} E + S_1 \rightleftharpoons ES_1 & (K_1) & ES_1' \rightleftharpoons E + S_1' & (K_1') \\ E + S_2 \rightleftharpoons ES_2 & (K_2) & ES_2' \rightleftharpoons E + S_2' & (K_2') \\ ES_1 + S_2 \rightleftharpoons ES_1S_2 & (K_3) & ES_1'S_2' \rightleftharpoons ES_1' + S_2' & (K_3') \\ ES_2 + S_1 \rightleftharpoons ES_1S_2 & (K_4) & ES_1'S_2' \rightleftharpoons ES_2' + S_1' & (K_4') \end{array} \qquad \text{I}$$

$$ES_1S_2 \underset{k'}{\overset{k}{\rightleftharpoons}} ES_1'S_2'$$

The equilibrium treatment of Michaelis and Menten [11] will be valid and gives the initial rate in terms of the dissociation constants of the enzyme complexes and the rate constants of the intramolecular reaction (Table 1).

(a) In the general case, there are 6 independent dissociation constants, since $K_1K_3 = K_2K_4$, and $K_1'K_3' = K_2'K_4'$. All 8 dissociation constants and the two rate constants may be calculated if the 8 kinetic coefficients for the forward and reverse reactions are determined. The Haldane relation $K_{Eq} = \Phi_{12}'/\Phi_{12}$ is common to this and several other mechanisms, but for this mechanism there is no relation between the coefficients themselves. Since this is the most complicated mechanism considered here, it would only be adopted if all the others had to be rejected. Mechanisms *II* (i) and II (ii, a) differ from it only in that they require the limiting relations $\Phi_0' > \Phi_1\Phi_2/\Phi_{12}$ and $\Phi_0 > \Phi_1'\Phi_2'/\Phi_{12}'$. The conclusion of Alberty [5] that these three mechanisms cannot be distinguished by initial rate data alone is valid only if these limiting relations are fulfilled.

The maximum rates are $1/\Phi_0 = k$ and $1/\Phi_0' = k'$, and the condition that this mechanism give linear reciprocal plots is that these rates be small compared with those of the other reaction steps. If one of the latter is accessible to direct measurement, it may be possible to test this condition; for example, the spectral shift, which accompanies the combination of reduced diphosphopyridine nucleotide with liver alcohol dehydrogenase [3] made it possible to study this step in isolation [2]. Also, the results of ultracentrifuge studies of enzyme-substrate compounds [17] may be compared with the apparent dissociation constants calculated from initial rate measurements [18].

(b) In the special case that the combination of the enzyme with one substrate does not influence its affinity for the other[19], then $K_1 = K_4$, $K_2 = K_3$, *etc.*, and there are only 4 independent dissociation constants. There is then a relation between the 4 kinetic coefficients for the reaction in each direction, $\Phi_0 = \Phi_1\Phi_2/\Phi_{12}$, which distinguishes the mechanism from all the others considered, and can be used to test the forward and reverse reactions separately. In consequence also, there is an additional distinctive Haldane relation, $K_{Eq} = \Phi_0\Phi_1'\Phi_1'/\Phi_0'\Phi_1\Phi_2$.

Type II. Only one of the substrates, in each direction, forms a binary enzyme compound, so that there is a compulsory order of reaction.

(i) Two ternary complexes:

$$\begin{array}{c} \mathrm{E} + \mathrm{S_1} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES_1} \\ \mathrm{ES_1} + \mathrm{S_2} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \mathrm{ES_1S_2} \underset{k'}{\overset{k}{\rightleftharpoons}} \mathrm{ES_1'S_2'} \underset{k_3'}{\overset{k_4'}{\rightleftharpoons}} \mathrm{ES_1'} + \mathrm{S_2'} \\ \mathrm{ES_1'} \underset{k_1'}{\overset{k_2'}{\rightleftharpoons}} \mathrm{E} + \mathrm{S_1'} \end{array} \qquad \text{II(i)}$$

This and the following mechanisms give an initial rate equation of the form of (2) by steady state treatment. The expressions given by Alberty [5] for Michaelis constants and maximum rates in terms of the rate constants in the

mechanism are incorrect. The 10 rate constants cannot all be calculated from the 8 kinetic coefficients for the forward and reverse reactions.

(ii) One ternary complex:

$$\begin{gathered} E + S_1 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES_1 \\ ES_1 + S_2 \underset{k_4}{\overset{k_3}{\rightleftharpoons}} EXY \underset{k_3'}{\overset{k_4'}{\rightleftharpoons}} ES_1' + S_2' \qquad \text{II(ii)} \\ ES_1' \underset{k_1'}{\overset{k_2'}{\rightleftharpoons}} E + S_1' \end{gathered}$$

(a) In the general case the 8 rate constants could all be calculated from the kinetic coefficients. This mechanism was the basic one assumed by LuValle and Goddard [20] in their discussion of enzyme oxidation-reduction mechanisms.

(b) In the special case that $k_4 \gg k_2$ and $k_4' \gg k_2'$, the maximum rate becomes equal to the rate of the last step *i.e.* $\Phi_0 = 1/k_2'$, $\Phi_0' = 1/k_2$, and there are relations between the kinetic coefficients identical with those for the Theorell-Chance mechanism. But Φ_2 remains a function of k_3, k_4 and k_4', although these rate constants cannot now be separately evaluated from the coefficients.

(iii) No ternary complex. This is the Theorell-Chance mechanism described previously.

These mechanisms of Type II have the following features in common.

1. The Haldane relationship, $K_{Eq} = \Phi_{12}'/\Phi_{12}$.
2. The rate constants for the formation and dissociation of the binary complex are given by $k_1 = 1/\Phi_1$ and $k_2 = \Phi_{12}/\Phi_1\Phi_2$, and its dissociation constant by Φ_{12}/Φ_2.
3. Φ_0' cannot be less than $\Phi_1\Phi_2/\Phi_{12}$, since the maximum rate cannot exceed the rate of the last step.

These three mechanisms are not in fact alternatives in a practical sense. Cases (i) and (ii, a) cannot be distinguished, and the second with 8 calculable rate constants would be preferred. Case (iii), in which no ternary complex is included, cannot be distinguished by initial rate measurements of the type considered here from (ii, b), in which the dissociation rate of the ternary complex is fast enough not to limit the maximum rate. The postulate of Theorell and Chance [2] was not intended to explicitly exclude a ternary complex. There is no direct evidence for the formation of a ternary enzyme complex, but it has generally been thought likely [20], and the recent work of Vennesland and Westheimer [21] makes it probable in the dehydrogenase reactions involving diphosphopyridine nucleotide. Case (ii, b) would therefore be a preferable hypothesis to (iii), although it is not possible to calculate k_3 and k_3' individually, but only as functions of k_4 and k_4' (Table 1). Recently Alberty [22] has shown that it may be possible to distinguish mechanisms (ii,b) and (iii) by initial rate measurements with product S_2' present at the start.

Type III. There are no binary complexes; a ternary complex is formed by a termolecular reaction:

$$E + S_1 + S_2 \underset{k_4}{\overset{k_3}{\rightleftharpoons}} EXY \underset{k_3'}{\overset{k_4'}{\rightleftharpoons}} E + S_1' + S_2'$$

Two of the terms in the initial rate eqn. (2) are zero. The intercepts of Lineweaver-Burk plots are independent of the concentration of the constant partner. The mechanism can therefore be distinguished from the others considered, although there is no distinctive Haldane relation. All the rate constants can be calculated from initial rate measurements in both directions.

Type IV. The enzyme reacts with each substrate in turn to form a product, itself undergoing intermediate chemical change, *e.g.* oxidation and reduction. Such a mechanism is in principle open to direct test with stoichiometric proportions of enzyme and one substrate.

(i) Binary enzyme-substrate compounds are formed:

$$E + S_1 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} EX \underset{k_1'}{\overset{k_2'}{\rightleftharpoons}} E' + S_1'$$

$$E' + S_2 \underset{k_4}{\overset{k_3}{\rightleftharpoons}} E'Y \underset{k_3'}{\overset{k_4'}{\rightleftharpoons}} E + S_2' \qquad \text{IV(i)}$$

In recent practical considerations of this mechanism [5,1,6] the fact that it is distinguished from the preceding ones by the absence of the last term of equation (2) from the initial rate equation, as well as by a distinctive Haldane relationship, seems to have been overlooked. The Haldane relationship differs from those for Mechanisms I(b), II(ii, b) and II(iii) only by the ratio Φ_0'/Φ_0 or its reciprocal, so that these mechanisms cannot be distinguished by the Haldane relationship when the forward and reverse maximum rates are about the same.

(ii) No enzyme-substrate compounds:

$$E + S_1 \underset{k_1'}{\overset{k_1}{\rightleftharpoons}} E' + S_1'$$

$$E' + S_2 \underset{k_2'}{\overset{k_2}{\rightleftharpoons}} E + S_2' \qquad \text{IV (ii)}$$

Since there are no enzyme-substrate compounds, the initial rate increases indefinitely with increase of substrate concentration. The slopes of Lineweaver—Burk plots will be independent of the concentration of the constant partner. The intercepts will be inversely proportional to the concentration of the constant partner, and the secondary plots of the intercepts will therefore pass through the origin. The Haldane relation given by Alberty [5], which apparently distinguishes this case from the preceding one, is indeterminate. The correct Haldane relation is the same as that for the preceding case.

APPLICATION

Sufficient experimental data for the application of the principles discussed appears to be available for only three enzymes. Two of these will be considered briefly; the third, liver alcohol dehydrogenase, will be discussed in detail elsewhere [8].

Yeast alcohol dehydrogenase. Application of the Haldane relations of Alberty [5] to initial rate and equilibrium data at pH 6.0 and pH 7.15 enabled Nygaard and Theorell [6] to show that the rapid equilibrium mechanism I(a) was a satisfactory hypothesis for the yeast alcohol dehydrogenase relation, and that the special case of this mechanism, I(b) and the Theorell-Chance mechanism, could be rejected. As regards the "enzyme oxidation" mechanism IV(i), it was considered that the discrepancy of 60 % between the value of the equilibrium constant calculated from the appropriate Haldane relationship, and the direct value, was not outside the possible combined experimental error in the kinetic constants involved, but this mechanism was rejected on other grounds. The preceding discussion permits extension of these arguments.

Values for the kinetic coefficients and a distinctive function of the coefficients (Table 1) are shown in Table 2. Mechanism IV(i) requires $\Phi_{12} = \Phi_{12}' = 0$, so that this possibility can be rejected from the kinetic data alone. The Theorell-Chance mechanism can be rejected by discrepancies from the required relations between the kinetic coefficients $\Phi_0 = \Phi_1'\Phi_2'/\Phi_{12}'$ and $\Phi_0' = \Phi_1\Phi_2/\Phi_{12}$ (primes denote coefficients for the DPN + C_2H_5OH reaction).

Mechanism I(a) was satisfactory as regards the values of $K_{Eq} = 0.81$ and 1.1×10^{-11} M, calculated from the appropriate Haldane relationship, which agree well with the directly determined value of 0.9×10^{-11} M, but the same Haldane relation is also fulfilled by the simpler mechanisms II(i) and II(ii) (*cf.* Table 1) which were not considered by Nygaard and Theorell [6]. The data of Table 2 show, however, that $\Phi_0 < \Phi_1'\Phi_2'/\Phi_{12}'$ at both the pH values, which is contrary to the requirements of Mechanisms II(i) and II(ii). This same discrepancy from the requirements of all Type II mechanisms has recently been observed with liver alcohol dehydrogenase at pH 7.15 [7, 8].

The special case of the rapid equilibrium mechanism, I(b), was rejected because the appropriate Haldane relation gave values of $K_{Eq} = 4.5$ and 18×10^{-11}. This mechanism also requires that $\Phi_0' = \Phi_1'\Phi_2'/\Phi_{12}'$ and $\Phi_0 =$

Table 2. Kinetic coefficients for yeast alcohol dehydrogenase, 23°C, calculated from the data of Theorell and Nygaard [6]

Substrates	Φ_0 sec.	Φ_1 μM sec.	Φ_2 μM sec.	Φ_{12} μM^2 sec.	$\Phi_1\Phi_2/\Phi_{12}$ sec.
pH 6.0					
DPNH, CH_3CHO (Φ)	0.0027	0.063	0.79	3.4	0.014
DPN, C_2H_5OH (Φ')	0.026	4.2	2.6×10^3	4.2×10^5	0.026
pH 7.15					
DPNH, CH_3CHO (Φ)	0.002	0.077	1.12	11.2	0.008
DPN, C_2H_5OH (Φ')	0.016	0.94	2.95×10^2	6.9×10^4	0.004

$\Phi_1\Phi_2/\Phi_{12}$. At pH 6.0 the first of these relations is satisfied, but the second is not and accounts for the whole of the discrepancy of a factor of 5 in the Haldane relation. Thus, Mechanism I(b) is satisfactory for the alcohol-DPN reaction, but not for the aldehyde-DPNH reaction, *i.e.* if mechanism I(a) is accepted, it can also be assumed that at pH 6 the combination of the enzyme with either DPN or alcohol does not affect its affinity for the other. At pH 7.15 this additional assumption is not valid.

Lactic dehydrogenase. From tests of initial rate data with the Haldane relations of Alberty, Hakala *et al.*[16] concluded that the Theorell-Chance mechanism and the enzyme oxidation mechanism could be rejected, and that any of the ternary complex mechanisms I, II(i) and II(ii, a) were satisfactory. Examination of their data shows that the limiting relations between the kinetic coefficients required by mechanisms II(i) and II(ii, a) are also satisfied, so that no further conclusions can be drawn, except that the special case I(b) is not satisfactory for either the forward or reverse reactions.

SUBSTRATE INHIBITION

Deviations from the linear reciprocal form of initial rate equation at high substrate concentrations are common. Liver alcohol dehydrogenase [1,2] and lactic dehydrogenase [16] show substrate inhibition with high concentrations of alcohol and pyruvate, respectively. With yeast alcohol dehydrogenase on the other hand, deviation towards higher activity occur at high alcohol concentrations [6]. In cases such as lactic dehydrogenase where the reaction conforms, at low substrate concentrations, to the requirements of a Type II mechanism, in which there is a compulsory order of reaction of the two substrates with the enzyme, inhibition at high concentrations of the second substrate might be accounted for by combination of the latter with the enzyme and/or with the active ternary complex to form inactive compounds. It will be seen that the effects of such substrate inhibition on Lineweaver-Burk plots with respect to the first substrate are to a large extent analogous to the effects of inhibition in single-substrate reactions, and competitive, uncompetitive and non-competitive types may be distinguished. At present there does not appear to be sufficiently detailed data available to test these mechanisms, but the treatment may serve as a guide in the planning of further experiments.

Competitive substrate inhibition. The second substrate forms an inactive binary complex with the enzyme:

$$\mathrm{E} + \mathrm{S}_2 \rightleftharpoons \mathrm{ES}_2 \quad (K_I)$$

$$\mathrm{E} + \mathrm{S}_1 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES}_1$$

$$\mathrm{ES}_1 + \mathrm{S}_2 \underset{k_3'}{\overset{k_3}{\rightleftharpoons}} \mathrm{ES}_1' + \mathrm{S}_2'$$

$$\mathrm{ES}_1' \underset{k_1'}{\overset{k'_2}{\rightleftharpoons}} \mathrm{E} + \mathrm{S}_1'$$

$$\mathrm{ES}_2' \rightleftharpoons \mathrm{E} + \mathrm{S}_2'$$

The last step will not influence the initial rate of the forward reaction, nor the first step that of the reverse reaction.

Steady state treatment gives for the forward reaction:

$$\frac{e}{v_0} = \frac{1}{k_2'} + \left(1 + \frac{[S_2]}{K_I}\right)\frac{1}{k_1[S_1]} + \frac{1}{k_3[S_2]} + \left(1 + \frac{[S_2]}{K_I}\right)\frac{k_2}{k_1k_3[S_1][S_2]} \quad (7)$$

$$= \Phi_0 + \left(1 + \frac{[S_2]}{K_I}\right)\frac{\Phi_1}{[S_1]} + \frac{\Phi_2}{[S_2]} + \left(1 + \frac{[S_2]}{K_I}\right)\frac{\Phi_{12}}{[S_1][S_2]} \quad (8)$$

$$= \left(\Phi_0 + \frac{\Phi_2}{[S_2]}\right) + \left(1 + \frac{[S_2]}{K_I}\right)\left(\Phi_1 + \frac{\Phi_{12}}{[S_2]}\right)\frac{1}{[S_1]} \quad (8a)$$

Intercept Slope

The Φ coefficients have the same significance in terms of rate constants as in the simple Theorell-Chance mechanism (Table 1, II (iii)), and K_I is the dissociation constant of the inactive complex. If one or two ternary complexes are postulated, eqn. (8) is also valid, and the Φ coefficients are identical with those for mechanisms II(i) and II(ii), respectively. If the inhibition factor is replaced by $\left(1 + \frac{[I]}{K_I}\right)$, eqn. (8) is quite general [13] for an inhibitor which competes with S_1 and includes the case when product S_1' (but not S_2') is present at the start [22].

With low concentrations of S_2 such that (i) $[S_2]/K_I \ll 1$, eqn. (8) reduces to eqn. (2), and initial rate data will conform to the requirements of the corresponding Type II mechanism. Plots of e/v_0 against $1/[S_2]$ will be linear only when (i) holds, and at some higher value of $[S_2]$ which will depend upon $[S_1]$, e/v_0 will pass through a minimum. Plots of e/v_0 against $1/[S_1]$ will be linear for all values of $[S_2]$ (eqn. 8a), and as in Lineweaver-Burk plots for a single-substrate reaction with competitive inhibition, the slope is increased by the inhibition factor but the intercept is unaffected. Φ_0 and Φ_2 can therefore be determined by a secondary plot of the intercepts against $1/[S_2]$. The slope is not a linear function of $1/[S_2]$ except when (i) holds, and will have a minimum value when (ii) $[S_2]^2 = \Phi_{12}K_I/\Phi_1$, as shown by differentiation. Theoretically Φ_1 and Φ_{12} can be obtained in the usual way by a secondary plot of the slope against $1/[S_2]$ for low values of $[S_2]$ such that (i) holds, and K_I can then be calculated from the value of $[S_2]$ at which the slope is minimum by (ii). However, the upper limit imposed on $[S_2]$ by (i) will make it difficult to get accurate values of Φ_1 in this way unless $\Phi_1 > \Phi_{12}/K_I$ (*i.e.* $K_I > k_2/k_3$), since otherwise Φ_1 will be negligible compared with $\Phi_{12}/[S_2]$ over the whole linear range. If the expression for the slope of equation (8a) is rearranged thus,

$$\text{Slope} = \Phi_1 + \frac{\Phi_{12}}{K_I} + \frac{\Phi_1[S_2]}{K_I} + \frac{\Phi_{12}}{[S_2]}$$

it is seen that a plot of the reciprocal of the slope against $-\log [S_2]$ over a wide range of the latter should give a bell-shaped curve, from which Φ_1, Φ_{12} and K_I could be determined by the method employed by Alberty and Massey [23]

to calculate the acid dissociation constants of an enzyme-substrate complex and the pH-independent maximum velocity [24].

When the inhibitor is not a substrate, the determination of the kinetic coefficients and the inhibition constant is obvious. The case in which S_1' is present at the start, when $K_I = k_2'/k_1'$, is discussed by Alberty [22].

Uncompetitive substrate inhibition. In single-substrate reactions, the effect of an inhibitor which combines with the enzyme-substrate complex but not with the free enzyme is to increase the intercept of the Lineweaver-Burk plot without affecting the slope, and this type of inhibition has been termed uncompetitive [25]. Haldane [4] discussed substrate inhibition of this kind, in which a second molecule of the substrate combines with the enzyme-substrate complex to form an inactive compound. An analogous situation in two-substrate systems would be the combination of a second molecule of one substrate with the ternary complex in mechanism II(ii) to give an inactive compound:

$$E + S_1 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES_1$$

$$ES_1 + S_2 \underset{k_4}{\overset{k_3}{\rightleftharpoons}} EXY$$

$$EXY + S_2 \rightleftharpoons EXYS_2 \quad (K_I')$$

$$EXY \underset{k_3'}{\overset{k_4'}{\rightleftharpoons}} ES_1' + S_2'$$

$$ES_1' \underset{k_1'}{\overset{k_2'}{\rightleftharpoons}} E + S_1'$$

Steady state treatment of this mechanism gives, for the forward reaction

$$\frac{e}{v_0} = \frac{1}{k_2'} + \left(1 + \frac{[S_2]}{K_I'}\right)\frac{1}{k_4'} + \frac{1}{k_1[S_1]} + \frac{k_4+k_4'}{k_3k_4'[S_2]} + \frac{k_2(k_4+k_4')}{k_1k_3k_4'[S_1][S_2]} \quad (9)$$

$$= \Phi_0 + \frac{[S_2]}{K_I'k_4'} + \frac{\Phi_1}{[S_1]} + \frac{\Phi_2}{[S_2]} + \frac{\Phi_{12}}{[S_1][S_2]} \quad (10)$$

$$= \left(\Phi_0 + \frac{[S_2]}{K_I'k_4'} + \frac{\Phi_2}{[S_2]}\right) + \left(\Phi_1 + \frac{\Phi_{12}}{[S_2]}\right)\frac{1}{[S_1]} \quad (11)$$

The Φ coefficients are identical with those for mechanism II (ii,a), (Table 1) and K_I' is the dissociation constant of the inactive complex. With low concentrations of S_2, such that $[S_2]/K_I'k_4' \ll \Phi_0$, the initial rate data will conform to the requirements of mechanism II(ii). With higher concentrations of S_2, plots of e/v_0 against $1/[S_2]$ will pass through a minimum. As for competitive substrate inhibition, plots of e/v_0 against $1/[S_1]$ will be linear for all values of $[S_2]$. In contrast to the preceding case, however, the slope is not affected by the inhibition term, and will yield values of Φ_1 and Φ_{12} by a secondary plot against $1/[S_2]$, whilst the intercept is no longer linear in $1/[S_2]$. A secondary

plot of the intercept against $1/[S_2]$ for low values of $[S_2]$, such that $[S_2]/K_I'k_4' \ll \Phi_0$, would give Φ_0 as intercept and Φ_2 as slope and at higher values of $[S_2]$ there will be a minimum value of the intercept when $[S_2]^2 = \Phi_2 K_I'k_4'$, from which $K_I'k_4'$ could be calculated. Alternatively, a plot of the reciprocal of the intercept against $-\log[S_2]$ should give a bell-shaped curve from which Φ_0, Φ_2 and $K_I'k_4'$ could be determined [4,23]. Since k_4' can be calculated from the coefficients for the forward and reverse reactions taken together ($\Phi_0 = (k_2' + k_4'/k_2'k_4'$; $k_2' = \Phi_{12}'/\Phi_1'\Phi_2'$), K_I' can be evaluated.

In contrast to the analogous single-substrate case, the whole maximum rate term in eqn. (11) is not multiplied by an inhibition factor. Only one of the two terms comprising Φ_0 is affected (eqn. 9), namely $1/k_4'$. If $k_4' \gg k_2'$, *i.e.* if the data at low S_2 concentrations conform to the special case II(ii, b), k_4' and K_I' cannot be separately evaluated, and also substrate inhibition will be deferred to much higher values of $[S_2]$.

Non-competitive substrate inhibition. If the second substrate can combine with both the free enzyme and the ternary complex to give inactive compounds, it is obvious from the preceding discussion that the initial rate equation will be

$$\frac{e}{v_0} = \left(\Phi_0 + \frac{[S_2]}{k_4'K_I'} + \frac{\Phi_2}{[S_2]}\right) + \left(1 + \frac{[S_2]}{K_I}\right)\left(\Phi_1 + \frac{\Phi_{12}}{[S_2]}\right)\frac{1}{[S_1]} \quad (12)$$

Again the plot of e/v_0 against $1/[S_1]$ should be linear for all values of $[S_2]$ but neither the slope nor the intercept will be linear in $1/[S_2]$. The kinetic coefficients and the inhibition constants may be determined as in the two previous cases.

The term non-competitive inhibition has usually been applied to single-substrate reactions in which the dissociation constants of the inactive compounds of the inhibitor with the free enzyme and the enzyme-substrate complex are equal, in which case the slope and the intercept of Lineweaver-Burk plots are multiplied by the same inhibition factor. It would seem to be logical to extend the use of the term to the more general case in which the dissociation constants are unequal, and the slope and intercept are affected to different extents. This is true of eqn. (12) even when $K_I = K_I'$.

SUBSTRATE ACTIVATION

Steady state treatment of Type I mechanisms in which there are alternative pathways for the overall reaction yields complex initial rate equations [26] which would be difficult to deal with experimentally. Such mechanisms yield the linear reciprocal rate eqn. (2) only if it is assumed that all steps except one are in equilibrium. It is evident, however, that if the enzyme has a much greater affinity for one substrate than for the other, the reaction may be effectively confined to one pathway over a certain range of substrate concentrations, and initial rate data would conform to the requirements of a Type II mechanism. It is of interest to consider under what conditions the initial rate equation obtained by steady state treatment of a mechanism of Type I will reduce to eqn. (2) over a reasonably wide range of substrate con-

centrations, and what kind of deviations might be observed outside this range. A simple case is an extension of the Theorell-Chance mechanism in one direction:

$$E + S_1 \underset{k_1}{\overset{k_2}{\rightleftharpoons}} ES_1$$

$$E + S_2 \underset{l_2}{\overset{l_1}{\rightleftharpoons}} ES_2$$

$$ES_1 + S_2 \underset{k_3'}{\overset{k_3}{\rightleftharpoons}} ES_1' + S_2'$$

$$ES_2 + S_1 \underset{l_3'}{\overset{l_3}{\rightleftharpoons}} ES_1' + S_2'$$

$$ES_1' \underset{k_1'}{\overset{k_2'}{\rightleftharpoons}} E + S_1'$$

The same rate constants as before are used for the preferred pathway, and l_1 *etc.* are the rate constants for the alternative pathway which will be assumed to be important only when $[S_2]/[S_1]$ is large. There is a compulsory relation between the equilibrium constants for the alternative reactions (i) $l_1l_3/l_2l_3' = k_1k_3/k_2k_3'$.

(a) For the forward reaction, steady state treatment gives:

$$\frac{e}{v_0} = \frac{1}{k_2'} + \frac{k_1[S_1](l_3[S_1]+l_2)+(l_3[S_1]+l_2)(k_3[S_2]+k_2)+l_1[S_2](k_3[S_2]+k_2)}{[S_1][S_2]\{k_1k_3(l_3[S_1]+l_2)+l_1l_3(k_3[S_2]+k_2)\}} \quad (13)$$

If $l_1 = 0$, this mechanism reduces to the Theorell-Chance mechanism, and if $l_1 \neq 0$ but $l_3 = 0$ it reduces to the competitive substrate inhibition type. Accordingly, substitution of $l_1 = 0$ and $l_3 = 0$, respectively, in (9) gives eqns. (1a) and (7). If (ii) $k_1k_3l_2 \gg l_1l_3k_2$, eqn. (13) approximates to

$$\frac{e}{v_0} = \frac{1}{k_2'} + \left(\frac{A}{A+l_3l_1[S_2]/k_1}\right)\frac{\Phi_2}{[S_2]} + \left(\frac{A+l_1[S_2]}{A+l_3l_1[S_2]/k_1}\right)\left(\frac{\Phi_1}{[S_1]} + \frac{\Phi_{12}}{[S_1][S_2]}\right) \quad (14)$$

where the Φ coefficients have the same significance as in the Theorell-Chance mechanism, and $A = l_3[S_1] + l_2$. If the first factors of the second and third terms of eqn. (14) are equal to unity, this equation reduces to the Theorell-Chance equation. This will be true if $l_1[S_2] \ll A$ and $l_1[S_2] \ll k_1A/l_3$. Conditions favouring these requirements are high values of k_1/l_1, l_2/l_1 and l_3/l_1, which are compatible with (ii). Thus, this mechanism may conform to the requirements of the Theorell-Chance mechanism over a wide range of substrate concentrations, even when k_3 and l_3 are of the same order of magnitude, if the complex ES_2 has a large dissociation constant and is formed much more slowly than ES_1. With sufficiently high values of $[S_2]/[S_1]$, Lineweaver-Burk plots against both $1/[S_1]$ and $1/[S_2]$ will be non-linear. Consider the

plot of e/v_0 against $1/[S_2]$ with a fixed concentration of S_1. The second term of eqn. (14) does not contain $[S_2]$ in the numerator, and with high concentrations of S_2 will produce deviations in the linear reciprocal plot towards higher activity. This will be true also of the third term if $l_3 > k_1$, and with this condition, therefore, substrate activation should be observed at high concentrations of S_2, regardless of the value of the fixed concentration of S_1. If $l_3 < k_1$, the third term of eqn. (14) will produce deviations towards lower activity, and the effects of the second and third terms will be opposed. Whether activation or inhibition occurs at high values of S_2 will depend upon the relative values of these two terms. High values of the fixed concentration of S_1 will make the third term smaller compared to the second, and therefore favour substrate activation. This situation provides a possible explanation of substrate activation by alcohol in the yeast dehydrogenase reaction, which occurs only with high concentrations of the coenzyme [6].

(b) For the reverse reaction, steady state treatment gives:

$$\frac{e}{v_0} = \frac{B}{k_2} + \frac{1}{k_1'[S_1']} + \frac{1}{(k_3'+l_3')[S_2']} + \frac{k_2'}{k_1'(k_3'+l_3')[S_1'][S_2']} \quad (15)$$

$$= B\Phi_0' + \frac{\Phi_1'}{[S_1']} + \frac{\Phi_2'}{[S_2']} + \frac{\Phi_{12}'}{[S_1'][S_2']} \quad (16)$$

The Φ coefficients have the same significance as in the Theorell-Chance mechanism except that, in Φ_2' and Φ_{12}', k_3' is replaced by $k_3' + l_3'$; and $B = \left(1 + \frac{l_3'k_2}{k_3'l_2}\right) \Big/ \left(1 + \frac{l_3'}{k_3'}\right)$. Corollaries of assumption (ii) in the preceding section, together with the compulsory relation (i), however, are that $l_3' \ll k_3'$ and $B \doteq 1$. Therefore under conditions for which it has been possible to show that the forward reaction will conform to the Theorell-Chance mechanism over a wide range of substrate concentrations, the reverse reaction will also conform to that mechanism.

Although mechanisms of this type, with alternative pathways, do not lend themselves readily to experimental evaluation, these considerations of a simple case emphasize the fact that, under less restrictive conditions than are assumed in the equilibrium treatment, such mechanisms may conform to the linear reciprocal initial rate eqn. (2), and provide a possible explanation of complex types of deviation at extremes of substrate concentration.

Acknowledgement. I wish to thank Professor Hugo Theorell for stimulating discussions and encouragement during this work.

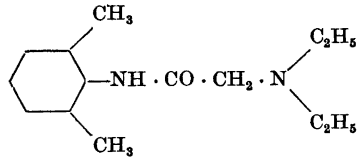
ACTA CHEMICA SCANDINAVICA 11 (1957) 1724—1737



Studies on Local Anesthetics XVI*

NILS LÖFGREN, CLAËS TEGNÉR and BERTIL TAKMAN

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden

Twentyfour new compounds, closely related to xylocaine **, have been synthesized and studied pharmacologically, especially for their surface anesthetic action on the rabbit cornea. Some conclusions have been drawn as to the relation between corneal anesthetic activity and chemical constitution.

As an extension of previous works on local anesthetics by Löfgren *et al.* twentyfour new analogues of xylocaine

Xylocaine

have been synthesized and tested pharmacologically. The compounds are of the general type

$$\text{Ar-NH} \cdot \text{CO} \cdot \underset{\displaystyle \text{R}}{\text{CH}}\text{-Am}$$

in which Ar is phenyl, 2-methylphenyl, 2,6-dimethylphenyl, or 2,4,6-trimethylphenyl, R hydrogen or methyl, and Am alkylamino, dialkylamino, *cyclo*-hexylamino, pyrrolidino, piperidino, or 2-methylpiperidino. The combinations

* For paper XV of this series see Lindström [1].
** Registered trade mark.

of the groups Ar, R, and Am are evident from Table 1 where the compounds (I—XXIV) are listed.

To synthesize these compounds, the arylamines ($Ar \cdot NH_2$) were first converted to the corresponding halogenoacylated compounds by reaction with a halogenoacyl halide (chloroacetyl chloride or α-bromopropionyl bromide) in an aqueous acetate buffer, the general directions of Löfgren [2] being followed. Thus the following N-(halogenoacyl) arylamines were prepared as intermediates for the synthesis of compounds I—XXIV, *viz.* for I: α-chloroacetanilide; II: α-chloro-2-methylacetanilide; III—V: α-chloro-2,6-dimethylacetanilide; VI—XI: α-bromo-2,6-dimethylpropionanilide; XII—XIX: α-chloro-2,4,6-trimethylacetanilide; XX—XXIV: α-bromo-2,4,6-trimethylpropionanilide. The halogeno derivatives produced were then heated with an excess of the necessary primary or secondary amine to give the products desired. In the reactions where primary amines were involved, a high excess of amine (5 moles of amine per mole of halogeno compound) was used to avoid the formation of compounds of the alkylimino-bis(N-acyl-arylamine) type:

$$\text{Alkyl-N}\begin{matrix}\diagup\ \text{acyl} \cdot \text{NH} \cdot \text{Ar} \\ \diagdown\ \text{acyl} \cdot \text{NH} \cdot \text{Ar}\end{matrix}$$

The compounds were tested for their local anesthetic action on the rabbit cornea and compared with xylocaine, the technique of Wiedling [3] being followed (*cf.* also Löfgren and Tegnér [4]). Xylocaine and all the other compounds were used as solutions of their hydrochlorides containing 0.85 % sodium chloride.

As a measure of the potency *relative activity* (RA) was used, *i.e.* the activity which is found by dividing the molarity of a standard xylocaine solution by the molar concentration of the actual compound at which the duration of anesthesia is the same as that of the xylocaine standard. The molarity of the latter was 0.0738 (= 2 % xylocaine · HCl solution). Before measuring the duration of anesthesia for the solution of the actual compound and that for xylocaine, both solutions were adjusted to the same pH, usually 6.0 *.

In the toxicity investigations the LD_{50} values were obtained from subcutaneous injections in white mice and calculated (a) as grams of the base per

* For a few compounds, test solutions of lower pH — but in no case lower than 5.3 — had to be prepared since the solubilities were too low at pH 6.0. These solutions were then compared with the 0.0738 M xylocaine solution adjusted to the same lower pH value. There is no reason to believe that the RA values originating from measurements of such solutions differ significantly from those which would have been obtained from a comparison of solutions of pH 6.0. Thus, for several of our compounds of which test solutions can be prepared at pH 6.0, solutions were made at various pH values between 5 and 6 and RA values were obtained by comparison with a 0.0738 M xylocaine solution of the same pH. No significant difference in the RA values could be found; *cf.* also Löfgren and Tegnér [4].

a) Uncorrected value.
b) Purified *via* the hydrochloride, see Table 2.
c) Titration of the base in 30 % ethanol with 0.1 N HCl; mixed indicator methylene blue — methyl red.

kilogram of body weight and (b) as moles per kilogram of body weight ("molar" LD_{50} value).

The ratio of the *molar* LD_{50} value for xylocaine to the corresponding value for one of the other compounds is called here the *relative toxicity* (RT) of the compound. For the quotient RA/RT we use the term *anesthetic index* (Q).

To determine the RA value of a compound, 10—30 animals were used. In general, the maximum error in the RA values is about 20 %. The error in the RT values is much less. The results of the pharmacological measurements are collected in Table 3. The material allows a study of the relationship between the chemical constitution and the pharmacological properties. Thus we

are able to analyse the influence on RA, RT and Q of certain variations in the groups R_1, R_2 and R_3 in the structure shown in Table 4. The change in RA, RT and Q is indicated by factors f_A, f_T and f_Q, respectively. In this connection, it should be emphasized that, in the following, an increase or a decrease in RA, RT or Q always means a proportional, and not an absolute, increase or decrease. The results may be summarized as follows:

1. A straight lengthening of a *normal* alkyl group R_1 by a single carbon atom (*cf.* Table 4: A) increases the activity RA ($1.2<f_A<2.5$) as well as the toxicity RT ($1.7<f_T<4.6$) — the increase of the latter being, however, greater so that the anesthetic index Q changes unfavourably ($0.5<f_Q<0.9$). The

next higher homologous *iso*alkyl group (*cf.* Table 4: B), sometimes increases and sometimes decreases the activity ($0.8<f_A<1.3$) — the change in no case being great — whereas the toxicity increases in all five cases ($1.1<f_T<3.25$), the increase being considerable in three of them ($1.7<f_T<3.25$). In these three cases the anesthetic index is altered very unfavourably ($0.3<f_Q<0.5$). In the other two, *i.e.* by replacing (a) the ethyl group in XX ($R_1 = C_2H_5$, $R_2 = R_3 = CH_3$) by an *i*-propyl group and (b) the *n*-propyl group in XXI ($R_1 = n\text{-}C_3H_7$, $R_2 = R_3 = CH_3$) by an *i*-butyl group, the anesthetic index remains approximately constant ($f_Q = 0.8$ and 1.0).

3. During the discussions in *1* and *2* we have at the same time obtained an idea of what would happen on replacing a *normal* alkyl group R_1 by an isomeric *iso*alkyl group. Direct information on this point is obtained by comparing the isomers available (comparison not tabulated), *i.e.* VII with VIII, IX with X, XII with XIII, XXI with XXII, and XXIII with XXIV. These comparisons show that the replacement of a *normal* alkyl group R_1 by an isomeric *iso*alkyl group in all five cases definitely decreases the activity ($0.5<f_A<0.7$). The toxicity increases slightly in three cases (VII→VIII, IX→X, XII→XIII; $1.05<f_T<1.2$), while in the other two, *i.e.* by replacing (a) the *n*-propyl group

in XXI ($R_1 = n$-C_3H_7, $R_2 = R_3 = CH_3$) by an i-propyl group and (b) the n-butyl group in XXIII ($R_1 = n$-C_4H_9, $R_2 = R_3 = CH_3$) by an i-butyl group, the toxicity is decreased more ($f_T = 0.5$ and 0.3) than the activity ($f_A = 0.7$ and 0.5), *i.e.* the anesthetic index is altered unfavourably in three cases ($0.4 < f_Q < 0.5$) and favourably in two ($f_Q = 1.3$ and 1.9).

4. By introducing a methyl group at the α-position of the amide-chain (*cf.* Table 4: C) the activity increases in all four available cases ($1.4 < f_A < 2.8$). In the first two of these (see Table), the toxicity increases more than the activity and, therefore, the anesthetic index is altered unfavourably ($f_Q = 0.6$ and 0.5). Introduction of the methyl group into XIII ($R_1 = i$-C_3H_7, $R_2 = H$, $R_3 = CH_3$), *i.e.* the third case, does not alter the toxicity and, since the increase in activity is considerable, the anesthetic index is changed favourably ($f_Q = 1.8$). In the fourth case, *i.e.* introduction of the methyl group in XV ($R_1 = i$-C_4H_9, $R_2 = H$, $R_3 = CH_3$), the toxicity increases ($f_T = 1.8$) approximately in the same ratio as the activity ($f_A = 2.1$) so that the anesthetic index remains practically unchanged ($f_Q = 1.1$). It should be emphasized that, due to the limited material at present available, the above examination includes only the introduction of a methyl at the α-position in such molecules that have their nuclear position *para* to the amide nitrogen occupied by a methyl group ($R_3 = CH_3$).

5. The introduction of a methyl group *para* to the amide nitrogen * (*cf.* Table 4: D) is in all six cases accompanied by an increased activity ($1.5 < f_A < 2.1$). The toxicity may increase, decrease or remain practically unchanged ($0.5 < f_T < 1.7$) and, since the increase is in no case greater than the corresponding increase in activity, the anesthetic index is in all cases improved ($1.2 < f_Q < 4.1$). In two cases, *i.e.* introduction of the methyl group in VIII ($R_1 = i$-C_3H_7, $R_2 = CH_3$, $R_3 = H$) and X ($R_1 = i$-C_4H_9, $R_2 = CH_3$, $R_3 = H$), the activity is increased to about double its value whereas the toxicity is decreased to about half its value so that the anesthetic index is increased greatly, *viz.* approximately four times.

* In the following this position is called the *p* position.

6. The discussions in *4* and *5* suggest that a transfer of a methyl group from the α position to the p position would lead to an improved anesthetic index. Direct information on this point can be obtained by comparing the isomers available (comparison not tabulated), *i.e.* VII with XII, VIII with XIII, IX with XIV, and X with XV. An examination shows that the said transfer in three of the four cases (VII→XII, VIII→XIII, X→XV) causes no appreciable change in the activity ($0.9<f_A<1.1$) and in one case (IX→XIV) decreases it slightly ($f_A = 0.7$). The toxicity decreases in all cases considerably ($0.3<f_T<0.5$). Accordingly, the anesthetic index changes favourably in all cases and calculation shows that the improvement throughout is considerable ($1.9<f_Q<3.7$).

In addition to what has been said under *1—6*, it should be emphasized that a certain structural change in one of the groups R_1, R_2 and R_3 is followed by an alteration in activity and/or toxicity which, as expected, is sometimes greatly dependent on the nature of the two other groups remaining unchanged. Thus, for instance, if in VII (R_1 = *n*-C_3H_7, R_2 = CH_3, R_3 = H), XII (R_1 = *n*-C_3H_7, R_2 = H, R_3 = CH_3) and XXI (R_1 = *n*-C_3H_7, $R_2 = R_3$ = CH_3) the *n*-propyl group is replaced by a *n*-butyl group (*cf.* Table 4:A) an increase in activity as well as toxicity will occur which in the last case is much greater than in the other two cases. In other words, if the α and p positions are *both* occupied by methyl groups and if a *n*-propyl group at the amino-end of the molecule is replaced by a *n*-butyl group, then this change is accompanied by an accentuated increase in activity and toxicity. Other examples: If the structure is changed in such a way that the resulting molecule is furnished with an *iso*alkyl group R_1 at the amino-end and with a methyl group in the α position as well as in the p position, *i.e.* a change which involves (a) the transformation of a *normal* alkyl group R_1 into the next higher homologous *iso*alkyl group (α and p positions with $R_2 = R_3 = CH_3$ kept unchanged; *cf.* Table 4:B) or (b) isomerization of R_1 from a *normal* alkyl group into an *iso*alkyl group (α and p positions with $R_2 = R_3 = CH_3$ kept unchanged; available examples: XXI → XXII and XXIII → XXIV; *cf.* also section *3*, p. 1729) or (c) introduction of a methyl group at the α position (p position occupied by a methyl group, R_1 being an *iso*alkyl group; *cf.* Table 4:C) or (d) introduction of a methyl group at the p position (α position occupied by a methyl group, R_1 being an *iso*alkyl group; *cf.* Table 4:D), then it is seen from the eight cases available that such a change is never accompanied by a marked decrease in anesthetic index. Thus, there is only one case of transformation (XX→XXII) which is associated with a slight decrease in the index ($f_Q = 0.8$) whereas, in the other seven cases, the index remains unchanged or is increased. In four of the cases (XIII→XXII, XXIII→XXIV, VIII→XXII, X→XXIV) the increase is very pronounced ($1.8<f_Q<4.1$).

The following comparison which does not fall within the above types of examination can also be made:

7. Replacement of the ethylamino group in VI (α-ethylamino-2,6-dimethylpropionanilide) by the isomeric dimethylamino group, *i.e.* the transformation of VI into XI, results in a considerable decrease in activity ($f_A \sim 0.3$) and a moderate decrease in toxicity ($f_T = 0.8$).

8. By cyclization of the diethylamino group in xylocaine to the pyrrolidino group, *i.e.* by transformation of xylocaine into IV, the activity is strongly decreased ($f_A \sim 0.2$). The toxicity is also decreased, though less ($f_T = 0.6$).

It should be realised that what has been said under *1—8* concerning the chemical structure and the pharmacological properties must be regarded as limited to the material treated here and great care chould be taken when trying to extend the results to other structures — even those which are closely related to the ones considered here.

Judged by the results hitherto obtained, fourteen of the compounds were considered worthy of a further study in subcutaneous anesthesia on man. These tests were undertaken merely from a clinical point of view and were thus restricted to the usual clinical technique, *i.e.* solutions of the same percentage concentration were made and, after injection of equal volumes, the duration was measured. The comparison with xylocaine was made in the presence as well as in the absence of epinephrine.

Solutions containing 0.5 % of the hydrochloride and a physiological NaCl content (0.85 %) * were prepared. From these solutions another series was made up by adding epinephrine to a strength of 1 : 100 000. The pH of the solutions was in both series adjusted to 4.0 **. Together with xylocaine, 3 or 4 compounds were compared at the same time on each individual in a group of twelve persons. The individuals in this group varied from time to time. The amount injected was always 0.5 ml and the injections were made on the volar side of the forearm, each compound being applied to the right as well as to the left arm. Thus, for each of the 3 or 4 compounds, two average values (presence or absence of epinephrine) were obtained, which were comparable with the corresponding values for xylocaine.

The following compounds were tested: III, VI, VII, XII—XVII, XIX—XXII and XXIV. With the exception of VI and XIII, each of these fourteen compounds has a RA value which is significantly larger than the corresponding value for xylocaine, most of the compounds having very high activities compared with xylocaine (*cf.* Table 3). Compounds VI and XIII have values (1.1 and 0.9, respectively) which are approximately equal to that of xylocaine (= 1.0). All fourteen compounds have Q values which are greater than the corresponding value for xylocaine.

Because of the RA values of these fourteen compounds, one could expect that all of them, with the exception of XIII and possibly VI, would, when injected under the above conditions, give greater durations than that of xylo-

---

* When preparing the solution of XVII glucose (5.5 %) was added instead of NaCl. The hydrochloride of this compound is so slightly soluble in water that the presence of NaCl lowered its solubility to such a degree that a 0.5 % solution could not be prepared.

** When a local anesthetic is used for infiltration anesthesia, the pH of its solution may be varied within wide limits without affecting the duration. This has been demonstrated by various investigators (*cf.* Adriani [5], Tainter, Throndson and Moose [6], Björn and Huldt [7], Huldt [8]). Investigations just on 0.5 % xylocaine · HCl solutions have been made by Löfgren and Lundqvist [9]. In a fairly large number of subcutaneous wheal experiments, the durations of 0.5 % xylocaine· HCl solutions (NaCl concn. = 0.85 %, epinephrine concn. = 1 : 100 000), adjusted to different pH values between 4 and 7, were measured and no significant differences between the values could be found.

caine *. The results from the measurements do not, however, support such a conclusion.

In the test series where no epinephrine had been added, only three of the fourteen compounds gave durations which were greater than that of xylocaine, the order of magnitude being as follows: XXI>XIII ≅ XXII>xylocaine ≅ III, VI, VII, XV, XVI and XXIV>XII ≅ XVII and XX>XIV>XIX. The most active compound in this series, *i.e.* XXI, has a duration approximately 60 % larger than that of xylocaine whereas the compound with the lowest action, *i.e.* XIX, has a duration about 70 % smaller. It is particularly notable that compound XIII, which one might expect to have the lowest duration, is one of those three which have durations higher than that of xylocaine and that XVII, which has the highest relative activity on the cornea, *viz.* no less than 14 (= the RA value 16 multiplied by a conversion factor (0.87); *cf.* above), is inferior to xylocaine.

In the test series where epinephrine was added, none of the fourteen compounds showed a duration significantly greater than that of xylocaine. The order of magnitude was: Xylocaine ≅ VII, XIII, XV, XX and XXI>III ≅ XXII and XXIV>VI ≅ XIV and XVII>XII ≅ XVI and XIX. The least active compounds in this series, *i.e.* XII, XVI and XIX, all show durations about 45 % less than that for xylocaine. It should be emphasized that, also in this series, XIII belongs to the most active of the compounds — here it has approximately the same duration as xylocaine — and that XVII belongs to those which are inferior to xylocaine.

There is therefore a great discrepancy between the durations which were found by the topical application to the rabbit cornea and those which were found by subcutaneous injection in man. This kind of discrepancy has been noticed previously [4,10].

In a special series of subcutaneous injections in man, the fourteen compounds were investigated as to their irritant action **. Here, the above-described solutions containing epinephrine were used. On each of 12 persons, 2 or 3 of the compounds together with xylocaine were tested at the same time by subcutaneous injection of 2 ml of their solutions on the *dorsum*. The reaction of the skin was observed after 16 h. To judge from these screening tests, VII, XVI, XVII, XX, XXII and XXIV did not seem to differ very much from xylocaine, *i.e.* they were considered harmless to the tissues, whereas the other compounds gave evidence of more or less irritating properties. However, XX was later tried topically as an anesthetic in bronchoscopy and it was then found that this compound can produce severe tissue reactions.

* Consideration has here been given to the facts that (a) the RA values — valid for surface anesthetic potency — refer to a quotient of *molarities* with equal durations (= the duration of a 0.0738 M xylocaine solution) and (b) in the subcutaneous anesthesia, the evaluated durations refer to the same amount by weight of the *hydrochlorides* (= 0.5 ml of 0.5 % hydrochloride solutions). To make the RA values valid for a mutual comparison on the gram scale of the hydrochlorides, we thus have to multiply each RA value by a factor equal to the quotient of the molecular weight of xylocaine hydrochloride and the molecular weight of the hydrochloride of the compound.

** In the subcutaneous tests which were performed for the evaluation of anesthesia durations (*cf.* above), the injected amount was so small that only very limited information about the irritant action was obtained.

From what has been discovered about these fourteen compounds selected for studies in infiltration anesthesia, it can be stated that two of them, *viz.* VII and XXII, should be regarded as possible competitors to xylocaine. For this reason, a summary of the observed characteristic features of VII and XXII together with some additional experiments made in order to obtain a clearer picture of their possible clinical value in infiltration anesthesia is given:

By LD_{50} measurements on white mice (*cf.* Table 3) it was found that VII is about 25 % more toxic and XXII approximately 30 % less toxic than xylocaine *. The subcutaneous tests in man showed that xylocaine, VII and XXII do not differ greatly as to their durations. This was found to be the case in the presence as well as in the absence of epinephrine. Concerning irritant properties the screening tests described above were negative and the present authors could not find any irritant action when these two compounds and xylocaine were later compared in block anesthesia of the fingers. In these experiments all three compounds were used in form of their 1 % hydrochloride solutions containing epinephrine (1 : 100 000) and the physiological amount of sodium chloride. From a considerable number of such block anesthesias, it was found that, in comparison with xylocaine, both compounds were somewhat inferior in duration, the value for both being approximately 20 % lower than that of xylocaine. The latency time of VII was about 100 % greater than that of xylocaine whereas XXII gave approximately the same rapid onset as xylocaine.

Since VII has a higher toxicity and a much greater latency time than xylocaine, the compound was not considered to merit clinical trials in infiltration anesthesia. Compound XXII, in view of its properties, was submitted to clinical tests in dental anesthesia (therminal anesthesia, mandibular block)**. These experiments were made in the presence of epinephrine (1 : 80 000). As compared with xylocaine, XXII gave a somewhat shorter duration and the incidence of anesthesia was somewhat lower.

EXPERIMENTAL

Preparation of N-(halogenoacyl)arylamines. Of these derivatives prepared as intermediates in the synthesis of compounds I—XXIV, α-chloro-2-methylacetanilide, α-chloro-2,6-dimethylacetanilide and α-chloro-2,4,6-trimethylacetanilide were made as described previously by Löfgren [2] and α-bromo-2,6-dimethylpropionanilide as described by Löfgren and Lundquist [11], *i.e.* all these compounds were prepared by coupling a halogenoacyl halide (chloroacetyl chloride or α-bromopropionyl bromide) with an arylamine in an aqueous sodium acetate buffer according to the general method described by Löfgren [2]. The same method was used for the preparation of α-chloroacetanilide and α-bromo-2,4,6-trimethylpropionanilide (*cf.* below).

α-Chloroacetanilide. Prepared from chloroacetyl chloride and aniline in accordance with the method mentioned above. The yield of white microcrystalline powder was 86 %. On recrystallization from ligroin the compound was obtained as needles. M.p. 134 – 135° (uncorr.), in agreement with the value given by Meyer [12] who previously synthesized the compound by reacting aniline and chloroacetyl chloride in dry ether.

* In the subcutaneous experiments, the durations refer to the amount of hydrochloride used (0.5 ml of 0.5 % hydrochloride solution). Therefore, in this comparison of the toxicities of VII, XXII and xylocaine, the LD_{50} values of their *hydrochlorides* are considered. (In Table 3 the LD_{50} values are those of the bases.)

** Experiments performed by S. Ekmanner.

α-Bromo-2,4,6-trimethylpropionanilide. Prepared from α-bromopropionyl bromide and mesidine (*cf.* above). Yield of white microcrystalline powder 88 %. Needles from di-*n*-butyl ether. M.p. 188–190° (uncorr.). (Found: C 53.5; H 5.99. Calc. for $C_{12}H_{16}BrNO$ (270.2): C 53.3; H 5.97.)

Preparation of compounds I–XXIV (*cf.* Table 1). For the synthesis of I, IV, V, XI, XVIII and XIX, which are all *tertiary* bases, a mixture of 0.10 mole of the appropriate N-(halogenoacyl)arylamine (*cf.* p. 1725), 0.26 mole of the secondary amine (*cf.* Table 1) and 70 ml of dry benzene was boiled under reflux for 5 h (for I, IV, V and XIX) or heated for 5 h at a temperature of 80° in an autoclave (for XI and XVIII). When cool the mixture, including a possible water-soluble precipitate of the hydrochloride of the starting amine, was extracted in a separating funnel twice with 4 N hydrochloric acid, first with 75 ml and then with 40 ml. The combined aqueous extracts were washed with ether and then made alkaline with concentrated ammonia. The liberated base was extracted with ether and the solution thus obtained was dried over anhydrous sodium sulphate. The ether and the residual amount of starting amine were removed by distillation, first at atmospheric pressure, and then at water pump *vacuum* with a bath temperature of 100°. From the residue the desired base was purified either by recrystallization or by distillation under reduced pressure (*cf.* Table 1).

To synthesize II, III, VI–X, XII–XVII, and XX–XXIV, which are all *secondary* bases, a mixture of 0.10 mole of the appropriate N-(halogenoacyl)arylamine (*cf.* p. 1725), 0.50 mole of the primary amine (*cf.* Table 1) and 100 ml of absolute alcohol was refluxed for 5 h (for II, III, IX, XIV–XVII, XXIII, and XXIV) or heated for 5 h at a temperature of 100° in a pressure bottle or an atuoclave (for VI–VIII, X, XII, XIII, and XX–XXII). From the mixture obtained, the alcohol and the excess starting amine were distilled off, first at atmospheric pressure and then at water pump *vacuum* with a bath temperature of 100°. To the residue, 125 ml of 4 N hydrochloric acid was added. The resulting mixture was kept at 50° for half an hour under mechanical stirring and then allowed to cool. If the mixture contained a solid, *i.e.* a hydrochloride which may be contaminated with a small quantity of a halogenoacylarylamine, then it was filtered off by suction. The solid was dried and washed with benzene. The acid filtrate was purified by extracting twice with ether. The solid hydrochloride was combined with the acid filtrate. The base was liberated from this mixture with a sufficient amount of 5 N sodium hydroxide solution, mechanical stirring being applied for half an hour. The alkaline mixture was extracted sufficiently with chloroform and the solution dried over anhydrous sodium sulphate. (If no hydrochloride had appeared after the addition of hydrochloric acid (*cf.* above), the mixture was filtered. The filtrate was extracted twice with ether and from the aqueous solution the base was liberated and treated as described above.) The chloroform was distilled off and the base was isolated from the residue by either recrystallization or distillation.

The bases thus produced were analysed by determining the equivalent weight * or by usual elementary analyses or by both methods. Further analytical characterization was obtained from elementary analyses of the salts prepared (*cf.* below).

Yields, melting and boiling points, solvents for recrystallization, and analytical data are shown in Table 1.

Preparation of salts. Hydrochlorides of all the compounds, except I, IV, V, VIII, X, XV, XVIII and XXIV, were made. The methanesulphonate of II and the perchlorate of XXIV were also prepared. The salts were made by dissolving the compound in dry ether and adding the required amount of dry acid dissolved in dry ether **. The colourless microcrystalline precipitate was then recrystallized from a suitable solvent.

Melting points, solvents for recrystallization, and analytical data are shown in Table 2.

The authors are indebted to Dr S. Wiedling of the Biological Department of A.-B. Astra, Södertälje, Sweden for performing the activity tests on the rabbit cornea and the toxicity measurements on white mice and also to Dr T. Edlund of the Institute of Pharmacology, University of Uppsala, Uppsala, Sweden for carrying out the subcutaneous tests in man.

* Titration of the base in 30 % ethanol with 0.1 N HCl; mixed indicator methylene blue — methyl red.

** When perchloric acid was used, the commercial 73 % acid was dissolved in absolute ether.

Isomerisation of ω-Dimethylaminoethyl-diethyl-thionophosphate

L.-E. TAMMELIN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The structures of ω-dimethylaminoethyl-diethyl-thionophosphate and the thiolo isomer S,ω-dimethylaminoethyl-diethyl-thiolophosphate, have been studied by infrared spectra. Some spectra of related compounds are given. Isomerisation of the thiono compound has been shown by means of infrared spectrophotometry and paper chromatography to yield S,ω-dimethylaminoethyl-diethyl-thiolophosphate. The reaction rate at 100°C of the isomerisation has been studied. Two tentative reaction mechanisms are given for the isomerisation.

Organophosphorus compounds containing an ω-dimethylaminoeththio group as, *e.g.*, S,ω-dimethylaminoethyl-diethyl-thiolophosphate have been described as potent insecticides and cholinesterase inhibitors [1, 2]. Reports have been given about their synthesis [1-3] and among the methods is isomerisation at elevated temperature of ω-dialkylaminoethyl-diethyl-thionophosphate [3].

Few details, however, have been given about the rearrangement from thiono to thiolo ester and no evidence has been given for the position of the sulfur atom. Since this reaction seems interesting both in connection with the syntheses of compounds of this type and with the confirmation of their structures, it was decided to study the reaction rate semiquantitatively with spectrophotometry and to investigate the reaction products qualitatively with paper chromatography. Infrared spectrophotometry seemed to be an applicable method for the kinetic studies as well as for a confirmation of the structures in general. It was thus decided to record spectra of S,ω-dimethylaminoethyl-diethyl-thiolophosphate and related compounds.

METHODS

Synthesis of dimethylaminoethyl-diethyl-thionophosphate

One mole of diethoxy-thionophosphorylchloride and one mole of sodium dimethylaminoethanolate are mixed in benzene at room temperature. The sodium chloride formed is filtered off, and the filtrate is fractionated under reduced pressure by distillation. Yield 60 %. B.p. 90°/0.1 mm $n_D^{20} = 1.4590$.

The compound was purified as the oxalate. One mole of dimethylaminoethyl-diethyl-thionophosphate (25 % solution in methanol) and 1.05 moles of oxalic acid (10 % solution in methanol) were mixed and the methanol evaporated. Recrystallisation from acetone gives colorless crystals M.p. 132°C (Kofler Heizbank). (Found: C 36.1; H 6.6. Calc. for $C_{10}H_{22}NO_7PS$ (331.3): C 36.3; H 6.7).

The oxalate of ω-dimethylaminoethyl-diethyl-thionophosphate was titrated in 0.10 M KCl with sodium hydroxide as described for analogous compounds in an earlier paper [2]. The mixed dissociation constant, as pK'_a, was determined by the curve fitting method [4]. The calculated amount of sodium hydroxide was found to be consumed. The thermodynamic dissociation constant, was estimated as in the earlier paper [2].

Infrared spectra and photometry

Spectra of ω-dimethylaminoethyl-diethylthionophosphate, S-ω-dimethylaminoethyl-diethyl-thiolophosphate and related compounds were determined with a Perkin and Elmer Mod. 21 spectrophotometer. The spectra were obtained using the following solvents: carbon tetrachloride between 2 and 12 μ, benzene between 12 and 14 μ and carbon tetrachloride between 14 and 15 μ. The solutions were 0.3 M.

In order to study the rearrangement of ω-dimethylaminoethyl-diethyl-thionophosphate, samples were taken at different lengths of time after the preparation of the pure compound, which was stored at 100°C. These samples were studied spectrophotometrically between 6 and 9 μ. Transmittance was determined at 7.95 μ. The refractive index of each sample was determined by an Abbe refractometer. Standard curves for the correlation of concentrations to I.R. transmittance ($T_{7.95}$) and to refractive index (n_D^{20}) were determined by mixing S,ω-dimethyl-aminoethyl-diethyl-thiolophosphate [2] with ω-dimethylaminoethyl-diethyl-thionophosphate in different proportions. The spectrophotometer was used with a sodium chloride prism, resolution = 927, response = 2 : 1170, gain = 5, speed = 1 μ/min, suppression = 3 and scale 5 cm/μ. The thickness of the cell was 0.116 mm.

Paper chromatography of the thiolo and thiono ester

Solvent [5]: *n*-butanol 8, ethanol 2, acetic acid 2 and water 3 parts by volume.
Reagent [5]: 0.2 g of dipicrylamine is dissolved in 50 ml of acetone and 50 ml of water (Reacts with the amino group).
Paper: Whatman 1. Height 35 cm.

Procedure: Spots of 10 μl of about 1 % solution of the samples were dried with hot air. The paper was equilibrated with air in equilibrium with the solvent for 1 h. An ascending technique was used at 25°C for 17 h. After drying with hot air the paper was sprayed with the reagent.

Paper chromatography of hydrolysis products

An approximately 10 % solution of S,ω-dimethylaminoethyl-diethyl-thiolophosphate was hydrolyzed at 50°C overnight in 0.1 M sodium hydroxide solution. The same experiment was done with the isomerized thiono compound. The hydrolysis products together with ω-dimethylaminoethanthiol were investigated as follows.

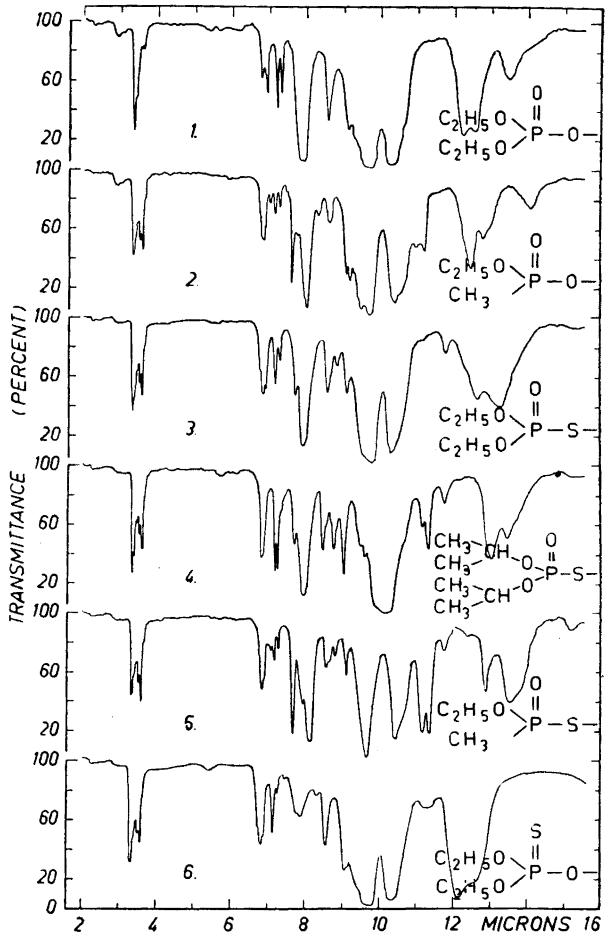

Fig. 1. Infrared spectra of ω-dimethylaminoethyl esters of organophosphorus acids.

Solvent: *n*-butanol 8, ethanol 2, acetic acid 1 and water 3 parts by volume.
Reagent: Grotes reagent [9] (SH-reagent).
Paper: Whatman 1. Height 35 cm.

Procedure: Spots of 10 μl of about 10 % solution of the three samples were dried with hot air. The paper was equilibrated with air in equilibrium with the solvent for 1 h. An ascending technique was used at 25°C for 17 h. After drying with hot air the paper was sprayed with the reagent. The papers were kept at 100°C for 5 min. Parallel tests were performed and developed by the dipicrylamine reagent [5] which colors amino groups.

Determination of the cholinesterase inhibiting effect (pI_{50})

The cholinesterase inhibiting effect of ω-dimethylaminoethyl-diethyl-thionophosphate was determined by means of an electrometric method. All conditions were identical with

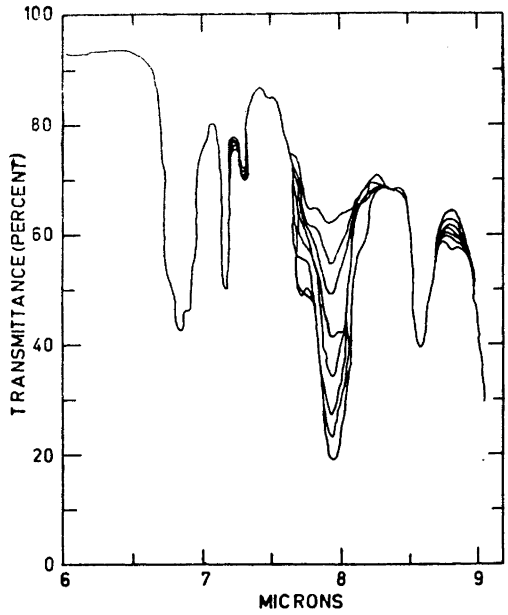

Fig. 2. Infrared spectra showing the isomerisation at 100°C of ω-dimethylaminoethyl-diethyl-thionophosphate. Samples taken at different times show increasing phosphoryl concentration by the decreased transmittance at 7.95 microns.

those in experiments with the thiolo ester [2]. Human erythrocytes and plasma were used as enzyme sources and acetylcholine as substrate. The results are expressed as the negative logarithm of the inhibitor concentration which decreases enzyme activity to 50 % (pI_{50}).

RESULTS

The infrared spectra obtained (Fig. 1) are in good agreement with those obtained from related compounds in earlier literature [6, 7]. They thus need few comments. However, at 11.76 μ the thiolo compounds show a weak absorption which seems characteristic. It has not been possible to correlate this band with some special part of the molecular structure. The phosphoryl group, as seen in Fig. 1, gives a strong absorption near 8 μ [6-8] which is not found in the thiono compounds, although a weak absorption in this region indicates contamination with thiolo isomer presumably formed during the distillation. Spectrophotometric measurements made in this region during the reaction were used for the study of the rearrangement. The result of the kinetic investigation is shown in Fig. 2 where the increasing concentration of a phosphoryl group is demonstrated and in Fig. 3 which shows the reaction rate. The specific change in the infrared spectra shown in Fig. 2 and the relatively good agreement of the results from different methods shown in E (Fig. 3) demonstrate that the reaction product is rather homogeneous. If the process is allowed to proceed for more than 5 h at 100°C, side reactions become obvious. The

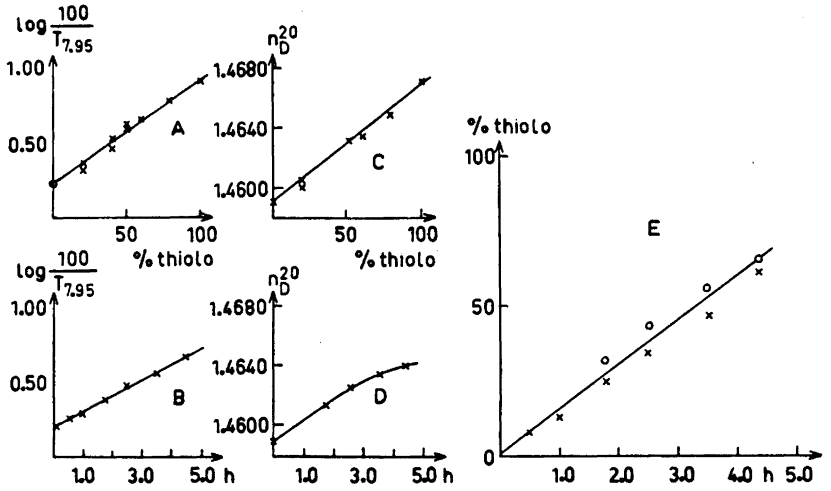

Fig. 3. The diagrams show the time dependence of the isomerisation of ω-dimethylaminoethyl-diethyl-thionophosphate to S,ω-dimethylaminoethyl-diethyl-thiolophosphate at 100°C. A and C are standard curves showing transmittance at 7.95 microns ($T_{7.95}$) and refractive index (n_D^{20}) as functions of the composition of the isomeric mixture. B and D show the primary results. E shows the velocity of the isomerisation at 100°C. The points O are from refractive index measurements and × from I.R. transmittance.

refractive index/time diagram (D, Fig. 3) bends against the time axis. A precipitate of white crystals with salt character is formed in the reaction vessel, and an unidentified absorption band at about 5.5 μ is found in the infrared spectrum. The precipitate has approximately the same percent composition as the original compound (C 34.9; H 8.3) but has not been investigated further. Tests with isomerisation at 70°C gave a slower reaction, but side reactions were not avoided.

Infrared spectra of S,ω-dimethylaminoethyl-diethyl-thiolophosphate prepared by direct synthesis and of the isomerized product show, on the whole, identical patterns, which seems to justify the conclusion that the main product of isomerisation is identical with the reference compound. However, at 8 μ and in the region between 12 and 15 μ the transmittance differs at the coinciding absorption maxima. This is probably caused by a residue of thiono component in the isomerized compound but might also be due to the other components in the reaction mixture.

The paper chromatogram obtained from a sample of dimethylaminoethyl-diethyl-thionophosphate which had been incubated at 100°C for 4 h gave only two tailless spots with $R_F = 0.76$ and $R_F = 0.87$. A mixture of oxalates of the thiono and thiolo [2] compounds which had been synthesized with direct methods gave two spots with $R_F = 0.74$ and $R_F = 0.87$. Separate experiments with thiolo compound as free amine gives $R_F = 0.75$ and thiono compound as oxalate (see syntheses) gives $R_F = 0.86$. The paper chromatography in order to study the hydrolysis products shows three identical spots ($R_F = 0.37$) corresponding to ω-dimethylaminoethanthiol, hydrolysates of S,ω-dimethyl-

aminoethyldiethyl-thiolophosphate and isomerized thionophosphate, respectively. The dimethylaminoethanthiol spot was obtained with both reagents [5,9]. Three other spots were obtained. Two of them were developed by both reagents and could be identified by their R_F values as unhydrolyzed thiono and thiolo compounds. The third spot, $R_F = 0.5$, was only developed by the sulfhydryl reagent [9] and might be caused by O,O-diethyl-thiophosphate. This result shows that ω-dimethylaminoethanthiol is among the main products of hydrolysis of the isomerized compound as well as of the S,ω-dimethylaminoethyl-diethyl-thiolophosphate. *These experiments together with the infrared spectrophotometric studies show that S,ω-dimethylaminoethyl-diethyl-thiolophosphate is the main product of isomerisation of ω-dimethylaminoethyl-diethyl-thionophosphate and exclude considerable formation of an ethyl thiolo isomer.*

The pK_a and pI_{50} values of the thio isomers and a related oxygen compound [2] are given in Table 1. The low pI_{50} value of the thiono ester compared to the thiolo ester emphasizes the specific role of a P—S—C structure in cholinesterase inhibitors.

Table 1.

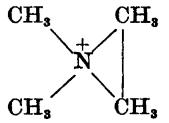
plasma	8.0	5.5	4

DISCUSSION



The mechanism of the rearrangement from thiono to thiolo isomer is not elucidated by the present experiments. However, some conclusions can be drawn from the results which may permit the postulation of a tentative reaction scheme.

The rate of the isomerisation is unexpectedly independent of the time, giving a picture (Fig. 3) which seems characteristic of a zero order reaction. During prolonged heating, an impurity with approximately the same composition as the starting compound but of salt character, which might be a quaternary ammonium compound, precipitates in considerable amounts. The isomerisation yields only one of the two possible thiolo isomers, the S,ω-dimethylaminoethyl-phosphoryl compound. These facts may be explained dy the following reaction scheme.

If steps 2 and 4 are rate determining (with saturated solutions of the salts as an added condition) the zero order reaction is explained by the scheme, which also excludes formation of other isomers than the S,ω-dimethylaminoethyl-diethyl-thiolophosphate. The quaternary ammonium compounds should be

the precipitate observed upon prolonged heating. Other types of possible quaternary ammonium ions than the one proposed above might be formed, *e.g.*

but formation of the dialkoxy-thiophosphate ion seems very probable.

Addendum: While this paper was in press a paper by Fukuto and Stafford [10] has appeared which gives strong experimental support to the idea that an immonium ion is formed during the process of isomerisation.

The Heats of Hydrolysis of Some Alkyl Thiolesters

INGEMAR WADSÖ

Thermochemistry Laboratory, University of Lund, Lund, Sweden

The heats of hydrolysis of some alkyl thiolesters have been determined at 25°. For the idealized, isothermal hydrolysis reactions

$$RSAc(l) + H_2O(l) \rightarrow RSH(l) + HOAc(l)$$

the changes in enthalpy at 25°C were found to be:
-0.95 ± 0.06 kcal.mole^{-1} for R = Et; -0.93 ± 0.06 kcal.mole^{-1} for *n*-Pr; -1.09 ± 0.06 kcal.mole^{-1} for *n*-Bu; -1.39 ± 0.07 kcal.mole^{-1} for *i*-Pr; -3.00 ± 0.07 kcal.mole^{-1} for *t*-Bu.

The interest which biochemists show towards S-acyl compounds today is fully evident. The role played by coenzyme A and its acyl derivatives in acyl transfer processes has stressed the importance of studying the energy relationships between different acylated compounds containing O-acyl, N-acyl and S-acyl bonds. The present investigation continues a research program which began with the study of the hydrolysis of thiolacetic acid [1], and aims at a mapping out of the enthalpy changes accompanying different types of trans-acylation processes.

EXPERIMENTAL

Materials

Preparation of the esters. The esters were synthesized in two different ways:

1. Acylation of the corresponding thiol [2]. This method was used to prepare EtSAc from EtSH and Ac_2O, and *t*-BuSAc from *t*-BuSH and AcCl.

2. Reaction between thiolacetic acid and the appropriate alkyl bromide [3]. The reaction was carried out in a 500 ml flask with a reflux condenser. To a solution of 0.5 mole of KOH in 150 ml 96 % ethanol was added 0.5 mole of HSAc. The mixture was cooled to room temperature and 0.5 mole of alkyl bromide was slowly added. After a few minutes the solution became warm and KBr precipitated. After one hour the mixture was poured into 2 l of water. The oil was separated and the water phase extracted twice with ether. The oil and the extract were combined, and washed with 2.5 N H_2SO_4, saturated $NaHCO_3$ solution and twice with water. The product was dried overnight with anhydrous Na_2SO_4. After removing the ether, the residue was fractionated. Yield *ca.* 80 %. This method was used to prepare *n*-Bu, *n*-Pr and *i*-Pr thiolacetates. The method is convenient and the use of evil-smelling thiols is avoided. Attempts to prepare *t*-BuSAc by this method failed.

Purity of the esters. The esters were purified by distillation through a 10-plate column. Purities were >99.5 %, as judged by measurements of their equivalent weights. The

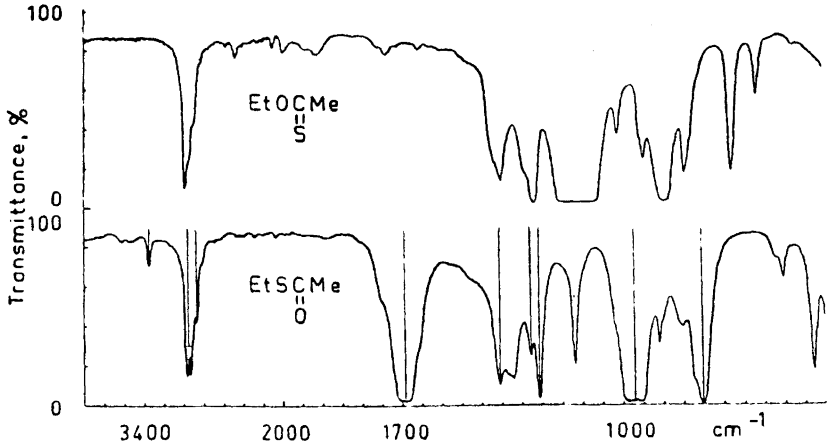

Fig. 1. Infrared spectra of ethyl thionester and ethyl thiolester.

esters showed a neutral reaction, and did not absorb iodine. The equivalent weights were determined after alkaline hydrolysis by titration of both RSH and HOAc.

Determination of RSH. The hydrolysing liquid consisted of an alcoholic NaOH solution (0.5 N NaOH in 50 % ethanol; 10 moles per mole of ester). In this medium the hydrolysis was quantitative within 10 min. However, the thiol formed is very sensitive to air oxidation at high pH values. The reaction was therefore carried out in a nitrogen atmosphere in a long-necked flask with glass stopper. A thinwalled glass ampoule containing 3 mmoles of ester was dropped into the flask and broken by shaking. After about 10 min the solution was cooled to *ca.* −10°C and an excess of glacial acetic acid added. The thiol was titrated with 0.1 N iodine solution in 90 % alcohol. It is well-known that *t*-BuSH cannot be titrated quantitatively with iodine [4].

Determination of HOAc. The hydrolysis was carried out as described above but in a weakly alkaline medium (2 moles NaOH per mole of ester). After leaving overnight the sample was titrated with 0.1 N HCl to pH 7. The thiol was then blown off with CO_2-free air and the solution was titrated to pH 10. Equivalent weight, density and refractive index for the thiolesters synthesized are listed in Table 1.

Table 1. Equivalent weight, density and refractive index for the synthesized thiolesters, RSAc.

R	Equivalent weight			d_4^{25}	n_D^{25}
	RSH	HOAc	Theoretical		
Et	104.6	104.9	104.17	0.9728	1.4568
n-Pr	118.5	118.5	118.19	0.9532	1.4580
n-Bu	132.9	132.9	132.22	0.9390	1.4590
i-Pr	118.1	118.3	118.19	0.9368	1.4510
t-Bu	—	132.3	132.22	0.9207	1.4511

Infrared spectra of the esters. The infrared spectra for the thiolesters have been determined and compared with that of ethyl thionester. It was found that the thiolesters did not contain any detectable amount of thion isomer. Fig. 1 shows the spectra of EtOCSMe and EtSCOMe. The vertical lines indicate the absorption maxima common to all the thiol esters. They are characterized mainly by the C = O stretching bond vibration frequency at 1 700 cm^{-1} and its overtone at 3 400 cm^{-1}.

Auxiliary substances. The thiols used were freshly distilled before their heats of solution were determined. The estimated purity (from determinations of equivalent weights) was better than 99 % except for EtSH which was 98.0 % pure. The density and refractive index for *t*-BuSH was d^{25}_4 0.7942; n_D^{25} 1.4205 in good agreement with values from the literature [5]. The acetic acid was purified by freezing out three times. The purity was found to be 99.5 % (titration with NaOH).

Apparatus

The reactions were carried out in an isothermal calorimeter which will be described in detail elsewhere. The system consisted of a steel reaction vessel with a combined stirrer and ampoule holder and a heating element. The vessel was surrounded by a thick-walled copper jacket. The space between the vessel and the jacket was evacuated to 0.1 mm Hg. The temperature change was determined by use of a thermistor (Stantel U 236120).

Calibration

The determination of the heat capacity of the calorimeter was carried out by passing a known current for a known time through the calibration resistance in the calorimeter. The overall error in the calibration measurements was ± 0.16 %. The calibrations were carried out on the system after the hydrolysis. Owing to the different behaviour towards oxygen of *t*-BuSH compared with other thiols the slope of the resistance-time curve was different in the two cases. Therefore, the hydrolyses were carried out at slightly different temperatures. In order to minimize errors from small variations in ε with temperature, two series of calibration experiments were performed, namely between the thermistor resistances 2 125 and 2 085 Ω (heat capacity ε_1) and between 2 155 and 2 115 Ω (heat capacity ε_2). Experiments corresponding to reactions III and IV (below) and reactions I and II for R = *t*-Bu were carried out in the latter temperature interval, reactions I and II where R = Et, *n*-Pr, *i*-Pr, *n*-Bu were performed between 2 125 and 2 085 Ω. A check on the accuracy of the heat capacity values was obtained by the determination of the heat of solution of KCl in water. The values obtained agreed within the limits of error with those in the literature.

Procedures

The calorimeter was charged with 90 ml of 0.8 N sodium hydroxide solution in water-ethanol (2 : 3). The sealed glass ampoule contained about 3 mmoles of ester (thiol, glacial acetic acid or water). After equilibration, the reaction was started by breaking the ampoule. The hydrolysis was quantitative within 5 min and the duration of the reaction period was 7 min. Thereafter, a linear time-temperature relationship was established. The short reaction period makes the corrections for heat exchange with the surroundings very small and the initial and final thermistor resistances (R_i and R_f, respectively) could thus be obtained graphically.

The large excess of alkali (*ca.* 25 times) greatly speeds up the hydrolysis reaction and is also favorable from another point of view since the degree of protolysis of the sodium mercaptides formed in the reaction becomes independent of small variations in the amount of ester hydrolyzed. As stated above, the thiols are extremely easily oxidized in an alkaline medium and the heat of oxidation is appreciable. Attempts to free the reaction system completely from oxygen were unsuccessful. Therefore, it was impossible to avoid a false slope of the time-temperature curve during the after period, leading to erroneous values of the heat leakage. Also, the oxidation occurring during the reaction period introduced a considerable error. The same errors, however, occurred in the determinations of the heats of solution of the thiols, and to some extent, these errors cancelled out in the final results. In order to ascertain that no errors should be introduced from variations in oxygen content of the calorimeter liquid, and also to ensure complete cancellation in the final results, 4 mmoles of the appropriate thiol were added prior to beginning the experiment. Thus, the oxidation occurred also in the initial period. The limiting factor on the rate of oxidation was the availability of oxygen as the thermal leakage values obtained were identical with those obtained in experiments without thiol present.

Corrections to standard states

The ideal isothermal hydrolysis reaction V is obtained from eqns. I to IV, corresponding to the reactions taking place under actual experimental conditions.

I	$RSAc(l) + H_2O(l) = RSH(soln) + HOAc(soln)$	ΔH_1
II	$RSH(l) = RSH(soln)$	ΔH_2
III	$HOAc(l) = HOAc(soln)$	ΔH_3
IV	$H_2O(l) = H_2O(soln)$	ΔH_4
V	$RSAc(l) + H_2O(l) = RSH(l) + HOAc(l)$	$\Delta H°$

$$\Delta H° = \Delta H_1 - \Delta H_2 - \Delta H_3 + \Delta H_4$$

Units of measurement

The results of the calorimetry experiments are expressed in terms of the defined calorie equal to 4.1840 abs. joules and refer to the isothermal process at 25° and to the true mass. The molecular weights were computed from the 1951 table of international atomic weights [6].

RESULTS

The experimental results are summarized in Tables 2 to 5. Table 2 gives two series of calibration experiments, one performed in the interval 2 125 to 2 085 Ω, the second between 2 155 and 2 115 Ω (ε_1 and ε_2, respectively). The first column gives the input of electrical energy, the second the expression proportional to the temperature increase and the third the value of the heat capacity in calories per unit in $\log(R_i/R_f)$.

Table 2. Calibration experiments.

Table 4 contains the pertinent heats of solution measurements.

Table 5 contains a summary of the observed data and the heat of hydrolysis of the idealized reaction V.

DISCUSSION

In biochemical literature the thiolesters are often spoken of as being "energy-rich" [7,8]. This expression is meant to imply that a large amount of standard free energy, $\Delta F°$, is released when the S-acyl bond is broken *i.e.* by hydrolysis. Quantitatively, it is sometimes stated that, if $-\Delta F°$ exceeds 8 kcal.*, the compound contains an "energy-rich" bond.

* See for example Fruton, J.S. and Simmonds, S. *General Biochemistry*, John Wiley & Sons, Inc., New York 1954, p. 355.

H_2O	3.168	1.17	0.69	0.22
	2.934	1.10	0.64	0.22
			Mean	0.22±0.02

The equation relating a change in standard free energy, $\Delta F°$, to changes in standard entropy, $\Delta S°$, and standard enthalpy, $\Delta H°$, is

$$\Delta F° = \Delta H° - T\Delta S°$$

Table 5. Summary of experimental data and values of heats of hydrolysis of the idealized reaction RSAc(l) + H_2O(l) = RSH(l) + HOAc(l).

R	$-\Delta H_1$	$-\Delta H_2$	$-\Delta H_3$	$-\Delta H_4$	$-\Delta H°$ at 25°C
Et	17.25	5.05	11.47	0.22	0.95
n-Pr	16.73	4.55	11.47	0.22	0.93
n-Bu	16.50	4.16	11.47	0.22	1.09
i-Pr	17.50	4.86	11.47	0.22	1.39
t-Bu	18.69	4.44	11.47	0.22	3.00

A large $\Delta F°$ value may be traced back either to a large $\Delta H°$-term or to a large $T\Delta S°$-term or to both terms, $\Delta H°$ and $\Delta S°$ in this case having different signs.

The present investigation shows that the value of $-\Delta H°$ for simple alkyl thiolesters is only from 1 to 3 kcal.mole^{-1}. Therefore, if $-\Delta F°$ is to be large, a large increase in entropy must occur during the hydrolysis.

The close analogy between the hydrolysis of an alkyl ester and an alkyl thiol ester

$$\mathrm{ROAc} + \mathrm{H_2O} \rightleftharpoons \mathrm{ROH} + \mathrm{HOAc}$$
$$\mathrm{RSAc} + \mathrm{H_2O} \rightleftharpoons \mathrm{RSH} + \mathrm{HOAc}$$

makes it unlikely that the hydrolysis of the S-acyl compounds should be accompanied by a large change in $\Delta S°$. It is known that $\Delta H°$ and $\Delta F°$ for the hydrolysis of an O-ester have nearly the same values, both being *ca.* 0—2 kcal.mole^{-1}. The change in entropy is therefore small. From known values of entropies of alcohols and thiols on one hand, and non-hydrogen bonding compounds like ethers on the other, it is likely that the $T\Delta S°$-term for the hydrolysis of a thiolester is *ca.* 1—1.5 kcal.mole^{-1}. It is therefore very probable that simple alkyl thiolesters are not "energy-rich" in the sense referred to above.

Acknowledgement. The author wishes to thank Professor B. Bak and co-workers, University of Copenhagen, for determining the infrared spectra. This investigation has been supported by the *Swedish Natural Science Research Council* and the *State Council of Technical Research.*

The Preparation of 6-Chloro-*ortho*cresol and 4,6-Dichloro-*ortho*cresol and the Corresponding *Ortho*toloxyacetic acids

SVEN NORD and BERTIL SJÖBERG

Research Laboratories, Skoghallsverken, Uddeholms AB., Skoghall, Sweden

From a mixture of the closeboiling *o*-cresol and 6-chloro-*o*-creso pure 6-chloro-*o*-cresol has been prepared over the corresponding acetates. From the 6-chloro-*o*-cresol pure 4,6-dichloro-*o*-cresol was obtained by chlorination. 6-Chloro-*o*-toloxyacetic acid and 4,6-dichloro-*o*-toloxyacetic acid have been synthesized and the infrared spectra of these compounds and *o*-toloxyacetic acid have been recorded.

In an earlier paper [1] describing the determination of chloro-2-methylphenoxyacetic acid by infrared spectrophotometry the preparation of 6-chloro-*o*-cresol (2-methyl-6-chlorophenol) and 4,6-dichloro-*o*-cresol (2-methyl-4,6-dichlorophenol) and the corresponding *o*-toloxyacetic acids was briefly mentioned. As an answer to many inquiries we now give the details about the preparation and further physical data.

By the chlorination of *ortho*cresol with an equivalent amount of chlorine the reaction product usually has the following composition: 5—10 % *ortho*-cresol, 57—60 % 4-chloro-*ortho*cresol, 22—26 % 6-chloro-*ortho*cresol and 3—7 % 4,6-dichloro*ortho*cresol. The boiling points of these compounds given in the literature are shown in Table 1.

Table 1. The boiling points of *o*-cresol and chlorinated *o*-cresols.

Compound	Boiling point, °C at 760 mm Hg
o-Cresol	191
6-Chloro-*o*-cresol [2]	189
4-Chloro-*o*-cresol [3]	220—225
4,6-Dichloro-*o*-cresol [4]	226.5

At the distillation of the crude chlorination product the first run will contain the low-boiling *o*-cresol and 6-chloro-*o*-cresol. These two compounds can hardly be separated by further distillation on account of their close boiling points. Neither can in the higher boiling fraction 4-chloro-*o*-cresol and 4,6-dichloro-*o*-cresol conveniently be separated by distillation.

In order to obtain better separation we transformed the mixture of *o*-cresol and 6-chloro-*o*-cresol from the distillation of the crude chlorination product into the corresponding acetates. *o*-Cresylacetate has previously been prepared by v. Auwers, Lechner and Bundesmann [5], who found a boiling point of 87°C at 12 mm Hg and by Raschig [6], who reports a boiling point of 212.5°C at 760 mm Hg. 6-Chloro-*o*-cresylacetate does not seem to have been prepared before. In the present investigation we found that 6-chloro-*o*-cresylacetate had an about 30°C higher boiling point than *o*-cresylacetate and that the two acetates could effectively be separated by fractional distillation. During the distillation we checked the purity of the fractions by means of infrared spectrographic analysis. The physical data of the carefully purified acetates are given in Table 2.

The pure 6-chloro-*o*-cresylacetate was hydrolyzed with dilute sodium hydroxide solution and from the alkaline solution 6-chloro-*o*-cresol was liberated with sulfuric acid. The cresol was distilled in vacuum and further purified by fractional freezing. In the pure 6-chloro-*o*-cresol no traces of other cresols could be found by vapor chromatography.

By chlorination of the pure 6-chloro-*o*-cresol with less than the equivalent amount of chlorine we obtained a 4,6-dichloro-*o*-cresol that could be purified by distillation and recrystallization. The physical data for 6-chloro-*o*-cresol and 4,6-dichloro-*o*-cresol are given in Table 2.

Table 2. Physical data

	Boiling point °C/mm Hg	Melting point °C	d_4^{20}	n_D^{20}	MR_D Calc.[10]	MR_D Found
o-Cresylacetate	63.5/1.5 210.7—210.9/774		1.0482	1.4998	41.82	42.12
6-Chloro-*o*-cresyl acetate	78/1.2 238.4—239.0/753		1.1778	1.5134	46.68	47.14
6-Chloro-*o*-cresol	191.0—192.3/757	1.5—2.0	1.1966	1.5452	37.32	37.68
4,6-Dichloro-*o*-cresol	231.6—231.9/739	52.5—52.7				
6-Chloro-*o*-toloxy-acetic acid		109.5—109.8				
4,6-Dichloro-*o*-toloxy-acetic acid		187.9—188.2				
o-Toloxyacetic acid		154.8—154.9				

From the cresols we prepared 6-chloro-*o*-toloxyacetic acid and 4,6-dichloro-*o*-toloxyacetic acid [7, 8] by reaction with monochloro-acetic acid in an alkaline solution as has been described earlier [1, 9]. The acids were carefully purified by recrystallization from benzene (physical data in Table 2). The infrared spectra of the acids were recorded (Figs. 1 and 2). As a comparison we also recorded the infrared spectrum of *o*-toloxyacetic acid (Fig. 3).

From the comparison of the spectra it is obvious that the acids are not contaminated with each other.

EXPERIMENTAL

Preparation of o-cresylacetate and 6-chloro-o-cresylacetate. 900 g of a mixture of about 22 % cresol and 78 % 6-chloro-*o*-cresol, obtained from the distillation of chlorinated

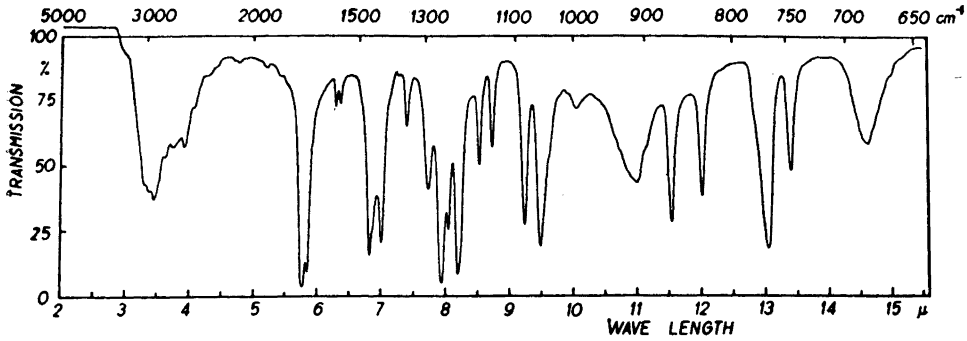

Fig. 1. The infrared spectrum of 6-chloro-*o*-toloxyacetic acid in KBr.

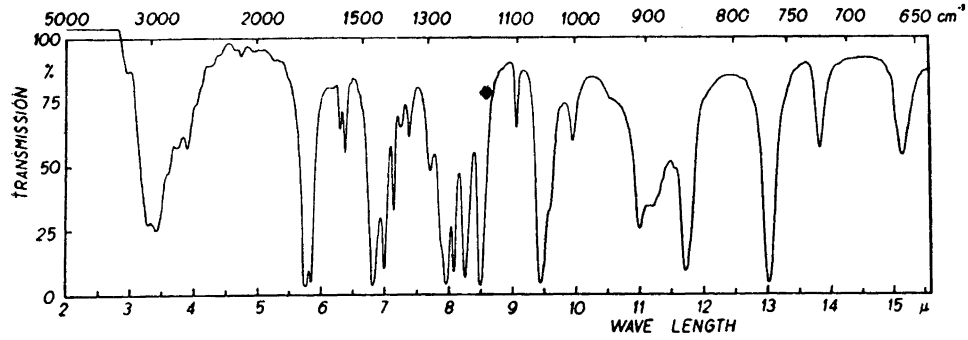

Fig. 2. The infrared spectrum of 4,6-dichloro-*o*-toloxyacetic acid in KBr.

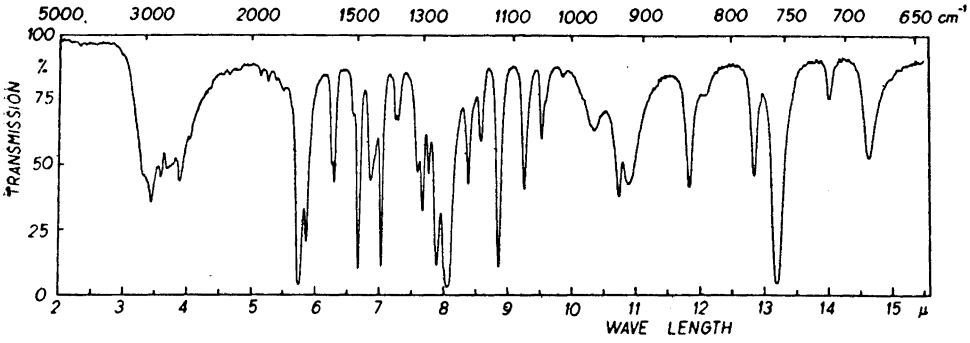

Fig. 3. The infrared spectrum of *o*-toloxyacetic acid in KBr.

o-cresol, was heated with reflux with 900 g acetic acid anhydride and 2 ml konc. sulfuric acid for about 2 h. From the reaction product most of the remaining anhydride and the acetic acid formed was distilled off at 100 mm Hg. The rest was fractionated in vacuum with an 1.5 m highly effective column. At about 90°C and 10 mm Hg we obtained 236 g *o*-cresylacetate and at about 105°C and 10 mm Hg 813 g 6-chloro-*o*-cresylacetate. The acetates were carefully purified by further distillation and the purity checked by infra-

red spectrometry. o-*Cresylacetate* (Found: C 71.4; H 6.74. Calc. for $C_9H_{10}O_2$: C 72.0; H 6.71). *6-Chloro*-o-*cresylacetate* (Found: C 58.3; H 4.79; Cl 19.26. Calc. for $C_9H_9ClO_2$: C 58.6; H 4.91; Cl 19.21).

Preparation of 6-chloro-o-*cresol:* 200 g sodium hydroxide dissolved in 500 ml water was heated to 110°. With good agitation 386 g 6-chloro-*o*-cresylacetate was added in about half an hour. After cooling to room temperature the reaction product was acidified with 300 ml sulfuric acid (50 %). The separated oil was washed with a saturated solution of sodium bicarbonate and distilled in vacuum. To prevent oxidation carbon dioxide was led through the capillary in the distillation pot. At 76°C and 10 mm Hg we obtained 285 g 6-chloro-*o*-cresol (yield 95 %). The cresol was redistilled and purified by fractional freezing. The purity of the 6-chloro-*o*-cresol was checked with vapor chromatography. We used a Perkin Elmer chromatograph, model 154 B with column C at a temperature of 190°C. No traces of other cresols could be found in the purified 6-chloro-*o*-cresol. *6-Chloro*-o-*cresol* (Found: C 58.4; H 4.87; Cl 24.99. Calc. for C_7H_7ClO: C 59.0; H 4.95; Cl 24.87).

Preparation of 4,6-dichloro-o-*cresol.* 150 g 6-chloro-*o*-cresol (1.05 mole) was heated to 50—60°C in a round bottom flask equipped with agitator and reflux condenser. At this temperature the cresol was reacted with 71 g chlorine which was slowly introduced during about 5 h. The reaction product was distilled in vacuum. After a forerun of 37 g, mainly containing unchlorinated 6-chloro-*o*-cresol we obtained 111 g 4,6-dichloro-*o*-cresol boiling between 111 and 113°C at 16 mm Hg (yield 60 %). The cresol was further purified by recrystallization from petroleum ether. *4,6-Dichloro*-o-*cresol* (Found: C 47.6; H 3.46; Cl 40.25. Calc. for $C_7H_6Cl_2O$: C 47.5; H 3.42; Cl 40.06).

Preparation of 6-chloro-o-*toloxyacetic acid.* 71 g 6-chloro-*o*-cresol (0.5 mole) and 27 ml sodium hydroxide solution (35 %) were charged in a round bottom flask equipped with agitator, two separating funnels as charging means, a reflux condenser, an antimony electrode with a calomel reference electrode and a heating device. The solution was heated to about 100°C. Then 57 g monochloroacetic acid (0.6 mole) dissolved in 15 ml water was added from one of the separating funnels in the course of about one hour. Through the other separating funnel sodium hydroxide solution of 35 % strength was simultaneously added to keep the solution during the whole reaction at a pH value of 10.5 as measured by means of the antimony electrode. Altogether 80 ml sodium hydroxide solution was added. After 3 h at 100°C the reaction mixture was cooled to room temperature and adjusted with acid to pH 7.0. Nonreacted 6-chloro-*o*-cresol was extracted with ether. The solution was then acidified to complete precipitation of the acid, which was filtered, washed and dried. Yield 92 g or 92 %. The acid was purified by recrystallization from benzene. *6-Chloro*-o-*toloxyacetic acid* (Found: C 53.8; H 4.46; Cl 17.69. Calc. for $C_9H_9ClO_3$: C 53.9; H 4.52; Cl 17.68).

Preparation of 4,6-dichloro-o-*toloxyacetic acid.* 80 g 4,6-dichloro-*o*-cresol (0.45 mole) was reacted with 52 g monochloroacetic acid (0.55 mole) in alkaline solution in the same way as described for 6-chloro-*o*-toloxyacetic acid. We obtained 89 g 4,6-dichloro-*o*-toxyacetic acid (yield 84 %) which was purified by recrystallization from benzene. *4,6-Dichloro*-o-*toloxyacetic acid* (Found: C 45.9; H 3.36; Cl 30.30. Calc. for $C_9H_8Cl_2O_3$: C 46.0; H 3.43; Cl 30.17).

The infrared spectra. The infrared spectra were recorded with a Perkin-Elmer spectrometer, Model 21a, with a rock-salt prism. Slit schedule 927, corresponding to program 4. Speed: 3 min/μ. The frequencies of the absorption bands are given below in cm^{-1}.

The Heat of Hydrolysis of *i*-Propenyl Acetate and *m*-Cresyl Acetate and the Heat of Enolization of Acetone

S. SUNNER

Thermochemistry Laboratory, University of Lund, Lund, Sweden

The heats of hydrolysis of *i*-propenyl acetate and of *m*-cresyl acetate were measured at 25°C in a reaction calorimeter. The experimental data yielded for the reaction

$$CH_2 = CMe \cdot OAc(liq) + H_2O(liq) \rightarrow Me_2CO(liq) + HOAc(liq)$$

the value $\Delta H°_r = -14.39 \pm 0.06$ kcal.mole^{-1} and for the reaction

$$m\text{-}MeC_6H_4 \cdot OAc(liq) + H_2O(liq) \rightarrow m\text{-}MeC_6H_4OH(liq) + HOAc(liq)$$

the value $\Delta H°_r = -4.39 \pm 0.07$ kcal.mole^{-1}. A comparison between these two reactions yielded for the enolization reaction of acetone

$$Me_2CO(liq) \rightarrow CH_2 = CMeOH(liq)$$

a value of the enthalpy change of $\Delta H° = 7$ kcal.mole^{-1} in excellent agreement with a value derived from the measurement of the equilibrium between acetone and *i*-propenol, made by Schwarzenbach and Wittwer [9].

EXPERIMENTAL

Apparatus, calibration and procedure have been described elsewhere [1]. The calorimeter was charged with 90 ml of 60 % by volume ethanol containing 0.8 equiv. of sodium hydroxide per liter. The sample of the ester was enclosed in a sealed glass ampoule.

Materials. i-Propenyl acetate (Eastman Kodak) was purified by distillation through a 75 cm packed column; the main fraction had a b.p. of 96.7°C at 749 mm Hg (corr.). The equivalent weight was determined by hydrolysis in 90 % ethanol containing twice the required amount of NaOH. Equiv. wt found: 100.2, 100.2, 100.0 and 99.7; mean value 100.05±0.10; calculated 100.11.

m-Cresyl acetate was synthesized [2] from *m*-cresol, distilled twice (b.p. 76° at 2 mm Hg and 102° at 22 mm Hg) and the resulting main fraction was frozen out four times (m.p. 9.8°, corr.). The purity was checked by alkaline hydrolysis. Neither the use of indicators and reference solutions nor of potentiometric titrations gave a sharp end point. The potentiometric titrations showed an equivalent weight 0.3 % too low.

Acetone, analytical reagent grade, was purified according to Vogel (method a) [3].

m-Cresol (B.D.H. Laboratory Reagent 98/100 %) was distilled and the main fraction (b.p. 71° at 3 mm Hg) was frozen out three times (m.p. 11.1°, corr.).

RESULTS

Calibration and heat of reaction measurements. The determinations of the heat equivalent of the calorimeter and of the heat of hydrolysis of *i*-propenyl acetate and *m*-cresyl acetate are summarized in Tables 1, 2 and 3, respectively.

The first column in all tables gives the number of the experiment. In Table 1, the second column shows the temperature increase, expressed as $^{10}\log R_i/R_f$, where R_i is the resistance of the thermistor at the initial temperature and R_f that at the final temperature of the reaction period. The third column gives the input of electrical energy in calories and the fourth column shows the value obtained for the proportionality constant, k, in the expression $q(\text{cals.}) = k \times {}^{10}\log R_i/R_f$.

In Tables 2 and 3 the second column gives the number of mmoles of acetate hydrolyzed, the fourth column the amount of heat evolved and the last column the increase in enthalpy on a molar basis.

Table 1. The heat equivalent of the calorimeter. Initial temperature 24.5° and final temperature 25.5°C. The current was passed for 570 sec, the duration of the reaction period was 11 min.

No.	$10^4 \times \log R_i/R_f$	q, cal	$k \times 10^{-2}$ cal
1 565	139.153	81.242	58.38
1 567	140.946	82.217	58.33
1 569	141.724	82.559	58.25
1 571	141.030	82.148	58.25
		Mean:	$(58.30 \pm 0.30) \times 10^{-2}$

Table 2. The heat of hydrolysis of *i*-propenyl acetate. Duration of the reaction period 7 min. $k = 0.5830$.

No.	mmoles	$10^4 \times \log R_i/R_f$	q, cal	$-\Delta H_1$ kcal.mole^{-1}
1 566	3.0262	131.157	76.464	25.27
1 568	3.1667	137.565	80.200	25.33
1 570	3.0230	131.277	76.534	25.32
1 572	3.2487	141.083	82.251	25.32
			Mean:	25.31 ± 0.015 kcal.mole^{-1}

Table 3. The heat of hydrolysis of *m*-cresyl acetate. Duration of the reaction period 10 min. $k = 0.7219$ (1 577), 0.7207 (1 579), 0.6965 (1 588).

No.	mmoles	$10^4 \times \log R_i/R_f$	q, cal	$-\Delta H_1$ kcal.mole^{-1}
1 577	2.968	83.894	60.563	20.41
1 579	3.022	85.762	61.809	20.45
1 588	3.006	88.400	61.571	20.48
			Mean:	20.45 ± 0.02 kcal.mole^{-1}

Correction to standard states. The actual reaction taking place in the calorimeter is represented by eqn. (1). In order to obtain the isothermal, ideal hydrolysis reaction (5), it is necessary to substract eqns. (2) and (3) from (1) and to add eqn. (4).

$$CH_2 = CMe \cdot OAc(liq) + OH^-(soln) \rightarrow Me_2CO(soln) + AcO^-(soln) \quad (1a)$$
$$MeC_6H_4 \cdot OAc(liq) + OH^-(soln) \rightarrow MeC_6H_4OH(soln) + AcO^-(soln) \quad (1b)$$
$$Me_2Co(liq) \rightarrow Me_2CO(soln) \quad (2a)$$
$$MeC_6H_4OH(liq) \rightarrow MeC_6H_4OH(soln) \quad (2b)$$
$$HOAc(liq) + OH^-(soln) \rightarrow AcO^-(soln) + H_2O(soln) \quad (3)$$
$$H_2O(liq) \rightarrow H_2O(soln) \quad (4)$$

$$CH_2 = CMe \cdot OAc(liq) + H_2O(liq) \rightarrow CH_3COCH_3(liq) + HOAc(liq) \quad (5a)$$
$$MeC_6H_4 \cdot OAc(liq) + H_2O(liq) \rightarrow MeC_6H_4OH(liq) + HOAc(liq) \quad (5b)$$

The heat of solution of acetone and *m*-cresol in a liquid phase of proper composition, eqn. (2), had to be determined in separate experiments. The heat of solution of glacial acetic acid, eqn. (3), and the heat of dilution of the liquid, eqn. (4), have been previously determined.

The heat of hydrolysis of the idealized reaction (5) at 25°C is then

$$\Delta H_r^\circ = \Delta H_1 - \Delta H_2 - \Delta H_3 + \Delta H_4$$

ΔH_2 was determined to be 0.498 ± 0.003 kcal.mole^{-1} (acetone) and -4.643 ± 0.007 kcal.mole^{-1} (*m*-cresol). ΔH_3 and ΔH_4 were found to be -11.61 ± 0.03 and -0.19 ± 0.01 kcal.mole^{-1}, respectively [4]. Thus

$$-\Delta H_r^\circ(liq) = 14.39 \pm 0.06 \text{ kcal.mole}^{-1} \quad (5a)$$
$$-\Delta H_r^\circ(liq) = 4.39 \pm 0.07 \text{ kcal.mole}^{-1} \quad (5b)$$

In order to calculate the heat of hydrolysis when both reactants and reaction products are in the gaseous state it is necessary to know the heats of vaporization for all the compounds at 25°C.

The heat of vaporization of acetic acid to form monomer gaseous molecules was calculated by Parks and Huffman [5] to be 12.5 kcal.mole^{-1}. The heat of vaporization of acetone [5] and water [6] have been determined to be 7.59 and 10.52 kcal.mole^{-1}, respectively. For *i*-propenyl acetate and *m*-cresyl acetate, the heat of vaporization was estimated from Klages equation [7] to be 8.9 and 13.2 kcal.mole^{-1}, respectively. For *m*-cresol the heat of vaporization was calculated from Stull's vapor pressure data [8] to be 12.0 kcal.mole^{-1}.
Thus, for the reaction,

$$CH_2 = CMe \cdot OAc(g) + H_2O(g) \rightarrow CH_3COCH_3(g) + HOAc(g) \quad (6a)$$
$$\Delta H_r^\circ(g) = -13.7 \text{ kcal.mole}^{-1}$$

and for the reaction

$$CH_3C_6H_4 \cdot OAc(g) + H_2O(g) \rightarrow CH_3C_6H_4OH(g) + HOAc(g) \quad (6b)$$
$$\Delta H_r^\circ(g) = -3.6 \text{ kcal.mole}^{-1}$$

THE HEAT OF ENOLIZATION OF ACETONE

The hydrolysis of *i*-propenyl acetate to acetone, (6a), may be split into two consecutive steps, *viz.* the hydrolysis to *i*-propenol, (6a 1) and the protomeric isomerization of *i*-propenol to acetone, (6a 2):

$$CH_2 = CMe \cdot OAc + H_2O \rightarrow CH_2 = CMeOH + HOAc \quad (6a\ 1)$$
$$CH_2 = CMeOH \rightarrow Me_2CO \quad (6a\ 2)$$

A knowledge of the value of the heat of reaction (6a 1) makes it possible to obtain a value for the heat of reaction (6a 2), which is the reverse of the enolization reaction of acetone.

Reaction (6a 1) is of course not experimentally accessible; it is therefore necessary to estimate the accompanying change in enthalpy indirectly. This has been achieved by a comparison of the hydrolysis of *i*-propenyl acetate with that of *m*-cresyl acetate. By subtracting eqn. (6a 1) from (6b) one gets

$$m\text{-}MeC_6H_4 \cdot OAc + CH_2 = CMeOH \rightarrow m\text{-}MeC_6H_4OH + CH_2 = CMe \cdot OAc \quad (7)$$

The complete symmetry in eqn. (7) suggests that $\Delta H_7 = \Delta H_{6b} - \Delta H_{6a\,1} = 0$. Thus $\Delta H_{6a\,1} = -3.6$ kcal.mole^{-1} and the heat of enolization of acetone in the gaseous state becomes $-\Delta H_{6a\,2} = +10$ kcal.mole^{-1}.

The heat of vaporization of acetone [5] is 7.6 kcal.mole^{-1} and that of *i*-propenol was estimated to 10.5 kcal.mole^{-1} from a comparison between saturated and unsaturated compounds. The heat of enolization of acetone in the liquid state is therefore equal to 7.0 kcal.mole^{-1}.

Schwarzenbach and Wittwer [9] determined experimentally the equilibrium between acetone and *i*-propenol in solution and found the change in standard free energy to be about 8 kcal.mole^{-1}. The change in entropy accompanying the isomerization can be estimated in the following way.

For the dehydrogenation reaction

$$Me_2CHOH(g) \rightarrow Me_2CO(g) + H_2(g) \quad (8)$$

the entropy change at 25°C is $\Delta S_8^\circ = 29.80$ e.u.[5] A comparison between different gaseous compounds of the two types RCH = CMe . R' and RCH_2—CHMeR' and with known values of ΔS° shows that the unsaturated compound has an entropy value which is in average 0.3 kcal. less than that of the saturated compound. This value combined with the known ΔS° value for gaseous hydrogen [6], 31.2 e.u., gives $\Delta S^\circ = -1$ e.u. for the isomerization *i*-propenol(g)→acetone(g). From estimated values of the vapor pressure (20 mm) and heat of vaporization (10.5 kcal.) of *i*-propenol at 25°C and those data of acetone [5], the entropy change for the isomerization in the liquid state was calculated to +3 e.u. Thus, the heat of enolization of acetone to *i*-propenol in the liquid state becomes 7 kcal.mole^{-1} in excellent agreement with the result from the present thermochemical investigation.

The Heat of Oxidation of Arsenious Oxide to Arsenic Oxide in Aqueous Solution

LARS BJELLERUP, STIG SUNNER and INGEMAR WADSÖ

Thermochemistry Laboratory, University of Lund, Lund, Sweden

The heat of reaction, $-\Delta H$, at 25°C and at a constant pressure of 1 atm, for the reaction of liquid bromine with arsenious oxide solution was measured with a glass Dewar calorimeter.

The experimental data yielded for the reaction

$$[As_2O_3 + 2H_2O](aq) + 2Br_2(liq) \rightarrow [As_2O_5 + 4HBr](aq)$$

the value $\Delta H_{25°C} = -56.92 + 0.12$ kcal/mole. Combination of this datum with established heat of formation data for aqueous hydrogen bromide and liquid water yielded for the reaction

$$As_2O_3(aq) + O_2(g) \rightarrow As_2O_5(aq)$$

$\Delta H_{25°C} = -78.0 \pm 0.1$ kcal/mole.

In connection with bomb calorimetric work on organic bromine compounds [1] an accurate value for the heat of reaction, $-\Delta H$, at 25°C and constant pressure for the reaction

$$As_2O_3(aq) + O_2(g) \rightarrow As_2O_5(aq) \quad (1)$$

was needed. Since a direct determination of this heat effect could not be undertaken a review was made of available experimental thermochemical data from which the required datum could be calculated. As a result of this review it was decided necessary to make a redetermination of the heat of reaction, $-\Delta H$, at 25°C and constant pressure of 1 atm, for the reaction

$$[As_2O_3 + 2H_2O](aq) + 2Br_2(liq) \rightarrow [As_2O_5 + 4HBr](aq) \quad (2)$$

This paper described the measurement of the mentioned datum. The heat capacity for the arsenious oxide solution used in the heat of reaction experiments was also determined.

EXPERIMENTAL

Apparatus. The calorimetric system [2] consisted of a silvered glass Dewar vessel, capacity 100 ml, mounted in a thermostat. The inner parts, stirrer, thermometer, heating coil and sample ampoule were mounted in a size 34 cone, fitting in the Dewar vessel. The temperature was measured with a small Beckmann thermometer.

Calibration. The energy equivalent of the calorimetric system at 25°C was determined electrically by passing a constant current through the heating coil for a measured length of time (about 180 sec). The resistance of the heating coil was known to within 0.05 % and the current was measured with the aid of a standard resistor in series with the heating coil. The potential drop across the standard resistor was measured by comparing it with a standard cell to within 0.02 %. The temperature readings of the after period were started 15 min from the end of the heating period in order to secure thermal equilibrium. The thermal leakage was calculated by the Regnault-Pfaundler method.

In the calibration experiments the calorimeter contained 75.00 ml of a 0.0624 M arsenious oxide solution. Two series of calibration experiments were performed — one with a temperature increase of the calorimeter, ΔT, of about 0.9 deg and one with a ΔT of about 0.45 deg, corresponding to the two different amounts of bromine used in the heat of reaction measurements.

Procedure. The calorimeter was charged with 75.00 ml of 0.0624 M arsenious oxide solution and with a sealed glass ampoule containing a known amount of bromine. At the end of the fore period the reaction was started by breaking the thinwalled glass ampoule by pushing it against the bottom of the calorimeter vessel. The reaction was completed within 5 min but the after period — as in the calibration experiments — was not started until 15 min after the completion of the heat evolution. In order to detect possible systematic errors, two different amounts of bromine were used, about 0.25 and 0.50 g, respectively. All measurements were made at 25°C.

Materials. The bromine used was a Merck, Darmstadt, *pro analysi* grade. In order to remove the small amount of chlorine known to be present in the commercial sample the bromine was stored over finely ground potassium bromide (Coleman & Bell's C.P. grade) for two days with occasional shaking. The bromine was then distilled from the mixture under vacuum at about 20°C. The distillate was free from chlorine.

The arsenious oxide was a Merck, Darmstadt, *pro analysi* grade and was used without further purification. Arsenious oxide solution was prepared by dissolving the substance in boiling water.

The concentration of the arsenious oxide solution was determined by potentiometric titration with potassium permanganate and was found to be $C_{As_2O_3} = 0.0625$ M. The density at 25°C of this solution was $d_4^{25} = 1.0067$ g/ml.

RESULTS

Calibration. Data obtained in the two series of calibration experiments are given in Tables 1 and 2.

The following quantities are listed in the tables:

q	amount of heat evolved in the calorimetric system,
ΔT	temperature increase in the calorimeter,
ε	energy equivalent at 25°C of the calorimetric system.

Heat of reaction measurements. The data obtained in the heat of reaction experiments with various amounts of bromine are given in Table 3.

The ε-values given in the table are the means from Table 1 and Table 2, respectively, to which have been added the heat capacities of the glass ampoule and the bromine used in the various experiments.

Of the dissolved substances participating in the reaction $HBr \cdot nH_2O$ is the only one for which heat of dilution data are available. Therefore, by

addition of the term $q_{\text{dil HBr}}$ to the experimentally determined q-value ($q = \varepsilon \cdot \Delta T$), all data have been reduced to a uniform final concentration of HBr, corresponding to infinite dilution.

Heat capacity measurements. In order to obtain a value for the heat capacity of the 0.0624 M arsenious oxide solution used in the heat of reaction experiments an electrical "calibration" of the calorimetric system was done with the calorimeter containing 75.00 ml of water instead of arsenious oxide solution. The data obtained are given in Table 4.

Table 4. "Calibration" with water in the calorimeter

q cal	ΔT deg	ε cal/deg
73.52	0.8074	91.06

Table 5. Comparison of results from various investigations

Investigators	$\Delta H_{25°C}$ (reaction 1) kcal/mole
Thomsen [5]	−78.2
Berthelot [6]	−76.2
Smith and Sunner [7]	−77.9
This work	-78.0 ± 0.1

Combination of the mean ε-values from Tables 1 and 4 with the value 0.99707 g/ml for the density of water at 25°C, the value 0.99892 cal/g deg for the heat capacity of water at 25°C and the value 1.0067 g/ml for the density of 0.0624 M arsenious oxide water solution at 25°C yielded the value 0.988 ± 0.002 cal/g deg for the heat capacity of 0.0624 M arsenious oxide solution at 25°C.

DISCUSSION OF RESULTS

Combination of reaction 2 with reaction 3

$$4\text{HBr(aq)} + \text{O}_2\text{(g)} \rightarrow 2\text{H}_2\text{O(liq)} + 2\text{Br}_2\text{(liq)} \qquad (3)$$

yielded reaction 1. From the standard enthalpies of formation $\Delta Hf°_{25°C}$ [HBr(aq)] = −28.90 kcal/mole[3] and $\Delta Hf°_{25°C}$[H_2O(liq)] = −68.3174 kcal/mole [4] the standard enthalpy change associated with reaction 3 was calculated to be

$\Delta H°_{25°C}$ (reaction 3) = —21.03 kcal/mole. Combination of this datum with the experimental value $\Delta H_{25°C}$ (reaction 2) = —56.92±0.12 kcal/mole yielded for reaction 1

$$\Delta H_{25°C} \text{ (reaction 1)} = -78.0+0.1 \text{ kcal/mole.}$$

Results from previous experimental investigations leading to ΔH-values for reaction 1 have been summarized in Table 5 for comparison with the result of this work. With the aid of certain approximations all data have been recalculated to apply to a temperature of 25°C.

As is seen from Table 5 the only discordant value is that of Berthelot. It should be mentioned that calculation of $\Delta H°_{25°C}$ (reaction 1) from the heat of formation compilations of Bichowsky and Rossini [8] and of the National Bureau of Standards [3] give the values —77.3 and —74.9 kcal/mole, respectively.

Reactions between Hydrazine, Thiocyanic Acid and Oxo-compounds

IV. Heats of Combustion and Derived Data for some Compounds Related to Thiosemicarbazide

S. SUNNER

Thermochemistry laboratory, University of Lund, Lund, Sweden

The heat of combustion was determined and the heat of formation at 20° was calculated for the following compounds: hydrazinium thiocyanate ΔHf(s) = 9.2±0.7 kcal · mole^{-1} and ΔHf(aq) = 17.1±0.8 kcal · mole^{-1}; thiosemicarbazide ΔHf(s) = 5.7±0.5 kcal · mole^{-1} and ΔHf(aq) = 13.5±0.7 kcal · mole^{-1}; acetaldehyde thiosemicarbazone ΔHf(s) = 15.0±0.8 kcal · mole^{-1}; acetone thiosemicarbazone ΔHf(s) = 4.6±0.8 kcal · mole^{-1} and compound A ($C_6H_{10}N_4S_2$) ΔHf(s) = 32.7± 1.6 kcal · mole^{-1}.

The thermochemical data have been used further to discuss the equilibrium between hydrazinium thiocyanate and thiosemicarbazide, to calculate the resonance energy of thiosemicarbazones and to compare the exothermicities of the reactions between hydrazinium thiocyanate and oxo-compounds.

THE EQUILIBRIUM BETWEEN HYDRAZINIUM THIOCYANATE AND THIOSEMICARBAZIDE

From a kinetic study at 100° of the isomerization of hydrazinium thiocyanate to thiosemicarbazide and of the reverse reaction in 0.4 M solution it was concluded that the equilibrium is composed of *ca.* 40 % thiosemicarbazide and 60 % hydrazinium thiocyanate *. Using an approximation of activity equal to molarity, one gets for the reaction

$$N_2H_5NCS \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} NH_2 \cdot NH \cdot CS \cdot NH_2$$

$$\Delta F^\circ = -RT \ln K = 0.3 \text{ kcal} \cdot \text{mole}^{-1}$$

* Ref.[1] From the data given in Table 2 the velocity constant, k_1 for the first order forward reaction, assuming $k_1/k_{-1} = 2/3$, was found to be 0.0016, 0.0016 and 0.0017 hour^{-1}. The data for the reverse reaction do not obey a simple first order rate equation.

From heat of combustion and solution data, the heat of formation of hydrazinium thiocyanate and thiosemicarbazide in aqueous solution at 20° was found to be 17.1 and 13.5 kcal · mole^{-1}, respectively. Thus, $\Delta Hr = -3.6 \pm 1.1$ kcal · mole^{-1}. Assuming ΔHr to be independent of temperature between 20 and 100°, the equilibrium constant at 20° is calculated to be 4.6, which gives $\Delta F° = -0.56$ kcal · mole^{-1}. At 20° the equilibrium mixture therefore consists of about 80 % thiosemicarbazide and 20 % hydrazinium thiocyanate. Thus, the position of the equilibrium at room temperature is favourable for the synthesis of thiosemicarbazide from hydrazinium thiocyanate; however, the reaction was found to be too slow to be utilized for this purpose [1].

It is of interest to compare this reaction with the isomerization of hydrazinium cyanate to semicarbazide. Baker and Gilbert [2] investigated this reaction and found $k_1/k_{-1} = 200\,000$ at 15° and 30 000 at 25°. Thus 95 % of a 0.5 M hydrazinium cyanate solution should isomerize within 11 min.

THE RESONANCE ENERGY OF THIOSEMICARBAZONES

The resonance energy of thiosemicarbazide was recently estimated [3] to be 28 kcal · mole^{-1}. It is of interest to compare this value with estimated values of the resonance energy of the thiosemicarbazones. For the purpose of calculating these quantities we computed the change in enthalpy of the reactions:

$$NH_2NHCSNH_2(g) + CH_3CHO(g) \rightarrow CH_3CH{=}N \cdot NHCSNH_2(g) + H_2O(g) \quad (1)$$

$$NH_2NHCSNH_2(g) + (CH_3)_2CO(g) \rightarrow (CH_3)_2C{=}N \cdot NHCSNH_2(g) + H_2O(g) \quad (2)$$

The following data were used for the computation: thiosemicarbazide [3] $\Delta Hf(g) = +24.7$ kcal · mole^{-1}; acetaldehyde [4] $\Delta Hf(g) = -39.76$ kcal · mole^{-1}; acetone [5] $\Delta Hf(g) = -52.6$ kcal · mole^{-1}; water [4] $\Delta Hf(g) = -57.80$ kcal · mole^{-1}.

The heats of sublimation of the thiosemicarbazones were related to that of thiosemicarbazide. A comparison between different amines and their corresponding aldehyde and ketone derivatives (aniline — anils; phenyl hydrazine — phenyl hydrazones; methoxamine — methyl oximes; ethoxamine — ethyl oximes; hydrazine — hydrazones — azines) showed that the boiling points of the aldehyde compounds are in average 5° lower, and of the acetone compounds in average 20° higher than those of the corresponding amines. Using Klages equation [6], the differences between the heats of sublimation of the aldehyde and acetone compounds and the parent amine was calculated to be -0.2 kcal · mole^{-1} and $+0.7$ kcal · mole^{-1}, respectively. The heat of sublimation of thiosemicarbazide [3] was estimated to be 19 kcal · mole^{-1} and thus for acetaldehyde thiosemicarbazone $\Delta Hf(g) = 33.8$ kcal · mole^{-1} and for the acetone compound $\Delta Hf(g) = 24.3$ kcal · mole^{-1}. This gives

$$\Delta Hr_1 = -9 \text{ kcal} \cdot \text{mole}^{-1} \text{ and } \Delta Hr_2 = -6 \text{ kcal} \cdot \text{mole}^{-1} \text{ *}$$

*. The thermochemical bond energy term value of the C = O double bond is 3 kcal larger for ketones than it is for aldehydes [8].

These values may be compared with the heat of reaction for

$$Me_2CH \cdot CHO(g) + H_2N \cdot n\text{-}Bu(g) \rightarrow Me_2CH \cdot CH = N \cdot Bu(g) + H_2O(g) \quad (3)$$

The heat of combustion of the aldimine was determined by Coates and Sutton [7]; for n-$BuNH_2$ a value is found in Kharasch's compilation [5].

The heat of combustion of *iso*butyraldehyde can be computed from known data [5] for heptaldehyde, (ΔHc(liq) = −1 062.4 kcal · mole^{-1}), methyl n-propyl ketone, (−735.6 kcal · mole^{-1}) and methyl i-propyl ketone, (−733.9 kcal · mole^{-1}), by adjustment to the gaseous phase [6] and utilizing the known CH_2-increment from values of heats of combustion of a homologue series [9], −154.6 kcal · mole^{-1}. Thus, for *iso*butyraldehyde $\Delta Hc(g)$ = −607.3 kcal · mole^{-1}. The formation of the aldimine is therefore accompanied by a change in enthalpy of ΔHr_3 = −9.5 kcal.

Thus, within the limits of error, the resonance energy for the thiosemicarbazones is the same as it is for the thiosemicarbazide.

REACTIONS BETWEEN HYDRAZINIUM THIOCYANATE AND OXO-COMPOUNDS

When a solution of hydrazinium thiocyanate reacts with acetone, acetone thiosemicarbazone is formed in good yield; the reaction with acetaldehyde is much more complex and a compound with a bicyclic structure is formed [10]. From the thermochemical data [5,4] the following values of the heats of reaction are calculated:

$$N_2H_5NCS(aq) + Me_2CO(aq) \rightarrow Me_2C = N \cdot NHCSNH_2(s) + H_2O(liq) \quad (4)$$
$$\Delta Hr_4 = -18.5 \text{ kcal} \cdot \text{mole}^{-1}$$
$$2N_2H_5NCS(aq) + 2MeCHO(aq) \rightarrow C_6H_{10}N_4S_2(s) + 2H_2O(liq) + N_2H_4(aq) \quad (5)$$
$$\Delta Hr_5 = -31 \text{ kcal} \cdot \text{mole}^{-1}$$

This reaction, however, is much better carried out in an acid, where an additional decrease in enthalpy of 10 kcal · mole^{-1} occurs due to the neutralization reaction:

$$N_2H_4(aq) + HCl(aq) \rightarrow N_2H_5Cl(aq) \quad (6)$$

The competing process (which does not occur):

$$N_2H_4NCS(aq) + CH_3CHO(aq) \rightarrow CH_3CH = N \cdot NHCSNH_2(s) + H_2O(liq) \quad (7)$$

is accompanied by a ΔHr_7 = 21 kcal · mole^{-1} which is almost the same value as in reactions 5 to 6 counted on a molar basis. The explanation for the easiness of formation of the more complex reaction product cannot therefore be sought in an extra stabilization of compound A ($C_6H_{10}N_4S_2$) but must be caused by different rates of reaction for the competing mechanisms.

HEATS OF COMBUSTION * AND SOLUTION

Materials. The samples of the substances were purified by repeated recrystallizations from at least two different solvents, pulverized and carefully dried. The purity was check-

* Dr. Lars Bjellerup made the combustions. I am very grateful for his kind co-operation.

ed by elementary analyses and titrimetric determinations [1]. From the analyses the lower limits of the purity of the substances were estimated and are given below.

Hydrazinium thiocyanate: m.p. 77.5°. Purity better than 99.8 % .
Acetaldehyde thiosemicarbazone: m.p. 146°. Purity better than 99 %.
Acetone thiosemicarbazone: m.p. 179°. Purity better than 99 %.

Compound A (tetrahydro-3,7-dimethyl-s-triazolo(a)-s-triazol-1,5-dithione) [10]: m.p. (decomp.) 170°. The purity could not be estimated from the analyses. The method of synthesis and the low solubility make a good reason for the belief, that the purity is fairly high.

Apparatus and method. The calorimeter and experimental procedure was described in a previous communication [11].

Units of measurement and auxiliary quantities. The results of the combustions are expressed in terms of the 15° calorie in which unit the certified heat of combustion of the benzoic acid (Kahlbaum, 6 324 cal/g "auf den luftleeren Raum bezogen") was given. Unfortunately, the conditions are not precisely known under which this value was obtained. Therefore, the reduction to standard conditions can be slightly uncertain, a value of 6 319 cal/g mass was used. The observed values for the heat of the bomb process were corrected to obtain values for the idealized combustion reaction in which all the reactants and products are in their standard states at 20° and no external work is performed [12].

The accuracy of the obtained results. The combustion experiments referred to in this paper were performed several years ago. At that time the method for the determination of heats of combustion of organo-sulfur compounds was not very well established. The results are therefore not as accurate as they may be obtained to-day, but are believed to be accurate to within 3 to 5 parts in a thousand. The internal consistency, however, is higher and probably about one part in a thousand. For this reason, the usual practice of giving primary data for the combustion experiments was considered of no real use and only the final results will be given.

Energy equivalent of the calorimeter: 4 707.7, 4 709.1, 4 708.7 and 4 712.2, average 4 709.5±1.4 (average deviation) cal/degree.

Heat of combustion of paraffin oil: 10 986, 10 976, 10 969, 10 971, and 10 988, average 10 978±7 cal/g mass.

Heat of combustion of rhombic sulfur: 4 559, 4 570, 4 540, 4 587, average 4 562±15 cal/g mass.

For the reaction

$$S(\text{rhombic}) + 1.5\ O_2(g) + 10\ 001\ H_2O(\text{liq}) = H_2SO_4, 10\ 000\ H_2O$$
$$\Delta Ec\ (293°) = 146.3 \pm 0.4\ \text{kcal} \cdot \text{mole}^{-1}$$

Recalculated to the formation of H_2SO_4, 115 H_2O the value becomes

$$\Delta Ec\ (293°) = 143.3 \pm 0.4\ \text{kcal} \cdot \text{mole}^{-1}$$

which is almost identical to that obtained when the method became better established [12].

Heats of combustion: Hydrazinium thiocyanate: 4 605, 4 615, 4 628, 4 608, average 4 614 cal · g mass^{-1}

Thiosemicarbazide: 4 578, 4 562, 4 582, 4 576 ,average 4 574 cal · g mass^{-1}
Acetaldehyde thiosemicarbazone: 5 821, 5 827, 5 825, average 5 824 cal · g mass^{-1}
Acetone thiosemicarbazone: 6 365, 6 358, 6 345, 6 362, average 6 358 cal · g mass^{-1}
Compound A: 6 100, 6 083, 6 084, 6 069, average 6 084 cal · g mass^{-1}
These values are valid for the formation of gaseous carbon dioxide, liquid water and H_2SO_4, 10 000 H_2O at 20° and constant volume.

Heats of formation. By use of the obtained value for the heat of combustion of rhombic sulfur to H_2SO_2, 10 000 H_2O, $\Delta Ec(293°) = 146.3$ kcal · mole^{-1}, and the known heats of formation of carbon dioxide and water $\Delta Hf(293°) = 94\ 050$ and 68 355 cal · mole^{-1}, respectively, the following values for the heats of formation from graphite, gaseous hydrogen, oxygen and nitrogen and rhombic sulfur were derived:

$C(graphite) + 2\frac{1}{2}\ H_2(g) + 1\frac{1}{2}\ N_2(g) + S(rhombic) = N_2H_5SCN(s)$
$\Delta Hf\ (293°) = +9.2 \pm 0.7$* kcal · mole^{-1}
$C(graphite) + 2\frac{1}{2}\ H_2(g) + 1\frac{1}{2}\ N_2(g) + S(rhombic) = NH_2NHCSNH_2(s)$
$\Delta Hf\ (293°) = +5.7 \pm 0.5$ kcal · mole^{-1}
$3\ C(graphite) + 3\frac{1}{2}\ H_2(g) + 1\frac{1}{2}\ N_2(g) + S(rhombic) = CH_3CH = NNHCSNH_2(s)$
$\Delta Hf\ (293°) = +15.0 \pm 0.2$ kcal · mole^{-1}
$4\ C(graphite) + 4\frac{1}{2}\ H_2(g) + 1\frac{1}{2}\ N_2(g) + S(rhombic) = (CH_3)_2C = NNHCSNH_2(s)$
$\Delta Hf\ (293°) = +4.6 \pm 0.8$ kcal · mole^{-1}
$6\ C(graphite) + 5\ H_2(g) + 2\ N_2(g) + 2S(rhombic) = C_6H_{10}N_4S_2(s)$
$\Delta Hf\ (293°) = +32.7 \pm 1.7$ kcal · mole^{-1}

Heats of solution. The heats of solution of hydrazinium thiocyanate and thiosemicarbazide were determined in an "isothermal" reaction calorimeter of the Dewar-type. The pulverized sample of the crystalline material was dissolved in distilled water and the temperature decrease was read on a Beckmann thermometer. The accuracy of the determinations was better than 1 %. The strengths of the final solutions were 1 % (hydrazinium thiocyanate) and 0.4 % (thiosemicarbazide).

$N_2H_5NCS(c) = N_2H_5NCS(aq)$; $\Delta H = +7.9$ kcal · mole^{-1}
$NH_2NHCSNH_2(c) = NH_2NHCSNH_2(aq)$; $\Delta H = +7.7$ kcal · mole^{-1}

Studies on the Extraction of Metal Complexes

XXX. The Dissociation, Distribution and Dimerization of Di-*n*-butyl Phosphate (DBP)

DAVID DYRSSEN

Research Institute of National Defence, Dept. 1 (FOA 1), Sundbyberg 4, Sweden

The solubility and acidity of DBP in water and the distribution of DBP between chloroform or hexone (methyl *iso*butyl ketone) and $HClO_4$—$NaClO_4$ solutions has been studied at 25°C. The distribution of DBP has been chiefly measured with DBP labelled with radioactive ^{32}P. It was thus possible to measure q, the net distribution ratio of DBP, at very low concentrations of DBP and to determine the very high dimerization constant, k_2, in chloroform.

From the data, the following constants were calculated by fitting the normalized curve, $\log y = \log (x+1)$ (*cf.* Refs. [17, 18]).

Dissociation of DBP in 0.1 M and 1 M $HClO_4$-$NaClO_4$

$$pk_a = 1.00 \pm 0.01$$

Distribution of DBP between chloroform or hexone and 0.1 M $HClO_4$-$NaClO_4$

$$\log k_d = 0.34 \pm 0.01 \text{ (chloroform)}$$
$$\log k_d = 1.36 \pm 0.01 \text{ (hexone)}$$

Dimerization of DBP in

chloroform (wet): $\log k_2 = 4.48 \pm 0.04$
hexone (wet): $\log k_2 = 1.19 \pm 0.03$
water (sat.soln.): $\log k_2 = 1.11 \pm 0.07$

Complex formation of DBP and TBP in chloroform

$$\log k_B = 1.6$$

These constants are discussed together with data for some carboxylic acids, and it is shown that the dimerization of DBP is much more pronounced than for these acids. Furthermore it is possible to calculate the distribution constant, k_D, for some of the dimers.

Di-*n*-butyl phosphate (DBP) has been shown to be a very suitable complexing agent for the extraction of elements such as scandium [1], yttrium [2, 3], zirconium [3], lanthanum [1], hafnium [1] and uranium [1, 4, 5]. It is also known that

DBP interfers with TBP extractions in reactor fuel processes [6]. In order to obtain a more complete understanding of the reactions of DBP in these systems it was necessary to determine the dissociation constant and partition coefficients of DBP. During these studies we found that DBP had a pronounced tendency to dimerize, and the values of the association constants in chloroform, hexone (methyl *iso*butyl ketone) and water were determined. Previously the dissociation constants for some dialkyl phosphates have been determined by van Hove [7], Drushel and Felty [8], and Kumler and Eiler [9]. Recently Peppard *et al.*[10] have reported that dialkyl phosphates in benzene solution are dimeric, and in measurements of the infrared spectra of DBP in non-polar solvents [11] it has not been possible to find any evidence of free hydroxyl-group absorption.

Symbols and formulas

$[\ ]$ or $[\ ]_{aq}$	concentrations in the aqueous phase
$[\ ]_{org}$	concentrations in the organic phase
C_A	initial total concentration of DBP in the organic phase
C_{org}, C_{aq}	equilibrium total concentrations of DBP
HA	di-*n*-butyl phosphate (DBP), $(C_4H_9O)_2PO(OH)$
H_2A_2	dimer of DBP
B	solvent molecule
$k_a = [H^+][A^-]/[HA]$	stoichiometric acid dissociation constant
$k_B = [HA \cdot B]_{org}/[HA]_{org}[B]_{org}$	association constant of HA and B
$k_d = [HA]_{org}/[HA]$	distribution constant for HA
$k_D = [H_2A_2]_{org}/[H_2A_2]$	distribution constant for H_2A_2
$k_2 = [H_2A_2]_{org}/[HA]^2_{org}$	dimerization constant in the organic phase
$k'_2 = [H_2A_2]/[HA]^2$	dimerization constant in the aqueous phase
q	net distribution ratio of DBP
V_{org}, V_{aq}	phase volumes

The experimental errors given were estimated from the fit obtained between the normalized curve $\log y = \log (x+1)$ and the experimental points.

REAGENTS AND APPARATUS

Our general experimental techniques have been described previously by other papers in this metal extraction series (*cf.* Ref. [12]). The DBP was kindly supplied by Albright & Wilson Ltd., London. Titration with alkali and analysis for C (Found: 45.0. Calc. for $C_8H_{19}PO_4$: 45.7) and H (Found: 8.7. Calc: 9.1) showed the compound to be at least 99 % pure. DBP labelled with radioactive ^{32}P was purchased from Radiochemical Centre, Amersham, England. This product was free of any non-acidic ^{32}P-products (*e.g.* TBP or pyrophosphate, TBPP). The specific activity was 4.7 mc per gram of DBP. The chloroform was washed three times with twice the volume of water to remove the 1 % alcohol. The hexone and TBP were washed with alkali, acid, and finally with water.

The radioactivity of $DB^{32}P$ was measured in 10 ml liquid counter tubes (type **M6**, 20th Century Electronics) with an approximate wall-thickness of 35 mg/cm^2. In order to determine the influence of the solvent on the counting rate, solutions were made of 0.5 ml of acetone with $DB^{32}P$ and 9.5 ml of different solvents. These values are given in Table 1

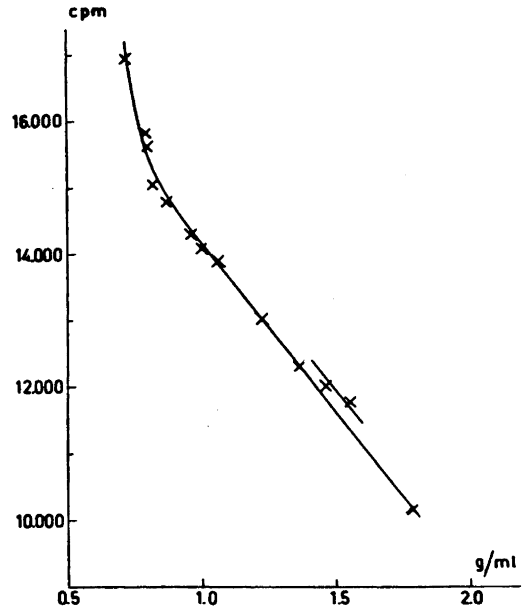

Fig. 1. Effect of solvent density on the counting rate of ^{32}P in a liquid counter.

and plotted in Fig. 1. The values of chloroform and carbon tetrachloride fall above the curve because of the comparatively low electron density of these two solvents. Similar results have been reported earlier [13, 14].

All experiments were carried out at 25°C, and all counting rates given are corrected for background activity and resolving time. Measurements of the hydrogen ion concentration were carried out with a Radiometer pHM3i valve potentiometer, equipped with a Radiometer glass electrode G 100 and a calomel electrode K 100. The two-phase titrations [15] were performed with the same potentiometer but with other types of glass and calomel electrodes.

THE SOLUBILITY AND ACIDITY OF DBP IN WATER

The solubility of DBP in water at 25°C was found to be 0.0818 M by titration with alkali. The pH of the saturated solution was 0.022 units higher than for a solution of 0.05 M $HClO_4$+0.05 M $NaClO_4$. If we use values of the activity coefficients given by Kielland [16] and the value of $pk_a = 1.00$ in 0.1 M ClO_4^-, which was determined in other experiments reported here, we may calculate the following values for the saturated aqueous solution of DBP.

$$-\log [H^+] = 1.340$$

$$[H^+] = [A^-] = 0.0457 \text{ M}$$

$$pk_a = 1.036 = \log [HA] - \log [H^+] - \log [A^-]$$

$$[HA] = 0.0227 \text{ M}$$

$$[H_2A_2] = \tfrac{1}{2}(0.0818 - 0.0227 - 0.0457) = 0.0067 \text{ M}$$

Table 1. The effect of the solvent on the counting rate of DB^{32}P for a Century Electronics M6 liquid counter tube.

Solvent	Density g/ml	Density of DB^{32}P solution [a]	I [b] cpm

[a] 2.5×10^{-5} M DBP, 5 % acetone
[b] Corrected for the decay of ^{32}P. Standard error approx. ± 130 cpm.

The assumption, that DBP dimerizes also in water, will explain the low value of [HA] that is obtained from the value of pk_a found in distribution experiments with radioactive DBP. The association constant may then be calculated as

$$k'_2 = [H_2A_2]/[HA]^2 = 13 \pm 2$$

THE ACIDITY IN THE AQUEOUS PHASE AS A FUNCTION OF THE CONCENTRATION OF DBP IN THE ORGANIC PHASE

Solutions of DBP (conc. C_A) in chloroform or hexone were shaken with an equal volume of 0.1 M $NaClO_4$, and the value of $-\log [H^+]$ was measured in the aqueous phase (the potentiometer was set to pH = 2.000 for a solution of 0.01 M $HClO_4$ + 0.09 M $NaClO_4$). The results are given in Figs. 2 and 3. With chloroform there seemed to be mainly dimers present in the concentration range studied (10^{-4} to 1 M). The following equations are valid in these experiments.

$$C_A = C_{org} + C_{aq} \quad (1)$$

$$C_{org} = 2[H_2A_2]_{org} + [HA]_{org} \quad (2)$$

$$C_{aq} = [HA] + [A^-] \quad (3)$$

$$[A^-] = [H^+] \quad (4)$$

Additional results were obtained by a two-phase titration [12, 15] of 0.5 mmoles of DBP in 75 ml chloroform or hexone. From these titrations C_{org} and $[H^+][A^-]$ were calculated.

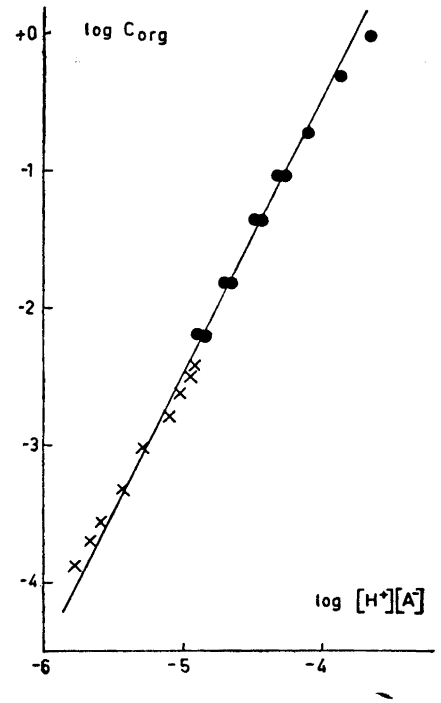

Fig. 2. Distribution of DBP between chloroform and 0.1 M $NaClO_4$ ● $[H^+]$ measured in the aqueous phase after equilibration and separation of the two phases. × $[H^+]$ measured in a two-phase titration.

From eqn. (2) and the definitions of k_2, k_d and k_a given above, the following equation may be derived

$$C_{org} = 2k_2(k_d/k_a)^2[H^+]^2[A^-]^2+(k_d/k_a)[H^+][A^-] \quad (5)$$

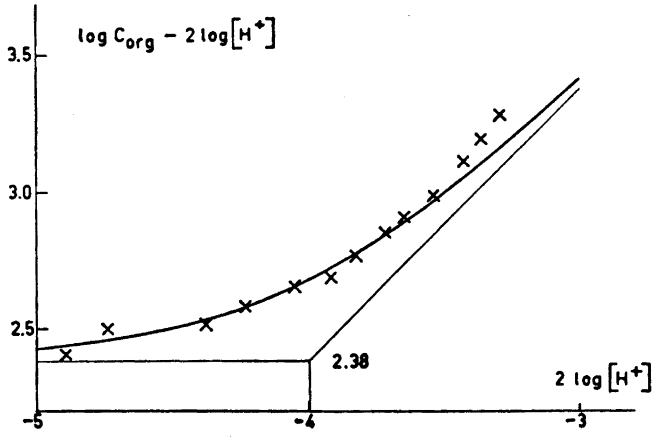

Fig. 3. Distribution of DBP between hexone and 0.1 M $NaClO_4$. $[H^+]$ measured in the aqueous phase. Position of horizontal asymptote ($pk_a+\log k_d = 2.38$) determined from a two-phase pH-titration.

1.33×10^{-5}	13 120	9 918	+0.195	−5.088
6.67×10^{-6}	1 867	1 590	+0.143	−5.412

[a] $q = I_{org} \cdot 1.186/I_{aq}$
[b] $C_{org} = C_A \cdot q/(1+q)$

For chloroform (Fig. 2) the points follow a straight line with a slope equal to 2 when log C_{org} is plotted against log $[H^+][A^-]$. This means that the monomer HA in the chloroform phase can be neglected (last term in eqn. (5)). From this line we obtained

$$\log k_2(k_d/k_a)^2 = +7.22 \pm 0.05$$

Table 3. Distribution of DB^{32}P between hexone and 0.1 M perchloric acid for different conc. of DBP. $V_{org} = V_{aq} = 15$ ml.

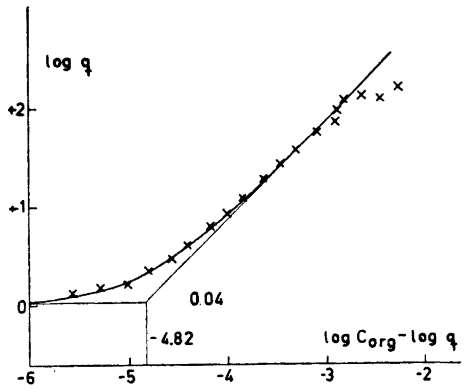

Fig. 4. The distribution ratio of $DB^{32}P$ between chloroform and 0.1 M perchloric acid as a function of the DBP conc. in the chloroform phase.

For hexone a plot (Fig. 3) of log C_{org} — 2log $[H^+]$ against 2log $[H^+]$ does not give a straight line. The normalized curve log y = log $(x+1)$ (*cf.* Refs. [17, 18]) fits the data except for the highest DBP concentrations (0.5 and 1 M). The horizontal asymptote (log y = 0) to the curve was obtained from a two-phase titration

$$pk_a + \log k_d = +2.38 \pm 0.01$$

The point of intersection of the two asymptotes (log y = 0 and log y = log x) gives

$$\log 2k_2k_d/k_a = +4.00 \pm 0.03$$

$$i.e., \log k_2 = +1.32 \pm 0.04$$

THE DISTRIBUTION OF DBP AS A FUNCTION OF THE CONCENTRATION OF DBP IN THE ORGANIC PHASE

In these experiments the distribution of DBP was measured by means of DBP labelled with radioactive ^{32}P. The results for chloroform and hexone are given in Tables 2 and 3 and in Figs. 4 and 5. The aqueous phase was 0.1 M

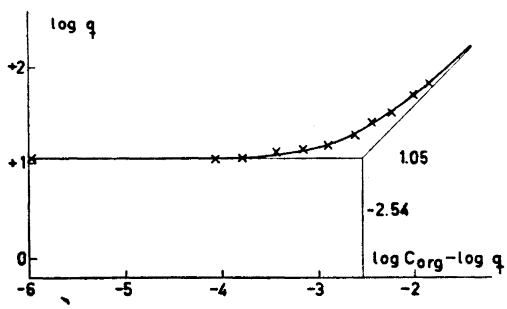

Fig. 5. The distribution ratio of $DB^{32}P$ between hexone and 0.1 M perchloric acid as a function of the DBP conc. in the hexone phase.

perchloric acid. Eqns (1)—(3) given above are also valid here. As C_{aq} is always low any formation of dimers in the aqueous phase can be neglected. The net distribution ratio is

$$q = C_{org}/C_{aq} \quad (6)$$

and from eqns. (2), (3), and (6) and the definitions of k_2, k_d and k_a follows that

$$q = 2k_2(k_d/\varphi)^2 C_{org}/q + k_d/\varphi \quad (7)$$

where φ is a constant in these experiments

$$\varphi = 1 + k_a/[H^+] \quad (8)$$

In Figs. 4 and 5 log q is plotted against log C_{org}—log q.

The normalized curve log y = log $(x+1)$ fits the data very well except for 0.5 and 1 M DBP in chloroform. The horizontal asymptote (log $y = 0$) gives

$$\log k_d/\varphi = +0.04 \pm 0.02 \text{ for chloroform (Fig. 4)}$$

$$\text{and} \quad \log k_d/\varphi = +1.05 \pm 0.01 \text{ for hexone (Fig. 5)}$$

and the point of intersection between the two asymptotes gives

$$\log 2k_2k_d/\varphi = +4.82 \pm 0.02 \text{ for chloroform}$$
$$\log 2k_2k_d/\varphi = +2.54 \pm 0.02 \text{ for hexone}$$

i.e., log $k_2 = +4.48 \pm 0.04$ (chloroform) and $+1.19 \pm 0.03$ (hexone).

The latter value for hexone is definitely lower than the value of 1.32 obtained in the previous part.

If we use the value of $k_a = 10^{-1.00 \pm 0.01}$ that was obtained in the experiments reported below, φ will be equal to 2.00 ± 0.02 (eqn. 8). The distribution coefficient of the monomeric form HA may then be calculated as

$$\log k_d = +0.34 \pm 0.02 \text{ for chloroform}$$

$$\log k_d = +1.35 \pm 0.01 \text{ for hexone}$$

For comparison with the results obtained from the acidity measurements with inactive DBP (given in brackets), the following values may be calculated

$$\log k_2(k_d/k_a)^2 = +7.16 \pm 0.06 \text{ for chloroform } (7.22 \pm 0.05)$$

$$pk_a + \log k_d = +2.35 \pm 0.02 \text{ for hexone } (+2.38 \pm 0.01)$$

$$\log 2k_2k_d/k_a = +3.84 \pm 0.04 \text{ for hexone } (+4.00 \pm 0.03)$$

Except for the value of log k_2 for hexone the agreement seems to be rather good. We consider the value of log k_2 obtained with radioactive DBP to be more reliable.

THE DISTRIBUTION OF DBP AS A FUNCTION OF THE ACIDITY IN THE AQUEOUS PHASE

These experiments were carried out in order to determine both the distribution coefficients and the acidity constant of DBP. The distribution of DBP was again measured with radioactive DB^{32}P. The results for chloroform and

Table 4. Distribution of DB^{32}P between chloroform and $HClO_4$-$NaClO_4$ solutions. Initial conc. of DBP in the chloroform layer 1.33×10^{-5} M.

	10 344	6 622	+1.170	1.00
	10 119	899	+1.001	1.30
	8 450	1 651	+0.658	1.70

[a] $q = I_{org} \cdot 0.915/I_{aq}$ for 0.1 M ionic strength and $q = I_{org} \cdot 0.890/I_{aq}$ for 1 M.

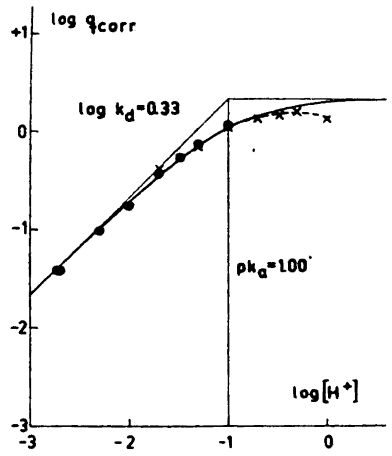

Fig. 6. Distribution of DB^{32}P between chloroform and $HClO_4$-$NaClO_4$ solutions. × = 1 M ionic strength. ● = 0.1 M ionic strength.

of dimers in the organic phase; for hexone no correction was needed. In these experiments the net distribution of DBP is given by

$$q = \frac{[HA]_{org}}{[HA]+[A^-]} \tag{9}$$

From the definitions of k_a and k_d it follows that

$$q = k_d/(1+k_a[H^+]^{-1}) \tag{10}$$

The same normalized curve, $\log y = \log (x+1)$, is thus valid for these experimental data if $\log q$ is plotted against $\log [H^+]$. The horizontal asymptote ($\log y = 0$) gives $\log k_d$ and the point of intersection of this asymptote with the asymptote $\log y = \log x$ gives $pk_a = -\log [H^+]$. From Figs. 6 and 7 we obtained the following values by fitting the normalized curve (*cf.* Refs. [17, 18]) to the data

$$pk_a = 1.00 \pm 0.01 \text{ for } 0.1 \text{ and } 1 \text{ M } ClO_4^-$$

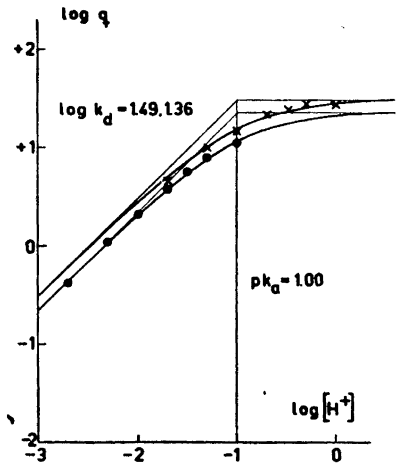

Fig. 7. Distribution of DB^{32}P between hexone and $HClO_4$-$NaClO_4$ solutions. × = 1 M ionic strength. ● = 0.1 M ionic strength.

Other acids, *e.g.* HCl and $HClO_4$ (*cf.* Ref. [16] p. 75), also have approximately the same mean activity coefficients in 0.1 M and 1 M solutions at 25°C.

$$\log k_d = 0.33 \pm 0.02 \text{ for chloroform/0.1 and 1 M } ClO_4^-$$
$$\log k_d = 1.36 \pm 0.02 \text{ for hexone/0.1 M } ClO_4^-$$
$$\log k_d = 1.49 \pm 0.02 \text{ for hexone/1 M } ClO_4^-$$

The values of $\log k_d$ for 0.1 M ClO_4^- agree with those found in the previous part.

For chloroform the more acid 1 M $HClO_4$-$NaClO_4$ solutions show a salting-in effect. Using activity coefficients given by Kielland [16] the thermodynamic dissociation constant may be calculated

$$pk_a = 1.00 + 0.17 = 1.17$$

This value is definitely lower than the value of 1.72 reported by Kumler and Eiler [9]. However, their results on other dialkyl phosphates are about 0.4—0.6 units higher than dissociation constants given by van Hove [7] and by Drushel and Felty [8].

THE DISTRIBUTION OF DBP AS A FUNCTION OF THE CONCENTRATION OF TBP IN THE CHLOROFORM PHASE

If DBP reacts with TBP (tri-*n*-butyl phosphate) in the chloroform phase the net distribution ratio will increase according to

$$q = \frac{k_d}{\varphi}(1 + k_B[B]_{org}) \qquad (11)$$

Table 6. Distribution of $DB^{32}P$ between chloroform and 1 M $HClO_4$ for different concentrations of TBP in the chloroform phase. Initial conc. of DBP in the chloroform layer 3.33×10^{-5} M. $V_{org} = V_{aq} = 15$ ml.

0	0	4 032	1 420	1.154	0.515

[a] $q = I_{org} \cdot A / I_{aq}$

where φ is given by eqn. (8) and k_B is defined by

$$k_B = [HA \cdot B]_{org}/[HA]_{org}[B]_{org} \quad (12)$$

In a plot log q against log $[TBP]_{org}$ (= log $[B]_{org}$) the data would then follow the normalized curve log y = log $(x+1)$. With a high value of φ or a very high specific activity of the radioactive DBP we could have made the conc. of DBP dimers negligible. But with 1 M $HClO_4$ ($\varphi = 1.10$) and an initial conc. of DBP equal to 3.33×10^{-5} M, TBP has to compete with the dimerization of DBP. The expression for q will therefore contain an additional term.

$$q = \frac{k_d}{\varphi}(1+2k_2 \frac{k_d}{\varphi} \cdot \frac{C_A}{1+q} + k_B[B]_{org}) \quad (13)$$

With this expression we calculated for $(TBP)_{org} < 0.4$ M

$$k_B = 40$$

As aspected the tendency for DBP to dimerize ($k_2 = 3 \times 10^4$) is much stronger than the tendency to associate with TBP. However, the effective concentration of TBP in chloroform may be lower than $[B]_{org}$ as TBP is known to associate both with H_2O and $CHCl_3$ according to McKay *et al.*[19] and Kosolapoff and McCullough [20] (*cf.* also Ref.[21]).

CONCLUSIONS AND DISCUSSION

From the experiments carried out the following data may be summarized:
Dissociation of DBP in 0.1 M and 1 M $HClO_4$-$NaClO_4$

$$pk_a = 1.00 \pm 0.01 \ (pK_a = 1.17)$$

Dimerization (association) of DBP in

chloroform (wet): log $k_2 = 4.48 \pm 0.04$

hexone (wet): log $k_2 = 1.19 \pm 0.03$

water (sat.soln.): log $k_2 = 1.11 \pm 0.07$

Distribution of DBP between

chloroform	and 0.1 M $HClO_4$-$NaClO_4$:	log k_d =	0.34 ± 0.01
hexone	and 0.1 M $HClO_4$-$NaClO_4$:	log k_d =	1.36 ± 0.01
hexone	and 1 M $HClO_4$-$NaClO_4$:	log k_d =	1.49 ± 0.02
TBP	and 1 M $HClO_4$:	log k_d =	1.87

Association (complex formation) of DBP and TBP in chloroform

$$\log k_B = 1.60$$

According to Drushel and Felty [8] and the result obtained by us the lower dialkyl phosphates are definitely stronger acids (10—20 times) than phosphoric acid ($pK_a = 2.12$). It might be suggested that H_3PO_4 is stabilized by three

Table 7. Summary of some dimerization constants in chloroform calculated from distribution measurements at 25°C.

internal hydrogen bonds while the hydrogen bonding in the dialkyl phosphates is disturbed by the free rotation of the two ester groups. The degree of hydration is probably also different for the two acid-base pairs, H_3PO_4—$H_2PO_4^-$ and $(RO)_2PO(OH)$ — $(RO)_2PO_2^-$.

The tendency for a dialkylphosphoric acid or a carboxylic acid to associate to double molecules depends on the tendency of the $P\langle^{O}_{OH}$ and $C\langle^{O}_{OH}$ groups to form hydrogen bonds. The dimerization is, however, very dependent on the solvent. Hitherto only the carboxylic acids have been investigated [23–33]. Usually very large dimerization constants are obtained in hexane, benzene and carbon tetrachloride. Smaller values (about 10 times) are obtained with chloroform, which is a weak donor for hydrogen bonds. The dimerization of carboxylic acids is very slight [25, 26] in oxygen-containing solvents like ethers and ketones, which are good acceptors for hydrogen bonds. Finally the dimerization is almost negligible [31–33] in hydroxyl-containing solvents such as water. From Table 7 it may be seen that the dimerization constant for DBP is much larger than for any of the carboxylic acids. It is therefore not astonishing that a considerable dimerization also takes place in hexone and water. There seems to be a general trend for k_2 to increase with K_a and k_d. However, many of the k_2-values in Table 7 are not very accurate. One of the reasons for this is that the aqueous phase has been unbuffered. Furthermore, the correction for ionization becomes too large when $K_a > 10^{-3}$. This emphasizes the necessity of measuring the distribution with constant ionic and acidity strength in the aqueous phase and carrying out the analysis of the acids, *e.g.* spectrophotometrically [26] or radiometrically as in this work. Table 7 shows furthermore the lowering effect on k_2 of OH, Cl and OCH_3 groups in the *ortho*-

Table 8. Distribution constants of some monomers and dimers.

position of benzoic acid: Cl and OCH_3 act as acceptors for the carboxylic hydrogen while the OH group in salicylic acid can act both as a donor and acceptor. Careful work [26] on 3,5-dinitrobenzoic acid has revealed no evidence of association. This result has surprised us, especially when compared with *m*-nitrobenzoic acid. The result suggests that the carboxylic hydrogen is bound intramolecularly, *e.g*, as follows

The dimerization in water, which could be estimated from our measurements of the acidity of DBP in water, has been calculated for some fatty acids [31–33]. Thus, if the dimerization constants in both the organic and aqueous phases and the distribution constant of the monomer are known, it is possible to calculate the distribution constant of the dimer

$$k_D = [H_2A_2]_{org}/[H_2A_2] = k_2k_d^2/k_2' \qquad (14)$$

Some values of k_D are given in Table 8. Some estimations of k_d and k_D for the fatty acids can be made. Collander [34] found in his investigations of the distribution of organic compounds between ether and water that k_d increases 2 to 4 times when a CH_2 group is added in a homologous series; this factor is here denoted with m. Furthermore it is reasonable to assume that the dimerization makes the carboxylic groups less hydrophilic, *i.e.* increases k_d by a factor n regardless of the length of the hydrocarbon chain. If the distribution constant k_d for acetic acid is a, the values of log k_d and log K_D for the fatty acids will increase as log a, log am, log am^2 and log anm, log $anmm^2$, log $anmm^4$. The values calculated in Table 8 have been obtained with $m = n = 4$ and $a = 0.044$. The deviation from the rather uncertain experimental values is not too serious. The assumptions made here lead also to the following relation

$$k_2/k_2' = k_D/k_d^2 = mn/a = 16/0.044$$

In fact k_2 ans k_2' do not vary much for the fatty acids (for k_2' see Ref.[32]) and the ratio k_2/k'_2 is thus rather constant. If the values in Table 8 for DBP with chloroform and hexone are compared, it may be seen that the increase of the distribution constant on dimerization is much larger for chloroform (5 100 times) than for hexone (27 times). This is also in agreement with Collander [35], who found that the distribution constants differed much less for *iso*butanol than for ether.

The association between chloroform and DBP is presumably rather weak (*cf.* Ref.[28]). The lowering of k_2 in hexone may then be ascribed to complex formation between hexone and DBP according to eqn. (12). This can also explain the larger value of k_d for hexone. For comparison with k_B for TBP we may then calculate k_B for hexone as

$$k_B = \frac{10^{\frac{1}{2}(4.48-1.19)}}{[\mathrm{B}]_{\mathrm{org}}} = 5.5$$

The complex formation is thus somewhat lower for hexone than for TBP ($k_B = 40$). The tendency for DBP to dimerize is however much stronger. It would be interesting to know if the eight-membered dimer ring is planar or not (*cf.* Ref.[36]).

The dimerization constant of DBP in chloroform is very large (3×10^4) and should be still larger in non-polar solvents such as carbon tetrachloride. This means that DBP will exist as dimers even at very low concentrations. Thus no shifts can probably be detected in the infra-red spectra within a measurable concentration range (*cf.* Ref.[11]). The dimerization constant in carbon tetrachloride may however be determined with radioactive DBP if a larger value of φ in eqn. (7) (higher pH) or a higher specific activity of DBP than in the experiments reported here is used.

The dimerization constant for water, k_2', has been determined with the distribution method for acetic acid [33]. This method could probably be also used for the lower dialkyl phosphates (*e.g.* dimethyl phosphate). For DBP k_d and k_2 are too large, and the concentration of DBP in water will be too low.

The author wishes to thank the head of FOA 1, Professor Gustaf Ljunggren, for his interest in our work, and Fil.kand. Bengt Carlsson and Mr. Ebbe Johansson for their technical assistance. Sincere thanks are due to Professor Lars Gunnar Sillén for his criticism of the manuscript and to Dr. Stuart Tobias for revising the English text.

Short Communications

A New Procedure for the Preparation of *Iso*nicotinic Acid Hydrazide

H. B. THOMASEN

Laboratory of Messrs. Dumex Private Ltd., Bombay, India

A well-known preparative method for aliphatic amides consists in the thermal decomposition of the ammonium salts of the acids. A simple example is the formation of acetamide from ammonium acetate by heating. Similarly the hydrazonium salts of the acids on heating give rise to the hydrazides. The preparation of acyl hydrazides by this method, though less well-known has been reported in the literature [1].

The reactions may be represented as follows:

$$R-COONH_4 \xrightarrow{\text{heat}} R-CONH_2 + H_2O$$

$$R-COONH_3-NH_2 \xrightarrow{\text{heat}} R-CONH-NH_2 + H_2O$$

If R is aromatic the reaction generally fails and the hydrazide can only be prepared *via* the corresponding ester, acid chloride or the anhydride. This involves an extra step in the process and it was, therefore, considered worthwhile to investigate the possibility of a direct conversion of the hydrazonium salt to the acid hydrazide.

In the last few years, *iso*nicotinic acid hydrazide has come into prominence as a valuable remedy against tuberculosis. The hydrazide is usually manufactured by the condensation of the ethyl ester of *iso*nicotinic acid or the acid chloride with hydrazine hydrate [2,3].

During, the study undertaken in our laboratory, it was realised that the reaction

$$R-COONH_3-NH_2 \rightleftharpoons R-CONH-NH_2 + H_2O$$

could be made to proceed to the right if the water formed in the reaction is constantly and almost completely removed.

Such a dehydration may be performed by azeotropic distillation with the help of a suitable water entrainer. Many such media are available but the choice is restricted as a certain temperature is also required to obtain a workable rate of reaction. It has been found that immiscible water entrainers having boiling points above 120° are most suitable, *e. g.* amyl alcohol, hexyl alcohol, or octyl alcohol, and hydrocarbons, *e. g.* toluene, xylene or mesitylene. It has thus been described how maleic anhydride can be prepared from the acid by an azeotropic removal of water by the use of xylene [4].

It is likely that the reaction mechanism is not as simple as represented above but perhaps passes through an ester stage where an alcohol is used as water entrainer or through the anhydride where a hydrocarbon is used. The experimental procedures finally worked out are described in the experimental section.

Experimental. Procedure 1. Normal amyl alcohol (60 ml) was added to a solution of *iso*nicotinic acid (30 g) in 60 % hydrazine hydrate (27 ml). The reaction mixture was slowly distilled when a mixture of amyl alcohol and dilute solution of hydrazine hydrate distilled over. A further quantity of dry amyl alcohol (40 ml) was added and the distillation continued till water ceased to appear in the distillate. The mixture was then refluxed for 3 h, the water formed at this stage removed by distillation, and the refluxing continued for another 3.5 h. The reaction product was cooled to 0° when crude *iso*nicotinic acid hydrazide crystallised out. The product was purified by recrystallisation from a small amount of ethyl alcohol yielding *iso*nicotinic acid hydrazide, m.p. 170—172°, and a purity of 98.5—99.0 %, when assayed by the B.P. procedure. Yield 24 g.

The amyl alcoholic mother liquor was acidified with hydrochloric acid to a pH 3.5 when the unreacted *iso*nicotinic acid (4—5 g) precipitated. Taking into consideration the recovered material, an yield of 86.5 % was obtained.

The mother liquor, after the precipitation of *iso*nicotinic acid, in the previous step, con-

tained some dissolved hydrazide besides other condensation products formed by side reactions. Further quantity of the acid was recovered by hydrolysing these products. The mother liquor was boiled under reflux with an excess of sodium hydroxide, acidified to a pH 3.5 and the precipitated acid collected by filtration. The total yield of the hydrazide, taking into consideration the recovered *iso*-nicotinic acid in both the steps amounted to over 90 % of the theory.

Procedure 2. To a solution of *iso*nicotinic acid (30 g) in 60 % hydrazine hydrate (27 ml), xylene (100 ml) was added and the mixture was heated in an oil bath at 170°. A mixture of xylene and hydrazine hydrate distilled over slowly during the first 2 h. The temperature of the oil bath was now lowered to 150° and maintained at this point for the next 4 h. During this period the last traces of xylene and a strong solution of hydrazine hydrate distilled over. The reaction product was cooled somewhat, water (20 ml) was added and the resulting solution filtered at a temperature between 70—75°. The filtrate was cooled to —3° when crude *iso*nicotinic acid hydrazide crystallised out; yield 24—25 g.

Recovery of *iso*nicotinic acid was carried out as described under procedure 1.

A New Synthesis of 4-*O*-Methyl-D-Glucose

HANS O. BOUVENG, BENGT LINDBERG and OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

The unambiguous synthetic routes leading to 4-*O*-methyl-D-glucose [1-3] are rather tedious and give low yields. As we required this substance and its methyl β-pyranoside we sought for other methods of preparing them. Bearing in mind the ease with which acyl migration takes place from the 4- to the 6-position, we investigated the direct methylation of the easily available methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside with methyl iodide and silver oxide. The alkalinity of the silver oxide we believed would probably be sufficient to effectively catalyse the acyl migration. This reaction has already been investigated in the α-series by Haworth, Hirst and Teece[4]. They found that methylation took place in the 2-position. On the other hand, Helferich and Lang [5] prepared methyl 2,3,6-tri-*O*-acetyl 4-*O*-methyl-β-D-glucopyranoside by the Purdie methylation of methyl 2,3,6-tri-*O*-acetyl-β-D-glucopyranoside. These results show that acyl migration is rather unpredictable and may proceed by several paths.

By methylation of methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside with methyl iodide and silver oxide in dimethylformamide, according to the method of Kuhn *et al.*[6], we have now obtained crystalline methyl 2,3,6-tri-*O*-acetyl-4-*O*-methyl-β-D-glucopyranoside in a yield of 45 %. A hydrolysate of the mother liquors contained 4-*O*-methyl-D-glucose as the main product, contaminated by glucose and by some methyl glucoses. 2-*O*-Methyl-D-glucose, which has almost the same electrophoretic mobility as 4-*O*-methyl-D-glucose but a higher R_F-value, was only present in traces. The pure, acetylated glucoside was converted by standard procedures to the crystalline methyl 4-*O*-methyl-β-D-glucopyranoside and to the amorphous 4-*O*-methyl-D-glucose. Paper chromatographic and paper electrophoretic examination of this latter product showed it to be indistinguishable from an authentic sample of 4-*O*-methyl-D-glucose but to be readily distinguishable from the other mono-*O*-methyl-D-glucoses. The values of the m.p. and optical rotations of the crystalline products were in good agreement with those previously recorded [1,2]. As comparatively few steps are needed, and as the yields are fairly good, this is probably the most convenient synthesis of 4-*O*-methyl-D-glucose and of its methyl-β-pyranoside.

Experimental. Methyl 2,3,6-tri-O-acetyl-4-O-methyl-β-D-glucopyranoside. Methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside (4.0 g) was dissolved in dimethylformamide (50 ml) and to this solution methyl iodide (12 ml) was added. Silver oxide (8.0 g) was added in four portions during 30 min under vigorous stirring and

tained some dissolved hydrazide besides other condensation products formed by side reactions. Further quantity of the acid was recovered by hydrolysing these products. The mother liquor was boiled under reflux with an excess of sodium hydroxide, acidified to a pH 3.5 and the precipitated acid collected by filtration. The total yield of the hydrazide, taking into consideration the recovered *iso*-nicotinic acid in both the steps amounted to over 90 % of the theory.

Procedure 2. To a solution of *iso*nicotinic acid (30 g) in 60 % hydrazine hydrate (27 ml), xylene (100 ml) was added and the mixture was heated in an oil bath at 170°. A mixture of xylene and hydrazine hydrate distilled over slowly during the first 2 h. The temperature of the oil bath was now lowered to 150° and maintained at this point for the next 4 h. During this period the last traces of xylene and a strong solution of hydrazine hydrate distilled over. The reaction product was cooled somewhat, water (20 ml) was added and the resulting solution filtered at a temperature between 70—75°. A New Synthesis of 4-*O*-Methyl-D-Glucose

HANS O. BOUVENG, BENGT LINDBERG and OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

The unambiguous synthetic routes leading to 4-*O*-methyl-D-glucose [1-3] are rather tedious and give low yields. As we required this substance and its methyl β-pyranoside we sought for other methods of preparing them. Bearing in mind the ease with which acyl migration takes place from the 4- to the 6-position, we investigated the direct methylation of the easily available methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside with methyl iodide and silver oxide. The alkalinity of the silver oxide we believed would probably be sufficient to effectively catalyse the acyl migration. This reaction has already been investigated in the α-series by Haworth, Hirst and Teece[4]. They found that methylation took place in the 2-position. On the other hand, Helferich and Lang [5] prepared methyl 2,3,6-tri-*O*-acetyl 4-*O*-methyl-β-D-glucopyranoside by the Purdie methylation of methyl 2,3,6-tri-*O*-acetyl-β-D-glucopyranoside. These results show that acyl migration is rather unpredictable and may proceed by several paths.

By methylation of methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside with methyl iodide and silver oxide in dimethylformamide, according to the method of Kuhn *et al.*[6], we have now obtained crystalline methyl 2,3,6-tri-*O*-acetyl-4-*O*-methyl-β-D-glucopyranoside in a yield of 45 %. A hydrolysate of the mother liquors contained 4-*O*-methyl-D-glucose as the main product, contaminated by glucose and by some methyl glucoses. 2-*O*-Methyl-D-glucose, which has almost the same electrophoretic mobility as 4-*O*-methyl-D-glucose but a higher R_F-value, was only present in traces. The pure, acetylated glucoside was converted by standard procedures to the crystalline methyl 4-*O*-methyl-β-D-glucopyranoside and to the amorphous 4-*O*-methyl-D-glucose. Paper chromatographic and paper electrophoretic examination of this latter product showed it to be indistinguishable from an authentic sample of 4-*O*-methyl-D-glucose but to be readily distinguishable from the other mono-*O*-methyl-D-glucoses. The values of the m.p. and optical rotations of the crystalline products were in good agreement with those previously recorded [1,2]. As comparatively few steps are needed, and as the yields are fairly good, this is probably the most convenient synthesis of 4-*O*-methyl-D-glucose and of its methyl-β-pyranoside.

Experimental. Methyl 2,3,6-tri-O-acetyl-4-O-methyl-β-D-glucopyranoside. Methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside (4.0 g) was dissolved in dimethylformamide (50 ml) and to this solution methyl iodide (12 ml) was added. Silver oxide (8.0 g) was added in four portions during 30 min under vigorous stirring and

with external cooling with tap water. The stirring was continued for 6 h, then the solution was filtered. The silver salts were washed with some dimethylformamide and, after chloroform (100 ml) had been added to the combined filtrate and washings, the solution was washed with 6 % aqueous potassium cyanide (100 ml). After washing the aqueous phase with chloroform (2 × 25 ml), the chloroform layers were combined and were washed with water (2 × 50 ml), dried over calcium chloride and concentrated. The remaining dimethylformamide was removed by co-distillation with butanol. The crystalline residue was recrystallised from ethanol, and this, together with the material obtained by working up the mother liquors, gave a total of 1.90 g having m.p. 104—105°. After further crystallisations the product had m.p. 110—111° (corr.) and $[\alpha]_D^{21}$ —35° (c = 1, in chloroform).

Methyl 4-O-methyl-β-D-glucopyranoside. By deacetylation of the above acetate the glycoside was obtained. After crystallisation from ethyl acetate it had m.p. 102—103° (corr.), $[\alpha]_D^{20}$ —18° (c = 1, in water).

4-O-Methyl-D-glucose. Acid hydrolysis of the glycoside yielded 4-*O*-methyl-D-glucose. $R_{Glucose}$ 2.40 (in butanol-ethanol-water, 10:3:5). M_G 0.17 (in 0.1 M borate buffer of pH 10). The corresponding values for 2-. 3- and 6-*O*-methyl-D-glucose were $R_{Glucose}$ 2.78, 2.67 and 2.47 and M_G, 0.17, 0.80 and 0.75, respectively.

The authors are indebted to Professor J. K. N. Jones for a gift of 4-*O*-methyl-D-glucose.

Preliminary Calculations of Mean Amplitudes of Vibration in *Cyclo*propane

O. BASTIANSEN and S. J. CYVIN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

Reinvestigations on the structures of the *cyclo*alkanes are in progress[1]. From the radial distribution curve of *cyclo*propane the root mean square amplitude of vibration (u) has been calculated for the C—H and C—C bond distances. Least square calculations were applied to fit Gaussian shaped peaks to the peaks of the radial distribution curve. It was observed that there was a reproducible deviation from the symmetric form due to anharmonicity[2,3]. However, this effect will not be discussed here. The electron diffraction results for values of u are listed in Table 1.

Table 1. Mean amplitudes of vibration in *cyclo*propane (Å units).

Distance	El.diff.	Spectr.
C—H	0.0784 ± 0.0015	0.0770
Distance	El.diff.	Spectr.
C—C	0.0480 ± 0.0015	0.0489

It is of interest to compare these values with theoretical ones calculated from spectroscopic data. Some simple, approximate methods, which yield data of sufficient accuracy for this purpose, shall be reported in this communication.

The C—H distances. The four C—H stretching fundamental frequencies have been separated from the remaining fundamentals. Thus an explicit approximate formula for the mean square amplitude could be evaluated, the result being[4]

$$u^2_{C-H} = h\ (\mu_H + \mu_C)^{1/2} / 4\pi k^{1/2}$$

where only the principal C—H stretching force constant (k) appears. μ_H and μ_C are the inverse masses of the H and C atoms. From the experimental fundamentals[5] (A_1') 3 029, (E') 3 024.4, (A_2'') 3 103.0 and (E'') 3 080 cm^{-1}, the value

with external cooling with tap water. The stirring was continued for 6 h, then the solution was filtered. The silver salts were washed with some dimethylformamide and, after chloroform (100 ml) had been added to the combined filtrate and washings, the solution was washed with 6 % aqueous potassium cyanide (100 ml). After washing the aqueous phase with chloroform (2 × 25 ml), the chloroform layers were combined and were washed with water (2 × 50 ml), dried over calcium chloride and concentrated. The remaining dimethylformamide was removed by co-distillation with butanol. The crystalline residue was recrystallised from ethanol, and this, together with the material obtained by working up the mother liquors, gave a total of 1.90 g having m.p. 104—105°. After further crystallisations the product had m.p. 110—111° (corr.) and $[\alpha]_D^{21}$ —35° (c = 1, in chloroform).

Methyl 4-O-methyl-β-D-glucopyranoside. By deacetylation of the above acetate the glycoside was obtained. After crystallisation from ethyl acetate it had m.p. 102—103° (corr.), $[\alpha]_D^{20}$ —18° (c = 1, in water).

4-O-Methyl-D-glucose. Acid hydrolysis of the glycoside yielded 4-*O*-methyl-D-glucose. $R_{Glucose}$ 2.40 (in butanol-ethanol-water, 10:3:5). M_G 0.17 (in 0.1 M borate buffer of pH 10). Table 1. Mean amplitudes of vibration in *cyclo*propane (Å units).

Distance	El.diff.	Spectr.
C—H	0.0784 ± 0.0015	0.0770
Distance	El.diff.	Spectr.
C—C	0.0480 ± 0.0015	0.0489

It is of interest to compare these values with theoretical ones calculated from spectroscopic data. Some simple, approximate methods, which yield data of sufficient accuracy for this purpose, shall be reported in this communication.

The C—H distances. The four C—H stretching fundamental frequencies have been separated from the remaining fundamentals. Thus an explicit approximate formula for the mean square amplitude could be evaluated, the result being[4]

$$u^2_{C-H} = h\ (\mu_H + \mu_C)^{1/2} / 4\pi k^{1/2}$$

where only the principal C—H stretching force constant (k) appears. μ_H and μ_C are the inverse masses of the H and C atoms. From the experimental fundamentals[5] (A_1') 3 029, (E') 3 024.4, (A_2'') 3 103.0 and (E'') 3 080 cm^{-1}, the value

$k = 5.120 \times 10^5$ dyn cm^{-1} have been computed, yielding the u value listed in Table 1.

The C—C distances. An approximate calculation of the mean amplitude of vibration of the C—C distances have been worked out by adopting the equilateral triangle model $(CH_2)_3$ for *cyclo*propane. The following explicit formula has been derived

$$u^2_{C-C} = (h\mu_X^{1/2} / 4\pi 3^{1/2}) \, [(k + 2\,k')^{-1/2} + 2^{1/2} \, (k - k')^{-1/2}]$$

k denotes here the principal C—C stretching force constant and k' the interaction force constant between two C—C stretches. μ_X is the inverse mass of CH_2. In this case it did not affect the result appreciably when the interaction constant was made equal to zero. Consequently, the formula could be simplified to

$$u^2_{C-C} = h\mu_X^{1/2} \, (1 + 2^{1/2}) / 4\pi(3k)^{1/2}$$

From the fundamentals [5] (A_1') 1 189 and (E') 868 cm^{-1}, the value $k = 4.064 \times 10^5$ dyn cm^{-1} have been obtained, and the resulting u value is listed in Table 1.

It is planned to perform more rigorous calculations of u-values in *cyclo*propane, including also the other C—H distances as well as the H—H distances.

A Photoactivated Polymerization of Hexabromoethane

K. TAUGBØL and J. B. DAHL

Joint Establishment for Nuclear Energy Research, Kjeller, Norway

Investigations of the photoactivated exchange reaction of bromine between hexabromoethane and free bromine in carbon tetrachloride solution by means of the radioactive isotope ^{82}Br, indicated a polymerization reaction occurring coincident with the exchange reaction.

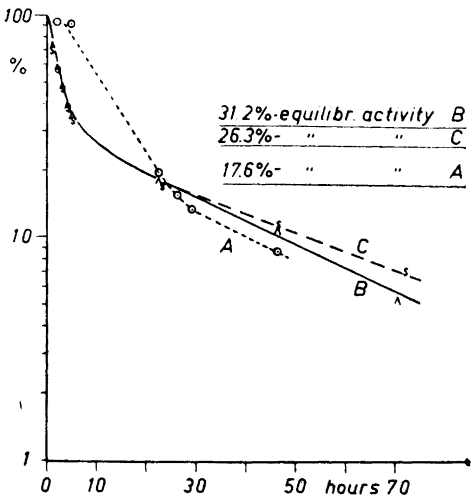

Fig. 1. Activity in organic phase as percentage of activity at zero time.

Curve A: $[C_2Br_6^*] = 1.04$ mmole/l, $[Br_2] = 14.56$ mmole/l. In air, 50°C.
Curve B: $[C_2Br_6^*] = 1.39$ mmole/l, $[Br_2] = 9.18$ mmole/l. In carbon dioxide atm, 20°C.
Curve C: $[C_2Br_6^*] = 1.39$ mmole/l, $[Br_2] = 11.50$ mmole/l. In nitrogen atm, 20°C.

A condensation of carbon tetrabromide to hexabromoethane has been described earlier [1], but this work did not indicate any polymerization of the hexabromoethane.

Procedure: Free bromine and hexabromoethane were irradiated in the pile, dissolved in carbon tetrachloride solutions and irradiated by an electric bulb. The solutions were in turn kept in a closed glass flask filled with dry, purified nitrogen or carbon dioxide.

The apparatus was placed in a thermostatic bath, and filling and removing of aliquots could take place without letting air into the system. Aliquots were taken at different times and free bromine extracted with reducing, aqueous solutions of sodium bisulphite. The organic phases containing the hexabromoethane were washed with distilled water, and the radioactivity measured with a scintillation counter.

The hexabromoethane was prepared according to the method of Mouneyrat [2] and recrys-

$k = 5.120 \times 10^5$ dyn cm^{-1} have been computed, yielding the u value listed in Table 1.

A Photoactivated Polymerization of Hexabromoethane

K. TAUGBØL and J. B. DAHL

Joint Establishment for Nuclear Energy Research, Kjeller, Norway

Investigations of the photoactivated exchange reaction of bromine between hexabromoethane and free bromine in carbon tetrachloride solution by means of the radioactive isotope ^{82}Br, indicated a polymerization reaction occurring coincident with the exchange reaction.

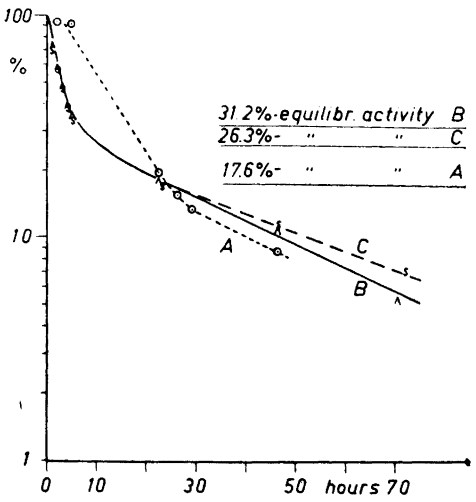

Fig. 1. Activity in organic phase as percentage of activity at zero time.

Curve A: $[C_2Br_6^*] = 1.04$ mmole/l, $[Br_2] = 14.56$ mmole/l. In air, 50°C.
Curve B: $[C_2Br_6^*] = 1.39$ mmole/l, $[Br_2] = 9.18$ mmole/l. In carbon dioxide atm, 20°C.
Curve C: $[C_2Br_6^*] = 1.39$ mmole/l, $[Br_2] = 11.50$ mmole/l. In nitrogen atm, 20°C.

A condensation of carbon tetrabromide to hexabromoethane has been described earlier [1], but this work did not indicate any polymerization of the hexabromoethane.

Procedure: Free bromine and hexabromoethane were irradiated in the pile, dissolved in carbon tetrachloride solutions and irradiated by an electric bulb. The solutions were in turn kept in a closed glass flask filled with dry, purified nitrogen or carbon dioxide.

The apparatus was placed in a thermostatic bath, and filling and removing of aliquots could take place without letting air into the system. Aliquots were taken at different times and free bromine extracted with reducing, aqueous solutions of sodium bisulphite. The organic phases containing the hexabromoethane were washed with distilled water, and the radioactivity measured with a scintillation counter.

The hexabromoethane was prepared according to the method of Mouneyrat [2] and recrys-

tallized repeatedly from carbon disulphide solutions. The carbon tetrachloride was purified by irradiation in the presence of chlorine and chlorine dioxide, followed by fractional distillations [3].

Results: In several experimental series the radioactivity in the hexabromoethane was found to fall far below the calculated exchange equilibrium values. Fig. 1 shows some typical results corrected for radioactive decay. Corresponding series in darkness at 20°C and 50°C showed no exchange in organic bound activity after 50 h.

Solutions containing radioactive hexabromoethane with no free bromine added, were irradiated 45 h and 48 h, respectively, with no change in organic bound activity. One of the solutions was then treated with dry chlorine gas and again exposed to light. This caused a continuous fall in organic bound activity followed for 143.5 h. The activity had fallen to 4.8 % of the original activity.

The other solution was kept in light over night. The reaction had then started, and the solution was coloured by free bromine. Similar results were obtained in other runs. Some free bromine, however, up to 20—30 % of the total activity, depending on the pile flux, is always present in the hexabromoethane due to recoil reactions. In all series the reaction was followed by a marked increase in pressure owing to liberated bromine.

Different samples of the reaction products were isolated. One sample was prepared from a nearly saturated solution of hexabromoethane in 70 ml of carbon tetrachloride. 3 ml of bromine were added. The solution was irradiated in nitrogen atmosphere for one week, and the reaction was followed by a manometer. A white, flaky material was then floating on the surface. The solution was carefully evaporated to dryness, and the residue washed with alcohol. Another sample was prepared in a similar way, but with chlorine instead of bromine. The product was a similar, white and light material, with low solubility in carbon tetrachloride and *cyclo*hexane.

Microscopical examinations showed no distinct crystals. The materials turned dark at about 140°C and charred later without melting and without visible evolution of bromine or chlorine gas. Hexabromoethane decomposes at 210—215°C and gives off free bromine. Infrared spectra of the two samples showed the materials to be high-symmetric, saturated,

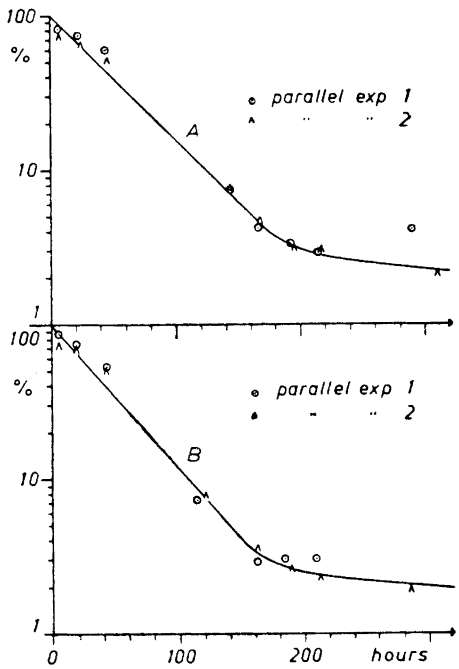

Fig. 2. Activity in organic phase as percentage of activity at zero time.

Curve A: $[C_2Br_6^*] = 1.24$ mmole/l, $[Br_2] = 28.2$ mmole/l.
Curve B: $[C_2Br_6^*] = 1.24$ mmole/l, $[Br_2^*] = 0.58$ mmole/l.

containing C—C bonds and to a small extent C—Br and C—Cl bonds, respectively. In the case of chlorine this has consequently exchanged with the organic bound bromine. There were no oxides, no C—H bonds and no functional groups.

To study the reaction without complications from the exchange reaction, hexabromoethane and free bromine were irradiated in the pile in two different ampulles placed in the same container to get the same specific activities. Different series of measurements with different concentrations of free bromine were carried out.

Fig. 2 shows two typical runs at 20°C in nitrogen atmosphere for two different bromine concentrations. In either case, two parallel experiments were carried out.

Fig. 2 shows that the reactions are represented by nearly straight lines on a semi-logarithmic scale. The slopes seem

nearly independent of the amount of free bromine in this region of concentration.

Runs with free iodine instead of bromine or chlorine gave no reaction.

An experiment with symmetric tetrabromethane and free chlorine gave a marked reaction. A yellow, viscous oil was isolated.

A rough test with radioactive free chlorine and inactive hexabromoethane showed an uptake of chlorine activity in the organic phase, later falling off again.

The curves, Fig. 2, show that the organic bound activities fall to at least 2 % of the original activities. Setting aside isotope effect, this may indicate a polymer consisting of some system of condensed carbon rings.

Further investigations are in progress.

The Precipitation of Neutral Polysaccharides by Cationic Detergents

HANS PALMSTIERNA, J. E. SCOTT* and S. GARDELL

Depts. of Chemistry and Bacteriology Karolinska institutet, Stockholm, Sweden

During an investigation on the charged polysaccharide luteic acid, described by Raistrick and collaborators in 1931 [1], the method of Scott was used as one step in the purification of it. It has been shown [2] that it is possible to use detergents for the precipitation and separation of mixtures of charged polysaccharides (and desoxyribonucleic acid). For obvious reasons neutral polysaccharides cannot be precipitated directly by the use of detergents such as cetylpyridinium chloride (C.P.C.) or cetyltrimethylammonium bromide (C.T.A.B.). If, however, the neutral polysaccharide is coupled to borate and C.P.C. is added, complete precipitation can be achieved. Since the work in this paper was carried out a short communication has appeared also recording this fact [3]. The precipitates are soluble in salt solutions, dilute acids and glycerol and galactose solutions.

To eliminate the effect of buffer salts on the precipitate, cetyl-trimethyl ammonium borate (C.T.A. Borate) was prepared and used as the precipitant. The pH dependance of the reaction was marked, as was observed by Barker *et al.*[3] Rat liver glycogen was not precipitated by C.T.A. borate, which had a pH of 8.5, but the addition of a few drops of ammonia resulted in good precipitation. Yeast mannan and ivory nut mannan were precipitated immediately without the addition of ammonia. Inulin, dextran and starch were not precipitated even in the presence of ammonia, but only on adding an appreciable concentration of potassium hydroxide. This latter type of precipitation in potassium hydroxide also took place in the absence of borate, and although the precipitates were soluble in salt solutions they were resistant to solvent action by glycerol or galactose.

It is therefore clear that there are two possibilities of precipitating neutral polysaccharides with amphipathic cations, due to the acquiring of polyanionic properties:

(1) by formation of borate complexes, and

(2) by the ionisation of hydroxyl groups at high pH.

The possibility of salt fractionation, such as is available with acidic polysaccharides [2], coupled with the differential solubilities of the precipitates in glycerol and galactose solutions, suggest that this reaction has great potential practical value. The following experiment describes a simple test of its utility (see also Barker *et al.*[3]).

The test system used was glycogen from *Escherichia coli* B alone or in combination with luteic acid. It was possible to separate these polysaccharides by precipitating the luteic acid directly with C.P.C. The glycogen was then precipitated by making the solution 0.01 M with regard to borate, adjusting the pH to 9.2 with KOH and finally adding C.P.C. to complete precipitation. This last operation should be finished within an hour, since the solution may otherwise be discoloured due to slight decomposition of C.P.C. in alkaline solutions. The supernatant contained hardly detectable amounts of polysaccharide.

The Precipitation of Neutral Polysaccharides by Cationic Detergents

HANS PALMSTIERNA, J. E. SCOTT* and S. GARDELL

Depts. of Chemistry and Bacteriology Karolinska institutet, Stockholm, Sweden

During an investigation on the charged polysaccharide luteic acid, described by Raistrick and collaborators in 1931 [1], the method of Scott was used as one step in the purification of it. It has been shown [2] that it is possible to use detergents for the precipitation and separation of mixtures of charged polysaccharides (and desoxyribonucleic acid). For obvious reasons neutral polysaccharides cannot be precipitated directly by the use of detergents such as cetylpyridinium chloride (C.P.C.) or cetyltrimethylammonium bromide (C.T.A.B.). If, however, the neutral polysaccharide is coupled to borate and C.P.C. is added, complete precipitation can be achieved. Since the work in this paper was carried out a short communication has appeared also recording this fact [3]. The precipitates are soluble in salt solutions, dilute acids and glycerol and galactose solutions.

To eliminate the effect of buffer salts on the precipitate, cetyl-trimethyl ammonium borate (C.T.A. Borate) was prepared and used as the precipitant. The pH dependance of the reaction was marked, as was observed by Barker *et al.*[3] Rat liver glycogen was not precipitated by C.T.A. borate, which had a pH of 8.5, but the addition of a few drops of ammonia resulted in good precipitation. Yeast mannan and ivory nut mannan were precipitated immediately without the addition of ammonia. Inulin, dextran and starch were not precipitated even in the presence of ammonia, but only on adding an appreciable concentration of potassium hydroxide. This latter type of precipitation in potassium hydroxide also took place in the absence of borate, and although the precipitates were soluble in salt solutions they were resistant to solvent action by glycerol or galactose.

It is therefore clear that there are two possibilities of precipitating neutral polysaccharides with amphipathic cations, due to the acquiring of polyanionic properties:

(1) by formation of borate complexes, and

(2) by the ionisation of hydroxyl groups at high pH.

The possibility of salt fractionation, such as is available with acidic polysaccharides [2], coupled with the differential solubilities of the precipitates in glycerol and galactose solutions, suggest that this reaction has great potential practical value. The following experiment describes a simple test of its utility (see also Barker *et al.*[3]).

The test system used was glycogen from *Escherichia coli* B alone or in combination with luteic acid. It was possible to separate these polysaccharides by precipitating the luteic acid directly with C.P.C. The glycogen was then precipitated by making the solution 0.01 M with regard to borate, adjusting the pH to 9.2 with KOH and finally adding C.P.C. to complete precipitation. This last operation should be finished within an hour, since the solution may otherwise be discoloured due to slight decomposition of C.P.C. in alkaline solutions. The supernatant contained hardly detectable amounts of polysaccharide.

* Present address. Institute of Pathology and Tropical Medicine, R. A. F. Halton Bucks, England.

The glycogen was easily dissociated from the borate-C.P.C. complex by lowering the pH to neutrality. This was followed by a dialysis against tap water. The luteic acid was separated from the C.P.C. by the following procedure [2].

The complex was dissolved in a solvent consisting of methanol 20 % v/v, saturated sodium chloride 30 % v/v and water to 100 %. This solution was treated with Lloyds reagent and the disappearance of the C.P.C. was followed spectrophotometrically.

It should be pointed out the method cannot be used when large amounts of protein contaminate the polysaccharide solution, because the proteins tend to form highly viscous cakes with detergents, thus enclosing the polysaccharides.

In microbiological work extracellular polysaccharides can in many instances be isolated by the above methods if the salt concentration of the medium is not too high. When the salt content is high it is advisable to dilute the medium or to dialyse it before precipitation with C.P.C.

Isolation of Oestradiol-17α from Bovine Meconium

WEIERT VELLE

Department of Sexual Physiology and Sexual Pathology, Veterinary College of Norway, Oslo, Norway

Investigations on oestrogens in the newborn calf have shown that significant amounts of oestrone and oestradiol-17α are excreted with the urine during the first days of life [1]. These observations led to investigations on the oestrogen contents of meconium in this species.

In this preliminary communication results are presented which strongly indicate the presence of significant quantities of oestradiol-17α in meconium from calves.

Experimental. Meconium was obtained from normal, healthy, newborn calves of both sexes and the analyses were undertaken immediately.

Reagents were of the same grade and manufacture as those used in a previous investigation [2]. The material was examined for the contents of both free and conjugated oestrogens:

a. For determination of free oestrogens specimens of meconium were suspended in distilled water and disintegrated in an "Ato-Mix" blender. The suspensions were then extracted repeatedly with ether. The combined ether extracts were processed as described in the following.

b. For determination of conjugated oestrogens the water phase from a. was freed from ether by evaporation, and concentrated HCl added to a final concentration of 10 %. Fitted with reflux condenser, the flask was kept at 100° C for 1 h. After cooling ether extraction was performed as before. The combined ether extracts were analysed according to the following procedures:

1. The chemical method for determination of urinary oestrogens, described by Brown [3] was applied with minor modifications [2]. This method is based on the chromatographic separation of the 3-methyl ethers of the oestrogens, using standardized alumina as adsorbent.

2. Chromatographic separation of the unaltered oestrogens were performed according to the method of Stimmel [4] as modified by Kakusjkina and Orlova [5].

3. The *cis-trans* test for the 17-hydroxy group of oestradiol was performed according to Kägi and Miescher [6], omitting the addition of bromine.

4. Absorption spectra of the isolated fractions were examined from 400—600 mμ using the Kober reagent described by Bauld [7], and from 240—500 mμ using fuming sulphuric acid according to Axelrod [8]. The registered spectra were compared with those of pure compounds. All readings were made in a Beckman Model DU spectrophotometer supplied with photomultiplier.

Results and discussion. Using the modified Brown procedure, a strongly reacting Kober chromogen was found present in the oestradiol fractions from both a. and b., indicating that the substance is partly excreted in free and partly in conjugated form. Considerably greater quantities were observed in the "conjugated" fractions.

In the oestriol and oestrone fractions no trace of Kober chromogen could be detected.

The glycogen was easily dissociated from the borate-C.P.C. complex by lowering the pH to neutrality. This was followed by a dialysis against tap water. The luteic acid was separated from the C.P.C. by the following procedure [2].

The complex was dissolved in a solvent consisting of methanol 20 % v/v, saturated sodium chloride 30 % v/v and water to 100 %. This solution was treated with Lloyds reagent and the disappearance of the C.P.C. was followed spectrophotometrically.

It should be pointed out the method cannot be used when large amounts of protein contaminate the polysaccharide solution, because the proteins tend to form highly viscous cakes with detergents, thus enclosing the polysaccharides.

In microbiological work extracellular polysaccharides can in many instances be isolated by the above methods if the salt concentration of the medium is not too high. When the salt content is high it is advisable to dilute the medium or to dialyse it before precipitation with C.P.C.

Isolation of Oestradiol-17α from Bovine Meconium

WEIERT VELLE

Department of Sexual Physiology and Sexual Pathology, Veterinary College of Norway, Oslo, Norway

Investigations on oestrogens in the newborn calf have shown that significant amounts of oestrone and oestradiol-17α are excreted with the urine during the first days of life [1]. These observations led to investigations on the oestrogen contents of meconium in this species.

In this preliminary communication results are presented which strongly indicate the presence of significant quantities of oestradiol-17α in meconium from calves.

Experimental. Meconium was obtained from normal, healthy, newborn calves of both sexes and the analyses were undertaken immediately.

Reagents were of the same grade and manufacture as those used in a previous investigation [2]. The material was examined for the contents of both free and conjugated oestrogens:

a. For determination of free oestrogens specimens of meconium were suspended in distilled water and disintegrated in an "Ato-Mix" blender. The suspensions were then extracted repeatedly with ether. The combined ether extracts were processed as described in the following.

b. For determination of conjugated oestrogens the water phase from a. was freed from ether by evaporation, and concentrated HCl added to a final concentration of 10 %. Fitted with reflux condenser, the flask was kept at 100° C for 1 h. After cooling ether extraction was performed as before. The combined ether extracts were analysed according to the following procedures:

1. The chemical method for determination of urinary oestrogens, described by Brown [3] was applied with minor modifications [2]. This method is based on the chromatographic separation of the 3-methyl ethers of the oestrogens, using standardized alumina as adsorbent.

2. Chromatographic separation of the unaltered oestrogens were performed according to the method of Stimmel [4] as modified by Kakusjkina and Orlova [5].

3. The *cis-trans* test for the 17-hydroxy group of oestradiol was performed according to Kägi and Miescher [6], omitting the addition of bromine.

4. Absorption spectra of the isolated fractions were examined from 400—600 mμ using the Kober reagent described by Bauld [7], and from 240—500 mμ using fuming sulphuric acid according to Axelrod [8]. The registered spectra were compared with those of pure compounds. All readings were made in a Beckman Model DU spectrophotometer supplied with photomultiplier.

Results and discussion. Using the modified Brown procedure, a strongly reacting Kober chromogen was found present in the oestradiol fractions from both a. and b., indicating that the substance is partly excreted in free and partly in conjugated form. Considerably greater quantities were observed in the "conjugated" fractions.

In the oestriol and oestrone fractions no trace of Kober chromogen could be detected.

The elution pattern of the methylated substance appearing in the oestradiol fraction closely followed the elution pattern of the 3-methyl ether of oestradiol-17α.

Oestradiol fractions isolated according to the modified Stimmel procedure showed intense pink colour and green fluorescence when subjected to the test of Kägi and Miescher. An identical reaction was shown by oestradiol-17α, while oestradiol-17β showed only a faint colour reaction.

The absorption spectra of the methylated oestradiol fractions, using the modified Kober reagent, closely followed the one of oestradiol-17α-3-methyl ether with the absorption maximum at 524 mμ.

The absorption spectra of the non-methylated oestradiol fractions, using fuming sulphuric acid as reagent, closely followed the one of oestradiol-17α, with distinct maxima at 300 and 430 mμ.

The Kober reaction is known to be highly specific to the oestrogenic hormones. Using the Brown method for isolation of the oestrogens, both the β- and α-isomer of oestradiol will appear in the oestradiol fraction. No other Kober chromogen is known to appear in this fraction. The conformity between the absorption spectra of the methylated and non-methylated substance isolated in the oestradiol fractions, and the absorption spectra of oestradiol-17α-3-methyl ether and oestradiol-17α * respectively, and the results of the *cis-trans* test for the 17-hydroxy group, support the validity of the concept that the Kober chromogen isolated from meconium of calves is identical to oestradiol-17α.

The quantities found is of the order of magnitude of 20 mg/kg in unconjugated, and 25—35 mg/kg in conjugated form, both figures representing free oestradiol-17α. There seems to be no significant difference between the sexes as regards the amounts present. This would indicate that the substance is of maternal origin.

As far as the present author is aware, the only previous paper reporting the presence of oestrogens in similar material is the one presented by Kinsella *et al.*[9], who in 1956 isolated oestriol from human meconium. No other oestrogen was present in this material.

Isolation of greater quantities of oestradiol-17α from bovine meconium is being carried out. The work shows that the substance is easily crystallized from ethanol-water mixtures.

* Gift from Ciba, Basel.

A detailed report of the work in progress will be published later.

Added in proof: By use of infrared spectroscopy it has now been definitely established that the isolated substance is identical with oestradiol-17α.

Carbohydrates in a Cold Water Extract of a Pine Forest Soil

E. ALVSAKER and K. MICHELSEN

Chemical Institute, University of Bergen, Bergen, Norway

In a preliminary communication Haworth *et al.*[1] state that levans have been isolated from polysaccharides obtained by extraction of soil with buffer solutions. We have not, however, been able to find any information about the existence of free fructose in soil. Forsyth[2] mentions the occurrence of small amounts of free glucose, xylose, rhamnose, and galactose in water extracts of several types of soil, but no details are given about methods of identification. Hot (85°C) water soluble soil polysaccharides have been investigated by Duff[3,4]. In the polysaccharide hydrolysates several aldoses could be identified by chromatographic methods.

An attempt was made to isolate levans from the uppermost layer (F-layer) of a pine forest soil from Western Norway, according to the experimental conditions described by Haworth, but the attempt

The elution pattern of the methylated substance appearing in the oestradiol fraction closely followed the elution pattern of the 3-methyl ether of oestradiol-17α.

Carbohydrates in a Cold Water Extract of a Pine Forest Soil

E. ALVSAKER and K. MICHELSEN

Chemical Institute, University of Bergen, Bergen, Norway

In a preliminary communication Haworth *et al.*[1] state that levans have been isolated from polysaccharides obtained by extraction of soil with buffer solutions. We have not, however, been able to find any information about the existence of free fructose in soil. Forsyth[2] mentions the occurrence of small amounts of free glucose, xylose, rhamnose, and galactose in water extracts of several types of soil, but no details are given about methods of identification. Hot (85°C) water soluble soil polysaccharides have been investigated by Duff[3,4]. In the polysaccharide hydrolysates several aldoses could be identified by chromatographic methods.

An attempt was made to isolate levans from the uppermost layer (F-layer) of a pine forest soil from Western Norway, according to the experimental conditions described by Haworth, but the attempt

failed. A cold water soluble polysaccharide complex could be isolated from the soil in question; by means of chromatographic analysis the same aldoses as those reported by Duff could be identified in the polysaccharide hydrolysate, but also in this case no ketoses could be detected.

On the other hand it was possible to identify fructose and other free sugars in a cold water extract. For identification of the chromatographically separated fructose a simple X-ray method has been devised [5]. The various sugars eluted from the paper chromatograms were also determined quantitatively according to Giri and Nigam [6]: Glucose 0.22, arabinose 0.04, fructose 0.035, xylose 0.03_5, galactose 0.02_5, and ribose <0.001, expressed as a percentage of dry (105°C) soil organic matter.

Experimental. 700 g samples of air-dry soil were first extracted with ether and then with water, both extractions carried out at room temperature (20°C). The water extract was concentrated *in vacuo* (maximum 40°C), and after precipitation of polysaccharides by means of ethanol the further concentrated filtrate was de-ionized with ion exchangers [7] and subjected to chromatographic analysis. Circular chromatograms on Whatman filter paper No. 1, obtained by the multisector and multiple development techniques described by Giri and Nigam [6], revealed several sugar bands. One of these bands reacted to colour tests in the following manner: Positive triphenyl tetrazolium bromide and α-naphthylamine phosphoric acid tests [6], negative aniline hydrogen phthalate test [8]. These reactions indicate the presence of ketoses and the absence of aldoses. The distance moved on the chromatogram corresponded to authentic fructose spotted on the same paper. As the R_F values of natural ketohexoses are very nearly identical, additional information is necessary for identification. It was not possible to obtain the eluted sugar in a crystalline state. Nor was it possible to analyze fructose derivatives precipitated direct from the water extract by the usual methods, because they were contaminated by considerable amounts of "humic matter". A larger sample was therefore prepared by means of a cellulose column [9]. The column eluates were examined by paper chromatography; one of the fractions revealed only one band, and this band reacted positively to ketose and negatively to aldose colour tests. A micro method for preparation of the osazone was successful, and the osazone could be identified by means of its powder diffraction pattern [5]. The sensitivity of this method also proved sufficient for identification of fructose eluted from paper chromatograms.

The other sugars mentioned could be completely separated on paper, and identified by colour reactions [6,8] combined with the distances moved as compared with those of authentic sugars on the same chromatogram. These distances were identical in three different developers (*n*-butanol-pyridine-water [6], ethyl acetate-pyridine-water [10], ethyl acetate-acetic acid-water [11]).

A Simple X-Ray Method for Identification of Chromatographically Separated Fructose

K. MICHELSEN and E. ALVSAKER

Chemical Institute, University of Bergen, Bergen, Norway

Minute amounts of crystalline fructose may be identified by means of the X-ray diffraction pattern [1]. It may, however, be difficult to obtain small sugar amounts in a crystalline state, and we therefore considered it an advantage if it would be possible to convert the sugar into a derivative that could easily be prepared and was suitable for X-ray analysis. The osazone acted up to these requirements.

failed. A cold water soluble polysaccharide complex could be isolated from the soil in question; by means of chromatographic analysis the same aldoses as those reported by Duff could be identified in the polysaccharide hydrolysate, but also in this case no ketoses could be detected.

On the other hand it was possible to identify fructose and other free sugars in a cold water extract. A Simple X-Ray Method for Identification of Chromatographically Separated Fructose

K. MICHELSEN and E. ALVSAKER

Chemical Institute, University of Bergen, Bergen, Norway

Minute amounts of crystalline fructose may be identified by means of the X-ray diffraction pattern [1]. It may, however, be difficult to obtain small sugar amounts in a crystalline state, and we therefore considered it an advantage if it would be possible to convert the sugar into a derivative that could easily be prepared and was suitable for X-ray analysis. The osazone acted up to these requirements.

Experimental. Approximately 50 μg fructose dissolved in 15 μl water is placed on a watch glass (diameter 4 cm) by means of a micro pipette. 4 μl phenylhydrazine reagent (phenylhydrazine, acetic acid, water 3:3:10 by volume) and 2 drops acetic acid are added. The watch glass is placed between two larger, matched watch glasses, and heated on a boiling water bath. The two larger watch glasses have been preheated, and the undermost has been wetted with a few drops of water in order to reduce evaporation. After 3—5 min the small glass is withdrawn and examined under the microscope. It is neither necessary nor suitable to the purpose to recrystallize or otherwise purify the product. The tough mass in which the crystals are imbedded is non-crystalline, and acts as an excellent adhesive when the specimen is to be mounted on the glass fiber. The mounting is easily done in the following manner: A small quantity of the material is collected with a spatula to a globe and then formed between thumb and forefinger with a light squeeze. The glass fiber is brought into contact with the specimen, and by rolling between the fingers the desired magnitude and shape are readily obtained.

For X-ray powder diffraction data (Table 1) nickel-filtered copper-radiation and a camera 11.46 cm in diameter have been used. The intensities have been visually estimated. Identical diffraction pattern is obtained for fructosazone prepared by the usual macro method. The osazones of fructose, glucose, and mannose being identical, additional information is necessary to distinguish between these sugars (chromatographic separation, colour reactions).

Table 1. X-Ray powder diffraction data for fructosazone.

d, Å	I/I_1	d, Å	I/I_1
17.02	0.37	3.22	0.37
8.86	0.50	3.12	0.08
6.10	0.08	3.04	0.08
5.78	0.25	2.94	0.30
5.16	0.25	2.84	0.20
4.94	0.63	2.72	0.20
4.52	1.00	2.66	0.25
4.40	0.15	2.60	0.08
4.20	0.50	2.58	0.08
3.96	0.37	2.42	0.05
3.72	0.30	2.38	0.15
3.60	0.50	2.32	0.02
3.40	0.50	2.28	0.10
3.32	0.25		

The method proved successful for fructose quantities as small as 18 μg; this figure, however, probably does not represent the lower limit for the practical applicability of the method. The sensitivity is sufficient for identification of fructose eluted from paper chromatograms [2].

The fructosazone prepared by the micro method has an appearance that differs from the usual crystal aggregates obtained by macro methods: The crystal needles are always arranged radially, thus forming spherulites about 0.05 mm in diameter.
